Grain protein content

Results indicated that the effects of Y, AA, DT, DI, DT×DI, Y × AA × DI, Y × DT × DI, AA × DT × DI, and Y × AA × DT × DI were significant on grain protein yield (*Table 6*). In the quadruple interaction, the highest grain protein yield was observed in 100% defoliation in V7 growth stage under AA application during the first-year experiment (1499 $kg.ha^{-1}$). Also, the lowest value of the trait was observed in 100% defoliation in the V5 growth stage under non-application of AA during the second year (471.9 $kg.ha^{-1}$) (*Table 7*).

Discussion

Effect of defoliation time and intensity

Defoliation caused by insects is common biotic stress in soybean [*Glycine max* (L.) Merr.] production (Xiangjun et al., 2009). The effects of defoliation on yield and yield components of soybean have been well studied, but time and intensity of defoliation have not been demonstrated. Defoliation affected soybean yield through a combination of reduced light interception resulting in decreased canopy photosynthesis, loss of leaf storage material, and/or shortening of the effective grain-filling period (Xiangjun et al., 2006). In the experiments of Xianjun et al. (2006, 2009), the effect of defoliation of soybean under salinity stress or application of nitrogen fertilizer were investigated. The effect of defoliation on growth and yield characteristics in plants varied with time and intensity of defoliation (Xiangjun et al., 2009). In the present study, effects of time and intensity of defoliation were significant on morphological traits, and yield and yield components such as plant height, first pod height, numbers of lateral and main branch, number of total pod, number of grain, 100-grain weight, biological yield, grain yield, and harvest index (*Tables 3* and *4*). Results illustrated by increases defoliation intensity was observed decreasing on yield and yield components. Also, defoliation in the reproductive growth stage (R1) had significantly reduced on studied traits. Several studies have shown strong relationships between the leaf-area index, defoliation intensity, light interception rate, and yield (Hammond et al., 2000; Xiangjun et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29112929

2006). Defoliation decreased soybean dry-matter production by reducing the effective leaf area for light interception and carbon fixation (Klubertanz et al., 1996). On the other, it may enhance growth through two mechanisms: compensatory regrowth and delayed leaf senescence, including delayed leaf abscission and increased leaf photosynthetic rates (Xiangjun et al., 2006). These mechanisms may aid soybean in tolerating defoliation during vegetative and early reproductive stages; however, the ability of these mechanisms to function in the presence of additional stresses is not known. In this regard, Ugese et al. (2011) reported that the defoliation time and intensity significantly affected on seedlings of *Vitellaria paradoxa,* which confirms the results of this study. Non-defoliation and mild defoliation intensity (50%) would not have a significant effect on yield reduction, but the severe defoliation intensity (100%) was caused decreasing in the studied traits. In this regards, the yield and growth reduction under severe stress conditions (100% defoliation) can be attributed to reduced photosynthetic parameters (net photosynthesis, transpiration rate, stomatal conductance, and chlorophyll content) (Zobiole et al., 2009, 2010). Defoliations in the early stages of growth apparently does not affect yield and yield components positively or negatively, an observation that is consistent with other types of crops, such as corn and garlic (Olfati et al., 2010). Xiangjun et al. (2009) reported that although defoliation temporarily reduced soybean dry weight and N accumulation during 15 days after defoliation.

Our finding that increasing levels of defoliation leads to progressive declines in grain oil and protein yield, but not significantly affected protein percentage (*Table 6*). This result agreed with the report by Turnipseed (1972) and Xiangjun et al. (2009) and that defoliation caused no decrease in seed protein content. Nitrogen (one of the important elements in protein synthesis) absorption following defoliation may be promoted. Although root growth usually is reduced following defoliation, the increase in nutrient uptake rate per unit root mass was found in a sedge (*Kyllinga nervosa* Steud.) plants (McNaughton and Chapin, 1985).

Effect of amino acid application

Amino acids are molecules with the following structure: a central carbon atom (C), usually asymmetric, attached to a carboxylic acid group (COOH), an amino group amidogen (NH_2) and hydrogen (H) atom (Moreira and Moraes, 2017). The AAs have several functions, and the most important are: i) protein synthesis, ii) intermediate compounds in the synthesis of endogenous plant hormones, iii) chelating effect on nutrients and other compounds, iv) greater resistance to drought stress and high temperatures, and v) greater disease resistance (Castro, 2009; Moreira and Moraes, 2017). In the current study, results indicated that the effect of the amino acid application was significant on yield and yield components as well as oil and protein yield (*Tables 4* and *6*). Application of amino acid significantly increased plant height, biological yield, grain yield, harvest index, and oil and protein yield. It is well documented that plants are capable of utilizing amino acids as nitrogen (N) and carbon (C) sources (Thornton and Robinson, 2005). Amino acid foliar fertilization has generally been sprayed onto plants to increase the crop yield (Souza et al., 2018). Amino acid foliar applications are biostimulants in plants because they enhance the nutrient uptake efficiency because of increases in the leaf cuticle permeability (Moreira and Moraes, 2017), better plant growth, and higher plant biomass and grain yield, and they reduce abiotic stresses (Azimi et al., 2013; Gazola et al., 2014; Mendes et al., 2016). Moreira and Moraes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29112929

(2017) found increases in common bean (*Phaseolus vulgaris* L.) yield after applying amino acid. Despite demonstrating these positive results regarding the efficient use of amino acids, some studies indicated that plant responses may vary under the influence of many factors such as the molecular weight of amino acids, anatomical features, growth stage, climate conditions and time of application (Fernández et al., 2013).

In all studied traits, the means of the traits from each growing season was different (*Tables 3, 4,* and *6*). We found 3233.8 kg.ha^{-1} (first year) and 2795.6 kg.ha^{-1} (second year) which means a reduction of 13% in the grain yield (*Table 4*). Similar to wheat and soybean, this reduction was caused by hydric stress at the beginning of the soybean development because this stage is the crucial moment for successful crop development, and the effects reflect on crop yield (Souza et al., 2018).

Conclusion

Results indicated that the defoliation time and intensity significantly decreased morphological traits and yield components as well as oil and protein contents. Server defoliation intensity (100%) during the R1 growth stage (reproductive stage) showed an intensive reduction effect. While defoliation in early growth stages had a negligible effect on the traits studied. On the other hand, the use of low molecular weight amino acid is aimed to increase nutrient uptake by leaves, with the consequent increase in productivity. The findings of this study showed that, on the average of two years of assessment, the foliar application of amino acid increased morphological traits, yield, and yield components. According to the present study, soybean is regarded generally as a defoliation-tolerant crop. Also, foliar application of amino acid could be used as an effective amendment for preventing defoliation injury in yield and yield components of soybean.

(Received 2nd Nov 2018; accepted 16th Jan 2019)

Abstract. In this study, we examined the content of Fe, Mn, Cd, Pb, Cu, Zn and Ni in fresh wooden trees and ash wood residues. The material of analysis was sampled in four different zones in Kosovo. Initially, the samples of wood were grinded and dried in room temperature, and then they were treated with HNO_3 and H_2O_2. The content of heavy metals was determined with atomic absorption spectrophotometer technique. The following results show that we have higher concentrations of some elements such as Cu, Zn and Ni, in the ash residues more than the Environmental Protection Agency standard (EPA Ecological Soil Screening Level) predicts for these elements to be as wastes in the soil. In order to preserve our health and environment, we must be cautious towards the amount of waste we dispose in the ground, for the reason that they straightforwardly end up in our food chain.
Keywords: *environmental, pollution, atomic absorption spectroscopy, EPA*

Introduction

The environmental problem in Kosovo in recent years has been a big and very serious problem. According to various measurements and numerous reports, our country was ranked among the world's first countries in terms of pollution. The Hydrometeorological Institute dealing with environmental monitoring in Kosovo has cited that the main causes of pollution are industries, transport and fossil fuels. According to this Institute, the air pollution has been increasing so drastically in the five last years that in some cases the permissible values have been exceeded (Kosovo Environmental Protection Agency, 2017)

Today it is a known fact through different researches that accumulation of heavy metals is related to different industrial activities, such as mining, smelting, energy and fuel production, traffic activities, agriculture etc. (Balabanova et al., 2014; Mooreet al., 2013; Yan et al., 2012; Kouamé et al., 2013; Jusufi et al., 2017). In our day, what is also known is that plants uptake these metals from various reactions: redox and ionic exchange reactions, precipitation-dissolution etc. (Mirecki et al., 2015). It is impossible to imagine life without trees because of their role in economic, environmental and industrial aspects, as well as spiritual, historical and aesthetic (Seth, 2004). However, in terms of environmental pollution, trees can also serve as long term accumulators of heavy metals and act as bio indicators of contamination.

In this paper, we evaluate the chemical distribution of Cd, Mn, Pb, Cu, Ni, Zn and Fe in fresh wood and their ashes. The importance of determining the scale of contamination in ashes is enormous, since the possibility of wood ending up in environment as ash residue is huge. Also, knowing the forms of toxic metals present in wood ash could indicate how much the emitted particulates pose risks to the human health and the environment (Odlare et al., 2007; Pettersson, et al., 2008).

Materials and methods

Area of study

Kosovo forests cover around 41 % (U.S. Department of State, 2008; Knaus and Warrander, 2010) of the entire territory of the country. Most of the forests are located in the southwest. There are various types of forestry in Kosovo, but for the most part are conifers. The regions with the highest diversity are the regions of the Sharr Mountains and the Albanian Alps. Kosovo's forests are threatened by fires and illegal logging. For this study, we chose four different regions in Kosovo where wood samples were collected.

Treatment procedure

In order to measure the heavy metal content, samples were inspected in fresh wood and calcinated form. The types of wood were beech and oak. The wood samples were mangled in fine parts before being grinded.

Initially, wood samples were left to dry at 60 °C for several hours before further study. For the analysis, 1 g of dried wood up to constant weight were taken and were placed in Teflon containers, where 12 ml of concentrated nitric acid (65%) was added. The mixture was heated at 105 °C and in small portions 4 ml of hydrogen peroxide (30%) were introduced to the mixture. The samples were left to evaporate until drying, then 1 ml of HCl were added. The mixture was filtered and leveled up to 50 ml with distilled water.

To treat the wood ash, fresh wood samples were initially calcinated at 400 °C for about two hours. 0.5 grams of calcinated sample were taken and placed in Teflon containers. 6 ml of HNO_3 were added and placed in heater at 105 ° C. Additionally, 2 ml of H_2O_2were added and after the sample was dried, it was removed and 0.5 ml HCl were added. The mixture was filtered and leveled up to 25 ml with distilled water.

Concentrations of heavy metals (Fe, Mn, Cd, Pb, Cu, Zn and Ni) were measured using the atomic absorption spectroscopy (AAS) technique.

Results and discussion

The purpose of this study was to determine the heavy metal content in wood which is burnt in conditions similar to domestic. A study of this form is very important since there are different studies of heavy metal uptake in vegetation (Peng et al., 2006; McLaughlin et al., 2011; Mingorance etal., 2007), but there are few data which examine the concentration of heavy metals in wood (Algreen et al., 2012; Świetlik et al., 2013).

The bioaccumulation of heavy metals in trees happens owing to climate, atmospheric depositions, the concentrations of heavy metals in soil, the nature of soil on which the trees are grown and the degree of maturity of the plants at time of harvest (Lake et al., 1984; Voutsa et al., 1996). Wood ash is one of the inorganic residues of wood burning, whereas CO_2 and water are the organic remains (Hannam et al., 2002; Reimann et al., 2008). The ash contents vary among types of trees, soil and climate. Campbell (1990) and Naik (2003) pointed out that it can also vary according to the method and manner of combustion, efficiency of the boiler, and other supplementary fuels used with wood.

Table 1 presents a summary of the wood samples: the ash content in percentage, moisture and the wood type.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29312941

Table 1. *List of analyzed samples and their properties*

Sample	Regions	Ashes %	Moisture	Type
1	Drenica	<0.9	7.4	Beech/oak
2	Ferronickel	<0.7	8.58	Beech/oak
3	Sharrcem	<0.8	6.96	beech
4	Sharr	<0.6	11.88	beech

The moisture was determined by weight loss and was used to correlate the results with dry weight, while the ash content was calculated before and after the burn, and was left at 105 °C to constant weight. Studies show that the percentage of ash content in wood can vary from 0.1 to 1.4% (Fengel and Wegener, 1989; Prosiński, 1984; Rowellet al., 2005; Szczepkowski and Nicewicz, 2008).

Table 2 presents the following basic statistical data of dry wood samples in mg/kg: average (AVG), range (min-max), standard deviation (SD), variance, first and third quartiles (Q1 and Q3) and median.

Table 2. *List of analyzed elements in fresh wood*

Elements	AVG (mg/kg)	Min-max	SD	Variance	Q1	Q3	Median
Mn	400.475	(20.4-1440)	694	481034	29	1102	71
Fe	105.81	(0.149-172)	72.1	5191.2	40.6	171	81.1
Zn	19.6	(10.05-39)	11.52	132.67	11.4	27.8	16.6
Pb	5.26	(0.05-18.9)	9.98	99.54	0.25	18.9	1.65
Cu	4.96	(0.6-10.85)	4.96	24.58	1	10.85	7.02
Ni	0.812	(0.05-2.55)	1.284	1.649	0.074	2.55	0.55
Cd	0.748	(0.4-0.943)	0.246	0.061	0.488	0.932	0.825

The concentrations of heavy metals are ranked in descending order of average concentration as follows: Mn>Fe>Zn>Pb>Cu>Ni>Cd. The average concentration of Zn is 19.6 mg/kg and ranges from 10.05-39 mg/kg. The results for lead and copper in wood content were similar, ranging from 0.049 to 18.9 mg/kg for lead with the average of 5.26 mg/kg, and the average for copper was 4.96 mg/kg, whereas it ranged between 0.6 to 10.85 mg/kg. The lowest concentration of heavy metals was found for Ni and Cd, with the average of Ni being 0.812 mg/kg and the average of Cd 0.75 mg/kg.

Table 3 presents the following basic statistical data of ash residue samples in mg/kg: average (AVG), range (min-max), standard deviation (SD), variance, first and third quartiles (Q1 and Q3) and median.

The mobility of an element, the form it occurs in the environment and other conditions determine whether that element is likely to enter the food chain. Highly mobile elements such as Mn or Zn are mainly taken up by the root system and are then transported from there to the leaves. Concentration of manganese was shown to be very high, and it can be explained as a result of the high content of this easily assimilative element in soil (Szczepkowski and Nicewicz, 2008). In our study it ranges from 5.99 to 2596 mg/kg. Kuokkanen et al. (2009) also found higher concentrations of this element.

If we compare the average values of the concentrations of heavy metals, we find that their order in ash samples is Fe> Mn> Zn> Cu> Ni>Pb> Cd. The global average of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29312941

cadmium content in soil is 0.41 mg/kg (Kabata-Pendias and Mukherjee, 2007), while in the surface layer of soil in Europe the average concentration of cadmium concentration is 0.15 mg/kg (Salminen et al., 2005). The standard of soils (Dutch list) defines the target concentration of Cd in soil to be 0.8 mg/kg. According to ecological soil screening levels established by USEPA (2003) (Eco-SSL) that serves for soil contamination, the maximum concentration of Cd is 32 mg/kg. In our samples, Cd ranges from 0.95 mg/kg to 7.85 mg/kg with an average of 4.51 mg/kg. By this definition of EPA, cadmium in our samples results to be in tolerated concentration.

Table 3. *List of analyzed elements in ashes residue*

Elements	AVG mg/kg	Min-max	SD	Variance	Q1	Q3	Median
Mn	978.25	(52.99-2596)	1192	1420019	67	2236	632
Cd	4.51	(0.95-7.85)	2.84	8.05	1.77	7.14	4.63
Pb	42.25	(32.35-48.05)	7.32	53.51	34.54	47.91	44.3
Cu	87.5	(38.25-195)	72.9	5308.6	40.5	163.6	58.4
Ni	58.8	(36.3-82.4)	20.2	407.4	39.6	78.6	58.3
Zn	229.39	(0.05-670)	300	89907	26	538	124
Fe	2095.013	(0.05-4705)	1956	3825547	393	4055	1838

The concentration of Cu in our samples ranges between 38.25 to 195 mg/kg, with an average of 87.5 mg/kg. The Dutch list defines the intervention concentration of Cu in soil to be 190 mg/kg. Eco-SSL classifies Cu as an element that should not exceed the concentration of 70 mg/kg when discharged on the soils. If we compare the average concentration of this element in ashes 87.5 mg/kg, we see that the maximum amount of copper is exceeded by almost 13%.

Zinc is an element with relatively low toxicity. In general, zinc toxicity is restricted to taking high doses. The global average of zinc content in soil is 90 mg/kg (Xie et al., 2000), while in the soils in Europe is around 48 mg/kg (Salminen et al., 2005). In our research for ash content of heavy metals, the average concentration of Zn is 229.39 mg/kg, ranging between 0.05 and 670 mg/kg. Eco-SSL maximum value for Zn is 160 mg/kg, thus it is over 40% higher than what EPA recommends.

The significance of nickel to the living organisms has been revealed in the last decades of the last century, bearing in mind by that time that nickel was considered to be toxic metal to the organism. Since then, this element is considered as "potential essential" for humans, although its role in the organisms is still relatively unknown. According to Kabata-Pendias and Mukherjee (2007), the global average content of Ni in soil is 29 mg/kg, while in the surface layer of soil in Europe is 18 mg/kg (Salminen et al., 2005). According to EPA's program issued for *ecological* soil screening levels, nickel should not exceed the amount of 38 mg/kg. In our ash samples it ranges from 36.3 to 82.4 mg/kg with the average of this metal being 58.8 mg/kg. As a conclusion, we see that the concentration of nickel is higher by 20 mg/kg.

For the concentrations of Pb we can say that we have lower concentration than the standard Dutch list. This list sets the maximum allowed concentration of Pb to 530 mg/kg. However, the comparison of these elements is different, because Pb is recognized as a much more toxic and dangerous element even in lower quantities. According to Kabata-Pendias and Mukherjee (2007) the average concentration of Pb in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29312941

soils of the world is 27 mg/kg, while in surface layer of soils in Europe is 23 mg/kg (Salminen et al., 2005). Eco-SSL defines the maximum concentration of lead as a discharged element to be 120 mg/kg. In our samples it varies from 32.35 mg/kg to 48.05 mg/kg.

It should be noted that these metals in the soil often come from various anthropogenic and natural pollutants, so their concentration is not dictated exclusively by ash residues. However, to avoid increasing the concentration of these metals, the most appropriate and ecofriendly methods should be identified.

To compare the results of heavy metals in fresh wood samples and their ash forms, a diagram is presented in *Figure 1*.

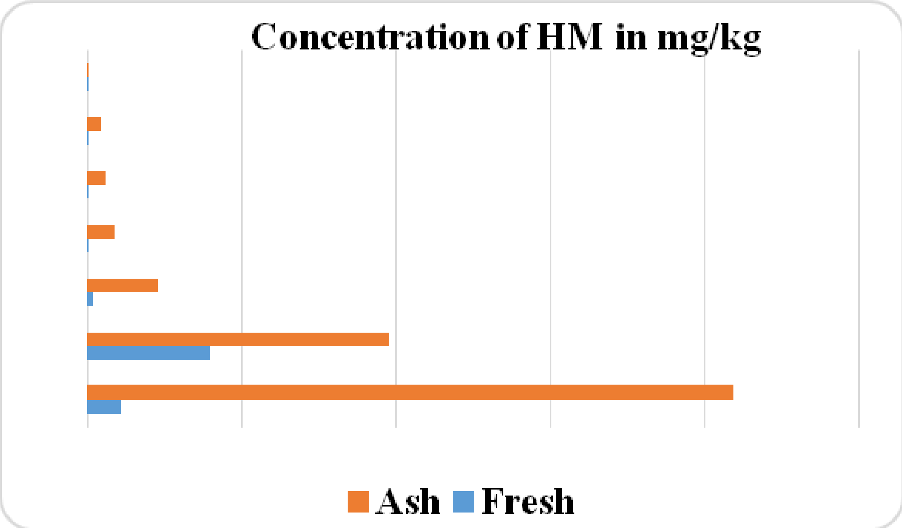

Figure 1. *Comparison of heavy metals in fresh and ash residues in woods*

In all cases we have a higher concentration for Zn, Fe, Mn, Ni, Cu, Pb and Cd. This is justified by the fact that ashes contain precisely these elements. Algreen et al. (2014) found similar results as our average results for Cd, Cu, Zn and Ni.

Correlation analysis

Table 4 shows the analysis of the similarity correlation of elements: Cd, Mn, Pb, Cu, Ni and Zn in measured areas. The statistical calculations were done by using the software Minitab 18.

Kosovo, though a rather small place in territory, is known as a rich country for many minerals. These elements in the environment can come from natural reserves, but anyway the anthropogenic influence has an impact on increasing their concentration.

From the correlation analysis it can be inferred that we have similarity sources of Mn and Pb in with more than 99% and Cd with Ni of about 99%. This shows that these elements occur as natural resources in Kosovo, but these elements can come also due to anthropogenic atmospheric pollution. On the other hand, we have a fairly large similarity of Fe with Cu, which stands at about 75 %.

Figures 2–7 show distribution of heavy metals in fresh wood and in their ash samples. The histograms show the frequency of different concentration brackets expressed in mg/kg.

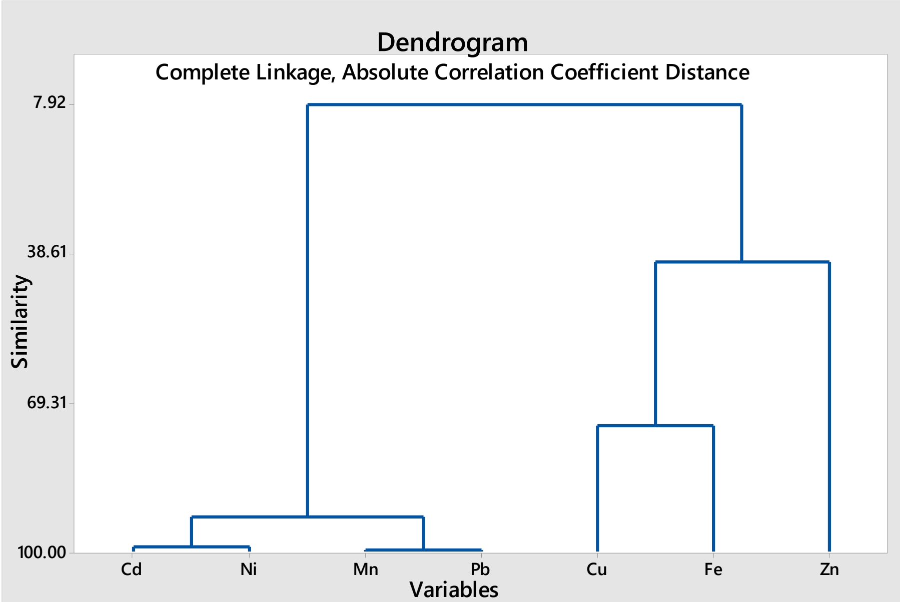

Figure 7. *Dendrogram showing the similarities of elements*

If we compare the results between fresh wood samples and ash residues, we see a significant difference in the concentration of heavy metals. In the case of manganese, its concentration is more than two times higher in ashes than in fresh wood; whereas in Fe, the concentration in ash residue is almost 20 times higher. In zinc, copper, lead, nickel and cadmium we also have significant increases in the concentration of heavy metals in ash samples. A part of these large increases in concentration can be explained by the fact that ashes themselves contain precisely these heavy metals.

Conclusion

The aim of this paper is the examination of the concentration of heavy metals in wood samples and in their ash form. In Kosovo, such a research is very important due to the many environmental problems and mismanagement of waste. In this country, the ash waste is typically disposed of in the ground, water or atmosphere without any of the necessary precautions. In this study, we have analyzed heavy metals and the consequences that can come from improper disposal of ash in the environment. The concentration of heavy metals is slightly higher than foreseen by the relevant standards due to pollution and lack of institutional control in these areas.

The presence of heavy metals in the ash samples from this study can lead to possible water contamination and environment in general.

In order to avoid environment pollution from ash, it is suggested to choose wood from unpolluted areas, free of contaminants, and the wood to undergo complete and careful burning.

If these conditions are met, then this ash can be used in various fields: regulation of pH levels in soil, heavy metal adsorption, remediation of pollutants in various forms, use in construction etc. But under the current conditions with the high concentrations of heavy metals, it is necessary to identify methods of prior treatment before considering the appropriate way of reusing the ash residue.

(Received 2nd Nov 2018; accepted 11th Jan 2019)

Abstract. The aim of this study was to investigate the occurrence and diversity of pathogenic bacteria in the environment at a livestock farm in Limpopo Province. Environmental samples were collected from three sampling locations: cattle camp (CC), sheep camp (SHC), and goat camp (GC). Samples were processed and analysed for total bacterial counts in the Biotechnology Laboratory, University of Limpopo, South Africa. Identifications were done with Matrix Assisted Laser Disorption Ionisation Time of Flight Mass Spectometry (MALDI-TOF MS) using the simplified on plate technique. The colony forming unit formula per gram of environmental sample (CFU/g) was used to determine total bacterial counts. High counts were observed in CC and low counts in SHC for both soil and faecal samples. *Bacillus species* were the most dominant across the sampling locations for soil samples. *Bacillus cereus* occurred in 36 samples (33%), however, the frequency of isolation dominated in the CC with (44.4%), GC (22.2%) and SHC (13%). *Staphylococcus aureus* had the least frequency (2.2%) followed by *Listeria monocytogene*s (4.4%). In faecal samples, the occurrence and level of contamination with bacterial species varied across sampling locations with *Escherichia coli* dominating in the CC with 20% frequency, and abscent from SHC and GC.
Keywords: *MALDI-TOF MS, livestock diseases, soil, Escherichia coli, Bacillus cereus*

Introduction

The rural communities of South Africa depend on livestock farming in various ways such as the provision of meat, milk, manure, improved livelihoods and socioeconomic relief (Meissner et al., 2013; Becker, 2015; Madziga et al., 2013). However, livestock diseases present a major threat to animal health. The increase in the circulation of infectious agents over the past decade as well as the emergence of antibiotic resistance and environmental pollution has placed human and animal health at risk. This highlights the importance of human-animal ecosystem interfaces in the evolution of emergence of pathogens (Destoumieux-Garzon et al., 2018). A better knowledge of causes and consequences of certain human activities, lifestyles, and behaviour in ecosystems is crucial for a rigorous interpretation of disease dynamics.

Threats from old and new pathogens continue to emerge as a result of changes in the climatic conditions. Young growing animals on pasture are especially prone to spore forming bacteria of the *Bacillus* and *Clostridium spp*. Livestock acquire the spores

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29432963

during grazing on contaminated pastures (Lange et al., 2010; Cooper and Valentine, 2016). Once the bacteria are in abundance on pasture, cases of the disease usually occur frequently in susceptible herds. Affected farms are usually those with irregular vaccination programs as farmers seek to minimise production costs (Maas, 2012). Limited studies focused on the ecology of transmission of livestock diseases (Morand and Figuié, 2016; Morand and Lajaurie, 2017; Cantor et al., 2017). In endemic areas, *Bacillus* and *Clostridium spp* may be present in soil and faeces (Dharmasena and Jiang, 2018). Christianssonn et al. (1999) reported bacterial contaminants of soil particularly *Bacillus cereus* to contaminate teats and udders of pasture fed cows leading to milk contamination and food borne diseases. Over the last few decades, several pathogens have either emerged or re-emerged. Livestock from small scale production systems in Limpopo Province suffer endemic diseases as they are kept under scavenging conditions which expose them to virulent factors.

In most cases, there is little attention to disease control and prevention in these livestock production systems (Gibbs, 2005). The extent of the diversity of microorganisms in soils determines the quality of pastures, since a wide range of pathogenic bacteria are involved in pasture contamination from livestock manure (Bagge et al., 2010). Bacterial species have always been of considerable medical and economic importance and the world is faced with changing landscape of infectious diseases due to pathogenic bacteria that affect man and animals posing significant threats to health and welfare of livestock (King et al., 2006). According to the 'one health', 60% of all human infections are directly or indirectly linked to livestock disease outbreaks (FAO et al., 2007). The documents and publications on the "One Health" approach, and the strategic framework developed around it, have largely focused on the battle against emerging zoonoses originating in domestic (Day, 2011) or wildlife (Dantas-Torres et al., 2012) and/or their interactions (Mencke, 2013). Bagge et al. (2010) reported manure to be the common pasture contaminant resulting in livestock infections. Based on the farm records, diseases and conditions such as blackleg, pulpy kidney, pink eye and mastitis are endemic at the farm. Therefore, identification of the causative agents in the farm is crucial for implementation of prompt therapeutic and control measures (Neumann et al., 2002). Therefore, the objectives of the study were to determine the total bacterial counts from environmental samples collected from the cattle and small stock camps in the farm using the colony forming unit (CFU) formula per gram of environmental sample and to identify the pathogenic bacteria isolated from soil and faecal samples.

Literature review

Arable land and pastures contaminated with the faeces of sick animals contribute considerably to pathogen transfer resulting in farm environment pollution (Trawińska et al., 2006; Nageswaran et al., 2012; Czekalski et al., 2012). Furthermore, the soil and manure in high producing farms provide diverse biological and physicochemical environments to microorganisms which pose a significant threat to humans and animals (Godwin and Moore, 1997; Whitman, 1998; and Douglas et al., 2003). Stecher and Hardt (2008) reported that bacteria in the gastro-intestinal tracts of animals can be excreted at high levels in faeces thereby contaminating soils and pastures. These bacteria may persist due to differences in local soil conditions (Dapilly and Neyrat, 1999; Gale, 2004). Extensive livestock farming poses a threat to the environment, as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29432963

livestock shed millions of bacteria through their faeces and contaminate the soil and pastures thereby elevating the risk of disease breakouts. Nonetheless, disease outbreaks can be prevented through vaccination when local strains are recognised and safeguarding of human and animal health can be ensured (Radostitis et al., 2000; Amin et al., 2013; Manyi-Loh et al., 2016).

Livestock practices influence the microbial composition of faeces shed by animals (Wang et al., 2004; Manyi-Loh et al., 2016). The ability of these pathogens in manure to pollute, contaminate and infect the environment and livestock depends on the pathogen's ability to survive in manure following excretion or the hygiene practices to prevent its entry into the food chain (Wang, 2004). Studies on diversity of spore forming bacteria in cattle manure reported pathogenic bacteria of particular concern for animal health as, *Clostridium spp,* particularly (*C. chauvoei*, *C. botulinum*, *C. tetani*) and *Bacillus spp* (*B. anthracis* and *B. cereus*) (Bagge et al., 2010; Adak et al., 2002*;* Pachepsky et al., 2006; Pell, 1997; Plaut, 2000; Chauret et al., 1999). *Campylobacter spp* (*C. jejuni* and *C. coli*)*, Salmonella enterica* (Adak et al., 2002*;* Pachepsky et al., 2006; Pell, 1997; Plaut, 2000), *Yersinia spp* (Y. enterocolitica and Y. pestis), *Leptospira spp* (*L. interrogans*) and *Coxiella burnetii* (Aitken et al., 2005; Nightingale et al., 2004), *Mycobacterium avium* sub species *paratuberculosis, Listeria monocytogenes, Escherichia coli O157* (Robert et al., 2017) are also reported as major threats to animal and human health. These bacterial species can cause serious clinical diseases in farm animals, when they are ingested in feed and have also been implicated in cases of food borne diseases in humans such as *L. mocytogenes* in human listeriosis.

Salihu et al. (2009) reported that *Ca. jejuni* and *Ca. fetus* cause abortion, stillbirths and birth of weak lambs in sheep during late pregnancy. The campylobacter species has highly been associated with feed contamination mostly in poultry as a result of faecal contamination. This alarms the need to identify these species at farm level so as to put hygiene strategies like proper manure management in place to prevent cross contaminations. Moreover, the depletion of medicinal plants due to increased population alarms the need to recognise local pathogen strains so that reliable drugs and vaccines can be produced for proper management of livestock diseases (Nishteswar, 2014). Thus, it is necessary that local pathogen strains be recognised so that vaccines can be developed for better disease management at farm level.

There is ample evidence showing that soil amendments that harbor enteric pathogens, such as raw animal manure or incompletely composted manure, are a means of introducing these pathogens in crop production systems (Kim et al., 2009; Nicholson et al., 2005; Ziemer et al., 2010). Products from mixed farming, including meat, eggs, and fresh produce, are at greater risk of cross-contamination as they are grown in the same facility and are currently considered to be high-risk foods (Adl et al., 2011). The source of contamination of fresh produce with enteric pathogens can frequently be traced back to environmental reservoirs associated with farm animals such as poultry, cattle, swine, goat, and sheep (Brinton et al., 2009; Park et al., 2014).

Materials and methods

Description of the study area

The study was carried out in a livestock farm in Limpopo Province, South Africa, coordinates: 23°49' S; 29°41' E. During the study period, no animal diseases or mortalities were reported. The total number of livestock kept at the farm was 225

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29432963

comprising 82 cattle, 77 sheep and 66 goats. The farm practices mixed livestock farming. Extensive livestock production system increases the chances of disease outbreak as livestock will have access to pastures and water supplies that may be contaminated with disease causing agents such as bacteria (McGuirk, 2015). The farm relies on chemoprophylaxis as a disease management tool, however, the practice is irregular. Environmental samples were collected from different resting points within camps in the farm. *Figures 1-4* depict the environment from where samples were collected.

Collection of environmental samples

Environmental samples (soil and faeces) analysed in this study were collected from the vicinity of sheep and goat housing facilities as well as cattle grazing pastures. Samples are collected over a period of three months, from January to March 2018. The samples were labelled according to the site of collection as cattle camp samples (CCS), sheep camp samples (SHCS) and goat camp samples (GCS). Hundred soil samples comprising of sixty CCS, twenty SHCS and twenty GCS were collected from locations that were perceived as high risk areas for bacterial contamination in a random zigzag pattern. Unpolluted and polluted top soil samples in the vicinity of faecal droppings were collected at different depths. Samples taken from below the soil surface were collected using a soil auger according to the procedure described by Brooks (2016). Seventy faecal samples comprising of thirty CCS, twenty SHCS and twenty GCS were collected. Cattle faecal samples were collected as cowpats on grazing land while sheep and goat faecal samples were collected as pellets. Approximately 100-200 g environmental samples were collected in sterile sealable plastic bags. The samples were then transported on ice, in a Styrofoam cooler box and transported to the University of Limpopo, Biotechnology Laboratory for microbial analysis

Microbial analysis of environmental samples

All the required consumables for the study were procured from Prestige Laboratories (Pty) Ltd, Durban, South Africa. Microbial analyses were performed under sterile conditions in a laminar flow with a Bunsen burner to avoid contamination from the environment. The collected samples were cultured on selective and general media for isolation of pathogenic bacteria.

Reinforced clostridia agar, Reinforced clostridia broth, sheep blood agar, anaerobic basal broth and nutrient agar were prepared and used for detailed investigation of pathogenic bacteria according to the manufacturer’s instructions. Environmental samples were serially diluted to reduce the bacterial concentration of the original soil sample to levels low enough for single colonies to be grown on agar plates, allowing for calculation of the initial counts of bacteria in the environmental samples (Koch, 1883).

Purification of bacteria and determination of total counts

Bacterial culture and purification were carried out according to the methodology of Bagge et al. (2009) while colony counts were determined according to Brugger (2012) (*Eq. 1*). Samples cultured on sheep blood agar grew and triggered haemolyses within

DOI: http://dx.doi.org/10.15666/aeer/1702_29432963

24 h of incubation at 37 °C. The isolates appeared flat and raised with the shape being filamentous to irregular, round and punctiform. They were smooth or wrinkled and the colour ranged from grey, cream to white and with few colonies being yellow (*Figs. 5-7*). Different colonies subcultured on nutrient agar for purification were able to grow under anaerobic conditions within 24 to 36 h of incubation at 37 °C.

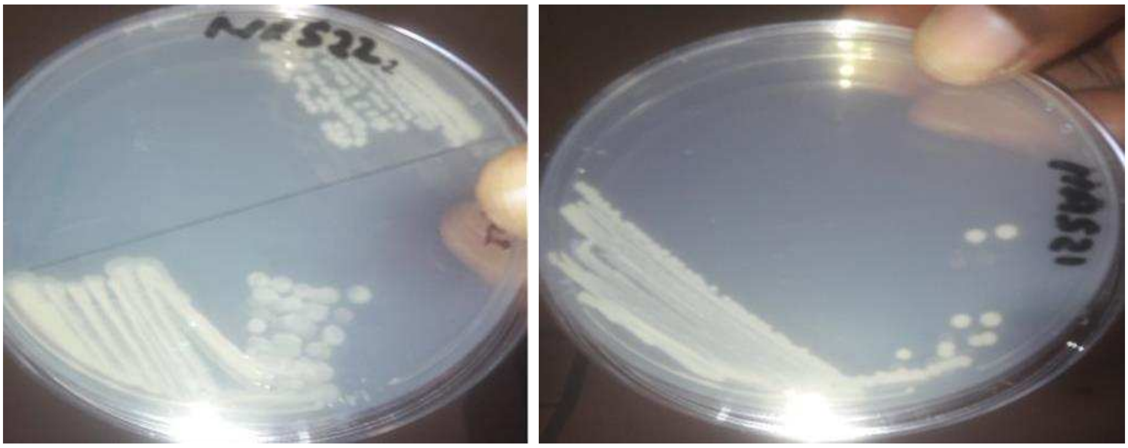

***Figure 7**. Plates with a four-way streaking of pure cultures on nutrient agar*

Proteomic identification of colonies

All bacterial isolates reported in this study were analysed by MALDI-TOF MS, using a Microflex LT bench top mass spectrometer (Bruker Daltonics, Maldi Biotyper, Bremen, Germany). The software for the control of the instrument was FlexControl 3.3 and Maldi Biotyper 3.1 (Bruker Daltonics) for the analysis of the spectra and comparison with the database. A bacterial test standard provided by the manufacturer was included in every run for calibration purposes. Default settings (acquisition of mass spectra in the linear positive mode within the 2e20 kDa range, ion source 1 (IS1) 20 kV, IS2 18.05 kV, lens 6.0 kV, linear detector 2,560 V) were applied for all the detections. A rapid, on-plate method that requires less time and reagents for its performance was followed in this study (Matsuda et al., 2012).

Data presentation

The numbers of viable bacteria per gram were obtained using a mathematical formula for colony forming units (CFU) per gram of environmental sample. Diversity, occurrence and frequency of isolation of pathogenic bacteria identified in environmental samples using MALDI-TOF MS are presented with descriptive statistics. Microsoft Excel, 2013 was used to compare the level of contamination in faecal and soil samples.

$$\mathrm{CFU}/g = \frac{\text{Number of colonies per agar plate} \times \text{Dilution factor}}{\text{Volume of culture plated}} \quad \text{(Eq.1)}$$

Results

Colony forming units per gram of environmental sample

Colony forming units were calculated using the formula of Harley (2005) (*Eq. 1*) based on average colony counts per plate. This was done to estimate the number of viable bacteria per gram of environmental sample. All samples were of similar weight (1 g) and exposed to same dilution factors of 10^{-5}, 0.1 ml of bacterial culture were plated per agar plate. Based on these calculations, there were differences in the average colony forming units of different sampling locations. The results indicated that the cattle

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29432963

camp had a higher level of contamination as compared to the goat and sheep camps for both soil and faecal samples. The highest counts were observed in samples from the cattle camp and the lowest counts were observed in samples from the sheep camp for both soil and faecal samples (*Figures 5* and *6*).

Diversity of bacterial species identified in soil and faecal samples

During the study period, a total of hundred and seventy environmental samples collected for microbial analysis of pathogenic bacteria were analysed by MALDI-TOF MS using the simplified on-plate method. Hundred and thirty-four (79%) of the samples comprising of 108 soil and 26 faecal samples were successfully analysed and tested positive for different bacterial species. The remaining thirty-six samples (21%) could

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29432963

not be identified by the technique used. *Tables 1* and *2* indicate the bacterial isolates identified upto genus/species level for faecal and soil samples respectively. Based on these results, it was observed that different farm environments harbour different bacterial species. However, minor similarities were observed with few bacterial species where *B. cereus* and *E. coli* were isolated in both manure and faecal samples. Using (*Eq. 2*) *Bacillus cereus* were identified as the most dominant species isolated from soil samples in 36 positive samples (33%), followed by *B. mycoides* in 24 positive samples (22%) (*Table 3*). Regarding faecal samples, 26 samples tested positive with *E. coli* being the most prevalent species, identified in 9 positive samples (34.6%), followed by *Acinetobacter baumannii* identified in 8 samples (30.8%), *Acinetobacter baumanii* in 5 samples (19.2%), *B. cereus* and *B. psedomycoides* were the least dominant with (7.7%) each (*Table 4*).

In the present study, the levels of environment contamination by pathogenic bacteria varied with respect to sampling location. However, there were some similarities with respect to the bacterial isolates prevailing across sampling locations (*Tables 3* and *4*).

Percentage frequencies in *Tables 3* and *4* were calculated using *Equation 2:*

$$\%Frequency = \frac{\text{Number of samples from a camp positive for a bacterial species}}{\text{Total number of positive samples from the farm/camp}} \times 100 \quad \text{(Eq.2)}$$

Discussion

This study utilised MALDI-TOF MS to identify bacterial isolates from environmental samples. The results indicated that 134 (79%) environmental samples out of the 170 collected tested positive for various bacterial species with MALDI-TOF MS identification. Urwlyer and Glaubitz (2015) reported MALDI-TOF MS to have a revolutionized speed and precision of microbial for clinical isolates to outperform conventional methods. This is evidenced in their study were MALDI-TOF MS showed the lowest number of false identification (4%) and 60% accuracy at genus level. In contrast, the biochemical-based system assigned 25% of genera incorrectly. In this study, MALDI-TOF MS provided identification at the genus level of 67% of the bacterial isolates. This agrees with Dupont et al. (2010), Justeen et al. (2011), Nagy et al. (2012), Wieser et al. (2012), Lee et al. (2015) and Florio et al. (2018) who reported the capacity of MALDI-TOF MS to identify bacterial microorganisms at the genus and species level according to the cut of values in this study (score value 2.000 - 2.299) ranging from 65.2 to 83.9%. Average colony forming units in both soil and faecal samples fell within the range reported by previous researchers for environmental samples (Okoh et al., 1999; Ogunmwonyi et al., 2008). Total bacterial counts were relatively higher in soil samples suggesting high contaminations as compared to faecal samples.

These results agree with the reports of Trawińska et al. (2006) who indicated that soil in the vicinity of high-production farms is commonly microbial-contaminated as arable land and pastures contaminated with the faeces of sick animals, especially, contribute considerably to pathogen transfer into the soil. Boes et al. (2005) and Ngole et al. (2006) reported that micro-organisms survival in the soil environment is favoured by high temperature and moisture. Oliver et al. (2006) stated that rainfall events result in faecal microbes being washed from the cowpats into the surrounding soils where their survival could be enhanced. This finding is further supported by the results of Muirhead (2009) who reported an increase in soil *E. coli* concentrations on the grazed camps which they believed coincided with an increase in rainfall during their study period. Furthermore, Kress and Gifford (1984) and Stoddard et al. (1998) reported that heavy rain or irrigation on a fresh cow pat is likely to result in far greater microbial mobilization and leaching. Mobilization and leaching of bacteria during rainfall could be the reason for high percentage prevalence of bacteria species in soil compared to faecal samples recorded in the current study. Bacteria leach with water into the soil, where they incubate and multiply resulting in contamination of pastures were animals graze (Kress and Gifford, 1984).

In the present study, *Bacillus species* was identified to be the most prevalent species in soil samples. This is in agreement with Gutiérrez- Mañero et al. (2003) and Amin (2015), who reported bacillus as naturally occurring soil bacteria and most abundant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29432963

genus in the rhizosphere of soil. From this genus, the most dominant species appeared to be *B. cereus,* which when allowed an opportunity to invade mammalian tissues is an opportunistic pathogen that may cause severe or local systematic infections such as endophthalmitis and septicaemia (Kotiranta et al., 2000). *B. cereus* has been reported to cause serious clinical diseases in farm animals, thereby causing economic loses to farmers. Songer and Post (2005), Nieminen et al. (2007) and Salih (2015) reported *B. spp* to occasionally cause mastitis in cattle. Furthermore, *B. cereus* has been reported as an important food borne pathogen. Tewari and Abdullah (2015) reported highly toxic strains of *B. cereus* responsible for food-related fatalities. Ranieri et al. (2009) and Gundogan and Avci (2014) reported *Bacillus spp* to be ubiquitous in nature. The ability of its spores to tolerate different environmental conditions including elevated temperatures result in these species being the most common isolated bacteria from food, air, soil, and faecal samples. However, the reports of Bavykin et al. (2004) indicating that bacillus is the most common genus in faecal samples are in contrast with the findings of this study as these bacteria tested positive only in faecal samples of cattle with a frequency occurrence of 6.6%.

In faecal samples, *E. coli* was the most frequently isolated pathogen. The dominance of *E. coli* in faecal samples reported in our study agrees with reports by previous researchers (Tahamtan et al., 2006; Raji et al., 2006; Hiko et al., 2008; Hashemi et al., 2010). Hogan et al. (1999) and Abakpa et al. (2015) reported *E. coli* to be naturally present in faeces of warm blooded animals. *E. coli* occurrence has been previously used as an indicator of faecal contamination, signaling the possible presence of faecal pathogens such as *Salmonella* and *Shigella* species (Odonkor and Addo, 2018). In a study by Rodrigues et al. (2015), MALDI TOF-MS identified 83% *E. coli* prevalence in faecal samples, however, the pathogenicity of the strains were not reported. Schmidt et al. (2015) reported *E. coli* to be free-living commensals in animal intestines. The prevalence of this bacterial species was found to be high in the cattle camp in comparison with the small stock camps. Sima et al. (2009), Kiranmayi et al. (2010) and Rahimi et al. (2012) reported domestic animals as the sources of *E. coli*. However, the major animal carriers seem to be healthy domesticated ruminants, primarily cattle and, to a lesser extent sheep.

These findings agree with the results of our study as *E. coli* were only identified in cattle faeces with zero prevalence in sheep and goat faecal samples. However, large variations have been described in the shedding patterns of individual animals, the proportion of shedding animals on farms that harbor them and, over time, in the amount of shedding on the same farm (Smith et al., 2010). Among cattle, shedding occurs intermittently (Hancock et al., 1997; Kulow et al., 2012; Sharma et al., 2012), and it was reported that, at any time, up to 50% of the healthy animals excrete *E. coli* in their stool (Lim et al., 2010). Freshly deposited faeces contain the nutrients required by bacteria, and replication presumably depends on the faeces retaining water and attaining suitable temperatures for growth. Cow pats are able to retain moisture when exposed to sunlight. The pats quickly form a skin, which thickens to a well-defined crust within 48 h favouring bacterial growth (Van Kessel et al., 2007). However, exposure of sheep and goat pellets to the sun results in drying of the pellets due to size and less moisture contained making the environment unfavourable for bacterial growth. Topp et al. (2003) studied the relationship between soil moisture content and prevalence of *E. coli* bacteria and concluded that elevated soil moisture levels were associated with increased number of bacteria in the soil. This could explain the low counts of *E. coli* in soil samples of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29432963

current study as soil samples were collected in early summer where moisture content in soil is believed to be relatively low. Of the twenty-two bacterial isolates isolated from the environmental samples in this study, some species have been reported previously to carry virulent strains which are responsible for livestock infections particularly in cattle, sheep and goats. These pathogenic bacteria include: *E. coli* (Olson, 2001; Chekabab et al., 2013), *B. cereus* (Nieminen, 2007; Manyi-Loh, 2016; Robert et al., 2017), *L. monocytogens* (Nightingale et al., 2004; Nicholson et al., 2005), *Staphylococcus aereus* (Toroitich, 2013), *Pseudomonas aeruginosa* (Radostits et al., 2000), *Seratia marcescens* and *B. licheniformis* (Olson, 2001).

Pathogenic bacteria in farm environments pose a major epidemiological threat (Amin et al., 2013). Although *E. coli* have been reported as harmless commensals of the intestines of warm blooded animals, the strain *E. coli* O157:H7 has been reported to be harmful (Titilawo et al., 2015). Shearer et al. (2003) reported *E. coli* as one of the major bacterial pathogens associated with livestock infections in farms. Healthy colonized cattle and other ruminants are the most significant animal reservoir harboring *E. coli* (Ferens and Hovde, 2011). Previous studies linked approximately 75% of the human *E. coli* outbreaks to food products of bovine origin (Callaway et al., 2009; Munns et al., 2016). Other reservoirs that may impact transmission include sheep (La Ragione et al., 2012; Soderlund et al., 2012; Gencay, 2014), goats Pao et al.(2005), La Ragione et al.(2009), Mersha et al.(2010), Alvarez-Suarez et al.(2016) and Swift et al.(2017).

According to Tomita and Hart (2001) *E coli* bacteria possess several pathogenic factors responsible for their pathogenicity, among which exotoxin A (*tox*A) and exoenzyme S (*exo*S) are the two major fatal toxins which are associated with subclinical mastitis infection in bovines (Toroitich, 2013) in a cross-sectional study to determine the prevalence of mastitis and identify the associated risk factors reported the most predominantly isolated bacterium to be *Staphylococcus aureus* with a prevalence of 36% followed by *E. coli* with a prevalence of 27.2% and *Pseudomonas* were least isolated with less than 1% prevalence.

In the present study, *L. monocytogenes* tested positive in cattle camp soils (4.4%). This falls in the same range as the findings of Mohammed et al. (2009) (5.4%) and less compared to the findings from previous studies by Moshtaghi et al. (2003) (17.7%) and Nightingale et al. (2004) (22.2%) and Locatelli et al. (2013) (38.1%). Several animal derived *L. monocytogenes*-contaminated food products, including raw milk, pasteurized milk, chocolate milk, butter, soft cheeses, and processed meat and poultry products, have been implicated as sources of human listeriosis cases and outbreaks (Buchanan et al., 2017). It has been reported that manure from infected or shedding animals represent direct links between human infections and *L. monocytogenes* in farm animals and farm environments as a result of consuming animal-derived food products that are not processed before consumption such as raw milk and raw foods of plant origin (Nightingale et al., 2004).

Previous studies reported *Campylobacter* species and *Clostridium* species to be pathogenic bacteria of livestock commonly isolated from environmental samples (Baserisalehi et al., 2007; Bagge, 2009). However, in the present study, all samples tested negative for *Campylobacter* species. *Clostridium species* were detected in 2 samples (5%). Bandelj et al. (2016) reported a 10% prevalence of *clostridium difficile* in cattle faecal samples. The use of selective media may have disadvantaged growth of other bacteria species in the samples. Olson (2001), reported the *Campylobacte*r genus to have fastidious growth requirements making conventional detection and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29432963

identification difficult. This could be the reason why all samples in the present study tested negative for *Campylobacter species*. The differences in bacterial contamination in the sampling locations in this study may be due to different management practices in the livestock camps were cattle are kept in their camp continuously resulting in piling of faecal samples increasing microbial habitat. In comparison with sheep and goats which are housed at night resulting in few fresh pellets in their camps. Spiehs and Goyal (2007), Hutchison et al. (2005) and Manyi-Loh et al. (2016) indicated that the levels and types of pathogens occurring in livestock faeces vary with animal species, dietary sources, health status and age of the animal.

Conclusions and recommendations

This study showed that diverse bacterial species contaminate the livestock grazing environment at the study farm. Although samples were collected from different locations within the farm, the bacteria isolated from soil samples were generally similar. However, with regard to faecal samples, bacterial isolates differed from one camp to the other entailing that different livestock harbour different bacteria in their faeces. Of the bacterial species isolated in the study, some genus have been reported to be highly pathogenic. This study demostrated contamination by opportunistic, food-borne bacteria like *B. cereus* and *L. monocytogenes* in the farm environment and the need for good hygiene practices to prevent its entry into the food chain. Rapid microbial identification is necessary for quick implementation of relevant disease management strategies at farms. The findings of this study show that MALDI-TO MS can identify bacteria rapidly in environmental samples. This method can be used to identify potential disease risk in an environment and allow for appropriate control measures.

(Received 7th Nov 2018; accepted 8th Feb 2019)

Abstract. Present study aimed to determine the effects of salt stress in 13 melon genotypes and 4 commercial melon varieties collected from the Van Lake Basin. Two doses of salt applications were conducted at 0 mM and 50 mM NaCl concentrations and the plants were cultivated in 3 repeats under 25 ± 2 °C temperature and 16/8 light/dark periods based on the randomized block experimental design in climate chamber conditions. In order to determine the effect of stress, traits such as 0-5 scale, shoot and root lengths, shoot diameters, leaf number, fresh and dry weights of shoots and roots, leaf relative water content, membrane injury index, stoma widths and lengths, stomatal areas and stoma densities were evaluated. The reaction of the genotypes against stress was determined via mixture modeling and PCA analysis. In PCA analysis, three PCA components explained 71.48% of the total variation at 0 mM, while four components explained 69.53% of the total variation at 50 mM. As a result of the mixture modeling analysis, it was observed that 4 sub-populations for 0 mM and 3 sub-populations for 50 mM were formed and it was revealed that the salt-tolerant genotypes were in the sub-population 3 and salt-susceptible genotypes were in the sub-population 1.
Keywords: *Cucumis melo L.,·soil salinity,·susceptibility,·tolerance, Van Lake Basin*

Introduction

Especially in arid and semi-arid regions with low precipitation, soil salinity, which occurs with the high surface evaporation due to the effect of incorrect applications such as excessive irrigation and fertilization, is among the increasingly significant abiotic stress factors (Maksimovic and Ilin, 2012; Yıldız and Balkaya, 2016). While salinity problem exists in 65% of global agricultural lands, this rate is around 20%in Turkey (Yetisir et al., 2016). Especially, 20% of the 230 million hectares of irrigated global farmlands face salinity problem (Peleg et al., 2011). Salinity causes stress in plants through different mechanisms. The plant initially undergoes water stress due to low osmotic pressure that occurs in the soil solution (Ashraf and Harris, 2004). Furthermore, ion imbalance and toxicity occur due to the accumulation of high amounts of Na^+ and Cl^-ions (Lauchli and Grattan, 2007; Aktas et al., 2009). Generally, in the salt stress induced by the Na^+ and Cl^-ions, the function and structure of the proteins deteriorate (Tuteja et al., 2012) and harmful effects occur in the function of metabolites at high concentrations of Na^+ (Agarwal et al., 2013).

Since the tolerance mechanisms, including different genes under environmental conditions, have a complex structure (Ashraf and Harris, 2004), plants develop extremely diverse responses to salt stress due to their genotypic differences (Çulha and Çakırlar, 2011). While Levitt (1972) indicated that plants often cope with the negative effects of salt stress through escape, avoidance or tolerance strategies, Munns and Tester (2008) claimed that plant tolerance against soil salinity was ensured through

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29652981

three components, namely, Na^+ exclusion, tissue tolerance against Na^+, and osmotic tolerance. It was reported that the most effective solution to salt stress is the development of varieties with tolerance (Dasgan and Koc, 2009).

Harlan (1951) indicated that Turkey, which is the second highest melon producer globally (FAO, 2013), was a micro-center for cucurbits, including melon (Sari et al., 2008). Furthermore, it was reported that Turkey is one of the gene centers for melon (Erdinc et al., 2013). Van province, which is located in the Eastern Anatolia region in Turkey, is known as one of the gene centers for cantaloupe melon (Turkmen et al., 2008). Thus, melon could be considered among the basic economic products of Turkey (Dasgan et al., 2012). It was noted that the threshold of Electrical Conductivity (EC) for the melon with moderate sensitivity against salt was 1 dS m^{-1} (Maksimovic and Ilin, 2012). It was reported that although most cultivated plants such as beans, carrots and onions were known to be susceptible to salt (Petropoulos et al., 2017), melon exhibited a medium tolerance to salt stress, yet the condition was different among varieties due to the presence of tolerant and susceptible varieties (Damianos and Savvas, 2016).

Selection and breeding studies, conducted to develop high-yield commercial varieties, resulted in a reduced genetic diversity, and inevitably led to a reduction in genetic variations and a lower tolerance of cultivars to abiotic stress conditions. It was considered that genotypes with qualified breeding properties could provide gene resources for future breeding programs through determination of high tolerance genotypes via screening studies.

Mixture modeling intends to recognize previously unobserved homogenous sub-populations involving an apparently heterogeneous data set (Wang et al., 1996; Dalrymple et al., 2003; Martinez et al., 2009) utilizing Akaike's information criteria (AIC) and Bayesian information criteria (BIC) (Yeşilova et al., 2010) to characterize and distinct sub-populations. Mixture modeling is a novel methodology and has two significant benefits than the cluster and factor analysis (Muthén and Muthén, 2014). The first, for every observation, mixture modeling is settled by the likelihood of consideration inside the subgroup classes. The second, mixture model gives the parameter estimates for every subgroup (Mao et al., 2013). Present study aimed to determine the effects of salt stress in melon genotypes via mixture modeling and PCA analysis.

Materials and methods

Materials

Fourteen genotypes collected from different regions in Lake Van Basin (*Fig. 1*), 3 hybrid cultivars and 1 foreign standard cultivar were used in the present study where the reactions of the melon genotypes to salt stress were examined (*Table 1*).

NaCl treatment

In the study designed with three replications with 5 plants per repetition in randomized block experimental design, the seeds were sown into non-drainage 3-L pots having 2:1 ratio of sterile peat: perlite mixture. The seedlings were irrigated with Hoagland solution (Aktas et al., 2009). For salt application, based on previous studies (Yasar et al., 2006; Kusvuran et al., 2007b; Yarsi et al., 2017) the most suitable dose was chosen and when the seedlings reached into two-true-leaf stage, 50 mM NaCl

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29652981

concentration was applied gradually for 2 days until a final concentration of 100 mM was obtained. The study was terminated after 18 days of salt application.

Seedling parameters

The morphological parameters such as shoot and root length, shoot diameter, leaf number, shoot-root fresh and dry weights were determined at the end of the experiment. The root: shoot ratio (Dry weight-DW%) (R: S) was determined after the dry weights were obtained.

Leaf relative water content (LRWC)

In order to determine the leaf relative water content in melon plants, primarily the fresh weights (FW) of the 3^{rd} and 4^{th} leaves of the three randomly selected plants in each repetition were determined and were stored in sterile distilled water for 4 h for the leaves to reach the maximum turgor weight (TW) and at the end of this duration their

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29652981

turgor weights were measured. Leaf specimens, which were tested for turgor weight, were placed in an oven at 80 °C temperature and dry weights (DW) were determined. After measurements were completed, LRWC was calculated using *Equation 1* (Yamasaki and Dillenburg, 1999), consequent to the completion of measurements:

$$LRWC = [(FW - DW)/(TW - DW)] \times 100 \quad \text{(Eq.1)}$$

Membrane injury index (MII)

The membrane injury index refers to the amount of electrolyte released from the cell. The amount of electrolyte released from the cell under stress conditions was determined with the methods developed by Dlugokecka and Kacperska-Palacz (1978) and Fan and Blake (1994). The discs retrieved from the third plant leaves were measured for their EC values after being kept in deionized water for 6 h at room temperature, then disc leaves were left in water at 100 °C for 10 min to retrieve the EC values again, and *Equation 2* was used for the calculations:

$$MII = \left[\frac{Lt - Lc}{1} - Lc\right] \times 100 \quad \text{(Eq.2)}$$

Lt: EC value before autoclaving of stressed leaf/EC value after autoclaving of stressed leaf.
Lc: EC value before the control leaf is autoclaved / EC value after the control leaf is autoclaved.

Visual evaluation of salt stress (0-5 scale)

In the scale, used for visual evaluation of the salt injury in the seedlings, the scale values were as follows (Dasgan, 2002; Kuşvuran et al., 2007a):

0- No effect; 1-Local yellowing and curling of leaves, slow growth; 2- Necrosis and chlorosis in 25% of the leaf; 3- Necrotic spots on the leaves and defoliation by 25-50%; 4- Necrosis by 50-75% and death of several plants; 5- Formation of severe necrosis in leaves by 75-100% and predominant deaths in plants.

Stomatal traits

In order to determine the stoma density (StD) (unit mm^2), stomatal area (StA) (µm^2), stoma width (StW) and length (StL) (µm), the lower epidermis of the 4th plant leaf was stripped and spread on a slide with two drops of water (Kurtar et al., 2016). The stoma count was calculated with LAS EZ 3.0 software under three-field light microscope (LEICA DM500) with 40× magnification in three randomly selected 0.08 mm^2 tissue specimen sections spread on the slide.

Stomatal area was calculated with *Equation 3* (Orsini et al., 2013):

$$StA = \pi \times (SW \times 0.5) \times (SL \times 0.5) \quad \text{(Eq.3)}$$

Statistical analysis

In the evaluation of the data obtained with the measurements and observations conducted in the study, the extent of the effects of salt stress on genotypes and varieties

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29652981

were based on the variation rates when compared to the control group and the data were compared using *Equation 4:*

$$\text{Percent change} = \left[\frac{\text{Control} - \text{Salt treatment}}{\text{Control}}\right] x100 \quad \text{(Eq.4)}$$

The mixture modeling statistical analyzes were performed with Mclust (mixture cluster) extension in R 5.2.3 statistical software (R Development Core Team, 2017). 0-5 scale, growth parameters, leaf relative water content, membrane injury index and stomatal features were classified with the Mclust Software. The principal component analysis (PCA) was conducted to identify the patterns of variation within the sets of melon accessions based on 14 properties using the PRINCOM procedure described by SAS (SAS Institute, 2015). Furthermore, Pearson correlation analysis was conducted with SPSS Software in order to determine the correlations among the variables.

Results and discussion

Seedling parameters

The leaf number, shoot diameter, shoot and root length values are presented in *Table 2.* It was observed that leaf number decreased in all genotypes and varieties due to salt stress, and the highest proportional decrease occurred in the genotype YYU29 (-54.24%) followed by cv. Lokum F_1 with a -52.61% decrease. YYU6 was the genotype that exhibited the lowest proportional decrease in leaf number due to salt stress (-7.46%). While the highest decrease in shoot diameter, -20.33%, was determined in genotype YYU10 when compared to the control group, the shoot diameter of 66.67% of the genotypes increased in saline conditions. It was established that salt stress affected the shoot length negatively in all melon genotypes and varieties. On the contrary, root length increased in half of the genotypes under salt stress. While YYU29 genotype and cv. Lokum F_1 were among the most adversely affected melons by salt stress in terms of shoot length (-62.93% and -62.59%, respectively), YYU15 genotype exhibited the lowest decrease in shoot length with a -21.42% decrease, when compared to the control group. Similar to the shoot diameter, YYU10 genotype was the most affected genotype by salt stress, similar to the decrease in root length (-25.31%). When compared to the control group, the highest increase in root length was observed in YYU6 genotype with 41.50%.

Although all genotypes and cultivars were adversely affected by salt stress, it was found that the shoot fresh weights of YYU18 and YYU6 genotypes were the least affected parameters (-13.94% and -18.55%, respectively). It was determined that the genotype with the highest decrease was YYU4, with -56.78%. In the presence of salt stress, increases in shoot dry weight were observed in only 3 genotypes, YYU6, YYU18 and YYU1 (20.00%, 6.76% and 1.11%, respectively). It was determined that about 67% of the genotypes exhibited an increase in root fresh weight in saline conditions and for root dry weight, the increase was 72%. The highest rate of increase was observed in YYU6 genotype in both cases (*Table 3*). The same trend was also reflected in the root to shoot ratio and 89% of the genotypes demonstrated an increase in root: shoot ratio due to salt stress. While, the highest increase was observed in the YYU6 genotype

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29652981

(403.24%), only YYU11 and YYU10 genotypes exhibited a decrease of -7.65% and -1.19%, respectively (*Table 4*).

It was determined that salt application commonly affected plant growth negatively. Hence, the first response of the plants to salt was the reduction of growth rate and toxic effect symptoms on the leaves and shoot ends (Dasgan et al., 2002). While all varieties and genotypes were adversely affected in leave number, shoot length and shoot fresh weight, it was established that there existed a variation between genotypes in shoot diameter, root length, shoot dry weight, root fresh and dry weight, and root:shoot rate. The reduction in leaf number ranged between 7.46 to 54.24%. Yetişir et al. (2016) also reported a reduction between 20 and 90% in Turkish gourd genotypes due to salt treatment. The soil salinity and low osmotic potential in the root zone reduce the water intake of plants (Lauchli and Grattan, 2007). These conditions create a negative effect especially on the fresh weight of plants that are salt intolerant. It was determined that once the amount of salt applied to the soil increased, the growth of plants, and thus the amount of dry matter decreased, hence in turn, the plant growth and the dry matter amount were affected more negatively (Romero et al., 2001). Although the root system is directly exposed to salinity, leaf growth is more susceptible to salt stress than root growth; therefore, root: shoot ratio increases under salt stress (Çulha and Çakırlar, 2011). Orsini et al. (2013) found that the root: shoot rate increased in plants under salt stress when compare d to control conditions. Thus, it was determined that there was a significant correlation between R: S ratio and RFW ($r = 0.501$, $p < 0.01$) and RDW ($r = 0.620$, $p < 0.01$) (*Table 5*).

Leaf relative water content (LRWC) and Membrane Injury Index (MII)

Among the genotypes and varieties examined in the present study, there was an increase in LRWC only in YYU10 and YYU18 (13.54 and 4.48%, respectively) in saline conditions, and it was determined that the LRWC decreased in all remaining genotypes and varieties due to salinity. While the injury rate varied between 6 and 41% in MII, which was evaluated 18 days after the salt treatment, it was determined that the YYU29 genotype and cv. Napolyon F_1 cultivar yielded negative values of -6.18% and -6.54%, respectively (*Table 4*). Salt stress decreased water uptake due to osmotic effect and furthermore led to membrane damage due to ion toxicity (Munns, 2002). The decrease in LRWC refers to low turgor pressure at limited water conditions (Katerji et al., 1997) and is, therefore, an important indicator of salt tolerance in cultivated plants (Sarabi et al., 2017). Membrane injury is caused by ion imbalance, which is caused by osmotic inconsistency inside and outside the cell under stress conditions such as salinity and drought (Ghoulam et al., 2002). It was found that membrane injury was lower in tolerant genotypes when compared to susceptible genotypes (Asha, 2007). Previous studies indicated that membrane injury increased due to salt stress and thus, MII could be used to determine the stress-effect rate in plants (Jamil et al., 2012).

Visual evaluation of salt stress (0-5 Scale)

In the 0-5 scale, which commonly assists the visual determination of leave damage, it was observed that cv. Lokum F_1 had the highest scale score (2.33) and YYU4, YYU10 and YYU11 genotypes were among the most affected genotypes with a scale score of 2.22. It was observed that YYU18 genotype had the lowest score with 1.33. Furthermore, it was found that 33.3% of the genotypes were more affected by salinity and their scores were above 2.0 (*Table 4*). Several studies reported that the scale findings could be used in estimating the reactions under salt stress by melon (Kusvuran

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29652981

et al., 2007a), tomato (Daşgan et al., 2002), bean (Kıpçak and Erdinç, 2016) species. It was determined that there were negative correlation between the findings of the 0-5 scale utilized in present study on SFW ($r = -0.553$, $p < 0.01$), LN ($r = - 0.585$, $p < 0.01$) and SL ($r = - 0.583$, $p < 0.01$) and there were positive correlations between R:S ($r = 0.588$, $p < 0.01$), and MII ($r = 0.647$, $p < 0.01$) findings (*Table 5*).

Stomatal traits

It was observed that 78% of the melon cultivars and genotypes exhibited a decrease in stoma length, 56% exhibited a decrease in stomatal width and 61% exhibited a decrease in stomatal area under salt stress, and stoma density increased in 94%. The only negative ratio was observed in stoma density with 11.11% in YYU21 genotype and it was found that the highest increase in LRWC was observed in YYU18 genotype (216.67%), which had prominent scale scores. Thus, it could be observed that the stoma density (StD) increased as StL, StW and StA values decreased under salt stress (*Table 6*). It was reported that this mechanism is a functional plant response to suppress salt stress, regulate the respiration and preserve plant performance (Orsini et al., 2011) and it was also indicated that increased StDdue to increase in salt stress led to an increase in photosynthesis (Chaves et al., 2009). Although several studies reported similar findings, indicating that salt stress led to a decrease in stoma dimensions and areas and an increase in stoma density (Orsini et al., 2013; Kurtar et al., 2016), Sarabi et al. (2017) reported that stoma density decreased due to the increase in salinity and interpreted this as a counter adaptation against salt stress.

Principle component analysis (PCA)

Principal component analysis (PCA) method was used to determine the traits that led to the variation. Eigen value and variances obtained in the analysis and the properties that led to the differences among the genotypes were determined (Sönmez et al., 2015). 71.48% of the total variance in fourteen different traits was grouped in 3 PCA groups for the control application and the 69.53% in the 50 mM salt application were grouped in 4 PC groups, and it was found that the two applications were similar in total variance. In the control group, the variation ratios for three principal components were 35.42%, 25.26%, and 10.80%, respectively, and these ratios were observed as 28.16%, 18.56%, 11.62%, and 11.19% in the 4 principal components of in 50 mM salt application group (*Table 7*). In a study conducted by Sarabi et al. (2017) on salt stress using physiological and biochemical parameters, it was reported that the total variance was 97.17% in the PCA analysis and the first principal component explained 66.96 of the variance. Furthermore, Shelke et al. (2017) determined that 82.65% of the total variance of 95.07% was explained by the first principal component. It is considered that in both studies, the researchers were able to increase the variance by working with an excessive number of salt concentrations and the variances could stem from the reactions that plants exhibited indifferent concentrations.

In the control group, it was found that 42% of the variance in PC1 was explained by SDW, StA explained 47% of the variance in PC2 and LRCW explained 61% of the variance in PC3, which were the highest ratios. The highest ratio in PC1, which is one of the principal components that occurred under salt stress, was observed with RDW (46%), in PC2, the highest ratio was observed with LN (59%), in PC3, the highest ratio was observed with LRWC (55%) and in PC4, the highest ratio was observed with SDW (49%). SDW and LRWC exhibited the highest variance in 0 and 50 mM, furthermore, SI (17%), which exhibited low variance in 0 mM, reached a higher value due to salt stress (48%) (*Table 7*). Genotypes and varieties were classified in two groups of 0- and 50-mM salt treatment (*Fig. 2*); YYU4, YYU20, YYU21 genotypes and cv. Lokum F1 in the control group and the YYU18, YYU20 genotypes and cv. Kırkağaç in the 50 mM salt treatment group were in the same group and the remaining genotypes and varieties were in the second group.

Mixture modeling

The number of homogeneous sub-groups for the genotypes was determined with the Gaussian mixture model through the evaluation of inspected properties in order to determine the reactions of melon genotypes to salt stress. Based on all properties scrutinized in the present study and using the smallest AIC and BIC criteria (Yeşilova et al., 2016), it was determined that genotypes could have 4 homogenous sub-groups under

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29652981

stress-free conditions and 3 sub-groups under conditions with salt stress (*Table 8*). Thus, it was found that the correct classification rate of entropy was 98% for 0 mM and 93% for 50 mM. In the control application, based on the sub-group distribution with respect to their traits, it was found that the highest mean values for all other traits except StD were observed in the second and fourth sub-groups, where no significant dispersion was observed in the lowest values and the majority of the lowest means were in the first group (*Table 8*). It was also determined that the high mean values were significantly observed in the first group based on the distribution of the variable means, and the low mean values were in the third group (*Table 8*). In other words, it is possible to state that the genotypes and varieties in the first group tend to increase their tolerance against salt stress. Thus, genotypes in the third group could be considered as more susceptible to salt.

0-5 scale	-	-	-	-	1.81	1.57	2.20

It was found that the resulting homogeneous sub-groups exhibited variations in distribution of genotypes for 0 mM, and majority of genotypes were in the 1st and 3rd sub-groups, where the means were low. Furthermore, based on the mean values obtained with the variables, it was determined that the genotypes and varieties in the first group were tolerant to salt, those in the second group had moderate tolerance, and those in the third group were susceptible to salt under 50 mM salt treatment. Accordingly, it was determined that YYU4, YYU10 and YYU11 genotypes could be susceptible to salt, YYU15, YYU18, YYU23 genotypes and cv. Galia could be medium-tolerant, YYU6, YYU13, YYU14, YYU20, YYU21 and YYU29 genotypes and cv. Kırkağaç F_1 and cv. Lokum F_1 varieties could be tolerant to salt stress (*Table 9*).

Conclusion

Salt stress is one of the most important stress factors for the majority of cultivated plants. Several studies were conducted on the subject. Tolerance to abiotic stress factors such as salinity displays a complex structure, and therefore, makes it difficult to develop tolerant varieties. Tolerance varies between plant varieties and even between variety genotypes. In the present study, it was determined that variations existed between the tolerances of studied genotypes against salt stress based on the examined traits. It was concluded that the examined traits could be used to determine the effect of salt stress, and the conducted correlation analysis demonstrated that there were correlations among various traits. It was found that traits such as leaf number, shoot length, shoot fresh weight and leaf relative water content of all genotypes were adversely affected under salt stress. While stoma length, stoma width and stomatal area decreased under salt stress, it was determined that the stoma intensity increased. It was observed that shoot dry weight, leaf relative water content and were among the traits that best explained the variance both salt stress and the control group in the PCA analysis. Mixture modeling analysis indicated that there was no significant difference between the 0 mM application sub-groups, however, especially in the 50 mM application, the distribution of the lowest and highest mean values of the variables was clearer; hence, the variance between the genotypes and varieties could be determined with mixture modeling analysis based on the reactions they exhibited against salt stress.

(Received 25th Nov 2018; accepted 16th Jan 2019)

Abstract. Due to high temperatures and dry summer in most subtropical regions, forest fires are of a regular occurrence. Fires emit CO_2 and other greenhouse gases which retroact on the ecological systems. This study provides CO_2 emission estimates from forest fires and risk zones in subtropical and temperate forests of Pakistan. CO_2 emission was calculated using average dry matter g/m^2, burned area, combustion factor (CF) and burning efficiency (E_f) following the guidelines of Inter-governmental Panel on climate change (IPCC). Fire risk zones were created by using GIS tools considering anthropogenic and natural geological factors. Results showed that average dry organic matter is 13837 ± 5774.64 gm^{-2}, while average annual CO_2 emission is 7280 ± 5369 Gg with 56.6% average annual increase of CO_2 emission. Meanwhile, highest emission of about 22799 Gg was recorded in 2009 corresponding to about 145.6 ha of burnt forests. Additionally, over 56% of the area or 9.33% (extreme risk zone) and 45.20% (high risk zone) is threatened by fire. Forest fire trends are mainly due to an increase anthropogenic activities and changes in weather conditions. Understanding forest fire threats and trends, will aid the government authorities in making appropriate conservation programs to curtail these forest fire threats and carbon dioxide emission trends.
Keywords: *burnt biomass, burning efficiency, Murree forest division, remote sensing, risk assessment*

Introduction

Globally, human activities and forest fires continue to reduce forest cover. This forest cover change distorts the forest and surrounding ecosystem functions, biodiversity conservation and hence forest regeneration (Tanvir et al., 2006; Beckline

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29833002

and Yujun, 2014). Forest fires occur at regular intervals and reduce plant growth and regeneration hence exacerbating soil erosion (Jaiswal et al., 2002; Mukete, 2018a).

Forest fires are also deleterious to trees where trees become more susceptible to fungal and insect attacks thus affecting wood quality and volume (Abd El-Kawya et al., 2011). Globally, tree cover loss was observed to have attained a record 2.97 million km^2 in 2016 (Weisse and Goldman, 2017), the loss is 51% higher than the previous year with forest fires being the primary cause of this spike. In the Brazilian Amazonian region tree cover loss was estimated at over 370,000 km^2 nearly three times more than in 2015, this increase mainly occurred in the states of Pará and Maranhão, which were heavily affected by fire in late 2015 and early 2016 (Chanthalath, 2017)

Forest fires are the greatest potential risk to stored terrestrial carbon and each year an estimated 2-3 PgC are released into the atmosphere corresponding to about 3-4 million km^2 of burnt forests (Giglio, 2006; Hansen et al., 2013; Weisse and Goldman, 2017). Forest fires cause changes in the earth's biological and physical characteristics which over the years, affect carbon exchange (Harden et al., 2000; Vilen and Fernandes, 2011). According to Wekesa et al. (2016), about 82-97% of released carbon dioxide (CO_2) constitutes total carbon stock. Therefore, emission of greenhouse gases such as CO_2 and methane (CH_4) from forest fires directly affects climate (Simpson et al., 2006; Hansen et al., 2013)

Forest fire risk zones are areas from where a fire is likely to have started and spreads to other areas (Leblon, 2005). The availability of forest fire risk zone mapping aids in the precise evaluation of the fire (Jaiswal et al., 2002). This risk-mapping involves the multi-criteria evaluation method that includes factors such as slope, elevation, aspect, land-use, climatic conditions, proximity to roads and settlements (Bacani, 2016; Mukete et al., 2018b). One of the most common practices of risk zoning is the assigning of the subjective layer to all classes according to the sensitivity of fire and ignition capabilities (Dong et al., 2005). For instance, Ito and Penner (2004) used GIS-grid based system and multi-criteria to map peat swamp forests in Pekan District, south of Pahang, Malaysia to develop weighted fire index model for fire hazards. However different studies use different methods such as meteorological data and occurrence of forest fires for the establishment of forest fire models and risk zone assessment (Alonso-Betanzos et al., 2003; Zhang et al., 2011). The other studies have developed forest fire models by maintaining environmental and physiographic factors that affect the wildfire (Mitchener and Parker, 2005; Thompson et al., 2017). Similarly, the combination of satellite remote sensing and modeling have opened up new opportunities for the quantitative assessment of pre and post- forest fires.

In Pakistan, sub-tropical and temperate forests are located in the northern part of the country along the Himalayan foothills (Mannan et al., 2018a; Amir et al., 2018). This dry sub-tropical climate makes sub-tropical and temperate forests vulnerable to forest fires. This is particularly from altitudinal variations which influence the spreading of forest fires at different elevations (Ali, 2013; Saeed et al., 2019). In Pakistan, each year a considerable area of subtropical and moist temperate forests come under fire mainly due to natural causes, human and accidents. According to FAO (2015) and Hansen et al. (2013) more than 80% fires in these forests are due to anthropogenic activities.

Although biotic and abiotic factors facilitate the assessment of heterogeneous distribution and occurrence of fire density, Pakistan lacks active fire management plans both at regional and national levels. These limits and diffuses the control and monitoring of the increasing trends in national carbon emissions (Krawchuk et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29833002

2009; Saeed et al., 2016, 2018; Mannan et al., 2018b; Adnan et al., 2018) which has therefore necessitated an urgent need for national fire management plans. This study strives to fill this knowledge gap by estimating carbon emissions in the subtropical and temperate forests of Pakistan. It focuses on carbon emission trends within the last two decades as well as the anthropogenic, topographic and climatic factors. Understanding forest fire threats and trends, will aid the competent government authorities in developing appropriate conservation policies such as to curtail these forest fire threats and carbon dioxide emission trends.

Materials and methods

Description of study area

The subtropical and moist temperate forests are primarily located at the foot of the Himalayan mountain ranges (550-2600 altitude) between 33° 46' 50.60" N to 33° 56' 01.48" N latitude and 73° 09' 36.76" E to 73° 33' 29.66" E longitude (Ashraf et al., 2014), as shown in *Figure 1*. The area spreads across over 46898 ha and it is administratively controlled by Murree Forest Division (MFD) and includes three forest types. These are subtropical broad-leaved evergreen forests, subtropical Chir pine forests and moist temperate forests. Common plant species include *Pinus roxburghii* (Chir-pine), *Pinus wallichiana* (Blue pine), *Abies spp, Cedrus deodara* (Diar), *Quercus incana* (Oak), *Aesculus indica* (Chentnut), *Dodonea spp* (snatha), *Olia spp* (Indian olive) (Shahzad et al., 2015)

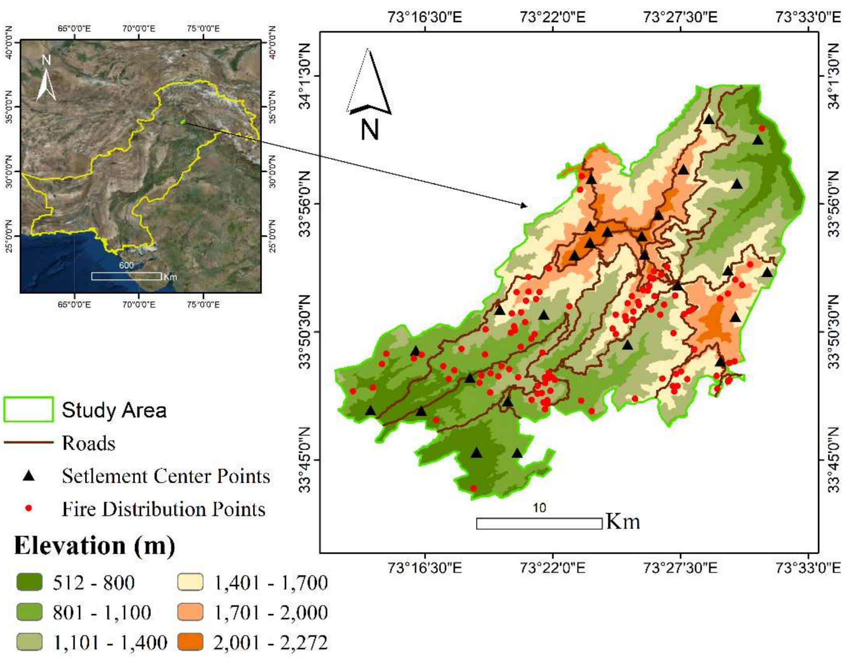

Figure 1. *Map of the study area, showing fire distribution, settlements centre points and roads*

The mean annual precipitation is 1800 mm, the mean annual max and min temperature are 24.3 °C and 11.4 °C, while the mean annual relative humidity is 53.06%, mean annual wind velocity is 3.22 km/h and mean annual solar energy is 18.4 J

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29833002

(PMD, 2015). Geologically the study area is composed of Cretaceous and Tertiary sedimentary strata having deep relief due to tectonic uplift during the tertiary period (Ashraf et al., 2014).

Data acquisition

The image of the study area was obtained from satellite (Sentinel-2), the cloud free image of 22nd October, 2017 was selected that is freely available on European space agency (ESA) website https://sentinel.esa.int/web/sentinel/home, topographic maps at scale of 1:25000 of the study area was obtained from survey of Pakistan (http://www.surveyofpakistan.gov.pk/). Digital elevation model (DEM) with the 30 m resolution was obtained from United States Geological Survey (USGS) https://earthexplorer.usgs.gov/. Forest type map, forest fire data (1998-2017) and Fire watch tower information were obtained from the office of the Murree forest division (MFD). Roadmap of Murree was obtained from National Highway Authority Islamabad (NHA) and Settlements map from the office of Pakistan Statistical Bureau (PSB) as shown in *Table 1*. The field data were collected by taking sample plots randomly distributed in the study area for biomass and CO_2 emission calculations.

Table 1. *Dataset and sources*

Data	Source	Abbreviation	Unit/resolution/Scale
Sentinel-2	European Space Agency (ESA)	Sent-2	10 m
Digital elevation model	Earth explorer (USGS)	DEM	30 m
Topographic map	MFD (Punjab forest department)	MFD	1:25000
Elevation	Derived from DEM	Elev	Meters (m)
Aspect	Derived from DEM	Asp	Classes 1-4
Slope	Derived from DEM	Slope	Classes 1-4
Distance from roads	Rod map from (NHA)	DisRd	Meters (m)
Distance from settlements	Settlements map from SBP	DisSet	Meters (m)
Watch towers	MFD	MFD	
Mean Annual Precipitation	PMD &NOAA	mm	Millimeters (mm)
Mean Annual Temperature	PMD &NOAA	Temp	Degree centigrade (°C)
Land-uses	From Satellite Image	Land-use	30 m

Biomass and CO_2 emission estimation

A total of 150 plots of size 20 m × 30 m were randomly sampled as shown in *Figure 2* and the stem volume (m^3/ha) measured for all the trees found within. In each sample plot, the diameter of all trees greater than 4 cm was measured at breast height (DBH). Using the Abney level, the height of 20 trees per species was recorded which were used to construct DBH/height function of a specific plot.

We first arranged the trees present in the sample plot into different classes based on their diameter (Dia classes), density of each diameter class i.e. no of trees per hectare were calculated and the basal area (B.A) of each diameter class was by using *Equation 1*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29833002

$$B.A = Density \times DBH \times \pi r^2 \, (^{m^2}/_{ha}) \qquad \text{(Eq.1)}$$

Stem volume was measured using *Equation 2* as described by Newbery (2009).

$$Stem\ Volume \left(^{m^3}/_{ha}\right) = B.A(m^2/ha) \times h(m) \times f.f \qquad \text{(Eq.2)}$$

where B.A is the basal area, h is height and form factor f.f is the volume of cylinder to actual tree form (Tenzin et al., 2017). In the Indian sub-continent, f.f is usually 0.37 for conifers and 0.6 for broad leaves is commonly used (Haripriya, 2002). Biomass t/ha was calculated by multiplying stem volume with the wood density (W.D) t/m^3 of particular species using IPCC proposed guidelines (IPCC, 2006b). The wood density values were also confirmed by previous research and reports (Sheikh, 1993; *Eq. 3*).

$$Stem\ Biomass \left(^{t}/_{ha}\right) = StemVolume \left(^{m^3}/_{ha}\right) \times W.D(^{t}/_{m^3}) \qquad \text{(Eq.3)}$$

Total Biomass t/ha (above ground biomass, understory vegetation biomass, litters and dead wood) was measured by using Biomass expansion factor (BEF) for subtropical and temperate forests of Pakistan as described by Haripriya (2002) and IPCC (2006a) (*Eq. 4*).

$$Total\ Biomass(^{t}/_{ha}) = Stem\ Biomass(^{t}/_{ha}) \times BEF \qquad \text{(Eq.4)}$$

Biomass carbon values of understory vegetation (USV) were measured by establishing sub-plot of 4 m × 4 m in each sample plot; the USV vegetation includes herbs, weeds, and grasses etc. The vegetation in each sub-plot was harvested by using sickle. The average fresh weight of the harvested material in kg/m^2 was recorded and all harvested vegetation was put into brown paper labeled bags. Then the paper bags were dried in gravity convection oven, model no (SG03) at 72 °C for 48 h and their dried weights in kg/m^2 were measured for Biomass Carbon Calculation. Similarly, we collected litter; dead wood and cones present in the sub-plot and measure the average weight kg/m^2. Tree biomass, USV biomass, litters and deadwood were added and the total biomass t/ha was calculated (Brown et al., 1982; Saugier et al., 2001; Malhi et al., 2004; Vilen and Fernandes, 2011), as shown in *Equation 5.*

$$Average\ dry\ organic\ matter\ B\ (\mathrm{g\ dm/m^2}) = Average\ Biomass\ (^{t}/_{ha}) \times 100 \qquad \text{(Eq.5)}$$

B is the average organic matter in particular ecosystem per unit area (g dm/m^2), after the dry organic matter was calculated, we used (Seiler and Crutzen, 1980; Vilen and Fernandes, 2011) formula for the calculation of total burned biomass (BBM) as shown in *Equation 6*.

$$BBM = A \times B \times CF \qquad \text{(Eq.6)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29833002

BBM is the burned dry biomass (g dry matter per unit time) in particular ecosystem burned. Where A is the annually burnt area m^2/year, B is Average organic matter per unit area g/m^2 and CF is the Combustion factor or biomass burning efficiency. Combustion factor is the exposed biomass that is actually consumed during combustion (Ito and Penner, 2004). Only a portion of the biomass is burnt but most biomass remains in the form of standing trees, charcoal or dead organic matter. This handicap was resolved by using 0.74 combustion factor for subtropical/tropical grasslands and 0.45 for temperate forests according to guidelines of IPCC (2006a; *Eq. 7*).

$$E_c = BBM \times E_{fc} \quad \text{(Eq.7)}$$

The total burnt biomass BBM was then converted into emitted CO_2 by using the equation, where the CO_2 emission factor (E_{fc}) that described the weight of CO_2 emitted per weight of dry burnt biomass. The amount of released compound by the amount of dry fuel consumed g/kg of dry fuel consumed is the emission factor (Andreae and Merlet, 2001; Saranya et al., 2016). According to IPCC (2006a) the emission factor E_{fc} 1531 g/kg for sub-tropical and temperate region is used to calculate the average annual carbon emission for the last two decades (1998-2017).

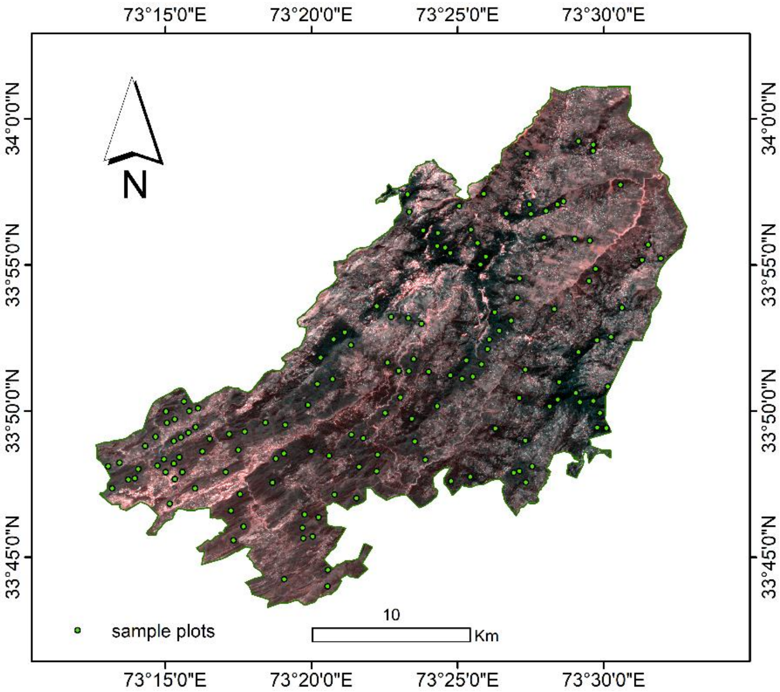

Figure 2. *Sample plots distribution*

Forest fire risk zoning and fire risk index

Forest fire risk zone map was generated by using vegetation type (broad-leaved forest, chirpine forest, and moist temperate forest), land-use (dense forest (DF), open forest (OF), bare land (BL), settlements (SM), agricultural land (AL), topography (slope, aspect, elevation), human factors (distance from roads, distance from settlements) and watch tower visibility in MFD. The topographic sheet of the study area

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29833002

and forest distribution map at the scale of 1:25000 of the study area was obtained from the office of the MFD**.** The topographic map and forest distribution map were scanned and exported into the processing software ArcGIS 10.2 and ENVI 5.1. The Shapefile was clipped by using the topographic sheet as a reference. Sentinel-2 image having 10 m resolution was downloaded for European space agency (ESA). First, the image pre-processing was performed in ENVI 5.1 and the geometric distortion of the image was removed from the topographic sheet as well as from the GPS by selecting 20 Ground Control Points (GCPs) around the study area. Image pre-processing is necessary before the classification or distribution for establishing a relationship between acquired data and biophysical processes (Abd El-Kawy et al., 2011; Iwan et al., 2004; Mannan et al., 2018). The geometrically corrected image was then used to clip the region of interest (ROI). After that, the image was classified into five different classes such as dense forest (DF), open forest (OF), agricultural land (AL), settlements (SM), and barren land (BL), Road (RD) with corresponding classes by assigning per-pixel signatures. On the bases of different digital number (DN) value of landscapes different colours assigned to differentiate them. After that Radiometric, the atmospheric and topographic correction was performed by using ArcGIS 10.2 and ENVI 5.1.

Training samples for each predetermined class were selected by delimiting polygons and spectral signatures for each land cover type derived from satellite imagery were recorded using pixels inside polygons. Supervised classification was performed by using a maximum likelihood algorithm. Accuracy of the land-use change was assessed by using confusion matrix in ENVI 5.1. We took 50 ground truth points in each land-use, for accuracy assessment. The kappa statistics was calculated by using *Equation 8*.

$$K\ (kappa) = \frac{Observed - Expected}{1 - Expected} \quad \text{(Eq.8)}$$

To improve the quality of classification and to classify the un-classed pixels, post classification smoothing was performed. Post classification smoothing is used to improve the classification quality, un-classified pixel (Harris and Ventura, 1995). The Land cover classification as shown in *Figure 6a,* gives meaningful information about the class value and also links the spectral characteristics of the image, that can be displayed as a map for researchers and scientists to evaluate the land-use classes (Weber and Dunno, 2001).

Spatial distribution and statistics of forest type were calculated from forest distribution map (*Fig. 7a*). The forest distribution map was first scanned imported to processing software ArcGIS 10.2. Geometric correction of the map was performed from the topographic sheet by selecting 50 Ground Control Points (GCP's) around the study area, DEM (30 m) was used to calculate the slope, elevation and aspect, as shown in *Figure 8a, b, c.* Reclassification tool was used for making their risk zone classes. Roadmap and settlements map of MFD was obtained from NHA and PBS, which was used to construct fire risk distance corridors. Euclidian distance tool in ArcGIS 10.2 was used for making 100 m, 200 m, 300 m and 400 m corridors of roads and settlement center points of the study area (see *Fig. 7b*).

For Fire rating index (FRI) determining first of all the risk ratings were assigned to the variable factors responsible for forest fire according to their fire causing potential, which was determined by referring previous research and historical record, as shown in *Table 2*. The higher rating shows that variable has a high influence on fire risk. Secondly, each variable is classified into classes i.e. (extreme, high, moderate, low and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29833002

no risk) and finally all the layers were integrated through GIS and by using *Equation 9* FRI is calculated.

$$FRI = 10(lu_i + ft_j) + 5sl_k + 3asp_l + 2ele_m + 2set_n + 2rd_o \qquad \text{(Eq.9)}$$

In FRI, *lu* is the land-use having (6 classes), *sl* is slope factor (4 classes), *asp* is aspect (9 classes), *ele* is elevation (4 classes), *set* is distance from settlements (4 classes) and *rd* is the distance from roads (4 classes). The superscripts (*I,j,k,l,m,n,o*) are the sub-classes. Finally, weighted overlay tool was used for overlay analysis and all the layers were combined to form final fire risk zone map of the study area shown in *Figures 3* and *10.*

Table 2. *Fire hazard factors*

Factors	Classes	Assigned value	Risk factor
Land-use (10)	Dense forest	5	Extreme
	Open forest	4	High
	Barren land	1	No risk
	Agricultural land	3	Moderate
	Roads	1	No risk
	Water	1	No risk
	Settlements	1	No risk
Forest type (10)	Sub-tropical broad leave evergreen forest	4	High
	Subtropical Chir pine (*Pinus roxburghii*) forest	5	Extreme
	Moist temperate forest	3	Moderate
Elevation (2)	500-1000 m	5	Extreme
	1000-1500 m	4	High

Visibility analysis

Fire watch towers are very important for early detection of forest fires. There are two fire watch towers in the study area which include the 17 m high and 12 km maximum range of visualization Ban fire tower and the 20 m high and 15 km of maximum visualization range Charihan fire tower. The visibility analysis of the study area was carried out with the view-shed tool in ArcGIS 10.2 by using DEM and fire towers geographical location (*Fig. 9* and *Table 3*)

Results and discussions

We performed field survey by random forest sampling in the study area. The study area includes Conifers and Broad-leaved trees. Conifers like *Pinus roxburghii, Pinus wallichiana, Abies pindrow, Picea smithiana* have more tree volume due to their tall height as compared to broad leaved trees like *Olea spp, Quercus incana, Aesculus indica* (Mannan et al., 2018a). The results showed that the average density in the study area is 556.68 (±128.19 std. dev.) trees per ha, while average BA is 40.27 (±10.124 std. dev.) m^2/ha, the average volume is 349.26 (±111.06 std. dev.) m^3/ha and mean DBH is 35.42 (±15.54 std. dev.) cm.

Forest fires and CO_2 emission trend

We have obtained forest fire data for the last two decades that include fire origin location, size, date of occurrence, forest type and ignition cause form MFD. The historical record shows that accidental fires are 72.2% of the total fires, while 25% are deliberate and 2.6% are lightning-caused fires. Accidental fires mostly occur due to cigarette disposal in or around forests, careless fire handling during forest picnics, vehicle transportation, and the burning of farm residues along forests.

The increasing trend of forest fire has been observed in the study area, the average annual fire in the first decade (1998-2007) was 276 ha while it reached to 651 ha in the second decade (2008-2017), with the total 928.79 ha burned as shown in *Figure 5*.

The average dry organic matter in the forests was found to be 13837 (±5774.64 std.dev.) g/m^2. The total estimated CO_2 emission in last 2 decades as obtained from the study is 145.60 (±5369.68 std. dev.) Tg CO_2, with estimated average annual CO_2 being 7280 (±5369 std. dev.) Gg CO_2. However, the largest fire events were observed in 2009 with 22799 Gg CO_2 emission. This was due to the fact that 2009 was recorded as driest summer year after 1980 (PMD, 2015). During the last two decades 788 (±175 std. dev.) Gg CO_2 was emitted in the month of June followed by 25.40 (±1.5 std. dev.) Gg CO_2 in May. The statistical analysis showed that average area burned in the first decade (1998-2007) was 27.69 ± 7.37^a (ha) which is significantly less than the second decade (2008-2017) which was 66.927 ± 7.37^b (ha), whereas the month of June found most critical for forest fire occurrence, with average forest fire of 23.13 ± 3.12^a (ha) significantly higher than 12.40 ± 3.12^b (ha) in May, while the occurrence of forest fire in the other months of the year was very less and showed non-significant relation with each other.

The historic fire record also showed that average net annual increase of CO_2 emission is 56%. According to Yi and Bao (2016) increasing temperatures and CO_2 concentration cause an increase in fuel availability. This increases the photosynthetic process which results into more plant growth and water use efficiency thus inducing more fires and CO_2 emission. *Figures 4* and *5* show that the rate of CO_2 emission increases steadily with increasing linear trend. Therefore, increases in temperatures exacerbate evapotranspiration which speeds-up the hydrological cycle (Finney et al., 2005). This ultimately causes more rainfall, vegetation growth, large fires and CO_2 emission. For instance, new settlements in Murree have been reported in the last decade, encroachment of forest area by land grabbers is a big issue, 1158 ha of forest land have encroached (Ashraf et al., 2014).

About 80% of fires occurred in areas accessible to humans, having road density and proximity to settlements, thus the patterns and occurrences of forest fires are related to human disturbances. Most of the fire events occurred in May and June burning over

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29833002

653.2 ha, as shown in *Figure 5*. This may be attributed to the fact that, pine trees particularly *Pinus roxburghii* shed dry needles in the summer season and also because May and June constitute the hottest months. Additionally, this may be related to the fact that a ban on green felling was imposed in 1992. This put a halt to management activities such as thinning, pruning, line clearing and prescribed burning which in combination with burning are the most effective methods of fire prevention (Finney et al., 2005; Kuenzi et al., 2008)

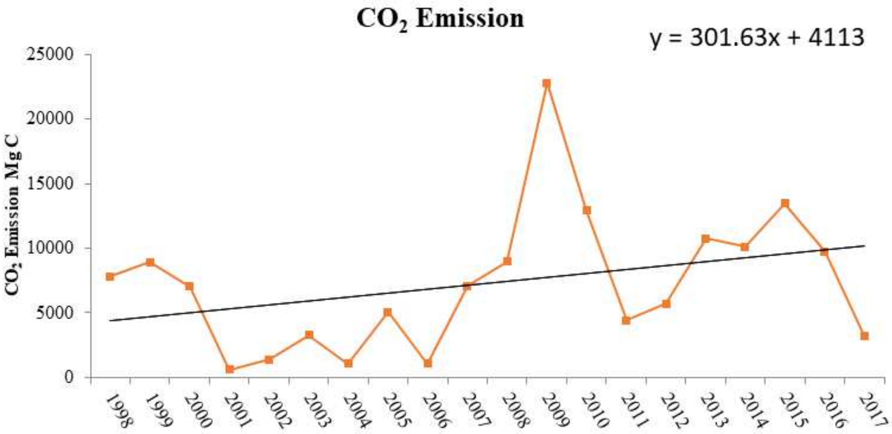

Figure 4. *CO_2 emission trend*

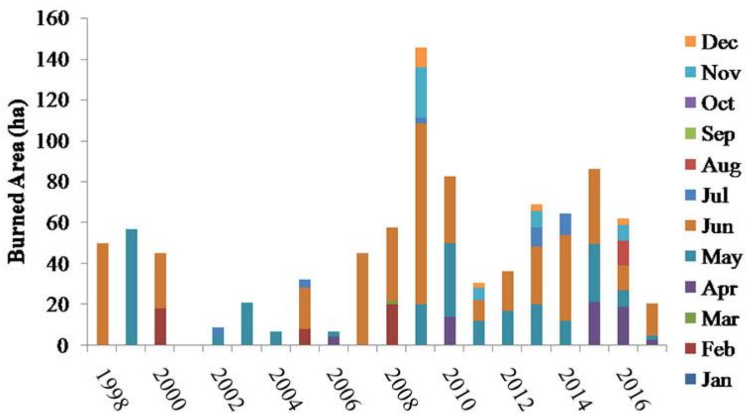

Figure 5. *Forest fire trend*

Fire risk zones and fire risk index

The Land-use map showed that 21.9% of the area includes DF which is in extreme risk zone, while 31.4% OF is in high-risk zone. Also, areas under low risks of fires AL are 6.6% and 39.9% which include water, roads, and barren lands (*Table 4* and *Fig. 6b*).

In the DF for instance, due to higher vegetation density, fuel is more available compared to the OF or BL. Thus, fire occurrence is more plausible and this is corroborated by another study by Martin et al. (2016) their study observed that forest fires are 70% more like to occur in dense vegetation as compared to sparse vegetation. The accuracy of land use map was assessed by formula as shown in *Equation 8,* and kappa statistics was 0.85.

DOI: http://dx.doi.org/10.15666/aeer/1702_29833002

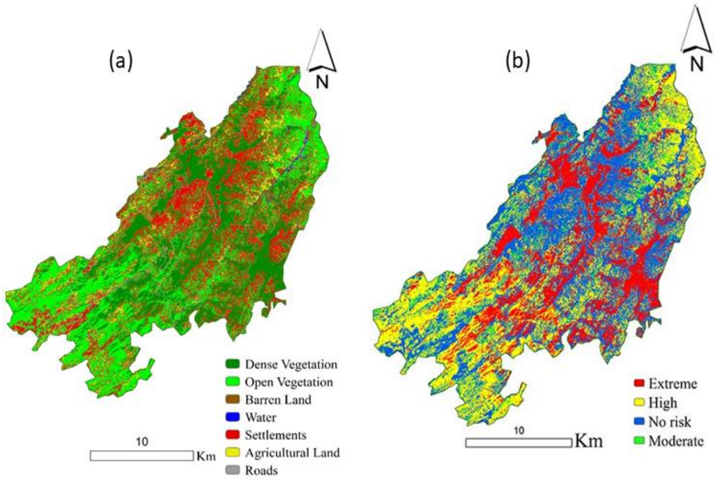

Figure 6. *Land-use map (a) and land-use risk zones (b)*

Similarly, from the forest distribution map, three forest types including broad-leaved evergreen forests, chirpine forests, and moist temperate forests were observed. Here, each forest type has its susceptibility level towards forest fires, and based on historical records obtained from the study area, Chirpine forests are most susceptible to forest fires mainly due to falling of dry needles in summer. Hence, their categorizations as extreme high-risk zones while the broad-leaved forests are categorized as high-risk zones and moist temperate forests as moderate risk zones. In a related study, Kumar et al., 2015 categorized Chirpine forests *(Pinus roxburghii)* as the major contributor to forest fires in Kangra region of Indian western Himalaya. Furthermore, the forest type map showed that more than half 51.14% of the area in the extreme risk zone, while 36.7% in a high-risk category and 12% in the moderate risk category (*Fig. 7a*).

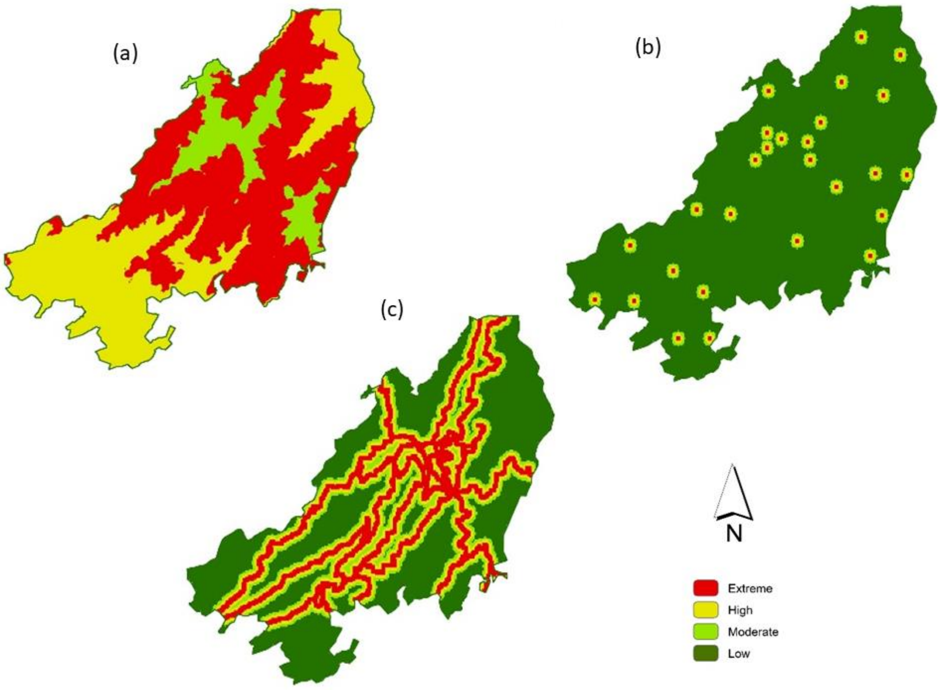

Figure 7. *Risk zones of forest type (a), settlement center (b), roads (c)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29833002

However, in sub-tropical broad-leaved evergreen forest which is present at lower altitudes of Himalayan Mountains, fire ignition chances are slightly lower due to the association of many plant species. According to Ye et al. (2017), various broadleaf species are fire resistant especially in the eastern parts of China. At higher elevations of Himalayan mountains, the chances of fire occurrence are lower, due to climatic conditions, studies also showed that 85% of fire occurred at the elevation lower than1000 m, hardly any fire was recorded above 4000 m (Martin et al., 2016),

Topography which includes slope and elevation is also important role in the ignition and expansion of forest fires. Topography is an important factor in forest fire ignition and it was given much importance in studying forest fire causes in western United States (Liu et al., 2015). In slope aspect the southern (S) and south-west (SW) slopes are dry in nature due to the sun's direct impact thus leading to higher weights (Brosofske et al., 2007). Due to less moisture, high temperatures, robust winds and low fuel moisture, chances of fire ignitions are higher in southern aspects (Finney et al., 2005). Similarly, there are less chances of fire occurrence on north (N), north east (NE), west (W), and North West (NW) slope as sunrays not fall directly upon them. From the aspect risk map, 22.04% of the area faces the south and is thus located in extreme fire risk zones (S) and south-west (SW) slope. Meanwhile, 17.02% is located in the high-risk zone facing south-east (SE) slope and 50.66% is located in the moderate risk zone facing north-west, west, north east (NE) and east (E) as shown in *Figure 8c* and *Table 4.* Fire spreads quickly along steep slopes than gentle slopes because the flame angle is closer to the surface and where wind effects supply thermal energy through convection (Zhong et al., 2003). Similarly, steep slopes are more venerable for fire spreading slope map showed 0.26%, 12.51%, 59.43% and 27.78% in extreme, high, moderate and low risk zones respectively (*Fig. 8a* and *Table 4*).

Human factors such as roads and settlements initiate forest with significant effects on forest ecosystem, land and water quality. The roads and settlement corridor map 0-100 m is rated as extreme risk zone, similarly 100-200 m, 300-400 m, and 400-500 m rated as high, moderate and low fire risk zones. However, 21.21% of the area of roads is located in the extreme risk zone, 15.93% in high risk and 12.68% in moderate risk zone (see *Fig. 7c*). Similarly, settlements map showed 0.26% to be located in the extreme risk zone, 12.51% in the high-risk zone and 27.78% in the moderate as shown in *Figure 7b*. Studies have also showed that the forest fires caused by human are often located in the proximity of roads and settlement corridors (Brosofske et al., 2007; Maingi and Henry, 2007; Syphard et al., 2007). Road edges are also served as the habitat for some exotic plant species (Parendes and Jones, 2000). These species provide more combustible material fuel wood that are more easily ignited (Arienti et al., 2009). While it was also reported by Abdi et al. (2012) optimum roads network can decrease the chances of fire occurrence.

The visibility analysis showed that 4.67% of the study area is visible from the Ban fire tower, while 14.15% is visible from the Charihan fire tower. The combined visibility of the two towers is 17.70% and the total invisible area is 82.29%. The visibility of Charihan fire tower is 14.15% and Ban fire tower is 4.67% of the study area (see *Table 3* and *Fig. 9*). The earlier detection of forest fire can minimize the forest damage up to 70%, however watch towers plays an important role for emergency response.

The Final Risk Zone Map (FRZM) (*Fig. 10*) was prepared by overlaying all the layers together according to the assigned weights in weighted overlay tool. FRZM showed 8.46% to be located in the extreme risk zone while the highest 46.30% area is in the high risk of the fire zone and the moderate risk zone has 5.22% and 40.02% in low risk zone, as shown in *Table 5*.

Table 5. *Extent of fire risk zones*

S No	Risk class	Area (ha)	Percent area (%)
1	Extreme	3998.513	8.46%
2	High	22059.487	46.30%
3	Moderate	2489	5.22%
4	Low	19053	40.02%

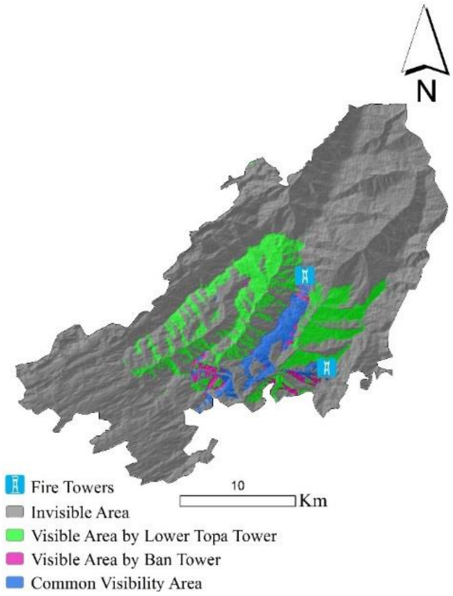

Figure 9. *Visibility analysis map of fire watch towers*

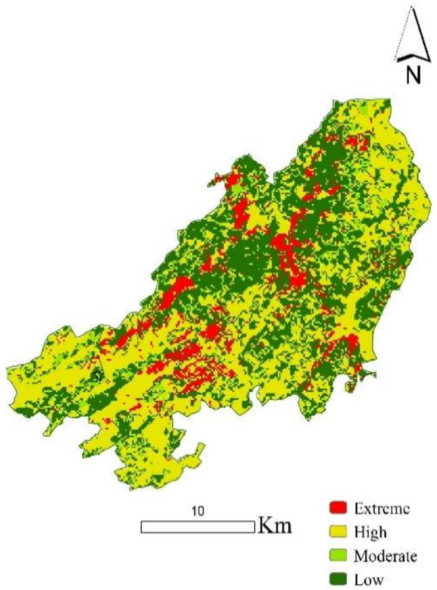

Figure 10. *Land use fire risk zones*

The FRZM shows fire vulnerability to be in more than half of the area is directly under the risk of fire. Finally, our FRZM was compared with actual fire-starting points, the majority of fire-starting points are in extreme and high fire risk zones.

Conclusion

The importance of forest fire risk zone assessment is well known but less attention has been paid towards the forest fire, CO_2 emission trend in subtropical and moist temperate forests of Pakistan.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29833002

In this study, we have calculated the CO_2 emission tend and forest fire risk zones. We found the CO_2 emission in the last three decades has been increased at accelerated rates. This increasing trend of CO_2 is directly linked with forest fire, and our study found that increase in forest fire due to more settlements, roads construction and human disturbance in the forest. Lightening caused forest fires are 2.6%, on other hand accidental fires 85% of the total fires. Although roads and settlements act as barriers to forest fires but 80% fires initiated from the corridors of roads and settlements.

This study integrates the historic fire record, ground sampling, remote sensing and GIS tools for fire risk zone assessment. The forest fire risk zone analysis showed that more than half of our study area is under extreme and high fire threat. This study provides risk assessment, factors and trends of forest fire, but further study on risk zone mapping of forest fire under predicted climate change is required, similarly forest fire trends and its effect on local climate is requited, as well as the role of emergency response team and watch towers in fire management is required. This risk zone analysis will provide a broad picture to management authorities for combating this increasing fire trend and also suggest the future management.

(Received 26th Nov 2018; accepted 4th Feb 2019)

Abstract. The aim of the paper was to present species composition and density of colony-forming units of entomopathogenic fungi (EPF) in the soil sampled from the herbicide fallow and sward strips of four blackcurrant (*Ribes nigrum* L.) fields in Poland. Samples collected in spring and autumn were used as study material. The fungi were isolated with the method of scattering diluted soil onto the selective medium. In order to protect the plants against pests, conventional plant protection was applied to all fields. In the soil taken from the blackcurrant fields three species of entomopathogenic fungi were found: *Beauveria bassiana* s.l. (Bals.-Criv.) Vuill., *Isaria fumosorosea* (Wize) and *Metarhizium anisopliae* s.l. (Metschn.) Sorokin. Both in spring and autumn isolated fungi produced more colony-forming units (CFU) in soil collected from the sward strips than from the herbicide fallow of the blackcurrant fields. In spring *B. bassiana* s.l. and *M. anisopliae* s.l. produced more CFU in the soil under sward than in the herbicide strip with intense chemical protection. In the case of *I. fumosorosea* in spring there was a tendency for CFU to be more numerous in the soil of the herbicide fallow.
Keywords: *herbicide fallow, colony forming units, Beauveria bassiana, Isaria fumosorosea, Metarhizium anisopliae*

Introduction

For many years Poland has been a leader in the production of blackcurrant fruit, which is an effect of a favourable economic climate and well developed fruit processing industry (Piotrowski et al., 2016). Chemical protection of blackcurrants is based primarily on a large number of chemical treatments, also used to maintain herbicide fallow under bushes and grass between rows of currants. Blackcurrants are perennial plants, which contributes to an increased possibility of pesticide accumulation and results in their residues in the soil. Within the framework of integrated pest management programme, it is recommended to limit significant amounts of chemicals, replacing them with agricultural and biological methods.

Constituting a large group of microorganisms colonizing the soil habitat, EPF have an ability to infect insects, and their development leads to the disruption of physiological processes in the host and to its death in the end (Zimmermann, 2007; Tkaczuk, 2008; Augustyniak-Kram et al., 2013). The anamorphic hypocrealean fungal genera *Beauveria*, *Metarhizium*, and *Isaria* are ubiquitous components of the soil microbiota in temperate regions including agroecosystems, undisturbed/natural landscapes and forests (Chandler et al., 1997; Klingen et al., 2002; Keller et al., 2003). Their basic advantage is the potential to reduce pest populations that infest agricultural and horticultural crops, fruit trees, as well as plants grown under cover (Vänninen et al., 2000; Zimmermann, 2007; Ropek et al., 2014). EPF are the basis for the production of bioinsecticides used increasingly in biological plant protection against pests (Faria and Wright, 2007; Zimmerman, 2007). Occurrence and biological activity of EPF are dependent on many factors affecting processes in the soil environment, like: type of soil, air temperature, its humidity, time of year, but also on the availability of hosts and methods of agricultural treatment (Vänninen et al., 2000; Krysa et al., 2012; Tkaczuk et al., 2014). Reports by many authors (Vänninen and Hokkanen, 1988; Miętkiewski et al., 1997; Tkaczuk, 2008; Tkaczuk et. al., 2012; Pelizza et al., 2015; Fiedler and Sosnowska, 2017) indicate that chemical substances in plant protection products can affect EPF and their natural occurrence, species composition, sporulation, colony growth, and infectiousness potential. With a wide range of pesticides used in chemical plant protection, fungicides and herbicides have the most negative effect on the population of fungi and their impact largely depends on the amount of the active substance and on the species of fungus (Andalo et al., 2004; Tkaczuk et al., 2012).

The purpose of this paper is to determine the species composition and density of colony-forming units (CFU) of EPF in soils taken from the grass strip and herbicide fallow of four blackcurrant fields.

Materials and methods

Soil sampling

Soil collected in 2012 in two periods (spring and autumn) from four blackcurrant fields located in two localities in Poland: Łuzki (Łosice County) and Żabokliki Kolonia (Siedlce County) was used as research material. Conventional plant protection against pests was used in the fields. Soil samples were taken from two habitats, i.e. from the herbicide fallow under blackcurrant bushes and from the sward between the rows. From 15-20 randomly selected points, soil material was sampled at a depth of 15-20 cm using a metal soil stick. Characteristics of the studied plantations are shown in *Table 1*.

Table 1. *Characteristics of the blackcurrant plantations*

Plantation/variety	Locality	Area of plantations (ha)	Age of plantation years	Herbicides used
I - Tisel	Łuzki	3	3	Glyphosate + MCPA
II - Ben Lomond		3	3	Glyphosate + MCPA
III - Ores	Żabokliki Kolonia	1	3	Glyphosate + MCPA
IV - Ruben		1	3	Glyphosate + MCPA

Soil samples were co-mingled into plastic bags and held at 4 °C. The soil samples were sieved with 3 mm mesh to separate debris, such as roots and pebbles, and then dried to a moisture content of approximately 25-30%. This is the optimal moisture content for fungal growth and is limiting for the development of entomopathogenic nematodes (Inglis et al., 2012).

Fungal isolation

To assess the density of EPF in tested soils, the number of colony forming units (CFU) per gram of dry soil were determined using a selective medium, developed by Strasser et al. (1996). Two grams of soil from each site were added to 18 ml of distilled water with addition of 0.05 ml of Triton X-100. Two serial dilutions were made (1:100 and 1:1000) per sample with a solution of autoclaved 0.10% Tween 80 surfactant, and four replicates of both dilutions were spread on separate 9 cm Petri dishes The solution was agitated for 35 seconds before 0.1 ml was applied to media using a sterile pipette. A sterile glass spatula was used to evenly spread the solution on media plates. The selective media consisted of: 20 g of glucose, 18 g of agar, 10 g of peptone, and the selective components: 0.6 g of streptomycin sulfate, 0.005 g of chlortetracycline, 0.05 g of cycloheximide and 0.1 g of dodine dissolved into 1 L of distilled deionized water. The supplements streptomycin sulfate, chlortetracycline, cycloheximide, and dodine were added after the media cooled to approximately 30 °C to avoid degradation. These selective supplements inhibit the growth of saprophytic bacteria and fungi and favour the growth of EPF. Four replicates per sample were prepared and incubated at 22 °C and after 8-10 days colonies of each fungus species were counted.

EPF were identified on the basis of morphological characteristics, using standard identification keys (Humber, 2012; Inglis et al., 2012). Given that only morphological methods were applied during the identification of fungi, the species *Beauveria bassiana* and *Metarhizium anisopliae* were defined *sensu lato*, because, as demonstrated by the latest phylogenetic studies based on DNA sequence (Bishoff et al., 2006, 2009; Rehner et al., 2011), there are numerous fungus species, both within the genus of *Beauveria* and *Metarhizium*, which are impossible to distinguish from each other without the application of molecular methods. The experiment was replicated three times for each soil sample. The findings were presented as the number of colony-forming units (CFU) of each species of EPF in 1 g of dry soil.

Data analyses

Since the main aim of the study was to show differences in the occurrence of CFU of particular fungal species between the investigated habitats (sward and herbicide fallow) of each of the four plantations, regardless of the season and location, therefore data on density of EPF CFUs in the field survey were analysed using a 1-way analysis of variance (ANOVA) and means were separated using Tukey's honest significant difference (HSD) test. Values of $P < 0.05$ were considered statistically significant.

Results and discussion

The main habitat of EPF is soil biomass, of which they constitute an essential part (Ritz and Young, 2004). Their occurrence as well as quantity is affected by a number of biotic and abiotic factors, and also by a wide range of agronomic treatments. The widespread use of pesticides destroying pests in plantations of soft fruit plants is the primary way to reduce their numbers and has a direct impact on the population of EPF in the soil.

This experiment studying the density of colony-forming units (CFU) of EPF in soil sampled from four fields of blackcurrants in two locations in spring and the autumn showed the existence of three species: *Beauveria bassiana* s.l., *Isaria fumosorosea,* and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30033011

Metarhizium anisopliae s.l. (*Tables 2* and *3*). Density of colony-forming units (CFU) of each species was varied depending on the time of year and on the habitat from which the soil was sampled.

Table 2. *The density of colony forming units of entomopathogenic fungi (CFU × 10^3 g^{-1}) in soil from blackcurrant plantations in spring*

Fungal species	Plantation							
	I		II		III		IV	
	A	B	A	B	A	B	A	B

Isaria fumosorosea	0.5 a	0.8 a	0.3 a	9.2 b	2.7 a	2.5 a	0.0	0.0
Metarhizium anisopliae s.l.	4.7 a	0.2 b	1.0 a	1.7 a	4.7 a	1.7 b	0.7 a	0.2 a

A - sward; B - herbicide fallow
I, II - Łuzki; III, IV - Żabokliki Kolonia; a,b - significance calculated for α < 0.05

In spring time, in soil sampled from the first blackcurrant field in the village of Łuzki (Łuzki I), *M. anisopliae* s.l. constituted the largest share of the fungi. There were more of its colony-forming units in the soil from the sward than from herbicide fallow, respectively, 4.7 and 0.2 × 10^3 g^{-1}. Another species present in this location was *I. fumosorosea*, which was more common in the herbicide strip than in the grass strip. In spring in the soil collected in the other blackcurrant field located in the same village a different relationship was found, where *I. fumosorosea* and *M. anisopliae* s.l. produced more colony-forming units in the soil of herbicide fallow than in the sward, respectively, 9.2 and 1.7 × 10^3 g^{-1}. In Łuzki I there was no the presence of the *B. bassiana* s.l. fungus in either of the strips, and in Łuzki II there was a small amount of it in the sward soil. Vänninen and Hokkaken (1988) found that in a field with soft fruit bushes the *B. bassiana* fungus was the most sensitive to herbicides commonly used to keep herbicide fallow. In the soil collected from both blackcurrant fields in Żabokliki, there were significantly more colony-forming units in the grass between the rows of bushes than in the herbicide fallow. The dominant species in the soil of Żabokliki Kolonia III turned out to be *B. bassiana* s.l., which in the grass alleys produced 15.9 × 10^3 g^{-1} colony-forming units (*Table 2*). Sapieha-Waszkiewicz et al. (2005) by examining the soil taken from blackcurrant and chokeberry fields found a clear domination of the *B. bassiana* fungus, while in the soil taken from an adjacent field there was a greater volume of the *M. anisopliae* fungus.

When considering all blackcurrant fields with all soil samples collected in spring *B. bassiana* s.l. and *M. anisopliae* s.l. produced significantly more colony-forming units in the soil taken from the sward area than in the soil of herbicide fallow, while in the case of the *I. fumosorosea* fungus the opposite tendency was reported (*Table 2*).

In soil samples taken in autumn in the Łuzki I field *B. bassiana* s.l. and *M. anisopliae* s.l. occurred to a greater volume in the soil of the fallow strip than in the sward, producing, respectively, 2.3 and 0.7 × 10^3 CFU in 1 gram of soil (*Table 3*). In the soil taken from the herbicide strip, with intense chemical protection, in the other field (Łuzki II) there were no colony-forming units of *B. bassiana* s.l. or *I. fumosorosea*, while in the sward strip they produced, respectively, 0.5 and 5.0 × 10^3 g^{-1} of them. The results

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30033011

demonstrated a negative impact of intensive chemical protection, especially herbicides used under blackcurrant bushes, on the density of colony–forming units of EPF. Kozanecka et al. (1996) reported that long-standing use of herbicides in an orchard in order to keep land fallow contributed significantly to the reduction of soil biological activity. On the other hand insects, plants and microbial populations will interact at the soil–root interface to affect EPF populations. Some EPF like *M. anisopliae* and *B. bassiana* are ubiquitous insect pathogens and possible plant symbionts, as some strains are endophytic or colonize the rhizosphere (St. Leger, 2008; Pava-Ripoll et al., 2011).

Table 3. *The density of colony forming units of entomopathogenic fungi (CFU × 10^3 g^{-1}) in soil from blackcurrant plantations in autumn*

Fungal species	**Plantation**							
	I		II		III		IV	
	A	B	A	B	A	B	A	B

Isaria fumosorosea	4.5 a	1.0 b	5.0 a	0.0 b	0.2 a	0.5 b	0.5 a	0.0 a
Metarhizium anisopliae s.l.	0.2 a	0.7 a	0.0 a	0.2 a	1.2 a	0.0 b	0.5 a	0.5 a

Explanations as for *Table 2*

I. fumosorosea clearly dominated in the soil of the sward in samples from both blackcurrant fields in Łuzki. In autumn in soil samples collected from the field located in Żabokliki Kolonia (III) *B. bassiana* s.l. and *M. anisopliae* s.l. were in greater quantities in the soil of the grass strip between the rows of shrubs, and *I. fumosorosea* produced much more colony-forming units in the soil of the herbicide fallow. In the case of the other field located in the village, *B. bassiana* s.l. and *I. fumosorosea* were in greater abundance in the soil collected from the sward, while the *M. anisopliae* s.l. species produced the same number of colony-forming units in the soil of both types of habitats.

The use of herbicide fallow in the rows of trees or bushes and grass in the inter-rows as a mechanism for maintaining soil in a good condition, creates specific environment for the development of soil microorganisms. Grassy vegetation roots in sward enable the rhizosphere microflora to develop. Under conditions of herbicide fallow, the biological activity of the soil depends primarily on multiannual, cumulative effect of herbicides (Akopyan and Avetisyan, 1990; Ehle and Laermann, 1991).

The main herbicide used on investigated blackcurrant plantations was glyphosate. A few herbicides, including glyphosate, have been shown to be fungistatic despite their use for weed control. Formulations of glyphosate have been shown to be fungicidal to plant pathogens including *Fusarium solani* (Martius) Sacardo and *Phytophthora* spp., but not detrimental to species like *Pythium* spp. (Kassaby, 1985; Kawate et al., 1992). A study by Morjan et al. (2002) investigated the effects of seven glyphosate formulations on EPF mycelial growth in solid media and found that the fungicidal properties of glyphosate formulations varied among fungal species but that *M. anisopliae* was susceptible to all glyphosate formulations. The fungicidal effects of herbicides like glyphosate may not occur under field conditions where the chemical can bind to clay

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30033011

particles in most soil types and reduce its bioavailability and movement through the soil substrate (Morjan et al., 2002).

Many authors point out that the way the soil is cultivated is a factor significantly affecting the species composition of EPF. Tkaczuk (2008) showed in his studies that long lasting use of chemical pesticides might cause resistance reactions of some species of EPF. The phenomenon of the formation of fungal strains with increased resistance to pesticides was also observed by Sapieha-Waszkiewicz et al. (2005). Poprawski and Majchrowicz (1995) holds that EPF probably have a specific system detoxing herbicides. According to the authors, it is a proven fact that some colonies of fungi start growing later, only after a few days of contact with a medium containing herbicides. According to Domsch (1972) soil microorganisms, including fungi, create a series of enzymatic reactions that help them in the process of pesticide degradation.

In all soil samples collected in autumn from all blackcurrant fields it was found that *I. fumosorosea* created on average significantly more colony-forming units in the sward than in the herbicide fallow. Density of colony-forming units of *M. anisopliae* s.l. was slightly higher in the soil of the grass strips than the herbicide fallow. The occurrence of *B. bassiana* s.l., both in the herbicide fallow and sward was on average at similar level.

The experiment showed that in the samples taken in spring and as well in autumn from all the fields, EPF produce together on average significantly more colony-forming units in the soil of the sward between rows of blackcurrant bushes, than in the herbicide fallow strips (*Fig. 1*). These values were lower in autumn than in spring. Hummel et al. (2002) after many years of carrying out field experiments found that pesticide application significantly limited the occurrence of EPF in the soil. This was confirmed by the research of Sapieha-Waszkiewicz et al. (2005), in which *G. mellonella* larvae in the soil of a blackcurrant field without any chemical protection against pests were infected by EPF to more than double degree compared to intensively protected field.

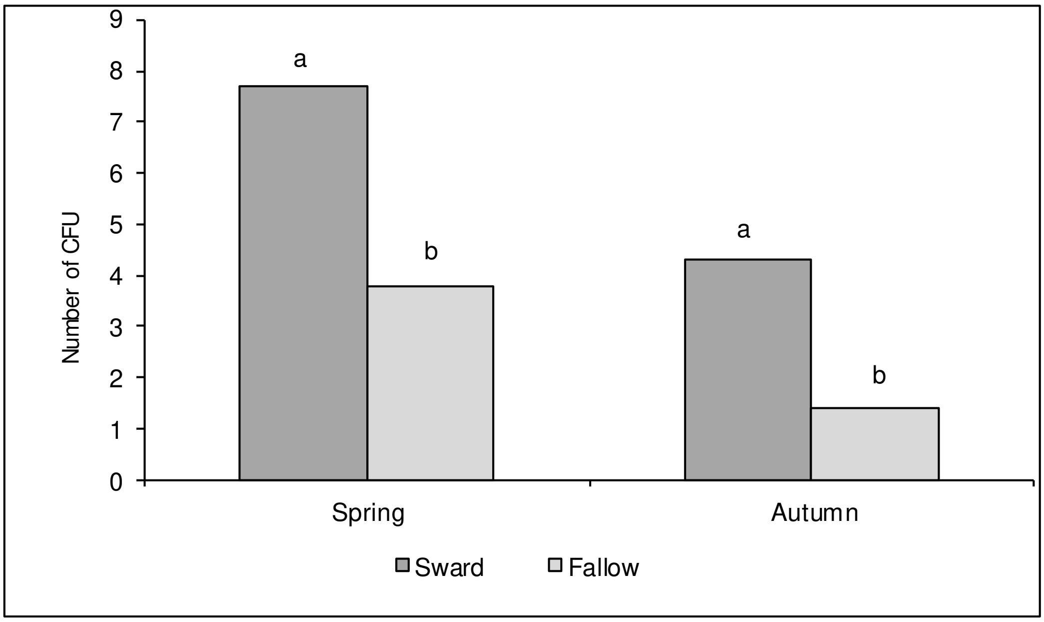

Figure 1. *The average number of colony forming units of entomopathogenic fungi in soil (CFU × 10^3 g^{-1}) from sward and herbicide fallow of black currant plantations (spring and autumn). Different letters above columns in each habitat indicate significant differences in the values at α < 0.05*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30033011

According to the Karg and Bałazy (2009) simplified crop rotation, chemical pest and weed control, and periodically repeated tillage treatments, aimed at raising crop yield, eliminate, directly or indirectly, arthropod pathogens together with the parasites and predators as a trophic group with special environmental and nutrient requirements. However, most fungi, including EPF, are characterized by large adaptive capacity to adverse environmental conditions, usually also having high reproductive and migration potential. They may settle back in a habitat during a short period of time, if, as a result of agricultural treatments, they have been eliminated, on condition that the fields or surrounded areas are suitable for their habitat.

Conclusions

With the method of spreading soil solution on the selective medium of the soil taken from the blackcurrant fields three species of entomopathogenic fungi were identified: *B. bassiana* s.l., *I. fumosorosea*, and *M. anisopliae* s.l.. The density of colony-forming units of individual species was varied and dependent on the habitat from which the soil was taken and on the time of year. Both in spring and autumn isolated entomopathogenic fungi produced totally more colony-forming units (CFU) in the soil under grass than in the herbicide strip of blackcurrant fields. When considering all blackcurrant fields, it was found that in spring *B. bassiana* s.l. and *M. anisopliae* s.l. produced more CFU in the soil under sward than in the herbicide strip with intense chemical protection. In the case of *I. fumosorosea* in spring there was a tendency for CFU to be more numerous in the soil of the herbicide fallow under the bushes. It meant that this species could be used together with pesticides in integrated protection of blackcurrants against pests. Further studies on pesticide resistance of different isolates of EPF can be performed to search of virulent strains to be applied simultaneously as biopesticides.

Abstract. A full Diallel cross among five cultivars of common wheat (*Triticum aestivum* L.) with their twenty F_1 progeny were evaluated at Kurdistan Reign-Iraq at two different locations, Kanipanka and Qlyasan, during the winter season of 2017-2018 using Completely Randomized Block Design (CRBD) with three replications. The mean squares of genotypes were highly significant for all studied characters. Parent Iba-95 at Kanipanka location produced highest value for grain yield/plant, while at Qlyasan location the highest value was provided by the Kauz parent. Maximum heterosis value for grain yield/plant at Kanipanka location produced by the reciprocal cross Klal×Kauz was 7.425%, while at Qlyasan location the diallel cross Hasad×Iba-95 reached 71.402%. Klal parent at both locations was the best general combiner for grain yield/plant and some yield components. The cross Aras×Iba-95 was found to be the best specific combiner for most characters at both locations. The inheritance of most characters is controlled by non-additive gene effect. Heritability in broad sense for most characters was moderate to high, while for narrow sense it was low to moderate. Grain yield/plant exhibited positive and significant correlation with most its important components at both locations. Maximum positive direct effect in grain yield recorded by weight of spikes/plant and biological yield/plant at both locations respectively.
Keywords: *common wheat, genetic analysis, combining ability, heterosis, heritability*

Introduction

Wheat species of the genus *Triticum* L. are members of the *Triticeae* Dum. Tribe of the Poaceae Barn family and represent the world's most important monocotyledenous cereals (Anonymous, 2015). The *aestivum* species is one of the most important crops all over the world. Increasing production per unit area seems to be one of the great factors for narrowing the hole between wheat production and consumption (Ismail, 2015). Bread wheat is the most important food crop in our country and is the main source of protein and energy. Among the cereals, bread wheat is commonly identified as a species with a higher requirement of nutrients (Al-Naggar et al., 2015). According to the FAO statistics, 349 million tons of wheat was produced in 2016 and more than 220 million hectare of the world farmlands were under wheat cultivation (FAO, 2016). Due to the persistent increase of the world population, wheat plays a key role in the national economy of developing countries. Wheat production can be increased either by bringing more area under cultivation or vertically by increasing per unit yield. It is not possible horizontally to increase area under wheat due to other competing crops and shortage of irrigation water. Therefore, the only alternative left is to increase yield/ha, which is possible by introducing genetically superior new high yielding cultivars that are adapted to a wider range of environments. Wheat breeders, all over the world, have been utilizing the existing genetic resources to modify the wheat varieties in order to meet the requirement of an ever increasing population (Sprague and Tatum, 1942). Most of the

DOI: http://dx.doi.org/10.15666/aeer/1702_30133032

wheat planted areas are located in arid or semi-arid regions where a biotic stresses, especially drought stress, are a major constraint for crop production (Tahmasebi et al., 2014). Wheat breeding in the semi-arid region aims to develop new cultivars combining high productivity and good a biotic stress tolerance. Thus, it is important to understand the genetic control of these traits (Zine El Abidine et al., 2017). Genetic improvement of wheat yield is the trait breeders aim to achieve the most to promote wheat production and face the request of a continuous population expansion. This goal can be achieved either directly by selecting for high yield or indirectly by improving yield components and morphological traits (Hannachi et al., 2013). Knowledge of the genetic control of these traits related to wheat grain yield is requisite in a breeding program to design a selection strategy and manage the progeny. Several authors have attempted to impose the genetic basis of traits interested in yield determination. The results are often inconsistent and scarce; however, a predominance of additive gene action has been noticed with dominance effects for most traits studied (Saad et al., 2010; Rashid et al., 2012; Nazir et al., 2014). The diallel cross designs are frequently used in plant breeding research to obtain information about genetic properties of parental lines or estimates of general and specific combining abilities and heritability (Baker, 1978; EL-Maghraby et al., 2005; Iqbal et al., 2007). In addition, the diallel cross technique was laid to supply early genetic information in the first generation (Chowdhry et al., 1992; Topal et al., 2004; Ataei et al., 2017). Understanding and knowing about gene action in breeding programs could improve the accuracy of selection and decrease the breeding cost and time. Therefore, the aims of this study were to investigate combining ability, gene action, heritability of some quantitative traits, correlation and path analysis in bread wheat.

Materials and methods

The current study was carried out at two locations in Kurdistan Region-Iraq. First Kanipanka Nursery Station (Lat 35° 22'; N, Long 45° 43'; E, 550 masl) in Sharazoor Valley 35 km East of Sulaimani City, and second was at Qlyasan Agricultural Research Station, College of Agricultural Sciences-University of Sulaimani located (Lat 35° 34' 307"; N, Long 45° 21' 992"; E, 765 masl) 2 km North West of Sulaimani City. Five varieties of common wheat (*Triticum aestivum* L.) were used namely (Aras, Hasad, Kauz, Klal and Iba-95). The varieties were selected according to the prior experience on some of them regarding the efficiency of these varieties and their suitability to the prevailing environmental conditions in the region and creating new combinations with other varieties that have not yet been tested in the region.

Name, pedigree and origin of parental genotypes

No.	Genotypes	Pedigree	Origin
1	Aras	(Sonora 64×Lerma Rojo 64) × Sentaelena	Mexico
2	Hasad	SNB//CMH79A955/3*CNO79/3/ATTILA	Iraq
3	Kauz	PVN/5*SUPER KAUZ	CIMMYT-Veery
4	Klal	KLEIN RECORD/38 MA//KLEIN PALANTELEN	CIMMYT
5	Iba-95	Veery "S"	Iraq

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30133032

All possible crosses including reciprocals were perfected from April 24 to May 8, 2017 to generate the 20 F_1s crosses at Qlyasan location. Seeds of 20 F_1s with their parents were sown on December 12, 2017 at Kanipanka location and on December 6, 2017 at Qlyasan location, according to Complete Randomize Block Design with three replications. Each treatment was one row of 2 m long, 40 cm between rows and 15 cm between plants within row. Five competitive plants (excluding border plants) were tagged, and data were recorded for:

1. Morphological traits:

Number of spikes/plant, Weight of spikes/plant (g), Average spike weight (g), Spike length (cm), Number of grains/spike, Weight of grains/spike (g), 1000-grain weight (g), Biological yield/plant, Grain yield/plant and Harvest index.

2. Genetic parameters:

General Combining Ability (gca) variances and effects, Specific Combining Ability (sca) variances and effects, Heterosis % as a deviation of F_1s from their mid parents, Broad Sense Heritability, Narrow Sense Heritability, Average Degree of Dominance (ā).

3. Association analysis and path coefficient analysis.

Statistical analysis

Combining ability analysis

The (gca) and (sca) were estimated using the general linear model for the analysis which takes the formula of (Singh and Chaudhary, 2007).

$$Y_{ijk} = \mu + g_i + g_j + s_{ij} + R_{ij} + r_k + \frac{1}{bc}\sum\sum e_{ij}$$

where:
Y_{ijk}: observed value of the experimental unit,
μ: populations mean,
g_i: general combining ability (gca) effect for the i^{th} parent,
g_j: general combining ability (gca) for the j^{th} parent,
s_{ij}: specific combining ability (sca) for the diallel crosses involving parent i and j,
R_{ij}: specific combining ability (rca) for the reciprocal crosses involving parent i and j,
r_k: replication (block) effect, and
$\frac{1}{bc}\sum\sum \varepsilon_{ijk}$: means error effect.

Estimation of general, specific combining ability and reciprocal effects

$$gi = \frac{1}{2p}\left(Yi + Yj\right) - \frac{1}{p^2}Y..$$

$$si = \frac{1}{2}(Yij + Yji) - \frac{1}{2p}\left(Yi + Yi + Yj + Yj\right) + \frac{1}{p^2}Y..$$

$$ri = \frac{1}{2}\left(Yij - Yji\right)$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30133032

where:
gi: effect of expected general combining ability for parents *I,*
si: effect of expected specific combining ability for single diall crosses
ij when $i = j$,
ri: effect of expected specific combining ability for reciprocal crosses *ij* when $I = j$,
Yij: F1s mean as a result of crossing parent *i* with parent *j*,
Y..: sum of the means of all parents and F1s hybrids, and
P: parents number

Estimation of heterosis

The percent increase (+) or decrease (-) of F1 cross over mid- parent was calculated to determined heterotic values for all characters (AGB301, 2004).

$$\text{Heterosis } (H)\ \% = [\frac{F'1 - M.P}{M.P}]\times 100 \qquad M.P = \frac{(P1+P2)}{2}$$

where:
F’1: mean of hybrid,
P1: parent one, and
P2: parent two.

Estimation of heritability

The term heritability has been further divided into broad sense and narrow sense, broad sense heritability was calculated by dividing genotypic variance by total variance and narrow-sense heritability was calculated by dividing additive genetic variance by total variance (Singh and Chaudhary, 1985).

$$h^2 b.s = \frac{\sigma^2 G}{\sigma^2 P} = \frac{\sigma^2 A + \sigma^2 D}{\sigma^2 A + \sigma^2 D + \sigma^2 e} = \frac{2\sigma^2 gca + \sigma^2 sca}{2\sigma^2 gca + \sigma^2 sca + \sigma^2 e}$$

$$h^2 n.s = \frac{\sigma^2 A}{\sigma^2 P} = \frac{\sigma^2 A}{\sigma^2 A + \sigma^2 D + \sigma^2 e} = \frac{2\sigma^2 gca}{2\sigma^2 gca + \sigma^2 sca + \sigma^2 e}$$

where:
$h^2{}_{b.s}$: heritability in broad sense,
$h^2{}_{n.s}$: heritability in narrow sense,
$\sigma^2{}_{gca}$: the variance of general combining ability,
$\sigma^2{}_{sca}$: the variance of specific combining ability,
$\sigma^2\ e$: the variance of experimental error, i.e. environmental variance,
$\sigma^2{}_A$: additive genetic variance,
$\sigma^2{}_D$: non-additive (dominance and epistasis) genetic variance,
$\sigma^2{}_G$: total genetic variance, and
$\sigma^2{}_P$: phenotypic variance (genetic and environmental variance).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30133032

Estimation of average degree of dominance

$$\bar{a} = \sqrt{\frac{2\sigma^2 D}{\sigma^2 A}} = \sqrt{\frac{2\sigma^2 sca}{2\sigma^2 gca}} = \sqrt{\frac{\sigma^2 sca}{\sigma^2 gca}}$$

If:
$\bar{a}$ = *zero* denote no dominance,
$\bar{a}$ < 1 denote partial dominance,
$\bar{a}$ = 1 denote complete dominance,
$\bar{a}$ > 1 denote over dominance.

Analysis of variance for full diallel cross according to (Griffing, 1956b), Method I, Model II (parents + diallel crosses + reciprocal crosses)

Total	$bp^2 - 1 = 74$	$\sum Yijk^2 - \frac{Y^2...}{bp^2}$		

Climate conditions of Sulaimani Governorate

The climate of Sulaimani governorate is semi-arid environment: hot and dry in summer; cold and wet in winter. During July and August, the average temperature is between 39-43 °C, and often reaching nearly 50 °C. Autumn means high temperatures are 20-30 °C in October, cooling slightly in November. Precipitation is limited to winter and spring months, and the overall average annual rainfall of 550-700 mm was at Sulaimani city. An overview of experimental conditions is given in (*Table 1*).

Table 1. *The meteorological data of the two locations*

Soil analysis

Soil samples belonging to both locations were taken from experimental sites in Sulaimani governorate in Kurdistan region, Iraq. The samples were taken from surface (0-30 cm), the soil samples were air dried and ground to pass through a 2-mm sieve prior to analysis, shown in (*Table 2*).

Table 2. *Some physicochemical properties of the soil samples for locations of the experiment*

Results

The analysis of variance represent in *Table 3* was carried out according to Fisher (1918) to estimate the significant differences among genotypes. General and specific combining ability variances and effects were determined. The analysis of variance revealed highly significant differences among the genotypes for all characters. This signified the presence of wide diversity among the genotypes at both locations. The estimates of gca and sca variances represented in the same table, confirmed that both additive and non additive gene effects were important for the inheritance of different characters. The mean squares for gca were highly significant for all characters except weight of spikes/plant, and grain yield/plant which were significant, and not significant for spike length, biological yield/plant and harvest index at first location, but at second location were highly significant for all characters except spike length and biological yield/plant which were significant and it was not significant for weight of spikes/plant and grain yield/plant. The mean squares for sca was highly significant for weight of spikes/plant, grain yield/plant and harvest index, and it is significant for spike length, and biological yield/plant at first location, while at second location it was highly significant for weight of spikes/plant, biological yield/plant and grain yield/plant, but it was significant for spike length, and harvest index.

Data in *Table 4* illustrate the performance of the genotypes at both locations. At the first location the cross Hasad×Aras produced maximum grain yield/plant reached 51.852 g, but for biological yield/plant it was 161.159 produced by the cross Iba-95×Klal. Iba-95 parent showed the best value for grain yield/plant 60.724 g, and some components such as weight of spikes/plant, number of grains/spike, and biological yield/plant reached 86.160, 80.733 and 170.901 g respectively. At the second location maximum grain yield/plant was 38.962 g recorded by the cross Hasad×Aras, and maximum weight of 1000-grain was 59.403 g produced by the same cross. Kauz parent at the same location produce the highest value for grain yield/plant, harvest index and weight of spikes/plant reached 33.902 g, 0.384 and 43.252 respectively.

The estimation of heterosis value represent in *Table 5* determined as the percentage of F_1s deviation from mid parental value. For all characters positive and negative heterosis values were present. Maximum positive heterosis value for the grain yield/plant was 7.425% recorded by the cross Klal×Kauz at the first location, while at the second location reached 71.402% for the cross Hasad×Iba-95, which recorded the highest positive heterosis for some components such as average spike weight and weight of grains/spike. All characters had shown considerable amount of heterosis over mid parents.

Table 6 illustrates the general combining ability effect of parents. Klal parent was the best general combiner for grain yield/plant and number of spikes/plant, while Hasad parent and Iba-95 was the best combiner for most components at the first location. At the second location Klal was the best general combiner for grain yield/plant, number of spikes/plant and weight of spikes/plant, while Hasad parent was the best general combiner for average spike weight, weight of grains/spike, 1000-grain weight and biological yield/plant. Present findings are in confirmation with Kumar et al. (2011), Singh et al. (2013), Raj and Kandalkar (2013), Aslam et al. (2014), Ismail (2015), Kalhoro et al. (2015) and Kandil et al. (2016); they found high positive value due to gca for these characters.

Data represent in *Table 7* illustrate the estimation of sca effects for crosses. The cross Kauz×Klal was the best specific combiner for grain yield/plant, but the cross Aras×Iba-95 was the best specific combiner for most traits including average spike weight, spike length, number of grains/spike, weight of grains/spike and harvest index in the first location. At the second location the cross Aras×Iba-95 was the best specific combiner for grain yield/plant, number of spikes/plant, weight of spikes/plant and spike length, while the cross Aras×Klal recorded the best specific combiner for average spike weight, number of grains/spike and weight of grains/spike, similar results reported previously by Kapoor et al. (2011), Singh et al. (2013), Raj and Kandalkar (2013), Desale et al. (2014) and Kandil et al. (2016).

Table 7. *Estimation of specific combining abilities effect for the diallel crosses at both locations ($\hat{s}_{ij}$) (Kanipanka upper value and Qlyasan lower value)*

The estimation of specific combining abilities for reciprocal crosses represent in *Table 8*. At first location the cross KauzxAras produced maximum rca value for grain yield/plant, spike length and harvest index, while at second location the reciprocal cross Iba-95xKlal exhibited the highest rca value for grain yield/plant, weight of spikes/plant and biological yield/plant, while the cross KauzxHasad was the best specific combiner for average spike weight, spike length and number of grains/spike.

Table 8. *Estimation of specific combining abilities effect for the reciprocal crosses at both locations ($\acute{r}_{ij}$) (Kanipanka upper value and Qlyasan lower value)*

Data in *Table 9* revealed that both additive and non additive gene effects were most important in the inheritance of different characters at both locations. The estimated value of σ^2gca for the characters average spike weight, weight of grains/spike and 1000-grain weight was higher than its σ^2sca, which indicates the predominance of additive gene effect as the ratio of σ^2gca/σ^2sca was more than unity, while the rest showed the predominance of non-additive gene action at first location. At the second location the estimated value of σ^2gca was higher than its σ^2sca for number of spikes/plant, average spike weight and 1000-grain weight. The average degree of dominance value for the characters average spike weight, weight of grains/spike and 1000-grain weight indicated partial dominance, and the rest showed over dominance at the first location, while at the second location the characters number of spikes/plant, average spike weight and 1000-grain weight showed partial dominance. The estimation of heritability in broad sense represent in the same table was found to be moderate to high for almost all characters, while in narrow sense it was found to be low to moderate for all characters at both locations except number of spikes/plant, average spike weight and 1000-grain weight at the first location which was found to be high.

***Table 9.** Estimation of some genetic parameters for the studied characters at both locations (Kanipanka upper value and Qlyasan lower value)*

The simple correlation coefficient among studied characters for both locations represent in *Table 10*. At first location number of spikes/plant correlated positively and significantly with weight of spikes/plant, biological yield/plant and grain yield/plant 0.498, 0.416 and 0.407 respectively, while it correlated negatively and high significantly with weight of grains/spike -0.670, but negative and highly significant correlation was recorded between number of spikes/plant and 1000-grain weight -0.543. Positive and highly significant correlation was recorded between weight of spikes/plant with biological yield/plant and grain yield/plant 0.802, 0.853 respectively. Spike length correlated positively and significantly with number of grains/spike 0.477. Number of grains/spike showed negative and highly significant with 1000-grain weight -0.644, but weight of grain/spike associated positively and high significantly with 1000-grain weight 0.610. Biological yield/plant recorded negative and highly significant correlation with harvest index -0.691, whilst it correlated positively and highly significant correlation with grain yield/plant. At second location number of spikes/plant showed positive and highly significant correlation with weight of spikes/plant and grain yield/plant 0.618 and 0.675 respectively, but it correlated negatively and significantly with 1000-grain weight -0.444. Weight of spikes/plant recorded positive and highly significant correlation with number of grains/spike and grain yield/plant 0.538 and 0.820 respectively, whilst it correlated positively and significantly with biological yield/plant 0.508. Number of grains/spike recorded positive and significant correlation with weight of grains/spike 0.417. Weight of grains/spike recorded positive and highly significant correlation with biological yield/plant 0.731. Negative and highly significant

correlation was recorded between biological yield/plant and harvest index -0.616, while positive and highly significant correlation was recorded between biological yield/plant and grain yield/plant 0.543. Previously it could be noticed that harvest index was significantly and positively correlated with number of spikes/plant, plant height, spike length, 1000-grain weight and grain weight/spike. Number of spikes/plant was significantly and positively correlated only with plant height, while it was negatively associated with spike length and1000-grain weight as well as positively correlated with grain weight/spike. Moreover, plant height was significantly and positively correlated with 1000-grain weight and grain weight/spike. In the same time, spike Length was significantly and positively correlated with 1000-grain weight and grain weight per spike.1000-grain weight were significantly and positively correlated with grain weight/spike (Mohsin et al., 2009; Fellahi et al., 2013; Motawea, 2017).

Data in *Table 11* illustrate the direct and indirect effects of grain yield components in grain yield/plant at both locations. At first location maximum positive direct effect recorded by weight of spikes/plant 0.504 and followed by biological yield/plant 0.493, while maximum negative direct effect was -0.079 recorded by spike length. Maximum positive indirect effect in grain yield/plant was 0.405 recorded by weight of spikes/plant via biological yield/plant, and followed by 0.395 for biological yield/plant via weight of spikes/plant. At second location biological yield/plant recoded maximum positive direct effect in grain yield/plant 1.094 and followed by harvest index 0.983. Maximum negative direct effect was -0.252 recorded by number of grains/spike and followed by -0.208 for number of spikes/plant. Maximum positive indirect effect in grain yield/plant was 0.551 recorded by biological yield/plant via weight of spikes/plant, and followed by 0.433 for biological yield/plant via spike length. Maximum negative indirect effect was -0.664 recorded by biological yield/plant via harvest index, and followed by -0.597 for harvest index via biological yield/plant.

Discussion

The analysis of variance confirmed highly significant genotype effect for all characters under the study. This provides evidence of the presence of sufficient genetic variability among genotypes at both locations. The mean squares due to genotypes were highly significant for all characters at both locations except number of spikes/plant and average spike weight which was significant at the second location. The results indicated that the data for all traits studied can be analyzed further to estimate general and specific combining ability effects. Similar results reported previously confirmed that both gca and sca variances were significant for most of the characters indicating importance of both additive as well as non-additive components of genetic variance in the control of these traits (Kumar et al., 2011; Burungale et al., 2011; Singh et al., 2013; Mandal et al., 2016; Rahul, 2017; Ljubičić et al., 2017). Combining ability describes the breeding value of parental lines to produce crosses (Romanus et al., 2008). The general combining ability has been equated with additive gene action and specific combining ability with non-additive gene action (Griffing, 1956b).

All characters had shown considerable amount of heterosis over mid parents. These results are in confirmation with Devi et al. (2013) and Rahul and Kandalkar (2018). To improve any character, plant breeders heavily rely on the availability of genetic variability generated from different matting designs. It is also well known phenomena that in a hybridization program, certain crosses pass on more favorable genes than the others. Thus, some cross associations may be superior as compared to their parents for improving any economic traits (Baloch et al., 2016).

Combining ability plays a major role for estimation of inbred in terms of their breeding value, which help to decide suitable breeding method to be used in segregating generation. The gca is primarily a function of additive genetic variance it helps in the selection of good general combiner parents for hybridization (Rahul and Kandalkar, 2018).

DOI: http://dx.doi.org/10.15666/aeer/1702_30133032

The estimation of sca effects for crosses is mainly a function of dominance variance, helps in the identification of superior cross combination for commercial exploitation of heterosis.

The non-additive gene effect controlled the inheritance of most characters. Several researchers reported the predominance of non-additive gene effect (Bhowmik et al., 1991; Khan et al., 1995; Ajmal et al., 2000; Subhani and Chowdhry, 2000; Singh, 2003; Chaman et al., 2005; Heidari et al., 2006; Kumar et al., 2011; Singh et al., 2012a, b), while some workers exhibited the importance of additive type of gene action (Rhahman and Krons, 1991; Bhutta et al., 1997; and Tawfiq et al., 2008).

Beche et al. (2013) and Baloch et al. (2016) reported high values of heritability for grain yield/plant. Grain yield/plant is the prime objective of plant breeders. High estimates of variability and heritability for this trait would be helpful for the breeders to select for the best combinations and to reach at the desirable level of yield potential.

Grain yield/plant exhibited positive and significant correlation with most its important components at both locations. These results are agreement with those reported by Tofiq (2004), Hama-Ali (2006), Hama-Ameen (2008), Mohsin et al. (2009) and Fellahi et al. (2013). Previous researches indicated the positive correlation between grain yield and yield component traits in wheat such as spike number/plant (Mondal and Khajuria, 2001), grains number/spike (Kashif and Khaliq, 2004), 1000-grain weight and biological yield/plant (Akbar et al., 1995). Estimation of the correlation between yield and its components alone is not sufficient to understand the importance of each one of these components in determining the grain yield reported by Bhutta et al. (2005), Anwar et al. (2009) and Ali and Shakor (2012).

Unlike the correlation coefficient, which measures the extent of the relationship, the path coefficient measures the magnitude of direct and indirect contribution of a component character to a complex character and it has been defined as a standardized regression coefficient which splits the correlation coefficient into direct and indirect effects (Arbuckle, 2009). Path coefficients have been used to develop selection criteria for complex traits in several crop species of economic importance such as wheat (Larik, 1979; Aydin et al., 2010). Path analysis grains/spike followed by 1000-grain weight, spikes/plant and harvest index had positive direct effects on grain yield of bread wheat obtained from Majumder et al. (2008). The path coefficient analysis provides more information among variables than do correlation coefficients since this analysis provides the direct effects of specific yield components on yield and indirect effects via other yield components (Arshad et al., 2006). In agricultural, path analysis has been used by plant breeders to assist in identifying traits that are useful as selection criteria to improve crop yield (Dewey and Lu, 1959; Milligan et al., 1990). In a study of path analysis it was indicated that 1000-grain weight had the highest positive direct effect on yield followed by spike length, while plant height and grains/spike had a negative direct effect on yield (Iftikhar, 2012).

Conclusion

It can be stated that enough genetic variation existed among the studied genotypes for most of the studied traits. Additive and non-additive gene effects were involved in the expression of all traits. Thereafter, it is recommended that breeding methods, which make the best use of additive effects such as direct selection, are applied for those traits where dominant effects are negligible. However, using hybrid vigor will be more

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30133032

efficient than selection for those traits that show high levels of dominant effects. Proportion of variances due to sca confirmed the predominance of dominant genes in the expression of majority of the traits. Among the parents, the Klal parent at both locations were the best general combiner for grain yield and some of its components, and thus can reliably be used in a hybridization program so as to select the desirable plants from segregating populations. So, it is concluded that this parent may be used in breeding program to develop high yielding wheat varieties. The cross Kauz×Klal was the best specific combiner for grain yield/ plant, but the cross Aras×Iba-95 was the best specific combiner for most grain yield components at the first location, while at the second location the cross Aras×Iba-95 was the best specific combiner for grain yield and most its components that can be used in developing cross varieties. The characters with high estimates of heritability indicated the presence of additive genes effect in their inheritance, and suggested reliable wheat improvement through selection.

Recommendation

Klal parent was a good general combiner for grain yield/plant, biological yield/plant, number of spikes/plant, weight of spikes/plant and number of grains/spike, which could be used in the development of high-yielding varieties using selection from promising segregating cross generations.

It was recommended to conduct a favourable selection method to the cross Aras×Iba-95 in the future to develop new common wheat variety.

The varieties should be tested at different locations along with growth seasons to evaluate these traits, so that these traits are more inconsistent in different growth seasons.

Abstract. The applicability of experimental and numerical models used for the solution of dam-break flows is vital for better dam projects and also in preventing related accidents. The high cost and the time-consuming nature of laboratory studies require consistency in the investigation of numerical models. In this study, the propagation of a flow using a fluid with a different density from that of normal water in the reservoir was investigated both experimentally and numerically. Salt water was preferred as a Newtonian fluid in order to observe the propagation of flows in different density after a sudden break. A small-scale channel was constructed and laboratory data were obtained using image processing techniques. For the numerical model, Smoothed-Particle Hydrodynamics (SPH) method and Reynolds Averaged Navier-Stokes (RANS) equations solved by Flow-3D software, were applied. Flow depth changes were observed in the reservoir and the downstream. The data obtained from all methods were compared with each other. The results of two numerical simulations point out that the disagreements on graphs in the time evolutions of the fluid levels in the SPH increase due to turbulence effects, whilst, these differences decrease in the RANS equations solved by Flow-3D software. Consequently, since the SPH provides taking the measures and developing intervention strategies to reduce the risks connected to the evolution of dam-break flows, it is thought that future validation studies of the model will be require with the use of data observed in this field.
Keywords: *dam-break, density effect, image processing, particle method, volume of fluid*

Introduction

Some environmental flows can be simulated like dam-break induced shock waves. The prediction of these flows is one of required elements in the design of a dam. Dams are constructed for specific purposes such as water supply, flood control, irrigation, navigation, sedimentation control and hydropower (Lee et al., 2018). Past examples show us that the dams can be destroyed due to various reasons. The reasons of failure can be different for each dam and each case. While rockfill dams usually fail after a certain amount of time elapses, concrete dams fail a lot more suddenly. In practice the release of dam-break flows will be more gradual than this idealization. However, the sudden release may be expected to give the worst scenario. The shock wave propagation, caused by a dam-break, produces damaging effects in the downstream. It can be seen common that the propagation of water mixture which of different density from water can be formed in the downstream after torrential rain or a dam collapse. Hence, the flood wave can damage both living species and the environment (Yenigun et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30333047

al., 2016). For the process of the dam construction and the evaluation of a demolition situation after the construction, it is important to simulate the flow characteristics on a dam-break problem with laboratory experiments and numerical models. Various dam-break flow problems, which use water as the fluid in the reservoir, was experimentally and numerically examined in the literature. Ritter was the first to examine this flow problem in 1892. He used Saint-Venant equations to solve the sudden dam-break problem in a horizontal, rectangular, frictionless channel and he considered the downstream as a dry bed and the reservoir in an infinite length (Vischer and Hager, 1998; Chanson, 2005). There are numerous studies investigating a dry and/or wet bed downstream (Stoker, 1957; Bellos et al., 1992; Mohapatra and Bhallamudi, 1996; Stansby, 1998; Janosi et al., 2004; Bukreev and Gusev, 2005; Gao et al., 2010; Oertel and Bung, 2012; Ozmen-Cagatay et al., 2014; Kocaman and Ozmen-Cagatay, 2015; Turhan, 2017; Turhan et al., 2019). It is possible to see many studies in which dam-break flow problem has been examined experimentally using image processing techniques in the literature. (Spinewine and Zech, 2007; Ozmen-Cagatay and Kocaman, 2010; Aureli et al., 2011; Yang et al., 2011; Kocaman and Ozmen-Cagatay, 2012; Lobovsky et al., 2013; Kunugi et al., 2013; Albano et al., 2014; Aureli et al., 2014; Amaral et al., 2016; Hui et al., 2017; Liu, 2018). There are a limited number of studies that include different density Newtonian fluids in the reservoir (Janosi et al., 2004; Ancey and Cochard, 2009; Shakibaeini and Jin, 2011; Li et al., 2013; Furuya et al., 2014). Concerning the research in this flow problem, using salt water as a Newtonian fluid in a dry channel in rapidly unsteady flow can be interpreted an original study. Since laboratory experiments are costly and time-consuming processes, using software program to solve these problems is essential (Karaer et al., 2018). With recent developments in computer technology, using particle methods has become more widespread and also, their sensitivity in modeling applications requires further testing. There are several software programs in which the dam-break flow problem is numerically simulated. In this study, Smoothed-Particle Hydrodynamics (SPH) method used as a particle method and it was first developed by Gingold and Monaghan (1977), Lucy (1977), Liu and Liu (2003) for astrophysical problems. Subsequently, it has been applied to various problems in fluid dynamics (Dalrymple and Rogers, 2006; Gomez-Gesteira et al., 2012; Dominguez et al., 2013; Crespo et al., 2015; Gu et al., 2017).

Dam-break shock waves usually affect large downstream regions and the common tendency is to comment flow characteristics in the horizontal scale rather than along the flow depth (Miao et al., 2011; Luo et al., 2017; Akbari, 2018). Recently, due to the increase in computer technology, Flow-3D, which is computational fluid dynamics (CFD) software based on volume of fluid (VOF) method, has been used widely to analyze free-surface flows among the other commercially available software programs (An et al., 2012; Ozmen-Cagatay et al., 2014; Robb and Vasquez, 2015; Hu et al., 2018). In the literature, the SPH model was applied to predict a dam-break flood propagation, which might occur in a specific living area. The studies in the literature represents the significant potentials of numerical and laboratory modeling in practical engineering applications. Moreover, the results obtained from all methods assisted to validate the results of each other in terms of SPH, RANS and laboratory experiments. (Chen et al., 2005; Albano et al., 2016; Gu et al., 2017; Xie et al., 2017).

In this paper, the sudden dam-break flow propagation of a different density Newtonian fluid in a small-scale, rectangular and horizontal channel was experimentally and numerically investigated. The purpose of this study is to model the flow movement

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30333047

in an idealized dam-break configuration in case of a Newtonian fluid in the reservoir. Normal water is a Newtonian fluid which of that the dynamic viscosity value is 0.001 kg/m.s and density value is 1000 kg/m^3 at the constant temperature of T_0 = 23.7 °C. Salt water was preferred as a Newtonian fluid to investigate the effect of a fluid with a different density to normal water. Thus, the behavior of a high density fluid has been tried to be analyzed. Experimental data were digitized using image processing techniques. Fluid free-surface profile graphs and snapshots were obtained at four downstream locations and at various specified distances in the reservoir and downstream. The SPH method and RANS equations, solved by the Flow-3D software program, were employed for the numerical models. The results obtained from the SPH were compared to laboratory experiments and RANS equations solutions.

Materials and methods

Experimental set-up

The reservoir and the downstream lengths of the rectangular and horizontal channel, in which the experiments employed, were designed to be 0.30 m and 0.916 m, respectively, as can be seen in *Figure 1*. In order to observe the sudden and unsteady flow behavior, the channel was selected in a small-scale. The channel was made of plexiglas and a gate of 0.35 m height was performed to simulate the dam-break flow problem. Furthermore, a pulley system, connected to the gate, was utilized to observe the sudden break situation. Moreover, a metal component with approximately 2 kg weight, which was attached to the hole on the gate with a rope, was designed. The rope was passed through two pulleys and it was bound to a load of about 12 kg filled with sand.

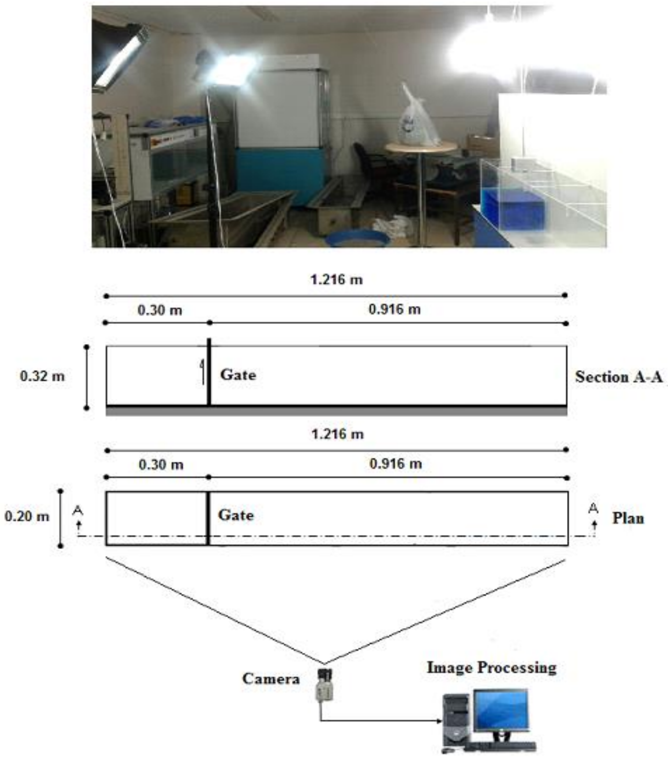

Figure 1. *Experimental set-up and gate mechanism (Turhan et al., 2018)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30333047

The temperature of the laboratory was measured at 23.7 °C during the experiments, hence this value was used in the numerical models. The viscosity was measured to be 18 cP (0.018 kg/m.s) at this temperature with the help of a viscometer. The mixing ratio of salt water was evaluated to be 20% and a homogeneous mixture was obtained by a mixer. As a result, the fluid density was specified to be 1200 kg/m^3.

The reservoir contained salt water at a height of 0.15 m (h_o) and the downstream have a dry bed. In order to create a sudden dam-break condition, the time of gate lifting should be less than $1.25(h_o/g)^{1/2}$ (h_o: initial height and g: gravitational acceleration) as suggested by Lauber and Hager (1998). This limit value has been used in many studies (Chanson, 2005; Spinewine and Zech, 2007; Ozmen-Cagatay et al., 2014; Kocaman and Ozmen-Cagatay, 2012, 2015; Aureli et al., 2014; Turhan et al., 2019). In order to obtain approximate value of data, ten experiments were performed and the average of the values was calculated. As h_o is 0.15 m, 0.155 s becomes the limit value for sudden dam-break and in this study lifting time was under approximately 0.10 s in the video images.

Flow measurement and camera calibration

The digital image processing is produced by transferring real images to digital media in different formats such as .jpg, .bmp, .png, etc. (Yıldırım et al., 2003; Aureli et al., 2011, 2014; Liu, 2018). In this technique, as seen in *Figure 2,* the image was divided into pixels and grid view was obtained. Normal water was used as the Newtonian fluid for camera adjustments and blue food dye was preferred to provide color.

The lighting in the laboratory, where the experiment was conducted, was improved to use image processing techniques effectively before starting laboratory experiments. In order to obtain better images from the experiment, continuous lamp source of approximately 500 W was employed in the laboratory. The optimum shooting option was evaluated to be 1/125 snapshot, 85 mm, f3.5 lens and 1250 ISO proof.

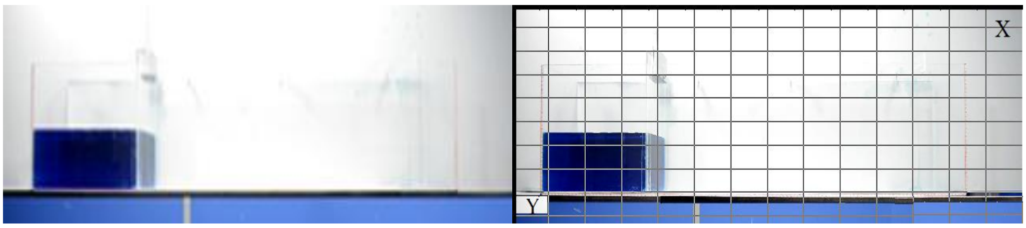

Figure 2. *Grid view in image processing (pixel)*

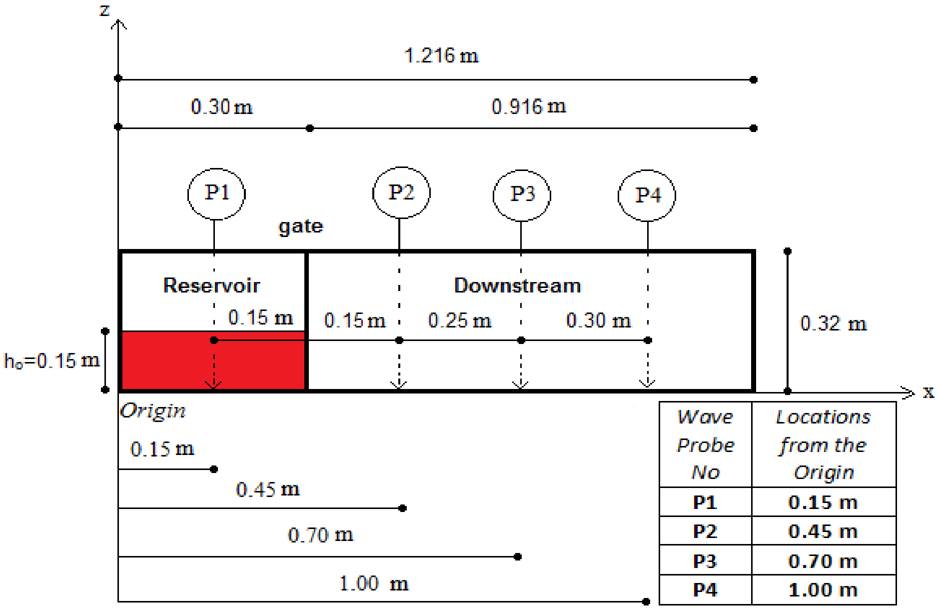
The frame rate and the resolution were set to 60 frames per second (fps) and 1280*720 pixels, respectively. The camera calibration process was performed with the images taken at different angles and the image distortions were eliminated. Camera shooting at the same coordinate significantly reduced the calibration error rate. The channel measurement points can be seen in *Figure 3*. Depth changes in the images were measured using a virtual wave probe (Kocaman and Ozmen-Cagatay, 2015). (x, y) coordinates were obtained by using an edge detection function at the specified locations, with the help of different colors. The simulation time and time-interval was assumed to be 3 s and approximately 0.017 (1/60 fps), respectively.

The level changes graphs are dimensionless (H-T) for all methods. For the dimensionless analysis, the values were calculated from the following equations

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30333047

$T = t(g/h_o)^{1/2}$ and $H = h/h_o$ where H and T are dimensionless terms and h denotes the changes in the fluid height over time. The use of dimensionless parameters can reduce the number of variables and therefore, dimensional effect-independent assessments become possible.



Wave Probe No	Locations from the Origin
P1	0.15 m
P2	0.45 m
P3	0.70 m
P4	1.00 m

Figure 3. *Channel measurement points*

Numerical modeling

Reynolds averaged Navier–Stokes (RANS) equations

RANS equations for an incompressible Newtonian fluid are shown in *Equations 1* and *2* (Luo et al., 2017):

$$\frac{\partial u_i}{\partial x_i} = 0 \qquad \text{(Eq.1)}$$

$$\rho\frac{\partial u_i}{\partial t} + \rho\frac{\partial (u_i u_j)}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \mu\frac{\partial}{\partial x_j}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) - \rho\frac{\partial\left(\overline{u_i' u_j'}\right)}{\partial x_j} + \rho g_i \qquad \text{(Eq.2)}$$

where ρ is density, u_i and u_j indicate the velocity component in the defined direction, t is time, p is pressure, μ is dynamic viscosity and g_i is gravitational force in the defined direction. When *Equation 2* is compared with the Navier–Stokes equations, it can be seen that there is an extra term, namely $\partial(\rho\overline{u_i' u_j'})/\partial x_j$ and it characterizes turbulence-induced stresses or Reynolds stresses. In the RANS equations, scalar values for all the physical properties of flow are evaluated as mean magnitudes. For laminar flow, the numbers of equation are equal to the unknown parameters. In the RANS, distinct terms have to be adjoined to the available equations. Hence, turbulence closure models are utilized to solve these problems. The term μ_t is used for turbulence viscosity, and it is found in the solution steps for the time varying RANS equations. Furthermore, the solution of this problem can be obtained with the help of many different turbulence

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30333047

models (Wilcox, 2000). The k-ε turbulence model is generally preferred for the final step of the process (Kocaman and Guzel, 2011; Souders et al., 2013; Ozmen-Cagatay et al., 2014; Heydari and KhoshKonesh, 2016; Bayon et al., 2016; Ozdil et al., 2017).

The numerical solutions for the RANS were computed using Flow-3D software CFD program based on the VOF method. This program contains a mesh–grid system. It comprises a fractional area/volume obstacle representation method (FAVOR) as cell porosity technique (Flow Science Inc., 2017). All the surfaces of the channel were presumed to be smooth. The channel sidewalls were considered to be symmetric, which implies no flux and shear of any property across it. Tangential and normal velocities were accepted as zero at the solid boundary according to the no-slip condition (Rostami and Siosemarde, 2015; Kocaman and Ozmen-Cagatay, 2015). For this study, a grid size was adopted as 5 mm after executing accuracy analysis for 2 mm and 10 mm. The time step Δt was specified according to the Courant–Friedrichs–Lewy (CFL) criterion and also, it was determined automatically with the help of the Flow-3D software.

Smoothed particle hydrodynamics (SPH) method

The SPH method is described as a technique that includes numerical solutions for fluid dynamics equations using a set of particles and fluid displacement (Dalrymple and Rogers, 2006). One of the most important features of this technique is that SPH is a Lagrangian mesh-free particle method. The Navier–Stokes equations, which are discretized in fluid dynamics problems, can be unified by the physical properties of the particles surrounding each particle position (Vacondio et al., 2012). The average smoothing length is calculated by *Equation 3:*

$$F(r) = \int F(r')\, W(r - r', h)\, (dr') \qquad \text{(Eq.3)}$$

where "W" is the kernel function and "h" is the smoothing length. "W" employed in the smoothing process, can involve several features. It is possible to consider some of these properties as being positive in a specified interaction region. Thus, it maintains gradually decreasing result values owing to the normalization and distance. The function is applied to a set of particles. Also, this function is called as application regions when defined by smoothing length. Therefore, a summation is applied to all particles within these application regions of the kernel (*Eq. 4*) (Ozbulut et al., 2014).

$$F(r_a) \approx \sum_b F(r_b)\, W(r_a - r_b, h)\Delta v_b \qquad \text{(Eq.4)}$$

In *Equation 4,* "a" and "b" symbolize individual particles. Furthermore, Δv_b points out the volume of the neighboring particle "b". As the volume is defined as $\Delta v_b = m_b/\rho_b$, where "m" is the mass and "ρ" is the density of particle, *Equation 4* can be modified as shown in *Equation 5* (Crespo et al., 2015):

$$F(r_a) \approx \sum_b F(r_b)\, \frac{m_b}{\rho_b} W(r_a - r_b, h)\Delta v_b \qquad \text{(Eq.5)}$$

The momentum equation is used to define the acceleration of a particle as a consequence of interaction with a neighboring particle (*Eq. 6*) (Altomare et al., 2015):

$$\frac{dV_a}{dt} - \sum_b m_b \left(\frac{P_b}{{\rho_b}^2} + \frac{P_a}{{\rho_a}^2} + \prod_{ab}\right) \nabla_a W_{ab} + g \qquad \text{(Eq.6)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30333047

In *Equation 6,* v is velocity, P is pressure, m is mass and W_{ab} is the kernel function. The kernel function also depends on the distance between two particles. The term Π_{ab} is called the artificial viscosity (Dominguez et al., 2012). The mass for each particle is constant and the differences in the fluid density are calculated by solving the conservation of mass or continuity equation (*Eq. 7*). Furthermore, Cubic spline was selected as the kernel function type for this study (Cunningham et al., 2014).

$$\frac{d\rho_a}{dt} = \sum_b m_b v_{ab.} \Delta_a W_{ab} \quad \text{(Eq.7)}$$

The pressure value of the flow is calculated using Tait's equation of state as can be seen in *Equation 8* (DualSPHysics Team, 2016):

$$P = b\left[\left(\frac{\rho}{\rho_0}\right)^{\gamma} - 1\right] \quad \text{(Eq.8)}$$

where $\gamma = 7$, $b = c_0^2 \rho_0/\gamma$, ρ_0: reference density, c_0: the speed of sound. The speed of sound value is calculated from *Equation 9* (Vacondio et al., 2012):

$$c_0 = c(\rho_0) = \sqrt{\left(\frac{\partial P}{\partial p}\right)}\,|_{\rho_0} \quad \text{(Eq.9)}$$

For this study, the Verlet algorithm was used in order to prepare the time stepping process. A variable time-step process was performed, which relies on applying the CFL condition, forcing terms and a viscous diffusion term (Barreiro et al., 2013). Moreover, a boundary condition, where the fluid–boundary interactions can be computed inside the same loops like the fluid particles, is suitable to fulfill due to computational simplicity in this paper. Seeing determine the optimum value of the artificial viscosity, different artificial viscosity values were tested and the optimum value obtained as 0.10. There are many studies in the literature about the use of various artificial viscosity values in the SPH (Gomez-Gesteira et al., 2012; Dominguez et al., 2013; Cunningham et al., 2014; Crespo et al., 2015; Gu et al., 2017; Zhu et al., 2017; Tantekin et al., 2017). SPH parameters can be seen in *Table 1*.

Table 1. *SPH parameters (Turhan et al., 2019)*

Property	Options
Version	DualSPHysics v4.0
Dimension	2D
Type of the kernel function	Cubic spline
Time-stepping	Verlet
Density filter	Shepard filter
Viscosity treatment	Artificial viscosity (α = 0.10)
Equation of state	Tait equation
Boundary conditions (BC)	Dynamic
Distance between particles (dp)	0.001
Smoothing length	1.0
The number of fluid particles	46857

Results and discussion

In this study, the fluid wave propagation was investigated over a dry bed. Experimental video records were digitized using image processing techniques and the SPH method and RANS equations were used for the numerical models. The propagation of salt water, in a small-scale channel under a sudden dam-break situation, was researched and the variation of fluid depth at four specified locations were examined. In order to show the variation in the free-surface profile of the flow for sudden dam-break flow conditions, the following time values, which represent the initial stages after suddenly lifting the gate, were selected as $t_0 = 0.00$ s, $t_1 = 0.017$ s, $t_2 = 0.083$ s, $t_3 = 0.134$ s, $t_4 = 0.184$ s and $t_5 = 0.234$ s. Moreover, time values, which represent the change of waves reflecting from the wall at the end of the channel, were selected as $t_6 = 1.002$ s, $t_7 = 1.252$ s, $t_8 = 1.670$ s, $t_9 = 2.004$ s, $t_{10} = 2.338$ s and $t_{11} = 2.989$ s (see *Figs. 4* and *5*).

According to the selected time values, the snapshots and level changes in selected locations were compared and the solution sensitivity of the SPH method was analyzed to better understand the unsteady flow behavior. With a sudden lifting of the gate, the fluid starts to move in the downstream direction due to gravitational force. At the initial stages of the propagation, all methods are in good agreement with each other (An et al., 2012; Albano et al., 2014; Bayon et al., 2016; Gu et al., 2017; Zhu et al., 2018). The shock wave front has a parabolic shape for the three methods at t = 0.083 s. At time t = 0.134 s, the wave front is subjected to the deformation and it becomes concave shape. As can be understood from the literature, a similar fluid behavior can be seen in the sudden wave propagation where the fluid is selected as water (Bellos et al., 1992; Stansby et al., 1998; Janosi et al., 2004; Spinewine and Zech, 2007; Ozmen-Cagatay and Kocaman, 2010; Gao et al., 2010; Girolami et al., 2012; Ye et al., 2016; Bayon et al., 2016; Hui et al., 2017; Turhan et al., 2019). However, in the numerical models, the wave front has a convex shape. This difference can be explained by the fact that the experimental channel has minor surface roughness compared to the numerical models.

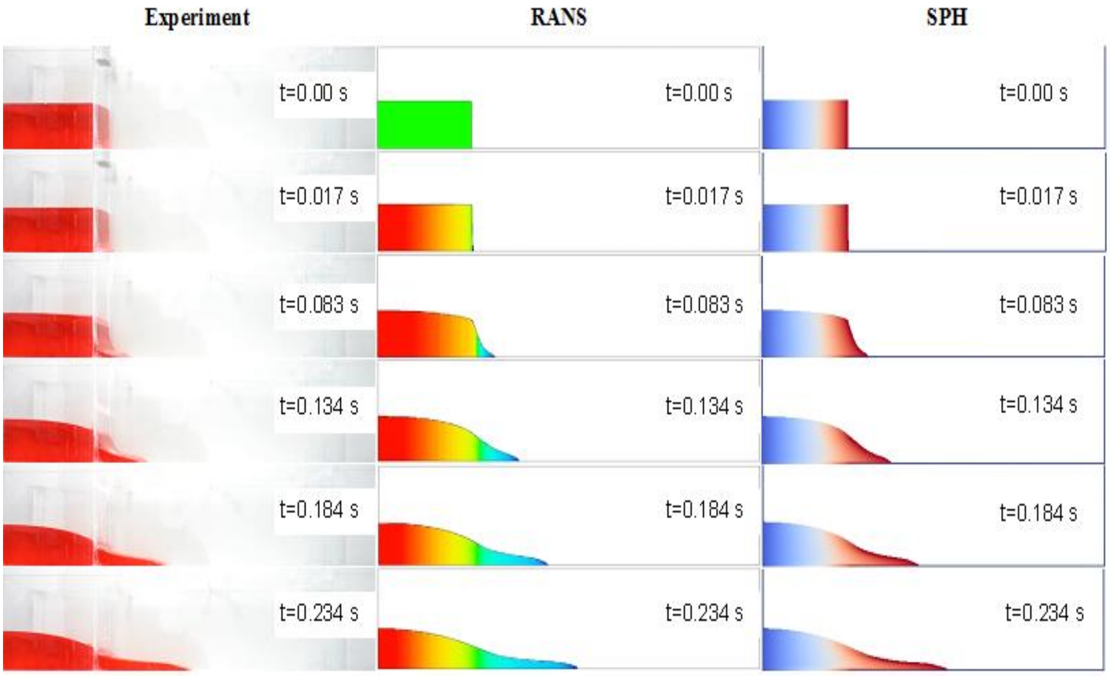

Figure 4. *Evolution of free-surface profiles with time at the initial stages after sudden lifting from t = 0.00 s to t = 0.234 s for experiment, RANS and SPH*

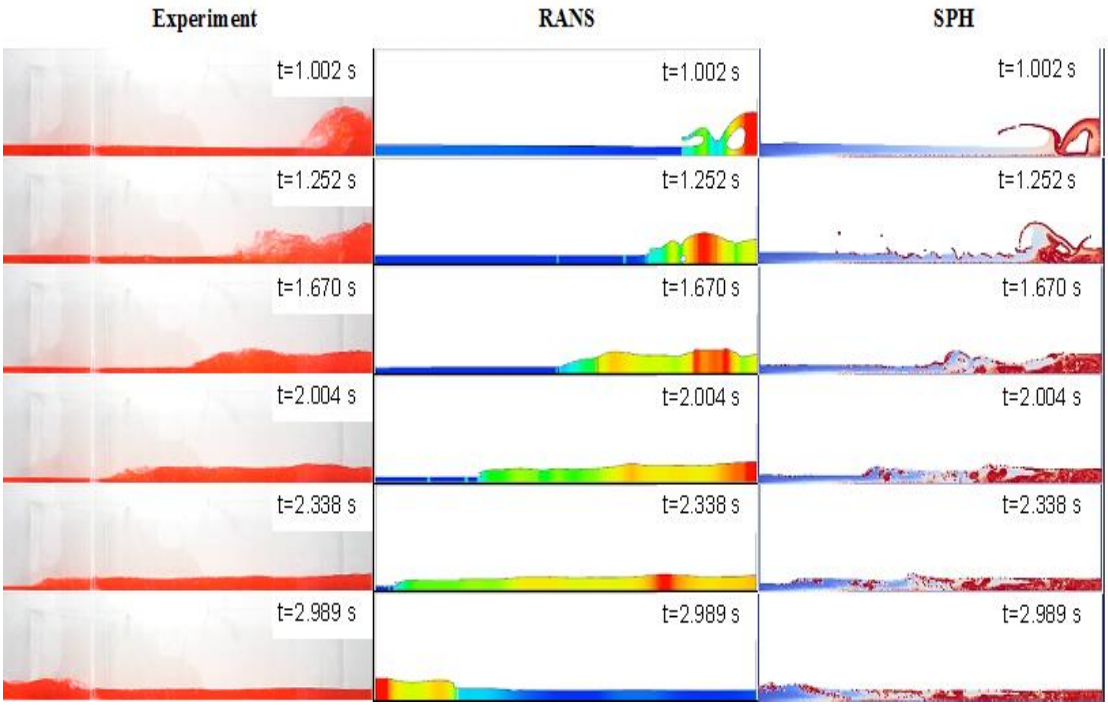

Figure 5. *Evolution of free-surface profiles of reflecting wave with time from t = 1.002 s to t = 2.989 s for experiment, RANS and SPH*

A dam-break flood shock wave over a dry bed can be separated two parts as an initial wave and a dynamic wave after the initial stages (Lauber and Hager, 1998; Chanson, 2005; Ozmen-Cagatay and Kocaman, 2010; Kocaman and Ozmen-Cagatay, 2015; Hui et al., 2017; Turhan et al., 2018). Nsom (2002) defines a convex shape of the wave front for highly viscous fluids. *Figure 5* shows the change in free-surface profiles in the experimental and numerical models for the selected locations in the case of a reflected wave. At t = 1.002 s, the wave rises on the channel surface for a while and the formation of air bubbles is observed in the wave front. When the wave is breaking in the RANS example, the wave jumps to a further point due to disintegration in the SPH. High energy losses in the experiments cause a decrease in the velocity because of the turbulence effect and the fluid level is observed at higher position (Kocaman and Ozmen-Cagatay, 2012; Souders et al., 2013; Rostami and Siosemarde, 2015; Gu et al., 2017; Turhan et al., 2019). At t = 1.252 s, the wave front has a different shape for each methods. In general, RANS results are compatible with the experimental results in terms of the wave front velocity (Ozmen-Cagatay and Kocaman, 2010; Bayon et al., 2016; Heydari and KhoshKonesh, 2016; Hu et al., 2018).

In *Figure 6,* for P1 = 0.15 m, the numerical and experimental results are in good agreement with each other except for T = 20 to 25. For P2 = 0.45 m, except for a few differences, the numerical methods show similar results to each other until T = 15. In the SPH method, between T = 15 and 20, it is seen that the fluid height increased at the initial stages but later, it decreased with time and also it is constant at H = 0.20. However, in the RANS method, the depth was observed to be higher than with the SPH (Turhan et al., 2019). At T = 20, the front of wave became vertical shape for the SPH due to the artificial viscosity coefficient. For P4 = 1.00 m and T = 8 to 10, some fluctuations were seen in the experimental results and the fluid height is lower

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30333047

compared to the SPH. Until the end of the propagation, the maximum H value is occurred for T = 10 in the particle method. For P4 = 1 m, the obtained results in RANS and experiments are quite similar except for T = 8 to 15.

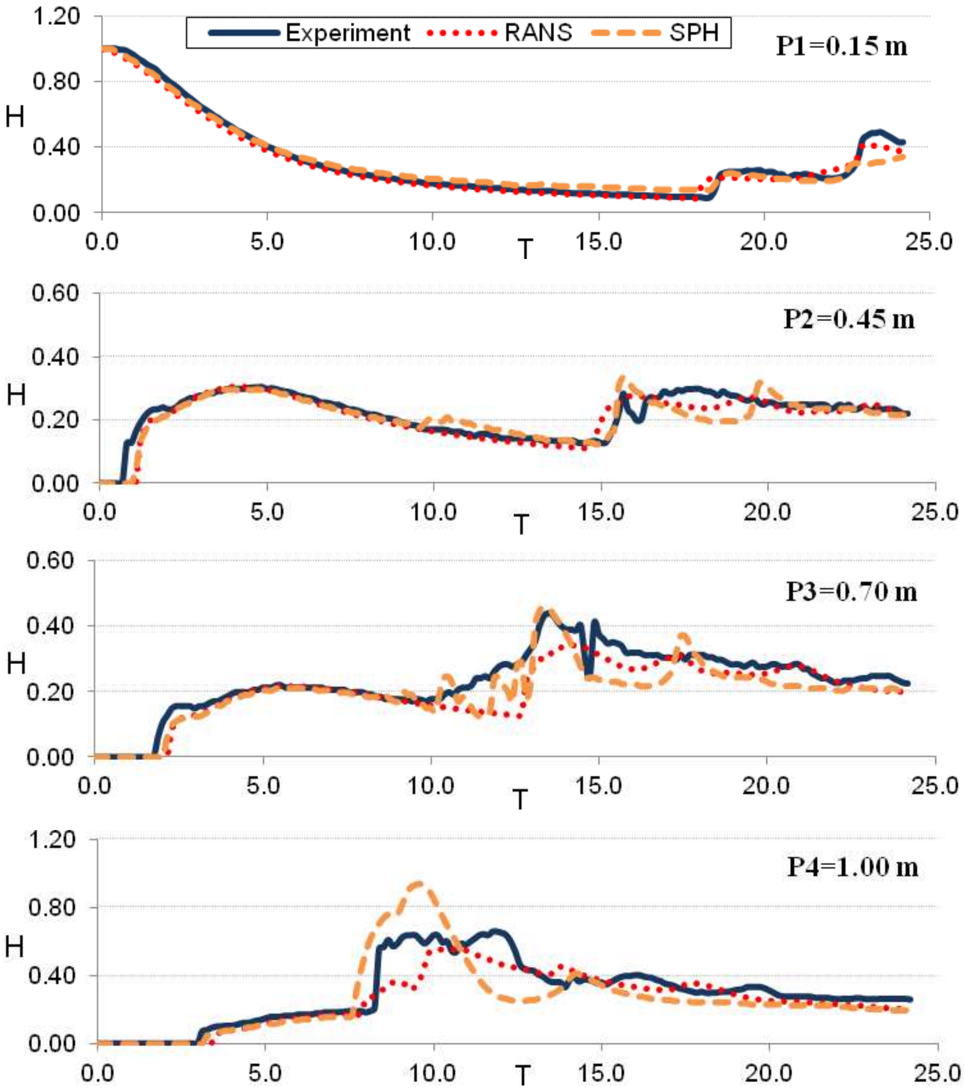

Figure 6. *Flow depth variations with time at P1, P2, P3 and P4*

At T = 10 to 15, the SPH results have been observed to differ from the experimental results. The disintegration of the reflected waves can be mentioned as one of the reasons for the differences due to particle collision in the flow. At T = 25, the experimental and SPH results in the graphs began to meet each other. Furthermore, a more sensitive analysis of the SPH parameters and modeling the wave motion with high-technology-aided computers will greatly increase the capability of the numerical solution (Dominguez et al., 2013; Valdez-Balderas et al., 2013; Turhan, 2017; Akbari, 2018). While the numerical model can generate highly compatible data in the initial stages of the dam-break, the differences between the results for various methods at P4 can be clearly observed due to the wall at the end of the channel. As a result, the propagation of flow in a Newtonian fluid with a different density, such as salt water for this study, can

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30333047

yield similar results with the cases in which water was used as a fluid in the initial stages for both experimental and numerical results.

In addition, the reflected waves after hitting the wall become more vertical shape in the propagation of water and the formation of bubbles on the front face of the wave draws more attention (Zhu et al., 2018; Turhan et al., 2018). For fluid propagation, wave breaking, jet and bubble formations can be observed for some time due to the turbulence effect (Janosi et al., 2004; Li et al., 2013; Hu et al., 2018; Liu et al., 2018).

Conclusion

Difficulties in the application of dam-break flow problems require from utilizing numerical methods because of rough real case conditions. In recent years, the advances in computer technology have enabled computer-aided software programs to easily solve these problems. Therefore, the validation of numerical methods can considerably provide to test the sensitivity of the experimental solutions. In this study, the dam-break flow problem, in which the liquid is salt water, was investigated both experimentally and numerically over a dry bed to gain a better understanding of the effects of different density fluid. According to the results, the values obtained from both numerical methods and experiments are close to each other, but when the turbulence effect is high, the free-surface profiles and graphs show some differences. In these periods, major changes are observed using the SPH method. However, RANS results are in good agreement with the experiments. The artificial viscosity and particle approach in the SPH cause differences in the results in terms of profiles and graphs. The use of artificial viscosity in the SPH increases the differences between the results in each case. Although the results obtained from the SPH is usually considered to be good in agreement with the results obtained from other methods, studies performing more sensitive analyses can make greater contributions with more consistency. It can be stated that SPH, a mesh-free particle based Lagrange method, may be adopted as a useful numerical method for solving complex open channel flow problems.

As further studies, force and velocity measurements in dam-break problems, the effect of channel base roughness and channel slope on flow characteristics can be examined. In addition, several artificial viscosity and smoothing length values can be investigated to observe the performance of the numerical model under different parameters.

(Received 3rd Dec 2018; accepted 4th Feb 2019)

Abstract. The importance of environmental reservoirs as a source from which antimicrobial resistance emerges and subsequently transferred is already established. To evaluate the role of small scale poultry slaughterhouses in resistance dissemination in Pakistan, a comparative genomic analysis of antimicrobial resistance genes (ARGs) and mobile genetic elements (MGEs) in the gut microbiome of broiler and household chickens (*Gallus gallus domesticus*) was performed. An array of 52 qPCR primers targeting the 16S rRNA gene, ARGs and MGEs was used in the experiment to analyse the abundance of selected genes in collected samples. A total of 22 ARGs and 7 MGEs were detected in all samples. The detection frequency of specific gene classes and diversity of genes was found to be higher in broiler as compared to household chicken. *Sul1* was the most abundant ARG with the highest percent relative abundance (2.4%). Total percent relative abundance of ARGs in broiler chicken was found to be significantly ($p < 0.05$) greater than household chicken fecal samples. A significant linear correlation ($R^2 = 0.89$) was found between relative abundances of *int1* and total ARGs. The clustering and correlation of selective ARGs with MGEs has implied that small scale poultry slaughterhouses can be a potential source for the dissemination of ARGs to other non-resistant environmental and/or clinical bacteria.
Keywords: *ARGs, MGEs, qPCR, AMR, microbiome*

Introduction

Antimicrobial resistance genes (ARGs) are emerging environmental contaminants causing serious public health concerns (Sanderson et al., 2016). The annual number of human deaths due to antimicrobial resistance is expected to reach up to 10 million by 2050 (de Kraker et al., 2016). Accumulating scientific evidence have suggested that the abuse of antibiotics in clinical and agricultural settings is mainly responsible for the emergence of antimicrobial resistance in microorganisms (Rather et al., 2017; York, 2017). Antibiotic resistant bacteria and associated ARGs can be transported from different environmental reservoirs contributing to the ever increasing global problem of antimicrobial resistance (Waseem et al., 2017a). The scientific community is already exploring new directions for evaluating the spread of the antimicrobial resistance from environmental routes to clinical pathogens (Andersson, 2015; Waseem et al., 2019; Williams et al., 2017). Fecal microflora from animals and birds harbours a vast variety

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30493063

of ARGs that can be transferred into other bacteria including human pathogens (Bonnedahl and Järhult, 2014; Zhao et al., 2018).

The poultry industry is one of the fastest growing agricultural sectors of the world. Use of antibiotics at therapeutic and sub-therapeutic levels as growth promoters have been employed in poultry for over half a century (Castanon, 2007). Although antibiotics utility for growth promotion has already been ostracized in many developed countries, but the situation is disquieting in developing countries like Pakistan and Egypt (Mund et al., 2017). In Pakistan, over the counter availability of antibiotics and less implementation of health and safety regulations in the poultry industry makes the challenge of antibiotic abuse and subsequent resistance dissemination far more intriguing. By 2030, the global consumption of antibiotics for cattle, chicken, and pigs is expected to reach 105,596 ± 3,605 tons (Van Boeckel et al., 2015). The consumption of antibiotics is continuously putting increasing pressure on environmental and clinical bacteria to acquire antimicrobial resistance. Apart from the resistance development under selection pressure for antibiotics, bacteria can also develop resistance by acquiring resistance genes via mobile genetic elements (MGEs) mediated horizontal gene flow (Oliveira et al., 2017).

One of the most useful strategies against the global antimicrobial resistance is to mitigate the spread of ARGs from environmental reservoirs. Surveillance and monitoring of such reservoirs are thus essential for curbing the dissemination of ARGs into the environment. Small scale poultry slaughterhouses are one of the potential reservoirs for antibiotic resistance. They are widely distributed throughout Pakistan. Chicken fecal waste from these small scale slaughterhouses, a source of resistant bacteria and ARGs, is generally being disposed of in the environment without any proper treatment. Chances of meat contamination with the antimicrobial resistant bacteria at the time of slaughtering in unhygienic conditions are also there (Amir et al., 2017). Additionally, ARGs can also be disseminated into the environment when poultry feces are used as organic fertilizers for fruits and vegetables.

Antibiotics can also influence ARGs to which they are not explicitly related (Foxman, 2012; Guo et al., 2018). Therefore, instead of antibiotic specific screening of ARGs in chicken *(Gallus gallus domesticus)* gut microbiota, analysis of ARGs from all major classes is recommended. Additionally, most of the research on antimicrobial resistance was focused on individual bacteria mainly foodborne pathogens (Lee et al., 2017; McMahon et al., 2007), which represents only a small fraction of the gut microbiome. Evaluation of resistance determinants from gut microbiome community can give a comprehensive analysis of dissemination and/ or fate of the ARGs into the environment.

To the best of our knowledge the status of AMR in gut microbiome of chicken in Pakistan yet remains elucidative to a greater extent. The primary purpose of the current study was to evaluate and compare the detection frequency, diversity, and abundance of selected ARGs from chicken fecal samples collected from small scale poultry slaughterhouses. The abundance and occurrence of selected MGEs have also been evaluated as they are believed to be involved in the dispersal of ARGs into non-resistant pathogenic bacterial strains. The possible correlations between ARGs and MGEs were also determined. Present research is a pilot scale study with only a limited sample set but it will likely provide first-hand information regarding ARGs dissemination from the small scale poultry slaughterhouses.

Materials and methods

Sample collection and DNA extraction

Sample collection was performed in early spring of 2018 from a small scale poultry slaughter house in Johar Town, Lahore, Pakistan. Pools of fresh fecal samples from different cages of broiler and household chickens were collected (*Fig. A1* in the *Appendix*). A total of 6 fecal samples 3 from broiler chickens and 3 from household chickens were collected in 30 ml falcon tubes using a sterile spatula. Samples were thoroughly mixed and homogenized before DNA extraction (*Fig. 1*). DNA was extracted from collected samples by using QIAGEN DNeasy PowerSoil kit (QIAGEN Inc., MD, USA) as per manufacturer's instruction. Extracted DNA was stored at -20 °C until the amplification was performed. All the experiments in our study were performed at Environmental Microbiology Laboratories, Department of Microbiology, Quaid-i-Azam University, Islamabad. The concentration of DNA from each sample was normalized to 10 ng/µl before using the DNA for qPCR reactions.

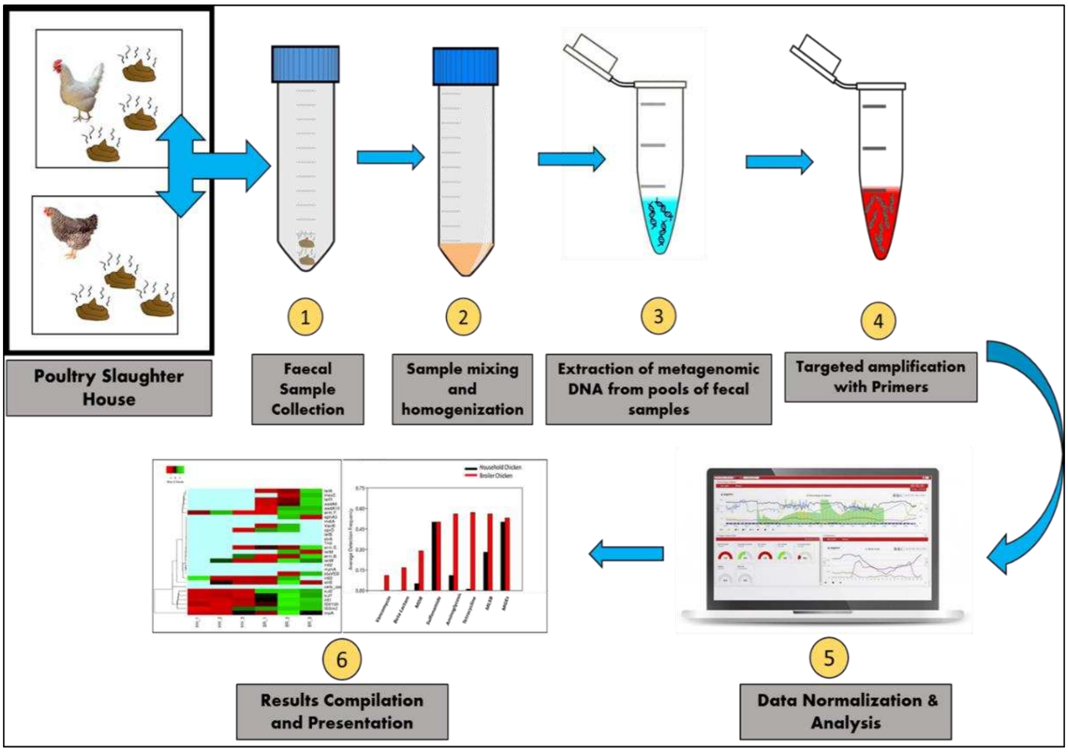

***Figure 1.** Diagrammatic flowchart of the whole experimental design*

Primers and qPCR

A total of 52 primers were used in this study for the evaluation of ARGs and MGEs abundance in fecal samples. The primers used in our study are a subset of qPCR Primer set 2.0 (Stedtfeld et al., 2018). The sequences of the qPCR primers can be found in the *Appendix* (*Table A1*). The primers were designed, validated and assayed as described in previous studies (Johnson et al., 2016; Karkman et al., 2016; Stedtfeld et al., 2017, 2018). The design protocol and parameters of each primer set are to target sequence diversity within a gene to analyse the environmental resistome. The array covered seven

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30493063

major antibiotic classes including MDR (7 genes), tetracyclines (7 genes), aminoglycosides (6 genes) beta-lactams (6 genes), macrolide-lincosamide-streptogramin B (MLSB) (6 genes), Vancomycin (6 genes) sulfonamides (3 genes) involved in different resistance mechanisms (*Fig. 2*).

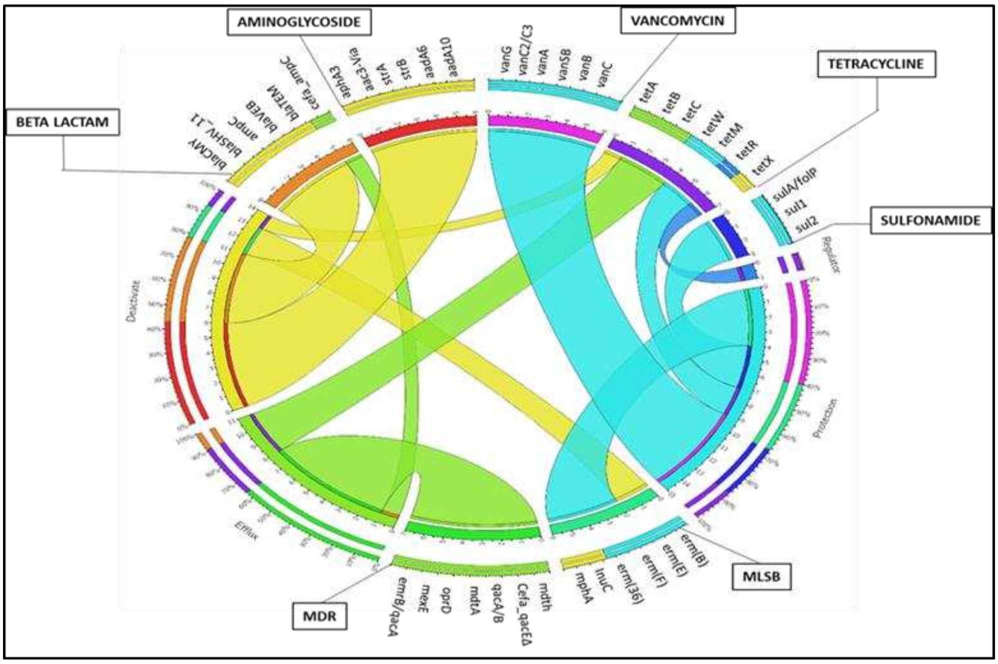

Figure 2. *Circos plot showing the antibiotic resistance class and mode of resistance mechanism of all 41 ARGs included in our array. The plot is made by using Cir-cos software (Krzywinski et al., 2009)*

A real-time qPCR thermocycler (Mastercycler® ep *realplex;* Eppendorf) was used to perform DNA amplification in 25 µl reaction volume. The contents used in qPCR are as follows: 2x Power SYBR Green PCR Master Mix (12.5 µl), 10 µm primer mix (1.25 µl), sample DNA (1 µl), and water (10.25 µl). Cycling conditions for qPCR reactions were as follow: an initial activation step at 95 °C for 10 min followed by 45 cycles of 95 °C for 15 s and 60 °C for 1 min. Gene copy number was estimated from the Cycle threshold (Ct) values based on the method previously described (Looft et al., 2012). A Ct value of 29 was used as the cut-off limit. All sample-primer assays were performed in triplicates. A negative control without sample DNA was also included for every assay. Genes detected from at least two out of three technical replicates were considered as true positive and all false positive results were removed. Overall a total of 1248 qPCR reactions were performed during the whole study.

Data analysis

Relative abundance was calculated by dividing the estimated gene copy number of the targeted gene with the gene copy number of 16S rRNA. A multivariate principal component analysis (PCA) of ARG profiles between sample types was performed in Paleontological Statistics Software Package for Education and Data Analysis (PAST: v3.20) (Hammer et al., 2001). The scale of the principal components was transformed into eigenvalues. Basic data processing of qPCR results was performed on Microsoft

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30493063

Excel 2010. A student t-test was applied to the sum of total ARGs and MGEs abundance in order to test the significant differences between two different types of chicken. Shannon diversity calculations and scatter plots were also made in PAST v3.20 using percent relative abundance of genes in order to see the diversity of the ARGs in different samples. A heat map based on the natural log-transformed values of the relative abundance of ARGs and MGEs was made by using heat mapper software (Babicki et al., 2016) to evaluate the presence of individual genes in fecal samples. Complete linkage clustering method and Euclidean distance measurement method was used to cluster the rows representing genes in the heat map (Yeung et al., 2003).

Results

Detection and diversity of ARGs and MGEs

For evaluating the ARGs of 6 fecal samples from 2 different types of chicken (broiler vs. household), a qPCR sub-array of 52 primer sets targeting 16S rRNA gene, antibiotic resistance genes (ARGs) and transposase genes related to horizontal gene transfer (HGT) were used in the present study (*Fig. 2*). Out of 52 targeted genes, a total of 22 ARGs were detected in the fecal samples. The detected ARGs represented every targeted class of antibiotics (*Fig. 3*). In addition to ARGs 7 MGEs were also detected in both groups. The detected MGEs belonged to insertion sequences, transposase, and integrase groups are believed to play a role in HGT. Out of 29 detected ARGs and MGEs 8 genes were detected all (6/6) samples while 6 genes were detected in only 1 out of 6 samples. Two genes conferring resistance to aminoglycosides (*aadA6*, *aadA10*) and two tetracycline resistant genes (*tetA*, *tetR*) were absent in all three samples from household chicken but were detected in all three samples from broiler chicken. Overall more genes were detected in broiler chicken samples as compared to household chicken samples.

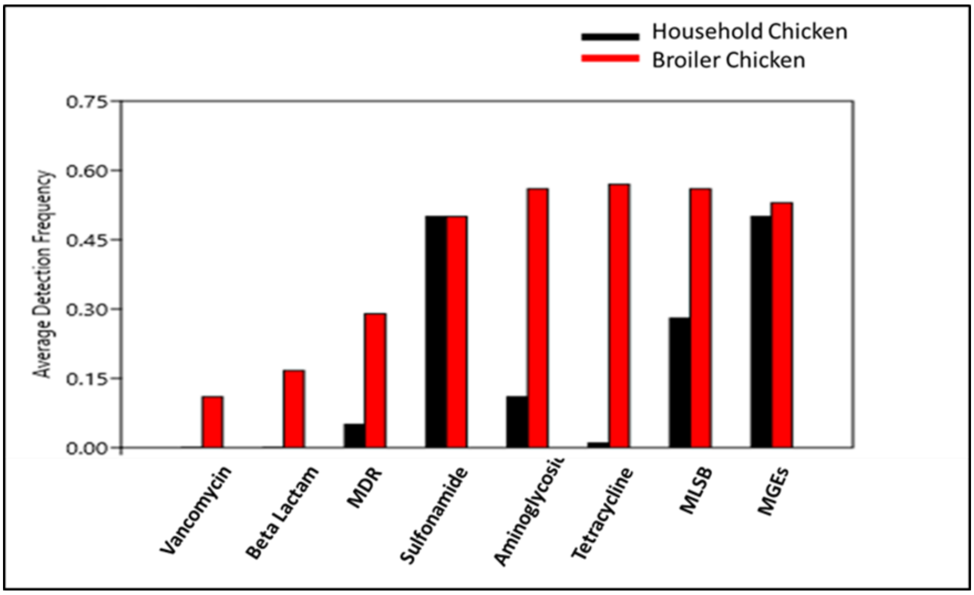

Figure 3. *Antibiotic resistance class wise average detection frequency. Average detection frequency is an average number of samples in which genes within a class is detected divided by total number of samples against which the genes are tested for one or more genes conferring resistance to that AR class*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30493063

The number of detected genes ranged from 8 to 13 in fecal samples from household chicken whereas the genes detected in fecal samples of broiler chicken ranged from 18 to 24. Shannon diversity indicating the richness and abundance of genes in the samples was calculated by taking an average of the relative abundance of the three technical replicates for each of the 6 samples. Shannon diversity of the broiler chicken samples was found to be higher than the household chicken (*Fig. 4*).

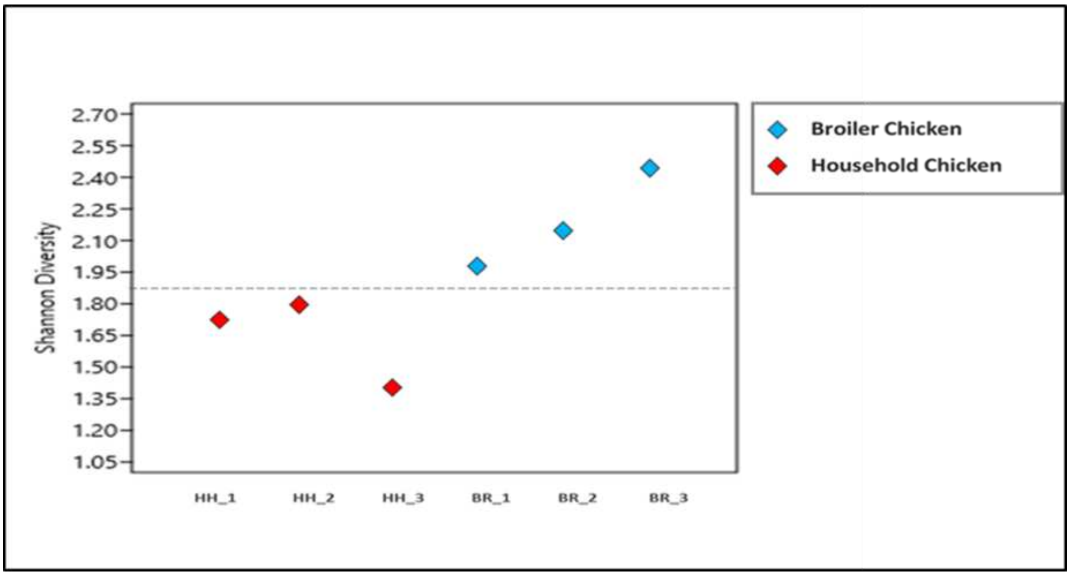

Figure 4. *Scatter plot showing the Shannon diversity of the ARGs and MGEs in 6 fecal samples*

The abundance of the ARGs and MGEs

To minimize the sampling variations, the estimated gene copy number of ARGs and MGEs was normalized to 16S rRNA gene copy number to achieve the relative abundance. The relative abundance of different genes varied significantly among the samples (*Fig. 5a*). The most abundant gene was *tnpA,* a transposase from IS-6 family detected in all 6 samples with percent relative abundance ranging from 0.52 to 4.68 whereas the least abundant gene was an ARG *vanB* from vancomycin group, the only gene detected from this group, ranged from 2.4×10^{-3} to 1.3×10^{-2}. Overall the summed relative abundance of ARGs ($p < 0.05$) and MGEs was higher in broiler chicken fecal samples than in broiler chicken samples (*Fig. 5b*).

Gene cluster patterns were observed by using ordination analysis. Relative abundances of the ARGs were used to perform multivariate PCA analysis in order to assess the distribution of ARGs among two chicken types (broiler vs. household). The PCA plot has revealed that the ARGs profile of fecal samples from two chicken groups is different from each other (*Fig. 6*).

Correlations among different gene classes were also evaluated in our study. Significant correlations were observed between total abundances of aminoglycosides, sulphonamides and tetracycline with *int1* and/ or total MGEs. The highest coefficient of determination (R^2) values was observed for aminoglycosides with MGEs and int1 (*Table 1*). The abundance of *int1* was also considerably correlated to the total relative abundance of the ARGs based on the linear regression analysis (*Fig. 7*).

Discussion

A large body of literature has provided information regarding the threats of antimicrobial resistance using conventional methods (Álvarez-Fernández et al., 2013; Khalili et al., 2012). In recent years, dissemination of ARGs via environmental routes has gained much attention. Characterization of mobile genetic elements along with other genes is becoming essential in antimicrobial resistance research (Waseem et al., 2017b). In our study, we have opted a relatively broader and comprehensive approach of targeting multiple genes (ARGs and MGEs) in the gut metagenomes of broiler and household chickens (*Gallus gallus domesticus*). Our data is useful for assessing the role of small scale poultry slaughterhouses, which are widely distributed throughout the country, in ARGs dissemination. Most of the conventional small scale slaughterhouses have improper blood and wastewater drainage system (Sohaib and Jamil, 2017) which further intensifies the threat of ARGs dissemination into the environment.

Fecal samples from broiler chickens, which get routine antimicrobial treatments, were found to have higher abundance and diversity of ARGs compared to the household chickens which had been on organic antibiotic-free feed. Our results are in accordance with many different studies where the resistance abundance or detection frequency of resistant genes was significantly higher in antibiotics treated chickens, pigs and cattle as compared to the controls (Cameron and McAllister, 2016; Guo et al., 2018; Looft et al., 2012). Our findings demonstrated that the detection frequency of MGEs was almost equal in two sample types but the total percent relative abundance was higher in broiler chicken. Similar results of elevated MGEs were also observed in small scale production birds as compared to household birds during a study of small scale production poultry operations in rural Ecuador (Moser et al., 2018). This signifies that apart from the selection of ARGs under the selection pressure of antibiotics, higher abundance of MGEs could also be a critical factor in the transfer of genes within chromosomes, across bacteria and even in between different species (Stokes and Gillings, 2011).

The most frequently detected ARGs (at least 5/6 samples) in our study were *sul1, sul2, ermF, strB, tetW.* The presence of ARGs in household chicken type is not surprising. The same genes were also detected in *Gallus gallus domesticus* feces and many other environmental matrices without antibiotic treatment (Berglund, 2015; Sui et al., 2016; Zhang et al., 2013). This implies some resistance genes could be ubiquitously present in the environment without antibiotic's selection pressure. For example, a diverse intrinsic antibiotic resistome was recently studied in bacteria isolated from a cave (Pawlowski et al., 2016). Such genes can provide a competitive advantage to environmental bacteria harbouring them over others.

Sulfonamide resistance in bacteria usually arises by acquiring sul genes, encoding dihydropteroate synthase that is not inhibited by the antibiotics (Antunes et al., 2005). Sul genes have been most consistent targets in poultry and animal live stocks studies (Kozak et al., 2009; McKinney et al., 2010). Both of these genes were detected in all 6 samples. Considerable differences were found in the relative abundance of these genes within each sample. The difference in the abundance of these closely related genes can be ascribed to the differences in their dissemination mechanism. *Sul2* is normally located on Inc. Q family of plasmids whereas *sul1* is believed to be distributed with the help of integrons (He et al., 2014). Similar observation of different relative abundance of these related genes has been reported in other environmental matrices as well (Cheng et al., 2013; Sui et al., 2016; Zhang et al., 2013). A study had reported the prevalence and distribution of sulfonamide resistance genes in soils around poultry and livestock

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30493063

farms in Jiangsu Province, Southeastern China. Distribution frequency of *sul* genes and most frequent combination of *sul*1 and *sul*2 was studied (Wang et al., 2014). Our results are in close agreement with this study as the type of animal and waste can affect the distribution of ARGs in the environment.

Transposon specific gene *tnpA*, integron specific gene *int1* along with two other MGEs have been clustered together with sulphonamide resistant genes (*Fig. 4a*). Transposons and integrons have been investigated in-silico (Loot et al., 2017) and also in environmental matrices (Stokes and Gillings, 2011) to evaluate the possible enrichment of ARGs. *TnpA* association with antibiotic resistance is also highlighted in many studies (Carnelli et al., 2017; Feng et al., 2017). The *int*1 gene is believed to be responsible for the evolution and dissemination of multiple antibiotic resistant bacteria and the spread of mobile genetic elements in the environments (Moura et al., 2012). In our recent publication *int*1 gene as a proxy for environmental surveillance of ARGs has also been reconfirmed (Stedtfeld et al., 2017). An important observation in our present study is the strong correlation among the relative abundance of *int*1 gene and total ARGs. The reason behind this correlation could be co-occurrence of *int*1 and ARGs on a single plasmid and/ or chromosome. Our results are supported by the finding of a recent study about distribution and characterization of class 1 integrons where it was reported that these integrons harboured genes belonging to class aminoglycosides (Sung and Oh, 2014).

*tnp*A and *int*1 genes were two of the most abundant genes in broiler chicken which is in accordance with the results from a study of ARGs analysis in production chicken in rural Ecuador where the relative abundance of these two genes were highest among others (Guo et al., 2018). The clustering of *intI*1 and *tnp*A with ARGs has implied that broiler chickens in small scale slaughterhouses can negatively play their role by spreading ARGs in clinically important strains and thus can produce multiple antibiotic resistant strains which can cause serious public health concerns. For example, Talebiyan and colleagues have isolated 318 multiple resistant *E. coli* from commercial broiler flocks that have been given different doses of antibiotics (Talebiyan et al., 2014). This signifies that the broiler chickens in small scale slaughterhouses can provide an appropriate environment for the proliferation of ARGs through horizontal and/ or vertical gene transfer. Our results about the abundance and detection of ARGs in chicken fecal samples are in accordance with the trends of ARGs abundance observed in other gut microbiomes (Waseem et al., 2019).

Concrete measures should be opted in order to mitigate the threat of antimicrobial resistance. In this regard, strict AMR centric environmental strategies should be implemented on commercial poultry farms so that the use of antibiotics in the poultry industry should be regulated. Small scale poultry slaughterhouses, especially located in clusters, should be encouraged to develop their own waste and water management systems. Use of untreated chicken feces and litter as fertilizer should be discouraged. Apart from formulating and implementing rules and regulations, general public awareness campaigns about antimicrobial stewardship should be launched. This can also increase the demand for organic meat and/ or household chicken thus forcing the poultry farm owners to restrict antimicrobials use as growth promoters.

DOI: http://dx.doi.org/10.15666/aeer/1702_30493063

Conclusion

Our study has provided an effective assessment and potential insight into the role and potential risk of small scale poultry slaughterhouses with the perspective of antimicrobial resistance. More clinically important ARGs were detected from the samples collected from cages of broiler chicken. Broiler chicken mostly raised in large scale commercial farms are usually located in outskirts of communities. Their transport poses a risk in the introduction of exogenous ARGs in the environment since such small scale poultry slaughterhouses are distributed widely throughout the country. Our research will aid in curbing the dissemination of antimicrobial resistance into the environment from such environmental reservoirs. Further research with larger sample size, more ARG and MGE targets along with bacterial community analysis will be helpful for validating the trends of ARGs spread in the environment.

(Received 6th Dec 2018; accepted 28th Jan 2019)

Abstract. Haqal is a small city located in north-western part of Arabian Peninsula. The anthropogenic activities in this region are evident. This region is targeted for future development by Saudi government. In this study, the surface sediment of Haqal coastal waters were analysed for heavy metals (Cd, Cu, Fe, Ni, Pb, and Zn). The total concentration (mg/kg dry weight) ranged from 0.012-0.186 for Cd, 0.582-1.13 for Cu, 0.51-2.18 for Ni, 0.68-2.64 for Pb, 1.97-4.52 for Zn while for Fe, it ranges from 0.155 to 0.254%. Based on ecological risk assessment results, the values of PERI were categorised as 'low ecological risk', thus all sampling sites were unpolluted with heavy metals. Despite that, this monitoring study had a positive result for non-heavy metal pollution, future mitigation of the heavy metal pollution in coastal areas of Tabuk should be given priority by the authorities. The present study can be considered as the first effort to monitor the pollution of heavy metals in Haqal. This provides baseline information for future ecotoxicological studies which can involve application of bioindicators to assess the quality of the marine environment in this region.
Keywords: *The Red Sea, marine environment, Arabian Peninsula, pollution*

Introduction

Sediment is an important sink where pollutants are accumulated from the water body, and a secondary pollution source which might impact the surrounding aquatic ecosystem (Birch and Taylor, 2002; Wang et al., 2011; Hahladakis et al., 2016; Kumwimba et al., 2017; Wong et al., 2017). Thus, determining the ecological risks to aquatic ecosystems posed by heavy metal toxicity is crucial to be determined (Kumwimba et al., 2017; Wong et al., 2017). In this study, two approaches were deployed to assess ecological risks for heavy metals in sediments, i.e. 1) sediment total metal concentrations, and 2) metal GFs in sediment. The sub-approaches that are based on total metal concentrations are i) comparisons with sediment quality guidelines (SQGs), ii) geochemical pollution indexes (Igeo), and enrichment factor (EF), iii) contamination factor (Cf), potential risk of individual metal (Er) and potential ecological risk index (PERI), proposed by Hakanson (1980). These SQGs are developed for marine and estuarine ecosystems (Long et al., 1995) via (a) the effect range low

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30653075

(ERL)/effect range median (ERM)/interim sediment quality value-low (ISQV-low) and (b) the threshold effect level (TEL)/probable effect level (PEL)/interim sediment quality value-high (ISQV-high) values.

Originating from Long and Morgan (1990), the SQG is an informal tool to evaluate sediment chemical data in relation to possible adverse effects on aquatic biota. The SQGs were proposed to be used as benchmark for evaluating sediment chemistry information to identify situations that are potentially harmful to aquatic organisms associated with bad sediments; as well as the benchmark to help set targets for sediment quality for the broader management strategy of long term aquatic ecosystem health sustainability management (CCME, 2002).

Among the basics of SQGs, SQGs based on ERL and ERM are used extensively in assessment of the pollutants' impact on environment. It has been tested against a large dataset gained in US EPA and US NOAA (National Oceanic and Atmospheric Administration, US). These datasets consisted of synchronized measurements of chemical and toxicological variables (O'Connor, 2004). However, O'Connor (2004) has made a clarification that SQG's ERL is not a threshold chemical toxicity in sediment and there is no basis for the assumption of pollutant concentration above ERL increase the probability of toxicity. However, there are still multiple recent heavy metal risk assessment studies that are employing ERL-ERM-based SQG at their assessment (Long and Morgan, 1990; Yap, 2010; Yap et al., 2002; Amin et al., 2009; Garcia et al., 2011; Ali et al., 2015). Therefore, the ERL and ERM approach of risk assessments are still viable approaches of heavy metal risk assessment and will still be used to evaluate the heavy metal risk in this study. In this study, the heavy metal levels in sediments were compared SQGs with multiple approaches (ERL, ERM, TEL and PEL) to assess and deduce the possible environmental impact of the sediment's heavy metals level. Hakanson (1980) has proposed a series of indexes as diagnostic tools for pollution control purposes, i.e. the contamination factor (Cf), risk index of individual metal (Er) and Total Risk Index (RI), and degree of contamination.

Ecological risk assessment (ERA) using above-mentioned approaches have been widely used in ERA-based studies. These studies reported have wide geographical distribution. In Asia region, there are such reports from Malaysia (Yap et al., 2002 and Yap, 2010), Khuzestan coastal waters, Iran (Madiseh et al., 2009), Northern Bohai and Yellow Seas, China (Luo et al., 2010), Dongjiang Harbor, China (Guo et al., 2010), Yangtze Estuary, China (Zhao et al., 2012), Lake Cıldır, Turkey (Kukrer et al., 2014), Ulsan Bay, Korea (Ra et al., 2014), and mangrove sediments of Peninsular Malaysia (Cheng and Yap, 2015).

Tabuk coastal areas including Haqal city supported high floral and faunal diversity. On the other hand, the environment of the coastal areas of Haqal is threatened by several human activities which may increase the pollution burden to the area. Studies on monitoring of heavy metals in these areas are scarce. On the other hand, this area has a promising future as it is targeted for future development with the country development plan. Thus, this study can be considered as pioneer in the assessment of heavy metal contamination of the coastal environment of Haqal. The present study aims to estimate the ecological risk assessments in the surface sediment collected from Haqal coastal waters based on 1) SQGs, 2) two geochemical pollution indexes, and 3) PERI.

Materials and methods

Study site

Haqal is a small city belongs to Tabuk region and is located in the north-western part of Arabian Peninsula. It is located within geographical coordinates of 29° 17’ 39” North, 34° 57’ 4” East. It is situated in the northwest of Saudi Arabia near the head of the Gulf of Aqaba adjacent to Aqaba across the Jordanian border (lies about 5 km from Jordanian border). This is coastal area is not a port used for the Red Sea shipping. However, coasts of the region are scenic. The climate of this city is arid with annual rainfall of less than 50 mm. The rainy season is in the winter and the annual mean temperature is 24° C. This region is targeted for future development under the NEOM project. Therefore, it is expected that this region will witnessed huge infrastructure development and the environmental assessment is a necessary tool at this stage.

Collection of sediment samples

The surface sediments (3-5 cm from surface sediment) in 15 sites of Haqal coastal areas were collected on early summer of 2018 (*Fig. 1*). The plastic spoon was used to collect the top-sediment to minimize the metal contamination. Sufficient amount of the sediment was collected from each site. The collected sediment samples were transferred into an acid-washed polyethylene bag and brought back to laboratory for temporary storage and analysis. The samples taken back to laboratory were frozen (-20 °C) in a freezer prior to analysis.

Figure 1. *Map showing sampling area in Haqal coastal waters in Tabuk, Saudi Arabia*

Before the analysis, sediment samples were oven-dried at 60 °C for at least 16 h until constant dry weights were achieved. Then the dried sediment particles were sieved

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30653075

through a 0.50 mm stainless steel sieve. During the sieving process, the samples were also shaken vigorously to produce homogeneity. Only sediment particles with size below 63 µm in diameter are considered for metal analysis.

The analyses of total Cd, Cu, Fe, Ni, Pb and Zn concentrations in sediment samples were done according to direct aqua-regia method. After sieving, about one gram of each dried sample (Particle size < 63 µm) was weighed and digested in a aqua-regia solution, which is a combination (ratio 4:1) of concentrated HNO_3 (AnalaR grade, BDH 69%) and $HClO_4$ (AnalaR grade, BDH 60%). The digestion was first conducted at low temperature (40 °C) for 1 h and then the temperature was elevated to 140 °C for a minimum 3 h until the samples have been fully digested. The resulting solutions of the digestion were than diluted to a fixed volume of 40 ml using double distilled water. The sample was then filtered filter paper (Whatman no. 1, pore size 11 µm) and the filtrates were stored until metal determination. Flame-Atomic Absorption Spectroscopy (FAAS; Perkin Elmer Model AAnalyst 800) was used to determine the concentration of Cd, Cu, Fe, Ni, Pb and Zn. The resulting data were expressed as mg/kg of samples' dry weight (dw).

To ensure the accuracy and credibility of the result, some pre-caution steps have been done. During metal analysis, a quality control sample was routinely analysed to ensure the accuracy of the analysis. As the result, the metal recovery of the quality control samples was acceptable at 90-110%. All glassware and equipment used during sample processing and metal analysis were soaked in 10% HNO_3 to wash away the possible metal contaminant. Certified Reference Materials (CRM) for Soil (International Atomic Energy Agency, Soil-5, Vienna, Austria) was used to assure the quality of direct aqua-regia method. The CRM was treated exactly the same as the other samples. The result of metal analysis was compared to the certified reference value of the respective metals. The recovery of the CRMs was found to be satisfactory.

Data treatment

Geoaccumulation index (I_{geo})

The values of I_{geo} were calculated according to Muller's (1969) formula (*Eq. 1*):

$$I_{geo} = log_2 \frac{C_n}{1.5 \times B_n} \quad \text{(Eq.1)}$$

where C_n is the sediment heavy metal concentrations and B_n is the "preindustrial reference values" (PRV; unit = mg/kg dw; Hakanson, 1980) which act as geochemical background values for each metal. The PRV for Cd, Cu Pb and Zn was 1.0, 50, 70 and 175, respectively (Hakanson, 1980). Owing to the absence of the PRV of Fe and Ni was taken from "upper continental crust" from Wedepohl (1995) and Rudnick and Gao (2003), in which the values were 3.09% and 47.0 mg/kg dw, respectively (*Table 2*).

To minimize the possible variation in background metal concentrations which might be contributed by lithogenic variations, a factor of 1.5 was introduced into the formula (Al-Haidarey et al., 2010; Hasan et al., 2013). It permits the content fluctuation of the metals in sediment and also some negligible anthropogenic influences (Loska et al., 1997; Hurley et al., 2017). Muller (1969) has classified the resulting Igeo values into six classes according to the extent of the metal geoaccumulation.

DOI: http://dx.doi.org/10.15666/aeer/1702_30653075

Enrichment factor (EF)

The EF in this study was determined using a formula defined by Buat-Menard and Chesselt (1979), with Fe as a normaliser (*Eq. 2*):

$$EF = \frac{\left(\frac{C_n}{C_{Fe}}\right)_{sample}}{\left(\frac{C_n}{C_{Fe}}\right)_{crust}} \quad \text{(Eq.2)}$$

where (C_n/C_{Fe}) sample is the metal to Fe ratio in the sediments; (C_n/C_{Fe}) crust is the metal to Fe ratio in the earth crust which considered as pre-industrial unpolluted metal value of a sediment.

The normalisation using Fe are necessary to correct for differences in sediment grain size and mineralogy (Schiff and Weisberg, 1999). The use Fe as normaliser was made based on the fact that Fe is a major sorbent phase for trace metals and is a quasiconservative tracer of the natural metal-bearing phases in fluvial and coastal sediments (Schiff and Weisberg, 1999; Hurley et al., 2017). According to Hasan et al. (2013), natural resources (98%) vastly dominated the input of Fe. In this expression, the normaliser (reference element) is assumed to have little variability of occurrence, and is present in trace concentration in the examined environment (Loska et al., 1997). The degrees of EF are categorised by Taylor (1964) and Birth (2003).

Ecological risk assessments

The contamination factor (C_f) was calculated to describe the contamination status of metals in the industrial drainages studied (Hakanson, 1980). C_f was calculated as *Equation 3:*

$$C_f = \frac{C_{sed}}{C_{ref}} \quad \text{(Eq.3)}$$

where C_f is the contamination factor; C_{sed} is the mean metal concentration in the sediment; C_{ref} is the PRV of metals in the sediments. Hakanson (1980) has classified the C_f values into 4 categories.

According to Hakanson (1980), the potential risk for individual metal (E_r) can be calculated using *Equation 4:*

$$E_r = TR \times C_f \quad \text{(Eq.4)}$$

where TR is the toxic-response factor for a metal (*Table 2*) Due to the fact that the absence of TR value for Fe, the E_r for Fe was not calculated. C_f is the contamination factor for the same substance. The E_r for each metals were defined in accordance of Hakanson’s (1980) standard.

The total risk index (RI) or potential ecological risk index (PERI) was calculated as *Equation 5:*

$$RI = \sum_{i=1}^{m} E_r = \sum_{i=1}^{m} (TR \times C_f) \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30653075

where E_r is the risk index of individual metal, TR is the toxic-response factor and C_f is the contamination factor. The PERI can be described according to categories suggested by Hakanson (1980).

The classification of SQGs along with its effects and comparison results are presented in *Table 2*. It is important to determine whether the total concentrations of heavy metals in sediments found pose a threat to aquatic life. In the present study, the sediment risk of each metal investigated is assessed by three sets of SQGs namely (1) Effects Range Low (ERL) and Effects Range Medium (ERM) by Long et al. (1995), (2) lowest effect level (LEL) and severe effect level (SEL) by NYSDEC (1999), and (3) threshold effects level (TEL) and probable effects level (PEL) by MacDonald et al. (1996) and MacDonald (2003). These three sets of numerical SQGs were directly applied (without normalization) to assess possible risk arises from the heavy metal contamination in sediments of the study area.

Results and discussion

The concentrations (mg/kg dry weight; except for Fe in %) of surface sediments collected from Haqal coastal waters are shown in *Table 1*. The surface sediment of Tabuk coastal waters from Saudi Arabia were analysed for Cd, Cu, Fe, Ni, Pb, and Zn. The metal concentrations (mg/kg dry weight) ranges for total concentration are 0.012-0.186 for Cd, 0.582-1.13 for Cu, 0.51-2.18 for Ni, 0.68-2.64 for Pb, 1.97-4.52 for Zn while for Fe, it ranges from 0.155-0.254%. These values of heavy metals are remarkably lower compared to those reported in Jeddah coastal surface by Badr et al. (2009).

All the values of metals are below ERL, indicating that adverse effects on aquatic biota should rarely occur. There should be no toxicological effects of Cd, Cu, Ni, Pb

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30653075

and Zn in the present study area and that may not occasionally be associated with adverse biological effects.

When compared to the LEL–SEL SQGs, among the metals, Cd, Cu, Ni, Pb and Zn concentrations are also below LEL in all sites. According to Thompson et al. (2005), the LEL represents the contaminant concentration below the harmful effects on benthic invertebrates. However, by comparison to the TEL–PEL SQGs, 100% of the concentrations of Cd, Cu, Pb and Zn in all the samples are below TEL. It is interpreted that TEL as the concentrations, below which adverse biological effects rarely occurs. Hence, it is considered to provide a high level of protection for aquatic organisms. This requires a lower level of protection for aquatic organisms.

In comparison to reference values (RVs) (*Table 2*), all the metals levels of all sites are below the levels of pre-industrial reference (PIR) level (Hakanson, 1980), and the upper continental crust (UCC) values proposed by Taylor and McLennan (1995), Wedepohl (1995) and Rudnick and Gao (2003).

Table 2. *Comparisons between total heavy metal concentrations (mean, µg/g dw; except for Fe in %) with those cited from sediment quality guidelines (SQGs) and reference values (RVs). The values of toxic-response factors, employed in this study are also presented*

The values of enrichment factor (EF), geoaccumulation index (Igeo), contamination factor (CF), ecological risk (ER) and potential ecological risk index (PERI) of heavy metals based on the surface sediments from all sampling sites are presented in *Table 3*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30653075

All the values of EF for Cd, Cu, Ni, Pb, and Zn are below 2.0, indicating ‘depletion of mineral enrichment’ (Sutherland, 2000; Hsu et al., 2016), except for 5 sites of Cd levels where the EF values are between 2 and 3, indicating ‘moderate enrichment’. Fro Igeo, all values are below 0.0 (in negative values), indicating ‘practically unpolluted’ (Muller, 1969). For CF for individual metal, all values are below 1.00, indicating ‘low contamination factor’ (Hakanson, 1980). For ER, all values are below 40.0, indicating ‘low potential ecological risk’ (Hakanson, 1980). Lastly, for PERI, all values are below 150, indicating ‘low ecological risk’ (Hakanson, 1980).

Conclusion

Based on the monitoring survey of the metal concentrations in the surface sediments of Haqal coastal waters of Saudi Arabia, the values of PERI were categorised as ‘low ecological risk’, thus all sampling sites were unpolluted by heavy metals. Nevertheless this monitoring study showed a positive outcome of non-heavy metal pollution, future mitigation of the heavy metal pollution at the study area should be given priority by the enforcement. Further studies concerning the heavy metal assessment in this region are needed to better understand the accumulation of heavy metals and their transfer in the food web of the living organisms.

Acknowledgements. We would like to express our sincere gratitude to the farms’ owners for facilitating the data collection. This study was supported by the Research Grant (S-1439-0036) provided by The Deanship of Scientific Research, University of Tabuk. This project was also partially supported by the Research Centre, College of Science, King Saud University, Riyadh.

Abstract. Traffic networks within megapolises is the factor of acceleration and modernisation of the socio-economic environment. However, there exist a number of problems, which restrict the possibilities of development of a city transport medium. Particularly, road design will only begin when the living environment of urban residents is completed. In this case, formation of the road network and making decisions in respect of its modernisation are performed in accordance with the actual workload of the city network. Authors of this article state that such planning is an inconsistent process, because it cannot predict the decline of the socio-economic environment. The article expressly demonstrates that use of traditional parameters in respect of quality of design of a road network does not comply with the modern requirements to the quality of the socio-economic environment, which must be in line with the already designed road network. Authors of this article believe that it is absolutely necessary to have clear definitions of those criteria, which will be universal ones for design and management of the road network within a modern megapolis. As concerns possible solution of this problem, authors of this article propose to use ecological indicators, as well as content of toxic elements and motor vehicle emissions near the road network.
Keywords: *road network, management, loaded system, socio-economic environment, simulation methods*

Introduction

Influence of the motor transport upon the ecological situation in Republic of Kazakhstan has achieved a critical limit already. Various environmental pollution sources exist, however motor vehicle systems (motor roads and motor vehicles) are the most dangerous ones. Analysis of the previous experience of ecological investigations in the road traffic sphere demonstrates that in many cases these investigations are performed separately for traffic flows and motor roads (Goniewicz et al., 2016). Environmentally destructive influence of the motor vehicle systems is widespread one due to the great mileage and branching of the motor road network, as well as due to high mobility of traffic flows along with the ever-growing quantity of the transportation facilities (Duduta, 2015; Ghahramani and Hemmatyar, 2017). Scales of contamination of the environment are also under the influence of irregularity of motor vehicle traffic flows within the cities, particularly in the places of delays before traffic lights and in the cases of road traffic congestions on the motor roads.

The aim of this investigation is the performance of ecological monitoring in the urban agglomerations to develop the relevant methods to decrease harmful influence of transport upon the environment with the help of the proper strict organisation of the road traffic. The presented research will help to ensure a sufficient level of ecological safety in the urban agglomerations, as well as determine the priority and volume of the environmental protection measures and provision of the ecological monitoring points with software applications, organisation and technical means and facilities for performance of such monitoring. Scientific novelty of the work: a general method has been developed for the integrated assessment of the technogenic impact of a road-transport complex on an ecosystem that considers the state of the ecosystem taking into account all the essential components of the object of study and the relationship between them in the "driver-car-road-environment" system; a number of indicators characterizing the impact of road transport on the environment were identified; the factors and spatial features of the impact of road transport on the environment were identified.

The results of the study can be applied in justification of targeted regional environmental and economic programs aimed at improving the ecological status of the region; in the study of the interaction of road transport systems and the environment in other regions and countries.

Materials and methods

Depending on the goal of an investigation, various methods can be used in order to define the road traffic characteristics: documentary methods, natural full-scale methods, as well as simulation methods (Goniewicz et al., 2016).

Documentary methods are based on the study and analysis of the planning, reporting, statistical materials, as well as design-and-technical materials. In addition, this group of methods includes questionnaire surveys in respect of the traffic flows and passenger flows. Such documentary methods use dependences between traffic volumes and volumes of production, density of population within traffic areas, travel behaviour of population etc. As a rule, these documentary methods are characterized as the labour-intensive techniques, which ensure low accuracy of final results (Kureckova, 2017). Methods of the natural full-scale surveys are based on the performance of direct measurements of the road traffic characteristics in various investigative areas. It is possible to obtain proper information with the help of direct observations or with the help of the automatic registration facilities (Chang et al., 2014).

Such natural full-scale surveys include local, zonal, and regional surveys. Local surveys are performed in order to study intensities, speeds, and composition of flows at the road intersections, as well as at certain sections of roads and streets (Chang, 2011).

Zonal surveys are performed in order to obtain spatial and temporal characteristics within a certain zone. These surveys are performed as the sample surveys. Regional surveys are performed in order to obtain summary values of parameters of traffic flows within a district, city, and region. These parameters are used for predicting trends of changes in the flow characteristics in the course of construction and reconstruction of objects. Advantages of methods of the natural full-scale surveys are connected with their simplicity and high accuracy. Their disadvantages are connected with high labour-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30773095

intensity of these surveys, as well as with the impossibility of utilisation of these methods for the objects that were designed earlier.

In addition, methods of simulation are often used. These methods are based on the use of mathematical and nonmathematical models (physical and analogous models) of changes of the traffic flow parameters. For example, main equation of the transportation flow is derived from the mathematical model, which describes interconnection between intensity, speed, and density of the traffic flow. Simulation methods ensure lower accuracy as compared with the methods of the natural full-scale surveys. However, these methods are simple in the course of their utilisation and they do not require engagement of many recorders. In addition, simulation methods can be applied for the already designed objects (Svensson et al., 2014).

In order to perform investigations of ecosystems, it is necessary to estimate physical level of emissions, degree of influence of motor vehicle flows upon the environment in the specific conditions of certain cities, as well as to define the most essential factors. These estimations and definitions must be made in accordance with the results of the natural full-scale observations (Marisamynathan and Vedagiri, 2018).

These investigations were performed on the basis of the reports on organisation of the traffic scheme of the transportation facilities within a city and its surroundings, as well as on the basis of the results of observations in respect of levels of physical and chemical pollution of the atmospheric air. Experimental investigations have been included the following areas for collection of the initial material: results of measurements of the meteorological data at the regime observation points; information on the nature of the transport and passenger flows; disposition of routes in respect of various tracks, scheme of their disposition on the city map; traffic charts over various routes.

To study the complex dependence of concentration of the summary emissions of the nitrogen dioxide, carbon oxides, sulphur dioxide, and hydrocarbons, the quantity and type of the motor vehicles passing through the relevant road intersection (*Fig. 1*, Shymkent, Republic of Kazakhstan) were calculated. And the multiple-factor correlation-and-regression analysis was used.

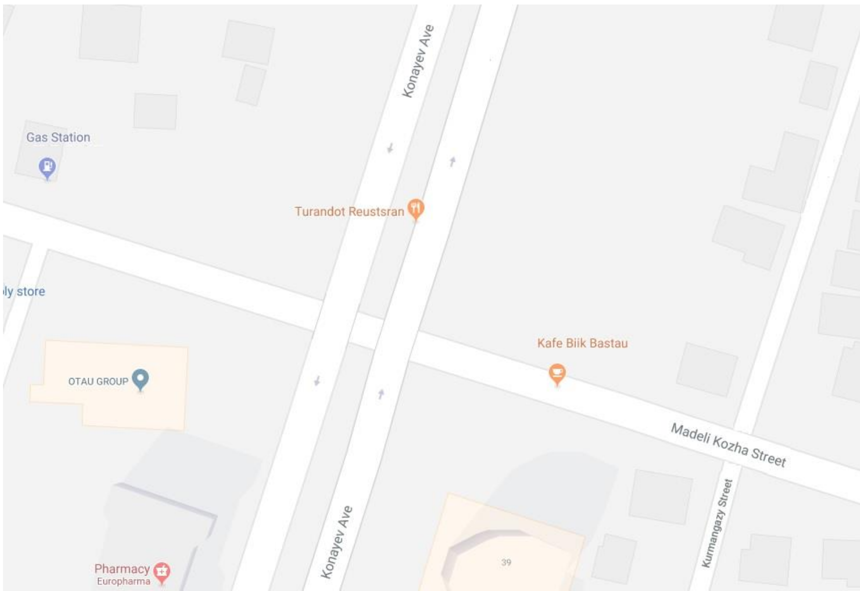

Figure 1. *Investigated road intersection (Shymkent, Republic of Kazakhstan)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30773095

In order to define characteristics of the motor vehicle flows in respect of the selected section of the certain street-and-road network, the following groups of motor vehicles were recorded (these vehicles moved in both directions):

- Gasoline-powered passenger cars (GPPC);
- Diesel-powered passenger cars (DPPC);
- Gasoline-powered lorries (GPL);
- Diesel-powered lorries (DPL);
- Gasoline-powered buses (GPB);
- Diesel-powered buses (DPB).

Calculation of the transportation facilities, which have been gone through the relevant road intersection, has been performed during 20 min on an hourly basis. In the cases of high traffic intensity (more than 2-3 thousand motor vehicles per hour), calculation of motor vehicles has been performed synchronously and separately in respect of each direction of traffic.

In order to define the maximum traffic load, observations have been performed during peak hours. Two maximums were assumed for the relevant road intersection: morning and evening maximums (7-11 a.m. and 4-7 p.m. respectively). In accordance with the results of this experimental investigation, which are presented in *Table 1*.

Results and discussion

Multiple-factor correlation-and-regression analysis

In order to investigate complex dependence of concentration of the summary emissions of the nitrogen dioxide (*Fig. 2*), carbon oxides (*Fig. 3*), sulphur dioxide (*Fig. 4*), and hydrocarbons (*Fig. 5*) from the quantity and type of the motor vehicles, which have gone through the relevant road intersection, we will use the multiple-factor correlation-and-regression analysis. This kind of analysis will make it possible to estimate degree of influence of each parameter upon concentration of the exhaust gases provided that average level of other parameters is fixed. In this case, the following

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30773095

condition is important: absence of any functional relationships between these parameters.

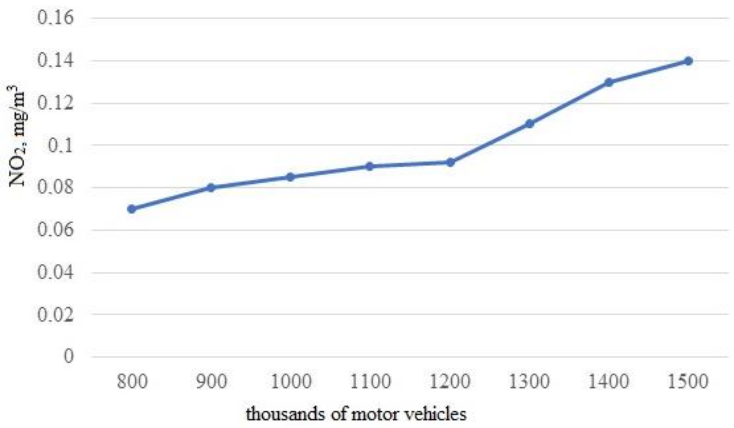

Figure 2. *Graphical dependence of the nitrogen dioxides concentration from quantity of motor vehicles at the experimental area 1 in 2017*

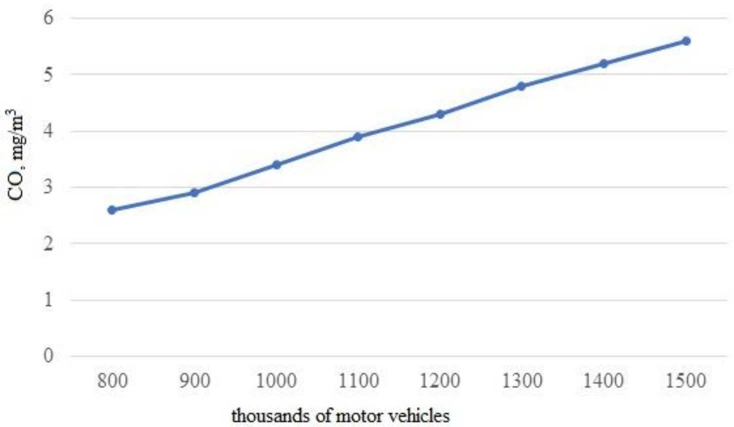

Figure 3. *Graphical dependence of the carbon oxides concentration from quantity of motor vehicles at the experimental area 1 in 2017*

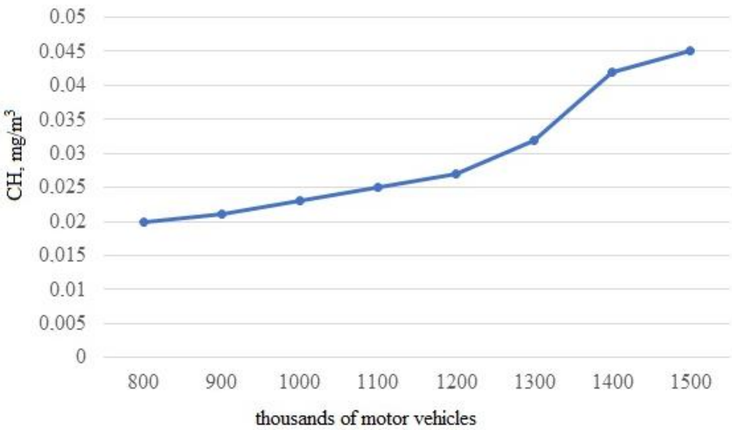

Figure 5. *Graphical dependence of the hydrocarbon concentration from quantity of motor vehicles at the experimental area 1 in 2017*

From a mathematical standpoint, the problem reduces to finding the analytic expression, which would describe relationships of the factorial characteristics with the resulting characteristics in the best way possible, that is, we have to find the following function (*Eq. 1*):

$$y = f(x_1.x_2,...,x_p,a_0,a_1,...,a_p) \qquad \text{(Eq.1)}$$

where $a_0, a_1,..., a_p$ are coefficients of the regression equation, which would ensure the least scatter of empirical values in respect of the surface, which is described by this function.

The most difficult problem is connected with selection of the form of interconnection, selection of the analytic expression. On the basis of this selection, it is possible to define the resulting characteristic, that is, the function, which is connected with the existing factors. This mass function describes actual interconnections between the parameter to be investigated and other relevant factors better than other possible functions. The empirical substantiation of the function type with the help of the graphical analysis of the interconnections for the multiple-factor models is almost impractical. Therefore, it is possible to define proper form of interconnection through the fitting of functions of various types, but it is connected with the great quantity of the unnecessary calculations. Despite of the fact that it is possible to transform any function of multiple variables (through logarithmation or with the help of replacement of variables) to the linear form, it is also possible to present a multiple regression equation in the linear form as follows (*Eq. 2*):

$$y = a_0 + a_1x_1 + a_2x_2 + a_3x_3 + ... + a_nx_n \qquad \text{(Eq.2)}$$

In our case, we will assume concentrations of the relevant exhaust gases as the resulting characteristics. In addition, we will assume quantities of the relevant motor vehicles as the factorial characteristics. Therefore, the sought-for equation of the linear six-factorial regression will be presented in the following form (*Eq. 3*):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30773095

$$y = a_0 + a_1x_1 + a_2x_2 + a_3x_3 + a_4x_4 + a_5x_5 + a_6x_6 \quad \text{(Eq.3)}$$

where *y* are calculated values of the resulting characteristics – functions (in our case), that is, concentrations of the exhaust gases; x_1, x_2, x_3, x_4, x_5, x_6 are factorial characteristics on the condition that: x_1 is the quantity of the gasoline-powered passenger cars; x_2 is the quantity of the diesel-powered passenger cars; x_3 is the quantity of the gasoline-powered lorries; x_4 is the quantity of the diesel-powered lorries; x_5 is the quantity of the gasoline-powered buses; x_6 is the quantity of the diesel-powered buses; a_0, a_1, a_2, a_3, a_4, a_5, a_6 are equation parameters, which are calculated in accordance with the least square method. Therefore, it is necessary to solve the system of normal equations (*Eq. 4*):

$$\begin{cases} na_0 + a_1\sum x_1 + a_2\sum x_2 + a_3\sum x_3 + a_4\sum x_4 + a_5\sum x_5 + a_6\sum x_6 = \sum y \\ a_0\sum x_1 + a_1\sum x_1^2 + a_2\sum x_1x_2 + a_3\sum x_1x_3 + a_4\sum x_1x_4 + a_5\sum x_1x_5 + a_6\sum x_1x_6 = \sum x_1y \\ a_0\sum x_2 + a_1\sum x_1x_2 + a_2\sum x_2^2 + a_3\sum x_2x_3 + a_4\sum x_4x_4 + a_5\sum x_2x_5 + a_6\sum x_2x_6 = \sum x_2y \\ a_0\sum x_3 + a_1\sum x_1x_3 + a_2\sum x_2x_3 + a_3\sum x_3^2 + a_4\sum x_3x_4 + a_5\sum x_3x_5 + a_6\sum x_3x_6 = \sum x_3y \\ a_0\sum x_4 + a_1\sum x_1x_4 + a_2\sum x_2x_4 + a_3\sum x_3x_4 + a_4\sum x_4^2 + a_5\sum x_4x_5 + a_6\sum x_4x_6 = \sum x_4y \\ a_0\sum x_5 + a_1\sum x_1x_5 + a_2\sum x_2x_5 + a_3\sum x_3x_5 + a_4\sum x_4x_5 + a_5\sum x_5^2 + a_6\sum x_5x_6 = \sum x_5y \\ a_0\sum x_6 + a_1\sum x_1x_6 + a_2\sum x_2x_6 + a_3\sum x_3x_6 + a_4\sum x_4x_6 + a_5\sum x_5x_6 + a_6\sum x_6^2 = \sum x_6y \end{cases} \quad \text{(Eq.4)}$$

Each coefficient of this equation determines degree of influence of the relevant factor upon the resulting parameter on the condition of the fixed values of the rest factors, that is, each coefficient determines degree of change of the resulting parameter in the case of change of a certain factor by one unit. The sample correlation coefficient and sample estimates a_0, a_l, a_2, a_3, a_4, a_5, a_6 of the regression parameters (which were calculated on the basis of the restricted quantity of the experimental data) always contain elements of randomness, and they themselves are random values in essence. In this connection, there occurs a necessity to check meaningfulness of these sample characteristics.

The criterion for testing adequacy of the regression function envisages testing of meaningfulness of the multiple correlation coefficient R. In this connection, the hypothesis “H0: R2 = 0” is proposed in respect of the fact that coefficient of determination R^2 of the general totality (from which this sample was obtained) is equal to zero. This hypothesis is equally matched with the hypothesis H_0: $a_0 = a_l = a_2 = a_3 = a_4 = a_5 = a_6 = 0$ in respect of the fact that none of those factors, which were included to this regression, has no essential (meaningful) influence upon the response *y*. Let us consider the hypothesis H1: $R^2 \neq 0$ as an alternative, that is, situation, when at least one of the regression coefficients $a_i \neq 0$. The following statistics (*Eq. 5*) is used in the course of testing this hypothesis:

$$F = \frac{R^2}{1-R^2} \times \frac{n-p}{p-1} \quad \text{(Eq.5)}$$

where *n* is quantity of those observations, on the basis of which value R has been calculated, while *P* is quantity of the regression parameters. In addition, in the course of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30773095

testing the hypothesis H_0, the right-side critical region $\Omega[f(\alpha; p-1; n-p), \infty)]$ is used, where $F_{кр} = f(\alpha; p-1; n-p)$ is the critical value of α order of the Fisher-Snedecor distribution with (p - 1) and (n - p) degrees of freedom.

Then the right-side critical region is defined by the inequality f > F_{crit}, while acceptance region of the zero hypothesis is defined by the inequality. If the calculated value of the f-statistics exceeds its critical value F_{crit}, that is, f < F_{crit}, then the zero hypothesis H_0 is rejected and the alternative hypothesis H_1 is assumed. In this case, the coefficient of determination R^2 differs from zero essentially, while the regression function is the statistically meaningful function, which describes the original data adequately.

We will estimate degree of influence of those characteristics, which are included in (3), in accordance with the results of testing the hypothesis concerning statistical meaningfulness of the coefficient of the relevant regression equation, which complies with proper characteristics.

With this aim in view, the hypothesis H_0: $a_i = 0$ is proposed in respect of the fact that factor x_i has no essential influence upon the response *y*. In addition, the hypothesis H_1: $a_0 \neq 0$ is proposed as an alternative. In the course of testing of this hypothesis the two-sided region $(|T| \geq t(\frac{\alpha}{2}; n-p))$ is used, where $T = t(\frac{\alpha}{2}; n-p)$ is the critical value of the order $\frac{\alpha}{2}$ of the Student distribution with (n - p) degrees of freedom. If $t_i \leq T_{cr}$, then the hypothesis H_0: $a_i = 0$ is assumed, otherwise it is thought that this coefficient is other than zero.

Concentration of the summary emissions of NO_2, CO, SO_2, CH

Taking into account the fact that volume of the data is a comparatively great one in order to find coefficients of the regression equation, it is possible to apply *Mathlab* application software, because it includes the built-in statistical functions, which make it possible to perform calculations quickly. We will perform these calculations separately for the carbon oxides (CO), nitrogen dioxide (NO_2), sulphur dioxide (SO_2), and for the hydrocarbons (CH). Results of these calculations are presented in *Table 2*.

Table 2. *Carbon oxides (CO) (2017)*

$3.12524 \cdot 10^{-5}$	$1.58101 \cdot 10^{-5}$	-0.000108872	$1.44834 \cdot 10^{-5}$	$-1.40348 \cdot 10^{-5}$	$6.46997 \cdot 10^{-6}$	4.141839001
$1.58577 \cdot 10^{-5}$	$4.87854 \cdot 10^{-6}$	$3.67525 \cdot 10^{-5}$	$3.16138 \cdot 10^{-5}$	$6.99962 \cdot 10^{-6}$	$9.99331 \cdot 10^{-6}$	1.01508043
0.9542	0.241512841	N/A	N/A	N/A	N/A	N/A
17.36	5	N/A	N/A	N/A	N/A	N/A
6.076024405	0.291642262	N/A	N/A	N/A	N/A	N/A

Therefore, we will obtain the following numerical data (*Eq. 6*):

Coefficients of regression: $a_0 = 4.141839001$; $a_l = 6.46997 \times 10^{-6}$; $a_0 = -1.40348 \times 10^{-5}$; $a_3 = 1.44834 \times 10^{-5}$; $a_4 = -0.000108872$; $a_5 = 1.58101 \times 10^{-5}$; $a_6 = 3.12524 \times 10^{-5}$; coefficient of determination: $R^2 = 0.9542$; calculated value of statistics F = 17.36; quantity of observations n = 12; quantity of the regression parameters with degrees of freedom of the denominator p = 7; quantity of degrees of freedom of the denominator p - 1 = 6; quantity of degrees of freedom of the numerator

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30773095

n - p = 5; root-mean-square deviations of the normal random variable εi: SE_{y0} = 1.01508043; SE_{y1} = 9.99331 × 10^{-6}; SE_{y2} = 6.99962 × 10^{-6}; SE_{y3} = 3.16138 × 10^{-5}; SE_{y4} = 3.67525 × 10^{-5}; SE_{y5} = 4.87854 × 10^{-6}; SE_{y6} = 1.58577 × 10^{-5}; dispersion ε: SE_{y2} = 0.241512841; sum of squares that is caused by regression: SS_{regr} = 6.076024405; residual sum of squares: SS_{resid} = 0.291642262.

Equation of regression will be written in the following form:

$$C_{CO} = 4.141839001 + 6.46997 \times 10^{-6} x_1 - 1.40348 \times 10^{-5} x_2 + 1.44834 \times 10^{-5} x_3 - \\ - 0.000108872 x_4 + 1.58101 \times 10^{-5} x_5 + 3.12524 \times 10^{-5} x_6 \quad \text{(Eq.6)}$$

Let us test meaningfulness of the coefficient of determination R^2. Let us test it in accordance with the meaningfulness level α = 0.05. Let us find critical value with the help of tables of F-distribution with quantity of degrees of freedom p - 1 = 6 and n - p = 5, that is, we will have F_{crit} = f(0.05;6;5) = 4.95. We will obtain the calculated value F = 17.36. Let us compare it with the table critical value F_{crit} = f(0.05;6;5) = 4.95 ≤ F = 17.36, then $F_{crit} \leq F$ means that coefficient of determination R^2 differs from zero substantially. Therefore, hypothesis H_0: $a_0 = a_l = a_2 = a_3 = a_4 = a_5 = a_6 = 0$ concerning absence of the regression dependence between variables C_{CO} and x_1, x_2, x_3, x_4, x_5, x_6 is rejected because this fact does not comply with actual data of observations.

Let us estimate meaningfulness of the sample regression coefficients a_0, a_l, a_2, a_3, a_4, a_5, a_6. Let us assume the following level of meaningfulness α = 0.05. Let us calculate the critical value of the Student distribution with n - p = 5 degrees of freedom (of the order α/2 = 0.025), that is, quantity T_{crit} = t(0.025;5) = 2.57. Let us use formula $t = \frac{a_i}{SE_i}$ and calculate value of statistics for all sample regression coefficients a_i. Results are presented in *Table 3*.

Table 3. *Values of regression coefficients for CO*

a_i	a_0	a_1	a_2	a_3	a_4	a_5	a_6
t	4.080306228	0.647429763	-2.005075304	0.458135006	-2.962295561	3.240750483	1.970797859

Not all calculated values exceed their critical values in absolute magnitude. That is, these values are lesser for the coefficients a_1, a_2, a_3, and a_6, that is, the parameters, near which these coefficients stand (namely: quantity of the gasoline-powered passenger cars; quantity of the diesel-powered passenger cars; quantity of the gasoline-powered lorries, and quantity of the diesel-powered buses), do not have any essential influence upon the resulting parameter (upon the concentration of the carbon oxide C_{CO}) (*Table 4*).

Table 4. *Nitrogen oxide (NO_2) (2017)*

-2.10713×10^{-6}	1.10808×10^{-7}	-3.49816×10^{-7}	3.11257×10^{-6}	5.882×10^{-7}	-3.53302×10^{-7}	0.146914115

DOI: http://dx.doi.org/10.15666/aeer/1702_30773095

Therefore, we will obtain the following numerical data (*Eq. 7*):

Coefficients of regression: $a_0 = 0.146914115$; $a_l = -3.53302 \times 10^{-7}$; $a_2 = 5.882 \times 10^{7}$; $a_3 = -2.10713 \times 10^{-6}$; $a_4 = 3.11257 \times 10^{-6}$; $a_5 = -3.49816 \times 10^{-7}$; $a_6 = 1.10808 \times 10^{-7}$; coefficient of determination: $R^2 = 0.9146$; calculated value of statistics $F = 8.9263$; quantity of observations $n = 12$; quantity of the regression parameters with degrees of freedom of the denominator $p = 7$; quantity of degrees of freedom of the denominator $p - 1 = 6$; quantity of degrees of freedom of the numerator $n - p = 5$; root-mean-square deviations of the normal random variable εi: $SE_{y0} = 0.015145818$; $SE_{y1} = 1.49108 \times 10^{6}$; $SE_{y6} = 2.3661 \times 10^{-7}$; dispersion ε: $SE_{y2} = 0.003603566$; sum of squares that is caused by regression: $SS_{regr} = 0.000695488$; residual sum of squares: $SS_{resid} = 6.49284 \times 10^{-5}$.

Equation of regression will be written in the following form:

$$C_{NO2} = 0.146914115 - 3.53302 \times 10^{-7} x_1 + 5.882 \times 10^{-7} x_2 - 2.10713 \times 10^{-6} x_3 + 3.11257 \times 10^{-6} x_4 - 3.49816 \times 10^{-7} x_5 + 1.10808 \times 10^{-7} x_6 \quad \text{(Eq.7)}$$

Let us test meaningfulness of the coefficient of determination R^2. Let us assume the following level of meaningfulness $\alpha = 0.05$. Let us find critical value with the help of *Table 4* of F-distribution with quantity of degrees of freedom $p - 1 = 6$ and $n - p = 5$ that is, we will have $F_{crit} = f(0.05;6;5) = 4.95$. We will obtain the calculated value $F = 8.9263$. Let us compare it with the table critical value $F_{crit} = f(0.05;6;5) = 4.95 \leq F = 8.9263$, then $F_{crit} \leq F$ means that coefficient of determination R^2 differs from zero substantially. Therefore, hypothesis H_0: $a_0 = a_l = a_2 = a_3 = a_4 = a_5 = a = 0$ concerning absence of the regression dependence between variables C_{NO2} and x_1, x_2, x_3, x_4, x_5, x_6 is rejected because this fact does not comply with actual data of observations.

Let us estimate meaningfulness of the sample regression coefficients a_0, a_l, a_2, a_3, a_4, a_5, a_6. Let us assume the following level of meaningfulness $\alpha = 0.05$. Let us calculate the critical value of the Student distribution with $n - p = 5$ of degrees of freedom (of the order $\alpha/2 = 0.025$), that is, quantity $T_{crit} = t(0.025;5) = 2.57$. Let us use formula $t = \frac{a_i}{SE_i}$ and calculate value SE_i of statistics for all sample regression coefficients a_i. Results are presented in *Table 5*.

Table 5. *Values of regression coefficients for NO_2*

The calculated values exceed their critical values in absolute magnitude, that is, all coefficients have essential influence upon the resulting parameter (concentration of hydrocarbons (CH)). In order to ensure formal characterization and development of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30773095

sustainability, it is necessary to define the model of correlation not only in respect of the ecological traffic safety, but also in respect of the possibilities for connection of the ecological safety parameters with the road traffic safety.

Table 9. *Values of regression coefficients for hydrocarbons (CH)*

a_i	a_0	a_1	a_2	a_3	a_4	a_5	a_6
t	3.498505	2.464577608	3.386289809	-2.684472656	6.038556981	-4.630032638	-2.705815029

Influence of the road conditions upon the traffic safety

In accordance with the traffic terminology, "road conditions" term is meant as the totality of geometrical parameters, road service qualities of roads, road pavements, and components of the engineering equipment, which have direct influence upon conditions of traffic (performance of relevant operations by drivers in the course of transportation of passengers and freight).

The above definition does not describe interconnections between the road conditions and traffic safety. At the same time, road conditions (which are the constant component of the complex system – "road conditions-transport flows-environment") have positive or negative influence upon the traffic safety in accordance with the quality state of the road conditions. Therefore, it is necessary to define this term more exactly and we will interpret road conditions as the totality of those factors, which have positive or negative influence upon the road traffic safety of transportation facilities and pedestrians. Such road factors include all the factors that exist on the roads except for the traffic participants and environment conditions.

It is worthy of note that road conditions are not constant/stationary ones in respect of a driver in the course of traffic: they are not changing all the time in themselves, they are changing in a driver's perception in the course of traffic. If a vehicle moves with the speed of 90 km/h (25 m/s), components of road conditions (road signs, guideposts, delineators, traffic dividers), bridges, pedestrian crossings, road intersections, and so on occur and change during several seconds only. During a short period of time, a driver acquires information, analyses it, makes a decision, and performs this decision. In the course of a time, the driver forgets previous information because he/she acquires new information without interruptions.

It is possible to reveal direct influence of the road conditions upon the traffic safety with the help of analysis of the actual mileage distribution of road traffic accidents (RTA) in respect of the road length.

If RTAs are uniformly distributed (without any obvious aggregations) over the length of the road sections that are analysed, then road conditions comply with the requirements of the traffic, which was organised in one way or another, and it is possible to describe these road conditions as the conditions that are supportive to the road traffic safety. If road conditions on a certain road section do not comply with the traffic safety requirements, and there exists an aggregation (concentration) of the RTAs, this fact suggests that there is a negative influence of one road factor or several road factors upon the road traffic safety. In order to ensure the road traffic safety of the on-the-road vehicles and pedestrians on the motor roads in operation, we have to analyse various factors of the road conditions (Dj).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30773095

Only strictly determined factors of the road conditions can be treated as the road conditions of a specific road section.

For example, the following factors can be treated as the road conditions of the one-level interchange with the jughandle left turns: vertical and horizontal road markings of the traffic way, metal traffic dividers, stopping lanes on the shoulders of roads, non-skid properties and friction factor of the traffic way, as well as road signs.

It is possible to describe the entire assembly of the specific road factors (complex of the road factors (K_d)), which are necessary in order to ensure the road traffic safety, with the help of the following formula (*Eq. 10*):

$$K_d = \left\{ D_1, D_2, ..., D_j, ..., D_k \right\}$$
$$j = \overline{1,h} \quad \text{(Eq.10)}$$

where K_d – complex of the road factors, which are conductive to the road traffic safety; Dj – j-th road factor, which has influence upon the road traffic safety.

Let us connect each specific road factor (Dj) with relevant probabilistic event (Aj) and vice versa (*Eq. 11*):

$$D_j \leftrightarrow A_j$$
$$j = \overline{1,h} \quad \text{(Eq.11)}$$

then *Equation 10* (taking into account *Eq. 11*) will be written in the following form (*Eq. 12*):

$$K_d = \left\{ A_1, A_2, ..., A_j, ..., A_k \right\} \quad \text{(Eq.12)}$$

where A_j – j-th probabilistic event, which corresponds to (Dj) road factor.

We will treat a specific road factor on the specific section of a road as the probabilistic event in respect of the road conditions. For example, availability of the road markings of the traffic way, specific road sign, and the speed change lane, that is, availability of the specific kinds of the installed road elements, which are conductive to the road traffic safety.

We will treat each specific section of the roads in operation as the probabilistic object with probabilistic factors. In accordance with the probabilistic point of view, we will understand “observation” as the analysis of the mileage distributions of the RTAs, as well as analysis of the road conditions over the specific sections of the motor roads in operation. Certain road conditions (such as physical reality, for example) contain the probabilistic essence, which is an imperceptible one for a driver in the course of traffic and which is connected with the improvidence of the pre-determined change in the existing road conditions, elements of roads, quality state of roads, in the geometrical dimensions in plan view, as well as in the longitudinal and cross profiles.

In the course of traffic, driver does not estimate length of the straightforward or curved sections, radiuses of bends in plan view and in the longitudinal profile, clear vision distance of the road surface, sight distance to the on-coming motor vehicle, he/she does not estimate width of the traffic way, width of the traffic lanes, tire-to-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30773095

surface friction coefficient of the road pavement, road pavement smoothness and all the rest circumstances. It is this factor that can become the direct or indirect reason of occurrence of the error, which results in the incorrect selection of the traffic condition by the driver in the case of occurrence of a conflict situation that is transformed into an emergency situation and results in occurrence of the RTA.

In the connection with the above-stated conclusions, one may state that there is a necessity in the permanent and targeted monitoring over the state of the road conditions. It is possible to perform such monitoring with the help of results of investigations and analysis of actual distributions of the RTA within the one-level road junctions, including road junctions with the jughandle left turns. Development of the prognostic stochastic models makes it possible to ensure operational finding the places or sections of possible occurrence of various RTAs, estimate existing conditions, and prevent accidents within these sections through the object-oriented improvement of the road conditions, which include the entire complex of interventions into relevant factors, as well as influence upon the traffic flow modes.

As concerns practice of the operational maintenance of roads, the road traffic safety is in direct dependence on the quality state of the road conditions because this state is one of the controllable components of the entire system.

Road junctions impact on the environment

The most difficult conditions for traffic of the transportation facilities occur on the motor roads junctions (Bevrani and Chung, 2012). These road junctions determine traffic capacity of the entire network, and they have influence upon the density and speed of traffic (Cao et al., 2016). Road junctions are the places, where one can always wait for occurrence of traffic congestions, increased risk of accidents, as well as growth of the emission rate of harmful components by motor engines to the environment (Yue et al., 2016).

Road junctions (highway crossings and road junctions) of motor roads are usually designed and constructed in one level or in several levels (Ghahramani and Hemmatyar, 2017). The one-level road junctions are the most dangerous ones. Intensity of traffic on any highway crossing is equal to the sum of intensities on the roads, which joint to the highway (Chaudhary et al., 2017). Therefore, motor roads near a highway crossing have greater loads as compared with other road sections (Cacciabue, 2018). Turns of certain motor vehicles from the right side and (particularly) from the left side create obstacles for traffic of those transportation facilities, which go without changes in the traffic direction (Lo and Tsai, 2009).

As concerns the one-level road junctions, there occur points of crossing, branching, as well as points of influence of the traffic trajectories of the transportation facilities (Tian et al., 2018). A simple four-side highway crossing includes 16 highway crossing points, 8 branching points, and 8 points of influence (Nagler and Ward, 2016). Such points are called the conflict points (Mendoza, 2017). The higher traffic intensity and the greater share of the transportation facilities, which make right and particularly left turns, the higher danger of occurrence of traffic congestions, which ensure growth of the increased pollution of the environment by the components, which are discharged along with the exhaust gases, as well as which ensure propagation of noise and vibrations (Wattana and Nishio, 2017).

As concerns the channelized road junctions, width of the traffic lane on the main road is determined at the level of 3.75 m (Bartoková et al., 2015). The least length of

such lane in both sides from an interchange on the main road is equal to 150 m if traffic intensity does not exceed 2,000 vehicle/day; 200 m if traffic intensity is equal to from 2,000 to 3,000 vehicle/day; 500 m if traffic intensity is equal to from 3,000 to 4,000 vehicle/day, and 900 m if traffic intensity is more than 4,000 vehicle/day. Width of the traffic lane of the secondary highways at the distance of no lesser than 50 m in both sides from an interchange is determined at the level of no lesser than 7 m for all categories of motor vehicles on the two-lane road. Width of the traffic lane on the ramps/exits of the channelized road junctions is determined at the level of from 4 to 5.8 m depending on the ramp/exit radius, which must be no lesser than 10 m (FISITA, 2011). It is also necessary to strengthen shoulders within the road junctions, while their width is to be defined at the level of 3.75 m for the main road and at the level of 2.5 m for the secondary road. At the same time, it is necessary to construct special speed change lanes (overtaking lanes) being no lesser than 3.75 m in width at all channelized and partially channelized one-level road junctions. It is recommended to design channelized road junctions at the summary consolidated traffic intensity from 2,000 to 8,000 consolidated transportation facilities per day (Duduta, 2015).

It is also recommended to design roundabout (traffic circle) one-level road junctions in the cases, if traffic intensities on the roads, which cross each other, are the same or if difference between these intensities does not exceed 20%, while quantity of flows of motor vehicles within the left-turn flows is equal to no lesser than 40% on both roads. A roundabout (circle) intersection with a big radius of the centre (rotary) island is the most dangerous one as compared with all other kinds of one-level road junctions. All manoeuvres of the transportation facilities on the roundabout road junctions are restricted to inclusion of motor vehicles into the traffic flow and subsequent exit from the flow (traffic convergence and divergence). Therefore, there exist interlacing of flows on the roundabout road junctions, but there are no any highway crossings. However, big quantity of interlacements of the traffic trajectories of the transportation facilities causes decrease of speed as compared with the speed on the approach roads. In addition, great areas are required for construction of the roundabout intersections. The one-level road junctions result in decrease of the traffic speed and traffic capacity of a road, as well as they cause growth of quantity of the road traffic accidents.

The authors have compaired the results, which were obtained in 2018, with relevant results for 2017 (the year, when organisation of traffic was changed). It is possible to state the following: quantity of harmful emissions (carbon oxides (CO), nitrogen dioxide (NO_2), sulphur dioxide (SO_2), and hydrocarbons (CH)) has decreased at the expense of the changes in the traffic organisation within relevant road intersection, as well as at the expense of decrease in the standing time of motor vehicles on the road intersection, and these factors have caused decrease of emissions of relevant gases. It is obvious from the investigation results that quantity of the gasoline-powered and diesel-powered buses has the biggest influence upon concentration of harmful emissions (this is the case for all groups of harmful emissions). Diesel-powered buses and lorries have essential influence upon emissions of the nitrogen dioxide (NO_2). High value of the correlation coefficient (within the limits from 0.88 to 0.97) confirms the great strength of interconnection between relevant variables.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30773095

Conclusions

Through analyzing the obtained results, it is possible to make the following conclusions:

1. Quantity of the diesel-powered lorries and quantity of the gasoline-powered buses (respectively) have the biggest influence upon concentration of the polluting substances in the atmospheric air. The diesel-powered passenger cars and diesel-powered lorries have somewhat less influence, while quantity of the gasoline-powered buses has almost insufficient influence upon concentration of the polluting substances.

2. All groups of motor vehicles have essential influence on hydrocarbons. The gasoline-powered buses have essential influence on the concentration of the carbon oxides (CO), while diesel-powered buses and lorries have influence on the concentration of the nitrogen dioxide (NO_2).

3. Not all calculated values exceed their critical values in absolute magnitude. That is, these values are lesser for the coefficients a_2, a_3, a_5, a_6, that is, the parameters, near which they stand, do not have any essential influence upon the resulting parameter (upon the concentration of the carbon oxides and concentration of hydrocarbons (CH)). Only quantity of the gasoline-powered passenger cars has essential influence upon this component of the atmosphere pollution, while quantity of the diesel-powered passenger cars has somewhat less influence in respect of this factor.

4. Having analysed the results obtained, the authors have proposed the following changes in organisation of the traffic on the road intersection under consideration: partial traffic decrease at the expense of organisation of the jughandle right turn and installation of additional sections of the traffic light. It was found that quantity of harmful emissions (carbon oxides (CO), nitrogen dioxide (NO_2), sulphur dioxide (SO_2), and hydrocarbons (CH)) has decreased at the expense of the changes in the traffic organisation within relevant road intersection, as well as at the expense of decrease in the standing time of motor vehicles on the road intersection, and these factors have caused decrease of emissions of relevant gases.

5. It was found that the development of the prognostic stochastic models makes it possible to ensure operational finding the places or sections of possible occurrence of various RTAs, estimate existing conditions, and prevent accidents within these sections through the object-oriented improvement of the road conditions, which include the entire complex of interventions into relevant factors, as well as influence upon the traffic flow modes.

6. The analysis of the drivers' specific features of perception of the road conditions let us to make the conclusion in respect of the fact that we must treat road conditions as the dangerous ones in the situations, where the sudden change in the traffic modes of the transportation facilities occurs as compared with the previous conditions and when drivers must work with the increased attention. These road conditions cause occurrence of the road traffic situations, which transform into accidents, and the RTA aggregation is observed.

Abstract. The objective of the present study was to evaluate soil organic carbon stock and mineralization characteristics in forest ecosystems in subtropical China. We explored the factors underlying soil respiration and vegetation in 12 soils at different altitudes in Jiangxi province, Wuyi mountain national nature reserve. Soil organic carbon was applied to analysis field survey and indoor cultivation techniques. Our results showed uneven distribution of four perpendicular bands: meadow grassland, subalpine elfin, mixed coniferous and broad-leaved forests. Differences in total carbon (TC) and total nitrogen (TN) content in the soil were not significant. Soil pH was acidic. The crown density representing relative soil water content suggested fewer differences in low dissolved organic carbon (DOC) with altitude. The soil microbial biomass carbon (MBC) was the lowest in the meadow grassland soil, and in that of the mixed needle leaved forest. The NO_3^--N levels decreased with altitude and the changes in NH_4^+-N were not obvious. The respiratory rate of the meadow grassland soil was the lowest, and the respiratory rate of the subalpine elfin forest was high. Cumulative emissions without soil CO_2 increased with altitude showing regular changes related to vegetation. In mixed needle the soil respiration was significantly stronger than in the meadow grassland and broad-leaved forest soil. Carbon emissions produced by soil respiration and total carbon (TC) and C: N were positively correlated ($P < 0.05$), with no obvious correlation with MBC. The soluble and microbial carbon levels in the soils at different altitudes were positively but not significantly related. Soil pH and TC were negatively correlated with TN and NO_3^--N. The effect of soil total carbon, total nitrogen and crown density partially controlled soil respiration.
Keywords: *Wuyi mountain, altitude, soil organic carbon, soil respiration, vegetation*

Introduction

Climate change is a major environmental challenge. The carbon cycle plays a key role. Soil organic carbon dynamics underlying soil carbon cycle is a hot issue of climate change (Williams et al., 2004). Soil respiration is an important component of terrestrial ecosystem comprising soil and atmospheric CO_2 exchange (Pierce et al., 2004). Global climate change due to increased temperature accelerates mineralization of soil organic carbon (Schlesinger et al., 2000; Zerva et al., 2005). The CO_2 released from soil respiration into the atmosphere further aggravates global warming. Therefore, soil respiration is an important factor underlying global climate change (Schlesinger et al., 1997).

Soil respiration is a complex process, which is affected by a variety of factors including hot soil water, texture, vegetation types, and land use practice (Wang et al., 2005; Maljanen et al., 2006; Yashiro et al., 2008; Yang et al., 2010). Changes in altitude affect vegetation composition and alter the soil environment, resulting in a significant impact on the size and dynamics of soil respiration and sensitivity to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30973106

temperature (Maljanen et al., 2006; Yashiro et al., 2008). Wuyi mountain national nature reserve is the central Asian tropical forest ecosystem, representing a vertical spectrum of vegetation distribution. It includes subtropical evergreen broad-leaved forest, mixed needle leaf and subalpine elfin forest and alpine meadow. The complete vegetation zone provides convenient conditions to study spatial and temporal heterogeneity of soil respiration. Wuyi mountain is a tourist destination. Human interference has tourists altered the original land use pattern and forest vegetation composition, and accordingly changed the soil carbon composition. Altered dynamics of soil respiration with altitudinal gradient is a key factor in predicting global climate change (Williams et al., 2004; Norby et al., 2001). Current studies mainly focus on differentiation of soil carbon, nitrogen and organic matter, and biodiversity due to the complexity of soil composition of organic carbon and factors influencing diversity (Lu et al., 2012a). Studies reported soil respiration in subalpine thickets of monsoon forest, coniferous and broad-leaved mixed forest soil with altitude (Xu et al., 2015). Studies have also investigated the trends in temperature and moisture levels of broad-leaved Korean pine, spruce and fir forest and *Betula ermanii* in Changbai mountain with changes in altitude (Wang et al., 2003). However, these studies have not systematically analyzed the relationship between altitudinal gradient and soil respiration. Data pertaining to relative changes in dynamic and quantitative description of soil carbon mineralization with altitude are lacking. These studies cannot reflect the dynamic balance in carbon levels between tropical and subtropical biota. In this study, the soil samples had been analysed in Wuyi mountain nature reserve at different altitudes. We measured the soil nutrient and respiration levels in laboratory, to determine the mechanisms underlying altered soil properties and respiration with altitude.

Materials and methods

Study site

This study was conducted in Wuyi mountain county, Jiangxi province national nature reserve, located in the transition zone of the subtropical marine and inland climate, southern China. Local meteorological data (2001-2010) show a mean annual precipitation of 2583 mm and a mean annual temperature of 15 °C, annual average relative air humidity of about 85%. The natural environment is unique, with a complex geological structure, and various types of landforms. Altitude in the area increases from 700 m in the northwest to 2100 m in the southeast. Huanggang mountain at 2160.8 m is the highest peak. Jiangxi province represents the main distribution area of virgin forest, with a wide variety of wild fauna and flora, and lush vegetation. The distribution of vegetation presents a perpendicular band spectrum, with vertical differentiation: evergreen broadleaf forest (EBF), 117°44.183’-117°44.183’E, 27°51.082’-27°51.082’N (altitude of 800-1100 m); coniferous broadleaf forest (CBF), 117°44.806’-117°44.806’E and 27°51.037’-27°51.133’N (altitude of 1100-1500 m); dwarf forest (DF), 117°45.447’-117°45.984’E, 27°50.329’-27°51.038’N (altitude of 1500-1900 m); and alpine meadow (AM), 117°46.214’-117°46.987’E and 27°50.362’-27°51.636’N (altitude above 1900 m), respectively. We tested selected samples representing the four vegetation types, respectively, at 1500 to 1900 m and random samples above 1900 m.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30973106

Experimental design and sampling

Soil samples were obtained in October 2013. In this study, we selected four different vegetation types across an altitude gradient to examine *Rs* variation, in soils of EBF, CBF, DF and AM, respectively. Samples of each vegetation type were tested in triplicate. There were totally twelve 20 × 20 m plots. Five soil sample replicates using a 7.5 cm diameter soil auger were mixed together at a depth of 0-20 cm, sieved using a 2 mm mesh, and stored at 4 °C in a refrigerator and until further laboratory analysis.

Soil respiration and properties

The soil samples were divided into two subsamples. One subsample was used to measure soil respiration using the alkali absorption method. In brief, we initially weighted 30 g of fresh soil and adjusted to 60% of the field water holding capacity (Chen et al., 2004). The adjusted soils were aerobically incubated at 22 °C in a 1L sealed glass jar. Soil respiration was trapped in 0.1 M NaOH and measured with 0.1 M HCl titration after 1, 3, 7, 14, 21, 28, 35, 42, 49 and 56 days. The total soil respiration was estimated by calculating the cumulative production of soil respiration from soils during the incubated 56 days.

Another subsample was used to measure soil properties: total carbon (TC), total nitrogen (TN), organic matter content (OM), dissolved organic matter (DOC), microbial biomass carbon (MBC), soil water content (SM) and pH. Briefly, TC and TN were measured using an elemental analyzer (Isoprime- EuroEA3000, Milan Italy). OM, DOC, MBC, SM and pH were measured by potassium dichromate oxidation-outer heating, high temperature catalytic oxidation, chloroform fumigation extraction, oven drying and potentiometric, respectively (Brookes et al., 1985; Vance et al., 1987).

Data analysis

Statistical analysis was carried out using SPSS 13.0 for Windows (SPSS Inc., Chicago, IL). Two-way ANOVA followed by Fisher's least significant difference (LSD) test was used to examine the effect of land use practice, soil depth and their interaction on soil properties. As *Rs* were measured repeatedly across time, we also used repeated measures ANOVA (RMANOVA) to examine variation in *Rs* with time. Simple linear analyses were used to examine the relationship of soil respiration with soil properties.

Results

Plant diversity

Climate conditions affected plant species as a dominant factor of vegetation distribution. Changes in terrain redistribution of precipitation and heat affected plant community and vertical zoning. Elevation was the primary factor controlling the pattern of mountain species distribution. Our results suggested that the distributions of vegetation types varied with altitude (*Table 1*).

Effect of different altitudes on soil physicochemical properties

No significant differences were found among soil TC and TN concentrations along altitudinal gradient (*Table 2*). The soil in the alpine meadow was acidic, but had a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30973106

significantly higher pH than the dwarf forest ($P < 0.01$). Bulk density in coniferous broadleaf forest was significantly lower than that in alpine meadow ($P < 0.01$). Forests in lower altitudes, including evergreen and coniferous broadleaf forests, had significantly higher crown densities than the other two vegetations in higher altitudes ($P < 0.01$). Soil moisture in evergreen and coniferous broadleaf forest was significantly lower than that in the other two vegetations (*Table 2*). In addition, there was an increasing trend in soil moisture along altitudinal gradient. Soil DOC concentrations were 1.693-2.196 mg g^{-1} and increased with increasing altitude. Soil MBC content was the highest in meadow grassland and the lowest in coniferous broadleaf forest. The NO_3^--N content decreased with an increase in altitude.

Effect of different altitudes on soil efflux

Soil respiratory rate

The patterns of soil respiratory rate were similar among different vegetations, with a decrease with incubation time (*Fig. 1a*). The respiratory rate sharply decreased after 7 days of incubation time and kept stable from the 14th days (*Fig. 1a*). It was the lowest in alpine meadow and highest in dwarf forest. Soil respiration in broad-leaved and coniferous broadleaf forests decreased faster after cultivation for 14 days. After 14 days, it decreased as follows: subalpine elfin forest > coniferous broadleaf forest > needle forest > meadow grassland. The soil respiration rate in subalpine elfin forest was significantly higher than that in meadow grassland ($P < 0.01$).

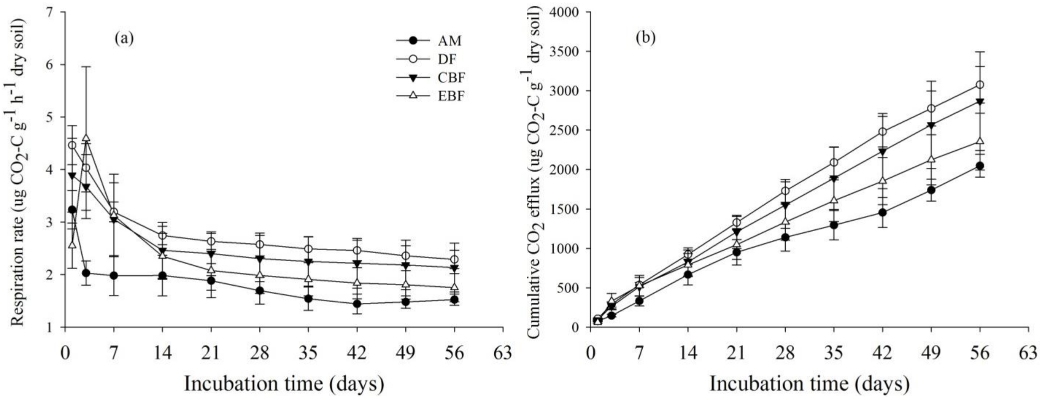

Figure 1. *Changes in (a) the rate of respiration, and (b) cumulative CO_2 efflux during 56-day incubation in soils of different treatments. The abbreviations of vegetation types are the same as Figure 1*

Soil cumulative CO_2 efflux

The soil respiratory emissions of CO_2 rapidly increased within 7 days of culture. Soil organic matter rapidly decomposed in soils regulated to 60% water holding capacity, due to microbial activity. The soil carbon emissions slowly increased after incubation for 7 days at different altitudes. No significant differences were seen between soil CO_2 accumulation emissions and altitude. However, soil CO_2 emissions were related to vegetation. The soil respiration in coniferous broadleaf forest was significantly stronger than in meadow grassland and broad-leaved forest soil ($P < 0.01$).

Correlation between soil carbon emissions and vegetation types

The vegetation types and soil nutrients were analyzed by principal component analysis (PCA) of soil at different altitudes. Our results showed that the differences in soil physiochemical properties were complex at different altitudes, and the first and second principal components explained 40.95% and 20.27% of the variation, respectively (*Fig. 2*). The soil carbon emissions and TC, and C: N were positively correlated ($P < 0.05$), but not between soil carbon emissions and MBC. No significant difference between DOC and MBC was observed at different altitudes. The soil pH and TC, TN and NO_3^-—N were negatively correlated ($P < 0.05$). In this study, we found that TC, TN, and crown density also played important roles in regulating *Rs* under different altitude gradients.

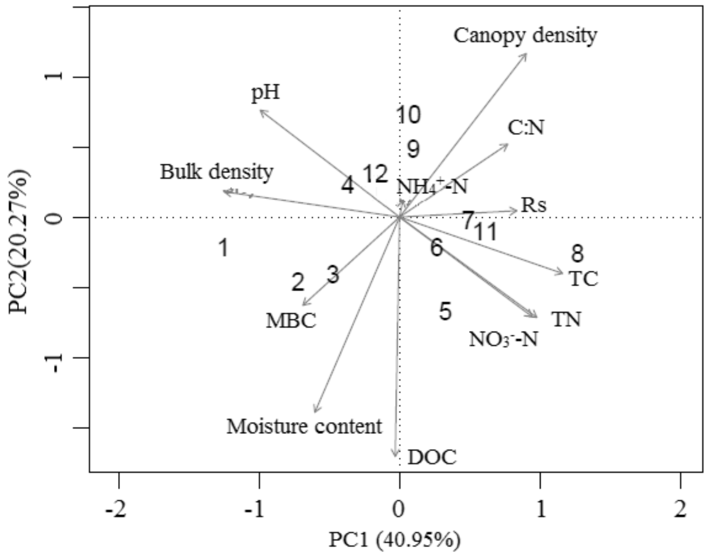

***Figure 2.** Principal component analysis (PCA) of physicochemical properties of soils from forests at different altitudes*

Discussion and conclusion

Vegetation type is heterogeneous in the Nature Reserve, dominated by the evergreen broad-leaf and coniferous broadleaf forests. The variation coefficients of different vegetation types were larger along the altitudinal gradient. The vegetation types along the altitudinal gradient are: artificial vegetation, bamboo forest, evergreen broad-leaved forest, coniferous broadleaf forest, coniferous forest, broadleaf needle elfin wood and mid-mountain meadow. The distribution of various vegetation types overlapped substantially at each altitudinal zone.

Zonal climate condition is the dominant factor of vegetation distributions by affecting plant species compositions. The temperature decreased with increasing altitude. The precipitation, solar radiation and atmospheric composition also changed in altitude. Changes in terrain redistribution of precipitation and heat affected plant community and vertical zoning. Altitude was the primary factor governing the pattern of mountain species distribution. However, the terrestrial factors affecting vegetation type and the contribution of soil nutrients, water availability and altitude alone and their interactive effect on *Rs* variation was still unknown. The zonal climate was the dominant factor for the distribution of plant species within the Wuyi Mountain Nature Reserve (Rouget et al., 2015). A vertical variation in hydrothermal factor along with decreased temperature with increases altitude was observed (Sarrazin et al., 2015). Terrain changes redistribution of precipitation and energy, affecting vegetation and vertical zonal distribution. Altitude is the primary factor controlling the pattern of mountain species distribution (Lou et al., 2000; Dolezal et al., 2002). Our results also demonstrated four perpendicular bands, and lack of typical and alpestrine mountain vegetation perpendicular band. The order of perpendicular bands with increase in altitude included evergreen broad-leaved forest, coniferous broadleaf forest, elfin wood and mid-mountain moss, and mid-mountain meadow vegetation types. Zonal warm coniferous forests were present at 1650-1700 m. The main vegetation types included evergreen broad-leaved and coniferous broadleaf forests, with an uneven distribution,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30973106

and an obvious vertical band with change of altitude in sites. The vegetation was limited by growing conditions above 1900 m. The vegetation was replaced with elfin forest or meadows for hilltop effect, elfin forest and coniferous broadleaf forest at 1500-1900 m and coniferous forest and coniferous broadleaf forest at 1100-1500 m. The hydrothermal condition was mainly observed at 800-1100 m, and the vegetation included evergreen broad-leaved forest.

Soil respiration is one of the important indicators of soil quality and reflects the strength of soil biological activity and metabolism. Soil respiration represents an index of soil biological activity, fertility and permeability (Li et al., 2010). Soil microbial competition for nutrients, however, is likely to drive the microbial community structure and corresponding alteration in nutrient mineralization (Yang et al., 2017). Our study showed that the level of CO_2 emissions due to soil respiration increased rapidly after cultivation for 7 days. Soil microbes were the most active and decomposed soil organic matter when soil moisture was adjusted to 60% water-holding capacity (Lu et al., 2012b). Soil carbon emissions slowly increased after cultivation for 7 days. The difference in soil CO_2 emissions with altitude was not obvious (Bai et al., 2008). However, soil CO_2 emissions were related to vegetation. Soil respiration of coniferous broadleaf forest was significantly stronger than that of meadow grassland and broad-leaved forest ($P < 0.01$), probably due to the microbial activity. There was no obvious influence of soil moisture on soil respiratory. Soil respiratory rate suggested the ability to release CO_2. The soil respiratory rate decreased with altitude (Lu et al., 2011; Gao et al., 2011). Soil respiratory rate decreased sharply within 7 days, and slowed down or remained steady, which was consistent with previous findings (Zhou et al., 2012). Soil respiration rate in meadow grassland was the lowest, while that of the subalpine elfin forest was the highest. Soil respiratory rate of broad-leaved and coniferous broadleaf forests decreased rapidly after cultivation for 14 days. The soil respiratory rate decreased as follows: subalpine elfin forest > coniferous broadleaf forest > needle forest > meadow grassland. The soil respiratory rate of subalpine elfin forest was significantly higher than that of meadow grassland ($P < 0.01$). No significant effect of soil moisture on the respiratory rate was observed, which was inconsistent with previous findings (Liu et al., 2009). These results suggest the combined effect of plant types, microbes and soil moisture. The change of soil moisture was minimal in plant growth, with less effect of soil moisture on the respiratory rate (Fang et al., 2001).

Soluble organic matter had an important effect on soil physicochemical and biological characteristics (Lu et al., 2012b). Soil organic matter is mostly composed of DOC from plant litter (Shen et al., 2015). The ground vegetation types were closely related to decomposition of humus, microbial biomass and root secretion. Our results suggest that soil DOC ranged from 1.693 to 2.196 mg g^{-1}, and gradually increased with increase in altitude, with a small amplitude. Our results were consistent with previous findings in that soil carbon of biological communities was high at low temperature and humidity. Soil organic matter accumulated at high altitude, low temperature and humidity. The organic type, quantity and quality of the soil influenced the properties of MBC. Meadows improved soil granular structure and activity to increase MBC (Wang et al., 2007). Our studies suggest that MBC increases with altitude, resulting in a significant positive correlation between soil organic carbon and MBC. The soil MBC was the highest in meadow grassland and the lowest in coniferous broadleaf forest. NO_3^--N decreased with increased altitude, and the change of NH_4^+-N was not obvious with altitude. DOC and MBC did not show similar correlation, which was consistent

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_30973106

with Liu's finding (Liu et al., 2012) and inconsistent with Han Lin's results (Han et al., 2010). Plants absorb nutrients from the soil organic matter by microbial decomposition. MBC reflects soil nutrient condition and activity of microorganisms. MBC was an effective index of evaluation of soil fertility and soil quality.

The differences and similarities in vegetation type and soil nutrient comprehensive status were analyzed by PCA of soil physicochemical properties at different altitudes (Wu et al., 2014). In our studies, the difference of soil physicochemical properties varied with altitude. The first and second principal components explain 40.95% and 20.27% of the variation, respectively.

Soil CO_2 emissions were positively correlated with TC, C:N ($P < 0.05$) by PCA (Liu et al., 2009), but not with MBC. There was no significant difference between DOC and MBC. The pH was negatively correlated with TC, TN and NO_3^--N. TC, TN. Crown density had a significant impact on soil respiration, and was used as a regulatory factor of soil respiration. Soil respiration showed significant negative correlation with organic matter and the correlation coefficient was 0.871 ($P < 0.05$) (Zhang et al., 2012). Soil moisture was low, and its effect on soil microbial activity reduced the soil organic carbon mineralization at low altitudes.

Acknowledgements. The work was funded by National Natural Science Foundation of China (31560168, 31660072, 31760136), Jiangxi Province Ministry Education Foundation of China (GJJ160312, GJJ170198). The authors take this opportunity to thank all for support extended for this study.

Abstract. The study was carried out to determine the soil properties of the Ornithogalum L. species in the West Mediterranean Region of Turkey and their effects on plant morphology. Plant and soil samples concerning species *Ornithogalum umbellatum* L., *O. oligophyllum* E.D. Clarke, *O. narbonense* L., *O. pyrenaicum* L., *O. lanceolatum* Labill., *O. pamphylicum* (endemic) O.D. Düşen & Sümbül, *O. montanum* Cirillo, *O. armeniacum* Baker, *O. neurostegium* Boiss. & Blanche, *O. orthophylum* Ten. and *O. chetikianum* (endemic) Uysal, Ertugrul & Dural were collected from 32 different populations between March and June in 2012. The soils of the plant taxa were textured with sandy loam, loam, silty loam, and sandy clay loam; their EC values were in the range 71-741 µmhos cm^{-1}; and their pH values varied between 6.9 and 8.3. The highest organic matter content was in *O. orthophylum*, whereas the lowest value was in *O. chetikianum* (endemic) and *O. pamphylicum* (endemic). According to the means, the highest values of phosphorus, potassium, calcium, and magnesium were determined in the soil samples belonging to *O. lanceolatum* (106.0 mg kg^{-1}), *O. lanceolatum* (657.5 mg kg^{-1}), *O. montanum* (6552 mg kg^{-1}) and *O. pyrenaicum* (746.8 mg kg- 1), respectively.
Keywords: *Ornithogalum, ecology, habitats, soil properties, morphological characters, Turkey*

Introduction

Asparagaceae is a family of flowering plants containing 143 plant genera and 3632 species. The genus *Ornithogalum* L. is in the family *Asparagaceae* in the major group Angiosperms. *Ornithogalum* L. is a perennial plant and is widely distributed in Europe, Asia, Africa and Madagascar. The genus *Ornithogalum* in tribe Ornithogaleae (Caurel) J.C. Manning & Goldblatt of subfamily Ornithogaloideae Speta (Hyacinthaceae *Batsch*) consists of about 200 species of bulbous herbs native to Southern Europe, the Mediterranean basin, and South Africa (Manning et al., 2009; Andric et al., 2015; Aykurt et al., 2016).

The West Mediterranean Region is one of the richest places of Turkey in terms of plant diversity. According to the latest research, there are 54 known *Ornithogalum* species in the world, with 17 of them being endemic to Turkey. The West Mediterranean Region possesses 18 *Ornithogalum* species and 5 of them are endemic to the region (Davis, 1988; Düşen and Deniz, 2005; Uysal et al., 2005; Mutlu and Karakuş, 2012).

Ornithogalum species is used for ornamental or medicinal plant and can also be consumed as vegetable (Kamanestsky and Okubo, 2012). There are a number of studies on the taxonomy, cytology, ecology, seed micromorphology (Goldblatt and Manning, 2011; Yılmaz, G., 2014; Rat et al., 2016; Corominas et al., 2017), and in vitro propagation of *Ornithogalum* (Yanagawa and Ito, 1988; Nayak and Sen, 1995; Ziv and Lilien-Kipnes, 2000; Kariuki and Kako, 2003; Malabadi and van Staden, 2004; Naik and Nayak, 2005; Ozel and Khawar, 2007).

Ornithogalum species in Turkey have distribution from 0 to 2600 m and in the Mediterrenean, Euro Siberian and Iranian Turan phytogeographical region.

To the best of knowledge, there is no study on the natural populations of Ornithogalum with the physical and chemical characteristic concentrations of the soils convenient.

Soil is a key environmental factor for wild plant populations since plant development depends largely on the nutrients of soil. Therefore, soil analyses of wild plant populations may be the means for understanding soil and its possible correlations with plants (Li and Mazza, 1999; Roca-Perez et al., 2004). Several studies showed that microelement contents in plants were affected by not only soil microelement concentrations but also the differences in chemical properties (i.e. pH and carbonate content) of the soil (Brun et al., 1998; Rapp et al., 1999; Saatçi and Yağmur, 2000; Roca-Perez et al., 2004).

Soil is known to have a significant impact on plants. Knowledge of the physical and chemical properties of soil helps to keep and grow plants effectively, and the use of the type of soil required for a plant will be essential for its faster cultivation and development (Reed, 2011).

The main aim of our study was aimed to determine the interactions between soil and plant properties in different *Ornithogalum* species growing in the West Mediterranean Region of Turkey, in order to provide information to the future cultivation studies in Ornithogalum species.

Materials and methods

The study was conducted in 32 populations of 11 Ornithogalum species (*O. umbellatum* L., *O. oligophyllum* E.C. Clarke, *O. narbonense* L., *O. pyrenaicum* L., *O. lanceolatum* Labill., *O. pamphylicum* O.D. Düşen & Sümbül 'endemic', *O. montanum* Cyr., *O. armeniacum* Baker, *O. neurostegium* Boiss. & Blanche, *O. orthophylum* Ten., and *O. chetikianum* Uysal, Ertugrul & Dural 'endemic' located in the West Mediterranean Region of Turkey. Soil samples were collected by means of a garden spade in a depth of 30 cm after removing the surface litter between March and June in 2012. Details of original locations of collected samples are shown in *Figure 1*.

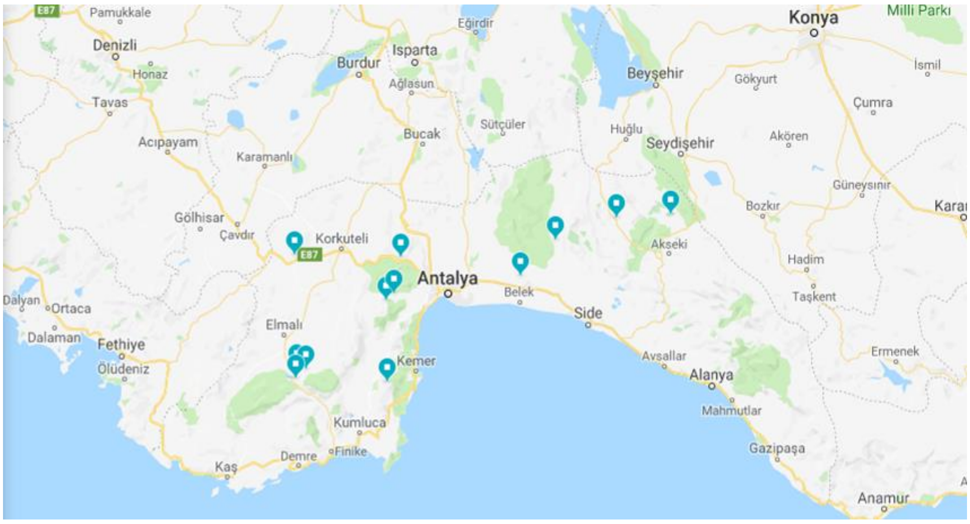

Figure 1. *The location of sampling site of Ornithogalum species*

DOI: http://dx.doi.org/10.15666/aeer/1702_31073121

Their appearances of flowering stage of the Ornithogalum species are presented in *Figure 2*.

Figure 2. *Some different genotypes of Ornithogalum species plant sampling flowering period.* ***a*** *O. pamphyllicum (endemic),* ***b*** *O. lanceolatum,* ***c*** *O. orthophyllum,* ***d*** *O. pyrenaicum,* ***e*** *O. narborense,* ***f*** *O. montanum,* ***g*** *O. umbellatum,* ***h*** *O. oligophyllum,* ***i*** *O. armeniacum*

At every site, four 1000-g soil samples were collected at three randomly selected points from an area of 25 m^2, placed in clear plastic bags (35 × 25 cm), sealed with a rubber band, and brought to the laboratory. Then, the air-dried soil samples were prepared for the analyses by sifting them through a 2-mm mesh sieve. The analyses were conducted in the soil analysis laboratory of the Batı Akdeniz Agricultural Research Institute (BATEM). The pH (potential of hydrogen-soil reaction) and EC (The Electrical Conductivity) values of the soils were analyzed in a 1:2.5 soil and water mixture, as recommended by Jackson (1967). The organic matter was determined using

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31073121

the Walkley-Black method, as suggested by Black (1965). The available P was found with the Olsen method (Olsen and Sommers, 1982). $CaCO_3$ was determined with the Scheibler calcimeter method (Kacar, 2009). The texture of soil was tested with the hydrometer method by Bouyoucos (1951), and the available K, Ca and Mg were found by using 1 N ammonium acetate extraction suggested by Kacar (2009). All the collected data were subjected to the analysis of variance, and the mean values were compared using Duncan's multiple range tests at the 0.05 level (Gomez and Gomez, 1984).

In the study, morphological characters of the plants such as flowering time (day), length of flower stems (mm/plant), bulb diameter (number/plant) and the number of flowers (number) were determined according to Martinez-Azorin et al. (2007). Taxonomic description was made according to Davis (1988). Morphologic characters of the five plants belong to each species were measured in natural habitats when the soil samples were collected. All the measurements were done by a compass and analytical balance.

The number of the soil samples varied from 2 to 6, because the number of location was limited for some species. The number of the soil sample was collected according to the number of location.

Results

Thirty-two soil samples were collected from different geographical sites distributed throughout the West Mediterranean, Antalya between March and June in 2012. *Table 1* presents the soil numbers, localities, habitats, and altitudes, while *Table 2* provides some properties of the soils (texture, pH, EC, CaCO3, organic matter, potassium, phosphorus, calcium and magnesium).

Table 1. *Soil samples, localities, altitudes and habitats of the Ornithogalum species*

Species	Soil number	Date of collection	Locality	Coordinates	Altitude (m)	Habitat

Ornithogalums are usually grown in open meadows, roadside or limestone rocky slopes. Their altitude ranges from 15 m to 2016 m. The flowers are generally starched, petals are green striped and there are 2-20 flowers. Flower stem lengths vary between 2-45 cm. Leaves are thin or long strip, linear or thick-fleshy, with bright dark green or matte gray-green colors, bulbs of different sizes (small to medium-large) are round or ovoid (*Table 3*).

***Table 3**. Morphological characters of natural Ornithogalum species*

Species	Bulb size-average bulb diameter (mm)	Leaf characteristics	Average number of flowers per inflorescence (number)	Stem length (mm/plant)	Flowering time
O. pamphylicum	Small, long-ovoid-6.5	Thin long strip	2-2.5	70-80	Mid May
O. lanceolatum	Big ovoid-26.7	Thick fleshy bright dark green	2	20-30	Mid April
O. orthophyllum	Small round-10.8	Quite thin	2.67-3.00	50-100	March
O. armeniacum	Medium round-17.0	Thin	4.5-6.00	100-250	April-early May
O. neurostegium	Medium long ovoid-18.7	Thin	5.63-6.63	200-250	Mid May
O. umbellatum	Numerous number of tooth shaped bulblet, Medium Round-18.3	Thin	12.00-18.00	100-200	Mid March

O. oligophyllum	Small round-12.7	Thick	8.00-9.25	100-150	Mid March-end of March

Statistical analyses of the results for the soil analyses and the soil classes of the *Ornithogalum* species are shown in *Tables 4* and *5,* respectively.

The soil analyses results are also shown in graphs (*Fig. 3a-h*). Some evaluations and interpretations of the soil analysis results are provided in detail below.

Table 4. *Results of the statistical analyses (Mean ± SE and minimum–maximum) on the soils of Ornithogalum species*

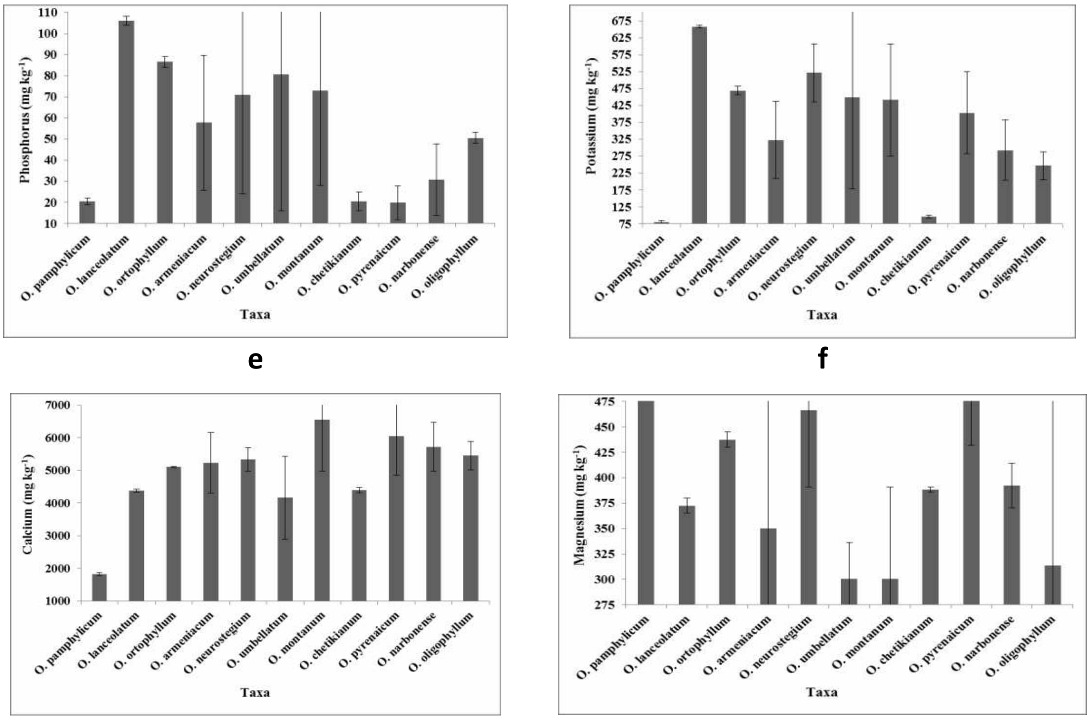

Figure 3. ***a*** *pH values,* ***b*** *EC values,* ***c*** *CaCO3 contents,* ***d*** *organic matter contents,* ***e*** *phosporus contents,* ***f*** *potassium contents,* ***g*** *calcium contents,* ***h*** *magnesium contents*

The results indicated that there were no significant differences in pH, EC (µmhos/cm), organic matter (%), phosphorus (mg kg^{-1}) or magnesium (mg kg^{-1}) values among the statistical averages of the soil samples ($P > 0.05$). Nevertheless, there were significant differences in the $CaCO_3$ (%), potassium (mg kg^{-1}), and calcium (mg kg^{-1}) values ($P < 0.001$) (*Table 4*). Regarding the soil texture, the species generally grew in the medium-textured types of soil. The soil samplesof the species were classified as 'loam', 'sandy loam', and 'silty loam' (*Table 2*). However, Soil Samples 28 (C3: Mt. Tahtalı, Tekirova, Antalya) and 32 (C3: The Ormana Village, İbradı, Antalya) were in the 'sandy clay' soil class. Furthermore, there were no differences in salinity among the values of the statistical test results. All soil samples were classified as 'non-saline' and 'very slightly saline'. An aggregation was present among the soils in terms of salinity. The EC values of the soil samples in the present study were low and varied between 71 and 741 µmhos cm^{-1}, while the highest EC value (741 µmhos cm^{-1}) was in *O. armeniacum* (C3: Mt. Termessos, Antalya) but the lowest EC value (71 µmhos cm^{-1}) in *O. narbonense* (C3: The Çakıllı Passage, Cevizli, Akseki, Antalya). Most *Ornithogalum* species grew in slightly alkaline soils. In the present study, the pH values were in the range 6.9-8.3, and both the highest pH values (C: Mt. Güllük, Termessos, Antalya) and the lowest (C3: The Serinyaka Village, Gündoğmuş, Antalya) pH values were determined in *O. armeniacum.* No significant difference in soil reaction (pH) existed among the species. The results demonstrated that the *Ornithogalum* species grew in soils with low to excess $CaCO_3$ levels. There was a significant difference among the species ($P < 0.05$). In terms of $CaCO_3$, the soils of *O. pamphylicum* (49.5%) were statistically quite different from the others ($P < 0.01$). The averages of the $CaCO_3$ contents of the species were very close to each other. *O. montanum* (13.2%)*, O. neurostegium* (10.3%)*, O. umbellatum* (21.8%) and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31073121

O. o*rthophyllum* (12.5%) grew in soils with a very high CaCO3 content. The soils, where *O. lanceolatum* (1.9%), *O. chetikianum* (2.7%), *O. pyrenaicum* (2.2%) and *O. oligophyllum* (2.5%) are grown had low $CaCO_3$ values (*Table 4*). According to the average $CaCO_3$ values, the soils belonging to *O. pamphylicum* were regarded as excess but the soils belonging to *O. narbonense* as low. In addition, the averages of the other species were in the 'medium' and 'very high' soil classes (*Table 5*). The species grew in soils mostly with high organic matter. There was no significant difference in organic matter among the soils of the species ($P > 0.05$). However, the evaluation of the organic matter contents showed that the soils of *O. oligophllum* and *O. orthophyllum* contained high organic matter. Additionally, the soils of the other species had low to high organic matter contents (*Table 4*), and there were great variations among the organic matter contents (1.2 and 13.3%) of the soil samples studied (*Table 2*), with the highest and the lowest organic matter contents recorded in *O. oligophllum* (C3: The Gembos Plateau, İbradı, Antalya) and *O. narbonense* (C3: Yukarı Karaman, Korkuteli, Antalya), respectively. No differences in phosphorus were present among the averages of the statistical test results. The phosphorus values of the soil samples were in the range 3.2-211.0 mg kg^{-1} (*Table 2*) and high in most of the soil samples (*Table 4*). In addition, both the highest (C3: Mt. Termessos, Antalya) and the lowest (C3: The Serinyaka Village, Gündoğmuş, Antalya) phosphorus values were found in *O. armeniacum* and the phosphorus values showed great variations (*Tables 1* and *2*). The *Ornithogalum* species grew in soils with high concentrations of potassium. According to the statistical tests, there was a significant difference in potassium among the species ($P < 0.05$). According to the values, the species were included in various classes. For instance, potassium was medium and low in the soils of *O. pamphylicum* and *O. chetikianum,* whereas the soils of *O. lanceolatum* (657.5 mg kg^{-1}) had the highest potassium values (*Tables 3* and *4*). The *Ornithogalum* species grew in soils with high concentrations of calcium. As the statistical tests showed, a significant difference in calcium was present among the species ($P < 0.05$). In terms of calcium, the soils of *O. montanum* (6552 mg kg^{-1}) and *O. pyrenaicum* (6046 mg kg^{-1}) were statistically quite different from those of the others. The averages of the calcium contents of the species were very close to each other, and the soil of *O. pamphylicum* (1825 mg kg^{-1}) had a medium concentration of calcium (*Table 4*). The *Ornithogalum* species grew in soils with high concentrations of magnesium. There was no significant difference in magnesium among the species according to the statistical tests ($P > 0.05$). As a result of the evaluation of the averages, magnesium was found high in most of the species (*Table 5*). Moreover, the highest and the lowest averages of magnesium were determined in *O. pyrenaicum* (746.8 mg kg^{-1}) and *O. umbellatum* (300.5 mg kg^{-1}), respectively (*Table 4*).

Discussion

As a result, physical and chemical properties of the soil of natural Ornithogalum species have been determined, and the relationship between the plant and soil was evaluated in the present study. It is thought that the results will provide significant contributions to the cultivation studies regarding of Ornithogalum in its natural habitat.

The soil samples of the Ornithogalum species were mostly medium-textured (classified as 'loam' and 'sandy loam). Their salt contents were very low (non-saline); they were generally slightly alkaline; and their $CaCO_3$ values ranged from low to excess. The organic matter contents showed great variability in the types of locality and varied

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31073121

between the ‘low’ and ‘high’ classes. Additionally, the P, K, Ca and Mg concentrations of the soil samples were generally high.

Soil texture affects many physical properties of soil such as the water-holding capacity, and the water infiltration rates. Sandy soils generally have high infiltration rates but poor water-holding capacity. All soil samples in the study were medium-textured; therefore, they had poor water infiltration rates and poor water-holding capacity. Soil texture influences the inherent fertility of soil as well. More nutrients can be absorbed by a gram of clay particles than by a gram of sand or silt particles, for the clay particles provide a much greater surface area for adsorption. Soil Samples 23, 24, 28, 30 and 32 had high Ca concentrations (8190, 7878, 8195, 7880, and 5880). According to Havlin et al. (2013), the pH values of soil samples are slightly alkaline. The level of acidity or alkalinity in a soil affects the availability of soil nutrients and the activity of soil micro-organisms and can affect the level of exchangeable nutrients. Soil Sample 9 had a lower pH value. pH affects the availability of nutrients to plants and can therefore be used to determine the production potential of the soil. pH preferences by plants can vary, though for most plants the desirable pH range is 6.0-6.5. At this level, microbial growth was also at the maximum level.

According to Dellavalle (1992), the EC levels become non-saline in the soil samples. Soil Sample 9 with a lower pH value had the highest EC level. Soil salinity affects a plant’s uptake of water and nutrients and limits plant growth. The salt contents of all soil samples analyzed were low; thus, it was hard to evaluate the *Ornithogalum* species in terms of resistance to salt. The resistance of plants to calcium carbonate ($CaCO_3$) is one of the parameters which limit expansion and cultivation of natural plant species. Differences in the $CaCO_3$ contents of the soils where the *Ornithogalum* species were grown were found among the varieties. The $CaCO_3$ contents were high in the soils of the *O. pamphylicum, O. armeniacum, O. umbellatum* and *O. narbonense* varieties, low and medium in the soils of the *O. lanceolatum, O. chetikianum, O. pyrenaicum* and *O. oligophyllum* varieties, and very high in the soils of the *O. orthophylum*, *O. neurostegium* and *O. montanum* varieties.

Organic matter is a source of nutrients for plants besides being effective on the physical and chemical properties of soils. In general, organic matter content of soils that Ornithogalum species are grown was found to be high. The most interesting situation in organic matter content results is that the endemic species have the lowest organic matter content. *O. pamphylicum* (endemic) and *O. chetikianum* (endemic) were found to be grown in soils with low organic matter content, *O. orthophylum* in soils with high organic matter content, *O. umbellatum, O. montanum*, *O. pyrenaicum* and *O. narbonense* in soils with low to high organic matter content, *O. armeniacum*, *O. neurostegium* and *O. oligophyllum* in soils with medium to high organic matter content.

Phosphorus is essential in photosynthesis, and it is involved in energy transfer. It improves root development and rapid growth; encourages blooming; and increases resistance to diseases. An excess amount of phosphorus does not damage plants. Phosphorus also improves microbial activity in the soil. All soil samples had a high P value. Khan et al. (2016) showed that phosphorus significantly affected bulb volume and number of bulblets per plant, except the number of bulbs per plant in *Polianthes tuberosa*. Moreover, high phosphorus supply increased tuber biomass; however, it decreased the number of flowers per plant in Zantedeschia (Scagel and Schreiner, 2006). Furthermore, high phosphorus content reduced the number of flowers. This situation can be explained

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31073121

by the fact that phosphorus is extremely important as a structural element of many components, particularly nucleic acids and phospholipids.

Potassium plays a vital role in the physiological and biochemical functions of plants. It is absorbed in large amounts by plants. Moreover, it is used to build proteins; increases resistance to diseases by strengthening stalks and stems; increases the cuticle (waxy layer) to prevent water loss; helps prevent wilting; and enhances fruit size and development. According to Olsen and Sommers (1982), the potassium levels in the soil are adequate for the plant. According to Claassens (1990), the potassium requirements of Ornithogalum are low and the highest potassium levels do not significantly reduce the yield, but low potassium levels may reduce the probability of inconsistent yields. Bulbs of *O. lanceolatum* have a bigger size than the other species's bulbs. In our study, the highest phosphorus and potassium contents were obtained from the soils of the *O. lanceolatum.*

Calcium, which is an essential part of the plant cell wall structure, provides for normal transport and retention of other elements as well as strength in the plant. It is also considered to counteract the effect of alkali salts and organic acids within a plant. Ghoname et al. (2007) reported that calcium treatment to the plant from the soil significantly affected the plant length, fresh and dry weight however, in the vegetative stage, there was no significant effect on the diameter of the bulb. According to the results, *O. pyrenaicum*, *O. narborense*, *O. montanum*, species had the maximum flower stem lengths. Calcium contents of these species were also found to be high.

Magnesium is part of the chlorophyll in all green plants and essential for photosynthesis. It also helps activate many plant enzymes needed for growth. Gerandas and Fuhrs (2013) reported that the degradation of anthocyanins at high temperature decreased by Mg applications in ornamental plants. Anthocyanins are important constituents for specific colouration to flowers in ornamentals. Ornithogalum species are white in color. In this study, there was no significant difference between the Ornithogalum species and Mg contents.

Conclusions

The bulbs of *O. nutans* species are collected from the natural habitat and exported for ornamental and medicinal purposes in Turkey. In some cases, harvesting from nature is illegal for the species; nevertheless, the populations are in decline and are not cultivated. Therefore, cultivation and breeding studies are urgently needed. Natural distribution area should be taken into consideration when *Ornithogalum* sp. is cultivated. Understanding the relationship between certain soil properties and plant relation for Ornithogalum species, which have an economic value, can act as a guide for florists and botanists for a particular purpose.

Abstract. The objective of this study is to compare the performance of different data fusion techniques for improving the land use/land cover types classification accuracy in Hat Yai district, Songkla province, Thailand. SAR Sentinel-1A and optical Landsat-8 satellites are used as standalone inputs as well as to perform a data fusion based on the resolution merge and LMVM techniques. The four input datasets are classified with a supervised maximum likelihood algorithm and compared against base land cover maps; the results indicate that resolution merge of optical and SAR satellite images can significantly improve the interpretation and classification accuracy of land cover and land use types at the area of interest.
Keywords: *multi-source data fusion, resolution merge, SAR, optical, LULC*

Introduction

Mapping land use/land cover of large cities is a main component of detecting rapid changes from non-industrial to industrial areas. Hat Yai district hosts the fourth largest city in Thailand undergoing rapid and fundamental landscape changes leading to increased urbanization. Therefore, mapping land use/land cover holds an important role in monitoring and assessing environmental changes, land use planning and decision-making activities (Dengsheng et al., 2012). Remote sensing is an effective technology for analysing land use/land cover change in attributes such as crop, forest and agriculture. South Thailand is located in the tropical climatic zone and is frequented by cloud coverage which is an impediment for passive microwave and optical sensors; active microwave sensors, such as Synthetic Aperture Radar (SAR), on the other hand, are weather independent systems. A combination of radar and optical data integrates complimentary information from two fundamentally different systems and improves land use/land cover classification accuracy (Sukawattanavijit, 2015). Image fusion is an active field of research in remote sensing (for a practical guide the reader is directed to Pohl and Genderen, 2016) and other application areas such as medical imaging and night vision (Li et al., 2017).

Several studies have attempted to fuse satellite data. For instance, Sukawattanavijit (2015) classified land cover in Wang Muang district located at the northern part of Saraburi Province, central Thailand by using RADARSAT-2 and Landsat-8 satellite

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31233135

images with wavelet-based fusion. The results showed that the fused image had higher accuracy compared to the single radar data. Dimov et al. (2016) found that the Ehlers fusion is the best technique when looking at crop areas in Fergana Valley in Uzbekistan. In another study Chen et al. (2017) investigate the performance of multi-source remotely sensed data fusion in the context of improving land cover classification; they found that the fused data, which integrated temporal, spectral, angular, and topographic features, achieved a higher mapping accuracy for land cover classification in comparison to the original data sources. Salman et al. (2017) demonstrated that fused dataset provided accuracy 99.6% of land use/land cover classification using machine vision. Similarly, Sukawattanavijit et al. (2017) suggested that genetic algorithms and Support Vector Machines (SVMs) lead to improve classification of up to 95% of different land cover types when fusing SAR RADARSAT-2 data and optical Thaichote (THEOS) data. In another case study, Puttinaovarat and Horkaew (2017) investigated the extraction of buildings from fused satellite images and on the basis of spectral indices instead of reflectance bands. It is worth noting, however, that there are other studies which mention that combining optical and SAR data does not guarantee improvement compared with using single data source for urban land cover classification (e.g. Zhang and Xu, 2018).

The objective of this study is to evaluate the capability of SAR Sentinal-1, optical Landsat-8 and their fusion resulting from two independent techniques for extracting land use/land cover information via supervised classification in Hat Yai district, Songkla province, Thailand.

Experimental

Study area

Hat Yai district is located in South Thailand, situated at 7°1’N latitude 100°28’E longitude, and encompasses the country’s fourth largest city. It covers a total area of approximately 852.796 km^2 and hosts a population of over 800,000 inhabitants. The climatic conditions of this tropical area are hot and humid. The dry season lasts from January to April and the wet season from May to December. Hat Yai is a commercial district with the predominant activities being tourism, fishing industries, agriculture, rubber and oil palm plantations (Appianing et al., 2016). The study area is depicted in *Figure 1*.

SAR data

Sentinel-1A is a SAR satellite providing medium and high resolution imagery at C-band (centre frequency: 5.405 GHz) under all-weather conditions. The C-SAR is useful for land and marine monitoring (ESA, 2016). In this study, a Sentinel-1A image with VV/VH dual polarization was used. The spatial resolution is 5 × 20 m and was acquired at Level-1 Ground Range Detected (GRD) mode with 250 km swath, multilook intensity only and Interferometric Wide (IW) swath mode. The specifications of Sentinel-1A are presented in *Table 1*.

Optical data

The Landsat-8 Operational Land Imager (OLI) image was acquired on 18th March 2015. Landsat-8 has 11 spectral bands with a spatial resolution of 15, 30 and 100 m for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31233135

the panchromatic, multispectral and thermal bands respectively. The specific image was selected based on the relatively low cloud coverage (<10%). Landsat-8 band specifications are presented in *Table 1*.

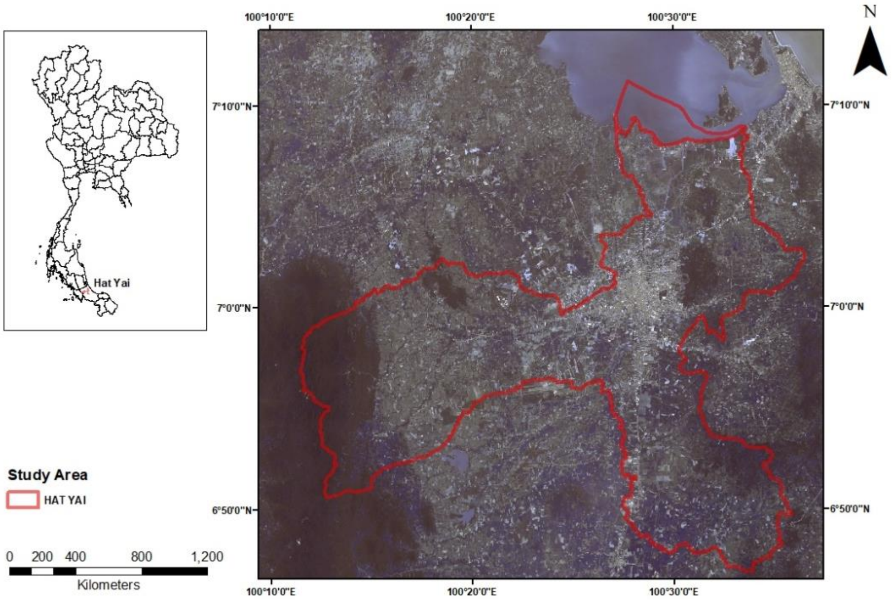

Figure 1. *Map of the location of the study area: Hat Yai district, Songkla province, Thailand*

Table 1. *Sentinel-1A and Landsat-8 OLI image specifications*

Specifications	Sentinel-1A	Landsat-8 OLI
Acquisition date	25th February 2015	18th March 2015
Acquisition time (hh:mm)	23:02 (UTC)	03:33 (UTC)
Imaging mode	IW swath mode	OLI and TIRS
Polarization	VV/VH dual polarization	-
Data product	Level-1 ground range detected mode	Level 1 Terrain
Resolution mode	20 m (full resolution)	30 m (except panchromatic (15 m) and thermal bands (100 m))
Bands	C-band (5.4 GHz)	0.43 - 0.45 (Coastal Aerosol) 0.45 - 0.51 (Blue) 0.53 - 0.59 (Green) 0.64 - 0.67 (Red) 0.85 - 0.88 (Near Infrared NIR) 1.57 - 1.65 (SWIR 1) 2.11 - 2.29 (SWIR 2) 0.50 - 0.68 (Panchromatic) 1.36 - 1.38 (Cirrus) 10.60 - 11.19 (Thermal Infrared - TIRS 1) 11.50 - 12.51 (Thermal Infrared - TIRS 2)

Ground truth data

Auxiliary data were provided by the GEO-Informatics Research Centre for Natural Resources and Environment and the Southern Regional Centre of Geo-Informatics and

Space Technology, Thailand. *Figure 2* depicts the map produced in 2015 (the same year with the two satellite image acquisitions) encompassing land use/land cover classes of urban area, paddy fields, plantations (fruits, palm oil and rubber), forests and lake. Land cover has been classified using high resolution satellite images and ground data.

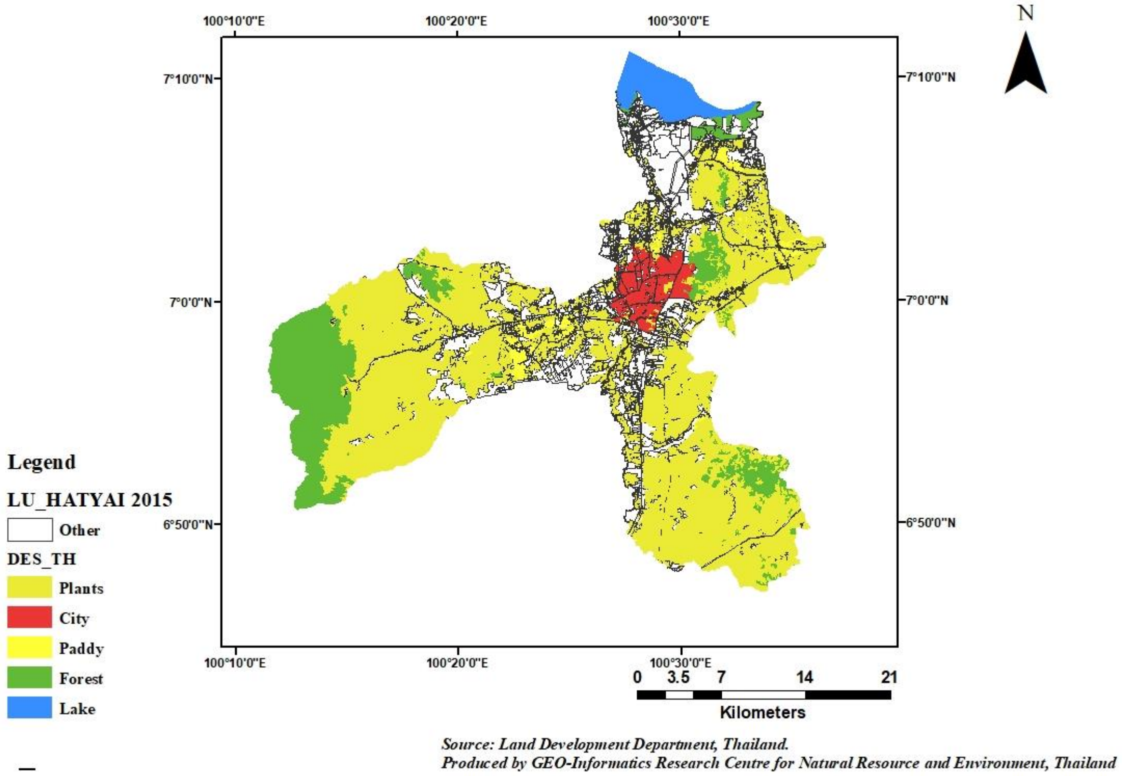

***Figure 2.** The auxiliary data from the Land Development Department, Thailand. (The data were taken with the permission of the Land Development Department, Thailand. Produced by the GEO-Informatics Research Centre for Natural Resources and Environment Southern Regional Centre of Geo-Informatics and Space Technology, Thailand 2015)*

Methodology

Pre-processing

The Sentinel-1A image at Level-1 GRD mode was first calibrated so that the pixel values represent the radar backscatter of the reflecting surface. Subsequently, the multilook of the SAR image was generated by averaging over the range and azimuth resolution cells to improve the radiometric resolution. A GammaMAP 5 × 5 window size was applied to reduce speckle noise. The Shuttle Radar Topography Mission (SRTM) 3sec Digital Elevation Model (DEM) was used for the terrain correction. Finally, the Sentinel-1A backscattered values were converted to decibel (dB) as shown in *Figure 3a*.

The Landsat-8 OLI image was converted from Digital Numbers (DN) to Top-Of-Atmosphere (TOA) reflectance with the ENVI 5.1 software. The Fast Line-of-sight Atmospheric Analysis of Spectral Hypercube (FLAASH) atmospheric correction method was used for retrieving the Top-Of-Canopy (TOC) spectral reflectance from the Landsat-8 OLI image as depicted in *Figure 3b*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31233135

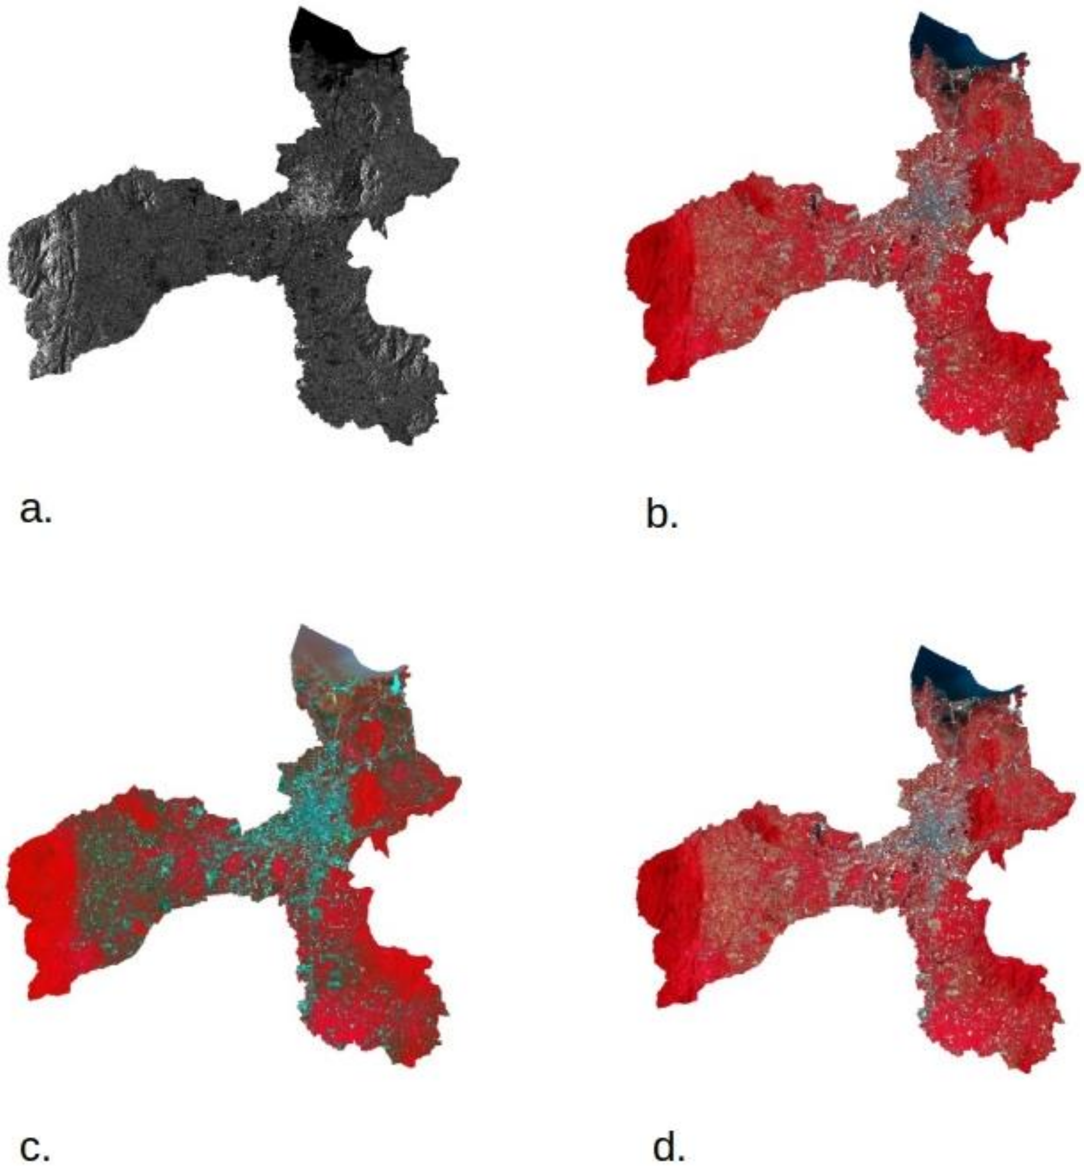

Figure 3. *The four input layers in the classification. a) Sentinel-1A, b) Landsat-8 (5-4-3), c) resolution merge, d) LMVM*

Data fusion

The VV/VH polarized C band Sentinel-1A image and a layer stack of three spectral bands (i.e. 5, 4, 3) from the Landsat-8 image were used for the two fusion methodologies. The Local Mean Variance Matching (LMVM) and the Resolution merge data fusion techniques were applied in this study and the final result is presented in *Figure 3c* and *d*.

The LMVM is a robust algorithm for fusing multispectral and panchromatic images of the same sensor (Nikolakopoulos, 2008). In this study, it was used to integrate the two images (*Eq. 1*), namely a high spatial resolution SAR Sentinel-1 A image with spectral information from a low spatial resolution multispectral Landsat-8 image (Chinsu et al., 2015; Zhang, 2004; Wald et al., 1997; Ranchin and Wald, 2000).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31233135

$$F_{K(i,j)} = P_{(i,j)} \times \frac{\overline{M}_{k(i,j)(w,h)}}{\overline{P}_{(i,j)(w,h)}} \quad \text{(Eq.1)}$$

where:

$F_{K(i,j)}$ = the fused image

$P_{(i,j)}$ = the high spatial resolution images at pixel coordinates (i,j)

$M_{k(i,j)}$ = the low spatial resolution images at pixel coordinates (i,j)

$\overline{M}_{k(i,j)(w,h)}$ = the local means calculated inside the window of size (w,h)

$\overline{P}_{(i,j)(w,h)}$ = the local means calculated inside the window of size (w,h)

The resolution merge combines images of differing spatial resolutions. VV/VH polarized C band Sentinel-1A image and three bands (i.e. 5, 4, 3) of the Landsat-8 multispectral image were merged together into a common image file format. This step prepares the fused multi-sensor data for classifications as in *Figure 3c* (Erdogan et al., 2008; Vaiopoulos et al., 2001).

Image classification

We classified the input layers using the maximum likelihood algorithm in the 5 main land cover / land use classes of the study area; namely forest, paddy rice, plantations, urban, lake, and unclassified. Ground truth and test data were collected from the Land Development Department, Thailand. A cumulatively large training and validation set for each representative class was selected based on the ground truth dataset to train and validate the classifier (*Table 2*).

Table 2. *Training and validation sets size used in the 4 classification scenarios*

Class	Training set (number of pixels)	Validation set (number of pixels)
Lake	1345	920
Forest	569	539
City	264	934
Paddy	1247	464
Plants	232	575

Accuracy assessment

The accuracy of the image classification was assessed against the reference data with a confusion matrix (Congalton, 1991). The main measures of comparison were the overall accuracy and the kappa coefficient of agreement (κ). Overall accuracy is the total number of correctly classified samples (i.e. the diagonal cells in the confusion matrix) divided by the total number of reference pixels. In essence, it presents the probability that a sample will be correctly classified by the algorithm. κ is a measure of the correctly classified samples adjusted to the amount of agreement that could be expected only due to chance. κ utilizes all elements from the confusion matrix by taking into account both errors of commission and omission, and thus provides a more complete picture of the information comprising the confusion matrix than the overall accuracy (Napoleon et al., 2013). The Kappa statistics and the overall accuracy assessment were calculated to compare the accuracy of the classified images.

DOI: http://dx.doi.org/10.15666/aeer/1702_31233135

Statistical analysis

Two statistical moments, namely the mean and the standard deviation (square root of the variance), are used as evaluation indicators to judge on the ability to use the two fusion image techniques. A low standard deviation is regarded as an indicator of higher class separability (Napoleon et al., 2013).

The mean is obtained by dividing the sum of observed values by the number of observations, N as in *Equation 2:*

$$\bar{X} = \frac{\sum fX}{N} \quad \text{(Eq.2)}$$

where f is the probability of the occurrence of the value of X.

The standard deviation is a measurement of the variation or dispersion from the average. A low standard deviation indicates that the data points tend to be very close to the mean (the so called expected value); a high standard deviation indicates that the data points are spread out over a large range of values. The standard deviation is calculated according to *Equation 3:*

$$Std = \sqrt{\frac{\sum(X - \bar{X})^2}{N}} \quad \text{(Eq.3)}$$

where:
Std is standard deviation,
X is sample,
$\bar{X}$ is sample mean,
N is number of score in sample.

Validation

Validation was engaged to assess the performance of this model. Lu et al. (2016) stated that R^2 is commonly used to validate a model. Two groups of data were chosen, namely observed and predicted. Observed data were derived from land-use ground truth data (Land Development Department, Thailand) and predicted data were obtained from the resolution merge image classification. We selected 5 land use types (city, forest, lake, paddy, plants and others) from observed data and resolution merge image classification for the validation. The linear regression was estimated to validate the model and the reliability was judged upon the high R^2.

Results and discussion

The results for the standalone classification of the Sentinel-1A SAR image indicate an overall accuracy of 58.50% and a kappa coefficient of 0.48 while for the Landsat-8 optical image an overall accuracy of 67.16% and a kappa coefficient of 0.59 is observed (*Table 3*). The individual SAR image is able to clearly extract the water class (i.e. lake). However, the extraction of other classes is not so accurate; especially at the hilly parts of the study area misclassifications occur for the vegetation classes as the forested,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31233135

plants and largely the urban areas are underestimated. Moreover, there are high overlaps with paddy and plants classes. The reason might be attributed to the fact that the speckle noise and the mixed pixel problem cannot be entirely eliminated. The Landsat-8 optical image provides a better representation of the forest class in comparison to the Sentinel-1 SAR image. However the urban class is overestimated in comparison to the base map. In the case of the classification of the fused products, the resolution merge provided an overall accuracy of 79.75% and a kappa coefficient of 0.75 which is higher than the individual satellite images while LMVM provided an overall accuracy of 59.84% and a kappa coefficient of 0.52. LMVM classification includes many unclassified pixels and its overall accuracy of 59.84% and kappa coefficient of 0.52 are similar to the performance of the standalone Sentinel-1A classification (*Table 3*). LMVM has been suggested as a robust algorithm when fusing multispectral and panchromatic images (Nikolakopoulos, 2008), however, in our case of merging multi-source data it does not offer any significant advantage. The thematic maps of the classification results are presented in *Figure 4*.

Resolution merge resulted to the most accurate representation with producer accuracy of the lake area being 83.91 while the user accuracy is 99.61%. The producer accuracies of forest, city, plants and paddy areas are 72.17%, 86.94%, 62.09% and 87.72%, respectively while the user accuracies for the above-mentioned classes are 99.49%, 88.65%, 64.67% and 57.73%, respectively. Apart from the highest classification accuracy, resolution merge is the result with the best visual agreement with the base map (*Fig. 2*). Our findings are in agreement with other studies which have concluded that the classification accuracy is increased after fusing data from separate satellite sources in comparison to stand-alone classification of a images from a single satellite sensor (e.g. Chen et al., 2016).

From overall classification of the Landsat-8, resolution merge and LMVM classified images we found that lake and forest recorded almost 100% classification accuracy while urban, plants and paddy showed the lower percentages accuracies of land use and land cover classes. This might be explained by the fact that the forest in dominated by dense evergreen and high-density trees. Plants and paddy were confused between each other and, consequently, this decreased the reliability of their accuracies when compared to other land use and land cover types classified (Nwaogu et al., 2017; Johnson et al., 2016). Another reason, might be that some areas from the secondary data were attributed another class in comparison to the classification of the satellite images in land use types (lake, forest, city, plants and paddy).

Table 3. *The overall classification accuracy of the classified images. PA and UA refer to producer's and user's accuracy, respectively. All values are in percentages (%)*

Land cover types	Sentinel-1A		Landsat-8		Resolution merge		LMVM	
	PA	UA	PA	UA	PA	UA	PA	UA
Lake	100.00	100.00	65.76	100.00	83.91	99.61	44.89	100.00
Forest	31.17	36.21	61.22	100.00	72.17	99.49	52.50	100.00
City	27.73	59.13	91.86	77.58	86.94	88.65	89.94	88.05
Plants	67.65	37.33	51.13	75.58	62.09	64.67	41.57	80.74
Paddy	58.62	49.19	46.98	39.21	87.72	57.73	60.13	42.92
Overall accuracy	58.50		67.16		79.75		59.84	
Kappa coefficient	0.48		0.59		0.75		0.52	

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

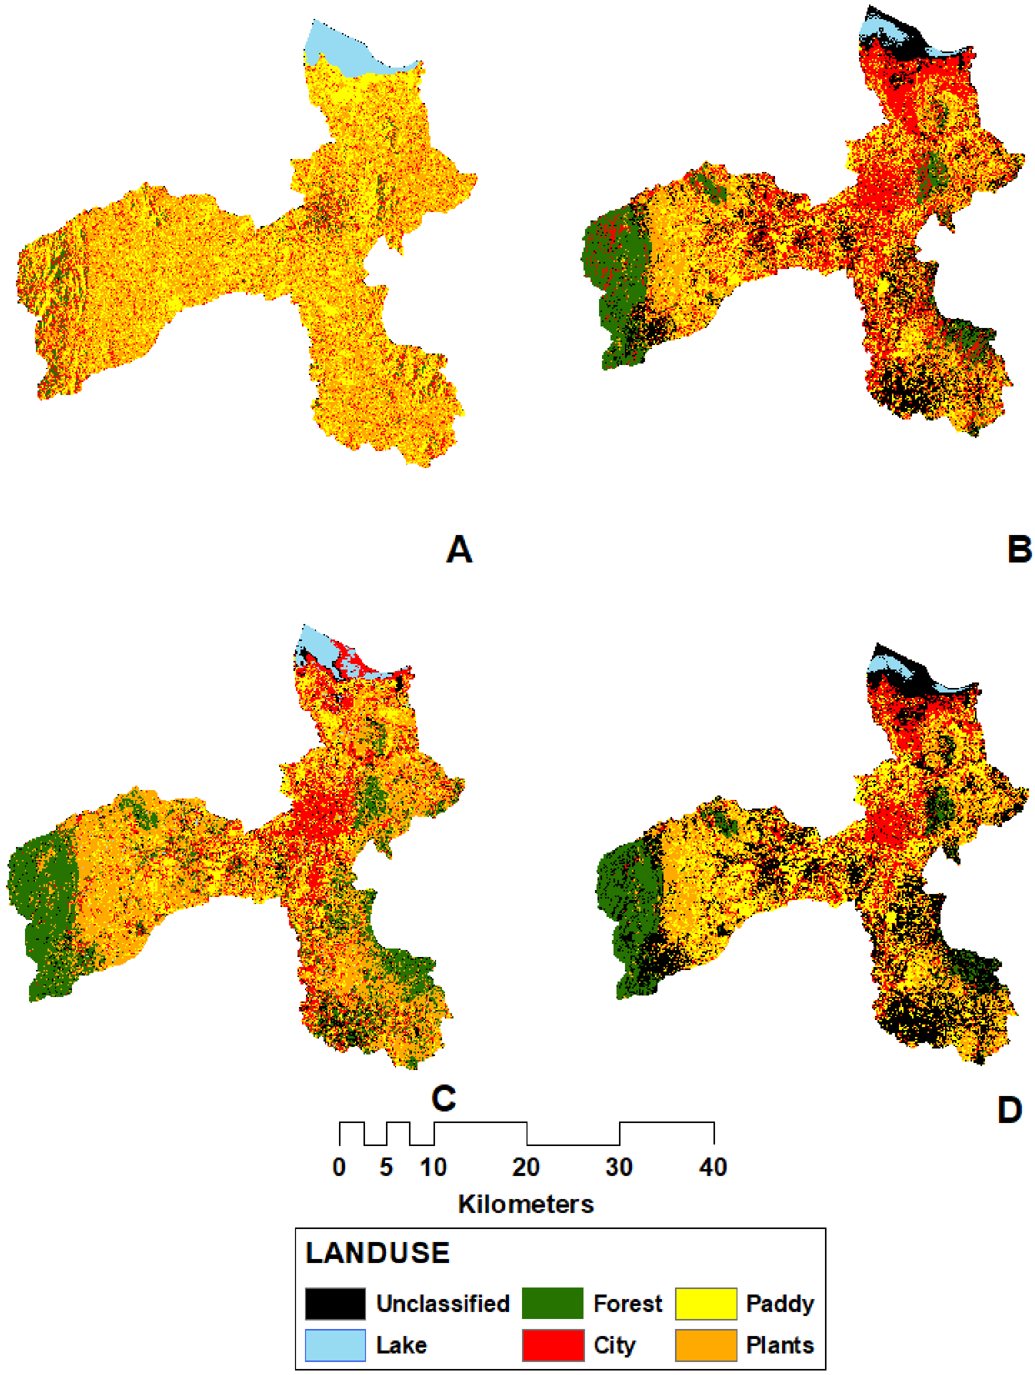

Figure 4. *Thematic maps produced from the maximum likelihood classification of the four input datasets: Sentinel-1A (A), Landsat-8 (B), Resolution merge (C) and LMVM (D)*

From the statistical analysis of the mean and the standard deviation as presented in *Table 4,* it is obvious that the highest standard deviation is 2.13 for Sentinel-1 and followed by 1.76 for Landsat-8, 1.72 for LMVM and 0.94 for resolution merge. As a good performance (i.e. higher class separability as suggested by Napoleon et al., 2013) is indicated by a low standard deviation, it is clear that resolution merge fusion technique perform the best in this study.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31233135

Table 4. *The mean and standard deviation of the 4 input layers*

Image	Mean	Standard deviation
Sentinel-1A	1.62	2.13
Landsat-8	1.39	1.76
Resolution merge	2.75	0.94
LMVM	0.98	1.72

The validation exercise resulted to *Table 5* and *Figure 5* and suggests that the correlation between the observed and predicted model gave a moderate R^2. This means that approximately 52% of the observed values could be explained by the predicted model. The linear regression analysis and the equation describing it are presented in *Figure 5,* where y is predicted value and x is observed value. The reason R^2 value resulted to moderate level is because the land use map from the predicted model were indicated otherwise as in *Table 5*. For example, the land use type of “others” was classified around 23.22% while predicted resolution merge resulted to just 48% in this case.

Table 5. *Statistics of the observed and predicted model for the resolution merge input*

LU	Observed (area km^2)	Observed (%)	Predicted resolution merge (area km^2)	Predicted (%)
City	26	3.16	154	19.09
Forest	112	13.89	161	19.94
Lake	28	3.40	22	2.77
Paddy	15	1.86	115	14.19
Plants	441	54.47	308	38.04
Others	188	23.22	48	5.98

Conclusions

The present study classified land use in Hat Yai in the year 2015 using two schemes; first the dual polarization Sentinel-1A and the Landsat-8 images standalone, therefore based solely on the SAR or optical information respectively; second, the Sentinel-1A was fused with the Landsat-8 image in an attempt to combine complimentary information acquired from the SAR and optical sensors. Resolution merge and LMVM techniques were used to fuse images in the latter case. The maximum likelihood supervised classification algorithm was used for the classification of the four experiments. The outcome VV/VH dual polarization image did not result to confident results. However, when combining an optical Landsat-8 image with a dual polarized (VV/VH) Sentinel-1A image, the results indicated that the images conserved the spectral characteristics in the original Landsat-8 data and also improved the spatial information. The fusion of a Sentinel-1A dual polarization image with a Landsat-8 image with the resolution merge technique outperformed the LMVM technique according to calculated statistical results. Our study strongly suggests that the most accurate and realistic classification scheme tested is the resolution merge fusion of the optical and SAR data. We showcased that the synergistic use of SAR and optical satellite data greatly improve the land cover and land use classification accuracy, in accordance with other studies in the literature (e.g. Otukei et al., 2015). In the future, it is recommended to consider other land use and land cover areas in the analysis and also use other SAR satellite images to investigate the impacts of different SAR input in the fusion outputs. In addition to that, image classification processes could be applied to evaluate the impacts of fusion algorithms over land use map production.

(Received 3rd Dec 2018; accepted 8th Feb 2019)

Abstract. Soils are natural resources that require preservation and good management due to their ever-changing structure. Among the soil management applications, organic material amendments are known to be the most practical soil management methods in the improvement of the chemical and physical properties of soils. Organic matter amendments are used to preserve water in coarse-textured soils and arid region soils. This study was carried out at Bingol University Research laboratory located in eastern Turkey. In the study, different doses of soil organic matter (SOM) including walnut sawdust (WS), earthworm manure (EM) and farmyard manure (FM) were applied to sandy soils to measure their effects on the saturated hydraulic conductivity (K*sat*) and available water-holding capacity (AWC) of the soils. Compared with the control application, the SOM amendments decreased the hydraulic conductivity of the sandy soils ($p < 0.01$). A comparison with the control application showed that the 8% WS application reduced the hydraulic conductivity of the soils by 51%, followed by the FM application with 35% and EM application with 39%. On the other hand, the SOM amendments increased the available water-holding capacity of the soils when compared with the control application ($p < 0.01$). The application with the most notable effect was determined to be the 1% WS application.
Keywords: *soil properties, soil management, vermicompost, agricultural wastes, soil water*

Introduction

In soil systems, saturated hydraulic conductivity (Ksat) is related to multiple soil properties and thus, is of great importance for engineers, scientists, and agriculturalists (Lal and Shukla, 2004; Gamie and De Smedt, 2018). Depending on the number and diameter of the pores in the soil, the hydraulic conductivity of a soil is a function of certain properties such as bulk density, porosity, pore size distribution and water-holding capacity (Kessler and Oosterbaan, 1974; Varallyay, 2002; Hillel, 2003).

Sandy soils are widespread around the world and have a sand content above 50%. According to the United States Department of Agriculture (USDA, 2010), they are classified as Entisols and cover 18% of the Earth's land surface. Sandy soils are described as soils comprising rocks and mineral particles and containing rocks such as limestone, quartz and granite. The shape, size, degree of weathering and geological origin of the mineral soil components can strongly affect the hydrophysical properties of the soil, especially its water-holding capacity and hydraulic conductivity (Martens and Frankenberger, 1992; Brouwer and Anderson, 2000; Cousin et al., 2003). Due to their low water-holding capacity and high permeability, soil conditioners have attracted attention in recent years for their use in soil improvement (Al-Omran and Al-Harbi, 1997; Zibilske, 1998). Various studies carried out using soil conditioners have reported aggregate development, increased water-holding capacity and decreased infiltration and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31373146

saturated hydraulic conductivity (Al-Omran et al., 1987; El-Shafei et al., 1994; Choudhary et al., 1995).

The organic soil materials used as conditioners contain an array of compounds such as proteins, fats and carbohydrates and high-molecular weight humic and fulvic acids. Today, many mineral and organic soil conditioners are used to improve the physical and chemical properties of problem soils. The increase in the water-holding capacity and decrease in the infiltration and saturated hydraulic conductivity are more evident in coarse-textured soils than in fine-textured soils.

Several studies have been carried out to determine the effect of mixing organic materials with soils on the physical properties. In their study, Unger and Stewart (1974) determined that organic matter amendment in clay soils increased the aggregate stability and soil permeability. In a similar study, Zebarth et al. (1999) reported that the most important effects of organic materials on soils were the decrease in the bulk density and increase in the water-holding capacity, aggregate stability, hydraulic conductivity and permeability. In their study, Nyamangara et al. (2001) investigated the effects of different doses of a chemical fertilizer and farmyard manure on the aggregate stability and water-holding capacity of soils. Their results showed that aggregate stability and water-holding capacity increased with the application of farmyard manure compared with the control and other applications. Asghari et al. (2009) applied 25 g/kg cattle manure to sandy loam soil and determined that, compared with the control, the application significantly increased the number of micropores and significantly decreased the number of macropores ($P \leq 0.05$) and correspondingly, led to an increase in the water holding-capacity. Eusufzai and Fujii (2012) reported that the application of compost, rice straw and sawdust to clay loam-textured soil increased the water-holding capacity, hydraulic conductivity and pore size of the soil.

The study aims to improve the physical properties of sandy soils and thus, the chemical properties of the soils were excluded from the study. There were many studies that aimed to determine the effects of worms on soil (Schrader and Zhang, 1997; Feng et al., 2001; Topoliantz et al., 2002; Panicker et al., 2007), but there is still a lack of information. The number of the studies investigating the relationship between earthworm manure and soil-water is limited. The studies have generally focused on the effects of earthworm population in manure on soil properties. On the other hand, it is not exactly known how food wastes (eg walnut shells) that are thrown or mixed after use have affected soil properties. This study investigates the effects of the application of different ratios of walnut sawdust (WS), earthworm manure (EM) and farmyard manure (FM) to sandy loam soil on the hydraulic conductivity (Ksat) and available water-holding capacity (AWC) of the soils.

Materials and method

The study was carried out under laboratory conditions to reduce the effects of environmental factors (climate, the effects of terrestrial and subterranean organisms, etc.) and prepare the conditions for the incubation of SOM. The study was conducted under laboratory conditions. During the study, mean humidity was 65 ± 5% and mean temperature was 25 ± 3 °C. The soils used in the study were collected from the Research and Application Farm of the Bingol University, Bingol, Turkey, from the depth of 0-30 cm. The general properties of the soil were determined by Demir (2016) and are given in *Table 1*. The organic matters (SOM) comprising walnut sawdust (WS),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31373146

earthworm manure (EM) and farmyard manure (FM) were procured from a commercial agricultural company (https://www.ekosol.net.tr; http://www.kabukcu.com.tr). The general properties of the material were determined by the company and are given in *Table 1*.

Table 1. *The general properties of the materials*

*1:2 H_2O, WS: Walnut shell, EM: Earthworm manure, FM: Farm manure, EC: Electrical conductivity, CEC: Cation exchange capacity, C:N: Rate of carbon on nitrate

The soils were analyzed by Demir (2016) and the size distribution of the sand, silt and clay fractions of the soils was determined using the Bouyoucos hydrometer method (Gee and Bauder, 1986). The pH and electrical conductivity were measured in accordance with Mclean (1982) and Rhoades (1982) under saturated soil conditions. The organic matter content of the soil was determined following the Smith Weldon method (Nelson and Sommers, 1982). Soil lime content was determined using a Scheibler Calcimeter by following the method proposed by Nelson (1982). The cation exchange capacity was determined using sodium acetate in accordance with Chapman (1965). The bulk density values of the soils were determined by following the method proposed by Blake and Hartge (1986).

Preparation of the study materials

The SOMs were prepared by sieving with a 0.5-mm sieve and mixed with the soils at ratios of 1%, 2%, 4% and 8% on a weight/weight (w/w) basis. SOM application rates were determined according to the farmer practices (between 0 and 8% w/w) in Turkey. The mixtures were prepared in three replications and added to the test containers. In addition, a non-SOM-containing mixture was prepared to minimize the errors that may occur during the experiment. The test containers were made of plastic (pot volume: 22 L; top diameter: 420 mm; height: 310 mm). The mixtures in the test pots were irrigated under laboratory conditions at the level of field capacity and incubated for three months (*Fig. 1*). The pots were irrigated at 3-day intervals to maintain the soil moisture content at around field capacity. For this purpose, irrigation was carried out at a certain rate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31373146

determined depending on the moisture hold by soils at field capacity (pF 2.54). The quality of the irrigation water was classified as C1S1 in accordance with the US Salinity Laboratory (USSL, 1954).

Figure 1. *Incubation of organic matter-soil mixture under laboratory conditions*

Hydraulic conductivity and water-holding capacity

The hydraulic conductivity (Ksat) of the soils under saturated conditions was determined using a permeameter by following Klute (1965). The Ksat was calculated using *Equation 1:*

$$Ksat = \frac{aL}{At}\ln\left(\frac{h0}{h1}\right) \quad \text{(Eq.1)}$$

Here, Ksat represents the hydraulic conductivity (cm/s), a represents the cross-sectional area of the burette (cm^2), A represents the cross-sectional area of the soil sample (cm^2), L represents the column length of the soil sample (cm), h0 represents the initial water height (cm), h1 represents the final water height (cm), and t represents the time between the start and end (s).

The available water-holding capacity and the moisture content at the field capacity (FC) and wilting point (WP) of the soils were measured using a pressure plate apparatus Cassel and Nıelsen (1986). Using a pressure membrane device, the field capacity of the undisturbed soil samples was determined using their moisture content at 1/3 atm and the permanent wilting point of the disturbed soil samples was determined using their moisture content at 15 atm.

The available water-holding capacity of the soils was calculated using *Equation 2:*

$$AWC = FC - WP \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31373146

Here, AWC represents the available water-holding capacity (%), FC represents the moisture content at field capacity (%) and WP represents the moisture content at wilting point (%).

The variance analysis of the results was performed using the SPSS software program (SPSS, 2015).

Results and discussion

The WS, FM and EM applications were determined to affect the hydraulic capacity of the sandy soils (*Table 2*). Compared with the control application, the SOM amendments reduced the hydraulic conductivity of the sandy soils ($p < 0.01$). The lowest mean hydraulic conductivity values were obtained with the WS and EM applications. The 8% dose of the SOM applications was more effective than the other doses. Compared with the control application, the 8% WS application decreased the hydraulic conductivity by 51%, followed by the FM application with 35% and EM application with 39%. Considering the average manure application dose, hydraulic conductivity was determined to decrease with increasing doses.

AWC: Awailable water content, WS: Walnut shell, EM: Earthworm manure, FM: Farm manure, SOM: Soil organic matter

The hydraulic conductivity of the sandy soil was also affected by the interaction between SOM and dose ($p < 0.01$). Within this context, the lowest K*sat* value was obtained with the 8% WS application. In other words, the 8% dose of the WS application was determined to decrease the hydraulic conductivity by 51%. The negative correlation between K*sat* and soil pore size results in increased water flow rate. The filling of large soil pores with fine organic materials leads to reduced K*sat* (Esmaeelnejad et al., 2017). Pulat et al. (2018) reported that the application of 1% biopolymer solution to a 70% sand-containing soil sample resulted in a 25-fold decrease in the hydraulic conductivity. In the same vein, Zhang et al. (2016) determined that the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31373146

application of ground biochar particles to sandy soil decreased the hydraulic conductivity and attributed the decrease to the destruction of the pore structure of the sandy soil by the materials added to the soil.

Addition of organic matters to soils is one of the most commonly used methods to increase the water-holding capacity of soils in soil management applications. Water-holding capacity is defined as the amount of water retained by soils for the use of plants. This amount is largely determined by the texture of the soil and to a certain degree, by the structure and organic material content (Soıl Management Guıde, 2008). *Table 3* shows the effects of WS, FM and EM applications to sandy loam soil on the water-holding capacity. The SOM amendments resulted in increased water-holding capacity in comparison with the control application ($p < 0.01$). The results of the study showed that the 1% WS application was the most effective application, while the 1% FM application had the lowest effect. In the study, both the differences between the averages of the SOM varieties and the averages of the treatment doses were statistically significant. *Table 3* shows that the averages of the application doses were in the same significance group, while the differences between the averages of the SOM varieties were in different statistical significance groups. The data indicated that the WS application resulted in a higher increase in the AWC of the soils than other SOM applications.

Table 3. *The effect of the organic materials on the available water-holding capacity of the soils*

AWC: Available water content, WS: Walnut shell, EM: Earthworm manure, FM: Farm manure, SOM: Soil organic matter

Considering the effect of the different doses of SOMs on the water-holding capacity, the highest effect was obtained with the 1% dose of the WS application, 2% dose of the FM application and 8% dose of the EM application. Thus, the effect of the dose varied depending on the characteristics of the SOM. Here, the most important issue is the effect of the organic matter on the moisture content both at field capacity (pF:2.54) and permanent wilting point (pF:4.2). When organic matters have the same effect at both levels, they do not have a significant effect on the water-holding capacity. However, when they have a higher effect at the field capacity than at the wilting point, they

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31373146

positively affect the water-holding capacity. Whether organic matter increases the water-holding capacity is an ongoing debate among many researchers. According to Hudson (1994), there is a positive correlation between the organic matter content and water-holding capacity of sandy soils (r = 0.79). Furthermore, Karhu et al. (2011) reported an 11% increase in the water holding capacity after biochar application to soil. Mınasny and Mcbratney (2018) analyzed the results of a total of 60 studies and reported increasing water-holding capacity with increasing amounts of organic carbon in soils and determined that this effect was more evident in sandy soils. The organic matters' retention of higher amounts of water than sandy soils is an expected outcome. This is attributable to the higher pore number of organic materials than that of sandy soils. In addition, the capillarity of organic materials is much higher than the capillarity of sandy soils. Indeed, the results of several studies agree with this theory. In various studies investigating the improvement of the water-holding capacity of soils, organic materials of different origins were used (farmyard manure, legume leaves, rice stalk, biochar) and the results have revealed that the use of organic materials led to increased available water-holding capacity (Yılmaz and Alagöz, 2008). Agreeing with previous studies, in the study, walnut sawdust was determined to increase the water-holding capacity of sandy soils.

Conclusions

The sustainable use of soils depends on knowing and preserving their properties. Soil organic matters, which have positive effects on various physical and chemical properties of soils, are also among the soil properties that require preservation and improvement. In the study, the application of walnut sawdust, earthworm manure and farmyard manure to sandy soil reduced the hydraulic conductivity of the soil. Moreover, the application of the materials to the soil increased the available water-holding capacity. In conclusion, the outcomes of the study can be summarized as follows:

1. The experiments showed that the application of the increasing doses of walnut shell, earthworm manure and farmyard manure to sandy-textured soil decreased the hydraulic conductivity.
2. Among the three organic waste types, the highest decrease in hydraulic conductivity was obtained with farmyard manure. In addition, in all applications, the highest decrease in hydraulic conductivity was obtained with the dose of 8%. This is of significance in terms of water conservation in sandy soils and especially in arid-region soils.
3. Another outcome of the study was the increased water-holding capacity due to organic matter application to soil. Furthermore, walnut sawdust increased the water-holding capacity more than other materials.
4. In this study, it is concluded that walnut shell waste decreases hydraulic conductivity in sandy soils and increases water holding capacity.
5. The use of the organic wastes that we use in our daily lives, such as walnut shell, in the improvement of the physical properties of problem soils should be investigated. If these materials are deemed suitable for this purpose, they should be used in soil management applications. They can especially be used effectively in combating erosion, which is the greatest soil problem worldwide.
6. The results of the study showed that earthworm manure improved the hydraulic conductivity and water-holding capacity of soils. However, its production in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31373146

limited amounts and high-cost restrict its use in large agricultural areas. In these areas, solely increasing the earthworm population in the soil layer will prove more beneficial. In the current circumstances, earthworm manures can be used in ornamental plant breeding and greenhouses.

(Received 5th Dec 2018; accepted 4th Feb 2019)

Abstract. In this study, the recreational opportunities, which were created by the Shah Goli Park for the users in terms of its functionality, having a historical and unique characteristic, which is located in Iran, Tabriz, are analyzed. Accordingly, its availability for the local people is examined, as well. The data collection tool is in the form of a questionnaire. The objective of this questionnaire is to define the park availability factors for those, who visit the Shah Goli Park. The options with regards to the availability of the park were on socialization, physical activity, nature involvement and relaxation. The respondents were asked to address questions in order to show their preferences within the scope of a 5-point Likert scale (1 = Strongly disagree, 2 = Disagree, 3 = Don't know, 4 = Agree, and 5 = Strongly agree) and the park's availability preference were measured using 14 items. Survey-analysis and questionnaire processes of the study were carried out in July-2018. The gathered data was subjected to an analysis by utilization of normal statistical methods within SPSS version: A set of park availability items were defined using the factor analysis, in order for designating the main and underlying factors, followed by a group mean comparison (t-test) in order to identify the differences between the demographic information and availability factors.
Keywords: *land use, recreation area, open-green spaces, sustainability, historical parks*

Introduction

Parks and open spaces, offering significant social and environmental functions, are valued leisure and amenity resources in cities. Urban parks are critical components within the metabolism of cities as well as the core scenes for open-air leisure communal activities. Historically, the functions of urban parks have been connected to leisure and aesthetics, but with the change of the surroundings and necessities of urban centres, leisure now includes sport activities, with the consequent implementation of fitness equipment, jogging tracks and sport courts (Almidia et al., 2018). Also, urban parks play a unique and indispensable role in providing public spaces and recreation opportunities for urban populations (Chan et al., 2018). As one of the most complex processes, overcrowding and unplanned growth are experienced, which raises concerns on the cities' sustainability, thus questioning how sustainable cities could be achieved. The objective of this study is to identify the potential advantages of historical urban green spaces with regards to the urban sustainability concept. In consequence, we consider sustainability concept, along with sustainable development, heritage, urban green spaces and quality of life and well-being as the main outline of the study, which are discussed in the following chapters. Urbanization processes, gathering pace with the growth of industrialization, has led the transformation of living areas of people from rural to urban. Today, in many of our large cities, witnessing the urbanization and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31473163

industrialization movements; the structural density, increasing in parallel with the population growth, along with other unplanned developments, improper selection of settlement areas, has led the connection of urban with the rural to be ruptured, thus causing the open and green spaces in urban areas to diminish (Gürbüz and Yılmaz, 2017). Open and green spaces, in other words "parks", having the potential to freshen up the people, instill a new dynamic, particularly providing the opportunity to be involved in recreational activities in megacities, facing with physical, social, biological and environmental problems, are deemed required (Yılmaz et al., 2007).

The phenomenon "city" can be described not only as a physical, but also as social, political, economical and cultural production areas (Altuntaş, 2012) – a dynamic concept evolving from simple to complex, bearing various meanings from past to date (Topal, 2004). In this context, cities are the complex structures, comprising in the interface of a number of different subjects like land use, demographical qualifications, social and cultural structure, economical characteristics, historical and environmental subjects. In a highly dynamic and variable urban system, it is quite challenging to complete the designing and planning processes one level having the ability to come up with solutions against problems. In this system, the first time the problems became a current issue concerning the urban areas that change in time based on the socio-economical and cultural structure of the society, characterized as the complete areas used by those urbanized on the urban land and where the urban-related events occur, and where the social or personal needs are met, was in the second half of 20th century, leading the physical and social problems to come to the forefront (Oktay, 2007). However, each and every characteristic is directly related to those urbanized in and of itself, which turns into a system running after being planned and designed as a whole, focusing on people (Akyol, 2006).

Urban spaces

More than half of the world's population nowadays live in cities. With more people coming to live and work in cities, urban public open spaces become even scarcer. Urban open spaces, such as squares, green spaces, or parks can provide environmental, ecological, social and economic benefits to cities and are indispensable for healthy urban living (Chen et al., 2015).

The first communities started to put down the roots in naturally enriched areas, along with those that were protected against natural powers, which were selected to meet their nutrition and accommodation requirements, as the most fundamental needs of people. Where people started to feel committed to an area, they also started to intervene the physical environment more, which emerged the need to build relatively more permanent structures. Having been experienced for centuries, this matter has reached to its peak point in today's world and led the emergence of modern cities (Özbilen, 1991; Çınar, 2008). Yet, increasing human population and rapid development of urbanization led to the destruction of nature and green areas (Yazıcı, 2015; Özdemir, 2007). In the case of the urban environment, it is both possible to define the city as one single ecosystem and to see the city as composed of several individual ecosystems, e.g. parks and lakes. Bolund and Hunhammar (1999) identify seven different urban ecosystems which we call natural, even if almost all the areas in cities are manipulated and managed by man. The ecosystems comprise of street trees, lawns/parks, urban forests, cultivated land, wetlands, lakes/sea, and streams (Bolund and Hunhammar, 1999). Rogers' reports that there is a continuing trend towards urbanization, both in Britain (in 1991, over 80% of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31473163

the population lived in towns and cities of over 10,000 people) and world-wide (today nearly 50% of the world's population live in urban settlements) (Thompson, 2002). Open spaces such as parks, playgrounds and plazas have been criticized in the past as a largely failing to serve their intended uses and users. Non-use of parks, vandalism, and outdated facilities are examples of problems commonly identified with urban open spaces. Indeed, urban open research originated from public awareness of the social failure of many urban open spaces (URL 1, 2018).

Urban green spaces play a remarkable role to reduce bad consequences of the rapid rate of urbanization (Li et al., 2017). Green spaces and other nature-based solutions offer innovative approaches to increase the quality of urban settings, enhance local resilience and promote sustainable lifestyles, improving both the health and the well-being of urban residents. Parks, playgrounds or vegetation in public and private places are a central component of these approaches and can help to ensure that:

- Urban residents have adequate opportunities for exposure to nature;
- Urban biodiversity is maintained and protected;
- Environmental hazards such as air pollution or noise are reduced;
- The impacts of extreme weather events (heatwaves, extreme rainfall or flooding) are mitigated;
- The quality of urban living is enhanced;
- The health and well-being of residents are improved (WHO, 2018).

There is evidence that rural residents experience a health disadvantage compared to urban residents, associated with a greater prevalence of health risk factors and socioeconomic differences compared to urban and suburban populations, along with the evidence of a health disadvantage associated with living in rural areas. Research in Canada has identified higher mortality rates, decreased life expectancy, greater incidence and prevalence of morbidity, and poorer self-reported health status in rural populations. For example, life expectancy at birth is at least 2 years less for men in rural areas compared to urban areas and the risks of death from circulatory disease or respiratory disease are as much as 10% higher in rural areas. This health disparity may be the result of differences in health risk factors, including health behaviours and socioeconomic status (SES). Additionally, differences in activity patterns between urban and rural populations may potentially lead to differences in exposure and risk(s) related to environmental contaminants, further contributing to the health disparity (Matz et al., 2015).

Urban parks

For the recreational life and outdoor activities of people, urban parks play a critical role. Parks are generally used by people in urban areas. As a result of the outdoor environment complexity, scarcely any steps have been taken to understand the impact of thermal environment on how people use the outdoor spaces (Thorsson et al., 2004; Çınar, 2008; Polat and Güngör, 2013). The sustainability and regeneration strategies of cities essentially focus on man-made and built components within the urban environment, when compared, attention to the natural components and urban structure's green spaces are still limited (Chiesura, 2004). However, it is discussed that the urban parks and open green spaces are of a strategic significance within the scope of the quality of our increasingly urbanized society's life. As a matter of fact, increasing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31473163

empirical evidence shows that the presence of natural assets (i.e. urban parks and forests, green belts) and components (i.e. trees, water) within urban contexts contribute to the quality of life under quite a lot of manners. Additionally, critical environmental services like air and water purification, wind and noise filtering or microclimate stabilization, the natural areas provide social and psychological service that are of vital importance with regards to the liveability of modern cities, along with the well-being of urban dwellers. Park experience bears the potential to reduce stress, enhancing contemplativeness, rejuvenate the city dweller, thus providing a sense of peacefulness and tranquility (Kaplan, 1983; Chiesura, 2004). Parks are important recreation areas within open and green area system (Onsekiz and Emür, 2008; Aksoy and Akpınar, 2012). Providing the societies with the opportunity to perceive the nature itself, while being used for recreational purposes for centuries, the parks have gained a gradually increasing importance and value, particularly in urban environments. Formed based on cultural values, political and socio-economical structure, the urban parks have taken its form with social changes thanks to aforementioned characteristics, thus acting as a reflector for them, as well (Kurtaslan, 2017).

Urban parks constitute an important place of leisure and recreation for city residents. They are also important because they tend to be among the few places that offer urban dwellers opportunities for contact with nature and vegetation (Mahrous et al., 2018). Urban parks offer multi-dimensional urban ecosystem functions as well as spaces for human-environment connection (Chan et al., 2018). Urban open-green spaces provide many advantages like creating areas for recreational activities, reducing the air pollution, balancing the atmospheric oxygen and carbon dioxide rate, regulating the micro-climate, minimizing the floods, providing shielding against noise and wind, creating living space for wild-life, contributing positively in physical and mental health, etc. (Waterman and Wall, 2009; Yazıcı, 2015). People in industrialized countries spend on average less than 10% of their time outdoors (Lee and Kim, 2015). One vital role that urban parks play is providing space for the expression of diversity, both personal and cultural; this raises issues of democratic provision for and access to public open space. It suggests, inter alia, that the role of the urban street as public space may need to be re-thought. The social and cultural values of open space include attitudes towards nature and the desire for connection with it, as well; contemporary understandings of ecology offer new insights into ways to serve both human needs and the broader ecological framework of urban open space structures (Thorsson et al., 2004)

Urban parks are valuable urban green areas serving for citizens to keep away from the stressful city life and relax thanks to its social and environmental functions. For this reason, the importance of urban parks is obvious with its advantages like providing an aesthetical view, minimizing the noise, clearing the air, along with its micro-climate affect and pollution control (Lam et al., 2005). Urban parks are green areas that keep people out of the intense and boring impact of a city, while providing various recreational benefits (Zaloğlu, 2006). Urban parks can also be described as open-green spaces, created with the combination of natural and cultural concepts towards meeting the active and passive recreations needs of those urbanized (Kızılaslan, 2007). Planning and management of urban parks are of significance for urban development. Urban parks possess critical ecological, social and economical functions. Therefore, social life styles, values, attitudes towards the nature and sustainability will increase the demand on urban parks in the future. Parks and open areas should not be deemed as luxury within the city (Loures et al., 2007). Urban parks are public service areas that are of crucial importance in re-establishing the ruptured relations of people with the nature itself, developing as a condition to urbanization within the complex urban organization, along with undertaking various functions (Kızılaslan, 2007).

Urban park standards

The factors that designate the standards required for the park areas in line with the life style of our time can be summarized as follows:

- Population,
- City size,
- Geographical location,
- Climate,
- Distance and density of use (Polat, 2006).

According to Oğuz (1998), park and green area sizes vary depending on every country, settlement and their needs. The need for green area increases as directly proportional to the population and structure.

The changes of open-green spaces are shown in *Table 1* (Özkır, 2007) – Open Green Spaces' Sizes and Locations (Tümer, 1976; Müftüoğlu, 2008; Yazgan, and Khabbazi, 2013).

Table 1. *Open-green spaces' sizes and locations (Tümer, 1976; Müftüoğlu, 2008)*

Park areas	Population criterion da/per capita		Area size criterion (da)		Its place in recreation areas
	Minimum	Optimal	Minimum	Optimal	
Quarter Park	6	12	20	40	As a single unit or within neighborhood parks
Neighborhood park	6	14	200	400	As a single unit or within neighborhood parks
Urban park	1	2	400	1000	Main recreation area in the urban fabric
Regional park	4	12	3000	4000	1 to 2 h drive around the city

On the other hand, classifies the parks based on the number of residences to which the park serves, dwelling unit and size (*Table 2*) (Özkır, 2007; Müftüoğlu, 2008; Yazgan and Khabbazi, 2013) and also represent the national recreation and park board's standards on parks (*Table 3*).

Table 2. *Figures concerning the sizes of park areas within the city (Özkır, 2007; Müftüoğlu, 2008; Yazgan and Khabbazi, 2013)*

Parks	Number of residences addressed	Required dwelling unit	Size
Quarter Park	700-1000	Primary school	1-4 ha
Neighborhood park	1000-5000	District	4-20 ha
Urban park	5000-10000	City	20-50 ha
Regional park	20000-30000	Region	200 ha and over

Table 3. *National Recreation and Park Board's Standards on Parks (Özkır, 2007; Yazgan and Khabbazi, 2013)*

Type	da/1000	Size	Population served	Accessibility
Quarter Park	10	20-80	2000-10000	400-800 m
Neighborhood park	10	80-400	10000-50000	800-4800 m
Urban park	20	Variable	Variable	30 min of drive
Regional park	80	1000 and over	The entire population in small cities	1 h of drive
Private areas	No applicable standard. It comprises trees, roads, beaches, transcendental areas, etc.			

The role of urban parks, quality of life and well-being

Urban parks and green spaces play an important role for environmental services such as air and water purification, wind and noise filtering, and microclimate stabilization. They also provide social and psychological services, which are important for public well being (Urban areas are recognized as one of the key components of sustainable cities, and accordingly, creating more sustainable urban areas is the key to sustainability (Özdemir, 2007). Sustainable areas can be described as those, which are created to support sustainable living primarily focusing on the economic, environmental and social sustainability (Huseynov, 2005). This has a unique significance for urban green areas, tending to imply and symbolize a distinct set of ideals concerning the city's identity, along with its history and culture on one side, and its local economic growth on the other. In this context, the urban landscape is recognized as quite positively linked to sustainability policies (Beck, 1992; Sachs, 1995; Ferris, et al., 2001; Loures et al., 2007). The empirical research, in addition to the theoretical study, has underlined the role of urban landscapes in the environmental, aesthetical, psychological, social and economical aspects of urban life (Grahn, 1985; Burgess et al., 1988; Conway, 2000; DeGraaf, 2003; Chiesura, 2004). Similarly, urban green spaces are recognized as the essential component within the scope of urban sustainability, for their beneficial services and also one possible step to the creation of sustainable urban environments. (Zhang et al., 2012). Hence, these aspects like "amount of urban green spaces per inhabitant," "public parks," and "recreation areas" are recognized to have strategic significance for improving the life quality (Teal et al., 1998), making the city livable, pleasant and appealing for citizens (Chiesura, 2004)

The term "well-being" has been defined in various ways using socio-economic, psychological, and psychosocial parameters as well as feelings of connectedness to nature (Bell, 2005; Dutcher et al., 2007). The World Health Organization (WHO, 2018) defines health and well-being as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity". Greenberg (1985) suggests that wellness (or well-being) differs from health; in that, "it is the integration of physical, emotional, mental, spiritual and social health at any level of health or illness". The term "well-being" includes material security, personal freedoms, good social relations and physical health, whereas the term "health" includes biological, sociological, economic, environmental, cultural, and political factors (Walter et al., 2005). Based on this definition, a person might be regarded as achieving the status of well-being within one of the domains of health, which is defined as asymmetrical health (Greenberg, 1985). Well-being is defined in this study as an inner state of wellness that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31473163

includes physical, social, mental, spiritual, and emotional states of consonance, which exist in healthy environments (Burns, 2006) or are achieved through connection or engagement with natural environments and green spaces.

Eventually, for making cities more sustainable, urban parks have the ability to play a key role, along with providing benefits for the habitat, air and water quality, and also letting the kind of high neighbourhoods densities, which are contributive in terms of lowering the energy consumption while increasing active, human powered transportation. Surely, it is critical to possess wide open spaces, and especially natural areas which provide habitat, as well as reinforcing the compact city design. Additionally, urban dwellers can be encouraged in order to appreciate the natural processes within their neighbourhoods, providing authentic facilities in which people are provided with the opportunity to gather either informally or more formally. Parks serve to connect people to the history of both the environment that was built, and also the natural processes in the area, as well. Altogether, these areas can be rick in cultural resources, allowing people to sustain the community life over time.

The present study aims to investigating the recreational opportunities, which were created by the Shah Goli park for the users in terms of its functionality, having a historical and unique characteristic, which is located in Iran, Tabriz.

Materials and methods

Case area: location, boundaries and geographical characteristics of Tabriz City

Tabriz is located at 38° 8’ and 46° 15’ East of Greenwich with an area of about 131 km^2 (Ghorbani, 2006). The city is located in 1200 m above sea level (Rahimi, 2006)’. In the winter, the average temperature is 12.4 °C (88.4 °F) and in the summer the average temperature can be up to 34.1 °C (110.1 °F). Lack of water resources is the most important climatic problem in the city; meanwhile the annual rainfall (snow and rain) is only about 321 m^2 and most of the rains occur during winter and spring. Despite harsh weather, the population of this city is 1,579,312, according to the Census Central Organization of Iran (*Fig. 1*).

Data collection instrument

The data collection tool is in the form of a questionnaire. The objective of this questionnaire is to define the park availability factors for those, who visit the Shah Goli Park. The options with regards to the availability of the park were on socialization, physical activity, nature involvement and relaxation. The respondents were addressed questions in order to show their preferences within the scope of a 5-point Likert scale (1 = Strongly disagree, 2 = Disagree, 3 = Don’t know, 4 = Agree, and 5 = Strongly agree) and the park’s availability preference were measured using 14 items.

Data analysis

The gathered data was subjected to an analysis by utilization of normal statistical methods within SPSS version: The set of park availability items were defined using the factor analysis, in order for designating the main and underlying factors, followed by a group mean comparison (t-test) in order to identify the differences between the demographic information and availability factors.

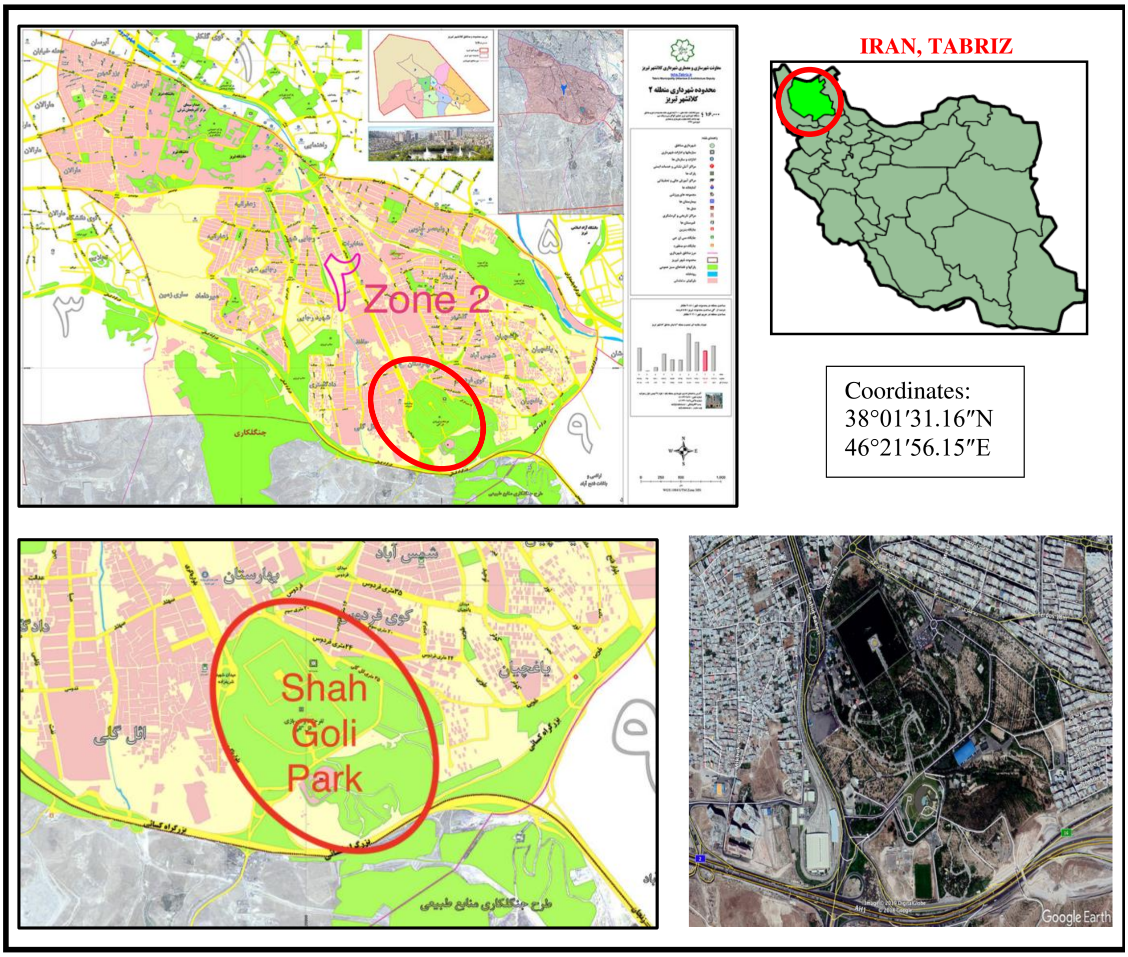

Figure 1. *Location of Shah Goli Park (Tabriz City Regional Planning, 2018)*

History of urban park in Iran

Iran's history of public space can be traced from the period when the Persian Empire around 500 years B.C. Throughout the history public spaces were being used for various purposes like a place for national ceremonies, declaring important news, crowning ceremonies, etc. During 14th century A.D., public spaces like "Chahar Bagh" were the most essential parts of the city. In this period, public spaces were used as a place of social communication, as well as national and religious ceremonies. Additionally, Persian gardens were introduced as an area in order for experiencing the nature, as well. During the early 20th century A.D., in Iran, including Tabriz, for recreation and socialization of people, Persian gardens started to be recognized as public urban parks in most of the large cities (Romianfar, 2008). What is more is that these public spaces can be recognized as multipurpose areas, too (Hami et al., 2011). Urban parks were not that common in the cities of Iran because of the insufficient amount of water resources; hence, a vast majority of available green spaces in the traditional cities were garden, generally built on a private land. Following the swift and modern urbanization of Persian cities, urban parks became popular choices for accessibility to green space. As per a previous study, people used to prefer urban parks mostly for passive entertainment and individual active activities like hiking (Hami et al., 2011), notwithstanding that,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31473163

some of the parks possess sport facilities like volleyball and tennis courts for the visitors. In general, urban parks in Iran are recognized as places for nature appreciation (Hami et al., 2011; Rostami et al., 2017) and social interactions like family gatherings (Hami et al., 2011). Therefore, landscaping of urban parks require considering up of public demands and needs.

Shah Goli Park

Shah Goli Park is also known as the “Old Park” in Tabriz and was built as a royal park by an unknown king in 1785 (Wilber, 1979). This was later declared as a public urban park in 1930 (Romianfar, 2008). El Goli covers an area of 60.7 Hectares (150 acres) (Ghorbani, 2006) and located in the Southwest part of Tabriz. Construction of the original building ponds is ascribed to the reign of Sultan Yaghoob Aghkoyunlular and consider its development from the Safavid period. Completion of especial esplanade and mansion for courtiers and its prosperity is ascribed to the time of Champion Mirza, the son of Abbas Mirza regent- who was the ruler of Azerbaijan. The Safavid dynasty in the pool Shah Goli was the largest water reservoir in the garden. Aghkoyunlular and Safavid and Qajar periods all within the catchment area of sand was empty and it was drawn on the walls of stone and lime. After the Qajar era this area was transferred to Tabriz municipality be a public walkway. With the construction of five-star hotel Elgolu Pars, this area has the international aspect and the space agencies of Tabriz city has become one of the most beautiful public parks (Rostami, 2017). In 1930, renovation was done to the park by Tabriz Municipality and it became a public park (Romianfar, 2008). During the renovation, an artificial lake was added and it becomes a prominent feature of Shah Goli Park. The artificial lake is 213.23 m (700 ft) long and 213.23 m (700 ft) wide covering 54,675 m^2 of area. In the eastern side, some terraces have been built and a row of poplars planted along the walls. The park was further expanded in 1989 and 1996 with new features added (*Fig. 2*) (Romianfar, 2008).

Name of park	**Thematic class of park**	**Position of park from satellite**

Results

Demographic profile of the participants

A total of 296 participants took part in the study. *Table 4* shows the participants' demographic information. The majority of participants were male (55.1%, n = 163), 18-30 years old (47.3%, n = 140), married (58.1%, n = 172), and had university level education (52.02%, n = 154) (*Figs. 3–6*).

Table 4. *Demographic description of the survey*

Variables	Number	Percent
Gender	296	100
Male	163	55.1
Female	130	43.9
Age		
18-30	140	47.3
31-40	87	29.4
41-50	36	12.2
Above 50	30	10.1
Marital status		
Single	121	40.9
Married	172	58.1
Education		
Guidance school	25	8.4
Under diploma	29	9.79
Diploma	88	29.7
University	154	52.02

Preferences for park usability

What is shown in the collected data is that "enjoy the landscape view" (mean = 4.72, sd = .55) has the highest preference rate among the other activities for parks, followed by 'to walk in the park' and 'to exercise ' (mean = 4.53, sd = 0.66), 'To watch water flow in the park' (mean = 4.46, sd= .87), 'To socialize with friends' (mean = 4.33, sd = .83), 'To sit under the trees shade' (mean = 4.37, sd= .78), 'To socialize with friends' and 'To have dinner with family or friends in the park' (mean = 4.33, sd= .83), 'To picnic' (mean = 4.27, sd= .93), 'To be with family' (mean = 4.04, sd = 1.11), 'To play with children in the park' (mean = 3.93, sd = .90), 'To socialize with people' (mean = 3.66, sd= .1.18) (*Table 5; Fig. 7*). These results show the areas that the participants preferred for highly social and environmental activities in the park. It seems clear that people are not provided with adequate space for exercising and hiking in a crowded city like Tabriz, arising the need for them to go parks, along with open public spaces in order for hiking and similar activities

Table 5. *Mean analysis for usability variables*

Variables	Mean	Std. dev.
To walk in the park	4.53	0.66
To picnic	4.27	0.93
To watch water flow in park	4.46	0.87
To socialize with friends	4.33	0.83
To enjoy the landscape view	4.72	0.55
To rest and sit under tree shade	4.37	0.78
To be with family	4.04	1.11
To socialize with other people	3.66	1.18
To exercise	4.53	0.66
To play with children in the park	3.93	0.90
To have dinner with family or friends in the park	4.33	0.83

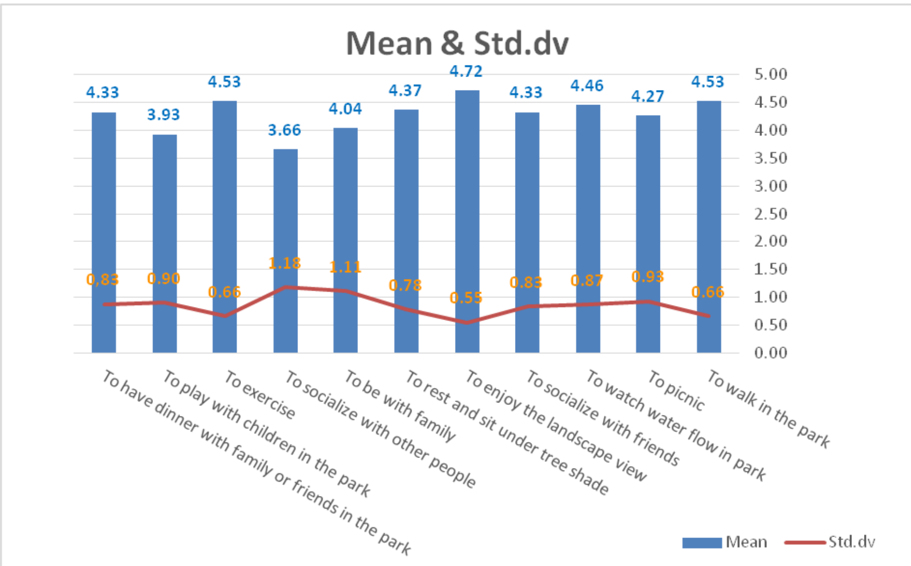

Figure 7. *Mean analysis for usability variables*

http://www.aloki.hu • ISSN 1589 1623 (Print) • ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31473163

Park usability underlying dimensions

In order to identify the underlying dimensions within the scope of park availability, a factor analysis was carried out on the collected data. Three dimensions were obtained following the analysis on the respective items (*Table 6*).

Activities like nature-related activities may seem appealing to more people for visiting the parks. What is interesting is that there is a relation between plants' contribution to activities done in urban park. A factor analysis on activity set forth that Social Activities (mean = 4.19, sd = 0.69), and five Environmental Activities (mean = 4.64, sd = 0.67) acquired the highest rate, respectively (*Table 6*).

Table 6. *Underlying dimensions of park usability*

Social activities	**Factors**	**Mean**	**Std. dev.**
		4.19	**0.69**
To be with family	.746		
To play with children in the park	.623		
To socialize with friends	.723		
To socialize with other people	.608		
To exercise	.544		
To have dinner with family or friends in the park	.595		
Environmental activities			
		4.64	**0.67**
To have a picnic	.701		
To walk in the park	.607		
To watch water flow in park	.730		
To rest and sit under tree shade	.488		
To enjoy the landscape view	.614		

Discussion

The role of historical parks as the provider of social services, along with its significance for city's sustainability has been determined in this research. For exploring the motives and perceptions of the visitors of Shah Goli Park, certain results of the questionnaire have been presented. Some of the concluded remarks are as follows:

To begin with, the study states that urban planning, along with the contributions it provides in tackling a number of detrimental environmental problems, which have been recently recognized as the characteristic of crowded city centers and urban environments, may be recognized as a premise in terms of creating sustainable urban life. Urban green spaces have the ability to gather people together, while increasing the public congregation and interaction along with increasing accessibility to public services and employment, which, by the way, may be the essential aims of sustainable urban policy.

Depending on the number of users, usage frequency, involved functional facilities and social carriage capacity of people, ecological carriage capacity of the area, the park's surface area may vary. These factors are directly related to the social and environmental structure of people. In this study, the survey was performed on 14 subjects in the park, with a total participant number that is equal to 296. A

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31473163

supplementary X2 significance test was carried out with over 296 questionnaires received from the visitors of park, of which results can be seen in *Table 6*. The aim of the study was to determine the individual features of users (gender, marital status, age, education) and differences among these features. From the results obtained, the individual features of 296 participants were as follows: for gender status, 55.1% of subjects was male and 43.9% was female; for marital status, 40.9% was married and 58.4% was single; for age, 47.3% was between 18-30, 29.4% was between 31 and 40, 12.2% was between 41 and 50 and 10.1% was above 50; for education level 8.4% was guidance school; 8.4% was under diploma, 29.7% was diploma and 52% was university graduate.

Conclusion

The results obtained set forth that the participants prefer to perform environmental activities like enjoying the landscape view, watching the water flow in the park and walking around the park. People seemed interested in direct involvement with the natural elements like plant materials and water, while carrying out the respective environmental activities. It is understood that green spaces and water features lead users to feel relieved, thus ensuring serenity in parks. The results indicate that the activities that are performed most frequently in urban parks are as follows: having a picnic, walking, sitting, admiring nature, and watching plant material scenes. So, it can be said for people that they wish to connect with green areas for entertainment and natural involvement in urban parks, attracting more people to visit parks. The study underlined the significance of plant material and water feathers arrangement and configuration within the scope of improving the social life of people. Additionally, activities that are performed by people in urban parks are required to be designed and planned in connection with the natural element's spatial configuration.

Considering the positive effects of open-green areas on human psychology, it can be clearly seen that recreative activities by people in green areas are of vital importance. The leading determinant in this matter is accessibility. People usually prefer going to parks and green areas that are close to where they live, but some people may choose to go distant places in line with the quality of time they spend. Increasing the ratio of urban green areas per capita will not only proportionally increase the options for town-dwellers, but they will also be provided with the opportunity to access areas that offer different activities. Existence of green areas affects both the physical health thanks to the, for example, plants that clear the air, and psychological health of people. In this context the life quality in urban areas increases with green areas, which ensures improvement in the sense of belonging and well-being.

(Received 3rd Jan 2019; accepted 8th Feb 2019)

Abstract. In this study, selective adsorption of U(VI) in aqueous solutions in the presence of various lanthanide ions was conducted by using U(VI)-imprinted cryogel polymer. For this purpose, the pHEMA-$(MAH)_3$-U(VI) cryogel polymer was prepared by free radical polymerization method. U(VI) was desorbed with 5.0 mol.L^{-1} HNO_3 and thus U(VI)-imprints were created on p-HEMA-$(MAH)_3$ cryogel polymer. To determine the optimum conditions, in the process of selective adsorption of U(VI) ion to U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer, some parameters such as pH, flow rate, initial U(VI) concentration were investigated. Under the optimum conditions, the maximum adsorption capacity was obtained as 74.80 mg.g^{-1}. Selectivity studies were also carried out in the presence of Nd(III), La(III) and Y(III) ions using U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer. The obtained adsorption order under competitive conditions was U(VI) > La(III) >Y(III) >Nd(III).

Introduction

Uranium is an important material in nuclear science and an important actinide in radioactive waste water and environmental samples (Wang et al., 2017a). Uranium is a natural element that quite effective in the nuclear industry and particularly as a fuel for electricity generation by nuclear power plants (Iliaa et al., 2017). Studies on uranium-containing rare earth minerals are causing uranium-containing radioactive pollutants (Li et al., 2018; Wang et al., 2017b; Lu et al., 2016; Wang et al., 2015). Therefore, the solvent extraction and separation of Uranium from rare earth minerals is quite important for the environmental protection (Zhu et al., 2015).

Uranium is the most important fuel element used in nuclear reactors. Therefore, the recovery of Uranium is of great importance for the sustainable development of nuclear industry (Gu, 2007). The content of uranium in the earth's crust is limited (Abdollahy et al., 2011). Anticipating the shortage of nuclear fuels in near future, the selective recovery of Uranium becomes necessary for the sustainable development of nuclear energy (Chmielewski, 2008).

The removal of uranium from the body has been studied by a number of investigators. Mostly, the low concentrations of uranium encountered and the presence of high levels of interfering matrix constituents prevent its direct determination. Because of this, various separation and preconcentration techniques are employed for the determination of uranium. Although liquid–liquid extraction has been widely used

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31653178

(Horwitz et al., 1992), it is time consuming. Extraction chromatography (Dolak, et al., 2011), solid-phase extraction (Yener et al., 2017; Kaminski et al., 2000), supercritical fluid extraction (Haerizade et al., 2018), ion exchange (Dolak et al., 2010) and adsorbents (İnam et al., 2001; Sana et al., 2015) have been extensively used for the separation and preconcentration of uranium ions. The process of using adsorbents is an effective method for heavy metals by using metal chelating resins prepared with containing aminoacid monomer ligands (Dolak et al., 2015; Keçili et al., 2018; Dolak, 2018), and for recovering uranium because of the high selectivity for uranium, the ease of handling, and environmental safety. The solid-phase extraction methods using molecular imprinted polymers are the most used methods for the separation and preconcentration of rare earth elements (Harkins and Schweitzer, 1991; Panahi et al., 2012; Wulff, 1995).

Molecular imprinting is a method for making selective binding sites in synthetic polymers by using molecular template. Metal cations can be used as templates for imprinting crosslinked polymers. After the removal of template (the cation), the remaining polymer is more selective. The selectivity of the polymer depends on various factors, like the charge on the cation, the size of the cation, the specificity of the interaction of the ligand, the coordination geometry, and the number of the cations. Transition metals can also be removed by using the molecular imprinting method (Pakdehi, 2016; Dhal and Arnold, 1992; Chen et al., 2017).

Molecular imprinting is a new technique has attracted the attention of researchers for effective recognition of chemical and biological molecules including aminoacids, proteins, enzymes, DNA, drugs and metal ions (Didaskalou et al., 2017; Székely et al., 2012a, b; Dolak et al., 2018). This technique allows selective and sensitive recognition of chosen target molecule by leaving artificial imprinted cavities in polymer matrix that provides high affinity to target molecule. To synthesize molecularly imprinted polymer, the template molecule and functional monomers which can arrange around template are complexed interactively before polymerization. Then the rigid polymer matrix is obtained by polymerization of formed pre-complex and cross-linker reagent. After removal of template molecule from the polymer with suitable desorption agent, the cavities remaining in the polymer that are complementary in shape, size and chemical functionality to the template. Consequently, the resultant polymer able to recognizes and rebinds selectively the template or other molecules that are chemically related to the template (Saylan et al., 2017). This technique is used in many applications such as selectivity recognition and separation (Sellerggren, 2001; Wei and Mizaikoff, 2007; Vedadghavami et al., 2018; Lasáková and Jandera, 2009), drug delivery systems (Alvarez-Lorenzo and Concheiro, 2004), catalysis (Vidyasankar and Arnold, 1995), sensor technology (Monier and Abdel-Latif, 2017). In addition, ion imprinted polymers (IIPs) have been used for the selective removal of metal ions from different matrices (Moussa et al., 2016; Moorthy et al., 2013; Monier et al., 2016; Mitreva et al., 2017; Msaadi et al., 2017; Roushani et al., 2015; Fayazi et al., 2016; Candan et al., 2009; Gao et al., 2015).

In this study, the selective adsorption of U(VI) in aqueous solutions and soil certified reference material in the presence of other lanthanide ions such as Nd(III), La(III) and Y(III) was performed by using U(VI)-imprinted pHEMA-$(MAH)_3$ cryogel polymer purposed. For this purpose, U(VI) was complexed with N-methacryloyl-L-histidine methyl ester (MAH) and the prepared $(MAH)_3$-U(VI) complex monomer was polymerized with 2- hydroxyethyl methacrylate (HEMA) cryogel to prepare pHEMA-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

$(MAH)_3$-U(VI) cryogel polymer by free radical polymerization method. U(VI) was desorbed with 5.0 mol.L^{-1} HNO_3 and thus were created U(VI) imprinted on to p-HEMA-$(MAH)_3$ cryogel polymer. In the process of selective adsorption of U(VI) ion to U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer, several factors such as medium pH, flow rate, initial U(VI) concentration were investigated to determine optimum conditions. Selectivity studies were also carried out in the presence of Nd(III), La(III) and Y(III) ions using U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer. The obtained adsorption order under competitive conditions was U(VI) > La(III) > Y(III) > Nd(III).

Materials and methods

Chemicals and reagents

The chemicals used in the study and their properties are given in *Table 1*.

Table 1. *Used chemicals and their properties*

Chemicals	For what	Manufacturer
Methacryloyl cloride	For monomer synthesis	Sigma Aldrich-Steinheim, Germany (purum, dist., ≥97.0% (GC), contains ~0.02% 2,6-di-tert-butyl-4-methylphenol as stabilizer)
L-histidine	For monomer synthesis	Sigma Aldrich-Steinheim, Germany (ReagentPlus®, ≥99%)
2-Hydroxyethyl methacrylate (HEMA)	For polymer synthesis	Sigma Aldrich-Steinheim, Germany (≥99%, contains ≤50 ppm monomethyl ether hydroquinone as inhibitor)
N,N,N,N-tetramethyl ethylene diamine (TEMED)	For polymer synthesis	Sigma Aldrich-Steinheim, Germany (BioReagent, suitable for electrophoresis, ~99%)
N,N-methylenebisacrylamide (MBAAm)	For polymer synthesis	Sigma Aldrich-Steinheim, Germany (99%)
Ammonium persulfate (APS)	For polymer synthesis	Sigma Aldrich-Steinheim, Germany (reagent grade, 98%)
Uranyl nitrate	For experimental optimization studies	Sigma Aldrich-Steinheim, Germany (extra pure, ≥99%)
Lanthanium(III) nitrate hexahydrate	For selectivity study	Sigma Aldrich-Steinheim, Germany (extra pure, ≥99%)
Neodymium(III) nitrate hexahydrate	For selectivity study	Sigma Aldrich-Steinheim, Germany (extra pure, ≥99%)
Yttrium(III) nitrate hexahydrate	For selectivity Study	Sigma Aldrich-Steinheim, Germany (extra pure, ≥99%)
All organic solvents	For synthesis ımprinted polymer	Sigma Aldrich-Steinheim, Germany

Instrumentation

The analysis of the U(VI) and the other lanthanide ions was performed using a Agilent 7700 Series inductively coupled plasma-mass spectroscopy (ICP-MS). System

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31653178

with the following parameters: RF Power = 1600 W, sampling depth = 5.3 mm, analyzer pressure = 7.92×10^{-5} Pa, helium flow in the collision cell = 4.98 $mL.min^{-1}$ and plasma temperature = 9883 K. the measurements were done with three replicates (95% confidence level). A Perkin Elmer model Spectrum 400 FT-IR spectrometer was used for the Fourier transform infrared (FT-IR) measurements. Scanning electron microscopy (SEM) analyses were carried out by using a FEI Quanta FEG 250 SEM system.

Preparation of U(VI)-imprinted and non-imprinted p-HEMA-$(MAH)_3$ cryogel polymer

Synthesis of N-methacryloyl-L-histidine methyl ester (MAH)

The preparation and characterization of N-methacryloyl-(L)-histidine methyl ester (MAH) was reported elsewhere (Bereli et al., 2011). The following procedure was applied for the synthesis of MAH monomer: 5.2 g of L-histidine methylester and 0.22 g of hydroquinone were dissolved in 150 mL of CH_2Cl_2 solution. Solution was cooled down to 0 °C. 12.83 g triethylamine was added to the solution. 4.0 mL of methacryloyl chloride was poured slowly into this solution under nitrogen atmosphere and then this solution was stirred magnetically at room temperature for 1 h. At the end of this chemical reaction period, unreacted methacryloyl chloride was extracted with 10% NaOH. Aqueous phase was evaporated in a rotary evaporator. MAH was crystallized in 20 mL (1:1) ethanol and ethyl acetate. The reaction efficiency was determined as 84% in the stoichiometric calculations based on the amount of reagents added to the reaction medium and the amount of MAH monomer obtained as a result of the process. In addition, it was determined that the purity of MAH monomer synthesized as a result of the characterization processes was greater than 98%.

Preparation of $(MAH)_3$-U(VI) complex monomer

For preparation $(MAH)_3$-U(VI) complex monomer, MAH (0.669 mg, 3.0 mmol) was dissolved in deionized water. After slow addition of $UO_2(NO_3)_2$ (0.394 mg, 1.0 mmol) to this solution, the solution was stirred for 24 h at room temperature. The obtained complex monomer was then filtered and extensive washed with EtOH and deionized H_2O. Then, it was dried at 50 °C for 24 h. For the yield of the synthesis of the synthesized MAH-Th(VI) complex monomer, it was initially determined by ICP-MS analysis of the remaining Th(VI) in the medium which was added to the medium and the complex formation yield was determined to be greater than 95%.

Synthesis of p-HEMA-$(MAH)_3$-U(VI) (IIP) and p-HEMA-$(MAH)_3$ (NIP) cryogel polymer

p-HEMA-$(MAH)_3$-U(VI) and p-HEMA-$(MAH)_3$ cryogel polymers was prepared according to a previously reported method (Baysal et al., 2018). For this purpose, 0.25 g MBAAm was dissolved in deionized H_2O, and then 2.0 mL HEMA and 2.0 mL $(MAH)_3$-U(VI) complex monomer were mixed with this solution. Initiator APS (25 mg)/TEMED (25 µl) was added and the final mixture was placed into a syringe closed with parafilm and allowed to polymerize at -18 °C for 24 h. The frozen solution was allowed to thaw at room temperature. Finally, the prepared imprinted cryogel polymer was washed with 100 mL (1:1) EtOH and deionized H_2O to remove impurities, which was then stored at +4 °C. Non-imprinted polymer were prepared in the same way but in the absence of the template.

DOI: http://dx.doi.org/10.15666/aeer/1702_31653178

Removal of U(VI) from p-HEMA-$(MAH)_3$-U(VI) cryogel polymer

To obtain the 3-D cavities for desorption of U(VI), the template U(VI) was successfully desorbed from the p-HEMA-$(MAH)_3$-U(VI) cryogel polymer (*Fig. 1*). For this purpose, the cryogel polymer was desorbed with 10 mL 5.0 mol.L^{-1} HNO_3 as the desorbtion solvent for 1 h by using a peristaltic pump. This washing step was repeated until no U(VI) was determined in the desorption solvent.

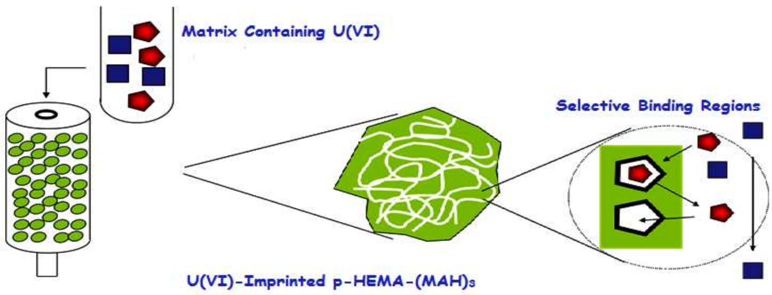

Figure 1. *The prepared U(VI)-imprinted column system and selective separation scheme of U(VI)*

Figure 1 shows schematically that only U(VI) is selectively bound when the mixture of La(III), Nd(III), Y(III) and U(VI) is passed through a prepared U(VI) imprinted p-HEMA-$(MAH)_3$ cryogel column.

Characterization studies

MAH monomer and prepared $(MAH)_3$-U(VI) complex monomer were characterized by FT-IR spectroscopy, whereas U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer were characterized by FT-IR spectroscopy and SEM technique.

To obtain FT-IR spectrum U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer, KBr was mixed with the dried polymer particles and pressed into a pellet form, and the spectra were then recorded.

For the SEM analysis of U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer were covered on the surface of platinum and coated with gold (thickness of 20 nm). Then, SEM analyses were carried out.

To calculate the swelling ratio of p-HEMA-$(MAH)_3$ cryogel polymer, the cryogel was dried and weighed until constant weight (m_{dried}). Then, it was placed in a 30 mL vial containing distilled water and kept at 25 °C for 2 h. The cryogel was removed from water, wiped by a filter paper and weighed again (m_{wet}). The swelling ratio was calculated according to *Equation 1:*

$$S = m_{wet} - m_{dried} / m_{dried} \quad \text{(Eq.1)}$$

For the measurement of macroporosity percentage (M%) of cryogels, the mass of water-saturated cryogels (m_{wet}) was weighed. The cryogel was squeezed to remove free water which is found in the pores ($m_{squeezed}$), and the mass of cryogel without water was weighted. M% was calculated according to *Equation 2:*

$$M\% = m_{wet} - m_{squeezed} / m_{wet} \quad \text{(Eq.2)}$$

Adsorption studies of U(VI) ion to U(VI)-imprinted (IIP) and non-imprinted (NIP) cryogel polymer

Continuous column system was used to adsorption U(VI) to U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer (IIP) and non-imprinted p-HEMA-$(MAH)_3$ cryogel polymer (NIP). For this purpose, firstly, columns containing IIP and NIP was washed with deionized H_2O and equilibrated with 0.1 mol.L^{-1} phosphate buffer at pH. 7.0. Then, aqueous solution of U(VI) was passed through the columns containing IIP and NIP at 1 mL.min^{-1} flow rate for 1 h. The amounts of U(VI) was determined by ICP-MS. Then, 5.0 mol.L^{-1} HNO_3 was used to desorption of U(VI) bound to the IIP and NIP. Several factors such as pH, flow rate and initial U(VI) concentration were also investigated to obtain the optimum conditions for the adsorption of U(VI). 10 ppm U(VI) solutions in different pH values (pH 3 to 10) was passed through the columns containing IIP and NIP at 1 mL.min^{-1} flow rate for 1 h in order to test pH influence on U(VI) adsorption to the IIP and NIP. Then, the samples came out from the column were analyzed by ICP-MS. The flow rates between 1.0 mL.min^{-1} and 5.0 mL.min^{-1} were applied for the investigation of the effects of these parameters on the adsorption of U(VI). The initial U(VI) concentration was varied between 10 ppm and 2000 ppm to determine maximum adsorption capacity.

Selectivity study

The selectivity of the prepared U(VI)-imprinted (IIP) and Non-imprinted NIP cryogel polymers toward U(VI) were investigated in the presence of U(VI)-Nd(III), U(VI)-La(III) and U(VI)-Y(III) ion pairs. For this purpose 25 mL of 10 ppm lanthanide solutions in 10 mM phosphate buffer, pH 7.0 were passed from columns containing IIP and NIP at a flow rate of 1 mL.min^{-1} at room temperature. Analysis of the lanthanide ions in the column output samples was performed by ICP-MS.

The distribution coefficient of U(VI) ion between the columns containing IIP and NIP and aqueous solutions was calculated using *Equation 3*:

$$K_d = (C_i\text{-}C_f/C_f) \times (V/m) \qquad \text{(Eq.3)}$$

where K_d is the distribution coefficient, C_i is initial U(VI) concentration and C_f is final U(VI) concentration, V represents the solution volume (mL) and m is the polymer mass (g).

The selectivity coefficient (k) and relative selectivity coefficient (k^1) for U(VI) in the presence of other competing lanthanide ions can be calculated applying *Equations 4* and *5:*

$$k = K_{(U(VI))} / K_{(\text{interfering ion})} \qquad \text{(Eq.4)}$$

$$k^1 = K_{(\text{imprinted})} / K_{(\text{nonimprinted})} \qquad \text{(Eq.5)}$$

where $K_{(U(VI))}$ is the distribution ratio of U(VI) ion and $K_{(\text{interfering ion})}$ is the distribution ratio of potentially interfering ions.

Reusability of U(VI)-imprinted cryogel polymer (IIP)

For the reusability studies, adsorption and desorption studies were repeated 10 times using same IIP. After each step, column was washed with 10 mL 5 mol.L^{-1} HNO_3 and deionized water.

Adsorption studies of U(VI) ion from soil certified reference material

Soil certified reference material was selected as the real sample for the selective adsorption of U(VI). For this purpose, 0.1 g soil certified reference material powdered was leached using concentrated HNO_3 and H_2SO_4 by microwave irradiation. Then, solution pH was adjusted to 7.0 using phosphate buffer and volume of the final solution was distilled to 100 mL by deionized water. The prepared solution was passed through the columns containing IIP and NIP the under the optimum conditions. Analysis of the ions in the column output samples was performed by ICP-MS.

Results and discussion

Characterization of MAH monomer and $(MAH)_3U(VI)$ complex monomer

Prepared $(MAH)_3$-U(VI) complex monomer were characterized by FT-IR spectroscopy, which proved that monomer and complex monomer were synthesized. The obtained FT-IR spectrum of the MAH monomer and $(MAH)_3U(VI)$ complex monomer is given in *Figure 2*.

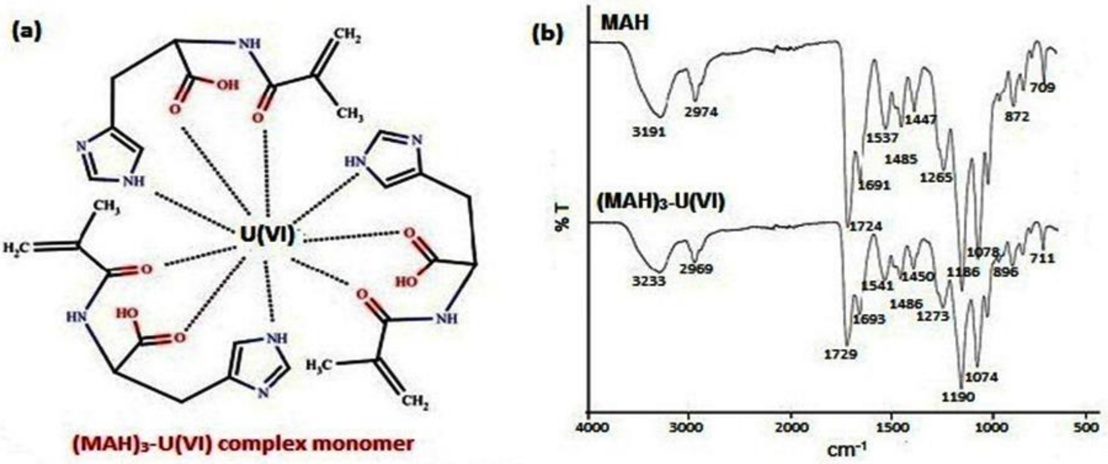

***Figure 2. a** Proposed structure for complex formed; **b** FTIR spectrum for the MAH monomer and $(MAH)_3U(VI)$ complex monomer*

Characterization of U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer (IIP)

p-HEMA and Th(IV)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer (IIP) were characterized by FT-IR and SEM. *Figure 3* shows the FT-IR Spectra p-HEMA and U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer. As can be seen, p-HEMA and U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer exhibited FT-IR patterns with small differences which confirms the similar polymer backbone.

The pore structure and pore size of U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer were visualized with SEM images as seen in *Figure 4*. As shown in *Figure 3,* the U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel polymer has interconnected pores and porous structure. Pore size was found about 50 µm.

The equilibrium swelling degree and macroporosity of the U(VI)-imprinted p-HEMA-$(MAH)_3$ cryogel were 6.12 g H_2O/g cryogel and 81.04%, respectively.

Adsorption studies of U(VI) on IIP and NIP

pH effect on U(VI) adsorption

The change in amount of U(VI) adsorption to the IIP and NIP as a function of pH was investigated, as seen in *Figure 5*. The maximum U(VI) binding to the IIP and NIP pH 7.0. This could be explained by electron transfer based covalent cross-linking between U(VI) and L-histidine of the functional monomer at pH 7.0. *Figure 5* clearly shows effect of pH on U(VI) binding to the IIP and NIP. As seen in the figure, the values higher and lower than pH 7.0 lead to low adsorption of U(VI) to the IIP and NIP, which can be explained by the repulsive electrostatic interactions between bound U(VI) ion and MAH monomer. The adsorption efficiency may decrease because of the size of conformation and the lateral electrostatic interactions between adjacent U(VI) ion on the IIP and NIP. The experiments were repeated 3 times and the statistical values were given as 95% confidence level relative standard deviation (RSD).

Flow rate effect on U(VI) adsorption

The flow rate of the U(VI) solution pumped through the cryogel is one of the crucial parameter for the control of binding process (Fayazi et al., 2016). The flow rate effect on the adsorption of U(VI) was explored by changing the flow rate from 1.0 to 5.0 $mL.min^{-1}$. 10 ppm U(VI) solution was used for this purpose. Owing to the back pressure produced by the column, the flow rates higher than 5.0 $mL.min^{-1}$ could not be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31653178

investigated. The experiments were repeated 3 times and the statistical values were given as 95% confidence level relative standard deviation (RSD). As shown in *Figure 6,* increasing flow rate resulted in a decrease in the adsorption of U(IV) from 96.56 ± 1.52% to 70.84 ± 1.26% adsorption capacity.

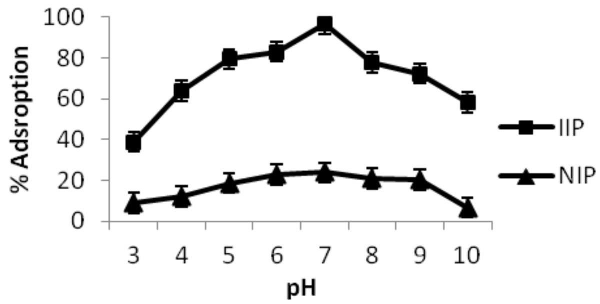

Figure 5. *Effect of pH on U(VI) adsorption (experimental conditions: initial U(VI) concentration: 10 ppm; temperature: 25 °C; flow rate: 1 mL.min*$^{-1}$*; time: 1 h)*

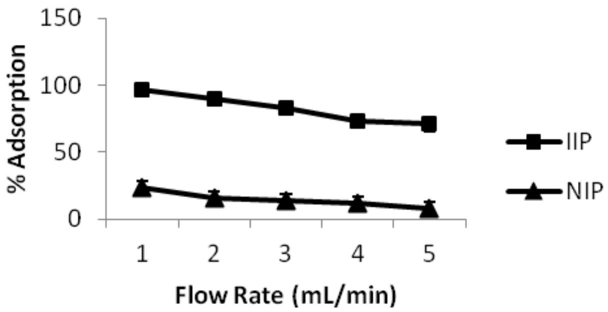

Figure 6. *Effect of flow rate on U(VI) adsorption (experimental conditions: pH:5; initial U(VI) concentration: 10 ppm; temperature: 25 °C; time: 1 h)*

The determination maximum adsorption capacity of IIP and NIP

Initial U(VI) concentration dependence of the bound amount of the U(VI) on to IIP and NIP is depicted in *Figure 7*. As can be seen *Figure 7,* U(VI) adsorption increased when initial U(VI) concentration is increased, and an equilibrium was obtained at a U(VI) concentration of 2000 ppm. The maximum adsorption capacity was obtained as 74.80 ± 1.33 mg.g^{-1} for IIP, while that of NIP was 14.76 ± 1.09 mg.g^{-1}. The experiments were repeated 3 times and the statistical values were given as 95% confidence level relative standard deviation (RSD). it was found that maximum adsorption yield obtained was good result when compared to other studies (Iliaa et al., 2017; Li et al., 2018; Zhu et al., 2015).

Regeneration and reusability of the IIP

One of the crucial advantages for an affinity material for the recognition and separation processes is its reusability (Kupai et al., 2017). To test the reusability of the prepared IIP, U(VI) adsorption and desorption cycle was repeated 10 times using the same cryogel (*Fig. 8*). The elution of U(VI) from the IIP was performed by using 10 mL 5.0 mol.L^{-1} HNO_3 as the desorption solution and complete removal of U(VI) was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31653178

achieved after the desorption step. It was found that the adsorption behavior of the IIP towards U(VI) did not changed significantly after ten adsorption and desorption cycles. Thus, one can easily say that the IIP are stable and the IIP can be used many times without significantly loss of their adsorption capacity.

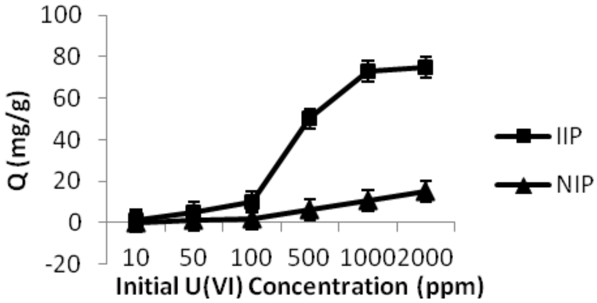

Figure 7. *Effect of initial U(VI) concentration on Th(IV) adsorption (experimental conditions: pH:5; temperature: 25 °C; flow rate: 1 mL.min^{-1}; time: 1 h)*

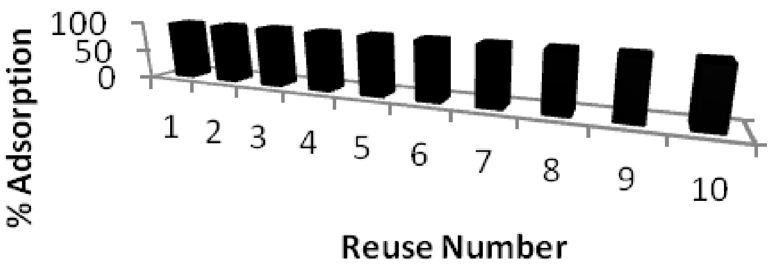

Figure 8. *Reusability of IIP (experimental conditions: pH:5; initial U(VI) concentration: 10 ppm; temperature: 25 °C; flow rate: 1 mL.min^{-1}; time: 1 h)*

Selectivity studies

Competitive adsorption of U(VI)-Nd(III), U(VI)-La(III) and U(VI)-Y(III) were also explored in a column system. The obtained results are given in *Table 2*. U(VI) imprinted cryogel polymer (IIP) exhibited higher selectivity toward U(VI) ions over Nd(III), La(III) and Y(III) ions. K_d values for the IIP were compared with NIP. The obtained results confirmed that the relative selectivity coefficients of the IIP for the U(VI)/Nd(III), U(VI)/La(III) and U(VI)/Y(III) were 129, 60 and 79 times higher than the corresponding NIP, respectively. As a result, it was found that the prepared U(VI)-imprinted cryogel polymer (IIP) exhibited a selectivity to U(VI) ion in the presence of other lanthanides.

Selective adsorption of U(VI) from soil certified reference material

The outcomes of the adsorption of U(VI) from certified reference material are given in *Figure 9.* The results showed that the IIP displayed 93.11 ± 1.47% adsorption toward U(VI) while NIP showed 18.74 ± 0.91% adsorption. The experiments were repeated 3 times and the statistical values were given as 95% confidence level relative standard deviation (RSD).

Conclusions

We have shown that U(VI)-imprinted cryogel polymer (IIP) that contains Poly-Hydroxyethyl Methacrylate-Methacryloyl-L-Histidine is selective and has high adsorption capacity for U(VI) ion. A High adsorption rate was observed at the beginning of the adsorption process and saturation values are reached within 60 min. The maximum U(VI) adsorption capacity of the cryogel polymer was 74.80 mg.g^{-1} for U(VI)-imprinted cryogel polymer, while that of non-imprinted cryogel polymer (NIP) was 14.76 mg.g^{-1}. The adsorption amount of U(VI) was maximum at pH 7.0. Competitive adsorption studies showed that, U(VI)-imprinted p-HEMA(MAH)$_3$ are only selective to U(VI) ion, even in the presence of other lanthanide ions such as, Nd(III), La(III) and Y(III) ions. Distribution (Kd), selectivity (k), and relative selectivity (k') coefficients were also calculated. The value of k' was found, 129, 60, and 79 for Nd(III), La(III), and Y(III), respectively. These k' values are high values if they are compared with reported research values. The obtained adsorption order under competitive conditions was U(VI) > La(III) >Y(III) >Nd(III). As a result, in our study to selectively remove the uranium used as fuel in nuclear reactors, it was determined that the prepared uranium-imprinted polymer exhibited effective uranium bonding activity and thus selectively separated from the matrix environment where uranium was found. After this stage, it is advisable to use sustainable membranes to purify the separated uranium and make it ready for use in the reactors (Fodi et al., 2017).

Abstract. The response of watercress *Lepidium sativum* L. to the basic properties and toxicity of the soils has been established. When assessing the ecological state of the soil cover in residential areas of the city of Perm, the concept of the urban pedocomplexes as combination of soil and man-made surface formations on the same soil-forming rocks within a certain functional zone was applied. The problem of choosing a test control was solved by using vermiculite with Knop solution as a root substrate. Phytotesting showed mainly satisfactory conditions of the upper layers of the soils in urban pedocomplexes. At the same time, in the area of relatively old buildings, a trend towards the emergence of soil toxicity was revealed.
Keywords: *ecological state, urban soils, watercress, toxicity, test-control*

Introduction

The soil cover of urban landscapes has a complicated mosaic pattern; it consists of transformed and degraded soils and technogenic surface formations (TSFs) which are distinctly different from natural soils and often times are instantiated by lower biological activity and toxicity level. The process of the urban soil cover formations, without reference to the location, involves the following general factors: destruction of natural soils and formation of organo-mineral and mineral layers instead, accumulation of urban artifacts and rock formations in the soil profile, discontinuity of soil formation due to building activities, accumulation of heavy metals, oil products and salts (Dobrovolskiy, 1997; Marcotullio, 2011; Bardina et al., 2013; Ivanov and Kudeyarov, 2015; Yang and Zhang, 2015).

Perm is a large industrial city of the Russian Federation (its area is 780 km^2, population – over 1 million people). It was founded in 1724 as a settlement at a copper smelter. Originally the current center of the city was mainly represented by wooden two- and three-storey buildings. The central part of the city was formed in the period between 1780 and 1860. There were a few stone buildings - mainly administrative buildings, churches, cathedrals, some of which have survived to the present day. In between 1930’s-1970’s new residential areas appeared in the place of former villages and pine forests; also selective reconstruction of the old part of the city was pursued as well. Currently, the city is located on both banks of the Kama River. The essential industrial and residential buildings are located on the left bank, as well as the public center of the city (Nechaev, 2000).

In the residential part of Perm artificial groups of plants predominate (parks, lawns, plantings in yards). The air quality of the urban environment depends on the state of the soil and vegetation. Therefore, optimization of the environment is not possible without the regulation of the soil cover functions and properties.

DOI: http://dx.doi.org/10.15666/aeer/1702_31793197

The territory of the city of Perm, which is located in the valley of the Kama River, has a natural soil-lithological heterogeneity. Some specific factors were involved in urban soil formation: the widespread use of carbonate gravel in building and road works; the use of de-icing salts (sodium chloride and, to a lesser extent, potassium) on the roads, dumping lowland peat on the surface of organo-mineral and mineral grounds; relatively short duration of urban soil formation (several decades). Due to the high horizontal and vertical heterogeneity of the current soil cover, it grants a possibility for the concept of urban pedocomplexes – a combination of soil and man-made surface formations on the same soil-forming rocks within a certain functional zone (Shestakov et al., 2013). The concept of urban pedocomplexes has greatly facilitated the mapping and assessment of the soil structure of the Perm Region cities (Eremchenko et al., 2016).

Toxicity and low biological activity of urban soils could be induced by both factors – unfavorable properties (compaction, alkalinity, etc.) and accumulation of pollutants (heavy metals, salts, petroleum, etc.) (Dobrovolskiy, 1997; Poyat et al., 2007; Byrne, 2008; Sizov, 2008; Pickett and Cadenasso, 2009; Lisovitskaya and Terekhova, 2010; Marcotullio, 2011; Ivanov and Kudeyarov, 2015; Yang and Zhang, 2015). Currently, biotesting methods are widely used in soil quality control. These methods are mandative in the environmental practice in the USA, France, Germany, Sweden, Japan (Keddy et al., 1995; Juvonen et al., 2000; Maxam et al., 2000; Rivett et al., 2011; Van der Vliet et al., 2012; Romero-Freire et al., 2015). Method of soil biotesting evaluates the reactions of animals, microorganisms and plants. However, the priority is often given to higher plants that creates photosynthesizing cover, which is the basis of trophic interactions in biocenosis. The sensitivity of plants to soil and chemical effects is reflected in growth, morphological and biochemical parameters. Phytotesting is the basis of a method for assessing soil toxicity and their resistance to pollution (Gong et al., 2001; Voronina, 2009; Mayachkina and Chugunova, 2009; Kolesnikov et al., 2010; Lisovitskaya and Terekhova, 2010; Timofeev et al., 2010; Terekhova, 2011; Bardina et al., 2013, 2014; Nikolaeva and Terekhova, 2017; Gareeva, 2018). Many authors showed the effectiveness of the use of cultivated plants' small seeds, in particular of the watercress *Lepidium sativum* L. This species showed its sensitivity in response to pollutant analysis, both by individual pollutants (heavy metals, hydrocarbons, radioactive substances), and their integrated effect (Shunelko and Fedorova, 2000; Czerniawska-Kusza et al., 2006; Sujetovienė and Griauslytė, 2008; Lisovitskaya and Terekhova, 2010).

The goal of our research is to assess the ecological state of the surface soil layers in urban pedocomplexes of residential areas of Perm using the phytotesting method.

Materials and Methods

Laboratory experiment design

At the first stage of our research, we worked on a problem of examining the response characteristics of *Lepidium sativum* L. as a testing culture to the basic properties of regional soils and their contamination with some heavy metals. We used upper horizons of Chernozems, Retisols (Humic) and Albic Retisols. Soils were contaminated with lead nitrate at the rate of 1000 mg Pb per 1 kg of soil, cadmium sulfate at the rate of 500 mg Cd per 1 kg of soil. Lead was introduced in an amount corresponding to the high level of pollution noted in the urban soils (Eremchenko and Moskvina, 2005). The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31793197

toxicity of Cd is several times higher than that of other heavy metals (Kabata-Pendias, 2011), so its dose was halved relating to Pb.

The study of the soil cover was carried out in the residential zone of the multistorey building on the left-bank part of the city, which occupies about 60 km^2. As an object of study, we took the surface soil layers within the urban pedocomplexes (UPC) on eluvial-deluvial loams with outcrops of indigenous carbonate rocks (UPC-1), on ancient alluvial sands (UPC-2), on low-power deluvium, underlain by sand and sandy sediments (UPC-3), on alluvial sediments (UPC-4). From 15 to 28 soil samples from a depth of 0-15 cm were taken within each UPC (*Fig. 1*).

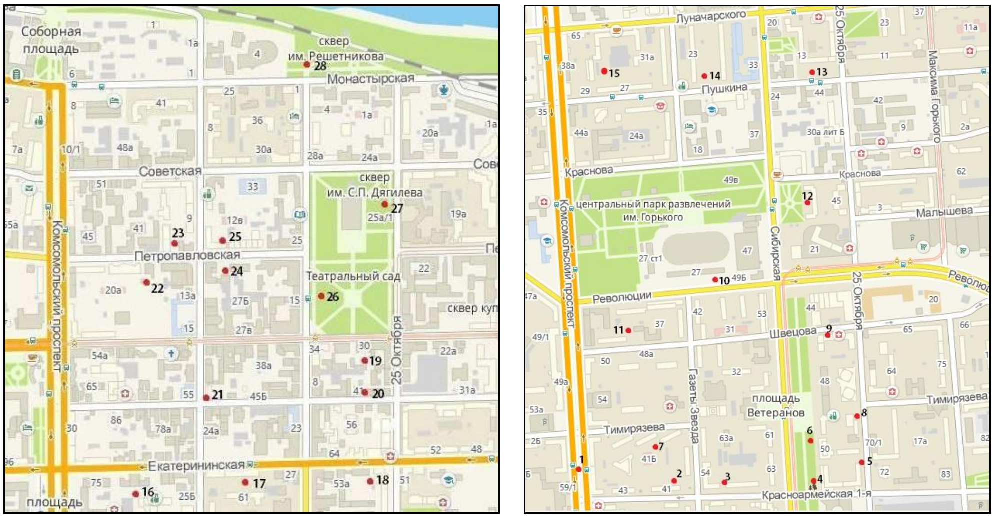

Figure 1. *Sampling points within the UPC-1*

In the samples of natural and urban soils there was determined:

- The content of organic carbon according to Tyurin.
- pH_{water}, pH_{KCl} –by potentiometric method.
- Hydrolytic acidity was determined by the Kappen method.
- Absorption capacity was calculated by adding the sum of the bases and hydrolytic acidity.
- Absorption capacity in carbonate samples - by the Melich method.
- Mobile phosphates and potassium - according to Kirsanov.
- The mobility of heavy metals, expressed in terms of their activity (-lg [Cd] and -lg [Pb]), by the ion-selective method using a pH-meter-ionomer.

Watercress was grown on natural and urban soils within 10 days. The total weight of plants (threefold), the height and weight of one plant in 30-fold repetition were measured. Of a test control there were plants grown on vermiculite with a Knop nutrient solution (1 g/l $Ca(NO_3)_2$, 0.25 g/l KH_2PO_4, 0.25 g/l $MgSO_4$, 0.125 g/l KCl, 0.0125 g/l $FeCl_3$), which was watering once after the seeds had been planted.

In the biotesting of urban soils, choosing the control turns to be very difficult. There are no analogues of these formation in nature. Their toxicity and low bioactivity can be caused by both a multitude of pollutants and common adverse properties. As a test control, we suggested plants grown on vermiculite, a natural mineral from the group of hydromica. Vermiculite of small fractions (up to 1 mm) is produced in the Chelyabinsk region, Russia, and is recommended for growing seedlings, germinating seeds and

DOI: http://dx.doi.org/10.15666/aeer/1702_31793197

rooting plants. The method we have developed has a patent of the Russian Federation (Eremchenko and Mitrakova, 2017), is positively recommended in the practice of various soil grounds biotesting.

For statistical processing of the obtained data, regression and correlation analyses were used at a 95% probability level. Comparison of the samples was carried out by the dispersive non-parametric method (Kruskal-Wallis test). Significant differences between the compared average values were considered with a confidence level of 95% and higher ($P < 0.05$). The significance of differences with the test control was evaluated statistically by Student's criterion ($P < 0.05$). The figures and tables show the arithmetic mean of biological replicates and standard errors.

Results

The response of the test culture on the basic properties of regional soils

During the phytotesting experiment of regional soils, the watercress responded to the humus content, pH, sufficiency of potassium and phosphorus available forms. The height and weight of the testing culture was closely correlated with the main indicators of soil fertility (*Figs. 2-6*).

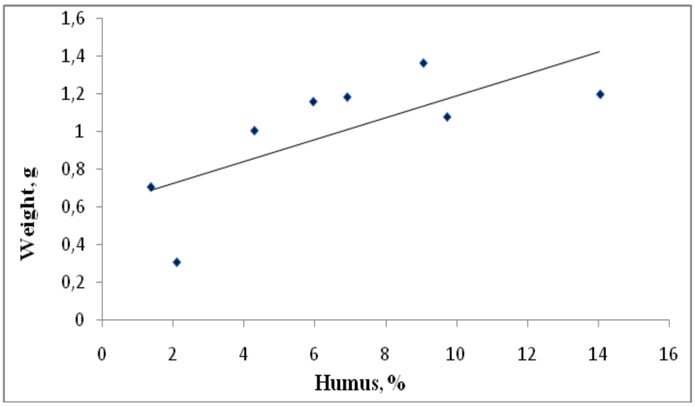

Figure 2. *Dependence of the total weight of watercress (g) on the content of humus (%) in soils:* $y = 0.676 + 0.055x$; $R = 0.64$; $F = 4.92$; $P = 0.021$ *(here and after: R – correlation coefficient, F – Fisher's criterion, P – the level of significance of the null hypothesis)*

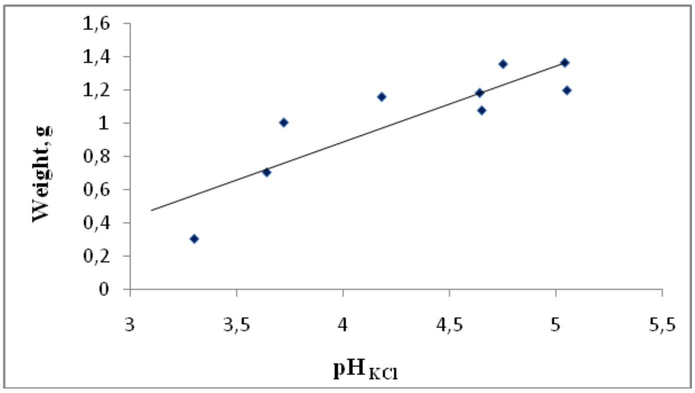

Figure 3. *Dependence of the total weight of watercress (g) on* pH_{KCl} *of the soil:* $y = -0.98 + 0.46x$; $R = 0.84$; $F = 17.4$; $P = 0.002$

In Perm Krai, which is considered to be an industrialized region with high transport load, indigenous soils accumulate Pb, Cd, Zn, Cu, Cr and other heavy metals (Voronchikhina and Zaporov, 1998; Eremchenko and Moskvina, 2005; Vasilyev and Chashchin, 2011).

In our experiments on the pollution of natural soils, it was established that the height and weight of the watercress depended on the contamination by cadmium and lead. Some dependencies between height, mass of the testing culture and the mobility of metals in dark gray soils are presented in the *Figures 7-10.*

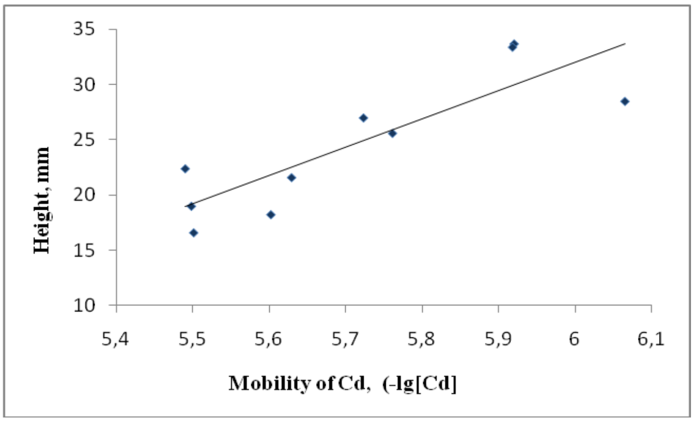

Figure 7. *Dependence of the plant height on cadmium mobility (-lg [Cd]), in dark gray soils: y = -116.8+ 24.8x; R = 0.84, F = 19.8; P = 0.005*

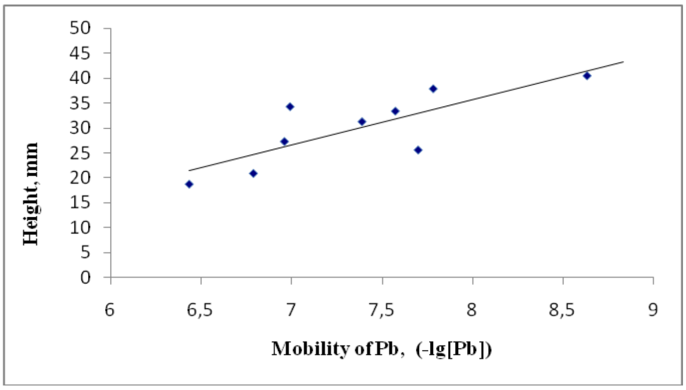

Figure 9. *Dependence of the plant height (mm) on the mobility of lead (-lg [Pb]) in dark gray soils: y = -36.7+ 9.064x; R = 0.80, F = 12.1; P = 0.0002*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31793197

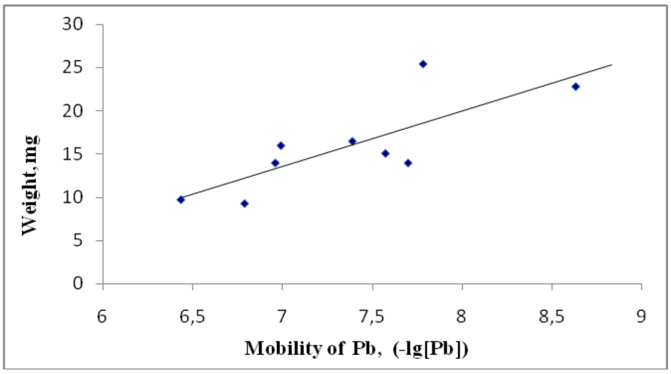

Figure 10. *Dependence of the plant weight (mg) on the mobility of lead (-lg [Pb]) in dark gray soils: y = -31.61+ 6.4x; R = 0.80, F = 11.9; P =0.003*

In the biotesting of urban soils, we considered plants grown on vermiculite with Knop's solution as a test-control. We compared height and weight of plants with watercress grown on the natural soils of our region.

Chernozems are the most fertile soil, so the height of plants that grew on chernozem was lowered by 30% compared to the test control, on dark gray soil (Retisols (Humic)) - by 50-60%, sod-podzolic soil (Albic Retisols) - 60-70%. The decrease in the mass of the plant was 33% on black soil, and 60-70% on gray soils and sod-podzolic soil relative to the test control. Thus, the properties of black soil were the most favorable for the plants, however, the height and weight of the plants were still lower than that of vermiculite. Apparently, the nutrients from the Knop solution turned out to be more accessible.

Based on the results of the experiment, we proposed the state of anthropogenic (man-made) soil or ground to be satisfactory with a decrease in the development of watercress relative to the test control by 10-30%; unsatisfactory - with a decrease of 30-50%; and at a reduction rate of more than 50%, it is environmentally hazardous (Eremchenko and Mitrakova, 2017).

Soil properties of residential areas of Perm

Urban soil is synlythogenic soil, as soil formation proceeds simultaneously with the accumulation of mineral and organic material on the surface; as a result, a profile of different thickness and degree of layering is being formed. The main diagnostic horizon of urban soils is the urbic horizon. In WRB (2006), the urbic horizon was defined as a qualifier for Technosols by the presence of a layer containing 20% of artifacts, including 35% of construction waste. In the Russian Federation, urban soils with a horizon urbic are classified as urbostratozem types (Prokof'eva et al., 2014).

Urbostratozems were prevailed in the UPC of residential areas of the city of Perm (*Fig. 11*). They are mainly formed during the cultivation by dumping (and repeated) lowland peat to the surface. Some properties of urbic are given in *Table 1*. Urbostratozems are not rich in humus, they have a slightly alkaline pH and an average cation exchange capacity.

In domesticated (peat-eutrophied) urbostratozems (*Fig. 12*), on the average, the amount of humus is 2 times higher, the pH is close to neutral, and the absorptive capacity is markedly increased. In the urbostratozem, as a rule, there was a small amount of carbonates.

Quasi-soils, in which mineral soils are covered with a layer of low-moor peat with a thickness of about 10 cm, are formed on well-maintained plots in relatively new residential areas. In quasi-soils, the “fresh” organogenic layer is characterized by the structure and properties of the peat (*Fig. 13*).

Figure 13. *Peat quasi-soil*

Over time, this layer is enriched with mineral matter, peat is humified, thus forming a compost-humus quasi-soil (*Fig. 14*). Quasi-soils, especially peaty ones, contain a lot of organic carbon, they are often characterized by acidity and high cation exchange capacity (*Table 2*).

The investigated UPCs were represented by Urbostratozems and Quasi-soils, which caused a high heterogeneity of the surface soil layers. Variability of soils properties is demonstrated through the example of UPC-1 on eluvial-deluvial loams (*Fig. 15-19*).

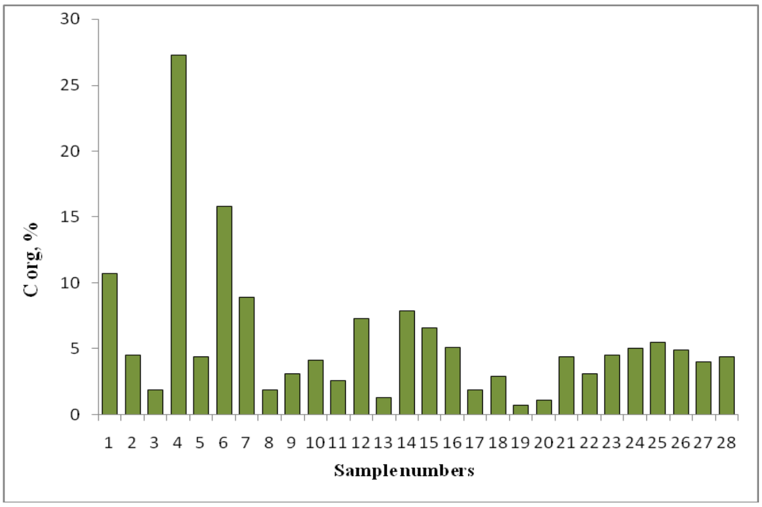

Figure 15. *The content of organic carbon in the upper soil layers of the UPC-1*

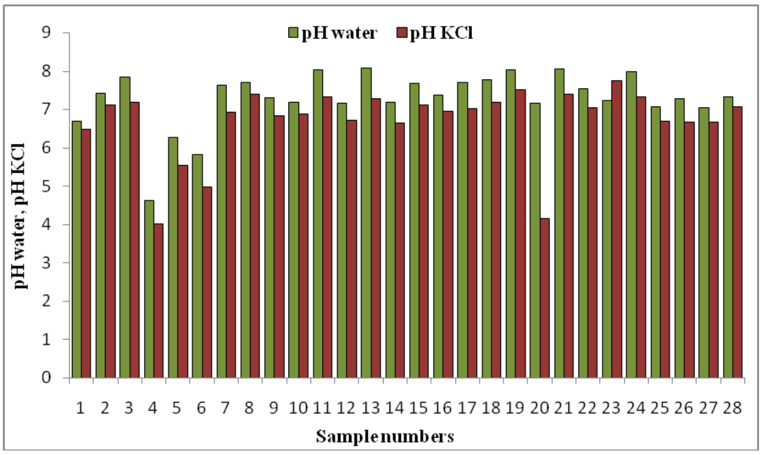

Figure 16. *pH value in the upper soil layers of the UPC-1*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31793197

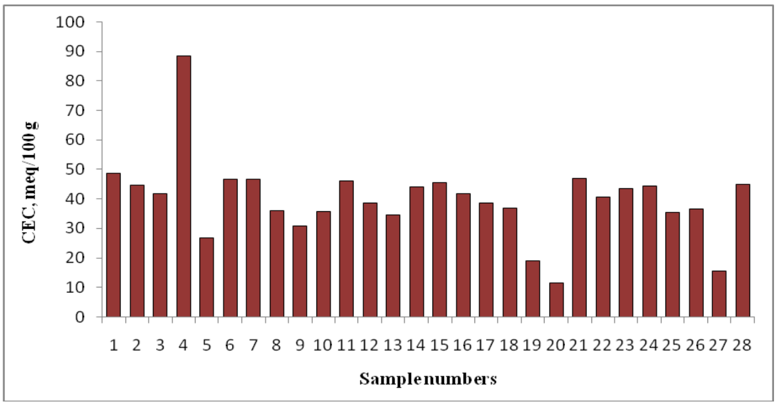

Figure 17. *Cation exchange capacity (CEC) in the upper soil layers of the UPC-1*

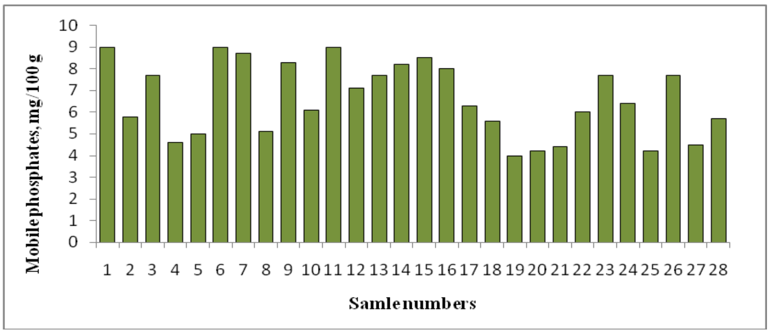

Figure 18. *The content of mobile phosphates in the upper soil layers of the UPC-1*

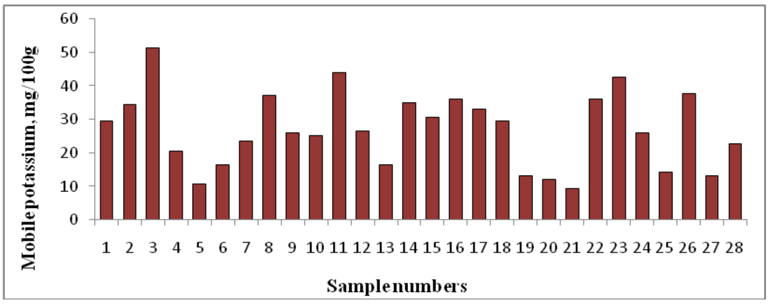

Figure 19. *The content of mobile potassium in the upper soil layers of the UPC-1*

In the upper layers of urbostratozems and quasi-soils, the mobility of heavy metals (*Fig. 20*), as a rule, did not exceed the threshold of previously established toxicity for the testing culture, the highest activity was shown by Cd.

At the same time, the state of the surface soil layers was influenced by the lithological differences of the UPC and the age of urban development. On the average, the increased content of organic carbon in the soils of the UPC-1 (*Fig. 21*) is due to the longer cultivation in this relatively old part of the city. The smallest soil humus content in the relatively young area (UPC-2) is due to weak cultivation, and initially low organic matter content in the sandy soils of the Kama River terraces. In addition, the sandy mineral base of urban soil formation does not contribute to the accumulation of humus.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31793197

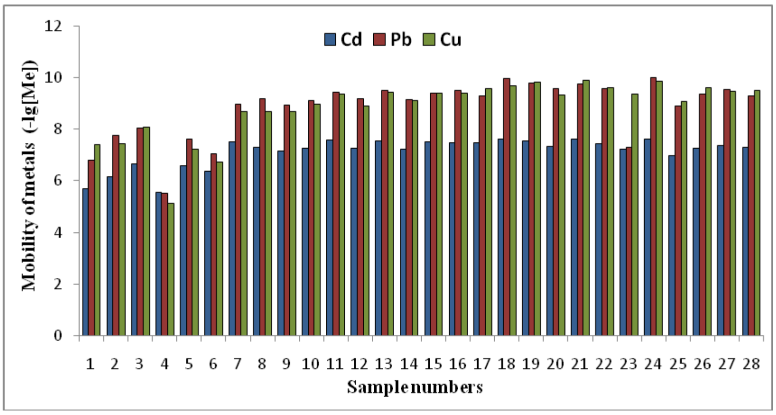

Figure 20. *Mobility of metals (-lg [Me]) in the upper soil layers of the UPC-1*

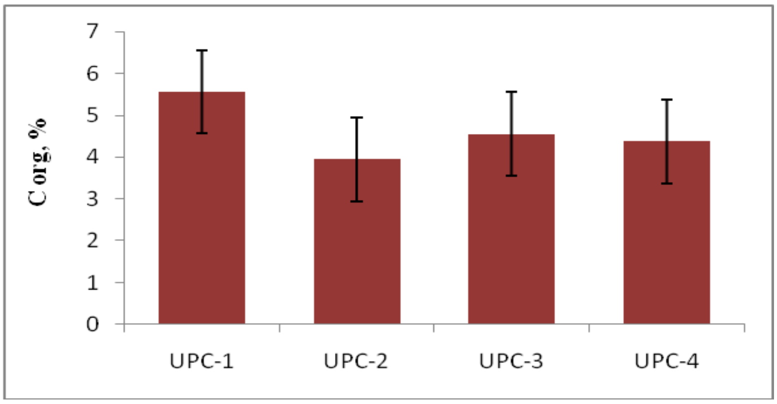

Figure 21. *The average content of organic carbon in the upper soil layers of the UPC*

The surface soil layers in UPC-1 were, on the average, characterized by lower alkalinity due to the introduction of sour peat (*Fig. 22*).

Due to the accumulation of organic matter and predominantly heavy loamy granulometric composition, the surface soil layers in UPC-1 were characterized by the highest absorption capacity (*Fig. 23*). The smallest absorption capacity was in sandy and sandy-loam soils in UPC-2.

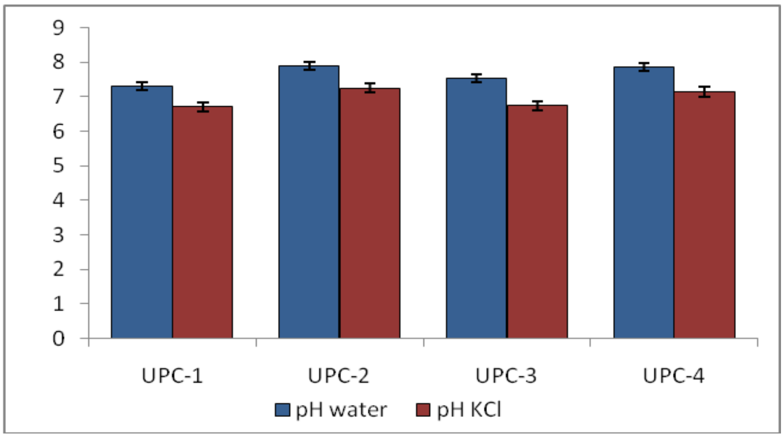

Figure 22. *The average pH in the upper soil horizons of the UPC*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31793197

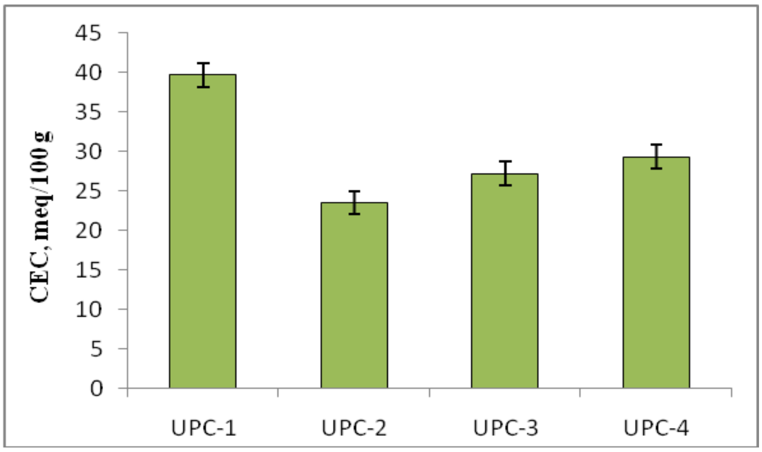

Figure 23. *The average cation exchange capacity in the upper soil horizons of the UPC*

Soils on ancient alluvial sands (UPC-2) and on alluvial sediments (UPC-4) are less supplied with mobile potassium (*Fig. 24*), probably because of the lighter granulometric composition of the rocks.

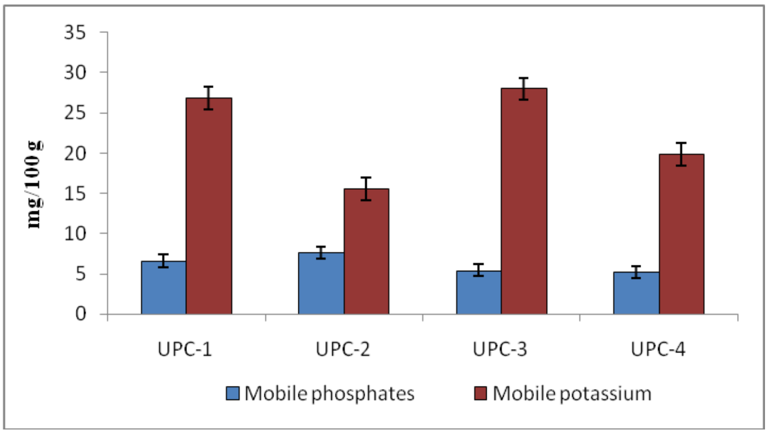

Figure 24. *The average content of mobile phosphates and potassium in the upper soil layers of the UPC*

Phytotesting of the soils of urban pedocomplexes in residential areas of Perm

Plants grown on samples from different soils and TSF, differed significantly in morphometric parameters. Watercress on soil samples from UPC-1 had a slight excess in height, or an allowable decrease (less than 30%) in height and weight relative to the test control, thus the soils had satisfactory ecological condition (*Fig. 25*). However, in 11% of soil samples watercress height was reduced by 31–36% and in 33% of samples weight was reduced by 31–55%. Thus, about the third part of the samples taken within the given residential areas showed the unsatisfactory condition of the surface layers of urbostratozems and quasi-soils.

Comparison of the height and weight of watercress grown on samples from different UPC showed, on the average, a less favorable ecological condition of the surface soil layers in the UPC-2, probably due to sandy and sandy-loam granulometric composition, poverty of organic matter and low content of mobile potassium (*Fig. 26*). Relatively

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31793197

better condition was found in plants on the soils of the UPC-3; that occurs due to the average granulometric composition, the cultivation of the soil in the household plots, and generally reduced anthropogenic load in the area of low-rise buildings.

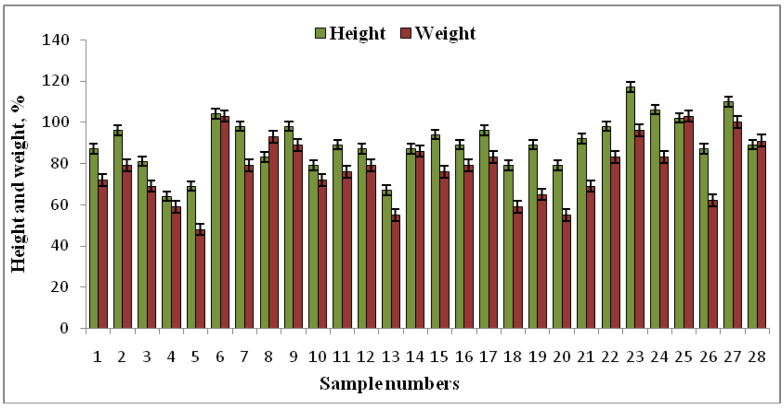

Figure 25. *The height and weight of the testing culture, grown on samples from the soil layers of the UPC-1, % of the test control*

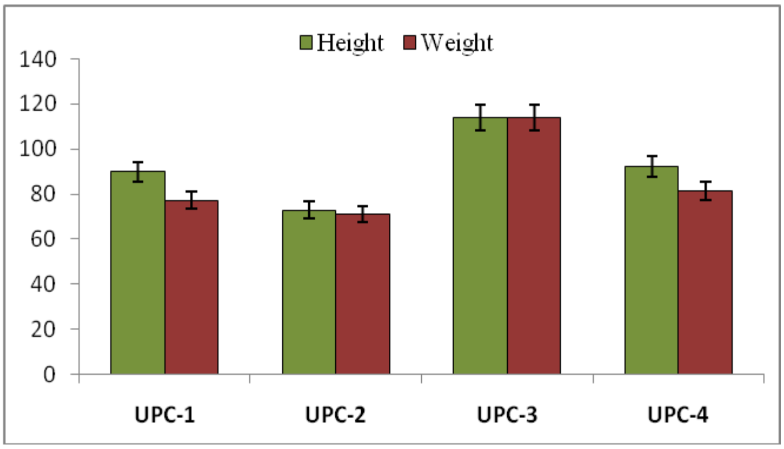

Figure 26. *Height and weight of the testing culture (% of test control) grown on samples from the upper soil layers of the UPC*

Using the correlation analysis, there was established the dependence of the watercress status on soil properties (*Table 3*).

DOI: http://dx.doi.org/10.15666/aeer/1702_31793197

The height and weight of plants were positively effected by the content of organic matter, the capacity of cation exchange, the content of mobile potassium in the surface layers of the soil. The test culture showed a negative reaction to the alkalinity of the soil. A positive response of plants to cadmium mobility was revealed (alongside its low activity), which is possibly due to the indirect effect of a decrease in soil alkalinity, in which the availability of the metal is slightly increased.

Discussion

Despite the general feasibility of using biotesting methods in studying the state of the soil, it is not easy to determine the response of organisms. It is believed that when assessing soil toxicity, it is necessary to involve several organisms from different trophic groups (Keddy et al., 1995; Debus and Hund, 1997; Bierkens et al., 1998; Stephenson et al., 2000; Lisovitskaya and Terekhova, 2010; Rivett et al., 2011; Terekhova, 2011; Pleshakova and Belyakov, 2014; Bardina et al., 2014; Romero-Freire et al., 2015). However, the cultivation of animals, plants, microorganisms requires professional skills. In addition, the reaction of remote groups (producers, decomposers, consumers) to the state of the soil is not straightforward; as a result, the authors often recognize that there is no universal method of biotesting that is suitable for all cases.

In our experiment to assess the ecological state of the soil, we used one type of higher plants - watercress, which showed a response to the genetic properties of the soil, to the mobility of lead and cadmium in them. Certainly, there is a large variety of pollutants in the tested urban soils, which are not determined by the reaction of this testing culture. Thereby, the test control was grown on vermiculite with Knop's solution, the ability of which to create conditions for watercress was compared with the ability of natural soils, including black soil - a standard of regional fertility. The application of the test control allowed to bypass the rule of the only difference that is required to be observed during the phytotesting of the test (polluted) and control soil (Eisentraeger et al., 2004; Lisovitskaya and Terekhova, 2010).

Natural-anthropogenic soil formation in residential areas of the city of Perm has led to the formation of a very heterogeneous soil cover, the properties of the surface soil layers vary in a wide range. Urbostratozems with the urbic horizon prevailed in the soil cover of residential areas, in relatively old areas they were formed alongside certain reclamation - by repeatedly dumping peat from the lowlands. There is a general tendency towards accumulation of carbonates in urban soils (Yang and Zhang, 2015), but on the territory of Perm the enrichment of the soil with dispersed carbonates is due to the widespread use of carbonate rubble and gravel. Due to the presence of carbonate salts, the soils have a neutral alkaline pH, which is affected for a relatively short period by the introduction of acidic peat.

The bioavailability of metals depends on the acid-base, redox properties, the quality and quantity of organic substances, the strength of the absorbing complex and other parameters; it decreases with the increase of pH and in the presence of other metals and chelators in the soil. The total accumulation of heavy metals does not always mean the increase of the soil toxicity, since the soil has a certain buffer capacity (Duchovskis et al., 2003; Romero-Freire et al., 2015). Despite the general accumulation of heavy metals in the non-acidic soils of our city (Eremchenko and Moskvina, 2005), their mobility was low. The negative effect of Cd, Pb mobility on the height and weight of the test culture has not been established.

The concept of "urban complexes" is used in the soil cover mapping of some large cities (New York City Soil Survey Staff, 2005; Sobocka, 2010). Our research has shown that a similar approach is very promising in assessing the ecological state of the surface soil layers. The soils of the UPC in Perm inherited some of the properties of the original soil-forming rocks and soils, primarily related to the particle size distribution, which regulates the water retention and absorption capacity, the availability of chemical elements, the rate of mineralization of organic matter, etc.

Despite the high variation of the soil and TSF properties in urban pedocomplexes, the use of phytotesting shows a generally satisfactory condition of the upper soil layers of residential areas. Soil biotesting in St. Petersburg also showed a satisfactory ecological condition of urban soils, in summer they had no toxicity (Bardina et al., 2013). However, in a relatively old area of the city of Perm, there were revealed the areas where the state of the soil was unsatisfactory. The tendency towards deterioration of the soil ecological condition will develop with modern ways land use and the accumulation of pollutants. According to the results of phytotesting, the most favorable condition was in the soil of a residential area with the distribution of low-rise buildings located near the park area.

Conclusions

This study validates the response of watercress to the leading parameters of soil fertility and the level of soil toxicity. This plant as a testing culture showed mainly a satisfactory condition of the upper layers of soil cover in residential areas of the city of Perm. At the same time, in the areas of relatively old development, a trend towards the emergence of soil toxicity was revealed. In the environmental assessment of soils and the subsequent monitoring of their condition, the idea of urban pedocomplexes occurred to be promising, since the included soils inherit lithological features, on which the specificity of urban soil formation depends. The usage of vermiculite with Knop solution as a test control can be used in the study of various man-made soils and grounds, and we recommend the preliminary comparison of the plants' condition (height and weight) on vermiculite with plants grown on fertile regional soils.

Abstract. This study investigated sediment oxygen consumption rates and geochemical characteristics using chamber experiments and geochemical analyses in the hypoxic area of Gamak Bay, Korea. The organic carbon contents of surface sediments in Gamak Bay were higher in the northern inner bay area, and dropped off toward the southern outer bay. The vertical profiles of calcium carbonate content in piston core sediments indicated that hypoxia has frequently occurred during the past century in the northern inner bay. Sediment chamber experiments were conducted in February, May, August, and November 2010 and 2011 in the hypoxic area of the bay. In the sediment incubation experiments at site C3 in the northern inner bay and site C17 in the southern outer bay, the sediment oxygen consumption rate ranged from 3.98–12.43 mmol m^{-2} d^{-1} and 3.28–8.18 mmol m^{-2} d^{-1}, respectively. When the oxygen was completely depleted, hydrogen sulfide was released at 1.38 and 1.3 mmol m^{-2} d^{-1} at sites C3 and C17, respectively.
Keywords: *hypoxia, ocean acidification, dissolved oxygen, sediment oxygen consumption rate, sediment incubation chamber*

Introduction

Hypoxia occurs seasonally in coastal areas such as estuaries, coastal upwelling areas, and eutrophic waters due to the excessive input of nutrients from rivers. Hypoxic water masses have a dissolved oxygen (DO) concentration $\leq$ 2 mg L^{-1} due to biochemical factors, and are mainly seen throughout the world in highly productive waters and semi-enclosed bays, such as lakes and upwelling areas (Severdrup et al., 1972; Hanazato, 1997; Karim et al., 2002; Wu, 2002; Turner et al., 2005). When there is a large input of organic matter to the ocean bottom layer, and the flow of seawater between the surface and bottom layers is blocked due to stratification, an environment is created in which hypoxia can occur.

Hypoxia is known to occur in the coastal areas of many Asian countries (Wu, 1982; Hong, 1987; Jeng and Han, 1996; Lim et al., 2006). In Korea, hypoxia is reported to occur often in the summer season in connection with red tides (Cho, 1991; Kim, 1990). There is insufficient evidence supporting the occurrence of hypoxic water masses in Cheonsu Bay and Gamak Bay (GB), but these Bays are a focus of concern due to massive organism deaths (Shin, 1995). The depletion of oxygen in a water mass directly affects the respiration and physiological functions of fish and shellfish, as well as the species composition and abundance of benthic organism populations (Hong, 1987; Wu,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31993214

2002; Karim et al., 2003). Bottom layer hypoxic water masses, which occur in coastal areas, not only directly damage benthic organisms, but can have various secondary effects on the coastal ecosystem. It is also known that the upwelling of hypoxic bottom layers can directly lead to organism deaths and cause the water to lose its self-purification functions (Yoon, 1998; Karim et al., 2002).

DO in ocean sediment is consumed by organic matter decomposition, benthic organism respiration, and the oxidation of chemical species. Most DO is consumed by organic matter decomposition, but it is also consumed by nitrification reactions in the nitrogen cycle, the reoxidation of reduced manganese and iron species, and the oxidation of hydrogen sulfide (Lee et al., 2008, 2010). These reactions occur after most of the oxygen has been depleted. If the flow of seawater is disrupted, the reactions can show high abundance and rapidly lead to an anoxic environment. If the anoxic bottom layer environment persists, organic matter decomposition occurs in an anaerobic state and produces ammonia, hydrogen sulfide, and methane. This can limit the distribution and movement of benthic organisms (Yoon, 1998).

The GB is a semi-closed bay in the central part of the Korean peninsula's South Sea. It has an oval shape with a north-south length of 15 km, an east-west length of 9 km, and large and small islands located at its entrance, giving it an almost-closed form. The central area of the GB has a depth of 6–7 m, and the northern inner bay has a depth of 9–10 m. The seabed has a concave, basin-like topography (*Fig. 1*). The bay's sedimentary layer was deposited over the last 6,000 years in accordance with high water levels. The thickness of the sedimentary layer is 5–25 m, being thickest in the central part of the bay and thinner toward the northern inner bay (Kim et al., 2014). The GB is surrounded by islands that strongly affect the conditions therein. Water from the open sea flows in through the bay entrance, and also from another source, Gwangyang Bay, causing different water masses to appear (Lee and Cho, 1990). Approximately 80% of the seawater flows in and out of the bay through its northern entrance, while ~20% flows in and out through a narrow channel. Seawater from both sides meets in the middle of the bay (Lee and Chang, 1982). In summer, stratification occurs readily in water masses in the northern inner bay due to the increased temperature of the surface water and the inflow of freshwater. During flood tide and ebb tide, seawater flow only occurs within the surface layer. It is known that in the northern inner bay, which has a concave seabed, the bottom water is very stagnant (Lee and Cho, 1990).

Hydrogen sulfide is a toxic gas produced when sulfate-reducing bacteria reduce sulfur compounds to hydrogen sulfide in an anaerobic state. Hydrogen sulfide is easily oxidized, which results in the formation of sulfur precipitates. In anoxic environments, hydrogen sulfide is released within the water column and causes mass death of organisms (Milby and Baselt, 1999; Cuevasanta et al., 2017). Hydrogen sulfide is highly toxic and causes great harm to organisms at concentrations of 500 ppm or more; above 1,000 ppm, it causes death (Guidotti, 1994).

The purpose of this study was to investigate the effect of sediment on the hypoxia occurring in GB in the summer of each year. We also investigated the phenomenon that can occur as the duration of hypoxia increases. This study used sediment chamber experiments to measure the oxygen consumed by sediments in regions of the GB where hypoxic water masses occur, to understand how oxygen consumption affects the formation of hypoxic water masses. This study also measured the hydrogen sulfide flux released from sediments during continual hypoxia.

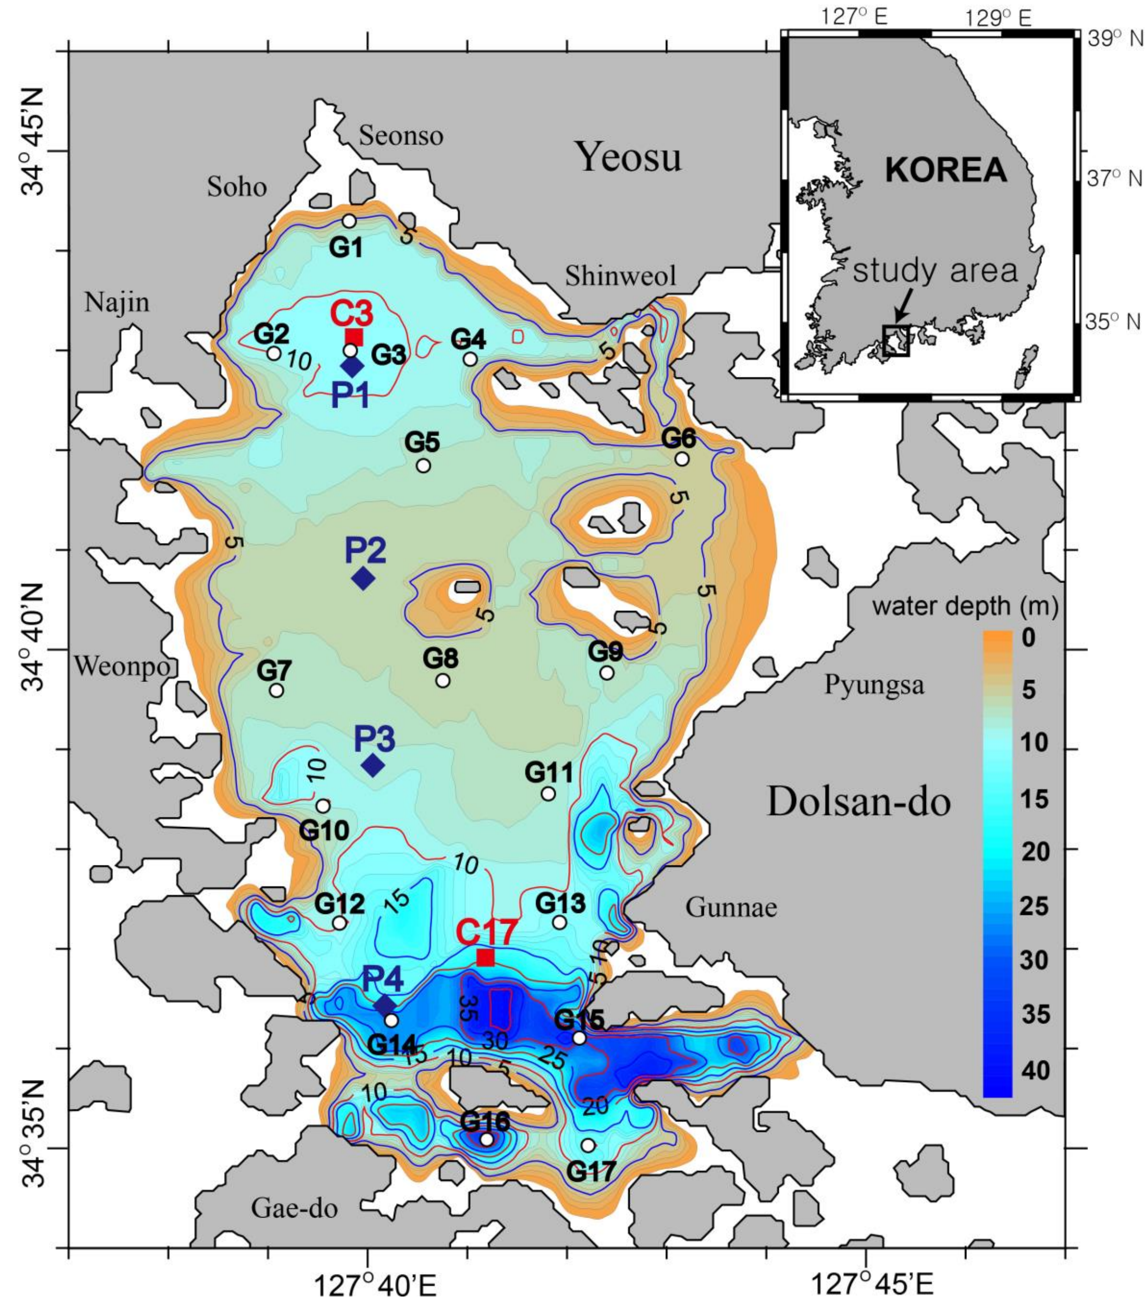

Figure 1. *The locations of piston coring sites (P1–P4), grab sampling sites (G1–G17), and chamber experiment sampling sites (C3 and C17) in Gamak Bay, Korea. The solid lines are contours of water depth; water depth is in meters*

Materials and methods

Surface layer sediments were collected for analysis at 17 sites (G1-G17) using a grab sampler. At 4 sites (P1-P4), a piston corer was used to collect core sediments. At 2 sites (C3 and C17), a box corer was used seasonally to collect sediments for incubation experiment (*Fig. 1*). In the bottom layer of site C3, a hypoxic water mass is formed every summer season. In the bottom layer of site C17, DO concentration is normally distributed. The incubation experiment samples were collected from 2 sites in May,

DOI: http://dx.doi.org/10.15666/aeer/1702_31993214

August and November, 2010 and February, May, August and November, 2011, respectively.

The surface layer sediment was placed in a sample bag and placed in cold storage. In the laboratory, sediment samples were dried and powdered for geochemical analysis, and particle size analysis was also performed. The core sediment was cut in the laboratory, and subsampling was conducted at each measured depth. After pre-treatment of the surface layer and core sediments, the particle sizes were analyzed. The pre-treatment consisted of a 10% hydrochloric acid (HCl) solution, used to remove carbonates, and a 30% hydrogen peroxide (H_20_2) solution to remove organic matter. The pre-treated sediment samples were cleansed several times with distilled water, and a 4 ϕ sieve was used to divide the sediment into particle sizes > 4 ϕ and < 4 ϕ. The particle sizes of sediments < 4 ϕ were analyzed with a particle size analyzer (Sedigraph 5100), and the proportion of sediment > 4 ϕ was evaluated statistically (Folk, 1954). After the sediment samples were transported to the laboratory and dried, their weight was measured to assess their water contents. The dried sediment samples were powdered, and their total carbon and inorganic carbon contents were measured. The total carbon and nitrogen contents were analyzed using a CHNS elemental analyzer (Carlo-Erba), and the inorganic carbon content was analyzed using a coulometric carbon analyzer (UIC). The total organic carbon (TOC) content was calculated by subtracting the inorganic carbon content from the total carbon content. The calcium carbonate ($CaCO_3$) content was calculated by multiplying the inorganic carbon content by 8.33.

After collecting sediment samples in a chamber, incubation experiments were performed in an environment similar to the field conditions in terms of temperature and light. Using a temperature-adjustable water bath, the chamber temperature was kept as similar as possible to that of the bottom water. A dark room with almost no natural light was created, so that exposure to light was minimal. Bottom water (~ 2 L) collected sites C7 and C13 was carefully poured into the chamber containing the sediment samples to cause minimal disturbance to the sediment, and contact with the air was completely blocked. The chamber was equipped with a Clark-type oxygen sensor, a pH sensor, and a hydrogen sulfide sensor (Unisense), and the hourly changes in all three parameters were recorded. The stirrer was connected to the decelerating motor and stirred at 9 rpm in the overlying water (*Fig. 2*). The sediment incubation was performed until the oxygen was completely depleted or the reduction in oxygen became steady. At the beginning and end of the incubation, overlying water was collected, and the DO concentration was adjusted via Winkler titration. The sediment oxygen consumption rate (SOCR) and hydrogen sulfide flux were estimated by reference to the changes in the concentrations measured by the respective sensors in the chamber, and using *Equation 1:*

$$F = dC/dt \times V/A \qquad \text{(Eq.1)}$$

where F is the net flux of substance via the water-sediment boundary layer (mmol m^{-2} day^{-1}), dC/dt is the slope of the changes in the concentration of substance over time (mmol L^{-1} d^{-1}), V is the chamber volume (L), and A is the area of the chamber's horizontal plane (m^2).

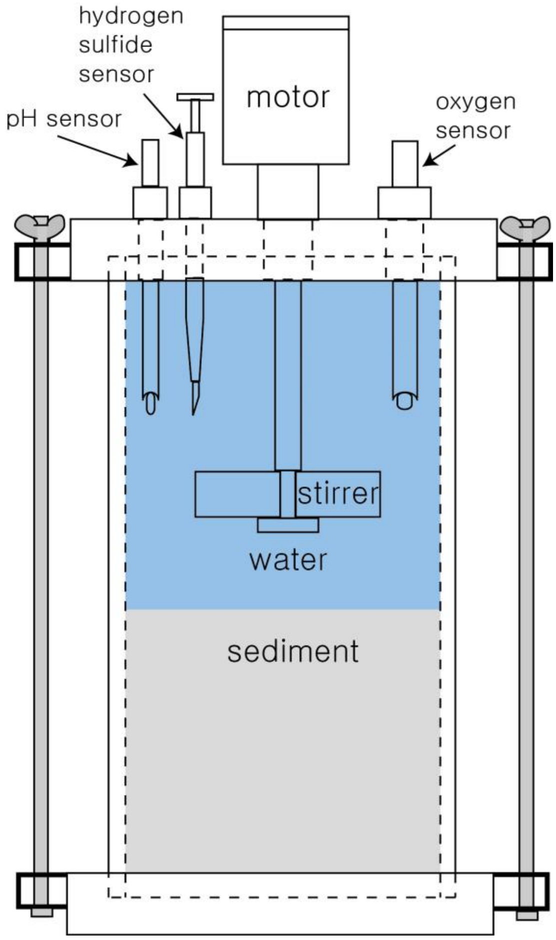

Figure 2. *A schematic diagram of a sediment incubation chamber*

Results

Surface sediment distribution

The surface sediment in the GB is mostly mud, and the amount of sandy sediment increases as one moves toward the southern outer bay. Some gravel sediment is distributed in the deep waterways in the southern outer bay (*Fig. 3a*). The mean particle size of the sediments tends to be fine in the northern inner bay, becoming coarser toward the outer bay. However, the overall bay contains fine sediment with a particle size above 8 ϕ, except at the entrance to the open sea (*Fig. 3b*). The surface layer sediment TOC content is high in the inner bay, at > 2%. In the middle of the bay, the TOC content is < 1% (*Fig. 3c*). The C/N ratio is > 8 in several regions that are adjacent to cities in the northern inner bay. However, the overall bay has a low C/N ratio of < 8 (*Fig. 3d*).

Core sediment vertical distribution

The TOC content was the highest at site P1, at > 1.5% of the sediment surface, with a gradually decreasing trend as the depth increases. However, at sites P2, P3, and P4, there was almost no change in organic carbon content according to depth, and the TOC was relatively low, at < 1% (*Fig. 4*). The $CaCO_3$ content showed an unusual distribution

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31993214

at site P1, with > 1% $CaCO_3$ in the surface sediment, but a very low content of < 0.1% below 20 cm in depth. Conversely, at sites P2, P3, and P4, the $CaCO_3$ content showed almost no vertical change and was fixed at ~2%. At a depth of ~200 cm at site P4, the $CaCO_3$ content was relatively high, at 4%.

Sediment oxygen consumption rate (SOCR)

In the sediments collected from sites C3 and C17 in May 2010, the DO concentration began to decrease as soon as the incubation experiment was started in the chamber, and the decrease was more rapid in the sediment from site C17 than in that from site C3 (*Fig. 4*). At site C17, there was a rapid decrease from the start of the incubation until 12 h, followed by a gradual decrease. This differed from site C3, where the decrease

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31993214

was gradual from the outset. At site C3, the SOCR was 3.58 mmol m^{-2} d^{-1}; at site C17, it was 9.25 mmol m^{-2} d^{-1}. Regarding the incubation results for May 2011, site C3 showed trends similar to those in 2010, while site C17 showed a smaller reduction in DO at the start of the incubation experiment. However, compared to site C3, the extent of DO reduction was larger; 32 h after the start of the incubation, the DO was completely depleted and the water became anoxic. The SOCR in May 2011 was 3.98 mmol m^{-2} d^{-1} site at C3 and 7.17 mmol m^{-2} d^{-1} at site C17.

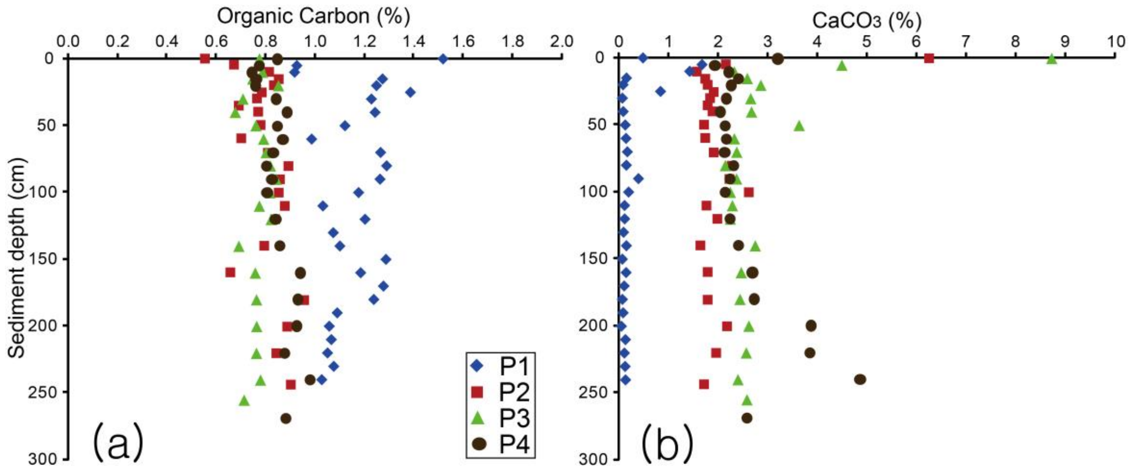

Figure 4. *(a) Vertical profiles of organic carbon contents and (b) calcium carbonate ($CaCO_3$) contents at four piston coring sites*

In the August 2010 sediment incubation experiment, there was no great difference between sites C3 and C17. Site C17 showed a slightly larger reduction in DO, but the reduction trends were almost the same. In contrast, in August 2011, the DO reductions at both sites were more rapid than in 2010. Site C3 became anoxic at 18 h after the start of the culture, and site C17 became anoxic after ~28 h (*Fig. 5*). In August 2010, the SOCRs were 3.94 and 4.31 mmol m^{-2} d^{-1} at sites C3 and C17, respectively; in August 2011, the SOCRs were 12.43 and 8.18 mmol m^{-2} d^{-1}, respectively.

In the November 2010 sediment incubation experiment, the DO decreased more rapidly than in August. The DO concentration in the bottom water was higher in November than in August, and the DO consumption was accelerated. The SOCR at site C17 remained high. Conversely, in 2011, the SOCR at site C17 was markedly lower than at site C3 (*Fig. 6*). The bottom water temperature in the GB in November 2011 remained comparatively high at 18 °C, and the DO consumption was accelerated by the high water temperature. In November 2010, the SOCRs at sites C3 and C17 were 5.35 and 6.21 mmol m^{-2} d^{-1}, respectively; in November 2011, the SOCRs were 6.40 and 3.28 mmol m^{-2} d^{-1}, respectively.

In the February 2011 sediment incubation experiment, sites C3 and C17 showed similar DO reductions. Despite having the highest DO concentration at the start of incubation, the SOCR was not large (*Fig. 6*). In February, the SOCRs at sites C3 and C17 were 4.43 and 4.23 mmol m^{-2} d^{-1}. As the sediment was incubated, the pH decreased in accordance with the reduction in DO concentration. The reduction in pH showed a similar trend to the oxygen consumption: when the DO decreased rapidly, the pH also

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31993214

decreased rapidly, and when the decrease in DO was gradual, the decrease in pH was also gradual (*Fig. 7*).

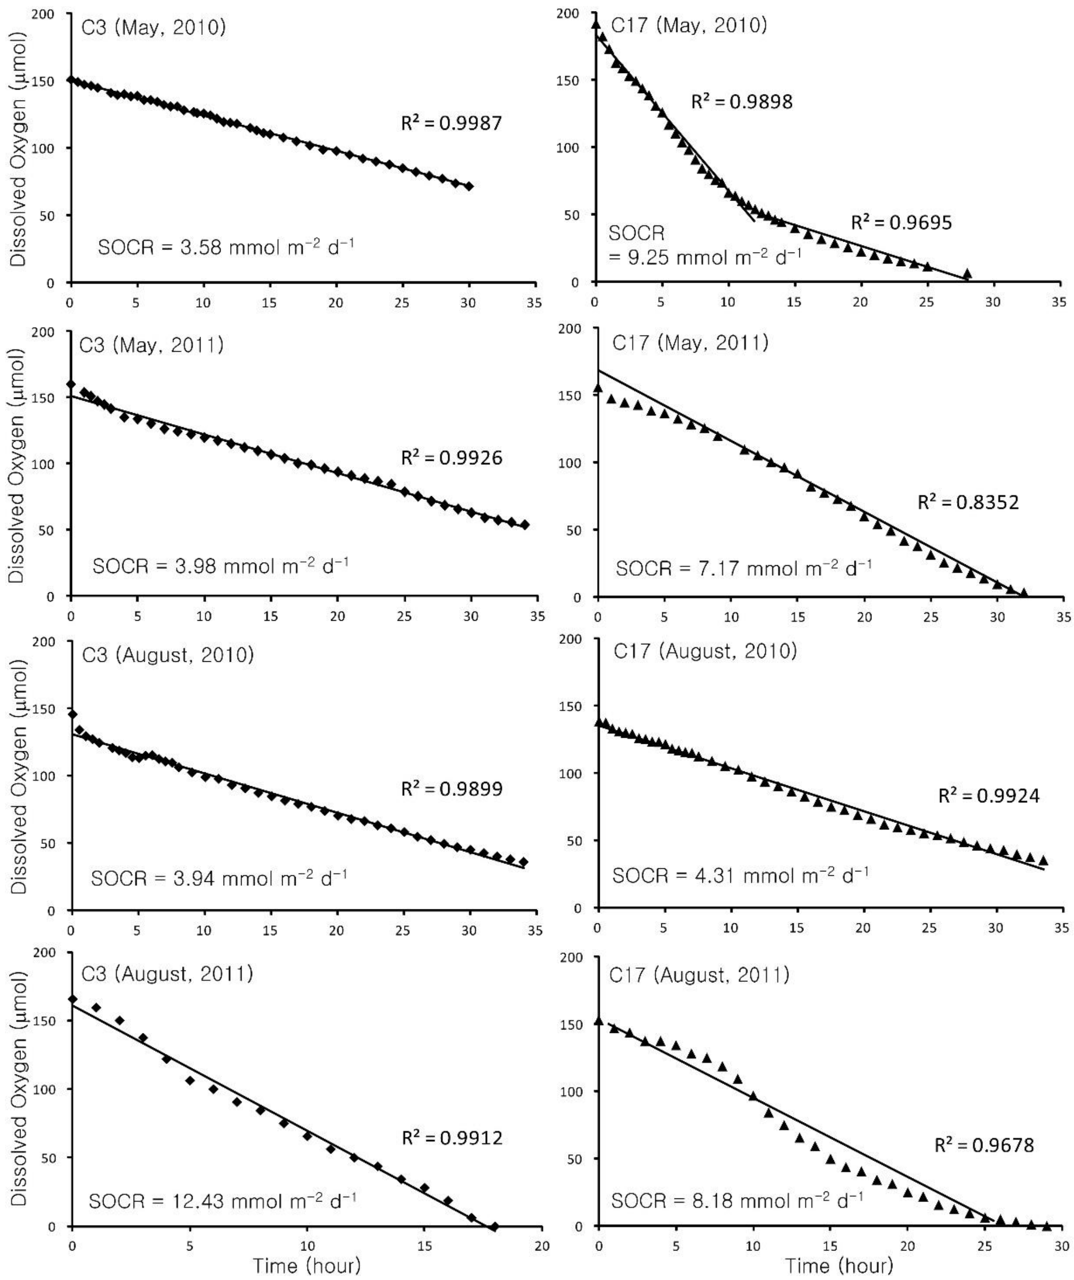

Figure 5. *Time-series of bottom water dissolved oxygen (DO) concentrations in chamber experiments using surface sediments from sites C3 and C17 in Gamak Bay, in May 2010, May 2011, August 2010 and August 2011. The solid lines indicate the results of linear regression at considerable oxygen reduced section*

Hydrogen sulfide release

To examine the substances released from sediments under anoxic conditions, a hydrogen sulfide sensor was installed in a sediment culture chamber in August 2011. During the experiment, the maximum oxygen consumption occurred, and the oxygen

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31993214

was depleted not long after the start of the culture, creating an anoxic environment. At site C3, hydrogen sulfide was released only a few hours after the DO was depleted. At site C17, hydrogen sulfide was released 50 h after the oxygen was depleted (*Fig. 8*). The hydrogen sulfide flux at the sediment surface layer was 1.38 mmol m^{-2} d^{-1} at site C3 and 1.31 mmol m^{-2} d^{-1} at site C17.

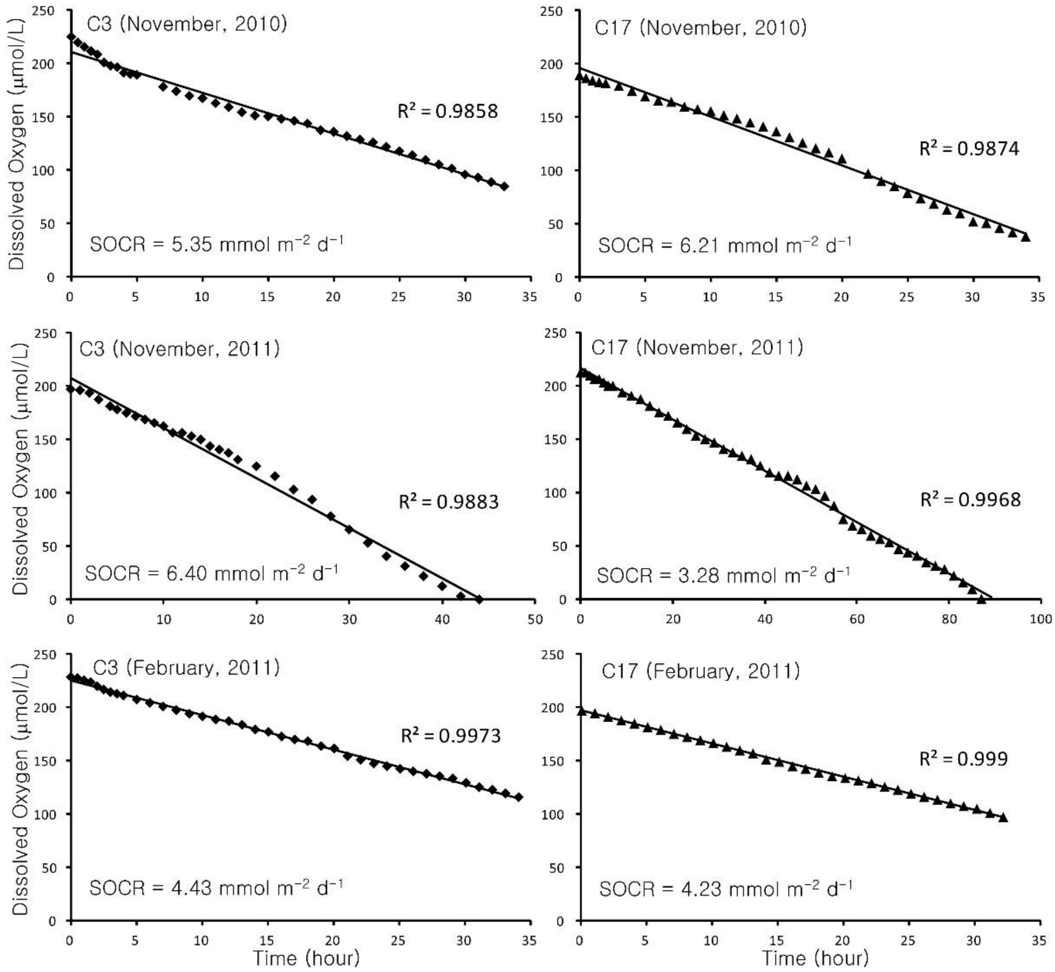

Figure 6. *Time-series of bottom water DO concentrations in chamber experiments using surface sediments from sites C3 and C17 in Gamak Bay, in November 2010, November 2011 and February 2011*

Discussion

Characteristics of sediment distribution

The northern area of the GB is close to a region with a dense urban population, and the ocean currents in the area are very slow. The sediment in the area is artificially inflowing organic matter, which immediately sinks and accumulates. The central area of the GB has a low organic carbon content due to the relatively steady ocean current flow, and deposited organic matter is actively decomposed. As the overall C/N ratio in GB sediment is < 8, the organic matter deposited in the bay primarily originates from the ocean (Prahl et al., 1994). In the inner area of the GB, some organic matter flows in from the land.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31993214

The surface layer sediments around site P1 had a relatively high organic carbon content distribution compared to the other sites, which corresponds with the core sediment analysis. The organic carbon content was high at the surface, and decreased with depth. This is due to the remineralization process caused by the decomposition of organic matter. However, at other sites, there was almost no change in organic carbon content with sediment depth, due to the relatively low level of organic matter remineralization. Due to the small proportion of organic matter that sinks to the bottom, relatively little remineralization of organic matter occurs.

At site P1, the vertical distribution of $CaCO_3$ exhibited relatively high contents at the sediment surface, but very low contents at a level only slightly deeper. The surface sediments had a relatively low $CaCO_3$ content compared to the other sites, but the contents further decreased with depth due to dissolution within the sediment. The vertical distribution suggests an environment in which $CaCO_3$ easily dissolves. When the pH is low, the $CaCO_3$ dissolution rate tends to increase, and it can be inferred that site P1 had a very low pH for some time; such low pH mainly occurs in hypoxic or anoxic environments. Deoxygenation can result in hypoxia (oxygen depletion detrimental to many organisms), and the combined processes are often referred to as ocean acidification and hypoxia (Klinger et al., 2017). The calcification process of marine organisms has mostly exhibited negative sensitivity to ocean acidification, which would lead to a decrease in larval supply and recruitment of adult population (Hendriks et al., 2010; Waldbusser et al., 2015). Ocean acidification can have a significant impact on oyster production in GB, where a large number of oyster farms are well developed.

According to Shin et al. (2012), the sedimentation rate in the central area of the GB is estimated at 2.5 cm $year^{-1}$, while that in the bay interior is estimated to be slightly lower. Based on this, sediments at the 250 cm depth are estimated to be 100 years old, and hypoxia may have occurred in the vicinity of site P1 for the past 100 years. This hypoxia is likely the result of the topography of the seabed, which is convex and basin-like in shape.

Sediment oxygen consumption and hydrogen sulfide release

The larger SOCR at site C17 compared to site C3 is due to numerous benthic organisms, such as bivalves, living in the sediment, where their respiration rapidly reduces the DO. There are relatively fewer benthic organisms living at site C3, and most of the DO is likely consumed by the chemical decomposition of organic matter and the oxidation of chemical species caused by early diagenesis. Similarly, the SOCR is higher at site C17, but hypoxia does not occur due to the relatively active seawater flow between the open sea and the southern outer bay (Lee and Chang, 1982), which provides a steady supply of DO.

The release of carbon dioxide during organic matter decomposition causes the bottom water carbon dioxide concentration to increase and the pH to decrease. The resulting formation of hypoxic water masses contributes to ocean acidification, and the lower pH can affect organisms directly and indirectly. In particular, the increased solubility of $CaCO_3$ affects both the $CaCO_3$ content in the sediment and the sediment-dwelling organisms, the bodies of which contain $CaCO_3$.

The incubation experiments showed similar SOCRs at sites C3 and C17. However, hypoxic water masses form at site C3, but not at site C17, likely due to the action of bottom layer currents. Stratification exists at site C3, and the flow of bottom water is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31993214

completely blocked, while the inflow and outflow of water from the open sea is relatively active at site C17 (KORDI, 2012). The concave basin-shaped seabed topography at site C3 is likely also a contributing factor.

Anthropogenic processes during the last century (e.g., nutrient and organic matter loading) have caused large increases in the number of areas suffering from hypoxia in the world's coastal oceans (Breitburg et al., 2018; Yoann et al., 2018). Global warming as a causes of oxygen loss in the global ocean (Brewer and Peltzer, 2016). Ocean warming reduces the solubility of oxygen and decreasing solubility is estimated to account for ~15% of current total global oxygen loss (Helm et al., 2011; Schmidtko et al., 2017).

Kim et al. (2010) examined the river pollution load that flows into the GB. The total monthly flux of the rivers was 87,220–191,686 m^3 day^{-1}, with a total nitrogen load of 1,112 kg day^{-1}, a total phosphorus load of 89 kg day^{-1}, and a TOC load of 285 kg day^{-1}. Higher pollution loads were seen in May and July when there was a lot of seasonal rain, as well as at the sewage treatment plant near point C3 and the drainage area near Seonso. It can be inferred that the pollution sources flowing in via rivers directly affect the formation of hypoxic water masses in the northern inner bay. Environmental restoration is greatly affected by the nature of the substances polluting the environment (Gray et al., 2002; Pereira et al., 2004). In the case of organic pollution, the environment recovers relatively slowly from substances with slow, complex decomposition processes, such as sewage, in comparison to the recovery from pollution caused by feed and primary production (Munari, 2003; Smith and Shackley, 2006). In the northern inner bay, excessive organic matter has accumulated due to human activity (Yoon et al., 2008). Therefore, the recovery will likely be very slow, and hypoxia will occur yearly. The SOCR is high when the bottom layer DO concentration is low and the bottom layer temperature is high (*Fig. 9*). Hypoxic water masses mainly occur during summer in the GB, because the SOCR increases due to high temperatures and the oxygen supply is interrupted by the formation of stratification. Hypoxic water masses in the GB onset in May and continue into November. The chamber experiments demonstrated the possibility of formation of an anoxic environment if the hypoxic water mass continues for a long time, depleting the oxygen in the bottom layer. If the bottom layer becomes anoxic, the pH might rapidly decrease, causing the release of nutrients and gaseous components, such as hydrogen sulfide, into the sediment.

Kim et al. (2011) estimated that over 70% of the phosphorous in the GB is labile, and can easily move into the water column due to environmental changes such as sediment disturbances or oxidation/reduction, thus becoming a large source of dissolved phosphorous in the water. Deoxygenation of the sediment increases the possibility of a large release of dissolved phosphorous into the water column. In an anoxic environment, hydrogen sulfide and methane would also be released into the water column.

In the chamber experiments conducted in this study, the hydrogen sulfide concentration in the overlying water was ~30 μmol L^{-1}, a level that is harmful to organisms. Hydrogen sulfide concentrations of 20–30 μmol L^{-1} cause liver damage and fatal gill necrosis in fish (Keimer et al., 1995). Hydrogen sulfide released from anoxic sediments is immediately oxidized by oxygen in the water column (Brooks and Mahnken, 2003). However, even at concentrations < 10 μmol L^{-1}, fish experience physiological stress and stunted growth (Black et al., 1995). Long-term anoxic conditions increase the risk that hydrogen sulfide concentrations will rise to levels fatal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31993214

to bay organisms. To date, there have been no reports of organism deaths due to hydrogen sulfide in the GB. However, there have been cases in which hypoxia occurred in July and persisted until October, and the ecosystem may have been disturbed by hydrogen sulfide release. This phenomenon is expected to occur more often in the near future due to global warming.

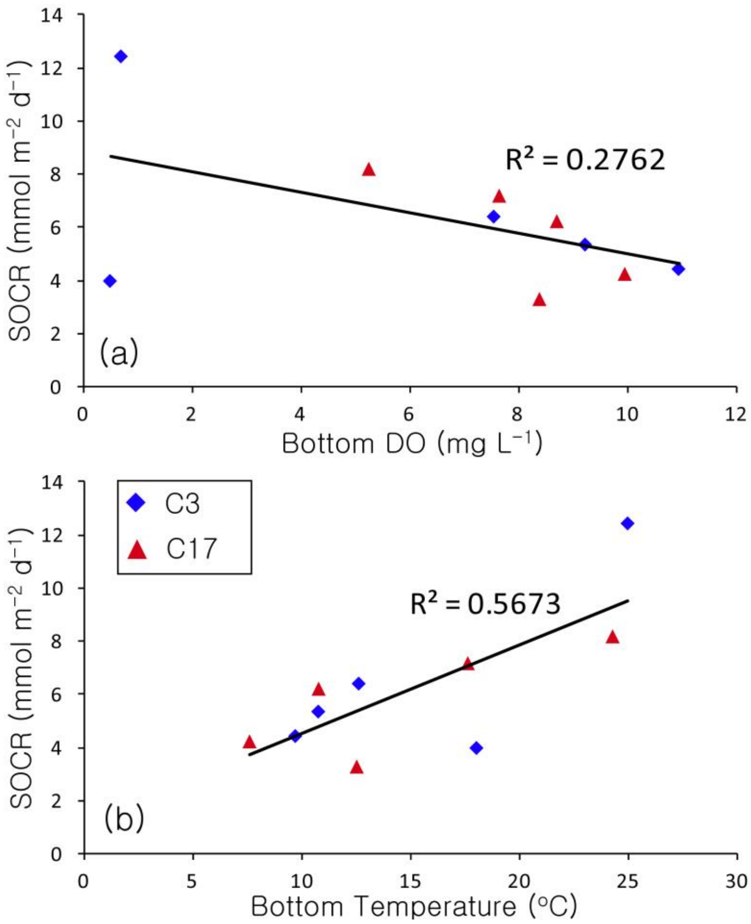

Figure 9. *Sediment oxygen consumption rate (SOCR) versus (a) bottom water DO concentration and (b) bottom water temperature at sites C3 and C17 in Gamak Bay*

Conclusion

In the GB, the surface sediment organic matter content is high in the inner bay, and decreases toward the open sea. Most sediment organic matter in the GB originates from the ocean. However, in the northern inner bay, several areas contain sediment organic matter originating from the nearby land. The hypoxic water masses that frequently occur during summer in the northern inner bay are caused by the high sediment organic matter content and obstruction of seawater flow. The core sediment from the northern inner bay exhibited very low $CaCO_3$ contents down to 260 cm in depth, indicative of a sediment environment with very low pH in which hypoxia can occur. This recurring hypoxic environment has persisted in these waters for hundreds of years.

At site C3, which is in the northern inner bay and frequently experiences hypoxia, the SOCR ranged from 3.98–12.43 mmol m^{-2} d^{-1}, while at site C17, which is near the open water and does not experience hypoxia, the SOCR ranged from 3.28–8.18 mmol

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_31993214

m^{-2} d^{-1}, which is largely similar. Despite the high SOCR, hypoxia does not occur at the southern part of the GB near the open sea due to the active flow of seawater and the steady supply of oxygen. The SOCR seems to be most closely related to the bottom water temperature. If the temperature is high, the bacteria related to organic matter decomposition are highly active, and when decomposition occurs more actively, more oxygen is consumed.

Hypoxic water masses, which continually occur during summer in the northern inner bay, can cause reductions in pH and affect ocean acidification. If a hypoxic water mass persists in the bottom layer, the water can become anoxic, and hydrogen sulfide and other chemicals may be released from the sediment. The hydrogen sulfide flux was 1.38 and 1.31 mmol m^{-2} d^{-1}at sites C3 and C17, respectively. The chamber experiment results demonstrate the possibility that hydrogen sulfide could be released at a concentration that is harmful to bay organisms.

(Received 12th Nov 2018; accepted 11th Jan 2019)

Abstract. Due to the lack of control over the spread of pathogens and effective pesticides with antibacterial activity bacterial diseases cause significant economic losses in vegetable production including tomatoes. Therefore, the search for ways of biocontrol of bacterial diseases pathogens in vegetable crops is an extremely urgent problem. The literature review presents a systematic analysis of modern measures of agrotechnical, chemical and biotechnological control of bacterial diseases in tomatoes, and increasing the resistance degree of these crops against phytopathogenic bacteria using traditional methods, cell selection and the involvement of genetic engineering approaches. It is shown that agrotechnical measures are preventive in nature, while using chemicals and antibiotics has side effects, in particular phytotoxicity and the appearance of resistant strains of pathogens. Effective and economically viable is the use of biotechnological preparations and the cultivation of the varieties resistant to pathogens of bacterial diseases in vegetable crops. Selection of varieties resistant to phytopathogenic bacteria is based on the use of wild species as resistance sources. The creation of genetically modified plants containing avr-genes, resistance genes against bacterial phytotoxins, PR-proteins and AMP is promising.
Keywords: *bacterial diseases, biopreparations, antagonists, cells selection, GM-resistant plants*

Introduction

One of the reasons for the limited production of vegetable products is the significant economic losses caused by bacterial diseases (Khaliluev and Shpakovski, 2013). In vegetable crops bacterial etiology describes 40 widespread pathogens (Hvozdiak et al., 2011). An intensive growth in harmfulness has been recently observed in the case of phytopathogenic bacteria, which is the result of: 1) the emergence of new bacteria strains affecting a wide range of vegetable crops; 2) global climate change, contributing to the expansion of areas of bacteria distribution; 3) lack of reliable control over the infection sources and circulation of pathogens; 4) introduction of new varieties and technologies of plant cultivation; 5) excessive fungicide application (Punyna, 2009).

The basis for the developing control methods for bacterial pathogens is timely and accurate diagnosis. After all, bacterial diseases often have external manifestations similar to the symptoms of diseases caused by micromycetes and mycoplasmas (Hvozdiak et al., 2011). Imperfect laboratory diagnosis leads to improper or even harmful use of the means meant to control pathogens.

Modern bases of protection of vegetable crops from bacterial diseases are based on complex use of methods of control of pathogens (Khaliluev and Shpakovski, 2013). For their effective use, it is necessary to reliably determine the direction of existing methods with respect to the nature and pathways of pathogens and sources of infection. The review presents agrotechnical and chemical methods, the use of biotechnological preparations, antibiotics, the cultivation of resistant and genetically modified plant varieties, wish are part of a complex system for control of tomato bacterial diseases agents.

Agrotechnical measures

Compliance with optimal temperature regimes (avoiding sudden changes between night and day temperatures), air and soil humidity, planting time, timely application of fertilizers and irrigation with water the temperature of which is not higher than 25 °C. In greenhouses, treating the tomato seeds with disinfectants, removal of crop residues and disinfection of equipment are recommended. In the field, as a result of the intensive development of bacterial diseases, crop rotation is used with the return of the culture not earlier than in the season, the removal of weeds and plant residues, minimization of mechanical damage to the culture, the destruction of infected plants or pruning of infected leaves. However, the existing measures are only preventive in nature (Tkalenko, 2012; Huliaieva et al., 2018).

Chemical measures

In production conditions fungicides are used against pathogens of bacterial diseases, as there are no special preparations with antibacterial activity among those registered in Ukraine (Kolomiiets et al., 2017a). In our research we have been investigated antibacterial action of about 50 pesticides with such active ingredients as dimethomorph, mancozeb metalaxyl, azoxystrobin, fenamidone, propamocarb hydrochloride, copper sulfate and oxychloride, mandipropamid, difenoconazole, aluminium phosphide, phosphorous acid, pyraclostrobin and metiram included in the List of pesticides and agrochemicals and allowed for use in Ukraine on tomato crops. It can be argued that the vast majority of pesticides used, does not suppress the development of pathogens of bacterial diseases in tomato plants. Slight antibacterial activity against strains of the pathogens of bacterial cancer, bacterial speak, and black bacterial spot of tomatoes has only aluminium phosphide and phosphorus acid, as well as mancozeb and mancozeb in combination with metalaxyl (Kolomiiets et al., 2017a). From this point of view, it is important to search, test and develop the methods for the use of special substances for the control of phytopathogenic bacteria (Dankevych et al., 2018).

Now, to control bacterial diseases of tomatoes, preference is given to preparations, in particular, sulfate, oxychloride and copper hydroxide (Khadija, 2002). Copper ions denature proteins and thereby destroy enzymes, which are crucial for the bacterial cells functioning (Mohsin et al., 2016). Copper destroys the cells of pathogens on the surface of plant leaves, but once they penetrate the host tissue, they are no longer sensitive to copper processing. Thus, copper sprays act as protective fungicidal / bactericidal methods in the early stages of infection, but are not characterized by prolonged and stable activity (Behlau et al., 2008).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32153230

Known that the use of copper hydroxide and mancozeb inhibits the development of bacterial cancer, which confirms a synergistic effect, as a separate application of mancozeb does not reduce the population and spread of *Clavibacter michiganensis* subsp. *michiganensis* (Hausbeck et al., 2000).

In our research we have found insignificant antibacterial activity of chemical defenses on the basis of copper hydroxide (770 g/kg) and mancozeb (800 g/kg) relative to gram-positive *C. michiganensis* subsp. *michiganensis* (Kolomiiets et al., 2017a).

The use of copper sulfate and 8-hydroxyquinoline resulted in a significant reduction in the symptoms of bacterial cancer of tomatoes was established (Leon et al., 2008). At the same time, a synergistic effect was observed of 8-hydroxyquinoline/ copper sulfate against *C. michiganensis* subsp. *michiganensis*. The combination of available substances in the conditions of reducing the concentration by half provided a more significant and reliable reduction of bacterial symptoms than the use of individual substances (Leon et al., 2008).

In our research we have established a slight antibacterial activity of copper sulfate (345 g/l) relative to *C. michiganensis* subsp. *michiganensis* with zones of growth inhibition of 20 – 50 mm. Relative to tomato bacterial mottle pathogen *P. syringae* pv. *tomato*, antibacterial activity was observed within the growth inhibition zones from 14 to 54 mm, and for the black bacterial spotting pathogen *X. vesicatoria* it did not exceed 18 mm (Kolomiiets et al., 2017a).

The use of bactericides based on copper in combination with fungicides, ethylene-bis-dithionate or MANCOZEB caused an increase in the level of control of even copper-tolerant populations of pathogens. The inductor of plant resistance acibenzolar-S-methyl (CGA-245704 or Actigard) ensured the formation of low indicators of control of the distribution of tomato black bacterial spotting and bacterial mottle (Itako et al., 2014).

It was found that hexanoic acid (Hx) reduces the development of symptoms caused by *P. syringae* pv. *tomato* DC3000 by 50% in treated plants when compared to untreated ones, which indicates the induction of Hx resistance against this pathogen (Scalschi et al., 2014). The effect of Hx is based on inactivation of bacterial virulence genes and slowing their expression or regression (Scalschi et al., 2014).

In the field (Itako et al., 2014) it was evaluated the effectiveness of acibenzolar-S-methyl, fluosines, pyraclostrobine, copper oxychloride, MANCOZEB/ copper oxychloride and pyraclostrobine/metiram for the control of tomato black bacterial spot. In 40 days after transplantation, the plants were inoculated with *X. perforans* (10^7 CFU/ml) in order to assess the degree of development of the disease. Promising results were obtained only under treatment with fluosine, pyraclostrobine, pyraclostrobine/metiram, copper oxychloride and mancozeb/copper oxychloride. The activity of enzymes of polyphenol oxidase and peroxidase was higher than in terms of application of acibenzolar-S-methyl, pyraclostrobine and pyraclostrobine/metiram on tomato leaves, which confirms their participation in the mechanisms of induction of resistance to the pathogen *X. perforans*.

In our research, in a series of studies, the preparation with the active substance pyraclostrobine (50 g/kg) metiram (550 g/kg) was somewhat active against gram-positive *C. michiganensis* subsp. *michiganensis* and did not show antibacterial activity against gram-negative *P. syringae* pv. *tomato* (Kolomiiets et al., 2017a). In our opinion, this is due to the structural features of the cell wall of gram-positive and gram-negative bacteria. This drug caused the maximum increase in the activity of the enzyme

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32153230

peroxidase in the leaves of plants for 12 h, which was 111.5–112.5 u.mg^{-1}·s^{-1} (Kolomiiets et al., 2017a).

However, in published literature chemical means of bacterial pathogen suppression is only partially effective, and under favorable conditions for the development of the disease (high temperature, precipitation) are generally ineffective. Intensive treatment with copper for commercial tomato cultivation for many years caused the appearance of resistant strains of phytopathogenic bacteria (Patyka et al., 2016), accumulation of copper in soils and water with subsequent toxic effects on plants, soil beneficial microflora and invertebrate organisms. As a result, there is an urgent need to develop fundamentally new alternative measures to protect vegetable crops from bacterial diseases.

Biotechnological preparations

The basis of the creation of biotechnological preparations of different functional orientation for biocontrol of phytopathogenic bacteria is the elective ability of microorganisms to exhibit antagonistic activity against phytopathogens and stimulate plant defense mechanisms. The prospects of creation of biological means of protection of vegetable crops on the basis of bacteria of the genus *Bacillus* are shown. It is believed that the high level of antagonism of bacilli against phytopathogenic bacteria is associated with the synthesis of a wide range of exometabolites (Bais et al., 2004; Stein et al., 2004; Butcher et al., 2007; Nagorska et al., 2007; Ongena et al., 2007; Ongena and Jacques, 2008; Roi et al., 2012). Anyway, the literature does not provide enough information about the exact mechanisms of action *B. subtilis* as an agent of biocontrol of pathogens on vegetable crops.

The antibacterial activity of surfactin (lipopeptide antimicrobial agent) was determinedby testing the mutant strain *B. subtilis* M1 with deletion in the surfactants gene, which was ineffective as a biocontrol agent of *P. syringae pv. tomato* DC3000 (Bais et al., 2004). Wild strain *B. subtilis* 6051 in terms of colonization of the roots formed stable and extensive biofilm and secreted surfactin, inhibiting the growth of the pathogen of tomato bacterial mottle, which confirms its bactericidal activity.

The treatment with the suspension *B. subtilis* (Quadra 136 and 137) and *Rhodosporidium diobovatum* (S33) prevents the development of bacterial cancer in greenhouse conditions, which is caused by *C. michiganensis* subsp. *michiganensis* was reported (Utkhede and Koch, 2004). Similarly, in terms of treatment of seeds with strains *B. subtilis*GBO3, *B. amyloliquefaciens* IN937a and *Brevibacillus brevis* IPC11 maximum protection of tomatoes against bacterial cancer was recorded.

In our research experiments, biological preparations Phytohelp, Phytocid and Extrasol on the basis of *B. subtilis* had different antibacterial activity to pathogens. Thus, Phytohelp and Phytocid showed high antibacterial activity against *C. michiganensis* subsp. *michiganensis* and *X. vesicatoria*, and the diameter of the zone of absence of growth ranged from 70 to 80 mm. For strains *C. michiganensis* subsp. *michiganensis* and *X. vesicatoria* in terms of action of the Extrasol preparation, it did not exceed 40 mm. Active to the causative agent of tomato bacterial mottle *P. syringae* pv. *tomato* was Extrasol with a diameter of the zone of growth absence of 20–26 mm. Other preparations did not affect this pathogen (Kolomiiets et al., 2017a).

It was described the antagonistic activity of endophytic bacteria *B. pumilus* and *B. amyloliquefacies* against *P. syringae* pv. *tomato* NS4, transformed by GFP-gene (Green

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32153230

Fluorescent Protein), and a wild-type NW strain. After using endophytic bacteria was monitored population decrease of *P. syringae* pv. *tomato* NW and NS4 on phyloplan, and number of bacterial spots on the leaves of tomatoes compared with standard chemical protection of the copper oxychloride. In terms of fluorescence microscopy it was monitored small number of labeled GFP cells *P. syringae* pv. *tomato* NS4, which colonized rich in the carbon organic compounds areas of phytoplan. Untreated with antagonists plant leaves contained a significant amount of labeled GFP cells *P. syringae* pv. *tomato* NS4 (Filho et al., 2013).

It was shown the efficiency of epiphytic bacteria *Paenibacillus macerans* and *B. pumilus* for biocontrol of *X. vesicatoria* (Lanna et al., 2010), that reduce by 70% the number of phytopathogenic bacteria cells in phytoplan. The test for antagonistic activity confirmed that epiphytic bacteria effectively inhibit the growth of phytopathogens.

According to data (Fousia et al., 2015), treatment of seeds with *B. subtilis* QST 713 significantly reduces the development of bacterial diseases and provides an increase in plant height when compared to the control. In addition, quantitative PCR-analysis of expression *PR1a*, *PR1b,* and *Pin2* (encoding enzymes for the biosynthesis of salicylic and jasmonic acids) confirmed the role of *Pin2* in protective activity of *B. subtilis* QST 713, as an ecspression of *Pin2* was significantly higher in the treated with *B. subtilis* QST 713 plants, infected by *P. syringae* pv. *tomato* when compared to the control. An early increase was determined in the activity of antioxidant enzymes of superoxide dismutase, catalase, peroxidase and polyphenol oxidase, and a decrease in the content of malonic aldehyde in terms of inoculation of *B. subtilis* QST 713, which plays a key role in reducing oxidative stress and induces systemic resistance of tomato plants against black bacterial spotting (Chandrasekaran and Chun, 2016).

Effective against pathogens of bacterial diseases were biopreparations based on bacteria of the genus *Streptomyces,* which are characterized by selectivity of action and high activity to phytopathogens in low concentrations, which allows avoiding their excessive accumulation in the fruits of vegetable crops. When compared to chemical products, they penetrate more intensively and are metabolized in plant tissues through the leaf surface, stems and roots, are less toxic, decompose quickly, do not pollute the environment and dominate most fungicides in terms of effectiveness (Ferraz et al., 2015).

To prevent loss of tomato crops in greenhouses, caused by the pathogen of bacterial wilt *Ralstonia solanacearum*, it was proposed the root treatment of plants with bacterial isolates *B. thuringiensis* CR-371 and actinomyces *S. avermectinius* NBRC14893 (Elsharkawy et al., 2015).

The possibility of using antagonists *S. setonii* UFV618 and *B. cereus* UFV592 to reduce the symptoms of black bacterial spotting and induce the synthesis of protective enzymes in the leaves of tomato plants that are infected by *Xanthomonas* has been established. The final degree of development of the disease decreased by 29.44 and 59.26% in treatments with *B. cereus* UFV592 and *S. setonii* UFV618. The activity of antagonists can be explained by the activation of protective peroxidase enzymes, polyphenol oxidase, β-1,3-glucanase, chitinase, phenylalanine ammonia-lyase and lipoxygenase involved in the formation of systematic resistance of plants against bacterial diseases (Ferraz et al., 2015).

The antibacterial activity of biopreparations based on *Streptomyces:* Avercom, Avercom nova, Violar, and Phytovit, synthesizing antibiotic substances active to a wide range of microorganisms and fungi have proved (Elsharkawy et al., 2015). Areas of no

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32153230

growth of strains *C. michiganensis* subsp. *michiganensis* in terms of action of piopreparations Avercom, Avercom nova, Violar i Phytovit were 16–50 mm. Biopreparations Phytovit and Violar ware inert the pathogens of tomato bacterial mottle *P. syringae* pv. *tomato* and black bacterial spot *X. vesicatoria* (Biliavska rt al., 2015).

Thus, in vegetable growing, promising is the use of biopreparations, which are based on living cultures and metabolic products of microorganisms. It was confirmed antagonistic activity of bacteria of genera *Bacillus* and *Streptomyces* to phytopathogenic bacteria, and biopreparations based on them are recommended for biocontrol of bacterial pathogens.

Antibiotics as means of protection of vegetable crops against bacterial diseases pathogens

Protection against bacterial diseases includes the treatment of vegetable crops with antibiotics, which have advantages in the fight against phytopathogenic microorganisms in comparison to chemicals. They easily penetrate into the tissues and organs of plants through the roots, stems, leaf surface and are metabolized in seeds, so their action is less dependent on climatic conditions; they have antibacterial effect, are relatively slow inactivated, and are non-toxic to the plant body (Kolomiiets et al., 2016). Especially quickly penetrate into plant tissue antibiotics of neutral and acidic nature (chloramphenicol, penicillin), slower – amphoteric (chlortetracycline, oxytetracycline) and antibiotics-the basics (neomycin, streptomycin) (McManus et al., 2002).

Antibiotics for plants are made in the form of powders that contain from 17 to 20% of the active ingredient, and are dissolved or suspended in water to a concentration of 50 to 300 parts per million, and then are applied as an aerosol to the plant organs susceptible to pathogens. They are relatively expensive, so they are primarily used in vegetable and fruit crops (McManus et al., 2002).

The most promising for vegetable production are streptomycin preparations, which suppress the proliferation of bacteria by binding to ribosomes and inhibiting protein synthesis at the stage of initiation of translation (Schluenzen et al., 2006; Schuwirth et al., 2006). The US environmental protection Agency assigned the lowest toxicity category and lack of carcinogenic and mutagenic activity to streptomycin and oxytetracycline. In New Zealand it was registered streptomycin-containing preparation Keystrepto™ for the control of *P. syringae* pv. *tomato, X. vesicatoria, C. michiganensis* subsp. *Michiganensis,* and *P. syringae* pv. *syringae* on tomatoes (Vanneste, 2011).

It was shown that neomycin from the liquid culture of the fungus *S. fradiae* HTP has antibacterial activity *in vitro* and *in vivo* against phytopathogenic bacteria *R. solanacearum*, *E. carotovora* and *X. vesicatoria*. In terms of concentration 200 mg^{-1} of neomycin the reduction in the degree of development of the disease is ranged from 69.07 to 80.51%, which is more effective than in terms of treating with streptomycin – from 50.00 to 72.56% (Tao et al., 2011).

In Florida (USA) it was estimated the influence of kasugamicine (commercial preparation Kasumin® 2L) on the pathogen of tomato bacterial mottle. During its application in the greenhouse there was a decrease in the degree of development of bacterial mottle by 37.5% when compared to the control (Vallad and Pernezny, 2010; EPA, 2005).

However, the use of antibiotics can cause the proliferation of antibiotic-resistant bacteria and the spread of antibiotic resistance genes in the environment or even in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32153230

humans (McManus et al., 2002). So, the appearance of streptomycin-resistant (Sm^R) pathogens makes it difficult to control bacterial diseases of vegetable crops. For example, in the USA streptomycin is allowed to be used on tomato and pepper plants for the control of *X. campestris* pv. *vesicatoria*, which is rarely used for this purpose, as resistant strains were first discovered in Florida in the early 1960s, which are now widespread. Sm^R include the other phytopathogenic bacteria such as *E. carotovora*, *P. chichorii*, *P. lachrymans*, *P. syringae* pv. *papulans*, *P. syringae* pv. *Syringee,* and *X. dieffenbachiae*. The use of kasugamicine is also contradictory, which, together with streptomycin have similar biological mechanisms of action.

It becomes evident that antibiotics are ineffective in protecting plants against bacterial diseases through their instability, blocking metabolic pathways, phytotoxic side effects, entering the human and animal food chain, high cost and development of resistant bacterial populations. Promising is the use of non-preparative forms of antibiotics, and biotechnological preparations, which are based on strains-producers.

Cultivation of resistant varieties of vegetable crops is one of the promising systems of biocontrol of phytopathogenic bacteria. The problem of complex resistance of genotypes against the most dangerous diseases has not been solved yet (Khaliluev and Shpakovski, 2013). The reasons for this are the genetic complexity of the trait, genome instability and microevolutionary changes in the host-pathogen system, as well as the emergence of highly resistant biotypes of pathogens against the background of the use of increased amounts of pesticides (Khaliluev and Shpakovski, 2013), the gradual increase in the duration of the average temperatures of the growing season, the proportion of monoculture and genetic homogeneity of the varieties that are grown. To provide breeding programs, it is necessary to search for new sources of resistance against bacterial diseases, which will allow optimizing, accelerating and increasing the effectiveness of the breeding process, creating the new varieties and hybrids with high resistance against pathogens (Khaliluev and Shpakovski, 2013).

There is evidence that microscopy of the stems of resistant tomato plants affected by *R. solanacearum*, showed restrictions on the spread of bacteria with thickening of the cell membrane and synthesis of suberin. The available samples are recommended to be used in the program for the selection of tomatoes against the bacterial wilting pathogen (Kim et al., 2016). In our research, the tomato plants of the resistant variety Chaika under the action of virulent strain *P. syringae* pv. *tomato* IZ-28 the cell walls were seeped with suberin and filled with lignin components, which is typical for the reactions of induced immunity. Lignin was intensively deposited on tangent and frontal anticlinal walls according to the potential directions of translocation of phytopathogenic bacteria, which created cell barriers to their spread (Kolomiiets et al., 2017b).

The localization and distribution of *R. solanacearum* in plants of 11 resistant tomato varieties from different genetic sources and susceptible variety Ponderosa was studied (Nakaho et al., 2004). The spread of bacteria in the stems of resistant tomato plants was suppressed by blocking the transition of pathogens from protoxylem or primary xylem to other xylem tissues. It was most noticeable on the Hawaii 7996 breeding line, which may be an alternative genetic source for tomato plant reproduction, resistant to bacterial wilting.

In Bulgaria they were obtained stable against two races T1 and T3 *X. vesicatoria* tomato lines for growing in the field. Lines created by hybridization between wild species *Lycopersicon L. pimpinellifolium* PI 126925, *L. chilense* LA 460, *L. peruvianum* var *humifusum* PI 127829, and *L. hirsutum* f. *glabratum*. PI 134418, were used as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32153230

sources of sustainability. They were tested more than a hundred lines of tomatoes, from which they were selected promising numbers 36, 44, 44/1, 163/1, 165/2, 167, 167/4, 267 and 270, which showed high resistance against the race T3 *X. vesicatoria*. Stable plants from the group I were obtained by hybridization with *L. pimpinellifolium* PI 126925. A significant number of stable lines were selected in the group II with the involvement of *L. chilense* LA 460 and *L. peruvianum* var *humifusum* PI 127829. Group III lines that occurred with *L. hirsutum* f. *glabratum* PI 134418, were less resistant to race T1. At the same time, their natural resistance against the T3 race has not changed. The available nine lines were marked by valuable morphological and agronomic traits, which were selected for the reproduction of resistant varieties of tomatoes and as a starting material in cross-breeding programs (Ivanova et al., 2006).

In Uruguay, where tomatoes are affected by the race T2 *X. vesicatoria*, were identified varieties Hawaii 7981, Loica and Ohio 8245, which can be used as new natural sources of resistance to the pathogen *X. vesicatoria* of the T2 race (Berrueta et al., 2016).

Now in the world market there are no varieties of tomatoes that would be resistant against *C. michiganensis* subsp. *michiganensis*. It was provided the screening of wild tomato species for resistance against *C. michiganensis* subsp. *michiganensis* (Sen et al., 2013). High tolerance was revealed in *S. arcanum* LA 2157, *S. peruvianum* PI 127829 i *S. arcanum* LA385 and average – in *S. habrochaites* LA 407 and *S. lycopersicum* cv. IRAT L3. Partial resistance against different strains of *C. michiganensis* subsp. *michiganensis* was identified in the wild relatives of the cultural tomato *Lycopersicon hirsutum – Lycopersicon entryion* (LA) 407. Resistance in LA407 was determined in population lines obtained by reverse crossing (IBC) BC2S4 in greenhouse and field conditions. Two lines of the IBC population, in particular IBL 2353 and IBL 2361, have been identified as sources that maintain high resistance at the genetic level with theoretical homology of the genome *L. esculentum* 87.5% (Francis et al., 2001).

For a long time the race R0 *P. syringae* pv. *tomato* was successfully controlled by the gene *Pto1*, resistance against which was overcome by race R1, which was discovered in 1982 in Canada. There are currently no commercial varieties of tomatoes that are resistant to the R1 race, although some wild tomato species have such genetically determined resistance. The presence of high level of resistance of isolates to California race R1 in the studied tomato lines was shown (Stamova, 2009). The disease spread index (DSI) of the resistant lines ranged from 1.00 to 1.93 on a five-point scale depending on isolate virulence. At the same time, the DSI of susceptible control varieties Chico III and ONT 7710 ranged from 4.70 to 5.00. The level of resistance of F1 plants was equal to the resistance of the maternal line.

Tomato lines with fruits different from the traditional red color were studied in order to find sources of resistance to races R0 and R1 *P. syringae* pv. *tomato* (Ganeva and Bogatzevska, 2017). Lines L1078 and L1083 with brown-red (black) fruits and L1130 with purple-red fruits were highly resistant against races R0 and R1. It was found that two lines with pink fruits L1088 and L584, which are resistant against the race R1 *P. syringae* pv. *tomato*, can be used in combined and heterosis breeding for breeding varieties of tomatoes resistant to bacterial mottle.

In order to create resistant varieties and hybrids of vegetable crops against bacterial pathogens, the use of cell selection methods is an alternative. Joint cultivation of plants with phytopathogens has become one of the effective means of plant breeding for resistance against bacterial diseases (Kolomiiets et al., 2017a). In cell selection, various

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32153230

plant cells and organs are used, as well as types of selective agents, which under optimal conditions can trigger a cascade of reactions to the pathogen similar to the whole plant. A plant or its tissue or organ, surviving under the pressure of selective assortment, is a potential source of resistance/ tolerance (Kolomiiets et al., 2017a).

In order to reduce the time of selection of tomato genotypes resistant against bacteriosis pathogens, we have developed a biomethod, which is based on the use of *in vitro* cultures of plant cells and tissues. It has been used to test the stability of 16 determinant varieties of tomatoes of Ukrainian selection. In our research, it was proven that tomato varieties Chaika, Klondike and Zoreslav are resistant against pathogens of bacterial cancer, mottle, and spotting; Flandriia, Lehin – against bacterial spotting, and Oberih, Atlasnyi, Hospodar and Kimmeriets – against bacterial mottle (Kolomiiets et al., 2017a). The selected promising genotypes can serve as a starting material for the creation of tomato varieties with high resistance against bacterial diseases.

Consequently, genetic resistance is gaining significant practical interest in the integrated biocontrol of bacterial diseases to reduce crop losses of vegetable crops. Genetic diversity, high mutation capacity and overcoming the genetic barriers of the pathogen are challenges for breeders in creating varieties that are resistant to bacterial diseases. An alternative strategy is to use partially resistant sources that involve several non-specific genes.

Genetically-modified (GM) plants are a priority in program for growing bacterial-resistant vegetable crops in many countries. However, efforts to obtain GM-resistant plants have been slowed down by complex resistance genetics and variable pathogen races (Horvath et al., 2012).

In the case of bacterial pathogens, the study of genes and mechanisms of pathogenesis and natural or induced plant resistance and parallel work with antibacterial proteins of different origins have become the fundamental basis for the implementation of molecular approaches, in particular the involvement of GM plants for the cultivation of new resistant forms. They are divided into three main categories: 1) the introduction of bacterial genes for avirulence, 2) inclusion of bacterial resistance genes against bacterial phytotoxins, and 3) expression of antibacterial proteins of plants, insects or bacteriophages as bactericidal or bacteriolytic agents (Horvath et al., 2012).

The first category includes several types of *avr*-genes that control the synthesis of race-specific elicitor (*Table 1*) (Singh et al., 2012). In order to increase plant resistance against phytopathogens, special attention is drawn to the use of genes responsible for pathogen recognition and signal transduction (R-genes) according to the concept of “gene for gene” (Singh et al., 2012), which is widely used in genetic programs of vegetable crops mainly due to the acquisition of plant full resistance to a particular pathogen. However, a significant disadvantage of the system is exceptional racial specificity. Resistance of plants is achieved due to the development of necrosis at the site of the lesion, as a result of which the infection does not get further spread. Necrosis induction requires the presence of signal peptide genes in the pathogen and the corresponding receptor in plants, the interaction of which is the trigger for the induction of hypersensitivity reaction (Khaliluev and Shpakovski, 2013).

To date, most of the known resistance genes have been characterized, in particular coding proteins with nucleotide binding site (NBS) and the region of leucine-rich repeats (LRR), which are the most abundant among cloned R-genes. Due to the established molecular structure and biochemical functions of encoded proteins, R-genes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32153230

of tomato plants are divided into four classes: TNL, CNL, RPL and mixed (Kopfmann et al., 2016; Martins et al., 2016) (*Table 2*).

Table 1. *The bacterial genes for avirulence*

Pathogen	Genes for avirulence
Pseudomonas syringae pv. *tomato*	*avrD (avrPtoA1), avrE (avrPtoE1)* *avrPto (avrPtoC1), avrRpt2 (avrPtoB1)* *avrBs1, avrBs2* *avrBs3, avrBsT* *avrBsP (avrBs3-2)*
Xanthomonas vesicatoria	*avrRxv, avrb7* *avrB101, avrBln* *avrB102, avrBn*

Table 2. *Resistance genes of tomatoes against bacterial pathogens*

Class	Resistance genes	Pathogen
TNL (TIR-NBS-LRR)	*Bs4* *Bs2*	*Xanthomonas campestris*
	Rx3	*Xanthomonas campestris*
CNL (CC-NBS-LRR)	*Prf*	*Pseudomonas syringae*
Mixed	*Pto*	*Pseudomonas syringae*

Gene of *Bs4* NBS-LRR class contains TIR-domain, encoding aminoterminal sequences with homology to the cytoplasmic regions of the receptor protein and the IL-1 receptor of mammals and provides for the formation of tomato resistance against *X. campestris* (Khaliluev and Shpakovski, 2013). Similarly, the resistance gene *Bs2* of pepper specifically recognizes and provides resistance against strains *X. vesicatoria*, which contains the corresponding bacterial avirulent gene *avrBs2*. It is proved that the presence of the gene *Bs2* in sensitive line VF 36 reduces the progression of the disease to very low levels, and VF 36 plants have the lowest percentage of the disease among the tested varieties and the commercial tomato lines. The yield of commercial fruits from GM lines was by 2.5 times higher than that of parents, which ranged from 1.5 to 11.5 times depending on weather conditions and infectious background of the disease (Horvath et al., 2012).

The second class includes genes encoding proteins, in which there is a spiral-twisted domain. Representatives of this class are genes that cause the formation of high resistance of tomato plants against *P. syringae* (*Prf*).

Another example of an R-gene is a gene *Pto,* encoding the intracellular serine/threonine specific protein kinases, which was isolated from wild species of tomato plants *S. pimpinellifolium* L. A gene *Pto* causes resistance of plants against *P. syringae* pv. *tomato* and expresses genes of avirulence *avrPto* and *avrPtoB* (Pedley and Martin, 2003). Transfer of cDNA of the gene Pto into susceptible varieties of tomato Moneymarker and Urfa-2 caused the development of resistance against bacterial spotting of fruits (Khaliluev and Shpakovski, 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32153230

The second category comprises the toxin-antitoxin (TA) system which is localized in plasmids and chromosomes of bacteria and contains dicistronic operons, encoding two small genes, one for the toxic component and the second – for antitoxin (Kopfmann et al., 2016). Most of the toxins are endoribonucleases that operate in free or ribosome associated mRNA, the others are focused on DNA-gyrase (CcdB, ParE), tRNA-synthetase (HipA), EF-Tu (Doc) and peptidoglycan predecessors (Martins et al., 2016).

In the third category, genes of hydrolytic enzymes that degrade the cell walls of phytopathogenic bacteria were used to create GM plants with high resistance against pathogenic bacteria. For this purpose, they are used genes of β-1,3-glucanase and inducible genes of plant chitinase with lysozyme activity (PR-2 and PR-3 families of protective proteins) (Goyal and Manoharachary, 2014).

Expression of heterologous plant genes of PR-proteins and antimicrobial peptides (AMP) is the most used genetic engineering concept to improve the degree of plant resistance against diseases of bacterial nature (*Table 3*).

Table 3. *Expression of antibacterial proteins of plants and antimicrobial peptides*

Family	Gen	Resistance
PR-1	*CABPR1*	*Pseudomonas syringae* pv. *tomato*
PR-2	*GLU*	*Ralstonia solanacearum*
PR-5	*thauII*	*Xanthomonas vesicatoria*
PR-12	*alfAFP*	*Ralstonia solanacearum*
PR-13	*Thi2.1*	*Ralstonia solanacearum*
PR-14	*LjAMP1*	*Ralstonia solanacearum*
Snakins	*SN2*	*Clavibacter michiganensis* subsp. *michiganensis*

According to the modern classification, 17 families of PR-proteins and 9 – of AMP are distinguished by similarity of amino acid sequences, biochemical characteristics, biological activity and cell localization (Khaliluev and Shpakovski, 2013). Protective proteins and peptides are relatively small in size, which are positively charged and contain a significant amount of cysteine residues, which stabilizes their tertiary structure by the formation of disulfide bonds (Rahnamaeian, 2011). It was found that the majority of protective PR-proteins and AMP in micromolar concentrations have high antibacterial activity (Edreva, 2005; Van Loon, 2006).

To increase the resistance of tomato plants against pathogens promising was the use of taumatin proteins, which are isolated in the family PR-5. In research (Korneeva et al., 2008), integration into the genome of a gene *thau II*, encoding a native super sweet protein thaumatin, allowed obtaining theGM lines, which have essentially high resistance against the pathogen of tomato black bacterial spot (Korneeva et al., 2011).

Antimicrobial peptides include cecropins, magainins, sarcotoxin IA and tachyplesin I. From potato tubers they were selected antimicrobial peptides (SN1, SN2) with a unique amino acid sequence, which are assigned to individual families AMP – snakins (Mohan, 2011). Their distinctive feature is the presence in the amino acid sequence of the site, which is characteristic of the hemolytic venom of snakes. Snakin SN2 super-production in GM tomato plants contributed to a significant delay and reduction in symptoms of the development of bacterial cancer when compared to the control (Khaliluev and Shpakovski, 2013; Balaji and Smart, 2012).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32153230

Using the method of agrobacterial transformation of the obtained tomato plants with the gene of a synthetic analogue of magainin II (MSI-99) – AMP, which is isolated from the skin of the African clawed frog (*Xenopus laevis*) (Alan et al., 2004). According to the results of plant testing for resistance against *P. syringae* pv. *tomato* it was found that the degree of symptoms of the disease in some lines was much less than in the control.

Vector construction pBI121-spCB, as part of the T-DNA of which it is localized natural gene of cationic lytic cecropin peptide B, isolated from the silkworm (*Hyalophora cecropia*), and with the signal sequence of the gene of α-amylase of barley used to produce the GM tomato plants resistant against bacterial wilt and bacterial black spotting (Jan et al., 2010).

It can be concluded that there is still no reliable information on the production of GM tomato plants that are resistant to bacterial diseases and suitable for commercial use. The complexity of obtaining such plants is explained by the genetic complexity and versatility of this feature, as well as the rapid loss of plant resistance acquired. It is predicted that the partial overcoming of the existing problems is expected by embedding into the genome of plants of simultaneously several genes of different families, protein products of which have different mechanisms of action (Khaliluev and Shpakovski, 2013).

Summary

It is shown that agrotechnical measures are clearly preventive in nature, while chemical and antibiotic use are low effective, showing side effects, in particular, phytotoxicity and spread of resistant strains of pathogens. It was confirmed antagonistic activity of bacteria of genera *Bacillus* and *Streptomyces* to phytopathogenic bacteria, and biopreparations based on them are recommended for biocontrol of bacterial pathogens. Effective and proved measures are the cultivation of resistant varieties, the selection of which is based on the involvement of wild species as natural sources of resistance, and GM vegetable crops containing avr-genes, genes of resistance against bacterial phytotoxins, PR-proteins and AMP.

Abstract. Several researches have been conducted to explain patterns of the abundance, richness and taxonomic diversity of benthic polychaetes; however, such analyses have ignored the functional diversity of polychaete communities, especially feeding guilds in intertidal rocky shores. The present study was carried out to describe and analyse the polychaete feeding guilds on intertidal rocky shores and then examine the effects of environmental factors. Twelve intertidal rocky shores from the coastal protected area of Essaouira (Atlantic coast of Morocco) were sampled during the summer of 2016. A total of 42 polychaete species belonging to 29 genera and 16 families were identified among the 4517 specimens collected. The medium biomass per sampling site was found to be 37.61 ± 15.80 $g.m^{-2}$. The polychaete species were classified into five feeding guilds, and nine feeding modes. The filter feeders were the dominant feeding guild (32%) followed by omnivores (23%), burrowers (20%), carnivorous (15%) and surface deposit-feeders (10%). The FDT (filter feeder, discretely motile, with tentacles) was the most abundant feeding mode, accounting for 24% of abundance (mainly represented by *Sabellaria alveolata*), followed by the ODJ feeding mode (omnivorous, discretely motile, with jaw apparatus) with 22%, and the SDT feeding mode (surface deposit feeder, discretely motile, with tentacles) with 18.9%. The highest trophic importance index and index of trophic diversity values were recorded in the southern region of Essaouira coastline. Based on the canonical correspondence analysis, composition and spatial distribution of polychaete feeding guilds were mainly related to the length of rocky shores and water temperature.
Keywords: *rocky shores, intertidal, environmental factors, functional diversity, feeding modes, filter feeders, trophic importance index*

Introduction

Polychaetes (Annelida) are one of the most important taxa in macrobenthic communities in coastal and marine environments, in terms of diversity and abundance (Fauchald and Jumars, 1979; Grassle and Maciolek, 1992; Hutchings, 1998). With more than 13,000 species described to date, polychaetes species are considered the most numerous among benthic taxa (Minelli, 1993; Jumars et al., 2015; Han et al., 2016).

Indeed, the polychaetes represent about one third of the total macrobenthic species in terms of richness and up to 80% of the total abundance (Fauchald and Jumars, 1979; Belan, 2004; Manokaran et al., 2013; Han et al., 2016). They are also crucial in marine food chains as important prey and predators for many organisms (Serrano Samaniego, 2012), and exhibit a high diversity of feeding modes, reproductive strategies and different levels of tolerance to the negative impacts induced by pollution and natural perturbations (Giangrande et al., 2005; MacDonald et al., 2010; Sivadas et al., 2010; Han et al., 2016).

According to Fauchald and Jumars (1979), feeding guild of any organism is defined as the set of relations among food particle size and composition, the mechanism involved in food intake, and the motility patterns associated with feeding. These authors classified feeding guilds of each polychaete family as herbivore, carnivore, filter feeders, surface deposit feeders, and sub-surface deposit-feeders. Later, Ruppert and Barnes (1994) suggested that omnivores also exist in the marine environment. According to Pinnet (2000), organisms of the same feeding guild would dominate a particular type of substrate. Indeed, the filter-feeders are the dominant feeding guild on hard substrate (Porras et al., 1996; Damianidis and Chintiroglou, 2000), while deposit-feeders are the dominant feeding guild on soft substrates (Paiva, 1994; Muniz and Pires, 1999; Mattos et al., 2012). Deposit feeders usually inhabit low-energy, muddy substrates because such substrates tend to have a high content of organic matter (Muniz and Pires, 1999; Wang, 2004; Méndez, 2013). By contrast, filter-feeders would not find enough suspended food in muddy substrates, but could be abundant on gravel and coarse-sand bottoms, since currents provide a continuous supply of suspended organic detritus and plankton (Wang, 2004).

Several biotic or abiotic factors can affect the composition and distribution patterns of polychaete feeding guilds. These include total organic carbon (Denisenko et al., 2003; Taurusman, 2010; Han et al., 2016), food availability (Dauwe et al., 1998; Rosenberg, 2001), depth and salinity (Rosenberg, 2001; Han et al., 2016). Physical characteristics of substrates and hydrodynamic factors may also modify distributions (Arruda et al., 2003; Sanders, 1958). Thus, feeding guilds can be used as a tool to analyse polychaete assemblage patterns, due to their dependence on the environmental variables, and studies on feeding guilds can permit ecologists to understand the ecological function of each species and predict if an ecosystem was susceptible to invasion by certain species (Fauchald and Jumars, 1979).

In Morocco, polychaetes represent an important group in terms of abundance and diversity on the continental shelf. The first attempt to explain patterns of abundance, richness and diversity of benthic polychaetes goes back to the beginning of 20th century with Charrier (1921) who drew up the first list of polychaetes from the region of Tangier. Subsequently, many studies have been carried out on the polychaetes of Morocco, up to the recent description of *Boccardia polybranchia* as a new species along the rocky shores of Safi (Goumri et al., 2017). However, these analyses did not consider the overall functional structure of polychaete communities. Some studies examined polychaete feeding guilds in sandy beach environments, such as the investigations of macrofauna communities carried out on the Atlantic coast between Tangier and Tarfaya by Bayed (1991), in Bou Regreg estuary by Cherkaoui et al. (2003) and in Merja Zerga by Bazaïri et al. (2003) and Touhami et al. (2017). On the Mediterranean coast, the lagoon of Smir was also studied by Chaouti and Bayed (2011). However, analyses of polychaete feeding guilds on intertidal rocky shores are virtually absent. The aim of this

paper was to describe, for the first time, the composition and spatial distribution patterns of polychaete feeding guilds in the intertidal rocky shores of Essaouira (Atlantic coast of Morocco), and their dependence to various environmental variables.

Materials and methods

Study area

The study area is located along the Atlantic coast of Essaouira province, Morocco. It lies between longitudes 9° 20' and 9° 90' West and between latitudes 31° 10' and 31° 50' North (*Fig. 1*). This coastal zone is made up of sandy beaches, rocky shores and dunes (fixed and shifting) with elevations ranging from 0 to 43 m. The lithology is composed of quaternary conglomerate, colluvial, and alluvial deposits and Jurassic limestone (Molua Mwambo et al., 2007). The hydrographic network includes a few rivers. The main ones are oued Ksob, oued Tidzi and oued Aghbalou which are located in the south of Essaouira while oued Tahria is located in the north. The area climate is semi-arid with a long dry period that lasts from April to October. The aridity decreases from east to west. In the western narrow coastal fringe around the town of Essaouira, the influence of the cold currents that flow onshore from the Canaries Island, create a microclimate with a very homogeneous average temperature of about 16.7 °C during the year (Bazairi et al., 2010). There is little difference between the average temperatures of the hottest and the coldest months. The coastal zone of Essaouira is endowed with ecological assets that have earned it a double protection status: Arganeraie Biosphere Reserve and site of biological and ecological interest (SIBE). The major economic activities in the Essaouira province include agriculture, fishing, mining, trade, industries, tourism, artisanal activities and handicraft industry.

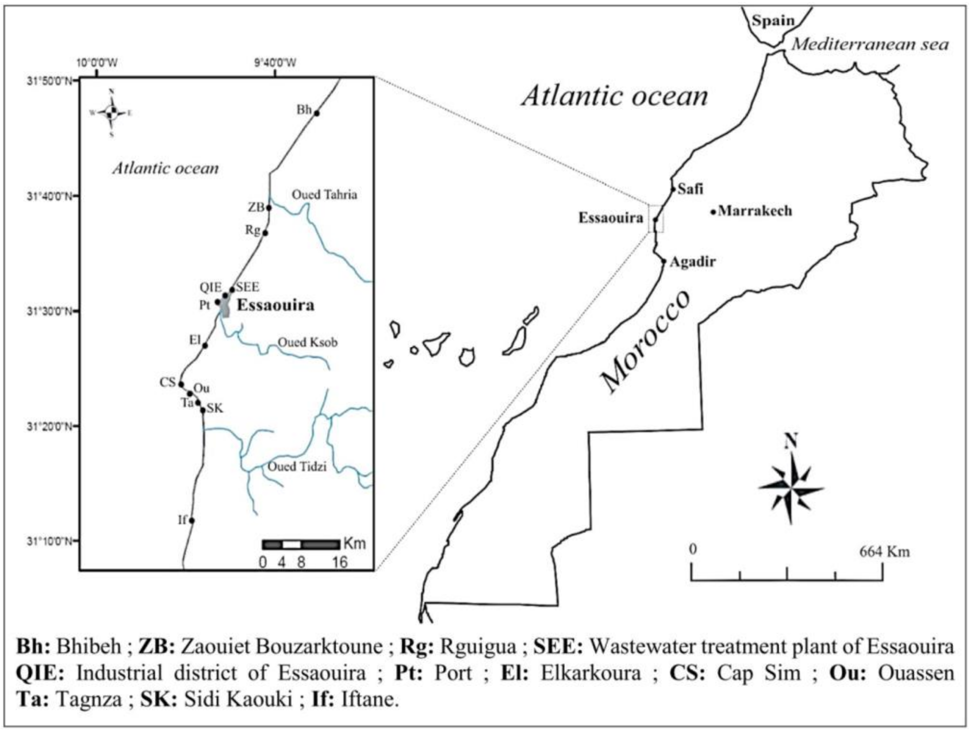

Figure 1. *Geographical position of study area and sampling sites for benthic polychaetes along the coast of Essaouira (9° 20' and 9° 90' W; 31° 10' and 31° 50' N), NW Morocco*

Sampling and laboratory techniques

Twelve sampling sites were investigated in summer 2016 (*Fig. 1; Table 1*). The samples were collected using a quadrat method (Misra, 1968) with four quadrats (each 25 × 25 cm, surface area 0.0625 m^2) in the intertidal zone of each site. Sampling was done by scraping the surface layer (sediments, algae) and digging 2 cm deep in the hard substratum using a hammer. The material was manually collected and then fixed in formaldehyde (8%). Water parameters such as pH, conductivity and temperature were recorded *in situ* using a multi-parameter (type VMR MU 6100 H, Germany), and the salinity was calculated from the conductivity and temperature of sea water (Aminot and Kérouel, 2004). At the same time, the length (m) of each rocky shore was measured from the low water to high water using a measuring tape. Rocks of 20 cm in length and 15 cm in width were collected for each sampling site using a hammer. All these samples were at least triplicated at each site to ensure the representativeness of the samples and measured parameters. In the laboratory, biological samples were rinsed in freshwater and preserved in 70% ethanol and the polychaetes were identified to species when possible with assistance of Dr. Patrick Gillet (Catholic University of the West, France) using various guides, e.g., Fauvel (1923, 1927) and Fauchald (1977), and then counted and weighed. The rock samples were cut and dozens of thin sections were prepared (*Fig. 2*), then grains size from these thin sections were measured using polarizing optical microscope (OLYMPUS BH 2), and the void percentage in each thin section was estimated using “Chart for estimating mineral grain percentage composition of rocks and sediments” (Compton, 1962).

Polychaetes feeding guild assignments

In this study, we assigned feeding guilds to all polychaetes collected according to the definitions of Fauchald and Jumars (1979), MacDonald et al. (2010) and Jumars et al. (2015), which are based on the stomach content analysis of polychaetes and also direct observations of feeding behavior. Feeding guilds of polychaetes are divided into two modes (macrophagous and microphagous) and five or six sub-modes (herbivores, carnivores, filter feeders, surface deposit feeders, burrowers and omnivores), according

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32313249

to their major feeding modes. The motility pattern was classified into motile, discretely motile and sessile, and the morphological structures used in feeding were classified into jawed, pumping, tentaculate or other structures, which are usually eversible sac-like pharynges (Fauchald and Jumars, 1979; MacDonald et al., 2010; Jumars et al., 2015). The feeding guilds annotations was performed as follows (*Table 2*): in the three letter codes, the letter in the first position indicates major mode, the second the motility pattern, and the last letter indicates the morphological structure used in feeding; in position 1:B, subsurface deposit feeder (burrower); C, carnivore; F, filter feeder; H, herbivore; O, Omnivore; S, surface deposit feeder; in position 2:D, discretely motile; M, motile; S, sessile; in position 3:J, jawed; T, tentaculate; X, other structures, usually eversible sac-like pharynges.

Statistical analysis

The trophic importance of each group was evaluated according to the trophic importance index (TI) proposed by Paiva (1994) and modified by Muniz and Pires (1999), using the following equation (*Eq. 1*):

$$\mathrm{TI} = \sum_{i=1}^{s} \ln ni\ (+0.1) \quad \text{(Eq.1)}$$

where s is the number of species of a trophic group in the sample, ln is the natural logarithm, n_i is the number of individuals of the *i*th species in the sample, and 0.1 is a constant.

The index of trophic diversity (1-ITD) was calculated as follows (*Eq. 2*):

$$\mathrm{ITD} = \sum \theta^2 \quad \text{(Eq.2)}$$

where θ is the contribution of the density of each trophic group to the total polychaete density. The 1-ITD ranged from 0.90 (the highest trophic diversity) to 0.0 (the lowest diversity; i.e. one trophic guild accounts for 100% of the polychaete density: Heip et al., 1985). The taxonomic similarity between sampling sites was elucidated by a cluster analysis (Bray-Curtis similarity, Complete Link) based on the values of trophic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32313249

importance index (TI). This analysis was carried out using the BioDiversity Pro statistical program (Version 2.0).

One-way ANOVA (analysis of variance) and Tukey's test were used to evaluate statistically significant differences of environmental variables means and Trophic Index means between the sampling sites. CCA (canonical correspondence analysis) was performed to explore the distribution of the polychaete feeding guilds in relation to the rocky shores and environmental factors. One-way ANOVA, Tukey's test and CCA analysis were conducted using the PAST software package (Hammer et al., 2001), Statistical Version 3.15 for Windows software.

Results

Environmental variables

The environmental characterization of the study area was presented in *Table 3*. The longest and shortest rocky beach measured were of 271.67 ± 12.58 m (CS) and 88.33 ± 7.64 m (Pt), respectively. The void percentage in the rock ranged from 1.00 ± 0.04% (El) to 43.00 ± 5.77% (QIE). The mean grain sizes varied from 0.19 ± 0.10 mm to 6.83 ± 6.27 mm on the (CS) and (Ta) rocky shores, respectively. The seawater temperature showed fluctuations between the sampling sites with a minimum value recorded at Pt (17.50 ± 0.50 °C) and a maximum value at SEE (21.00 ± 0.15 °C). The pH value showed a similar trend, ranging from 8.00 ± 0.01 (Ou) to 8.51 ± 0.01 (If). The values of conductivity were typical of seawater, (~50 $ms.cm^{-1}$, Rodier et al., 2009). The salinity was relatively high compared to the average oceanic salinity (35‰) and ranged from 36.26 ± 0.24 ‰ (SEE) to 39.81 ± 0.08 ‰ (Pt). The differences in mean values of these environmental variables were found to be significant at all sites ($p < 0.05$) except for conductivity.

Taxonomic and feeding guild composition

In this study, 42 polychaete species belonging to 29 genera and 16 families were identified among the 4517 specimens collected (see *Appendix*). The mean biomass

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32313249

(expressed as g wet weight per m^2, with 0.001 g accuracy) was found to be 37.61 ± 15.80 $g.m^{-2}$. The abundance of polychaetes varied from 388 individuals per m^2 ($ind.m^{-2}$) at Elkarkoura site to 3388 $ind.m^{-2}$ at Iftane site. The number of species ranged between 13 and 27 with the highest number (27 species) observed at Iftane site which is 51 km from any source of urban pollution of Essaouira city, and the lowest species number (13 species) at the site SEE. The latter site is within the effluent outflow of the wastewater treatment plant of Essaouira. Families such as Sabellaridae (24% of the individuals), Nereididae (23%), Orbiniidae (9%), Lumbrinereidae (9%) and Terebellidae (8%) were found to be dominant in terms of abundance. *Sabellaria alveolata* ranked as the top species in abundance (24%), followed by *Perinereis cultrifera* (12%), *Platynereis dumerilii* (8%), *Terbella lapidaria* (8%), *Scoletoma impatiens* (8%) and *Scolaricia typica* (8%).

The polychaete assemblage found in the study area comprised five different feeding types, namely; surface deposit feeders, carnivores, filter feeders, subsurface deposit feeders, omnivores, and nine feeding modes: BDX (burrower, discretely motile, other structures), CMX (carnivore, motile, other structures), SDT (surface deposit feeder, discretely motile, with tentacles), CMJ (carnivore, motile, with jaw apparatus), BMJ (burrower, motile, with jaw apparatus), ODJ (omnivore, discretely motile, with jaw apparatus), BMX (burrower, motile, other structures), FDT (filter feeder, discretely motile, with tentacles) and FST (filter feeder, sessile, with tentacles) (*Table 4*).

Table 4. *List of polychaete taxa recorded throughout the sampling sites and relevant feeding guilds. In the three letter codes, the letter in the first position indicates major mode, the second the motility pattern, and the last letter indicates the morphological structure used in feeding; in position 1:B, subsurface deposit feeder (burrower); C, carnivore; F, filter feeder; H, herbivore; O, Omnivore; S, surface deposit feeder; in position 2:D, discretely motile; M, motile; S, sessile; in position 3:J, jawed; T, tentaculate; X, other structures, usually eversible sac-like pharynges*

On the intertidal rocky shores of Essaouira, the filter feeders were the dominant feeding guild (32%) followed by omnivores (23%), burrowers (20%), carnivores (15%) and surface deposit-feeders (10%) (*Fig. 3A*). The FDT was the most abundant feeding mode, accounting for 24% of abundance (mainly represented by *Sabellaria alveolata*), followed by the ODJ feeding mode with 22%, and the SDT feeding mode with 18.9% (*Fig. 3B*), it seems that these 3 groups were present in almost similar proportions. Most feeding modes occurred at all studied sites (12 sampling sites), except for SDT feeding mode absent from the EL site, and the BMX feeding mode absent from the SEE and EL sampling sites.

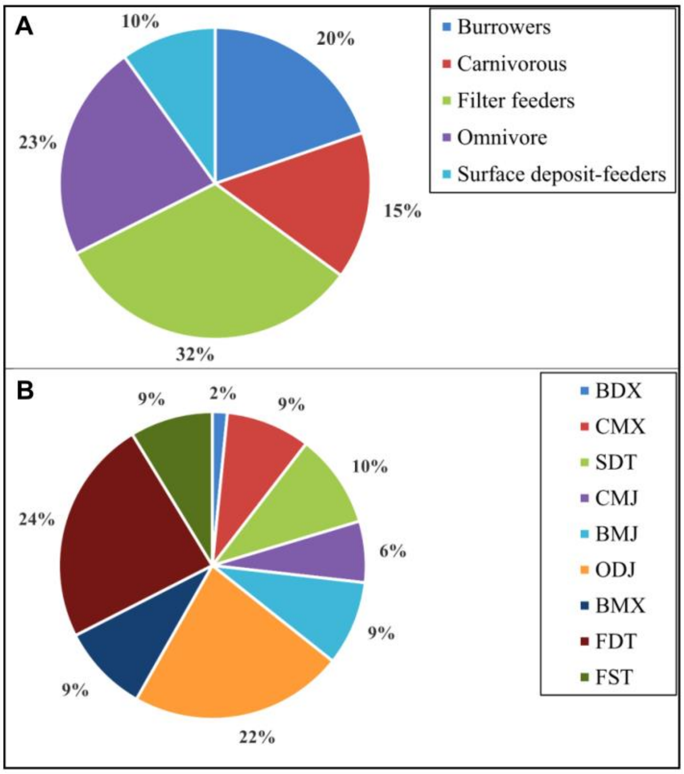

Figure 3. *Relative abundance (%) of the feeding guilds (A) and feeding Modes (B) of polychaetes sampled in the study area. BDX (burrower, discretely motile, other structures); CMX (carnivore, motile, other structures); SDT (surface deposit feeder, discretely motile, with tentacles); CMJ (carnivore, motile, with jaw apparatus); BMJ (burrower, motile, with jaw apparatus); ODJ (omnivore, discretely motile, with jaw apparatus); BMX (burrower, motile, other structures); FDT (filter feeder, discretely motile, with tentacles); FST (filter feeder, sessile, with tentacles)*

Feeding guild characterization

The spatial distribution of feeding guilds at different sampling sites of Essaouira intertidal rocky shores is presented in *Figure 4*. The results of a one way ANOVA shows a highly significant difference (F = 2.46; df = 11; N = 5; Pp < 0.05) of Trophic Index mean between the investigated sites. The burrowers were very common in the studied area, and the most abundant species were *Scoletoma impatiens* and *Scolaricia typica*. The highest TI of this feeding guild was recorded at CS, SK and QIE sampling sites, with TI = 33.97, TI = 32.91 and TI = 32.62 respectively. The lowest TI was

DOI: http://dx.doi.org/10.15666/aeer/1702_32313249

recorded at ZB (TI = 12.23) and EL sites (TI = 15.58). Carnivores were very abundant in the study area, and the main species of this group were *Bhawania goodei* and *Eulalia viridis*. Their Trophic index was highest at If (TI = 42.45) and lowest at CS (TI = 12.80). Filter feeders were abundant in the whole study area, and represented mainly by *Sabellaria alveolata*. The highest TI of this group was recorded in the southern region of Essaouira, with TI = 34.54, TI = 32.91 and TI = 31.86 at Ta, SK and If, respectively. The lowest TI was recorded north of Essaouira at SEE (TI = 8.86) and ZB sites (TI = 12.80). Omnivores were also common in the study area, but not very abundant as compared to filter feeders. Their main representative species were *Perinereis cultrifera* and *Platynereis dumerilii*. The highest TI of this group was recorded in Essaouira city with TI = 22.40 at Pt. The lowest TI was recorded south of Essaouira at Ou (TI = 7.92). Finally, the surface deposit-feeders, represented mainly by *Terebella lapidaria*, were not very common in the study area because of their absence in the El sampling site. The highest TI of surface deposit-feeders was recorded at the southernmost site at If (TI = 26.57), and the lowest TI was recorded north of Essaouira at ZB (TI = 4.14).

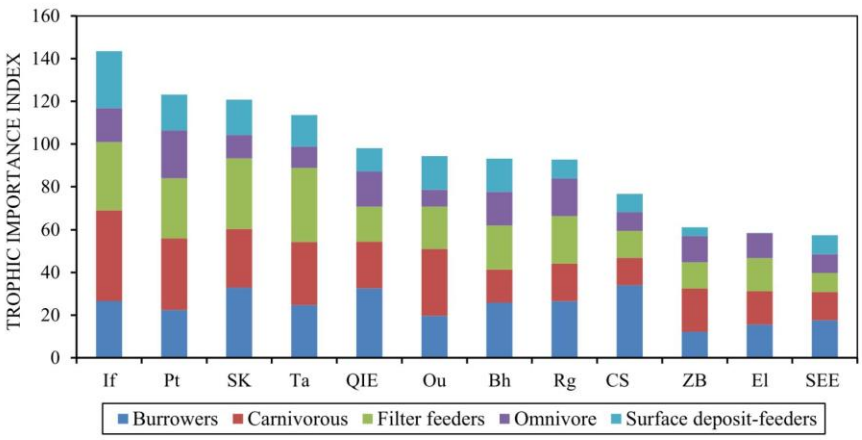

Figure 4. *Trophic importance index values for sampling sites of Essaouira rocky shores*

The index of trophic diversity (1-ITD) values were highest south of Essaouira (Ou, If, Ta, CS, El and SK sampling sites) and lowest in the urban area of Essaouira at QIE (*Fig. 5*).

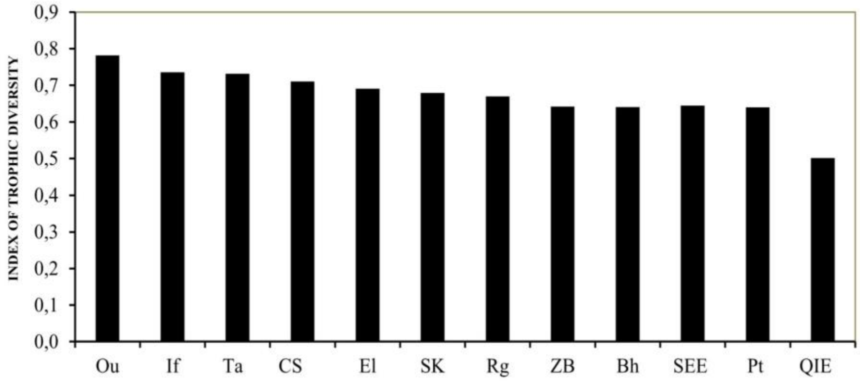

Figure 5. *Index of trophic diversity values for the sampling sites of Essaouira rocky shores*

The results of the cluster analysis based on the values of trophic importance index (TI) are illustrated in *Figure 6*.

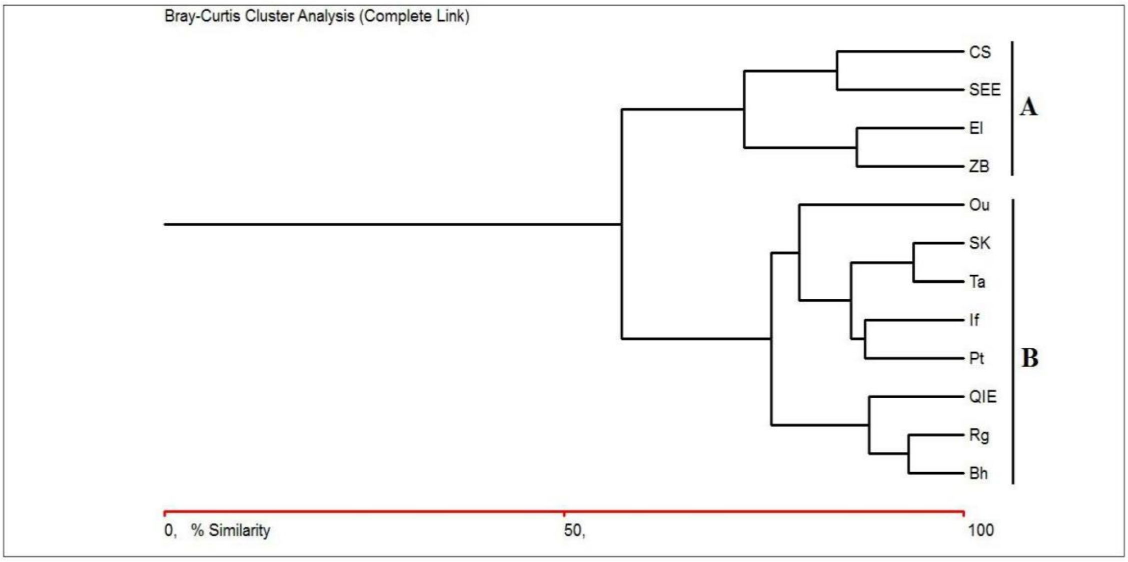

Figure 6. *Distinct groups of sites established by cluster analysis for the 12 sampling sites considered on Essaouira coastline*

According to these analyses, there are two distinct assemblages (A and B) with a level of dissimilarity less than 50% even though both groups included five feeding guilds and nine feeding modes:

- Group A consists of four rocky sites (ZB, El, SEE, and CS) and the dominant feeding guilds, burrower and filter feeder groups, comprised 26.89% and 26.77% of all individuals respectively, while ODJ was the most abundant feeding mode (23.84%). This assemblage was characterized by a medium Trophic Importance index (TI = 63.47 ± 8.96) and moderately high Index of trophic diversity (1-ITD = 0.67 ± 0.034) (*Table 4*).
- Group B includes eight rocky sites (Ou, SK, Ta, If, Pt, QIE, Rg and Bh). The dominant feeding guild was filter feeder with 35.84% of all, while FDT was the most abundant feeding mode (26.48%). This assemblage was characterized by a high Trophic Importance index (TI = 109.93 ± 18.47) and moderately high Index of trophic diversity (1-ITD = 0.67 ± 0.085) (*Table 5*).

Relationships between feeding guild composition of polychaetes and abiotic factors

The canonical correspondence analysis (CCA) indicated that abiotic factors contributed significantly to explaining the variation in polychaete feeding guilds among the rocky shores studied. The first and second axes accounted for 39.7 and 29.9% of the variance observed in the feeding guild data, respectively. On the CCA plot (*Fig. 7*), communities at Bh, ZB, Pt, El, SK and If are moderately associated with salinity. By contrast, communities at Ta and Ou (but not Rg) positively related to the length of the rocky shores, higher grain-size and higher water temperature but negatively with salinity.

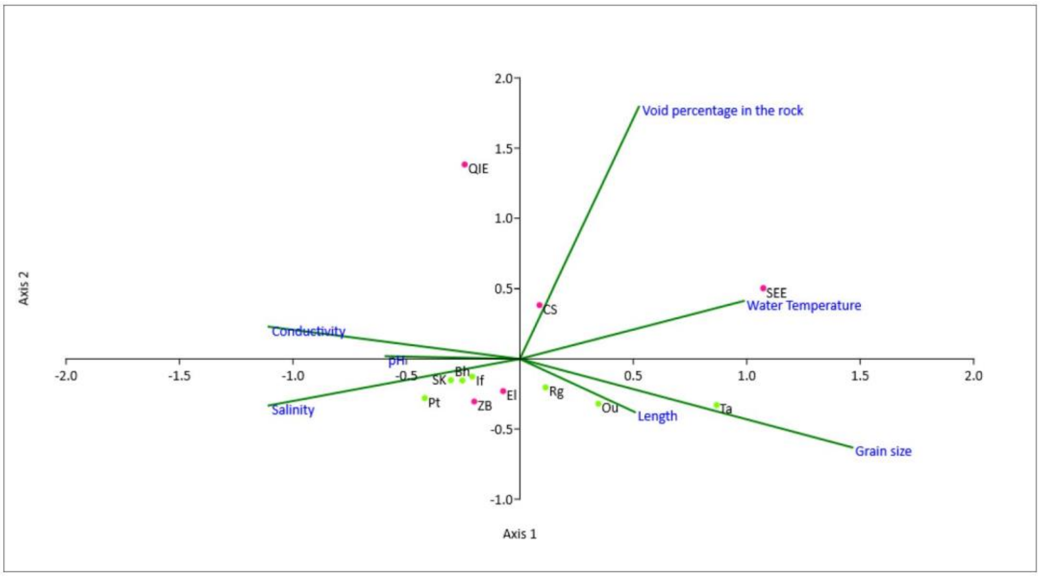

Figure 7. *Canonical correspondence analysis (CCA) ordination of the polychaete feeding guild scores and environmental parameters in the study area (Axis 1: 39.7%; Axis 2: 29.9%)*

Discussion

The present study provides the first characterization of the composition and spatial distribution patterns of polychaete feeding guilds along the rocky shores of Essaouira on the Atlantic coast of Morocco, and their relationship with environmental variables such as temperature, pH, conductivity, salinity, length and void percentage in the rock, and grain size of the rock. In this study, polychaete feeding communities at 12 sites were classified into five feeding guilds (Surface deposit feeders, Carnivores, Filter feeders, Subsurface deposit feeders and Omnivores), and nine feeding modes (BDX, CMX, SDT, CMJ, BMJ, ODJ, BMX, FDT and FST). We have included the omnivore feeding guild in this work since it is difficult to assign some Nereids in a particular feeding guild. Fauchald and Jumars (1979) classified several Nereid species as both carnivores and herbivores. Later, Gaston (1987) characterized them as surface deposit-feeders, Bianchi and Morri (1985) featured them once again as herbivores, and Jumars et al. (2015) specified that Nereids are clearly omnivorous, although digestive physiology suggests more likely specialization. According to Lindsay and Woodin (1995), Hentschel and Larson (2005), there are some species that can change their feeding mode depending on the availability of resources. As there are no consensus in the literature, we preferred classifying the Nereids of Essaouira intertidal rocky shores as omnivores.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32313249

The filter feeders were the dominant feeding guild (32%) followed by omnivores (23%), burrowers (20%), carnivores (15%) and surface deposit-feeders (10%), and the FDT (filter feeder, discretely motile, with tentacles) was the most abundant feeding mode, followed by the ODJ feeding mode (omnivores, discretely motile, with jaw apparatus) and the SDT feeding mode (surface deposit feeder, discretely motile, with tentacles) accounting for 24%, 22% and 18.9% of abundance, respectively. Denny (1988) suggested that the wave action is one of the main factors influencing the establishment and development of intertidal and shallow subtidal benthic communities. This factor represents a constant stress source that forces populations to acquire specific adaptations that allow them to survive in a stressful environment. One of these adaptative aspects is the suspension-feeding mode, which allows organisms to feed on material brought in by water movements (Okamura, 1990; Mann and Lazier, 1991). Thus, it is not surprising that in our case this feeding guild was dominant and present in all study areas, and is probably further enhanced by the influx of nutrient-rich cold waters brought to the surface by upwelling. This phenomenon usually occurs from June to October (Belvèze, 1983; Gentile, 1997; Simone, 2000; Bazairi et al., 2010; Benazzouz, 2014). The main representative species of this guild was *Sabellaria alveolata*, contributing 73.2% to total filter feeder abundance. Similarly, other studies have shown a large number of polychaete feeding guilds in marine environments (*Table 6*). According to these studies, the filter-feeders were the dominant feeding guild on hard substrate while the deposit-feeders were the dominant trophic group on soft substrates.

Paiva (1994) indicated that the density approach is more coherent to evaluate the importance of each feeding guild, especially when working with polychaete worms, since it indirectly estimates the biomass and production as these communities are composed of species with analogous life cycles. However, recruitment events and patchy distribution, not necessarily linked to increased food supply, can lead to an overevaluation of the feeding guild. Consequently, the use of the species richness gives more reliable results. During this study, we applied “Trophic group Importance index” (TI) proposed by Paiva (1994) which reduces the importance of density by applying log- transformation of abundances thus preserving the species richness factor. TI index was proved to be practical and very informative. Highest values of TI were recorded on the southern region of Essaouira where the beaches are sheltered and relatively far from human activities.

To accurately define the spatial organization of polychaete feeding guilds of Essaouira’s rocky shores, we used the cluster method which allows a discrimination between the sampling sites. Spatial differences in the structure of polychaete feeding guilds clearly discriminated between two groups: the first was group A (sites ZB, El, SEE, and CS) that characterized by the dominance of burrower and filter feeder feeding guilds, and ODJ feeding mode. The second one was group B which includes eight rocky sites (Ou, SK, Ta, If, Pt, QIE, Rg and Bh), with the dominance of filter feeder feeding guild and FDT feeding mode.

Several authors have observed strong relationships between polychaete feeding guilds and environmental factors, among which granulometry of sediments seems to be the most important (Maurer and Leathem, 1981; Carrasco and Carbajal, 1998; Muniz and Pires, 1999; Pagliosa, 2005; Mattos et al., 2012). Muniz and Pires (1999) and Méndez (2013) concluded that organic matter level in sediments could also strongly influence the feeding guilds of polychaetes, while Carrasco and Carbajal (1998) found no relationship with this variable, but a strong influence of depth. According to Paiva (1994), depth contributes to the sediment stabilization and consequently increases the feeding guild variety. Salinity, dissolved oxygen and temperature were also found to be important factors in determining trophic structure (Maurer and Leathem, 1981; Castanedo et al., 2012). In this study, the CCA results indicate that the length of rocky shores and water temperature are the most influential factors on the composition and spatial distribution of polychaete feeding guilds. Indeed, the rocky shores of Essaouira are long and rich in microhabitats, providing habitats for a large range of species which favours the increase of feeding guild diversity in this area. However, water temperature acts negatively on the diversity and abundance of feeding guilds via its negative influence on species richness and abundance of polychaetes.

Conclusion

This study on the composition and spatial distribution of polychaete feeding guilds of Essaouira intertidal rocky shores led to the identification of five feeding guilds (Surface deposit feeders, Carnivores, Filter feeders, Subsurface deposit feeders and Omnivores), and nine feeding modes (BDX, CMX, SDT, CMJ, BMJ, ODJ, BMX, FDT and FST). Compared to other marine ecosystems and geographical areas, we can conclude that the rocky shore of Essaouira is relatively rich in polychaete feeding guilds. The abiotic factors such as length of rocky shores and water temperature are the major factors affecting the composition and spatial distribution of polychaete feeding guilds in this

area. The data from this study can be used as a baseline reference for future scientific research programs, and may be a useful tool for authorities in charge of protection and management of this protected coastal area. Nevertheless, a detailed study during different seasons is required, in order to better understand the biotic and abiotic factors determining the structure and organisation of feeding guilds, determine the possible anthropogenic influences on this ecosystem, as well as to predict if this protected coastal area can be invaded by some invasive species.

Abstract. Endosulfan is known for its non target toxicity in various compartments of ecosystem. Its presence in hotspots and agricultural fields is an environmental concern. In this study spent mushroom compost extract of *Pleurotus ostreatus* (SMCE) was evaluated for its potential in bioremediation against Endosulfan in different microcosms. Activities of Laccase and MnP were also monitored to observe their possible role in this process. The SMCE alone (M_1) and SMCE with H_2O_2(M_2) exhibited no significant difference in reduction of α- and β-Endosulfan. This suggested that stimulation of ligninolytic enzymes, Laccase and Manganese peroxidase, after addition of H_2O_2 as observed by monitoring their activity had no effect on bioremediation of this pesticide. In soil microcosms however, there was a significantly higher reduction in M_4(H_2O_2 + SMCE) than M_3(SMCE) suggesting that SCME not only served as source of complex enzymes but also as carbon resulting in enhanced soil indigenous microbial communities and enzymes. Under the effect of H_2O_2, certain enzyme complexes either already present in soil or introduced after SMCE addition worked in symbiotic way and resulted in higher reduction. Endosulfan sulfate was detected in all microcosms expect Endosulfan Sulfate while Endosulfan lactone was only formed in M_3 and M_4.

Keywords: *enzymatic bioremediation, spent mushroom compost, Endosulfan, soil, microcosms*

Introduction

In the past few decades use of agrochemical residues increased in the ecosystem, causing momentous contamination in many terrestrial regions resulting in poisoning of human foods (Carvalho, 2017). Organochlorine pesticides (OCPs), group of such agrochemicals are also known for high persistence and non target toxicity within ecosystem at each level of food chain (Jayaraj et al., 2016). Because of their bio accumulative nature (Zhang et al., 2015) these are among the priority pollutants according to the Stockholm convention (Tsai, 2010). Despite the ban, indiscriminate use of OCPs for farm activities is still in practice (Yadav et al., 2017). Majority of these

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32513267

pesticides are located in overpopulated tropic and sub tropic areas (Wang et al., 2016; Buah-Kwofie and Humphries, 2017) but due to atmospheric circulation, they could be transported to areas where there was no history of their usage and production (Hageman et al., 2015).

Endosulfan, an important OCP, was also banned but its residues are still a bio concern in the ecosystem (Hu et al., 2014; Lal et al., 2010; Barcelo-Quintal et al., 2008; Wang et al., 2016) and because of their widespread nature they are considered nowadays a "global pollutant" and a challenge for land management agencies. The conventional methods for remediation of contaminated soil are costly and not ecofriendly (Ojuederie and Babalola, 2017), an alternative effective approach for detoxification of Endosulfan in the soil is an environmental responsibility. Few such methods include bio-augmentation, intrinsic bioremediation and phytoremediation (Singh and Singh, 2017) was investigated in the past and found the best because of their effectiveness in decontaminations (Uqab et al., 2016) and considered as the major pathway for Endosulfan degradation in soil (Ozdal et al., 2017).

One of the Endosulfan bioremediation approach is exploiting white rot fungi (WRF) for its treatment (Kamei et al., 2011). However, direct application of them in the soil under actual treatment is not a viable option because WRF are not stable in the soil under physiological stress due to extreme environmental conditions (Hatakka, 1994; Crawford and Ramachandra, 1993). The resultant end product of certain WRF is spent mushroom compost (SMC) which is left after production of fruiting bodies. Application of farmyard waste (Fogarty and Tuovinen, 1991) and other solid composts have got attention in the past for biodegradation of various OCPs including Endosulfan (Mukherjee, 2012; Al-Hassan et al., 2004). Application of organic wastes (solid and liquid form) alter the physicochemical behavior of pesticides in the soils (adsorption-desorption, mobility, degradation, etc.) and also has positive effects on soil quality (Marín-Benito et al., 2016). However, relatively long microbial lag phases tend to increase contaminant sorption within soil microspores (Manilal and Alexander, 1991).

In the past SMC of *Pleurotus* was used for treatment of polycyclic aromatic hydrocarbon (Li et al., 2010), biocide/fungicide (Juárez et al., 2011), synthetic and textile dyes (Papinutti and Forchiassin, 2010) and many other pollutants (Cole, 1998; Marín-Benito et al., 2016) because of its ability to tolerate and/or detoxify pesticides of complex nature (Ellouze and Sayadi, 2016) at high concentrations. SMC Extract (SMCE) contains variety of immobilized enzymes including Cellulose-degrading enzymes, xylin-degrading enzymes and lignin degrading enzymes (Nakajima et al., 2018) which were reported to be involved in process of bioremediation (Lim et al., 2013; Ko et al., 2005; Karigar and Rao, 2011). These enzymes are viable under stress condition which make SMC the best candidate to treat the contaminants under field conditions. Application of WRF directly at field level has not had much success due to the difficulties in growth to adequate biomass in soil (Chirnside et al., 2011). For bioremediation of certain pollutants in soil, production of sufficient biomass and acclimatization of that particular fungus is essential (Husaini, 2014). Extracellular ligninolytic enzymes of these WRF fungi do not lose their identity in soil and can be successfully used as bio remedial agent for treatment of herbicides Application of WRF directly at field level has not had much success due to the difficulties in growth to adequate biomass in soil (Chirnside et al., 2011). For bioremediation of certain pollutants in soil, production of sufficient biomass and acclimatization of that particular fungus is essential (Husaini, 2014). Extracellular ligninolytic enzymes of these WRF

fungi do not lose their identity in soil and can be successfully used as bio remedial agent for treatment of herbicides (Chirnside et al., 2011).

This showed that there is a clear gap in knowledge regarding role of ligninolytic enzymes in effluent treatment. In the present study we sought to determine the role of ligninolytic enzyme extract obtained from SMC of *Pleurotus ostreatus* in the treatment of Endosulfan. For this purpose, we tried to address this gap by extracting and concentrating two ligninolytic enzymes from SMC of this fungus, Laccase and Manganese peroxidase (MnP) and studied their potential for detoxification of this pesticide under incubation studies of soils using biometric flasks.

Materials and methods

Chemicals/gases

Endosulfan (analytical grade) was purchased from Sigma Aldrich (St. Louis, Missouri) (99.99%). Pestanal® grade organic solvents including n-hexane, acetonitrile and acetic acid were used. The salts used for extraction of Endosulfan from samples e.g., magnesium Sulfate (anhydrous) and sodium acetate trihydrate ($NaCH_3COO.3H_2O$) were also of Analytical grade. Gases used for GC-MS (helium) and for GC-µECD (nitrogen) were 99.999% pure. All the other chemicals used to monitor the activity of enzymes, Carbon dioxide, physicochemical properties of soil and SMC were of laboratory grade. Millipore water was used for measuring physicochemical properties of soil and SMC and extraction of pesticides.

Physicochemical properties of soil

Fine loamy Soil obtained from Organic Farming Orchard, National Agriculture Research Centre, Islamabad, Pakistan (73.127855°E, and latitude 33.666042°N) with no history of OCPs (established by GC-µECD analysis) was used for this study. The physical and chemical parameters e.g., particle size distribution (sand, silt and clay), pH, electrical conductivity (EC), total organic carbon, total nitrogen, Calcium Carbonate content ($CaCO_3$) were measured by using standard procedures (Sparks et al.,1996; Dane et al., 2002) and results are given in *Table 1*. The basic characterization of soil and incubation studies were carried out in Soil Environment laboratory, Land resources research Institute, National Agricultural research center, Islamabad, Pakistan.

Table 1. *Physicochemical properties of soil used in experiment (n = 5)*

Properties (units) of soil	
pH	8.04

Concentrated SMC extract (SMCE)

Culture of *P. ostreatus* (WC-814) were shipped from Mushroom Research Program, Pennsylvania State University.

(i) Preparation of Spawn: Spawn was prepared by placing mycelium of above mentioned fungus onto steam-sterilized wheat grains (Cooled) at 22 °C. When the mycelium was completely grown through all the grain, the grain/mycelium mixture (known as spawn) was used to “seed” mushroom compost. (ii) Preparation of SMC: It was prepared by using 2 kg well chopped wheat straw, ½ kg of wheat bran and small quantity of calcium hydroxide $Ca(OH)_2$ in polyethylene bag. The bags were entirely sterilized by autoclaving at 121 °C and 15 psi for 50 min. On cooling the spawn (10 g) was added in each bag and was allowed to yield fruiting bodies. At the end of generation of fruiting bodies, the product leftover was called as SMC. (iii) Preparation of SMCE: 3 g fresh SMC Fresh (ground and sieve through 10 mm) was taken in an Erlenmeyer flask and then 30 mL sodium tartrate buffer (pH = 5.2) was added. The suspension was shaken at 22 °C and 150 rpm for 2 h as described by Lang et al. (1998) with slight modifications. Then, contents were extracted by squeezing manually using mira cloth and fluids was centrifuged (make and model) at the rate of 10,000 × g for 30 min (Márquez Araque et al., 2007). (iv) Concentration of SMCE: It was concentrated using Vivaspin 20 (10 kDa cutoff) – a disposable ultra-filtration device with twin vertical membrane for unparalleled speed in Centrifuge at the speed of 2800 × g.

Physicochemical properties of SMC

Physicochemical properties of concentrated extracellular SMCE e.g., pH (707 soil/compost pH meters), total organic carbon (TOC) (Tandon, 2005), protein and C: N ratio were determined using standard methods already used by Marín-Benito et al. (2016). Total N in SMC was determined by Kjeldahl method (Helrich, 1995) (*Table 2*).

Table 2. *Physicochemical properties of concentrated spent mushroom compost extract used in experiment (n = 5)*

Sr. No	Properties (units)	
1	pH	7.25
2	Total carbon (%)	16.62
3	Total nitrogen (%)	1.036
4	Total protein (%)	8.19
5	Organic matter (%)	30.66
6	C:N ratio	15:1

Ligninolytic enzymes activity of SMCE

UV-VIS (Perkin-Elmer-Lambda-25) at different wavelengths was used to monitor ligninolytic enzymes activities of concentrated extract with/without additions of hydrogen peroxide (H_2O_2) periodically (*Table 3*). Activities of manganese peroxidase (MnP) were determined by O-dianisidine ($C_{14}H_{16}N_2O_2$) oxidation at 460 nm (molar extinction coefficient = 29,400 M^{-1} cm^{-1}) (Paszczyński et al., 1988). Similarly, Laccase activities were monitored using 2, 2’-azino-di-[3-ethyl-benzo-thiazolin-sulphonate (ABTS) as a substrate while activities of Lignin Peroxidase (LiP) were measured by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32513267

oxidation of Veratryl Alcohol ($C_9H_{12}O_3$) to veratraldehyde ($C_9H_{10}O_3$) at 310 nm (Tien and Kirk, 1988).

Table 3. *Ligninolytic enzyme activities of various microcosms during four-week incubation studies (n = 3)*

*SMCE: spent mushroom compost extract, M_1 and M_2 mean microcosm 1 and 2

Experimental set up for biodegradation of OCPs

Using concentrated aqueous SMC extract (SMCE)

Concentrated SPME was used as bio remedial to treat Endosulfan. Erlenmeyer flasks (250 ml) were autoclaved twice and were spiked with Endosulfan at the final concentration of 25 mgL^{-1}. Microcosms were treated in the following manner

a) Microcosm 1(M_1): 10 mL of the collected concentrated SMCE
b) Microcosm 2(M_2): 10 mL of the SMCE and 800 µl of H_2O_2 (0.4 mM)
c) Control 1(C_1): 10 mL of boiled SMCE (to denature all the enzymes present in it). This control was used as associated control of M_1
d) Control 2(C_2): 10 mL of boiled SMCE and 800 µL of H_2O_2 (0.4 mM). This control was used as associated control of M_2.

Application of concentrated SMCE in soil

Biometric flasks (250 mL) (Bellco, Glass Inc., Vineland, NJ) were used for preparation of soil microcosms while SMCE extract was used as bio remedial for Endosulfan decontamination. The main body of biometric flasks consisted of soil (25 g) spiked Endosulfan at final concentration of 25 $mgkg^{-1}$. During the experiment, side arm of flasks was filled with 50 ml solution of 0.4N NaOH [CO_2-free Double distilled water (DDW)] and was used as trap to monitor CO_2. Following five treatments were applied in main body of flasks already contaminated with mixture of Endosulfan isomers to access role of SMCE, derived from *P. ostreatus* in the process of bioremediation:

1. Microcosm 3(M_3): Fresh soil (20 g) was amended with 10 mL of freshly prepared SMCE.
2. Microcosm 4(M_4): 20 g fresh soil + 10 mL SMCE + 800 µL H_2O_2 (0.4 mM).
3. Control 3(C_3): Associated control of M_3: 20 g soil+ denatured SMCE (10 ml).
4. Control 4(C_4): Associated control of M_4: 20 g soil + denatured SMCE +H_2O_2(800µL H_2O_2 (0.4 mM) to monitor role of H_2O_2 activated sterilized SMCE in contaminated soil.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32513267

5. Microcosm 5(M_5) (abiotic control): 20 g double autoclaved soil + denatured SMCE to find role of other soil inhabitant microbes in biodegradation.

During both the experiment flasks were incubated at 22 °C for 28 days. During the experiment, moisture level (60%) was maintained by taping DDW. The flasks were weighed and corrected for evaporative water loss by addition of sterile water prior to sampling at each time series. At the end of experiment, the samples were immediately put in boiling water and subsequently mixing with 10 mL acetonitrile to stop enzymes activity. All the experiment was conducted with three replicate flaks to improve the confidence of results. Required number of microcosms were taken off (sampled as whole) after each seven days till the end of experiment.

Measurement of carbon dioxide (CO_2)

Sodium hydroxide (NaOH) present in trap of biometric flasks was used to monitor CO_2 production using traditional acid titration method (Paul et al., 1999). Acid/base titration was done (at the same time intervals) for measurement of total carbon dioxide evolved. Samples were taken at day 0, 7, 14, 21 and 28 and production of CO_2 was monitored. The total amount of CO_2 evolved from the treatment bio meters was used as measure of rate of mineralization.

Extraction of OCPs from microcosms and analysis

Extraction from SPME microcosm

SMCE microcosms contents were transferred to centrifuge tubes and thoroughly mixed for 1 min using vortex mixer (Velp scientific centre, Bohemia, NY). After addition of 10 mL of acetone: water (1:3, v/v), the content was transferred to separating funnel (Pyrex® Squibb, Corning, New York), acetonitrile (2 mL) added and shaken vigorously for 5 min manually followed by addition of petroleum ether (2.0 mL). Aqueous portion was discarded and organic layer was dried with 1 g Sodium sulfate ($NaSO_4$) (anhydrous) and gauged at 2 mL using rotary evaporator (Buchi-Rotavapour.R-210) (Hernandez-Rodriguez et al., 2006)

Extraction from soil microcosm

Quick, easy, cheap, effective, rugged, and safe (QuEChERS) extraction method (with cleanup) (Boes et al., 2015) was used for extraction of selected OCP from soil with slight modifications. After hydration of samples (10 g) for 30 min using water (10 mL) and acidified acetonitrile (10 mL) (99:1 v/v) in 50 mL tube, the contents were mixed for 5 min using vortex mixer (Velp scientific centre, Bohemia, NY) and dried and buffered by adding 4.0 g magnesium sulfate (anhydrous)($MgSO_4$), 1.0 g sodium chloride (NaCl), 1.0 g trisodium citrate dehydrate ($C_6H_5Na_3O_7.2H_2O$) and 0.5 g disodium hydrogen citrate sesquihydrate ($C_6H_8Na_2O_8$). Centrifugation was done at 5000 × g for 5 min. After separation of acetonitrile layer, it was concentrated to 5 ml and was later mixed with water (2 mL) and n–hexane (10 mL) and swirled for 1 min. After 2 min, an aliquot of 9 ml of the upper n–hexane layer was collected and reduced again to 1.4 mL in an amber glass vials and stored at -20 °C. Analysis of Endosulfan in extracted samples was done using Gas Chromatography (7890B Agilent) equipped with micro-electron capture detector (G3440B). HP-5(30 m × 0.25 µm I.D × 0.320 mm) capillary column was used.

Kinetic studies and statistical analysis

Simple first-order kinetics (SFO) was used found the most fitted kinetic equation for the set of experiments**.** The reduction in extractable amount of Endosulfan from the artificially spiked soil was calculated using *Equation 1* (Yang et al., 2014)

$$lnC = a + K_1 t \quad \text{(Eq.1)}$$

where *lnC* is natural logarithm of concentration, *t* is time given to compound for degradation and K_1 is first order rate constant.

Half-life (DT_{50}) was calculated by *Equation 2:*

$$DT_{50} = t_{1/2} = \frac{0.693}{k1} \quad \text{(Eq.2)}$$

For DT_{50} and DT_{90} calculations, a computer program R (version 3.0.3) with the kinfit software package was used. The best fitted SFO (simple first-order kinetics) was used. The data was statistically analyzed (analysis of variance) using complete randomized

design with two factors (treatments and times) at $\alpha = 0.05$ by Statistix 8.1 (Analytical Software, USA) computer program.

Results and discussion

This study was designed to find the potential of ligninolytic enzymes extract obtained from SMC to treat this pesticide in soil. In order to make the enzymatic effect clear, concentration of the enzyme and treatment of the microcosms with or without H_2O_2 was done. SMC has many immobilized enzymes that could serve as bio remedial agent (Valentin et al., 2010). Therefore, some researchers applied SMC directly in soil to treat contaminants (Marín-Benito et al., 2016). Direct application is beneficial because it acts as the substrate to change the bioavailability and immobilization of pesticides in the soil. However, while studying the role of ligninolytic enzymes in bioremediation, direct use of SMC is also a big problem because of adsorption of pesticides onto fungal biomass and compost which hinders true revelations. Therefore, extraction of enzymes from SMC and their application in soil is another option.

Bioremediation of Endosulfan using only SMCE

After application of Endosulfan in flask, microcosms were treated with SMCE and bioremediation of both the isomers of this pesticide was studied. In M_1 where H_2O_2 was added in microcosm to stimulate the effect of enzyme in SMCE, 24.99% of applied α-Endosulfan was reduced at the end of first week of incubation. At the end of 4^{th} week, 58% of applied extractable α-Endosulfan was removed. However, 56.85% of removal was observed in M_2, where no H_2O_2 was added. It showed addition of H_2O_2 did not play any substantial role in reduction of applied α-Endosulfan as there was no significant difference ($\alpha = 0.05$, $p < 0.01$) in both above mentioned microcosms, M_1 and M_2 (*Table 6*).

Table 6. *Bioremediation of Endosulfan under different microcosms to access the role of extracellular enzyme extract, where M_1 and M_2 are Microcosm 1 and 2, while C1 and C2 are their associated controls ($\alpha = 0.05$; $p < 0.01$)*

α-Endosulfan: LSD for Days 2.69; LSD for treatments 3.21
β-Endosulfan: LSD for Days 1.22; LSD for treatments 1.46

The calculated rate of dissipation using SFO kinetics was not substantially different in both the microcosms which resulted in DT_{50} equal to 22 days and 21 days for M_1 and M_2 respectively (*Table 7*). C_1 and C_2 which were the associated control of M_1 and M_2,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32513267

showed the reduction of only 12.36% and 10.25% of applied α-Endosulfan, respectively. Ultimate DT_{50} calculated for C_1 was 154 days ($K_1 = 0.0045$) while under C_2 it was 173 days ($K_1 = 0.004$). However, there were a significant difference between each microcosm and their associated controls (*Table 6*). In the past, it was reported that presence of H_2O_2 in ligninolytic system is responsible for faster bioremediation or decolonization (Vyas and Molitoris, 1995; Eichlerová et al., 2006). However, in this case, addition of H_2O_2 did not pose any effect on reduction of M_2 than M_1 where no H_2O_2 was added.

The other isomer of Endosulfan, β-Endosulfan showed the similar reduction pattern (*Table 6*) but the rate of this reduction was about ⅓ of that observed in case of α-Endosulfan. Total removal of this isomer, during incubation period, in M_1 and M_2 was 20.87% and 21.49% respectively showing there was no significant difference ($\alpha = 0.05$, $p < 0.01$) in bioremediation efficacy of SMCE with or without H_2O_2 (*Table 6*). It shows that stimulation of enzymes by adding H_2O_2 as were mentioned in another study (Chirnside et al., 2011) had no role in reduction of β-Endosulfan. DT_{50}, calculated for M_1 and M_2 were 80 days and 82 days respectively. It also showed autoclaving to denature the SMCE was responsible for the slow rate of removal (*Table 7*) because it eliminated biotic factor including enzymes and microbes in associated controls.

SMCE of *P. ostreatus* was monitored for two main ligninolytic enzymes MnP and Laccase enzyme activities in all the microcosms (*Table 3*). Immediately after addition of H_2O_2 on day zero, the activities of both the enzymes, Laccase and MnP, were higher showing stimulatory effect of H_2O_2 on M_1 (*Table 3*). All the activities had downward trend at each sampling time which shows that with the passage of incubation time, the enzymes activities were declined. The activities of MnP and Laccase in M_2 where no H_2O_2 was added were lower than M_1 at each time interval (*Table 3*). M_1 showed significantly more activities of Laccase and MnP than M_2 but there was no significant difference in reduction of both the isomers of Endosulfan. For example, a study conducted by Ulčnik et al. (2013) showed that purified laccase obtained from this fungus and other related ligninolytic enzymes were found to play no role in the process of bioremediation. Another study conducted by Purnomo et al. (2010) also showed that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32513267

ligninolytic enzyme are not involved in the bioremediation of OCPs. Same is proved in our case.

During the course of study, oxidation occurred and only one dechlorination metabolite, Endosulfan sulfate was formed in flasks from day 7 and no other metabolite was detected on GC-MSD.

Bioremediation of Endosulfan using SMCE in Soil

For preparation of soil microcosms, biometric flasks containing soils treated with SMCE were incubated for 28 days at 22 °C. NaOH solution was added in the side arm of biometric flask and served as trap of CO_2. Application of SMCE in fresh soil (M_3) resulted in total reduction of 41.62% of applied concentration of α-Endosulfan at the rate 0.013 days^{-1}. Resultantly, calculated DT_{50} was 51 days (r^2 = 0.98). Addition of H_2O_2 along with SMCE in soil (M_4) resulted in total reduction up to 47.16% while under M_5 (abiotic microcosm), the reduction of 7.42% at the rate K_1 = 0.013 days^{-1} was observed which is less than both M_3 and M_4. Denaturation of all the biotic factors present in soil and SMCE (M_5) resulted in least reduction of applied α-Endosulfan (*Fig. 1*). There was a significant difference in reduction between M_3 and M_4 (α = 0.05, $P < 0.01$). Since there are various other constituents in the soil that could be stimulated by addition of H_2O_2 (not necessarily enzymes from added extract) which resulted in significant difference in amount of reduction of α-Endosulfan in M_4 than M_3. The role of addition of SMCE in M_3 and M_4 in bioremediation was assessed by running associated controls (C_3 and C_4). The reduction of α-Endosulfan under M_3 was significantly different from its associated control (C_3). Same was true for M_4 and associated control.

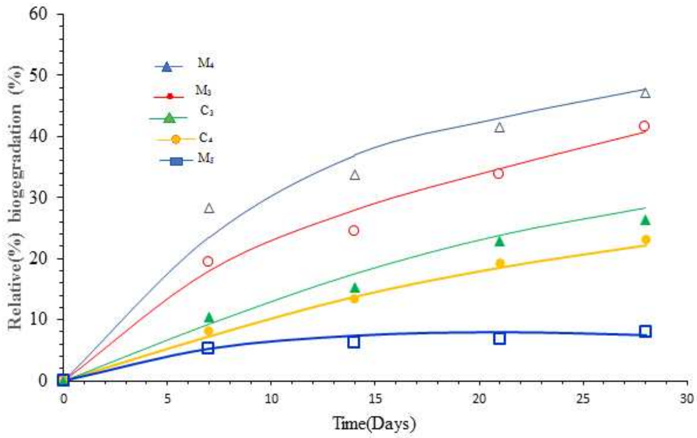

Figure 1. *Relative reduction of α-Endosulfan in soil using spent mushroom compost extract in different microcosms*

Similarly, recorded reduction for β-Endosulfan under M_3 was 32.40% at the rate of 0.016 day^{-1} while its associated control C_3 exhibited reduction equals to 20.05% at the rate of 0.0078 day^{-1} (*Fig. 2; Table 8*). Similar pattern was observed in M_4 and its associated control C_4. Removal of Endosulfan isomers in C_3 and C_4 revealed the role of denatured SMCE as carbon source (Kodjo-Wayo, 2006) (*Fig. 2*). In case of abiotic control (M_5), total of 2.84% of applied β-Endosulfan was reduced. Detailed DT_{50} calculated based on equation 2 and rates of all the treatments are given in *Table 8*.

Addition of SMCE initiates oxidative pathways and produces free radicals in soil which are removed by soil constituents and cause less reduction of toxic compounds in soil bio meters (Chirnside et al., 2011) than flasks which contained only SMCE (M_1 and M_2). This was evident in this finding where SCME alone reduced more Endosulfan than after addition in soil. The overall reduction of both the isomers was higher in SMCE microcosms without soil (M_1 and M_2) than the microcosms where SMCE was added in soil (M_3 and M_4). Presence of total organic carbon (TOC) in denatured SMCE resulted in decontamination of Endosulfan in soil because of its role in increasing the indigenous population of soil microbes (Guerin, 1999; Özyer et al., 2016). In our case, SMCE was rich in organic carbon (*Table 2*), which further helped to enhance the population of indigenous microbes (Zhang et al., 2013) in the soil. This increase in Endosulfan removal in H_2O_2 amended microcosm of soil M_4 indicated that addition of H_2O_2 in soil amended with SMCE stimulated certain soil enzymes and microbes which were not present in sole SMCE. Addition of SMCE within the soil involves couple of reactions whose nature is very difficult to explore. The less degradation of β-Endosulfan by application of SMCE in soil than α-Endosulfan could be due to inter-conversion of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32513267

α-isomer to β-Endosulfan (Rice et al., 1997; Schmidt et al., 2001) and also microbial species prefer α-Endosulfan for degradation over β-Endosulfan (Siddique et al., 2003).
The bioremediation pathways for Endosulfan after application of SMCE were built based on the time of appearance of peaks, their position and centre of mass of concentration profiles of the metabolites detected by GC-MS. In all associated controls and treatments of M_1 and M_2, only Endosulfan sulfate was formed (*Fig. 3*). Endosulfan lactone was only formed in M_3 and M_4 soil microcosms. Under M_5, there was no appearance of any metabolites. This is possibly because of absence of process of oxidation because of un availability of microbes or enzymes. Formation of Endosulfan lactone is also in line with the findings of (Kataoka and Takagi, 2013). Other expected bioremediation products could be Endosulfan diol, Endosulfan ether, Endosulfan hydroxyether and Endosulfan monoaldehyde (Kullman and Matsumura, 1996) which were not detected during the course of this study. However, formation of Endosulfan lactone is evident for the formation of other above mentioned intermediate products and the fact that hydrolysis also occurred in the soil treated with SMCE.

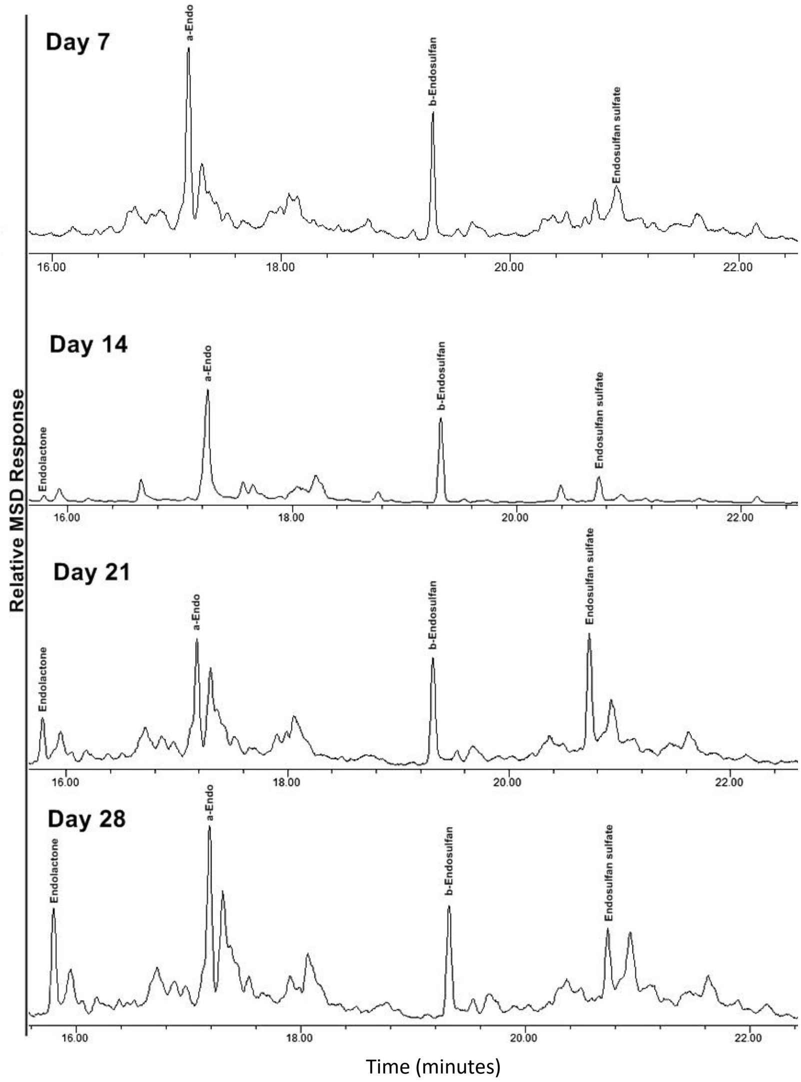

Figure 3. *The metabolic products of Endosulfan detected at GC-MS after incubation of soil with spent mushroom compost extract. Formation of Endosulfan sulfate indicate oxidation while generation of Endosulfan lactone is the result of hydrolytic pathways*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32513267

Emission of carbon dioxide is a bioremediation indicator and contaminant depletion can be estimated from the amount of carbon dioxide emitted from the system (Schoefs et al., 2004). Amount of CO_2 produced in spiked bio-meter flask with M_3 and M_4 was much more than associated controls of containing denatured SMCE (*Fig. 4*). Evolution of CO_2 was increased exponentially as experiment progressed. The evolution of CO_2 from M_5 flask was the slowest of all the microcosms. The highest amount of CO_2 generated was in M_4. It is observed that the emission and measurement of CO_2 was good qualitative indicator of bio mineralization. This similarity also existed for abiotic controls where the CO_2 production stayed very low. It can be assumed that since OCPs are very persistent and complex compounds therefore free radicals did not play any role in their oxidation. Nevertheless, the inactivated extract, used as control, showed significantly less Endosulfan decrease than the activated SCME extract. This suggested that that both wash-off and volatilization had no impact on OCPs loss. This is in accordance with the studies conducted by Juárez et al. (2011). Since it is proved that Laccase and MnP have no role in bioremediation here, there could be another enzyme or enzymatic complex which is responsible for the degradation of Endosulfan. Although role of laccase in biodegradation of many pollutants has been widely studies (Karigar and Rao, 2011) but there is no direct evidence which connect the effect of presence or quantity of this enzyme in biodegradation of Endosulfan.

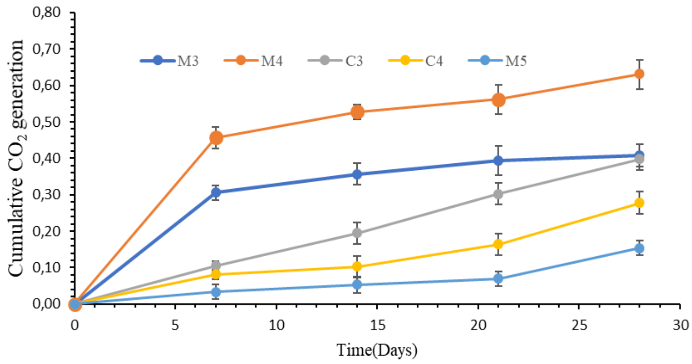

***Figure 4.** Evolution of CO_2 during the incubation studies of the Endosulfan bioremediation by application SMCE treatments in soil, where M_1 is microcosm having fresh soil and SMCE and M_2 is microcosm that contain H_2O_2 along with while C_1 and C_2 are the associated controls of microcosms 1 and 2. M_5 is the abiotic control microcosm*

Conclusion and recommendation

In order to avoid the problem of adsorption, instead of its direct application spent mushroom compost extract was used to evaluate the role of enzyme complex in bioremediation of Endosulfan. Five different microcosms along with associated controls were used to demonstrate the role of SMCE. This study revealed that ligninolytic enzyme stimulation after addition of H_2O_2 does not affect the bioremediation efficacy of SMCE, rather it has certain other extracellular enzymes that could possibly be involved in process of decontamination. This was evident from almost equal reduction of this pesticide in the presence and absence of H_2O_2. In soil, this extract showed some effect of addition of H_2O_2. There was significantly more reduction of both isomers in the soil microcosm containing SMCE spiked with H_2O_2 than the other where H_2O_2 was not spiked. Associated controls showed if SCME was denatured after sterilization, there

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32513267

was less reduction in both isomers of Endosulfan. It also indicated the role of stimulation of indigenous soil microbes/enzymes in the presence of H_2O_2 and the role of SMCE as carbon source to enhance the microbial population of soil. All these results provide a basis for the development of new bioremediation strategy for decontamination of Endosulfan in soil. However, there is a strong need of understanding the complex nature of reactions involved in symbiotic interaction between SMCE and soil constituents which were responsible for more reduction of Endosulfan in soil.

Acknowledgements. We are thankful to Staff of Mushroom Research Laboratory, National Agriculture Research Centre, Islamabad, Pakistan for cooperation in mushroom culture, spawn and compost preparation. We are also very thankful to Soil Environment Lab for facilities of SMC and soil physicochemical properties. Many thanks to laboratory staff of Ecotoxicology Research Program especially, National Agriculture Research Centre, Islamabad, Pakistan.

Abstract. Heavy metal contaminations are a major cause of global environmental pollutions. The release of heavy metals into the environment has increased the threat of serious health issues for living organism. Among the known heavy metals, chromium is released into the environment by various anthropogenic activities causing various ill effects on the life forms. Hence in the present study which was carried out in Vellore Institute of Technology, Tamil Nadu, India and the phytoextraction of chromium enhanced with metal chelator ethylenediamine tetraacetic acid was studied in *Sesbania grandiflora* in VIT, India. To asses this, various treatments were prepared with combinations of chromium and chelator. The antioxidant enzyme activities such as Superoxide dismutase, Catalase, Ascorbate peroxidase and Glutathione reductase activity were determined in the presence of metal and chelator. The results showed an increase in all the antioxidant enzymes in the presence of metal and chelator due to the increased metal uptake. To reduce the stress levels created by the metal and chelator, sodium nitroprusside a nitric oxide donor was exogenously sprayed on to the plants and a comparative study was made in the presence and absence of sodium nitroprusside. The results indicated that the presence of sodium nitroprusside had a positive role in combating the stress created by the metal and chelator which was evident by the reduced antioxidant enzyme levels in spite of metal uptake. Hence sodium nitroprusside could be considered for its wider application against metal stress conditions to combat oxidative stress. The plant *Sesbania grandiflora* showed higher withstanding capacity to the heavy metal stress and was effective in extracting the metal out of the contaminated soil.
Keywords: *heavy metal, Sesbania grandiflora, superoxide dismutase, catalase, sodium nitroprusside, chelator, oxidative stress*

Introduction

Heavy metals pose a critical concern to human health due to their increasing usage as industrial inputs (Alloway, 1995; Diels et al., 2002). Chromium (Cr) is an environmental pollutant that ranks seventh in abundance in the earth crust. The major contributors of Cr contamination are the leather tanning, electroplating, and stainless steel industries. India is one of the largest producers of leather, and nearly 80% of the tanneries are engaged in the chrome-tanning process. Chromium being toxic interferes with metabolic processes in plants, which causes several morphological and physiological changes causing reduced growth, impaired photosynthesis and can lead to death of the plant. Chromium exists in two forms Cr (III) and Cr (VI). Among them Cr (VI) exists in the forms of chromate anions (CrO_4^{-2}), dichromate ($Cr_2O_7^{2-}$) and chromium trioxide (CrO_3) which are considered the most toxic forms of chromium, since they possess high oxidizing potential, high solubility, and mobility across the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

membranes in living organisms and in the environment (Azmat and Khanum, 2005). Clean up of contaminated soils needs special attention because these soils support agricultural crops and so the consumption of crop plants grown on these soils may create serious health hazards.

Plants sequester heavy metals in roots and/or shoots and, therefore, significantly contribute to metal removal from the environment through the mechanism of phytoremediation (Jadia and Fulekar, 2009). The uptake and translocation of such heavy metal by plants can be made bio available by the addition of natural or synthetic chelators (Schmidt, 2003; Quartacci et al., 2006) like, ethylenediamine tetraacetic acid (EDTA), ethylenediamine di (o-hyroxyphenylacetic acid) (EDDHA) and hydroxyethylethylene-diaminetriacetic acid (HEDTA). Among them, EDTA is most effective chelating agent which enhances the accumulation of metals, by mobilizing metal cations, water soluble complexes (Lestan et al., 2008) there by modifying the availability of the metals in soils to the above ground parts of plants (Garba et al., 2012b), and increasing the uptake of heavy metals.

One of the mechanisms that make a plant tolerant to heavy metal stress is the presence of strong antioxidant defense system (Metwally et al., 2005; Qureshi et al., 2005; Israr et al., 2006 and Diwan et al., 2008). Heavy metals stress causes molecular damage to plants, either directly or indirectly through reactive oxygen species (ROS) formation. Further, plants growing in chromium-stressed environment suffer due to potential risk from reactive oxygen species (ROS) like superoxide ($O_2^{\bullet -}$), hydroxyl radicals (•OH) and hydrogen peroxide (H_2O_2). However, plants possess their own defense system to combat these toxicity problems like cellular antioxidants and antioxidant enzymes that play a vital role in protecting the plant from various physiological damage caused by ROS (Mittler, 2002., Baek and Skinner, 2003) that make a plant species tolerant to heavy metal stress (Metwally et al., 2005; Qureshi et al., 2007; Israr et al., 2006; Diwan et al., 2008). Antioxidant system consists of enzymatic and non-enzymatic compounds. Enzymatic antioxidants include superoxide dismutase, catalase, peroxidases, glutathione reductase and ascorbate reductase. Non-enzymatic antioxidants are ascorbate, glutathione, tocopherol and carotenoids (Mittler, 2002; Candan and Tarhan, 2003).

Nitrite oxide (NO) is a lipophilic molecule that diffuses through membranes. Although first described as a signal molecule in animals, accumulating evidence shows that NO is an important signal molecule involved in plant response to biotic and abiotic stresses (Delledonne et al., 1998; Carlos and Lorenzo, 2001; Uchida et al., 2002).

Based on the above observation, the objective of the present study is to investigate whether exogenous sodium nitroprusside (SNP) plays a positive role in protecting *Sesbania grandiflora* against antioxidative stress created by chromium in the presence of EDTA.

Materials and methods

Soil spiking and experimental setup

The study was done in Vellore Institute of Technology (VIT), Tamil Nadu, India. The experiments were conducted during the months of June-August. Pot experiments were conducted using the soil samples taken from VIT garden. The soil was air-dried and sieved. The study was a comparison made by conducting two experiments (Exp), namely Exp 1 and Exp 2. Five pots each containing 2.7 kg of soil + 0.3 kg of manure

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

was mixed along with five different concentrations of chromium and ethylenediamine tetraacetic acid (EDTA) in case of Exp 1. The study was done to assess the efficiency of chromium accumulation by *Sesbania grandiflora*. This was studied in comparison with Exp 2 containing in addition 10 ml of 250 µM of SNP as foliar spray along with chromium and EDTA. The various treatments that were considered in Exp 1 and Exp 2 are given in the following treatment tables:

Treatment name (Exp 1)	**Concentrations**
C1	20 mg Cr Kg^{-1}
C2	40 mg Cr Kg^{-1}
C3	60 mg Cr Kg^{-1}
C4	80 mg Cr Kg^{-1}
C5	100 mg Cr Kg^{-1}
C1+EDTA	20 mg Cr Kg^{-1} + 0.35 mM EDTA
C2+EDTA	40 mg Cr Kg^{-1} + 0.35 mM EDTA
C3+EDTA	60 mg Cr Kg^{-1} + 0.35 mM EDTA
C4+EDTA	80 mg Cr Kg^{-1} + 0.35 mM EDTA
C5+EDTA	100 mg Cr Kg^{-1} + 0.35 mM EDTA

Treatment Name (Exp2)	**Concentrations**
C1	60 mg Cr Kg^{-1}
C2	100 mg Cr Kg^{-1}
C3	60 mg Cr Kg^{-1} + 0.35 mM EDTA
C4	100 mg Cr Kg^{-1} + 0.35 mM EDTA
C5	60 mg Cr Kg^{-1} + 250 µM SNP
C6	100 mg Cr Kg^{-1} + 250 µM SNP
C7	60 mg Cr Kg^{-1} + 0.35 mM EDTA + 250 µM SNP
C8	100 mg Cr Kg^{-1} + 0.35 mM EDTA + 250 µM SNP
C9	Control + 250 µM SNP
C10	Control

Control plants were free of chromium and EDTA (Exp 1) and contained SNP in case of Exp 2. All the treatments were done in triplicates. The control and the treated soil were left to equilibrate for 3 weeks during which it was occasionally turned and mixed to ensure thorough mixing. The seeds of *Sesbania grandiflora* were sterilized in 3% formaldehyde and sown in plastic trays for one week to attain the seedling stage (*Fig. 1a*). About 6 seedlings were transferred to the spiked soil pots after three weeks of incubation. Totally 33 pots from Exp 1 and Exp 2 were maintained in a randomized block design (*Fig. 1b*). Both the experiments were performed at the same time period. The harvested plants were collected during every morning at the end of 30, 60 and 90 days and were stored at -20 °C for a short duration and all the enzyme assays were performed within a week's time from the harvest.

Enzyme extraction and activity of antioxidant enzymes

500 mg of fresh leaves was weighed and homogenized in 3 ml of extraction buffer containing 0.5 ml of 50 mM potassium phosphate buffer (pH 7.5), 0.5 ml of Triton X-100, 1 g of polyvinyl pyruvate (PVP) and 3.72 mg of EDTA. The homogenate were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

filtered and centrifuged at 15,000 × g for 20 min at 4 °C. The supernatant was used for assaying superoxide dismutase (SOD), ascorbate peroxidise (APX) and glutathione reductase (GR) activities.

a **b**

***Figure 1. a** One week old seedling of Sesbania grandiflora; **b** randomized block design of treatment pots*

Superoxide dismutase (SOD) (EC1.15.1.1)

SOD activity was assayed using a modified NBT method according to Beyer and Fridovich (1987). The 2 ml assay reaction mixture contained 50 mM phosphate buffer (pH 7.8) containing 2 mM EDTA, 9.9 mM L-methionine, 55 µM nitro blue tetrazolium (NBT), and 0.025% Triton-X100. 40 µl of diluted (2×) sample and 20 µl of 1 mM riboflavin were added and the reaction was initiated by illuminating the samples under a 15 W fluorescent tube. Duplicate tubes with the same reaction mixture were kept in the dark and used as blank. Absorbance of the samples was measured immediately after the reaction was stopped at 560 nm against blank. The enzyme activity grams^{-1} f.w of a sample was determined from a standard curve obtained by using pure SOD.

Native polyacrylamide gel electrophoresis (PAGE) of crude extract (25 µg) combined with loading buffer (containing neither SDS nor P-mercaptoethanol) was performed in a mini-gel system (Medox) at 150-200 V. SOD activity in native polyacrylamide gels was determined by the nitroblue tetrazolium (NBT) method of Beauchamp and Fridovich (1971). SOD activity was visible after several minutes as an achromatic band against a blue background.

Catalase (CAT) (EC 1.11.1.6)

The Catalase assay was performed by the method of (Luck, 1974). The enzyme extract (0.02 ml) was added to the reaction mixture containing 3 ml of hydrogen peroxide (H_2O_2) and 0.067 M phosphate buffer (pH 7.0) and the optical density change was measured at 240 nm, the time taken for decrease in the absorbance from 0.45 to 0.4 is noted as ΔT. The activity of the enzyme is expressed in the terms of µmole of H_2O_2 consumed/min/ mg protein. The activity was determined by calculating the concentration of H_2O_2 using the extinction coefficient 0.036 per µmole per ml.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

Ascorbate peroxidase (APX) (EC1.11.1.11)

The APX activity was determined by the method followed by Nakano and Asada (1987). The 1 ml reaction mixture contained 0.1 ml of 100 mM potassium phosphate buffer (pH 7.0), 0.5 mM ascorbate, 0.3 mM H_2O_2 and 50 µl of enzyme extract. The oxidation of ascorbic acid was measured by the decrease in absorbance at 290 nm for 3 min using a spectrophotometer. The enzyme activity was calculated using the extinction coefficient 2.8 mM^{-1} cm^{-1} and expressed in enzyme units (mg protein)$^{-1}$. One unit of enzyme is the amount necessary to decompose 1 µmol of substrate per min at 25 °C.

Glutathione reductase (GR) (EC 1.6.4.2)

The activity of GR was measured by monitoring the glutathione dependent oxidation of (Nicotinamide adenine dinucleotide phosphate) NADPH described by Rao et al. (1996). 1 ml reaction mixture contained 0.1 ml of 100 mM potassium phosphate buffer (pH 7.5), 0.1 ml of 1 mM EDTA, 0.02 ml of 0.2 mM NADPH, 0.05 ml of 0.5 mM oxidized glutathione and 50 µL of enzyme extract. The reaction was allowed to run for 3 min and the absorbance was measured at 340 nm using a spectrophotometer. The enzyme activity was calculated using extinction coefficient 6.2 mM^{-1} cm^{-1} and expressed in enzyme units (mg protein^{-1}). One unit of enzyme is the amount necessary to decompose 1 µmol of NADPH per min at 25 °C.

Determination of ascorbate oxidase activity (AAO) (EC 1.10.3.3)

Assay of ascorbic acid oxidase activity was carried out according to Oberbacher and Vines (1963). 0.1 ml of the enzyme extract was added to 3 ml of the substrate solution (8.8 mg of ascorbic acid in 300 ml phosphate buffer, pH 5.6). The absorbance change was measured at 265 nm for every 30 s for a period of 5 min. One enzyme unit is equivalent to an absorbance change of 3.58 per minutes.

Non-enzymatic antioxidants glutathione estimation

The level of glutathione in the treatments with and without EDTA containing chromium was determined according to Tukendorf and Rauser (1990), using Ellman's reagent. About 500 mg of the plant material was homogenized with mortar and pestle in 5 ml of cold extraction buffer containing, 0.1 M Tris-HCl (pH 8.0), 10 mM $MgCl_2$, 3 mM Sodium-EDTA. The homogenate was centrifuged for 30 min at 15 000 g at 4 °C. The reaction mixture contained 1 ml of the supernatant, 2 ml of 0.4 M Tris-HCl buffer (pH 8.9), 50 µl of 10 mM 5,5'-dithiobis(2-nitrobenzoic acid) DTNB. All the samples were incubated for 1 h at 37 °C. The absorbance was measured at 412 nm after 2 min in a spectrophotometer ($\sum 412 = 13.6$ mM^{-1} cm^{-1}).

Statistical analysis

The data observed in the experiment were statistically analyzed for the mean, standard deviation (SD), standard error (S.E.) and least significant difference (LSD) to determine the critical level of significance ($P \leq 0.05$) of the differences between means of treatments.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Results and discussion

Effects of Cr, EDTA and SNP on superoxide dismutase activity

The results of SOD activity are presented in *Figure 2a* showing the effect of different concentration of chromium with and without EDTA on superoxide dismutase activity (Units mg^{-1}protein) in *Sesbania grandiflora* and in *Figure 2b* showing the effect of chromium and EDTA in the presence of SNP on superoxide dismutase activity (Units mg^{-1}protein) in *Sesbania grandiflora* respectively. The results after 30 days time period from *Figure 2a* showed an increase in the SOD activity with increase in the concentration of Cr. When compared with control plants the C5 treatment plants showed 80.7% increase with respect to the SOD activity. Further in the presence of chelator EDTA, the SOD activity was observed to be increased in all the treatments with EDTA when compared with control. Significant difference was noted for the treatment with highest concentration of Cr at both the levels $P \leq 0.05$ and $P \leq 0.01$. During 60 days of growth significant difference at both $P \leq 0.05$ and $P \leq 0.01$ were observed for the treatments C4, C5 and C5+EDTA, whereas treatments C3+EDTA and C4+EDTA showed significant difference only at one level $P \leq 0.05$. The highest SOD activity was represented by the treatment C5+EDTA at 60 days of growth with 116.01 units/mg protein. Whereas in absence of EDTA the C5 plants showed 22.48 % decrease in the SOD activity, this justifies the role of EDTA in enhanced metal uptake and increased oxidative stress, thereby increasing the SOD antioxidant enzymes. At 90 days there was a significant difference for C3+EDTA, C4+EDTA and C5+EDTA at both $P \leq 0.05$ and $P \leq 0.01$, whereas in the absence of EDTA, C3 and C4 showed difference only at $P \leq 0.05$, whereas C5 showed significant difference at both the significant levels. Hence the significant difference between the treatments Cr without and with EDTA shows that, in the presence of EDTA the concentration of Cr is higher and it also increased with the time period. The elevation of SOD activity in general is a clear indication to detoxify the O^{-2} and other ROS in downstream pathways under metal stress. But in the presence of EDTA, the levels of SOD are still higher.

SOD activity increased with 150 µg/g Cr in the presence of EDTA in *Cucumis utilissimus* (Sinam et al., 2011). The increase in SOD activity after 12 hr of application of 50 µmol/L of Cr (VI) was also reported in *Vigna radiata* cv. CO_4 (Shankar et al., 2005). In maize the SOD activity increases with 300 µM of Cr in Sartaj variety (Maiti et al., 2012).

The result represented in *Figure 2b* depicts the effects of exogenous nitric oxide in the presence of chromium and EDTA. From the figure it was clear that, when the concentration of chromium is increased from 60 mg/Kg Cr to 100 mg/Kg Cr, the SOD activity also increases corresponding to the heavy metal increase enhanced by EDTA, which is vivid from the treatments C1-C4. This phenomenon of increase in SOD activity corresponding to the metal increase has been reported by different authors. Due to oxidative stress created by the metal the plant has adapted a defensive mechanism by increased production of anti-oxidative enzymes, among the known antioxidative enzymes, SOD is considered to be the first line of defense for plants anti oxidative defense system. In the presence of SNP, this condition is reversed in the present study. From this it is concluded that, C3 and C4 plants when compared with that of C7 and C8 plants, the presence of SNP in latter in spite of metal and EDTA concentration it decreased the SOD activity in those plants (i.e. C7 and C8) by 34.4% and 32.90% respectively at the end of 30 days growth period. Significant difference was depicted in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

activity of SOD in C3 and C7 for varying time periods. This shows that in the presence of SNP the SOD activity have been reduced. Based on the literature (Ferreira et al., 2010) the decreased SOD activity during treatment with SNP clearly states that nitric oxide (NO) action has created lower substrate availability and created a reversed effect. This fact was detected in the present study with the plants supplied with 250 µM of SNP.

Similar results were reported in ryegrass and in *Arabidopsis* under Cu stress (Dong et al., 2014; Cobbett, 2000). Reports in sunflower and rice leaves under Cd stress by Laspina et al. (2005) and Hung and Kao (2003) have detected that in the presence of SNP, the SOD levels decreases and this low SOD activity was due to decrease in lipoperoxide levels. It increased the photosynthetic ability of the plant and confers the plant protection against oxidative stress. Similar to the above results (Caro and Puntarulo, 1998) observed the lowered levels of substrates for SOD due to NO presence in soybean embryo. Reports also suggested that nitric oxide play role even as an antioxidant thereby directly quenching the super oxide anion and regulates the oxidative damage as seen in *Triticum aestivum* roots grown under Pb induced toxicity (Kaur et al., 2015). Thus based on the above reports by various authors it could be correlated in the present work, that NO gradually scavenged the superoxide radical when SNP is supplied exogenously in the treatments C5 and C6. Even in the presence of combined effect of Cr and EDTA in the treatments C7 and C8, presence of SNP had a positive role in attenuating the oxidative stress generated by the metal and chelator.

(Lower case letters that are different denote the treatments which are significantly different. Same letter indicates the treatments which are not significantly different.)* ***c*** *Superoxide dismutase (SOD) isoenzymes activities in native gels in leaves of Sesbania grandiflora under various combinations of chromium, EDTA and SNP*

SOD enzyme was distinguished by native Polyacrylamide gel electrophoresis (PAGE) experiment to determine the isoenzymes of SOD in the presence of SNP-treatment. The finding in *Figure 2c* shows the superoxide dismutase (SOD) isoenzymes activities in native gels in leaves of *Sesbania grandiflora* under various combinations of chromium, EDTA and SNP, this shows the presence of one manganese superoxide dismutase (Mn-SOD) in both the control and chromium treated plants. When plants were exposed to higher concentration of chromium with 100 mg Cr Kg^{-1}, it was observed that MnSOD was apparently affected in SNP treated plants which is clear from the bands which were clearly less intense (lane 8) than the other treatments (lane 4) in the absence of SNP.

Effects of Cr, EDTA and SNP on catalase activity

Catalase, a tetrameric heme-containing enzyme, that degrade H_2O_2 rapidly and more sensitive to excess Cr, where it readily binds to thiol groups and inactivates the thiol-containing enzyme (Luna et al., 1994). Similar to SOD activity, the catalase activity in the study represented in *Figure 3a* shows the effect of different concentration of chromium with and without EDTA on catalase activity (Units mg^{-1} protein) in *Sesbania grandiflora*. The activity was found to be increased with higher concentrations of Cr in the presence of EDTA. When compared with the control, the highest catalase activity was noted for higher concentration of Cr in presence of EDTA (C5+EDTA) which was observed to be 55.5% increased than non-EDTA plants (C5) at 60 days growth period. The CAT activity also increased with the time period from 60 days compared to 90 days due to the persistent effect of chromium action. Hence under this metal stress reactive

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

oxygen species (ROS) production is elevated leading to oxidative damage. Statistically it was noted that at 60 days significant change was exhibited at $P \leq 0.05$ and $P \leq 0.01$ for the treatments C1, C1+EDTA and C2+EDTA. Similarly at 90 days C4 and C2+EDTA showed significant difference ($P \leq 0.05$ and $P \leq 0.01$). Statistically also EDTA proves its higher metal enhancement activity, since from *Figure 3* it is clear that, at 60 and 90 days of the growth the treatment C2+EDTA alone showed significant difference at the p values $P \leq 0.05$ and $P \leq 0.01$, stating that the presence of EDTA with higher concentration of Cr had influence on the increased activity. The combined action of SOD and CAT is critical in mitigating the effects of oxidative stress, since SOD show customary action on the superoxide anion converting it to H_2O_2 which is another reactive intermediate and later H_2O_2 gets converted it to water and oxygen (Mates, 2000). Catalase enzyme increases with increasing concentration of Cr in *Ocimum tenuiflorum* and *Sesbania sesban* (Rai et al., 2004; Bakiyaraj et al., 2014).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

The results of catalase activity in the presence of chromium and EDTA, and exogenous application of SNP are represented in *Figure 3b* showing the effect of chromium and EDTA in the presence of SNP on catalase activity expressed in (Units mg^{-1} protein) in *Sesbania grandiflora.* From the figure it is clear that, the catalase activity increased with increase in chromium and EDTA levels, which is apparent from the treatments C2 and C4. But the treatments C5-C8 with SNP the activity of catalase decreased, with corresponding increase in the concentration of chromium.

According to Ferreira et al. (2010), the cause of the decrease in CAT activity was due to reduced substrates for CAT activity as observed in SNP-pretreated soybean plants. This fact was paralleled with the present study that the decreased H_2O_2 production as a consequence of the NO effect, approve protection against ROS in SNP administered C7 and C8 plants. Our study is in concordance with the above statement that, in the presence of SNP the catalase activity is reduced in C5 and C6. This is also applicable to the treatments C7 and C8, where in spite of chromium and EDTA the catalase activity was reduced in these plants. Thus when a comparison was made between C3 and C4 plants with their counter parts C7 and C8 plants, presence of SNP in latter, reduced the CAT activity by 31.6% in case of 60 mg Cr, SNP and EDTA and 18.94% in case of 100 mg Cr, SNP and EDTA at 90 days growth period. Hence compared with the control the antioxidant activity was decreased in SNP treated plants which clearly explains the potential of NO, which confers resistance to heavy metal stress created oxidative damage in *Sesbania grandiflora.* And moreover the reduction of catalase activity and its decreased levels to normalcy was experienced after addition of SNP indicating the cell response to NO action and thus decreasing the ROS generation inside the cell. Similar results were reported by Dalurzo et al. (1996) in Pea leaves and (Cobbett, 2000) in *Arabidopsis* showing the decline in CAT activity.

Effects of Cr, EDTA and SNP on ascorbate peroxidase (APX) activity

The APX activity for Exp.1 is presented in *Figure 4a* showing the effect of different concentration of chromium with and without EDTA on ascorbate peroxidase activity (Units mg^{-1}protein) in *Sesbania grandiflora.* From the figure, it is clear that the APX activity increased in the treatments of chromium in the presence of EDTA than experienced by the treatment in the absence of EDTA. The levels of APX increased in 30 days of plant growth, and when compared with the control, the value of 4.6 units/mg protein observed in C5+EDTA plants, is 10.96% higher than C5 plants with 0.51 units/mg protein of APX. A significant difference in the treatments was observed for the higher concentration at both the levels $P \leq 0.05$ and $P \leq 0.01$ in the presence of EDTA (C4+EDTA and C5+EDTA). After 30 days, the APX activity increased with increase in the chromium concentration. This increase in the enzyme activity could be correlated with action of ascorbate peroxidase that was more efficient in destroying H_2O_2 under Cr stress in the presence of chelator. Statistically at 60 days, there was a significant difference noted for all the treatments at both $P \leq 0.05$ and $P \leq 0.01$, except for C2+EDTA and C5+EDTA which showed significant difference only at one level $P \leq 0.05$. Among the EDTA treated plants C1+EDTA was the only treatment that showed significant difference at $P \leq 0.05$, whereas all the treatments in the absence of EDTA significantly differed ($P \leq 0.05$ and $P \leq 0.01$). When compared with the control, the progressive level of APX showed an increase in the activity of APX in the treatment C5+EDTA at 90 days with 8.6 units/mg protein of the enzyme. The study is in agreement with the reports of (Karuppanapandian et al., 2006a) that, the antioxidant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

enzyme increase was due the antioxidative capacity stimulated by Cr, which caused the conversion of H_2O_2 to H_2O and O_2. The high levels of APX produced, due to the higher concentrations of Cr in the presence of EDTA, uses ascorbic acid as a reductant in the first step of the ascorbate-glutathione cycle (Mittova et al., 2003 and Smirnoff, 2000). Similar results were reported by Rai et al. (2006) in sugarcane plants exposed to hexavalent chromium. Cr and Al induced H_2O_2 accumulations in wheat and green gram seedlings were also found to significantly elevate the APX activity (Sharma and Sharma, 1996). APX plays an important role in scavenging H_2O_2 which is a systemic signal for the induction of APX (Morita et al., 1999).

Figure 4. a *Effect of different concentration of chromium with and without EDTA on ascorbate peroxidase activity (units mg^{-1} protein) in Sesbania grandiflora. (Significance at $P \leq 0.05$ = b, significance at $P \leq 0.01$ and $P \leq 0.05$ = ab.)* ***b*** *Effect of chromium and EDTA in the presence of SNP on ascorbate peroxidase activity (units mg^{-1} protein) in Sesbania grandiflora. (Lower case letters that are different denote the treatments which are significantly different. Same letters indicate the treatments which are not significantly different)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

The effects of APX activity in the presence of chromium and EDTA, with exogenous application of 250 µM SNP are represented in *Figure 4b* showing the effect of chromium and EDTA in the presence of SNP on ascorbate peroxidase activity (Units mg^{-1} protein) in *Sesbania grandiflora.* From Exp.1, it was concluded that, the APX activity was found increased at higher chromium levels with EDTA, due to higher metal accumulation which was assisted in presence of EDTA. From Exp.1 also it is evident that, in order to overcome the oxidative stress, the APX activity increased in EDTA treated plants as a plant adaptive defence mechanism, which is evident from the treatments C3 and C4 (60 and 100 mg Cr kg^{-1} with 0.35 mM EDTA). The increased APX activity was observed for higher concentrations of chromium with increase in time period (C5, C5+EDTA), whereas C2, C4 and C2+EDTA plants exhibited lesser variation in APX activity during 90 days. Similarly the plants supplied with 250 µM SNP, showed decreased APX activity. This is obvious when comparison is made between C3 and C4 and C7 and C8 plants, that presence of SNP has decreased the APX activity by 17.56% (between C3 and C7) and 47% (between C4 and C8). Significant difference was depicted in C8 during 60 and 90 days compared to C4. This decrease in APX activity from the present study could be correlated with Hiner et al. (2000) and Talukdar (2012b) that, low availability of reduced ascorbate, its co-factor, or inhibition of its isoforms by excess H_2O_2 or both, caused reduced APX activity in *Lathyrus sativus* by the latter. Hence in the present study the lower ascorbate levels created by the nitric oxide have reduced the stress levels and hence a reduced APX activity was observed. Similar results were reported in wheat roots (Singh et al., 2008).

Effects of Cr, EDTA and SNP on glutathione reductase (GR) activity

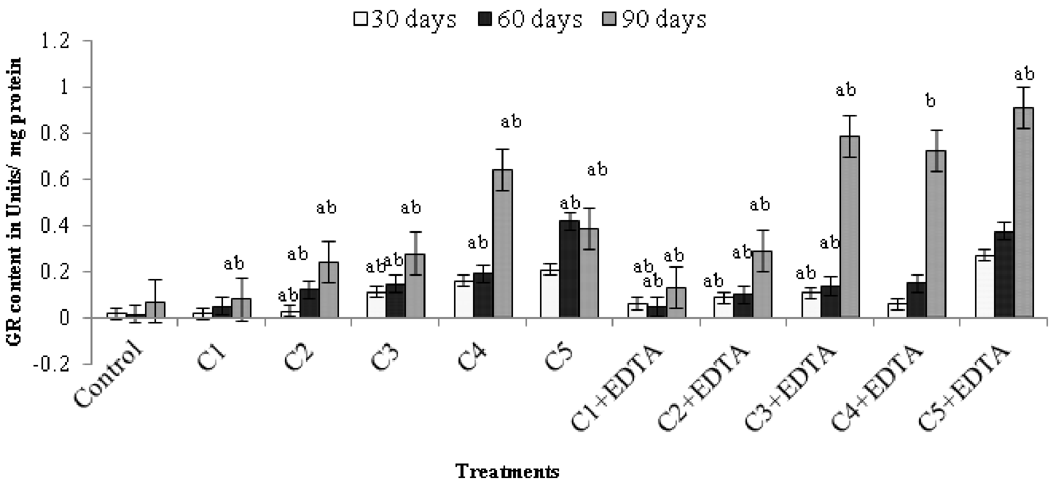
The results for GR activity after 30, 60 and 90 days are presented in *Figure 5a* showing the effect of different concentration of chromium with and without EDTA on glutathione reductase activity (Units mg^{-1} protein) in *Sesbania grandiflora.* The figure denoted an increasing GR activity corresponding to the increasing concentration of the chromium and increased further in the presence of EDTA. The treatment C5 was recorded with 0.38 units/mg protein of GR content which corresponds to a decreased percentage of 58.24%, when compared with that of C5+EDTA plants with 0.91 units/mg protein. Statistically there was significant difference for the treatments C5, C3+EDTA and C5+EDTA after 30 days at $P \leq 0.05$ and $P \leq 0.01$. During 60 days of growth C4, C5 and C3+EDTA showed significant difference. At 90 days there was statistical difference for $P \leq 0.05$ and $P \leq 0.01$ in all the treatments with and without EDTA, except for C1. Thus the determination of GR content from Exp.1 concludes that, the GR levels increased with the concentration of the treatments and it is duration dependent. Similar results were also reported in Indian mustard (Diwan et al., 2009) stating that the activity of GR under Cr treatment was concentration as well as duration dependent.

GR is a flavoenzyme, oxidoreductase, which catalyze the conversion of oxidized glutathione to reduced glutathione, which is found in both prokaryotes and eukaryotes. It is a prospective enzyme for the (Ascorbate glutathione) ASH-GSH cycle and plays a vital role in defense system against ROS by sustaining the reduced status of (Glutathione) GSH (Romero-Puertas et al., 2006; Gill and Tuteja, 2010).

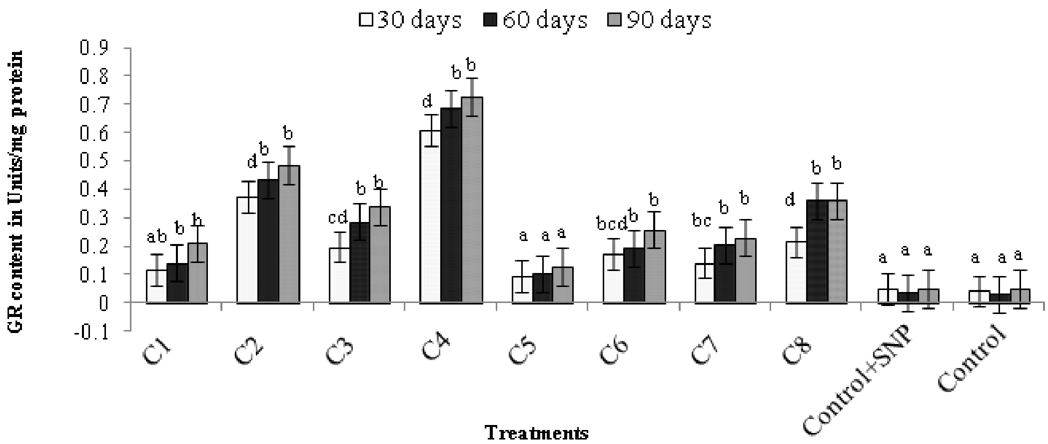
GR content increased under Cr stress in *Vigna radiata* roots (Shankar et al., 2004). In another study (Nehnevajova et al., 2012), the activity of GR was strongly increased in young seedlings exposed to heavy metals and the enzyme activities were particularly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

pronounced in mutant lines of sunflower. Increased GR activity was noted (Thounaojan et al., 2012) in Cu treated *Oryza sativa* over control and, the roots showed greater activity than shoot. According to Yadav et al. (2010) chromium stress induced the production of the GR and Cr detoxification in *Jatropha curcus* plant.



a



b

Figure 5. ***a*** *Effect of different concentration of chromium with and without EDTA on glutathione reductase activity (units mg^{-1} protein) in Sesbania grandiflora. (Significance at P ≤ 0.05 = b, significance at P ≤ 0.01 and P ≤ 0.05 = ab.)* ***b*** *Effect of chromium and EDTA in the presence of SNP on glutathione reductase activity (units mg^{-1} protein) in Sesbania grandiflora. (Lower case letters that are different denote the treatments which are significantly different. Same letters indicate the treatments which are not significantly different)*

According to Diwan et al. (2012) APX and GR maintain the H_2O_2 level. The increased level of H_2O_2 when exported to cytosol, create an adverse effect due to formation of hydroxyl radicals through the metal-catalyzed Haber–Weiss reaction. In the present study the increased activities of APX and GR in higher concentrations in Cr treated plants in the presence of EDTA shows that they were functioning concurrently to remove H_2O_2.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

Glutathione reductase catalyzes the reduction of GSH, a molecule involved in many metabolic regulatory and anti oxidative processes in plants. GR catalyses the NADPH dependent reaction of disulphide bond of GSSG (oxidized glutathione). It is thus important for maintaining the GSH (reduced glutathione) pool (Reddy and Raghavendra, 2006). GR and GSH play crucial role in determining the tolerance of a plant under various stress (Chalapathi Rao and Reddy, 2008).

The GR activity with SNP treated plants are represented in *Figure 5b* showing the effect of chromium and EDTA in the presence of SNP on glutathione reductase activity (Units mg^{-1} protein) in *Sesbania grandiflora.* It depicts that there is an elevation of the scavenging enzyme in the treatments C3 and C4 in order to counter act Cr-induced stress in the presence of chelator compared to its absence in C1 and C2. According to Shigeoka et al. (2002) APX and GR are the two main enzymes of the ascorbate-glutathione cycle, which are localized mainly in chloroplasts and play an important role in combating oxidative stress. This is proved in the present study that in plants treated with Cr and EDTA, there is a considerable increase in the GR content.

Further comparing with other treatments, it is slightly reversed upon addition of SNP. The treatment plants C5 and C6 supplied with 250 µM of SNP in the presence of 60 and 100 mg Cr kg^{-1}, the oxidative stress created by the metal is reduced. In treatments C7 and C8 despite the presence of EDTA and Cr, addition of SNP reduced the stress by showing reduction in the enzyme activity which reduced the stress by 33.3% (C3 and C7) and 50% (C4 and C8) respectively. In other words, SNP as a NO donor has an ameliorating effect on Cr and EDTA induced stress. Supporting facts by Singh et al. (2008) reported similar reduction in GR activity upon SNP treatment against Cd toxicity in wheat roots.

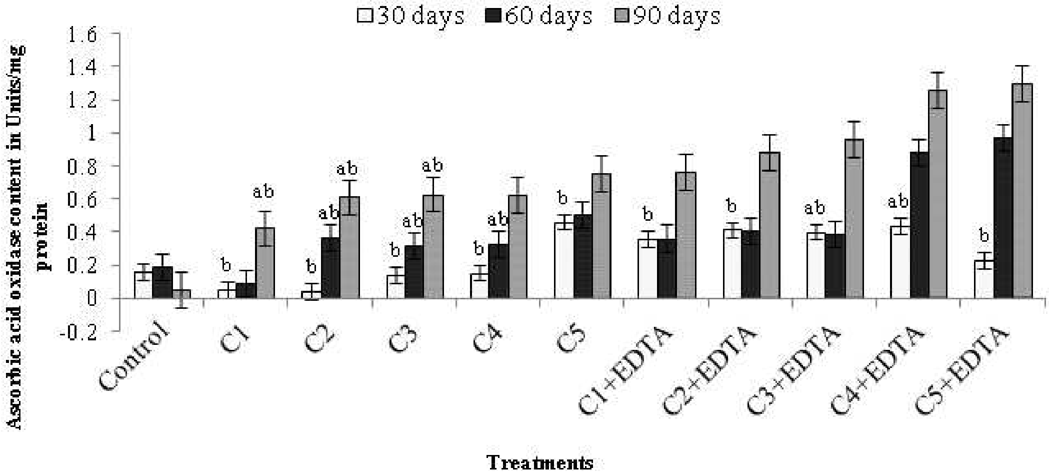
Effects of Cr, EDTA and SNP on ascorbic acid oxidase activity

The activities of Ascorbic acid oxidase determined in the leaves of *Sesbania grandiflora* are presented in *Figure 6a* showing the effect of different concentration of chromium with and without EDTA on ascorbic acid oxidase activity (units mg^{-1} protein) in *Sesbania grandiflora.* From the results it is clear that when the concentration of the chromium increases from 20-100 mg, there is an increase in the activity of the antioxidant enzyme ascorbic acid oxidase. Moreover when compared with the control, the activity of the enzyme increased by 89.4%, 115.7%, 105.2%, 363.1% and 410.5% in the presence of EDTA in C1+EDTA to C5+EDTA plants respectively corresponding to chromium concentration noted after 60 days of growth. When compared with C5 plants, C5+EDTA showed 94% increase in ascorbic acid oxidase activity. Statistical significant difference was noted in all the treatments at $P \leq 0.05$. After 30 days of growth, treatments C3+EDTA and C4+EDTA showed significant difference at both the levels $P \leq 0.05$ and $P \leq 0.01$. At 60 days of growth C2, C3, and C4 showed significant difference at $P \leq 0.05$ and $P \leq 0.01$. Similarly after 90 days, significant difference was exhibited by the treatments C1, C2 and C3. Thus the present study shows that EDTA had an influence on the ascorbic acid oxidase enzyme concentration determination in the presence of increasing concentrations of Cr.

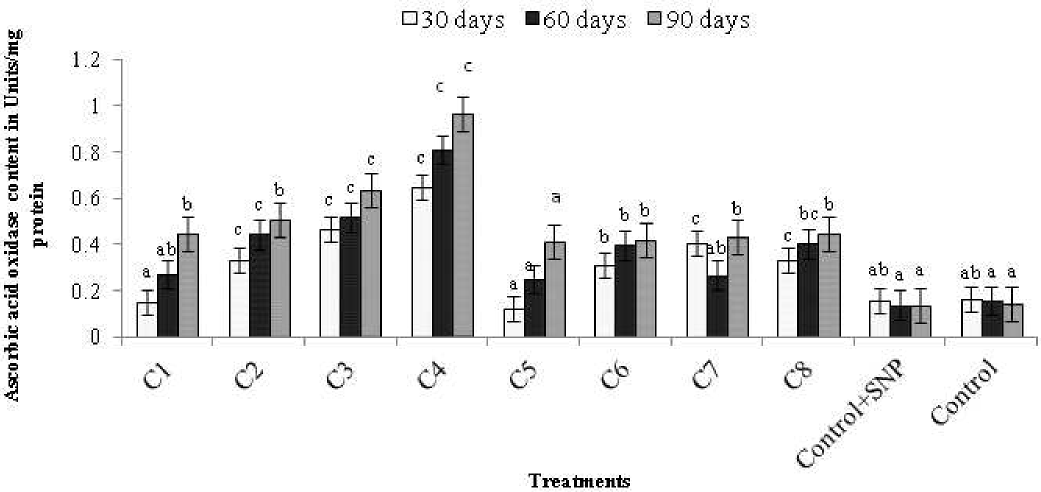
Ascorbate is a universal soluble antioxidant that is involved in various physiological mechanisms of plant, which exists in photosynthetic organisms. The ascorbate is considered to be the most important substrate for decomposition of hydrogen perodxide H_2O_2 detoxification (Singh et al., 2005). High AO activity is associated with the cell wall ascorbate and cell wall localized ascorbate oxidase (AO) that function to control

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

growth and expanding cells and as a model that links wall ascorbate and ascorbate oxidase to cell wall extensibility (Smirnoff, 1996).



a



b

***Figure 6. a** Effect of different concentration of chromium with and without EDTA on ascorbic acid oxidase activity (units mg^{-1} protein) in Sesbania grandiflora. (Significance at $P \leq 0.05$ = b, significance at $P \leq 0.01$ and $P \leq 0.05$ = ab.) **b** Effect of chromium and EDTA in the presence of SNP on ascorbic acid oxidase activity (units mg^{-1} protein) in Sesbania grandiflora**.** (Lower case letters that are different denote the treatments which are significantly different. Same letters indicate the treatments which are not significantly different)*

Ascorbate is considered to be the primary as well as a secondary antioxidant, which binding to the metals, affects their movement across biological membranes, or act as a reductant. Reports suggested that, the ascorbate content in *Vigna aconitifolia* roots increased significantly under cadmium stressed conditions (Vijendra et al., 2016). Similarly the activity of ascorbate oxidase enzyme was determined for a period of three months for the plants treated with 60 and 100 mg of Cr with 0.35 mM EDTA and 250 µM SNP. The result represented in *Figure 6b* explains the effect of chromium and EDTA in the presence of SNP on ascorbic acid oxidase activity (Units mg^{-1} protein) in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

Sesbania grandiflora. The figure articulates that, the enzyme activity increased from 30 to 90 days in treatments (C1-C4) in the presence of chromium and EDTA as a defensive mechanism for the plant to withstand the oxidative stress formed due to the reactive oxygen species (ROS) liberated due to high metal concentrations. But in the treatments (C5-C8) the result showed that, the presence of nitric oxide in the plants under the treatments showed decline in the enzyme levels, where the C8 plants showed a decreased percentage of 54.1% when compared with C4 plants in the absence of SNP, stating the fact that nitric oxide can counteract Cr and EDTA induced oxidative stress.

Such effects were confirmed by the other antioxidant enzymes studied and such studies reported that NO can detoxify or scavenge ROS directly or it can also react with $O_2^{\bullet-}$ and generate peroxynitrite ($ONOO^-$) (Martinez et al., 2000; Neill et al., 2003). Thus SNP protects plants against Cr+ EDTA induced oxidative stress. The SNP effect in the present study represents the antioxidant property of NO for suppression of high levels of Cr-triggered ROS.

Effects of Cr, EDTA and SNP on glutathione activity

Glutathione (GSH), a tri-peptide is most abundant low molecular weight thiol in all mitochondria-bearing eukaryotes including plants. In plants, GSH is involved in defence against ROS (Foyer and Noctor, 2005; Mullineaux and Rausch, 2005), sequestration of heavy metals (Cobbett and Goldsbrough, 2002) and is one of the major source of non-protein thiols in most plant cells (Freeman et al., 2004). The glutathione content in the chromium treated plants with and without EDTA in the present study represented in *Figure 7a* shows the effect of different concentration of chromium with and without EDTA on glutathione content (µg. FW^{-1}) in *Sesbania grandiflora.* When compared with the control the glutathione content increased with the increase in the concentration of Cr in the presence of EDTA. The highest glutathione content was recorded for the treatment with 100 mg of Cr + 0.35 mM EDTA with 280.63µg.

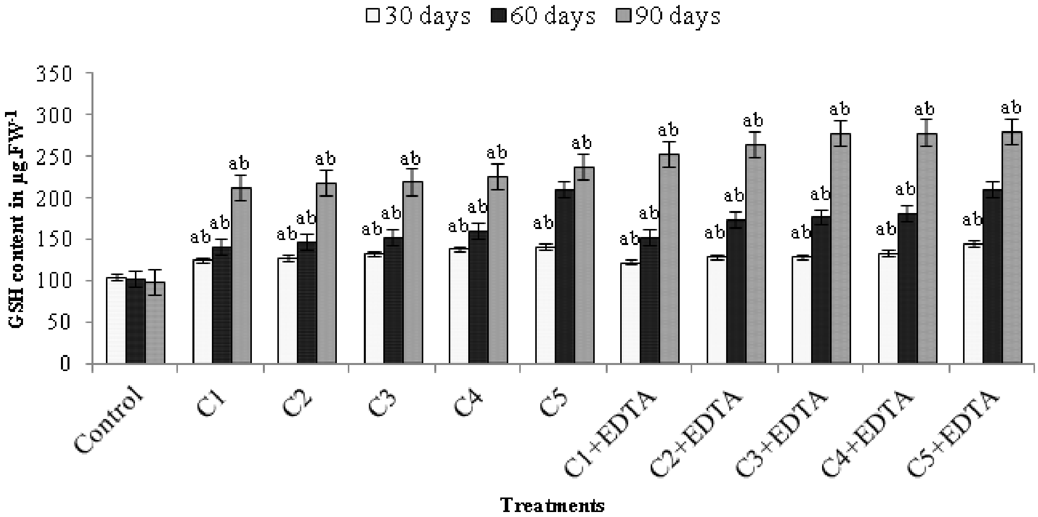
With increase in time period from 30 to 90 days the glutathione content was found to be increased by 92.9% in C5+EDTA plant. All the treatments showed significant difference at both levels $P \leq 0.05$ and $P \leq 0.01$. But at 60 days of growth all the treatments showed significant difference at both levels $P \leq 0.05$ and $P \leq 0.01$ except C5 and C5+EDTA. This validates that, higher concentrations of Cr have influence on glutathione concentration in plant under heavy metal stress and this effect being more pronounced in the presence of EDTA. Thus at higher concentration of Cr/chelator the level of glutathione increased with time.

Furthermore, elevated GSH concentration is correlated with the ability of plants to withstand metal-induced oxidative stress. Enhanced antioxidant activity in the leaves and chloroplast of *Phragmites australis* was mainly associated with a large pool of GSH resulting in protection of many photosynthetic enzymes against the thiophilic bursting of Cd (Pietrini et al., 2003). Similarly, increased concentration of GSH has been reported in *Pisum sativum*, *Sedum alfredii* and *Vigna mungo* (Metwally et al., 2005; Sun et al., 2007; Molina et al., 2008).

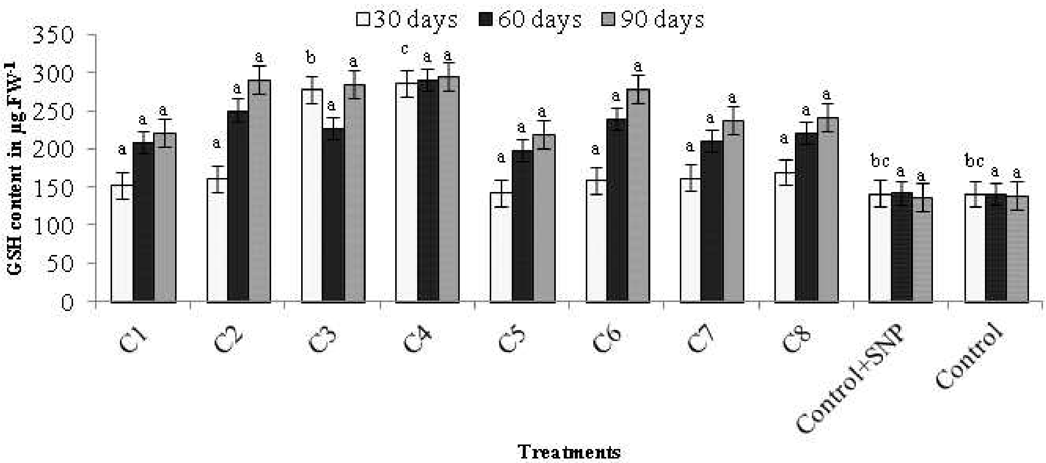
Various non enzymatic antioxidants play an important role in plant defense mechanism under heavy metal stress. In *Oryza sativa* there was no observed significant change in the ascorbate (AsA) content in developing seedlings under Cr (VI) (Panda, 2007); however, the reduced glutathione (GSH) content increased by 30% and 52% at 50 mM and 100 mM of Cr (VI), respectively, after 48 h of exposure. Elevated expression of genes encoding these enzymes under Cr (VI) toxicity suggests defensive

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

role of glutathione under heavy metal stress according to Zulfiqar et al. (2011), these observations show the involvement of glutathione metabolism in the alleviation of Cr (VI) toxicity by providing protection against oxidative stress.



a



b

Figure 7. a *Effect of different concentration of chromium with and without EDTA on glutathione content (µg.FW^{-1}) in Sesbania grandiflora. (Significance at P ≤ 0.05 = b, significance at P ≤ 0.01 and P ≤ 0.05 = ab.)* ***b*** *Effect of chromium and EDTA in the presence of SNP on glutathione content (µg. FW^{-1}) in Sesbania grandiflora. (Lower case letters that are different denote the treatments which are significantly different. Same letters indicate the treatments which are not significantly different)*

A marked increase in GSH levels in *Zea mays*, *Brassica spp*. and *L. esculentum* upon exposure to 5–10 mg l^{-1} Cr (VI) (Sanita di Toppi et al., 2002). A positive correlation between GSH and Cr levels has also been observed in *Salvia natans* (Dhir et al., 2009) and *Brassica juncea* (Diwan et al., 2010).

GSH is one of the crucial metabolites in plants which are considered as most important intracellular defense against ROS induced oxidative damage. GSH is necessary to maintain the normal reduced state of cells so as to counteract the inhibitory

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32693291

effects of ROS induced oxidative stress. It is a potential scavenger of $^1O_2$, H_2O_2 and most dangerous ROS like OH^-.

The observations made on the glutathione content with SNP treated plants represented in *Figure 7b* show the effect of chromium and EDTA in the presence of SNP on glutathione content (µg. FW^{-1}) in *Sesbania grandiflora* depicts that increased glutathione content with chromium and EDTA treated plants (C1-C4) was reduced in the presence of SNP. From the figure, it shows that treatments, C5 to C8 exhibited reduced glutathione content when compared with control and other treatment plants.

A comparison between the treatments in presence and absence of SNP showed that, presence of SNP in C7 and C8 plants showed a decreased percentage of glutathione content with 16.5% and 17.9%, with that of their respective counterparts C3 and C4 plant.

The reports indicate that the heat-treated *Triticum aestivum* plants showed a reduced GSSG content compared to heat treated plants, due to the SNP supplement (Hasanuzzaman et al., 2012). Literatures also suggest that during stress conditions the glutathione levels inside the cell increases as a consequence to confer resistant against oxidative stress created by heavy metal (Hasanuzzaman et al., 2017). This was paralleled with the present study that the GSH content was found to increase with higher concentrations of chromium in the presence of EDTA. But Exp.2 concluded that, though there was increase in GSH content in chromium and EDTA treated plants, the SNP supplemented plants showed a decreased GSH content than the normal.

This could be justified that the oxidative stress generated by metal and chelator was mitigated by the action of SNP, there by manifesting the key role of nitric oxide in acting as a direct scavenger of ROS and thus reduced the oxidative stress in *Sesbania grandiflora* subjected to metal stress induced by chelator. The reduced GSH levels in the present study could be attributed to the fact that, the reduced stress levels has limited the accumulation of GSH inside the plant due to NO activity.

Conclusion

The present study concludes that exogenous nitric oxide supply ameliorates the Cr-toxicity in the presence of chelator EDTA. Nitric oxide also helped in ameliorating oxidative stress by decreasing the antioxidant levels in response to increasing metal and chelator concentration. Hence SNP when supplemented to heavy metal accumulating plants will reduce the stress levels in plants. Further studies are required to elucidate the changes in molecular levels, to identify the isoenzymes or proteins that are involved in mediating the ameliorating action of NO.

Acknowledgements. The authors would like to thank the VIT management for the constant support provided during the entire period of study.

Abstract. Selenium (Se), as an essential element, has its effects on the growth and development of plants. Present study aimed to assess Se mediated chlorophyll contents, net photosynthesis, biomass accumulation and activity of carbon metabolism enzymes. Three different levels of Ethylenediamine tetra acetic acid - chelating Se (EDTA-Se) at 10(E1), 30(E2) and 50(E3) μmol L^{-1} were overhead applied at initial heading stage of two aromatic rice cultivars i.e., *Xiangyaxiangzhan* and *Meixiangzhan2*, the treatment without Se were served as control (CK). Results revealed that exogenous Se applications enhanced the chlorophyll content as well as net photosynthetic rate (Pn), meanwhile, grain weight at maturity and the biomass accumulation during the filling had been remarkably improved. Furthermore, growth, yield and quality components were also improved by Se application. Hence, Se proved better for both rice cultivars whereas the E2 was the best treatment with the highest yield, biomass accumulation and net photosynthesis rate.
Keywords: *selenium, rice, net photosynthetic rate, biomass accumulation, chlorophyll content*

Introduction

Rice production is the cornerstone of Chinese food safety system. Recently, as the human populations swell across the world, the demand for rice has been increasing, while available cultivated land for it has been decreasing. The study of Krishnan et al. (2007) showed that it was possible there would be 10 billion people on the earth. In the coming decades, it would lead to increasing the demand for rice. Aromatic rice is a delicacy in rice and has always been the focus of the people because of its predominant tasty, captivating fragrance and other unique features. Despite aromatic rice has been fetching an extremely high price, interestingly, the demand for it keeps growing steadily (Mo et al., 2016). However, just like other rice cultivars, the yield of fragrant rice is affected by many uncertain factors such as climate condition and other environmental factor. For example, Mo et al. (2015) demonstrated that shading the aromatic rice plant during the grain filling stage could significantly reduce its yield. Further study on lead (Pb) stress caused a huge loss in yield of fragrant rice (Ashraf et al., 2018). Meanwhile, a series of researches indicated that certain artificial regulation and application could improve the quality and yield of aromatic rice. Ren et al. (2017) found that fertilizer treatment and severe drought conditions applying separately not only improved the yield of aromatic rice significantly, but also enhanced the 2-acetyl-1-pyrroline (2-AP), the key element of the fragrance of aromatic rice, content in the plant (Yajima et al., 1979). The investigation of Pan et al. (2017) also found that mechanized deep placement of nitrogen fertilizer elevated aromatic rice yield dramatically.

Multiple microelements are available to promote fragrant rice performance. Li et al. (2016) demonstrated that Manganese (Mn) could regulate yield information of aromatic rice and enhanced 2-AP content in grains by improving the synthesis of proline and pyrroline-5-carboxylic acid (P5C) (2-AP's precursors) as well as promoting activity of proline dehydrogenase (ProDH). The report of Mo et al. (2017) revealed that Silicon (Si) application had ability to improve the growth, yield, quality and 2-AP contents of fragrant rice because of the net photosynthetic (Pn) rates, proline contents and activity of ProDH being enhanced.

Selenium (Se), as a significant element, plays an essential role for humans, animals and plants. An analysis (Gladyshev et al., 1999) of Se revealed that poor immune function, high risk of mortality, and cognitive decline had been associated with deficiency of Se while taking Se supplementation had improved the virus inhibitory effect and reduced the risk of catching an autoimmune thyroid disease. With the advance of research, Se was proven to be able to against toxic elements such as arsenic, antimony, mercury and copper (Srivastava et al., 2009; Gotsis, 1982). Moreover, the research of Wang et al. (2012) generated a selenium-enriched rice with high production and enough bioavailability by using selenite fertilization.

Photosynthesis, as an important physiological process in rice, affected rice growth and yield significantly (Zhong et al., 2019; Cao et al., 2018). Normally, the proportion of cop biomass which is directed towards the harvested part could decide the potential of rice yield. To date, there are few reports about fragrant rice photosynthesis and the effect of Se application on fragrant rice. Moreover, Ethylenediamine tetra acetic acid - chelating Se (EDTA-Se) is a new exiting form of selenium element. Hence, it has much room for investigation and based on the hypothesis that exogenous Se application in initial heading stage could enhance the rice photosynthetic characteristics during the filling stage, this study was conducted in Guangdong province (major rice producing province in South China) in order to study the effect of EDTA-Se on rice photosynthesis and dry matter accumulation during the filling stage.

Materials and methods

Plant materials and growing condition

Two aromatic rice cultivars, *Xiangyaxiangzhan* and *Meixiangzhan2*, which are widely cultivated at South China, having 111-114 days of growth period were planted in late season at Experimental Research Farm, College of Agriculture, South China Agricultural University, Guangzhou, (23°09'N, 113°22'E and 11 m from mean sea level) China (*Fig. 1*) during the July and November in 2017. This region has subtropical-monsoonal type of climate with mean annual air temperatures of 26.6 °C, mean annual maximum and minimum air temperatures of 14°C in November and 37 °C in August, respectively. Before sowing, the seeds were soaked in water for 24 h, germinated in manual climatic box for the next 24 h,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32933303

dried in the shade. Then the germinated seeds were sown in PVC trays for nursery raising. 20-day-old seedlings were transplanted to the field at the planting distance (30 cm × 12 cm). The experimental soil was sandy loam with of 25.65% organic matter content, 1.360% total N, 0.956% total P, and 17.460% total K.

Figure 1. *The location of the experimental site*

Treatments descriptions

Experimental treatments were as described:
CK: Overhead sprinkle with double distilled water at initial heading stage of rice.
E1: Overhead sprinkle with EDTA- Se liquor (10 μmol L^{-1} pure selenite concentration) at initial heading stage.
E2: Overhead sprinkle with EDTA- Se liquor (30 μmol L^{-1} pure selenite concentration) at initial heading stage.
E3: Overhead sprinkle with EDTA- Se liquor (50 μmol L^{-1} pure selenite concentration) at initial heading stage.

Plant sampling and determination of biomass accumulation

At heading stage and maturity stage, the rice plants were harvested from six unit sampling areas (1 m^2) in each plot. The leaves, stem-sheaths and grains were separated from the plants and dried under the condition of 80 °C respectively in order to get the estimation of dry matter. The thirty fresh flag leaves were separated and collected from the rice plants at the 15th day after heading stage, washed with double distilled water and stored under the condition of -80 °C for the sake of chlorophyll analysis.

Biomass accumulation during filling stage (BADF) was calculated as: BADF = Total dry weight at heading stage per hill – total dry weight at maturity per hill.

Determination of photosynthesis

Portable photosynthesis system (LI-6400, LI-COR, USA) was used to determine net photosynthetic rate at 09:00–10:30 a.m. according to the standard method (Pan et al., 2015). The photosynthesis was measured on 15th day after the heading stage.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32933303

Estimation of chlorophyll contents

The contents of total chlorophyll (total Chl), chlorophyll a (Chl a) and chlorophyll b (Chl b) were determined by the methods of Anjum (2016). Grinding leaf sample (about 0.1 g) was placed in 15 ml centrifuge tube along with 95% absolute ethyl alcohol (10 ml) and then kept at dark condition until the color of sample transformed turn into white. Then with the help of UV-visible spectrophotometer, Chl a, Chl b and total Chl contents were estimated at 645 nm, 652 nm and 663 nm.

Determination of yield and yield related traits

At maturity stage, the rice grains were harvested from seven unit sampling area (1 m^2) in each plot and then threshed by machine. The harvested grains were sun-dried and weighted in order to determinate the grain yield. Twenty hills of rice from different locations in each plot were sampled for estimate the average effective panicles number per hill. Then, three hills representative plants were taken for estimation of the yield related traits.

The economic coefficient (EC) was calculated as: EC = grain weight / whole plant weight.

Statistical analysis

Data were analyzed using statistical software ‘Statistix 8.1’ (Analytical Software, Tallahassee, FL, USA) while differences amongst means were separated by using least significant difference (LSD) test at 5% probability level. Graphical representation was conducted via Sigma Plot 14.0 (Systat Software Inc., California, USA).

Results

Chlorophyll contents

Exogenous Se applications affected chlorophyll contents at filling stage significantly (*Fig. 2*). For *Xiangyaxiangzhan*, compared with CK, all Se treatments markedly increased the contents of both total chlorophyll and chlorophyll a (except E3) while chlorophyll b content of E2 was 1.32-fold higher than CK. For *Meixiangzhan2*, the highest total chlorophyll, chlorophyll a and chlorophyll b were all recorded in E2 while the chlorophyll contents under E1, E2 and E3 treatments were all higher than CK respectively.

Net photosynthetic rate

As shown in *Figure 3,* net photosynthesis varied with different Se applications in both rice cultivars. The E1 treatment had highest value of net photosynthetic rate while there was no distinct difference between E1 and E2. The trend of net photosynthetic rate was recorded as: E1 > E2 > E3 > CK for both *Xiangyaxiangzhan* and *Meixiangzhan2*.

Dry matter accumulation

Different Se applications affected the dry matter accumulation during the filling stage of fragrant rice (*Table 1*). For *Xiangyaxiangzhan*, E2 treatment significantly increased the weight of stem and leaf as well as total aboveground weight when the

DOI: http://dx.doi.org/10.15666/aeer/1702_32933303

specimen had been taken in both heading stage and maturity. Only E1 and E2 treatments improved the biomass accumulation significantly. For *Meixiangzhan2*, E2 remarkably improved grain weight at maturity and the biomass accumulation during the filling stage. All Se applications enhanced the total aboveground weight at maturity.

Yield and its traits

Overall, foliar applications of EDTA-Se at initial heading stage can increase grain yield of *Xiangyaxiangzhan* and *Meixiangzhan2* (*Table 2*). For *Xiangyaxiangzhan*, E1, E2 and E3 had significant higher yield than CK, which were 4.20, 4.33, 4.21 and 4.00 t ha^{-1}, respectively. For *Meixiangzhan2*, there was no remarkable difference among CK, E1, E2 and E3 in panicle number, grain per panicle and filling percentage while both E1 and E3 increasing grain weight significantly and the highest yield was also recorded in E2.

Correlation analysis

As shown in *Table 3*, yield of fragrant rice had significant correlation with grain per panicle, biomass accumulation during filling stage and net photosynthetic rate. There exited a positive correlation between 1000-grain weight and biomass accumulation at

Discussion

Photosynthesis plays an important role in rice growth and yield information (Zhong et al., 2017). Mitchell and Sheehy (2010) had already explained the relationship between photosynthesis and rice yield, this discovery also proposed the view of supercharging rice photosynthesis to increase yield. Our study evidenced the contributions of photosynthesis to fragrant rice yield by showing the significant positive correlation between yield and net photosynthesis rate at filling stage.

Photosynthesis is a complicated phenomenon in plants and is affected by a variety of factors. A previous study already discussed the relationship between the leaf photosynthetic capacity and leaf nitrogen while reviewing the factors which are limiting the photosynthesis under different growth environments (Mae, 1997). Study of Krishna et al. (2016) showed that cytokinin has ability to delay dark-induced senescence in rice by maintaining the chlorophyll cycle and photosynthetic complexes. There were also certain researches about the effects of metallic and non-metallic elements on the crop photosynthesis. The investigation of SultanaIkeda and Itoh (1999) indicated that NaCl salinity decreased the photosynthesis at the reproductive phase by closing the stomatal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_32933303

and reducing transpiration rate, leaf water content and biochemical constituents. For example, Chen et al. (2011) demonstrated that Silicon fertilizer could improve plant water status, photosynthesis and mineral nutrient absorption and alleviate the damage to rice plants caused by drought stress. In our study, we discovered that the net photosynthetic rate of fragrant rice at filling stage was enhanced significantly due to exogenous Se application. It might because the Se treatments increased the chlorophyll contents where absorbing and converting light energy in photosynthesis process. It was also strongly corroborated by the investigation of Wu et al. (2000) which revealed that the electron transfer rate of chloroplast increased with low Se concentration while high concentration of selenium leads to electron transfer rate decreased in chloroplast.

Furthermore, the production of rice photosynthesis is carbohydrate and the biomass accumulation of rice plants mostly depends on the net photosynthetic rate in whole growth period. The sucrose is not only the main form of the production of photosynthesis, but also the major transport form for photosynthetic carbon assimilates. The transport rate directly affected the development of library organs and was one of the important factors limiting the further increase of crop yield (Slewinski et al., 2009). Normally, the accumulation of sucrose in leaves is controlled by synthase and decomposition enzyme related to the activity of key enzymes of sucrose metabolism including SPS, SS and sucrose invertase. SPS catalyzes sucrose synthesis reaction whilst SS had the duality of synthesizing and decomposing sucrose (Baxter et al., 2003; Tobias et al., 2008; Miswar et al., 2008). For example, SS mainly catalyzes sucrose synthesis in leaves; however, in grains it catalyzes sucrose degradation. Present study observed that the dry matter accumulation of aromatic rice during the filling stage was improved because of Se treatments. In this study we considered that was the result of the enhancement of net photosynthetic rate.

Normally, the carbohydrate assimilation is the primary source of rice growth while reserving a complementary source for grain filling in rice (Dingkuhn and Gal, 1996). In this study, we observed that yield had remarkable positive correlation with dry matter weight accumulation during the filling stage. This result agreed with the investigation of Dingkuhn et al. (1990) in which study they demonstrated that about 40 to 45% of panicle dry matter come from measured canopy photosynthesis while 55 to 60% might be the translocation. Another study (Dingkuhn et al., 1990) also revealed that canopy photosynthesis provided 58% and 74% for panicle weight at maturity in direct-seeded and transplanted rice, respectively. Present study evidenced that EDTA-Se treatments improved dry matter accumulation during filling stage. Hence, we discovered that Se could be used to increase it because it could improve photosynthesis and finally increase yield.

Conclusion

As a plant growth regulator, 10–50 μmol L^{-1} EDTA-Se concentration could increase the rice photosynthesis at filling stage and thus improved the dry matter accumulation and grain yield. Furthermore, the EDTA-Se applications enhanced the chlorophyll content and activities of SPS and SS and it might be the reason of Se treatments improving rice photosynthesis. For revealing the mechanism of how EDTA-Se affects rice physiology, much work should be done at molecular and physiological level.

(Received 30th Nov 2018; accepted 4th Feb 2019)

Abstract. Pepper is quite sensitive to water stress, thus changes in irrigation levels may have significant effects on yield, organic acids and phenolics of peppers. Improper irrigation levels may generate a water stress and resultant stress then create serious oxidative damages on cell membranes. Such damages can be prevented with proline-like antioxidative substances. This study was conducted in Çanakkale – Turkey to investigate the effects of different irrigation levels and proline treatments on yields, quality parameters and organic acid composition of pepper *(Capsicum annuum* L. cv. Yalova Yağlık 28*)* in the years of 2013 and 2014. Experiments were conducted in randomized blocks split plots experimental design with 3 replications. Three different irrigation levels were arranged as to apply certain percentages of total evaporation from Class-A pan (Kcp_{50}, Kcp_{100}, Kcp_{150}). Proline treatments (12 mM) were applied at 3 different growth stages (three equal portions on 20, 30 and 40th days, single treatment on 30th day and single treatment on 40th day of growth). In both years of the experiments, decreasing citric acid contents and increasing ascorbic acid contents (in the first year of experiments, Kcp_{50}=84.54, Kcp_{100}=175.48, Kcp_{150}=198.92 mg/100g) were observed with increasing irrigation levels. Different irrigation levels and proline treatments had significant effects on yield (g/m^2), total phenolics (mg/100g), soluble solids content (SSC, %) and internal proline content (µmol/g) of pepper fruits. Adversely affected parameters as yield (g/m^2) and ascorbic acid content due to limited irrigation positively affected with some proline treatments.
Keywords: *Industrial pepper, water stress, ascorbic acid, citric acid, total soluble solids*

Introduction

Besides fresh consumption, capia peppers are also produced for industrial purposes (pepper paste, canned food). They are also called oil-pepper. Since pepper is quite sensitive to water stress, irrigation plays a significant role in pepper production. Pepper roots are quite sensitive to excess water; therefore, sufficient moisture should continuously be available at root zone (Campos et al., 2014; Penella et al., 2014; Vural et al., 2000).

As a cellular adaptation mechanism to water deficits, plants try to preserve proper water potential and cell turgor through accumulation of dissolved osmolites including proline (Bray, 1997). Proline is accumulated as a response to different stress conditions. It is also mentioned as an osmolite and free-radical (reactive oxygen species) scavenger (Reddy et al., 2004; Trovato, 2008).

In previous studies on different irrigation levels (Erken, 2012; Korkmaz et al., 2015), significant increases were reported in proline contents with decreasing irrigation levels. Reactive oxygen species serve as signaling molecules under normal conditions, but they create oxidative damages on stress-exerted cells (Sharma et al., 2012). Proline then

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33053323

emerges as a non-enzymatic antioxidant able to prevent such oxidative damage (Gill and Tuteja, 2010).

Under deficit moisture or water stress conditions, reactive oxygen species generate damages especially on cell membranes where lipids are concentrated. For instance, hydroxyl radicals attack polyunsaturated fatty acids sensitive to peroxidation and initiate lipid peroxidation (Gutteridge, 1995). It was indicated in previous studies that external proline treatments prevented stress-induced negative conditions (Silva Sa et al., 2016; Öztekin, 2009).

Pepper is quite a significant vegetable for our country's economy. Health impacts of antioxidant compounds, ascorbic acid, carotenoids and phenolics of the peppers were pointed out in previous studies (Howard et al., 2000; Marin et al., 2004)

Secondary metabolites are structurally and chemically different from the primary metabolites like sugar, fatty acids, amino acids and nucleic acids. They are not directly needed for basic photosynthesis and respiration metabolisms, but are considered as compounds encountered in specialized cells required for plants to stay alive. Phenolics are the most common secondary metabolites encountered in plants and they play significant roles in various physiological processes in plants (Balasundram et al., 2006; Lattanzio et al., 2006; Nascimento and Fett-Neto, 2010). Several stress factors including high light intensity, low temperature, pathogen infections, mineral deficiency, UV radiation and negative moisture regime may increase the production of free radicals and the other oxidative species. Plant phenolics play important roles as defense compounds against such stressors moreover biotic and abiotic stressors were reported to stimulate the production of secondary metabolites (Chanishvili et al., 2007). Arnnok et al. (2012) reported total phenolics in pericarp section of paprika peppers (*Capsicum annuum* L.) as between 0.782-4.52 g GAE kg^{-1} fresh weight.

Peppers are quite rich in ascorbic acid and several health benefits of ascorbic acid were reported in previous studies (Pereira et al. 2009; Li and Schellhorn, 2007; Siddique, 2006; Carr and Frei, 1999). Citric acid is an organic acid and used in canned foods and other food processing industries to reduce pH levels, heat requirements, to provide sourish taste, to prevent color and flavor losses and tarnishing (Dauthy, 1995). Oxalic acid is a free acid and generally encountered as calcium salt (Çalışkan, 2000). Oxalate quantities greatly vary based on plant family and organs, growing conditions, climate and growth periods. When high oxalate-containing vegetables (spinach: 1959 mg/100g) were consumed, oxalate forms insoluble complexes with divalent cations and results in formation of calcium oxalate stone. As compared to those vegetables, peppers have quite low oxalic acid contents.

Ascorbic acid is an important organic acid and is required mostly to prevent scurvy. There are earlier studies indicating decreasing (Subramanian et al., 2006) or increasing (Nahar and Gretzmacher, 2002) ascorbic acid contents with different irrigation levels. Role of proline was also mentioned in ascorbate glutathione cycle including ascorbic acid (Islam et al., 2009; Aggarwal et al., 2011).

Besides the studies indicating insignificant differences in phenolic quantities with water stress, there are also some other studies indicating increasing proline contents, soluble solids content and total phenolics with water stress treatments. Researchers also reported significant correlations of antioxidant activity with total phenols and ascorbic acid content of peppers (Estiarte et al. 1994; Mohamed et al. 2014; Ghasemnezhad et al., 2011).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33053323

Peppers are known to be sensitive to water stress and proline has protective effects against certain stressors. Therefore, this study was conducted to investigate the effects of different irrigation levels and proline treatments on yield parameters, soluble solids content, total phenolics, proline content and organic acids of peppers.

Materials and methods

This study was conducted at the experimental fields of Research and Implementation Center of Çanakkale Onsekiz Mart University Agricultural Faculty in Turkey from 2013 to 2014 (*Figure 1*). Seedlings of Yalova Yağlık 28 pepper cultivar (Asgen Tarım A.Ş.) *(Capsicum annum* L. cv. Yalova Yağlık 28*)* was used as the plant material of the study which is a preferred cultivar by farmers in region especially for it's speciality as an industrial pepper. Yalova yağlık 28 is a mid-season cultivar growing for industy and fresh consumption and avaliable for field or greenhouse cultivation. It has sweet and industrial type fruits which are large and conic. Average fruit weight is 90 g, fruit colour is dark red and fruit flesh thickness is 4.8 mm and these characters strictly infleunced by irrigation.

Figure 1. *Photos from area of experiment, organic acid, total phenolics and internal proline analyzes*

Three different irrigation levels were used in experiments. For different irrigation levels, pan-coefficients (Kcp) were used (Kcp_{50}, Kcp_{100}, Kcp_{150}). For each pan-coefficient, proline treatments (12 mM) were performed at 3 different growth stages.

Cumulative evaporations from Class-A pan placed at experimental site were measured with a depth gauge and irrigations were performed as to have Kcp_{50}= 50%, Kcp_{100}= 100% and Kcp_{150}= 150% of cumulative evaporation at a single irrigation interval (3-day) through constant-pressure drip lines (4 lt/h) (Yıldırım, 1996; Doorenbos and Pruit, 1992). Calculation of irrigation water quantity to be applied is shown at *Table 1*.

Seedlings were divided into three groups as to cover each pan-coefficient. The first group was subjected to proline treatments three times at 10-day intervals with the first treatment applied 20^{th} day of seedling plantation. The second group was subjected to single proline treatment on 30^{th} day of seedling plantation. The third group had also a single proline treatment on 40^{th} day of seedling plantation.

Proline (Merck KGaA 64271 Darmstadt Germany) treatments were applied at the dose of 12 mM through foliar sprays. In the first group, total dose was separated into 3 equal doses and applied at 3 different periods. In the second and third groups, total dose was applied in a single treatment (Silva Sa et al., 2016). Experiments were conducted in randomized blocks split plots experimental design with 3 replications. Each treatment had 5 plant rows with 7 plants in each row (35 plants for each treatment). Experiments were then composed of 1260 (35*12*3) plants and 36 (12*3) plots. Analyses and measurements were performed on 10 plants randomly selected from 15 plants left after removing 20 plants as to consider side effects. Experimental design was separated into 3 blocks and the first replication of each treatment was placed in every block.

Soil samples were taken from 0-30 cm soil profile and a fertilization program was applied based on soil analysis results (*Table 2*).

Table 2. *Soil analysis results*

	2013		**2014**

Investigated parameters

Yield (g m^{-2})

Fruit weights were measured with a precise balance (± 0.01) (GM2202, Sartorius, Göttingen, Germany) and total yield of each treatment was determined.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33053323

Total Soluble Solids Content (%)

Atago PAL 1 model digital hand refractometer (Pal-1, Atago, Tokyo, Japan) was used to determine soluble solids content (%).

Total Phenolics (mg/100g)

Total phenolics of the samples were determined from 5 g fruit puree in accordance with Folin-Ciocalteu method at 765 nm absorbance value of a Shimadzu UV-VIS spectrophotometer (UV-Vis Spectrophotometer, Shimadzu Corporation, Tokyo-Japan) (mg/100 g). For each sample, 5 g fruit juice was supplemented with 5 ml Methanol. The mixture was centrifuged at 4000 rpm for 10 minutes. Samples were then supplemented with 2,5 ml 10% Folin-Ciocalteu and 2 ml 1 M Na_2CO_3 and this mixture was kept in hot-water bath at 45°C for 15 minutes. Samples were removed from the hot-water bath and readings were performed at 765 nm absorbance value of a spectrophotometer against 10% Folin-Ciocalteu and results were expressed in total gallic acid equivalent (GAE) mg/100 g (Zheng and Wang, 2001).

Internal Proline Content (µmol/g)

For proline contents, 0.5 g fresh leaf samples were finely chopped and homogenized in 10 ml 3% 5-Sulphuric acid for 2 minutes. Resultant homogenate was filtered through Whatman No. 2 filter paper and placed into tubes. About 2 ml of filtrate was supplemented with 2 ml ninhydrine and 2 ml glacial acid in a test tube and put into reaction in a water bath at 100 °C for 1 hour. Then the test tubes were taken into ice-bath and reaction was terminated. Samples were then supplemented with 4 ml toluene and reaction mixture was mixed in a tube-mixer for 15-20 seconds. The chromophore phase was aspired with a thin-probe pipette into spectrophotometer tubes. When reached to room temperature, chromophore-containing toluene tubes were then subjected to absorbance readings in Shimadzu UV-VIS spectrophotometer (UV-Vis Spectrophotometer, Shimadzu Corporation, Tokyo-Japan) at 520 nm. Toluene was used as the control (Bates et al., 1973).

HPLC analysis for organic acids (mg/100g)

The simultaneous determination of oxalic, tartaric, malic, lactic, acetic, citric, succinic acids and ascorbic acids using liquid chromatography was carried out according to (Arnetoli et al., 2008). The chromatography analysis was carried out using a HPLC system (Shimadzu, Japan). The equipments of HPLC system consist of LC-20AD SP pump, SIL- 10AP Auto sampler, SCL-10A vp system controller, SPD-20A Prominence UV detector, CTO-20AC sp column oven and LC solution (version: 1.23 sp1) software. An Inertsil ODS-III C18 column (46x150 ID, 5 µm particle size) was used for the chromatographic separation. The mobile phase was carried out with 125 mM KH2PO4 adjusted to pH 2.5 with o-phosphoric acid. The flow rate of mobile phase was performed as 1 ml/min. The wavelengths of the UV detection were performed at 210 nm for oxalic, tartaric, malic, lactic, acetic, citric, succinic acids, and 254 nm for ascorbic acid.

DOI: http://dx.doi.org/10.15666/aeer/1702_33053323

Statistical analysis

Experimental data were subjected to variance analysis with SAS.9.1.3 software. Significant means were compared with LSD test. Biplot analysis was used for interpretation of organic acids data.

In the first year of the experiments, fruit yield per plant of irrigation treatments were gathered under three groups. Yields increased with increasing irrigation levels (*Table 4*). With regard to effects of proline treatments on fruit yields, treatments were gathered under two groups. Proline treatments yielded similar values, but greater values than the control treatments. With regard to effects of interactions (irrigation x proline) on fruit yields, interactions were gathered under 4 groups. In treatments without proline (1, 5, 9), increasing fruit yields were observed with increasing irrigation levels (Kcp50=397,48, Kcp100=663,67, Kcp150=737,58).

In treatments without proline, similar yield values were observed at the same irrigation levels.

Similar statistical groups were observed in the second year of the experiments and for the mean values of years.

Soluble Solids Content, SSC (%)

In the first year of the experiments, soluble solids content (SSC) of irrigation treatments were gathered under three groups and increasing SSC values were observed with decreasing irrigation levels (*Table 5*). The differences in SSC values of the proline treatments were not found to be significant. With regard to effects of irrigation x proline interactions on SSC values, interactions were gathered under three groups and increasing SSC values were observed with decreasing irrigation levels (Kcp_{50}= 9,4%, Kcp_{100}= 8,1%, Kcp_{150}= 7,8%)..

The differences in SSC values of the treatments with and without proline were not found to be significant at the same irrigation level.

Similar statistical groups were observed in the second year of the experiments and for the mean values of years

Total Phenolics (GAE mg/100g)

In the first year of the experiments, total phenolics of irrigation treatments were gathered under three different groups and decreasing total phenolics were observed with increasing irrigation levels (*Table 6*). Considering the mean values of proline treatments, it was observed that treatments were gathered under two different groups and proline-treated group had greater total phenolics than the untreated group.

With regard to effects of irrigation x proline interactions on total phenolics, interactions were gathered under three different groups and increasing total phenolics were observed with decreasing irrigation levels in treatments without proline (Kcp_{150}=1317,9, Kcp_{100}=1383,1, Kcp_{50}=1447,3 mg GAE/100g). In Kcp_{50} irrigation

DOI: http://dx.doi.org/10.15666/aeer/1702_33053323

treatments, total phenolics had similar values in proline-treated groups (2, 3, 4) and such values were greater than non-proline-treated group (1). In Kcp_{100} irrigation treatments, proline-treated and untreated groups (5, 6, 7, 8) had similar total phenolics. In Kcp_{150} irrigation treatments, a similar case was observed in proline-treated and untreated groups (9, 10, 11, 12). Similar statistical groups were observed in 2014 and for the mean values of the years.

Table 6. *Effects of different irrigation levels and proline treatments on total phenolics (GAE mg/100g) (P- = Treatments without proline, P1= Proline treatments on 20, 30 and 40th days, P2= Proline treatments on 30th day, P3= Proline treatments on 40th day.)*

Internal Proline Content (µmol/g)

In both years and for the average of years, effects of irrigation treatments on internal proline contents were gathered under 3 different groups and increasing internal proline contents were observed with decreasing irrigation levels (*Table 7*). With regard to effects of proline treatments on internal proline contents in the first year of the experiments, treatments were gathered under 4 different groups and proline-treated groups had greater internal proline contents than the untreated groups. In the second year of the experiments, proline treatments gathered under 3 different groups and again proline-treated groups had greater internal proline contents than the untreated groups. In the years 2013 and 2014 and in average of years, the lowest internal proline content in proline treatments was obtained from the treatment with proline treatments on 40^{th} day.

In the first year of the experiments, in non-proline-treated groups (1, 5, 9), the greatest internal proline content (67.37 µmol/g) was obtained from Kcp_{50} irrigation level and the lowest value (13.58 µmol/g) was obtained from Kcp_{150} irrigation level (Yooyongwech et al., 2013). Similarly in proline treatments on 20th day (2, 6, 10), internal proline contents decreased with increasing irrigation levels (Kcp_{50}=96.81 µmol/g, Kcp_{150}=22.52 µmol/g). Decreasing proline contents were observed with increasing irrigation levels also on 30th day proline treatments (3, 7, 11) and 40th day proline treatments (4, 8, 12). In Kcp_{50} irrigation level, proline-treated groups (2,3,4) (Kcp_{50}=96.81 µmol/g, Kcp_{50}=87.81 µmol/g, Kcp_{50}=90.87 µmol/g) had greater values than untreated group (1) (Kcp_{50}=67.37 µmol/g). The proline content of the treatment with proline treatments on 20, 30 and 40th days (2) was significantly greater than the proline content of the other proline treatments at Kcp_{50} irrigation level and it was the greatest value at all. In Kcp_{100} irrigation level, proline-treated groups (6,7,8) (Kcp_{100}=43.31 µmol/g, Kcp_{100}=50.69 µmol/g, Kcp_{100}=42.55 µmol/g) had greater proline contents than the untreated group (5) (Kcp_{100} =33.84 µmol/g). Similarly in Kcp_{150} irrigation level, proline-treated groups (10, 11, 12) (Kcp_{150}=22.52 µmol/g, Kcp_{150}=29.63 µmol/g, Kcp_{150}=21.14 µmol/g) had greater proline contents than the untreated group (9) of the same irrigation level (Kcp_{150}=13.58 µmol/g). In Kcp_{100} and Kcp_{150} irrigation levels, 30th day proline treatments (7, 11) (Kcp_{100}=50.69 µmol/g, Kcp_{150}=29.63 µmol/g) had greater values than the other proline treatments of the same levels (6, 10, 8, 12) (Kcp_{100}= 43.31 µmol/g, Kcp_{150}=22.52 µmol/g, Kcp_{100}=42.55 µmol/g, Kcp_{150}=21.14 µmol/g). Similar statistical groups were observed in the second year of the experiments and for the mean values of years.

Organic Acid Compositions

Effects of different irrigation levels and proline treatments on organic acid composition were assessed through Biplot analysis. Two principle components (PC1 – 1st principle component; PC2 – 2nd principle component) were used to generate biplot graph (*Figure 2*). Organic acid composition values under different irrigation levels and proline treatments in the first year of the experiments (mg/100g) is also shown in *Table 8*.

In the first year of the experiments, PC1 and PC2 scores for 3 organic acids were able to explain 92% of 3 irrigation levels and proline treatment interactions (*Table 8*).

In biplot graph, over the citric acid axis, the Kcp50 irrigation level without proline treatment (1) was the furthest treatment to ascorbic acid axis and such a case indicated that this treatment had quite low ascorbic acid content and high citric acid content. Increasing citric acid contents were reported with drought stress (Sağlam et al., 2010).

Table 8. *Organic acid compositions under different irrigation levels and proline treatments in the first year of the experiments (mg/100g)*

Treatments	Ascorbic Acid	Oxalic Acid	Citric Acid
1	84.54	34.62	486.42
2	171.84	26.30	311.90
3	192.99	27.77	441.20
4	130.43	56.32	260.15
5	175.48	37.83	226.11
6	142.45	28.19	477.73
7	183.92	19.33	380.05
8	191.11	15.21	315.10
9	198.92	20.77	212.79
10	161.55	18.84	274.32
11	185.83	23.27	268.62
12	195.19	24.42	285.22

Considering the treatments without proline (9, 5, 1), at Kcp50 irrigation level, treatment (1) was placed on positive side of oxalic acid axis (PC1>0, PC2>0), negative side of ascorbic acid axis (PC1<0) and on citric acid axis (PC1>0, PC2>0), at Kcp100 and Kcp150 irrigation levels, treatments (5,9) were placed on positive side of ascorbic acid axis and negative side of citric acid axis (PC1<0, PC2<0). Such cases indicated that these treatments (5,9) had greater ascorbic acid and smaller citric and oxalic acid contents than the treatment (1) at Kcp50 irrigation level. As compared to treatment (5) without proline at Kcp100 irrigation level, the treatment (9) without proline at Kcp150 irrigation level was close to ascorbic acid axis and far from citric and oxalic acid axes. Such a case indicated that treatment (9) had greater ascorbic acid and lower oxalic and citric acid contents than the treatment (5).

At Kcp50 irrigation level, 40th day proline treatment (4) was the closest treatment to oxalic acid axis. Such a case indicated that this treatment had the greatest oxalic acid content.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33053323

At Kcp50 irrigation level, the proline treatments on 20, 30 and 40th days (2) was placed on graph origin (*Figure 1*). Such a case indicated that this treatment had quite less variations in all three organic acids than the other treatments. The treatment (1) without proline at Kcp50 irrigation level, treatment (4) with proline treatments on 40th day at Kcp50 irrigation level and treatment (6) with proline treatments on 20, 30 and 40th days at Kcp100 irrigation level were placed further from the ascorbic acid axis as compared to the other treatments. Such a case indicated that these treatments (1, 4, 6) had lower ascorbic acid contents than the other treatments.

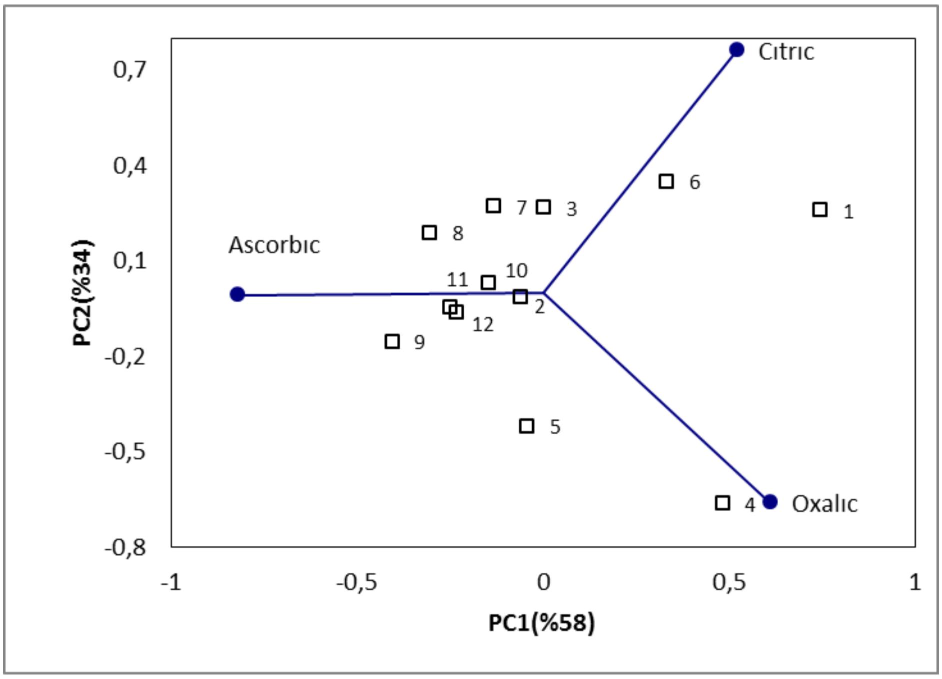

Figure 2. *Biplot for the effects of different irrigation levels and proline treatments on organic acid compositions in the first year of the experiments*

In the second year of the experiments, PC1 and PC2 scores for 3 organic acids were able to explain 94% of 3 irrigation levels and proline treatment interactions (*Figure 3*). Organic acid composition values under different irrigation levels and proline treatments in the second year of the experiments (mg/100g) is also shown in *Table 9*.

Considering the treatments without proline (9,5,1), Kcp_{50} irrigation level (1) was further placed to ascorbic acid axis and closer to citric and oxalic acid axes than the Kcp_{100} and Kcp_{150} irrigation levels (5,9) and Kcp_{150} irrigation level (9) was placed on negative side of citric acid axis (PC1<0, PC2<0). The closest location of Kcp_{150} irrigation level with proline treatments on 40th day (12) to ascorbic acid axis indicated that this treatment had the greatest ascorbic acid content. Again, the closest location of Kcp_{50} irrigation level with proline treatments on 40th day (4) to oxalic acid axis indicated that this treatment had the greatest oxalic acid content.

The Kcp_{100} with proline on 20th day (6), Kcp_{100} with proline on 40th day (8), Kcp_{150} (9), Kcp_{150} with proline on 20th day (10) and Kcp_{150} with proline on 30th day (11) were placed on the negative side of citric acid axis. Such cases indicated that these treatments had lower citric acid contents. The Kcp_{50} with proline on 20th day (2), Kcp_{50} with proline on 30th day (3) and Kcp_{100} with proline on 30th day (7) were placed on positive

DOI: http://dx.doi.org/10.15666/aeer/1702_33053323

side of citric acid axis and such cases indicated that these treatments had greater citric acid contents.

12	273.92	15.78	316.81

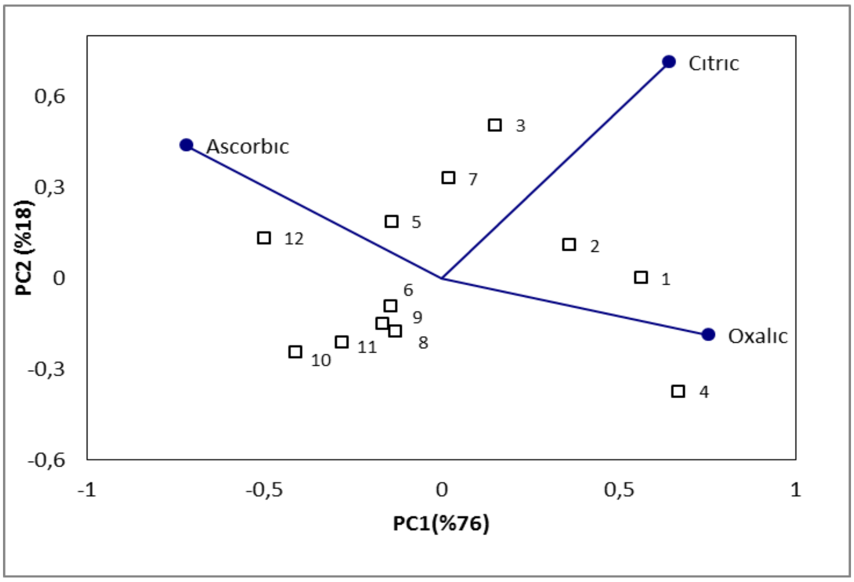

Figure 3. *Biplot for the effects of different irrigation levels and proline treatments on organic acid compositions in the second year of the experiments*

Discussion

Present findings revealed that the increase in yield achieved with increasing irrigation levels from Kcp50 to Kcp100 was greater than the increase achieved with increasing irrigation levels from Kcp100 to Kcp150. Decreasing yields were also reported in pepper, tomato and eggplant with water deficits (Kırnak et al., 2016;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33053323

Mitchell et al., 1991; Kırnak et al., 2001). As approached to maximum yield, water use efficiencies decreased and such a case may be related to prevailing climate conditions. Excessive water uses in irrigation is considered as the primary reason of water deficits, thus it was thought that water-yield relations would play significant roles in future water deficits. At Kcp50 irrigation level, an increase was observed in yields with proline treatments, but yields of proline-treated and untreated groups were similar at the other irrigation levels. Such findings indicated that proline treatments were more effective in deficit irrigation conditions.

Farzana (2014) carried out a study with wheat cultivars (BARI Gom-24, BARI Gom-26) and reported increasing yields with proline treatments under water deficit, but reported insignificant differences in yields of BARI Gm-24 cultivar with proline treatments under non-water deficit conditions and increasing values in some parameters of BARI Gom-26 cultivar with proline treatments. Increasing yields were reported in tomatoes with proline treatments under salt stress (Öztekin, 2009).

Soluble solids contents (SSC) increased with decreasing irrigation levels, but did not changed significantly with proline treatments. Generally, high SSC values are desired in industrial-type peppers. Either unchanged or increasing SSC values were reported in peppers and tomatoes with drought stress (Shao et al., 2014; Mitchell et al., 1991; Dağdelen et al., 2004). Dorji et al. (2005) applied deficit irrigation and relative root zone dry out treatments to chili pepper (Ancho St. Luis) and reported 21% increase in SSC values in green and red periods with deficit irrigation. Soluble solids content of tomatoes increased, decreased or remained unchanged with proline treatments under salt stress (Öztekin, 2009). Similar statistical groups were observed in 2014 and for the average of the years. The lowest SSC value (7,3%) obtained from Yalova Yağlık-28 pepper cultivar was greater than the minimum values specified for red peppers (6-6,5%) (Tadesse et al., 2002) and such a case indicated that SSC values of this pepper cultivar will not pose any problems for the producers.

Proline is a non-enzymatic antioxidant (Hossain et al., 2014) and accumulation of proline-like osmatic regulators in cells reduces drought-induced damages in plants (Rontein et al., 2002). Significant correlations were reported between antioxidant capacity and total phenolics of the plants (Li et al., 2008). Anti-radical and antioxidant effects of phenolic acids were also reported (Sroka and Cisowski, 2003) and different free radical-scavenging effects of different phenolics were indicated in previous studies (Aboul-Enein et al., 2007). Nunez Ramirez et al. (2011) investigated the effects of different nitrogen doses (32, 80, 160, 320 kg N ha^{-1}) on Habanero chili pepper (*Capsicum chinense jacq.*) plants and reported increasing TETA values, but unchanged antioxidant activity and total phenols with increasing nitrogen doses. About 86% increase was reported in total phenolics of sugar beet with water stress (Stagnari et al., 2014).

Internal proline contents increased with decreasing irrigation levels. Such a case indicated a correlation between proline treatments and adaptation to stress conditions. Proline treatments at Kcp50 irrigation level contributed plant adaptation to water stress. Besides proline contents, phenolics playing great roles in prevention of various diseases and contributing fruit color and taste parameters also increased with decreasing irrigation levels.

Ascorbic acid contents increased and oxalic acid contents decreased with increasing irrigation levels. Fluctuations were observed in ascorbic acid contents with proline treatments. In both years of the experiments, the Kcp50 irrigation with proline

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33053323

treatments on 20, 30, 40th days and on 30th day (2, 3) had greater ascorbic acid contents than Kcp50 irrigation without proline treatments (1). Such a case indicated positive effects of proline treatments on ascorbic acid contents at this irrigation level. Such an increase in ascorbic acid contents with proline treatments was attributed to increasing enzyme activities in ascorbate glutathione cycle (Islam et al., 2009). Decreasing ascorbate contents were reported in tomatoes with drought stress (Ünyayar et al., 2005) and increasing ascorbic acid contents were reported in wheat (Chakraborty and Pradhan, 2012) and tomatoes (Shao et al., 2014) again with drought stress. In a study carried out with soybean, ascorbic acid contents started to increase from the second day of water deficit and started to decrease after the 8th day of water deficit (Angra et al., 2010).

In another study on tomatoes, ascorbic acid contents were similar in normal and slight drought treatments, but greater in moderate and severe drought treatments (Subramanian et al., 2006). However, it was observed in this study that increasing ascorbic acid contents were also related to water deficit conditions, treatment periods and doses. Such cases indicated in general that citric and oxalic acid contents decreased and ascorbic acid contents increased with increasing irrigation levels. Timpa et al. (1986) indicated that 2-3 times increase in citric acid under drought stress pointed out osmatic regulation. Emam et al. (2014) reported increasing oxalic acid contents in paddy with drought stress treatments. Moreover, decreasing ascorbic acid content (Osuagwu & Edeoga 2012, Subramanian et al. 2006) and increasing oxalic acid contents (Emam et al. 2014) were reported with water stress.

In treatments without proline, ascorbic acid content at the lowest irrigation level (Kcp50) was lower than the ascorbic acid contents of the other irrigation levels. Such a case indicated that irrigation quantities below certain levels reduced ascorbic acid quantities, which is a significant quality parameter with various positive impacts on human health. Citric acid contents increased in both years with decreasing irrigation levels. Fluctuations were observed in citric acid contents with proline treatments.

Conclusions and recommendations

In this study, which investigated the effect of proline applications on pepper cultivated with different irrigation levels, the yield was increased with increasing the amount of water. In addition, many quality parameters have also increased. In addition, proline applications had a positive effect on these parameters at the irrigation level with the least amount of water applied, but the effect of proline was found to be decreased at higher irrigation levels. As the irrigation level increased, ascorbic and citric acid values increased and oxalic acid values decreased. It has been determined that proline applications generally have a positive effect on increasing the ascorbic acid value in the subjects where irrigation level is decreased. It can be thought that proline may be effective in improving yield and some other yield and quality parameters, especially in regions with limited irrigation opportunities. High citric acid content is considered as an advantage for the peppers used in canned food industry. Citric acid contents increased with decreasing irrigation levels, thus it was concluded that lower irrigation levels (Kcp50) may be recommended for pepper fruits more available for canned food production. However, more detailed studies on this subject will also help especially the producers producing pepper processed in industry. For this purpose, it will be useful to perform studies in different cultivars.

ANALYSIS OF HYDROLOGICAL DROUGHT TRENDS IN THE GAP REGION (SOUTHEASTERN TURKEY) BY MANN-KENDALL TEST AND INNOVATIVE ŞEN METHOD

YILMAZ, B.

Manisa Vocational School of Technical Sciences, Manisa Celal Bayar University
Sehit Prof. Dr. Ilhan Varank Campus, 45140 Yunusemre, Manisa, Turkey
(e-mail: baris.yilmaz@cbu.edu.tr)

(Received 10th Dec 2018; accepted 14th Feb 2019)

Abstract. The analysis of drought trends plays a significant role in the efficient water resource management, especially in arid and semi-arid regions. Assessing the drought trends by drought indices, of which the Standardized Precipitation Index (SPI) is the most popular, is a reasonable way, because the drought indices measure the climatic anomalies through their severity, duration and frequency. In this study, the possible hydrological drought trends in the GAP region (Southeastern Turkey) were investigated by the use of 12- and 24-month SPI series. The SPI series were determined by 48-year-long (1970-2017) monthly precipitation data monitored at nine selected stations (Mardin, Adıyaman, Batman, Diyarbakır, Siirt, Şırnak, Gaziantep, Kilis and Şanlıurfa) in the GAP region. In the analyses, a recent graphical trend detection method entitled Innovative Şen Metod (ISM) and Mann-Kendall trend test (MK) were used. The ISM has non-parametric basis without any restrictive assumption, moreover, its application is rather simple when compared with the other trend identification methods. The ability to identify the trends of low, medium and high values of a series is the innovative side of the ISM. Since the significance test is a crucial factor to identify the possible trends scientifically, the results were statistical tested at the 0.05 significance level in the methods. The ISM and MK test both revealed that, Mardin is the most vulnerable province in the region, due to the significant decreasing trend, which determined by 12-month and 24-month SPI values. Şanlıurfa, Kilis, Siirt, Diyarbakır and Batman are second order drone prone provinces. In accordance with the results of the ISM, there is an increasing trend in normal and wet conditions in Gaziantep, Şırnak and Adıyaman. Specifically, the results highlight that the central of the GAP region has a tendency toward the heavier droughts in the future. It is also concluded that the ISM is a valuable tool with its simplicity as well as the inherent properties to deduce qualitative information.

Introduction

In recent decades, managing the water resources has become a major concern due to the impacts of climate change, which is generally characterized by increasing air temperatures and the variations in occurrence frequency and magnitude of the precipitation. Since the changing hydrological system components are not distributed uniformly, the distribution of hazardous events such as floods and droughts also varies around the world. Among these natural disasters, droughts play a more significant role due to its inherent direct effects on socio-economic development and environmental degradation. Therefore, understanding drought phenomena is paramount for the appropriate planning and management of water resources (Yevjevich et al., 1983). However, drought is a complicated phenomenon and is among the least understood natural hazards due to its multiple causing mechanisms or contributing factors operating at different temporal and spatial scales (Kiem et al., 2016).

The general approach to quantify the droughts is using indices. World Meteorological Organization (WMO) and Global Water Partnership (GWP) has given a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33253342

wide and detailed literature and findings of drought indices for researchers in the domains of meteorology, hydrology, agricultural research and application, remote sensing, and water resources management (WMO and GWP, 2016). Using the drought indices, several researchers have analysed drought events in several parts of the world. Among the large, and still increasing number of researches, the most recent ones were Jang (2018), Buttafuoco et al. (2018), Tigkas et al. (2018), and Zhang et al. (2018).

Undoubtedly, the most well-known drought index, the Standardized Precipitation Index (SPI), suggested by McKee et al. (1993), is the most popular among the existing indices for the estimation of drought severity. One of the main advantages of SPI is that it use only precipitation data with easy calculation steps as well as flexible time scales (e.g. 1, 3, 6, 12, 24 months). Hayes et al. (2011) concluded none of the indices has the universal applicability of the SPI, and WMO has recommended the SPI as the main meteorological drought index that countries should use to monitor and follow drought conditions. It has been extensively applied in different countries (Saada and Abu-Romman, 2017; Logan et al., 2010; Manatsa et al., 2010; Patel and Yadav, 2015; Raziei et al., 2009; Zhai and Feng, 2009).

On the other hand, investigations on variations of the drought characteristics are particularly important in identifying and understanding the impacts of climate change on the hydrologic cycle. To this end, the SPI trend analyses, which provide scientific information for better modeling, prediction, and control mechanism of the phenomenon concerned, are the essential efforts (Golian et al., 2015; Zhai et al., 2010; Caloiero, 2018).

There has been a wide range of researches subject to trend analyses on hydro-climate data in the literature (Fathian et al., 2014; Addisu et al., 2015; Chattopadhyay and Edwards, 2016; Bacanli, 2017; Onyutha, 2015; Zhao et al., 2015); however, they principally base on nonparametric tests, as the Mann–Kendall (MK) analysis (Mann, 1945; Kendall, 1975), the Spearman's rho (Yue et al., 2002) and the Sen trend slope calculation methodology (Sen, 1968). As Mohorji et al. (2017) concluded these objective approaches necessitate a set of assumption validity in the historical records (e.g. independent serial correlation structure, probability distribution functions, seasonality) and did not specify if low or high precipitation contributed to the detected trends (Caloiero et al., 2018). However, almost all the hydro-climate records have significant serial correlations at least on short memory basis, and efficient, effective, and optimum management of water resources requires identification of trends not only monotonically over a given time period but also whether the low, medium, and high values have separate trends (Şen, 2012, 2017). For this reason, Şen (2012) proposed the Innovative Şen Metod (ISM), which has found wide application in hydrology researches (Haktanir and Çitakoglu, 2014; Öztopal and Şen, 2017; Sonali and Kumar, 2013; Dabanli et al., 2016; Mishra and Coulibaly, 2014; Timbadiya et al., 2013). The ISM does not require any assumptions, and it base on the comparison of the two ascendingly ordered halves from the original time series.

The Southeastern Anatolia Project (in Turkish the GAP) is one of the most ambitious regional development projects in Turkey encompassing not only hydropower and irrigation infrastructure development, but also all related sectors including industry, transportation, rural and urban infrastructure, environmental protection and social sectors (Kankal et al., 2016). Therefore, an integrated approach that especially focuses on water resources is essential to achieve the planned objectives. In the GAP region, assessment of climate change impacts (e.g. floods and droughts) on water resources

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33253342

plays a crucial role, and climate change models has vital importance on achieving the project targets. To this end, trend analyses, which provide scientific information for better modeling, better prediction and better control mechanism of the phenomenon concerned, are the essential efforts.

This study aims to identify the drought-prone areas in the GAP region through the use of the SPI time series obtained for different timescales and by the Innovative Şen Metod (ISM) that allows the trend identification of the low, medium, and high values. First, the SPI values obtained at various time scales (12 and 24 months) based on 48-year-long (1970-2017) precipitation data at nine selected stations (Mardin, Adıyaman, Batman, Diyarbakır, Siirt, Şırnak, Gaziantep, Kilis and Şanlıurfa) in the GAP region and then the SPI series were investigated by using the ISM and the results were compared with MK test results.

Study area and data

The Southeastern Anatolia Project region, in Turkish GAP region, spreads along 75 10^3 km^2 (9.6% of Turkey's surface area, 780.6 10^3 km^2) and includes nine provinces of Mardin, Adıyaman, Batman, Diyarbakır, Siirt, Şırnak, Gaziantep, Kilis and Şanlıurfa (*Fig. 1*). The Euphrates and Tigris Rivers, located in the GAP, have the largest flow volume of 16.9% and 11.4% of Turkey's average annually runoff (186 10^9 m^3), respectively (Altinbilek and Tortajada, 2012; Kankal et al., 2016). In general, the summer season in the region is very hot and under the influence of dry and warm tropical air mass while the winter is warm and rainy. The mean annual temperature is about 18 °C, due to the high summer temperatures that approach 40 °C in daytime (Yilmaz, 2018).

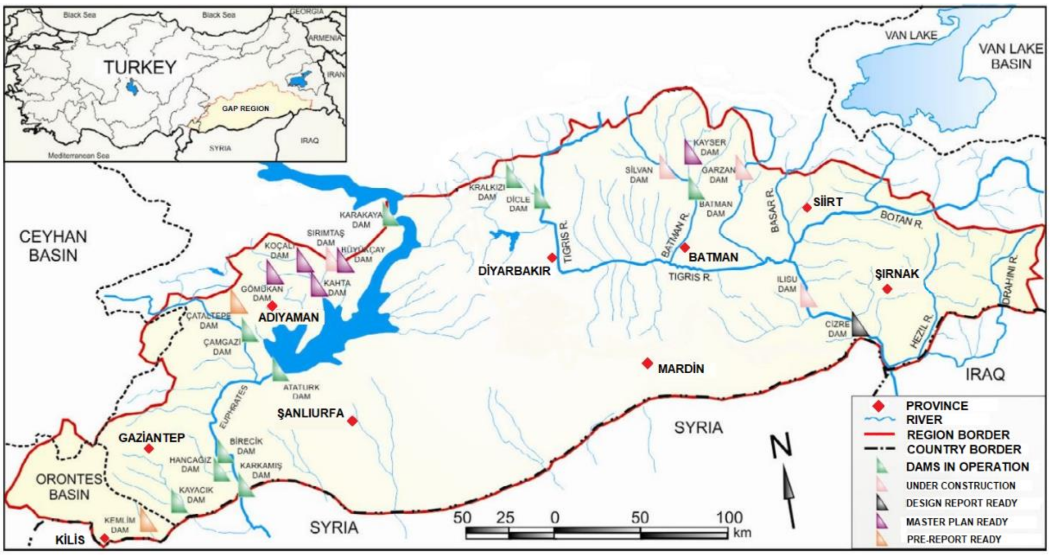

Figure 1. *Water structures and provinces in the GAP region (Kankal et al., 2016)*

The GAP region constitute approximately 10.7% of Turkey's total population (80.8 million, in 2018), and it is estimated that approximately 20% of total irrigable land and 28% of the country's energy potential are in this region (GAP, 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33253342

An irrigable area of 18 10^3 km^2 is planned to be irrigated in the GAP region, and at the first stage, economically irrigable area of 10.6 10^3 km^2 is foreseen to be completed. The progress of the dams and hydroelectric power plants in the GAP region is presented in *Figure 1* according to the project level. In the fertile lands, the agriculture is the main activity, and almost 25% of the economically active population was engaged in agriculture in 2017 (GAP, 2018). That is why the droughts have vital importance on socio-economic development in the region.

For a more detailed description of the GAP, interested readers can refer to the website published by Southeastern Anatolia Project Regional Development Administration (GAP, 2018).

In this study, the monthly precipitation data of the GAP provinces for the period 1970-2017 were obtained from the General Directorate of Meteorological Services of Ministry of Forestry and Water Affairs, Turkey. *Table 1* shows the geographical co-ordinates, elevations and the average annual precipitation of the meteorological stations. The monthly averages of precipitation during the study period (1970-2017) and the seasonal distribution of annual precipitation are presented in *Table 2*. In the GAP region, the annual precipitation ranges from 431 mm to 697 mm, and approximately 80% of the annual total is recorded in winter and spring seasons. Since the summer season is almost dry in the region, the irrigation is a key factor for the agriculture.

Methodology

Standardized precipitation index (SPI)

The SPI quantifies the precipitation deficit and surplus, taking into account the time series (at least 30 years long) of cumulative precipitation for various reference periods (e.g. 6, 12, and 24 months). First, an appropriate probability density distribution is fitted to the frequency distribution of cumulated precipitation and then it is subsequently converted to a standard normal distribution (Tarawneh et al., 2009). In particular, the gamma distribution (two parametric) which generally fits better to the precipitation data is used in the analyses (Ganguli and Reddy, 2014; Zhang et al., 2015). In addition, Guttman (1999) and Angelidis et al. (2012) showed that there are only minor differences between the other distributions (e.g. normal, log-normal) with respect to the results.

Table 1. *The meteorological stations used in the study*

Stations	Station ID	Latitude (N)	Longitude (E)	Elevation (m)
Mardin	17275	37.3103	40.7284	1040

For a given time series of precipitation, the probability density function is defined as (*Eqs. 1-2*):

$$g(x) = \frac{1}{\beta^{\alpha}\tau(\alpha)} x^{\alpha-1} e^{-x/\beta} \quad \text{(Eq.1)}$$

$$\tau(\alpha) = \int_0^{\infty} y^{\alpha-1} e^{-y}\, dy \quad \text{(Eq.2)}$$

where $\alpha > 0$ is a shape parameter, $\beta > 0$ is a scale parameter, $x > 0$ is the amount of precipitation, and $\tau(\alpha)$ is the gamma function. Fitting the distribution to the data requires the estimation of shape (α) and scale (β) parameters, and using the approximation of Thom (1958), these parameters are estimated as (*Eq. 3*):

$$\alpha = \frac{1}{4A}\left(1 + \sqrt{1 + \frac{4A}{3}}\right) \quad \beta = \frac{\bar{x}}{\alpha} \quad A = \ln(\bar{x}) - \frac{\sum \ln(x)}{n} \quad \text{(Eq.3)}$$

where n is the number of observations. Integrating the probability density function with respect to *x* yields the following expression G(x) for the cumulative probability (*Eq. 4*):

$$G(x) = \int_0^{x} g(x)\, dx = \frac{1}{\beta^{\alpha}\tau(\alpha)} \int_0^{x} x^{\alpha-1} e^{-x/\beta}\, dx \quad \text{(Eq.4)}$$

Substituting $t = x/\beta$, *Equation 4* is reduced to (*Eq. 5*):

$$G(x) = \frac{1}{\tau(a)} \int_0^{x} t^{a-1} e^{-1} dt \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33253342

Since the gamma distribution is undefined for x = 0, in order to account for zero values that occur in a sample set, the cumulative probability function for gamma distribution is modified as (*Eq. 6*):

$$H(x) = q + (1 - q)G(x) \quad \text{(Eq.6)}$$

where q is the probability of zero precipitation.

Finally, the cumulative probability distribution is changed into the standard normal distribution to yield the SPI. Following the approximate conversion provided by Abramowitz and Stegun (1965), it results (*Eqs. 7-8*):

$$z = SPI = -\left(t - \frac{c_0 + c_1 t + c_2 t^2}{1 + d_1 t + d_2 t + d_3 t^3}\right) \quad t = \sqrt{ln\left(\frac{1}{(H(x))^2}\right)} \quad \text{for } 0 < H(x) \leq 0.5 \quad \text{(Eq.7)}$$

$$z = SPI = +\left(t - \frac{c_0 + c_1 t + c_2 t^2}{1 + d_1 t + d_2 t + d_3 t^3}\right) \quad t = \sqrt{ln\left(\frac{1}{(1 - H(x))^2}\right)} \quad \text{for } 0.5 < H(x) \leq 1.0 \quad \text{(Eq.8)}$$

where the mathematical constants are: c_0 = 2.515517, c_1 = 0.802853, c_2 = 0.010328, d_1 = 1.432788, d_2 = 0.189269, d_3 = 0.001308.

The average of SPI values is 0, and the standard deviation is 1. For the studied area and studied period, one can identify the wet and dry conditions in accordance with the classification scale of SPI (*Table 3*).

Table 3. *Classifications scale for SPI values (Lloyd-Hughes and Saunders, 2002)*

SPI value	Category	Probability (%)
SPI ≥ 2.00	Extremely wet	2.3
1.50≤SPI≤1.99	Severely wet	4.4
1.00≤SPI≤1.49	Moderately wet	9.2
0.00≤SPI≤0.99	Mildly wet	34.1
-0.99≤SPI≤0.00	Mild drought	34.1
-1.49≤SPI≤-1.00	Moderately drought	9.2
-1.99≤SPI≤-1.50	Severe drought	4.4
SPI≤-2.00	Extreme drought	2.3

The SPI has the ability to reflect the impact of drought on the water resources. However, streamflow, groundwater and reservoir storage reflect the longer-term precipitation anomalies, while soil moisture conditions respond to precipitation anomalies on a relatively short scale (Tsakiris and Vangelis, 2004). In a general classification, it is possible to use the 1 to 3-month SPI for meteorological drought, 3 to 6-month SPI for agricultural drought and 12 to 24-month SPI for hydrological drought analyses and applications (Bonaccorso et al., 2003).

In this study, the SPI values at different time scales (12 and 24 months) were computed by the use of the raw precipitation data, and the software entitled SPI_SL_6.exe which could be download from the link given in the WMO (2012), is used in the calculation process.

Mann-Kendall trend test

The non-parametric MK test (Mann, 1945; Kendall, 1975) is the most widely applied method to detect the trends in a time series. This test is based on the statistic *S* (*Eq. 9*):

$$S=\sum_{k=1}^{n-1}\sum_{j=k+1}^{n} sgn(X_j-X_k) \quad sgn(\Phi)=\begin{cases}+1 \ if \ \Phi=X_j-X_k>0 \\ 0 \ if \ \Phi=X_j-X_k=0 \\ -1 \ if \ \Phi=X_j-X_k<0\end{cases} \tag{Eq.9)}$$

where *n* is the number of data, *x* is the data point at times *j* and *k* (*j*>*k*) and *sgn(Φ)* is the sign function. In cases where the sample size $n \geq 10$, the mean of *S* and variance are given by (*Eq. 10-11*):

$$E[S]=0 \tag{Eq.10}$$

$$var(S)=\frac{[n(n-1)(2n+5)-\sum_{i=1}^{m} t_i(i-1)(2i+5)]}{18} \tag{Eq.11}$$

where *m* is the number of tied groups and t_i indicates the number of data in the i_{th} tied group. The statistic *S* is approximately normal distributed provided that the following standardized test statistics *Z* as follows (*Eq. 12*):

$$Z=\begin{cases}\frac{S-1}{\sqrt{var(S)}} & S>0 \\ 0 & S=0 \\ \frac{S+1}{\sqrt{var(S)}} & S<0\end{cases} \tag{Eq.12}$$

The positive (negative) value of *Z* shows the upward (downward) trend. In this study, trends were tested with a significance level of $\alpha = 0.05$. The null hypothesis of no trend is rejected if the absolute value of *Z* is greater than 1.96, the critical Z values at 95% two-tailed confidence intervals.

Innovative Şen method (ISM)

In the ISM, proposed by Şen (2012), the time series is divided into two equal parts, which are separately sorted in ascending order. Then, the first and the second half of the time series are located on the *x-axis* and on the *y-axis*, respectively, of a Cartesian coordinate system. If the data are collected on the 1:1 straight line (45°), there is no trend in the time series (*Fig. 2*). If data are located on the upper triangular area of the ideal line, an increasing trend in the time series exists. If data pile up in the lower (upper) triangular area of the 1:1 line, there is a decreasing (increasing) trend in the time series.

It is also possible to have time series in which there are scatter of points on both sides of 1:1 line. These cases correspond to non-monotonic trends where within the same time series there are increasing and decreasing trends at different scales even hidden ones. All possible trend types are given in (*Fig. 2*). Moreover, low, medium and high values of a parameter can be evaluated graphically with this method (Dabanlı et al., 2016; Öztopal and Şen, 2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33253342

The statistical significance test of the method has also proposed by Şen (2017), in which a meticulous description could be find. In short, the test is based on the construction of confidence intervals by taking into consideration the difference between two population means. Steps of this method are given by *Equations 13-18.*

In the equations, the notations imply as below, where, $\bar{y}_1$ and $\bar{y}_2$: arithmetic averages of the first and the second halves of the data, ρ: correlation between the first and the second halves of the data, $E(s)$: expectation of the slope (*Eq. 13*), n: number of data, σ: standard deviation of all data, σ_s: slope standard deviation (*Eq. 14*), and s_{cri}: Z critical values in one-way hypothesis at 95% ($\alpha = 0.05$) confidence level ($s_{cri} = \pm 1{,}645$).

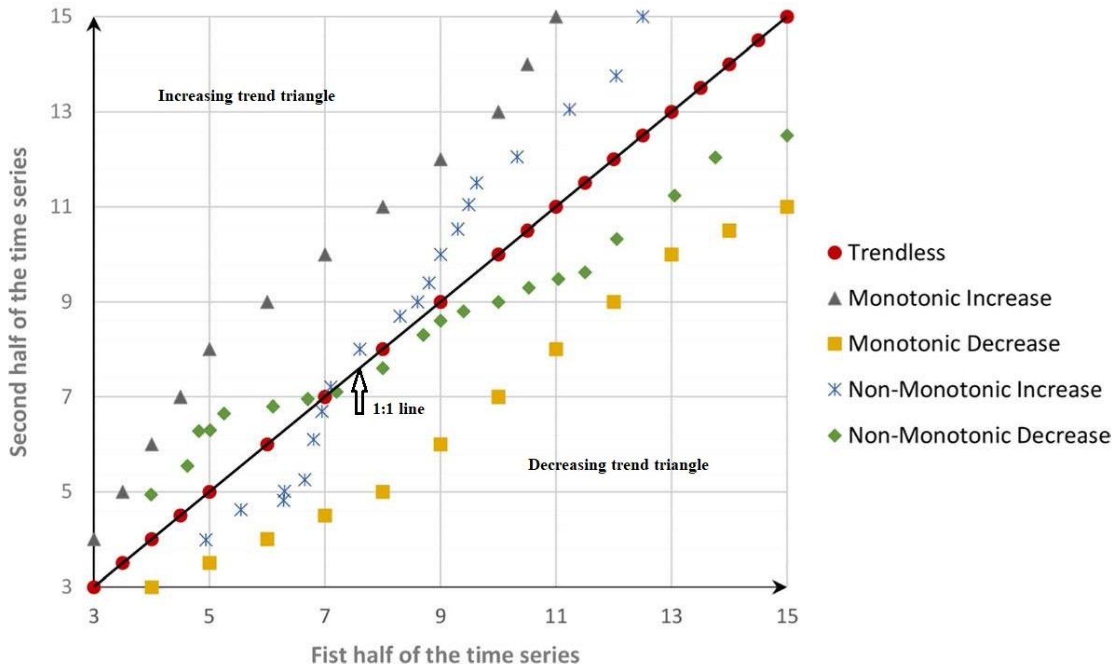

Figure 2. *Illustration of trend types in the ISM (Dabanlı et al., 2016)*

Critical upper and lower limits calculated by *Equation 18* are used to make for hypothesis test. If slope value, s, is outside of the lower and upper confidence limits, thus, the alternative hypothesis, (H_a – *Yes trend*), is approved, otherwise the null hypothesis, (H_0 – *No trend*) is accepted. The type of trend depend in accordance with the slope (s) sign. Slope value (s) can be positive or negative. This means that there is an increasing (+) or a decreasing (-) trend in time series (Şen, 2017; Ay and Özyıldırım, 2017).

$$E(s) = \frac{2}{n}[E(\bar{y}_2) - E(\bar{y}_1)] \quad \text{(Eq.13)}$$

$$\sigma_s^2 = \frac{4}{n^2}[E(\bar{y}_2{}^2) - 2E(\bar{y}_2\bar{y}_1) + E(\bar{y}_1)] \quad \text{(Eq.14)}$$

$$\rho_{\overline{y_2 y_1}} = \frac{E(\bar{y}_2\bar{y}_1) - E(\bar{y}_2)\,E(\bar{y}_1)}{\sigma_{(\bar{y}_2)}\,\sigma_{(\bar{y}_1)}} \quad \text{(Eq.15)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33253342

$$\sigma_s^2 = \frac{8}{n^2}\,\frac{\sigma^2}{n}\left(1 - \rho_{\overline{y_2 y_1}}\right) \qquad \text{(Eq.16)}$$

$$\sigma_s^2 = \frac{2\sqrt{2}}{n\sqrt{n}}\,\sigma\,\left(1 - \rho_{\overline{y_2 y_1}}\right) \qquad \text{(Eq.17)}$$

$$CL_{(1-\alpha)} = 0 \pm s_{cri}\,\sigma_s \qquad \text{(Eq.18)}$$

Results and discussion

In this study, with the aim to detect possible hydrological drought trend in the GAP region, the ISM method was applied to the 12 and 24-month SPI series. All the SPI series were divided into two 24-year sub-series: from 1970 to 1993, and from 1994 to 2017. In order to easily and better identify the possible trend of the dry, normal and wet conditions, two vertical bands have been added in *Figures 3* and *4,* where a red band corresponding to the drought limit (SPI = ≤ -1.0) and a green band corresponding to the wet conditions limit (SPI = ≥ 1.0). The area between the two bands represents the normal conditions. In the figures, 1:1 line indicates neutral (no trend) line and in the case of no trend the centroid point falls on the 1:1, and therefore, $E(s) = 0$. Any deviation from 1:1 line indicates existence of a trend in the given variable (Şen, 2017). The arithmetic averages of the two halves appear as the centroid that falls on the trend line (red dashed line), where the vertical difference between the trend line and 1:1 line is related to the slope (s) of the existing trend in the variable. The vertical distance is equal to the difference between the arithmetic means of the two halves, given as the centroid. It is obvious that in the case of increasing (decreasing) monotonic trend, the trend line falls above (below) the 1:1 line.

Assessment of the 12-month drought trends

The results of the ISM obtained by the use of 12-month SPI values was given in *Figure 3*, and the main findings are summarized below. In *Table 4*, all the necessary calculations of the ISM and the Mann-Kendall significance test results are presented.

In Mardin, there has been a decreasing trend in all SPI values, which lead to heavier droughts and weaker wet periods (*Fig. 3a*). It is also possible to conclude that the droughts follow a monotonic decreasing trend, and the decrement is more evident for the wet periods.

In *Figure 3b*, a slight increasing trend is significant in accordance with the ISM results. In particular, there is an increasing trend in lowest values of SPI and that demonstrates Adıyaman experienced less extreme droughts in 1994-2017 period than the 1970-1993 period. A mild increase in wet conditions is also striking.

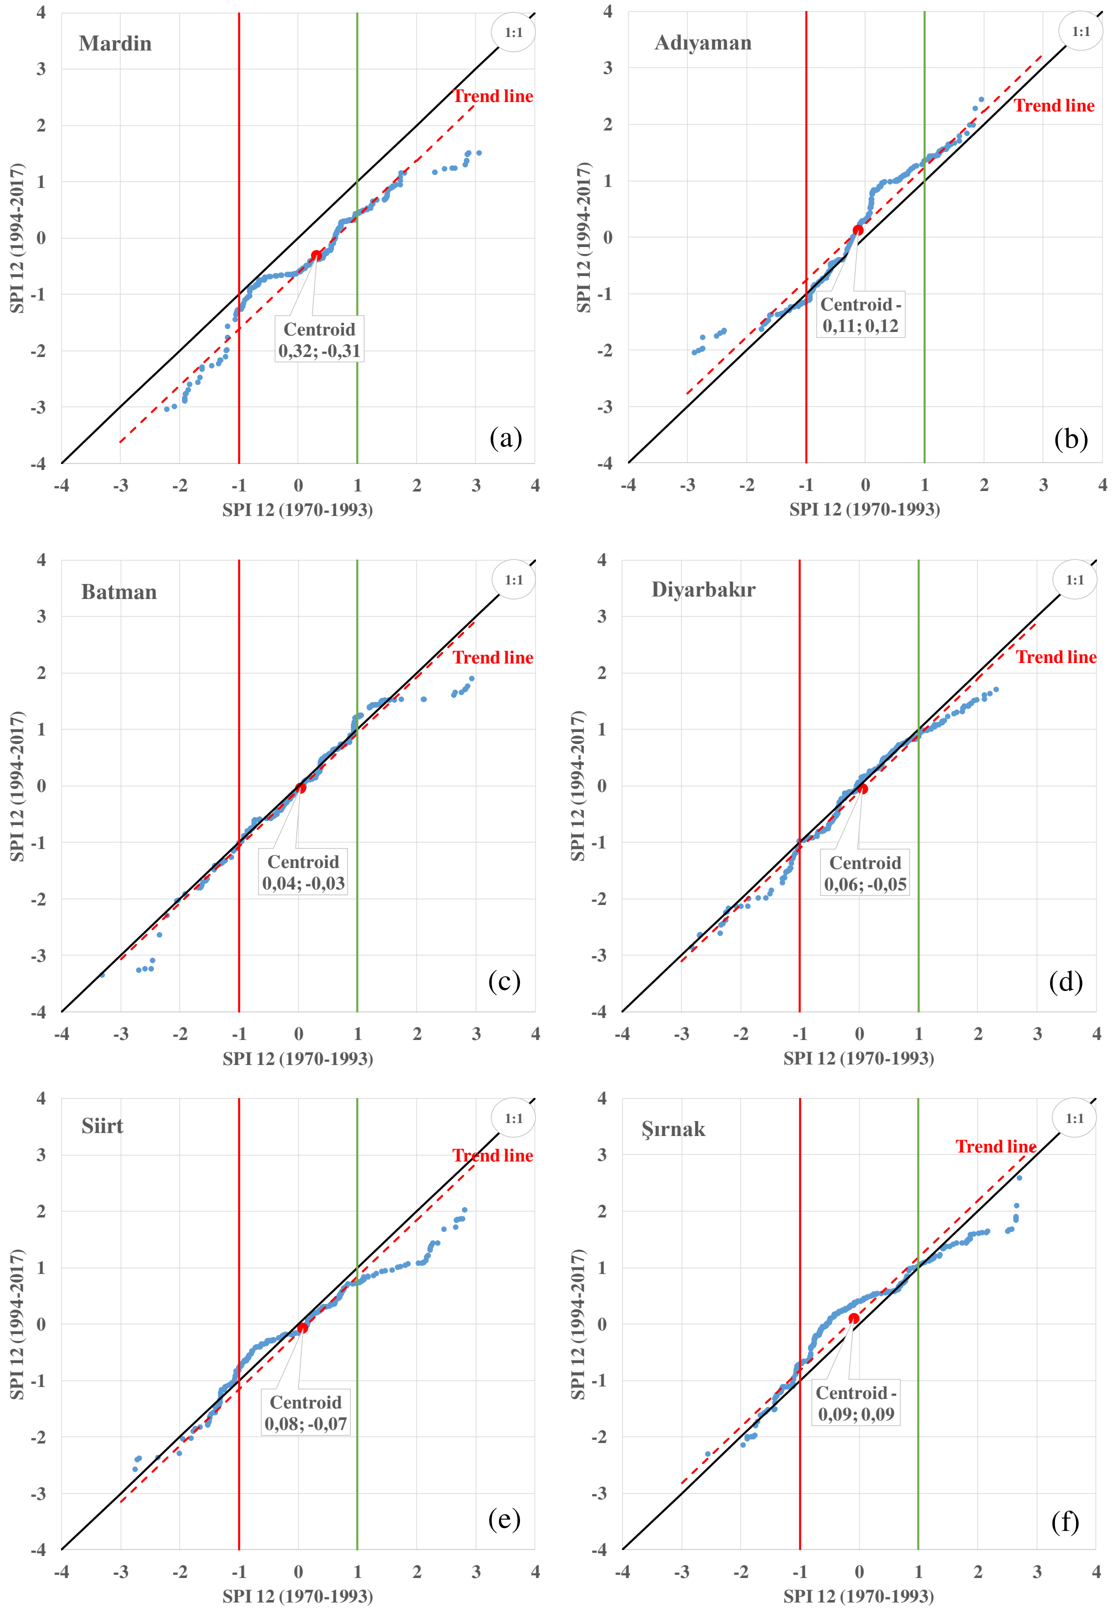
Batman, Diyarbakır, Siirt and Şırnak have almost trendless for dry (SPI ≤ -1) and normal conditions; however the index values follow a decreasing trend for wet (SPI ≥ -1) conditions (*Fig. 3c-f)*. Accordingly, the weaker wet periods have been evidenced.

Similar to Adıyaman, in Gaziantep, there is a general increasing trend in normal and wet conditions (*Fig. 3g*). However, here, both the highest and lowest SPI values increase, and that reveals Gaziantep subject to weaker extreme droughts and heavier extremely wet conditions.

In Kilis, decreasing trend in the lowest SPI values correspond heavier drought condition, and there is almost trendless series for normal and wet conditions (*Fig. 3h*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33253342

In *Figure 3i,* where the ISM results for Şanlıurfa is illustrated, a sharp increasing trend in the lowest SPI values (weaker extreme droughts) is striking, and the normal and wet periods did not show a clear tendency.



http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33253342

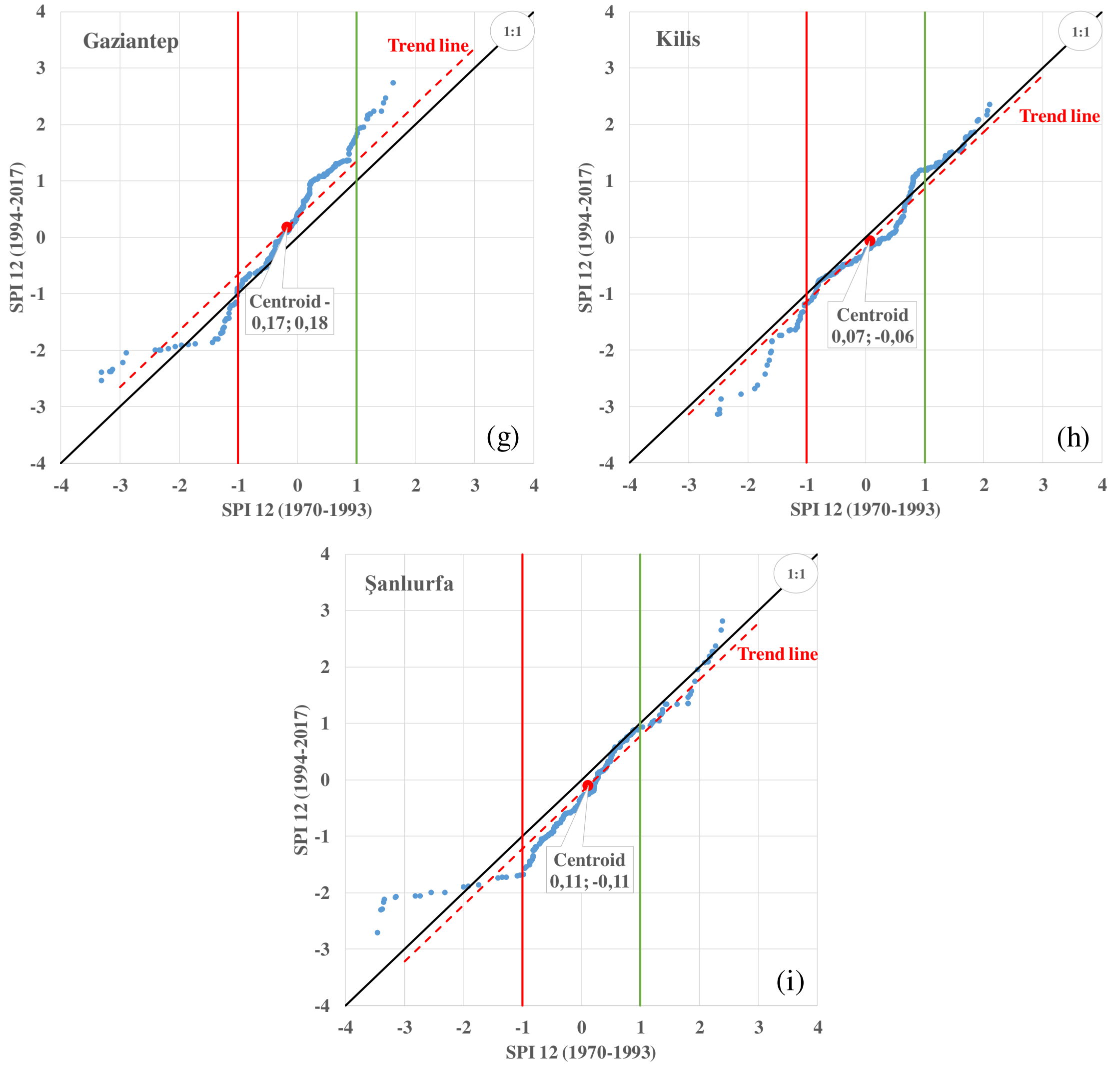


Figure 3. *The scatter diagram of the ISM method for 12-month SPI in the GAP region*

The ISM, a graphical trend analyses approach, allow the above qualitative analyses for dry, normal and wet conditions for the all GAP provinces. The significance analysis for both the ISM and MK test were also performed in accordance with the steps given in the previous sections. Considering the SPI-12 time series as a whole, for five provinces (Mardin, Kilis and Şanlıurfa (decreasing) and Şırnak and Gaziantep (increasing), the same results were obtained both in MK test and in the ISM (*Table 4*).

Assessment of the 24-month drought trends

As regards to the ISM results of 24-month SPI values, almost the same results were obtained. However, it should be noted that there is a clear increase in the trend slope for all provinces (*Fig. 4*). In other words, when the drought trends analyzed with a prolonged time (e.g. 24 months), the lowest SPI values follow a significant decreasing trend with respect to 12-month SPI values, excluding Şırnak and Gaziantep. Another important finding is that there is no significant increase in wet condition through the region, again excluding Gaziantep.

In Mardin, an increasing trend for the extreme droughts is much more pronounced than the SPI-12 trend. It is also possible to say that a decreasing trend under normal and wet conditions (*Fig. 4a*).

For Adıyaman, although there is a decreasing trend in extreme droughts base on SPI-12 evaluations, the ISM results of SPI-24 revealed the increasing trend in normal and wet conditions in addition to almost trendless series in extreme droughts (*Fig. 4b*).

Batman, Diyarbakır and Şanlıurfa have an increasing trend in droughts, especially in the extreme drought cluster (*Fig. 4c-d* and *i*). Moreover, a monotonic decreasing and a non-monotonic increasing trend were determined in normal conditions of Şanlurfa and Batman, respectively. The results revealed that trendless wet conditions for all provinces.

The extreme wet conditions are in a decreasing trend in Siirt (*Fig. 4e*), where the almost trendless series are seen in the normal and dry conditions.

In Şırnak, there is decreasing trend for the extreme droughts, and trendless series in wet conditions. An increasing trend in normal conditions also obtained by the scatter diagram (*Fig. 4f)*.

Figure 4g depicts Gaziantep with an increasing trend both in normal and wet conditions, additionally, it is very clear that there is no trend (increasing or decreasing) in droughts.

In Kilis, a slight increasing trend in wet periods is determined in addition to a mild decrease in normal conditions and trendless series in droughts (*Fig. 4h*).

In *Table 5*, the overall summary of the ISM and MK test results can be found. Similar to SPI-12 results, Mardin, Kilis and Şanlıurfa follow a decreasing trend also in SPI-24 series. Here, a differentation is higher *z* scores of MK test and higher slope values determined by ISM. Adıyaman, Şırnak and Kilis are the provinces with an increasing trend in SPI-24 values, so, they can be seen as the provinces that seem to be the most robust against drought. For Batman, Diyarbakır and Siirt, there is not a consensus between the MK and ISM, since for SPI-24 index values the MK test reveals trendless series while the ISM accept the decreasing trend.

The correlation between the trend slope values and z scores is explanatory for the reliability of the analyses. The correlation coefficient (*r*) is calculated as 0.869 and 0.876 for 12 and 24 month SPI, respectively. That reveals a high correlation between Mann-Kendall test (quantitative, non-parametric and statistical) and Innovative Şen Metod

Conclusions

Trend analysis is one of the most significant elements in any climate change study and provides a foresight for meteorological, hydrological, and climatological variables from past observations to future changes. The well-known trend test, Mann-Kendal (MK) trend test, which is misleading in the presence of data autocorrelation, requires few basic assumptions, which may not be valid in natural hydro-climatological time series. However, the Innovative Şen Method (ISM) does not require assumption, and it is based on the comparison of the two ascendingly ordered halves from the original time series. It also makes it possible to identify significant sub-trends of low, medium and high values. Moreover, due to its simplicity, it may be considered as a first step in the detailed climate change researches, for getting a general idea about the study area.

In this study, the ISM and the MK trend test were applied to the 12- and 24-month standardized precipitation index (SPI) time series, determined for the 1970-2017 period, in order to demonstrate the possible heydrological drought trends in the GAP region (Southeastern Turkey). Since the deficits in the precipitation reflect itself in water resources after a prolonged time, the 12- and 24-month SPI are the main index for demonstration of hydrological drought that refers to shortages of water resources in groundwater, in reservoirs or streams.

The ISM and MK test both revealed that, Mardin is the most vulnerable province in the region, due to the significant decreasing trend determined in 12-month and also in 24- month SPI values. Moreover, the increasing droughts were confirmed by the ISM for all corresponding conditions, referenced as dry, normal and wet. Şanlıurfa, Kilis, Siirt, Diyarbakır and Batman are second order drone prone provinces. In accordance with the results of the ISM, it is noted that there are an increasing trend in normal and wet conditions in Gaziantep, Şırnak and Adıyaman.

This study represent the Innovative Şen Metod with SPI values. However, future studies that focus on the similar methodologies and using the other drought indices that incorporate the evapotranspiration (e.g. Reconnaissance Drought Index) are recommended. When coupled with this study the future efforts would provide more results that are reliable for water resources managers. Moreover, since the various evapotranspiration estimation methods would differ the index values, using a wide range of estimations in the studies would provide possible trends in a more accurate and appropriate manner.

(Received 16th Dec 2018; accepted 8th Feb 2019)

Abstract. Selenium (Se) is an essential element to humans, animals and plants, but little is known about roles of Se in yield and antioxidant enzyme activities of rice. In this study, sodium selenate with 10 (T1), 30 (T2) and 50 (T3) μmol L^{-1} concentrations and distilled water (CK) were sprayed onto rice cultivars, or more precisely *Meixiangzhan-2* at rupturing stage during the experiments in South China, 2017. Treatments were arranged in a split-plot design with three replications. The result showed that spraying 10, 30 and 50 μmol L^{-1} sodium selenate at rupturing stage could improve the activities of oxidant enzymes such as peroxidase (POD), superoxide (SOD) and catalase (CAT) and lower the malonaldehyde (MDA) concentrations at filling stage. Furthermore, Se applications could enhance the chlorophyll content at middle and late phase of filling stage and grain yield at maturity. Therefore, Se applications could alleviate the detrimental effects of rice leaf senescence by regulating the activity of enzymatic antioxidants and also increasing chlorophyll content at the filling stage which will be helpful to sustain growth and yield formation in rice production.
Keywords: *aromatic rice, selenate, chlorophyll, antioxidant enzyme, malonaldehyde,*

Introduction

Rice is one of the most important crops, and a staple food all over the world and its production is an essential part of Chinese food security. A previous study showed that the world population may rise to 10 billion people, which means the need for rice will increase dramatically in next few decades (Krishnan et al., 2007). Therefore, it would be a challenging task to ensure the stabilization of rice yield, and exogenous plant growth regulators might come in handy.

A previous study showed that about 90% of the dry matter formed during the growth and development of crops came from photosynthetic assimilates (Petridis et al., 2018). Normally, the photosynthesis of rice will decrease with the leaf senescence at filling stage. The senescence of plant leaves is a complex and highly ordered process accompanied by the degradation of macromolecular materials, which is an important manifestation of plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33433351

adaptation to the environment in the process of evolution (Zhang et al., 2018; Li et al., 2018; Toscano et al., 2018). Early researches on plant leaf senescence mainly focused on the morphological and anatomical features at the organ level, the changes of physiological and metabolic features of senescence and the index of classification of senescence types (Osborne, 1959, 1962; Shaw and Srivastava, 1964; Jacobs et al., 1962). From early 1960s to late 1980s, plant aging was studied at tissue, cellular, and subcellular levels (Mae, 1990; Davies and Grierson, 1989; Davies et al., 1990; Adams et al., 1990). Since the late 1980s, with the wide application of modern molecular biology technologies such as in vitro translation technology, cDNA difference display, differential subhybridization, antisense RNA technology and functional genome research in the field of aging biology, the molecular mechanism of aging in plant leaves has been gradually revealed (Hafsi et al., 2000; Morris et al., 2000). Many researchers studied the mechanism of plant aging from different perspectives, and put forward some hypotheses about the mechanism of plant aging, including gene regulation theory, light-carbon imbalance theory, nutrition imbalance theory, hormone balance theory and free radical damage theory (May et al., 2017; Diao and Wang, 2018).

Selenium (Se) is an essential element to humans, animals and plant. Se deficiency had been associated with poor immune function, increased risk of mortality, and cognitive decline (Yang et al., 2018; Ishizawa et al., 2018). The research of Lee even revealed that Se could be a cancer-protective agent (Lee, 1996). Plants varied considerably in their physiological response to Se because some plant species growing on seleniferous soils were able to accumulate very high concentrations of Se, but some were Se non-accumulators and Se-sensitive (Terry et al., 2000). Early investigations had evidenced that Se application could against toxic elements such as arsenic, antimony, mercury and copper (Terry et al., 2000). Moreover, the study of Wang (Wang et al., 2012) even generated a selenium-enriched rice with higher yield and bioavailability by using selenite fertilization. Therefore, Se might have potential to be an exogenous regulator which could help to ensure the food security in rice production.

Present study was conducted in Guangdong province (major rice producing province in South China) with the hypothesis that exogenous sodium selenate application in rupturing stage could delay the leaf senescence of rice during the filling stage.

Materials and Methods

Plant materials and growing condition

The fragrant rice cultivar, *Meixiangzhan-2*, having 111-114 days of growth period was in planted in late season of 2017 in Guangzhou, Guangdong, China (23°13’ N, 113°81’ E). The experimental sites had subtropical-monsoon type climate. Before sowing, the seeds were soaked in water for 24 h, germinated in manual climatic box for the next 24 h, shade dried and the germinated seeds were sown in PVC trays for nursery raising. 20-day-old seedlings were transplanted to the field at the planting distance (30 cm × 12 cm). The seeds were sow in July, transplanted in August and harvested in November. The experimental soil was sandy loam with of 20.12% organic matter content, 1.408% total N, 1.068% total P, and 15.767% total K. This region has subtropical-monsoonal type of climate with mean annual air temperatures of 26.6°C, mean annual maximum and minimum air temperatures of 14°C in November and 37°C in August during the experiment, respectively. ‘Special biological organic fertilizer (Dao Feng Xiang)’ manufactured by Guangzhou Huayuan Agricultural Ltd, China comprised of N+ P2O5+K2O ≥74%, active living bacteria ≥20 million g^{-1}, and organic matter ≥10% was applied at 900 kg ha^{-1} with 60% as basal dose and 40% at tillering.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33433351

Treatments and plant sampling

Experimental treatments were as described:

- CK: Overhead sprinkle with double distilled water at rupturing stage of rice.
- T1: Overhead sprinkle with 10μmol L^{-1} sodium selenate at rupturing stage of rice.
- T2: Overhead sprinkle with 30μmol L^{-1} sodium selenate at rupturing stage of rice.
- T3: Overhead sprinkle with 50μmol L^{-1} sodium selenate at rupturing stage of rice.

A special Knapsack Electric sprayer (3WBD-Qianfeng Agricultural machinery, Yangjiang, Guangdong, China) with 0.2–0.5 mPa pressure and 16–18 L capacity fitted with a special windproof atomizing spray nozzle was used for sprinkle. The thirty fresh flag leaves were sampled from the rice at heading stage, 7, 14, and 21 days after heading stage and at maturity (Maturity was 28 days after the heading stage). The leaves were washed with double distilled water and stored at -80°C for physio-biochemical analysis. The measurements were repeated in triplicate and averaged.

Grain Yield

At maturity stage, the rice grains were harvested from six unit sampling area ($1m^2$) in each plot and then threshed by machine. The harvested grains were sundried and weighted in order to determinate the grain yield.

Estimation of malondialdehyde (MDA) and anti-oxidants responses

The MDA content and activities of POD, SOD and CAT were determined according to the methods described by Kong (Kong et al., 2017). MDA reacted with thiobarbituric acid (TBA) and the absorbance was read at the 532 nm, 600 nm, and 450 nm. The content of the reaction solution was calculated as: MDA content (μmol/L) = 6.45(OD532 −OD600) − 0.56OD450, while the final result was expressed as μmol/g FW.

The peroxidase (POD EC1.11.1.7) activity was estiamated after the reaction which the solution was including enzyme extract (50 μl), 1 ml of 0.3% H_2O_2, 0.95 ml of 0.2% guaiacol, and 1 ml of 50 mM l^{-1} sodium phosphate buffer (pH 7.0) while One POD unit of enzyme activity was expressed as the absorbance increase because of guaiacol oxidation by 0.01 (U/g FW). The superoxide (SOD, EC 1.15.1.1) activity was measured by using nitro blue tetrazolium (NBT). 0.05 ml of enzyme extract was added into the reaction mixture which contained 1.75 ml of sodium phosphatebuffer (pH 7.8), 0.3 ml of 130 mM methionine buffer, 0.3 ml of 750 μmol L^{-1} NBT buffer, 0.3 ml of 100 μmol L^{-1} EDTA-Na 2 buffer and 0.3 ml of 20 μmol L^{-1} lactoflavin. After reaction, the absorbance was recorded at 560 nm. One unit of SOD activity is equal to the volume of extract needed to cause 50% inhibition of the color reaction. Catalase (CAT, EC1.11.1.6) activity was estimated by adding an aliquot of enzyme extract (50 μl) to the reaction solution containing 1 ml of 0.3% H_2O_2 and 1.95 ml of sodium phosphate buffer and then the absorbance was read at 240 nm. One CAT unit of enzyme activity was defined as the absorbance decrease by 0.01 (U/g FW).

Determination of Chlorophyll contents

The contents of total chlorophyll, chlorophyll a, chlorophyll b and Carotenoid were determined by the methods of Anjum (Anjum, 2016). Grinding leaf sample (about 0.1 g) was placed in 15 ml centrifuge tube along with 95% absolute ethyl alcohol (10 ml) and then kept at dark condition until the color of sample transformed turn into white. Then, the liquor was read at 665, 652, 649 and 470 nm.

Statistical analysis

Data were analyzed using statistical software 'Statistix 8.1' (Analytical Software, Tallahassee, FL, USA) while differences amongst means were separated by using least significant difference (LSD) test at 5% probability level. Graphical representation was conducted via Sigma Plot 14.0 (Systat Software Inc., California, USA).

Result

Chlorophyll content

Figure 1 showed the effect of different concentration of sodium selenate on chlorophyll content in flag leaves of rice at different time intervals during the filling stage and heading stage. T2 treatment increased significantly the chlorophyll content in rice flag leaves at whole filling stage. At HS and 7d AH, the highest total chlorophyll content was recorded in T2 while the trend of chlorophyll content at 21d AH and 28d AH was recorded as: T3 > T2 > T1 > CK. Similar conditions were also found in Chlorophyll a, Chlorophyll b and carotenoid content.

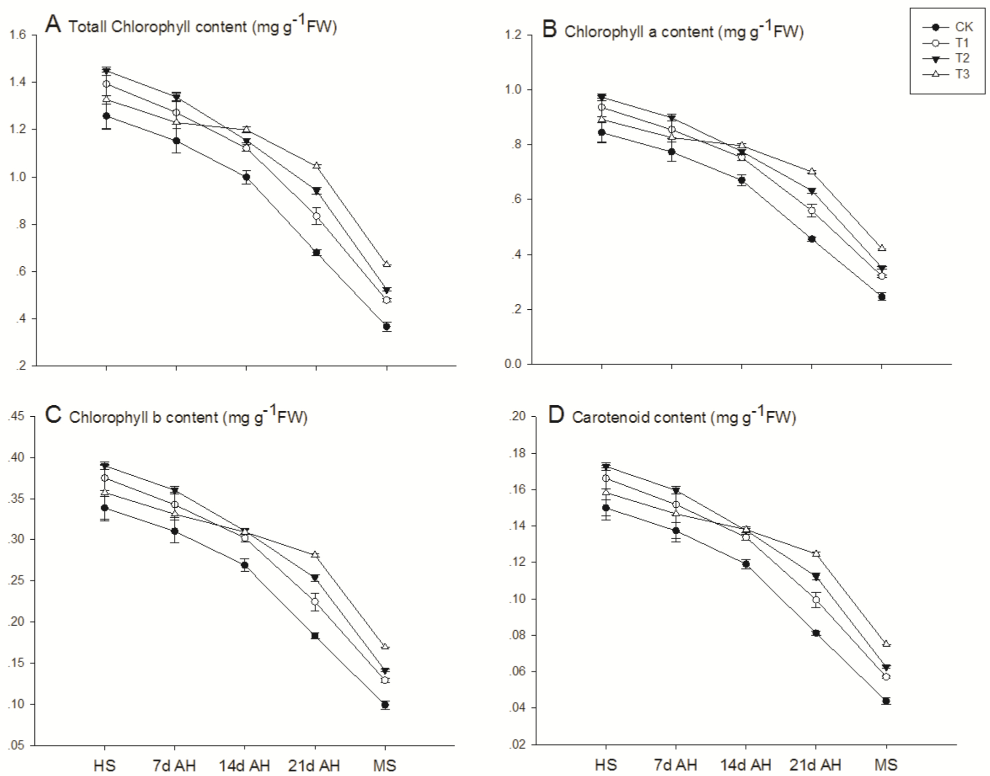

***Figure 1.** Effect of exogenous selenium selenate on chlorophyll content during the filling stage. **A**: Total Chlorophyll conten; **B**: Chlorophyll a content; **C**: Chlorophyll b content; **D**: Carotenoid content; **HS**: heading stage; **7d AH**: 7 days after heading; **14d AH**: 14 days after heading; **21d AH**: 21 days after heading; **MS**: maturity. Capped points represent S.E. of three replicates and significance between treatments at (P≤ 0.05) according to least significant difference (LSD) test. The same as below*

DOI: http://dx.doi.org/10.15666/aeer/1702_33433351

Anti-oxidant enzyme activities and MDA contents

As shown in *Figure 2*, different foliar of selenium selenate affected activities of antioxidant enzymes in rice leaves differently. For SOD activity, both T1 and T2 increased the SOD activities significantly during the early and middle phase of filling stage (HS, 7 and 14d AH). There was no remarkable difference between CK and Se3 at HS and 7d AH whilst the SOD activity of T3 at 14d AH was significantly higher than CK and at 21d AH and maturity, the highest activity was recorded in T3; For POD activity, compared to CK, Se1 treatment increased significantly the POD activity at HS, 7 and 14d AH. At 21d AH and maturity, the POD activity in T2 and T3 were significantly higher than CK while the highest activity was recorded in T3. In addition, there was no significant difference between CK and T1 in POD activity at maturity; For CAT activity, At HS and 7d AH, the highest CAT activity was recorded in T1 and there was no significant difference between CK and T3. However, at 14d AH, the CAT activity of T1, T2 and T3 were significantly higher than CK. At maturity, the highest CAT activity was recorded in T3 while there was no remarkable difference between CK and T1 at maturity; For MDA content, at early phase of filling stage (HS and 7d AH), T1 treatment reduced MDA content significantly compared with CK. At 14 and 21d AH, MDA contents of all Se treatments (T1, T2 and T3) were lower than CK. At maturity, there was no remarkable difference between CK and T1 while T3 remained the lowest level content.

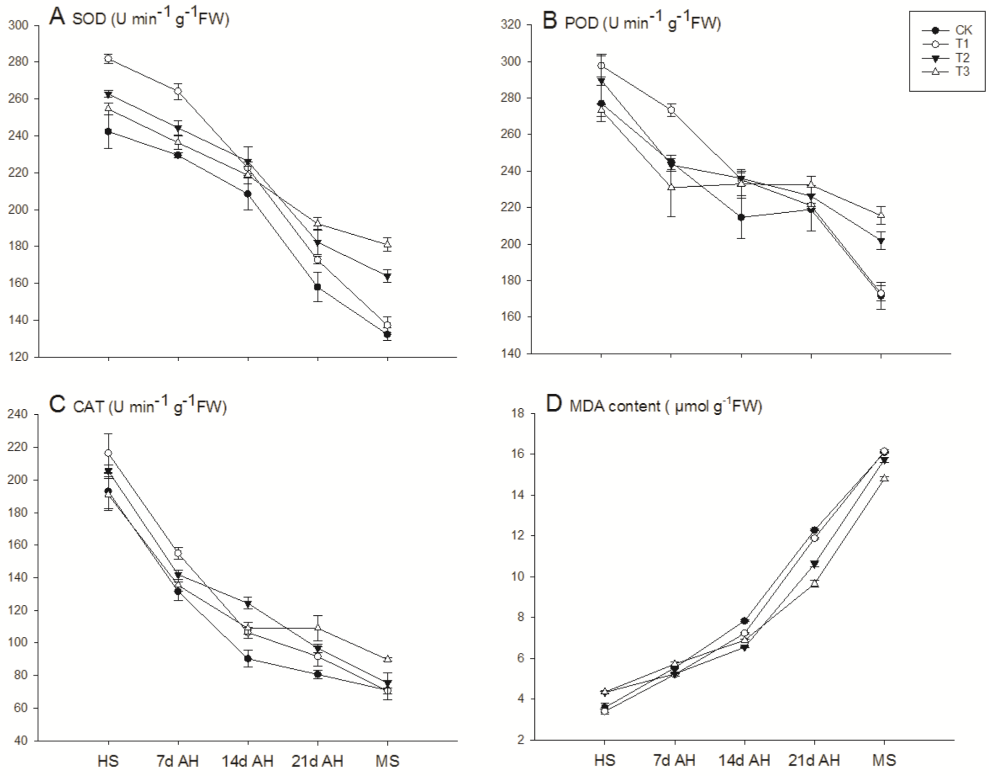

***Figure 2.** Effect of exogenous selenium selenate on antioxidant enzyme activity and MDA content during the filling stage. **A**: SOD activity; **B**: POD activity; **C**: CAT activity; **D**: MDA content*

Grain yield

Overall, foliar application of selenium selenate at rupturing stage can affected rice grain yield (*Figure 3*). Compared with CK, there was significant difference between CK and T2 while there was no remarkable difference among CK, T1 and T3.

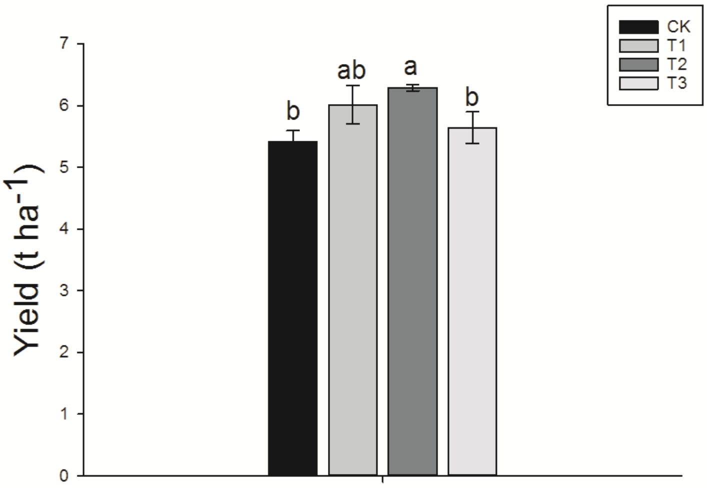

Figure 3. *Effect of exogenous selenium selenate on rice yield. Capped bars represent S.E. of three replicates. Means sharing a common letter don't differ significantly at (P≤ 0.05) according to least significant difference (LSD) test*

Discussion

Se plays important roles in plant growth and development (Nawaz et al., 2014). The most important biological function of Se in plant is a consist element of the glutathione peroxidase system (GSH-PX), which was involved in the REDOX reaction in the body, scavenging free radicals, and reducing the body peroxidation damage caused by biofilm (Qiang et al., 2011). The study of Xin et al. (2004) revealed that Se improved the activity of GSH-PX and the oxidizing ability of rice roots while reducing the MDA content under ferrous stress. Yu et al. (2013) demonstrated that Se application significantly enhanced the antioxidant capacity of wheat, corn, soybean and rape while maintain the normal growth of rice. In our study, there were some noticeable effects on rice antioxidant system with foliar application of Se. We observed that Se treatments regulated the antioxidant enzymatic activities at filling stage in terms of POD, CAT and SOD while decreasing the lipid per-oxidation (MDA concentration). This result agrees with the find of Ríos (Ríos et al., 2009) who found that application of selenite at low rate could induce higher increases in activities of enzymes that detoxify H_2O_2, especially glutathione (GSH) peroxidase and SOD. SOD, POD and CAT are key antioxidant enzymes which aid cells to remove the harmful oxygen species. Our result suggested that Se application was able to partially alleviate the detrimental effects of rice leaf senescence by enhancing the activity of antioxidant enzymes which can help in sustaining rice growth at filling stage and yield formation.

The grain yield of rice is one of the most important goals in rice production. There were significant effects on grain yield by spraying exogenous sodium selenate. Boldrin et al. (2012) studied that the applications of both selenite and selenate increased rice

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33433351

yield. A previous study (You et al., 1996) also showed that the sodium selenite and selenium-antaining humie acid compound fertilizer increased the yield and selenium content of grain in these crops with low cost and high profit. In present study, foliar sodium selenate at 30μmol L^{-1} increased the grain yield significantly. Our result agreed with the investigation of (Mengxing et al., 2016) who demonstrated that selenium application at appropriate concentration can remarkably increase the seed-setting rate and grain weight and finally enhance the grain yield of aromatic rice.

Furthermore, we observed that the chlorophyll contents under Se treatments were remained at higher level at filling stage. It might because the improvement of activities of antioxidant enzymes delayed the leaf senescence and it also might be the reason why the Se applications improved the grain yield. The study of Cao et al. (2002) revealed that there exited a significant positive correlation between photosynthesis at filling stage and grain yield. The chlorophyll plays an important role in photosynthesis process for absorbing and converting light energy (Wu et al., 2000). Hence, possible that foliar sodium selenate could be a useful application in increasing grain yield and ensuring the stability of rice production.

Conclusions

Spraying sodium selenate with 10, 30 and 50 μmol L^{-1} at rupturing stage could improve the activities of oxidant enzymes such as POD, SOD and CAT and lowered the MDA concentrations at filling stage. Furthermore, Se applications could enhance the chlorophyll content and the grain yield. Whether or not this would be sufficient to apply in rice production should require more detail and long-term investigation in different rice genotypes.

Abstract. Bacteria play essential roles in soil ecosystems. This study aims to investigate rice rhizosphere bacterial communities, soil nutrition, and grain yield affected by long-term (30 years) fertilization practices. Four fertilizations were applied to experimental red paddy soils: no fertilizer (NF), chemical fertilizer (CF), harvested residue returned to soil (HRR), and 60% organic manure plus chemical fertilizer (OCF). Bacterial communities were then assessed by means of denaturing gradient gel electrophoresis (DGGE) targeting 16S rRNA genes. Results showed that the bacterial community structure of OCF was similar to HRR, which was the most diverse and stable compared to the other treatments. Moreover, CF's effects were similar to NF, which was markedly less diverse. Eight bacterial phyla were identified by sequence analysis of the DGGE bands from rhizosphere inhabitants in the red paddy soils. In addition, soil microbial biomass C and N were significantly higher in HRR and OCF than in CF and NF. Furthermore, double rice grain yield and dry matter in OCF plots were significantly highest ($P < 0.05$). Long-term treatment of organic matter containing fertilizers promoted rhizospheric bacterial diversity and soil quality. The combination of inorganic and organic fertilizers (OCF) improved grain yields more than solely inorganic (CF) or organic (HRR) fertilizers.
Keywords: *bacterial community, rhizosphere soil, denaturing gradient gel electrophoresis (DGGE), long-term fertilization, double rice, dry matter*

Introduction

Soil quality is an important indicator of ecosystem health and soil sustainability. It can be assessed by physical, chemical, and biological approaches (Karlen et al., 2003). Bacterial communities are one of the most sensitive biological indicators of soil quality (Kennedy, 1999). Appropriate community structure, abundant diversity, and high bacterial activity are all significant factors in maintaining the sustainability and productivity of agro-ecosystems. Research on the relationship between bacterial communities and soil quality has gained traction in the past decade, primarily due to environmental issues that arise from soil degradation in various farming systems.

Rice (*Oryza sativa* L.) paddy fields can be defined as an anthropogenic soil type formed under long-term water management with seasonal submergence. In China, red soil is one of the most typical arable soils in the subtropical regions covering approximately 1.13 million km^2, accounting for 11.8% of its land surface, and producing 80% of the rice for 22.5% of the population (Zhang, 2006). However, due to rapid economic and social development, red soils are subject to degradation, characterized by low organic carbon content and low crop productivity (Wang, 1998). In order to maintain the productivity of red soils, different chemical and organic fertilizers have been applied. Studies have shown that crop yields as well as soil physicochemical and biochemical characteristics change

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33533370

with different fertilization treatments (Fierer et al., 2012; Mooshammer et al., 2014; Williams et al., 2013).

Previous studies on the effects of long-term fertilization on microbial community structure and soil quality are however limited. Yet, the few existing studies have revealed that long-term fertilization affects crop yields (Chen et al., 2017), the structure of microbial populations (Gao et al., 2015), the diversity of arbuscular mycorrhizal fungi (Wu et al., 2011), and soil organic matter fractions (Gong et al., 2009). Thus, long-term field trials are important in assessing management, particularly in terms of crop production, soil fertility, and environmental impact (Dobermann et al., 2000).

Therefore, this study has focused on how bacterial community structure, soil quality, and crop yield are affected in double rice-cropping systems by long-term application of inorganic fertilizer (CF), rice straw (HRR), and organic manure plus chemical fertilizer (OCF). This has been done as to provide further information about the complex interactions among soil microbes, soils, and plants. Our highest priority aim has been to evaluate rice rhizospheric bacterial communities in red soils with various fertilization types at different growth stages. Towards this end, denaturing gradient gel electrophoresis (DGGE) and following bands' sequencing were employed to phylogenetically determine the dominant bacterial members.

In sum, we have described the bacterial communities in rice rhizosphere soils that had been subjected to different fertilization regimes since 1986. In addition, the quality of soil and the yield of plants from soils with various treatments were also assessed by evaluating soil biomass, rice grain yields, and dry matter. Our results provide more insight into the effects of fertilization on soil bacteria populations. This in turn helps farmers select best fertilization practices in order to improve soil quality in southern China.

Materials and methods

Experimental site

This study was conducted at the experimental field of the Soil and Fertilizer Institute, Hunan Academy of Agricultural Sciences, Ningxiang County, Hunan Province (110°72'E, 28°52'N), China. The annual average temperature of this region is 14.7-22 °C, and annual rainfall is 1232 mm. The properties of soil before sampling was characterized and listed as follows: soil pH of 5.3, soil containing organic carbon (50.7 g kg^{-1}), total N (2.1 g kg^{-1}), total P (0.73 g kg^{-1}), available N (135.2 mg kg^{-1}), available P (29.8 mg kg^{-1}), and available K (52 mg kg^{-1}).

Experimental design

The rhizospheric soil samples were collected from control and long-term fertilizer treatment soils during April-October 2016. The four treatments were no fertilizer (Gu et al.) as a control, chemical fertilizer (CF), harvested rice straws returned to the soil (HRR), and organic manure plus chemical fertilizer (OCF). The chemical fertilizer was composed of P_2O_5 (75 kg hm^{2-1}), K_2O (100 kg $hm^{2\ -1}$), and urea (200 kg $hm^{2\ -1}$). Rice straws with equal amount of nitrogen as chemical fertilizer were returned to the field in HRR. The manure of OCF was post-fermented and purchased from a pig farm. The average composition of the pig manure was 588 of organic matter (g kg^{-1}), 26.7 of N (g kg^{-1}), 17.6 of P (g kg^{-1}), and 51.6 of K (g kg^{-1}) with a pH of 8.5, the dosage being 1.7 t hm^{-2} (dry weight basis). Twelve plots (4 treatments with 3 replicates) of size 5 × 6 m^2 were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33533370

randomly distributed, having been used for double-rice and winter ryegrass rotation since 1986.

Grain yields and dry matter

The seeding rate for the rice was 200,000 seedling/hm^2 for both early and late rice. At maturity, three sites of 1 m^2 were chosen randomly from each plot in order to determine the grain yield and dry matter. Plant samples were separated into straw and grain by a manually-operated thresher. The dry weight of roots, parts of above ground, and grain were determined after oven drying at 75 °C to the constant weight. Panicles, spikelets per panicle, grain filling percentages (the filled spikelet number/total spikelet number × 100%), and 1000-grain weights were estimated in order to calculate grain yield.

Soil sampling and analysis

The soils from the rhizosphere were sampled at time points standing for four growth stages: the early rice tilling stage, the early rice mature stage, the late rice tilling stage, and the late rice mature stage; these samplings were taken on May 7, July 7, August 4, and October 12 in 2016. Rhizosphere soil samples were collected as reported by Smalla et al. (2001). One composite sample was taken that consisted of roots of 5 random rice plants. The roots were shaken vigorously in order to separate soil not tightly adhering to its roots. The soils from rhizosphere were then collected, kept on ice, and stored, half of each sample at -70 °C for soil DNA extraction, and the other half at 4 °C for soil microbial biomass.

Soil microbial biomass C (MBC) and N (MBN) were determined through fumigation with ethanol-free $CHCl_3$ and extraction with K_2SO_4 (Vance et al., 1987), the organic C in the extracts was determined using an automated total organic C (TOC) analyzer (Shimadzu, TOC-Vwp, Japan), and the N was detected by the Kjeldahl method. Correction factors of 0.45 (K_{EC}) (Wu et al., 1990) and 0.57 (K_{EN}) (Jenkinson, 1988), were used for the calculated MBC and MBN values, respectively.

DNA extraction, PCR, and DGGE analysis

Three soil replicates were mixed, PCR and DGGE were run 3 times. Total microbial DNA was extracted from approximately 0.5 g of soil by using a Soil DNA Out Kit (TIANDZ, Beijing, China), following the manufacturer's instructions. The variable (V3) region of the 16S rRNA gene was amplified by PCR using the primers of V357F-GC clamp (5'-CGCCCGCCGCGCGCGGCGGGCGGGGCGGGGGCACGGGGGGCCTACGGGAGGCAGCAG-3)'and V517R (5'-ATTACCGCGGCTGCTGG-3'), as described by Muyzer (1993). All amplifications were performed in 50 µl of PCR reactions containing 2.5 ng of template DNA, 1 µl of each primer at 20 µM, 4 µl of 10 mM dNTP, 2.5 U of Taq DNA polymerase, 5 µl of 10×PCR buffer with Mg^{2+} supplied with Taq DNA polymerase (Takara BIO, Tokyo, Japan) and deionized-distilled H_2O. The following parameters were used for PCR amplification: initial denaturation for 3 min at 94 °C, followed by 28 cycles of 30 s at 94 °C, 30s at 59 °C, and 1 min 30 s at 72 °C, with a final extension step at 72 °C for 10 min. The PCR products were verified by electrophoresis in 1.5% agarose gels (containing 0.02% ethidium bromide) within 1×TAE buffer (40 mM Tris acetate, 1 mM EDTA, pH 8.3).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33533370

The DGGE analysis of microbial community structure was performed by using the D-Code Universal Mutation Detection System (Bio-Rad Laboratories, Hercules, CA, USA). 13 μl of PCR products (approx. 300 ng μl^{-1}) and 7 μl of loading buffer were loaded onto 6-12% (w/v) polyacrylamide gels in 0.5x TAE buffer. The denaturing gradient was established with 30–50% denaturant (100% denaturant corresponding to 7 M urea and 40% (v/v) deionized formamide). Electrophoresis was performed at a constant voltage of 200 V for 5 h at 61 °C. The gel was stained by SYBRs Green I (Molecular Probes, Eugene, USA) for 30 min, and scanned using the Alpha Imager 2200 Imaging System (Alpha Innotech, USA).

Specific and dominant bands in various treatments were excised from the DGGE gel and eluted overnight in a diffusion buffer at room temperature for re-amplification, as described above. Specific bands were those which were unique between each treatment, whereas dominant bands were those present with a high intensity. The amplified 16S rRNA gene segments were then inserted into pEASY-T3 vectors (TransGen Biotech, Beijing, China) and transformed into *Escherichia coli* DH5α. The recombinants were cultured in LB medium, from which white clones were randomly selected and inoculated in LB/Amp^+, then sequenced by an ABI 3730XL DNA Sequencer (Perkin Elmer, USA) at the Sun Biotech Developing Center (Beijing).

The closest match to each sequence was obtained by using the NCBI basic local alignment search tool (http://www.ncbi.nlm.gov/blast/). The alignment of similar 16S rRNA gene sequences were conducted by Mega 5.

Data analyses and statistics

All results were based on three replications in the field. The data was subjected to analysis of means and standard deviations. The diversity analysis of DGGE patterns was conducted using Quantity One 4.2.3 software (Bio-Rad Laboratories, Hercules, CA, USA) by the unweighted pair-group method with arithmetic averages (UPGMA). Soil microbial community diversity was assessed by the Shannon–Weaver index (H) and richness (S) according to the *Equation 1* (Shannon, 1949), based on the number of bands and their intensities in each lane:

$$H = -\sum_{i=1}^{s}(p_i)(\log 2 p_i) \qquad \text{(Eq.1)}$$

where p_i is the relative intensity of the *i*th band calculated as $p_i = n_i / N$, in which n_i is the intensity of the *i*th band and N is the total intensity of all bands. Richness was recorded as the number of DGGE bands of each sample. The principal component analysis (PCA) of DGGE profiles was performed using the SAS 8.2 statistical program (SAS Institute Inc., Cary, USA). Statistical analyses were performed by one-way ANOVA followed by LSD multiple comparison tests of significance. A probability value (*P*) of <0.05 was considered as statistically significant.

Results

Bacterial community structure and diversity

PCR-DGGE is a molecular fingerprinting method that allows direct comparative overview of the composition and diversity of dominant soil bacteria. DGGE has been

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33533370

used in many studies of environmental microorganisms, and proven a powerful method in investigating bacterial communities in rhizosphere soils (Qiao et al., 2012; Watanabe et al., 2004) since its first application (Muyzer et al., 1993). Soil samples from the 4 different growth stages of the control and 3 different fertilizer treatments were analyzed using PCR-DGGE in order to examine total microbial DNA.

In *Figure 1,* bands 1-25 stand for the common and specific clones of the bacterial species in the control and 3 different treatments. The twenty-five clones included 7 clones from NF, 5 clones from CF, 7 clones from HRR, and 6 clones from the OCF treatment (*Fig. 1*). Bands at the same position of each lane were common bacterial specie in all treatments such as B15, but some bands were only present in one lane or several lanes, such as B1 in lanes 3 and 8, B22 in lanes 3 and 7, B25 in lane 13, etc. Naturally, these bands represent specific bacterial species in different treatments. The more bands that showed up in a given lane, the greater the richness of bacteria identified in the fields.

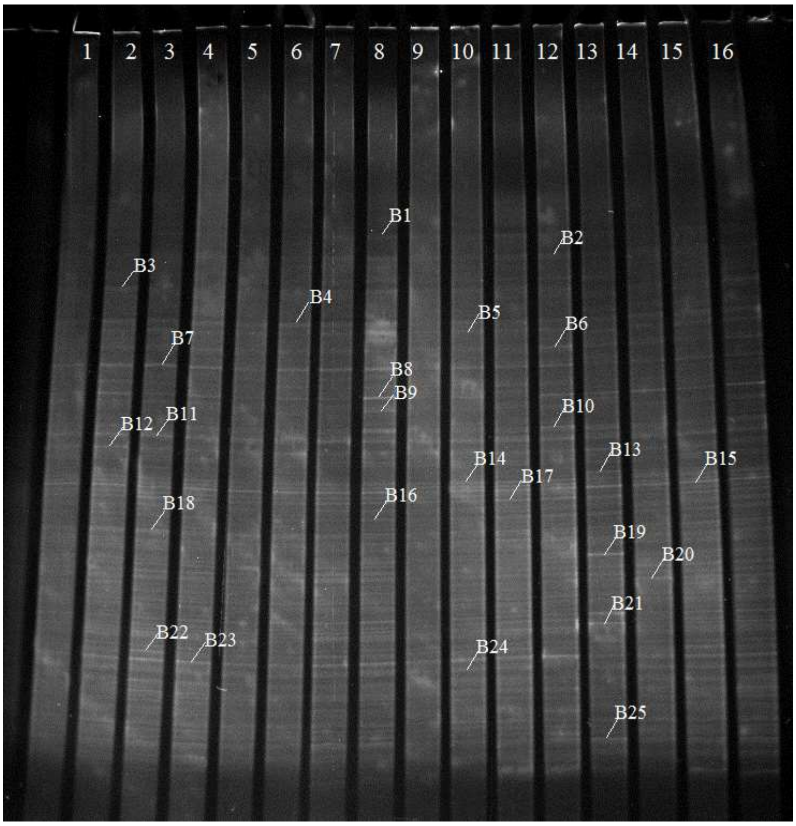

Figure 1. *PCR-DGGE patterns of 16SrRNA gene fragments obtained from soil DNA extracted during four progressive rice growth stages in 2016: May 7, July 7, August 4, and October 12. Lane 1-4: no fertilizer (NF); lanes 5-8: chemical fertilizer (CF); lanes 9-12: harvested residue returned to soil (HRR); lanes 13-16: 60% organic manure plus chemical fertilizer (OCF). Letter B followed by numbers indicates the bands that were extracted from the gel prior to sequencing analysis*

Based on PCR-DGGE banding patterns, the Shannon-Weaver diversity index (H) and corresponding richness (S) were calculated (*Table 1*). Among the three treatments and control, HRR had the highest Shannon-Weaver index at stage 3 (3.88), while the lowest was OCF at stage 1 (3.04).

	Oct 12	16	46.32c	3.80a

Means in each column by different letters are significantly different at $P < 0.05$ level, n = 3. Lane No. was the number shown in *Figure 1*

Variance analysis between different stages in each group showed that the diversity of the bacterial community had a significant increase ($p < 0.05$) from the early rice stage to the late rice stage in three treatment groups, but not in the control group. Further, except for NF, bacterial community diversity generally increased with a given growth stage in three treatment groups, and increased dramatically from the early rice stage to late rice stage for OCF. This increase was from 3.04 to 3.80, although it should be noted that the index between the two stages of early rice (between early rice tilling and the mature stage) or the last rice stages (between late rice tilling and the mature stage) was not significant in the treatments (*Table 1*). This indicates that the bacterial communities in red paddy soil with various treatments matured from early rice to late rice.

Dendrogram analysis

In order to describe the integrated change of the bacterial community shown by H and S in response to fertilization regimes, PCA and UPGMA cluster analyses were used to compare the different effects of the four groups. PCA based on DGGE banding patterns separated the bacterial communities into two groups: NF and CF in one group, and OCF and HRR in another (*Fig. 2*). The first two principle components of the PCA plot accounted for 20% and 31% of the overall variance, respectively. However, sample 9 in the HRR group (May 2015) was clearly separated from the other two groups and could be considered an outlier. Possible reason for this is that sample 9 was in the early rice tilling stage of HRR, and harvested residue may cause something different to occur in the early days, which would need to be further studied.

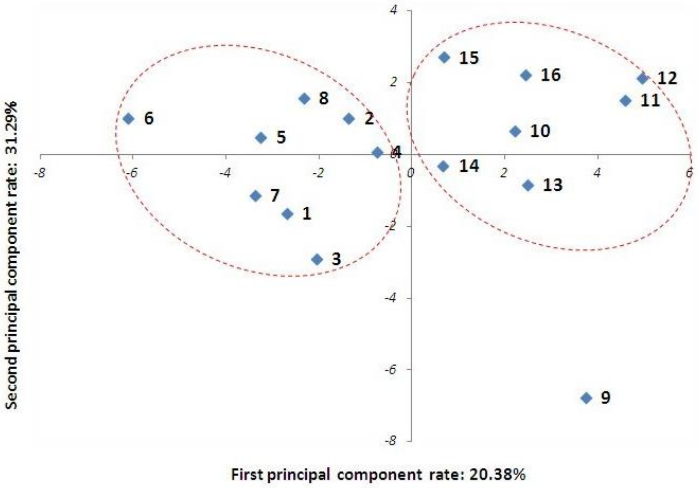

***Figure 2.** Principle component analysis (PCA) of microbial diversity indices of rhizosphere bacterial communities in different fertilization and growth stages based on DGGE profiles of bacterial 16s rRNA. The codes 1–16 are as defined in Table 1*

In general, clustering analysis corroborated the visual interpretation of the DGGE profiles. A dendrogram was obtained using the UPGMA clustering analysis, and the similarity coefficient of Pearson was based on the DGGE profiles of bacterial 16s rRNA gene fragments (170 bp). The clustering analysis revealed that two clusters were separated at 54% similarity, eliminating outlier sample 9. One cluster included samples from HRR and OCF, while another included samples from NF and CF. This suggests that DGGE patterns of CF soil are similar to that of NF soil at all growth stages, while the bacterial community of HRR soil is more similar to that in OCF soil (*Fig. 3*).

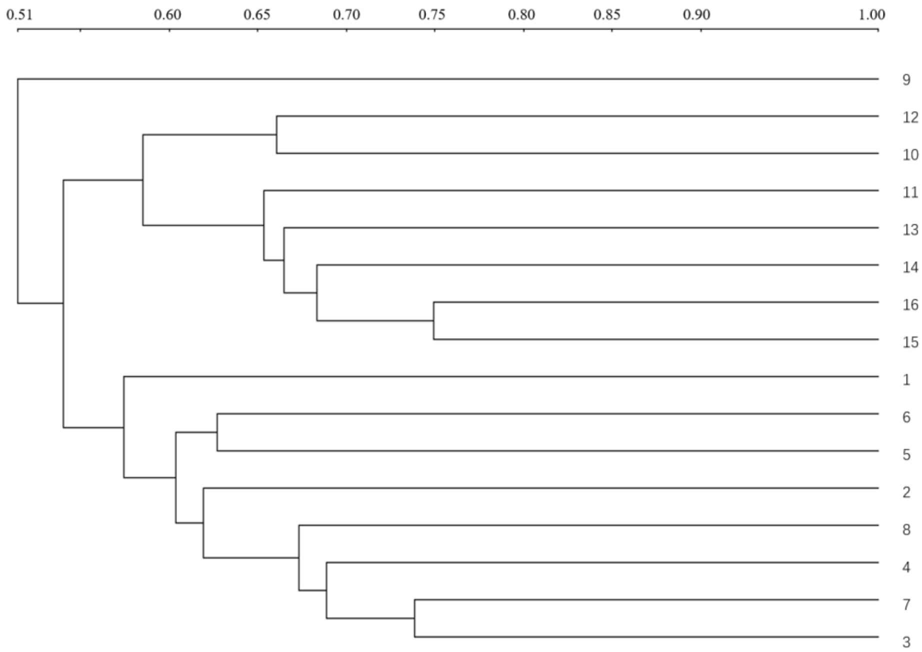

***Figure 3.** UPGMA clustering represents the similarity of 16S rRNA gene fragments from PCR-DGGE profiles generated from soil DNA extracted from different fertilizations and growth stages. The codes 1–16 are as defined in Table 1*

DOI: http://dx.doi.org/10.15666/aeer/1702_33533370

At 65% similarity, the soil samples representing the HRR group separated from those of OCF. Four growth stages in the OCF group clustered together, but the growing stages of NF and CF were not separated, which indicates that the difference between the bacterial community structure of NF and CF was not as distinct as that between HRR and OCF.

Sequenced bacterial bands and phylogenetic analysis

Twenty-five specific and intensive bands were excised from the DGGE gel (16S rRNA), then re-amplified, transformed, and sequenced to identify dominant bacterial populations in various soil samples. The 16S rRNA gene sequences (170 bp) of the 25 clones were submitted to the NCBI nucleotide sequence database (*Table A1* in the *Appendix*). Since more than 50% of the retrieved sequences were closely related to 16S rRNA genes of uncultured bacteria, the first hit in Blast-N matching to a culturable strain was also considered. These sequences were classified into eight phyla: *Proteobacteria* (B5, B6, B7, B9, B10, B14, B15, B16, B17, and B18), *Gemmatimonadetes* (B11 and B20), *Chloroflexi* (B22, B23, and B24), *Acidobacteria* (B1, B3, B13, and B19), *Actinobacteria* (B8, B12, and B25), *Firmicutes* (B4), *Bacteroidetes* (B2), and *Planctomycete* (B21) (*Table 2*).

The relative abundance of dominant bacterial phylum taxa in the control and three treatments are shown in *Figure 4*. All eight bacterial phyla could be detected in the fertilization treatments except for CF, in which *Planctomycete* was not detected in all growing stages. It was clear that the abundance of each bacterial phyla showed explicit differences among the treatments. *Proteobacteria* was the most abundant bacteria under various treatments, with relative abundance ranging from 31 to 48%. More, relative abundance of *Planctomycete* and *Acidobacteria* were greater in the HRR and OCF groups as compared to NF and CF. On the contrary, *Gemmatimonadetes* decreased in HRR and OCF treatments. A hierarchical heatmap of bacterial phyla separated the samples into two groups, with 10, 11, 12, 13, 15 and 16 grouped together, the other samples grouped together. In the first group, all samples were from HRR and OCF, in the other group, most of samples from NF and CF, except 9 and 14 (*Fig. 5*).

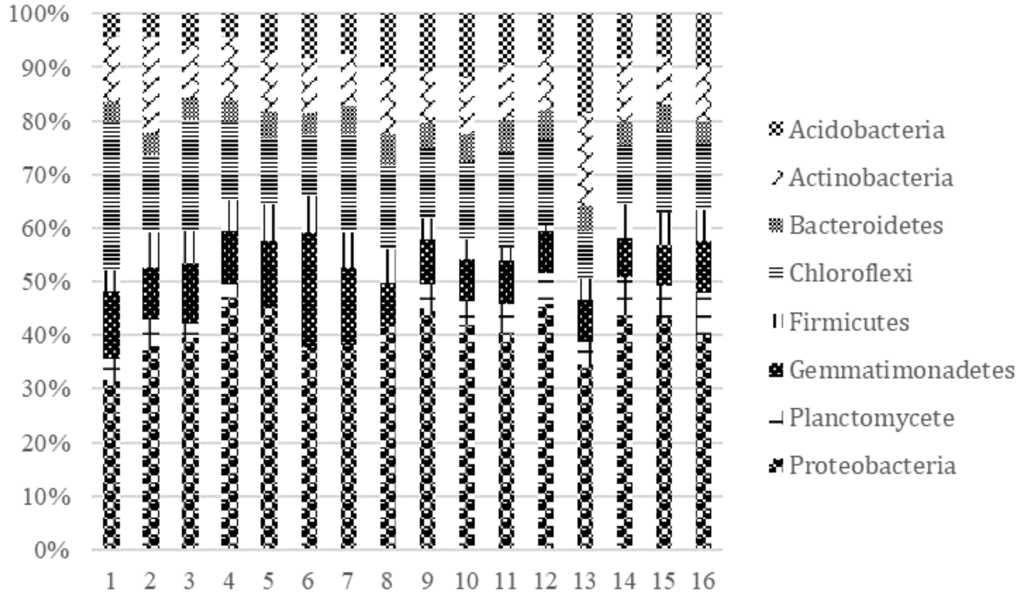

Figure 4. *The relative abundance of all detected phyla in different fertilizations and growth stages treatments. The codes 1–16 are as defined in Table 1*

Soil microbial biomass and crop yields

Plants depend on rhizosphere microbiota to make nutrients accessible. The above data showed that rhizosphere microbiota varied across the fertilizer treatments. In order to examine whether different fertilizers affect both soil quality and crop yields, soil biomass, grain yields, and dry matter were evaluated.

Soil MBN was significantly higher ($P < 0.05$) in HRR and OCF than in CF and NF during the sampling period, whereas MBC was significantly higher ($P < 0.05$) only in May and Oct. Both MBN and MBC did not differ significantly between CF and NF in all stages, but there was a difference between OCF and HRR (*Table 3*). Further, MBN was significantly higher in OCF than in HRR in July and October, while MBC in OCF was significantly higher in May but lower in Oct than HRR. These results indicate that different fertilizer treatments resulted in different values for MBC and MBN, especially fertilizers with organic components such as HRR and OCF, which in turn led to significantly higher biomass in the soils compared to CF or NF.

***Table 3.** Effect of different fertilizations on soil microbial biomass C (MBC) and soil microbial biomass N (MBN)*

	Treatment	May 07	Jul 07	Aug 04	Oct 12	Average
MBC ($mg.kg^{-1}$)	NF	145.7c	210.6b	266.2a	263.4b	221.5b
	CF	150.2c	209.5b	268.2a	267.1b	223.8b
	HRR	185.4b	238.2a	269.3a	330.0a	255.7a
	OCF	256.4a	215.5ab	267.6a	287.8b	256.8a
MBN ($mg.kg^{-1}$)	NF	7.5b	6.8c	3.3b	9.5c	6.8b
	CF	7.9b	8.0c	3.9b	11.2c	7.8b
	HRR	13.8a	16.4b	6.8a	18.8b	14.0a
	OCF	15.4a	18.9a	6.3a	22.0a	15.6a

Means in each column within MBC and MBN followed by different letters are significantly different at $P < 0.05$ level, n = 3. NF: no fertilizer, CF: chemical fertilizer; HRR: harvested residue returned to soil; OCF: 60% organic manure plus chemical fertilizer

Double rice total grain yield (i.e. the sum of early and late rice grain yield) in all three treatments were significantly higher than that in NF plots. Among the fertilizer treatments, the grain yield of OCF plots was highest ($P < 0.05$), there being no significant difference between CF and HRR. Compared to NF, grain yields of CF, HRR, and OCF were increased by 26.5%, 26.5%, and 38.9%, respectively (*Table 4*). Further,

HRR	11392.6b	1087.6b	20120.3c
OCF	12503.5a	1262.9a	22448.2a

Means in each column followed by different letters are significantly different at $P < 0.05$ level, n = 3. NF: no fertilizer, CF: chemical fertilizer; HRR: harvested residue returned to soil; OCF: 60% organic manure plus chemical fertilizer

Discussion

In this study, we assessed the structure of microbial communities in response to three types of fertilization on different stages of growth. Broadly, the structure and composition of the bacterial communities were grouped into two clusters: chemical fertilization (CF) and the control treatments in one group, and HRR and OCF in the other (*Fig. 2*).

Previous studies demonstrate that the activity and diversity of soil microorganisms are directly influenced by changes such as soil temperature (Fierer et al., 2005), moisture (Hollister et al., 2010), pH (Rousk et al., 2010), nutrient availability (Cusack et al., 2011), soil type (Xu et al., 2009), and plant type (Berg et al., 2006); following that fertilization is one of the most significant anthropogenic activities that greatly alter soil characteristics. Many studies showed that fertilizers, regardless of type, affect soil bacterial community structure (Enwall et al., 2007; Gu et al., 2009; Marschner et al., 2003). We've concluded that HRR and OCF showed similar influences on soil bacterial communities, but that CF soil had a similar bacterial community structure as NF. Chu et al. previously concluded similar results, in which inorganic fertilization did not affect the DGGE banding pattern (Chu et al., 2007). In contrast, higher bacterial community diversity and structure change were observed in soils with chemical plus organic rice straw treatments in double rice cropping system by using 16S rRNA sequencing (Wu et al., 2011; Yuan et al., 2013), although it should be noted that manure and chemical fertilizers did not change the bacterial community structure significantly in maize or wheat cropping system (Ge et al., 2008; Shen et al., 2010).

In our study, both microbial community diversity and biomass of CF soils were similar to that of NF soils, but were significantly different from that of OCF and HRR soils (*Tables 1* and *3*). A possible reason for this is that organic matter in OCF and HRR provide available substrates for microbial growth and further, that there is a positive correlation between MBC and soil organic matter, as previously reported (Wu et al., 2013).

Compared to inorganic fertilizers, organic fertilizers diversify bacterial communities. Previous studies have found that soil organic matter exerted significant influence on the diversity and structure of soil microorganisms (Cusack et al., 2011; Gu et al., 2009; Hartmann et al., 2015). This is consistent with our results, as HRR and OCF increased

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33533370

the diversity of bacterial communities in soil. Moreover, the diversity of bacterial communities with HRR was highest because straw, the most natural and suitable organic resource of the energy for bacterial activities in soils, was found in greater amounts. Additionally, soil was found to be healthier when straws were returned to fields in HRR (Lou et al., 2011).

Likewise, OCF treatment greatly increased organic substances and adjusted the balance of carbon and nitrogen in soils, both beneficial to soil microbes (Chen et al., 2017). However, OCF showed lower bacterial diversity than HRR, which might be due to its combination with chemical fertilizer. Overall, our results indicated that HRR was the best fertilizer practice, measured as bacterial community diversity against CF and OCF.

In previous studies, microbial diversity and community structure in rice field soils have been reported to change with season and fertilizer management practices (Ahn et al., 2012; Doi et al., 2011). Except for NF, we have found that the growth stages of rice affect bacterial diversity (*Table 1*). Further, the diversity of CF and OCF in two late growth stages were significantly higher than those at the two early stages, while not varying much between early and late stages in HRR. We theorize that CF and OCF having more evident effects than HRR may be that HRR diversified the microbe community quickly then keeping bacterial richness steady at a high level, thus leading to less notable effects with growth stages. Further, diversity at the start of the early stage was low, but significantly increased at the late stage in OCF, which could be explained by OCF being a slow-release fertilizer. Additionally, variation of bacterial communities in various growth stages is also indirectly related to environmental characteristics and root exudates (Tian et al., 2013). However, the influences of these factors are lower than direct fertilizer application.

Our results demonstrated that the dominant bacterial species in these four groups belonged to eight phyla (*Table 2; Fig. 4*). The eight phyla identified were the same as those detected in rice soils by means of pyrosequencing (Ahn et al., 2012). Two of these were Gram-positive bacteria (*Firmicutes and Actinobacteria*), the others being Gram-negative. Hence, the predominant bacteria in rice rhizosphere were Gram-negative bacteria, especially *Proteobacteria*, irrespective of soil type and growth stage. Moreover, the microbial community possessing more Gram-negative bacteria was found to be more active as well as relatively stable and resilient (Peng et al., 2016). These findings are consistent with DGGE analysis results from Ikenaga et al. (2003).

Acidobacteria usually functions in biogeochemical cycling of carbon and is more abundant in acidic soils (Sait et al., 2006). The increase of *Acidobacteria* in fertilizer treatment groups compared to the control group may be explained by CF's decreased pH of soils that made them more acidic. Meanwhile, HRR and OCF increased soil organic carbon and its production. Previous studies have demonstrated that *Planctomyces* is a marine bacterium existing in habitats rich with organic nutrients and oxidizing ammonium. Our study demonstrated that *Planctomycete* did not exist at all in CF treated soils, further suggesting that inorganic components in CF are not suitable for this type of bacteria. Therefore, HRR and OCF but not CF provided organic matter that promoted *Planctomycete* growth. Moreover, compared to NF treated soil, organic fertilizers demonstrated significantly lower soil bulk density (Rasool et al., 2008), which make soils more suitable for the survival of *planctomycete.*

Last, the decline of the relative abundance of *Gemmatimonadetes* in HRR and OCF was probably due to their preference for drier soils. *Gemmatimonadetes* have been

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33533370

found in a variety of arid soils, so it tends to be more dependent on the moisture availability than aggregation (DeBruyn et al., 2011). Organic matter lead to soil aggregation, and thus dryness-favored bacterial *Gemmatimonadetes* decreased. The moisture-favored bacterial *Planctomyces,* by contrast, increased in HRR and OCF.

Rice is the most important crop in China, thus, fertilization is an important agricultural practice for increasing crop yields. Traditionally, farmers have used organic fertilizer such as manure and crop residues to maintain soil fertility. However, chemical fertilizers have increasingly been applied to rice paddies in China as of the 1980s. This has been done in order to meet food demand of increasing populations, primarily because inorganic fertilizers directly boost crop yields and are more affordable. Consequently, fewer organic fertilizers are currently used, and large chemical fertilizer input has caused soil acidity major croplands (Guo et al., 2010).

Long-term fertility experiments provide insight into the consequences of land management strategies. In our study, compared to other fertilizers, OCF improves both grain yields and soil biomass; this is due to the combination of organic manure and chemical fertilizer, in which chemical P availability plays a vital role in improving rice productivity as what Ding et al. (2018) recently reported. Moreover, previous studies demonstrated that P, N, and MBC increased in soils with organic manure treatment, significantly improving rice yields and microbial activity (Zheng et al., 2016). However, the grain yields of CF (containing chemical P) and HRR (containing organic straw residuals) were not significantly different, indicating that the combination of both organic and inorganic fertilizers is the best method to improve grain yield.

Similarly, previous studies have demonstrated that chemical N increased in HRR but that chemical P did not change (Zheng et al., 2016). Further, it has been demonstrated that N fertilization promoted crop productivity only after following the supplement of P (Lv et al., 2011), which explains why CF or HRR did not promote significant grain yields. Although HRR has similar effects as chemical fertilizer (CF) on grain yield, HRR had more beneficial effects on soil sustainability, such as increased microbial diversity and biomass (*Table 3*).

Generally, soil microbial biomass plays an important role in maintaining soil structure, facilitating microbial metabolic processes, and regulating the release of nutrients. Our results suggest that OCF and HRR had similar MBC and MBN (*Table 3*), and thus similar microbial community structures (*Figs. 2* and *3*). However, our results also suggest that OCF has more advantages on improving grain yields, while HRR is more beneficial to soil quality and microbial structures.

In sum, chemical fertilizer plays an important role in increasing yield, but large fertilizer input in the field usually causes environmental problems. This has become a major concern for scientists, environmental groups, and agricultural policymakers worldwide. Figuring out how to assess and design healthy fertilizer practices that achieve optimum yields and maintain soil sustainability is challenging, and it will be our focus in future studies.

Conclusions

This study has reported the effects of three long-term fertilization treatments (CF, HRR, and OCF) on bacterial community structure and abundance at different rice growth stages of red paddy soils in southern China. It has also reported the corresponding microbial biomass and grain yields. PCR-DGGE results revealed that among the three fertilizer practices, both HRR and OCF showed positive and lasting effects on soil quality, but that the soil microbial community in HRR was steadiest and most diverse. The bacterial diversity of OCF was next after HRR, with OCF demonstrating lasting effects on the bacterial community with growth stages.

The bacterial species belonged to 8 different phyla, and the abundance of each phylum of bacteria changed with various treatments. *Planctomycete* was not present in the CF group, suggesting the lower bacterial diversity in CF. HRR and OCF treatments significantly increased soil micro biomass compared to NF, whereas CF did not. Furthermore, OCF with both inorganic and organic compositions promoted dry matter and total grain yield compared to any other treatment.

Overall, HRR is the fertilizer that best increases bacterial diversity in red paddy soils, whereas OCF is the best to promote crop yield. Broadly, this study has provided insights into the impact of different fertilizers on rhizospheric bacterial community structure, soil quality, and crop yield, providing critical information in selecting the optimal fertilization treatment. Further studies should focus on the application of combined inorganic and organic fertilizers, and balancing the economic and environmental benefits between crop yields and soil sustainability.

(Received 13th Dec 2018; accepted 20th Feb 2019)

Abstract. In this study, protective effects of Curcumin (CUR) against Chlorphyrifos (CPF)-induced oxidative stress on blood serum, liver and gill tissues of rainbow trout (*Oncorhynchus mykiss*) were investigated. In the first group, normal water and recommended diet were used as the control group. The second fish group was exposed to water containing 0.040 mg/l CPF. The third fish group received only 0.5% (CUR1) and the fourth group received only 1% CUR (CUR2). The fifth group was exposed to water containing 0.040 mg/l CPF and received only 0.5% (CPF + CUR1). The sixth group was exposed to water containing 0.040 mg/l CPF, giving and received only 0.1% (CPF + CUR2). Samples were taken from the blood, liver and gill tissues and total antioxidant capacity (TAC), total oxidant status (TOS) and oxidative stress index (OSI) were measured. The supplementation of CUR with CPF attenuated the adverse effects of CPF intoxication by reducing TOS and OSI and increased TAC in serum and liver. These results showed that CPF, alone, increased oxidative stress in rainbow trout but CUR reduced oxidative stress alone or when combined with CPF in the serum and liver, but not in the gill.
Keywords: *insecticides, turmeric, liver, gill, blood antioxidant, fish*

Introduction

Pesticides are synthetic or organic compounds used to destroy organisms that negatively affect human activities. The pesticides used in the struggle against weeds, insects and other harmful substances in the fields where the cultivated plants are grown pollute to the groundwater sources in various forms and can reach aquatic environments through infiltration (Karacan, 2007). Chlorpyrifos (CPF) [O, O-diethyl O- (3, 5, 6-trichloro-2-pyrrolidyl)-phosphorothioate)] is a broad-spectrum organophosphorus insecticide used to control insect and arthropod populations in agricultural areas (Girón-Pérez et al., 2006). CPF, which has low water solubility, directly affects neurotransmission through inhibiting acetylcholinesterase activity in the organism. Unlike other organophosphorous pesticides, CPF has a long lasting effect and accumulates in fat tissues (Kammerbauer and Moncada, 1998).

In aquatic environments, living creatures, especially fishes, are primarily affected by pesticides. In genotoxicity studies in aquatic environments, various tests that were prepared for mammals in order to determine the clastogenic effects of chemical

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33713385

substances, have been modified in different ways and used on aquatic creatures such as especially fish, mussels and other crustaceans (Burgeot et al., 1995; Sanchez-Galan et al., 1998). In acute toxicity studies, it has been reported that 50-70% mortality was seen in *Aulacomya ater* (Molina, 1782) (Bivalvia: Mytilidae) at 0.050 mg/l CPF levels and inhibited enzyme activity of 0.02-0.16 mg/l acetylcholinesterase (Fuhrer et al., 2012).

Curcumin (CUR) has many effects such antiinflammatory, antioxidant, anticancerogenic, antimutagenic, anticoagulant, antidiabetic, antibacterial, antiviral and nerve preservative effects in a broad spectrum which is made of turmeric/curcuma that is used as a spice and gives yellow color to the meals (Turmeric, *Curcuma longa*) (Naik et al., 2011). CUR has been extensively investigated for its protective effect on the cardiovascular system, as it facilitates the release of many reactive oxygen radicals, especially superoxide anions, nitrogen dioxide radicals and hydroxyl radicals (Sreejayan, 1997; Duan et al., 2012). In these studies, CUR has been shown to inhibit endotelial and smooth muscle cells from damage (Srivastava and Mehta, 2009), to prevent heart damage (Nirmala et al., 1999), to accelerate the restructuring of heart and vessels have been reported to improve oxidative damage (Morimoto et al., 2008; Bala et al., 2006).

Among all creatures living in aquatic environments, fish have a very important place in the use of these tests because they can be easily kept, fed and grown up in laboratory environments. Akdemir et al. (2016) investigated the effects of different rates of CUR on the growth performance of trout and reported that CUR extract reduced the negative impact of high stocking intensity on performance of rainbow trout. Cao et al. (2015) found that Carp (*Cyprinus carpio*) which are fed CUR at different doses for 60 days increased their oxidative tolerance to carbon tetrachloride-induced liver damage. Similarly, the protective effect of CUR on the *Anabas testudineus* (Bloch) was studied and for this purpose, fish were fed for 2 to 8 weeks with fish feed to which two doses of CUR (0.5% and 1%) was added. As a result of the research, the antioxidant status, protein content and texture of fish were investigated acutely and chronically. In all groups fed with CUR, the lipid peroxidation value was reduced or unaffected. The antioxidant enzyme activity level is increased as the glutathione level changes depending on the time and the dose. In addition, the protective effect of CUR was also determined in histological analyzes (Manju et al., 2012).

Organophosphates are the insecticides most commonly used worldwide in the pest control of crops. The global pesticide market is growing at around 1% per annum as tonnage. Herbicides are ranked first in agrochemicals with a share of 47%. This is followed by insecticides by 29% and fungicides by 19%. Herbicides and insecticides that make up more than 70% of agricultural drugs are distributed around the land use (Dağ et al., 2000). The effects of these pesticides are different according to the environment and amount of accumulation. CPF is commonly used in agricultural areas around the dam reservoir (EPDA, 2004).

Organophosphorus insecticide (OPI) has been reported to alter oxidative stress characteristics (Malkovics, 1995). Recent studies on pesticide poisoning have highlighted the oxidative stress caused by free radicals produced by pesticides. The generation of hydrogen peroxide (H_2O_2) is catalyzed by the dismutation reaction of superoxide dismutase (SOD) and superoxide anion (O_2^-). Hydrogen peroxide is catalytically decomposed by water (CAT) activation and molecular oxygen. If the free radical production crosses endogenous antioxidant levels, they can lead to cell damage or death (Malkovics, 1995; Zámocký et al., 1999).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33713385

CPF intoxication has been shown to significantly reduce reduced glutathione (GSH), catalase (CAT) and glutathione S-transferase (GST) activities in the rat liver. As a result of zinc treatment, CPF-treated animals have been shown to have an elevation in the levels of GSH, catalase and GST, as well as a significant decrease in the levels of SOD (Goel et al., 2005).

Dimethoate, an organophosphate pesticide, has been reported to increase catalase, (CAT), superoxide dismutase (SOD), glutathione peroxidase (GPx) and glutathione reductase (GR) activity in hepatic cytochrome P450 enzymes, brain and liver lipid peroxidation in acutely exposed male rats (Sharma et al., 2005).

These results show that organophosphorus (CPF) may be an oxidant. This study is important because the treatment of CPF exposed fish and CUR is also important in preventing toxic effects. Therefore, it is aimed to determine the protective effect of CUR against the toxic effect of Chlorpyrifos. There was no information on this subject in the literature search.

In this context it is planned within three main objectives; 1) to investigate the oxidative stress of CPF in some tissues 2) to examine the effects of CUR alone on the oxidative mechanism 3) to determine the protective effects of CUR on the oxidative stress resulting from CPF toxicity. So, the protective effects of Curcumin against chlorpyrifos-induced oxidative stress on serum, liver and gill tissues of rainbow trout (*Oncorhynchus mykiss*) were investigated.

Materials and methods

Materials

Chemicals

CUR, CPF (96.5% purity (technical grade)), were purchased from Sigma Chemicals (Sigma-Aldrich, Turkey). All other chemicals were purchased from standard commercial suppliers (St Louis, MO, USA).

In the study; the establishment and implementation of the feeding experiment was carried out in concrete pools in the Department of Fisheries and Aquaculture at Harran University Bozova Vocational School for Higher Education for 30 days. 120 male rainbow trout (*O. mykiss*) (2 replicate) of 2 years old, with an average weight of 80-100 g, were obtained from Karacalar Food, Agriculture, Aquaculture Import and Export Limited Company. Water temperature, pH and dissolved oxygen were 15.0 ± 1.5 °C, 7.8 ± 0.9 and 8.8 ± 0.3 mg/L, respectively.

It is produced from marine raw materials and have high digestibility and high protein content supplied from a commercial company.

CPF was dissolved in acetone as stock solution (0.1%) and this stock solution was mixed into pools at defined ratios. It was stored at 4 °C and from these daily requirements is added to pools. The use of fish and experimental application protocols were supervised by the Dollvet A.Ş. Animal Experiments Local Ethics Committee (Şanlıurfa-Turkey). Analyzes of the tissues were carried out at Harran University Biology Department laboratories.

Methods

Rainbow trout was kept in 500 l pools with continuous aeration for 30 days. In the study, pellet trout feed was given two times a day as once in the morning and once in the evening for feeding fish in the pools which shall be ventilated continuously. The stock solutions of CPF, the pesticide, given to the environment where fish live, were prepared and the water in the pools was changed by 1/3 per day. CUR, which will be used in the study, is adjusted to 0.5% and 1.0% of the total weight of the fish (Manju et al., 2012). The CUR extract was dissolved in DMSO and stock solutions were prepared in PBS at pH 7.2 and given intraperitoneally to fish. The fish was placed in 12 pools as 10 fishes (2 replicates) in each pool. Fish were divided into 6 groups (control group, CPF, CUR1, CUR2, CPF + CUR1, CPF + CUR2). In the first group, normal water was used as the control group and the fish were given feed without additives (Control). The second fish group was exposed to water containing 0.040 mg/l CPF (Doğu et al., 2015). The third fish group received only 0.5% CUR (CUR1), received eight doses (two doses per week) of CUR by intraperitoneal injections (IP) and the fourth group received only 1% CUR (CUR2), received eight doses (two doses per week) of CUR by IP. The fifth group was exposed to water containing 0.040 mg/L CPF and given CUR (CPF + CUR1) at a rate of 0.5% of the total weight of the fish, received eight doses (two doses per week) of CUR by IP. The sixth group was exposed to water containing 0.040 mg/L CPF and given CUR (CPF + CUR2) at 1.0% of the total weight of the fish, received eight doses (two doses per week) of CUR by IP. Experimental conditions are summarised in *Table 1*.

Table 1. *Experimental design of the study*

	Experimental groups					
	Control	**CPF**	**CUR1**	**CUR2**	**CPF+CUR1**	**CPF+CUR**
CPF (mg/l)	-	0.040	-	-	0.040	0.040
CUR (%)	-	-	0.5	1	0.5	1

At the end of the study 0.6 mL/L 2-phenoxyethanol was administered as an anesthetic agent before taking blood samples from all experimental groups. Subsequently, blood samples from each fish were transferred individually to heparinized test tubes. The anesthetized fish were rinsed with distilled water prior to the dissections to avoid the external pesticide residue.

Fish were dissected and liver and gill tissue were collected and stored at -20 °C for examination. Blood from the fish was transferred to EDTA glass tubes and allowed to stand at +4 °C at 3000 rpm for 1 h at +4 °C before being centrifuged for 15 min by refrigerated centrifugation. After centrifugation, the plasma was separated from the erythrocytes and blood samples were stored at -20 °C until the enzymatic antioxidants were examined. Then the following tests were applied. Liver and gill were collected and perfused with isotonic salt solution (0.9% NaCl) to remove blood and others and used for preparation of tissue homogenate.

Preparation of tissues homogenate

The whole liver and gill tissues were homogenized in phosphate saline buffer (100 mM) containing EDTA (1 mM; pH 7.4; 1:10 w/v) and then centrifuged (12,000×g, 30 min, 4 °C). The supernatant was separated and used for biochemical analysis.

Oxidative stress test

Total antioxidant status (TAC)

Intracellular total oxidant capacity (TAC) was measured using Rel Assay Diagnostics total oxidant capacity measurement kit (Gaziantep/Turkey). In this measurement method, 2,2' -azinobis- (3-ethylbenzothiazoline-6-sulfonic acid) radical (ABTS radical) is used. ABTS radical loses its blue and green color (faded) according to antioxidant concentration and antioxidant capacity. This color change is assessed by measuring the absorbance value at 660 nm. The principle of this measurement method is based on the fact that the ABTS molecule in the presence of hydrogen peroxide is oxidized to the ABTS+ molecule. The color of radical which is dark brown at 30 mmol/L acetate buffer and t pH: 3.6 is faded at 0.4 mol/L acetate buffer and pH: 5.8. There is an inverse relationship between color change and the amount of antioxidant in the sample. The reaction rate was expressed as Trolox equivalent/L by calibrating with the standard method Trolox (Erel, 2005).

Total oxidant status (TOS)

Intracellular total oxidant status (TOS) was measured by using Rel Assay Diagnostics total oxidant capacity measurement kit (Gaziantep/Turkey). In this method; Reagent 1: The main solution is prepared by dissolving 25 mM H_2SO_4 in 140 mM NaCl solution. The main solution is prepared by first dissolving 10% glycerol and then dissolving 250 µM xylenol orange in total volume. Reagent 2: Reagent is prepared by dissolving 10 mM o-Dianisidine dihydrochloride in the main solution and then dissolving 5 mM ammonium ferrous sulphate. Principle: The oxidants present in the sample oxidize the ferrous ion-o-dianisidine complex to the ferric ion. The glycerol in the medium accelerates this reaction to about three fold. Ferric ions form a colored complex with xylenol orange in acidic environment. The intensity of the color associated with the amount of oxidants present in the sample will be measured spectrophotometrically, in units of mol H_2O_2 Eqv./L (Erel, 2005).

Oxidative stress index (OSI)

The TOS: TAC ratio was used as the oxidative stress index (OSI). To perform the calculation, the units of TAC, mmol Trolox equivalent/L, was converted to µmol Trolox equivalent/L. OSI was calculated and expressed as Unit AU (Arbitrary Unit) and as shown the formula below (Erel, 2005):

$$OSI = (((TOS,\ \mu mol/L) / (TAC,\ \mu mol\ Trolox\ equivalent/L)) / 100)$$

Statistical analysis

Statistical analysis of the data was carried using SPSS 16.0 software. Analysis of variance (ANOVA) and Tukey' post hoc test was employed to compare the differences in TOS, TAC and OSI in the serum, liver and gill. A p value less than 0.05 was considered as statistically significant. All data are expressed as mean ± SE.

Results

The results of the examined parameters of blood serum are given in *Figures 1, 2* and *3*. There were significant differences in serum TOS, TAC and OSI values ($p < 0.001$) in serum. Serum TAC was similar when compared to the control groups given CUR 0.5% and 1%. The serum TAC values of the CPF group were significantly lower than those of the CUR-1 group. When combined CUR with CPF, serum TAC values were significantly lower than those of the groups which were given only CUR-1. When compared with the control, the highest TOS was obtained in the CPF group, whereas the TOS values of the CUR-treated groups and CPF+CUR in both doses were similar. CUR (0.5% and 1.0% quantities) supplied with CPF significantly reduced the TOS values when compared to the CPF group in serum. Serum OSI were significantly higher in CPF groups compared to control group ($p < 0.001$). There were no significant differences between control and Curcumin groups, control and CPF+CUR groups in OSI, except CPF+CUR2 in OSI (*Fig. 3*).

The results of the examined parameters of liver tissue are given in *Figures 4, 5* and *6*. Significant differences were observed between the groups in liver TOS, TAC and OSI values ($p < 0.001$). Liver TOS values were lowest in the CUR group and the highest in the CPF group compared with the control group. In the CPF + CUR group, TOS were significantly lower than in the CPF group, although similar to the control group. Liver TAC was found to be at the highest level of CUR 1.0% when compared with the control group. The CPF group had the lowest TAC compared to the control group. Liver OSI was the lowest in the CPF group and the highest in CUR group compared to the control group, but similar in the other groups.

The results of the examined parameters of gill tissue are given in *Figure 7, 8* and *9*. In the gills, the TOS were significantly higher ($p < 0.001$) in the CPF and CPF + CUR-1 groups when compared to the control. The TOS in both CUR and CPF + CUR-2 groups were similar to those of the control group. The TAC in the all groups in the gill was not found to be significant when compared to control group. Only the gill TAC value of the fish given CUR at % 1 was higher than the fish that received 0.5% CUR with CPF ($p < 0.05$).

The gill OSI values were significantly higher ($p < 0.01$) in the CPF + CUR-1 group when compared to the control. OSI values of fish fed both doses of CUR were significantly lower than that of fed the CPF + CUR-1 group ($p < 0.05$). The OSI in gill in fish fed at a dose of 0.5% of CUR were lower than the fed with CPF and CPF + CUR-1.

Discussion

CPF is one of the environmental toxicants, and hepatoxicity, genotoxicity, behavioral toxicity, neurotoxicity have been reported in fish (Deb and Das, 2013). Blood and liver is an important indicator for evaluating the physiological and pathological conditions in the organism when exposed to environmental pollution. Free radicals attack the membrane components of erythrocytes and cause a change in membrane structure and function (Prieto et al., 2006; Cunha-Oliveira et al., 2013; Mustafa, 2016). In order to test the oxidative stress in vivo, TOS, TAC and OSI were used in the blood serum, liver and gill tissues.

The results showed that CPF increased levels of TOS and OSI in blood serum. When CUR was given alone and in combination with CPF, TOS values were similar to the control group. These results showed that CPF alone increased oxidative stress and CUR reduced oxidative stress when the combination of CPF and CUR is given. CUR given alone did not have a significant effect on TOS and OSI levels. Therefore, CUR may be thought to have oxidative stress-reducing effect caused by CPF. Previous studies have similarly reported that the toxic effects of various toxicants such as metal, solvent and 6-OHDA are weakened by CUR (Yadav et al., 2010; Jaisin et al., 2011; Yang et al., 2014). The superiority of TAC test is to show the antioxidant capacity of all the antioxidants in the sample (Kusano and Ferrari, 2008; Hismiogullari et al., 2015). In the present study, 0.5% and 1.0 levels of CUR did not change the level of blood serum TAC according to the control group. TAC level in CPF and CPF + CUR-1 groups were similar to control group. TAC level in CPF + CUR-2 groups were lower that of the control. These results indicate that CUR does not have a significant effect on blood antioxidant levels in fish at these levels in feed. However, it has been reported that CUR has antiradical/antioxidant activity and potential cell regenerative properties (Mustafa, 2016; Karahan et al., 2016). In fact, the combined delivery of CPF and 1.0% of CUR significantly reduced TAC levels compared to the control group. Thus, it can be said that when high levels of CUR combined with toxic substances reduces the level of antioxidants.

Oxidant and antioxidant levels in liver homogenates can be used as a marker of hepatocellular sensitivity. In the present study, liver TOS and OSI levels increased significantly while TAC levels decreased in CPF-treated fish compared to controls. Free

DOI: http://dx.doi.org/10.15666/aeer/1702_33713385

radicals and ROS are key factors in cell damage. These factors have been shown to impair function and structural integrity in a few cells (Estebe et al., 2011; Karahan et al., 2016). Reactive oxygen species and lipid peroxidation lead to degradation in membranes and protein liver cells. Microcystin's (MCs) toxicity has been shown to increase lipid peroxidation as an indicator of oxidative damage in *Brycon amazonicus* liver homogenates (Martins et al., 2017). Furthermore, 0.5% and 1.0% levels of CUR reduce the TOS levels, while 1.0% level of CUR increased the TAC levels significantly. In addition, this is an indication of non-hepatotoxic potential of both doses of CUR. When both amounts of CUR (CPF + CUR-1 and CPF + CUR-2) were given in combination with CPF, the TOS level significantly decreased compared to the CPF alone. This shows that antioxidants derived from CUR are used in the liver to reduce the effects of oxidation of the liver caused by CPF. Furthermore, it may be suggested that CUR has a hepatoprotective effect against toxic substances such as CPF. The CUR antioxidant activity is due to 2 phenolic OH groups (Prasad et al., 2014. These phytochemicals may have increased levels of cellular antioxidants and increased levels of antioxidants (Dinkova-Kostova et al., 2000). Intraperitoneal application of CUR and dexmedetomidine in rats has been shown to reduce ischemia-reperfusion injury and oxidative stress in the kidney (Karahan et al., 2016).

The TOS values in the gill homogenate were higher only in the CPF and CPF + CUR-1 groups than in the control group. CUR did not cause significant changes in TOS values in the gills, compared to control. Similarly, TAC levels of all groups were similar to control groups. CPF increased TOS levels by causing oxidative damage in the gills. CUR has not been able to reduce oxidative damage in the gills and has not been associated with antioxidant levels. These results suggest that antioxidant activity is limited in the gills. Similarly, the gill GPx activity of *Brycon amazonicus* (Martins et al., 2017) and *O. niloticus* (Prieto et al., 2006) exposed to microcystin toxicity has been altered but significantly increased in the liver. Martins et al. (2017) reported oxidative damage to Microcystin toxicity in the gills of *Brycon amazonicus*. CUR has been shown to inhibit and stimulate apoptotic signaling (Khar et al., 1995; Somasundaram et al., 2002). CUR may induce oxidative damage by caspase-3 activation. However, the mechanism of CUR that causes the induction of ROS formation is not fully understood (Hsuuw et al., 2005).

As you seen in the findings, the OSI can better point out the oxidative stress status. For this reason, TAS and TOS could be determined and then OSI values should be calculated. This could be more beneficial for estimation of comprehensive oxidative stress status (Wu et al., 2017). Intraperitoneal application of CUR and dexmedetomidine in rats has been shown to reduce ischemia-reperfusion injury and oxidative stress in the kidney.

Conclusions

The results of the research show that the level of antioxidants varies among tissues and is highest in the liver. It was observed that the dose of 0.040 mg/l CPF at toxic level increased the oxidation level and lowered the antioxidant level of blood and liver in fish but not having any effect on the gill antioxidant level. CUR, given at a rate of 0.5% according to the live weight, increased the antioxidant level in the blood serum. In the presence of toxic substances such as CPF, CUR can also trigger oxidation in blood. The effect of CUR on tissues is not stable, but may increase the level of antioxidants or

DOI: http://dx.doi.org/10.15666/aeer/1702_33713385

oxidants, depending on the presence of toxic substances such as CPF, tissue and the amount of toxic substances in feed. Also, our findings were showed that oxidative stress index could be often used as an indicator of oxidative stress in trout. Future studies should focus on molecular mechanism involved in protective effect of CUR on CPF-ınduced cell damage.

(Received 18th Dec 2018; accepted 14th Feb 2019)

Abstract. Sanjiang plain wetland is the largest freshwater ecosystem in northeast China, and with its richness in animal and plant species, it displays a high biodiversity. This study provides information about benthic macroinvertebrate diversity and functional groups in association with physicochemical parameters in wetland habitats of Sanjiang plain. Benthic macroinvertebrate samples were collected using a D-frame aquatic net. Shannon-Wiener, Simpson and Pileou's evenness indices were calculated in terms of abundance. The relationship between measured physicochemical variables and benthic macroinvertebrate functional feeding groups (FFGs) was explored using CCA. A total of 57 macroinvertebrate taxa were collected from the 16 sampling sites. Aquatic insects were the most abundant with 11 families, Dytiscidae, Chironomidae, Leptophlebiidae, Belostomatidae, Corixidae, Gerridae, Corduliidae, Gomphidae, Macromiinae, Libellulidae and Phryganeidae. Chironomids were the most diverse and abundant with 26 taxa. The metrics of abundance, Shannon-Wiener, Simpson and Pileou's evenness indices differed significantly among the 16 sampling sites ($p = 0.0163$, $p = 0.0092$, $p = 0.0474$, $p = 0.0222$, respectively). The findings showed that these 57 benthic macroinvertebrate taxa were categorized in six functional feeding groups, including 19 predators, 15 gathering-collectors, 7 scrapers, 6 filtering-collectors, 5 omnivores and 5 shredders. CCA results displayed that benthic macroinvertebrate functional feeding groups had strong relationships with the physicochemical characteristics in the wetlands of Sanjiang plain.
Keywords: *aquatic macroinvertebrate fauna, functional group composition, water parameters, wetland, China*

Introduction

Wetland ecosystems account for 5-8% of the Earth's surface area (Sui et al., 2017) with their characteristic mix of land and water. They display the richest biodiversity, highest productivity, and highest ecological impact of all terrestrial ecosystems (Sui et al., 2017). They are important for the reduction of greenhouse gas emission, conservation of biodiversity, and contribute to regulating the balance of the Earth's ecosystem (Galloway et al., 2004; Dentener et al., 2006). Aquatic ecosystems are mostly affected by the large-scale agricultural expansion which influences the overall quality of the ecosystems by directly altering habitat, channel structure, and water quality posing severe threats to aquatic biodiversity (Vitousek et al., 1997; Allan, 2004; Azrina et al., 2006; Dudgeon et al., 2006; Smith and Lamp, 2008; Carlson et al., 2013;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33873402

Narangarvuu et al., 2014). Most aquatic macroinvertebrates reside in the benthic biotope for at least part of their life, relatively immobile, and very sensitive; therefore any disturbances in the aquatic environment may cause them to disappear or a reduction in their diversity (Hilsenhoff, 1988; Zamora-Muñoz et al., 1995; Morse et al., 2007; Narangarvuu et al., 2014). Hence, biomonitoring is considered as one of the alternatives for rapid assessment of the aquatic environment status (Tan and Beh, 2016).

Aquatic macroinvertebrates are widely used as biological indicators of the ecological conditions, their abundance and diversity being used to evaluate the occurrence of pollution (Abel, 1966; Hellawell, 1986; Metcafe, 1989; Lenat, 1993; Rosenberg and Resh, 1993; Rosenberg et al., 2008; Southerland et al., 2008; Shabani et al., 2016). While macroinvertebrates in wetlands share some of their attributes in streams and rivers useful such as ubiquity, sedentary nature, moderately long life cycles, environmental sensitivity (Rosenberg and Resh, 1993), they have many other attributes that reduce their ability to reflect environmental quality such as strong responses to weather and seasonality, and frequent dispersal into and out of habitats (Rosenberg et al., 2008).

In standing and flowing water ecosystems, aquatic macroinvertebrates are important elements in the ecological dynamics (Hynes, 1970), playing an important role in the cycle of materials and in trophic transfers (Cummins, 1974; Vannote et al., 1980; Cummins et al., 1989; Dunbar, 2010; Shabani et al., 2016; Safari et al., 2018). They are important animal organisms both economically and ecologically (Li et al., 2007).

Understanding the distribution and abundance of invertebrates in aquatic ecosystem has long been a goal of aquatic ecologists (Bergon, 1996). Immature stages of aquatic invertebrates are a vital link between primary producers and fish (Yapo et al., 2018). Most aquatic macroinvertebrates are sensitive to changes in pH, dissolved oxygen, temperature, salinity, turbidity, conductivity, availability of food and other changes in their biotope (Gage et al., 2004; Crisci-Bispo et al., 2007). They are useful surrogates of ecosystem attributes, and the relative abundance of functional groups reflects anthropogenic impact (Merritt et al., 2002; Cummins et al., 2005; Masese et al., 2014).

Sanjiang plain wetland is the largest freshwater wetland in northeast China (Zheng et al., 2013; Liu et al., 2014; Taufik et al., 2015; Wu et al., 2017), and with its richness in animals and plant species, it displays a high biodiversity. It is world-renowned for hosting many rare, large-sized water birds; several most notable ones are globally threatened cranes, such as the Oriental stork (*Ciconia boyciana*), white-naped crane (*Grus vipio*), and red-crowned crane (*G. japonensis*) (Zhang et al., 2009a). Its role in maintaining the ecological balance in the region is irreplaceable (Zheng et al., 2013; Liu et al., 2014). However, qualitative and quantitative studies of aquatic macroinvertebrates in the area remain generally scarce due to the lack of large-scale investigations and insufficient data. Thus, the conservation status of many benthic macroinvertebrates in the Sanjiang plain wetland is not yet assessed. In order to reach a rational and sustainable management of freshwater wetlands of Sanjiang plain, it is very crucial to implement a follow-up study program, to monitor and classify the freshwater macroinvertebrates (Shabani et al., 2016). The identification of species and their distribution patterns provide more information for monitoring and conserving these important ecosystems (Maneechan and Prommi, 2015). Community indices, diversity indices, and functional feeding groups (FFGs) were the most effective measures that can be used in water quality assessment, and have a response across a range of human influence (Rosenberg and Resh, 1993; Merritt et al., 1996, 2002; Karr and Chu, 1999;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33873402

Masese et al., 2014). FFGs are a classification approach that is based on morpho-behavioral mechanisms of food acquisition rather than taxonomic group (Merritt et al., 1996). This study aimed to collect benthic macroinvertebrate fauna, and explore the relationships between macroinvertebrate FFGs and water physicochemical properties in the wetland environments of Sanjiang plain.

Materials and methods

Study area

The Sanjiang Plain is located in the northeast boarder part of the Heilongjiang Province in NE China (Zhang et al., 2009a; *Fig. 1*). It is in a low alluvial plain of Heilong River, Songhua River, and Wusuli River (Zhou and Liu, 2005; Zhang et al., 2009a; Jiang et al., 2011), from 129°11E to 135°05E and from 43°49N to 48°27N, covering a total area of 108,900 km^2 (Liu and Ma, 2002; Jiang et al., 2011; Du et al., 2018). The Sanjiang plain supports one of the largest freshwater wetland complexes in China, and its wetland areas are strongly affected by agriculture drainage and reclamation efforts (Wu et al., 2017). Its elevation in the southwest is higher than in the northeast. The climate in this area belongs to the temperate humid or sub-humid continental monsoon climate. The mean annual temperature ranges from 1.4-4.3 °C (Du et al., 2018), with average maximum of 21-22 °C in July and average minimum -18 °C in January (Wang et al., 2015). The mean annual precipitation is 500-650 mm and 80% of rainfall occurs between May and September (Jin et al., 2015). The frost-free period is 120-140 days (Yang et al., 2018). Most of the rivers in the area have the characteristics of the wetland river: the slight gradient and large channel curve coefficient. There are four main soil types: meadow soil, swamp soil, washed and black soil. They account for more than 95% of the whole area. Main types of vegetation in Sanjiang plain include *Phragmites communis*, *Carex lasiacarpa*, *Carex pseudocuraica*, *Carex meyeriana*, *Alnus sibirica*, *Betula fruticosa*, *Salix brachypoda*, *Lythrum salicaria*, *Calamagrostis anagustifolia* (Wang et al., 2018), and the Sanjiang plain wetland has been designated within list of wetlands of international importance (Zhang et al., 2009). Due to the relatively cold weather, deep surface waters, large marsh patches, and sparse population, reclamation of small Sanjiang plain marshes started relatively late, and the Honghe National Nature Reserve and Sanjiang National Nature Reserve were created (Zhang et al., 2009; Du et al., 2018).

Benthic macroinvertebrate procedures

Sixteen sampling sites were selected based on prospected freshwater ecosystems and accessibility (catchment areas including sites 1, 2, 3, 4, 5 and 6; ponds: sites 7 and 15; marshes: site 8; rivers: sites 9, 11, 12, 13 and 16; lake: site 10; ditches: site 14). The latitude and longitude of the 16 sampling sites were determined using a portable global positioning system (GPS, *Table 1*). Benthic macroinvertebrates were collected using a D-frame aquatic net (30 × 30 cm frame, 500 µm mesh) and the sampling gears were washed thoroughly between sites during three seasons: autumn, spring and summer of year 2016. In each sampling period, 3 replicate samples were collected at each site and the sampled specimens were sieved through a 500 µm mesh sieve in the field for approximately 30-40 min. Macroinvertebrate populations were separated from the sand, mud and substrates by hand. The specimens were grouped according to the sites and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33873402

dates of sampling and placed in 100 ml labelled plastic containers, preserved in 95% ethanol, and then transported to the laboratory for further analysis.

In the laboratory, the macroinvertebrate communities were keyed to species or genus and counted using identification keys of Thorp and Covich (1991); Morse et al. (1994); Merritt et al. (1996); Tong (1996); Dudgeon (1999); Duan et al. (2010).

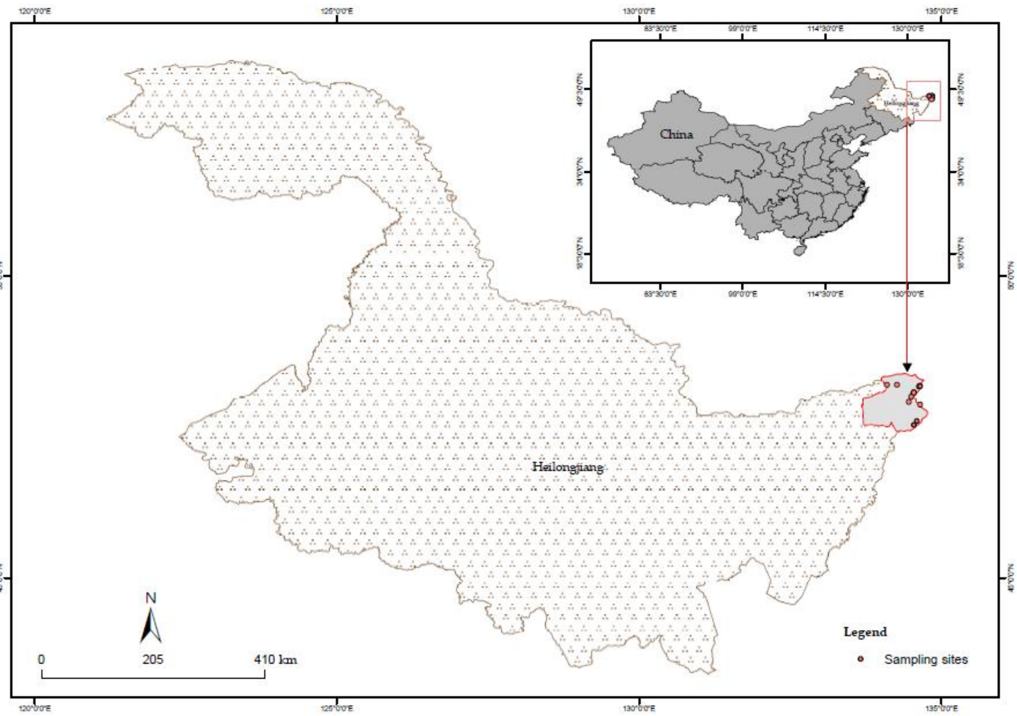

Figure 1. *The location of study area with sampling sites within China*

Functional group composition

Major functional feeding groups were assigned based on invertebrate morphological and behavioral adaptations for food acquisition (Merritt et al., 2002; Merritt et al., 1996) and 6 FFGs (shredders, scrapers, filtering-collectors, gathering-collectors, predators and Omnivores) that were identified. The FFGs are: 1) shredders (SH) feeding on coarse particulate organic matter >1 mm in size, either live aquatic macrophyte tissue or coarse terrestrial plant litter; 2) scrapers (SC) scraping off and consuming the organic matter attached to stones and other substrate surfaces, primarily live plant stems; 3) filtering-collectors (FC) sifting fine particulates 1000 to 0.45 µm from the flowing column of water; 4) gathering-collectors (GC) which gather fine particulates of organic matter from the debris and sediments on the stream beds; 5) predators (PR) feeding on other animals, i.e. live prey; and a sixth category, other, includes species that are omnivores (OM), or simply do not fit neatly into the other categories (Zhang et al., 2014; Masese et al., 2014; Fu et al., 2016).

Measurement of physicochemical factors

Simultaneously with benthic macroinvertebrate sampling, the water temperature (T °C), electrical conductivity (EC, µS/cm), pH, chlorine (Cl^-, mg/l), turbidity (NTU),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33873402

chlorophyll a (Chl, mg/l) were measured using multi-parameter probe YSI Professional (YSI 06E2512AG). The transparency (cm) was measured with a Secchi disc. Water samples were collected from each sampling site in 500 ml labelled plastic containers. Chemical parameters such as chemical oxygen demand (COD_{Mn}, mg/l), biological oxygen demand (BOD_5, mg/l), total nitrogen (TN, mg/l), ammonia-nitrogen (NH_3-N, mg/l), nitrate (NO_3^-, mg/l), and total phosphorus (TP, mg/l) were analyzed in the laboratory based on standard methods procedures (APHA, 2012).

Data analysis

The Shannon-Wiener, Simpson, Pileou's evenness and alpha (α) biological diversity indices were calculated in terms of abundance using PAST software (Hammer et al., 2001; Hammer and Ryan, 2008). A principal component analysis (PCA) based on a correlation matrix among samples was used to analyze the physicochemical parameters. Canonical correspondence analysis (CCA) was also used to describe community trends in macroinvertebrate data and to identify physicochemical variables that best explained species distribution patterns at study sites. PCA and CCA were performed using RcmdrPlugin.FactorMineR and vegan packages, respectively in R software (version 3.5.1). One-way analysis of variance (ANOVA) test was used to test the significance of physicochemical factors on macroinvertebrate abundance and FFGs differences among the sixteen wetland sites. The non-parametric Kruskal-Wallis test was used if normality was not achieved after transformation (Zar, 1984). ANOVA and Kruskal-Wallis tests were computed using Rcmdr package in R software. Canonical correspondence analysis was used to select linear combinations of physicochemical variables that account for most of the variation in macroinvertebrate distributions (Niba and Sakwe, 2018).

Results and discussion

Benthic macroinvertebrate communities

A total of 57 benthic macroinvertebrate taxa belonging to 24 families were collected from the sixteen sampling sites. Insects were most caught with 11 families Dytiscidae, Chironomidae, Leptophlebiidae, Belostomatidae, Corixidae, Gerridae, Corduliidae, Gomphidae, Macromiinae, Libellulidae and Phryganeidae. In general, Chironomids were the most diverse and abundant family, which possessed 26 taxa followed by Gomphidae with 4 taxa (*Table 2*). Among all populations, *Cipangopaludina ussuriensis* (Viviparidae) was the most abundant species representing up to 18.2% and occurring at almost each sampling site expect for sites 1, 2, 6 and 13. *Leander modestus* (Palaemonidae) was dominant on site 7, and *Cipangopaludina ussuriensis* on sites 16 and 10, respectively. Total taxon richness was higher in spring and at site 16. The Shannon-Wiener diversity index was higher at sites 8 and 14, respectively (*Fig. 2*). We observed that these sites were dominated abundantly by aquatic Poaceae vegetation. Aquatic vegetation plays an important role in structuring macroinvertebrate populations via the provision of living space (Angradi et al., 2001; Sipkay et al., 2005; Ali et al., 2007; Valinoti et al., 2011; Gleason et al., 2018) or the selecting species traits related to population dynamics and feeding habits (Céréghino et al., 2008).

According to the ANOVA results, the abundance, Shannon-Wiener, Simpson and Pileou’s evenness indices were significantly different ($p = 0.0163$, $p = 0.0092$, $p = 0.0474$, $p = 0.0222$, respectively) among the sixteen sampling sites. On the other hand, it appeared that there’s no significant difference in the total abundance and taxa richness of macroinvertebrate communities caught during spring, summer and autumn seasons ($p = 0.229$, $p = 0.7662$, respectively, *Fig. 2c*).

Our results agreed with the findings of Wang et al. (2007); Zhao et al. (2012); Zhang et al. (2014); Rosser and Pearson (2018), who reported that insects represented the most diverse group and Chironomids were the most abundant family. Macroinvertebrate biodiversity is mainly determined by the number of taxa and individuals, and higher

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33873402

diversity can be detected in complex habitats because of more living space or surface area (Shostell and Williams, 2007).

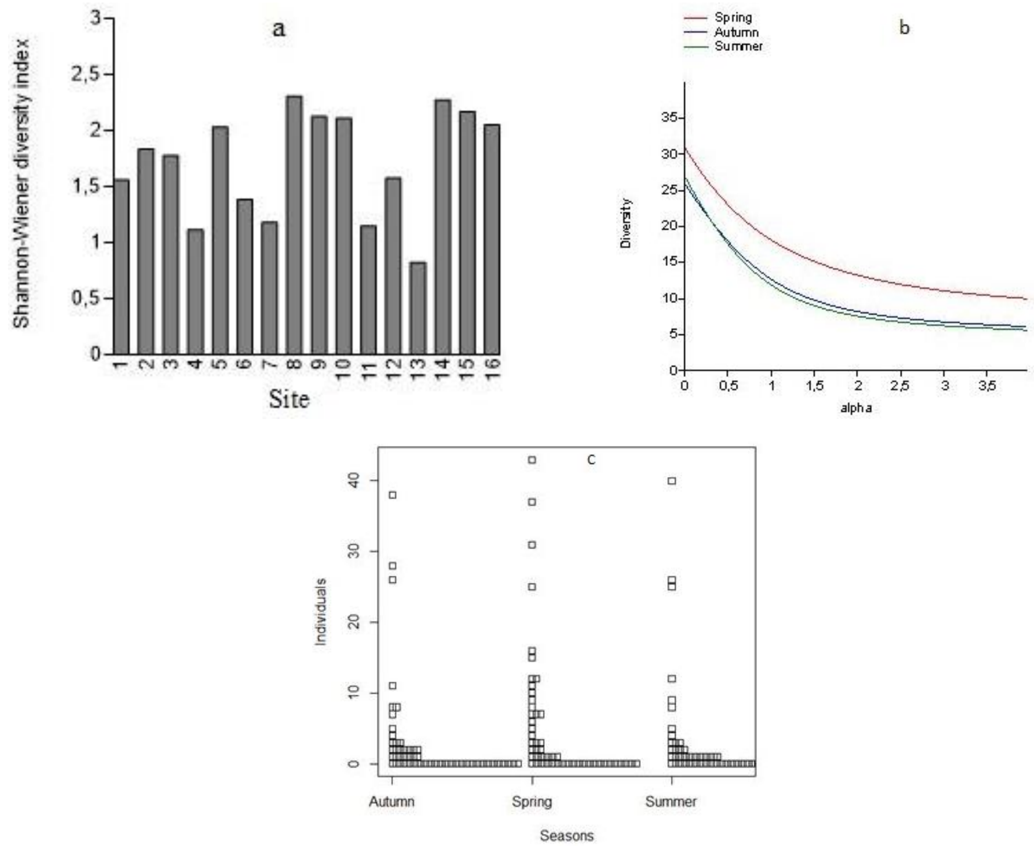

Figure 2. *Trends in Shannon-Wiener (a) and alpha (b) diversity indices, and comparison of mean values (c) of the total abundance for each sampling site during autumn, spring and summer seasons. Autumn (26 species, n_{ind} = 165), spring (31 species, n_{ind} = 287) and summer (27 species, n_{ind} = 158)*

Physicochemical variables at sites

As summarized in *Table 3*, some of the measured physicochemical characteristics changed with seasons. Temperature, chlorophyll a, TN, pH and COD_{Mn} (Kruskal–Wallis test, $p < 0.001$) and NO_3^-, TP, BOD_5 and turbidity (Kruskal–Wallis test, $p < 0.05$) significantly varied among the sampling sites during these three seasons. While conductivity, chlorine, NH_3-N and transparency did not vary significantly (Kruskal–Wallis test, $p > 0.05$) during autumn, spring and summer seasons. Temperature, conductivity, NO_3^-, transparency, TP, COD_{Mn} and BOD_5 increased during the summer, while chlorine, NH_3-N, turbidity and TN increased during the spring. Moreover, pH and chlorophyll increased during the autumn. The pH values indicating the waterbodies of Sanjiang plain tends to be neutral to alkaline. These pH values were nearly similar to those recorded by Narangarvuu et al. (2014) in the Xindian watershed, Taiwan. According to Grady et al. (2011), at this pH level, the denitrification process performs well and forms nitrate.

DOI: http://dx.doi.org/10.15666/aeer/1702_33873402

The sixteen sites were different in terms of water quality (*Fig. 3*); the first two axes accounted for 62.24% of the cumulative variance. The sites 1, 4 and 6 were characterized by high concentrations of total nitrogen, temperature, chemical oxygen demand, BOD_5 and chlorophyll a. While the sites 9, 11, 12, 15 and 16 were characterized by high concentrations of ammonia-nitrogen, conductivity, chlorine, turbidity and total phosphorus. The site 10 was characterized by concentrations of NO_3^- and pH. There was also a significant positive correlation between pH and NO_3^-.

Relationships between physicochemical variables and macroinvertebrate FFGs

The CCA identified 13 physicochemical variables that were significantly correlated with the benthic macroinvertebrate FFGs within the sites (*Fig. 4*). The first two CCA axes respectively explained 38.27 and 30.58% of macroinvertebrate FFGs variance, with eigenvalues of 0.33 and 0.27.

The 57 benthic macroinvertebrate taxa were categorized as follows: 19 predators, 15 gathering-collectors, 7 scrapers, 6 filtering-collectors, 5 omnivores and 5 shredders. According to the percentage contributions of the various macroinvertebrate FFGs (abundance data) within sites, scrapers dominated the benthic communities and accounted for 38.4% of the total abundance followed by omnivores (17.4%), filtering-collectors (15.7%), predators (11.1%), gathering-collectors (10.0%) and shredders (7.4%). Our findings are similar to the results from Zhang et al. (2014), scrapers were the most widely distributed and made up the largest proportion in streams and rivers of a highly developed region, lake Taihu basin, China. Fu et al. (2016) found that predators made up the most contributions to the FFGs (25 taxa) in the Dongjiang River basin, southeast China. Fu et al. (2016) added that shredders and predators mainly included insects, while scrapers were mainly gastropods.

As shown in the *Fig. 4*, the distribution of scrapers including *Bithynia fuchsiana Cipangopaludina cathayensys, Cipangopaludina ussuriensis, Gyraulus convexiusculus, Lymnaea stagnalis, Semisulcospira amurensis* and *Viviparus chui* at sites 8, 9 and 16, which consume algae and associated material were largely influenced by TP and BOD_5. Mccormick et al. (2004) reported that TP is an important factor controlling the macroinvertebrate FFG communities. Turbidity, conductivity, ammonia-nitrogen, nitrate, chlorine and TN were the most important variables to impact the distribution of the filtering-collector FFGs (*Glyptotendipes cauliginellus, G. pauens, G. tokunagaai, Sphaerium lacustre, Tanytarsus mendex* and *Unio douglasiae*), which collect FPOM from the water column using a variety of filters at sites 3, 11, 12 and 13.

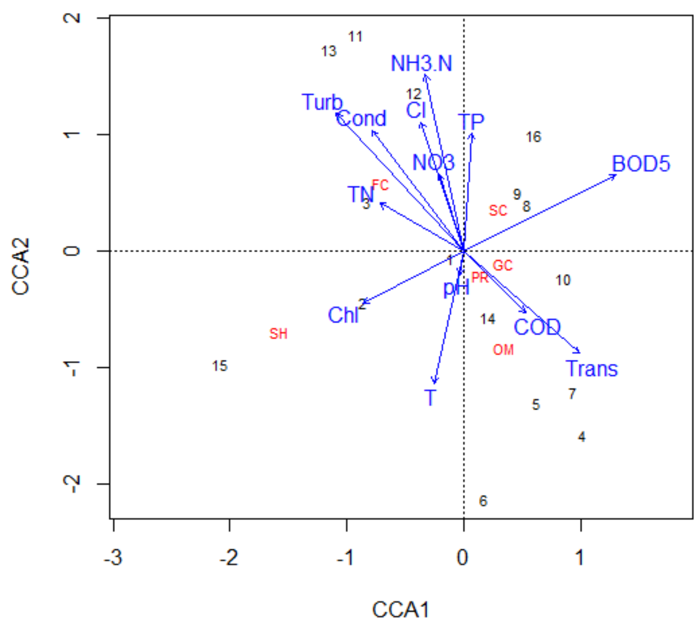

Figure 4. *Canonical Correspondence Analysis (CCA) lot relating the macroinvertebrate FFGs to physicochemical factors. SH = shredders, SC = scrapers, FC = filtering-collectors, GC = gathering-collectors, PR = predators, OM = omnivores*

DOI: http://dx.doi.org/10.15666/aeer/1702_33873402

The distribution of gathering-collectors (*Branchiura sowerbyi*, *Chironomus anthracinus*, *C. circumdatus*, *C. flaviplumus*, *C. kiiensis*, *C. pallidivittatus*, *C. plumosus*, *Dicrotendipes tritomus*, *D. nervosus*, *Einfeldia dissident*, *Leptophlebia* sp., *Limnodrilus amblysetus*, *L. hoffmeisteri*, *Nais simplex* and *Orthocladius roussellae* soponis), predators (*Brachythemis* sp., *Corixa substriata*, *Cryptochironomus defectus*, *Cybister cimbatus*, *Epophthalmia* sp., *Erpobdella octoculata*, *Gastrogomphus* sp., *Glossiphonia lata*, *Gomphinae* sp., *Ictinogomphus* sp., *Kirkaldyia deyrollei*, *Parabdella quadrioculata*, *Parachironomus arcuatus*, *Propsilocerus* sp., *Ranatra chinensis*, *Sinictinogomphus* sp., *Somatochlora* sp., *Tanypus formosanus* and *Whitmania laevis*), and omnivores (*Chinonomus lugubris*, *C. riparius*, *C. salinarius*, *Leander modestus* and *Stictochironomus maculipennis*) at sites 4, 5, 6, 7, 10 and 14 was strongly associated with transparency and COD_{Mn}. Fu et al. (2016) found that many gathering-collectors are tolerant to disturbance and organic pollution, such as *Tubifex* spp., *Limnodrilus* spp., *Branchiura* sp., and *Chironomids*, which are abundant in polluted rivers. Niba and Sakwe (2018) suggested that benthic macroinvertebrate species populations differently respond to disturbance regimes, and many species have various habitat requirements at each stage of their developmental life cycle (Simaika and Samways, 2011).

The physicochemical factors, such as chlorophyll a, pH and temperature correlated with the composition of shredders (*Cricotopus anulator*, *C. trifasciatus*, *Phryganea* sp., *Polypedilum bubifer* and *P. nubeculosum*) which consume leaf litter or other CPOM, were ordinated on the negative part of CCA axis 1 (*Fig. 4*). Jonsson et al. (2001); Fu et al. (2016) noted that shredders are an important ecological guild in headwater streams, playing a vital role in the process of leaf litter decomposition. They facilitate the release of nutrients into stream ecosystems and provide other invertebrates with food sources in the form of coarse particulate organic matter (CPOM) and fine particulate organic matter (FPOM) (Li and Dudgeon, 2008, 2009; Yule and Gomez, 2009). Nutrient loads could influence macroinvertebrate community structure as a consequence of increased food availability where nutrients stimulate primary production (Gao et al., 2011; Wu et al., 2011; Zhang et al., 2014). Niba and Sakwe (2018) concluded that habitat patch level management along the aquatic ecosystem should aim at preserving sufficient indigenous vegetation categories (riparian, aquatic macrophytes and algae), especially during summer season when habitat requirements are optimal for most growth stages of benthic macroinvertebrate species. The results of Wang and Tan (2017) showed that macroinvertebrate assemblage variations were better explained by water quality factors than land use based on variance partitioning procedures.

Conclusion

During the three sampling seasons in the wetlands of Sanjiang plain, we recorded 57 taxa of benthic macroinvertebrates belonging to 6 FFGs, including predators, gathering-collectors, scrapers, filtering-collectors, omnivores and shredders. Insects were the most species-rich group, with 39 taxa and occurred at all sites during spring, summer and autumn. We found higher numbers of macroinvertebrate species and individuals in spring. The results of this study contributed the interesting information about benthic macroinvertebrates FFGs and their relationships with physicochemical parameters in the wetland ecosystems. It was found that predator and scraper FFGs may serve as potential candidates for assessing the health of wetlands. These findings might recommend a need for conservation and management to be targeted in the wetland environments. We

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_33873402

suggest that further research should be complemented on the composition and structure of macroinvertebrate fauna with an evaluation of density and biomass of FFGs to observe changes from a functional perspective and to obtain an overview on the wetlands of Sanjiang region.

Acknowledgements. This work was supported by a fund from the Ministry of Science and Technology, National Key Research and Development Project (Fund N°. 2016YFC0500406). The authors thank the Ministry of Science and Technology for the realization of this work. Our thankful feelings are also addressed to Wenjie Bai from Sanjiang National Nature Reserve, who helped us collect samples during field work.

THE EFFECT OF ANNUAL TEMPERATURE CHANGES ON SOME IMPORTANT QUALITY TRAITS OF SOYBEAN *(GLYCINE MAX* L.*)* GENOTYPES

ARSLAN, H.

Field Crops Department, Faculty of Agriculture, Siirt University, Siirt, Turkey
(e-mail: huarslan@siirt.edu.tr)

(Received 19th Dec 2018; accepted 14th Feb 2019)

Abstract. The study was conducted to investigate the changes in yield, fat and protein ratios and micronutrient concentrations of 9 soybean *(Glycine max* L.*)* lines and 2 standard varieties in semi-arid climatic conditions during soybean production seasons in 2012 and 2013. The experiments were established in a randomized block design with three replicates and were started on 08 May and 06 May in 2012 and 2013, respectively. The plot length was 6 m and each plot had 4 rows. The interrow spacing was 70 cm and intra row spacing was 5 cm. Yield, fat and protein ratios and micronutrient concentrations in seeds of soybean varieties/lines were different in two growing seasons. Average temperature during the first growing season was higher than in the second season. The difference in temperature significantly affected the yield, fat and protein ratios and micronutrient concentrations in seeds. The Ca, Cu, Fe, K, Mg, Na P and Zn concentrations of soybean seeds in the first year were higher than those obtained in the second year. The differences in nutrient concentrations between years indicated the effects of temperature differences on mineral compositions of seeds in addition to the yield, fat and protein ratios.
Keywords: *micro element, yield, mineral composition, climate factors, fat and protein ratios*

Introduction

Soybean (*Glycine max* L.), which has an important place in human and animal nutrition, is an industrial legume crop with an average of 18-22% fat, 38-56% protein in seeds, growing upright, pile rooted, annual, summer crop and grown as main or second crop (Baydar and Erbaş, 2014). Soybean has a nitrogen-fixing symbiotic life with *Rhizobium japonicum* bacterium, therefore it is an extremely important plant to improve the physical and chemical structures of soils. Soybean is used as soybean oil, soybean sprout and flour in human nutrition as well as in the production of dough products, baby foods, confectionery products, hypoallergenic milk and dairy products, special dietary products, artificial meat products, dry/cold ready food blends. Soybean is used in the production of insecticides as well as to produce wax, soap, candle oil, biodiesel, glue, paper raincoats and plastic materials. Soybean pulp contains 40 to 46% protein, 1 to 6% fat, 30 to 31% carbohydrate and 5 to 6% cellulose, and is used in animal feeding (Singh and Shivakumar, 2010). Studies on soybean demonstrated that soybean is protective against cancer and individuals fed with soya and soy products are less likely to develop different types of cancers. Soybean has also positive effects on prevention of many other diseases (menopause, cholesterol, osteoporosis, cardiovascular and chronic diseases - coronary heart diseases) (Uesugi et al., 2002; Lovati et al., 1987; Messina, 1999; Xiao, 2008; Brouns, 2002).

Soybean is the most widely produced oilseed plant in the world (USDA, 2018). Although 30 °C temperature is considered optimum for dry matter accumulation of soybean plants (Raper and Kramer, 1987), soybean is grown in regions of temperate and tropical climate with various environmental conditions (Hasanuzzaman et al., 2016). According to the oldest records known in China, soybean had been known by mankind

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34033414

since 11th century or a little earlier time (Hymowitz and Shurtleff, 2005). Soybean, originated from China, was brought from the old world to the new world in the middle of the 17th century, and began to gain importance all over the world in the early 20th century. The introduction of soybean to Turkey coincides to the World War I (Arıoğlu, 2007). The soybean in 2016 has been cultivated on approximately 121 million ha land throughout the world, and 335 million tons of soybean have been produced (FAOSTAT, 2017). Soybean consumption per person in the world is 40.64 kg year^{-1} considering that entire soybean produced in the world have been consumed by human being. However, a large part of the produced soybean is used in animal feeding. In Turkey, 150.000 tons of soybean have been produced in 34.000 ha land. Soybean ranks 4th with 1,073,757 tons among imported agricultural products by Turkey and processed soybean products ranks the 3rd with 1.0867.4 million tons (FAOSTAT, 2017).

Studies on cultivation and adaptation of soybean, which is important as a raw material in human nutrition and in the industry, are also of great importance. Studies indicated that climate, soil and other environmental factors have significant influences on yield and quality traits of soybean (Jumrani and Bhatia, 2018; Shah and Paulsen, 2003; Hasanuzzaman et al., 2016). This study was conducted to determine the yields, fat and protein ratios and micronutrient contents of different soybean genotypes grown under semi-arid climatic conditions and to investigate the relationships among soybean characteristics determined.

Materials and methods

The study was conducted during the main crop soybean production season in 2012 and 2013 using 2 standard soybean varieties (Ataem-7 and Türksoy) and 9 advanced soybean lines (6, 11, 13, 17, 24, 27, 834, 1021 and 1022) as plant materials. The pedigrees of lines were given in the *Table 1*.

Table 1. *Pedigrees of lines used in the study*

The field experiments were carried out in Gündaş research station of GAP (Southeast Anatolian Irrigation Project) Agricultural Research Institute during soybean growing seasons of 2012 and 2013 in different plots. Gündaş station is located at 36044’ 05.22 N and 380 48’ 49.76 E within the borders of Akçakale town of Sanliurfa province, Turkey (*Fig. 1*). The summers are dry and hot, and the winters are relatively warm. The average

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34033414

temperature in July and August is 40 °C, while in some nights the temperature goes above 30 °C (Turkish State Meteorological Service, 2017).

***Figure 1.** Location of experimental site within GAP Agricultural Research Institute*

The experiments were conducted in 2012 and 2013 at the same locations. Particle size distribution of soils were determined by water saturation method (Richards, 1954). Soil reaction (pH) was measured in saturation paste with a pH meter (Richards, 1954). Calcium carbonate content of soils was analyzed by using Scheibler calcimeter method (Çağlar, 1949), plant available phosphorus content was determined according to Olsen method (Olsen et al., 1954). Available potassium was extracted using 1 N ammonium acetate (pH = 7.0) solution (Pratt, 1965). Organic matter content of soils was determined by using modified Walkey-Black wet combustion method (Nelson and Sommers, 1982). Boron concentration of soils was determined by azomethine-H method (John et al., 1975). Micronutrient concentrations were extracted using diethylene triamine penta acetic acid (DTPA) and determined by an atomic adsorption spectrophotometer (Perkin Elmer Analyst 800) (Lindsay and Norvell, 1978). The results were presented in *Tables 2* and *3*.

***Table 2.** Soil characteristics of experimental sites*

Years	Water saturation (%)	pH	EC (dS m^{-1})	$CaCO_3$ (%)	P_2O_5 (kg ha^{-1})	K_2O (kg ha^{-1})	Organic matter (%)
2012	64	7.53	0.51	26.6	56	2490	2.32
2013	69	7.47	0.89	24.3	51.9	3000	2.45

***Table 3.** Micronutrient concentrations of soils in experimental sites*

Years	Cu	Fe	Mn	Zn	Ca	Mg	Na	K	B
	(mg kg^{-1})								
2012	1.461	9.386	26.79	0.508	7811	464.9	79.27	884.8	1.041
2013	1.915	9.572	15.3	0.641	7383	942.8	169.8	807.7	1.693

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34033414

Soils were neutral in reaction (Ülgen and Yurtsever, 1995), non-saline (Richards, 1954), highly calcareous, low in phosphorus, high in potassium and moderate in organic matter content (Ülgen and Yurtsever, 1995). Soil water saturation (%), pH level, salinity (EC dS m^{-1}), calcium carbonate (%), plant available phosphorus (P, kg ha^{-1}), available potassium (K, kg ha^{-1}) and organic matter content of soils in experimental sites were not significantly different from each other (*Table 2*).

Concentrations of soil Cu, Mg, Na and B in the second year were significantly higher than that of the first year, while Fe and Zn concentrations were slightly higher in the second year. In contrast, Mn and Ca concentrations of soils in the second year were lower compared to that of the first year. Soils contained sufficient amount of Cu, Fe and Mn however, Zn concentration of soils was at critical level (Lindsay and Norvell, 1978). Boron concentration of soils was sufficient (Sürücü et al., 2018).

The average temperatures in June, July and August of 2012 which are the vegetative and generative development periods of soybean were higher compared to the temperatures in 2013 (*Table 4*).

*LTA: long-term average (1927-2013)

The experiments were established in a randomized block design with three replicates on May 08 and May 06 in 2012 and 2013, respectively. The plot length was 6 m and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34033414

each plot had 4 rows. The interrow spacing was 70 cm and intra row spacing was 5 cm. Irrigation, hoeing and all other maintenance works of experimental sites have been carried out as needed. Plants were harvested between October 01 and 10, 2012 in the first year and October 05 and 10, 2013 in the second year. *Rhizobium japonicum* bacterial inoculation could not be carried out during planting. Soybean seed yield, fat ratio, protein ratio and seed micro nutrient concentrations which have significant effect on soybean seed quality (Kacar and İnal, 2008) were determined.

The data obtained were subjected to analyses of variance using JUMP statistic software package and average values for each of traits were grouped according to LSD test. The correlation test was also conducted to determine the relationship between the characteristics examined. The correlation test was also performed using JUMP statistical software. Since the study was not carried out under controlled climatic conditions, the effects of environmental factors were not analyzed.

Results

Average yield (kg ha^{-1}), fat ratio (%) and protein ratio (%) of varieties/lines were given in *Table 5*. Yield values (kg ha^{-1}) of different soybean varieties/lines in 2012 were significantly different ($p < 0.01$), while fat and protein ratios were not significantly different. Yield of varieties/lines varied between 2044.30 (line 11) and 2950.00 kg ha^{-1} (line 6). The highest fat ratio was obtained with line 1022 as 18.18%, while the lowest fat ratio (15.44%) was obtained with line 13. The highest protein ratio (37.46%) was obtained with line 13 and the lowest protein ratio (34.73%) was with line 24. Yield and fat ratio obtained for soybean varieties/lines in 2013 were significantly different ($p < 0.01$), while protein ratio values did not significantly change among soybean varieties/lines. Yield values of varieties/lines in 2013 ranged from 2892.90 kg ha^{-1} (line 24) to 4464.60 kg ha^{-1} (line 11). The fat ratio of varieties/lines varied between 18.49% (line 13) and 22.56% (line 1021). The highest protein ratio (37.43%) was obtained with line 13 and the lowest ratio was (34.30%) with line 1021.

Average soybean seed B, Ca, Cu, Fe, K, Mg, Mn, P and Zn concentrations in 2012 were significantly different ($p < 0.05$) among varieties (*Table 6*). In contrast, Na concentration of seeds was not significantly different. The concentrations of B, Ca, Cu, Fe, Mg, Mn, P and Na in 2013 were not significantly different, while Zn was significantly different ($p < 0.01$). The differences in Zn response is probably resulted from the differences in genetic structures of the genotypes. Boron concentration in seeds of varieties ranged from 2.11 to 10.04 mg kg^{-1} in 2012. Boron concentration of line 1021 was higher than the rest of the varieties/lines. Calcium concentration of varieties was between 1800.33 and 2601.00 mg kg^{-1}. Calcium concentrations of line 1021 and Ataem-7 variety were similar to each other and higher than other lines/varieties investigated. Cupper concentration of lines/varieties ranged from 19.80 to 26.58 mg kg^{-1}. Cupper concentrations of Türksoy variety and lines 27 and 1021 were similar to each other and higher compared to the other lines/varieties. Average seed Fe content was 65.81 mg kg^{-1} and the highest Fe content was obtained with line 1021. Potassium concentration in seeds of lines/varieties varied between 33798.33 and 38106.67 mg kg^{-1} and the highest K concentration was obtained with line 1021. Magnesium concentration in seeds of lines/varieties ranged from 1598.33 to 1901.67 mg kg^{-1} and line 1022 had the highest Mg concentration. Manganese concentration in seeds varied between 26.26 and 51.41 mg kg^{-1} and Mn concentrations of lines 1022 and 6 were similar to each other and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34033414

higher than the rest of the lines/varieties. Sodium concentration of lines/varieties ranged from 79.49 to 119.63 mg kg^{-1}. The highest Na concentration was obtained with line 13. Phosphorus and Zn concentrations of lines/varieties ranged from 3627.667 to 4825.33 mg kg^{-1} and from 29.74 to 46.93 mg kg^{-1}, respectively Phosphorus concentration of line 13 and Zn concentration of line 834 were higher compared to the other lines/varieties investigated. Boron concentration of all lines/varieties in 2013 increased, while Ca, Cu, K, Mg, Na and P concentrations decreased relative to that of 2012. The Fe concentration of Gapsoy-16 increased in the second year, while decreased in all other lines/varieties. The Mn concentration of lines 1022, 6 and 1021 decreased relative to the first year, whereas Mn concentration of other lines/varieties in the second year increased. The Zn concentration of lines 1022 and 24 increased in the second year, while decreased in other lines/varieties.

Relationship between grain yield and micronutrient concentrations of lines/varieties

Correlation analysis was conducted to reveal the relationship between yield, fat ratio, protein ratio and seed micronutrient contents. In the first year, soybean yield had a significant positive correlation with K concentration and negative relationship with Cu and Fe concentrations. The relationship can be attributed to plant growth and explained by the dilution effects of plant nutrients. Although not statistically significant, yield had negative relationships with fat ratio, protein ratio, Ca, Mg, Mn and P concentrations, while yield had positive relationships with B, Na and Zn concentrations (*Table 7*). In the second year, yield had non-significant negative relationship with Ca, Fe, Na and P concentrations while yield had positive relationship with fat ratio, protein ratio, B, Cu, K, Mg and Mn concentrations. Yield had significant negative relationship with Zn concentration. The correlation analysis indicated that soybean yield had positive relationship with B and K contents of seeds in both years, while yield had significant positive relationship with Ca, Fe and P concentrations of seeds.

Relationship between micronutrient contents of soybean seeds and fat and protein ratios

The relationship between fat ratio and Na, B, K and Zn contents in 2012 was negative, which was only statistically significant for Na content. In contrast, correlations between fat ratio and Ca, Cu, Fe, K, Mg, Mn, Na, P and Zn concentrations were positive, which was only statistically significant for Mg content. Positive correlation between fat ratio and Mg content indicated that increasing Mg content in soybean seed favors the fat accumulation in seed. The relationship between fat ratio and Ca, Cu, Fe, K, Mg, Mn, Na, P and Zn contents in the second year was negative, which was statistically significant for Ca and Fe contents. Fat ratio had positive relationship between B content in the second year and the relationship was not statistically significant.

DOI: http://dx.doi.org/10.15666/aeer/1702_34033414

The relationships between protein ratio and micronutrient contents of soybean seeds were not statistically significant in both 2012 and 2013. Protein ratio had positive relationship with B, Mn and Na in the first year and negative relationship with Ca, Cu, Fe, K and Mg contents. In the second year of the study, non-significant positive relationship was obtained between protein ratio and Ca, Fe, Mg and Mn contents, while the relationship was negative for B, Cu and K contents.

Discussion

Average seed yield obtained in the first year (2492.00 kg ha^{-1}) was lower than that of the second year (3943.20 kg ha^{-1}). Higher maximum, minimum and total temperatures during growing season (June, July, August, September) of the first year compared to the second year may cause lower seed yield in the first year (*Table 3*). Increasing temperature during growing season leads to water stress in soybean plants (Jumrani and Bhatia, 2018; Shah and Paulsen, 2003; Kırnak et al., 2010; Dornbos and Mullen, 1992), which has negative impact on fertilization of the flowers and also causes the flowers to fall down.

The results revealed that genetic structure of lines/varieties, temperature stress and micronutrient contents of soils have significant effects on soybean yield and micronutrient content of seeds. Significant impacts of environmental factors on chemical composition of soybean seeds in addition to genetic structures of varieties have also been reported by Jumrani and Bhatia (2018) and Shah and Paulsen (2003).

Fat ratio is also an important trait of soybean along with high yield. Differences of genotypes in response to environmental factors indicated that fat ratio of seeds was significantly affected by environmental factors in addition to the genetic characteristics. High temperatures in 2012 caused decreasing the fat ratio of seeds in addition to the decline in yield. Similar results have been reported from studies conducted to investigate the effects of environmental factors on fat ratio of soybean seeds (Piper and Boote, 1999; Wang et al., 2015).

The difference in protein ratio between years was not significant, though protein ratio obtained in the first year was higher than the second year. In contrast to yield and fat ratio, protein ratio did not respond to the changes in temperatures, and protein ratio did not change with changes in temperatures. However, negative correlation between soybean yield and protein ratio in seed indicates that protein ratio decreases as soybean yield increases. Therefore, impact of environmental factors on soybean yield indirectly affects the protein ratio of seed, which is not directly affected by the environmental factors. Similar results have also been reported by Rotundo et al. (2009) and Kumar et al. (2006).

The Ca, Cu, Fe, K, Mg, Na P and Zn concentrations of soybean seeds in the first year were higher than those obtained in the second year. The differences in nutrient concentrations between years indicated the effects of temperature differences on mineral compositions of seeds in addition to the yield, fat and protein ratios. Contrasting results have been reported by studies investigating the effects of temperature differences during growing period on mineral composition of seeds. Kresović et al. (2017) reported significant effect of temperature on mineral composition, while Gibson and Mullen (2001) found increases and decreases in nutrients of soybean seeds. Researchers also indicated that differences in temperatures have indirect effect on quality of food produced by using soybean (Lim et al., 1990; Gibson and Mullen, 2001).

Conclusion

Yield, fat ratio, protein ratio and seed mineral nutrient composition of soybean seeds were determined to investigate the performances of different soybean genotypes grown under arid conditions in two different growing seasons (2012-2013). Yield, fat ratio, protein ratio and some of important mineral nutrients of soybean lines/varieties obtained in two different seasons were different from each other. Temperatures over optimum temperature requirements of soybean had negative effect on soybean yield. High temperatures had also negative impact on fat ratio which is an important quality criterion for soybean, while protein ratio was not directly affected by high temperatures. The results also revealed that micronutrient contents of soybean seeds have been affected by the increasing temperature.

Significant impact of growing conditions on yield and quality criteria of soybean indicates the necessity to develop regional varieties. Therefore, further studies under controlled climatic conditions may increase the chance of success. The adaptation studies also should be carried out to determine the appropriate varieties prior to the initiation of soybean production in a region.

Acknowledgements. This study was conducted by the supports of General Directorate of Agricultural Research and Politics affiliated to the Turkish Republic Ministry of Food, Agriculture and Livestock within the scope of Soybean Breeding Project (TAGEM/TA/09/05/01/0014). Soybean line 11 was registered as GAPSOY-16 in 2016 by the Directorate of Seed Registration and Certification Center affiliated to the Ministry of Food, Agriculture and Livestock of Turkey.

Abstract. This study examined the level of damage caused by pine shoot moth (*Rhyacionia buoliana* (Den. & Schiff) between 2014 and 2016 in the seed orchards of Camiyanı Black Pine (*Pinus nigra* Arnold. *subsp. pallasiana* (Lamb.) Holmboe). When the variance analysis (ANOVA) was applied, and observations and counts of the seed orchard were evaluated, a statistically significant difference was found between the clones in terms of number of individuals affected by $P < 0.001$. When Duncan Range Test results were examined, 20 groups were formed in total, with a $P < 0.05$ confidence level in terms of the average number of individuals damaged by the pine shoot moth. In this respect, it was determined that the clones which had the highest damage in the seed orchard number 70, clones 21, 25, 26 and 29 were damage the most, while the clones that had the least amount of damage are clones 2, 6, 8 and 23. The differences in the average number of clones which the pine shoot moth damage were investigated. When the ANOVA results were examined, it was determined that there was a statistically significant difference in $P < 0.001$ confidence level between 2014, 2015 and 2016 in terms of the mean number of clones exposed to pine shoot moth damage. There was no significant difference between the blocks in terms of the mean number of clones which the pine shoot moth damaged. When the results of regression analysis were analyzed, strong relationships were found between clone and number of damaged individuals and the number of clones damaged by pine shoots for years.

Introduction

Forests are special ecosystems that carry out important tasks in protecting the health and ecological balance of the products and services they provide. Therefore, it is important to ensure that the forest resources develop and shape under completely open field conditions, and are protected from harmful biotic and abiotic factors, to ensure the future of humanity. First of all, forests play an important role in the prevention of global warming by mitigating carbon emissions in particular, which is the most relevant environmental problem of our day. Forests transform carbon dioxide through photosynthesis, and store carbon. Thus, it creates an important balance between carbon dioxide and oxygen gases under natural conditions. For example, a well-developed 100-year-old beech can absorb up to 40 million m^3 of air through photosynthesis, turning 1200 m^3 of carbon dioxide in this air to 6 tonnes of carbon as a biochemical transformation. On the other hand, it is reported that a forest can bind 13-30 tons of carbon dioxide for annual compulsory dry biomass production (Görücü and Eker, 2009). However, in today's modern forestry approach, forest resources being used as a multi-faceted collective of services (recreation, erosion prevention, hydrological

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34153426

resources, non-wood forest products etc.) are decreasing rapidly both in our country and in the world. As a matter of fact, according to the latest statistical figures, it is reported that the average annual forest loss in the less developed and developing countries has reached approximately 18% of the world total forest area (FAO, 2016). Our country has valuable ecological, economic and silvicultural forest ecosystems on different elevation levels in terms of tree species type and stand structure characteristics with the effect of different ecological conditions (Saatçioğlu, 1969; Ata, 1995). However, these valuable forest resources, which are estimated to be 22 million hectares in our country, have been significantly damaged by the impact of biotic and abiotic factors such as inadequate technical applications, illegal cuttings, fires, storms, insects and other harmful factors, (GDF, 2016). On the other hand, as a result of the damage caused by these factors in forest resources, 6.7% of amphibians, birds, mammals and reptiles in the forests, approximately 3.9% of plant communities, including endemic plants in Turkey are threatened (Kırış and Toprak, 2009). In this context, preserving forest resources is obligatory for the products and services obtained from these sources and for the protection of biodiversity. Successful natural and artificial regeneration promoting methods and afforestation studies are needed to achieve this (Genç, 2004). For this purpose, the use of seedlings produced from genetically modified seed sources is very important in terms of increasing the quality and health of new forests (Tunçtaner, 2007). In this respect, these seed sources are of the highest genetic quality. Seed orchards are important facilities established by high amounts labor, time and money (Ürgenç, 1982). However, these seed sources need to be protected against biotic and abiotic factors to ensure the continuity of genetically improved seed yields from seed orchards. One of the factors that have a negative impact on seed orchards is insect damage. It can reduce seed production by up to 50% especially in seed orchards with primary pests (Tunçtaner, 2007). The pine shoot moth (*Rhyacionia buoliana* (Den. & Schiff) is one of these primary pests that cause significant damage (Çanakçıoğlu, 1993). Especially *Pinus contorta* var. *latifolia* orchards in Sweden, this pest was determined that it was one of the pest caused significant damage (Lindelöw and Björkman, 2001).

In this study, wide area of usage and economically valuable ecotype of the Camiyanı Anatolian black pine (*Pinus nigra* Arnold. subsp. *pallasiana* (Lamb.) was used. The level of damage on the clones was examined both years, and the most resistant clones were determined.

Materials and methods

The seed orchard is located in Karabük-Yenice region and is established with cuttings taken from Bakraz region in Yenice of black pine ecotype called Camiyani black pine (*Fig. 1*). 30 saplings were taken from Bakraz provenance and were planted with an 8 × 8 m spacing distance in 1990 in 70 numbered divisions. The seed orchard has a size of 11.3 ha and its elevation is 100 m with a land slope of 10%. The general exposure of the seed orchard is southern. The soil structure in the seed orchard has clay texture and the pH varies between 6.06 and 7.80 (Ertekin, 2006). The average annual temperature in the research area is 12.8 °C, with a maximum temperature of 42.8 °C, and a minimum temperature of -18.6 °C, while the average annual precipitation is 1040.5 mm with an average relative humidity of 73.6% (Anonymous, 2016).

Figure 1. *Research area*

The seed orchard, which forms the research area, consists of 30 clones and 3 blocks. In this context, in order to determine the damage of pine shoot moth in each block in accordance with the purpose of the study, individuals belonging to all clones were examined. In the research, it was accepted that insect damage occurred in clone in case of damages in single shoot of trees representing clone. In this context, in the 3 blocks of seed orchard, observations and counts were started to be made with the start of vegetation period randomly in the individuals belonging to all clones in the 3-year period covering 2014-2016, and the individuals whose pine shoot moth damage was detected were separated each year by marking a different color with a spray paint and in this way, the damage occurred in both years is determined and the damage at the level of clones were tried to be determined. In this respect, clones and individuals were identified, while any damage in the height of the tree in a single exile was determined that the clone was considered damaged. Likewise, the same method was applied in similar studies on this subject (Fabre et al., 2004; Turgeon et al., 2004). Thus, the damage caused by the pine shoot moth in the seed orchard has been revealed in the most delicate and detailed manner.

In the study, various statistical analysis methods were used to reveal the pine shoot moth damage in terms of clones, years and blocks in the seed orchard. For this purpose, Kolmogorov-Simirnov (K-S) test was used to determine whether the data obtained from the determinations and counts carried out in the seed orchard during the 3-year period covering 2014-2016. Then, a multi-way ANOVA was applied in order to compare the pine shoot moth losses that occurred due to clones, years and blocks of seed orchard. In the case of a statistically significant difference due to any factor as a result of the variance analysis, Duncan Test was performed, observation years and blocks were required. For this purpose, the mean of the data obtained after observations and determinations for pine shoot moth damage was used (Ercan, 1997). In addition, stepwise regression analyzes were applied to correlate the number of clones with the pine shoot moth. All statistical analyzes were conducted with SPSS 22.0 Statistical Package Program.

Results

Damages at the clones level

Figure 2 shows the distribution of the pine shoot moth damages in 2016 as a result of observations and determinations in the seed orchard where the research was carried out.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34153426

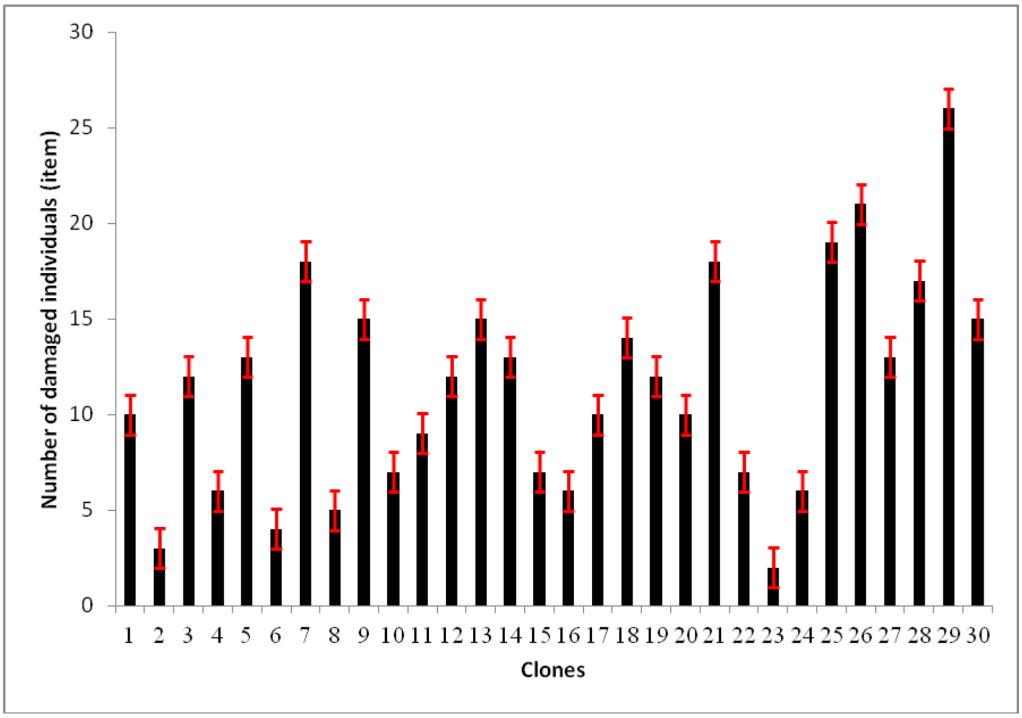

Figure 2. *Distribution of number of damaged individuals by clones*

As a result of observations and determinations carried out in 2016, it has been determined that the average number of individuals exposed to pine shoot moth damages is between 2.3 and 26.2. In this context, variance analysis was performed to determine whether there was a statistically significant difference between clones in terms of the average number of individuals in which insect damage occurred (*Table 1*).

Table 1. *Results of ANOVA*

Variance sources	Sum of squares	df	Mean square	F	Sig.
Between clones	2857.567	29	98.537	5495.639	*0.000****
Within clones	1.076	60	0.018		
Total	2858.643	89			

***P < 0.001 significance level

When ANOVA results in *Table 1* were evaluated, it was determined that there was a statistically significant difference between the clones in terms of $P < 0.001$. In this context, Duncan Range Test was applied to group clones in terms of the number of individuals in which the pine shoot moth was damaged (*Table 2*).

When the Duncan Test results in *Table 2* were examined, 20 groups were formed in total $P < 0.05$ confidence level in terms of the mean number of individuals damaged by pine shoot moth. In terms of the number of injured individuals, clone 29 constitutes the first group alone and clone 23 constitutes the first group. In this respect, it can be said that the clones having the highest damage in the seed orchard 70 are the clones which are the most damaging pine shoot moth.

Damage level according to years

The change in the mean number of clones that the pine shoot moth has caused damage in the seed orchard in the period of 2014-2016 in which the research was carried out is shown in *Figure 3*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34153426

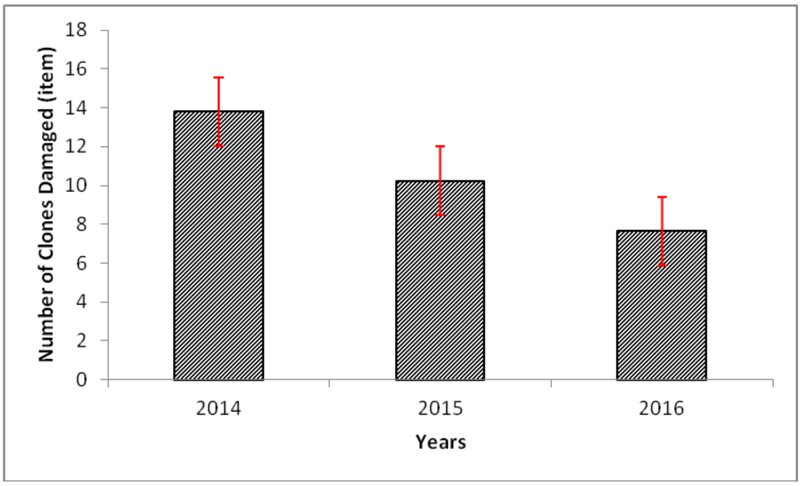

Figure 3. *Mean number of clones damaged over the years*

According to *Figure 3,* there is decreasing trend towards 2014 from the year 2016, when the study was conducted in terms of the average number of clones in which pine shoot moth was damaged. According to this, the average number of clones was 13.78 in 2014, 10.23 in 2015 and 7.64 in 2016. Variance analysis was performed to determine if there were any statistical differences in terms of the average number of clones in which pine shoot moth damage occurred (*Table 2*).

Table 2. *Results of ANOVA*

Variance sources	Sum of squares	df	Mean square	F	Sig.
Between clones	2996.314	2	97.271	6987.118	*0.000****
Within clones	0.075	87	0.023		
Total	2996.389	89			

****P < 0.001* significance level

When the ANOVA results in *Table 2* were examined, it was determined that there was a statistically significant difference in $P < 0.001$ confidence level between 2014, 2015 and 2016 in terms of the mean number of clone number exposed to pine shoot moth damage. In this context, Duncan Range Test was applied at $P < 0.05$ confidence level and the results are given in *Table 3*.

Table 3. *Results of Duncan range test*

Years	Number of clones damaged	Significance level
2014	13.78[a]	
2015	10.23[b]	***P < 0.05***
2016	7.64[c]	

As a result of the Duncan Range Test, 3 different groups have emerged in terms of the average number of clones in the $P < 0.05$ confidence level. Accordingly, 2014 was the first group in which the most damages occurred during the 3-year period during

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34153426

which the survey was carried out, while this group was followed by the second group formed by 2015 alone, and 2016 was the third group alone (*Table 3*).

Damages level according to blocks

The seed orchard, which forms the research area, consists of three random blocks of experimental design. Therefore, investigations and evaluations have been made in terms of the mean number of clones in which pine shoot moth has caused damage. In this context, the change in the average number of clones that have been damaged in 2016 by blocks is shown in *Figure 4*.

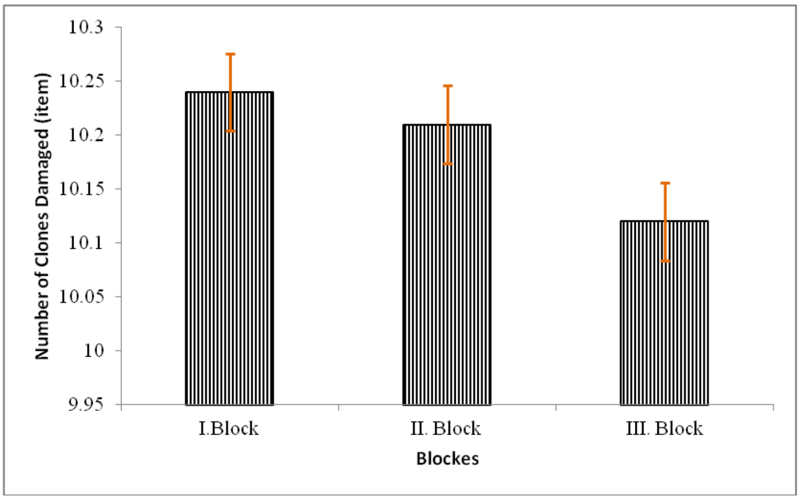

Figure 4. *Mean number of clones damaged by blocks*

When *Figure 4* is examined, it has been determined that there is a tendency towards the decrease in the number of average clone numbers that have been damaged by pine shoot moth as of 2016. According to this study, the average number of damaged clones determined in block I 10.24, block II 10.21 and block III 10.12, respectively. In this context, ANOVA was performed to determine whether there were any statistically significant differences in terms of the mean number of clones exposed to pine shoot moth damage between the blocks (*Table 4*).

Table 4. *Results of ANOVA*

Variance sources	Sum of squares	df	Mean square	F	Sig.
Between blocks	1023.017	2	0.021	0.001	*0.998*^{ns}
Within blocks	0.042	87	32.857		
Total	1023.059	89			

ns: non significant

According to the analysis of variance in *Table 4*, it was determined that there were no statistically significant differences between the blocks in terms of the average number of clones in the pine shoot moth.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34153426

The relationships between the variables examined in the research

In the research, the level of the damage caused by the pine shoot moth 70 in the division seed orchard was determined. For this purpose, detection, counting and observations were made in 3 blocks of seed orchard and 30 clones in the 3 year period of 2014-2016. As a result of detection, counting and observations performed; the number of individuals affected by the clone, the number of clones in which the damage occurred and the number of blocks and the number of clones damaged were also investigated (*Table 5*). In this respect, stepwise regression analysis method was used.

Table 5. *The type, model and relationship degrees of the relationships between variables*

Variables	Type of relation	Model	R^2
Number of clone-damaged individuals	Second order polynomial	$y = 0.0171x^2 - 0.2474x + 9.9537$	0.95
Years-damaged clones	Linear	$y = 3.07x + 4.41$	0.99
Blocks-damaged clones	Linear	$y = -0.06x + 10.31$	0.92

When the results of the double regression analysis in *Table 5* are examined; a second-order polynomial relationship was found to be positively influenced by the number of individuals affected by the clone. On the other hand, the relationship between the clone and the number of individuals affected by the clone was found to be quite strong ($R^2 = 0.95$). In the study, the relationship between the number of clones damaged by pine shoot moth factor and the years has been investigated. According to this analysis, it was found that there was a strong positive correlation between these two variables ($R^2 = 0.99$) and a positively effective linear relationship. Another double relationship examined in the study is between the blocks and the number of clones damaged by the pine shoots moth. As a result of the study, it was determined that there was a strong ($R^2 = -0.92$) and a negative effective relationship between these two variables.

Discussion

In this study, pine shoot moth damage in Yenice-Bakraz provenance of seed orchard which is located in Bartın region were investigated. In research process, there are no determinants of natural factors affecting insect damage. As a result of the determinations and counts conducted between 2014 and 2016, the pine shoot moth has different effects on 30 clones that constitute the seed orchard. For this purpose, according to 2016 data, the average number of individuals exposed to pine shoot moth damage was found to vary between 2.3-26.2 units (*Fig. 2*). As a result of the variance analysis performed in this context, a significant difference was found between the clones in terms of the number of individuals affected by $P < 0.001$ (*Table 1*). As a result of this study, 30 clones of $P < 0.05$ confidence level were sequenced and grouped according to the number of individuals affected by pine shoot moth (*Table 2*). Accordingly, a total of 20 groups were formed as a result of Duncan Range Test. In terms of the number of damaged individuals, clone 29 constitutes the first group alone and clone 23 constitutes the first group. In this respect, it can be said that the clones which have the highest damage in the seed orchard 70 number division which is the research subject of the pine shoot moth are clones with 21, 25, 26 and 29 clones and the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34153426

clones with the least damage are clones with 2, 6, 8 and 23 (*Table 2*). As a matter of fact, there is a *Pinus contorta* var. *latifolia* plantations in Sweden have caused significant damages, and in this context, the clonal production of the species and the need to determine the origin of local clones resistant to these and similar pests are emphasized (Lindelöw and Björkman, 2001). On the other hand, a study conducted at Bosnian Pine (*Pinus helderichii* H. Christ. (1863) syn. *Pinus leucodermis* Ant. (1864)) found that pine shoot moth caused different rate of damage in the natural distribution area of the Bosnian pine and the seed sources established at the origin level (Vendramin et al., 2003). A study conducted in New Zealand on *Pinus radiata* found that some insect species, such as pine shoot moth, as well as snow, frost and drought damages caused significant damages in plantations and genetically modified seed sources; therefore, it has been reported that clones and origins are obtained from these damaging factors by intra-site crossover studies (Dungey et al., 2003). In this context, in the light of the results obtained from this research carried out in the Camiyanı black pine, it can be said that the clones, which the pine shoot moth has created the least damage during the 3-year period, constitute an important potential in terms of resistance improvement studies against this pest. There are significant benefits in monitoring the temporal course of damage to examine the effects of bacterial, fungus and insect on forest resources. In this study, the damage caused by the pine shoot moth on clones in the seed orchard in 2014, 2015 and 2016 was investigated. According to the results of 3-year observations and determinations, the average number of clones in 2014 was 13.78, in 2015 it was 10.23 and 7.64 was in 2016 (*Fig. 3*). As a result of the variance analysis, it was found that there was a statistically significant difference in $P < 0.001$ confidence level between the years in terms of the average number of clones that the pine bend-twist caused by membrane (*Table 2*). In this context, Duncan Range Test was applied at $P < 0.05$ confidence level. As a result of the Duncan Range Test performed, 3 different groups emerged in terms of the average clone number variable damaged by pine shoot moth at $P < 0.05$ confidence level. Accordingly, 2014 was the first group in which the most damages occurred during the 3-year period during which the survey was carried out, while this group was followed by the second group formed by 2015 alone, and 2016 was the third group alone (*Table 3*). Accordingly, it is possible to say that there is a significant decrease in the level of the damage caused by the pine shoot moth in the seed orchard. As a matter of fact, in a study conducted in Canada, pheromone traps placed in natural forest area, special seed sources and city centers were determined to show significant increases in monthly and yearly periods of pine shoot moth population in periods when the average temperature was above -2.2 °C (Heeley et al., 2003). On the other hand, in a study conducted in China, it has been determined that 39 insect species detected in native coniferous species are continuous and if the necessary measures are not taken, the severity of this situation increases. As a matter of fact, in the same study, it was found that there were many insect in the fir trees of spruce, douglas fir and hybrid species in China (26 species), and that the same insects caused significant damages in the seeds of 72 broad leaf species in the world in a very short time (Roques et al., 2003). In another study, it has been tried to determine the damages caused by *Rhyacionia frustrana* (Comstock) which is a different species of pine shoot moth in the seed orchard of the Turkish Red Pine (*Pinus brutia* Ten.) it has been determined that the pine shoot moth, especially in green cones, has caused damage that has a high rate of severity in different periods of different years (Can and Özçankaya, 2006).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34153426

In the seed orchard with the necessary examination and determinations in the study, 3 random blocks were formed depending on the experimental design in the organization and the average clone numbers were determined in the blocks in which the pine shoot moth was damaged (*Fig. 4*). As of 2016, pine shoot moth has been damaged in terms of the average number of clones in Block I, III. A downward trend towards the block was determined. Accordingly, the average number of damaged clones determined in Block I as a result of the findings and counts performed in 2016 was 10.24, II. The average number of damaged clones detected in the block was 10.21 and III. The average number of damaged clones detected in the block was 10.12. In this context, variance analysis was performed to determine whether there were any statistically significant differences in terms of the mean number of clones exposed to pine shoot moth damage between the blocks (*Table 4*). As a result of the analysis of variance, no statistically significant difference was found between the blocks in terms of the average number of clones in which the pine shoot moth was harmful (*Table 4*). As a matter of fact, no studies have been carried out in Sweden about the difference in damage caused by pine shoot moth between blocks in seed orchard (Lindelöw and Björkman, 2001). In another research carried out in the *Pinus brutia* seed orchard in Turkey, there was no significant difference between the blocks in terms of the average number of clones exposed to the damage caused by the pine shoots (Can and Özçankaya, 2006). In this study, which was carried out over a 3-year period covering the years 2014-2016, the relationship between the number of individuals affected by the clone, the number of clones damaged by years, and the number of blocks and the number of clones damaged were also investigated with the help of binary regression analysis (*Table 5*). When the results of the binary regression analysis are examined; a second-order polynomial relationship was found to be positively influenced by the number of individuals affected by the clone. On the other hand, it was found that the relationship between the clone and the number of individuals damaged was quite strong (R^2 = 0.95). In the study, the relationship between the number of clones damaged by pine shoot moth factor and the years has been investigated. According to this analysis, it was found that there was a strong positive relationship (R^2 = 0.99) between these two variables. Another double relationship examined in the study is between the blocks and the number of clones damaged by the pine shoots moth. As a result of the study, it was found that there was a strong (R^2= -0.92) and negative relationship between these two variables (*Table 5*). These strong relationships have also enabled the creation of some models and use in practice in determining the extent of the damage to be caused by the pine shoot moth in the seed production (*Table 5*). The strong relationships between the variables investigated in this study were obtained in a similar study of *Pinus radiata* seed sources (Dungey et al., 2003).

Conclusions

In this research carried out in the seed orchard number 70 of Camiyani black pine, an important ecotype of black pine, which has a wide natural distribution area and geographical variation in Turkey, significant time, effort and money were spent in established, were damaged by the *Rhyacionia buoliana* level of the damage was investigated between 2014-2016. In this study, although no determinations and determinations have been made about the effects of clones on seed efficiency, which caused a particularly high level of damage, a research was carried out which is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34153426

important in terms of the damage caused in the seed orchard and the determination of clones that can be resistant to this damage. In accordance with the information obtained from this research, the level of damage caused by pine shoot moth should be closely monitored in the seed orchard which constitutes the research object. More detailed studies should be determined precisely and the chemical and biological control should be started in a planned way without any loss of time in order to prevent these pests from causing damages that cause greater losses in the seed orchard. On the other hand, in accordance with the findings obtained from the research, it was determined that the clones that were affected from the shoot moth caused by the environmental conditions of the seed orchard were the least affected clones 2, 6, 8 and 23 respectively. Accordingly, planned vegetative reproduction of these clones, which are determined to be resistant to this pest, in the form of residual breeding techniques and use in afforestation studies of individuals obtained by clonal production with cuttings taken from clones, biotic and abiotic causes caused by the change of environmental conditions of afforestation and artificial regeneration studies. Resistance to pests will significantly improve your success.

Abstract. This research was conducted within the border of Bartın province between the years of 2015-2018 for making detailed research on the biology of the important walnut pest *Garella musculana* identified for the first time in Turkey. The pupas collected from the study area were brought to the laboratory and monitored. It was observed that some pupas were parasitic, and the type of parasitic species that emerged from these pupae was also recorded and the species were diagnosed. As a result of the diagnosis, the parasitoid species were identified as *Pimpla spuria* (Gravenhorst, 1829). This was the first parasitoid recorded on *Garella musculana* in Turkey. This situation should be helpful of biological control on *Garella musculana* in walnut orchards.
Keywords: *Garella musculana, walnut, Pimpla spuria, parasitoid, first record, Turkey*

Introduction

Walnut (*Juglans regia*), an income-generating species, has a large distribution area and is a very old and important fruit of Turkey. Turkey's walnut production is the fourth in the world (FAO, 2016). *Garella musculana*, one of the important pests of the walnut plant, was determined for the first time in Turkey in the studies carried out in Bartın province in 2015.

Garella musculana is one of the most important pests of walnut fruit and young shoots in infected countries. Larvae damage fruit as a result of nutrition, and usually there are 1 larvae in the fruit, while sometimes 2 and rarely 3 larvae have been observed. In fruit, larvae are only nourished in the green shell (pericarp). As a result of the damage of larvae, fruits become deformed and there is no normal fruit development. As a result of the damage of the species 70-80% yield decrease can occur in the nuts. In addition to the loss of product in Walnut, this insect can cause seed distress for regeneration of natural *Juglans regia* forests. In the years of low fruit production, larval nutrition in shoots causes the death of shoots and this is usually a more serious danger for young trees (Orozumbekov and Moore, 2007).

One of the reasons for the rapid spread of invasive species in the area where they first infect is the absence of natural enemies. Therefore, in this study we tried to determine the natural enemies of *Garella musculana* in Bartın province.

Townes et al. (1965) reported that most of the species belonging to the Ichneumonidae family parasite Lepidoptera larvae and some species parasite Coleoptera

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34273431

larvae. Especially *Pimpla* (F.) species belonging to the type of polyphagous pests many species under pressure has been recorded. Borror et al. (1981) indicate that species belonging to the Ichneumonidae family have a large host distribution.

Ichneumonids, as hosts, use a range of insects and arachnids can play an important role in the normal functioning of terrestrial ecosystems. They were also successfully used as biocontrol agents (Gupta, 1991).

Ichneumonidae species are present as internal and external parasites in larvae and pupae of species belonging to Lepidoptera, Coleoptera and Hymenoptera (Oğurlu, 2000).

In this study conducted between the years of 2015-2018, parasitoid species of *Garella musculana* were investigated and *Pimpla spuria* was determined as the first parasitoid record for the related pest which can be used as a biological control agent.

Materials and methods

In Bartın province, in order to carry out detailed studies about pest, pupas under the bark (*Fig. 1*) from the study areas of different localities such as Karasu, Akıncılar were brought to the laboratory and monitored after the adult exits. Preparation of the parasitoid species derived from some parasitoid pupas was made and photographed under microscope and sent to the diagnosis and species was identified.

***Figure 1.** Pupae cocoons of Garella musculana*

Results and discussion

In this study, parasitoid species *Pimpla spuria* (F.) (Hymenoptera: Ichneumonidae) was obtained from pupae cocoons of *Garella musculuna.* This parasitoid is reported for the first time on *G. musculuna* (*Fig. 2*).

Pimpla spuria is a common species that is widely distributed in the Holarctic/Palaearctic and Oriental regions (Kolarov et al., 2014). In Turkey, this parasitoid has been identified in Adana, Adıyaman, Ankara, Afyon, Artvin, Balıkesir, Bilecik, Burdur, Bursa, Çanakkale Denizli, Edirne, Erzincan, Erzurum, Gaziantep, Giresun, Hatay, Isparta, Mersin, Istanbul, Kars, Kırklareli, Kocaeli, Konya, Manisa, Muğla, Rize, Şanlıurfa, Tekirdağ, Tunceli, Trabzon, Uşak and Yalova so far (Konca, 2015; Çoruh et al., 2014; Kolarov et al., 2014; Coruh and Kolarov, 2010). This is the first time Bartın has been added to its distribution area.

***Figure 2.** Pimpla spuria. **a** General view of adult, **b** wings, **c** antenna, **d** head*

As the hosts of *Pimpla spuria*; *Ostrinia nubillis* (Özdemir, 1981) and *Lobesia botrana* (Özdemir and Kılınçer, 1990) were recorded in Turkey. Aslan (2015) identified *Pimpla spuria* as the most densest species in a study of *Lobesia botrana* parasitoids that harmful in vineyards in Gaziantep province.

Yurtcan and Beyarslan (2005) identified 21 species of Pimpline and Polysphinctinini (Hymenoptera: Ichneumonidae: Pimplexae) in the Trakya region and *Pimpla implemporator* (Müller, 1776) and *P. spuria* (Gravenhorst, 1829) as the most common species.

Aydoğdu (2014) *P. spuria* has been detected as parasitoid of *Archips rosana* (L., 1758) (Lepidoptera: Tortricidae) in organic cherry orchards the first time. And also, in the cherry orchards of Sultandağı Basin, including *Pimpla spuria*, 30 species from the Ichneumonidae family were identified (Özdemir and Güler, 2009).

Pimpla spuria was identified as pupa parasitoid of *Sesamia nonagrioides* (Lepidoptera:Noctuidae) in Cukurova region. At the same time, Oztemiz et al. (2004) reported as pupa parasitoid of *Sesamia nonagrioides* (Lepidoptera:Noctuidae) and *Ostrinia nubilaris* (Lepidoptera:Pyralidae) of the same species.

In Bulgaria, *Pimpla spuria* (Gravenhorst, 1829) was identified as parasitoid of *Cydia pomonella* and *Grapholita funebrana* species. *Grapholita funebrana* was given to the new host of *P. spuria* (Velcheva and Atanassov, 2016).

The natural enemies of *G. musculana* can play an important role in regulating its populations. Sixteen species of parasitoids and predators belonging to Ichneumonidae, Braconidae, Pteromalidae, Torymidae, Trichomammatidae, Carabidae, Raphididae and Formicidae are recorded as *G. musculana*. The most common of these, *Trichogramma*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34273431

sp. and *Pimpla instigator*. Sometimes, caterpillars are infected by bacteria *Bacillus thuringiensis* or fungi *Beauveria bassiana* (Degtyareva, 1964; Dzhaparov, 1990).

Conclusion

Garella musculana which is harmful to walnut trees causes severe damage and brings about economic loss since first detected in Turkey. In order to control *G. musculana,* added to the A2 list in 2003 by the European and Mediterranean Plant Protection Organization (EPPO), some biological control methods are investigated against this pest. In our study conducted within the border of Bartın Province; it was observed that some pupas collected from the study areas were parasitic. As a result of the diagnosis, the parasitoid species were identified as *Pimpla spuria.* The importance of this identifying is*; P. spuria* was the first parasitoid recorded on *Garella musculana* in Turkey.

The abundance and effectiveness of *Pimpla spuria*'s host diversity is thought to play an active role in control of the important walnut pest *Garella musculana*.

Acknowledgements. We are thankful to Oleksandr Varga for the identification of this Ichneumonidae species.

SIDE EFFECTS OF DIFFERENT DOSES OF AZADIRACHTIN ON PREDATORY MITE *METASEIULUS OCCIDENTALIS* (NESBITT) (ACARI: PHYTOSEIIDAE) UNDER LABORATORY CONDITIONS

YANAR, D.

Department of Plant Protection, Faculty of Agriculture, Tokat Gaziosmanpasa University 60240 Tokat, Turkey
(e-mail: durdane.yanar@gop.edu.tr, durdane.yanar@gmail.com; phone: +90-356-252-1616/2185; fax: +90-356-252-1488)

(Received 4th Jan 2019; accepted 14th Feb 2019)

Abstract. *Metaseiulus* (=*Galendromus* or *Typhlodromus*) *occidentalis* (Nesbitt) (Acari: Phytoseiidae) is an important and effective predator of pest mites in agricultural crops and is commercially available in the United States. Azadirachtin is a biorational pesticide, which contains azadirachtin A (10 g/l) as the basic active compound. The active compound has several properties useful for insect control (repellency, feeding and oviposition deterrence) and is considered safe for the environment. With the use of natural compound like azadirachtin A in integrated pest management programs, it is important to know whether the compounds have any side effects on predatory mite such as *M. occidentalis.* Therefore, the current study aimed to examine the toxic effect of different doses (0.1 ml (NZ-1*2), 0.05 ml (NZ-1), 0.025 ml (NZ-2), 0.01 ml (NZ-3), 0.005 ml (NZ-4) and 0.001 (NZ-5)/ 10 ml water) of NeemAzal-T/S (a.i. 10 g/l azadirachtin A) on *M. occidentalis.* The mortality rate of *M. occidentalis* was 77.5% 24 h after application of NeemAzal-T/S at 0.1 ml/10 ml water dose. The mortality caused by the recommended dose (0.05 ml/10 ml water) of NeemAzal-T/S was 62.31%, 70% and 73.07%, 24, 48 and 72 h after application, respectively. It is concluded that NeemAzal-T/S is moderately toxic against the predatory mite *M. occidentalis.* Therefore, the use of NeemAzal-T/S to control the pest mites in agricultural crops might affect the populations of predatory mites.
Keywords: *azadirachtin, spider mite, Metaseiulus occidentalis, side effect, pesticide*

Introduction

Plant protection strategies, pest management in particular, have focused on minimizing the use of pesticides in the recent years. The use of organic pesticides, i.e., derived from plants or living organisms has gained attention in this regard. However, the evaluation of the side effects of organic pesticides is required to know whether or not these pesticides are fatal to the natural enemies.

Agricultural crops are infested by several pests, some of them may be controlled by using pathogens, predators, and parasitoids in addition to pesticides. However, selective pesticides are required to achieve a satisfactory control of complexes of pests (Cloyd et al., 2006) when using living organisms for pest control. Most of the biological control agents, including predators and parasitoids can provide excellent management of many pests. There is great potential for reducing pesticide use in pest management through exploiting natural enemies of the pests (Kavousi and Talebi, 2003) as alternatives to pesticides. Alternative pest management approach includes the use of predator mites along with pesticides instead of using pesticides or biocontrol agent alone (Sato et al., 2000).

It is very important to determine the positive/negative impacts of selective insecticides/acaricides that could be used in combination with biological control agents (Martin and Woodcock, 1983) for pest management. Phytoseiidae mites are one of the most important biological control agents effective on different kinds of pests on various

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34333440

greenhouse plants and orchards (Schmutterer, 1990). *Metaseiulus occidentalis* (Nesbitt) (Acari: Phytoseiidae) is one of these mites. It is a predatory mite species, specialized in the phytophagous red spider mite species (Tetranychidae) in North America (Hoy et al., 1982; Hoy, 2011). This predatory mite species has been adapted to semi-arid conditions, can produce large populations in low relative humidity environments, thus suppresses spider mites (Mc Murtry, 1982; Mc Murtry and Croft, 1997). The length of time taken from egg to adult is aproximately 8.5 days. The average eggs laying capacity of adult female is 2.2 eggs/day and capable of laying 34 eggs during the entire life cycle, longevity of *M. occidentalis* females is approximately 20 days (Laing, 1969). The length of time from egg to adult varies greatly with temperature and as the temperature increases, the development time is shortened with increasing temperature. While the length of time from egg to adult is 7-10 days at 24 °C, it become 8.7, 7.4 and 5.2 days at 27 °C, 29 °C, and 32 °C respectively (Tanigoshi et al., 1975).

Phytoseilus persimilis and *Neoseiulus californicus* are commercially available and actively used in the biological control of two-spotted spiders. *Metaseiulus occidentalis* is a predator mite belonging to the Type II group and is feed with Tetranychidae mite species and rust mites (McMurtry and Rodrigues, 1987).

One of the botanical pesticides is Azadirachtin (10 g/L). Azadirachtin (10 g/L) is the commercially available plant orginated pesticide; It has been reported that it is effective on more than 200 plant pests, such as aphids, White flies, leafminers, Thrips, Colarado potato beetle, woolly Apple aphid, scale insects, mealy bugs, leafhopper, Noctuids, Coleopters, Yponometua species, American White fly, Pine processionary caterpillar, Oriental fruit moth, Olive fruit fly, Cherry fruit fly, leaf tortrix moths, and spider mites. It is also widely used in organic farming (Schmutterer et al., 1981; Isman, 2006). The active substance diffuses into the leaves and is partly systemically dispersed in the plant; insects take this active substance by mouth (by sucking or chewing) during feeding. Azadiractin inhibits the feeding and molting of the exposed inscets. At the same time, it decreases the fecundity of insect and may causes infertility (Isman, 2006).

This study was aimed at evaluation of different doses of Azadiractin on *Metaseiulus occidentalis*.

Materials and methods

Tetranychus urticae

The adults, nymphs and especially eggs of *Tetranychus urticae* are needed to feed the predator mites. Therefore *T. urticae* was reared on green bean plants, *Phaseolus vulgaris*. The bean plants used in the experiment were grown at 25 ± °C and 16:8 h L:D photoperiod in the growth chamber (*Fig. 1*).

Neem formulation

Neem Azal is a commercial formulation of neem seed kernel extract containing10 g/LAzadirachtin.

Effect of azadirachtin on Metaseiulus occidentalis

The predatory mites *Metaseiulus occidentalis* were obtained from Emeritus Prof. Dr. Marjorie Hoy, University of Florida, USA and fed with *T. urticae*. *M. occidentalis* is nonnative to Turkey; therefore, necessary permission was obtained from Turkish Agricultural Ministry to work with this predatory mite species. The experiments were carried in Petri dishes (90 mm in diameter) by placing ten adult females of *M. occidentalis* per Petri dish. Dry film method was used to determine the toxicity of azadirachtin on *M. occidentalis* (Birah et al., 2008). Inner sides of Petri dishes were coated with 60 µl solution of six different doses (0.1, 0.05, 0.025, 0.01, 0.005, 0.001 ml/10 ml of water) of azadirachtin (10 g/l) (*Table 1*). The solution was spread uniformly and allowed to dry at room temperature for 30 min. Ten adult females of *M. occidentalis* were released onto the film in each Petri dish and the dishes were wrapped with parafilm to prevent evaporation. Thereafter; the predatory mite was exposed to the solution for a period of 24 h. Thereafter the adult females were transferred to bean leaf disk (2 cm in diameter) which was placed inside a petri dish on moist cotton. The experiments were carried out at 25 ± 2 °C and 16:8 h L:D photoperiod and 45 ± 5% humidity in the growth chamber. Each treatment was replicated 5 times. The experiments were repeated two times. The number of living and dead *M. occidentalis* adults was monitored 24, 48, 72, 96, 120 and 144 h after exposure to azadirachtin. The number of eggs laid by each female after 24 h period was recorded to investigate the effects of tested doses of azadirachtin on eggs laying capacity of the female.

Table 1. *Different doses of azadirachtin used in the study*

Treatments doses (ml per 10 ml water)	
Control (C)	Distilled water
NZ - 1*2	0.1
NZ - 1	0.05
NZ – 1/2	0.025
NZ - 3	0.01
NZ - 4	0.005
NZ - 5	0.001

The results were expressed as percent mortality with correction for untreated mortality using Abbott’s formula (Abbott, 1925). The data were subjected to ANOVA tests and the means were compared by Tukey test, using SPSS 17.0 software program (SPSS, 2008).

Results and discussion

One of the practical and environmentally safe biological pesticides are plant-derived products, due to their bio-degradability and target-specific nature (Birch, 2011). The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34333440

combined effect of both botanical pesticides and predators or parasitoids as biological control agents is expected to have greater effects on target insects than both approaches opted alone. The predatory mites can be combined with safe doses of botanical pesticides, which have minimum negative impacts on natural enemies and provide enough control over target pests. Therefore, the knowledge of safe dose of a botanical pesticide is required to maintain the pest population below an economic threshold level without effecting the population of predatory mite. Toxicities of different doses of azadirachtin (10 g/l) on predatory mite *M. occidentalis* were evaluated in the current study and results are summarized in *Table 2*.

*Means followed by the same letter in each column are not significantly different (P < 0.05)

Females of *M. occidentalis* were more sensitive to double (0.1 ml/10 ml water) and recommended (0.05 ml/10 ml water) doses of azadirachtin than the other doses tested in the study. The female mortality was decreased with decreasing dose. At double dose, the mortality rates were 77.5, 82.5 and 86.25% after 24, 48, and 72 h of exposure, respectively. Similarly, recommended dose of azadirachtin caused a significant reduction in the viability of *M. occidentalis* 24 to 72 h after exposure, highlighting the negative effect on predatory mite. Mortality of *M. occidentalis* ranged from 62.31 to 73.8% at 0.05 ml/10 ml water concentration 24 to 72 h after exposure (*Tables 2* and *3*). These results are consistent with the findings of Mourao et al. (2004) who reported that neem cake caused 88% mortality of *Iphiseiodes zuluagai* Denmark and Muma (Acari: Phytoseiidae) adults. Several studies showed the compatibility of neem-based products with predatory mites, e.g., azadirachtin at 4.5% concentration was found compatible with *Phytoseiulus persimilis* (Bernardi et al., 2013; Duso et al., 2008; Cote et al., 2002). The effects of neem-derived compounds can vary, depending on the predatory mite species, formulation of pesticide or the plant part used.

Our study indicates that mean longevity of alive adult females of *M. occidentalis* was also decreased with increasing dose of azadirachtin. While the longevity of female adults was 7.55 days in control treatment and with the same category at 0.01, 0.005 and 0.001 ml/10 ml water concentrations statistically, at 0.01, 0. 05 and 0.025 ml/10 ml concentrations it was 3.42, 3.62, 5.62 days respectively ($F = 114.49$; $df = 6$; $P < 0.001$) (*Table 4*).

Fecundity of female adults of the mite was significantly reduced as the total number of eggs laid per female were decreased at 0.1 and 0.05 ml/10 ml water concentrations, which were significantly lower than the control treatment (*Table 5*) (F = 45.25; df = 6; P < 0.001). These results are consistent with the findings of Irigaray and Zalom (2006), who reported significant influence of acequinocyl on fecundity of *M. occidentalis* females. Additionally, there was significant difference in the mean number of eggs deposited per mite/per day. The female exposed to double (0.1 ml/10 ml water) and recommended (0.05 ml/10 ml water) doses of azadirachtin deposited significantly lower number of eggs than the females in control treatments (p ≤ 0.05) (0.29, 0.61 and 1.30/per day/per female, respectively) (F = 26.24; df = 6; P < 0.001) (*Table 6*).

Hatched larvae to reaching the adulthood stage of predatory mite ranged between 66.67 and 100%, b ut at 0.001 ml/10 ml concentration, there was no larval hatching (*Table 7*). Yanar and Hoy (2017), found that surviving females held for 2 and 4 f week cold storage laid eggs at the same rate as control females of *M. occidentalis*. Nicoli and Galazzi (1998) found that survival of predatory mites during storage decreased but the surviving females show greater longevity, fertility and fecundity.

Table 7. *Effects of azadirachtin on larval hatching and reaching adulthood from larva of Metaseiulus occidentalis*

NZ – 2	40.91	66.67
NZ – 3	50.00	100.00
NZ – 4	42.86	83.33

Conclusion

The data obtained from this study will be useful for commercial producers and pest management specialists wishing to use these predatory mites in integrated pest management programs. Considering the results of present study, it can be concluded that recommended and half doses of azadirachtin (10 g/L) should not be used in IPM programs where *M. occidentalis* is used to control pest mites. Lower concentrations (0.01 and 0.005 ml/10 ml water) can be used in combination with *M. occidentalis,* reducing the selection pressure and development of resistance (Marcic, 2007). Herron et al. (1993) and Cheon et al. (2007) suggested that acaricides at reduced rates might be used to adjust the predator/prey ratio.

Acknowledgements. The results of this study was presented as an oral presentation at Turkey 6th Plant Protection Congress 5-8 September 2016, Konya, Turkey and abstract was published in congress proceedings book. I would like to thank Agricultural Engineer Havva Öz Tural for her help during experiments.

(Received 22nd Jan 2019; accepted 14th Feb 2019)

Abstract. The aim of this study was to determine the effects of socio-demographic and economic factors of households and household heads on monthly expenditures of food away from home (FAFH) in Turkey. The sample size was determined as 11290 households. The data were analyzed by generalized Heckman type sample selection models. The results showed that both the probability and monthly spending levels of household FAFH increased with male household heads, household income, whilst the married household heads, the households that receive cash income aids from the government and private sector, decreased both the probability and spending levels of FAFH in Turkey. The findings in the study may provide useful information for more effective identification and implementation of the marketing strategies of the stakeholders operating in the sector and also help the relevant public and private institutions determine more effective nutritional policies towards families with a certain profile.
Keywords: *eating out, consumption, expenditure patterns, Heckman Sample Selection Model, Turkey*

Introduction

Many countries have experienced changes in eating habits over the last decades in terms of individual consumers and households. These changes generally were from home consumption towards food away from home (Stewart et al., 2004; Akbay and Boz, 2005; Gül et al., 2007; Drescher and Roosen, 2013; Bozoglu et al., 2013; Niyonzima et al., 2017; Mottaleb et al., 2017). Changes were generally derived from convenience and increasing food availability, but demographic changes such as a higher share of working women and an increasing number of single households contributed as well (Nayga and Capps, 1992; Robson et al., 2016). One of the discouraging factors on the preparing the meal at home was reported to be working longer hours (Blick et al., 2017). In many studies, it was stated that globalization, urbanization, income, education, marketing, religion, culture, tourism women's participation in the labor force and consumer attitudes increases in FAFH consumption (Nayga, 1995; Ma et al., 2006; Bozoglu et al., 2013; Liu and Niyongira, 2017).

Worldwide, food consumption trends have been moving towards FAFH in many countries (Mancino et al., 2009; Bozoglu et al., 2013; Liu et al., 2013). For instance, the ratio of FAFH in household food expenditure of the United States of America (USA) increased twofold from 25% in 1954 to 50% in 2014 (USDA, 2018). This rate rose to 32% in 1992 in Canada (Jensen and Yen, 1996). FAFH ratio in 2002 was 24% reaching to 31% in 2008 in Brazil (Bezerra et al., 2013). In the last two decades, the percentage of FAFH rose to 25% in 1996 and 30% in 2006 in Spain (Mutlu and Gracia, 2006; Angulo et al., 2007). Again, the period of 2004-2010 experienced an increase from 20% to 25% FAFH consumption in Slovakia (Cupak et al., 2016), while in the 1987-1999 period FAFH consumption rate rose from 13% to 23% in Ireland (Keelan et al., 2009).

Turkey has also experienced similar changes in the pattern of food consumption expenditures mainly due to changes in the socio-economic structure of Turkish

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34413455

population in the last two decades. Composition and size of households, consumer lifestyles, per capita income, age distribution of the population and urbanization had a significant effect in FAFH. Thus, more efficient marketing strategies are required in the sector. Money spent of food, including non-alcoholic beverages as a share of total household spending continued to shrink, from 26.7% in 2002 to 19.5% in 2016, while expenditures on hotels, restaurants, and pastry shops (FAFH) as a share of total household spending increased from 4.4% in 2002 to 6.4% in 2016 (TURKSTAT, 2018).

The current work has identified the effects of socio-demographic and economic factors of households and household heads on their FAFH consumption expenditures using a Double Hurdle (DH), Heckman Sample Selection (HSS) and Log-Heckman Sample Selection (LHSS) models. The study, which is rich in terms of household socio-demographic and economic profiles, also presented marginal impacts of exogenous variables on spending of FAFH. The presentation of such marginal effects may provide useful information for more effective identification and implementation of the marketing strategies of the stakeholders operating in the industry. This study will also help the relevant public and private institutions determine more effective nutritional policies towards families with a certain profile.

Materials and methods

Turkish Statistics Institute (TSI)' Household Budget Surveys data of 2015 was used as main material of this study. These data are regularly collected by TSI on the annual basis so as to cover the period between January 1 and December 31 and cover 10 thousand households on average across the country. The sample size was determined as 11290 family observations after deleting incomplete data and outliers.

Table 1 shows the descriptive statistics for sample. The results of this study showed that 77.3% of households had monthly expenditures on food away from home. In some studies conducted in different parts of Turkey, this ratio was reported as 55.4% (Gül et al., 2007), 83.6% (Uzunöz et al., 2011), 74.5% (Bozoglu et al., 2013) and 68.4% (Traş and Şengül, 2017). The reported figures for some countries, were as follows: Slovakia, 62.0% (Cupak et al., 2016), Brazil, 40.0% (Bezerra et al., 2013), China, 83.0% (Liu et al., 2015), Egypt, 38% (Fabiosa, 2008) and Malaysia, 71.9% (Heng and Guan, 2007). Monthly average FAFH consumption expenditures of households were found to be 180.14 Turkish Liras (TL). These figures were as follows for different parts of Turkey: 137.66 TL (Bozoglu et al., 2013), 371.00 TL (Onurlubaş et al., 2015) and 131.82 TL (Traş and Şengül, 2017).

Three censored models competing with one another and at the same time compatible with the maximization of the utility function of consumers were considered. The mathematical representation of each econometric model were made here while referring to the textbooks on how these models are derived from the utility function under the good in question (e.g., food away from home). Before moving on to the presentation of each econometric model, it is worth mentioning a very important point here. Some families may not be able to consume FAFH and such observations are often reported as zero. Food away from home may not have been consumed, either because its current price is too high or because the family income is not affordable for the consumption or because of some health concerns and psychological factors. The Heckman sample selection (HSS) model is characterized by a selection equation (d_i) (e.g., the decision on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34413455

the expenditure of the food away from home) and level equation (y_i) (e.g., monthly expenditure level for the food away from home) as follows (*Eq. 1*):

$$\begin{aligned} d_i &= 1 \quad if \quad z_i'\alpha + u_{1i} > 0 \\ &= 0 \quad if \quad z_i'\alpha + u_{1i} \leq 0 \\ y_i &= x_i'\beta + u_{2i} \quad if \quad z_i'\alpha + u_{1i} > 0 \\ &= 0 \quad if \quad z_i'\alpha + u_{1i} \leq 0 \\ &(can\ be = unobserved) \ if \quad z_i'\alpha + u_{1i} \leq 0 \end{aligned} \tag{Eq.1}$$

where z and x are sets of exogenous factors affecting the household decision and expenditure levels on food away from home, respectively whilst α and β are vectors of associative parameters to be estimated for each equation, respectively. u_1 and u_2 are error terms unknown to researchers. The error terms (u_1, u_2) are distributed as truncated bivariate normal with zero means, standard deviations (1, σ), correlation ρ, and covariance ρσ, all indicating:

$$\begin{bmatrix} u_{1i} \\ u_{2i} \end{bmatrix} \sim N\left(\begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 1 & \rho\sigma \\ \rho\sigma & \sigma^2 \end{bmatrix} \right)$$

The corresponding sample likelihood function is (*Eq. 2*)

$$L = \prod_{d_i=0} \{1 - \Phi(z_i'\alpha)\} \prod_{d_i=1} \left\{ \frac{1}{\sigma} \phi\left(\frac{y_i - x_i'\beta}{\sigma} \right) \Phi\left(\frac{z_i'\alpha + \frac{\rho}{\sigma}(y_i - x_i'\beta)}{(1-\rho^2)^{1/2}} \right)^{-1} \right\} \tag{Eq.2}$$

where Φ and ϕ are the univariate standard normal cumulative and probability distribution functions, respectively. The log-transformed Heckman SSM (LHSS) is characterized by replacing y_i with log y_i in *Equation 2* with its corresponding likelihood function as (*Eq. 3*):

$$L = \prod_{d_i=0} \{1 - \Phi(z_i'\alpha)\} \prod_{d_i=1} \left\{ y_i^{-1} \frac{1}{\sigma} \phi\left(\frac{\log y_i - x_i'\beta}{\sigma} \right) \Phi\left(\frac{z_i'\alpha + \frac{\rho}{\sigma}(\log y_i - x_i'\beta)}{(1-\rho^2)^{1/2}} \right)^{-1} \right\} \tag{Eq.3}$$

The same distributional assumption for error terms (u_1, u_2) as in Heckman-SSM are maintained and y_i^{-1} is the Jacobian of transformation from log y_i to y_i. Now, augmenting the binary decision $z_i'\alpha + u_{1i}$ with an additional mechanism $x_i'\alpha + u_{2i}$ the double-hurdle (DH) model can be stated as follows (*Eq. 4*):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34413455

$$\begin{aligned} y_i &= x_i'\beta + u_{2i} \quad if \quad z_i'\alpha + u_{1i} > 0 \text{ and } x_i'\beta + u_{2i} > 0 \\ &= 0 \qquad\qquad\; if \quad z_i'\alpha + u_{1i} \le 0 \text{ and } x_i'\beta + u_{2i} \le 0 \end{aligned} \tag{Eq.4}$$

The error terms (u_1, u_2) in the double-hurdle model are distributed as the bivariate normal as in Heckman's (1979) sample selection model (HSS) without truncation. The sample likelihood function is (*Eq. 5*):

$$L = \prod_{d_i=0}\left\{1-\Phi_2\left(z_i'\alpha, \frac{x_i'\beta}{\sigma}, \rho\right)\right\}\prod_{d_i=1}\left\{\frac{1}{\sigma}\phi\left(\frac{y_i - x_i'\beta}{\sigma}\right)\Phi\left(\frac{z_i'\alpha + \frac{\rho}{\sigma}(y_i - x_i'\beta)}{\left(1-\rho^2\right)^{1/2}}\right)\right\} \tag{Eq.5}$$

where Φ2 is the standard bivariate cumulative distribution function. By imposing parametric restriction ρ = 0 in model, The HSS, LHSS and DH models reduce to their two-part models. This can be done via the conventional tests such as Wald, Likelihood Ratio, or Lagrangian Multiplier (LM). On the other hand, the choice between the three competing models can be done by a non-nested Vuong's specification test.

While the probability of both the HSS and LHSS models are the same, their conditional and unconditional, expenditure level equations vary greatly (*Eq. 6*):

$$\Pr\left(y_i > 0\right) = \Phi\left(z_i'\alpha\right) \tag{Eq.6}$$

Conditional and unconditional means of y_i of the HSS model are respectively (*Eq. 7*):

$$E\left(y_i \mid d_i = 1\right) = x_i'\beta + \rho\sigma\frac{\phi\left(z_i'\alpha\right)}{\Phi\left(z_i'\alpha\right)} \text{ and } E\left(y_i \mid d_i = 1\right) = \Phi\left(z_i'\alpha\right)x_i'\beta + \rho\sigma\phi\left(z_i'\alpha\right) \tag{Eq.7}$$

While the conditional and unconditional mean levels for the LHSS model is respectively (*Eq. 8*):

$$E\left(y_i \mid d_i = 1\right) = \exp\left(x_i'\beta + \sigma^2/2\right)\frac{\Phi\left(z_i'\alpha + \rho\sigma\right)}{\Phi\left(z_i'\alpha\right)} \text{ and } E\left(y_i \mid d_i = 1\right) = \exp\left(x_i'\beta + \sigma^2/2\right)\Phi\left(z_i'\alpha + \rho\sigma\right) \tag{Eq.8}$$

However, the probability, conditional and unconditional mean levels of monthly household food away from home product in DH is, respectively (*Eq. 9*):

$$\begin{aligned} &\Pr\left(y_i > 0\right) = \Phi_2\left(z_i'\alpha, \frac{x_i'\beta}{\sigma}; \rho\right) \\ &E\left(y_i \mid y_i > 0\right) = x_i'\beta + \sigma\Phi_2\left(z_i'\alpha, \frac{x_i'\beta}{\sigma}; \rho\right)^{-1}\left\{\phi\left(\frac{x_i'\beta}{\sigma}\right)\Phi\left[\frac{z_i'\alpha - \rho x_i'\beta/\sigma}{\sqrt{1-\rho^2}}\right] + \rho\phi\left(z_i'\alpha\right)\Phi\left[\frac{x_i'\beta/\sigma - \rho z_i'\alpha}{\sqrt{1-\rho^2}}\right]\right\} \\ &E\left(y_i\right) = \Pr\left(y_i > 0\right)E\left(y_i \mid y_i > 0\right) \end{aligned} \tag{Eq.9}$$

Marginal effects can be obtained by differentiation each equation with respect to z and x variables. Delta method is used to construct the variance-covariance of marginal impact estimates.

Results and discussion

Specification tests and maximum-likelihood estimates

Before discussing the marginal impacts of the preferred model, some specifications applied to the data and models were taken into consideration. First, in each model under consideration, the two-part models were rejected using Wald statistic (W = $\frac{\rho^2}{Var(\rho)}$, df = 1, where Var (ρ) is the estimated variance of the correlation coefficient, ρ, between the decision to participate at food-away from home and its expenditure level). Therefore, the error terms generating the relationship between the decision to spend and the spending levels on FAFH are statistically interrelated, affecting one to other equations. In addition, Vuong non-nested tests discriminating competed models were used (see *Table 2*). In all pair comparison, the error-dependent log-Heckman sample selection (LHSS) model outperforms over its competitors (e.g., the double-hurdle and conventional error-dependent Heckman models). Most likely, the logarithmic nature of the model correcting outliers and minimizing the persistent heteroscedasticity in the data gives an advantage to the LHSS model to outperform the other two competing models (e.g., HSS and DH). In this case, all correlation coefficients are statistically significant, indicating after controlling exogenous variables in models, uncontrollable factors that affect the decision to spend also significantly affect the spending level on FAFH. The correlation coefficient in the LHSS model is negative, indicating that the uncontrollable factors that boost the likelihood to spend also reduce expenditure level or vice-versa. Also sings of most of the estimated parameters echoed with the economic theory. Since these parameters do not indicate the direct marginal effects of regressors on both the probability and the spending level, the marginal impacts derived from *Equations 6–9* were discussed in subsequent section.

Table 2. *Some specification tests comparing independence and used models*

Specification tests	Test-statistic
Independence	
Heckman SS	Wald 491.3661, df = 1, p < 0.0001
Log-Heckman SS	Wald 1009.967, df = 1, p < 0.0001
Double- hurdle	Wald 196.0345, df = 1, p < 0.0001
Vuong's non-nested test	
Double-hurdle versus Heckman SS	z = 54.3073, p < 0.0001
Double-hurdle versus Log-Heckman SS	z = -14.0318, p < 0.0001
Heckman SS versus Log-Heckman SS	z = -30.2837, p < 0.0001

Note: The null hypothesis under Vuong's test for non-nested models is that the expected value of competing log-likelihood ratios equals zero, indicating the competing pair models are equally away from the data being modelled. Under this test, if z > 1.96 the first listed model is preferred, while if z < -1.96 the second listed model is chosen. However, if |z| < 1.96 then no decision is made among the competing pairs

Marginal effects

Marginal effects of explanatory variables on the probabilities, conditional level, and unconditional level of FAFH households are presented at *Table 3*. According to these results, it was observed that various socio-demographic and economic factors of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34413455

households and heads of households had significant effects on FAFH expenditures. The subsequent discussion will continue only on statistically significant variables for the preferred LHSS model.

Because of culinary skills, households under the supervision of the male are reported to have higher FAFH expenditures (Byrne et al., 1996). Our results confirmed that hypothesis. Households with a male headed were 8.32% more likely to consume FAFH and spend 25.18 TL more per month than households with a female headed Bozoglu et al. (2013) found that male household heads tended to 13.84% more likely to consume FAFH and spend 51.05 TL more per month than their female peers. Previous findings is consistent with our findings (Byrne et al., 1996; Ham et al., 2004; Binkley, 2006; Angulo et al., 2007; Keelan et al., 2009; Fanning et al., 2010; Liu et al., 2013; Blick et al., 2017).

Heng and Guan (2007) reported that the young differed from the old as regards tastes, food preferences, lifestyle, eating habits and opportunities to socialize. In the study, there was a negative relationship between the age of the head of household and the monthly average expenditure on FAFH. Household with households heads whose ages between 30-50 and over 50 years tended 0.51% and 8.50% points less likely to consume FAFH and they spent 33.12 TL and 27.04 TL less than households whose heads aged below 30 years. These negative effects of ages were also reported in previous studies conducted in Turkey (Akbay et al., 2007; Gül et al., 2007), in South Africa (Blick et al., 2017), in China (Min et al., 2004; Ma et al., 2006), in USA (Stewart and Yen, 2004; Binkley, 2006), in Ireland (Keelan et al., 2009), in Slovakia (Cupak et al., 2016), in Egypt (Fabiosa, 2008), in Brazil (Rezende and Avelar, 2012), and in Spain (Mutlu and Gracia, 2006; Angulo et al., 2007).

Households with a married head were 5.12% points less likely to consume FAFH and spent 87.30 TL less per month than single headed households. The results indicated that married households were less likely to consume FAFH and spent less than single headed households. Bozoglu et al. (2013) found that married household heads tended to 4.14% points less likely to consume FAFH and spent 18.60 TL less per month than that of unmarried peers. Our results were consistent with the earlier findings (Ham et al., 2004; Keelan et al., 2009; Drescher and Roosen, 2013; Piekut, 2016; Traş and Şengül, 2017).

Compulsory health insurance played a positive role in the probability of consume FAFH, but negatively affected the expenditure levels. Households whose heads had a compulsory health insurance were 3.71% points more likely to consume FAFH but spent 52.52 TL less per month than those without insurance. Employment played a role on FAFH, households with an employed head were 6.16% points more likely to consume FAFH and spent 90.77 TL more per month than their unemployed counterparts. The findings showed that households with employed head in Turkey had significantly higher probability of entering the FAFH market and they spent more on FAFH. Bozoglu et al. (2013) and Traş and Şengül (2017) reported a positive employment effect on FAFH in Turkey. These positive effects of employment were also reported for USA (Jensen and Yen, 1996; Stewart and Yen, 2004), for Spain (Angulo et al., 2007), for Mexico (Langellier, 2015) and for Slovakia (Cupak et al., 2016).

Households with a retired head were 2.43% points more likely to consume FAFH but spent 49.08 TL less per month than their not retired counterparts. Retired played a positive role in the probability of consume on FAFH, but negatively affected expenditure levels. These results were in line with the expectations because retired household head, on average might be older than those not retired and similar health and/or financial reasons in the retired group might result in less consumption of FAFH. Piekut (2016) found that in Poland, households with a retired head were less likely to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34413455

consume FAFH and spent 15.96 PLN per month than those not retired households head. Negative effects of retired household head on FAFH were also reported in earlier studies (Jang et al., 2007; Drescher and Roosen, 2013).

In the study, the households receiving financial aid from the state resources had lower probability of consumption and related expenditure levels by 3.39% points and 62.51 TL, respectively, in comparison to those who were not receiving financial aid from public resources. This finding was in line with findings of Binkley (2006). The finding was in accordance of expectations. The major reason could be income levels and high quality life due to financial support provided by the government. Therefore, it is expected that the expenditures on such households on FAHF would be lower.

Households residing in rental house were 2.93% more likely to consume FAFH and spent 27.25 TL more per month than those residing state apartments. This result was consistent with Bozoglu et al. (2013), who reported a positive relationship between households residing in rental house and FAFH expenditures. Home ownerships had a higher income compared to no home ownership due to high income and low cash flow effects, which is contradictory, the effects of homeowner status on FAFH is reported to be unclear (Yen, 1993). This means that homeowner would show a less probability of FAFH and less expenditure on FAFH in comparison of hypothesized a lack of homeowner. Homeowners were 2.97% points less likely to consume FAFH and spent 16.91 TL less per month than those residing state apartments, similar to findings by Ham et al. (2004), but contradicts to those by Jensen and Yen (1996), Mutlu and Gracia (2006), Jang et al. (2007) and Keelan et al. (2009).

Having an internet connection at home increased the probability of consuming FAFH (2.90%) and it also had a significant and positive effect on FAFH expenditures for households (34.53 TL). This result was consistent with Bozoglu et al. (2013) who reported a positive relationship between having an Internet connection at home and FAFH expenditures.

Households with only one and two children were 5.72% and 4.37% points more likely to consume FAFH and spend 54.08 TL and 29.21 TL more per month than households without children, respectively. These results agreed with the expectations. Piekut (2016) found that in Poland, households with a children are more likely to consume FAFH and spent 16.49 PLN per month than childless households. Similar findings were also reported by Stewart and Yen (2004) and Bozoglu et al. (2013).

Education level increases the probability of the FAFH decision and also increases expenditures on FAFH. Households with a primary, secondary, high and college school head were 5.36%, 5.25%, 7.63% and 5.36% points more likely to consume FAFH, and spent 29.81 TL, 31.79 TL, 47.67 TL and 32.33 TL more per month than their illiterate counterparts, respectively. The findings were consistent with the previous findings (Jensen and Yen, 1996; Mihalopoulos and Demoussis, 2001; Stewart and Yen, 2004; Angulo et al., 2007; Zan and Fan, 2010; Langellier, 2015; Cupak et al., 2016; Piekut, 2016; Traş and Şengül, 2017).

Households who had pre-school children is reported to have spent less FAFH expenditures compared to other families mainly because of difficulties feeding children in public places (Heng and Guan, 2007). Our results confirmed this expectation. In the study, households with a young children aged 0–5 and aged 6-14 were 2.88% and 2.09% less likely to consume FAFH and they spent 15.81 TL and 11.49 TL less than their counterparts without such young children, respectively. Presence of children (aged 0–5 and aged 6–14) decreased FAFH expenditure of households. Negative effects of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34413455

pre-school (aged 0-5) and school children (aged 6-14) on FAFH were also reported in the earlier studies (Mihalopoulos and Demoussis, 2001; Keelan et al., 2009; Chang and Yen, 2010; Drescher and Roosen, 2013; Leschewski et al., 2018; Rezende and Avelar, 2012).

As the total expenditure of households increased, the probability of consuming FAFH increased by 6.04% points and spending increased by 33.14 TL per month. These positive effects of total expenditure might be related to the increased income because household's total expenditures are generally viewed as proxy for income. The positive effects of total expenditure of households on FAFH expenditures were consistent with the earlier studies (Mihalopoulos and Demoussis, 2001; Fabiosa, 2008; Traş and Şengül, 2017).

Level of FAFH expenditure and the probability of consumption in the FAFH market were affected positively from household size. Each additional household member increased the probability of consuming FAFH by 0.10% point, the conditional expenditure by 19.39 TL per month. While these positive effects of household size on FAFH was in consistent with the findings of some earlier studies (Mihalopoulos and Demoussis, 2001; Ham et al., 2004; Chang and Yen, 2010; Cupak et al., 2016), it contradicted with some other findings of Stewart and Yen (2004), Heng and Guan (2007), Akbay et al. (2007), Drescher and Roosen (2013) and Mottaleb et al. (2017).

Households with an average monthly income between 2000 and 5000 TL and over 5000 TL spent 90.65 TL on FAFH and 233.04 TL more than households with an average monthly income below 2000 TL. This was consistent with the applied theoretical framework and other empirical studies investigating the link between income and FAFH spending (Byrne et al., 1996; Min et al., 2004; Ma et al., 2006; Zan and Fan, 2010; Liu et al., 2013; Cupak et al., 20016; Piekut, 2016; Blick et al., 2017; Traş and Şengül, 2017). The results were as it is expected. The major reasons could be households with relatively high income would tend to have more expenditure on products and services including dinning (Bozoglu et al., 2013).

Conclusions

In the study, the characteristics of households and the heads of households had a significant effect on determining the probability of consuming FAFH and the related expenditure. The findings were supported by analyses. Results showed that 77.3% of Turkish households participated in the FAFH market.

The results also showed that both the probability and monthly spending levels of household FAFH increased with male household heads, decreasing in age of household heads, educational levels of household heads, working household heads, household size, household income, reside in rental house, use of internet and the number of adults in a family, whilst the female headed households, married household heads, the households receiving cash income aids from the government and private sector, homeowner, the number of properties in family and families with children 0-5 and 6-14 years old, decreased both the likelihood and spending levels of food away from home in Turkey.

These findings are very important especially for the companies and enterprises operating in the non-home food industry. Because knowing the factors that increase and decrease the food consumption expenditures of households FAFH will provide important clues to the companies and enterprises operating in this sector for what kind of services they will develop for households. For example, children's play areas for

households with children, car parking for car-owners, low-income households and large households multiple alternative options will have a positive impact on household consumption expenditures. Increasing demand for FAFH will probably ensure further growth in industry. In these days, industry provides employment for many people and creates demand for other food chains from farmers to retailers.

Abstract. Currently, new solutions are searched for in crop production that will provide plants with favourable conditions for growth and development, ensuring high consumer quality of harvested products further to being friendly for the environment. One of the most important features negatively affecting the quality of consumer quality of edible potato tubers is the increased content of total sugars and especially reducing sugars. Therefore, the aim of the experiment was to determine the impact of five methods of care using the growth biostimulators and herbicide on the content of total sugars and reducing sugars in tubers of three edible potato varieties. A series of three-year field experiments was carried out in the years 2015-2017 in the region of Eastern Poland (52°02'N; 23°07'E). The experiments were assumed with random sub-blocks method in three repetitions, on light acidic soil. The examined factors were: I factor – three early edible potato varieties (Owacja, Bellarosa, Vineta), II factor – five methods of care using growth biostimulators: GreenOk – Universal Pro and Asahi SL and their combination with Avatar 293 ZC herbicide. As a result of the studies, it was concluded that genetic features of the cultivated varieties, as well as methods of care applied in the experiment did not have a significant impact on the content of total sugars and reducing sugars in tubers of potato. The value of these characteristics substantially depended only on the course of thermal-precipitation conditions in the given years of research. Significantly higher content of total sugars (an average 0.74%) was shown by the tubers harvested in a warm and dry growing season of the year 2015, whilst the highest content of reducing sugars in tubers was recorded in a cool, wet growing season of 2017 (an average of 0.39%).
Keywords: *Solanum tuberosum L., anti-nutritional components, GreenOk-Uniwersal Pro, Asahi SL, Avatar 293 ZC*

Introduction

Potato (*Solanum tuberosum* L.) is one of the most important cultivated plants not only in Poland (potato consumption in Poland amounts to approximately 100 kg/person/year) but it also constitutes the basis of diet of a growing number of people worldwide – it is grown in about 160 countries. Current consumption of fresh potatoes has a decreasing trend, however the processed products have become more and more popular; especially fried potatoes (French fries, crisps), dried, pasteurized, blanched, as well as sliced and subjected to an initial heat treatment (Camire et al., 2009; Ezekiel et al., 2013; Grużewska et al., 2016).

The nutritional value of potato results mainly from the chemical composition of the tubers. The components that are of large importance in human nutrition include: starch, complete protein, fibre, vitamins and minerals. Contrary to the prevailing opinion, Potato tubers are low-calorie and easily digestible. The caloric value of the tubers is approximately 50-90 kcal/100 g and is comparable to the energy value of apples (54

DOI: http://dx.doi.org/10.15666/aeer/1702_34573468

kcal) or milk (62 kcal) and is 10 times less than the caloric value of chocolate (563 kcal) (Navarre et al., 2009; Zarzecka et al., 2013; Zgórska, 2013; Wegner et al., 2015).

In the edible potato production, particular attention should be paid to the contents of sugars: total (glucose + fructose + sucrose) and reducing sugars (glucose + fructose), which are important features indicating the usefulness of tubers intended for direct human consumption, frying, or drying. In the weight of fresh tubers intended for direct consumption and processing, the total sum of sugars should not exceed 1% and reducing sugars 0.5%. Whist within the potatoes used for the production of French fries and crisps the content of reducing sugars should not be greater than respectively 0.25 and 0.15%. Increased content of total sugars (>1%) gives the tubers sweet taste and causes them to darken faster, which results in deterioration of the culinary quality of tubers (Cropp et al., 2000; Finaly et al., 2003; Zgórska and Sowa-Niedziałkowska, 2005; Storey, 2007; Grudzińska et al., 2014).

In potato tubers, the increased content of reducing sugars is especially undesirable and dangerous to human health (Hebeisen et al., 2005). Their negative impact is revealed during the preparation of potato products, fried foods (French fries, crisps), as well as baked or roasted ones (at temperature >120 °C). Reducing sugars with amino acids are involved in *Maillard's reactions* (this is a series of chemical reactions, which occur frequently under the influence of heat between amino acids and reducing sugars). They adversely affect the colour, taste and smell of food products, as well as give rise to acrylamide (C_3H_5NO) very harmful for our health – a compound with neurotoxic and carcinogenic action. According to Mojska et al. (2008) and Żyżlewicz et al. (2010) in French fries and crisps there may be significant content of acrylamide (from 50 to 2400-2600 µg/kg), whilst French fries prepared at home tend to have a higher content of acrylamide than those prepared in industrial conditions.

The use of raw material with low (0.1-0.2%) concentration of reducing sugars is considered the primary factor limiting the formation of acrylamide toxicity (Amrein et al., 2004; Biedermann-Brem et al., 2003; De Wilde et al., 2006; Wójcik-Stopczyńska et al., 2012).

The content of total sugars and reducing sugars in tubers of potatoes depends on numerous factors, such as a genetic factor of the cultivated varieties, climatic conditions, as well as the applied agrotechnical treatments (Grudzińska and Zgórska, 2008, 2010; Grudzińska et al., 2014; Zarzecka et al., 2017).

In plant production, including also in potato agro-technology, all sorts of preparations friendly to agro-eco-systems have been increasingly applied, which are referred to as biostimulators. They restrict the use of agrochemicals and thus contribute to the development of sustainable crop production methods (Du Jardin, 2012; Calvo et al., 2014; Baranowska et al., 2017). Biostimulators are synthetic or natural preparations which enhance stimulating of the life processes of plants and increase the resistance of plants to stress conditions (Ziosi et al., 2013; Matyjaszczyk, 2015). Their chemical composition includes a whole range of bioactive compounds such as humus substances, algae, microorganisms, mineral elements, vitamins, amino acids, nitrophenols, cytokinins, auxins and other substances classified as plant hormones (Bulgari et al., 2015).

However, the possibility of using biostimulators in farming practice is not yet fully discovered, and in Poland so far there have been no scientific studies on the impact of GreenOk-Uniwersal Pro on more important qualitative features of potato tubers. Therefore, the aim of the experiment was to determine the impact of the five methods of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34573468

care using growth biostimulators and herbicide on the content of total sugars and reducing sugars in tubers of three edible potato varieties.

Materials and methods

Experiment and plant material

The three-year field experiment was executed in the years of 2015-2017 in the region of Eastern Poland, in Biała Podlaska municipality (52°02'N; 23°07'E), in the Lublin Voivodeship on light, acidic soil (*Fig. 1*). The soil was characterized by a very high content of assimilable forms of phosphorus and potassium and high to very high form of magnesium.

Figure 1. *One of the experiment objects*

The experiment took place in the split-plot system in three repetitions. The impact of the two factors was studied (*Table 1*).

Table 1. *Factors of the experiment*

I. Factor – Three early edible potato cultivars: Bellarosa, Owacja, Vineta	
II. Factor – Five methods of treatment with the application of growth biostimulators and herbicide:	
1.	Standard object – mechanical treatment (without biostimulators and herbicide).
2.	From sprouting of potato plants – mechanical treatment and after sprouting – GreenOK Universal–PRO bioactivator, three times to leaves: at a dose of 0.10 dm^3 ha^{-1} (phase BBCH 13-19) + 0.15 dm^3 ha^{-1} (phase BBCH 31-35) + 0.15 dm^3 ha^{-1} (phase BBCH 51-55).
3.	From sprouting of potato plants – mechanical treatment, and after sprouting – Asahi SL bioactivator, three times to leaves at a dose of 0.50 dm^3 ha^{-1} (phase BBCH 13-19) + 0.50 dm^3 ha^{-1} (phase BBCH 31-35) + 0.50 dm^3 ha^{-1} (phase BBCH 51-55).
4.	From sprouting – mechanical treatment, and after the final shaping of ridges and just before sprouting Avatar 293 ZC herbicide at a dose of 1.5 dm^3 ha^{-1} (phase BBCH 00-05). After sprouting – three applications of GreenOK Universal–PRO bioactivator at a dose of 0.10 dm^3 ha^{-1} (phase BBCH 13-19) + 0.15 dm^3 ha^{-1} (phase BBCH 31-35) + 0.15 dm^3 ha^{-1} (phase BBCH 51-55).
5.	From sprouting – mechanical treatment, and after the final shaping of ridges before sprouting of potato plants – Avatar 293 ZC herbicide at a dose of 1.5 dm^3 ha^{-1} (phase BBCH 00-05).

The characteristics of potato varieties and preparations used in the experiment have been presented in *Tables 2* and *3*.

***Table 2.** Characteristics of varieties of potatoes grown in the experiment. (Source: Plant Breeding and Acclimatization Institute – National Research Institute, Poland 2015)*

Variety	Year of inscription to the variety register	Breeder of variety	Usefulness of varieties for food processing
Bellarosa	2006	Europlant, Pflz. GmbH, Germany	Cooked products, French fries
Owacja	2006	PMHZ Strzekęcino, Poland	Puree, pancakes, cooked products
Vineta	1999	Europlant, Pflz. GmbH, Germany	Canned goods, frozen goods, salads, cooked products

***Table 3.** Characteristics of preparations used in the experiment. (Source: Information disclosed by agents' manufacturers)*

Name of preparation	Content of active substances
Avatar 293 ZC herbicide	Clomazone 60 g dm^3 (5.13%), metribuzin 233 g dm^3 (20.64%)
GreenOK Universal–PRO bioactivator	Humus substances ≥ 20 g dm^3, (NPK 0.13-0.09-0.7), dry mass 22 g dm^3, humidity 96%, organic substances 3%, pH 7-9
Asahi SL bioactivator	Sodium para-nitrophenolate 3 g dm^3 (0.3%), sodium orto-nitrophenolate 2 g dm^3 (0.2%), sodium 5-nitroguaiacolate 1 g dm^3 (0.1%)

During each year of the experiment, in autumn, the manure fertilization at a dose of 25 t ha^{-1} and phosphatic fertilization P: 44.0 kg ha^{-1} kg and potassium K: 124.5 kg ha^{-1} were applied, and in spring – fertilization with nitrogen at a dose of N: 100 kg ha^{-1}. Tubers of potato were planted in the second decade of April (in 2015 and 2016) and the third decade of April (in 2017). Treatments for protection against pests (diseases and pests) were used in accordance with the recommendations of the plant protection. The plantation was protected by applying spraying with the following insecticides: Actara 25 WG (thiamethoxam 250 g kg^{-1}) at a dose of 0.08 kg ha^{-1}, Calypso 480 SC (thiacloprid 480 g dm^3) at a dose of 0.1 dm^3 ha^{-1} and fungicides: Copper Max New 50 WP (copper – 500 g kg^{-1}) at a dose of 2.0 kg ha^{-1}, Dithane Neo Tec 75 WG (mancozeb 750 g kg^{-1}) at a dose of 2.0 kg ha^{-1}. Tuber collections were carried out in the phase of technological maturity.

Chemical analysis methods

In order to perform chemical analyses of all experimental objects, the tubers from 10 randomly selected plants of potato were sampled (with the exception of the marginal plants). Chemical analyses were performed in three repetitions for each combination of the experiment (90 tests in total). The content of reducing sugars (glucose + fructose) and total sugars (total sugars) were marked in the fresh tuber mass not selected by means of the method of *Schoorl-Luff* (Krełowska-Kułas, 1993). The results were expressed as percentage of fresh mass.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34573468

Statistical analysis

Results of research were statistically elaborated by means of the analysis of variance (one-way and two-way Analysis of Variance ANOVA). The significance of the variation sources was studied through test F of Fisher-Snedecor, and the assessment of significance of differences at the significance level 0.05 between the compared averages using multiple compartments of Tukey (post hoc test).

Weather conditions

Weather data came from The Weather Station of the Cultivars Research Centre (COBORU) in Słupia Wielka and were prepared for the Experimental Station of the Evaluation of Varieties in Cicibór Duży, localized within 6 km from Biała Podlaska. The weather conditions in growing seasons of 2015-2017 were described on the background of the multi-year period 1981-2010 based on deviations of average monthly air temperature (°C) and total precipitation (mm) and of hydrothermal Sielianinov coefficient (Chereszkowicz, 1979; Skowera, 2014).

The precipation-thermal conditions during the research were varied (*Table 4*). The total rainfall in the year 2015 reached approx. 63 mm lower than average rainfall during the multi-year period (1981-2010), while the average temperature was about 1.1 °C higher than the average long-term air temperature. The biggest deficiency of precipitation was specific for the months of June, July and August. The hydrothermal Sielaninov coefficient (K = 0.99) indicates that the growing season of the year 2015 was a dry season. During the execution of the experiment, the moistest and coolest growing season was in 2017. In this season, the rainfall was higher by 74 mm from the average rainfall from the respective period of the multiannual period, and hydrothermal Sielianinov coefficient was the highest in relation to the rest of the years of research and was 1.50. In 2016, during the period of the largest potato demand for precipitation, the conditions of thermal runoff were more favourable compared to the growing season of 2015 and 2017 (*Table 4*).

Results and discussion

One of the most important characteristics that determine the usefulness of potato tubers for direct consumption as well as for processing is the content of total sugars and reducing sugars, which in fresh tuber mass should not exceed 1% (Grudzińska et al., 2016).

As a result of the executed research, it was found that the content of total sugars in tubers of potato was on average 0.659% while reducing sugars 0.321% (*Tables 5* and *6*). The methods of care applied in the experiment, as well as the genetic features of the varieties, did not have a significant impact on the content of total sugars and reducing sugars in tubers of potato. The value of these characteristics depended on the course of thermal-precipitation conditions in the relevant years of research (*Tables 5* and *6*).

Treatment methods using growth biostimulators and herbicide (object 2-5) have contributed to a slight increase of the content of total sugars and reducing sugars compared to the control object that uses only mechanical treatment (without growth biostimulators and herbicide) (object 1) (*Tables 5* and *6*). Also, Trawczyński (2014) after the application of amino acid biostimulators in the cultivation of potatoes did not note their significant impact on the content of reducing sugars in tubers. Similar test

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34573468

results were obtained also by Maciejewski et al. (2007) by applying foliar feeding of potato plants with Asahi SL and SL Atonik biostimulators. Furthermore, Rudzińska-Mękal (2000) has proved that the growth biostimulators caused a significant increase in the content of reducing sugars in tubers of potato, which may have resulted from inhibition of the biosynthesis of oligo-and polysaccharides due to the decrease in the concentration of potassium in the tubers of potato.

Table 4. *Meteorologic conditions according to the Research Centre for Cultivar Testing (COBORU) in Słupia Wielka Poland*

Study year	Deviations from the long-term (1981-2010) mean

Air temperature (°C)							
2015	+0.4	–1.1	+0.1	+0.8	+3.7	+2.4	+1.1
2016	+1.8	+1.1	+1.8	+1	+0.8	+2.5	+1.5
2017	–0.2	–0.1	+1.4	–0.3	+2	+2	+0.8
Sielianinov hydrothermal coefficient *(K)							
2015	1.43	2.28	0.59	0.80	0.11	1.66	0.99
2016	1.19	0.47	1.53	1.97	0.48	0.26	1.00
2017	2.68	0.93	1.97	1.24	0.66	2.37	1.50

*Sielianinov hydrothermal coefficient *(K)* – formula as in research methodology;
**Month's classification according to: Chereszkowicz (1979) and Skowera (2014): extremely dry $K \leq 0.4$, very dry $0.4 < K \leq 0.7$, dry $0.7 < K \leq 1.0$, quite dry $1.0 < K \leq 1.3$, optimal $1.3 < K \leq 1.6$, quite humid $1.6 < K \leq 2.0$, humid $2.0 < K \leq 2.5$, very humid $2.5 < K \leq 3.0$, extremely humid $K > 3.0$

In the studies of Gugała et al. (2013) and Sawicka and Pszczółkowski (2005), the applied herbicides, as well as their mixtures did not have a significant impact on the content of sugars in tubers, however, they caused a slight increase in the content of total sugars and reducing sugars. In contrast, Zarzecka et al. (2017) have shown that herbicides: Plateen 41.5 WG (metribuzin + flufenacet) and Racer 250 EC (fluorochloridone) significantly increased the content of total sugars, and herbicide Plateen 41.5 WG increased the content of reducing sugars. Zarzecka and Gugała (2018) after applying herbicide Sencor WG 70 (metribuzin) and growth regulator Asahi SL have found a significant increase in the content of total sugars and reducing sugars in tubers of potato.

Also, the potato varieties cultivated in the study did not differ significantly in terms of discussed quality features. The varieties were characterised by a similar concentration of total sugars – an average from 0.635 to 0.681% and reducing sugars, on average from 0.314 to 0.345% (*Tables 5* and *6*), what is confirmed in studies carried out by Sawicka and Pszczółkowski (2005), who found no significant effect of the genetic characteristics of varieties on the content of total sugars and reducing sugars. However, close relationship of the sum of sugars and reducing sugars in cultivated tubers of potato was recorded in the works of Jarych (2004), Zgórska and Grudzinska (2012) and Bhattacharjee et al. (2014). In studies of Maciejewski et al. (2007) after application of biostimulators Asahi SL and Atonik SL, the variety Ditta resulted in the

DOI: http://dx.doi.org/10.15666/aeer/1702_34573468

reduction of the content of reducing sugars, while the variation of Satina gathered more of them.

In the studies of Gugała et al. (2013) and Sawicka and Pszczółkowski (2005), the applied herbicides, as well as their mixtures did not have a significant impact on the content of sugars in tubers, however, they caused a slight increase in the content of total sugars and reducing sugars. In contrast, Zarzecka et al. (2017) have shown that herbicides: Plateen 41.5 WG (metribuzin + flufenacet) and Racer 250 EC (fluorochloridone) significantly increased the content of total sugars, and herbicide Plateen 41.5 WG increased the content of reducing sugars. Zarzecka and Gugała (2018) after applying herbicide Sencor WG 70 (metribuzin) and growth regulator Asahi SL have found a significant increase in the content of total sugars and reducing sugars in tubers of potato.

Also, the potato varieties cultivated in the study did not differ significantly in terms of discussed quality features. The varieties were characterised by a similar concentration of total sugars – an average from 0.635 to 0.681% and reducing sugars, on average from 0.314 to 0.345% (*Tables 5* and *6*), what is confirmed in studies carried out by Sawicka and Pszczółkowski (2005), who found no significant effect of the genetic characteristics of varieties on the content of total sugars and reducing sugars. However, close relationship of the sum of sugars and reducing sugars in cultivated tubers of potato was recorded in the works of Jarych (2004), Zgórska and Grudzinska (2012) and Bhattacharjee et al. (2014). In studies of Maciejewski et al. (2007) after application of biostimulators Asahi SL and Atonik SL, the variety Ditta resulted in the reduction of the content of reducing sugars, while the variation of Satina gathered more of them.

The implemented statistical calculations have shown that changing weather conditions prevailing in the years of research substantially modified the content of total sugars and reducing sugars in tubers of potato.

The largest total sugar content – an average of 0.741% was characterized by tubers harvested in 2015, in which during the period from June to August there was a high deficit of precipitation and air temperature in August (before the harvest of tubers) was higher by 3.7 °C from the average multiannual temperature (*Tables 4* and *5*). While most reducing sugars – an average of 0.395% were recorded in 2017, when the lowest air temperature and rainfall compared to the other years occurred (*Tables 4* and *6*). These results are consistent with the research of Gugała et al. (2013) and Zarzecka et al. (2017), who reported a significant effect of diverse weather conditions on the content of total sugars and reducing sugars in tubers of potato. Also according to other authors, Rodriguez et al. (2010), Murniece et al. (2011) and Brazinskiene et al. (2014), the content of sugars in tubers of potato is not stable and is subject to significant changes in individual years of research.

Sawicka and Pszczółkowski (2005) noted the highest content of total sugars and reducing sugars in the growing season with the most intense sunlight and rainfall. According to Grudzińska et al. (2014), a decisive influence on the content of reducing sugars in the tubers of potato is triggered by air temperature and total precipitation for ten days before harvesting and during the time of harvesting tubers. The authors, by studying 268 potato varieties over the course of fourteen years, found that the higher the air temperature and rainfall deficiency before harvest tubers, the less content of reducing sugars in tubers; whilst Frydecka-Mazurczyk and Zgórska (2002) stated that the potatoes, which before the harvest experienced autumn overcooling, collected reducing sugars more intensely. According to Nourian et al. (2003), this may be due to the activity of the enzyme which catalyses sucrose to glucose and fructose.

An in-depth analysis revealed a significant effect of interaction of weather conditions and genetic features of varieties on the content of total sugars and reducing sugars in edible potato tubers (*Table 7*).

Bellarosa variety cumulated substantially less total sugars than the remaining varieties in humid and cool growing season of 2017, whilst in the favourble growing season of 2016, less total sugars were gathered by the tubers of Owacja variety.

In the season of 2017 also a significant effect of genetic features of varieties was reported on the content of reducing sugars. The majority of reducing sugars was cummulated by the tubers of Bellarosa variety, whilst the least –tubers of Owacja variety. No substantial differences in terms of the discussed features were noted in the warm and dry growing season of 2015 (*Table 7*).

Table 7. *Impact of weather conditions on the average content of sugars in fresh potato tuber mass, considering genetic features of varieties (%) (in-depth analysis)*

Conclusions

Currently, an increasing interest in agricultural practice and teachings has been inspired by preparations referred to as growth biostimulators. Therefore, it is very important to familiarize oneself with their impact on the more important quality characteristics of crops, including potato, which occupies an important place in human diet and which has been one of the most frequently cultivated plants (in the global crop production it occupies the fourth place after wheat, rice and maize).

The content and quality of biological substances included in the chemical composition of potato decide about the dietary value of tubers. In tubers, however, there can be substances, whose increased content affects the consumer quality. The priority size of the tubers for food processing is the content of total sugars and reducing sugars. Understanding the impact of agricultural science treatments on the value of these features is a challenge for research not only in Poland but also on the international level.

In own studies, the treatment methods using growth biostimulators as well as cultivation of potato varieties do not have a significant impact on the content of total sugars, as well as the reducing sugars compared to the control object (on which growth biostimulators and herbicide were not applied). The value of these characteristics depended only on the course of weather conditions in the years of research. More total sugars were collected by tubers in a warm and dry growing season of 2015 while reducing sugars – in humid and cool growing season of 2017.

Abstract. In order to improve the quality of water, the enrichment of different heavy metal ions by aquatic plants is studied—taking duckweed as an example. The site of the experiment is in Sichuan University of China, mainly from the following aspects of research: the heavy metal content in water, the heavy metal content in duckweed, chlorophyll content, adsorption capacity of Cadmium ions in different concentrations of nitric acid solution, enrichment capacity of Cadmium ion and the relationship between heavy metal content in duckweed and that of water. The study shows that the aquatic plants such as duckweed have a strong enrichment to Cu, Pb and Zn in the complex water body of heavy metals Cu, Pb and Zn, and their enrichment ability is higher than that of the water plants. With the increase of Cd^{2+} concentration, the content of chlorophyll a and b in duckweed decreased significantly, and the decline is increased with the increase of Cd^{2+} concentration. In 3 mg/L Cadmium nitrate solution, duckweed has a maximum absorption rate of Cd^{2+} reaching 87%, the adsorption of duckweed decreased with increasing concentration and the enrichment of Cd^{2+} in duckweed showed a nonmonotonic curve with the increase of treatment time. The concentration of Cd^{2+} in the duckweed of 8d reached the maximum value (1.6 mg/g), and the concentration of Cd^{2+} is reduced in the 9-12d duckweed, the concentration of heavy metals in water is significantly correlated with the concentration of Cu, Pb, Zn and Mn in aquatic plants duckweed. The method can effectively analyze the supposed enrichment. The sensitivity of duckweed can be used to detect changes of heavy metals in water, which can be used as an bioindicator of environmental pollution. At the same time, the accuracy of heavy metal determination by this method is high.
Keywords: *duckweed, heavy metal ions, enrichment, chlorophyll content, determine*

Introduction

Since 1970s, with the development of industry and agriculture, all kinds of untreated sewage have been discharged into lakes and rivers, and the amount of heavy metals in the water increased. Most of these have the characteristics of enduring hazards, geochemical recycling and ecological risk. Aquatic plants such as duckweed are part of the ecosystem, and they play an important role in material circulation, migration of elements and purification of sewage. A large number of studies have shown that the heavy metal content in water has a positive correlation with the heavy metal content in aquatic plant, the amount of many of elements in duckweed are hundreds of times as much as these in the water, therefore, the content of heavy metals in duckweed is used to reflect the level of heavy metals in water (Li and Wang, 2016). The heavy metals absorbed by aquatic plants are mainly derived from their growing environment. If the concentration of heavy metals in water increases, the content heavy metals in aquatic plants will also increase. That is to say, the higher the heavy metals level in the pollution, the higher the concentration of heavy metals in plants. The toxic effect of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34693482

metals on duckweed has been studied by scholars. After sampling, different heavy metal ions were analyzed to compare the different enrichment of duckweed. The analysis basis for sewage treatment is provided and improves the quality of water (Unsal and Soylak, 2015).

Tang et al. in order to screen duckweed varieties which can efficiently remove heavy metal Cadmium from water and accumulate biomass rapidly, 12 duckweed varieties with tolerance to 30 mg/L Cd^{2+} concentration are screened again at 0.5 mg/L and 10 mg/L Cd^{2+} concentrations. The best variety of *Landoltia punctata* ZH0049 is obtained. At the same time, the relationship between the change of chlorophyll content and the concentration of Cadmium stress are analyzed. However, the results of this method were not accurate (Tang et al., 2015a); Fan et al. take duckweed as the research object and applied phosphate to study the response mechanism of antioxidant enzyme system and the enrichment ability of Uranium under different concentration of Uranium stress. There is a problem that the research time is too long (Fan et al., 2018). In view of the above problems, the enrichment of different heavy metal ions by aquatic plants is studied, taking duckweed as an example.

Materials and methods

Materials

Duckweed samples of size 1-2 mm (1 mm × 1 mm) are collected in the lake water, specifically in TaiHu Lake (120° 36’ E and 31° 22’ N), JiangSu province. The samples are collected by duckweed fishing vessel with a sample quantity of 5 kg. 150 clean plastic drums with a volume of 14 L are selected. The human nutrient solution is injected into each barrel without heavy metal ions to be measured, and an open foam plate is placed on the barrel as the growth carrier of the plant. Duckweed is transferred into three round holes of foam carrier, and its root is immersed in 1/10 Hoagland solution. The growth and management of plants are cultivated in the open air, watered every 3 days and supplemented with 1/10 Hoagland solution, which kept the plants well ventilated and illuminated. Plant samples are collected after 15 days.

Finally, the collected samples will be rinsed repeatedly with tap water and distilled water. After sucking the water with the absorbent paper, the fresh weight is measured. Then it was dried in a ventilated and dry place, and the dry weight was measured after drying. The crushed and mixed samples were kept in grinding bottles and jars. The site of the experiment is in Sichuan University of China, the GPS coordinates of the experimental site are 104° 08’ E and 30° 63’ N.

Methods

Determination of heavy metal content in water

The sealed water samples are brought back to the laboratory, and the content of heavy metals in water is measured by flame atomic absorption spectrometry, repeated three times.

Determination of heavy metal content in duckweed

The nitrate and perchloric acid (HNO_3 40 mL, $HCLO_4$ 40 mL) added to 0.3 g duckweed powder were digested and heated on the electric heating board, and set up to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34693482

100 mL by deionized water. The atomic spectrophotometer is used to determine the content by air acetylene flame (Zhao and Shi, 2015).

Determination of chlorophyll content in duckweed

Plants with good growth and uniform leaf size are selected for continuous cultivation of 3d in plastic pots containing tap water (Park and Kim, 2013). They are transferred to 1/10 Hoagland solution for 1 week and treated with Cadmium.

$CdCl_2$ is added to the 1/10 Hoagland solution, and 7 concentration gradients of Cd^{2+} are set up as 0 (control), 1, 2, 4, 6, 8 and 10 mg/L. Each treatment set up 3 parallel samples with 20 plants. The growth of the plant must be observed during the treatment. The duckweed is cultured in the PGX multi section light culture box. When the light of 4500 lux is irradiated for 12 h/d, the temperature was (25 ± 1) °C, the chlorophyll fluorescence parameters of duckweed after 24, 48, 72 and 96 h are determined, respectively.

The chlorophyll fluorescence parameters are determined by underwater luminoscope. Before measuring, add duckweed that is sucked out of water into a Petri dish wrapped in tin foil. After 10 mins, the fibers are aligned to the colorimeter and the modulation light is opened to determine the minimum fluorescence (F0). Then the saturation pulse is opened and the maximum fluorescence (Fm) is measured to calculate the maximum light chemical quantum yield (FV/Fm); The photochemical light of setting intensity continuous irradiation time is 3 min, and a saturated pulse (4000 mu mol/m^2 s) with a time interval of 20 s and a duration of 0.8 s is opened, then the quenching analysis is carried out. After the determination of the fluorescence parameters, the stable fluorescence value was obtained and analyzed (Lalau and Mohedano, 2015). The calculation formula of chlorophyll fluorescence parameters is as follows (*Eqs. 1–7*):

$$F_V / F_m = (F_m - F_0) / F_m \quad \text{(Eq.1)}$$

$$\Phi_{PSII} = (F'_m - F_t) / F'_m \quad \text{(Eq.2)}$$

$$qP = (F_m - F_t) / (F_m - F_0) \quad \text{(Eq.3)}$$

$$rETR = \Phi_{PSII} \times PAR \times 0.5 \times 0.84 \quad \text{(Eq.4)}$$

$$F_V / 2 = (F_m - F_0) / 2 \quad \text{(Eq.5)}$$

$$qN = (F_m - F'_m) / (F_m - F_0) \quad \text{(Eq.6)}$$

$$F_0 / F_V = F / (F_m - F_0) \quad \text{(Eq.7)}$$

Where F'_m the maximum fluorescence output is obtained when the saturation pulse is opened; F_t represents the fluorescence output measured at any time; PAR indicates the light and effective radiation intensity (μ mol/m^2 s) of the incident to the samples.

It should be made clear that the bioaccumulation coefficient is used in the determination. Bioaccumulation coefficient is the ratio of the concentration of certain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34693482

elements or refractory compounds in an organism to the concentration of the substance in the environment in which it exists, and can be used to indicate the degree of biological concentrations. The calculation formula is as follows (*Eq. 8*):

$$B = \frac{\text{Concentration of refractory compounds}}{\text{Total concentration of substances in the environment}} \tag{Eq.8}$$

The determination of chlorophyll content:

After 96 h, the centrifuge tube containing 0.5 g samples is frozen in the fridge for 1 H, then the 10 mL 95% ethanol heated to 50 °C in the water bath is added into, and the content of chlorophyll (Tang et al., 2015b) is determined by taking the supernatant in the dark cabinet and taking the supernatant in the dark cabinet. After Shaking and keeping quiet for 3 hours in dark room, the chlorophyll content is measured.

The chlorophyll absorbance A (Wan and Wu, 2018) is determined by spectrophotometer, and the chlorophyll concentration is calculated according to the following formulas (*Eqs. 9* and *10*):

$$Chla = 12.7A_{663} - 2.69A_{645} \tag{Eq.9}$$

$$Chlb = 22.9A_{645} - 4.68A_{663} \tag{Eq.10}$$

Where *Chla* and *Chlb* represent the concentration of chlorophyll a and b (mg/L) respectively; A_{663} and A_{645} mean the absorbance of chlorophyll solution at 663 nm and 645 nm respectively. The experimental data are analyzed and processed by SPSS15.0 software.

Enrichment of duckweed response to Cadmium ions in different concentrations of nitric acid solution

The lethal concentration and the actual situation of duckweed in Cd^{2+} solution are studied. The solution of 1 mg/L, 3 mg/L and 5 mg/L $Cd(NO_3)_2$ is disposed by the solid of Cadmium nitrate. The duckweed with good long potential, similar size and fresh weights 1.6 g is added into the 200 mL solution of 1 mg/L, 3 mg/L, 5 mg/L $Cd(NO_3)_2$, and the is added to the experiment (Xiong and Jiao, 2014). The other two groups are reserved, repeat it.

Enrichment of duckweed response to Cadmium ions in different periods of time

The solution of 3 mg/L $Cd(NO_3)_2$ is prepared with Cadmium nitrate solution. Duckweed with good growth, similar size and 7 g fresh weights is placed in the 3 glass cylinders containing 1 L solution of 3 mg/L $Cd(NO_3)_2$, respectively. A glass cylinder containing 1 L solution of 3 mg/L $Cd(NO_3)_2$ without duckweed was also used as a control. The concentration of Cadmium, the chlorophyll content in the duckweed, and the content of Cadmium in duckweed (Allende and Mccarthy, 2014) is measured in turn in the 3 cylinders solution after 4, 8 and 12d. The other two groups are reserved, repeat it.

Determination of relation between heavy metal content in aquatic plants and heavy metal content in water

Duckweed with good growth, similar size and 4.5 g fresh weights is respectively placed in the 2 beakers containing 600 mL solution of lake water. Another 600 mL water beaker without duckweed is used as a control group. The two groups is added with nutrient solution and placed in the place with adequate light and suitable environment (Chen and Liang, 2016). After 4 days, the concentration of Cu, Zn, Ni and Cr in the solution (Chaudhary and Sharma, 2014) and the chlorophyll content in the duckweed is measured. Another group was prepared, repeat triple times.

Results

Results of heavy metal content in water

The contents of Cu, Pb, Zn, Cd and Mn in water samples are compared with the standard of Surface Water Environmental Quality (GB3838-2002). The contents of Cu, Pb, Zn, Cd and Mn in the waters of Taihu Lake (120° 36' E and 31° 22' N) are described in *Table 1*.

Table 1. *Water quality and heavy metal contents in water and surface water V (mg/L)*

Item	Cu	Pb	Zn	Cd	Mn
Water sample	7	1.02	5	4	4.38
V class standard	1	0.1	2	0.01	1

Analysis of heavy metal content in aquatic plants such as duckweed

The bioaccumulation coefficient is an important index for measuring the accumulation capacity of heavy metals in plants, the greater the BCF, the stronger the enrichment capacity (Jain and Verma, 2015). The heavy metal content and the BCF of the aquatic plants are described by *Table 2* and *Figures 1* and *2*.

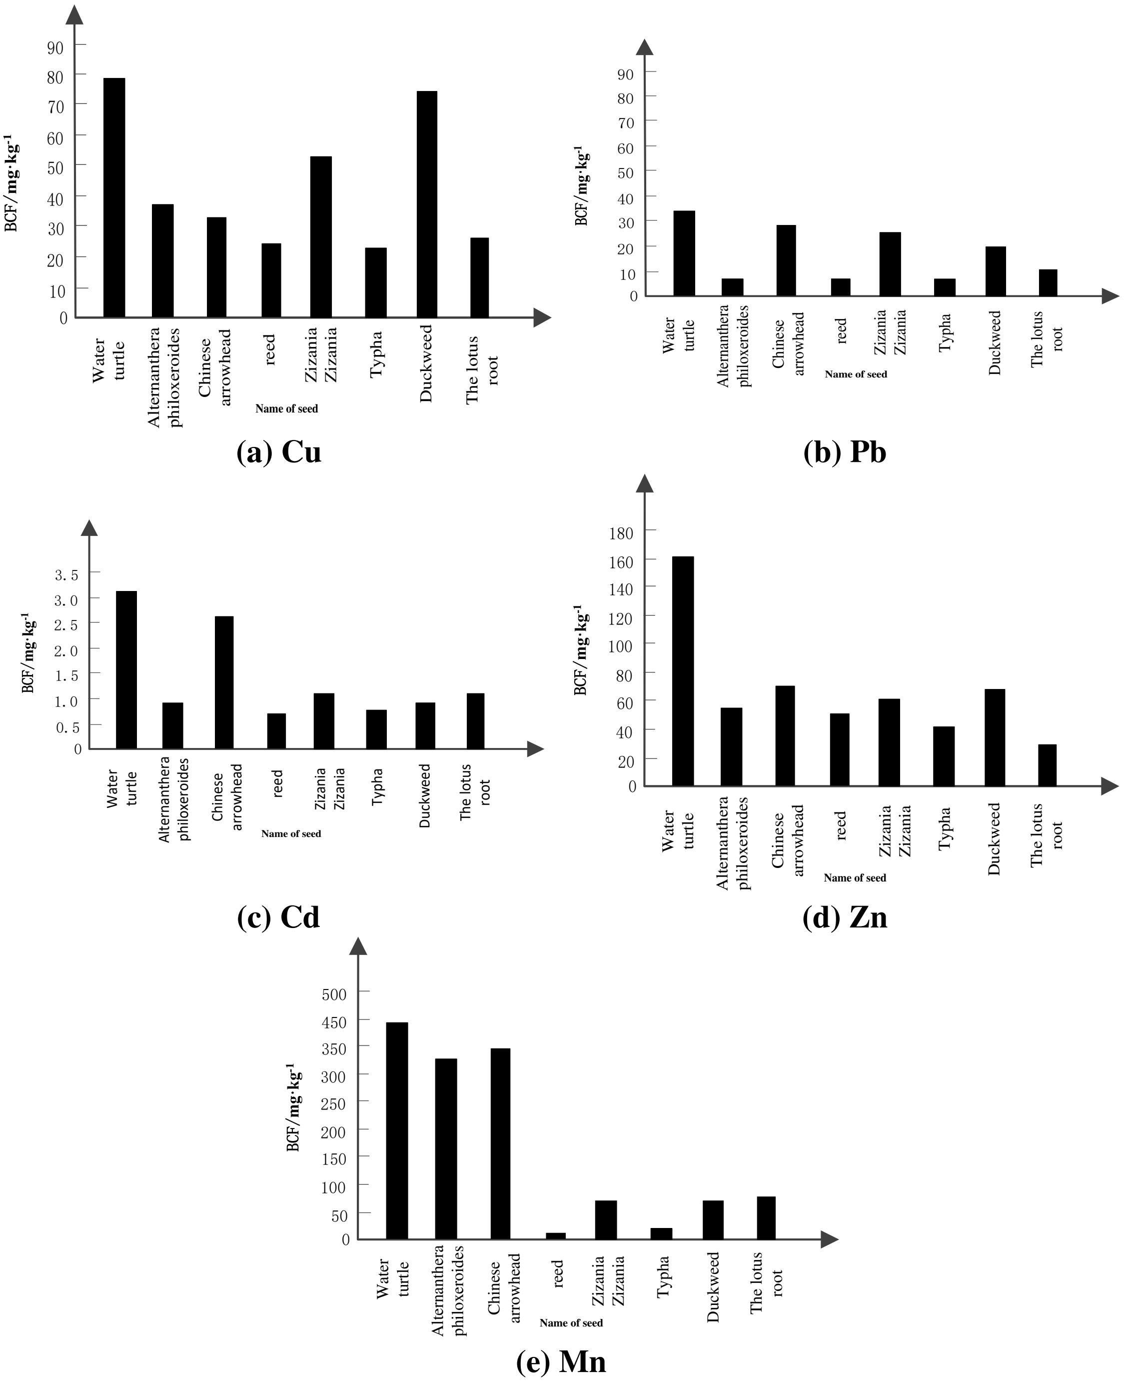

Figure 1. *Contents of heavy metals in the roots of duckweed and other aquatic plants*

The relationship between heavy metal content and BCF of the aquatic plants can be seen from *Table 2* and *Figures 1* and *2*. The uptake of heavy metals by different plants is quite different. The accumulation of Cu, Pb and Zn in aquatic plants is relatively large, and the BCF of roots, stems and leaves is all more than 1. It can be seen that the aquatic plants have strong accumulation ability of Cu, Pb and Zn, and the accumulation ability of heavy metals in duckweed is generally higher than that of floating plants. According to *Table 2* and *Figures 1* and *2,* compared with other organisms, the contents

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34693482

of heavy metals in leaves of duckweed are higher, which indicated that the enrichment ability of leaves of duckweed is stronger.

values, that is, the ratio of the chlorophyll fluorescence value measured by the daily Cadmium stress (the following is represented by 0 h). In fluorimetric analysis, the maximum photochemical quantum yield F_V / F_m of PSII is the most commonly used parameter. It reflects the initial light energy conversion efficiency of PSII (PSII apparatus). In normal physiological state, the change is smaller, but it will fall after the plant is stressed (Park and Kang, 2014). Therefore, it is an important parameter for the good environment of plant growth, and could indicate the damage to photosynthesis by Cadmium ions in the short time of the plant being broken. The effects of different concentrations of Cadmium ions on the growth of duckweed are shown in *Figures 3* and *4*.

Discussion

Discussion on the determination of heavy metal content in water

In *Table 1,* the test results of the heavy metal content in water indicated that the content of Cd^{2+} and Mn^{2+} in water body is obviously greater than that in other aquatic plants, but the content of Mn^{2+} in the root of soft shelled turtle is slightly higher than that of water. This is due to the continuous oxidation of plant rhizosphere. the root surface and the root outer body are oxidized to form iron and manganese film, preventing the toxicity caused by excessive absorption of Cd^{2+} and Mn^{2+}, resulting in the lower content of Cd^{2+} and Mn^{2+} in the aquatic plants of duckweed and other aquatic plants. In order to prevent the toxicity caused by excessive absorption of Cd^{2+} and Mn^{2+}, the iron and manganese films might be formed on the root surface and the root outer body, which led to the lower content of Cd^{2+} and Mn^{2+} in the aquatic plants.

Discussion on the determination of chlorophyll content in duckweed

In *Figure 3,* when the concentration of Cadmium stress is low (1, 2, 4 mg/L), the change of F_V / F_m is smaller. With the increase of Cadmium stress (6, 8, 10 mg/L), the change of F_V / F_m becomes sensitive. The F_V / F_m values of 8 and 10 mg/L Cadmium stress are decreased by 28.97% and 75.95% at 24 h, respectively, and are declined by 74.86% and 95.95% at 48 h, respectively. While the concentration of Cadmium is 6 mg/L, it decreased by 14.95% at 72 h.

Figure 4 showed the changes of Φ_{PSII}. The Φ_{PSII} changes in the 0, 1 and 2 mg/L groups are small in 24 h, and the Φ_{PSII} of 4, 6, 8 and 10 mg/L groups respectively, while that are decreased by 25.49%, 33.33%, 55.16% and 85.79%, compared with 0 h. Therefore, the declined of the Φ_{PSII} value increased with the increased of Cd^{2+} concentration, the magnitude of the decreased.

As can be seen from *Figure 5,* with the increasing of Cd^{2+} concentration, the contents of chlorophyll a and chlorophyll b are declined significantly, compared with the control group, and the declining of chlorophyll a content is remarkable than that of chlorophyll b, but also the ratio of chlorophyll a to chlorophyll b is decreased.

This indicated that the decline of chlorophyll a is larger than chlorophyll b, which is similar to previous studies (Zhao and Shi, 2015).

Discussion on enrichment of duckweed response to Cd^{2+} in nitric acid solutions with different concentration

From *Figure 6,* it can be seen that the adsorption of Cd^{2+} on duckweed decreased with increasing concentration. These suggested that Cd^{2+} is more toxic to duckweed and affects the normal growth of it.

Discussion on enrichment of duckweed response to Cd^{2+} in different periods of time

In *Figure 7,* the concentration of Cd^{2+} in Cadmium nitrate solution gradually decreased with the increased of treatment time, and the reduction rate of Cd^{2+} concentration slowed down gradually.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34693482

The concentration of Cadmium in duckweed did not show a monotonous curve with the increase of the processing time, and the concentration of Cadmium in the duckweed reached the maximum (1.6 mg/g) at 8 days.

Discussion on relationship between heavy metal contents in aquatic plants and heavy metal contents in water

In the *Table 3,* the concentration of heavy metals in water is significantly correlated with the concentration of Cu, Pb, Zn and Mn in aquatic plants duckweed. The heavy metals can be absorbed and accumulated by duckweed. Therefore, the metals sensitivity of duckweed can be used to detect changes of heavy metals in water, which can be used as a bioindicator of environmental pollution.

To verify the effectiveness of this method, the accuracy rate of heavy metal determination in duckweed is compared with Tang et al. (2015a) and Fan et al. (2018). The results are shown in *Figure 8.*

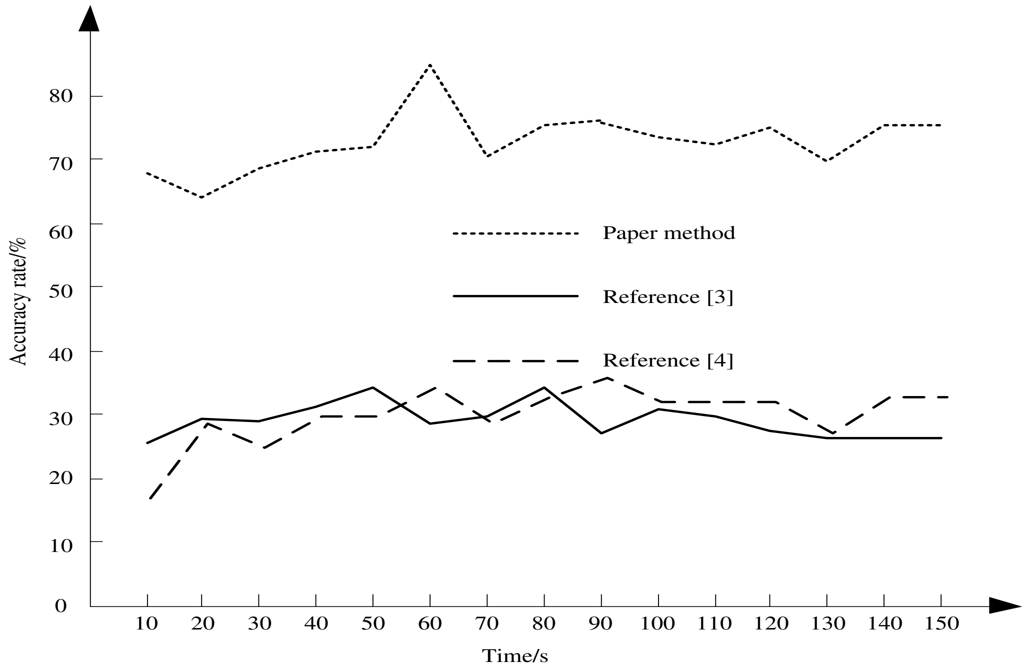

Figure 8. *Comparison of accuracy of different methods*

According to *Figure 8,* the accuracy of this method is much higher than that of Tang et al. (2015a) and Fan et al. (2018), and the average accuracy is more than 70%, while the accuracy of Tang et al. (2015a) and Fan et al. (2018) is less than 30%.

Conclusions

In the paper, the enrichment of duckweed response to different heavy metal ions in water is analyzed from the following aspects: the heavy metal content in water, the heavy metal content in duckweed, chlorophyll content, adsorption capacity of Cadmium ions in different concentrations of nitric acid solution, enrichment capacity of Cadmium ion and the relationship between heavy metal content in duckweed and that of water.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34693482

The content of heavy metals in water is measured by flame atomic absorption spectrometry; the atomic spectrophotometer is used to determine the content by air acetylene flame atomic absorption spectrophotometry; the chlorophyll fluorescence parameters and chlorophyll content in duckweed are measured by grinding and underwater luminoscope. Different concentrations of Cd^{2+} solution are used to observe the lethal concentration and actual situation of duckweed.

Duckweed is cultured in the same concentration of Cadmium nitrate solution, and the enrichment of duckweed response to Cadmium ions in different periods of time is studied.

The average content of heavy metals in different aquatic plants is calculated, and the correlation with the concentration of heavy metals in water is analyzed by setting up the control group.

In short, in order to prevent the toxicity caused by excessive absorption of Cd^{2+} and Mn^{2+}, the iron and manganese films are formed on the root surface and the root outer body, which led to the lower content of Cd^{2+} and Mn^{2+} in the aquatic plants. The aquatic plants have strong accumulation ability of Cu, Pb and Zn, and the accumulation ability of heavy metals in duckweed is generally higher than that of emergent plants. With the increased of Cd^{2+} concentration, the content of chlorophyll a and chlorophyll b significantly decreased, compared with the control group, and the declined of chlorophyll a, but the chlorophyll b content increased. The absorption rate of Cadmium nitrate solution at 3 mg/L is the largest, reaching 87%, and the adsorption of Cd^{2+} on duckweed decreased with increasing concentration. The concentration of Cadmium in duckweed did not show a monotonous curve with the increased of the processing time, and, the concentration of Cadmium in the duckweed reached the maximum (1.6 mg/g) at the 8 days. The concentration of heavy metals in water is significantly correlated with the concentration of Cu, Pb, Zn and Mn in duckweed. The heavy metals can be absorbed and accumulated in the duckweed, and the absorption of heavy metals varies with the change of water environment.

As a new green pollution control technology, phytoremediation is still in the experimental research stage. There is still much work to be done in order to be widely used in wild.

(1) Strengthen the mechanism of metal removal by microbes and plants. The ecological and physiological characteristics of plant communities combined with plant roots, the role of root exudates in the selection of microbial communities and the mechanism of interaction between plant roots and rhizosphere microbial communities need to be further studied.

(2) In the future, genetic factors of superaccumulative plants or microbes growing in heavy metal contaminated environments will be applied to non-superaccumulative plants or microbes through transgenic technology; therefore, it is possible to develop super-enriched plants with strong adaptability, large biomass and enrichment ability to various target pollutants.

(Received 29th Aug 2018; accepted 7th Nov 2018)

Abstract. In recent years, the Ningxia Section of the Yellow River Basin of China has become water-stressed due to the reduction of the upstream precipitation, to the serious water and soil loss in the midstream, to the increased water consumption in industrial and agricultural areas and to other reasons. To fully understand the runoff variation of the Yellow River in the Ningxia Section of China and to rationally carry out the water dispatching and the water resource management, the applicability of the SWAT model for water balance in this basin is explored. Based on the improved SWAT model, the distributed hydrological model of the Ningxia Section of the Yellow River Basin of China has been constructed. The meteorological and hydrological data of the Ningxia Section of the Yellow River Basin of China from 1990 to 2017 have been used for simulation. The relative error R_e, the correlation coefficient R^2 and Nash-Suttcliffe coefficient Ens have been used as the standards, while the sensitive parameter of the measured monthly runoff from 2005 to 2011 to the model used for the calibration, and the model have been validated by the measured monthly runoff from 2012 to 2017. The research results show that the simulation results basically meet the model evaluation requirements, indicating that the SWAT model is applicable to the runoff simulation of the Ningxia Section of the Yellow River Basin of China, and it can provide decision-making basis for water resource management in the Ningxia Section of the Yellow River Basin of China.
Keywords: *SWAT model, Yellow River Basin in Ningxia Section, runoff simulation, hydrological modeling, water resource*

Introduction

The water quality and quantity play a very important role in the aquatic ecosystem. To protect the river ecosystem, the scientific hydrological knowledge is required (Armanini et al., 2011); a Canadian Ecological Flow Index was developed based on benthic macroinvertebrate flow sensitivity index for Canadian rivers. The river runoff plays a pivotal role in water quality and ecology, including phytoplankton, zooplankton and Bacterial communities (Godlewska et al., 2003; Sokal et al., 2010; Wu et al., 2015), and also including hydrological indicators and their application to ecological management and research, such as basin or river health assessments (US EPA, 2015; Biggs et al., 2002).

DOI: http://dx.doi.org/10.15666/aeer/1702_34833497

Hydrological systems are complex and difficult to understand. To overcome these difficulties, hydrologists have studied hydrological systems with a simpler approach that is the hydrological model (Xu, 2002; Woessner, 2012). To research the different influencing factors of hydrological systems, the hydrological model has been continuously improved (Chow et al., 1988). In order to clarify some of the characteristics of the hydrological system, the hydrological model is used to simulate hydrological systems in the basin under climate change conditions, such as climate change, land use and soil (Leavesley et al., 1983; Viessman et al., 1989).

The SWAT (Soil and Water Assessment Tool) model was used to simulate the hydrological processes in the research area as they are influenced by the input data, namely slope, soil, land cover and climate. The SWAT model is the one used for simulating hydrological processes, and related to the input data, soil, climate and land use, as well as other factors. The SWAT model is a distributed watershed hydrological model developed by the Agricultural Research Service (ARS) of US Department of Agriculture (USDA) (Arnold et al., 1998). It is currently a relatively advanced international watershed hydrological model, and this model is mainly used to simulate the water quality and quantity of surface water and groundwater. It can predict the impact of the land management measure on the yield of hydrology, sediment and agricultural chemicals in large and complex watersheds with various soils, land use and management conditions.

The SWAT model is widely used in the world. Schuol et al. (2008) have verified the applicability of the model in the Lunnehe Basin under different hydrometeorological and underlying conditions. Arnold et al. (1998) have verified the applicability of the model in the Mississippi tributary, etc. under different hydrological conditions, different topographic features and different time and space. Fohrer et al. (2017) have found that the land use change had the highest impact on runoff by simulating the Aare River Basin in Germany. Joel and Jiben (2012) have clarified the impacts of various land use patterns on runoff by studying the land use and cover change of the Wami Basin 13a in Tanzania. Nie et al. (2011) have studied the relationship between land use pattern and water balance in the special years of the San Pedro Basin, and found that the urbanization is the biggest influencing factor. Lin et al. (2015) have studied landuse change impacts on catchment runoff using different time indicators based on SWAT model. Lotz et al. (2018) have studied factors of runoff generation in the Dongting Lake basin based on a SWAT model and implications of recent land cover change. Liu et al. (2017) researched the impacts of manure application on SWAT model outputs in the Xiangxi River watershed, Tamm et al. (2018) studied the effects of land use and climate change on the water resources in the eastern Baltic Sea region using the SWAT model. The SWAT model has been modified and adapted to simulate the changes in landuse, fertilizer management and tillage management (Amon-Armah et al., 2013; Maharjan et al., 2016; Liu et al., 2013, 2014). With the best parameters, the SWAT model will be used to simulate the pollution conditions in the selected watersheds (Dechmi et al., 2012; Liu et al., 2016).

In this paper, to fully understand the runoff variation of the Yellow River in the Ningxia Section and to rationally carry out the water dispatching and the water resources management, the applicability of the SWAT model for water balance in this basin is explored. Based on the improved SWAT model, the distributed hydrological model of the Ningxia Section of the Yellow River Basin has been constructed.

Material and methods

Research area

The Yellow River has the entrance in the Xiaheyan in Zhongwei City, Ningxia, China. It flows through Zhongning County, Qingtongxia City, Litong District, Lingwu City, Yongning County, Yinchuan City, Helan County, Pingluo County, Dawukou District and Huinong District, and flows into Inner Mongolia in Shizuishan. There are three hydrological stations on the main stream of the Yellow River, including: Xiaheyan, Qingtongxia and Shizuishan Hydrological Stations. The Yellow River Basin in Ningxia Section is located in the north latitude 36°0′-39°23′ and east longitude of 104°17′-107°39′, and the drainage area is 51400 km^2. Its landform type is the alluvial plain of the Yellow River, and its terrain is flat; its ditches are vertical and horizontal, and its elevation is between 1100 and 2500 m. It is a temperate arid zone with sufficient sunshine. The average annual sunshine hour in the Basin is 2750-2950 h, and the annual average wind speed is 1.7-2.5 m/s. Its temperature difference is large; the heat is rich, and the frost-free period is longer. The Basin is continental climate, with drought and little rain, and its average annual precipitation is 180-220 mm. The annual precipitation changes are weakened from the north to the south. The monthly average difference of precipitation in its Yellow River irrigation area is relatively significant, and the distribution in the year is extremely uneven. The precipitations in arid area in central Ningxia and the southern mountainous areas are relatively flat during the year, showing the seasonal changes. The precipitation in the Basin is unevenly distributed during the year, and the dry and wet seasons are obvious. The precipitation in July-September accounts for 60%-70% of the annual precipitation, and its evaporation is strong, with an average annual evaporation of 1100-1600 mm. The land use types mainly include grassland and cultivated land accounting for 33.74% and 48.76% of the basin area respectively, while the forest land accounts for 3.60% of it, the water area 1.43% of it, the urban and rural industrial and mining resident land 1.46% of it, and the unused land 11.01% of it.

Theory of the SWAT model

The SWAT model has a sub-module for each link of the water cycle, and its design idea is advanced. Such design method is very beneficial for the expansion and application of the model. The model establishes an important connection between the river basin process and the land use activity. Therefore, the applicability of various decisions in the basin management can be evaluated. Different sub-models can be selected and used based on different research purposes. It is also very unique in its operation mode. The SWAT model uses a specific command code control method to control the evolution of water flow in the river network and between sub-basins.

According to the river network system, SWAT divides the studied basin into multiple sub-basins, and maintains the spatial relationship between the geographic location of basin and the sub-basin. There are different meteorological, hydrological, land use, soil, agricultural management measures and pesticide application in each sub-basin. Then, the sub-basin is divided into multiple HRUs (hydrologic response units) based on factors, such as land use type and soil type and their common attributes. The hydrologic response unit is used as the minimum hydrological simulation unit to simulate the various parts of the water cycle and its quantitative transformation relationship, and then the sedimentation, runoff and non-point source load of each hydrologic response unit in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34833497

the sub-basin are summarized; finally, the water balance of the basin is obtained through the river network convergence calculation.

The SWAT model is essential for water balance in the basin simulation process. The hydrological simulation of the basin is divided into two parts: one is the land phase of the water cycle, which is mainly used to control the water, sediment, nutrients and pesticide amount; the other part is the calculation phase of the water cycle, which is used to define the movement of water, sand and other substances through the basin water network to the outlet part of the basin.

The SWAT model simulates the land phase of water cycle by using the following water balance expression:

$$SW_t = SW_0 + \sum_{i=1}^{t}(R_{day} - Q_{surf} - E_a - w_{seep} - Q_{gw}) \quad \text{(Eq.1)}$$

where, SW_t is the final soil water content (mm); SW_0 is the initial soil water content (mm); t is the time step (day); R_{day}, Q_{surf}, E_a, w_{seep}, Q_{gw} are respectively precipitation, surface runoff, evaporation, lateral stream flow of soil aquifer and infiltration amount, groundwater content (mm) of the i^{th} day.

The land phase of the water cycle of the SWAT model is mainly composed of meteorology, hydrology, sedimentation, vegetation growth, soil temperature, pesticides, nutrients and agricultural management, etc., while the calculation phase of the water cycle of the SWAT model is divided into two parts of the main channel and the reservoir, and mainly determines the transport movement of water, sand and other substances from the basin river network to the basin exit. The SWAT model has a number of modules that can be run separately or in combination with several of them depending on the object and content being simulated. The structural design adopted by the SWAT model is modular, which fully reflects the specific links from the beginning of precipitation to the formation of runoff in the basin.

Construction of SWAT model database

Before the simulation with the SWAT model, it is necessary to prepare relevant digital elevations, land use and soil maps and related database files to facilitate the generation of SWAT model input data sets. Considering the artificial disturbances, such as irrigation channels, drainage channels and river channels in the plain irrigation area, the SWAT model is improved in the extraction method of the ditch river network, the sub-basin and the division module of the hydrologic response unit. Specific practice includes that: according to the spatial distribution of natural river channels and artificial drainage ditch networks in the study area, the “burn-in” algorithm is used to sag the DEM. The principle of this method is to convert the digital river system and the drainage ditch network into the grid form, and its grid cell size is consistent with that of the original DEM. These grid cells are transformed into the unified coordinate system after the projection, and overlaid into the original DEM through the superposition. Keep the elevations of all grid cells in correction channel unchanged, and increase the elevations of the grid cells in non-correction channel perpendicular to the river direction by a small value, so that the elevation of the grid of the river channel is lower than the coastal elevation. Then, the modified DEM is processed again to generate a new basin

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34833497

river network. For the artificial water distribution channel, the DEM is processed by the principle of the elevation increment superposition algorithm. To make the sub-basin of the SWAT model in the irrigation area consistent with the irrigation area covered by the dry-drainage system in the irrigation area, and to avoid that too many sub-basins generated in the process of spatial discretization result in excessive spatial data conversion and calculation, the areas covered by the backbone channel and the drainage ditch are used as the dividing standards to set reasonable minimum channel catchment area threshold to divide the sub-basin, and then to divide each sub-basin according to the consistency of land use and soil type. Later, considering different crop planting structure, the farmland is refined to form the hydrologic response unit.

DEM data

The digital elevation model is essential when the SWAT model is used for basin division, water system generation and hydrological process simulation. The most common DEM map is grid type. Using DEM data can not only calculate the slope and slope length parameters of each sub-basin, but also define the basin river network. The channel slope, slope length and width of the basin river network and other characteristics are extracted from the DEM data. The basin river network can be used to determine the quantity and distribution of the sub-basin.

Most parts of DEM are relatively smooth terrain surface models, but for the error and the existence of some special terrain, there are some concave areas on the surface of DEM, which leads to low-precision water flow direction and makes the original DEM data unable to meet the research needs. Therefore, before most of simulation experiments, the original DEM data will be filled in depression by the hydrological analysis model of ArcGis Software, and finally the non- depression DEM data meeting the research requirements will be obtained.

The high-resolution DEM data SRTM (Shuttle Radar Topography Mission) 90-meter resolution data used in this paper can be downloaded from the International Scientific Data Service Platform of the Chinese Academy of Sciences (http://datamirror.csdb.cn/index.jsp), and cropped within the scope of the study area, see *Fig. 1*.

Land use data

Using the SWAT model to simulate water resources in the basin and the land use map are very important. Humans will not easily change the topography and soil in the basin, but the land use will be changed by humans. Therefore, it is recommended to use the latest land use map for simulation. For the projection coordinate system of the land use distribution map, in case it is different from that set in the research, the projection module Projections of ArcToolbox needs to be used for projection transformation. The categories for land use map definition should be re-classified, and based on the classification determined by the SWAT's land cover/vegetation type database and the city database. Then a lookup table in the required format is generated to determine the code of each land use type on the land use map in the SWAT model (where 4 characters are required).

The national land use map collected in this paper is in shp format. It is first cut based on the boundaries of the basin, and then converted into the Grid format. Since the land use classification system of the SWAT model is classified based on the US classification system and is different from China's land use classification system, it is necessary to reclassify the land use types and convert the code in the land use map into the one that the SWAT model could identify. Refer to the Land Use Status Classification Standard (GB/T21010-2007) and the land use attribute database of the SWAT model, and then establish the land use database for the Yellow River irrigation area. The land use types reclassified are shown in *Table 1*.

Soil data

The soil type charts collected in this paper is shp format. Same with the land use type, it is firstly cut based on the basin boundary, and then converted into the Grid format required for the model.

The soil types in Ningxia section of the Yellow River Basin mainly include the Light sierozems, Neo-alluvial soils, Aeolian soils, Calcic skeletal soils, Fluro-aquic soils, Wet fluro-aquic soils, Salinized fluro-aquic soils, Surface-rusted fluro-aquic soils, Cumulated There are 12 categories of irrigated fluro-aquic soils, Meadow solonchaks, Aquic irrigation silting soils, Surface-rusted irrigation silting soils, among which Light sierozems is the most widely distributed, accounting for 35.66% of the total area, followed by Aeolian soils and Neo-alluvial soils, Yellow River. The soil types and SWAT model codes of Ningxia section of the Yellow River Basin are shown in *Table 2*.

Table 2. *Soil type and code table of Ningxia section of the Yellow River Basin*

Soil type	Original code	SWAT code	Soil type involved	Area (10^4hm^2)	Proportion

When the SWAT model is simulated, the soil data required mainly includes two types: chemical attribute data and physical attribute data. The chemical attribute is optional data and chemical attributes of the soil are mainly used to assign the initial values to the model; the physical attribute is required, the physical attributes of the soil play an important role in water cycle of the hydrologic response unit, which determines the movement conditions of water and air in the soil profile. Before simulation, the hydrological and water conductivity attributes of various soils should be input into the SWAT model and divided into two parameter types, which are input by the soil type and soil layer. The soil particle size composition, soil layer and organic matter content used in the research can be found in Ningxia Soil. The international system standards and Kaczynski system are used for soil texture in China, and the soil particle size standard used in the SWAT model is the American system, therefore, the domestic data cannot be directly used in the SWAT model and the soil particle size should be converted from the international system to American system. The two classification criteria are shown in *Table 3* and the conversion is required. There are different methods

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34833497

for soil texture conversion. Generally, the soil particle size distribution model in the parametric form is more suitable for general model, because it is more convenient for establishment of standard procedures and comparison and unification of particle size analysis data from the different sources. The empirical logic growth model of the two-parameter correction is used to convert the soil texture in this paper. The Levenberg-Marquardt+ general global optimization algorithm of the nonlinear fitting program in the 1STOPT software is used, and the values of the parameters *u* and *c* are obtained by the relevant regression iteration, and the content of clay, silt, sand, rock (gravel) is finally determined. Other soil parameters such as soil bulk density, effective field capacity and saturated hydraulic conductivity are calculated using the Soil-Water-Characteristics (SWCT) module in the soil water properties software SPAW developed by Washington State University. The soil erosivity factor can be calculated based on the known soil organic carbon and particle composition data and by using the soil erodibility factor K estimation method in the EPIC model.

Table 3. *Soil particle size classification*

International system		**American system**	
Particle size range (mm)	**Name**	**Particle size range (mm)**	**Name**
>2	Rock	>2	Rock

0.02-0.2	Fine sand	0.002-0.05	Silt
0.002-0.02	Silt	<0.002	Clay
<0.002	Clay		

Weather data

The daily weather data required for SWAT model stimulation includes the following: maximum temperature, minimum temperature, rainfall, wind speed, solar radiation and relative humidity etc. If the measured data is partially missing, the SWAT model defines the weather generator used to supplement the missing data. The weather generator requires input of meteorological data related to the basin and monthly meteorological data for at least 20 years, mainly including monthly average maximum temperature (°C), monthly average minimum temperature (°C), maximum temperature standard deviation, minimum temperature standard deviation, monthly average rainfall (mm), monthly average rainfall standard deviation, rainfall skewness coefficient, monthly number of dry days (dry d), monthly number of wet days (wet d), average rain days (d), dew point temperature (°C), monthly average solar radiation [KJ/(m^2.d)], monthly average wind speed (m/s) and maximum half-hour rainfall (mm).

The daily observation data of Ningxia Zhongning, Yinchuan, Huinong and Taole for 23 consecutive years from 1995 to 2017 is used in this paper, including daily maximum/minimum temperature, rainfall, wind speed, relative humidity, etc. The above data is processed in .dbf format required for SWAT model. If the weather generator is used to calculate the parameters one by one, the workload is complicated; however, the simple and easy-to-operate calculation program SwatWeather.exe saves a lot of working time for the model users. As long as the files are input in required format, the required data can be calculated and saved according to the prompts.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34833497

Division of hydrological response unit

When the SWAT model was used for simulation in the past, the hydrological response units were divided basically based on natural basins; however, the irrigation network in Ningxia section of Yellow River Basin was completely completed by artificial canals and the irrigation districts along Yellow River currently have 17 large and medium-sized diversion main canals and main canals. In this paper, based on the actual situation of the Ningxia section of the Yellow River Basin, the artificial canal network is used as the water system to divide the Ningxia section of the Yellow River Basin into several hydrological response units based on the division principles of hydrological response units.

Results

The SWAT model needs to perform the sensitivity analysis according to the actual situation of the research area, and analyze and judge which input parameter values are sensitive to the output results. The analog value of the model is close to the measured value by adjusting these parameter values. The SWAT model parameter analysis module is used to continuously adjust the parameters in the model. The adjustment process should analyze and determine which parameters are sensitive to the results and the degree of influence on the simulation results based on the actual situation and the parameter thresholds, which will make the simulation more accurate. After the sensitivity analysis on the model input parameters, the measured series data is subsequently divided into two parts, one part is used for model parameter calibration and the other part is used for model validation. After completing the model parameter calibration, the measured series data and simulated data are analyzed and compared to judge whether the simulation accuracy meets the requirements; the model applicability and reliability is validated, if the simulation value meets the requirements, the model can be used for hydrological simulation of the Ningxia section of the Yellow River Basin. In the basin simulation, the parameters sensitive to the runoff simulation results include the soil evaporation compensation coefficient $ESCO$, the number of runoff curves CN_2 and the available water amount in the soil.

In the SWAT model simulation process, the relative error R_e, correlation coefficient R^2 and Nash-Suttcliffe coefficient Ens are generally selected to evaluate the model applicability. The relative error calculation formula is as below:

$$R_e = \frac{Q_p - Q_0}{Q_0} \times 100\% \qquad \text{(Eq.2)}$$

where R_e represents the relative error of model simulation; Q_0 represents the measured value; Q_p represents the stimulated value. If $R_e > 0$, it indicates that the model simulation value or predicted value is too large; if $R_e < 0$, it indicates that the model simulation value or predicted value is too small; if $R_e = 0$, it indicates that the simulation result matches with the measured value. The correlation coefficient R^2 is obtained by using the linear regression method in Excel. If $R^2 = 1$, it indicates that the results are very matched; when $R^2 < 1$, the smaller the value, the lower the degree of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34833497

data matching.

The calculation formula of Nash-Suttcliffe coefficient Ens is as below:

$$Ens = 1 - \frac{\sum_{i=1}^{n}(Q_0 - Q_p)^2}{\sum_{i=1}^{n}(Q_0 - Q_{avg})^2} \quad \text{(Eq.3)}$$

where Q_0 is the measured value; Q_p is the stimulated value; Q_{avg} is the measured average value; n is the number of measured data. When $Q_0 = Q_p$, it indicates that the measured value is well matched with the stimulated value; if $Ens < 0$, it indicates that the model simulation average value has a lower reliability than directly using the measured average value.

Model parameter calibration

The SWAT model parameter calibration can be conducted by using the "Brute Force" method in two stages. In the first stage, the step size to be calibrated is estimated and the parameter value is appropriately adjusted based on the estimated step size and within the value range, subsequently the parameter is calibrated and the parameter optimal value range is determined by calculating and evaluating the system values; in the second stage, the initially estimated parameter adjustment step size is further refined. As some variables have the great impacts on the results at the initial model operation period, for example, the initial value of soil water content is zero, which has a great impact on the simulation results. Therefore, for this case, the initial simulation period is used as the model operation start period to reasonably estimate the initial variables of the model. The digital filtering technique is used to divide the measured total runoff into the base flow and the direct runoff. The difference between the model simulation value and measured value and its percentage with the measured average value (relative error) should be within the specified range and the evaluation coefficient R^2 and Ens of the monthly average stimulated value should also meet the specified accuracy standards. If the measured value and stimulated values meet the calibration requirements, but R^2 and Ens do not meet the requirements, the inspection should be conducted and the full consideration should be taken on spatial non-uniformity of simulated rainfall and correct stimulation of plant growing season. For the runoff parameter calibration, the annual average error between the simulated and measured values should be less than 20% of the measured value, and the evaluation coefficient of the monthly average value is $R^2 > 0.6$ and $Ens > 0.5$; after the base flow parameter calibration, the same evaluation method is used to the surface runoff for parameter calibration. Considering that the total runoff parameter adjustment will affect the base flow, the base flow should be re-inspected continuously in the adjustment process.

In this paper, the measured monthly runoff data of Qingtongxia Hydrological Station and Shizuishan Hydrological Station from 2005 to 2011 are used for model parameters adjustment. *Figs. 2 and 3* show the comparison between the measured and simulated values of the monthly runoff of the Qingtongxia Hydrological Station and the Shizuishan Hydrological Station in the calibration period.

Model validation

The observed monthly runoff data of Qingtongxia Hydrological Station and Shizuishan Hydrological Station from 2012 to 2017 are used for model validation, the parameters obtained in the model parameter calibration process are used and the relative error R_e, correlation coefficient R^2 and Nash-Suttcliffe coefficient Ens are used to evaluate the model validation results. *Figs. 4 and 5* show the fitting comparison of the observed values and simulated values of monthly runoff of Qingtongxia Hydrological Station and the Shizuishan Hydrological Station in the validation period.

Discussion

In the calibration period, as can be known from the *Figs. 2 and 3*, the simulated and measured values of the Qingtongxia Hydrological Station are approximately in the same change trend, the peak value has the higher matching degree and the relative error R_e is between -12.98% and 14.58%; the monthly average runoff correlation coefficient R^2 and the Nash-Suttcliffe coefficient Ens are 0.86 and 0.83 respectively. The change trend of simulated value and measured value of the monthly runoff of Shizuishan Hydrological Station is well matched, the peak value has a higher marching degree and the relative error R_e is between -11.98% and 13.14%; the monthly average runoff correlation coefficient R^2 and the Nash-Suttcliffe coefficient Ens are respectively 0.87 and 0.84. Both meet the simulation evaluation requirements.

In the validation period, for the fitting comparison of the observed values and simulated values of monthly runoff of the Qingtongxia Hydrological Station, the relative error R_e is between -13.23% and 14.67%; the monthly average runoff correlation coefficient R^2 and The Nash-Suttcliffe coefficient Ens are 0.88 and 0.86 respectively. For the fitting comparison of the observed values and simulated values of monthly runoff of the Shizuishan Hydrological Station, the relative error R_e is between -12.09% and 13.97%; the monthly average runoff correlation coefficient R^2 and the Nash-Suttcliffe coefficient Ens are 0.89 and 0.85 respectively. The simulated and observed values of the model have a small difference and meet the simulation requirements.

Conclusion

In this paper, the GIS software is used for to cutting, projection transformation and reclassification of DEM, land use and soil data for Ningxia Yellow River Irrigation District, and convert these data formats into Grid format required for the model; based on the actual situation of Ningxia Yellow River Irrigation District, a attribute database such as meteorological, hydrological, and soil physical attributes required for the SWAT model is established. The constructed SWAT model is used for hydrological

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34833497

simulation of Ningxia section of the Yellow River Basin, the observed monthly runoff data of Qingtongxia Hydrological Station and Shizuishan Hydrological Station from 2005 to 2017 are used for model parameters sensitivity analysis, calibration and validation and continuous adjustment, the relative error R_e, correlation coefficient R^2 and Nash-Suttcliffe coefficient Ens are used for model applicability evaluation. The results show that the observed values and stimulated values of monthly runoff of Qingtongxia Hydrological Station and Shizuishan Hydrological Station in the calibration period are approximately in the same change trend, the peak value has the higher matching degree, for Qingtongxia Hydrological Station, the relative error R_e is between -12.98% and 14.58%, the monthly average runoff correlation coefficient R^2 and the Nash-Suttcliffe coefficient Ens are 0.86 and 0.83 respectively. For Shizuishan Hydrological Station, the relative error R_e is between -11.98% and 13.14% and the monthly average runoff correlation coefficient R^2 and the Nash-Suttcliffe coefficient Ens are respectively 0.87 and 0.84. The observed values and stimulated values of monthly runoff of Qingtongxia Hydrological Station and Shizuishan Hydrological Station in the validation period have the small difference, for Qingtongxia Hydrological Station, the relative error R_e is between -13.23% and 14.67% and the monthly average runoff correlation coefficient R^2 and The Nash-Suttcliffe coefficient Ens are 0.88 and 0.86 respectively. For Shizuishan Hydrological Station, the relative error R_e is between -12.09% and 13.97% and the monthly average runoff correlation coefficient R^2 and the Nash-Suttcliffe coefficient Ens are 0.89 and 0.85 respectively. The simulated and observred values of the model have a small difference and meet the simulation requirements. The constructed SWAT model is suitable for the hydrological process simulation of the Ningxia Yellow River Irrigation District, which lays the foundation for the subsequent water supply prediction.

(Received 12th Oct 2018; accepted 16th Jan 2019)

Abstract. Nowadays, suburban forest recreation is one of the most important forms of daily leisure activities of urban residents; therefore, it is of great significance to study the recreation suitability of suburban forest parks. On the basis of previous research results and in combination with the recreation suitability characteristics of the present suburban forest park, this paper uses the analytic hierarchy process (AHP) and the expert scoring method to build a suitability evaluation model. The results show that the model includes three criteria layers, 7 first-level index layers and 31 second-level index layers of resource conditions, basic conditions, and development and utilization conditions. In the distribution of index weight, that of resource conditions is the highest, followed by basic conditions and development and utilization conditions. Taking the Baiyun Forest Park in Lishui City, China, as an example, the scoring criteria of fuzzy comprehensive evaluation are adopted to evaluate its recreation suitability. The evaluation results show that the overall evaluation of recreation suitability of Baiyun Forest Park reaches the level of "good" and has a strong recreational nature. "Forest Resource", "Environment Quality" and "Location Condition" are rated excellent, while "human resources" and "supporting facilities" are rated average. Suggestions on developing forest natural resources, protecting the environment, earning positive cultural connotations, improving infrastructure and defining the tourist source market to enhance the suitability of recreation in parks are put forward on the basis of the evaluation result.
Keywords: *forest park, recreation suitability, evaluation index system, analytic hierarchy process (AHP), fuzzy comprehensive evaluation method, Lishui City in China*

Introduction

Recreation, a kind of entertainment method which allows people in modern society to relax themselves both physically and psychologically, refers to the leisure activities which individuals or groups take part in to feel pleased and satisfied in their spare time (Zhang, 2001) and the effect of the relaxation is amplified, when people can establish a positive connection to nature (Park et al., 2015). Forest recreation has become a tendency and fashion of modern ecological leisure activities. A forest park, due to its ecological system, mainly provides extraordinary environmental resources, health and fitness protection functions, sightseeing, recreation, sports and positive experiences to promote the soundness of body and mind for tourists. Recently, with the advance of industrialization and urbanization, many problems arise in human settlements. The suburban forest park is not only an important part of the urban ecological system, which provides ecological benefits and a pleasant landscape, but also promotes healthiness and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34993512

fitness for people's body and mind while serving as a recreational site for the residents. Therefore, more and more cities have begun to construct suburban forest parks as "living" ecological systems (Wang et al., 2017) and the suburban forest park has become an important commodity for urban residents to form a healthy and civilized lifestyle.

With the recreation function of the suburban forest park gradually becoming the research focus, many scholars have done research and evaluation on the forest's recreation. America, as the most developed country in the aspect of forest recreation industry in the world at present, is the center of this research field, and the special research institutes are set up and the relevant managerial laws and regulations are formulated there (Qi et al., 1995). The foreign scholars think that the forest recreation is a summary of all the outdoor recreation forms which happen in the forest area, make statements about the planning, management, scientific research and selection of recreation location etc., learn about the tourists' needs about the urban forest recreation and the types of recreation activities and propose the suggestions on how to build a healthier and more comfortable environment (Douglas, 2000; Hunter, 2001). In recent years, some foreign scholars started from the forest's recreational value and did research on the leisure and entertainment value the forest can provide through the space analysis method (Baerenklau et al., 2010; Bestard and Font, 2010). Other foreign scholars analyzed the forest's spatial heterogeneity and the heterogeneity of tourists' preference through the research on the forest's property (Abildtrup et al., 2013; Termansen et al., 2013). The research into the forest recreation in China started a little late in early 1980s and afterwards, the construction and theoretical research into the forest recreation are gradually promoted (Liao, 2003). The State Forestry Administration of PRC has issued a series of laws and regulations successively to ensure the development of suburban forest parks (Chen and Wang, 1999). The scholars also do the research into the forest recreation from different aspects and angles. The research contents include: (1) The concept, characteristics and evaluation methods of forest recreation and so on (Chen and Shen, 2000); (2) The forest environment, animals and plants, and waters etc. such as monitoring the effect of the anion density and atmosphere quality inside the recreation area (He et al., 2015; Cai and Gu, 2005); (3) The forest's recreation value etc. (Yang and Zhang, 2010). To analyze the level of all the aspects of suburban forest park comprehensively and accurately in the research, all the dynamic factors inside the park need monitoring and the comprehensive evaluation model such as the principal component analysis method (PCA), clustering analysis method, fuzzy comprehensive evaluation method and landscape visual evaluation method are used to make objective analysis (Wang et al., 2017; Qi et al., 2015).

There needs the further research on how to evaluate and analyze the recreation suitability of suburban forest park. The Baiyun Forest Park in Lishui City, China belongs to the typical suburban forest park with outstanding geographic position and good recreation conditions. The paper chooses the Baiyun Forest Park of Lishui as the empirical research subject for analysis and combines the expert scoring method, AHP and FCE together to evaluate and discuss the recreation suitability of suburban forest park. It aims to provide the beneficial reference for the development of leisure recreation function of the suburban forest park and offer some guidance for further improving and promoting the recreation activities of the suburban forest park.

Materials and methods

General description and data source of research area

Baiyun Forest Park is 2 km away from the northern part of Lishui urban area in the mountain area of Southern Zhejiang and middle reaches of Oujiang River and is bounded by the urban area with superior location and convenient traffic. It mainly serves the residents living in and around the city with the total area of 26.71 km^2. The geographic coordinates are east longitude 119°52'~119°58' and northern latitude 28°23'~28°27'.

The hilly area in the park belongs to Xianxia Ridge remaining vein which rise amid permanent peaks with ups and downs. The highest altitude is 1073.2 m. The geotectonic element of the park area belongs to Southern-east Zhejiang belt of folded strata which is mainly Longquan–Suichang broken rock with partial distribution of Cretaceous red sandstone and granite. There are a dozen of streams in the park which belong to Oujiang water system and among them, the largest one is Liyang pit and its total length is 9.5 km. Besides, its length in the park is 5.3 km and the drop in elevation is 520 m. The climate is mid semi-tropical monsoon climate with four distinctive dry and wet seasons as well as abundant rainfall. The average yearly temperature is 18.1 °C, the highest temperature of the year is 38 °C (the extreme highest temperature in the urban area is 43.2 °C) and the lowest temperature of the year is -7.7 °C (the extreme lowest temperature of Taishan is -14 °C). The forest in the park is covered with lush vegetation and rich vegetation types and the coverage rate reaches 97.2%. Besides the abundant natural resources, there are also profound human history and religious beliefs in the park.

The research data mainly come from the field investigation of Baiyun Forest Park with the method of recording, consulting the material on the Internet and questionnaire. First, do the field investigation in the park to have a rough understanding of the research area's topography, water system, landscape characteristics, vegetation planting and animals and plants resources etc. and then do the detailed survey and record the plant types, quantity, road condition and infrastructure condition etc. inside the research area in detail. Meanwhile, hand out the questionnaire to investigate the tourists' feelings about the park's recreation suitability. Lastly, sort out the field investigation condition and collected data and make analysis for the further research. The statistics in this paper come from the relative news website such as Lishui Statistics Information Network (http://tjj.lishui.gov.cn/sjjw/tjnj/201811/t20181119_3477511.htm; http://www.lsnews.com.cn/images/gg_banmian/lyp_baiyunshang090915/gg_bys090915.html).

Research method

Expert scoring method

Expert Scoring Method, also called "Delphi Method", refers to judging the current status and future trend of events by collecting experts' opinions and now it has been widely used in different subjects and organizations (Loo, 2002). The paper, on the basis of referring to a lot of research results about the related evaluation system and doing the field investigation, combines the own characteristics of suburban forest park and the conditions suitable for the recreation, summarizes the various analysis and research, concludes the primary index system of affecting the recreation suitability of suburban

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34993512

forest park and makes the questionnaire for 30 experts from related fields to judge and score. The related fields refer to the forest recuperation, forest health care-based tourism, ecotourism, town and country planning, and garden landscape. Experts are asked to assign the value to the importance “Score 1 for the Unimportant, Score 2 for the Less Important, Score 3 for the Important, Score 4 for the More Important, Score 5 for the Most Important” and screen the primary index. Through the multiple rounds of experts scoring and after consulting experts’ comments, accepting the feedback and making adjustments multiple times, the index factors are screened, deleted and revised to perfect the whole index system and confirm the final evaluation index system (*Table 1*). The system is divided into the target layer, criterion layer, seven first-level index layers and 31 second-level index layers.

Analytic hierarchy process

Analytic Hierarchy Process (AHP), which is proposed by T. L. Saaty, an American operational research expert in the early 1970s, is a systematic and hierarchy analysis method of confirming the weight factor by combining the qualitative and quantitative together (Chiclana et al., 1998). The method is applied to multiple research fields, such as commercial investment analysis (Aragonés-Beltrán et al., 2014), exploration planning (Rahmati et al., 2015) and multi-criteria decision analysis (Xu and Liao, 2014). The paper determines the evaluation index factor weight of suburban forest park recreation suitability with AHP.

Build the structure model

The research confirms the index factor after taking a lot of research data in the literature, the comments from the related experts and field investigation into consideration, unfolds the evaluation system of suburban forest park recreation suitability with Analytic Hierarchy Process (AHP) level by level and forms a multi-layer and multidimensional index system with 4 layers and 31 evaluation index factors, as shown in *Figure 1*.

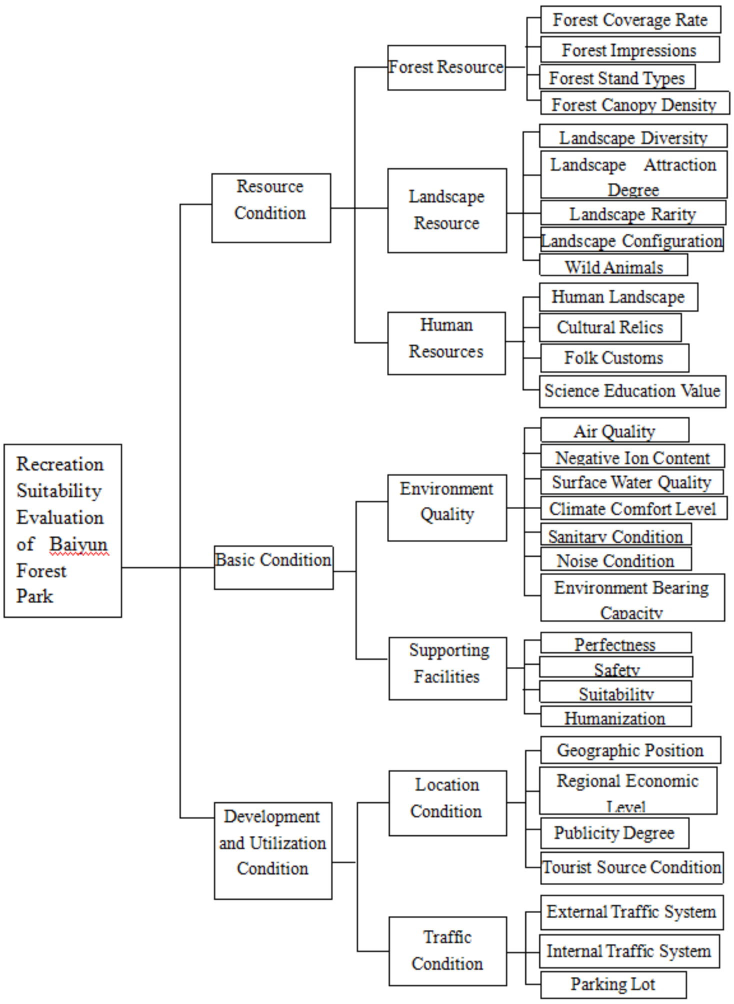

***Figure 1.** Hierarchical structure model of recreation suitability evaluation of suburban forest park*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34993512

Build the judgement matrix

The judgement matrix, which is built based on the above established evaluation model, is a prerequisite of doing the weight calculation and an important reference standard for sequencing. When building the judgement matrix, collect the related experts' comments about the index importance by the 1-9 proportional scaling method, get the average value of the obtained experts' valuation and build the judgement matrix initially and at the same time, make appropriate adjustments by referring to the research results of related fields at home and abroad. Lastly, the judgement matrix in the paper is built after combining the scores in the questionnaire and the related research.

Weight value calculation and conformity verification

After building the judgement matrix of each index, calculate the weight value. In this paper, the square root method is used to calculate the maximum characteristic root λ_{max}, obtained by *Equation 1,* in which W is the characteristic vector corresponded with λ_{max}. The characteristic vector is gained by the normalization processing of the vector. To get the rational and effective weight value, do the consistency verification test to the judgement matrix. Random consistency ratio *CR* is obtained by *Equation 2* and *CI* can be obtained by *Equation 3,* in which n is judgement matrix order and RI is average random consistency ratio. When $CR = 0$, the judgement matrix has the complete consistency; When $0 < CR < 0.1$, the judgement matrix conforms to the consistency requirement; When $CR \geq 0.1$, the consistency of the judgement matrix is not acceptable and all the factors of the matrix need adjusting again until it meets the requirement of consistency verification (Liu, 2012).

$$AW = \lambda_{\max} W \tag{Eq.1}$$

$$CR = \frac{CI}{RI} \tag{Eq.2}$$

$$CI = \frac{\lambda_{\max} - n}{n-1} \tag{Eq.3}$$

Do the normalization processing to the weight of all the index factors according to the above method, get the weight value of each index through calculation and make the importance sequencing, namely, overall ranking (*Table 2*).

Fuzzy comprehensive evaluation method

The fuzzy comprehensive evaluation method is used to do the quantitative comprehensive evaluation to the recreation suitability of Baiyun Forest Park and the final score obtained in this way will determine the recreation suitability of Baiyun Forest Park. It is highly scientific and reliable to use the fuzzy comprehensive evaluation method, which combines the fuzzy theory and math model (Jiao et al., 2016) and does a quantitative analysis to the fuzzy object so as to get a comparatively scientific result (Ye, 2010). First, build a fuzzy comprehensive evaluation set of evaluation factors and then the judgement set V = (V1, V2, V3...Vm). Usually, the fuzzy five-point scale scoring system is used and it is classified into five levels: V1

stands for “Excellent”, V2 for “Good”, V3 for “Average”, V4 for “Bad” and V5 for “Very Bad” (Wang et al., 2017; Xue, 2011). The fuzzy scoring standard of each index factor in the evaluation system is made in accordance with the above requirement, as shown in *Table 3*.

Table 2. *Evaluation index weight of recreation suitability of suburban forest park*

Target layer	Criterion layer	Weight	Factor layer	Weight	Index layer	Weight	Sequencing
Recreation suitability evaluation of suburban forest park A	Resource condition B1	0.625	Forest resource C1	0.405	Forest coverage rate D1	0.211	1

					Wild animals D9	0.013	21
			Human resources C3	0.076	Human landscape D10	0.020	18
					Cultural relics D11	0.039	7
					Folk customs D12	0.009	25
					Science education value D13	0.006	28
	Basic condition B2	0.238	Environment quality C4	0.179	Air quality D14	0.056	5
					Negative ion content D15	0.034	8
					Surface water quality D16	0.014	20
					Climate comfort level D17	0.028	12
					Sanitary condition D18	0.012	22
					Noise condition D19	0.032	10
					Environment bearing capacity D20	0.008	26
			Supporting facilities C5	0.060	Perfectness D21	0.023	17
					Safety D22	0.024	16
					Suitability D23	0.005	29
					Humanization D24	0.007	27
	Development and utilization condition B3	0.137	Location condition C6	0.034	Geographic position D25	0.017	19
					Regional economic level D26	0.004	30
					Tourist source condition D27	0.010	24
					Publicity degree D28	0.003	31
			Traffic condition C7	0.103	External traffic system D29	0.066	4
					Internal traffic system D30	0.027	13
					Parking lot D31	0.011	23

After building the factor set, quantify every factor of the evaluation subject. According to the evaluation standard, design the questionnaire to investigate the tourists and the related working staffs of Baiyun Forest Park and carry out a statistical analysis on the investigation results to get the fuzzy relationship judgement matrix:

$$R=\begin{Bmatrix} r_{11} & r_{12} & \cdots & r_{1m} \\ r_{21} & r_{22} & \cdots & r_{2m} \\ \cdots & \cdots & \cdots & \cdots \\ r_{n1} & r_{n2} & \cdots & r_{nm} \end{Bmatrix}.$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34993512

Then get the factor weight W = (W_1, W_2, W_3...W_m) according to the weight value of each index confirmed by the AHP, work out the comprehensive judgement result in accordance with *Equation 4* and then gain the final evaluation level according to the maximum membership principle.

$$Vi = Wi * Ri \quad \text{(Eq.4)}$$

Table 3. *Fuzzy scoring criteria for evaluation factors of recreation suitability of Baiyun Forest Park*

Target layer	Data source	Index score				
		5	4	3	2	1
Forest coverage rate	Statistical data	≥90%	80%≤X<90%	70%≤X<80%	60%≤X<70%	<60%

Parking lot	Questionnaire	More	Many	Average	Few	Less

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34993512

To show the recreation suitability of Baiyun Forest Park more clearly and directly, it is necessary to figure out the final scores of each index factor and the whole respectively of recreation suitability. First, assign the value $V_1 = 5, V_2 = 4, V_3 = 3, V_4 = 2, V_5 = 1$ to each judgement set in the $V = \{V_1, V_2, V_3, V_4, V_5\}$ respectively and get the scores of each factor according to *Equation 5*.

$$W_A = \sum_{k=1}^{n} B_{Ak} V_k \qquad \text{(Eq.5)}$$

in which, B_{Ak} (k = 1,2,3,4,5) is the kth membership of B_A.

Results and analysis

Analysis on the suburban forest park index factor weight

Through the above calculation and statistical analysis, it can be concluded that in the evaluation system of suburban forest park recreation suitability, the total weight value of criterion layer B is 1. The result shows that the sequence of the three index factors in the criterion layer is resource condition (0.625) > basic condition (0.238) > development and utilization condition (0.137) and the resource condition accounts for most, which indicates that in the suburban forest park recreation, the resource condition is the most important and it is also an essential factor of attracting the tourists. Whether the forest park has the suitable condition for the tourists to have recreation largely depends on whether it has the excellent resource condition or not. The basic condition and the development and utilization condition rank second and third and the weight difference between the two is not big, which means that in the recreation suitability, there is a lot of upside potential for the basic condition and the development and utilization condition, which also are the indispensable condition in the suburban forest park recreation suitability evaluation system.

In the criterion layer, the importance order of index factor in the resource condition (B1) is forest resource (0.405) > landscape resource (0.144) > human resources (0.076), and the forest resource accounts for a large part, which indicates that in the suburban forest park resource condition, the forest resource is the most important, next is the landscape resource, which is followed by human resources. This shows that in the forest park, the natural and ecological forest resource can attract a lot of tourists to come here for recreation and the human resources have the smallest influence in the forest park. In the forest resource, the weight value (0.211) of forest coverage rate is the largest index weight and also the factor whose weight ranks first in the whole evaluation index system. This reflects that the higher forest coverage rate in the suburban forest park is of great significance to attract the tourists.

In the basic condition (B2), the importance order of index factor is environment quality (0.170) > supporting facilities (0.060). For the suburban forest park, the outstanding environment quality still appeals to many tourists, which directly affects the recreation suitability. Since the environment quality has a big influence on the people's body and mind and nowadays people have a preference for the health care-based tourism, the weight ratio of forest park environment quality is comparatively big and that of the supporting facilities is relatively small. In the development and utilization condition (B3), the importance order of index factor is traffic condition (0.103) >

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34993512

location condition (0.034). The suburban forest park needs to have the superior geographic position. The traffic condition has the direct limitation and influence on the number of tourists, so the traffic condition is of great importance to the park recreation. Besides, the location condition is also important, because if the suburban forest park is in the remote and inaccessible area, there will be fewer tourists, it will be not suitable for recreation and it is also hard to give a full play to its original value.

Analysis on the recreation suitability of Baiyun Forest Park

The calculation result obtained according to the fuzzy comprehensive evaluation method is the final score of Baiyun Forest Park recreation suitability. The evaluation level can be gained according to the corresponding evaluation index factor. From the above evaluation result, get all the levels of Lishui Baiyun Forest Park recreation suitability and the specific evaluation level of each evaluation factor, as shown in *Table 4*.

Table 4. *Summary of fuzzy comprehensive evaluation results of Baiyun Forest Park*

Target layer	Evaluation score	Criterion layer	Evaluation score	First level index	Evaluation score	Second level index	Evaluation score

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34993512

It is concluded from the evaluation result that the final score of Baiyun Forest Park recreation suitability is 3.809 and the whole evaluation result is “Good”. Based on the divided evaluation set score, the recreation suitability of Baiyun Forest Park belongs to the good level with strong recreation suitability. The evaluation result complies with the actual fact of the park. In the criterion layer, the basic condition is rated as “Excellent” and the resource condition and development and utilization condition are rated as “Good”; In the first level index, the forest resource, environment quality and location condition are rated as “Excellent”, the landscape resource and traffic condition are rated as “Good” and the human resources and supporting facilities are rated as “Average”; In the second level index, such factors as forest coverage rate, landscape diversity, air quality, negative ion content, sanitary condition, noise condition, geographic position and external traffic system are rated as “Excellent”, the factors such as forest impressions, forest stand types, landscape attraction degree, landscape configuration, climate comfort level, environment bearing capacity, regional economic level and tourist source condition are rated as “Good” and the factors such as forest canopy density, landscape rarity, human landscape, cultural relics, science education value, surface water quality, facility suitability, facility humanization, internal traffic system and parking lot are rated as “Average”; the factors such as folk customs, facility safety and publicity degree are rated as “Bad” and the only factor that is rated as “Very Bad” is wild animals. Based on the result, in the suburban forest park, the most important things are still the rich forest resource, outstanding environment quality and superior location condition. The fact that Baiyun Forest Park is in the suburb makes the unique location condition, which increases the park’s recreation suitability.

Resource condition evaluation

Based on the evaluation result, the general evaluation result of Baiyun Forest Park in the aspect of resource condition is “Good”. In it, the “Forest Resource” is rated as “Excellent”, which indicates that Baiyun Forest Park has rich forest resource with good quality, high forest coverage rate, good forest impressions, causing the strong overall recreation suitability. “Landscape Resource” is rated as “Good”, which shows the whole landscape is beautiful. However, “Landscape Rarity” is rated as “Average”, which means that many tourists think the landscape in the park is too common with no distinctive characteristics; “Wild Animals” is rated as “Very Bad”, indicating that there are nearly no wild animals. “Human Resources” is rated as “Average”, which is unsatisfactory. For example, the insufficient cultural deposits, the unattractive human landscape, few cultural relics, thin folk custom atmosphere and low science education value, lowering the recreation suitability relatively. Some profound historical cultural value is not utilized effectively, showing that the park needs to strengthen the preservation and exploitation in these aspects, especially the development of culture history and science education.

Basic condition evaluation

Based on the evaluation result, the general evaluation result of Baiyun Forest Park in the aspect of basic condition is “Excellent”. In it, the comprehensive evaluation result of “Environment Quality” is “Excellent” and the level of air quality and negative ion content is the highest in the evaluation layer of each item; the sanitary condition and noise condition are rated as “Excellent”; the climate comfort level and environment

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34993512

bearing capacity are rated as “Good”, showing the environment quality of Baiyun Forest Park is good, which is beneficial for the health care and leisure recreation as well as the well-being of people’s body and mind. The surface water quality is rated as “Average” and it is found that the water body surface in the park is partially polluted; therefore, the improvement of surface water quality in the park should be one of the most important problems to be solved. The support facilities are rated as “Average”. The public toilet, road signs, shopping and accommodation and catering service are imperfect and not all of tourists’ needs can be met. Whether the supporting facilities are perfect or not will affect the park’s recreation suitability to a large extent, therefore, the perfectness, safety and humanization of supporting facilities in the park need further improving.

Development and utilization condition evaluation

Based on the evaluation result, the general evaluation result of Baiyun Forest Park in the aspect of development and utilization condition is “Good”. “Location Condition” is rated as “Excellent”. In it, the geographic position is rated “Excellent”, indicating that Baiyun Forest Park is a typical suburban forest park with clear location advantage. The superior geographic position strengthens the park’s recreation suitability. The tourist source condition and geographic position have mutual effect on each other. Because the park’s geographic position is superior, the tourist source condition is rated as “Good”; the publicity degree is rated as “Bad”. Although all the conditions of Baiyun Forest Park are good, the publicity is far from enough, therefore, it ss necessary to strengthen the publicity degree; “Traffic Condition” is rated as “Good” and the external traffic system is rated as “Excellent”, which means that people have easy access to Baiyun Forest Park. It is found in the investigation that there are many buses in the downtown by which people can get to the park gate directly and this also strengthens the park’s recreation suitability. The internal traffic system and the parking lot are rated as “Average”, indicating they cannot meet tourists’ requirements and need further improving.

Discussion and conclusion

1. The paper, by using the expert scoring method, systematically builds the suburban forest park recreation suitability evaluation system which includes 4 layers with 31 index factors after multiple rounds of screening and adjusting. The system is made up of three criteria layers, including the resource condition, basic condition, development and utilization condition, in which the resource condition and basic condition are the prerequisite and material guarantee and development and utilization condition is the factor affecting the coordination of forest park recreation suitability.

2. Confirm the weight value of all the index factors with the AHP and, on this basis, adopt the fuzzy comprehensive evaluation method to do the empirical study to Baiyun Forest Park in the Lishui city. Based on the evaluation result, the score of Baiyun Forest Park is 3.809 out of 5, indicating that the recreation suitability belongs to the good level. With the superior natural resource condition, environment quality and geographic position, the park has obvious tourism location advantage and high recreation suitability. Based on the fuzzy comprehensive evaluation result, the factors rated as “Excellent” include the “Forest Resource”, “Environment Quality” and “Location Condition”, showing that Baiyun Forest Park has rich forest resource, excellent environment, fresh air, which are important characteristic resources of Baiyun Forest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_34993512

Park and are beneficial for the recreation suitability. Besides, Baiyun Forest Park has the superior geographic position and increasing the accessibility to the park will increase the tourist amount. “Human Resources” and “Supporting Facilities” are rated as “Average”, indicating that problems exist in these two aspects of Baiyun Forest Park and they need further improving.

3. Due to the limitation of its own resource condition, there is difficulty in improving the recreation suitability greatly for Baiyun Forest Park. In the recreation development, put much emphasis on the forest health care function, make full use of the advantage of rich forest resource, strengthen the appreciation of multi-seasonal colored plants, keep the environment not being polluted continuously, clarify the park’s tourist source market, mainly base the development on the Lishui city as well as the surrounding counties and cities, dig the inherent cultural resource, rebuild the characteristic landscape, strengthen the publicity degree and meanwhile, improve the bearing capacity of recreation infrastructure to increase the park’s recreation suitability.

Abstract. Species distribution models are powerful tools for predicting species distributions and for assessing whether particular areas are at risk from invasive weeds, but they may produce different results when different climate data scales are used in the estimate. The results of species distribution models were compared across different spatial scales, and then evaluated the spread of invasive weeds in Chinese nature reserves under several models of climate change. We used Maxent software to estimate the potential spread of 10 phylogenetically diverse alien weeds in the largest 333 Chinese nature reserves. The estimates of invasive weed spread in nature reserves were not stable against changes in spatial scale. The 2.5 arc-minute data was selected to evaluate the ability of invasive weeds to spread in Chinese nature reserves under climate change. Nature reserves with a high risk of invasive weed spread were mainly distributed in southern China. We found a significant relationship between increased invasive weed spread and low and high concentration scenarios, suggesting we should prioritize the prevention and control of invasive weeds now to lessen their impact on nature reserves in the future. It is suggested that other studies may benefit from integrating different scales into the distribution models of invasive weeds.
Keywords: *ALIEN weeds, China, climate change, plant spread risk, Maxent, nature reserves, scale effect*

Introduction

Species distribution models (SDMs) are powerful tools for predicting species distributions and thus they support biological conservation and risk assessment of biological invasion in nature reserves (Alagador et al., 2011; Araújo et al., 2011; Elith et al., 2011; Velásquez-Tibatá et al., 2013; Wan and Wang, 2018). These models have used climate data to assess the distributions of invasive weeds (Chejara et al., 2010; Costa et al., 2013; Sheppard, 2013; Qin et al., 2014). Because invasive weeds represent introduced plant species with generally broad physiological niches and/or some special traits and may respond quickly to changing environmental conditions (Stratonovitch et al., 2012), climate change may increase the possibilities for invasive weeds to invade nature reserves and subsequently damage the efficacy of nature reserves for conservation (Ingwell and Bosque-Pérez, 2015; Thalmann et al., 2015; Merow et al., 2017). Hence, the management of invasive weeds in nature reserves is urgent (Foxcroft et al., 2017). The use of SDMs in biological invasion gives us the new insights into the prevention and control of invasive weeds in nature reserves.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35133533

However, there are still many technical challenges associated with the use of SDMs in the prediction of invasive weeds. Understanding the effects of input data on SDM outputs may increase the precision of the models, thereby improving their usefulness to the risk management of invasive weeds in nature reserves (Elith et al., 2011; Merow et al., 2013).

One notable challenge with SDMs is that their predictive accuracy may vary at the different scales of input data (Rahbek and Graves, 2001; Wang et al., 2012). Some studies have demonstrated that SDMs at finer scales may reduce the uncertainty of the model output (Franklin et al., 2013; Bean et al., 2014). However, a particular scale of input localities may not meet the requirements of the model due to spatial bias in the species distribution data. This would have the potential to strongly distort our view of large-scale biodiversity patterns (Beck et al., 2014). For instance, some studies have shown that databases such as Global Biodiversity Information Facility (GBIF) have a spatially biased dataset due to uneven effort of sampling, data storage and mobilization (Beck et al., 2013, 2014). These studies have found that the most robust estimates of potential species distributions use the data at coarse resolutions (Beck et al., 2013, 2014). SDMs at coarser scales may over-estimate the size of a species distribution in the present and under different climate scenarios (Bean et al., 2014; Suárez-Seoane et al., 2014). These findings suggest that selecting the appropriate spatial scale is important for researchers to accurately estimate robust distribution models (Franklin et al., 2013).

Climate change studies have found that distribution patterns and the variables that determine distribution ranges vary when different spatial scales are used (Rahbek and Graves, 2001; Wang et al., 2012; Porfirio, 2014; Wan et al., 2016). One reason for this variation may be that the scale effect may be particularly pronounced in ecologically complex situations such as climate change (Rahbek and Graves, 2001). On the other hand, as a species expands its area of distribution, the explanatory power of climate variables may also increase, while the explanatory power of habitat heterogeneity and human activities may decrease (Wang et al., 2012). Hence, spatial scale affects estimates of the potential distribution of species under climatic change and the most appropriate scale to model the species distribution must be identified. Franklin et al. (2013) proposed selecting the appropriate scale by finding the smallest bias between results from different scales. There is usually a linear relationship between SDM model estimates at fine and coarse scales (Franklin et al., 2013). This relationship suggests that SDMs need to balance data scale with distribution estimate accuracy (Metzger et al., 2005; Wan et al., 2016).

Previous studies have used different scales (from 0.5 to 10.0 arc-minutes) to model the potential species distributions in nature reserves and did not consider the effect of spatial scales (Araújo et al., 2011; Elith et al., 2011; Jiménez-Alfaro et al., 2012; Thalmann et al., 2015). Not only that, few studies used SDMs to evaluate the risk of weed spread in nature reserves by predicting the potential distributions of invasive weeds at a large spatial scale. Thus, a challenging question is to predict whether and how invasive weeds spread in nature reserves that have been established to protect threatened native species, habitats and ecosystems under future climate change (Vanderhoeven et al., 2011). Therefore, we propose a method to integrate different spatial scales into SDMs in order to assess the vulnerability of Chinese nature reserves to invasive weeds under three climate change scenarios. To address the issue of spatial scale, a simple method was developed to improve SDM estimates for nature reserves

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35133533

using data at several different spatial scales, and to identify the appropriate scale with which to model potential distributions of invasive weeds.

The main aim of our study is to evaluate the spread of 10 invasive weeds in Chinese nature reserves under climate change scenarios in consideration of different scales. For achieving this aim, we used 10 important invasive weeds in 333 Chinese nature reserves as the study cases. The Maxent software was used to model the current and future potential distributions of 10 invasive weeds across four spatial scales (grid resolution ranged from 1 to 256 km^2; Crall et al., 2015) and quantified the ability of invasive weeds to spread in nature reserves. Our approach is useful to identify the appropriate data scale for SDMs and our method can be especially useful to assess the spread of invasive weeds.

Materials and methods

Nature reserves in China

In 2012 China had 2,588 nature reserves covering a total area of ca. 149 million km^2 and representing ca. 14.17% of the land area (www.nre.cn). The world database of protected areas (WDPA; www.protectedplanet.net) was used to identify nature reserves (IUCN I–VI) in China with areas greater than 256 km^2 and thus, covering at least one grid cell of 256 km^2.

Invasive plant data

We modelled the potential spread of 10 invasive weeds including Bidens pilosa, Amaranthus spinosus, Cassia mimosoides, Conyza Canadensis, Daucus carota, Euphorbia hirta, Medicago sativa, Physalis angulate, Sonchus oleraceus and Vicia sativa in 333 nature reserves in China (Li, 1998; Xu and Qiang, 2011; *Table A1* in the Appendix). The species were chosen for this study according to four criteria: (1) the species had the most distribution records in China based on the study of Xu and Qiang (2011) and on the Chinese Virtual Herbarium (CVH; www.cvh.org.cn), (2) species occurrence records were dense enough to support a robust SDM (Phillips and Dudík, 2008), (3) species were widely distributed in China (Xu and Qiang, 2011) and (4) species have the negative impact on a variety of endangered plant species and ecosystem (Xu and Qiang, 2011). Occurrence records for the 10 invasive weeds, especially herbarium specimens or recorded sightings, were compiled from GBIF (www.gbif.org) and CVH (www.cvh.org.cn; Bird et al., 2014; Crall et al., 2015). We used descriptions of species locations in CVH to determine the localities within Google Earth and ArcGIS 10.2 (Bird et al., 2014; Zhang and Zhang, 2014; ESRI, 2014; *Table A1*). The occurrence records of 10 invasive weeds can cover the distribution range of species in China.

Bioclimatic data

The current potential distributions of invasive weeds in nature reserves were modelled using 19 bioclimatic variables available on the WorldClim database (averages from 1950-2000; www.worldclim.org). We removed those with absolute Pearson correlation coefficients > 0.8 in order to eliminate multi-collinearity effects in the parameter estimates of species distribution models (Sheppard, 2013; Porfirio, 2014). The resulting eight bioclimatic variables (the same as future bioclimatic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35133533

variables) can influence the distribution and physiological performance of invasive weeds (Sheppard, 2013; *Table A2*). We used the average values of four global climate models for the 2080s (2071-2099; GCMs; i.e., bcc_csm1_1, csiro_mk3_6_0, gfdl_cm3 and mohc_hadgem2_es) and two greenhouse gas concentration scenarios, i.e., Representative Concentration Pathways (RCPs): 4.5 (mean: 780 ppm; range: 595 to 1005 by 2100) and 8.5 (mean: 1685 ppm; range: 1415 to 1910 by 2100; IPCC 5th Assessment Report) to model the future potential distributions of invasive weeds in the 2080s (2071-2099; www.ccafs-climate.org; Liang and Fei, 2014). RCP 4.5 is different from RCP 8.5 in that RCP 8.5 has a greater cumulative concentration of carbon dioxide than RCP 4.5. Thus, RCP 8.5 predicts a different climate due to anthropogenic accumulation of greenhouse gases and other pollutants. RCP 8.5 and RCP 4.5 were used as the high and low concentration scenarios, respectively (http://www.ipcc.ch/). We used bioclimatic variables at four levels of resolution (0.5, 2.5, 5.0 and 10.0 arc-minutes, namely, 1-256 km^2) because these are the most commonly used data types in SDMs.

Species distribution modelling

The Maxent software (ver. 3.3.3k; http://biodiversityinformatics.amnh.org/open_source/maxent/) was used to model the current and future potential distributions of the 10 invasive weeds across four spatial scales (0.5, 2.5, 5.0 and 10.0 arc-minute resolutions; Franklin et al., 2013). Maxent estimated the function of the potential distributions of the 10 invasive weeds based on maximum entropy and then modeled the geographic locations of the distributions based on environmental variables (Phillips and Dudík, 2008; Elith et al., 2011). Pixels in the Maxent results map with a value of 1 have the highest possibility of the species being located there, while pixels with a value of 0 have the lowest possibility of the species being located there (Phillips and Dudík, 2008; Elith et al., 2011). The pixel value reflects the potential distribution that was used to evaluate the risk of invasive weeds for nature reserves (Hoffman et al., 2010; Bean et al., 2014).

Climatic variables at four arc-minute resolutions were used as environmental input layers in Maxent. We used a 4-fold cross-validation approach to divide the presence dataset into 4 approximately equal partitions, and used 75% of the occurrence points for each species to train the model and the remaining 25% were used to test the model (each run used a different random sample of points; Merow et al., 2013). We set the regularization multiplier (beta) to 2.0 to produce a smooth and general response (Radosavljevic and Anderson, 2014). Auto features were used and other values were kept at default settings of Elith et al. (2011). The importance of bioclimatic variables was tested using the jackknife method (Phillips and Dudík, 2008; Elith et al., 2011).

The receiver operating characteristic (ROC) curves evaluated each value of the prediction result as a possible judging threshold. We assessed the performance of the Maxent model using the area under the ROC curve (AUC; Phillips and Dudík, 2008). This statistic regards each value of the estimate as a possible threshold based on the corresponding sensitivity and specificity when randomly selected background points are removed from the dataset. To ensure the high precision of SDM on four spatial scales, we only used SDMs with AUC values greater than 0.7 (Phillips and Dudík, 2008; Elith et al., 2011; Suárez-Seoane et al., 2014).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Evaluating the spread of invasive weeds in nature reserves

Alagador et al. (2011) used a fixed threshold to match plant species with a nature reserve when the data were at different resolutions of environmental data. However, some studies have indicated that thresholds are problematic and can produce bias in predictions (Calabrese et al., 2014; Merow et al., 2013). The method of Alagador et al. (2011) and Calabrese et al. (2014) was used to evaluate the possibility of the potential distribution of all 10 invasive weeds in each pixel at the scales of 0.5, 2.5, 5.0 and 10.0 arc-minutes in ArcGIS 10.2, respectively (ESRI, 2014) (*Eq. 1*):

$$E_j = \sum_{k=1}^{k} p_{i,k} \quad \text{(Eq.1)}$$

where E_j represents the potential for invasive weeds to be present in each pixel j; k is the number of species in pixel j; i is species i; and $P_{i,k}$ is the probability of the appropriate potential distribution for species i in pixel j.

We also assessed the ability of the 10 invasive weeds to spread in each nature reserve in ArcGIS 10.2 as follows (Araújo et al., 2011; Calabrese et al., 2014; ESRI, 2014) (*Eq. 2*):

$$S_t = \sum_{j=1} X_j Y_j \quad \text{(Eq.2)}$$

where S_t is the ability of all 10 invasive weeds to spread in nature reserve t; X_j represents the potential for the presence of invasive weeds in each pixel j in nature reserve t; Y_j is the distribution area percentage of all invasive weeds in nature reserve t.

Several studies have shown that the scale of the data can potentially affect the SDM estimate (Pineda and Lobo, 2012; Franklin et al., 2013; Bean et al., 2014). There is a significant linear relationship between the potential distributions of species and fine and coarse spatial scales of the input data, and the medium prediction results computed by the scales would be stable (Kunin, 1998; Wilson et al., 2004; Franklin et al., 2013). Here, the medium results (S_t) was selected to assess the change in the ability of invasive weeds to spread within a nature reserve under climate change (Franklin et al., 2013).

We calculated the change in the ability of invasive weeds to spread within a nature reserve between the current scenario and the 2080s (in the low and high concentration scenarios) (*Eq. 3*):

$$A_t = \frac{S_{Future} - S_{Current}}{S_{Current}} \quad \text{(Eq.3)}$$

where A_t is the change in the ability of invasive weeds to spread in nature reserve t and S_{Future} and $S_{Current}$ are the future and current ability of invasive weeds to spread in nature reserve t.

Finally, we assessed the aggressiveness of each invasive weed by calculating the average values of the potential distribution possibilities of pixels within 333 studied nature reserves in China at medium scales.

Results

The WDPA identified 333 Chinese nature reserves with an area greater than 256 km^2 that we sampled for our study (*Fig. 1*). There was no significant correlation between the number of invasive weed locations and AUC ($P > 0.05$). However, AUC measurements of SDM accuracy were greater than 0.9 (from 0.9030 to 0.9816; *Table A1*), indicating highly accurate predictions (*Fig. 2*). The most important variables for the 10 invasive weeds across all of the spatial scales were temperature seasonality and mean diurnal range (*Table A3*). We found no significant differences in the importance of bioclimatic variables for any of the species associated with changes in the spatial scales (correlation coefficient (R) > 0.935 across all the scales; $P < 0.001$; *Table A3*). However, the response of all the species to particular bioclimatic variables differed between scales (*Table A3*). For example, the average temperature seasonality range changed quite a bit from 0.5 to 10.0 arc-minutes for all the invasive weeds (from 26.660 ± 12.994 to 30.527 ± 13.388; *Table A3*).

The average ability of invasive weeds to spread in nature reserves would logically increase by using a coarser spatial scale (e.g., from 0.5 to 10.0 arc-minutes) (*Fig. 3*). Invasive weeds were able to increase their distribution the most using a data scale of 10.0 arc-minutes, and they increased their distribution the least using a scale of 0.5 arc-minutes (*Fig. 3*). We found that Maxent predictions of the spread of invasive weeds were unstable. In other words, they fluctuated when using different data scales (*Figs. 3* and *A1* in the *Appendix*). Jiaxi is a good example to show the various results of different data scales (*Fig. A1*). We found that using 2.5 arc-minute data could have the medium results to estimate invasive weed distributions in nature reserves at all data scales in the present and future (*Fig. 3*). Therefore, we selected the 2.5 arc-minute data as the appropriate data scale to evaluate the risk of invasive weed spread in Chinese nature reserves under climate change.

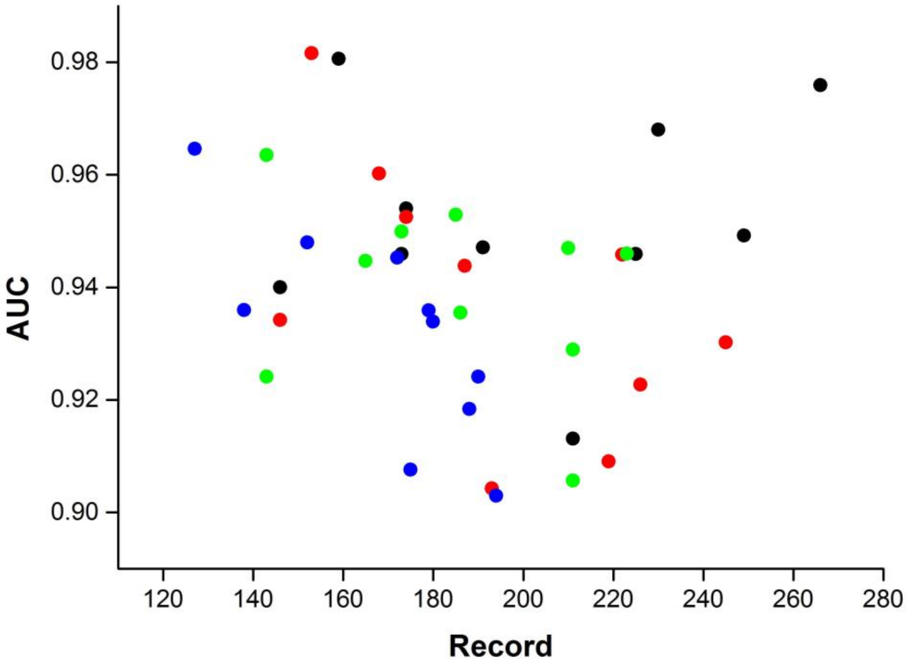

Figure 2. *The number of occurrence records and AUC values for 10 invasive weeds when using these different data scales. The black points represent 0.5 arc-minutes; the red points represent 2.5 arc-minutes; the green points represent 5.0 arc-minutes; the blue points represent 10.0 arc-minutes*

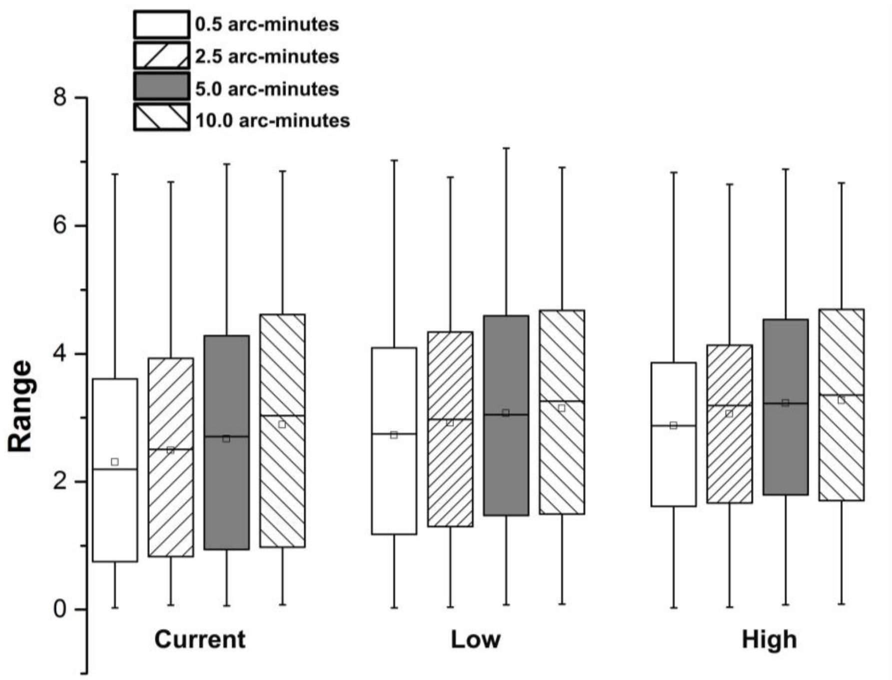

Figure 3. *The ability of invasive weeds to spread in nature reserves modeled using different spatial scales in current, low and high gas-concentration scenarios. Range: the ability of invasive weeds to spread in nature reserves bounded by horizontal bars; Current: present day; Low: low-gas-concentration scenario predicted into the future; High: high-gas-concentration scenario predicted into the future. The block point of the box is the mid-value value of the range and the line of box is the mean value of the range*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35133533

There was a significantly positive relationship between the spread of invasive weeds in nature reserves with low and high concentration scenarios, suggesting pressure from invasive plants will continue at a similar rate even when different data scales are considered at either low and high concentration scenarios ($R^2 > 0.943$; $P < 0.001$; R^2 of 2.5 arc-minutes: 0.9618; $P < 0.001$). Furthermore, the average increase in the ability of invasive weeds to spread within nature reserves was larger in the high concentration scenario than the low concentration scenario (+70.25% (high) *vs.* +37.08% (low); *Table A4*). Hence, we used a high concentration scenario to map the spread risk of invasive weeds in nature reserves.

We found that *M. sativa* had the largest ability to spread within nature reserves, and *A. spinosusin* had the smallest spread ability in current and high concentration scenarios (*Table 1*). Meanwhile, *D. carota* and *M. sativa* would have the most significant increasing trends of spread risk under climate change (*Table 1*). Nature reserves with a high risk of invasive weed spread (e.g., Wuzhishan, Jiaxi, Jianfengling (Hainan province) and Tawushan (Sichuan province)) were mainly distributed in southern China (*Fig. 4a; Table A4*). These nature reserves are currently dominated by invasive weeds and our estimates predict many of them will continue to be so in the future (*Fig. 4a* and *b; Table A4*). We found that 291 of 333 nature reserves would be at higher risk for all 10 invasive weeds in the high concentration scenarios than in the present day (*Fig. 4; Table A4*). In addition, 303 of 333 nature reserves would be at higher risk of all 10 invasive weeds in the low concentration scenarios (*Table A4*). We found that nature reserves that had the highest increases in their risk for invasive weeds in the high concentration scenario were distributed in southwestern, northwestern and northeastern China (*Fig. 4c; Table A4*). In southern China, nature reserves had increased risk of invasive weeds, but the change in risk was not as large as in the rest of the country (*Fig. 4*). Jiaxi and Wuzhishan had the highest risk of all 10 invasive weeds in the current and future concentration scenarios (*Table A4*), and Kekexili and Aerjinshan had the highest increases in their risk for invasive weeds under climate change (*Table A4*).

Table 1. *Potential risk of the spread of 10 invasive weeds in Chinese nature reserves in the present day and high gas-concentration scenario at a spatial scale of 2.5 arc-minutes. Current indicates the spread of 10 invasive weeds in the nature reserves in the present days. High indicates the spread of 10 invasive weeds in the nature reserves in the high concentration scenario. High-change indicates the changes in the ability of invasive weeds to spread in the nature reserves in the high concentration scenario*

Discussion

Our study is an example of how SDMs can be applied to estimate the risk of weed spread in nature reserves with the different scales. Our results showed that using different spatial scales results in different estimates of invasive weeds distributions in current, low and high concentration future scenarios. This indicates that the spatial scale may under- or over- estimate the ability of invasive weeds to increase their distribution in nature reserves. We also found that the risk of invasive weeds in nature reserves was largest at scales of 10.0 arc-minutes. Thus, SDM prediction uncertainty caused by spatial scales could result in inaccurate estimates of invasive weed distributions and their effect on nature reserves. Previous studies have determined the appropriate scale of data to use in SDMs by comparing relationships of potential distributions between fine and coarse scales and subjectively choosing the "best" data scale based on the results (Franklin et al., 2013; Suárez-Seoane et al., 2014). Franklin et al. (2013) selected the appropriate scale by computing the extent and location of the predicted distribution area under current climate conditions depending on the differences in the estimates between fine and coarse scales. The selection of an appropriate data scale should incorporate the variance found when using different scales in SDMs (based on *Fig. 2*) and stabilize the predicted distribution of invasive weeds (Franklin et al., 2013). Hence, by comparing the SDM results of different scales, we used 2.5 arc-minutes, the second-finest scale (also, the medium scale), to evaluate invasive weed risk in nature reserves under climate change scenarios.

Millions of dollars have been invested in the global control of invasive weeds and many scientists have proposed methods to prevent and control the invasion of invasive weeds (Dewey et al., 1995; Rinella and Luschei, 2007). Some scientists have proposed designing long-term management plans at the regional or national scale to mitigate weed spread due to climate change (Chejara et al., 2010; Bohan et al., 2011; Sheppard, 2013; Qin et al., 2014). However, few studies paid attention to the spread of invasive weeds in nature reserves at the national scale. The spread of invasive weeds into nature reserves may cause serious problems (Van Wilgen et al., 2012; Lindenmayer et al., 2015). The invasive weeds can displace native species, alter community structure and ecosystem functions, and cause landscape change and habitat fragmentation (Lindenmayer et al., 2015; Thalmann et al., 2015). Consequently, nature reserves may lose their function of protecting concerned species, habitats or ecosystems (Ingwell and Bosque-Pérez, 2015; Thalmann et al., 2015). We found that nature reserves in southern China are currently dominated by invasive weeds and our estimates predict most of them will continue to be so in the future. Our data supports the need for long-term monitoring of these nature reserves to prevent the spread of invasive weeds due to climate change (Wang et al., 2017). Our finding that the ability of invasive weeds to spread within nature reserves would increase more severely in the high concentration scenario than the low concentration scenario indicated that climate change due to the increasing gas concentration may facilitate the spread of invasive weeds in nature reserves. More importantly, we found a significant relationship between increased invasive weed distributions and low and high concentration scenarios, suggesting we should prioritize the prevention and control of invasive weeds now to lessen their impact on nature reserves in the future (Rannow et al., 2014). Therefore, the prevention and control of invasive weeds in nature reserves is extremely urgent now. The challenge for biological conservationists will be in minimizing the opportunities for invasive plant species to be introduced into nature reserves under climate change. Based on the assessment of expansion risk for invasive weeds and nature reserves, we propose the following measures: (1) detailed monitoring of climate change, (2) improvement of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35133533

effective management for human activities near or inside nature reserves, and (3) control of the introduction of invasive weeds with a high ability to naturally disperse (Foxcroft et al., 2017; Merow et al., 2017).

Our suggestion is that researchers integrate model evaluation of several different spatial scales (0.5, 2.5, 5.0 and 10.0 scales widely used in SDM studies) into their SDM analyses on invasive weeds. Although our study did not validate the Maxent estimates with ground truthing or ecological monitoring this work should be prioritized as a way to test our approach for quantifying invasive species risk (Alagador et al., 2011). Using the correct scale for SDM may lead to more accurate predictions that allow researchers and land managers to make reasonable decisions regarding the management of invasive weeds (Costa et al., 2013; Sheppard, 2013; Qin et al., 2014). Therefore, studies on the effect of data scales on SDMs must continue. We hope that future studies can expand the application of SDMs to provide practical suggestions for mitigating the impact of scale effects on SDM predictions of weeds.

Conclusion

We put forward a simple method to balance various results modeled by different spatial scales for avoiding the over- or under-estimation of SDM results due to the selection of spatial scales, and take the impact of different scales on SDM results into consideration for invasion risk of weeds. Nature reserves with a high risk of invasive weed spread were mainly distributed in southern China. We should prioritize the prevention and control of invasive weeds now to lessen their impact on nature reserves in the future. Here, we proposed the useful suggestions for the evaluation of risk of invasive species: (1) we need to compute two indicators: the ability of invasive weeds to spread in nature reserves and spread potential of invasive weeds for nature reserves; (2) we should balance the various impacts of different spatial scales on the results of SDMs; (3) we should determine the regional scales of spread risk of invasive weeds under climate change. Finally, we hope that future studies can expand the application of SDMs to provide feasible suggestions for risk evaluation of invasive species under climate change.

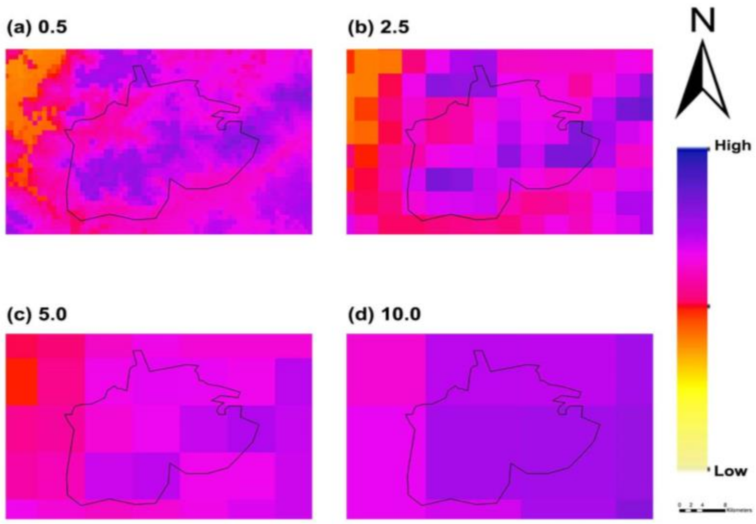

Figure A1. *The spread of invasive weeds in Jiaxi nature reserve in the present day at different spatial scales (i.e., 0.5, 2.5, 5.0 and 10.0 arc-minute resolutions)*

Table A4. *Potential risk of the spread of 10 invasive weeds in Chinese nature reserves at a spatial scale of 2.5 arc-minutes. Name refers to the names of nature reserves based on WDPA database. Current refers to the spread of 10 invasive weeds in the nature reserves in current concentration scenario. Low signifies the spread of 10 invasive weeds in the nature reserves in the low concentration scenario. High indicates the spread of 10 invasive weeds in the nature reserves in the high concentration scenario. Low-change: the changes in the ability of invasive weeds to spread in the nature reserves in the low concentration scenario; High-change: the changes in the ability of invasive weeds to spread in the nature reserves in the high concentration scenario*

(Received 12th Nov 2018; accepted 4th Feb 2019)

Abstract. Fish scale investigation has been used in many ways. Recently several species' scale shape was used to differentiate species, populations or stocks. Effects of allometric growth on scale shape proved to be a common phenomenon in case of numerous species, however there is no information regarding the impact of temporal (ontogenetic timescale) changes. In this study the effect of intrapopulation age distribution on the scale shape was tested. Seven age groups of a gibel carp (*Carassius gibelio*) population were identified and analyzed using landmark-based geometric morphometric methods. The results indicated a clear trend of ontogenetic-driven shape change of gibel carp scales: the adult fish specific scale shape occurs at the age of 3+, along with sexual maturation, the alterations among the older age classes show no significant differences. These results suggest that the asymmetric age distribution of fish populations should be taken into consideration during scale morphometric analyses.
Keywords: *geometric morphometrics, shape analysis, allometry, Carassius gibelio, age*

Introduction

Increasing number of papers reported the usefulness of morphometrical studies of fish scale shape (Avigliano et al., 2017; Ibanez and Jawad, 2018; Albertson et al., 2018). The methodology has numerous advantages in fish population studies (e.g. cheap, fast), however more precise assessment of application conditions are necessary. Previous studies described that allometric growth has to be taken into consideration during scale shape analyses (Ibáñez et al., 2012; Staszny et al., 2012.), however the correlations of the specimens' age and scale shape were neither considered, nor studied yet. The correlation between the age and body shape was proved in the case of fish (Wimberger, 1992), and similar patterns were observed in wide taxonomical range, e.g. in case of the human ribcage (Gayzik et al., 2008) or the wing shape of Blackcaps (*Sylvia atricapilla* Linnaeus, 1758) (Pérez-Tris and Tellería, 2001).

As an easily conductible, well-repeatable, non-destructive method, fish scale shape related analyses might emerge importance in various ecological studies (Takács et al., 2016); therefore, assessment of the source of shape variability within a studied group is crucial. The aim of our study was to test the effect of within-population age distribution on scale morphometric analyses, in order to assess the presence of ontogenetic changes in scale shape.

Review of literature

Answers can be found for many population level questions, encoded in fish scales. Generally, fish scales are used in taxonomy in species identification (e.g. in case of gut content analyses of Piscivores (Bräger et al., 2016)), also used in population level separations (as a cheaper alternative of population genetic methods) (Ibáñez et al., 2007; Garduño-Paz et al., 2010; Staszny et al., 2012; Ibáñez, 2015) and species separation (Şerban and Grigoraş, 2018). It is suitable for age determination and for the back-calculation of individual- or population-level growth in temperate climate zone (Pompei et al., 2011; Soriguer et al., 2000). Similarly to other body parts, the phenotype of scales is affected by genetic, environmental and their covariate effects, during the lifespan of the fish (Ibáñez et al., 2012; Staszny et al., 2013). This phenomenon is partially confirmed by the study of Garduño-Paz et al. (2010), which successfully discriminated sympatric ecotypes of Arctic charr (*Salvelinus alpinus* Linnaeus, 1758) within Loch Tay lake and Loch Awe lake, based on their scale shape.

Materials and methods

Fish samples were collected during the summer of 2011 from the littoral zone of the Kis-Balaton Water Quality Protection System (Hungary, Coordinates N46.657537 E 17.194324) (*Fig. 1*), using a battery-powered electric fishing device (SAMUS 725MP).

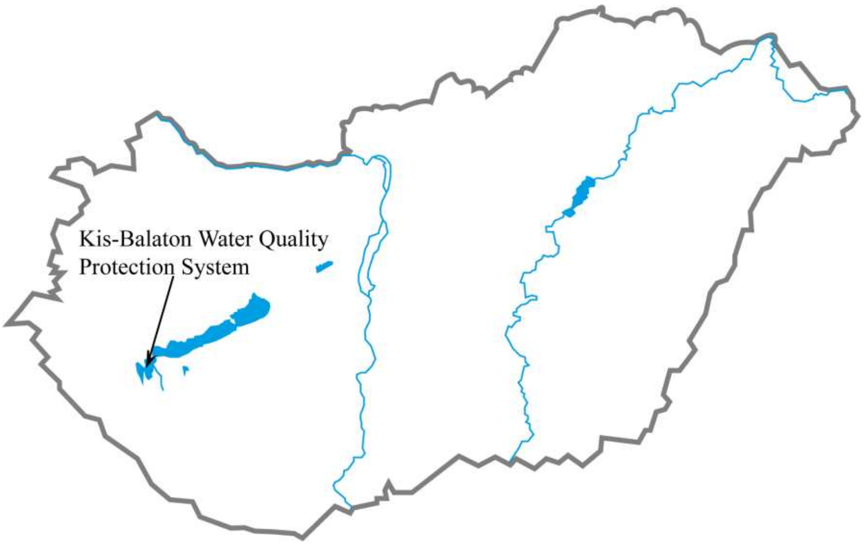

Figure 1. *The sampling area of the study*

The non-indigenous Cyprinid gibel carp (*Carassius gibelio* Bloch, 1782) was selected as model species. Scale samples (one per specimen) were collected from the flank, anterior to the dorsal fin (Garduño-Paz et al., 2010), from the left side of the body in order to avoid the variance caused by the fluctuating asymmetry (Sheridan and Pomiankowski, 1997). Scales were then placed between two glass slides and digitalized by using a HP ScanJet 5300C XPA scanner at 2400 dpi (upper lighting). Altogether 273 gibel carp specimens were collected. The age of each fish was determined based on the number of annual rings, determined based on the digital images by the same expert. Seven experimental groups were created using the scales of randomly selected 20-20

DOI: http://dx.doi.org/10.15666/aeer/1702_35353544

specimens from age groups of 0+ - 6+, where 0+ stands for young-of-the-year individuals and 6+ represents seven year-old fish. The average standard length and weights of the age groups are shown in *Table 1*.

Table 1. *Average standard length (mm) and weights (g) of the age groups*

Age group	Weight (g)	Standard length (mm)
0+	30.18±19.41	89.27±29.02
1+	35±11.98	101.06±12.52
2+	119±51.98	146.67±23.23
3+	289.67±66.23	205.5±17.73
4+	411.92±57.07	234.54±12.55
5+	586.67±111.35	257.89±17.93
6+	790.67±60.74	287.17±10.74

Shape was analysed by using landmark-based geometric morphometric methods (Zelditch et al., 2004). Seven easily definable landmarks (Ibáñez et al., 2007) were recorded on each scale by using tpsUtil (Rohlf, 2015) and tpsDig2 (Rohlf, 2005) software (*Fig. 2*). Landmarks 1 and 3 are the ventro- and dorso-lateral tips of the anterior portion of the scale. Landmarks 4 and 6 are at the boundary between the area covered by other scales and the exposed area, landmark 7 is positioned at the tip of the posterior portion of the scale. Landmark 2 is in the center of the anterior edge of the scale, and landmark 5 is the focus of the scale.

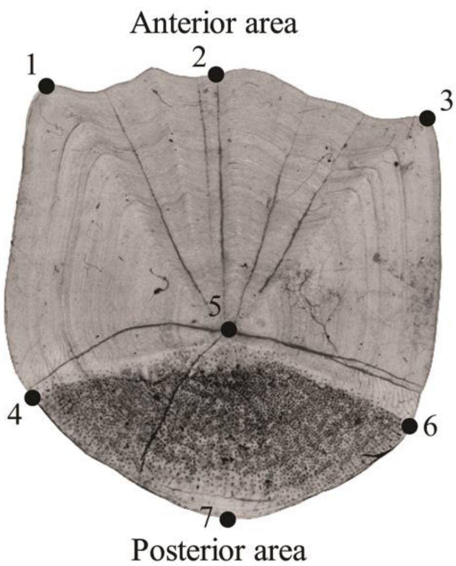

Figure 2. *Landmarks used to define the shape of the scales. The areas of the scales are described with respect to the fish position*

MorphoJ software package was used for further multivariate analysis (Klingenberg, 2011). Generalized least-squares Procrustes superimposition (GLS) was applied to the coordinates of raw landmarks to scale, translate and rotate and get new shape variables independent of the scale size (Rohlf, 1990). A regression analysis was performed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35353544

between the logarithm of centroid sizes and Procrustes coordinates within each group to eliminate the within-group size-variances. Canonical Variates Analysis (CVA) and Discriminant Function Analysis (DFA) were performed to examine the separation of different age groups. Permutation test was performed (10 000 iterations) to assess the reliability of the results.

Results

The result of the regression analysis shows significant allometry in all age groups ($p = 0.001$). The average variance of size accounted for 3.47% of the whole shape variance. All experimental groups could be discriminated significantly from each other, except two pairs (3+-5+ and 4+-5+) (*Table 2*).

Table 2. *Analysis of the seven age groups of gibel carp (Carassius gibelio) scale shape using geometric morphometrics. Left half-matrix: T^2 statistics; right half-matrix: p-values; diagonal in italics: average similarities in groups. The non-significant results are in bold.*

	0+	1+	2+	3+	4+	5+	6+
0+	*0.645*	0.027	<0.001	<0.001	<0.001	<0.001	<0.001
1+	32.72	*0.636*	0.006	<0.001	<0.001	<0.001	<0.001
2+	147.29	42.81	*0.498*	0.002	0.02	0.022	<0.001
3+	616.94	135.57	49.56	*0.498*	0.049	**0.207**	0.008
4+	357.96	147.64	34.81	28.57	*0.373*	**0.145**	<0.001
5+	340.58	97.12	33.92	**19.06**	**21.47**	*0.458*	0.004
6+	761.58	214.29	115.26	40.92	75.64	46.15	*0.484*

CVA analysis revealed that scale shape of younger age groups (0+ – 2+) could be discriminated along with the first canonical axis, while older age-classes (3+ - 6+) form an integrated group, which is only dissolved along the second canonical axis, accounted for considerably less variance (7.3%; *Fig. 3*).

The classification rates proved to be high: 91.6 ± 7.37 % (mean ± SD) (not including the non-significant groups) (*Table 3*).

The comparison of average scale shape of the different age groups shows that up until the 3+ group the change in direction of shape is very similar (*Fig. 4*). Between the 3+ and 4+ groups the scales begin to widen, then the caudal edge starts to narrow and the proportion of the exposed area decreases.

The experimental groups were further categorized, based on the CVA results: the former age groups were ranked into three categories, referring as "life stages" (juvenile: 0+, 1+; subadult: 2+; adult: 3+, 4+, 5+, 6+) (Harka and Sallai, 2004). Another CVA was performed on the three new groups ("life stages"). Based on the results of regression analysis the size affected the shape significantly ($p < 0.001$), in similar degree (4.59%) as in age groups. All the three groups separated from each other significantly ($p < 0.001$) (*Table 4*).

Table 4. *Examination of three life stages of gibel carp (Carassius gibelio) scale shape with geometric morphometrics. Left half-matrix: T^2 statistics; right half-matrix: p-values; diagonal in italics: average similarities in groups*

	Juvenile	**Subadult**	**Adult**
Juvenile	*0.79*	<0.001	<0.001
Subadult	72.2	*0.368*	<0.001
Adult	509.37	76.92	0.241

The three groups separated from each other along the first canonical axis (*Fig. 5*), which is accounted for the 98% of the total variance.

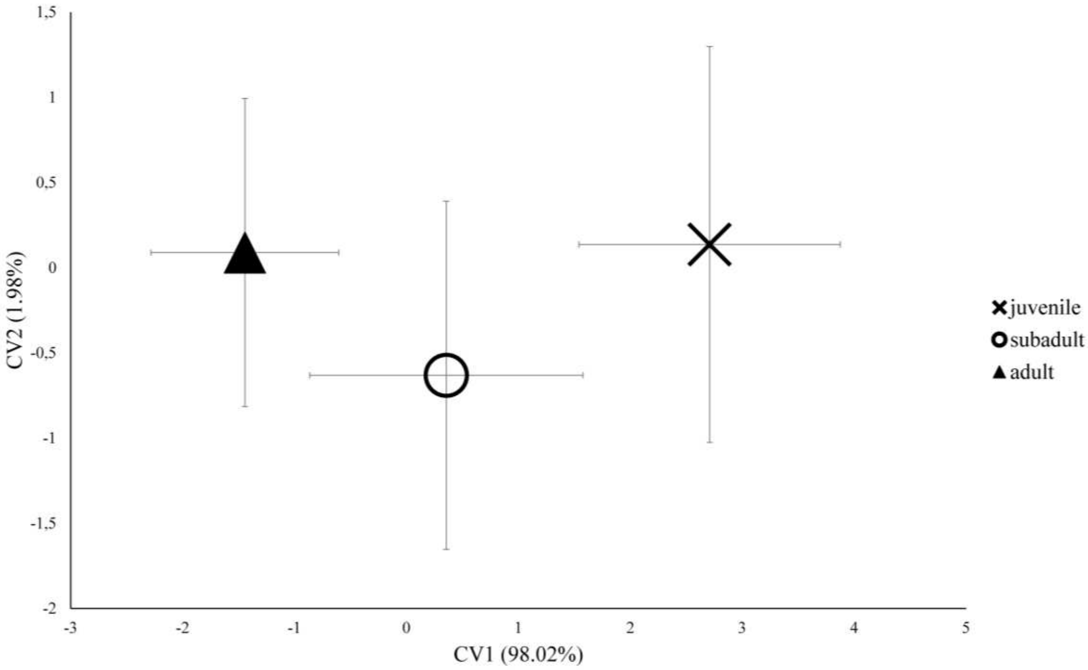

Figure 5. *Separation of the gibel carp (Carassius gibelio) three life stages based on scales shape. Symbols show the groups average, crosshairs show the standard deviation, percentage values shows the carried variance proportions of the axes.*

The classification rates were very similar to the analysis of the seven age groups, (mean ± SD): 89.9 ± 3.54% (*Table 5*).

	Juvenile	Subadult	Adult
Juvenile		88.75%	93.75%
Subadult	81.25%		86.90%
Adult	96.90%	76.25%	

Discussion

Our analyses revealed a clear trend of scale shape development in case of gibel carp, which was separated into three stages: ‘0+-1+’: juvenile; ‘2+’: subadult; ‘3+ -6+’: adult. Microstructural, histological changes, and genetic background processes of scale development are well known during the ontogenesis of fishes (Breitler-Hahn and Zylberberg, 1993; Sire and Akimenko, 2004; Levin, 2011), however according to our knowledge no comparable data is available regarding the shape changes of other fish species. Our results suggest that however the scale itself appears in a very early life stage (e.g.: at 8 mm standard length in case of zebrafish (Le Guellec et al., 2004)), the shape might have its own ontogenetic development.

In the case of gibel carp, the background of scale shape changes might be related to the sexual maturity, since the time of maturation could be dated to the 3+-4+ age in Central Europe (Szczerbowski, 2001). *Figure 3* shows a clear pattern with opposite shape changes amongst the groups, which is possibly in connection with maturation. In the case of young groups (0+-3+), the groups follow each other step by step in a negative direction along the first canonical axis. Later the groups were separated along the second canonical axis. This phenomenon is likely in connection with the ontogenetic development of body shape, which was described in detail in several studies. In case of red-bellied piranha (*Pygocentrus natterei* KNER 1858) the study of Zelditch and Fink (1995) demonstrated that during the ontogenetic development the middle section of the body, the postorbital section of the head, as well as the nape area are elongating, and the whole head becomes higher. It was also reported in case of cascarudo (*Callichthys callichthys* L. 1758) that the body and the postorbital region elongated, the caudal peduncle became thinner and the height of abdominal region increased (Reis et al., 1998). Hood and Heins (2000) had similar findings in Blacktail shiner (*Cyprinella venusta*), which suggests that ontogenetic changes in reproductive status is in connection with body shape change. The results of our study coincide with these findings. As the number of scale lines are fixed along the body of the fish, after the age 3+, the body height increased relative to body length, which cause the widening of the scales. After that, the middle section of the fish elongated (the body and the scales were growing in higher proportion to cranio-caudal direction), that is the reason of the scales narrowed in dorso-ventral direction.

Conclusion

In conclusion, the age structure of the sample may have an important role in scale shape morphometric studies. In our opinion this finding has to be taken into consideration in further comparative scale morphometric analyses, while the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35353544

asymmetric age distributions might affect the results significantly, false population level separation could be observed without the presence of genetic and/or environmental differences. Furthermore, involvement of specimens' size as a supplementary variable in the scale morphological analyses (Ibáñez and O'Higgins, 2008) became questionable, since length is strongly correlated with the age of the fish (Le Cren, 1951). Further studies needed to test our findings on different other species and the quantified effect of the asymmetric age distribution of the compared groups.

Abstract. Pattern of vertical distribution of plant roots determines plant water and nutrient uptake and influences various soil processes under field conditions. However, information of root distribution in the whole rooting profile is rarely available in practice. This paper documents a method to quickly quantify root vertical distribution pattern using limited root length density data obtained from soil cores under field conditions. It was implemented through the development of a Minitab macro and an R script, with sample calculations conducted on field collected root length density data from the winter wheat crop in Texas, USA. The method is potentially useful for quantifying plant root activities in natural soils where deep roots are difficult to access by physical means and data of root length density distribution are only available in the upper root zone.
Keywords: *computer code, data processing, field measurement, rooting depth, soil core*

Introduction

Vertical distribution of roots of land plants generally follows an exponential decay pattern (Weaver, 1926) and this has been frequently recognized in models describing plant water uptake from the soil profile (Ojha and Rai, 1996; Wu et al., 1999; Yadav et al., 2009; Dong et al., 2010; Dong, 2016). This fashion of root distribution is also an important trait dictating plant resource acquisition from the soil environment (Xue et al., 2003; Acuña and Wade, 2013; Sharma et al., 2014; Wasson et al., 2014; Hodgkinson et al., 2017). For example, the depth at which the densest roots locate in the soil profile influences plants' capacity to tolerate drought stress (Wan et al., 2000; Yu et al., 2007). The roots of numerous plants can easily reach 2 meters deep in the soil (Coupland and Johnson, 1965), but it is difficult to measure the roots from deeper soil profile. As a result, field studies usually only report root data collected from upper soil layers (Xue et al., 2003), and a major challenge for researchers is to extract the most information from the limited survey data of plant roots. The need for obtaining simple indices to summarize root distribution becomes more acute for large field experiment involving a complex design structure. The pattern of vertical distribution of plant roots in the soil profile is described elsewhere (Wu et al., 1999; Zuo et al., 2004; Yadav et al., 2009; Zuo et al., 2013). Despite complexities due to variations in plant growth and soil micro-environment, a salient feature pervading the literature is the exponential decay of the roots with the increase of soil depth. This fashion of root distribution allows calculation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35453552

of the normalized root length density (Wu et al., 1999) that has important applications in describing water uptake by plant roots. The main purpose of this paper is to describe a simple procedure for estimating root distribution pattern using limited field data. This will include an automated calculation to extract root information from large survey data sets, so that variables such as normalized root length density can easily be obtained based on field survey data of root length density distribution.

Method

The relative importance of roots located in a particular soil layer to plant water uptake is conveniently described by the normalized root length density L_{nrd} (dimensionless), which can be calculated according to Wu et al. (1999):

$$L_{nrd} = \frac{L_d(z_r)}{\int_0^1 L_d(z_r)\,dz_r} \quad \text{(Eq.1)}$$

where $L_d(z_r)$ is root length density (cm cm^{-3}), $z_r = z/L_m$ is the relative soil depth containing plant roots and z (cm) and L_m are soil depth and the maximum rooting depth (cm), respectively. It has been shown that *Equation 1* can be used as a weighting factor to partition potential transpiration into components of root water uptake occurring from different soil layers (Wu et al., 1999; Zuo et al., 2013).

Under field conditions, values of L_m at different growth stages of a crop may be estimated using a sigmoidal growth curve (Wu et al., 1999; Dong et al., 2010), or based on the ratio of potential transpiration and measured maximum rooting depth at the peak growth stage (Ojha and Rai, 1996). While $L_d(z_r)$ can easily be measured for a particular soil layer by destructive sampling, the denominator of *Equation 1* normally needs to be estimated based on measured root length density data, as well as a model describing root length density as a function of soil depth. Assuming that root length density $L_d(z)$ is measured for the first L' cm of soil for n intervals, each of L'/n cm in depth, root length density as a function of soil depth may be described using an exponential decay function

$$L_d(z) = Ke^{-\alpha z} \quad \text{(Eq.2)}$$

in which K and α are parameters that can be estimated using a nonlinear least-squares regression procedure. Then, with the estimated values of K and α, the total lengths of roots (per unit of soil surface area) contained in the soil depth from L' to L_m can be estimated by integrating *Equation 2:*

$$L_{bottom} = \int_{L'}^{L_m} Ke^{-\alpha z}dz = -\frac{K}{\alpha}\left[e^{\alpha L_m} - e^{\alpha L'}\right], \quad \text{(Eq.3)}$$

where K is maximum root length density near soil surface (z = 0 cm), α is a parameter determining the rate of decay of root length density with soil depth z (cm).

The normalized root length density (*Equation 1*) for the ith soil layer can be calculated as

$$L_{nrd,i} = \frac{L_m L_{d,i}}{\sum_{k=1}^{n} \Delta z_k L_{d,k} + L_{bottom}}, \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35453552

where the 2nd term of the denominator (L_{bottom}) is calculated according to *Equation 3*. Also, we used the relation $\int_0^{L_m} L_d(z)dz/L_m = \int_0^1 L_d(z_r)dz_r$. *Figure 1* shows the distribution of normalized root length density at different relative depths of soil.

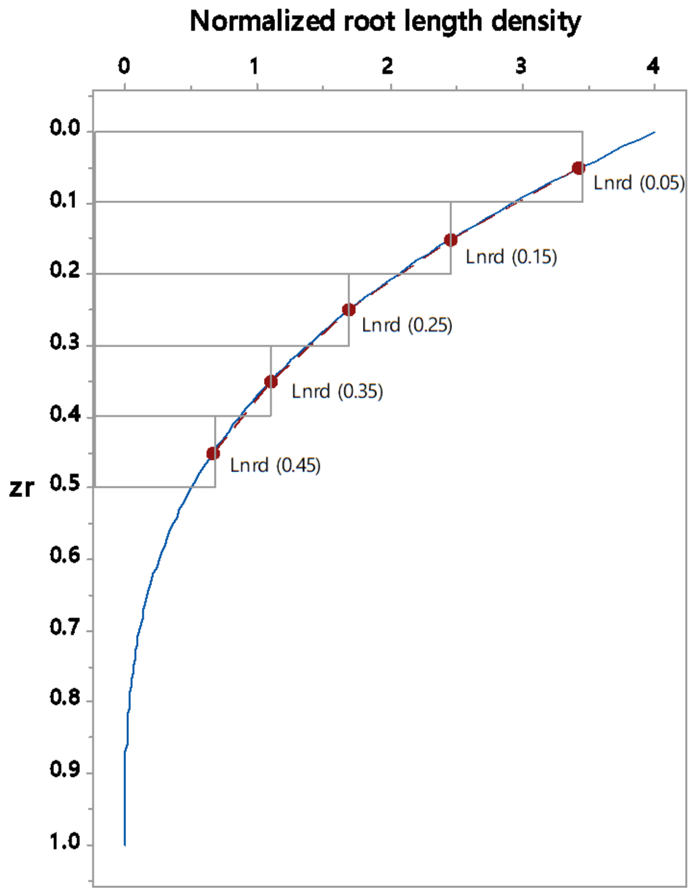

***Figure 1.** Normalized root length density (L_{nrd}) as a function of relative soil depth (z_r), based on measured root length densities in the upper root zone (rectangles). Numerals enclosed in parentheses indicate the relative depths of centers of the soil depth intervals with root measurement. Also shown is the predicted distribution of L_{nrd} in the root zone, assuming $\beta = 3.0$*

The normalized root length densities calculated in *Equation 4* will be fitted to a one-parameter nonlinear model of Ojha and Rai (1996), assuming maximum rooting depth (L_m) is known:

$$L_{nrd} = (\beta + 1)(1 - z_r)^{\beta}, \quad \text{(Eq.5)}$$

where β is the unknown parameter to be estimated using nonlinear least-squares. Compared with the four-parameter polynomial equation of Wu et al. (1999), *Equation 5* is simpler, containing only one parameter. It attains the maximum value near soil surface when $z_r = 0$; it gives zero value at bottom of the root zone ($z_r = 1$). Also, the integral of *Equation 5* over the root zone is unity: $\int_0^1 L_{nrd}(z_r)dz_r$. It should be noted that *Equation 5* was also obtained independently from a different derivation by Zuo et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35453552

al. (2004, 2013) as a generalized root length density function. It was used by Dong et al. (2010) to characterize plant root distribution pattern in a mixed-grass prairie. The best parameter can be estimated using nonlinear curve-fitting method based on measured root length density data.

Once the values of β are estimated based on experimental data, *Equation 5* can be employed to calculate the relative soil depth $z_{r,95}$ (or absolute soil depth z_{95}) above which 95% of roots are found. Knowing how much deep into the soil profile should we dig in order to find 95% of roots will surely help our future root survey by concentrating our efforts in the depth of soil that is most important for root growth and function. We can estimate $z_{r,95}$ by evaluating the following definite integral:

$$\int_0^{z_{z,95}} (\beta + 1)(1 - z_r)^{\beta} dz_r = 0.95, \quad \text{(Eq.6)}$$

which yields

$$z_{r,95} = 1 - e^{\frac{ln(0.05)}{\beta+1}}. \quad \text{(Eq.7)}$$

Using *Equations 6* and *7,* the absolute depth above which 95% of plant roots are found (i.e., z_{95}) can be calculated as $z_{95} = L_m z_{r,95}$.

Computer code with sample data testing

The root distribution parameters can be calculated using the Minitab macro **len.mac**, or the R script **len_R.txt**, as can be found in the *Appendix*. As a test of the computer code, a sample input data file, **soil.csv**, is provided and the output results are shown in **out.csv**. The main output results include (a) distribution pattern of root length densities as measured from soil coring (not normalized within the whole root zone; see the documentation of **len.mac** in the *Appendix*); (b) the ratio of total roots contained in the upper and lower profile (the dividing line between the upper and lower profile is set at 40 cm in the illustration, but this can be changed easily); (c) the distribution pattern of normalized root length density as measured from soil coring; and (d) the estimated depth of soil containing 95% of total root lengths. Parameter values estimated from the nonlinear regression procedure are accompanied by estimated standard errors. As can be seen from the sample output file **out.csv**, standard errors of the model parameters for some soil depths are quite high, primarily due to the small sample size (5 for each soil core in the testing data set). The errors could be reduced for larger sample sizes with soil layers divided into thinner segments. It has been found that root vertical distribution is strongly influenced by soil bulk density (Zhang et al., 2012). Thus, under some situations, such as one in which there exists a hard plow pan, root distribution can become more complex. In that case, different nonlinear models may be used in place of current ones (modifications may be made to lines marked with *** in **len.mac**), as well as some other minor changes to properly collect the outputs from new nonlinear models.

The current setup of the programs gives reasonable estimates of the average root distribution patterns of winter wheat varieties from a relatively large data set obtained in field conditions, as seen in *Figure 2,* in which fitted values for normalized root length densities for 240 soil core samples are compared against the measured ones. The root samples were collected in two seasons in 2016 and 2017 during the flowering stage

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35453552

from the same set of ten winter wheat varieties planted in two locations in Texas: Amarillo and Uvalde. The soil in Amarillo is clay loam (Xue et al., 2003) while that in Uvalde is clay (Sharma et al., 2014). Amarillo (35°52'N, 101°58'W; elevation 1114 m) is located in Texas High Plains, with an annual rainfall of 516 mm, average temperature of 14.1 °C and average wind speed of 6.4 m/s. Uvalde (29°13'N, 99°45'W; elevation 283 m) is located in the southwest of Texas (Wintergarden), with an annual rainfall of 594 mm, average temperature 27.6 °C and average wind speed 3.1 m/s. Root samples were taken using a hydraulic soil corer from 1 m profile at 20 cm intervals. The samples were promptly stored in a -20 °C freezer and later washed to obtain the fine roots, which were scanned into digital images and measured for root length using the WinRhizo software version 2013b (Reagent Instruments Inc., Quebec, Canada). Root length density was expressed as the total length of roots contained in unit soil volume (cm/cm^3). The winter wheat plots were planted with a seeding rate of 5.8 g/m^2 and row spacing of 19 cm (see Liu et al., 2018 for detail).

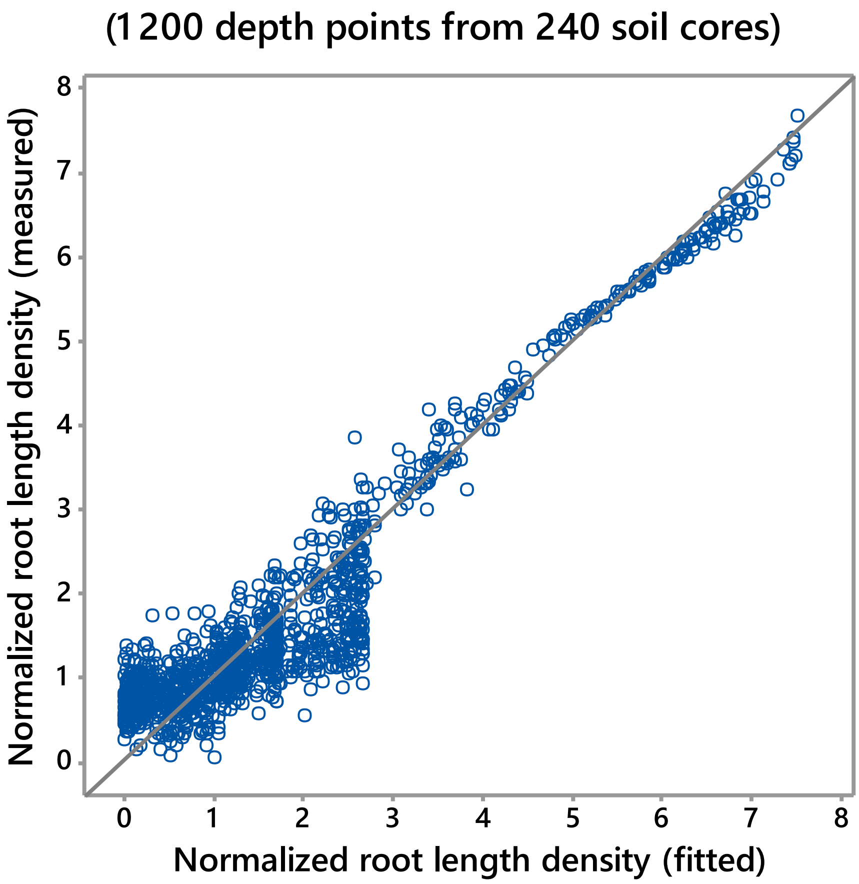

Figure 2. *Measured normalized root length density (L_{nrd}) as compared against the values fitted using the nonlinear regression based on 1200 depth points from 240 soil cores collected in winter wheat fields in Uvalde and Amarillo, Texas, USA. Also shown is the 1:1 line*

The proposed root data processing method allowed us to estimate average soil depths (z_{95}) containing 95% of roots in two Texas locations. As seen in *Figure 3,* the average depth of z_{95} in Amarillo was 117 cm, while the value for Uvalde was only 63 cm. A further discussion of the agronomic significance of these data is out of the scope of this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35453552

method paper, but we do see clearly that the shallow rooting depths in Uvalde are associated with the heavy clay soil prone to compaction, while the soils in Amarillo are of clay loam type that promote deep root growth, especially for winter wheat (the dry, windy weather conditions in Amarillo may also be a factor influencing root distribution). Full data of root length density used to generate the results in *Figures 2* and *3,* as well as other related results, are collected in the *Appendix*. Finally, the computer code (both R script and Minitab macro), testing data and full data set are freely available at Zenodo (https://zenodo.org/record/1484655#.W-o6BzFReUk).

Plant root distribution is frequently described by an empirical equation relating the cumulative proportion of roots to soil depth according to $Y = 1 - \beta^D$, where Y is the cumulative proportion of roots (from 0 to 1), D is soil depth (cm) and β is a fitted extinction coefficient (Gale and Grigal, 1987; Jackson et al., 1996). While this equation can also be used to calculate the soil depth at which 95% of roots can be found, the parameter β is defined differently from that in *Equation 5,* in which β is associated with normalized root length density, a quantity that is directly useful for modeling root water uptake (Wu et al., 1999).

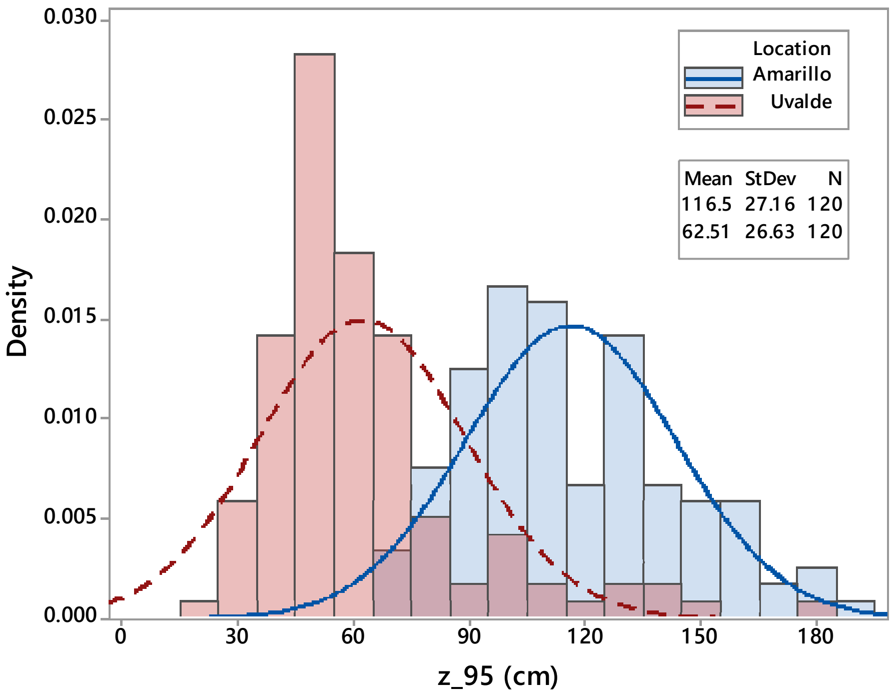

Figure 3. *Histograms of soil depths that contain 95% of total root lengths (z_{95}) for 240 plots of winter wheat growing in Amarillo and Uvalde of Texas, USA. The values of z_{95} are calculated according to Equation 7 of the main text, which uses the estimated values of corresponding to each of the 240 soil core samples. "Density" in the vertical axis indicates probability density of the fitted normal distribution curves*

Implications and potential uses of the computer code

Although root densities of plants generally tend to decrease exponentially from top to lower soil layers, the rate at which this decrease occurs may change under different situations. The computer code documented in this paper can facilitate a rapid extraction of parameters dictating root distribution patterns, with the potential of uncovering root

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35453552

traits associated with different genotypes, environment or management interaction scenarios. With the accumulation of field data of root distribution patterns in regional and global scales, rapid methods, such as the one proposed in this paper, are much needed in order to conduct meta-analysis using large data sets. In particular, the method proposed in this application note can handle variable sample sizes (one sample is defined as one set of roots obtained from one soil core divided into different segments), as well as flexible depth intervals (i.e., variable and/or uneven depth intervals for samples collected from the same ecosystem by different researchers under different circumstances). Finally, as the current method relies on the nonlinear regression procedure, the precision of parameter estimation is heavily dependent on the quality of field data (i.e., with soil cores sampled at fine, instead of coarse, segments).

Acknowledgements. We thank Shane Sieckenius and Dalton Thompson at the Uvalde Research Center and Kirk Jessup at the Amarillo Research Center for field assistance. We also thank Cathy Akritas at Minitab, Inc. for helpful suggestions for the development of the Minitab macro. (Received 30th Nov 2018; accepted 18th Feb 2019)

Abstract. It is known that forest management practices and land use affect soil quality worldwide. This study was conducted to assess the potential effects of stand density on soil quality in Chinese fir plantations. Low- (1,450 trees/ha with 2.36 × 2.36 m spacing), intermediate- (2,460 trees/ha with 1.83 × 1.83 m spacing), and high-density (3,950 trees/ha with 1.44 × 1.44 m spacing) stands in a 10-year-old Chinese fir monoculture plantation were examined, and different soil quality indicators were measured. The results indicated that stand density affected nitrogen (N), phosphorous (P), and magnesium (Mg) content, whereas potassium (K) and calcium (Ca) were not affected. Total N and total P contents were higher in the low-density stands, whereas total Mg was higher in the intermediate-density stands. Available N was higher in the low-density stands, whereas available P was higher in the intermediate-density stands. No significant difference was observed in the contents of available K, total K, and total Ca among all densities. Soil organic matter was significantly higher in the intermediate-density stand than in the high- and low-density stands. Soil bulk density increased from the surface layer to the 40-60 cm soil layer. Soil pH was lowest in the surface layer of soils of all three densities and increased from the 0-20 cm layer to the 20-40 cm layer; however, it decreased from the 20-40 cm layer to the 40-60 cm layer. Soil pH differed significantly between soils of different densities but remained within an optimum range (4.1-4.5) for Chinese fir plantations. Soil moisture content was significantly higher in the high-density stand than the other stands. The observed effects of stand density on soil quality may be useful for policy makers and forest managers to implement improved forest conservation practices for preserving soil quality and stand production.
Keywords: *forest conservation, soil health, sustainable forestry, nutrient status, competition*

Abbreviations: SOM−soil organic matter, SMC−soil moisture content, BD−soil bulk density, DBH−diameter at breast height, TN−total nitrogen, TP−total phosphorus, TK−total potassium, TCa−total calcium, TMg−total magnesium, AN−available nitrogen, AP−available phosphorus, AK−available potassium, EC−soil electrical conductivity, SO−silty oxisol

Introduction

Chinese fir (*Cunninghamia lanceolata* (Lamb) Hook) is an indigenous, typically evergreen, sub-tropical conifer species, and it is a widely cultivated timber specie in China due to its high yield, excellent timber quality, and fast growth. According to the Eighth National Forest Inventory, the planting area of Chinese fir covers more than 11 million ha, which accounts for about 18.2% of all forest plantations in China, and for 6% of the global forest plantation area (State Forestry Administration, 2014). The yield of Chinese fir plantations has declined continuously over the past years (Yang et al., 2005a), and standing wood volumes in the second and third rotations were 30% and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35533566

47% less those in the first rotation, respectively (Bi et al., 2007). Serious concerns have been raised regarding the decrease in yield and the long-term decline in the productivity of Chinese fir (Ma et al., 2007; Zhao et al., 2013; Zhou et al., 2015). In other countries such as Brazil, deforestation rates are either decreasing or stabilizing; however, in China, Malaysia, and Indonesia, deforestation rates are increasing due to the increasing demand for wood-derived products (Margono et al., 2014; Abood et al., 2015).

In forest research, soil quality monitoring has been recognized as a primary aspect for sustainable management. Soil quality can vary due to management and land use practices, which is strongly correlated with physio-chemical, bio-chemical, and biological soil properties (Dudley et al., 2014). Land over-use and intensive cultivation resulted in millions of ha of degraded land, and soil erosion has led to the loss of topsoil and exposure of soils with low nutrient content (Liu and Zhao, 1993; Wei et al., 2006; Zhou et al., 2006). For commercial purposes such as timber production, deforestation continues to be carried out globally on a large scale, leading to significant decreases in soil quality and ecosystem productivity, and Chinese fir plantations are no exception (Wang et al., 2014).

In Chinese fir plantations, surface soil hydrolysable nitrogen (N) and available phosphorous (P) declined under continuous cropping (Horner et al., 2010). Various studies demonstrated a reduction in soil nutrient availability, microbiome structure, microbial enzyme activity (Yang et al., 2010; Vitali et al., 2016; Wang et al., 2017; Zhang et al., 2017b), N stocks, and soil organic carbon after conversion of native forests to plantations (Chen et al., 2013; Marin-Spiotta and Sharma, 2013; Guan et al., 2015; van Straaten et al., 2015). Therefore, a decline in timber yield and productivity under the current management practices of Chinese fir plantations is likely a response to impoverished soils.

Soil quality indicators have been assessed in previous studies in different regions of China with the main research focus on different provenances or age of the plantations. These studies are useful, however, there is no comprehensive understanding of soil quality in Chinese fir stands of different planting densities. The current study was conducted to fill this gap by studying different soil quality indicators in Chinese fir monoculture plantations of the same age (ten years) but with different stand densities. The soil quality parameters total soil nutrient and available nutrient content, soil organic matter content (SOM), soil pH, soil bulk density (BD), and soil moisture content (SMC) were analyzed at low-, intermediate- and high-density stands. We hypothesized (1) that due to competition by higher under-story vegetation and higher number of trees in low- and high-density stands respectively, total and available nutrient content should be higher in intermediate-density stands; (2) that stand density should have no effect on soil pH and electrical conductivity (EC), while SOM and SMC should be higher in high-density stands than in low- and intermediate-density stands due to maximum shade and less sun light availability.

Materials and methods

Study site

The Xinkou Experimental Forest Farm was established in 2007 as Chinese fir monoculture plantations, in Sanming City, Fujian Province, China (*Fig. 1*). The study site was located at 26°10′ N and 117°27′ E. Soils were acidic and the climate of the region was a typical mid-subtropical monsoon climate (Zhou et al., 2015), with mean

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35533566

annual rainfall of 1,612 mm and a mean annual temperature of 19 °C, according to an on-site meteorological station. The average monthly temperature and precipitation is shown in *Table 1*. Before the plantation was established, the area was cut clear, the debris was piled and burned, and complete tillage was carried out. After this, the surface biomass was burned before establishing stands, and one-year-old Chinese fir seedlings were planted. Three plantation stands with different densities were selected and categorized as low-, intermediate-, or high-density stands. The understory vegetation in the selected Chinese fir stands were *Maesa japonica*, *Woodwardia japonica*, *Callicarpa kochiana*, *Selaginella moellendorffii*, *Ilex pubescens*, and *Alpinia japonica.* Further details on the plantation stands are shown in *Table 2*.

Soil sampling

Soil was sampled in the second week of November 2017. Four plots of 20 × 20 m were established in each stand, and in each plot, four pits were dug diagonally. A soil corer was used to obtain soil samples from 0-20, 20-40, and 40-60 cm depths from each pit. After collection, the soil samples from the four sampling pits were mixed to produce one sample for each soil layer and measure pH. Eight composite samples per density from a 0-60 cm depth were prepared to measure the total and available nutrient content, SOM, and SMC. All samples were sealed in clean, air-tight polythene bags. Three soil samples were collected from each stand to determine soil BD at 0-20, 20-40, and 40-60 cm depths using 200 cm^3 volumetric rings.

Figure 1. *Location of the study area, Xinkou Experimental Forest Farm, in Sanming City, Fujian province, China*

Sample preparation

All samples were transferred to a laboratory for further analyses. Debris and roots were removed carefully by hand. The soil samples were air-dried at room temperature and then crushed and passed through sieves of 2 mm and 0.15 mm mesh size for subsequent analyses. To determine soil BD, the samples were weighed and then dried to constant weight before re-weighing.

Laboratory analyses

All measurements were conducted in the key laboratory of soil and water conservation, College of Forestry, Fujian Agriculture and Forestry University, China. The respective analysis methods are shown in *Table 3*.

Table 3. *Methods and equipment used for soil quality analyses*

Analysis	Method/Equipment
pH	Potentiometric method (1:2.5 soil:water)
Electrical conductivity (EC)	Conductivity meter
Bulk density (BD)	Core method of the Nanjing Institute of Soil Science (1978)

DOI: http://dx.doi.org/10.15666/aeer/1702_35533566

Statistical analyses

All measurements are reported as mean ± standard error. A one-way analysis of variance was used to determine correlations between soil quality indicators and stand densities using the SPSS software (SPSS 13.0, SPSS Inc., IL, USA). Means of variables that showed significant differences were compared using Tukey's test at a 5% level of significance. Origin 9.1 and ArcGis software were used to produce graphs and figures.

Results

Variation in total soil nutrient contents

A significant difference in total N and P contents between stands was observed at $P < 0.05$. Total N content was 0.99 ± 0.2 g/kg, 0.74 ± 0.1 g/kg, and 0.92 ± 0.08 g/kg, and total P content was 0.59 ± 0.03 g/kg, 0.48 ± 0.1 g/kg, and 0.59 ± 0.2 g/kg in low-, intermediate- and high-density stands, respectively. Both total N and total P contents were highest in the low-density stand and lowest in the intermediate-density stand.

Total Mg contents were highest in intermediate-density stand and lowest in the low-density stand. No significant differences between stand densities were found in total K and Ca contents. Total K contents were 22.5 ± 7.5 g/kg, 21.2 ± 8.2 g/kg, and 21.8 ± 2.5 g/kg and total Mg contents were 7.41 ± 3.9 g/kg, 8.51 ± 3.7 g/kg, and 7.91 ± 0.5 g/kg in low-, intermediate-, and high-density stands, respectively. Total Ca contents were 2.23 ± 0.4 g/kg, 2.25 ± 1.09 g/kg, and 2.14 ± 0.9 g/kg in low-, intermediate-, and high-density stands, respectively (*Fig. 2*).

Variability in available soil nutrient contents

Available N and available P were significantly different between soils of different stand densities, whereas available K contents did not differ significantly. Available N contents in soils of low-, intermediate- and high-density stands were 67.69 ± 2.2 mg/kg, 59.04 ± 3.0 mg/kg, and 54.07 ± 1.9 mg/kg, respectively, and available P contents were 3.92 ± 0.2 mg/kg, 5.16 ± 0.4 mg/kg, and 4.79 ± 0.5 mg/kg, respectively. Available K contents in soils of low-, intermediate- and high-density stands were 87.23 ± 2.1 mg/kg, 81.44 ± 3.9 mg/kg, and 87.30 ± 5.4 mg/kg, respectively.

Available N was highest in the low-density stand and lowest in high-density stand, whereas available P was highest in the intermediate-density stand lowest in the low-density stand. Available K did not differ significantly between the low- and high-density stand, both of which differed significantly from the intermediate-density stand (*Fig. 3*).

Soil pH, BD, SOM, EC, and SMC

Modest variations in the pH values were observed between stands in each soil layer (*Fig. 4a*). Soil pH in the 0-20 cm soil layer was 4.21 ± 0.1, 4.28 ± 0.04, and 4.27 ± 0.2 in the low-, intermediate-, and high-density stands, respectively. The soil pH values in the 20-40 cm soil layer were 4.27 ± 0.03, 4.37 ± 0.02, and 4.29 ± 0.1, respectively. In the 40-60 cm layer, the pH values were 4.15 ± 0.04, 4.28 ± 0.02, 4.27 ± 0.1 in the low-, intermediate-, and high-density stands, respectively. The soil pH values in the 0-20 cm layer was lower in intermediate- and high-density stands compared to the 20-40 cm and 40-60 cm layers (*Fig. 4a*). Soil pH was higher in the 20-40 cm layer and lower in the

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 17(2):3553-3566.

DOI: http://dx.doi.org/10.15666/aeer/1702_35533566

40-60 cm layer. There was no consistent decline from the 0-20 and 40-60 cm layers in the intermediate- and high-density stands, however, these layers differed significantly different in the low-density stand.

Soil BD generally increased with increasing stand density, which was consistent in the 0-20 cm, 20-40 cm, and 40-60 cm soil layers (*Fig. 4b*). In the surface layer, soil BD was 1.06 ± 0.1 g/m^3, 1.24 ± 0.04 g/m^3, and 1.36 ± 0.2 g/m^3, and in the 20-40 cm layer soil BD was 1.19 ± 0.2 g/m^3, 1.24 ± 0.1 g/m^3 and 1.34 ± 0.3 g/m^3 in low-, intermediate-, and high-density, respectively. Furthermore, in the 40-60 cm layer, soil BD was 1.04 ± 0.1 g/m^3, 1.15 ± 0.3 g/m^3, and 1.29 ± 0.1 g/m^3 in the low-, intermediate-, and high-density stand, respectively. In the surface layer, soil BD differed significantly between stands and increased from the low- to the high-density stand. Soil BD in the 20-40 cm and 40-60 cm layers was higher in the high-density stand and lowest in low-density stand (*Fig. 4b*).

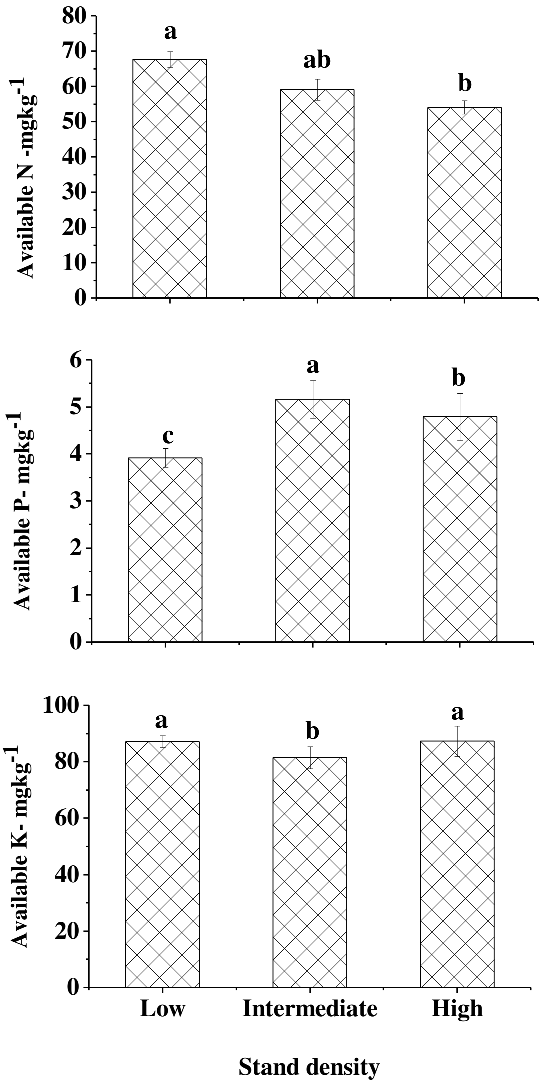

Figure 3. *Available N, available P, and available K at low-, intermediate-, and high-density stands (N = 24). Columns indicate mean ± SE, different letters indicate significant differences at P < 0.05*

At a 0-60 cm soil depth, the soil pH was highest in the intermediate-density stand and lowest in the low-density stand. In both the intermediate- and the high-density stands the soil pH values were significantly different from the low-density stand. Soil pH values were 4.21 ± 0.04, 4.31 ± 0.03, and 4.27 ± 0.03 in the low-, medium- and high-density stands, respectively. Soil BD was highest in the intermediate-density stand and lowest in the high-density stand. Soil BD was 1.22 ± 0.07, 1.28 ± 0.01, and 1.16 ± 0.09 in low-, medium-, and high-density stands, respectively, and differed significantly between stands (*Table 4*).

No significant difference in soil EC was observed among the stands. SOM was higher in the intermediate-density stand and lower in low-density stand; the SOM values were 31.90 ± 1.34 g/kg, 36.56 ± 1.61 g/kg, and 35.47 ± 0.8 g/kg in the low-, intermediate-, and high-density stands, respectively. No significant difference was observed between the intermediate- and high-density stands; however, both were significantly different from the low-density stand. SMC was higher (17.2%) in the high-

Discussion

In forest conservation and management, stand density is an important factor influencing the trees' competition for growth space, light, and below-ground resources (nutrients and water) (Farinelli and Lemos, 2012; Fan et al., 2014; Sitienei et al., 2016). The soil quality indicators used in the current study were successfully used in previous studies on different forest ecosystems (Kay and Grant, 1996; Wei et al., 2009; Bautista-Cruz et al., 2012; Zhijun et al., 2018), suggesting that these parameters can be used for effective soil quality evaluation.

Watt et al. (2005, 2008) identified total P as important soil quality indicator due to its pivotal role in biochemical reactions and in the nutrient cycling of plantation systems (Reganold and Palmer, 1995; Turrión et al., 2007). In the present study, stand density had a significant effect on total N, available N, total P, available P, and total Mg but had no significant effect on total Ca, total K, and available K. In these plantations of ten years of age, both total N and total P were higher in the low-density stand and lower in the intermediate-density stand. Available N content was higher in the low-density stand and lower in the high-density stand, whereas available P content was higher in the intermediate-density stand and lower in the low-density stand. Our results contradicted those of Fang et al. (2017) who found that stand density had no significant effect on total soil N and on C:N ratio. Cancellier et al. (2011) reported that varying planting density influenced the soil chemical properties, and in low planting density, available P and exchangeable Mg, N, and Ca concentrations were significantly higher than at other planting densities, but little difference was observed in soil organic matter content. Furthermore, our results support the assumption that total P is an important indicator of soil quality for conifer plantations (Yang et al., 2004; Ma et al., 2007; Ross et al., 2009).

SOM acts as a storage reservoir for soil nutrients and is an important parameter for assessing sustainable forest management (Haynes and Beare, 1996; Tanaka et al., 2005). Availability of C and N in soil is crucial regarding SOM and abundance of the microbial biomass (Xing et al., 2010; Zhang et al., 2017a). According to our results, SOM was affected by stand density and was significantly higher in the intermediate-density stand than in the other stands. Moreover, previous studies showed that in Chinese fir plantations SOM increased due to a large quantity of debris input following artificial thinning (Lin et al., 2001; Ma et al., 2014). Besides stand population density, continuous rotations can also have a significant impact on soil fertility (Black, 2013). Huang et al. (2004) stated that in Chinese fir plantations SOM decreased significantly with continuous cultivation (by 10% and 15% in second and third rotation, respectively). Soil enzyme activity and microbial diversity decreased with successive rotations (Chen and Wang, 2003; Liu et al., 2010). According to a different study, continuous planting does not necessarily affect soil degradation, SOM, total P, total K, and available N content; it was therefore hypothesized that sustainability and soil fertility could be consolidated under a continuous cropping regime if plantation stand density was optimized (Wei et al., 2012). In contrast to our results, Wright (1992) reported that plant density has no substantial effect on soil fertility. Taken together, the relationship of plant density and soil fertility seems not to be entirely consistent.

Soil pH is an important indicator of soil quality, influencing plant nutrient availability and soil chemical reactions (Schoenholtz et al., 2000; Cheng et al., 2016). Previous studies have emphasized the importance of pH as a soil quality indicator for assessing different land use and forest conservation practices (Doran and Parkin, 1994; Bautista-Cruz et al., 2012; Yu et al., 2017). Soil pH was lowest in the surface layer of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35533566

soils of all three densities and increased from the 0-20 cm layer to the 20-40 cm layer; however, it decreased from the 20-40 cm to 40-60 cm layer. No significant difference in pH was observed between intermediate-density and high-density stands, both of which differed significantly from the low-density stand; however, the pH values generally remained within the optimum range for Chinese fir plantations (Zhou, 1985). Soil BD increased from the surface to the 40-60 cm soil layer, and significant differences between the stands were observed in each layer. Our results differed from those of Fang et al. (2017) who found that stand density had no significant effect on soil pH and BD.

The understanding of stand density and soil heath under continuous cropping conditions have become important for understanding forest productivity, plant population dynamics, and land use for sustainable production (de Bello et al., 2010; Van der Putten et al., 2013). Nutrients are typically removed from growing sites due to stem harvesting and clear cutting (Chen et al., 2013). Yang et al. (2005b) found that nutrient removal due to clear-cutting was higher than that due to pre-burning; furthermore, the total N and organic C contents of topsoil were reduced by 19% and 17%, respectively. Therefore, besides fertilization, plant residues should be buried on site to replenish the soil nutrient contents. A lack of sufficient soil remediation may lead to a reduction in soil nutrient availability, which may, in turn, limit harvesting potential to only a few rotations (Zhou et al., 2016).

Conclusions

Assessing the effect of stand density may help maintain and enhance sustainable crop production and soil health. Our results indicated that stand density had a significant impact on total and available N and P but not on total and available K. Moreover, total Ca was not affected by stand density. Total P may be a useful indicator for assessing soil quality in Chinese fir plantations. A significant difference in soil pH between stand densities was observed; however, soil pH was within the optimum range for Chinese fir plantations. Soil BD was higher in the intermediate-density stand, and SMC was higher in the high-density stand; SOM was higher in the intermediate-density stand and lower in the low-density stand. No significant difference in the SOM was found between intermediate- and high-density stands, both of which were significantly different from the low-density stand. Soil nutrients typically decline due to clear cutting; therefore, the residues should be buried on site to increase soil fertility. A long-term strategy for maintaining and improving yield and sustainable land use requires that policy makers and managers have access to information on the quantitative relationship between stand density and soil quality. To preserve soil quality and ensure high timber production, variations in soil quality parameters, which are affected by stand density, may help policy makers develop better management practices. Moreover, the influence of aspects, such as enzymatic activity, biological variables and microbiological communities, on soil functioning should also be investigated.

REDUCTION OF GLYCOALKALOIDS IN POTATO UNDER THE INFLUENCE OF BIOSTIMULATORS

MYSTKOWSKA, I.

State School of Higher Education, Sidorska 95/97, 21-500 Biała Podlaska, Poland
(e-mail: imystkowska@op.pl)

(Received 30th Nov 2018; accepted 14th Feb 2019)

Abstract. The aim of the conducted research was to determine the effect of biostimulators on the content of glycoalkaloids in leaves and tubers of three edible potato varieties. The experiment was established in a split-plot system in three replications. The examined factors were: I – three varieties of edible potato: Honorata, Jelly, Tajfun, and II – five types of using biostimulators: biostimulator BrunatneBio Złoto Cytokinin®, GreenOk®, Kelpak SL®, Titanit®, control variant. In the biostimulators group there were products containing functional elements, eg titanium, products based on algae extracts, and products containing amino acids. The lowest concentration of glycoalkaloids in leaves and tubers of edible potato was found in the Jelly variety –251 mg·kg^{-1} on average in leaves, and – 80.5 mg·kg^{-1} in tubers, while the largest in the Tajfun variety – on average in leaves 370 mg·kg^{-1}, in tubers 110 mg·kg^{-1}. Under the influence of all bioregulators, there was a significant reduction in the content of harmful glycosides as compared to the control variant. The lowest concentration was recorded under the influence of the BrunatneBio Złoto biostimulator – on average in the leaves 293 mg·kg^{-1}, in tubers 91 mg·kg^{-1}.
Keywords: *Solanum tuberosum L., glycosides, BrunatneBio Złoto Cytokinin®, GreenOk®, Kelpak SL®, Titanit®*

Introduction

Glycoalkaloids (TGA - total glycoalkaloids) are toxic steroid glycosides naturally occurring in a potato plant (*Solanum tuberosum*) (Friedman, 2006). In leaves, stems, flowers and sprouts, the content of these compounds is several times higher than in tubers. The maximum content of glycoalkaloids, regardless of the variety, is up to 200 mg·kg^{-1} of fresh tuber weight (Mazurczyk and Lis, 2000; Barceloux, 2008). In the studies of many authors (Mazurczyk and Lis, 2000; Percival and Dixon, 1997; Lachman et al., 2001), the total content of glycoalkaloids (cTGA; content of total glycoalkaloids) in potato tubers usually ranged from 10 to 150 mg·kg^{-1} of fresh weight. Wroniak and Mazurczyk (2006), on the basis of many years of research between 1988–2005, including studying 145 varieties showed that fluctuations in the content of glycoalkaloids constituted from 3 to 350 mg/kg of fresh tuber mass. TGA accumulation in tubers above 100 mg·kg^{-1}of fresh mass causes significant deterioration if taste (Mazurczyk and Lis, 2000), reducing their nutritional value and may also adversely affect human health. Consumption of potatoes with excessive content of glycoalkaloids may be toxic, damaging the nervous system and cause gastrointestinal disorders (Friedman and Dao, 1992; Percival et al., 1996). According to Grenda (2003), Pusz and Pląskowska (2008), Von Bennewitz Alvarez et al. (2008), Matysiak et al. (2011) and Bulgari et al. (2015) biostimulators used in the cultivation of plants are a natural method of better utilization of plant growth conditions (temperature, air and substance humidity, amount and intensity of light) and nutrients, which in turn contributes to the increase in the quantity and quality of the crop.

Our hypothesis was that the use of biostimulators reduce the concentration of glycoacaloids in potatoes. Here we present the impact of the types of biostimulators on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35673574

the content of anti-nutritional compounds called glycoalkaloids in leaves and tubers of three edible potato varieties.

Materials and methods

The experimental site

Field research was carried out from 2015 to 2017 in an individual farm in Międzyrzec Podlaski (51°59' N i 22°47' E), Biała Podlaska county, Poland (*Figure 1*).

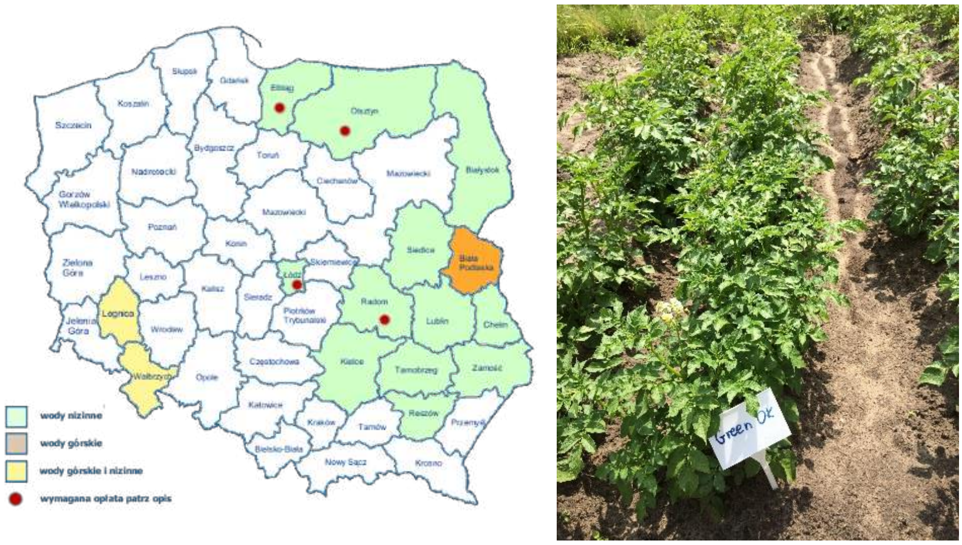

***Figure 1.** Location of the experiment*

The experiment was established in three replications using the split-plot method, on the soil included in the very good rye complex, of the IV a soil class. In individual years of research, soils differed in the content of organic matter and available macro-elements. In 2015 and 2016, the soil was characterized by slightly acidic reaction, and in the last year of research, alkaline. The content of organic matter ranged from 15.0 to 18.7 $g \cdot kg^{-1}$. The content of available phosphorus (P) was from high to very high, potassium (K) from medium to very high, and magnesium (Mg) was high. The first factor were three moderately early varieties of edible potato: Honorata, Jelly and Tajfun, and the second one, four types of biostimulators used in three dates (beginning of flowering, fully flowering and after flowering of plants):

- Control variant – without the use of biostimulators spraying with distilled water.
- Biostimulator BrunatneBio Złoto (active substances – plant hormones: auxin – 0.06 $mg \cdot l^{-1}$ and cytokinin - 12 $mg \cdot l^{-1}$) at a dose of 0.20 $l \cdot ha^{-1}$.
- Biostimulator GreenOk® (active substance – humus substances 20 $g \cdot l^{-1}$) at a dose of 0.20 $l \cdot ha^{-1}$.
- Biostimulator Kelpak®SL (active substance - *Ecklonia maxima* algae extract), containing plant hormones: auxin - 11 $mg \cdot l^{-1}$ and cytokinin – 0.031 $mg \cdot l^{-1}$, at a dose of 0.20 $l \cdot ha^{-1}$.
- Biostimulator Tytanit® (active substance – titanium) at a dose of 0.20 $l \cdot ha^{-1}$.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35673574

The forecrop for potato in particular years of research was winter wheat. After harvesting the forecrop, a team of post-harvest crops was made. In autumn, each year preceding planting, organic fertilization in the form of manure in the amount of 25.0 $t \cdot ha^{-1}$ and mineral fertilization with phosphorus-potassium in the amount of P – 44.0 (100 $P_2O_5 \cdot 0.44$) $kg \cdot ha^{-1}$ (lubofos for potatoes 7%) and K – 124.5 (150 $K_2O \cdot 0.83$) $kg \cdot ha^{-1}$ (lubofos for potatoes 25%) was applied. These fertilizers were plowed pre-season plowing. Nitrogen fertilizers were applied in the spring in an amount of N 100 kg/ha (nitro-chalk 27%) and mixed with the soil using a cultivator. Potatoes were planted manually under the marker at a spacing of 67.5 x 37 cm, in the third decade of April (2015, 2016, 2017). Each plot with an area of 15 m^2 accounted of five ridges. Cultivation and care treatments were carried out in accordance with the requirements of correct. During the growing season, the potato plantation was protected with the following incidences: Actara 25 WG (thiametoksam) at the rate of 0.08 $kg \cdot ha^{-1}$ and Caliypso 480 SC (thiacloprid) at the rate of 0.1 $l \cdot ha^{-1}$, and fungicides: Copper Max New 50 WP at the rate of 2.0 $kg \cdot ha^{-1}$ and Dithane Neo Tec 75 WG the rate of 2.0 $kg \cdot ha^{-1}$. Samples of potato leaves (10 leaves from central part of a stalk) for chemical analyses were taken from each treatment at the flowering stage in July (after chemical treatments). Samples of potato tubers (50 tubers) were taken from each of the plots during harvest and stored at 10-12°C, for 8-10 days. Chemical analyses were performed using fresh material from 10 representative tubers in three replications. The content of glycoalkaloids in leaves and tubers of potatoes was determined by the Bergers colorimetric method (Bergers, 1980). Fresh potatoes were homogenized; then, 150 ml of ethanol were added to a 50 g sample and extraction in a water bath was performed at 90°C. , the filtered extract was evaporated at 60°C using a rotary evaporator to the volume of 5 ml. After addition of 50 ml of 10% acetic acid and centrifuging, the liquid part was poured into a flask, the sediment was poured to the supernatant (solution above the sediment) and 4 ml of ammonia were added (NH_3) to adjust to pH = 10 The flask was heated in a water bath (70°C) for 20 min, then cooled at 4°C for 3 h and centrifuged. The sediment was dissolved in 5 ml 7% phosphoric acid ($H_3P\ O_4$). Next, 0.2 ml of the solution were mixed with 2 ml of 85% phosphoric acid with paraformaldehyde (30 $mg \cdot l^{-1}$) and mixed again. After 40 min, absorption was recorded at the wavelength of 600 nm (solution colour changes to blue and then gets lighter). The amount of potato total glycoalkaloids was calculated based on the L-solanine standard curve. The results of the analyses are given as mg per 1 kg of fresh matter.

Table 1. *Weather conditions during of potato vegetation [Zawady Meteorological Station, (52°03'N and 22°33'E), Poland]*

Months	Air temperature (°C)				Rainfall (mm)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35673574

Meteorological conditions

In the years of research, varied weather conditions prevailed (*Table 1*). The growing season of 2015 proved to have an average of air temperature of 15.2°C, higher by 0.2°C than the long-term mean and precipitation of 295.1 mm. The highest average air temperature was recorded in 2016 and it amounted to 15.8°C, it was higher than the long-term average by 0.8°C, while this year was characterized by the lowest precipitation – 200.9 mm, lower by 134.5 mm from the long-term sum. The highest number of rainfall was recorded in the growing season 2017–325.4 mm and the lowest average air temperature –14.6°C.

Statistical analysis

Results of the study were analysed by ANOVA. Significance of sources of variation was checked with the Fisher-Snedecor test and the significance of differences between means was tested using the multiple comparison Tukey's test at the significance level of P = 0.05. Statistical calculations were performed in Excel using the authors' own algorithm based on the split-plot mathematical model.

Results and discussion

The content of glycoalkaloids in potato tubers depending on the types of biostimulators used (*Table 2*). Statistical evaluations showed a significant effect of cultivars on the content of glycoalkaloids in potato tubers. The TGA content was the highest in the Tajfun variety, an average of 109.7 mg·kg^{-1}, and the lowest in the Jelly variety, an average of 80.5 mg·kg^{-1}. The results are similar to the results presented by Eltayeb et al. (2003), Hamouz et al. (2014) and Valcarcel et al. (2014), who stated that the genotype had a dominant effect on the content of glycoalkaloids in potato tubers. The biostimulators used in the experiment reduced the content of glycoalkaloids in tubers compared to the control. The lowest TGA concentration was noted in tubers from variants sprayed with the BrunatneBio Złoto biostimulator (variant 5), an average of 91.3 mg·kg^{-1}. In the studies by Zarzecka et al. (2015), there was an increase in glycoalkaloids after application with herbicide and biostimulator. While Hamouz et al. (2004; 2005) and Wierzbicka (2014) observed a trend towards increased TGA accumulation in edible potato tubers.

Table 2. *Total glycoalkaloid content in potato tubers mg·kg^{-1} fresh matter*

Types of biostimulators (variants)	Cultivars			Years			Mean
	Honorata	Jelly	Tajfun	2015	2016	2017	
1. Control variant	85.5a	81.5a	110.3a	92.6a	91.2a	93.5b	92.4a
2. Kelpak SL	84.8b	80.5b	109.8b	91.8b	90.4b	93.3b	91.8b
3. Tytanit	84.9b	80.7b	109.7b	91.6bc	90.3bc	93.5b	91.7b
4. GreenOk	84.9b	80.2c	109.4c	91.3c	90.0c	93.5b	91.5c
5. BrunatneBio Złoto	84.8b	79.8d	109.3c	90.7d	89.4d	93.9a	91.3d

Explanation: cultivars – a; variants – b; years – c

There are many changes in the literature confirming the growth of TGA in tubers during the growing season due to stress conditions such as too low or too high

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35673574

temperature, prolonged cold or heat conditions, lack of water or its excess, and strong sunlight (Sinden et al., 1984; Bejarano et al., 2000; Hamouz et al., 2014). The cooperation of years and used biostimulators has been proved, which indicates a different effect of the biostimulators in changing climatic conditions during the tests (*Table 2*). Under the influence of the BrunatneBio Złoto biostimulator in the growing season 2015-2016, the lowest TGA concentration in tubers was obtained – on average from 90.2 to 91.6 mg·kg^{-1}, while in 2017 under the influence of Kelpak SL biostimulator, the lowest concentration of glycoalkaloids was obtained, on average 93 mg·kg^{-1}. Weather conditions during the study years differentiated the level of glycoalkaloids in potato tubers. The least glycoalkaloids were found in 2016 with the highest average air temperature of 15.8°C and were higher than the long-term average of 0.8°C, this year characterized by the lowest precipitation – 200.9 mm, lower by 134.5 mm from the multiannual sum. The interaction of years with varieties confirmed the different accumulation of TGA in the years of research. Most TGA was found in three studied varieties in 2017, and the least in 2016 (*Table 4*). Similar results were described by Morris and Petermann (1985).

The content of glycoalkaloids in potato leaves depending on the types of biostimulators used (*Table 3*). The lowest concentration of glycoalkaloids in potato leaves was found in the Jelly variety – an average of 251 mg·kg^{-1} and the largest in the Tajfun variety – an average of 370 mg·kg^{-1}. The content of glycoalkaloids in potato leaves was three times higher than in tubers. Zaczecka et al. (2015) in her studies found that the content was ten times higher in leaves than tubers, while Uppal (1987) and Żołnowski (2001) showed a 40-50 times higher concentrations in leaves compared to potato tubers. Biostimulators used in the experiment reduced the glycoalkaloids content in the potato leaves as compared to the control object. The smallest concentration of these compounds in potato leaves was obtained on plots sprayed with the BrunatneBio Złoto biostimulator (average of 293.5 mg·kg^{-1}). Other authors (Gugała et al., 2016) in relation to potato, using herbicides in combination with biostimulators (Harrier 295 ZC 2.0 l·ha^{-1} + Kelpak SL 2.0 l·ha^{-1} and Sencor 70WG 1.0 kg·ha^{-1} + Asahi SL 1.0 l·ha^{-1}) received an increased concentration of glycoalkaloids in leaves and tubers in relation to the control plot.

Table 3. *Total glycoalkaloid contents in potato leaves mg·kg^{-1} fresh matter*

Explanation: cultivars – a; variants – b; years – c

Statistical evaluations showed the cooperation of varieties with the types of biostimulators used (*Table 2*). As a result of the use of biostimulators in the tested varieties, a significant reduction in the content of glycoalkaloids was observed. Regardless of the biostimulators used, the Jelly variety accumulated less of these

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35673574

compounds than the Honorata and Tajfun varieties. The cooperation of years and biostimulators used has been proven, which indicates different effects of the biostimulator in changing climatic conditions during the tests (*Table 2*). Under the influence of the BrunatneBio Złoto biostimulator in all growing seasons, the smallest TGA concentration was obtained – on average from 291 to 298.2 $mg \cdot kg^{-1}$. Weather conditions in the study years differentiated the level of glycoalkaloids in potato leaves. The least glycoalkaloids were found in 2015, while the most of this component was accumulated by tubers in 2017, where the highest rainfall was recorded –325.4 mm and the lowest average air temperature –14.6°C (*Table 4*).

Table 4. *Content of glycoalkaloids in fresh mass of edible potato tubers and leaves depending on the cultivars and years of conduct of tests (mg kg^{-1})*

Explanation: cultivars – a; variants – b; years – c

In the present study, an interaction was observed between the varieties studied. The content of glycoalkaloids in potato leaves and tubers has a significant impact on the genetic characteristics of the variety, and weather conditions during the growing season. The use of four biostimulators contributed to the reduction in TGA in leaves and tubers of edible potato.

Summarizing, three varieties of edible potato grown in the study differed in terms of glycoalkaloid content in leaves and tubers. The lowest concentration of glycoalkaloids was found in the Jelly variety. Biostimulant BrunatneBio Gold reduced the content of glycoalkaloids in leaves and tubers of edible potato compared to the control. The weather conditions during the growing season of the potato crop can largely affect the content of glycoalkaloids in leaves and tubers of potato. The lowest content of glycoalkaloids in the leaves was found in the year 2015, and in tubers in the year 2016.

Conclusions

The use of four biostimulators contributed to the reduction in TGA in leaves and tubers of edible potato. Summarizing, three varieties of edible potato grown in the study differed in terms of glycoalkaloid content in leaves and tubers. The lowest concentration of glycoalkaloids was found in the Jelly variety. Biostimulant BrunatneBio Gold reduced the content of glycoalkaloids in leaves and tubers of edible potato compared to the control. The weather conditions during the growing season of the potato crop can largely affect the content of glycoalkaloids in leaves and tubers of potato. The lowest content of glycoalkaloids in the leaves was found in the year 2015, and in tubers in the year 2016. In the experiment discussed in this paper, TGA levels did not exceed 200 $mg \cdot kg^{-1}$ fresh weight of tubers. The three cultivars examined are thus safe for human consumption.

Abstract. The importance of chromophoric dissolved organic matter (CDOM) and water parameters for the structure and function of rivers and lake ecosystems has led to the development of a way to estimate the amount of CDOM, TP (total phosphorus) and TN (total nitrogen) in rivers and lakes over large geographic areas. Operational Land Imager (OLI) images have been obtained of the North and South Islands of New Zealand for the March 2014 and 2015, with in-situ measurements of bio-optical properties and the water parameters of 18 stations. Satellite images of the date closest to the water sampling were used to statistically correlate the in-situ measurements with various combinations of Landsat 8 bands in order to develop algorithms that best describe those relationships and calculate accurately the aforementioned water quality components. Optimal models were selected based on statistical criteria and indices; finally, the predictive models of CDOM, TP and TN concentrations involving the combination of ultra-blue (B1), blue (B2) and green (B3) OLI bands of Landsat 8 satellite sensor were achieved. As a result of the validation process, CDOM absorption at 420 nm (R = 0.35), TP (R = 0.57) and TN (R = 0.71) concentrations were shown to be the most accurately estimated components, respectively.
Keywords: *CDOM, algorithm, TN (total nitrogen), TP (total phosphorus), water quality*

Introduction

Dissolved organic matter (DOM) is the main structuring constituent of aquatic ecosystems. Imported terrestrial dissolved organic matter constitutes a carbon source for heterotrophic bacteria within the aquatic ecosystems, thereby making them partly independent of the primary production of organic substrates within the aquatic ecosystems (Kutser et al., 2005a). Coloured (chromophoric) dissolved organic matter (CDOM) is the part of DOM which absorbs light. According to Slonecker et al. (2016), “CDOM is the humic-rich, optically active fraction of dissolved organic matter that is present in natural waters from the decomposition of detritus and other organic substances”. They are also known as chromophoric dissolved organic matter, yellow substance and humic colour (Slonecker et al., 2016; Hoge et al., 1995).

The importance of measuring water quality and CDOM has important implications for drinking water, aquatic ecosystems and element transport (Sloneker et al., 2016; Häder et al., 2007). Generally, there is a strong correlation between the concentrations of DOM and CDOM (Tranvik, 1990) in aquatic ecosystems. The absorption of light by CDOM affects the availability of light for the primary producers (Jones, 1998). For instance, CDOM reduces the light availability in the water column and tends to prevent biological activity, such as photosynthesis, thereby controlling growth in phytoplankton populations, which are essential to aquatic food chains (Slonecker et al., 2016; Häder et al., 2007).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35753589

The CDOM efficiently absorbs short wavelength solar radiation, which effects photochemical reactions, and protects aquatic biota from UV-B induced damage, an effect that is perhaps particularly significant in high latitude waters (Pienitz and Vincent, 2000; Kutser et al., 2005b). The importance of DOM and CDOM to the structure and function of the aquatic ecosystems is a procedure that is necessary to estimate their amounts in freshwater over extensive regions would be highly beneficial. CDOM reflectance happens in the ultraviolet-blue part of the electromagnetic spectrum, but has no unique identifying spectral absorbance or reflectance features. CDOM displays a gently decreasing slope from the ultraviolet through the blue regions (*Fig. 1*).

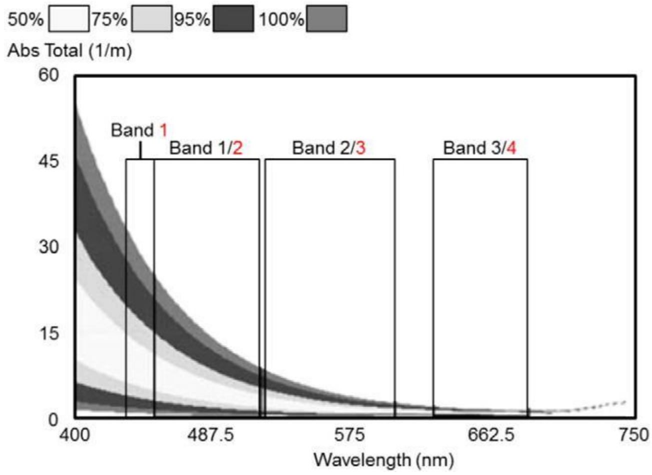

***Figure 1.** The gradually decreasing absorbance of CDOM in the electromagnetic spectrum and the band location of typical multispectral satellite sensors. Dark numbers represent earlier Landsat sensors and red numbers indicate Landsat 8 bands and the improvement of Band 1 relative to the available energy. The shaded intervals represent typical ranges of 500 simulations (Slonecker et al., 2016)*

CDOM is typically derived using absorbance or fluorescence techniques. Spectral absorbance measures how much light at a specific wavelength (typically 254 nm or 440 nm) is absorbed over a range of wavelengths. The main problem in regards to CDOM is that it is neither measured nor reported uniformly. CDOM is sometimes explained as a function of colour at 440 nm (C440) (Brezonik et al., 2005).

The remote assessment of CDOM helps to get a comprehensive view of the distribution and accessibility of DOM in water and to investigate the response of water DOM concentrations to climate change. Optical remote sensing potentially provides the means to make synoptic measurements of the rivers' and lakes' CDOM over large geographic areas. In summary, remote sensing easily solves the considerable problems of CDOM, since in rivers, CDOM is the dominating absorbing composition with a predictable effect on the reflectance spectrum (high absorption of UV, decreasing exponentially with increasing wavelength) (Kutser et al., 2005a).

A new generation of land observation sensors, such as the Advanced Land Imager (ALI) and Operational Land Imager (OLI), have modified spatial, spectral and radiometric resolution (Kutser et al., 2005a; Slonecker et al., 2016). In practice, such measurements have been limited by main three factors:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35753589

- River and lake size is often small with limited width compared to the most aquatic remote sensing satellite sensors.
- High absorption of CDOM associated with shallow rivers or lakes results in low reflectance and therefore requires satellite measurements of high radiometry sensitivity.
- Limitation in finding suitable images, particularly those areas with high cloud coverage.

The absorption by CDOM decreases with increasing wavelength, thus the influence of CDOM on the remotely sensed signal in OLI band 1 (430-450 nm) is stronger than band 2 (450-510 nm). Band 1 on Landsat 8 is a new addition to the Landsat suite of bands and could be potentially important to CDOM research as it is relatively narrow and centred in a part of the spectrum that is sensitive to coastal phenomena (Markogianni et al., 2017). Atmospheric correction of the blue wavelength (band 1) always creates a problem, particularly in the case of high turbidity or strongly absorbing waters with inappropriate reflectance, such as in rivers. As such, these cases' sensitivity of blue sensors is often insufficient, especially in cases where blue wavelengths are close to zero in the case of brown, CDOM-rich rivers or lakes. On the other hand, phytoplankton absorption also influences band 1 more than band 2. Therefore, the ratio band 2/band 3 is more suitable than the band 1/band 3 ratio for CDOM. This is similar to the band 2/band 3 relationship reported by Kutser et al. (2005a) and Slonecker et al. (2016). In addition, the band 2/band 3 relationship on the Landsat 8 OLI sensor shows a potentially important relationship with respect to a_{CDOM} remote sensing.

Kutser et al. (2005a) and Slonecker et al. (2016) mapped CDOM values and Landsat potential respectively for ALI and OLI water pixels utilising a simple power function (*Eq. 1*):

$$a_{\text{CDOM}}(420) = 5.20x^{-2.76} \qquad \text{(Eq.1)}$$

where x is the ratio of ALI bands 2 (565 nm) and 3 (660 nm), and a_{CDOM} (420) is the absorption coefficient of CDOM at 420 nm. According to Kuster et al. (2005a), there was a strong correlation between in-situ CDOM measurements and the ALI band ratio ($R^2 = 0.83$).

According to Proffitt (2010) investigates on the state of New Zealand's freshwater, pollution and water-related issues as the number one environmental issue facing New Zealand. Many rivers show excessive nutrients, reduced visual clarity due to suspended sediments, and pollution by faecal bacteria. Water quality is appreciably worse at several hundred sites in lowland rivers monitored by regional councils and it was showed among 134 lakes monitored, 56 percent are eutrophic or worse.

The monitoring of water quality is the first step toward understanding the characteristics of water pollution and designing effective mitigation strategies; however, basically water quality parameters (WQPs), such as total nitrogen (TN) and total phosphorus (TP), are obtained by routine monitoring methods (colorimetry) of field sampling and laboratory analyses (Zhang et al., 2018; Song et al., 2012). In addition to cost and labour intensiveness, these traditional approaches are not suitable for monitoring a large number of water bodies at a regional or national scale because of spatial heterogeneity and temporal changes of water quality across aquatic ecosystems. This condition is especially true for urban lake and river systems, where numerous point

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35753589

and non-point inputs occur over relatively short distances (Li et al., 2013). With the permanent development of environmental information technology, remote sensing plays an important and effective role in monitoring water quality, because of its large coverage, better efficiency, and lower cost than traditional sampling methods (Liu et al., 2014).

A number of satellite sensors have been applied to the study of surface water quality (Mathews, 2011). Kutser (2012) has recently provided a significant review of remote sensing instruments which can be applied to assess water quality in inland and inshore coastal waters. Although Landsat sensors were not designed for aquatic applications (McCullough et al., 2012), many examples of applications of Landsat images for estimating and/or monitoring inland water quality are founded. Several studies proposed reliable algorithms between Landsat data and water quality parameters, including chlorophyll, phytoplankton concentrations (Brezonik et al., 2005), water quality (Guan et al., 2011), CDOM (Brezonik et al., 2005), blooms of cyanobacteria (Vincent et al., 2004) and total suspended sediments (Zhou et al., 2006).

Few studies have attempted to monitor and model nutrient data, since those data do not have optical properties, and regression models were achieved from statistically insignificant results (Chen and Quan, 2012). Chen and Quan (2012) particularly used Landsat TM imagery to attempt to predict nutrients (nitrogen and phosphorus) concentrations in Tiahu Lake, China with some acceptable results for phosphorus and less successful results for nitrogen. In general, the previous research considerably increases knowledge of water quality, and most of their developed algorithms are commonly based on empirical relationships using classical, simple linear regression models between remotely sensed reflectance values and measurements collected at the same times in the field.

Because CDOM is one of the most important water color parameters and is closely linked to nutrients, some studies have proposed defining the lake trophic state using the nutrient-color paradigm, which includes CDOM absorption (Liu et al., 2014) and this study was one of the first study in this area which has done. Therefore the aims of this study were to explore whether mapping of CDOM is possible for a larger variety of rivers in the case of satellite images collected in variable illumination conditions and the assessment of various water quality parameters (e.g. TP and TN) in the area to develop predictive algorithms for these parameters in order to discuss the potential application of assessing and monitoring the trophic state of the rivers. Finally, developed model and then applied by using operational land imager (OLI)/Landsat-8 images to show the a_{CDOM} (440), TP and TN distributions. Selected optimal algorithms were applied to another Landsat 8 images of different dates with available in-situ CDOM, TP and TN absorption data, in order to validate the results.

Methods

Source of data and dataset reduction

During this study background information and the data were obtained through this web portal: https://hydrowebportal.niwa.co.nz/, and Larned et al. (2015). We had no control over the quality of data provided to us, but most analytical laboratories have quality assurance programmes in place, and are accredited by International Accreditation New Zealand (the national authority for testing laboratories).

In the present study, surface water samples were collected for laboratory analysis. The amount of CDOM is demonstrated by the absorption coefficient at wavelength 440 nm, $a_{CDOM}(440)$, obtained from spectrophotometric measurements of filtered water (pore size 0.45 µm) in a 4 cm cuvette, relative to a reference of distilled water (Davies-Colley and Vant, 1987; Verburg, 2011). Absorption units were converted to absorption coefficients using the following relationship (Bricaud et al., 1981):

$$a(\lambda) = 2.303 * A(\lambda)/l \qquad \text{(Eq.2)}$$

where $a(\lambda)$ = absorption coefficient (m^{-1}), $A(\lambda)$ = absorbance, and l = cell's light path length (m).

The $a_{CDOM}(420)$ values are calculated from the $a_{CDOM}(440)$ using the common formula of Bricaud et al. (1981):

$$a_{CDOM}(\lambda) = aCDOM(440)exp[-S(\lambda - 440)] \qquad \text{(Eq.3)}$$

According to Kirk (1994), *S* varies between 0.01 and 0.02 nm, and even over a wider range according to Kowalczuk (1999). In addition, according to estimations by Davies-Colley and Vant (1987), the slope factor S = 0.0187 nm^{-1} gives the best results for New Zealand freshwater. Based on Kutser et al. (2005a), using the *Equation 2* to process the data for a time period of ten days before and after the OLI image acquisition allowed us to drive $a_{CDOM}(420)$ values from 18 stations (*Table 1; Fig. 2*) in this research.

Figure 2. *Map showing sampling station from the New Zealand*

During present study, satellite images were downloaded from the USGS Hazard Data Distribution System Explorer (http://earthexplorer.usgs.gov) for March 2014 and 2015. Scenes were then atmospherically corrected and processed for CDOM following methods detailed in Kutser et al. (2005a), Griffin et al. (2011) and Slonecker et al. (2016). For this study, and at all stations, the in-situ data were available for nearest dates coinciding with the OLI scenes, therefore making absolute CDOM levels possible to estimate. Unfortunately, relatively limited images were applicable due to the fact that the sky was often cloudy.

Atmospheric correction of satellite measurements is critically important in aquatic remote sensing as a considerable amount (more than 90% in many cases) of radiation detected by a satellite sensor is backscattered from the atmosphere without ever penetrating the water. Therefore, removing atmospheric effects is especially important when using multiple images.

In this study, and to validate the coloured dissolved organic matter estimation algorithm, and based on two months of field data (2015) and nine OLI images, we used three images from the North and South Islands of New Zealand that were available in the OLI data archive. The rivers in these images are included in the National Institute of Water and Atmospheric Research (NIWA) monitoring programs; thus, water colour determinations are included in these programs and are available.

The water colour measurements enabled us to compute a_{CDOM} (420), as it was described in the methods section (*Eq. 3*) for comparison with a remote estimate of a_{CDOM} (420). The estimated values of a_{CDOM} (420) from the OLI image were correlated with the a_{CDOM} (420) values calculated from the water colour monitoring data.

In order to classify the water quality of the areas, the EPA classification system was used (EPA, 2000). Based on this scheme, the classification of water quality in rivers and lakes is according to the TP, TN and trophic index (Trophic State Index-TSI). Based on Zhang et al. (2018), the trophic index TSI is calculated for each classification quality parameter as follows (*Eqs. 4–6*):

$$TSI\ (TP) = 10(9.436 + 1.624\ln TP) \quad (Eq.4)$$

$$TSI\ (TN) = 10(5.453 + 1.694\ln TN) \quad (Eq.5)$$

$$TSI = 0.219TSI(TN) + 0.230TSI(TP) \quad (Eq.6)$$

where TSI (TP) and TSI (TN) were trophic state indexes in relation to TP and TN, respectively; TP and TN were the total phosphorus (mg/L and total nitrogen (mg/L).

Predictive algorithms

Numerous researchs have investigated one bands, band combinations and band ratios to estimate mainly chl-*a* and CDOM absorption and to a lesser extent nutrient concentrations in freshwater bodies (Tebbs, et al., 2013; Brezonic, et al., 2015). Firstly, attempts were made to find combinations, transformations, or logarithmic transformations of Landsat 8 OLI bands which would provide more information about the under study parameters in the rivers than only one bond. Such combinations are: ratios of B2/B3, B2/(B1+B2+B3), B1/(B1+B2). Subsequently, pixel values of each transformed image were retrieved from those regions where the 18 sampling stations are located among all stations (*Table 1; Fig. 2*).

To develop predictive $a_{CDOM\ (440)}$ and nutrients (TN and TP), different regression models and MLR (Multi Liner Regression) relating to in-situ data and reflectance values of the selected bands and band combinations were established. Several regressions resulted in unsuccessful results accompanied by statistically insignificant correlations. Taking into account certain previously mentioned statistical indices, optimal models were recorded for each studied water quality parameter.

Data analysis

In this study, statistical analysis including the mean values as well as linear and non-linear fitting, were performed using Statistical Program for Social Sciences (SPSS) 15.0 software. The data from March 2014 were used to establish the relationships and March 2015 data were used to validate between parameters. Distribution maps of rivers and sampling sites were made using ArcGis 11.2 and other data graphs were made using Excel 10 software. In this study, atmospheric correction of the images was performed using the FLAASH (Fast Line-of-sight Atmospheric Analysis of Spectral Hypercubes) software package in ENVI 5.1.

Results

In this study, it was not possible to use existing data at all stations at exactly the same time as the satellite overpassed. For instance, in both the North and South Islands, field data was gathered from the stations during two weeks, and the satellite overpass took

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35753589

place at the end of the first week. Images acquired during fieldwork, particularly in the South Island, were too cloudy for analysis, and that hindered the way first suitable OLI images were acquired ten days before and after the field data were collected. Since, there was not significant differences between the amounts of CDOM in before and after sampling dates so we assumed that the CDOM concentration did not vary dramatically within the time frame that separated the in-situ measurements from the satellite overpasses. Nevertheless, the optical remote sensing make synoptic measurements of inland water CDOM over large geographic regions. In total, measurement of CDOM should be problem that is easily solved by remote sensing.

In this research, the relationship between the B2/B3 ratio calculated from the atmospherically corrected OLI images and CDOM absorption coefficient at 420 nm measured is shown in *Figure 3*. The logarithmic model showed the strongest relationship ($R^2 = 0.65$) and highly significant ($p = 0.0001$) (*Fig. 3*). From the results of this study, the reflectance modelling results suggest that the B2/B3 ratio is the best for estimating CDOM concentration in rivers as it was suggested by Kutser et al. (2005a) and Slonecker et al. (2016).

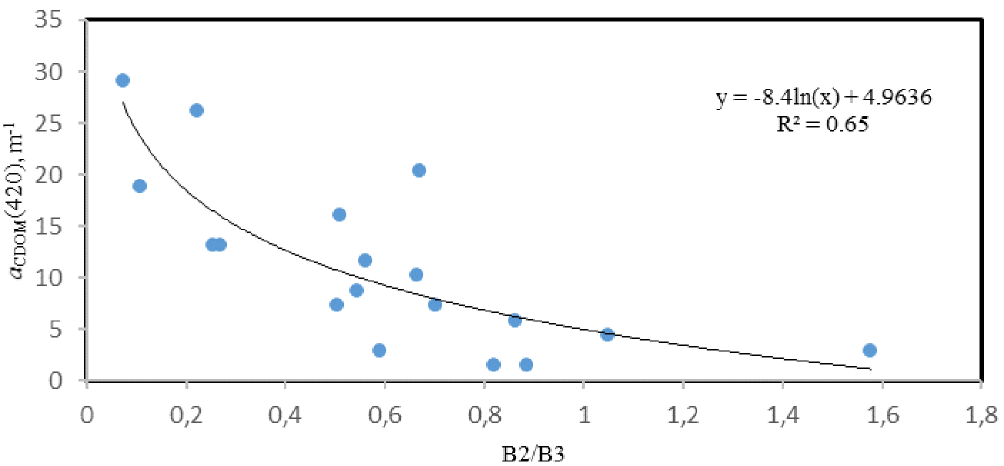

Figure 3. *Correlation between OLI band 2 (B2: 520-600 nm) and band 3 (B3: 630-690 nm) ratio calculated from atmospherically corrected OLI images acquired and CDOM absorption coefficient at 420 nm measured from water samples and the important regression algorithm (logarithmic model)*

During present research, the sampling sites covered a wide range of nutrient compositions and trophic states (*Table 2*). The TN and TP values ranged from 0.019 to 0.719 mg/L and 0.001 to 0.040 mg/L, respectively. The maximum values of TN, TP and TSI were 0.719, 0.040 and 19.064 and showed about 38, 40 and 35 fold greater than the minimum values, respectively. However, the TSI values showed smaller variations from 0.541 to 19.064, revealing oligotrophic rivers, which are according to the standard trophic categories (Jing et al., 2008): TSI < 30 indicates oligotrophic (*Table 3*).

During this study, the multi-liner regression model, including the spatial correlation structure and relating it to Landsat 8, bands 1 (ultra-blue), bands 2 (blue) and 3 (green), was shown to be the most appropriate for forecasting CDOM absorption at 420 nm and total phosphorus built on the logarithmic models. The correlation coefficient is equivalent to 0.81, while the Durbin-Watson value shows independence of residuals to CDOM (*Table 4*).

</table>

***Table 4.** Water quality parameters and best predictive models summary*

Model	R	R^2	Std. error of the estimate	Adjusted R square	Durbin-Watson
$a_{CDOM420}$ = -8.4 Ln[B2/B3] + 4.964	0.81	0.65	5.04	0.63	1.637
TP = -0.01Ln [B2/(B1+B2+B3)] -0.001	0.53	0.29	0.01	0.24	1.393
TN = 0.209 * $[B1/(B1+B2)]^{1.308}$	0.28	0.08	1.04	0.02	2.037

In the present work, the ideal model for calculating the total phosphorus was confirmed to be the one established on the logarithmic model. While the amount of the correlation coefficient is equivalent to 0.53, the Durbin-Watson value of 1.393 for TP indicates independence of the residual value as well. The best estimating model of total nitrogen concentrations involves band 1 (ultra-blue) and 2 (blue), which is the power model, while the correlation coefficient is 0.28.

To investigate the consistency of the final predictive models, regression between Landsat 8-estimates of the a_{CDOM} (420), total phosphorus and total nitrogen in the stations versus corresponding in-situ data from 2014 were determined (*Fig. 4*). Several models (linear, logarithmic, quadratic, cubic, power and exponential) have been utilised to discover the best possible concurrence between the monitored and satellite approximated values with the cubic model showing the highest correlation coefficients for all parameters (*Table 5*). However, the reasonable fit between in-situ and anticipated water quality parameters by each particular MLR showed these models to have adequate and low predictive power, especially the topmost correlation coefficient regarding the a_{CDOM}420 estimation was 0.35 with a standard error of 0.665 m^{-1}. The resulting correlation coefficients of total phosphorus and total nitrogen concentrations were determined to be 0.57 and 0.71 with standard errors of 0.017 and 0.037 mg/l, respectively.

Discussion

Remote sensing offers appropriate data regarding water quality and aquatic systems management. During this study, we demonstrated the applicability probability of Landsat 8 OLI imagery combined with in-situ water parameter concentrations to distinguish applicable algorithms for water quality representation in an oligotrophic water body, New Zealand's rivers. Water specimens from these rivers were evaluated in March 2014 concerning the concentrations of total nitrogen, total phosphorus and CDOM concentration, which then was established as absorption at 440 nm, $a_{CDOM(440)}$, inferred from the absorption spectra.

Multiple linear regressions were conducted among available data, and insignificant statistical correlations characterised the majority of models. Optimal models were selected based on statistical criteria and indices but they presented low coefficients and unsuccessful results. The selected predictive models of TN, TP and CDOM concentrations involved the combination of ultra-blue (B1), blue (B2) and green (B3) OLI bands of Landsat 8 satellite sensor. These results are in accordance with those of Pahlevan et al. (2014) and Markogianni et al. (2017).

Pahlevan et al. (2014) found out that in waters with relatively low CDOM concentrations ($a_{CDOM(440)}$ < 0.5 m^{-1}), the blue and green bands exhibit the highest sensitivity, whereas the red band was found insensitive to the changes in CDOM absorption. In general, it was found that the OLI is, on average, sensitive to changes in CDOM absorption larger than 0.1 m^{-1}. Although actual retrievals can be improved by the use of multiple bands, in our case detected changes to a lesser extent in CDOM absorption are slightly equal to the aforesaid threshold values which could be the main

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35753589

reason for lack of precision assessment results. Furthermore, Pahlevan and Schott (2013) used a physics-based approach to fully examine the potential of OLI in terms of its enhanced features in a water constituent retrieval framework. Based on the results of Pahlavan and Schott (2013), it was concluded that the disparity between the response functions of OLI is more noticeable in turbid waters than in clearer waters when mapping CDOM absorption. Development of reliable methods to retrieve CDOM information from spectral reflectance data is difficult. Indeed, among the major water quality variables measurable by remote sensing (e.g. suspended solids, chlorophyll, Secchi depth), for many reasons, CDOM may be the most difficult to measure accurately in inland waters. CDOM absorbs but does not scatter or reflect light while it has no absorbance peaks, such as those found in plant pigments; instead, light absorption by CDOM follows a simple quasi-exponential decrease with increasing wavelength. There are no wavelength bands in the visible spectrum unlikely associated with CDOM that can be used for measurement purposes. Thus, measurement of low to moderate levels of CDOM in optically complex Case-2 waters is particularly difficult because light scattering by these particles dominates their reflectance spectra (Markogianni et al., 2017).

Predicting the concentration of total nitrogen and phosphorus in inland waters can be a hard task since very few studies have attempted to monitor data with non-optical properties, such as nutrient concentrations. Furthermore, not many previous studies have been able to provide total nitrogen and phosphorus models with statistically significant results or reasonable adjusted R^2 values (Isenstein and Park, 2014). Our research resulted in the total nitrogenous predictive model incorporating ultra-blue, and blue bands yielding a regression coefficient equal to 0.71, regarding the validation process. Similar results, regarding the utilised wavelengths, presented by Dewidar and Khedr (2001) and Isenstein and Park (2014), who detected the strongest correlation among total nitrogen and phosphorus with Landsat TM bands 1 (blue), 2 (green). Meanwhile the latest researchers have predicted total nitrogen concentrations with Landsat TM bands 1 (blue), 2 (green), 3 (red), and 4 (NIR), although all of these results were not very successful ($R^2 = 0.24$).

The outcome of this study initiates new perceptions in limnology over various scales. For instance, it is conceivable to investigate the unpredictability and dynamics of CDOM concentrations in a limited area, such as lakes, rivers and estuaries. This research revealed that the spatial variability of CDOM concentrations within bigger lakes or rivers could be substantial since those wider and deeper sites showed acceptable results by comparing the results of in situ with the satellite images. A single OLI image comprises a wide area and permits research into river and lake CDOM distribution on a regional scale. The results of this study showed that more measurement accuracy was particularly impeded from the very low concentrations which effectively describe rivers and the absence of any value differentiation among the specimen locations. However, some model predictions applied to oligotrophic water bodies are not so exact (McCullough et al., 2012), and the models resulting from this research increase understanding of water quality deterioration.

Conclusion

This paper was intended to provide a framework that would lead to method of mapping CDOM for New Zealand inland waters using satellite images and open a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35753589

discussion about the possibility of developing an algorithm to assess and monitor rivers water quality.

The results of this study showed that extremely low concentrations and inland waters are significant factors that hiders the assessment accuracy which strongly characterize inland waters of any value differentiation among the sampling stations. Although, different models predictions applied to oligotrophic lakes are less accurate and normally these models increase knowledge of their water quality and can be useful indicators of water deterioration.

From the results of this study, it is recommended that future work is still needed to establish the fundamental equations linking the remotely sensed data to the in-situ measurements. The specific research considerations include:

1. More direct considerations between in-situ sensors and Landsat 8 overpasses, especially for lakes and estuaries.
2. More corrections for Landsat 8 surface reflectance product, since there is still a high degree of variability in Landsat 8 reflectance values that could potentially be adjusted by additional spectral and atmospheric corrections.
3. Comparative research of CDOM in lakes, rivers, estuaries and coastal environments are needed to understand significant differences, especially in terms of remote sensing capabilities.

Acknowledgements. Special thanks to NIWA (National Institute of Water and Atmospheric) for providing the data, my Supervisor Dr. Luitgard Schwendenmann in University of Auckland to her guidance during my sabbatical for generous help, particularly in data analysis.

(e-mail: sara.demir@btu.edu.tr; phone: +905553564771)

(Received 4th Dec 2018; accepted 20th Feb 2019)

Abstract. This paper presents the case of Mary Valley's protected catchment, which is located in the northeast Black Sea Region of Turkey, and was declared a national park in 1987. The study area has sensitive ecosystems, with rare and endangered endemic plants. Nevertheless, current unsustainable economic activities, uncontrolled tourism and population migration have adversely affected its sensitive ecological integrity. This research aims to monitor and analyze the landscape dynamics changes of land use-land cover and landscape structure by change detection and landscape metrics in 1987, 1998, 2009 and 2016. The relationship between LULC and habitat changes linked to those of endemic plants were aimed to be determined. The findings indicated that forest areas with the highest loss transformed into grassland, shrubland and bare land areas, while bare land experienced the highest gain. However, forest area has the highest and bare land has the lowest habitat function. Additionally, endemic plant habitats have an inverse relationship with the habitat value of forest and bare land areas and a direct relationship with shrublands. These unsuitable changes can adversely pressure the sensitive landscape dynamics of Mary Valley protected area. Thus, landscape dynamics and their changes should be monitored to protect and manage for the sustainable development of Mary Valley resources.
Keywords: *environmental monitoring, landscape dynamics change, habitat function, landscape metrics, protected area*

Introduction

Landscape is an area where there is action, interaction and various relationships between natural and/or cultural resources (CE, 2000). These effects and relationships inevitably cause a change in landscape dynamics. Since the dawn of time, the change of landscape patterns, landscape sensitivity and landscape dynamics have been generated by natural disasters and unsustainable, unplanned decision making (Antrop, 2000). The idea to analyze landscape changes has been raised for the determination of the complex and significant interactions among natural, cultural and social processes (Esbah et al., 2010; Martinuzzi et al., 2015). Thus, the need for monitoring and analyzing the temporal and spatial changes of natural and cultural areas and providing for their sustainable development have become essential concerns in the last few decades (Lausch and Herzog, 2002).

Protected areas are valuable components for biodiversity, culture and history. Nevertheless, they have been under pressure due to uncontrolled and unmanaged land use and land cover change (LULCC) caused by anthropogenic activities that are mainly influenced by socioeconomic, political and technological factors (Braimoh, 2006; Esbah et al., 2010; Mariota et al., 2013; Scullion et al., 2014). Thus, monitoring and assessment are important for sustainable land management because they can define environmental trends that can be used in the planning of future endeavors in protected areas, solving problems of the landscape, and finally sustainably using resources (Estes et al., 2012; Angonose and Grau, 2014; Tian et al., 2014; Oinam et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35913613

LULCC is a key driver of global landscape change and can describe the relationship between humans and the use of the surrounding land (Fichera et al., 2012; Scullion et al., 2014). LULCC in landscape patterns is related to urban and population growth, negative impacts of anthropogenic uses, socioeconomic, political and technological variables. It increases impervious land use and deforestation and decreases agricultural and grassland areas (Seto et al., 2005; Bozkaya et al., 2015). Effective monitoring and assessment of LULC is a suitable way to assess landscape mechanisms and ecological processes, provide ecological and cultural sustainability, understand sensitivities of landscapes based on erosion and flood risk, biodiversity and habitat potential or loss, soil, water and air quality, predict future change in landscape patterns, mitigate undesirable effects on landscape resources and solve problems of landscape dynamics (Estes et al., 2012; Fichera et al., 2012; Tian et al., 2014; Demir, 2017).

Landscape ecology is focused on characterizing habitat function using landscape metrics at the patch, class and landscape level, i.e. number, size, density, edge and shape of patches (McGarigal and Marks, 1995; Lausch and Herzog, 2002; Seto and Fragkias, 2005). Overall landscape is defined by analyzing the landscape structure to understand its habitat function using landscape metrics (Turner et al., 2001; Malaviya et al., 2010; Mairota et al., 2013; Demir and Demirel, 2018). Therefore, these metrics can describe the distribution of landscape disturbance and explain sustainable landscape development and landscape patterns and dynamics (Neel, 2008; Esbah et al., 2010, Fan et al., 2018). Understanding landscape dynamics is associated with landscape functions and changes (Seto and Fragkias, 2005; Ghosh et al., 2012; Bruton et al., 2016). LULCC integrated with landscape metrics generates useful information for land use researchers, landscape and urban planners, decision and policy makers that can be effectively used for landscape planning and management (Esbah et al., 2009; Malaviya et al., 2010; Fichera et al., 2012). Due to this, monitoring and analyzing LULCC and landscape structure have gained attention internationally in recent years (Lausch and Herzog, 2002; Kara et al., 2013).

Unsustainable land use can damage and reduce biological diversity and cultural-historical resources of protection areas (Martinuzzi et al., 2015). Therefore, they cannot be assessed in isolation, separately from their surroundings (Demir et al., 2016) because ecological processes form an integrated system that is not limited by administrative boundaries. This study monitored and analyzed Altindere Valley National Park and its surrounding Mary Valley catchment, based on ecological boundaries, located in the Maçka District of Trabzon, Turkey. With its protected ecological and cultural resources, Mary Valley has gained national and international tourism potential. Especially the historical Sumela Monastery is visited each year by Orthodox Christians from around the world. It is host to 31 endemic plants species (Salapaş, 2002; Uzun, 2002). Although there are many ecological, cultural and touristic attractions in the park, the human population of the study area diminished by about 25% from 1987 to 2016 due to migration to urban areas (TURKSTAT, 2016). This study monitored and analyzed temporal and spatial LULCC and habitat function in the protected Mary Valley. In this context, this study's objectives are to determine temporal habitat value based on landscape structure analysis using landscape metrics (1) and to identify the relationships among LULCC, habitat function and endemic plant distribution areas (2). To reach this aim, temporal landscape dynamics were evaluated to understand the changes of LULC types, endemic plant habitats and their value. The use of landscape structure analysis integrated with the normalization method and determining the effects of LULC changes

DOI: http://dx.doi.org/10.15666/aeer/1702_35913613

on sensitive endemic plant habitats were the primary objectives of this research. Therefore, the findings of this research can be an example for Turkey and other developing counties to support ecological and cultural integrity of protected areas.

Methodology

The research process included the characterizing the study area, data collection, image pre-processing, image classification, determining and comparing LULCC and determining habitat function using landscape structure metrics analysis (*Figure 1*).

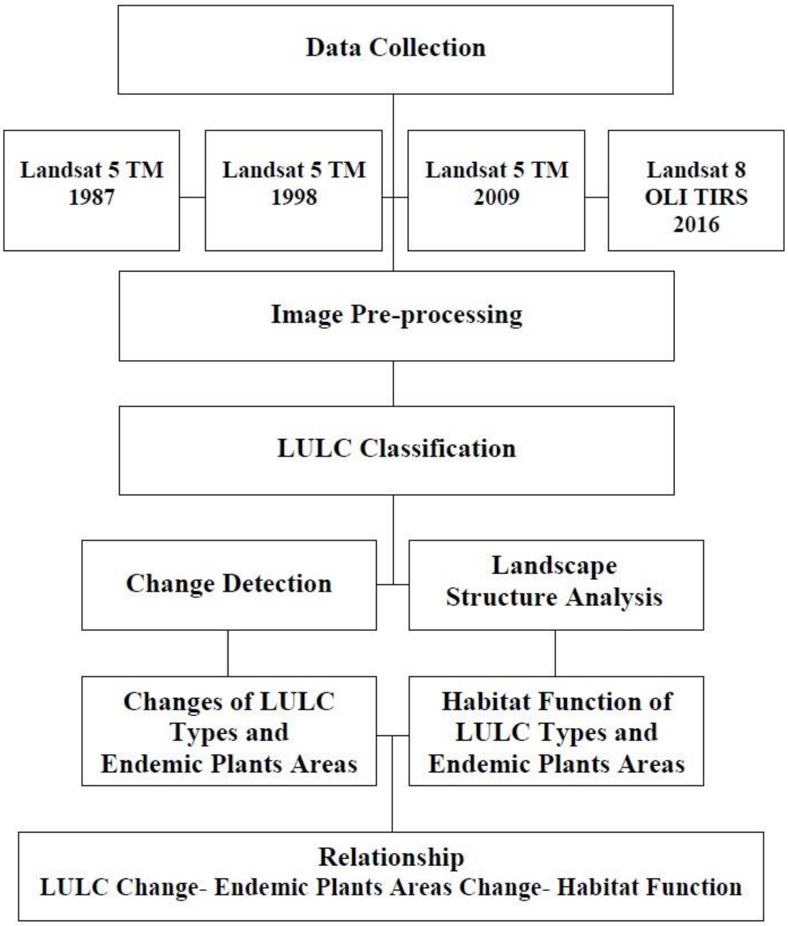

Figure 1. *Flowchart of the research process*

Study area

Mary Valley, located in the Maçka District of Trabzon Province in Turkey's Northeast Black Sea Region, lies in a catchment area of approximately 7,802 hectares (40° 45' 48"-40° 37' 17" N, 39° 35' 55"-39° 42' 26" E) (*Figure 2*). It is a rural area with six traditional villages and plateau settlements on the steep and deep valley, with a rich natural, cultural and historical landscape. Therefore, Mary Valley is one of the most internationally and nationally important protected areas and tourism destinations of Turkey. 4,468 hectares of the study area were declared as the Altindere National Park in 1987 by the Ministry of Environment and Urbanism.

DOI: http://dx.doi.org/10.15666/aeer/1702_35913613

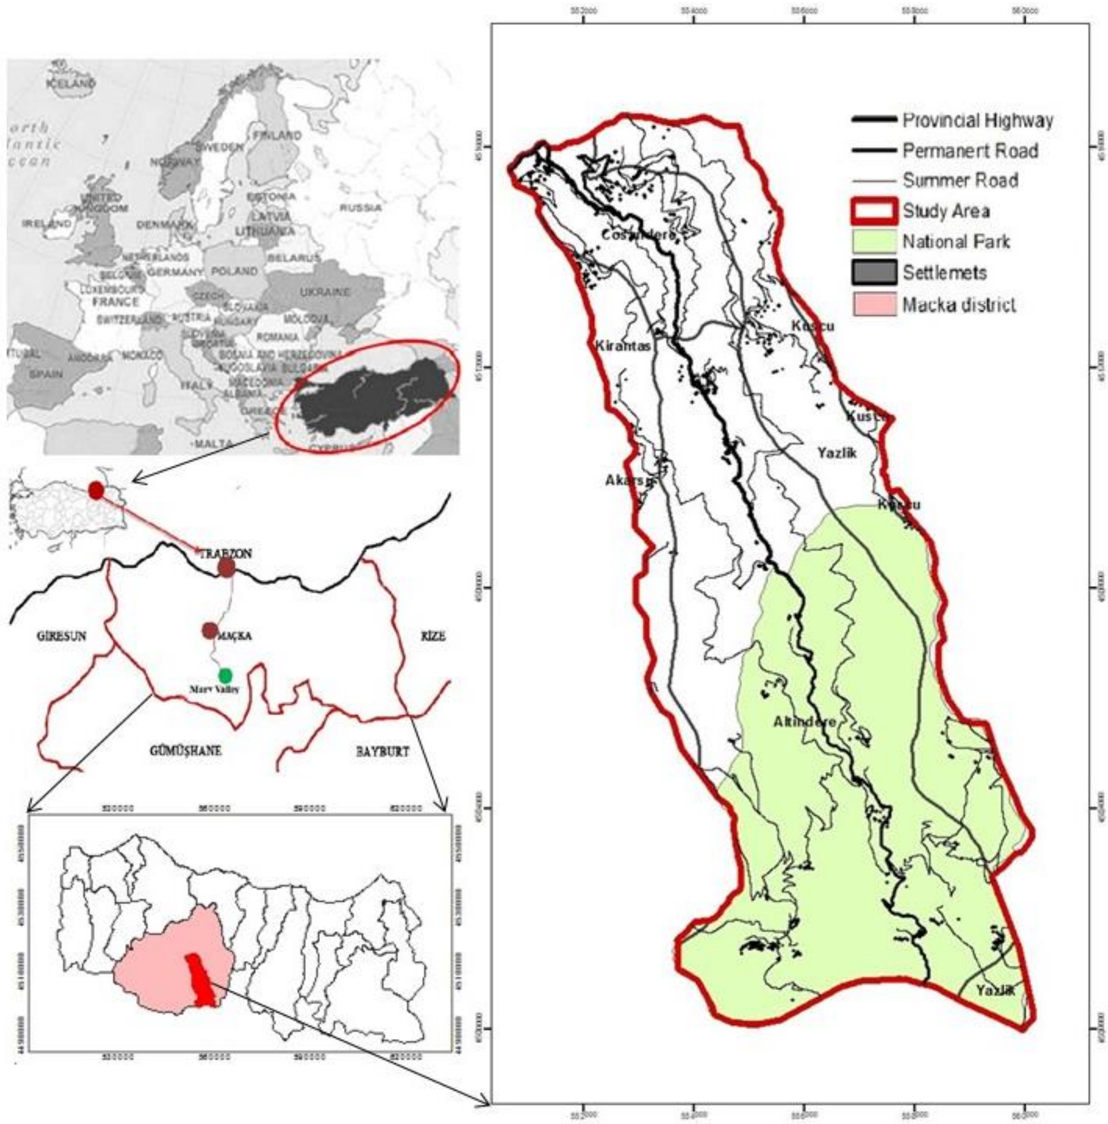

***Figure 2.** The study area of Mary Valley, Turkey*

A difference in elevation from 480 meters to 2,718 meters shapes the area's topography, climate and vegetation (Doganay, 2003; Demir, 2017). The study area includes different kinds of ecosystems including riparian buffers, dense broadleaf forests (1,350 m-1,750 m), coniferous forests (1,750 m-2,000 m), and alpine meadows (2,000 m and higher). It hosts 31 endemic plants species (*App. 1*) that are declared on the red list of IUCN as threatened species (Salapaş, 2002; Uzun, 2002; Demir, 2017). It has been designated as an Important Bird Area concerning Eastern Europe's bird migration (BirdLife International, 2015; Development Plan, 2005). The historical Sumela Monastery has an archaeologically and historically important cultural landscape value that manifests in the religious ceremonies of monks and pilgrims (Zaman, 2010; Demir et al., 2015).

The current land cover types of the study area include forests, shrublands, grasslands, croplands, bare land and settlements. The main economic activities are tourism, agriculture, forestry and livestock breeding. Forestry and agricultural activities are restricted within the national park's boundaries. These reasons lead to the migration of locals to big cities, and the population of study area diminished from 4,142 to 1,602 people between 1987 to 2016 (TURKSTAT, 2016). Additionally, the conservation status Mary Valley was under changed from 1972 to 1998. Mary Valley has gained national and international conservation value and tourism potential due to its wide range of natural and cultural resources. Thus, ecology-based tourism has been proposed for this protected catchment area by the KAMAG (2011) and in DOKA (2012) projects and by several studies (Demir et al., 2015; Pirselimoğlu and Demirel, 2015a, 2015b). The changes of LULC and habitat can be a determining factor in promoting sustainable development of this area.

Data collection

Three different Landsat 5 TM images taken on September 8, 1987, September 22, 1998, and September 4, 2009, in addition a Landsat 8 OLI TIRS image taken on September 3, 2016 were downloaded from the USGS website and used in this research to examine LULCC in Mary Valley. The spatial resolution of Landsat 5 TM images and the Landsat 8 OLI TIRS image is 30 meters. All these images had cloud cover of less than 5%. Moreover, one rectified digital aerial photo with a spatial resolution of 3 m taken on August, 12 2013 and a map with a spatial resolution of 30 m called Globeland 30-N37 from September 16, 2010 was used for visual interpretation and accuracy assessment (GLC30, 2015). Demographic data (TURKSTAT, 2016) and endemic plant species data (Salapaş, 2002; Uzun, 2002) were examined for habitat and local population change. ERDAS 2014 software was used for image pre-processing, classification and haze reduction. ENVI+IDL programs were used to reduce the black line gaps of the images based on the Landsat gap fill process. ARCGIS 10.2 was used for geometric corrections, converting raster data to vector data and determining the LULCC. FRAGSTAT 4.2 (McGarigal et al., 2012) was used to determine habitat value of land cover types using landscape structure metrics.

Image pre-processing

The 5 TM images taken in the year 1987, 1998 and 2009, in addition to the Landsat 8 OLI TIRS image taken in the year 2016 were evaluated directly for image pre-processing. For this step, Image pre-processing was used to eliminate band combination based on stack layers, top of atmospheric radiances (TOA), atmospheric correction, and for haze reduction. Firstly, the digital number (DN) layers were combined with the stack layer modeler. For next step, a top of atmospheric radiance and reflectance computation (TOA) modeler was created for each image to minimize atmospheric effects (Özyavuz et al., 2011; Tian et al., 2014). The radiative transfer model was used for the atmospheric correction of these four satellite images from 1987, 1998, 2009 and 2016 using the simulation of the satellite signal in the solar spectrum (5S) to compute the atmosphere's attenuation of the solar radiation that reflected radiation or radiance from a surface. Then all the values were evaluated for the satellite images, separately. The Landsat images were geometrically corrected and registered in the Universal Transfer Mercator projection system (datum WGS 84, zone 37N) for geometric correction. The Landsat fill gap was used to eliminate and reduce the black line gap and haze effects in the visible bands of Landsat images (Yale, 2015) to enhance the accuracy of classification. Images of four different times were used to determine landscape dynamics changes through LULC and landscape structure analysis.

Image classification

The classification process groups pixels that have similar spectral values (Kara et al., 2013; Bozkaya et al., 2015). This research was carried out using the maximum likelihood supervised classification algorithm to detect land use and land cover types. In this process, 342, 329, 303 and 325 pixels were selected for 1987, 1998, 2009 and 2016, respectively. After that, forest areas (deciduous and coniferous), shrublands, grasslands, bare land (gravel and bare ground) and croplands were identified as land use and land cover classes. These classified data were compared with the GlobeLand 30-N27 map and the digital aerial photo (2013) using on-screen digitizing to improve the accuracy rates of the classification maps and solve the mixed pixel problem. Overall accuracy was calculated using 800 independent test pixels. The statistical results were 94% 94% 92% and 93% respectively for the 1987, 1998, 2009 and 2015 classified images.

Change detection

Change detection was used to compare two years using from-to analysis (Francisco and Hochschil, 2012; Tian et al., 2014). It is the most effective technique for detecting the differences between two images and demonstrates the transformation of LULCC by post-classification comparison (Fichera et al., 2012; Kara et al., 2013; Hussain et al., 2018). This comparison indicates the percentage of each class on diagonal and off-diagonal axes (Congalton et al., 2014; Tian et al., 2014; Rawat and Kumar, 2015). The changes in LULCC were determined and described for three intervals: 1987-1998, 1998-2009 and 2009-2016. According to Leitao et al. (2006), Esbah et al. (2009, 2011), Erdogan et al. (2013) an at least 100 meter buffer zone area is a viable way of protecting the sensitive core zone of a habitat. Therefore, this zone was created for the point data of endemic plant species in order to detect and monitor the LULCC (Leitao et al., 2006; Esbah et al., 2011; Erdogan et al., 2013) of these areas from 1987 to 2016. This process was summarized in terms of net change, total change, persistence, gross gains, losses and swaps in LULCC (Braimoh, 2006; Angonese and Grau, 2014). After detecting the different areas of persistence, gain and loss for LULCC, these areas were associated with the endemic plant habitats. This post- classification method (from-to) was used by comparing images taken at different times to monitor the transitions of LULC and endemic plant habitats.

Landscape structure

Landscape metrics analysis was used to assess the habitat function and landscape changes for the quantification of landscape pattern to compute the complexity of landscape structures (Leitao et al., 2006; Esbah et al., 2010; Gökyer, 2013). In this research, 16 landscape metrics were used in FRAGSTAT 4.2 software at the class level for four LULCC classified map-years (*Table 1*). The metrics were categorized in four groups according to their characteristics (McGarical et al., 2002): 1) area/edge metrics; including percentage of landscape (PLAND), total edge (TE), edge density (ED), patch number (PN), patch density (PD), mean patch size (MPS), area weighted patch size (AWP); 2) shape metrics, including mean size index (MSI), area weighted mean size index (AWMSI), area weighted mean perimeter-area ratio (MPAR), area weighted mean fractal (FRAC_AM); 3) core metrics, including total core area (TCA), mean core area index (CAI_MN), and 4) the isolation/contiquity metrics, including mean euclidean nearest neighbors distance (ENN_MN), mean contiquity (CONTIG_MN).

***Table 1.** Explanation of relationship between landscape metrics and habitat function (Turner et al., 2001; Esbah et al., 2009; Demir and Demirel, 2018)*

Landscape Metrics	**Symbol**	**Explanation**
Percentage of Landscape	PLAND	It measures the percentage of the each land cover class according to all landscape cover classes.
Mean Patch Size Area Weighted Mean Patch Size Patch Number Patch Density	MPS (AREA_MN) AWMPS (AREA_AM) PN PD	MPS measures the size of discrete patches summarized across all patches of a particular land cover class. If the patch size is bigger, it has more habitat potential. If it is used by Patch Number (PN) and Patch Density (PD), it can serve as a fragment. Displays the magnitude of the presence of similar patches in the landscape, indicates isolation if PD decreases. More patches (PN) mean more boundaries between land cover classes, which can mean barriers to movement between habitats. MPS and PD are directly proportional and PN is inversely proportional to habitat function. MPS is interpreted better by PLAND, PN and PD.
Total Edge Edge Density	TE ED	Total Edge (TE) is the total edge numbers for each landscape class. Edge Density (ED) is the total length of per hectare for each landscape class area. TE and ED are inversely proportional to habitat function, because more edges mean higher possibility of edge effects. Edge effects alter vegetation structure and animation abundance.
Mean Size Index Area Weighted Mean size Index Area Weighted Mean Perimeter-area Ratio	MSI (SHAPE_MN) AWMSI (SHAPE_AM) MPAR (PARA_AM)	It measures the average of the mean patch shape for each land cover class. AWMSI and MSI are related to the complex geometric shapes of a patch because these affect the edge effects and cross boundaries. Linear, corridor-like, lobed, complex and convoluted patch shapes have a higher amount of boundaries than round, compact and simple patch shapes. Rounded, compact and simple patch shapes garner a higher habitat potential than others because more boundaries mean higher possibility of edge effects. If the number is close to 1, it means the class can have a higher habitat value. Most of shape metrics have a relationship with perimeter-area metrics. MPAR is inversely proportional to habitat function.
Area Weighted Mean Fractal	FRAC-AM	It measures the total edge length of the patches of each land cover class. It displays the fragmentation of habitat. If the number is smaller, it means the fragmentation is not so severe. FRAC-AM is inversely proportional to habitat function.
Mean Contiquity	CONTIG_MN	It measures the average possibility of neighbors (contiguity) of each land cover class. CONTIG-MN is inversely proportional to habitat function.
Mean Euclidean Nearest Neighbors Distance	ENN_MN	It measures the average distance of the nearest neighbors (contiguity) of each land cover class. ENN_MN is inversely proportional to habitat function.
Total Core Area Mean Core Area Index	TCA CAI_MN	It measures the total core area of each landscape classes.100 m is based on the core area. It can be assessed with CAI-MN to display the detection of habitat function of each land cover class.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35913613

The directly and inversely proportional metrics that affect habitat function were evaluated separately for each category. Finally, one of the well-known linear normalization methods called Min-Max method was used to normalize the data linearly. Minimum; refers to the lowest value, maximum; refers to the highest value that data can receive. The Min-Max normalization method (*Equation 1*) sorts data in the range of 0 to 1 (Wang and Cumming, 2011; Yavuz and Deveci, 2013). Data is calculated according to the following *Equation 1*:

$$x' = \frac{x_i - x_{\min}}{x_{\max} - x_{\min}} \qquad \text{(Eq.1)}$$

In this formula x' is normalized data, x_i is input value, x_{min} is the smallest and x_{max} is the largest number in the input set (*Equation 1*). In this context, Min-Max normalization method was preferred to generalize objectively the range of landscape structure metrics values of each LULC type.

Results and discussion

Land use and land cover change

The LULC types in the study area consist of forests, grasslands, bare land, shrublands and croplands. According to the LULC distributions from 1987 to 2016, the dominant LULC types were forests and grasslands (*Figure 3*). The LULC types gained bare land at the cost of losing forest, grassland, shrubland and cropland, respectively. Forests decreased from 49.87% in 1987 to 43.92% in 2016, while bare land increased significantly. In 2016, the forests were still dominant followed by croplands. The bare land area increased significantly in 2016 compared to previous years, while forests declined sharply in 2016 (*Figure 4*).

The change detection indicated the amounts of net change, total change, persistence, gains, losses and swaps of LULCC types from 1987 to 2016. *Table 2* shows that grasslands had the highest total change (13.06%) and highest swap (12.10%) in terms of gain and loss amounts. Cropland had the lowest total change (gain+loss) and the lowest swap amounts. The highest net change (gain-loss) of LULCC belonged to bare land, and the lowest change was that of croplands. Forests experienced the highest loss with 580.23 ha, whereas bare land experienced the highest gain with 615 ha (*Table 2*).

Eventually, the LULC types of the research area include forest, grassland, bare land and shrubland. Forest and grasslands are the main LULC types of this research. Loss of forest is most likely due to lumber production and the expansion of the road network for villages, summer homes and ski centers, whereas gain in bare land is due to the transformation of grasslands. Cropland areas decreased constantly from 1987 to 2016 (*Table 2*). The main causes of this decline were the limitations on agricultural and forestry activities in the national park, and local migration. Although forestry activities were limited, the forestry area had a similar decreasing trend due to hydroelectric power plants, road networks, deforestation and floods. In these cases, forest areas were transformed to grasslands, shrublands and bare land within 29 years, showing that, besides anthropocentric activities, lack of conservation and management strategies negatively affected LULCC.

Endemic plant areas change

The research area has 31 endemic plants species in the highlands (*Figure* 5). According to Leitao et al. (2006), Erdogan et al. (2013), Esbah et al. (2009, 2011), a 100 m wide buffer zone was created to protect the core zone for each sensitive and endangered endemic plant habitat. The species, listed in the IUCN red list category of threatened species, are most often located in grasslands, forests and shrublands. The LULCC affected endemic plants significantly through the increase of bare land and the loss of grasslands and forests. Even though these plants are protected by the IUCN categories, some changes were found in each endemic plant habitat. LULCC adversely affected their habitats and diminished the environmental properties of the buffer area.

The LULCC distributions from 1987 to 2016 showed that grasslands have the most endemic plants (*Figure 5*), although the highest loss, swap and especially net change amounts were observed in grasslands. *Table 3* included that endemic plant occurrence in shrublands, which is the subdominant LULC type, decreased significantly from 8.70 % in 1987 to 1.81 % in 2016 with the highest loss area. It indicated that the endemic plant habitat in shrublands was under threat with this sharp, constant decline trend. The bare land area experienced more gain, on the contrary, grassland, forest and shrubland experienced more loss from 1987 to 2016.

DOI: http://dx.doi.org/10.15666/aeer/1702_35913613

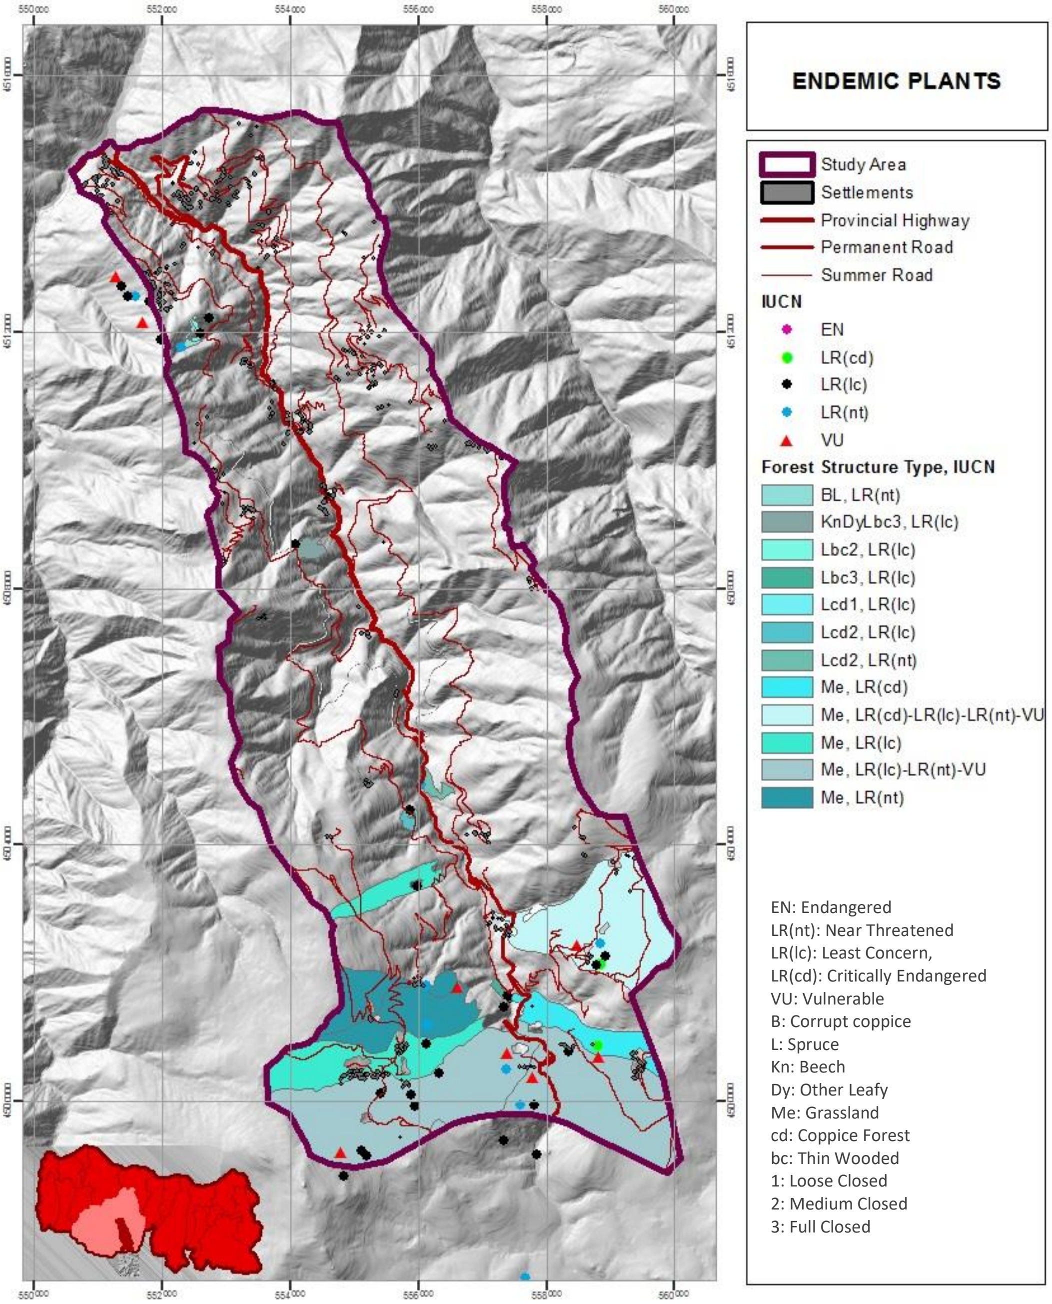

Figure 5. *Endemic plants in LULC (land use-land cover) types*

Each endemic plant habitat has its own specific ecosystem characteristics (Salapaş, 2002; Uzun, 2002; Scullion et al., 2014). Therefore, the LULCC of the surrounding endemic plants had negative effects on their ecological integrity (Neel, 2008; Esbah et al., 2009). The grassland, forest and shrubland areas, habitats for endemic plants changed dramatically from 1987 to 2016. These changes can put pressure on sensitive, rare and endangered endemic plants (Ghosh et al., 2012; Demir, 2017). These negative effects on endemic plant areas from 1987 to 2016 can affect the sustainability of local resources in the protected zone.

LULCC may currently be the most important threat to endemic plants (Neel, 2008; Bozkaya et al., 2015). Conservation plans should be created for tourism and land management and should be supported by local participation to ensure sustainable protection (Malaviya et al., 2010; Francisco et al., 2012; Mairota et al., 2013). In this research, continuous annual data on the population density of endemic plants was missing. Utilizing continuous annual data would enhance understanding of the seasonal distributions of endemic plants.

Habitat change of LULC

Landscape has interaction with and influence on natural and cultural values (CE, 2000). Due to this, monitoring the changes of landscape dynamics has a key role in this research. In this context, the natural and cultural landscape resources of Mary Valley were examined and habitat potential based on landscape sensitivity was determined to observe changes of LULC and endemic plant populations.

The quantification of landscape dynamics of a landscape pattern using landscape metrics is a basic way to determine habitat function and landscape changes (Forman and Godron, 1986; Turner, 2001; Fan et al., 2018). Therefore, the habitat function of the research area was evaluated using landscape structure metrics for LULCC types from 1987 to 2016 in four categories. The landscape metrics grouped in the area/edge metrics class from 1987 to 2016 indicated that the values of TE, ED and PN of grassland and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35913613

cropland are higher; conversely, PD and MPS values are lower than those of other LULC types. Therefore, grasslands and croplands had smaller and more fragmented patches, which led to a decreased habitat potential.

According to the shape metrics group, the low MSI and AWMSI values of shrublands indicated more regular patch shapes that conduce to higher habitat values than other LULC types. On the contrary, bare land and croplands have small and irregular geometric patch shapes, which means lower habitat potential.

The core metrics group is important for protecting landscape values. According to it, forest areas had the highest values of TC and TCA, because forest areas lie in the middle of the watershed valley with low PN, MPS values, and low fragmentation, thus they had a higher habitat potential. Core areas of shrubland and bare land types were quite small, resulting in low habitat values.

According to landscape metrics results of isolation/contiguity metrics, croplands had the highest CONTIG_MN and ENN_MN values, which led to a decreased habitat potential. On the contrary, shrub areas had the lowest continuity and isolation values. Grasslands, forest and bare land, respectively, have similar habitat potential due to the topographic shape of deep valley.

The low ED of forest and grassland indicated that they had higher habitat values with more interior differences in the richness of species. PN of bare land was the highest with a low PD. Therefore, this LULC type became more fragmented than other types. Grasslands and croplands with high CONTIG_MN, ENN_MN and FRAG_MN values demonstrate more heterogeneous and fragmented habitats. Furthermore, croplands with low PN and AWMSI had a potential to shrink. Generally, croplands had the lowest habitat potential in this research, due to the fact that croplands had been decreasing since 1987, and the patches of croplands were quite fragmented and dispersed. The high values of TC, and CAI_MN in forest areas had high habitat potential, conversely, shrublands had the opposite effect. In addition, the low MPAR and FRAC_AM values of shrubs indicated a high habitat potential. In addition, shrublands with high PN, PD and low MSI means improved habitats. However, their habitat potential was lower due to their high ED, CONTIG_MN, ENN_MN and low MPS values, which mean a high level of fragmentation (*Table 4*).

According to the linear normalization of all metrics from 1987 to 2016, the habitat function of the LULC types from highest to lowest were forests, shrublands, croplands, grasslands and bare land, respectively (*Figure 6*). The habitat function of forests decreased suddenly in 1998 compared to other periods. This loss of forest habitat led to an increase in shrubland, cropland and bare land areas. The habitat potential of shrublands was the highest among the LULCC types in 1998, and the habitat value of bare land was the lowest. In 2016, forests experienced the highest habitat function at 1.00 due to uniform, compact and un-fragmented patches, followed by grasslands at 0.540. Bare land experienced the lowest habitat function at 0.00. This landscape structure analysis integrated with the normalization method is a first in terms of ranking the habitat changes of LULC on the same scale to provide a more objective approach.

The values of habitat function assess each LULCC pattern according to ecological integrity (Esbah et al., 2009; Demir and Demirel, 2018; Hussain et al., 2018). External influence should be considered in habitat function because unsustainable use and lack of administrative structure can negatively affect it (Bruton et al., 2016; Demir et al., 2016).

For example, more than 40% of the uncontrolled wood cutting of local people and road networks in 1998 represented a key factor in the decline of forest habitats in Mary Valley. The habitat function of landscape patterns is calculated using different types of landscape metrics and indicates direct or inverse effects (Malaviya et al., 2010; Fichera et al., 2012). All metrics were evaluated separately, depending on their direct or inverse relationships with the habitat function changes of each LULC types through the linear normalization (Norm.) called Min-Max method (*Figure 6*). As a result, objective values for the habitat function of all LULC types were calculated. This normalization statistical technique was an effective and easy way to enhance our understanding and to measure the effects of metrics on habitat function. A high number of metrics creates difficulties for the evaluation of habitat function (Esbah et al., 2009; Fichera et al., 2012; Bruton et al., 2016). A research was suggested to limit and categorize them using a statistical method such as factor or cluster analysis with the assistance of an expert (Mairota et al., 2013). Thus the 16 metrics selected were categorized in 4 groups based on their characteristics and were evaluated objectively using linear normalization method.

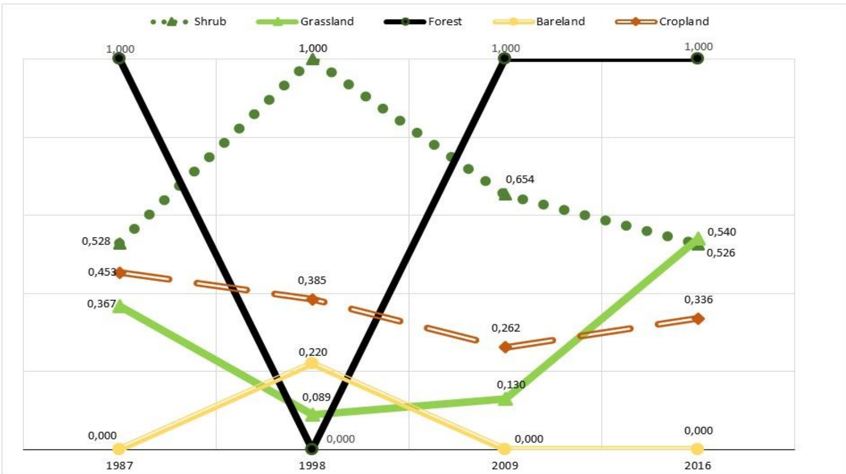

***Figure 6.** Total habitat changes (ha) of LULC (land use-land cover) by linear normalization*

LULC change of endemic plant areas

Changes in the endemic plant habitats were compared with the habitat function of each LULC type. The changes in these species' distribution areas were inversely related to the habitat function of bare land and forest areas, but directly related to habitat function of shrublands (*Figure 7*). In the grasslands, the endemic plants habitats were inversely related to habitat function. The results of these analyses, conducted along the distribution areas of endemic plants, has allowed detecting a significant relationship with the habitat function of LULC.

The decline in shrublands diminished the habitat function of endemic plant distribution areas. Generally, shrublands have a valuable habitat status for endemic plants (Salapaş, 2002; Estes et al., 2012; Bruton et al., 2016). Thus, the transformation of shrublands should be stopped to protect the species. Bare land areas have increased over 29 years and adversely affected the habitat function of sensitive, unique and rare endemic plant habitats. The rise in the total area of bare land should also be reduced to prevent negative effects. Unlike the bare land trend, forest area inversely affected them.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35913613

This method is a first in terms of identifying changes in endemic plant habitats to prove the effect of LULC type changes on sensitive habitats.

Endemic plants are located in different LULC types (Uzun, 2002; Estes et al., 2012; Scullion et al., 2014). Due to this reason, future conservation decisions can be prepared based on the separate environmental requirements of endemic plants to sustain each habitat function. Uncontrolled tree cutting and infrastructure expansion connect the decline of the habitat function of forest areas to the increase in bare land and grassland habitat functions based on area/edge, shape, core and isolation/contiguity metrics. Since 1998, the habitat function of forest areas for endemic plants has increased. This result showed that forest habitat renewed itself with ecological processes. Conservation and management plans should respect ecological processes to ensure the ecological integrity of the research area.

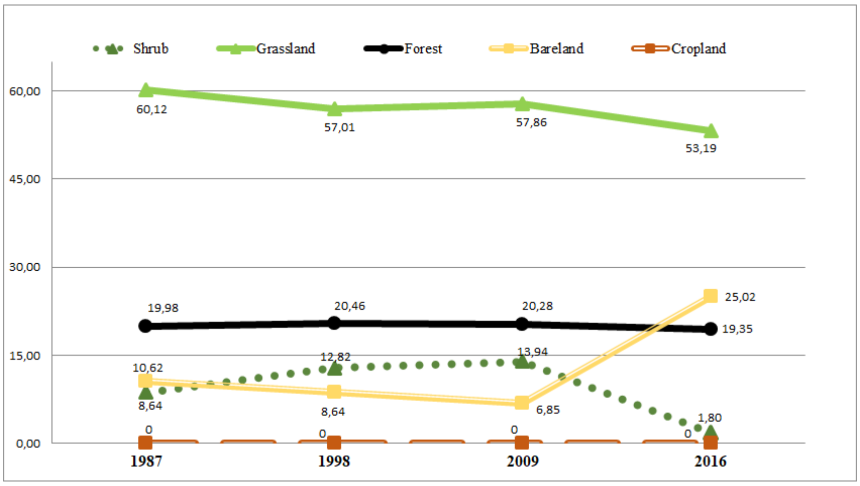

Figure 7. *LULC (land use-land cover) change of endemic plant areas (ha) from 1987 to 2016*

Other related changes

The spatial and temporal monitoring model supplied quantitative results of past to present day changes and can estimate the direction and extent of future transformation (Malaviya et al., 2010; Fichera et al., 2012; Mairota et al., 2013) However, this research has some limitations. It is still too difficult to determine the unpredictable effect of other changes such as decreasing local population and insufficient visitor management. Local people play an important role in the protection of their own landscape resources (Chaminuka et al., 2012; Estes et al., 2012; Fichera et al., 2012; Scullion et al., 2014; Demir et al., 2016). Nevertheless, according to data of TURKSTAT (2016), the population decreased from 4,142 in 1987 to 1,605 in 2016 in Mary Valley's protected area. Demographic projections for Mary Valley (Demir et al., 2015; Demir, 2017) forecast that this declining trend will continue until 2040 (1,373 in 2020 and 743 in 2040). This decline was due to restrictions within the boundaries of the national park banning forestry and agricultural activities. The forestry area had constantly decreased since 1987 due to mostly uncontrolled deforestation and new road infrastructure. Another limitation was related to climate, which restricts tourism activities to July and August.

The research area is part of a valuable national park with tourism and recreation potential (Demir et al., 2015; Pirselimoglu and Demirel, 2015a, 2015b). Consequently,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_35913613

a future conservation plan and ecotourism activities with local cooperation in participatory management can be offered as a way to partially solve the problems of the natural environment and the populace (Estes et al., 2012; Francisco and Hochshil, 2012). Such a plan and ecotourism can create socio-economic prosperity for local people to return to the valley and protect its natural and cultural landscape. Local awareness on the protection of ecological values can be raised. All protection rules and ecotourism activities can be controlled by an interdisciplinary scientific council responsible to the related ministries, experts and other stakeholders. This can make it possible to provide special local protection and effectively prevent smuggling of the area's fauna, flora and historical resources.

In the study area, there is no capacity control or monitor visitors of the national park or tourism and recreation activities in general. These problems can put pressure on its ecological and cultural values and diminish its environmental characteristics. Thus, while conservation oriented plans are being made, tourism management and land resource management strategies based on landscape planning can be carefully considered not only for the national park, but for the entire catchment area in a future research. This method can be an efficient and effective way for future researches to monitor LULCC and habitat function worldwide and to determine conservation and management strategies.

In relevant literature, there are many studies in which LULC change detection and habitat change is studied. However, there researches on protected areas are quite limited, especially where changes of endemic plants habitat and the evaluation of landscape metrics by grouping are involved. Similar to Mary Valley’s research, the Mairota et al. (2013) developed a quantitative method based on landscape structure metrics to monitor protected areas. It only analyzed the landscape structure of protected areas, but LULC changes from past to present day could be an important key element to monitor habitat function change of landscape dynamics to support the findings. On the contrary, in the research of Mary Valley, the effect of LULC changes on endemic plants was monitored with change detection and landscape metrics (individually and in four groups) which has an important role in improving sustainable planning and management strategies for the protected area. Malaviye et al. (2010) monitored 34 years of LULC changes to determine changes of habitat diversity of a mining area. Fichera et al. (2012) analyzed and monitored 50 years of LULC and habitat changes. The oldest image dated back to only the year 1987 of Marry Valley, because the satellite images of this study area were limited due to cloudy days and snow cover on highlands. Therefore, for the further research, the images of the study area should date back to before the conservation status was established, to provide an exhaustive analysis of want went on before and after that date. Although these researches analyzed LULC and habitat change in spatial and temporal scales using change detection and a few landscape structures metrics, they did not consider the relationship of LULC and habitat change with the endemic plants of the area, and neither did they group landscape metrics to qualify the landscape structure of LULC and endemic plant habitats. Furthermore, the main difference between Mary Valley’ research and these sample studies is that the spatial and temporal LULC and habitat changes of protected area under four landscape metric groups, paired with the relationship of endemic plants were all analyzed. Therefore, these methods were developed to contribute guidance to future researches and practices worldwide.

Conclusions

The objectives of this study were to determine temporal habitat function based on landscape structure analysis using landscape metrics and to identify the relationships between the change of LULC, habitat function and endemic plant distribution areas by temporal and spatial monitoring and analysis. First of all, changes of LULC and endemic plant areas were monitored, followed by habitat function of LULC types and endemic plant distribution areas, based on related studies conducted nationally and internationally. Through landscape habitat and landscape structure analysis, the temporal changes of LULC, endemic plants and habitats were determined for the research area. Mary Valley protected area has a catchment and archeological site. However, this research area has been under pressure due to habitat changes of LULC types and endemic plants distribution areas. Therefore, connectivity of landscape patches of each LULC types can be improved for sustainability, and ecological and cultural integrity of the study area, through establishing healthier conservation and management strategies by improving existing ones.

This research examined habitat function of LULC and endemic plants distribution areas based on landscape sensitivity, using landscape dynamics. The spatial and temporal landscape pattern was investigated on four different dates (over 29 years), which enabled us to monitor the changes of landscape dynamics. According to the findings on LULC change with change detection, forest areas lost the most area, whereas bare land areas significantly increased, gaining most of it from lost forests, grasslands and croplands. Furthermore, the most endemic plants are located in grasslands, although the highest loss and net change amounts were also indicated in grasslands. In addition, shrublands were under threat with a sharp constant decline trend. In the context of habitat function of LULC types and endemic plant distribution areas evaluated using landscape structure metrics with linear normalization scale, the endemic plant distribution areas had adverse effects on habitat function due to the edge effect, which diminished environmental resources. The forest had the highest, while bare land had the lowest habitat potential with high fragmentation. This study evaluated temporal LULC and habitat changes. In this research, the landscape structure analysis integrated with normalization method and the determination of the effects of LULC changes on sensitive endemic plants habitats were a first, and thus these new approaches may set an example for future studies related LULC and LULC changes on sensitive areas. These methods and findings can help control sensitive landscape dynamics for further sustainable development of protected areas. Thus, this research can set an example for Turkey and other developing countries in supporting the sustainability of ecological and cultural integrity of protected areas.

(Received 10th Dec 2018; accepted 20th Feb 2019)

Abstract. It is a challenge to adequately represent meteorological data for river basin modelling in data-scarce regions. Hydrological models may benefit from alternative climate data sources such as the Climate Forecast System Reanalysis (CFSR) weather data. A proposed method was applied to evaluate the applicability of CFSR data in the Soil and Water Assessment Tool (SWAT) eco-hydrological model for the 1.8×10^6 km^2 Yangtze River Basin (YRB) in China. The CFSR data were first validated by ground-based meteorological station (GMS) data to confirm sufficient accuracy to predict the hydrology for the YRB. It was determined that the CFSR simulation was able to generate acceptable accuracy with calibrated parameters of GMS-based model. The R^2 and ENS of the monthly results from both GMS- and CFSR-SWAT simulations were > 0.70 in both calibration and validation periods. The monthly streamflow hydrograph from GMS and CFSR simulations showed two different patterns: distinct differences in baseflow and less discrepancy for the peak flows, such as the patterns at Cuntan and Yichang gauge stations, whereas the results are characterized as close matches the peaks and the recession periods at Hankou and Datong gauge stations. The CFSR simulation generated better results in the middle and lower reaches than in the upper reach of the basin. To a certain extent, the CFSR provides an alternative to quickly build hydrological model in data scarce area for large basins.
Keywords: *SWAT model, data scarce area, model calibration, meteorological forcing data, large-scale watershed*

Introduction

Traditionally, weather data collected at ground-based meteorological stations (GMS) are utilized to drive eco-hydrological models; therefore, it is important to collect adequate and representative weather data. It is difficult and time-consuming to obtain adequate meteorological data for hydrological models to accurately represent climate patterns for some watersheds, especially those located in data-scare regions, due to inadequate overall coverage of the watershed area provided by ground-based meteorological station (GMS) data. In developing countries or ungauged areas (Lu et al., 2018), weather data are also unavailable because of financial limitations and/or inadequate technology (Vu et al., 2012). In addition, there are shortcomings related to GMS data in regards to supporting rapid development of watershed models. For a small-scale watershed, GMS data are sometimes located outside of the investigated watershed and consequently, the collected records from GMS may not accurately represent the actual weather that occurred at the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_36153632

watershed (Fuka et al., 2014). The scarcity of GMS, especially in developing countries, increases the uncertainty in precipitation inputs for each model sub-basin (Worqlul et al., 2014). In addition, because of the data management policies of governments for state security in some countries, it is usually difficult to collect sufficient data for hydrological models.

The availability of other sources of data (i.e., satellite precipitation and reanalysis data) where there is no conventional GMS has recently attracted the interest of hydrologists. The hydrological model can benefit from satellite observation data and global reanalyzed weather data such as TRMM (Tropical Rainfall Measuring Mission), ECMWF (European Centre for Medium-Range Weather Forecasting), ERA-40 (40-year reanalysis), CFSR (Climate Forecast System Reanalysis) produced by National Center of Environmental Prediction (NCEP), APHRODITE (Asian Precipitation-Highly-Resolved Observational Data Integration towards Evaluation of Water Resources), and PERSIANN-CDR (Precipitation Estimation from Remotely Sensed Information using Artificial Neural Network-Climate Data Record) to overcome data shortages (Behrangi et al., 2011; Ward et al., 2011; Worqlul et al., 2015; Tan et al., 2017).

Concerns have been increasing on the subject of climate change as a driver of hydrological changes within the Yangtze River Basin (YRB) in China (Zhang et al., 2008; Zhu et al., 2011) based on satellite observation data and global reanalysis weather data. Previous studies were carried out to evaluate the remotely sensed weather products and their reanalysis datasets by application in different basins. Yang et al. (2014) found that gridded precipitation products poorly reproduced hydrologic processes except that the APHRODITE and trend surface data can give stable and desirable results in a relatively flat test basin, in an evaluation of a gridded precipitation-driven Soil and Water Assessment Tool (SWAT) eco-hydrological model application for the upper reaches of Three Gorges Reservoir. Sun et al. (2013) investigated the spatiotemporal rainfall patterns of the YRB using TRMM/PR (TRMM/ Precipitation Radar) data in a decadal scale, which reveals that there are possible linkages between major precipitation patterns and hydrological extremes. Li et al. (2015) conducted water balance and streamflow studies for multiple time scales using three global satellite rainfall products [TMPA (TRMM Multi-satellite Precipitation Analysis) 3B42 V7, TMPA 3B42 Real Time (RT), and CMORPH (Climate Prediction Center morphing technique)] during 2003 to 2012 in the YRB. They found that the 3B42 V7 data generally resulted in improved annual water budgeting and monthly streamflow performance. The 3B42 RT tends to overestimate streamflow in the upper Yangtze River, and, in contrast, CMORPH shows serious underestimation in downstream sub-basins. Worqlul et al. (2014, 2015) compared to rainfall estimations by TRMM 3B42, MPEG (Multi-Sensor Precipitation Estimate–Geostationary) and CFSR with ground-observed data for the Lake Tana basin and Upper Blue Nile in Ethiopia. The MPEG and CFSR satellites provided the most accurate rainfall estimates, and both the gauged data and the CFSR precipitation estimates were able to reproduce the hydrology well for both models and both watersheds. Tan et al. (2017) analyzed the accuracy of three long-term gridded climate products (APHRODITE, PERSIANN-CDR and NCEP-CFSR) for two tropical river basins in Malaysia. The APHRODITE data resulted in strong results for streamflow simulations, while NCEP-CFRS data showed unsatisfactory performance.

The satellite-based precipitation products and their reanalysis weather data provide an alternative data source to study hydrology and climate change. The application of remotely-sensed data and corresponding reanalysis precipitation data within eco-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_36153632

hydrological models is gradually increasing in many regions; however, use of such remains limited in many areas of the globe including the YRB. Therefore, gridded precipitation products must be evaluated to improve the performance of the watershed model in this data-scarce area. In addition, the SWAT eco-hydrological model (Arnold et al., 1998; Arnold et al., 2012; Gassman et al., 2007, 2014) has recently been applied to parts or all of the YRB to predict the water balance, sediment transport, and nutrients. Ouyang et al. (2008) used SWAT to evaluate the impact on streamflow and nonpoint source pollutants from the conversion of cropland to forest in Bazhong City, located in the central YRB region. Zhang et al. (2011) investigated the water balance of Three Gorges Reservoir in the upper reach of the Yangtze River with the aid of SWAT model. Sun et al. (2016) mapped the water vulnerability of the YRB using SWAT for 1994 to 2013; the statistical results showed that the simulated output accurately replicated the observed data during both the calibration and validation periods. Chen et al. (2017) and Su et al. (2017) assessed the impacts of climate change on river discharge in the upper reaches of the YRB based on hydrological models under different climate projections. Several other studies reported predicted water budget, water quality, and/or the impacts of climate change or land use management using SWAT for various YRB sub-regions (Yang et al., 2014; Huang et al., 2009, 2014; Zhou et al., 2013). The applicability of global reanalysis climate data for hydrological model predictions has not so far been adequately investigated in such a large watershed: the entire Yangtze River basin.

Therefore, the aim of this study was to assess the performance of CFSR weather data versus GMS data for predicting YRB hydrology using SWAT. To evaluate the applicability of CFSR weather data in the watershed model, the same hydrological parameters of the model calibrated using GMS weather data were used in both models, and then both the results were validated against observed data. The simulated results of streamflow from the SWAT model driven by CFSR weather data with and without calibration were compared. Finally, the monthly averaged streamflow simulated by the models driven by CFSR and GMS weather data were investigated to evaluate the performance of CFSR as input weather data.

Materials and Methods

Study area

The Yangtze River, also called the Changjiang, which means ‘Long River’ in Chinese, is the longest river in China and the third longest in the word, with a length of approximately 6,380 km and a drainage area of 1.8×10^6 km^2. Originating from the Tibetan Plateau, the Yangtze River flows across the Qinghai-Tibet Plateau in west China, Sichuan basin in the middle China, and east China Plain with an average elevation of 3000 m, 1000 m, and 100 m, respectively (Gong et al., 2006). Generally, the Yangtze River is divided into three reaches: upper, which drains the area controlled by the Yichang gauge station, middle, which captures drainage between the Yichang and Hukou gauge stations, and lower, which covers the area downstream of the Hukou gauge station to the estuary (*Figure 1*).

The YRB is located in the Asian monsoon region, which manifests as two independent components: the Indian summer monsoon and the East Asian summer monsoon which affect the upper and mid-lower YRB sub-regions, respectively (Ding et al., 2005). Because of the large area and extensive range of elevation, precipitation varies considerably between the different climatic zones. The annual precipitation in most areas

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_36153632

of the YRB is 800-1600 mm, whereas it is less than 400 mm in the river source areas in the arid zone. The area with precipitation larger than 1600 mm is mainly located in the Sichuan, Jiangxi, Hunan and Hubei provinces. Large floods are frequent in the summer due to the heavy monsoon rainfall influence. Precipitation declines across the basin from east to west, ranging on average annually from 1528 mm in the east to 859 mm in the west. The upper Yangtze region is characterized by the highest elevation and the least precipitation (Chen et al., 2014). The weather data of GMS over the YRB for 65 weather stations (*Figure 1*) were collected for model setup. The mean annual temperature in the middle and the lower Yangtze basin is 19 and 15°C from the west to east respectively (Zhang et al., 2006). The annual average streamflow of the Yangtze River is 9.5×10^{11} m^3, and the average runoff depth is 526 mm, which is the largest streamflow in China, comprising 35% of the streamflow of all of China's rivers.

Datasets and model setup for the YRB

Spatial data

The spatial databases used to establish the SWAT model included the Digital Elevation Model (DEM), land use and soil type. The DEM describes the spatial distribution of regional topography and serves a fundamental role in the definition of the basin boundary, division of sub-basin, generation of river network, extraction of various hydrological parameters and division of HRUs (Tao et al., 2015; Lu et al., 2017). The DEM (*Figure 1*) with 90-m resolution used in this study was generated from the Shuttle Radar Topography Mission (SRTM) DEM (http://srtm.csi.cgiar.org/SELECTION/inputCoord.asp) processed with ArcGIS 9.3 software. Land use affects the runoff process on the land surface and has an important influence on the results of the simulation. The land use data used here were produced by the Department of Geography, University of Maryland (Hansen et al., 2000). This land use / cover products were generated using the AVHRR (Advanced Very High Resolution Radiometer) images which were analyzed to distinguish fourteen land use and cover classes with a spatial scale of 1 km pixel resolution. These images were analyzed to distinguish fourteen land use and cover classes with a spatial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_36153632

scale of 1 km pixel resolution. The land use was then reclassified to nine classes for the SWAT model input (*Figure 2a*). The main land use type is forest, accounting for 36% of the area, whereas pasture (23.5%) and crop land (23%) make up the next largest proportions of the YRB.

The original China soil data that are parts of the HWSD (Harmonized World Soil Database) dataset were produced by the Institute of Soil Science, Chinese Academy of Sciences based on the Second National Soil Survey of China (Shi et al., 2006). Soil properties were extracted by 1:1,000,000 HWSD version 1.1 (*Figure 2b*). The main soil type is Haplic Luvisols with higher organic matter, Cumulic Anthrosols with human improvement of water and fertility conservation, and Gelic Leptosols with thin layer that are sensitive to the temperature with the percentage of 16.1%, 13.8%, and 11.3% respectively in the YRB.

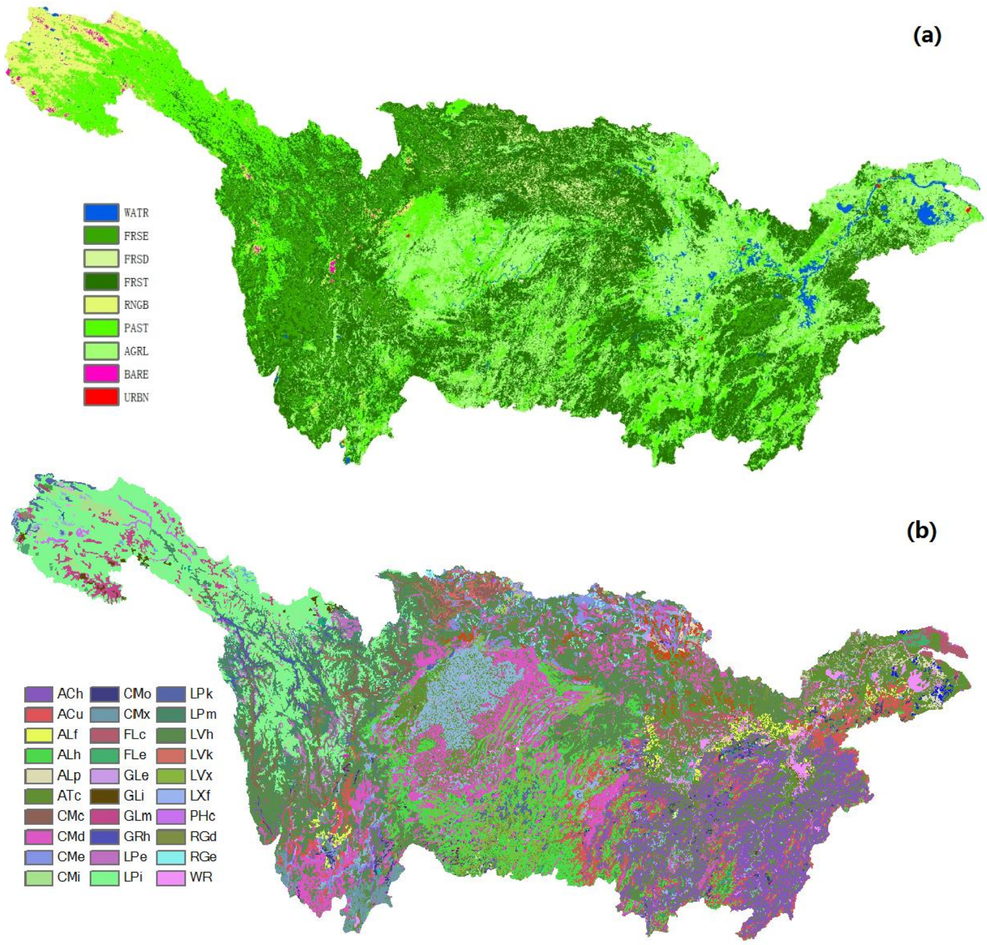

Figure 2. *Land use (a) and soil type data (b) for the YRB*

Hydro-meteorological data

Four main hydrological gauge stations (Cuntan, Yichang, Hankou, and Datong), which controls the runoff from different tributaries in the upper, middle and lower reaches of the YRB, were selected for measured streamflow data (*Figure 1*). Monthly streamflow were acquired for these four hydrological gauge stations for the time period 1981-2002 from the Bureau of Hydrology, Changjiang (Yangtze River) Water Resources Commission for China

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_36153632

(http://www.cjh.com.cn/). The GMS weather data covered over the YRB were downloaded for 1981 to 2005 from the China Meteorological Data Sharing Service System (http:// http://data.cma.cn/). Weather data for each station included observed daily precipitation, average temperature, minimum and maximum temperature, relative humidity, wind speed and direction and solar radiation data that were all the input data required for the hydrological model.

The CFSR weather data are produced using cutting-edge data assimilation techniques, (which reflects both conventional meteorological station observations and satellite irradiances) as well as highly advanced atmospheric, oceanic, and surface-modelling components. These data are available globally at an hourly time step since 1979. The CFSR dataset consists of hourly weather forecasts generated by the NCEP Global Forecast System of the U.S. National Weather Service. The horizontal resolution of the CFSR is ~38 km (Saha et al., 2010). CFSR data (precipitation, wind, relative humidity, and solar) over the YRB for the period of 1981 to 2005 were downloaded in SWAT file format (Dile and Srinivasan, 2014) from the website (https://globalweather.tamu.edu/). More than 2,000 CFSR gridded points were initially imported (*Figure 1*), and data for 69 points were selected automatically for the SWAT simulations based on the sub-basin delineations.

Model setup

The SWAT model, a river basin or watershed scale eco-hydrological model, was developed by United States Department of Agriculture (USDA) and Texas A & M University (Gassman et al., 2007; Williams et al., 2008). SWAT is able to predict water, sediment, nutrient, pesticide, and fecal bacteria yields using spatial distributed data on topography, soils, land cover, land management, and weather. The hydrological parameters are calculated by SWAT model based on the minimum research units, hydrologic response units (HRUs) which consist of homogeneous slope, land cover, and soil characteristics. Since SWAT has already been widely applied to watersheds around the world for stream flow simulation, it will also present sophisticated performance on the simulation in the YRB. One of the SWAT versions ArcSWAT 2009.93.3 integrated in ESRI ArcGIS 9.3 was used in this study which is one the major releases of SWAT version 2009.

In this study, the YRB was divided into 69 sub-basins and 613 HRUs according to land use, soil type and slope characteristics in the watershed. The performance of the SWAT model for the YRB was evaluated by the following three statistical indexes: The coefficient of determination (R^2), Nash-Sutcliffe Efficiency Coefficient (E_{NS}) and Percent bias (PBias) (Moriasi et al., 2007, 2015). In the period of sensitivity analysis, the Automated Sensitivity Analysis tool integrated in SWAT was applied to the YRB, which is based on the LH-OAT (Latin Hypercube Sampling-One at A Time) analysis method (van Griensven et al., 2006). SWAT usually must be calibrated before being applied to analyze the hydrology of a given watershed, considering the complex hydrological processes and limitations of the model (Gassman et al., 2007). Therefore, following a sensitivity analysis, model calibration was carried out and was executed using external SWAT-CUP software in which the SUFI-2 (Abbaspour et al., 2007) procedure was applied to calibrate SWAT in this study.

The SWAT parameter sensitivity analysis was initially conducted as a function of the GMS weather data, to compare the predicted streamflow for each hydrological gauge station to select the most sensitive parameters for hydrology prediction at each station. In order to maintain consistency, both the GMS- and CFSR-driven models were calibrated separately within SWAT-CUP at the four hydrological gauge stations (Cuntan, Yichang, Hankou and Datong). The parameters identified as being adjusted were based on the most

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_36153632

sensitive aspects of predicted hydrographs in comparison with observed monthly streamflow from 1981 to 1992, and the simulated results were validated with observed data from 1993 to 2002. The calibrated parameters in the GMS simulation were then applied in the CFSR-driven SWAT model in order to compare to the result of GMS simulation at the same condition. Finally, the CFSR-driven SWAT model was completely calibrated and validated to investigate the differences of the hydrological parameters and modelling results between the GMS- and CFSR-based models.

Results

CFSR Precipitation and temperature validation by GMS weather data

The CFSR data at grid points that involved in SWAT model computation was firstly validated by the GMS data including precipitation and maximum and minimum temperature. CFSR grid points near the GMSs Huize (2110 m.a.s.l. (meters above sea level)), Mianyang (522 m.a.s.l.), Badong (334 m.a.s.l.), Ji'an (78 m.a.s.l.) and Yuanling (143 m.a.s.l.) (Their locations can be found in *Figure 1*), which represent different elevations in this area, were selected to compare the precipitation and temperature between the two data sources.

The scatter plots of the monthly precipitation and the linear regression lines at Huize, Mianyang, Badong, Ji'an and Yuanling for the GMS versus CFSR weather data from 1981 to 2005 are shown in *Figure 3*.

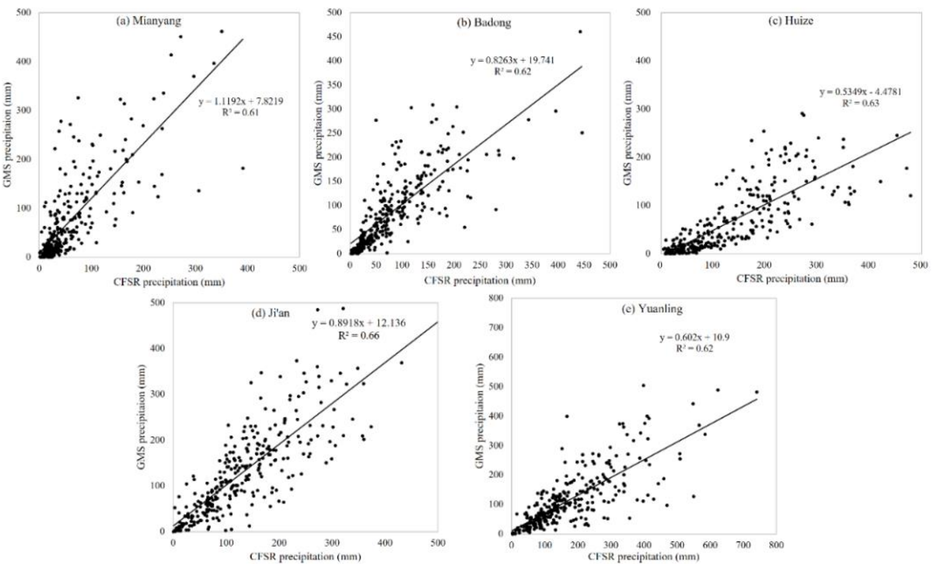

Figure 3. *Comparison of monthly precipitation between the CFSR and GMS climate data sources during 1981 to 2005 at: (a) Badong, (b) Mianyang, (c) Huize, (d) Ji'an, and (e) Yuanling meteorological stations*

The CFSR precipitation underestimated the GMS observed precipitation, based on the regression comparison for the Mianyang station. The precipitation was underestimated when it was < 113 mm and overestimated when > 113 mm. The most extreme underestimations of CFSR precipitation, as compared to the GMS data, occurred at the Huize station. The Huize station is located at much higher altitude than the Mianyang and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_36153632

Badong stations, which may be the reason for the greater discrepancy. According to the coefficient of the regression equation the accuracy of the estimated precipitation at the Mianyang station, which is characterized by high elevation, was lower than the computed accuracy for the Ji'an station. However, the R^2 between the GMS and CFSR monthly average precipitation was larger than 0.60 at all five meteorological stations from 1981 to 2005, which showed that the CFSR weather data provide sufficient accuracy to build the hydrological model.

To validate the CFSR temperature, the monthly average minimum and maximum temperature were calculated to compare with the corresponding GMS temperature. *Figure 4* shows the comparison between the monthly average minimum and maximum temperature at Mianyang, Badong, and Huize meteorological stations and corresponding CFSR grid points during 1981 to 2005. The CFSR monthly average minimum temperature was slightly underestimated at all five meteorological stations, especially at the Badong and Huize stations, although the R^2 at both meteorological stations was > 0.96. Both the monthly average maximum and minimum temperature was underestimated by the CFSR weather data at the Badong meteorological station, and the monthly average minimum temperature was underestimated at the Mianyang, Huize and Yuanling meteorological stations. However, the estimated temperature from the CFSR weather data was highly correlated with that from the GMS weather data, with an R^2 larger than 0.9 at all five meteorological stations.

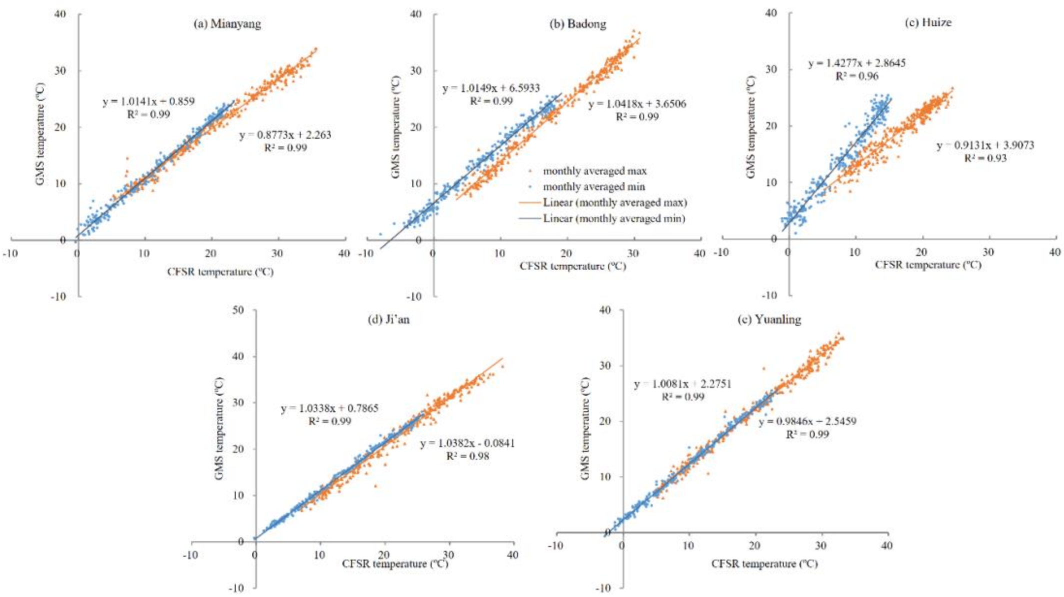

***Figure 4.** Comparison of the monthly average maximum and minimum temperature from the CFSR and GMS weather data at (a) Badong, (b) Mianyang, (c) Huize, (d) Ji'an and (e) Yuanling meteorological stations in the years 1981-2005*

Based on the validation of the CFSR weather data with the GMS weather data at these five representative meteorological stations from the year 1981 to 2005 in the YRB, the CFSR weather data have reasonable accuracy to represent the weather conditions occurring in the watershed. Therefore, to a certain degree, the CFSR weather datasets representing the weather occurring over the watershed are able to drive hydrological model.

Parameter sensitivity analysis and calibration in the GMS- and CFSR-driven models

To decrease model uncertainty, streamflow was calibrated at each of the four gauge stations. For each simulation, with models driven by GMS and CFSR weather data, parameter sensitivity analysis and parameter calibration were conducted at each gauge station separately. After sensitivity analysis was performed, the most sensitive parameters were selected as calibration parameters at each gauge station. In this study, the following parameters were calibrated in both models using SWAT-CUP: CN2, CH_K2, ESCO, CANMX, RCHRG_DP, ALPHA_BF, GW_DELAY, HRU_SLP, SLSUBBSN, SFTMP, and CH_N2 (their descriptions can be found in *Table 1*). According to the parameter calibration by SWAT-CUP, the values of the most sensitive parameters were determined in the different models. The most sensitive parameters calibrated in each simulation at each stations and their values are listed in *Table 1*.

Table 1. *Hydrological parameters calibrated during 1981 to 1992 in the SWAT models driven by GMS and CFSR weather data for simulations at different hydrological gauge stations*

Parameters	Parameter description	GMS-driven model				CFSR-driven model			
		Cuntan	Yichang	Hankou	Datong	Cuntan	Yichang	Hankou	Datong
CN2	runoff curve number for moisture condition II	94.00	89.00	97.87	35.00	87.00	87.50	82.55	44.38

Calibration and validation of the SWAT model driven by GMS weather data

The SWAT model for the YRB was firstly driven by GMS weather data. After parameter sensitivity analysis, the observed streamflow and simulated results at Cuntan, Yichang, Hankou and Datong hydrological gauge stations were presented during the calibration (1981-1992) and validation period (1993-2002) in *Figure 5*. For the calibration period, there was general agreement between the simulated and observed monthly streamflow from 1981 to 2002. From the evaluation indexes presented in *Table 2*, the R^2 are greater than 0.80, while the E_{NS} are greater than 0.70 during both calibration and validation periods. The results can be rated as "good" according to suggested performance ratings for a monthly time step (Moriasi et al., 2007, 2015). There were several months in which the peak simulated streamflow under predicted the observed peak streamflow at the Datong and Cuntan stations, respectively. In contrast, at Hankou and Cuntan stations, the peak simulated streamflow replicated the observed peak streamflow. There were fewer discrepancies of the peak streamflow between the simulated and observed data at Hankou and Datong stations than that at Cuntan and Yichang stations.

As the purpose of the study was to compare the performance of CFSR simulation in relation to conventional GMS simulation, all parameters calibrated in the GMS-driven

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_36153632

model were hold constant and used in the CFSR-driven model. The results from the CFSR-driven SWAT model with Calibrated parameters of GMS model (hereafter called CSWCG) were obtained. The observed streamflow was used to validate both modelling results: the results from the GMS and CSWCG simulations and the CSWCG results. The SWAT simulation with the GMS data generated good results for baseflow conditions, whereas the CFSR results replicated observed peak streamflow compared with the observed data, particularly at Hankou and Datong gauge stations. There were larger discrepancies between the observed and simulated results at Cuntan and Yichang gauge stations than at Hankou and Datong gauge stations. However, the evaluation indexes (*Table 2*) at Yichang gauge station were superior to that at Hankou and Datong stations in both the calibration and validation periods. From *Figure 5*, the simulated streamflow from CSWCG closely match peak streamflow for the lower reaches of the Yangtze River, which was demonstrated by the comparison of the simulated results and the observed streamflow at the four gauge stations in the upper, middle, and lower reaches of the Yangtze River.

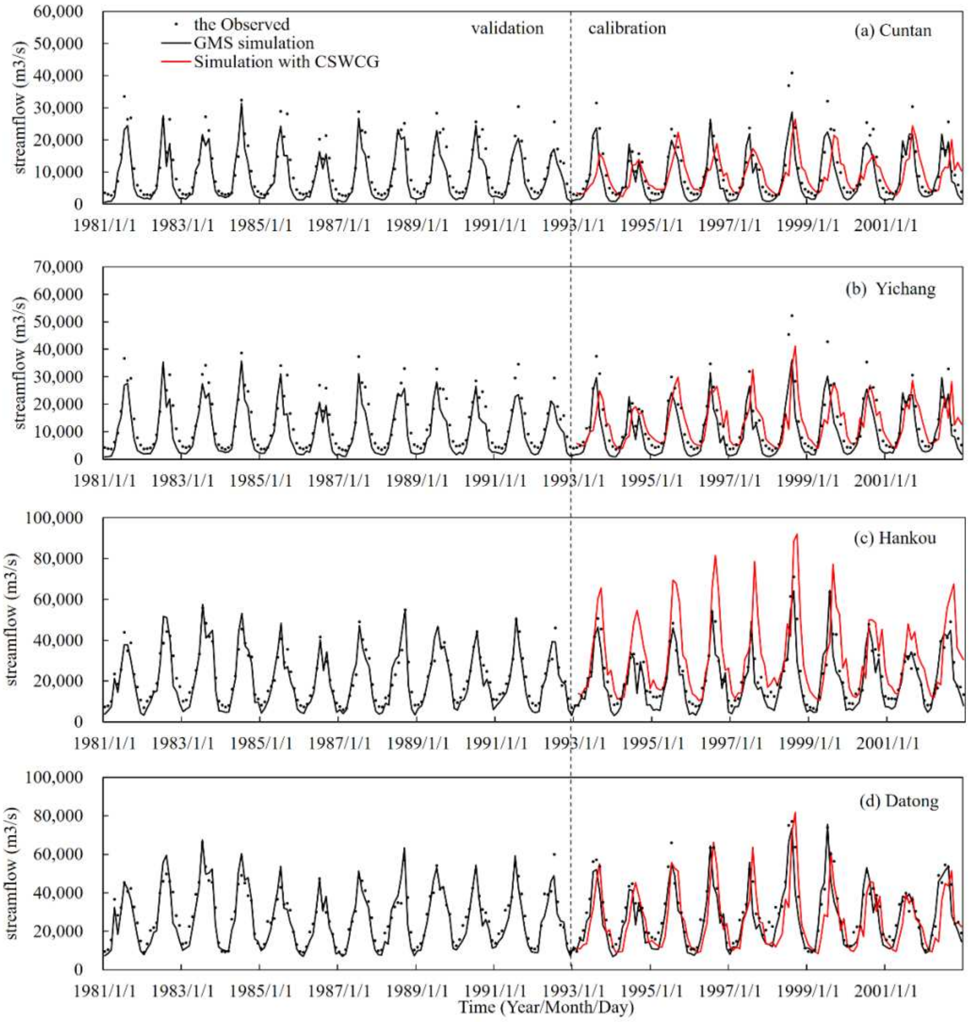

Figure 5. *Calibration (1981-1992) and validation (1993-2002) of the ground-based meteorological station (GMS) simulation and comparison to the results from the CFSR-driven SWAT model with calibrated parameter of GMS model (CSWCG) using the monthly observed streamflow at (a) Cuntan, (b) Yichang, (c) Hankou and (d) Datong gauge stations*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_36153632

Table 2. *Performance evaluation for the SWAT model driven by the ground-based meteorological station (GMS) weather data in the calibration and validation period and comparison to the results from the CFSR-driven SWAT model with calibrated parameters of GMS model (CSWCG)*

	Calibration			Validation			Validation of CSWCG		
	R^2	E_{NS}	PBias/%	R^2	E_{NS}	PBias/%	R^2	E_{NS}	PBias/%
Cuntan	0.91	0.81	23.30	0.83	0.73	24.44	0.78	0.71	11.22
Yichang	0.92	0.78	25.00	0.85	0.71	27.03	0.85	0.83	1.43
Hankou	0.92	0.76	6.00	0.88	0.82	12.5	0.89	0.82	-12.01
Datong	0.89	0.74	5.00	0.88	0.82	12.6	0.88	0.81	-5.82

To explicitly present the performance of the GMS simulation in the YRB, the evaluation indexes for the SWAT model driven by GMS weather data in the calibration and validation periods and comparison to the results from the CFSR simulation with calibrated parameters of GMS model (CSWCG) are listed in *Table 2*. The R^2 and E_{NS} were greater than 0.80 in both the calibration and validation periods except Cuntan station. The model underestimated streamflow at Cuntan and Yichang stations while overestimated at Hankou and Datong. The comparison between the observed data and the results from the CFSR simulation showed rather high accuracy, with R^2 and E_{NS} larger than 0.80, except that at Cuntan gauge station. As for the values of PBias, it is slightly underestimated at Yichang gauge station and overestimated at Hankou and Datong gauge stations. The E_{NS} and R^2 of the validation of the simulation with GMS data are all larger than 0.80, and PBias is less than 10%; therefore, the results in this validation period can be rated as "very good" according to the research on performance ratings for a monthly time step (Moriasi et al., 2007, 2015). However, the results of validation in CSWCG at Cuntan and Hankou gauge stations are rated as "good" because their absolute values of PBias are larger than 10%. The E_{NS} value is less than 0.75 only at Cuntan station, and it is "good" at Yichang and Datong gauge stations.

Calibration and validation of the SWAT model driven by CFSR weather data

The sufficiency of the modelling performance is highly dependent on the calibrated parameters. Therefore, it is necessary to investigate the performance of the SWAT model setup with CFSR global weather data in the YRB. The CFSR weather data were used to establish a SWAT model for the YRB, which was calibrated and validated in CFSR-driven SWAT model by the discharge data at Cuntan, Yichang, Hankou, and Datong hydrological gauge stations (*Figure 6*). From the tendency of monthly streamflow comparison from 1981 to 2002, the simulated results from the CFSR-driven SWAT model fit closely to the observed data, especially at Hankou and Datong gauge stations, with E_{NS} and R^2 greater than 0.75. The simulated baseflow closely matched observed, and there was little discrepancy between the peak streamflow, especially in July and August of 1998, during which heavy floods occurred along the Yangtze River. The daily discharge of 87,000 m^3/s, with the largest water level in history, was recorded at Datong gauge station on July 27, 1998, and exceeded the average monthly discharge of 56,800 m^3/s in the wet season. From the validation of the CFSR precipitation data at Huize, Mianyang and Badong stations, the CFSR precipitation was underestimated in the period of heavier rainfall especially at the peak rainfall at Huize and Mianyang station compared with the GMS observation. The underestimated precipitation in the upper reaches with higher elevation led to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_36153632

difficulty to reach the observed peak streamflow. The simulated peak streamflow nearly reached the observation at Hankou and Datong gauge stations in the middle and lower reaches of the Yangtze River. From the illustration of the *Figure 6*, the CFSR-driven SWAT model driven matches the observations in the lower streamflow period for the whole area and generates better results in the middle and lower reaches of the Yangtze River than in the upper reaches, because the CFSR precipitation has better accuracy for representing weather occurring in the middle and lower reaches than in the upper reaches of the Yangtze River basin.

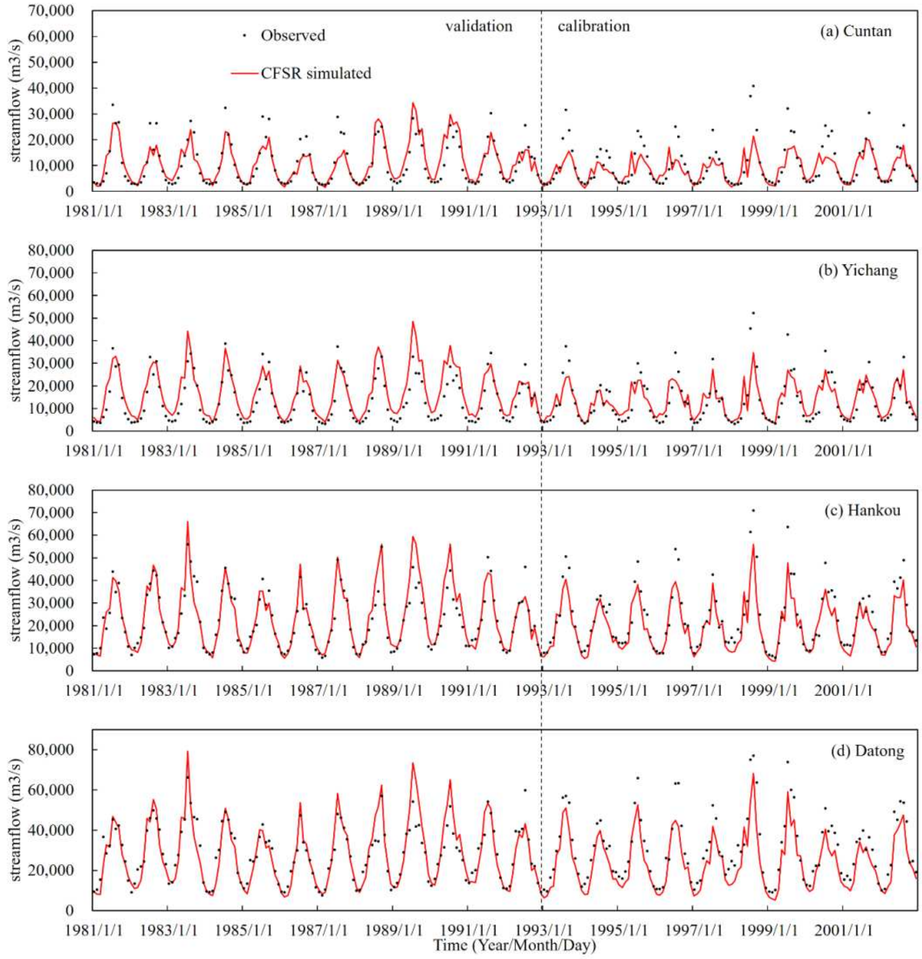

Figure 6. *The Climate Forecast System Reanalysis (CFSR) driven SWAT model calibration (1981-1992) and validation (1993-2002) using monthly observed streamflow at (a) Cuntan, (b) Yichang, (c) Hankou, and (d) Datong gauge stations from 1981 to 2002*
