Time-activity budget studies of wintering waterbirds give information about seasonal microhabitat selection and the influence of hunting pressure, habitat alteration and other threats on behaviour (Poulton et al., 2002; Michot et al., 2006; Crook et al., 2009). In this manner, such studies can be used to evaluate habitat quality and quantity, to compare activity patterns of populations in different geographic regions and contribute to wetland management or species conservation plans (Woodin and Michot, 2006).

Whooper swan (*Cygnus cygnus*) is mainly a winter visitor species to Europe and Turkey. Except reproduction period, they migrate in small flocks and congregating into flocks of up to 300-400 individuals in the winter (Johnsgard, 1978; Madge and Burn, 1988). The overall population trend is uncertain. Population size in Europe is estimated at between 25300-32800 pairs and the status is shown as “LC” in the IUCN category (Anonymous, 2015a). A limited number of studies about the Turkey population of the whooper swan indicate that the species has been wintering in the Van Lake Basin since the early 1990s. The species arrives to the basin from the beginning of the winter and stays at the basin until the beginning of spring and then leaves. Depending on the year,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_21792185

the population size of the species wintering at Van Lake Basin ranges between 50-240 individuals (Adızel, 1995; Adızel et al., 2010; Azizoğlu et al., 2016, 2017; Çelik et al., 2016). In recent years, the number of individuals wintering in the Basin has increased while there is a lack of data about behaviour pattern of the species. The aim of this study was to determine the daily behaviour of a colony of whooper swan wintering in the Van Lake Basin.

Materials and methods

Study area

This research was carried out at Göründü Delta (38.328637° N, 42.927174° E) in the southern part of Van Lake. Göründü Delta that located on the 58th km of Van-Bitlis highway, is a wetland with 124 ha (*Fig. 1*). The delta, 1648 m in altitude and 5 km^2 in width, is an internationally important wetland that hosts large numbers of migratory and the resident waterbirds (Anonymous, 2015b; Aşur, 2017). In recent years, one of the unique habitats where the whooper swans were wintering in the eastern of Turkey is the Göründü Delta.

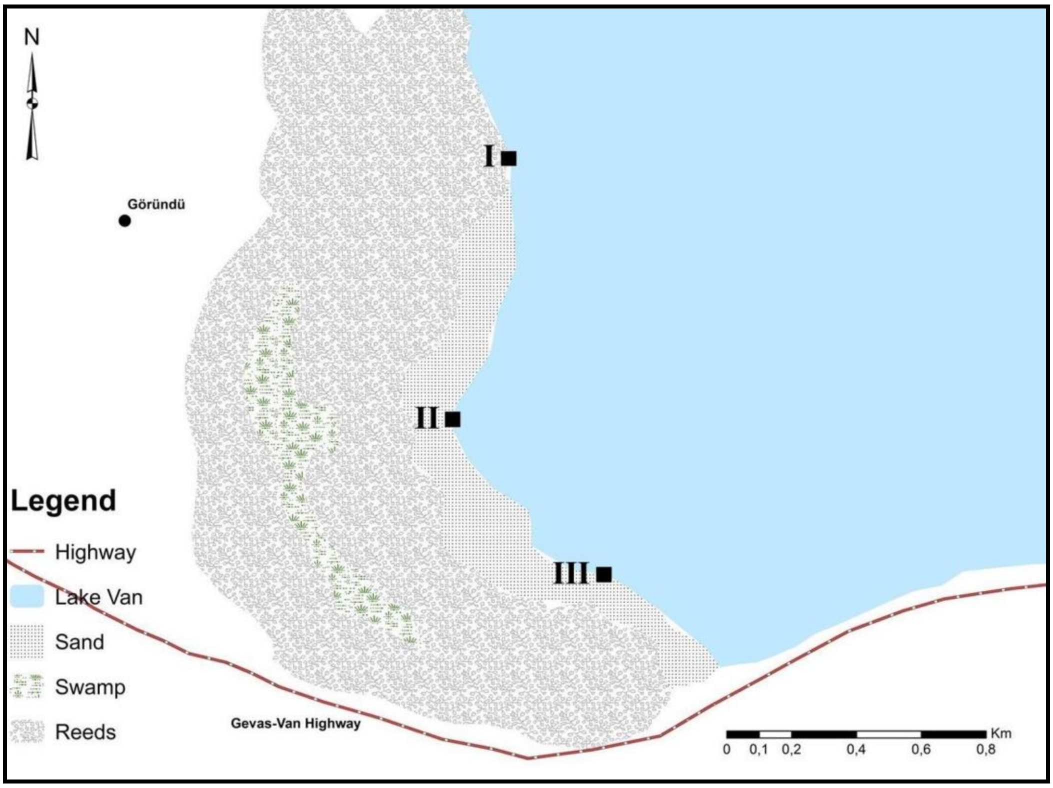

Figure 1. *Observation points at Göründü Delta*

Behavioural observations

In order to identify the wintering behaviour of whooper swan, observations were conducted between November 2015 and March 2016 on days without precipitation or strong wind. During this study period, a total of 70 days between November and March were used for diurnal observations.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_21792185

Scan sampling and focal sampling methods were used to evaluate different daily wintering behaviour of adults and juveniles (Altmann, 1974). The observations started in the morning before sunrise (06:00) and continued until sunset (17:00). This period was divided into 3 equal parts as morning (06:00-08:30), midday (08:30-13:30) and late day (13:30-17:00) with equal numbers of focal sample observations within them. Scan samplings were made at the beginning of each period to assess the total number of birds. When using this method, the behaviour of all individuals in a flock were recorded at predetermined time intervals during the daytime hours. In total 1540 observation sessions and 192.2 h of scanning were performed. Six main activities of whooper swan were evaluated in this study: resting, feeding, preening, swimming, flying and moving on land. In the determination of the behaviours, random focus observation method was used. The instantaneous behaviour of each individual in a flock with 90 individuals was recorded with a telescope in half-hour intervals. After scanning maximum 30 individuals, other individuals were evaluated as second and third groups. The scanning started from the first individual and continued towards left until the last individual. We quantified time-activity budgets by calculating the proportion of time spent in each behaviour for each focal sample.

Statistical analysis

The statistical software SPSS 20 was used to perform all statistical analyses. We identified diurnal period and winter period differences with ANOVA.

Results and discussion

During the five months of survey, daily activities of a whooper swan showed a major variation which occurred majorly due to the hydrobiological condition and ecological status of the coastal area. We detected that in winter season the whooper swans spent most of the time by resting (55%) and the rest by feeding (12.48%), preening (10.98%), walking on land (8.94%), swimming (7.73%) and flying (4.87%) (*Fig. 2*).

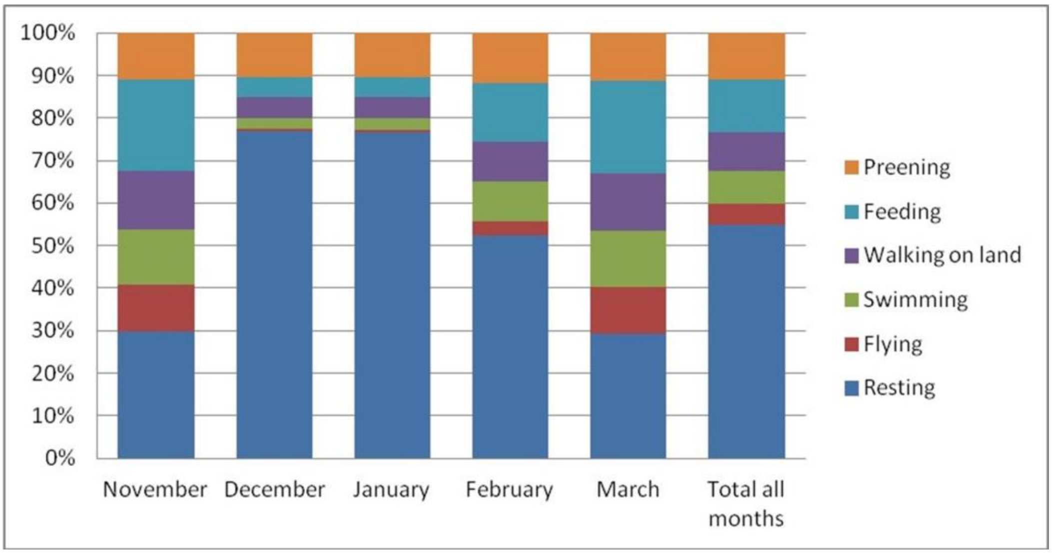

Figure 2. *The percentage of time spent to the activities by whooper swan at different parts of winter time (monthly and in total)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_21792185

Resting, feeding and preening were the main diurnal activities. Resting peaked in midday while feeding was observed frequently in morning and late afternoon (*Table 1*). The feeding pattern recorded was similar to patterns recorded earlier studies of swans (Tatu et al., 2007; Peihao et al., 2011).

Table 1. *Mean percentage of winter-time diurnal activities of the whooper swan in different time periods of the day*

Behaviour	**Morning (06:00-8:30) n: 43.45h**	**Midday (08:30-13:30) n: 87.5h**	**Late day (13:30-17:00) n: 61.25h**	**Overall**
Resting	41.8	62.9	60.3	55
Feeding	27.1	7.8	2.54	12.48
Preening	11.39	10.6	10.95	10.98
Walking on land	8.82	6.2	11.8	8.94
Swimming	7.25	6.74	9.2	7.73
Flying	3.64	5.76	5.21	4.87

n: observed hour

Temperature at a wintering site is an important determinant of the waterbirds' time budgets (Guillemain et al., 2002). The temperature averages according to the months were; November (4.4 °C ± 0.2), December (-2 °C ± 0.3), January (-3 °C ± 0.3), February (-4 °C ± 0.2) and March (-1 °C ± 0.4). The higher average temperature in November and March compared to the temperature average of December, January and February, affected the activities of the species. Resting activity in December, January and February was significantly higher whereas more time was spent on feeding activity in November and March ($P < 0.05$) (*Fig. 2*).

In this study, we detected that mean percentage of time spent to feeding activity was similar in November and March and the resting was similar in December and January. It was identified that all the activities in February shows temporal differences with the activities in the other months (*Table 2*).

Table 2. *Statistical analysis of the monthly activity budgets of whooper swan*

*$P < 0.05$, n: individual number

When the activities of the species in November and March were considered, we revealed that diurnal activities as flying, swimming and moving on land were similar within themselves ([a]) ($P < 0.05$), feeding and resting were homogeneous within

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_21792185

themselves ([c]) ($P < 0.05$). Preening was totally different from feeding and resting. However it was similar with the other activities ([a,b]) ($P < 0.05$). When daily activities in December and January were considered, feeding and resting were similar with themselves ([a]), while flying, swimming and on land movement were showing similarities within themselves ([c]). The preening activity was independent from both groups ([b]) ($P < 0.05$). In February all diurnal activities were similar with each other except preening (*Table 2*).

Results of our work confirm the findings by Squires and Anderson (1997) that swans spent more time resting as winter temperatures decreased. Percent of time spent on different daily activities differed significantly between day periods in mild and severe winter (*Fig. 2*). They spent the most of severe winter period inactive, apparently relaying on accumulated energetic reserves. Increasing energetic expenditure in the period of low temperatures is often compensated through more intensive and longer foraging (Guillemain et al., 2002; Meissner and Ciopcinska, 2007). However, during the harshest winter weather observation period in the Göründü Delta whooper swans reduced all daily activities primarily foraging and feeding. They spend less time on locomotion, but the most striking difference concerned feeding time. In December, January and February where the air temperature is the lowest -17 (average -4), the resting ratio is about 76%, and this ratio decreases 29% in November and March.

Despite lower air temperature in late winter period (in February), whooper swans had increased the total feeding time and they were more active. Because they had to store energy and increase fat reserves before the long migration period. At the same time they begin getting the nutrient reserves required for reproduction.

Black et al. (2010) indicated that 44.9% of the daily activities of the Tundra swan (*Cygnus columbianus*) in the Eel River Delta were related to the foraging activities. Rees and Bowler (1991) reported a similar proportion of 48.4% feeding in swan flocks in England in late winter/spring period. According to our results, daily foraging activities of whooper swans were decreased in the late winter period but lower than these rates. We think that the most important reason for this situation is low nutrient density, food availability and different climatic conditions in Göründü Delta.

Laubek et al. (1999) pointed out that the whooper swans use open water surface while performing their daily activities during the winter months. Similarly, we observed that the whooper swans were performed almost all their daily activity in water.

Conclusion

In the Göründü Delta where ducks winter in high density, whooper swans spent most of the brief severe winter period almost inactive, probably relying on accumulated energetic reserves. Diet of whooper swans mostly consist of aquatic plants such as *Algae* sp., *Chara* sp. and *Zostera* sp (Brazil, 1981; Del Hoyo, 1992; Kantrud, 1990; Squires and Anderson, 1995). Since the study area is associated with Van Lake and has soda-water, it is poor in terms of water plants. This factor reduces the feeding time of the species. The whooper swans were feeding in shallow water line and reeds. The caloric value in aquatic plants is lower than in terrestrial plants (Dourado et al., 2004). During the winter the species is known also to feed on agricultural land and takes agricultural grain (Brazil, 2003). Nevertheless, grazing on land was observed just a few times only in March. Intensive hunting pressure in the field is the most important reason for this situation. More comprehensive studies about whooper swans' winter food

DOI: http://dx.doi.org/10.15666/aeer/1702_21792185

supply and nutritional diversity would help to inform habitat management and protection for the swans.

Abstract. A field experiment was conducted to evaluate the efficiency of foliar application of different concentrations of Se fertilization (37.50, 56.25, 75.00, 93.75, and 112.50 g ha^{-1} of Se) at the early grain filling stage on nutritional quality of colored-grain wheat. The results showed that Se plays a role in influencing the nutrients concentration of colored-grain wheat. When it was more than 75.00 g ha^{-1}, the Se concentration in the common wheat was excessive. However, when it was more than 37.50 g ha^{-1}, the Se concentration in the colored-grain wheat was excessive, indicating that colored-grain wheat was likely to be more sensitive to Se accumulation. Se concentration of colored-grain wheat was significantly increased under the optimal foliar application of Se concentration at 37.5 g ha^{-1}, decreased starch concentration, without affecting the yield. Particularly, the concentrations of gliadin and glutenin were significantly increased while both albumin and globulin were reduced with the increased Se concentration. Additionally, our research showed that foliar application Se increased the concentration of iron (Fe), zinc (Zn), but decreased the concentration of copper (Cu) and manganese (Mn). More importantly, the intake of Se promoted the production of amino acids and anthocyanins. This indicates the potential roles Se plays on regulating nutrition value in colored-grain wheat.

Introduction

Hidden hunger or micronutrient deficiency occurs when the food quality does not meet the requirements of essential nutrient need for the growth and development of humans. The main cause of hidden hunger is the deficiency of minerals (for examples, selenium, zinc, iron, and iodine), lack of vitamins in diet, and large consumption of staple food (wheat, rice, and maize) which lack these nutrients (Zhao et al., 2016). Hidden hunger is affecting approximately 2 billion people around the world including 300 million people in China (Toppe and Chomo, 2015; Kennedy et al., 2003; Maberly et al., 1994). Many chronic diseases, including diabetes, cardiovascular disease, cancer, and obesity were linked to the imbalance or deficiency of nutrient intake.

Selenium (Se) is an essential trace element for humans and animals. Numerous previous studies have proven it is beneficial to plants, however, it is considered non-essential for plant growth and development. Se plays an important role in the growth, development, and maintenance of the immune system of human and animals (Shenkin, 2006; Yadav et al., 2005; Speckmann and Grune, 2015). Se deficiency in the human body could cause about 40 kinds of diseases, such as Keshan and Kashin-Beck diseases (Tan et al., 2002; Zhang et al., 2014; Fernandes and Gandin, 2015; Chen et al., 2012; Kolesnikova et al., 2015). In 1982, it was reported that almost 72% of regions in China are facing the Se deficiency and about two-thirds of the population are experiencing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_21872202

deficiency of Se intake. Thus, the biofortification technology for increasing Se concentration in food crop has been paid more and more attentions by many researchers (Ma et al., 2008; Khanam and Platel, 2016).

Fertilization is short term and an effective method for improving micronutrient concentrations in food crop (Zhao and McGrath, 2009; Welch, 2008). Se fertilization is applied in soil and/or as a foliar application (Wang et al., 2017). Foliar fertilization is the most effective and safest way to increase the absorption of essential micronutrients in grain. Wheat is the most popular cereal crops worldwide and is a staple food for nearly half of the population in China where more than 85% of wheat is consumed as flour-derived products (Shewry, 2009; Li, 2006). Therefore, increasing Se nutrition in wheat grain is of the utmost importance when it comes to improving the nutritional status of people in China and other countries (Liu, 2007). In Hungary, colored-grain wheat cultivars are less known in contrast to East-Africa, New Zealand, Canada, and China, for example, where such forms occur in cultivated varieties (Varga et al., 2013). Wheat varieties with special colored-grain such as blue and purple grains had been proven to be rich in protein, amino acids, and trace elements or minerals (Zeven, 1991). It is well known that anthocyanins are functioning as antioxidants and, in addition, they also have anti-carcinogenic effects. Similarly, Se has anti-carcinogenic capabilities. Because of these health benefits, the combination of colored-grain wheat and Se is more beneficial to the development of food industry. Thus, colored-grain wheat is considered to be beneficial to the human body due to their high nutritional value and has become a special raw material for food industry (He et al., 2012). In addition, it was reported that colored-grain wheat was richer in Se than common wheat, suggesting a practical way to solve Se deficiency (Shi, 2006).

At present, there is little known about the enhancement of trace elements in colored-grain wheat and Se-enriched colored-grain wheat has not been fully utilized. The purpose of this study is to evaluate the effect of biofortification of Se in colored-grain wheat in Se deficient region of Northern China. In the present study, field experiment was conducted to (i) investigate the uptake of Se concentration in grains from three different varieties of colored-grain winter wheat in the middle area of Shanxi province in China, (ii) evaluate the effect of foliar applications of Se on yield, protein concentration, the concentration of Se and other minerals, starch and amino acid concentration of the grain, and (iii) examine the relationship between Se and anthocyanin.

Materials and methods

Field site description

The field experiment was carried out from September 2016 to June 2017 in an experimental site at Shanxi Agricultural University, Taigu (37°42’ N, 112°58’ E), Shanxi province, China (*Fig. 1*). The altitude of field experiment was 767-900 m, belong to the warm temperate zone continental climate, average annual precipitation was 450 mm, average temperature was 10 °C and average frost-free period is 160-190 d. The experimental field was plain and water land, planting one crop a year. There were four distinctive seasons. Soil samples were collected from the surface layer with a depth of 0-20 cm and the initial nutrient indices of the sampling soil were analyzed as follows: organic matter: 12.6 g kg^{-1}; total nitrogen: 1.8 g kg^{-1}; alkali-hydrolyzable nitrogen: 53.6 mg kg^{-1}; available phosphorus: 9.6 mg kg^{-1}; exchangeable potassium:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_21872202

137.5 mg kg^{-1}; total Se: 0.171 mg kg^{-1} and available zinc: 4.375 mg kg^{-1}. Above mentioned indices were measured using the methods of potassium dichromate volumetric, Kjeldahl determination, alkali-hydrolyzable proliferation, sodium bicarbonate extraction, ammonium acetate flame photometric, hydride generation atomic fluorescence spectrometry, and concentrations of DTPA-extractable micronutrients respectively.

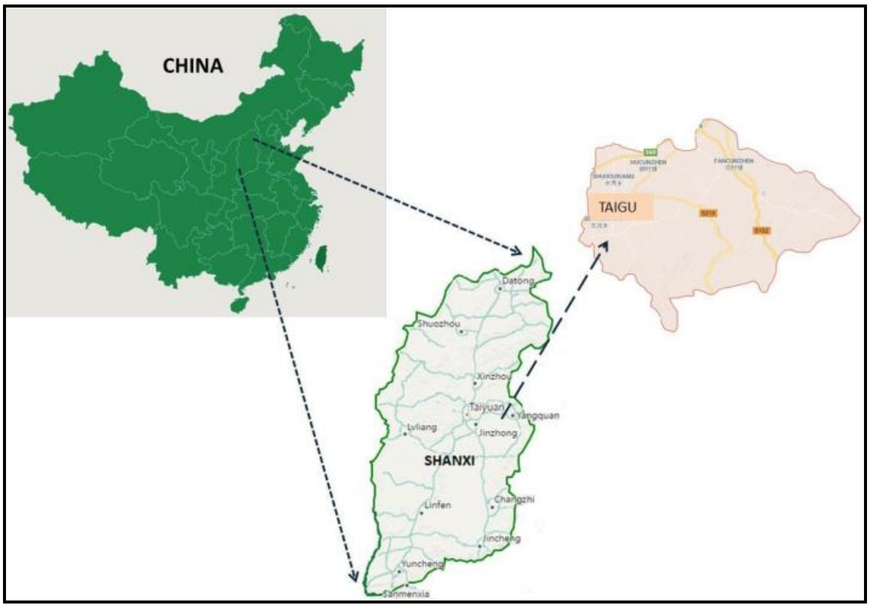

Figure 1. *Map of experimental region in China*

Experimental design

Two factors split plot design was used to optimize Se foliar fertilization content of colored-grain wheat by taking cultivars as a main factor and Se concentrations as a subplot factor. Three winter wheat cultivar Shannong 1 (purple), Shannong 031244 (blue), and Shannong 129 (white) were used in the experiment, among which Shannong 1 and Shannong 031244 were colored-grain wheat cultivar, while Shannong 129 was common wheat. Shannong 1 has a plant height of 60 ~ 70 cm, compact plant type, neat tiller, high heading rate, long awn, purple seed coat and rapid grouting. Shannong 031244 has a plant height of 80 ~ 90 cm, compact plant type, neat tiller, high heading rate, long awn, purple seed coat and rapid grouting. Shannong 129 has a plant height of 70 ~ 80 cm, compact plant type, neat tiller, high heading rate, long awn, white seed coat and rapid grouting. Se was added in the form of Na_2SeO_3 at rates of 0 (control), 37.50 g ha^{-1}, 56.25 g ha^{-1}, 75.00 g ha^{-1}, 93.75 g ha^{-1}, and 112.50 g ha^{-1} respectively. The six concentrations of Na_2SeO_3 were diluted with distilled water. A handheld compression sprayer was used to spray foliar fertilizer uniformly and about 750 L ha^{-1} solution was sprayed once. Wheat seeds were sown on September 30, 2016 at a sowing density of 600×10^4 plant ha^{-1} and row spacing of 20 cm. At the grain filling stage of winter wheat (May 20, 2017), each cultivar was sprayed with Se. No rainfall occurred after the spray. The plot sprayed with the same amount of distilled water was taken as the control. The harvest time was June 16, 2017. Each treatment was repeated three times. There were 54 plots in total. Area of each plot was 4 m^2 (2 m × 2 m) and total area was 216 m^2. Before sowing, 750 kg ha^{-1} of NPK compound fertilizer (N: P_2O_5: K_2O = 18%: 22%: 5%) was applied as a based fertilizer. Other field management measures (such as irrigation and weed maintenance) were carried out as common practices (*Fig. 2*).

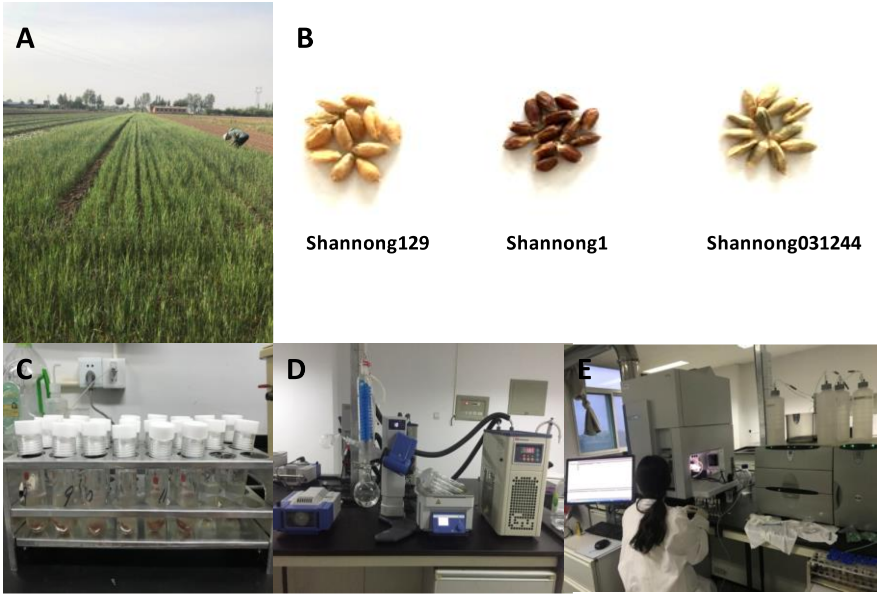

Figure 2. *Sampling sites for indices analysis at Shanxi province, China*

Se and minerals analysis

Wheat was harvested at full maturity stage to determine the yield as well as the contents of Se and minerals in grains. After determination of the yield, the obtained grain samples were washed carefully and rapidly with distilled water, and then dried at 65 °C for 10 h, grinded and sieved. The obtained flour samples were used to investigate the contents of total Se, minerals, protein, and the components. The flour samples were digested by using a HNO_3-H_2O_2 mixture in an alimentary furnace reaction system (LWY84B, China), and then the concentration of Se and minerals were measured by using an inductively coupled plasma mass spectrometer (ICP-MS, Agilent 7700x; Agilent Technologies, USA) (*Fig. 2*).

Protein and starch analysis

The flour protein and its components were measured using Kjeldahl nitrogen method (He, 1985). Amylasein and amylopectin were determined by dual wavelength method. The sum of the amylasein and amylopectin is the total starch.

Amino acids and anthocyanin analysis

The hydrolyzed samples were analyzed according to the national food safety standard of the China (GB5009.124-2016). The grain were dried, crushe and sieved (< 0.15 mm), which was weighed and put in the hydrolysis tube. First, 10 mL HCl and phenol (3-4 drops) were added. Second, the hydrolysis tube was put into the refrigerant (3-5 min) and attached to the suction pipe of the vacuum pump and fill nitrogen (fill

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_21872202

nitrogen three times). After that the hydrolysis tube was sealed and put in thermostat (110 °C, 22 h). The hydrolysate was filtered into a 50 mL volumetric flask and constanted to the scale. The filtrate was put into the test tube. In a test tube enrichment apparatus decompression drying in 48 °C heating environment. The dried residue was dissolved by water. Then the solution was vacuumed and dried again and until the top up. Finally, the buffer solution of pH 2.2 sodium citrate was added to the test tube. The solution is to be measured passing through 0.22 nm membrane. Amino acid samples were separated by ion exchange chromatography and measured using the automatic amino acid analyzer (model Biochrom 30+, England). The anthocyanin analysis using pH differential method (Siriwoharn et al., 2004) (*Fig. 2*).

Statistical analysis

The experiment was laid out in a two factors split plot design with three parallel measurements. The data were subjected to a separate analysis of variance (ANOVA) for each cultivar, and the Tukey's multiple range test at $p < 0.05$ was used to determine differences between treatment means. The Pearson correlation procedure and general line regression model was used to evaluate the relationship between grain Se and anthocyanin. SAS software (SAS 8.0, USA) was used for all analyses.

Results

Grain yield and Se concentration

To evaluate the effects of foliar application of Se fertilizer to the grain yield and Se concentration in grains, we conducted the ANOVA analyses on the grain yield, concentration of the grain total Se and grain Se cumulant. The grain yield and Se analysis carried out on the experimental field with the colored-grain wheat showed foliar application of Se fertilizer at different concentrations did not significantly affect the yield of colored-grains ($p > 0.05$, *Table 1*). The grain yield of Shannong 1 and Shannong 031244 were higher than Shannong 129.

Nevertheless, there were significant effects of the total Se and Se cumulant of three wheat varieties ($p < 0.05$). The total Se and Se cumulant of three wheat varieties were increased significantly with the increase the concentration of foliar Se fertilizer. By the foliar application of the same concentrations of Se at grain filling stage of different colored-grain wheat, results of the total Se and Se cumulant showed colored-grain wheat (Shannong 031244 and Shannong 1) > common-grain wheat (Shannong 129). Compared to the grain Se concentration in the untreated control, the concentration of added Se increased by up to 18-fold at the maximum Se application of Shannong 129. However, it increased up to 10-fold and 8-fold in the colored-grain wheat (Shannong 031244 and Shannong 1) respectively. It indicated that the wheat grain had strong ability to concentrate exogenous Se under the condition of foliar application. Although there was a increase between the total Se concentration and the amount of Se applied in the grain, the utilization rate of Se decreased with the increase of the concentration of foliar Se fertilizer. When the concentration of foliar Se fertilizer was 37.50 g ha^{-1}, utilization rate of Se reached the maximum, with the pattern of (Shannong 031244 and Shannong 1) > common-grain wheat (Shannong 129) displayed in three wheat varieties. According to the National Food Safety Standard in China, Se concentration in Se-enriched wheat was prescribed in the range of 0.15-0.30 mg kg^{-1} (GB/T 22499-2008,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_21872202

China). When it was more than 0.30 mg kg^{-1}, the high concentration could be unhealthy for humans. The Se concentration in the grain of common wheat was over the above range when foliar application of Se concentration greater than 75.00 g ha^{-1}. However, when foliar application of Se concentration was more than 37.50 g ha^{-1}, the Se concentration in the colored-grain wheat was excessive. The results indicated that colored-grain wheat was more sensitive to Se accumulation.

Table 1. *Grain yield and Se concentration of colored-grain wheat affected by the different concentrations of Se fertilization*

Treatments		**Selenium (g·ha^{-1})**

Values were means of three replicates. Different line lowercase letters (a, b, c, d, e, f) indicated significant differences among Se treatments, at p < 0.05 in Tukey test. Different column uppercase letters (A, B, C) indicated significant differences among cus, at p < 0.05 in Tukey test

Minerals concentration

To further understand the effects of different concentrations of Se on colored-wheat grains, the concentration of mineral elements in colored-grain wheat are analyzed and shown in *Figure 3*. The concentration of mineral elements in colored-wheat grains was higher than that in common wheat, indicating that the nutritional value of colored-wheat was higher than that of common wheat. After leaves were sprayed with Se concentrations of 37.50 g ha^{-1}, the concentration of Iron (Fe) in Shannong 1 and Shannong 031244 were significantly increased by 1.2-fold and 0.7-fold, respectively (p < 0. 05), the concentration of Zinc (Zn) in Shannong 1 and Shannong 031244 were significantly increased by 1.2-fold and 0.7-fold, respectively ($p < 0.05$). The concentration of Fe and Zn decreased but it was still hiher than the control value with the increase of Se concentration in foliar fertilizer. This indicates that the change of Fe and Zn in wheat grain presents a trend, which was low concentration promoted and high concentration inhibited by Se application. However, the supply of Se would inhibit the production of Copper (Cu) and Manganese (Mn). The decreased concentration range of Cu and Mn of all wheat were the same, indicating that the concentration variations of Cu and Mn of wheat grains were only affected by Se concentration other than wheat

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_21872202

varieties. Overall, the results showed that the sensitivity of mineral concentration to Se in common wheat was lower than that of colored-grain wheat. The sensitivity of Se showed different in two colored-grain wheat, and purple wheat more sensitive than the blue one.

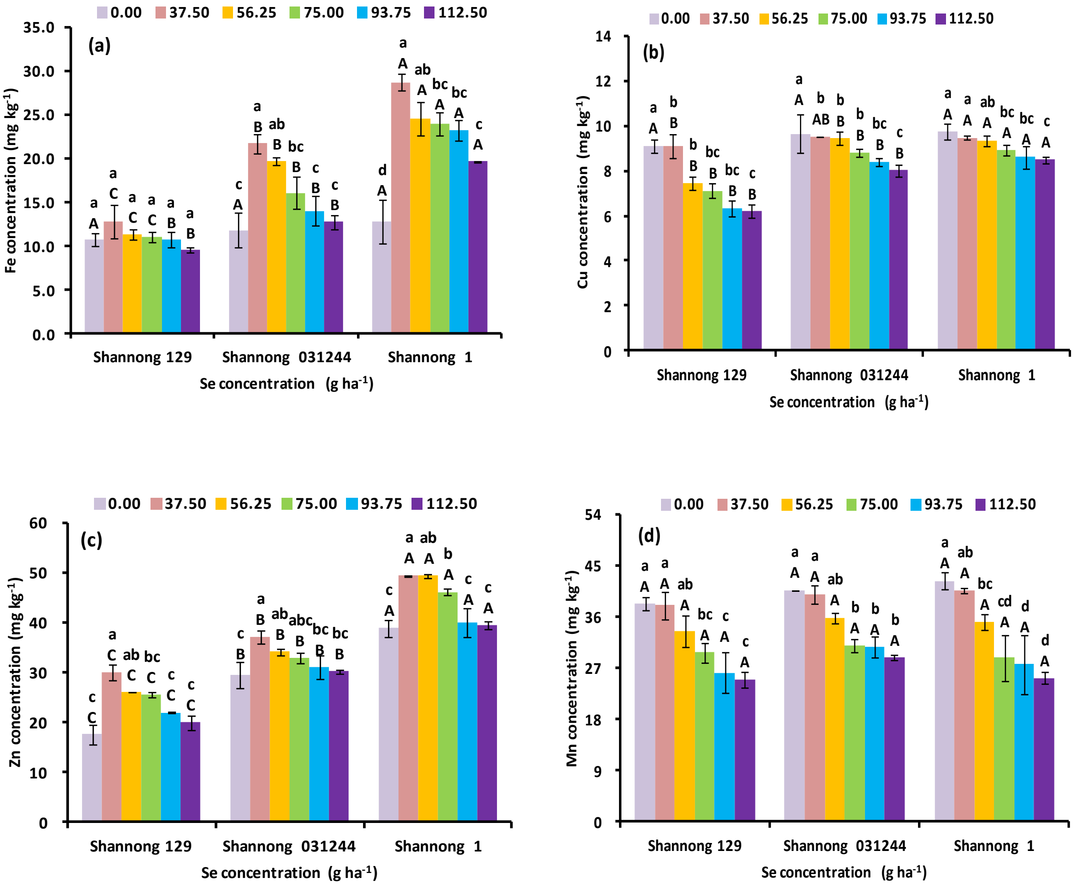

Figure 3. *Minerals in grains of colored-grain wheat cultivar under foliar application of Se. X axes show the concentrations of Se. Y axes show the concentrations of different minerals. Values were means of three replicates. The subfigures (a-d) show the concentrations of Fe, Cu, Zn and Mn, respectively. Different line lowercase letters (a, b, c, d) indicated significant differences among Se treatments, at p < 0.05 in Tukey test. Different column uppercase letters (A, B, C) indicated significant differences among cultivars, at p < 0.05 in Tukey test.*

Concentration of total protein, protein components

The concentrations of total protein and protein components showed significant changes within colored-grain wheat (*Fig. 4*, $p < 0.05$). Overall, total protein concentration was significantly lower in Shannong 129 than in Shannong 031244 without Se ($p < 0.05$). The concentration of total protein increased with the increase the concentration of foliar Se fertilizer. The concentration of albumin and globulin were increased, however, which concentration Se increase amplitude gradually decreased with the increase the concentration of foliar Se fertilizer with the foliar application of 37.5 g ha^{-1} which decreased at higher concentrations of Se, while gliadin and glutenin concentration s were increased in all wheat cultivar with increased concentrations of Se ($p < 0.05$). The highest gliadin and glutenin concentration was found at the highest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_21872202

concentration of Se. Glutenin concentration of colored-grain wheat (Shannong 1, Shannong 031244) was significantly higher than common wheat (Shannong 129); however, the concentration of albumin was highest in common wheat (Shannong 129). This indicates that the effect of foliar Se was significantly different for cultivar in terms of the protein components and total protein concentration.

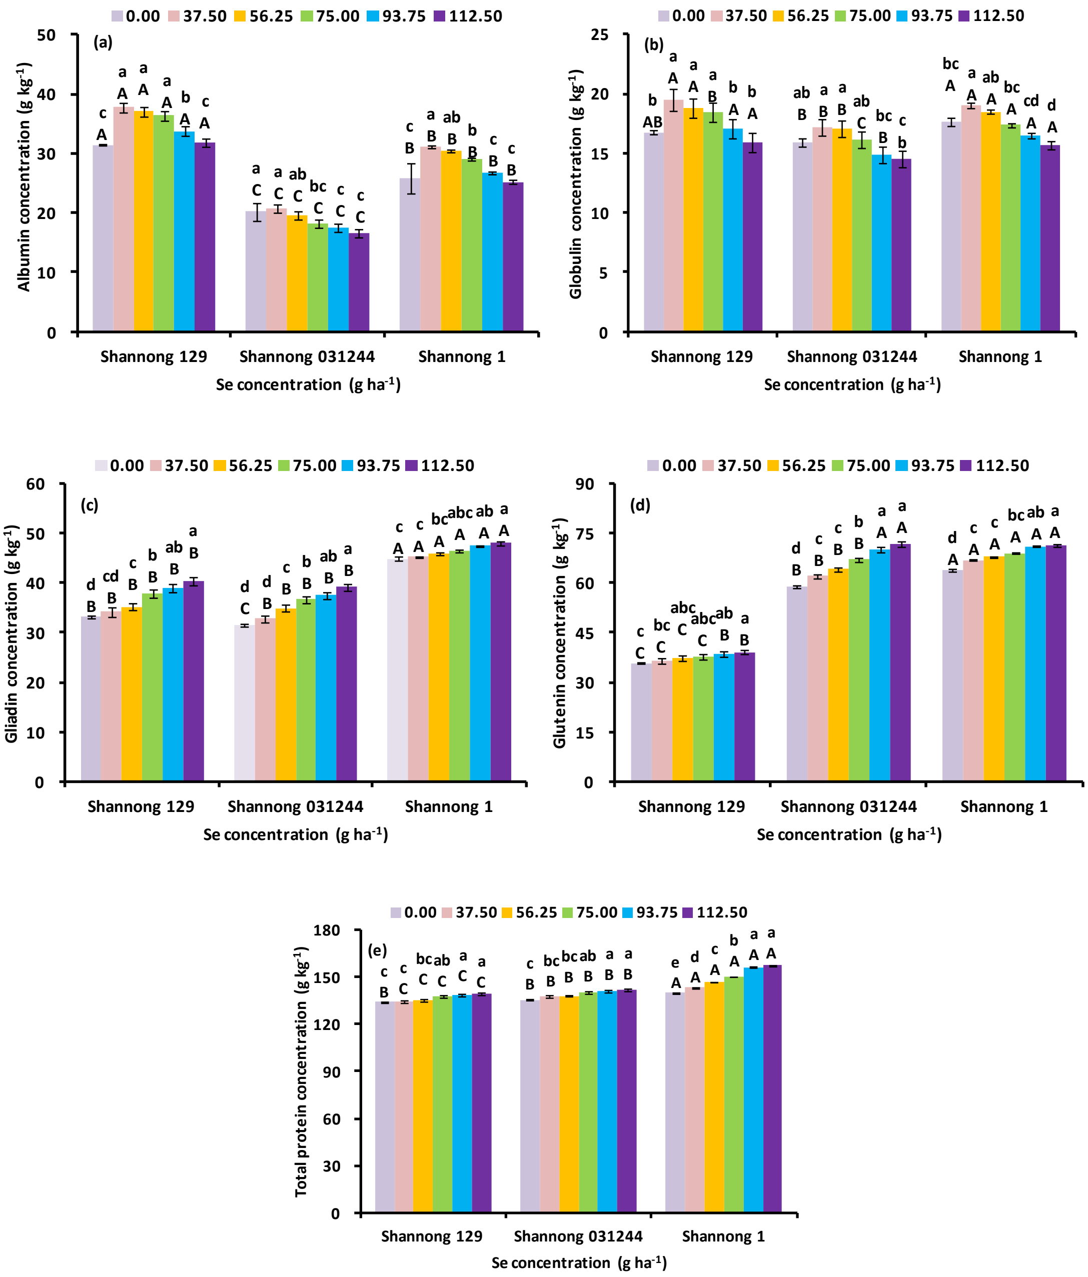

Figure 4. *Concentrations of total protein and protein components in grains of colored-grain wheat cultivar under foliar application of Se. X axes show the concentrations of Se. Y axes show the concentrations of different concentrations of total starch and different starch components. Values were means of three replicates. The subfigures (a-e) show the concentrations of albumin, globulin, gliadin, glutenin and total protein, respectively. Different line lowercase letters (a, b, c, d) indicated significant differences among Se treatments, at p < 0.05 in Tukey test. Different column uppercase letters (A, B, C) indicated significant differences among cultivars, at p < 0.05 in Tukey test.*

Concentration of total starch and its components

The concentration of total starch and its components showed significant changes within colored-grain wheat (*Fig. 5, p* < 0.05). Overall, the concentration of amylase was significantly lower in Shannong 129 and Shannong 031244 than in Shannong 1 without Se ($p < 0.05$). The highest concentration of total starch and its components was found at the Se concentration of 37.5 g ha^{-1} under foliar application. The concentration of total starch, amylase, and amylopectin first increased then decreased with the increase the concentration of foliar Se fertilizer. This indicates that the effect of foliar Se was significantly different for cultivar in terms of the starch components and total starch concentration.

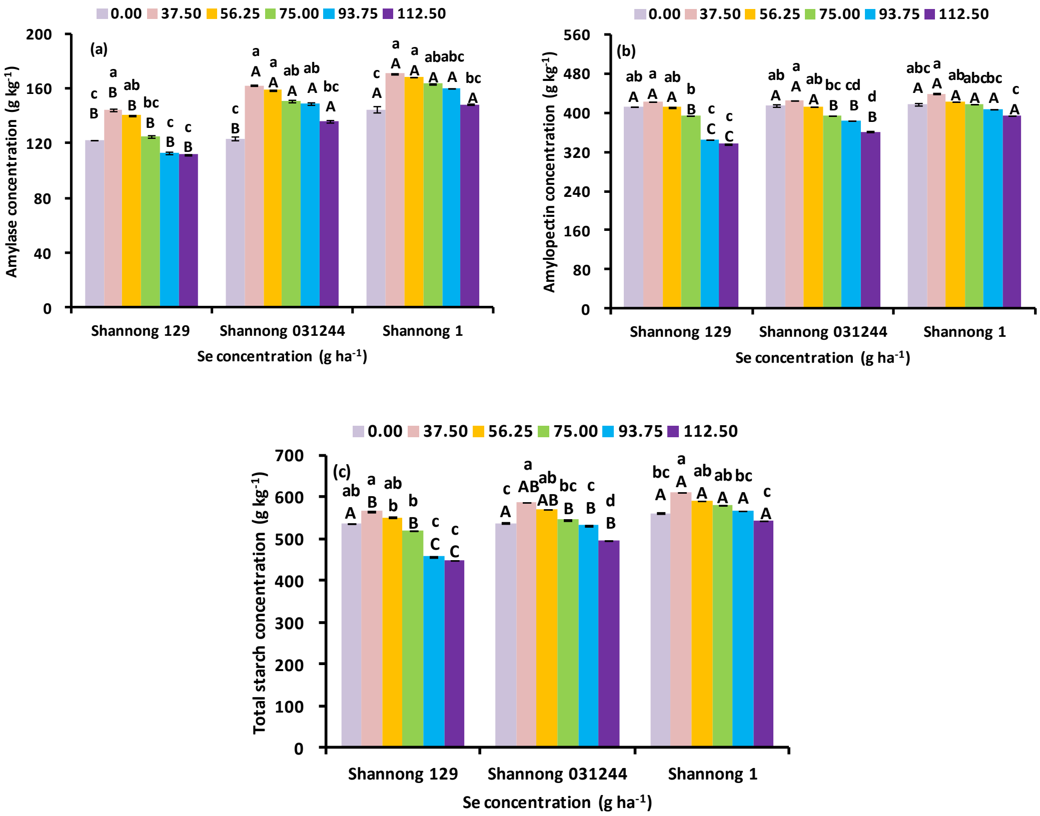

Figure 5. *Concentrations of total starch and different starch components in grains of colored-grain wheat cultivar under foliar application of Se. X axes show the concentrations of Se. Y axes show the concentrations of different concentrations of total starch and different starch components. Values were means of three replicates. Different line lowercase letters (a, b, c) indicated significant differences among Se treatments, at p < 0.05 in Tukey test. Different column uppercase letters (A, B, C) indicated significant differences among cultivars, at p < 0.05 in Tukey test.*

Concentration of amino acids and anthocyanin

The concentration of amino acids was higher in colored-grain wheat than in common grain wheat without Se treatment (*Fig. 6*). In the present study, a small dose of Se had a positive effect on the concentration of the total amino acids.

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 17(2):2187-2202.
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_21872202

However, higher levels of Se supplementation did not result in further increase of the concentration regarding the total amino acids. After applying a larger dose of Se, there was a small decrease in the total content of amino acids, but the overall concentration of amino acids was still larger than the control. There was a decreased trend after application Se concentration of 37.50 g ha^{-1} in colored-grain wheat, however, a decreased trend was found after Se concentration of 75.00 g ha^{-1} in common-grain wheat. The sixteen amino acids were detected (including seven essential amino acids and nine non-essential amino acids). All essential amino acids were significantly affected except leucine (Leu) ($p < 0.05$). The concentration of essential amino acids was significantly lower in Shannong 129 than in Shannong 1 and Shannong 031244 with Se. However, with the increase of Se concentration in foliar fertilizer, there were no significant effects of the essential amino acids of three wheat varieties ($p > 0.05$). The results for non-essential amino acids are also listed. The application of Se markedly influenced the concentration of non-essential amino acids except arginine (Arg) and tyrosine (Tyr) ($p < 0.05$). Meanwhile, with the increase of Se concentration in foliar fertilizer, there were aslo no significant effects of the non-essential amino acids of three wheat varieties ($p > 0.05$).

To examine the relationship between anthocyanins and Se, the concentration of anthocyanins was measured in colored-grain wheat (*Fig. 7*). We found the synergistic effect between anthocyanins and Se in colored-grain wheat, which indicated there was likely to be a great Se-enrichment potential in colored-grain wheat.

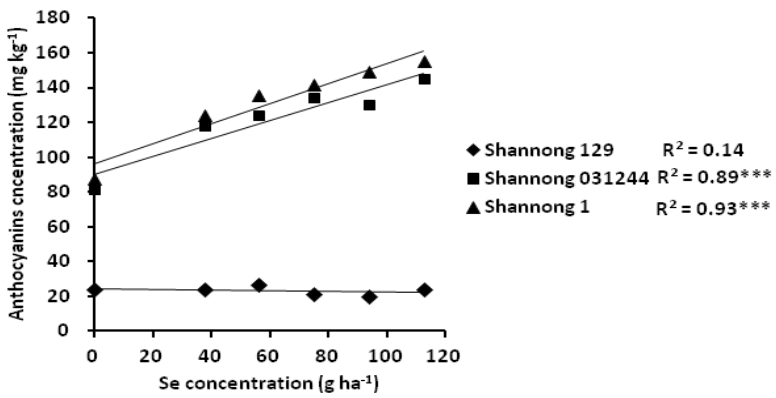

Figure 7. *The correlation between anthocyanin and foliar application of Se in grains of colored-grain wheat. X axes show the concentrations of Se. Y axes show the concentrations of different minerals*

Discussion

The customer's acceptance of innovative, new products is dependent on their feedback to the sensory and functional properties of flour, including color, flavor, nutritional value, and overall acceptability. In particular, for flour, it is necessary to maintain the typical sensory and nutritional characteristics for commercial success in the development of functional foods. The evidence that Se enrichment of colored-grain wheat improves the nutritional aspect of the flour without altering its sensory properties is critical for consumers to accept Se-enriched flour (Ficco et al., 2014). However, nutritional analyses of bio-fortified colored-grain wheat flour have not been studied extensively. Our study focused on the evaluation of the effect of Se on the nutritional

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_21872202

contents of colored-grain wheat and provided a valuable practice on the development of new functional selenium-fortified colored-grain wheat.

The soil Se-supplement, dress seeds, soaking seeds, foliar application of Se and exogenous Se supplementation can increase the amount of Se in agricultural products (Ducsay et al., 2009). Among above foliar application of Se has the advantages of fast, efficient, low cost and low environmental risk. Our findings suggested the effectiveness of foliar Se fertilization as a suitable strategy to improve nutritional quality of colored-grain wheat, which is consistent with the previous studies which have shown the greater effectiveness of foliar Se treatment than other Se supply methods in wheat (Zhang et al., 2010; Galinha et al., 2015). Moreover, we found that all of the Se treatments were highly effective at increasing the Se concentration in the colored-grain wheat, for three wheat cultivars, and that the Se concentrations in the grain increased with increasing concentrations of Se application according to a positive correlation. This evidence is in agreement with several previous studies in which high correlation values were observed (Broadley et al., 2010; Rodrigo, Santamaría, López-Bellido and Poblaciones, 2013). The Se-enriched wheat required Se concentration to be 0.15-0.30 mg kg^{-1} (GB/T 22499-2008, China). Therefore, appropriate external Se will be necessary to make up the deficiency to develop the Se-enriched wheat flour. In our result, when the foliar application of Se at the optimal dose (37.5 g ha^{-1}), the concentration of Se in colored-grain wheat had reached the above standard. When the wheat flour above this standard will not be good for people to eat. The absence of Se poisoning observed in our study is an important consideration for farmers, because this foliar Se application could not cause any reductions in yield through a wide range of Se concentrations.

There was no significant difference in the yield of colored-grain wheat by foliar application of selenium fertilization, which was consistent with the previous studies, in which pre-harvest foliar application of mineral elements did not affect grain yield of crops (Chen et al., 2002; Rodrigo et al., 2013). There was much research about the effect of foliar application Se on common wheat, but little research has been done on colored-grain wheat. In the control group of our study, the Se concentration in the common wheat grain was a little lower than in the colored-grain wheat, which confirmed high nutritional value in the colored-grain wheat. The concentration of Se and the accumulation of Se increased with the increase of Se concentration; however, the increase varies depending on wheat varieties. The Se concentration in colored-grain wheat was significantly higher than common grain wheat which might be caused by the absorption, transformation, and transport capacity of the exogenous sodium Se solution of colored-grain wheat. The utilization efficiency of Se in wheat is similar to other elements, that is, under relatively stable technical conditions, the Se concentration of wheat increased with the increase of Se injection, but the utilization of Se goes down. This explains the high concentration of Se inhibited plant growth due to Se toxicity interfering with the plant metabolism. Clearly, our results showed the beneficial role of Se at low concentrations could promote colored-grain wheat growth, which is consistent with previous studies (Boldrin et al., 2016; Guerrero et al., 2014). For the first time, we compared the Se accumulation between common wheat and colored-grain wheat, and reported the significant increase of mineral concentrations in the colored-grain varieties comparing to the common variety, which indicated a great potential to increase the nutritional content of colored-grain wheat flour for the commercial uses by the strategy of Se foliar spray.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_21872202

It is generally considered that high dosages of Se may be toxic to plants by competing with some essential elements, such as Mn, Zn, Cu and Fe (Kabata-Pendias and Pendias, 2011; Fargasova et al., 2006), however, in some cases, the stimulating effects of Se on uptakes of Cu, Fe and Zn in plants were also observed (Feng et al., 2009). Intriguingly, foliar application of Se had a significant effect on mineral concentrations in wheat grains. The colored-grain wheat varieties had significantly higher mineral concentration than the common wheat. Our results showed foliar application of Se promoted the accumulation of Fe and Zn and inhibited Cu and Mn accumulation, similar to the previous suggestion by Feng et al. (2009).

As Se is incorporated into proteins as selenoaminoacids, the different aptitudes of these colored-grain varieties to accumulate Se might be linked to dissimilarities in their protein content (Barclay and MacPherson, 1992). If the protein content in wheat grain is high, Se is mainly associated with plant proteins. Nossier et al. (2011) found selenium was related to protein function. Se was further reported to be involved in protein metabolism as a component in an RNA chain in plants, with the main physiological function of transporting amino acids to synthesize proteins (Garousi, 2017; Schiavon et al., 2017). In our research, Se foliar fertilizer showed a significant impact on protein components in grains of colored-grain wheat varieties too. The content of albumin and globulin were significantly reduced but the content of gliadin and glutenin were significantly increased with the increase the concentration of foliar Se fertilizer. The significant effect of the high Se concentration on the protein components of colored-grain wheat was observed, with being more prominent in the deeper colored varieties. Furthermore, there was no effect of Se fertilization on gluten quality, similar to previous suggestions by Broadley et al. (2010). In addition to the protein components, the Se fertilization had no effect on either gluten or fat parameters, which indicated the foliar spray of Se will not affect other main organic nutrient than proteins in colored-grain wheat. Furthermore, the starch is the main source of wheat extract. In theory, amylose was converted into fermentable sugar and amylopectin was converted into fermentable sugar and low molecular dextrin under the action of enzyme. The possible reason for the decline of starch is that the high dose of Se supply made the grain filling speed decrease, thus preventing the transformation of starch component.

The significant influence of amino acid concentration in plant tissues can be caused by nutrition and fertilization, such as Se (Munshi, 1990). For exemple, methionine (Met) was the limiting essential amino acid, and application of Se in our study affected the Met content of colored-grain wheat. Moreover, the application of Se markedly influenced the content of aspartic acid (Asp) and Asparagine (Asn) which is resulted from amidation of Asp. Both Asp and Asn are important in the transport and storage of nitrogen in plant tissues (Lea et al., 2007). In addition, we found the synergistic effect between anthocyanins and Se in colored-grain wheat, which indicated there was likely to be a great Se-enrichment potential in colored-grain wheat.

In the future studies, the following aspects are expected to be focused: (i) The physiological regulation mechanism of Se in the process of migration, distribution, and accumulation in colored-grain wheat plants and the antagonistic mechanism of Se and heavy metals in colored-grain wheat plants. (ii) Further uses of advanced biotechnology on selecting and breeding new varieties of Se-enriched colored-grain wheat.

DOI: http://dx.doi.org/10.15666/aeer/1702_21872202

Conclusion

It is the first time to report the Se-enrich colored-grain wheat with the nutritional analyses and evaluation upon different Se concentrations applied in foliar spray. The optimal fertilization of Se could enhance nutritional quality of colored-grain cultivar including the concentrations of protein, minerals and amino acid without affecting the grain yield, gluten, and fat content, however, the starch concentration was decreased. Additionally, wheat grain was reported to be enriched with Se through exogenous Se under the foliar application of Se. Thus, the foliar application of Se at the optimal dose (37.5 g ha^{-1}) is suggested to be used for Se bio-fortification of colored-grain wheat cultivar. Moreover, the purple grain wheat is more Se-enriched than blue one. Further studies are expected to understand the mechanisms of micro-nutrient uptake and transport to acquire more efficient accumulation of nutrients in colored-grain wheat. Our study provides a valuable practice in nutrition analyses of the colored-grain wheat and the development of nutrient-enriched wheat flour.

Abstract. *Fusarium oxysporum* f. sp. *radicis-lycopersici* (FORL) causes Fusarium crown and root-rot diseases and *Tomato yellow leaf curling virus* (TYLCV, Israel, Mild, Sardinian strains) infection leads to low yield and poor quality fruits, which causes important economic losses in tomato growing areas. In this study, previously developed molecular markers for FORL and TYLCV were used with 418 tomato genotypes which have characteristics of high yield, quality fruit and resistance to abiotic stresses. 62 tomato lines were obtained from Cukurova University (CU), 196 and 160 of tomato lines were generated from Western Mediterranean Agricultural Research Institute (BATEM) and private sector, respectively. All genotypes were tested with classical and molecular methods where species specific resistance RAPD and $SCAR_{Frl}$ primers for FORL, CAPS and Co-dominant SCAR primers for TYLCV resistance were used. Analyses revealed that 102 tomato genotype are resistant to FORL, 46 and 35 of plant genotypes contain *TY3* and *TY1* loci respectively. Three genotypes from BATEM and 4 genotypes from private sector contained the 3 target genes (FORL+TY1+TY3), however, none of the tested CU tomato genotype was resistant to the 3 target genes. Furthermore, yield and some fruit quality characteristics of 7 tomato lines which were resistant to both diseases were determined in molecular and classical tests.
Keywords: *Fusarium crown and root-rot, marker assisted selection, PCR, Tomato yellow leaf curl virus, tomato*

Introduction

It is extremely difficult to control the most significant form of Fusarium crown and root-rot disease (*Fusarium oxysporum* f. sp. *radicis-lycopersici* / FORL) that economically limits greenhouse tomato production since it is a soil borne disease (Colak and Bicici, 2011). FORL leads to recurrent infections during the season due to the spread of microconidia, especially in greenhouses, and results crop losses up to 90% in greenhouse tomato cultivation (Hibar, 2002). Commercially viable, agent-resistant indigenous varieties with adequate resistance to Fusarium crown and root-rot induced by FORL are not yet developed (Ozbay et al., 2004). In a study conducted in greenhouse tomato fields in Adana and Mersin provinces, *formae specialis* and strains of 87 *Fusarium oxysporum* isolates were determined in different locations and 60% of the isolates were identified as FORL while 40% isolate were identified as FOL. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22032218

results of this study demonstrated that FORL disease spreads rapidly in the region (Çolak and Biçici, 2013).

Tomato yellow leaf curl virus (TYLCV) is one of the most common diseases in greenhouse tomato fields for the last 20 years. Similar to other viral diseases, TYLCV is the most devastating virus disease active on tomatoes that can cause an 80-100% loss in tomato yields through epidemics in several countries and there are no chemical control agents against the disease which exhibits genetic differences similar to all virus diseases. It was first reported in 1964 on tomato plants (Moriones and Navas, 2000). TYLCV is persistently transported by silver leaf whitefly (*Bemisia tabaci*, Biotype B and Q). TYLCV has a quite broad host range. TYLCV is not mechanically transported and there are no records of transport via seeds (Czosnek, 2007; Mabvakure et al., 2016). Different TYLCV strains were reported at different parts of the world. The most common of these strains is the *Tomato yellow leaf curl virus*- Israel (TYLCV - IL), Israel strain. It is followed by *Tomato yellow leaf curl virus*- Sicily (TYLCSV - Sic), *Tomato yellow leaf curl virus*- Mild (TYLCV - Mld) and Sardinia (TYLCV - Sa) strains (Anfoka et al., 2005; Belabess et al., 2015). A study was conducted to identify the TYLCV strains present in Turkey in tomato cultivation fields in Antalya, Mersin and Adana provinces. The study determined that TYLCV-IL, TYLCV-Sa, TYLCV-Mld strains were present. It was observed that 93% of the whitefly samples collected on the infected tomato plants were *B tabaci* Biotype - B (*B. argentifolii*) and sample of 7% were Biotype - Q (Fidan et al., 2011; Torre et al., 2018).

Parallel to the international studies, the use of resistant varieties in the control of plant diseases is the preferred method in Turkey to reduce the negative effects of the use of chemicals in the control of plant diseases. The development of resistant varieties in breeding work is obtained as a result of long-term studies. Several resistance genes, expected in a variety in breeding studies, could result in undesirable properties along with desirable ones (Scott, 2005). The morphological determinants used in traditional breeding studies could be affected by environmental conditions, although they help distinguish the genotypes. Homozygous, dominant and heterozygous individuals cannot be identified if any one of these characters is recessive. In recent years, molecular marker assisted selection (MAS) in disease resistance has been developing rapidly (Yan et al., 2017). Thus, hundreds of plants can be selected concurrently, reliably, and rapidly, by saving time and space in the selection of disease-resistant varieties (Darling and Brickell, 1994; Barone et al., 2005; Devran et al., 2018).

The FORL-related genetic resistance is controlled by a single (*Fr1* gene) dominant gene (Roberts et al., 2001). Studies on identification of a marker associated with *Frl* demonstrated that *Frl* is located on the ninth chromosome in the tomato (Vakalounakis et al., 1997). In the study where the connections between RAPD-DNA markers and *Fr1* were determined, 1000 different RAPD primers were tested for sensitive and resistant tomato lines. In the study, *Frl* gene connection distances were examined and it was determined that the UBC 194 was the closest primer with 5.1 cM. The selection of the closest primer in breeding studies is important for the reliability of the results. Since CAPS, SCAR and Co-dominant SCAR primers, which are a further stage of RAPD primers in the identification of FORL resistance, were not developed for this disease or were not patented and published, UBC 194-RAPD primer is used by several researchers (Fazio et al., 1999).

DOI: http://dx.doi.org/10.15666/aeer/1702_22032218

Transferring the resistance in wild varieties to culture plants is one of the frequently used methods for TYLCV resistance. For this purpose, variety breeding was conducted with TY1 resistance marker developed with *Solanum chilense* (LA1969). However, it was determined that varieties with this resistance gene do not provide the desired level of protection (Castro et al., 2007). In most Mediterranean countries, TYLCV-Israel and Mild strains are common, and TYLCV Sardinia and Sicilian strains can also be found (Fidan et al., 2011). To ensure resistance against all these strains, it was reported that tomato lines that contain both Ty3 marker, developed from *Solanum chilense* (LA1932), and Ty1 gene provide significant resistance. Similar to all viral diseases, developing resistant varieties against this viral disease, which cannot be controlled chemically and possesses high genetic variability, became one of the most important strategies in recent years (Jensen et al., 2007).

The present study aimed to identify and validate the resistance against Fusarium crown and root-rot (FORL) disease and *Tomato yellow leaf curl virus* (TYLCV / Israel, Mild and Sardinia strains (TY1 + TY3 gene) that are significant problems in tomato cultivation with molecular and classical (symptomatologic) methods. For this purpose, 418 tomato lines, which were determined to be superior in terms of yield and certain fruit quality properties and determined to be resistant to abiotic factors, were used. Thus, yield and certain fruit quality properties of line and/or variety candidates that are resistant to both diseases (FORL + TY1 + TY3) were determined.

Materials and methods

Plant material

The main material included 418 F_2 generation tomato lines procured from Cukurova University (CU, 62 lines), West Mediterranean Agricultural Research Institute (BATEM, 160 lines) and private sector (AYER, 196 lines). Fla.7781, *Solanum chilense* LA2779, Tayfun F1 and sensitive variety Hazera 5656 were used as positive controls in molecular and classical tests (symptomatologic) conducted to determine FORL and TYLCV resistance (Colak and Bicici, 2011; Kabaş et al., 2012).

Molecular Studies

Genomic DNA isolation and amplification studies

DNA Prufication Mini Kit (Thermo Scientific GeneJET Plant - K0792) was used in total genomic DNA isolation of tomato lines. For this purpose, 100 mg young leaves obtained from positive controls and tomato line during the 2-4-leaf period. The DNAs were adjusted to 40 ng using a spectrophotometer, and controlled in 0.8% agarose gel and stored at -20°C.

PCR conditions and agarose gel electrophoresis studies

PCR studies were conducted on 418 F_2 generation tomato lines for FORL and TYLCV resistant.

In the study, FORL resistance was determined with UBC194 RAPD (Fazio et al., 1999) and $SCAR_{Frl}$ (Mutlu et al., 2015) primers. In the study, PCR studies were conducted on tomato lines resistant to all three agents (FORL + TY1 + TY3) based on the new publication of $SCAR_{Frl}$ primer (*Table 1*). PCR reaction (final volume 25 µL) for FORL and TYLCV was conducted with 11 µL DreamTaq Green PCR Master Mix

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22032218

(ThermoScientific-K1082) (containing 0.5 mM Taq polymerase (2 U), 2X DreamTaq Green buffer, 0.4 mM (200 µM) of dATP, dCTP, dGTP and dTTP each and and 4 mM $MgCl_2$), 1 µL F + 1 µL R primer and 1 µL DNA (10 ng) and added 11 µL ddH2O.

PCR conditions for the FORL-UBC194 primer were as follows: 3 min pre-denaturation at 95°C, followed by 40 cycles of 1 min at 95°C, 1 min at 38°C, 1 min at 72°C, and 1 cycle 10 min final elongation at 72°C min were programmed.

Table 1. *Nucleotide sequences and size of the primers used for the FORL, TY3 and TY1 resistance in the experiment*

Primer	Annealing temperature (^{0}C)	Primer sequence (5'3')	Product size (bp)	References
UBC194 (FORL)	34	5'-AGGACGTGCC-3'	590 bp resistance	Fazio et al., 1999 Morid et al., 2012
$SCAR_{Frl}$ (FORL)	53	5'-CACATTCATCATCTGTTTTAGTCTATTC3'	950 bp susceptible 1000 bp resistance 950-100 bp heterozygous resistance	Mutlu et al., 2015
P6-25-F2 (TY3)	53	5'GGTAGT GGA AAT GAT GCT GCT C-3'	320 bp susceptible 650 bp resistance	Jensen et al., 2007 Ji et al., 2007abc
P6-25-R5 (TY3)		5'-GCTCTGCCTATTGTCCCATATATAACC-3'		
JB1F (TY1)	55	5'-AACCATTATCCGGTTCACTC-3'	400 bp susceptible 450 bp resistance	Castro et al., 2007
JB1R (TY1)		5'-TTTCCATTCCTTGTTTCTCTG-3'		

PCR conditions for the FORL-$SCAR_{Frl}$, TY3 and TYl primers were as follows: 3 min pre-denaturation at 95°C, followed by 35 cycles of 30 sec at 95°C, 45 sec at 53°C, 45 sec at 72°C and 1 final elongation cycle at 72°C for 10 min were programmed. The PCR products obtained for TY1 were cut with TaqI restriction enzyme to determine their resistance. Digestion was conducted according to Thermo Scientific. Restrictions of 10 µl of the amplified products, ddH_2O µl 17, 10 × Fast Digest Green Buffer 2 µl and FastDigestenzyme 1µL were conducted at 37°C in a total volume of 30 µl with 10 U/ µl.

A GeneAmp 9700 thermocycler (Eppendorf) was used for all PCR amplifications. Digestion products were analyzed with agarose gel electrophoresis (2% agarose w/v with TBE 1buffer) and visualized by ethidium bromide staining, and the results were recorded.

Classical testing for FORL and TYLCV Pathogenicity

Classical testing were conducted on three genotypes (B26, B40, B178) from BATEM and four genotypes (A-31, A-41, A-48 A-66) from private sector were containing the 3 target resistant genes (FORL + TY1 + TY3).

DOI: http://dx.doi.org/10.15666/aeer/1702_22032218

Isolate, material supply and storage

The FORL isolate was obtained from Mersin greenhouse tomato plants and it was determined that it was a molecular (PCR) FORL isolate with high virulence, and the study was conducted with the FORL isolate coded Tarsus-0 (Tarsus / Mersin isolate) and stored at -20°C (*Figure 1*) (Colak and Bicici, 2011).

Figure 1. *FORL and TYLCV symptoms in tomato plants*

In the TYLCV tests; the isolate containing all three TYLCV strains obtained from Mersin greenhouse tomato fields was used as an inoculum source (*Figure 1*) (Fidan et al., 2011). Vector whiteflies (*Bemisia tabaci*) were procured from the collection regularly produced in Adana Biological Control Research Institute Directorate (BMAE).

Classical testing for FORL resistance

The FORL isolate was developed for 7 days in PDA and inoculated to 250 mL medium that contained 100 mL of PDB (Potato Dextrose Broth) and incubated for 10 days. Seedling root immersion method was used for FORL inoculation. For this purpose, the soil on 3-4 weeks old tomato seedlings were washed out, the roots were shaved and inoculated by immersion into $1x10^6$ spores/ml FORL spore suspension for 4-5 min (Colak and Bicici, 2011). Then, the experiment was set up by planting 3 tomato seedlings from each FORL-inoculated tomato line in 5-replicates into pots (15 × 15 cm) that contained sterilized peat:perlite (1:1). Experiments were set up based on random lots experimental design. The control plants were planted after immersion into sterile water. The genetic resistance to FORL disease is controlled by a single (*Fr1* gene) dominant gene (Roberts et al., 2001). Thus, in FORL resistance tests, to determine the resistance of the lines, the plants were rooted, and the roots and vascular structures were examined, and the presence of the disease was recorded. The evaluation was conducted by observing the symptoms in the plants and browning on roots and root crowns and the scoring was conducted with a 0 - 4 scale, and resistant (0: symptom-free plants, no disease) and sensitive (>1: plants indicating symptoms, disease is present) plants were determined (Vakalounakis et al., 1997; Morid et al., 2012).

Classical testing for TYLCV resistance

Vector whiteflies (*Bemisia tabaci*) were used to infect the tomato plants in the experiment. In the cage studies, tomato plants infected with all three strains (TYLCV Israel, Mild and Sardinia strains) were used (Fidan et al., 2011). In the study, after the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22032218

actual second leaf stage of the plants in the cages, 30 whiteflies per plant were released to the cages. After the whiteflies fed for 48 hours after the release, the whiteflies were terminated using an insecticide. During infection, the suction damage to the plants was prevented. For this purpose, 20 pots with 20 cm diameter containing peat:perlite (1:1) were placed in the cages (80x100x160 cm), and the experiment was set up with 4 pots per line and 3 plants per pot based on the random lots experimental design. Observations were conducted when the symptoms were obvious on the plants 15 - 21 days after the experiment was set up and maintained for 3 weeks. The plants with disease symptoms were considered sensitive and those without symptoms were considered resistant in the experiment (Lapidot and Friedman, 2002).

All classic test experiments for FORL and TYLCV were conducted at of 26 ± 2°C temperatures, 60 – 70% relative humidity, 16 hours light - 8 hours dark conditions in a climate chamber at BMAE.

Greenhouse Experiments and Determination of Fruit Quality Properties

FORL and TYLCV resistant tomato genotype seedlings were grown in the greenhouses of institutions that possessed both resistant lines. The seedlings were planted in the greenhouse with 80 cm inter-row and 50 cm intra-row distances (2500 plants/da) on March 2, 2016 (BATEM) and February 24, 2016 (AYER). All basic maintenance procedures were conducted regularly throughout the experiment (Günay, 2005).

In the study, harvested tomato fruit mean weight (g/fruit/FMW), mean yield per plant (g/plant/MYP), total yield (kg/da/TY) and certain fruit quality measures were obtained after the initial harvest. In the greenhouses in both institutions, 10 fruits were randomly selected from each line and each lot in the third tomato harvest and fruit quality properties [fruit diameter (mm / FD) and height (mm / FH), fruit water soluble dry matter (% / WSDM), fruit titratable acidity (% / TA), vitamin C (L - Ascorbic Acid) content (mg / 100g / CV), pH of fruit juice, fruit juice EC measurement (ms / cm)] were determined (Guillén et al., 2006; Cemeroğlu, 2007). Fruit diameter (mm / FD): The diameter was measured at the equatorial region of the tomato fruit by using the digital caliper (Miyutoyo 500-181-30). Fruit height (mm / FH): The longitudinal section of the tomato fruit was measured by the digital caliper (Miyutoyo 500-181-30) for fruit height. Fruit water soluble dry matter (% / WSDM): The few drops of extracted tomato juice was measured by a hand refractometer (Atago, Tokyo, Japan) for WSDM. Fruit titratable acidity (% / TA): Titratable acidity was determined by titration of 5 ml tomato juice with 0.1 N sodium hydroxide to an endpoint of pH 8.1, results are presented as % citric acid. Vitamin C (L - Ascorbic Acid) content (mg / 100g / CV): For ascorbic acid content, tomatoes were ground with a warring blender and 5 g sample was mixed with 45 ml 0.4% oxalic acid and then filtered. One ml filtrate and 9 ml 2,6-Dichlorophenolindophenol sodium salt solution ($C_{12}H_6Cl_2NO_2$-Na) mixed and then transmittance values 520 nm in a spectrophotometer (Perkin Elmer, Lambada 850 UV/Vis). Results are expressed as mg 100 g^{-1} (Ozdemir and Dundar, 2006). pH of fruit juice: The pH of the tomato juice was measured with WTW 315i model pH meter. Fruit juice EC measurement (ms /cm): The EC of the tomato juice was measured with WTW 315i model EC meter. At the end of the experiment, whether there were differences between the tomato genotypes based on the examined properties was determined with variance analysis of the obtained data using Jump software and the comparison of the means were conducted with LSD test.

Results

Determination of FORL and TYLCV resistance of tomato genotypes with molecular studies

PCR optimizations were conducted with FORL and TYLCV resistant and sensitive controls to determine the resistance of 418 tomato line samples that constituted the study material (*Figures 2 and 3*). The PCR study conducted on 196 pure tomato lines developed by BATEM breeding department with UBC 194 primer used in FORL resistance demonstrated that 60 tomato genotypes were found FORL resistant (*Figure 2*). Again, PCRs conducted with TY3 allele used for TYLCV resistance on the same samples demonstrated that 34 out of 196 samples were resistant of TY3. It was determined that 25 samples were resistant to TYLCV as a result of the PCR conducted with TY1 locus primers that are effective on TYLCV resistance. It was determined that 3 tomato lines coded B26, B40 and B178 were resistant to FORL and both strains of TYLCV (FORL + TY1 + TY3).

As a result of the molecular studies, it was determined that 160 pure tomato lines belonging to private sector (AYER) were resistant to FORL of 42 line, 10 lines were TY1 resistant, and 12 lines were TY3 resistant. Four tomato lines, namely A31, A41, A48 and A66, were identified as resistant to all three (FORL + TY1 + TY3) among the 160 pure tomato lines belonging to AYER. It was determined that none of the 62 tomato line genotypes belong to Çukurova University were resistant to any of the three resistance resources. A total of 7 tomato lines were identified as resistant to both diseases (FORL + TY1 + TY3) as a result of the conducted PCR study at FORL resistance developed by Mutlu et al. (2015) with $\mathrm{SCAR_{Frl}}$ confirming the findings by Mutlu et al. 2015 (*Figures 3 and 4*). It was suggested that this new primer, used in resistant lines and confirmed with classical testing in the present study, was efficient in determination of FORL resistance and could safely be used in future breeding studies.

Classical testing results for FORL and TYLCV resistance

In classical testing for FORL resistance, the two-repeat experiments were set up with B26, B40 and B178 tomato genotypes from BATEM Institute and A31, A41, A48 and A66 tomato genotypes from AYER in BMAE controlled climate rooms. The experiments were terminated after 20 days, when foliage wilting and turgor loss, slowed growth, marked blackening and deaths in the root and root crown were observed as a result of FORL agent inoculation in the control plants (Hazera 5656 / FORL sensitive).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22032218

It was determined that there were no symptoms of FORL induced crown and rot-root disease in all tomato genotypes in the experiment group as a result of the plant and root assessments (*Figure 5).*

Figure 5. *Classical test study of A-31 and B-40 genotypes from resistant tomato lines of FORL disease*

In classical TYLCV resistance testing studies; whiteflies fed on the plants infected with three TYLCV strains were collected with infusion tube after 2 days and released onto the tomato genotypes. TYLCV-specific symptoms such as yellowing on leaf edges and shrinkage of leaves, contraction in the leaves were observed and the leaves curled upwards starting from the margins on the 16-18th day of the experiment in sensitive control Hazera 5656 plants planted in addition to resistant line and varieties in each cage (*Figure 6*). The 7 tomato lines belonging to AYER and BATEM that were determined as TYLCV-resistant in molecular studies did not exhibit symptoms in classical testing cage study conducted with whitefly inoculation, thus both findings were confirmed. The use of molecular markers in development of disease resistance provides great advantages in terms of time, cost and reliability (Agrama and Scott, 2006; Anbinder et al., 2009; Ji et al., 2009). It is not possible to test hundreds of lines accurately and reliably with classical methods or to determine the inheritance of resistance (heterozygote or homozygote resistance).

In classical testing of resistant genotypes, breeders determine TYLCV resistance as the natural infection occurs in the fields for non-mechanical vector TYLCV. If molecular marker selection is not implemented in this viral disease with the sole vector of whiteflies, it is not always possible to wait for the natural infections through whiteflies in the field, and then conduct the analysis and it is not an accurate and reliable method (Verlaan et al., 2013). Because, it is not possible to understand whether the plants that appear resistant were exposed to the viral infection or whether they were infected by the whiteflies, but do not exhibit symptoms due to their resistance.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22032218

Furthermore, it is not possible to set up experiments with whiteflies for hundreds of breeding lines. In the present study, the use of molecular markers reduced the number of genotypes from 418 to 7 tomato genotypes (B26, B40, B178, A31, A41, A48 and A66) that were resistant to all three factors (FORL+TY1+TY3), making it easier and more economic to verify these findings with classical tests. Although molecular markers provide a great advantage in terms of speed and cost, classic validation tests should be performed (Lee et al., 2015). This is due to the fact that it is important to perform classical validation tests (smyptomatologic) in determination of MAS-selective resistance, which taking the distances between the developed markers and the gene and human and marker-based errors into consideration (Caro et al., 2015; Scott et al., 2015).

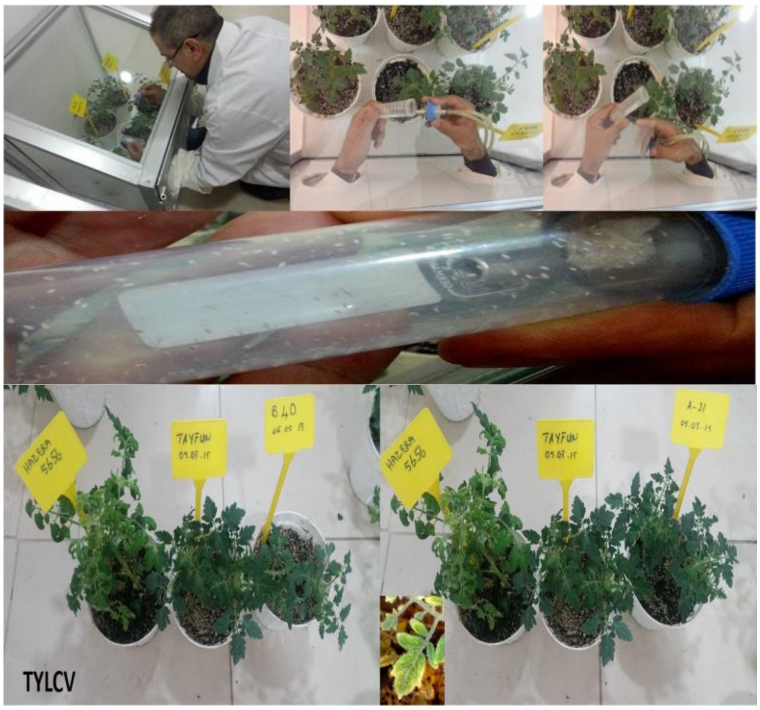

Figure 6. *The release of white flies collected on TYLCV infected plants in special cages for tomato lines taken to the TYLCV resistance test and classical test study of A-31 and B-40 genotypes from resistant tomato lines of TYLCV disease*

Determination of the yield and certain fruit quality properties in disease resistant tomato genotypes

In order to determine the yield and certain fruit quality properties of FORL and TYLCV resistant tomato genotypes, greenhouse experiments were set up in Antalya. Fruit harvest was initiated when tomato fruits ripened and turned red. Eight harvests were conducted in BATEM greenhouses and 6 harvests were conducted in AYER greenhouses. The tomato fruit yield and certain fruit quality property data throughout the cultivation season are presented in *Tables 2 and 3*.

The average yield values per plant (g/plant) and decare yield values (kg/da) were found to be statistically significant in 7 tomato genotypes determined to be resistant to FORL and TYLCV belonging to Ayer and BATEM. Among the tomato genotypes belonging to Ayer, the per plant yield ranged between 1101.8 and 2258.6 g/plant and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22032218

the per decare yield ranged between 2754.4 and 5646.6 kg/da, the per plant yield, for tomato genotypes belonging to BATEM varied between 1206 and 2922 g/plant and per decare yield varied between 3015 and 7304.7 kg/da (*Tables 2 and 3*). In previous studies on tomato yield, it was reported that genotypes might have different responses based on their locations, climate conditions, and plant nutrition (Şen et al., 2004; Ozbay and Ateş, 2015; Demirtaş et al., 2016). The highest mean fruit weight was observed in A-48 (166.07 g/fruit) genotype among the four Ayer tomato varieties. The highest mean fruit weight was obtained in B26 (163.57 g/fruit) genotype, while the lowest mean fruit weight was obtained in B178 (98.70 g/fruit) genotype among the three tomato genotypes from BATEM. Although certain findings in the greenhouse experiments were parallel to various studies, certain differences could be observed due to varieties, ecological conditions, plant nutrition, differences in irrigation and harvest ripeness periods (Özdemir and Özer, 2016).

The water-soluble dry matter content (WSDM) is an important quality criterion in tomato fruit, and it was determined that the highest WSDM content was in A-48 genotype with 4.7% among AYER tomato genotypes and the highest WSDM content was in B178 genotype with 5.40% among BATEM genotypes (*Table 3*). It was reported that the water soluble dry matter content in tomato fruits varies between 2.9 and 5.9% (Özbay et al., 2012). The titratable acidity (%) may vary based on the variety and ripeness period of the fruit in tomato fruit juice (Ozbay and Ateş, 2015). It was determined that the acidity rates varied between 0.46-0.24% in AYER tomato genotypes and between 0.30-0.39% in BATEM tomato genotypes.

It was found that the difference between pH values of AYER tomato genotypes was significant in the experiment and the highest pH was obtained with the A41 genotype (5.2), and the lowest pH was obtained with the A66 tomato genotype (4.3) (*Table 2*). BATEM tomato genotype pH values ranged between 4.47 and 4.55 (Bozköylü and Daşgan, 2010). There were no differences between the fruit quality properties of EC and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22032218

vitamin C content of AYER tomato genotypes. The highest EC and vitamin C values were obtained in the A41 genotype (4.6 ms/cm-25.02 mg/100 mg). The highest EC value was obtained in the B40 genotype with 4.5 ms/cm in among BATEM genotypes. All tested varieties exceeded the limit value of 8.4 mg/100 g for Vitamin C in tomatoes (Özbahçe and Padem, 2007).

Discussion

Using molecular markers in breeding studies, the choice of the closest of the gene in the primers used in disease resistance is important in terms of the reliability of the results. Since CAPS, SCAR and co-dominant SCAR primers, which are a further step from RAPD primers in determination of FORL resistance, were not developed or patented and published for this disease, several studies, similar to the present study, have used UBC 194 RAPD primers, which is closest to the gene, to determine FORL resistance (Fazio et al., 1999). However, the fact that the RAPD markers obtained in these studies were not reproducible, the difficulties in clear definition in agarose gel and the lack of inheritance of FORL resistance (heterozygous or homozygous) demonstrated that further studies should be conducted (Tanyolac and Akkale, 2010). For this purpose, Truong et al. (2011) developed RAPD markers and transformed these into SCAR and made these available for use in breeding experiments. Mutlu et al. (2015) developed the SCAR marker into a Co-dominant SCAR, obtaining the $SCAR_{Frl}$ marker, at a distance of 0.016 cm to the gene and almost on top of the *Frl* gene, and which could demonstrate whether the inheritance is heterozygous or homozygous. It was determined in the present study once more that the co-dominant $SCAR_{Frl}$ marker is reliable for determination of the heterozygous or homozygous status of inheritance in F2 and F3 populations in breeding studies, it can be accurately and easily identified in agarose gel, reduces the hybridization study costs, saves time and promotes rapid commercialization of the lines when compared to the previous FORL resistance markers.

In the study, seven genotypically resistant lines (B26, B40, B178, A31, A41, A48 and A66) against both TY1 and TY3 were infected with whiteflies to confirm the symptomatologic results of the markers in tomato plant. Infections demonstrated that primers of the genes that provide TY1 and TY3 resistance (*Ty-1*, JB1 and *Ty-3*, P6-25) could be used in resistance studies. It was reported that the TY1 gene was not very effective alone due to the presence of several TYLCV strains and controlled with a high number of genes (Zamir et al., 1994). It was reported that the TY3 marker could be used effectively in MAS since it is located on the 6^{th} chromosome and close to the gene (0.3 cM), its Co-dominant SCAR characteristic, and could reflect heterozygous, homozygous resistant and sensitive genotypes concurrently with single PCR (Ji et al., 2007c). Although the TY4, TY5 and TY6 markers were developed since the development of TY3 marker, the present study confirmed that the most effective resistance was TY1 and TY3 resistance. The knowledge on the existing strains in Turkey and their resistance to the resistance markers and their effectiveness were determined and confirmed. The existence of different TYLCV strains, especially in Asia, revealed that different markers should be tested in these areas (Hutton et al., 2012). Israel and Mild strains of TYLCV are the most prevalent strains globally, and the TY1 and TY3 markers developed against these strains maintain the status of being the most used marker in breeding studies in the world (Lee et al., 2015).

Conclusion

In today's conditions, there is a need for resistance against at least 3 and more disease agents depending on the production site and time. As the number of required resistances increases, breeding period gets longer, and it could even become impossible. Thanks to the present study findings, resistance to significant biotic factors (FORL + TYLCV) were determined, saving time for the line owner organization in commercialization of multi-resistance seven tomato variety candidates. This study showed that both disease resistant and argonomic as the market value of the highest new kind of candidate (A31 and B40) by determined by line with the institution will contribute greatly to quickly pass the commercialization and market presentation stages. In this study, multiple markers were tested for a gene, for the determination of FORL resistance, UBC-194 and SCARFr1 markers, TY1 and TY3 markers for TYLCV resistance have been confirmed. The results of the study will reveal the possibility that molecular markers used in the development of resistant lines and varieties of these diseases may be an alternative to classical testing and will shed light on future studies. Furthermore, with the determination of the parents who will be used as father or mother and resistant to one of the FORL and TYLCV disease, it became possible to design alternatives projects (F1 hybrid) to obtain new varieties based on the globally prominent fruit quality criterion requirements.

Abstract. Forest edges created by silvicultural treatment influence micro-climatic conditions and available light in forest stands. Studies regarding the impacts of forest edges on regeneration is limited in mixed Oriental beech (*Fagus orientalis* Lipsky)-Scots pine (*Pinus sylvestris* L.) stands. In this study, the influences of forest edges on height growth, root-collar-diameter growth and density of seedlings in an adjacent stand of Oriental beech-Scots pine were observed. In addition, the effects of stand basal area and height-to-crown on height growth, root-collar-diameter growth and seedlings density were monitored. The study was conducted within Samatlar Forest Planning Directorate, in Kastamonu city, Turkey. In the selected Oriental beech-Scots pine stand, twenty-five transects were installed perpendicular to the forest edge, and all the measurements were taken within these transects. There were statistically significant relationships between the distance from the forest edge and the growth of Scots pine seedlings ($p<0.05$), while the stand edge did not have any effect on the growth of Oriental beech seedlings. Density of Scots pine seedlings decreased, while Oriental beech seedling density increased from the edge into the intact stand ($p<0.05$). Stand basal area and height-to-crown did not significantly change from the edge into the intact stand ($p>0.05$). The differences in seedling growth and seedling density between the two species can be associated with their dissimilar tolerance to shade. The initial results obtained in this study point out the importance of forest edges on the regeneration of Oriental beech and Scots pine seedlings. Data suggest that regeneration of mixed Oriental beech-Scots pine should be successful using group methods rather than traditional shelterwood method within entire stand.
Keywords: *establishment, growth, regeneration, edge, silviculture*

Introduction

Forest canopy structure plays an essential role in energy fluxes between the atmosphere and the land (Smith et al., 2008). Canopy structure influence understory light availability, soil temperature and moisture, soil nutrients and several other factors in a forest (Aussenac, 2000; Xue et al., 2011). Measurement of forest canopy structure is crucial for prediction of forest productivity and development (Smith et al., 2008). Forest canopy structure is manipulated by forest managers and landowners through silvicultural practices to modify understory growth conditions (Lhotka and Stringer, 2013). Seedlings respond to natural and anthropogenic disturbances by various ratio of growth and survival (Rubin et al., 2006). Silvicultural disturbances not only influence the understory environment of the treated area, but also the microclimatic conditions of the untreated adjacent forest areas by creating forest edges in between (Baker et al., 2016).

Forest edge effect is due to the separation of the interaction between two adjacent ecosystems with a sudden transition (Murcia, 1995). Forest edges include the edges

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22192231

formed by the forest roads, rivers, forestry practices and power lines, as well as the natural openings such as rocks (Meister, 2007). Silvicultural treatments usually create forest edges with an adjacent stand, and these edges influence micro-climatic conditions within the stand (Baker et al., 2016). Factors such as air temperature, air humidity, vapor pressure, soil moisture, soil physical and chemical properties and light intensity vary between the outer and inner parts of the forest edges (Lhotka and Stringer, 2013; Dovčiak and Brown, 2014; Wekesa et al., 2018). Thus, understanding of the edge effects is crucial in forest management and woodlands (Ouin et al., 2015). In order to quantify the spatial scale at which stands are affected, the depth of forest edge effects has been observed in several studies (Laurance, 2000; Ries et al., 2004; Lhotka and Stringer, 2013). Research shows that the edge effects can extend at least ten meter into the adjacent stand, and these differences usually disappear after the first fifty meters from the edge towards interior stand (Murcia, 1995).

Oriental beech (*Fagus orientalis* Lipsky) and Scots pine (*Pinus sylvestris* L.) are economically and ecologically important deciduous and conifer tree species with wide distribution areas in Turkey (Boydak et al., 2011; Atik, 2013). Vast acreage of mixed stands comprised of these tree species is also present in the country. The sustainability of these mixed forests is possible through the successful regeneration of these tree species. Oriental beech is known to be a shade tolerant species, while Scots pine is intolerant to shade (Kara, 2018a, 2018b). Mixed Oriental beech-Scots pine stands have been commonly managed using traditional shelterwood method in Turkey (Odabaşı et al., 2004). Shelterwood systems are high-forest systems in which seedlings are established under the parent trees, and includes the systems of successive regeneration (Matthews, 1991). However, due to the differences in their tolerance to shade, group or group shelterwood methods are considered more appropriate to manage this forest type. With group methods, the group clearings or the groups with relatively lower density create edges with the intact stand. In general, Scots pine seedlings can be attained in groups, while Oriental beech is regenerated using traditional shelterwood method within the rest of the stands using relatively higher stand density. It is also likely to obtain Scots pine seedlings outside the groups and close to edges created. Studies comparing the edge of the forest with that of the inner forest have indicated that there is a higher amount of light on the forest edge, and it usually increases tree growth and the density of understory plants at or near the edges (Gehlhausen et al., 2000; Lhotka and Stringer, 2013). However, our knowledge on the influence of forest edge, and its extend on mixed Oriental beech-Scots pine stands is limited.

Several studies have explored the effects of forest edges on understory plants within interior parts of stands (Jiquan Chen et al., 1992; Gehlhausen et al., 2000; Burton, 2002; Hamberg et al., 2009; Gatti et al., 2019). However, to improve our understanding regarding the forest edges, it has been stated that more research on the forest edges is need for different forest types in different regions (Šálek et al., 2013). To our knowledge, no such study has been conducted in mixed Oriental beech-Scots pine stands. Moreover, recently, there has been a growing concern by Turkish forester on the decreasing proportion of Scots pine trees in the mixed beech-pine stands, which would result in the conversion of these mixed stands into pure beech stands in Turkey. Thus, understanding of the forest edges in these forests will help forest managers develop more appropriate management practices for the sustainability of these mixed forests in Turkey. The determination of the edge effects will help improve the success of group methods when naturally regenerating these mixed forests types as well. Understanding of the forest edges effects on the Oriental beech and Scots pine seedlings is essential for the sustainability of mixed stands of these tree species. Therefore, in this study, the influences of forest edges on the seedling density (ha^{-1}), height growth (cm) and root-collar diameter growth (mm) of Oriental beech and Scots pine seedlings in a mixed stand were observed. It is also aimed to examine how far the edge effect is from the edge of the stand to the interior stand. Moreover, the effects of stand basal area (m^2 ha^{-1}) and height-to-crown on the height growth and root-collar-diameter growth of seedlings of both species, when moving from the edge to interior stand, were monitored.

Materials and Methods

Study area

This study was conducted in a mixed Oriental beech-Scots pine forest managed by Samatlar Forest Directorate, within the boundary of Kastamonu Forest Regional Directorate in Kastamonu, Turkey (*Figure 1*). The study area was located within the compartment 90. Total forested area is 49.149 ha, which is approximately 74% of the entire area within Samatlar Forest Directorate. Kastamonu is situated in the Euro-Siberian fito geographic region (Çolak et al., 2009). Study area is located within the natural range of Oriental beech and Scots pine species. In addition to Oriental beech and Scots pine, black pine (*Pinus nigra* subp. *pallasiana*), Calabrian pine (*Pinus brutia*), Trojan fir (*Abies equi-trojani*), juniper (*Juniperus* sp.), oaks (*Quercus* sp.) and hornbeam (*Carpinus* sp.) are other tree species of the region. Blackberry (*Rubus* spp.), rockrose (*Cistus laurifolius*), heath (*Erica* sp.), cranberry (*Cornus* sp.) and ferns (*Pteridium aquilinum*) are the common understory species within study region. Average altitude of the study area is 1340 meter above the sea level, and average slope ranges from 10 to 30% across the study area. Study area is in the transition zone between Anatolian terrestrial and Black Sea temperate climates, therefore, cold/wet winters and rainy/wet summers occur in the region. The average annual temperature is 10.9°C within the study area ranging between -1.1 and 26.6. The average annual precipitation is 570 mm ranging from 250 to 689.5 m in the last twenty years. In the study region, the vegetation period lasts approximately 137 days starting from late April through later August. Sandy clay and loamy-clay soils are usually examined in the study region. The dominant soil group is mostly brown calcareous in the study region.

DOI: http://dx.doi.org/10.15666/aeer/1702_22192231

Study Design

The study was established along a mixed Oriental beech-Scots pine forest matrix that surrounded a forest opening of approximately 0.3 ha in size (*Figure 2*) in the spring of 2016. The study site is located at Longitude of 33.167075, and Latitude of 41.302296. About 90% of the stand basal area (m^2 ha^{-1}) composed of Oriental beech and Scots pine trees. The opening has been untreated to serve as a foot plot for wildlife animals for a prolonged time. The stand has been managed using the traditional shelterwood method. The topography of the opening was relatively flat, with a slope less than 10 %. This study used the edge environment around a forest opening to examine whether distance from the edge affected the root-collar-diameter growth and height growth of Oriental beech and Scots pine seedlings in a mixed stand of these tree species.

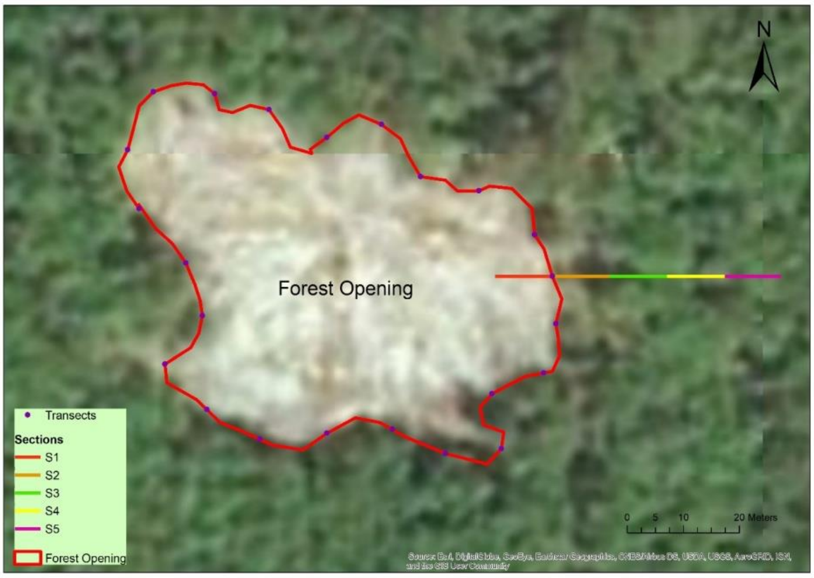

Figure 2. *Study area and a sample transect*

As suggested by Lhotka and Stringer (2013), the stand edge was determined as the border between the two nearest trees growing along the boundary of the forest opening. First, twenty-five sampling locations were chosen every ten meter along the perimeter of the forest opening (*Figure 2*) in the spring of 2016. Next, at each sampling location, twenty-five transects were installed perpendicular to the forest edge, and they extended 10 meter from the edge into the opening, and 40 meter from the edge into the stand (*Figure 2*). The width of transects was 1 meter, and there was not any canopy gaps along transects. Moreover, due to a recent understory control treatments, there was not any other species rather than Oriental beech and Scots pine understory of the study stand.

Measurements and Analysis

Measurements were taken in the summer (July and August) of 2016. Each transect was divided into five sections; one section within the opening (S1) and four sections within the stand (i.e., S2, S3, S4 and S5 for intervals of 0-10, 10-20, 20-30 and 30-40 m, respectively). In each section, all trees larger than 5 cm in diameter at breast height

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22192231

(d.b.h.) were measured. Using the d.b.h. measurements, basal area of each tree was determined using the formula below, and then, it was converted to basal area per hectare.

$$\text{Tree basal area} = \text{d.b.h.}^2\ (0.0000785) \quad \text{(Eq.1)}$$

Number of seedlings for each species was counted in each section, and it was converted to calculate number of seedlings for unit area (i.e., one ha). Within each section, five-year old Oriental beech and Scots pine seedlings were individually selected in 2017. It should be noted that seedlings' age were determined by counting the whorls following DeYoung (2016). Small single branches between major whorls were not included when counting age as suggested (DeYoung, 2016). Root-collar-diameter (mm) of selected seedlings was measured with a digital caliper to monitor total root-collar-diameter growth of seedlings of both species over five-year period. For each seedling, one root-collar-diameter measurement was taken first, and next, the second measurement, which was perpendicular to the first one, was conducted. Two measurements were averaged to attain the root-collar-diameter of each seedling.

In addition, height (cm) of selected seedlings was determined with a ruler to attain the total height growth of seedlings at age five. Distance (m) of each selected seedlings to the edge border was measured using a measuring tape height-to-crown, which refers to the vertical distance (m) from the surface to the first living branch of tree (Lhotka and Loewenstein, 2008), was measured every two meter in each section with a TruPulse Laser Rangefinder (Laser Tech Inc.). Height-to-crown measurements taken in each section were averaged to obtain average height-to-crown for each section.

Lhotka and Stringer (2013) stated that the study design used in this study is not manipulated by nature, thus, each transect can be treated as "replicate" because they are treated identically. Thus, there was 25 replicates of edge effects in this study. Root-collar-diameter of seedlings at age five were averaged for each categorized distance intervals (i.e., sections). Same procedure was repeated for seedling height for each section. Log-transformation was utilized for five-year root-collar-diameter growth and height growth data to enhance residual homogeneity and normality (Mcdonald, 2013).

Mixed-effect Analysis of Variance (ANOVA) model of was utilized to define the relationships between the distance from the edge and seedling root-collar-diameter and height growth (α=0.05). The test incorporated the transects as as random effect, while the distance from the edge was treated as fixed effect. The "lmer" function of "nlme" package in R-Statistical software (R Development Core Team, 2010) was used for this analysis. Tukey's pairwise comparison method for testing statistical significance of seedling density, root-collar-diameter and height growth among the categorized distance intervals (i.e., sections) was used (α=0.05). The categorized distance intervals (i.e., sections) were the experimental units for the mixed-effect ANOVA model as suggested (Lhotka and Stringer, 2013). In addition, the influences of the distance from the edge on the number of seedlings was found using poisson regression with the "glmer" funtion in R-Statistical software, since this test is recommended for the count data such as number of seedlings per hectare. Moreover, the influences of stand basal area and height-to-crown on the total root-collar-diameter growth and total height growth of seedlings over five years were determined using the mixed-effect linear regression method for each species, in which the transect was incorporated as as random effect, while basal area and height-to-crown were treated as fixed effects. The "lme" function of "nlme"

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22192231

package in R-Statistical software (R Development Core Team, 2010) was used for this analysis. Normality and homogeneity of variance were tested with residual analysis. R-Statistical software (R Development Core Team, 2010) was utilized for all statistical analyses.

Results and Discussion

Canopy Structure

Stand basal area and height-to-crown were measured to examine canopy structure across transects. Basal area ranged from 4.73 to 65-m^2 ha^{-1} across all transects (*Table 1*). Tukey's pairwise comparison test showed that there was not significant differences between S2-S3 (p= 0.99), S2-S4 (p= 0.99), S2-S5 (p= 0.92), S3-S4 (p= 0.99), S3-S5 (p= 0.85) and S4-S5 (p= 0.59) pairs in terms of stand basal area. Due to few trees within S1, basal area was lower in this section. Basal area of S1, which was located inside the opening, was significantly different from the basal areas of sections located inside the stand (i.e., S2, S3, S4 and S5) ($p<0.05$). Even though not statistically significant ($p>0.05$), the furthest section from the edge (i.e., S5) had relatively lower basal area (26.67 m^2ha^{-1}) than the other sections located interior stand (i.e., 32.33, 32.89 and 35.47 m^2 ha^{-1} for S2, S3 and S4, respectively). This is likely due to the decreasing amount of light from the edge towards to interior stand.

Our findings on the basal area among the sections seem to be consistent with previous studies. Previous researches, which compared the edge of the forest with that of the inner forest, have found out that there were higher amount of light close to the forest edge, and it usually increased tree growth at or near the edges (Gehlhausen et al., 2000; Lhotka and Stringer, 2013). It has been also stated that amount of light in open-field conditions is usually higher than it is inside forests (Heithecker and Halpern, 2007), as we observed in this study. We found that basal area started to decrease in S5 that is at least 30 m away from the edge suggesting that forest edge had influence on overstory trees within 30 m range from the edge into the intact forest in Oriental beech-Scots pine forests. This is also supported with previous studies such as Heithecker and Halpern (2007), and Lhotka and Stringer (2013) since they revealed that the edge effects could extend 10-30 m into the adjacent stand.

Table 1. *Descriptive statistics for basal area (m^2 ha^{-1}) and height-to-crown (m). SD refers to the standard deviation of the variables*

Variables	Min.	Max.	Mean	SD
Basal area	4.7	65	31.6	17.9
Height-to-crown	0.7	17.2	6.99	*3.34*

Height-to-crown was ranged from 0.7 to 17.2 m across all transects in Oriental beech- Scots pine forests (*Table 1*). There was not statistically significant relationships among sections in terms of height-to-crown (p= 0.218, F= 1.476), that is, height-to-crown did not significantly change from the open field conditions to the interior stand. Tukey's pairwise comparison test showed that there was not any significant differences between S2-S3 (p= 0.63), S2-S4 (p= 0.88), S2-S5 (p= 0.74), S3-S4 (p= 0.98), S3-S5 (p= 0.99) and S4-S5 (p= 0.99) pairs in terms of height-to-crown. When comparing height-to-crown among sections, we attained the lowest height-to-crown (3.85 m) in S1, which

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22192231

was located inside the opening. Average height-to-crowns were 6.02, 7.68, 7.10 and 7.43 m for S2, S3, S4 and S5, respectively. This is likely because the trees inside the forest opening have grown under open-grown conditions and deprived of self-pruning, and consequently, developed branches that are lower to the ground. In a similar study, Lhotka and Stringer (2013) monitored the changes in the canopy height (i.e., height-to-crown) from open-field conditions into the intact forest in a mixed deciduous forest, and discovered that height-to-crown was lowest inside the opening, and did not significantly change from edge into the stand. Given the findings in the literature, our findings regarding stand basal area and vertical canopy structure seem to be logical.

Seedling Density

The number of Oriental beech seedlings increased from open field conditions into the intact forest (*Table 2*). There was a statistically significant relationships between number of Oriental beech seedlings and distance to the stand edge ($p<0.001$). However, Tukey's pairwise comparison test showed that there was not any significant differences between S2-S3 ($p= 0.98$) and S4-S5 ($p= 0.97$) pairs in terms of number of Oriental beech seedlings per ha. In other words, only the number of Oriental beech seedlings in S1, which was located inside the opening, was significantly different from the sections located inside the stand (i.e., S2, S3, S4 and S5) ($p<0.05$). Increasing density of Oriental beech towards into the intact stand could be associated with Oriental beech's tolerance to shade, since this species can survive under overstory trees for a prolonged time (Odabaşı et al., 2004). Previous research has showed that Oriental beech seedlings can establish better under canopy than open-field conditions (Szwagrzyk et al., 2001; Parhizkar et al., 2011). Parhizkar et al. (2011) examined the effects of varying light intensities on Oriental beech stands, and reported that there was no significant differences in seedling density across the light intensities at age five. Stand basal area and height-to-crown had no significant effect on the density of Oriental beech seedlings ($p>0.05$).

Table 2. *Average number of seedlings per hectare for each species in each section*

Sections	Oriental beech	Scots pine
S1	400	7160
S2	5040	4080
S3	5320	1880
S4	7560	1240
S5	7720	680

Contrary to Oriental beech, the number of Scots pine seedlings decreased from open-field conditions towards to interior stand (*Table 2*). There was a statistically significant relationships between number of Scots pine seedlings and distance to the stand edge ($p=0.001$). It was likely that light transmittance through canopy decreased from open-field conditions to interior stand. Therefore, data showed the importance of light for Scots pine existence, which is an intolerant species to shade (Barbeito et al., 2009). Moreover, it is likely that Scots pine seedling could not compete with Oriental beech seedlings for light and nutrients under the shade of overstory trees. Previous research have explored the influence of light on the presence of Scots pine seedlings under forest canopy, substantiating the decreasing number of Scots pine seedlings attained in deeper

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22192231

part of the stand (Barbeito et al., 2009; Pardos et al., 2007). Stand basal area had no significant effect on the density of Scots pine seedlings either (p>0.05).

Seedling Growth

Average height growth of Oriental beech seedlings ranged from 9.5 to 178 cm with an average of 78.34 cm, while root-collar-diameter growth ranged between 1.65 and 20.8 mm (average 10.52 mm) across all sections over five year period. In a similar study conducted in Iran, it was concluded that average seedling height and root-collar-diameter growth were 67.85 cm and 10.56 mm, respectively (Abkenar and Keshavarz, 2005). Parhizkar et al. (2011) monitored the influence of varying light intensities on Oriental beech seedlings, and found that average seedling growth ranged from 57.3 to 150 cm, while root-collar-diameter ranged from 8 to 19 mm. Our findings also fall between the ranges presented by Parhizkar et al. (2011). The distance from the stand edge did not any statistically significant influence on the height growth of Oriental beech seedlings following five year period (p=0.12) (*Figure 3*). Average height of Oriental beech seedlings did not significantly change from open-field conditions into the intact stand. In addition, there was not any statistically significant relationships between the root-collar-diameter growth of Oriental beech seedlings and the distance from the stand edge (p= 0.25) (*Figure 3*). Moreover, stand basal area had no significant influence on the height growth (p= 0.08) and root-collar-diameter growth (p= 0.13) of Oriental beech seedlings over five year period. Height-to-crown did not significantly affected the height growth (p= 0.6) and root-collar-diameter growth (p= 0.09) of Oriental beech seedlings either.

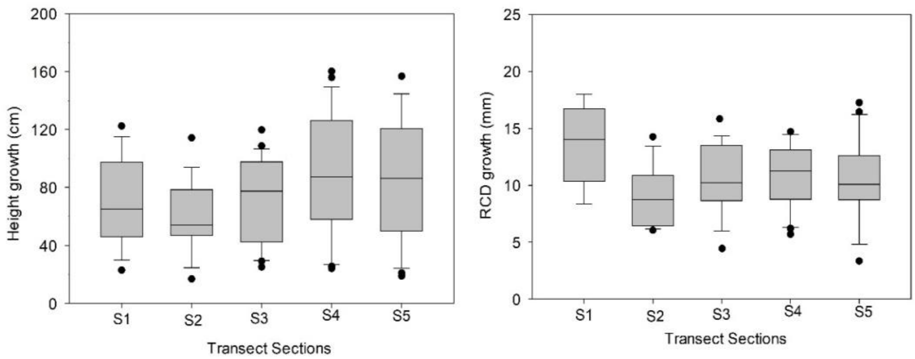

Figure 3. *The means of the height and root-collar-diameter (RCD) growth of Oriental beech seedlings under varying distances to the stand edge. Bars represent the standard deviations for the amounts of needle removal while the dots indicate the potential outliers*

The mean seedling height was 43.86 ranging from 13.3 to 98.85 cm for Scots pine seedlings, while root-collar-diameter growth ranged between 4.35 and 26.5 mm (average 10.03 mm) across all sections at age five. The growth rates of Scots pine seedlings observed in this study were consistent with previous studies. In a study conducted in Sweden, it was found that Scots pine seedlings planted under a canopy reach an average height of 40 cm at the end of the five growing seasons (Egnell and Valinger, 2003). In a different study, which monitored the effects of varying stand density on root-collar-diameter growth of Scots pine seedlings, an average of 13 mm in root-collar-diameter was determined (Gerelbaatar et al., 2015). The distance from the

DOI: http://dx.doi.org/10.15666/aeer/1702_22192231

stand edge had statistically significant effect on the height growth of Scots pine seedlings following five year period (p= 0.0001) (*Figure 4*). Average height of Scots pine seedlings decreased with increasing distance from the stand edge. In addition, there was statistically significant inverse relationships between the root-collar-diameter growth of Scots pine seedlings and the distance from the stand edge (p= 0.001) (*Figure 4*). Moreover, since stand basal area did not significantly change from the edge into the stand, it had no significant effect on the height growth and root-collar-diameter growth (p>0.05) of Scots pine seedlings over five year period. Height-to-crown had also no significant effect on the height growth and root-collar-diameter growth (p>0.05) of Scots pine seedlings.

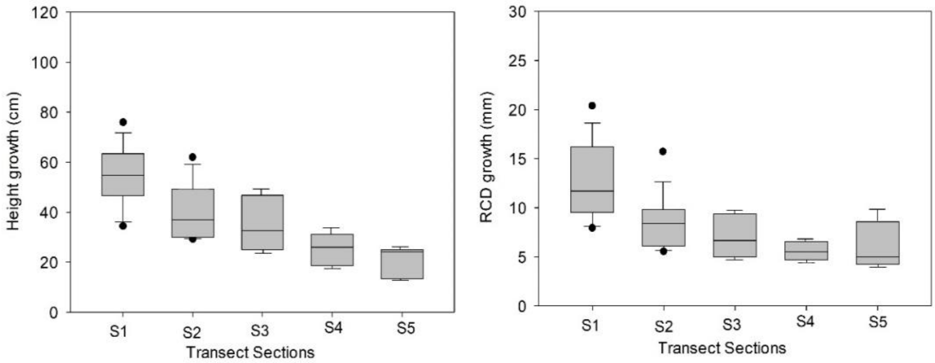

Figure 4. *The means of the height and root-collar-diameter (RCD) growth of Scots pine seedlings under varying distances to the stand edge. Bars represent the standard deviations for the amounts of needle removal while the dots indicate the potential outliers*

Understanding of the relationship between edge effects and seedling growth is essential for the establishment of understory seedlings when natural regeneration is aimed. Forest edges affect the understory light environment (Lhotka and Stringer, 2013). This study support the notion that the amount of light under the forest canopy affect seedling growth of intolerant tree species such as Scots pine. Even though stand density (i.e., basal area) and height-to-crown did not significantly change from the stand edge into the stand, Scots pine seedling growth significantly decreased towards interior stand. Thus, the decreasing seedling growth from the edge into the stand can be associated with the edge effect. Our finding suggests that forest edge was effective for light environment, within 40 m from edge, in Oriental beech- Scots pine forests. In previous research, Carus (2004) and Pardos et al. (2007) also found out that understory light is usually the most limiting factor which influence the growth of Scots pine seedlings. In a similar study, Gerelbaatar et al. (2015) examined the growth of Scots pine seedlings under varying intensities, and found higher seedling growth under higher light intensity.

The opposite pattern in Oriental beech seedlings (i.e., increasing growth of seedlings from the edge into the stand) may be related to its competition with Scots pine seedlings. Scots pine seedlings are more light-demanding species than Oriental beech seedlings. Thus, under open-field conditions, Scots pine seedlings' rapid growth likely suppressed Oriental beech seedlings, and became denser. On the other hand, Scots pine seedlings could not compete with Oriental beech seedlings interior stand due to lower amount of light, therefore, Oriental beech seedlings had more growing space and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22192231

nutrients inside stand, and presented higher density. Data suggested that decreasing light through the edge effects did not have any negative influence on the growth of Oriental beech forests. Similarly, Abkenar and Keshavarz (2005) observed the height growth of Oriental beech seedlings under canopy and in canopy opening, and found that seedling growth did not significantly differ between the two conditions. In another study, Parhizkar et al. (2011) observed the growth of Oriental beech seedlings under varying light intensities, and revealed that there was not any relationship between light intensity and seedling growth. Given the data in previous research, our findings regarding Oriental seedling growth seem to be acceptable.

Traditional shelterwood method has been widely used in Oriental beech-Scots pine forests in Turkey Odabaşı et al. (2004), including the study area. Approximately 5000-7000 seedlings per ha at age five for each species are recommended for natural regeneration of these forests in this method (Odabaşı et. al., 2004; Calama et al., 2015). Given these numbers in the literature, our data showed that there was insufficient number of Scots pine seedlings when moving more than 10 m from the edge into the stand in the study stand. Therefore, the results suggest that shelterwood method within the entire area may be unsuccessful in these forests. Instead, Scots pine seedlings could be obtained in open-field conditions and near the edges. Groups could be created with complete clearing of vegetation, or using group shelterwood with a canopy closure of 40% in this stand type in favor of Scots pine (Odabaşı et. al., 2004). Data also showed that adequate number of Oriental beech seedlings could be obtained under the shade of overstory seedlings, thus, any partial cutting such as shelterwood or singletree selection methods outside the groups may be successful for the natural regeneration of Oriental beech in these stands. Mean height and root-collar-diameter growth of Scots pine seedlings after 10 m from the edge were lower that what observed in previous studies (Egnell and Valinger, 2003; Gerelbaatar et al., 2015) (*Figure 4*), that is, stand edge has negative effects on Scots pine seedlings after 10 m from the edge. Therefore, the size and number of groups when conducting group methods should be decided taking the range of edge effects (i.e., 10-40 m) into account in mixed Oriental beech-Scots pine stands.

Conclusions

This study presented the relationships between the distance from stand edge and growth of Scots pine seedling, while no effect of the edge on Oriental beech seedlings was observed. Data showed that the edge effect on Scots pine seedlings was present after 10 m from the edge into stand, and may extend up to 40 m into the stand adjacent to a forest opening. Study results add knowledge to the scientific understanding of the edge effects in mixed Oriental beech-Scots pine stands. Initial results suggest that Scots pine seedling can be established in canopy gaps or group clearing, while Oriental beech should be successfully attained under canopy within the rest of the stands. Traditional shelterwood method has been commonly used to regenerate mixed Oriental beech-Scots pine stands in Turkey; however, our results indicate that Scots pine seedlings may not well develop under overstory trees, and the stands may turn into pure stands of Oriental beech in long term. The influence of edges created by silvicultural treatments should be taken into account when group methods are aimed in this forest type. The data presented in this study will be helpful for forest managers who aim to enhance seedling development and establishment in mixed Oriental beech-Scots pine forests. However,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22192231

more research should be conducted on the use of group selection method in the mixed Oriental beech-Scots pine stands. In addition, this study was conducted on a single forest opening; thus, forest edge effects along varying gap sizes should be considered in the future studies. Moreover, direct light measurements thorough the sections of the lines should be taken in further research. We also stated that there has been a growing concern on the decreasing proportion of Scots pine trees in the mixed beech-pine stands and other mixed stands that contain Scots pine; therefore, similar studies should be conducted in mixed stands of Scots pine and other tree species such as oak (*Quercus*), fir (*Abies*) and spruce (*Picea*) in Turkey.

Abstract. Although there have been obvious land use changes in Xinjiang, China, the effect of reclamation (ecological restoration) of abandoned farmlands on soil microbial properties is rarely reported. Natural restoration of abandoned farmland was used as a control treatment, and the effects of different reclamation (ecological restoration) patterns on soil microbial properties in Shihezi, Xinjiang, China were analyzed. The results showed that there was a significant difference between different reclamation (ecological restoration) patterns in soil chemical and microbial characteristics ($P < 0.05$). These results indicate that the highest values for soil organic matter and available P were in accordance with the highest values for soil microbial communities (fungi, bacteria and total microbial amount), and the higher the value of pH, the lower the activity of urease and soil microbial biomass carbon. Land use patterns, both ecological restoration and reclamation types, were useful when only soil quality improvement was considered. Because of the advantages of improvement in soil fertility, the agroforestry pattern could be used as the preferred reclamation pattern for abandoned farmland in salinized regions. By increasing the soil water content and promoting the establishment of vegetation, the water recharge pattern could be a good choice during the early stage of ecological restoration of abandoned farmland.

Keywords: *Manas river basin, agroforestry pattern, soil biochemical properties, principal component analysis, land use change, arid regions, salinization*

Abbreviations: RRAF: reclamation (ecological restoration) of abandoned farmlands, MES: *Medicago* sp., CIS: *Citrullus lanatus* spp., AGF: agroforestry, SWR: soil water recharge, ENP: enrichment planting, ACS: *Achnatherum splendens*, NAR: natural restoration of abandoned farmlands, SOC: soil organic carbon, SOM: soil organic matter, SAN: soil available N (alkali-hydrolyzable N), SAP: soil available P, MBC: microbial biomass C, MBN: microbial biomass N, URE: urease activity, SUC: sucrase activity, PHO: phosphatase activity, CAT: catalase activity, BAC: bacteria, FUN: fungi, ACT: actinomycetes, TMA: total microbial amount

Introduction

RRAF in arid regions is critical to ensure both sustainable development of agriculture and environmental protection (Suding, 2011; Yang et al., 2016; Zhou et al., 2017). The land use changes caused by RRAF are one of the most important reasons for global environmental changes (GLP, 2005).

Artificial measures involving fertilization, irrigation and ploughing in the process of RRAF will change plant types, which eventually leads to changes in the biochemical properties of the soil (Li et al., 2013; Liu et al., 2013; Nadimi-Goki et al., 2017). Soil biochemical properties include its microbial communities and soil enzyme activity (Bastida et al., 2008; Stott et al., 2010). Soil microbial communities are an important part of soil microbial processes, which play a critical role in nutrient

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22332247

transformation, soil health and sustaining the productivity of soil (Nannipieri et al., 2003). Soil enzyme activity is the basis for ensuring soil microbial quantity and soil physicochemical properties, and has a close relationship with the carbon and nitrogen cycle in soil (Mersi and Schinner, 1991). Moreover, soil enzyme activity can reflect the effects of plant type and crop rotation, as well as that of organic and inorganic fertilizers, etc., on soil quality (Bastida et al., 2012; Singh and Ghoshal, 2013). Soil biochemical properties are more sensitive to environmental stress than other physicochemical characteristics, which often reflect changes in soil quality, and can therefore be used to monitor soil biological processes in different land use patterns (Patra et al., 2005; Xue et al., 2008; Nadimi-Goki et al., 2017).

Unsustainable agricultural practices have resulted in the degradation and desertification of many arid ecosystems around the world (Castellanos et al., 2005), which has led to abandoned farmlands becoming a major issue worldwide (Bonet, 2004). However, there is a generalized lack of research about RRAF in arid environments (Romo-Leon et al., 2016).

In particular, inadequate use and overuse of land has contributed to serious environmental problems of land degradation in Xinjiang, northwest China (UN General Assembly, 1997). In the 50 years from 1949 to 2000, land use changes in Xinjiang were huge, indicating both abandoned farmlands caused by secondary salinization, and large-scale land reclamation caused by social and economic development (Luo et al., 2003; Fan et al., 2008; Feng et al., 2011). Land use change in the Manas river basin was especially typical in Xinjiang: the population increased from 59,000 in 1949 to 1,109,000 in 2004 (Li et al., 2008), which made it become the largest artificial oasis in Xinjiang and the fourth-largest irrigated agricultural land area in China (Feng et al., 2011). With the widespread application of drip irrigation technology since 1996, large areas of abandoned farmlands have been reclaimed, and the reclamation area exceeded the abandonment area in 1999 (Qian et al., 2006).

However, the soil physical and chemical properties, vegetation composition, history of abandonment, climatic features and the plant types of reclamation (restoration) varied with the changes to abandoned farmlands; the effects of RRAF patterns on soil biochemical properties changed in different regions, and there were even some opposing conclusions. Some researches have reported that soil microbial communities and enzyme activity increases after land reclamation (ecological restoration) (Tan and Kang, 2009; Liu et al., 2013; Guo et al., 2014). Nevertheless, other studies have found that the decline in soil organic C results in a decrease in soil bacteria, fungi and actinomycetes (Yin et al., 2013), the catabolic diversity of soil microbial communities (Degens et al., 2000) and urease activity (Raiesi and Beheshti, 2014) after RRAF.

For the Manas river basin, RRAF generally involves planting of economic crops, such as *Medicago* sp. and *Citrullus lanatus* spp., and agroforestry, etc., and RRAF generally includes water recharge, enrichment planting (native plants with resistance to salt and drought stress) or planting *Achnatherum splendens*, etc. For the Manas river basin which has drought stress and severe secondary salinization of soil, however, little is known about the effects of RRAF on soil microbial communities and enzyme activity, and which reclamation (ecological restoration) pattern is suitable for this basin.

Based on extensive investigation among existing RRAF patterns in the Manas river basin, six representative RRAF patterns were set in Shihezi, Xinjiang. The objectives

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22332247

of this paper were to: (1) compare the differences in chemical properties, microbial communities and enzyme activity of soil among different RRAF patterns; and (2) analyze correlations between microbial communities, enzyme activity and chemical properties. We expected to provide references for RRAF in drought and salinized regions.

Materials and methods

Experimental set-up and environmental conditions

The sample plot was located in Shihezi, Xinjiang, northwest China (85°35.275′E ~ 85°38.634′ E, 44°32.493′N ~ 44°33.989′ N, *Fig. 1*). Halosols are the dominant soils in plot. The plot is situated in the Manas river basin and has a temperate continental climate. Meteorological factors such as temperature, relative humidity, sunshine, precipitation and soil chemical properties are shown in *Table 1*. Six RRAF patterns, namely, planting MES and CIS, AGF, SWR, ENP and planting ACS were selected for the sample plot in 2008. According to the difference in ecosystem functions after reclamation (ecological restoration), the six RRAF patterns were classified into reclamation types including MES, CIS and AGF, and ecological restoration types including SWR, ENP and ACS. NAR was set as a control (*Fig. 2*). AGF consisted of tree (*Populus russkii* Jabl.) – wheat intercropping. SWR plots were irrigated once with 225 m^3/hm^2 in spring and autumn, respectively. ENP was set via enrichment planting of native plants, such as *Reaumuria soongorica* (Pall.) Maxim, *Suaeda salsa* L., etc., with a height of 10–15 cm and density of 20,000 individuals/hm^2. The seedling density of *A. splendens* was 3,000 individuals/hm^2 in ACS.

Soil samples were taken in an S-shaped pattern (0–20 cm) from five points in each plot in 2011. The five soil samples were mixed, and 1 kg subsamples were extracted for analysis using the quartering method (Rasapoor et al., 2009). Three subsamples within each RRAF pattern were collected, totaling 21 subsamples.

Measurement of soil chemical properties, soil microbial communities and enzyme activity

Soil chemical properties were measured from air-dried soil samples, and soil microbial communities and enzyme activity were measured from fresh soil samples. Soil pH was measured using an Ampholine (LKB Producter AB, Stockholm, Sweden) pH meter (3310, water-to-soil ratio 2.5:1). Soil EC was determined using the electrical conductivity method (DDSJ-308A conductivity meter, water-to-soil ratio5:1, dS/m). SOC was measured by the potassium dichromate oxidation method (Vance et al., 1987). SOM was calculated according to *Equation 1:*

$$\mathrm{SOM} = {}^{\mathrm{SOC}\ (\%)}/_{58\%} \qquad \text{(Eq.1)}$$

SAN was measured using the alkaline solution diffusion method. SAP was analyzed colorimetrically using the ascorbic acid molybdate method.

Fresh soil samples were gently sieved through a 2 mm sieve and used for determining soil biological parameters. The soil microbial population (BAC, ACT, FUN and TMA) was measured by dilution plating, as described by Bulluck et al. (2002). Soil MBC and soil MBN were measured using the chloroform fumigation extraction method (Brookes et al., 1985; Vance et al., 1987). URE was measured using the indophenol blue method (Keeney and Nelson, 1982). SUC was determined using 3,5-dinitrosalicylic acid colorimetry. PHO was determined with the phenylene-disodium phosphoric acid colorimetric method (Guan, 1986). CAT was measured using the potassium permanganate titration method (Zhou et al., 2011).

Statistical analysis

All data were analyzed using SPSS 15.0 software (SPSS Inc., USA). Differences in soil variables between different RRAF methods were analyzed using a Duncan test in one-way ANOVA for multiple comparisons. Correlation analyses were carried out using Pearson two-tailed tests between the mean value by pattern of the soil chemical variables and the soil microbial properties, and between each of the soil microbial properties. The significance of the explained variation was analyzed using a generalized linear model (GLM, type III sum of squares, McCullagh and Nelder, 1989) according to *Equation 2:*

$$Y = \mu + T + P(T) + \varepsilon \qquad \text{(Eq.2)}$$

In *Equation 2,* Y is the response variable, μ is the general mean, T is the effect of the type, $P(T)$ is the effect of the pattern (within a type) and ε is the error term.

Soil microbial communities and enzyme activity were anaSlyzed using principal component analysis (PCA). The scatter plot was drawn using the scores of principal components. According to the scatter plot, combinations of soil microbial communities and enzyme activity between different RRAF patterns were analyzed.

Results

Soil chemical properties for different RRAF patterns

There were significant differences between soil chemical properties for different RRAF patterns (P < 0.05, *Table 1*). The values of soil pH and EC were highest, and the values of SOM, SAN and SAP were lowest in NAR. The values of soil chemical properties in AGF were contrary to those in NAR (except soil EC). For other patterns, differences between soil pH in MES, CIS, SWR, ENP and ACS were not significant (P > 0.05). The difference between soil EC in MES and ACS was not significant (P > 0.05). SOM in MES, SWR, ENP and ACS was similar (P > 0.05). There was no significant difference in SAN between CIS and AGF, or between MES, SWR and ENP (P > 0.05). Differences between SAP in SWR, ENP and ACS were not significant (P > 0.05).

Variation in soil chemical properties and biochemical properties for different RRAF patterns

The GLM showed that for type factors, only SAP, CAT and ACT significantly affected soil chemical properties and biochemical properties (P < 0.01). The pattern factor significantly affected soil chemical properties and biochemical properties apart from soil pH and CAT (P > 0.05, *Table 2*). For most of the soil chemical properties and biochemical properties (13 out of a total of 15), the pattern factor significantly explained the total variation. In particular, variation was highest for the effect of pattern factor on TMA, which was up to 1670.86.

Soil enzyme activity

For all patterns, all soil enzyme activity for NAR was at the lowest level; URE, SUC and PHO in AGF were the highest, and there was a significant difference in soil enzyme activity between AGF and NAR (P < 0.01, *Fig. 3*). URE in CIS, ENP and NAR was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22332247

similar (P > 0.05), and URE in SWR, ACS and AGF was similar (P > 0.05). The difference between SUC in MES and AGF was not significant (P > 0.05). The difference between CAT in SWR, ENP and ACS was not significant (P > 0.05), and CAT in SWR, ENP and ACS was significantly higher than for other patterns (P < 0.05, *Fig. 3*).

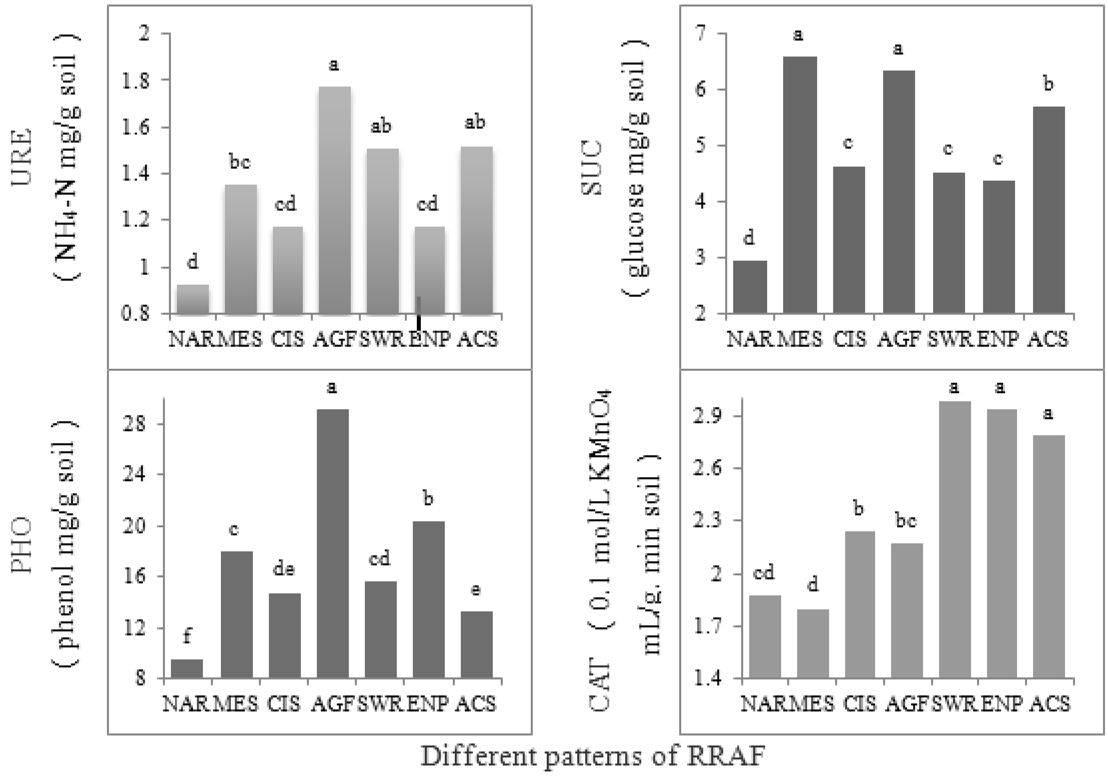

Figure 3. *A comparison of four soil microbial enzyme activities*

Soil microbial communities

Trends for soil microbial communities for different patterns were similar to those for soil enzyme activity: the values of soil microbial quantities and biomass in NAR were the lowest, while the values of soil microbial quantity and biomass in AGF were the highest. There was a significant difference between soil microbial communities in NAR and AGF (P < 0.01, *Fig. 4*). For other patterns, MBC in CIS, SWR, ENP and NAR was similar (P > 0.05); MBC in MES, ACS and AGF was similar (P > 0.05). The difference between MBN in CIS, SWR, ENP and ACS was not significant (P > 0.05). There was no significant difference in BAC between SWR, ENP and ACS (P > 0.05). The difference between ACT in SWR, ENP and ACS was not significant (P > 0.05, *Fig. 4*).

PCA of soil microbial communities and enzyme activity

Certain soil microbial communities and enzyme activity were well separated by pattern, according to soil chemical properties (*Fig. 5A*), and the classification of soil chemical properties for different patterns is shown in the PCA scatter plot (*Fig. 5B*): TMA, BAC and FUN were in accordance with the positive scores for PC1, and characterized the soil chemical properties of AGF; CAT was in agreement with the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22332247

negative scores for PC1, and characterized the soil chemical properties of NAR. CAT, URE and MBC were in accordance with the positive scores for PC2, and characterized the soil chemical properties of ACS; ACT, TMA and MBN were in agreement with the negative scores for PC2, and characterized the soil chemical properties of NAR.

Soil enzyme efficiency

To indicate how RRAF pattern affects soil enzyme efficiency, soil enzyme activity was normalized, and expressed as enzyme activity per gram of soil MBC or MBN (URE normalized to N, and SUC, PHO and CAT normalized to C). There were significant differences in soil enzyme efficiency between different patterns after the soil enzyme activity was normalized ($P < 0.01$, *Table 3*). When comparing normalized data with non-normalized data, no significant effects were found between enzyme activity in NAR, CIS, SWR and ENP. However, URE was significantly changed in AGF, URE now being the lowest in AGF when compared to other patterns (*Table 3*).

Relationships between soil chemical properties and microbial variables

Regression analysis between soil microbial variables showed the following significant relationships at $P < 0.05$ level (*Table 4*): URE was positively related to SUC (r = 0.772), URE was positively related to MBC (r = 0.834), SUC was positively correlated with BAC (r = 0.774), SUC was positively correlated with TMA (r = 0.774), PHO was positively related to BAC (r = 0.804), and PHO was positively related to TMA (r = 0.799). The following significant relationships were found at $P < 0.01$ level (*Table 4*): SUC was positively related to MBC (r = 0.878), PHO was positively related to MBN (r = 0.885), and PHO was positively correlated with FUN (r = 0.863). In particular, significant relationships at $P < 0.01$ level were found between MBN, FUN, BAC, ACT and TMA (*Table 4*).

Regression analysis between soil chemical properties and microbial variables showed the following significant relationships (*Table 4*): pH was negatively correlated with URE (r = −0.786), SUC (r = −0.951) and MBC (r = −0.935); SOM was positively related to URE (r = 0.822), PHO (r = 0.894), MBN (r = 0.806), FUN (r = 0.882), BAC

Discussion

Soil chemical properties, microbial communities and enzyme activity were studied for different RRAF patterns in Shihezi, Xinjiang. For most soil parameters, more variation was explained by pattern than by type (*Table 2*), which shows that soil chemical properties, microbial communities and enzyme activity are significantly affected by pattern; significant differences between soil properties for different patterns also proved the result (*Figs. 3* and *4*).

The variation in soil microbial communities (BAC, FUN, ACT and TMA) was significant for different patterns, and the variation was especially high in TMA (*Table 2*), indicating that different patterns have a significant influence on microbial communities. BAC, FUN and ACT in soil are important in regulating ecological processes such as SOM decomposition, energy flow, carbon storage, etc. (Paul and Clark, 1997). FUN, BAC, ACT and TMA for each pattern were significantly higher than for NAR (except that ACT in SWR, ENP, ACS and NAR was similar); in particular, FUN, BAC, ACT and TMA in AGF were the highest (*Fig. 4*), which indicates that AGF has the strongest effect on soil microbial communities. It may be that the growth of microorganisms in AGF has been promoted by differences in litter quality and quantity, and root exudates (Monokrousos et al., 2006; Maestre et al., 2015). The values for SOM and SAP were lowest in NAR and were highest in AGF (*Table 1*); SOM was significantly related to FUN, BAC and TMA, and SAP was significantly related to FUN, BAC, ACT and TMA (*Table 4*). These correlations indicate that different patterns significantly influence microbial communities by improving SOM and SAP, and are in accordance with the report by Tan and Kang (2009). Significant relationships were found between FUN, BAC and ACT (*P* < 0.01, *Table 4*), which indicates that microbial communities have the same response to changes in soil environment for different patterns. FUN, BAC and ACT showed significantly positive correlation with SAP, suggesting that SAP may be the dominant factor affecting the growth of microbial communities.

Soil enzymes mainly come from microbial metabolic processes, soil animals and plant root exudates and residues (Bandick and Dick, 1999). In soil, enzyme activity is the foundation to ensure soil microbial quantity and soil physicochemical characteristics, which are closely connected to the cycles of C and N (Mersi and Schinner, 1991). As we expected, significant variation was found between soil enzyme activity for different patterns (*Table 2*). The soil enzyme activity for the six patterns was higher than for NAR (except for URE in CIS and ENP, and CAT in MES) (*Fig. 3*), showing the notable effects of different patterns on soil enzyme activity (Singh and Ghoshal, 2013; Nadimi-Goki et al., 2017). URE, SUC and PHO in AGF were the highest when compared to other patterns (*Fig. 3*), indicating that AGF can promote the utilization of N, efficiency of the C cycle and the availability of soil P (Frankenberger and Johanson, 1983; Nannipieri et al., 2002).

Many studies have shown that soil enzyme activity is positively correlated with SOM (Bastida et al., 2012; Liu et al., 2013; Liang et al., 2014; Mahajan et al., 2016; Zhang et al., 2017), because SOM serves as a precursor for enzyme synthesis (Liu et al., 2013). Our research showed that SOM was positively correlated with URE and PHO ($r = 0.822$, $P < 0.05$; $r = 0.894$, $P < 0.01$, respectively, *Table 4*). While soil pH was negatively related to URE and SUC ($r = -0.786$, $P < 0.05$; $r = -0.951$, $P < 0.01$, respectively, *Table 4*), we did not find a significant relationship between soil EC and soil enzyme activity. These correlations indicate that the effect of soil pH on URE and SUC is greater than that of EC. This may be due to the tolerance of plants in different patterns to salt stress, and the high value of soil pH was the limiting factor for URE and SUC.

Generally, soil enzyme activity represents active members of microbial communities (Bradford et al., 2008). After soil enzyme activity was normalized by MBC or MBN, we could distinguish whether the microbial communities allocated energy to microbial growth or enzyme production (Schimel and Schaeffer, 2012). Intriguingly, when enzyme activity was normalized to MBC or MBN, MBN in AGF supported lower URE (*Table 3*), but was contrary to the data for non-normalized enzyme activity (*Fig. 3*). This shows a weak N cycle in AGF when compared with SWR and ACS. Namely, URE in AGF may respond more slowly to land use changes than the other two patterns. Changes in normalized URE in AGF also showed a change of physiological function in microbial communities: allocating more energy to microbial growth rather than to enzyme production (Bradford et al., 2008; Schimel and Schaeffer, 2012).

The PCA results indicated that PC1 of AGF, with a maximum positive score, characterized the highest values of both SOM and SAP, and was in agreement with the highest values of FUN, BAC and TMA. This indicates that higher values of SOM and SAP would mean higher soil microbial biomass (FUN, BAC and TMA). The soil properties in NAR were in contrast to those for AGF. Significant positive correlations between SOM and FUN, BAC and TMA, and between SAP and FUN, BAC and TMA also prove this result (*Fig. 5; Table 4*).

PC2 of ACS, with a maximum positive score, characterized the lowest value of soil pH, which was in accordance with the highest URE and MBC, showing the high activity of soil enzymes. URE and MBC were lowest in NAR, indicating that the higher the pH value, the lower URE and MBC, as also was proved by the negative relationship between soil pH and URE and MBC (*Fig. 5; Table 4*).

In addition, variations in most soil parameters were not significant between reclamation type and ecological restoration type (*Table 2*), which shows that there was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22332247

no significant difference between the soil properties in different types, whether the reclamation type characterized the economic benefits or the ecological restoration characterized the ecological benefits. There was a significant difference between characteristics of soil chemistry and biochemical properties were observed for different patterns. The higher the values of SOM and SAP, the greater the values of MBN, FUN, BAC and TMA, and the higher the value of soil pH in accordance with lower values of URE, SUC and MBC in soil. These correlations indicate that different plant composition, soil biochemical characteristics and human activities in different patterns have significant influences on soil biochemical properties (Lal, 2005; Singh and Ghoshal, 2013).

Conclusions

In this paper, changes in soil chemical and biochemical properties with different patterns were studied. In terms of improving soil quality, it is meaningful to use both the reclamation type and ecological restoration type in abandoned farmlands. Most soil chemical and microbial characteristics for AGF were significantly higher than for other patterns and NAR (*Table 1; Figs. 3* and *4*), demonstrating the obvious effects of AGF on soil fertility improvement (Tian et al., 2013). AGF could be used as the preferred reclamation pattern for abandoned farmland in salinized regions, because it accounts for the vulnerability of the ecological environment (arid, low temperature and salinization stress) in the sample area, as well as having both economic and ecological benefits. It should be noted that SWR could be a good choice during the early stage of RRAF, by increasing the soil water content (data not shown), and improving soil quality (particularly in soil EC, SOM, SAN, URE, SUC, PHO, CAT, FUN, BAC and TMA) when compared to NAR, thus promoting the establishment of vegetation. All patterns in our experiment have certain effects on improving the quality of soil, and this will provide references for RRAF in drought and salinized regions.

Although an optimal RRAF pattern can be selected by comparing soil chemical and biochemical properties, however, further study is needed to focus on the hydrological cycle to ensure the sustainable utilization of water resources in arid regions. Moreover, the long-term dynamic study also needed for more objective evaluation on RRAF.

CADMIUM-INDUCED CHANGES IN GROWTH AND MICRONUTRIENT COMPOSITION OF TWO PEPPER CULTIVARS

BARUT, H.

East Mediterranean Agricultural Research Institute, 01321 Adana, Turkey
(e-mail: barut.hatun.hb@gmail.com; phone: +90-322-334-0055)

(Received 8th Dec 2018; accepted 28th Jan 2019)

Abstract. The present research was conducted to investigate the effects of cadmium (Cd) treatments on shoot and root dry weight, SPAD values, shoot and root Cd accumulations and micronutrient compositions of two pepper cultivars (*Capsicum annuum* L. cvs. 'Demre' and 'AT58'). Plants were grown under controlled conditions with 0 and 15 µM Cd supplies. Decreasing root and shoot dry weights were observed with increasing Cd doses ($P < 0.05$). Decrease in shoot and root dry weights with 15 µM Cd supply was higher in Demre cultivar than in AT58 cultivar. Cd-induced decreases in SPAD values were greater in Demre cultivar than in AT58 cultivar. Shoot Cd concentrations were lower and root Cd concentrations were greater in AT58 cultivar than in Demre cultivar. Decreasing shoot zinc (Zn), iron (Fe), manganese (Mn) and copper (Cu) concentrations and root Zn and Mn concentrations were observed with Cd treatments. Considering the Cd uptake and transport to shoot, it was observed that there were differences in tolerance of cultivars to Cd toxicity, but it was thought that these differences were not necessarily related to microelement uptake and transport of the cultivars.
Keywords: *heavy metal, SPAD value, zinc, iron, manganese, copper*

Introduction

Cadmium (Cd) is a highly toxic heavy metal and poses significant threats to human health and environment. Developed industrial and agricultural practices lead to significant increases in soil cadmium levels (Sarwar et al., 2010). Phosphorus fertilizers, Cd-containing wastewater treatment sludge, livestock manure, wastewater effluents, various metal processing industries, cement facilities and urban traffic are considered to be the greatest sources of Cd for soil (Alloway and Steinnes, 1999; Yang et al., 2004). Although cadmium is not considered as an essential nutrient for plants, soil available Cd is easily up taken through the roots and accumulated in the plant tissues and pose serious health risks on humans through the food chain (Zhou and Qiu, 2005). High cadmium concentrations also damage plant roots, destruct photosynthetic activity, recess plant growth and development and hinder plant nutrient and water uptake from the soil (Jibril et al., 2017). High cadmium levels influence cell membrane permeability (Sengar et al., 2008) and destruct antioxidant defense mechanisms of the plants against oxidative stress conditions through elevated lipid peroxidation (Benavides et al., 2005).

Plant normal cadmium concentrations were reported as between 0.2-0.8 mg kg^{-1} and toxic levels as between 5-30 mg kg^{-1} (Allen, 1989; Kloke et al., 1984). Similar with the other stressors, Cd also hinders plant nutrient uptake, interacts with the soil available nutrients and ultimately results in imbalanced mineral nutrition (Khan et al., 2007). There is a great competition between Cd ions and the other essential plant nutrients including Ca, Mg, K, Cu, Zn, Fe, Ni and Mn required for plant growth and development (Clarkson and Luttge, 1989; Rivetta et al., 1997). In a previous study, either synergistic or antagonistic effects of cadmium were reported on plant nutrients (macro or micro) of different wheat cultivars (Zhang and Huang, 2000). In other studies, either negative

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22492256

(Bhandal and Kuar, 1992) or positive (Mitchel et al., 2000) correlations of cadmium were reported with nitrogen. Similarly, antagonistic (Li et al., 1990) and synergistic (Nan et al., 2002) interactions of cadmium were reported with zinc. Cadmium treatments increased Cu and Mo levels and decreased K, Ca, Mg and Mn levels of Birch seedlings (Gussarsson, 1994). Increasing Cd levels resulted in greater Cd, Zn, Fe, Mn and Cu accumulations in roots and slight Cd transfer to shoots (Wang et al., 2007).

Different plants have various cadmium accumulation capacities (Yang et al., 1996; Obata and Umebayashi, 1997; Yildiz, 2005). However, variations were also reported among the different cultivars of wheat (Naeem et al., 2016), barley (Tiryakioglu et al., 2006), maize (Ekmekci et al., 2008), soybeans (Shamsi et al., 2008), tomato (Hussain et al., 2015) and chilli peppers (Xin et al., 2013). Kuboi et al. (1986) classified Cd accumulation capability of the plants into three groups (high, moderate and low accumulators). Pepper is the second crop after tomato produced in greenhouses of Turkey and high-quality yield is the most critical issue in pepper cultivation in greenhouses (Abdel Latef, 2013). Therefore, the present research was implemented to investigate the Cd accumulation in two pepper (*Capsicum annuum* L.) cultivars of *Solanaceae* family. The primary target was to identify the effects of cadmium treatments on plant development and micronutrient compositions of pepper cultivars with different Cd accumulation levels.

Materials and methods

Experiment and analyses

Demre and AT58 pepper cultivars were used as the plant material of this study. The plants were grown under controlled climate conditions (26/22 °C day/night temperature, 16/8 h photoperiod, 350 µmol m^{-2} s^{-1} light intensity supplied with Osram HQI/2000/D lamps and 65-75% relative humidity). Surface-sterilized seeds with 1% (w/v) calcium hypochlorite for 10 min were rinsed through distilled water. Seeds were then sown in perlite-filled pots and allowed to germinate for 7 days. When the seedlings reached to two true-leaf stage in perlite media (12 days old), they were transferred to 2.7 L plastic pots (four seedlings per pot) filled with continuously aerated and diluted 1:3 nutrient solution for 2 days to ensure time for plant growth. Thinning was performed then as to have two seedlings in each pot. Nutrient solutions were prepared with distilled water and 2.0 mM $Ca(NO_3)_2$, 0.88 mM K_2SO_4, 1 mM $MgSO_4$, 0.25 mM KH_2PO_4, 0.1 mM KCl, 100 µM Fe-EDTA, 10µM H_3BO_3, 0.5 µM $MnSO_4$, 1 µM $ZnSO_4$, 0.2 $CuSO_4$ and 0.02 µM $(NH_4)_6Mo_7O_{24}$. Cadmium ($3CdSO_4$ $8H_2O$) was supplemented into nutrient solutions at five-to-six true leaf stage (25 days old) of growth for 8 days. All solutions were adjusted as to have a pH of 6.3 ± 0.1. Nutrient solutions were replaced in every 3-4 days throughout the growing period. Leaf chlorophyll contents were identified with the aid of a chlorophyll meter (SPAD-502, Minolta, Japan) before the harvest. The 32-day old plants were harvested and at harvest, roots were rinsed through 0.5 mM $CaSO_4$ and de-ionized water for 15 min, and dried at 70 °C to determine the dry weights.

Dried shoots and roots were ground; wet-digested in a microwave with 2 ml 35% H_2O_2 and 5 ml 65% HNO_3. Digested samples were then subjected to elemental analyses for Cd, Zn, Fe, Mn and Cu by an inductively coupled plasma optical emission spectrometer ICP-OES; Varian-Vista Pro) device. Measurements were checked with the readings on reference samples of National Institute of Standards and Technology (Gaithersburg, MD, USA).

DOI: http://dx.doi.org/10.15666/aeer/1702_22492256

Statistical analysis

Experimental data were subjected to variance analysis in accordance with randomized plots design with 3 replications. Means were compared by least significant difference (LSD) test at 5% probability level.

Results and discussion

Dry matter yields, SPAD readings and cadmium in shoots and roots

Cadmium treatment (15 µM) reduced shoot dry matter yield by 37% in AT58 cultivar and by 48% in Demre cultivar and reductions in root dry matter yields were respectively observed as 21 and 29% (*Table 1*). Cd-induced regress in plant growth was also reported for wheat (Naeem, 2016), tomatoes (Kumar et al., 2015), sunflower (Azevedo et al., 2005) and pepper (Abdel Latef, 2013). In this study, more chlorosis and necrotic patches were observed over the oldest leaves of Demre cultivar than the leaves of AT58 at 15 µM Cd dose. Root browning degrees were also greater in Demre cultivar than in AT58 under Cd treatments. Generally, reduced root elongation (Dong et al., 2005) and browning (Liu et al., 1995) are the initial symptoms for cadmium toxicity in roots and chlorosis and rolling are the initial symptoms for cadmium toxicity in shoots (Weigel and Jäger, 1980).

SPAD values significantly decreased with Cd treatment in both cultivars and the decrease rates with 15 µM Cd treatment were found to be 15% in AT58 and 30% in Demre cultivar (*Table 1*). Sandalio et al. (2001) indicated the reason of Cd-induced reductions in chlorophyll content as chlorophyll degradation or destructions in chlorophyll biosynthesis and membrane integrity.

Table 1. *Effects of cadmium (-Cd = 0 and +Cd = 15 µM) treatments on shoot-root dry weights and SPAD values of AT 58 and Demre pepper cultivars*

Cultivars	Dry matter yields (mg plant^{-1})*				SPAD values	
	Shoot		Root			
	- Cd	+ Cd	- Cd	+ Cd	- Cd	+ Cd
AT58	1139 aA	723 bA	154 aB	122 bB	53 aA	45 bA
Demre	1240 aA	643 bA	234 aA	167 bA	42 aB	30 bB

*Means indicated with different small letters (between Cd treatment, in each cultivar) and by the same capital letters (between cultivars, in each Cd treatment) are significantly different at $p < 0.05$

Cadmium treatment (15 µM) significantly increased shoot Cd concentrations and contents of both cultivars (*Table 2*). Demre had higher shoot Cd concentration and content than AT58. While shoot Cd concentration and content of Demre cultivar at 15 mM Cd treatment were 148 mg kg^{-1} DW and 95.1 µg plant^{-1}, the values in AT58 cultivar were 90.5 mg kg^{-1} DW and 65.1 µg plant^{-1}, respectively. Root Cd concentrations and contents of AT58 were greater than Demre (*Table 2*). Root Cd concentration and content of AT 58 were respectively measured as 1529.7 mg kg^{-1} DW and 186.8 µg plant^{-1}. For both cultivars, roots had greater Cd concentrations and contents than the shoots (*Table 2*). Cataldo et al. (1983) pointed out that large portion of cadmium retained in plant roots and a small portion was transferred to shoots. Blum (1997) reported the greatest Cd content for roots and the least Cd content for seeds;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22492256

stem, leaves and fruits were placed in between them. Regardless of the concentrations, both cultivars differ in their root and shoot Cd accumulation capacity. Although root Cd contents were not influenced significantly by cadmium treatments, high root Cd content of AT58 than Demre was found to be compatible with root Cd concentrations of these cultivars (*Table 2*). Previous researches tried to explain the differences in Cd-tolerance of plants with the differences in their Cd-uptake and accumulation levels (Hall, 2002; Kochian et al., 2002). Complying with these hypotheses, AT58 cultivar of the present study had greater root Cd concentration and smaller shoot Cd concentration than Demre cultivar. Such findings indicated that AT58 cultivar retained greater Cd quantities in roots.

Table 2. *Effects of cadmium (-Cd = 0 and +Cd = 15 µM) treatments on shoot-root Cd concentration and content of AT58 and Demre pepper cultivars*

Cultivars	**Cd concentrations (mg kg^{-1} DW)***				**Cd contents (µg plant^{-1})**			
	Shoot		**Root**		**Shoot**		**Root**	
	- Cd	**+ Cd**	**- Cd**	**+ Cd**	**- Cd**	**+ Cd**	**- Cd**	**+ Cd**
AT58	0.3 bA	90.5 aB	2.9 bA	1529.7 aA	0.4 bA	65.1 aB	0.5 bA	186.8 aA
Demre	0.4 bA	148.0 aA	3.7 bA	1036.1 aB	0.5 bA	95.1 aA	0.9 bA	173.0 aA

*Means indicated with different small letters (between Cd treatment, in each cultivar) and by the same capital letters (between cultivars, in each Cd treatment) are significantly different at $p < 0.05$

Shoot and root micronutrients

Cadmium treatment (15 µM) significantly decreased ($p < 0.05$) shoot Zn, Mn, Cu and Fe concentrations and contents of both cultivars (*Table 3*). Shoot Zn, Mn, Cu and Fe concentrations of AT58 cultivar decreased with Cd treatment at slightly greater rates than at Demre cultivar. The average Cd-induced decrease was 55% for Zn and Mn and 69% for Fe and Cu (*Table 3*). Cd-treatment also reduced root Zn and Mn levels significantly. Cd treatments reduced Zn and Mn levels of wheat root and shoots, but did not influence shoot and root Fe and Cu levels (Jalil et al., 1994). Cadmium toxicity mostly comes from the interactions of Cd with the other essential nutrients, especially with the same valence (Skrebsky et al., 2008). In a hydroponic experiment with barley, Cd treatments significantly decreased root and shoot Zn, Cu and Mn concentrations and shoot Fe concentrations (Wu et al., 2003).

In the present study, while root Cu content of AT58 decreased significantly with Cd treatment, root Cu content of Demre and root Cu concentrations of both cultivars did not change (*Table 3*). Iron concentration and accumulation in roots of spinach was not affected by Cd treatments (Abul Kashem and Kawai, 2007). Similar with those findings, present root Fe concentrations and contents of both pepper cultivars remained unchanged with Cd supply (*Table 3*). Kabata-Pendias and Pendias (2001) indicated strong bonds of Cu and Fe in root cells.

Present differences in shoot Zn and Cu levels were mostly attributed to Cd-induced regress in plant growth and development. Thusly, shoot Zn and Cu concentrations were not significantly different (*Table 3*). Similarly, shoot Fe and Mn concentrations-contents were not also significantly different at 15 µM Cd treatment (*Table 3*). Under Cd supply, there seems to be antagonistic relationships between root Cd concentrations-contents and root Zn concentrations-contents (*Table 3*). Under controlled conditions, Demre

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22492256

cultivar generally had greater quantities of Zn, Fe, Mn and Cu than AT58 cultivar (*Table 3*). Such a case may result in significantly different Zn and Cu accumulation levels under Cd supply. Differences in cultivars may be related to present Cd dose, exposure duration to this dose and micronutrient levels of the cultivars under controlled conditions.

*Means, indicated with different small letters (between Cd treatment, in each cultivar) and by the same capital letters (between cultivars, in each Cd treatment) are significantly different at $p < 0.05$

Conclusion

Cadmium treatment generated significant decreases in both root and shoot dry matter yields. Such decreases were greater in Demre cultivar than in AT58 cultivar. Similarly, greater decreases were observed in SPAD values of Demre cultivar than of AT58 cultivar with Cd treatment. Regardless of shoot Cd uptake and accumulation, it was observed that there were differences in Cd toxicity tolerance of the cultivars, but these differences were not attributed to differences in microelement uptake and transport of the cultivars. For Cd-polluted sites, AT58 can be recommended to reduce yield losses. Further studies are recommended to compare antioxidative defense mechanisms of AT58 and Demre pepper cultivars with different root and shoot Cd accumulation levels.

ESTIMATION OF LIVE WEIGHT OF HOLSTEIN-FRIESIAN BULLS BY USING BODY LINEAR MEASUREMENTS

TUTKUN, M.

Department of Animal Science, Faculty of Agricultural, Dicle University
21280 Diyarbakır, Turkey
(e-mail: tutkunmuhittin@yahoo.com; phone: +90-412-241-1000; fax: +90-412-241-1048)

(Received 5th Nov 2018; accepted 28th Jan 2019)

Abstract. The objective of this study was to estimate the body weight of Holstein-Friesian cattle by using multiple regression analysis. Data were collected from 29 Holstein-Friesian bulls, whose live weight, body length (BL), height at withers, chest depth, heart girth (HG), shin circumference (SC), rump height, and back rump height were measured. There was a relationship between dependent and independent variables. The estimated multiple regression equation was –431.8 + 2.438 HG + 21.21 SC + 1.041 BL, with a determination coefficient of 0.9987 and a standard error of the estimate of 5.240.
Keywords: *body weight, Holstein, heart girth, measurement, regression analysis*

Introduction

Estimating the live body weight of animals through body measurements is a practical, faster, easier, and cheaper method in rural areas where resources are scarce (Nsoso et al., 2003). Knowing the animal live weight is important for breeders, since this information allows them to estimate market prices for live animals and to determine the right dosages in drug administration and the amount of feed to be supplied for growth, maintenance, and production (Mahieu et al., 2011; Chitra et al., 2012; Tsegaye et al., 2013).

Body measurements have been widely used for estimating live weight. There is a relationship between live weight and the various body lengths, heights, and girths measured on live animals.

Using body measurements to estimate live weight with a simple measuring stick and tape may provide relative accuracy and consistency.

Live weight forms the basis for a range of research and management activities including assessment of growth rates, animal responses to different diets and environmental conditions, and determination of feed requirements. Knowing the animal weight and weight changes is also important in determining responses to genetic selection (Touchberry and Lush, 1950).

The use of linear body measurements in fattening beef cattle carries some advantages over subjective methods of cattle evaluation that involve visual assessment and scoring (Essien and Adesope, 2003). Some authors have also suggested this approach to be more reliable than weight measured with a weighing scale, since the latter can be subject to short-term effects such as gut fill, urination, and defecation (Russell, 1975).

These measurements can be taken at lower costs (when labor costs are relatively low) with a simple measuring tape and may provide relative accuracy and consistency (Guilbert and Gregory, 1952)

This is not only a sign of adult weight of the breed but also important for prediction of the daily weight gain and making the feeding programs (Tüzemen and Yanar, 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22572265

There are several methods to estimate live weight in cattle. The polynomial regression was used to predict live weight in cattle (Assogba et al., 2017). Body weight and wither height were regressed on the other body traits. Regressions of body weight including the linear, quadratic, and cubic effects of a single independent variable (heart girth, wither height, hip width or body length) indicated that each measurement would be useful in predicting body weight (Heinrichs et al., 1992)

Digital Image Analysis was used in order to predict of body weight and carcass performance of beef cattle as well (Bozkurt et al., 2008)

However, the linear body measurements are used mostly to predict live weight in cattle and small ruminants. It is based on the measurement of heart girth, which is reported to be highly correlated with body weight in cattle (Heinrichs, 2007; Swali et al., 2008).

The objective of this study was to develop the best prediction models to estimate body weight based on linear body measurements.

Materials and methods

The experiment was conducted in Dicle University, Cattle Research Center in Diyarbakir Province, Turkey (37°57'41 N and 40°13'54 E, 650 m asl).

The study material consisted of monthly live weight and body measurement records of 29 male Holstein-Friesian bulls collected between the years 2016 and 2017. The initial weight was taken at age of 4 month. Different amounts of concentrate and roughage were provided ad libitum to the bulls considering the average live weights obtained from the monthly weighings.

A measuring stick was used to determine body length (BL), height at withers (HAW), chest depth (CD), rump height (RH), and back rump height (BRH), whereas a tape measure was used to determine heart girth (HG) and shin circumference (SC). Body measurements were taken once monthly with the bulls standing in a squeeze chute. Bulls were weighed before feeding and drinking water in the early morning.

The animals were weighed monthly using an electronic weighing scale with 1,500-kg capacity. Body measurements were taken by same observers so as to minimize bias. All the data were recorded in centimeters.

Descriptive statistics was used to present the simple means and standard deviation for all variables. Regressions of live weight (LW) on HG, CD, RH, HAW, SC, BRH, and BL were performed using simple and multiple linear regressions with the various body measurements as continuous variables. The obtained data were analyzed using Minitab 18 statistical software (Pearson’s correlation coefficients), where correlations between body weight and different body measurements were computed.

Regression analysis was employed to predict live weight from different body measurements. The best-fitting regression model was chosen based on the coefficient of determination (R^2) and standard deviation (SD). Multiple regression models were followed to estimate body weight from body measurements.

The Stepwise regression model of the measurements (all seven linear body measurements) was defined as follows (*Eq. 1*):

$$Y = \beta_0 + b_1 \beta_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_4 X_4 + \beta_5 X_5 + \beta_6 X_6 + \beta_7 X_7 + e_i, \qquad \text{(Eq.1)}$$

in which:

DOI: http://dx.doi.org/10.15666/aeer/1702_22572265

Y = dependent variable (live weight),
βo = intercept,
β's = regression coefficients,
$X_{(1\ to\ 7)}$ = independent variables (HG, CD, RH, HAW, SC, BRH, and BL) and
e_i = error.

Results

In the statistical analyses, the mean and standard deviations were calculated for each attribute (*Table 1*).

P-value < 0.01

All possible regression equations were employed in the selection of a best fitted regression equation as represented in *Table 2*. The results showed that the multiple regression equation for estimation of body weight of Holstein-Friesian bulls had tree independent variables, x_1 (heart girths), x_2 (shin circumference) and x_3 (body length) with high adjusted coefficients of determination ($R^2 = 99.87$) and low standard error of estimation (S = 5.240) in equation (Y_3; *Eq. 2*).

$$Y_3 = -431.8 + 2.438\ \mathrm{HG} + 21.21\ \mathrm{SC} + 1.041\ \mathrm{BL} \tag{Eq.2}$$

R^2 was calculated as 0.973 by using multiple linear regression analysis based on the HG to design a body-weight prediction model. When SC was added to regression model R^2 value was found as 0.9986. The best-fitting model, with the highest R^2 value (0.9987), was obtained by adding BL to the equation (*Table 3*).

DOI: http://dx.doi.org/10.15666/aeer/1702_22572265

Live weight and linear body measurements were significantly correlated with each other. Body weight had a higher correlation with HG than with any other body measurements (CD, RH, HAW, SC, BRH, and BL). In all fattening periods evaluated, the highest R^2 was obtained when the SC and BL measurements were included in the regression equations, which suggests that body weight could be more precisely estimated by the association of two or more linear measurements. However, the association of different body measurements (body length and shin circumference) would produce the best prediction equation for body weight, in this study.

The coefficients of correlation between heart girth and body weight were 0.973 for all of the 29 Holstein-Friesian bulls, and highly statistically significant. The relationship between live weight and heart girth was illustrated by graph shown as *Figure 1*.

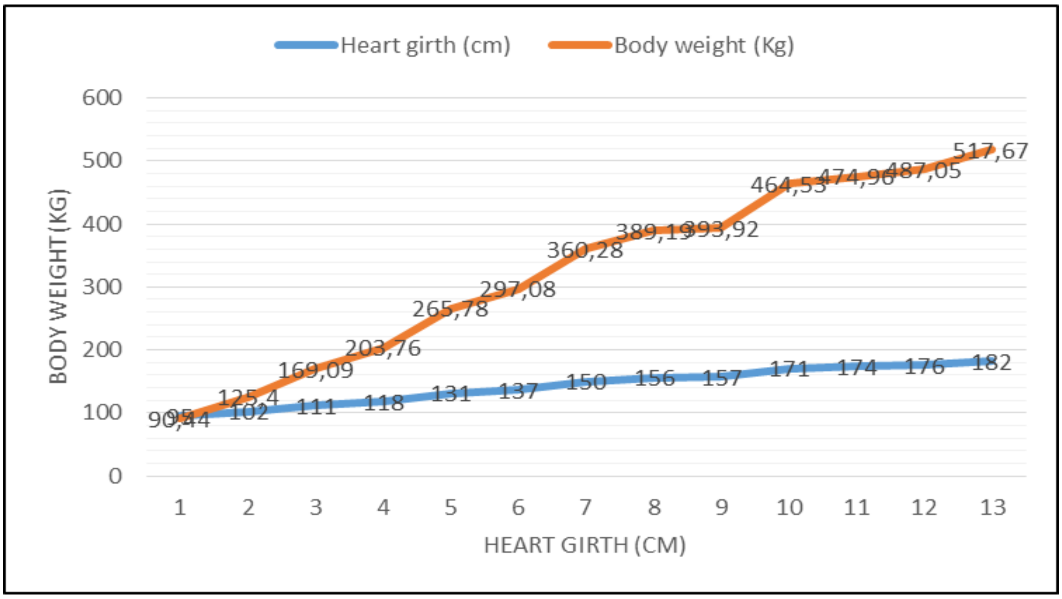

Figure 1. *Relationship between live weight and heart girth*

The regression of body weight on heart girth indicated a straight-line relationship.

The body weight of Holstein- Friesian cattle were estimated by using the multiple regression equation between the live weight and heart girth (Y_1) represented in *Table 4* and the comparison between the real values and the predicted values of body weight of Holstein-Friesian cattle was shown in *Table 5*.

Discussion

The present findings corroborate Katongole et al. (2013), according to whom HG, WH, and body condition score (BCS) were the variables with the highest R^2 value for predicting body weight. Siddiqui et al. (2015) reported that the HG and BL were the best variables for this purpose, with $R^2 = 0.968$. Our results also agree with those published by Yan et al. (2009), who found that HG, BL, and BCS were better suited parameters for estimating body weight.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22572265

The highest correlation obtained in this study was between LW and HG measurement while the lowest was with CD. The high correlation between LW and HG can be attributed to the fact that, in comparison to length and HW, HG more closely reflects body condition of cows (Goe et al., 2001). This fact may also be supported by the stronger correlation observed in the present study between HG, LW and body condition scores compared to BL. Such correlations have also been reported by other workers (Francis et al., 2002; Gunawan and Jakaria, 2010; Heinrichs et al., 1992, 2007; Kashoma et al., 2011; Msangi et al., 1999; Yan et al., 2009; Lukuyu et al.2016).

The relationship between body linear measurements and LW could be exploited in designing appropriate management and selection programs in that high positive relationships among the traits suggests that an increase in one could lead to a corresponding increase in the other trait (Assan, 2013).

Body weight was highly correlated with heart girth in cattle, as concluded by Abdelhadi and Babiker (2009), Bagui and Valdez (2007) and Nesamvuni et al. (2000).

The current results are similar to those reported by Soysal and Konak (1992), Tüzemen et al. (1995), Yanar et al. (1995), Mantysaari (1996), Seokgeum et al. (1998), Adeyinka and Mohammed (2006), Koç and Akman (2007), Sawanon et al. (2011) and Mekparyup et al. (2013).

Conclusions

The high values coefficients of correlation (R^2) of the equation obtained by multiple regression analysis suggest that heart girth can be practically used alone to estimate live weight. Regression coefficients for heart girth indicate that such estimators could be used independently to estimate body weight in Holstein-Friesian bulls. Estimating the body weight of Holstein-Friesian cattle using three independent variables heart girth, shin circumference and body length appears to be a useful strategy. Linear body measurements, specifically heart girth, are useful predictors of live weight in cattle. Heart girth is the most practical parameter for predicting live weight in field conditions, especially for smallholder farmers.

Abstract. Seed orchards are an important seed source because they have the most important link between tree breeding and plantation forestry. The aim of this study is to evaluate the potential of Adaptive Neuro-Fuzzy Inference Systems of artificial neural networks to predict the amount of cone in clonal seed orchards of Anatolian black pine. It was found that the coefficient of determination (R^2), the mean absolute error (MAE) and the root mean square error (RMSE) of the artificial neural network model were 0.85, 14.83 and 18.85, respectively. The amount of cone in clonal seed orchards of Anatolian black pine was predicted with high efficiency through artificial neural networks. Considering the lack of forestry studies based on the artificial neural network, this study will enable further researches to provide a new perspective.
Keywords: *ANN, Bartin, flower, forestry, Pinus nigra, Yenice-Camiyanı*

Introduction

Seed orchards are an important seed source for forest plantations. They constitute the most important link between tree breeding and plantation forestry. Considerable progress has been made in understanding the reproductive biology of conifers in seed orchards (Kang, 2001; Bilir et al., 2006). These are by far the most important outlets to forestry of breeding programs and they can be useful in gene conservation. Investment in seed orchards is often by the most cost-efficient way of increasing future forest production (Bilir et al., 2009).

Researches of seed orchard are probably the most cost efficient research possible to create better forests. It is desirable to improve the function of seed orchards. There are worries about the genetic diversity of the seed orchard crops and its impact on the future forest. Low production of sound seeds is a common problem. Seed production and collection is often expensive. Basic data on seeds and cones in seed orchards and their occurrence and variation and the possible causes of variations are desirable to get a better understanding of possible improvements of seed orchard's function, economy and impact to the forest (Bilir et al., 2009). In addition, such information is needed to establish and select seed sources and genetic conservation areas, and for future studies

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22672273

by governmental and private sectors because of potential of monumental plants in the species, and also to contribute potential theoretical studies on estimation of fertility variation and related variables such as effective number, status number and genetic diversity (Bilir et al., 2017).

Anatolian black pine (*Pinus nigra* Arnold. subsp. *pallasiana* (Lamb.) Holmboe) is one of the most common and important forest tree species in Turkey due to the usefulness of its wood regarding commercial uses (Sıvacıoğlu and Ayan, 2010). The species occupies about 4.2 million ha in Turkey (Anonymous, 2015). The seed for this species is mainly supplied from the current 54 seed orchards (462.8 ha) in Turkey (Anonymous, 2018).

Artificial neural network models are a powerful empirical modelling approach and yet relatively simple compared with mechanistic models (Ji et al., 2007). Artificial neural network, possessing various types, becomes crucial especially in innovating and developing better products for society as it can solve many problems that linear system is incapable to resolve (Khairunniza-Bejo et al., 2014). Artificial neural network structure is based on the human brain’s biological neural processes. Interrelationships of correlated variables that symbolically represent the interconnected processing neurons or nodes of the human brain are used to develop models. Artificial neural network models find relationships by observing a large number of input and output examples to develop a formula that can be used for predictions (Pachepsky et al., 1996; Ji et al., 2007). Thus, the use of artificial neural network in forestry modeling can be efficient for predicting cone production of Anatolian black pine. In this study, we aimed at evaluating the potential of artificial neural networks for predicting the amount of cone for Anatolian black pine from clonal seed orchards.

Materials and methods

In this study, measurement results from Anatolian black pine seed orchard with Yenice-Camiyanı origin were used. This seed orchard has an area of 11.3 ha and is established within the boundaries of Bartın Forest Management Directorate in 1990 (Anonymous, 2018). In the study, 90 randomly selected samples from 120 experimental data were used to test the model while the remaining 30 were modeled. We used Average Female Flower Count (2015), Mean Diameter Value (2015), Average Number of Two-Year-Old Cones (2015) as input, and Average Number of Two-Year-Old Cones (2017) as output.

Adaptive Neuro-Fuzzy Inference Systems (ANFIS) is an artificial intelligence method created by combining of artificial neural networks that have parallel computing - learning capability and a fuzzy logic has syllogize ability. The functional based on the equilibrium between fuzzy logic as Takagi Sugeno Kang (TSK) and limited radial basis neural network (Lezanski, 2001). Output values calculated directly by weighting the input data according to fuzzy rules. These rules, which known databases, determined thanks to the computational algorithm based on neural networks. The learning algorithm of ANFIS is a mixed learning algorithm consisting of the least squares method and the back-propagation learning algorithm. The six-layer ANFIS structure is shown in *Figure 1*.

The structure of the ANFIS layers is as follows (Demirel et al., 2010; Gemici, 2011):

1. Layer (Input Layer): All input signals from each node directed to the next layers.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22672273

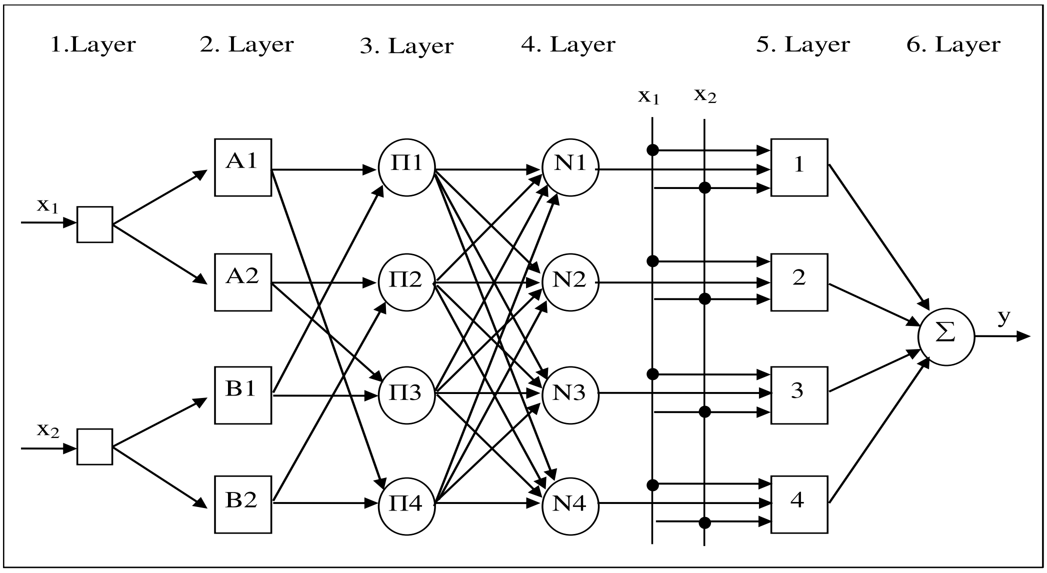

***Figure 1.** The six-layer ANFIS structure*

2. Layer (Blur Layer): Output of each node consists of the membership ratings depending on the input values and the selected membership function. The membership degrees in second layer are described $\mu_{A_j}(x)$ and $\mu_{B_j}(y)$.
3. Layer (Rule Layer): The nodes in this layer indicate the number of rules and numbers determined by the Sugeno fuzzy logic inference system. The output of each rule node (μ_i) is shown in *Equation 1,* accordingly the result of the membership degree from layer 2 is (j = 1,2) and (i = 1,…, n).

$$y_i^3 = \prod i = \mu_{A_j}(x)\ \mu_{B_j}(y) = \mu_i \quad \text{(Eq.1)}$$

At this point, y_i^3, the output values of the third layer and "n" indicates the number of nodes in this layer.

4. Layer (normalization): The nodes in this layer accept all other nodes from the rule layer as input values and calculate the normalized value of each rule. The outputs of this layer defined as the normalized firing level. Each node in this layer is an N-labeled node. The calculation of the normalized firing level found $\overline{\mu_i}$ according to *Equation 2.*

$$y_i^4 = N_i = \frac{\mu_i}{\sum_{i=1}^{n} \mu_i} = \overline{\mu_i}\ , \quad (i = 1, \dots, n) \quad \text{(Eq.2)}$$

5. Layer (Rinse Layer): In this layer calculated the weighted result values of rule. At this point, the value of node "I" calculate regarding *Equation 3*.

$$y_i^5 = \overline{\mu_i}\ [p_i x_1 + q_i x_2 + r_i]\ , \quad (i = 1, \dots, n) \quad \text{(Eq.3)}$$

(p_i, q_i, r_i) variables are the set of result parameters of the rule "i".

6. Layer (Total Layer): This layer contains only one node labelled Σ. The output value of each node summed in the layer 5 then the actual output value found.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22672273

The function defined the output value of the system according to *Equation 4* (Özçalık et al., 2003).

$$y = \sum_{i=1}^{n} \overline{\mu_i} \, [p_i x_1 + q_i x_2 + r_i] \tag{Eq.4}$$

Results and discussion

In order to obtain a successful ANFIS model, several types of membership function types and number of membership functions should be tried and different models should be installed. In the study, triangular, trapezoidal, gauss, gauss2 and pi membership function types as membership function were applied to the model in different number of membership functions from 1 to 6. *Table 1* shows the model parameters showing the type and number of membership functions for which the best results are obtained. In order to measure the model success, it is necessary to estimate the result parameter from the model and compare it with the actual results using the input parameters that the model has never seen before. The measured 2-year-old cones values used in the testing phase and the 2-year-old cones values obtained from the model are shown in *Table 2*. The most important parameter showing the success of the ANFIS model is the going graph showing the compatibility of the measured test data shown in *Figure 2* with the model test data. The performances of the model trials measured according to the mean absolute error (MAE), square root mean square error (RMSE) and determination coefficient (R^2).

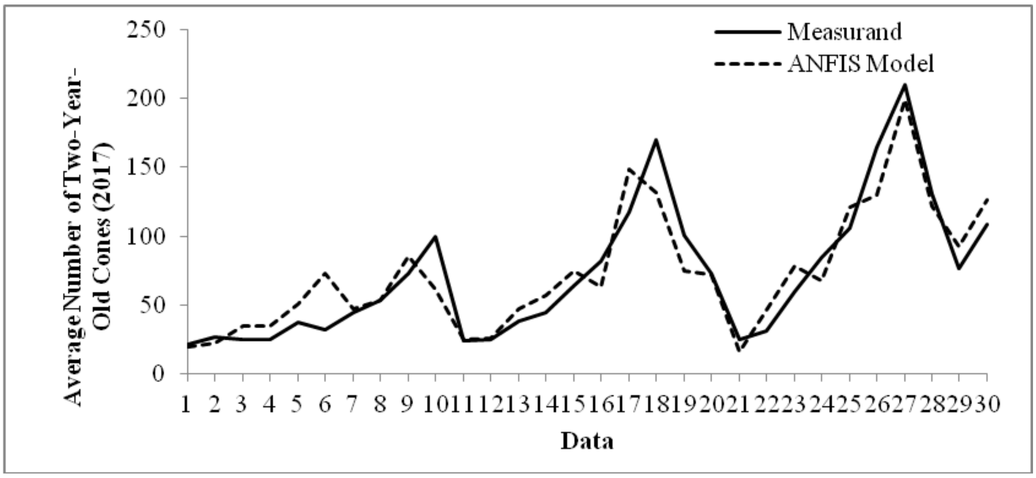

Figure 2. *ANFIS model test phase going graph*

MAE, RMSE and R^2 values found using *Equations 5–7,* respectively.

$$\text{MAE} = \frac{1}{N}\sum_{i=1}^{N}|y_{measurand} - y_{model}| \quad \text{(Eq.5)}$$

$$\text{RMSE} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(y_{measurand} - y_{model})^2} \quad \text{(Eq.6)}$$

$$R^2 = 1 - \frac{\sum_{i=1}^{N}(y_{measurand} - y_{model})^2}{\sum_{i=1}^{N}(y_{measurand} - y_{mean})^2} \quad \text{(Eq.7)}$$

Regarding the results of the test phase, R^2 = 0.850, MAE = 14.83, RMSE = 18.85 in the three input ANFIS model (*Table 1*).

This ANFIS model, in 2017 two-year old cones are estimated using the number of female flowers measured in 2015, the average diameter, and the average of two-year old cones numbers. The model estimates give significant results considering the test phase values of going and scattering graphs (*Figs. 2* and *3*).

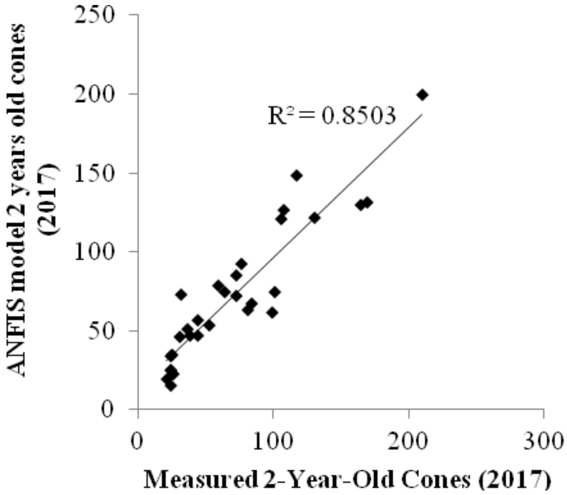

***Figure 3.** ANFIS model test phase scattering graph*

Today, it is possible to estimate the amount of cones in following two years by using the number of female flowers, mean diameter and number of two-year old cones (*Table 2*). Similarly, ANN models proved to be superior for accurately predicting rice yields under typical Fujian climatic conditions (Ji et al., 2007) and for predicting the cactus pear yield (Guimarães et al., 2018). Although the new model used by Calama et al. (2016) for annual cone production surpass the detected deficiencies of previous models, accurately predicting recent decay in cone production, Kaul et al. (2005) stressed that ANN has better predicted yield variability rather than other methods.

Conclusion

The amount of cone is crucial to sustaining forestry management. In this study, predictions of the amount of cone in clonal seed orchards of Anatolian black pine are obtained with high efficiency through Adaptive Neuro-Fuzzy Inference Systems of artificial neural networks. Considered the lack of forestry studies based on the artificial neural network, this study will enable further researches to provide a new perspective.

(Received 24th Nov 2018; accepted 11th Jan 2019)

Abstract. Alfalfa (*Medicago sativa*) is a high-yielding perennial legume, cultivated worldwide with rich nutritional characteristics, and active compounds. A total of 48 crossbred (Duroc × Landrace × Yorkshire) piglets weaned at 28 days old with an average body weight of 8.42 ± 1.88 kg was used in this study. The results indicated that the supplementation of 6-12% alfalfa fibre significantly ($P < 0.05$) increased the growth performance. The digestibility of crude protein (CP) increased at higher dietary alfalfa fibre concentrations. The crude fibre (CF) and dry matter (DM) levels increased first and then decrease at higher alfalfa fibre concentration. The inclusion of alfalfa fibre increased the nitrogen (N) metabolism through increasing N digestibility and utilization and decrease fecal and urinary N content. In addition, the supplementation of alfalfa fibre increased the albumin, globulins, and total protein levels. However, dietary alfalfa fibre decreased blood glucose levels, cholesterol, triglyceride, aspartate aminotransferase, and alanine aminotransferase. There was a significant increase in the villus height (VH), crypt depth (CD), and villus height to crypt depth (VH-CD) ratio after introducing alfalfa fibre in the diet. Therefore, the inclusion of alfalfa fibre to piglet's diet is significant in improving the production performance and health in piglets.
Keywords: *Medicago sativa, gastrointestinal tract, digestibility, performance, pigs*

Introduction

The increasing consumer demand for organic food products such as natural pork and the emergence of antibiotic resistance among many pathogenic microorganisms has necessitated the search for an alternative approach to healthy production systems and the control of microbial infection in pigs (Che et al., 2018; Adams et al., 2019a, 2019b). The use of different plant base components such as dietary fibre, prebiotics, and polysaccharide seem to be promising (Griggs and Jacob, 2005; Che et al., 2018; Adams et al., 2018a). However, there are differences in the nutritional composition of different fibre containing feedstuffs (Jarrett and Ashworth, 2018). Dietary fibre can be defined as the indigestible portion of food obtained from plants which form the main component of many animals (pig) diet (Jarrett and Ashworth, 2018). Dietary fibre influences the functions of the gastrointestinal tract and the health of both animals and human (Bikker

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22752295

et al., 2006; Adams et al., 2018b). The consumption of high dietary fibre decreases the bioavailability of some key nutritional components such as some minerals and vitamins (Adams et al., 2018b) and may influence the rate of digestion of food substances and energy metabolism (Adams et al., 2018c). The intake of high-fibre diet can also increase the activities of the gut microbial composition (Varel 1987; Metzler and Mosenthin 2008), hence producing short-chain fatty acid that accounts for 10-30% of the total energy requirement of animals (Christensen et al., 1999).

Alfalfa is a high-yielding perennial legume which is cultivated worldwide with rich nutritional characteristics and active compounds (Yu et al., 2014; Chen, et al., 2016). Alfalfa fibre is primarily composed of insoluble dietary fibre, such as cellulose, lignin, and xylans, which represents more than 90% of the total dietary fibre composition of alfalfa (Bach Knudsen, 1997; Chen et al., 2013a). Alfalfa meal is high in protein and minerals as well as vitamins (Ensminger, 1992). For example, alfalfa contains vitamins such as: A, B1, B2, B6, B12, C, D, E, K, Niacin, Panthothanic acid, Inocitole, Biotin, and Folic acid with minerals such as: Boron, Calcium, Chlorine, Copper, Cobalt, Iron, Magnesium, Manganese, Molybdenum, Phosphorus, Potassium, Sodium, and Sulphur, as well as, well balanced amino acids, rich in carotenoids, and xanthophylls (Sen et al., 1998; Ponte et al., 2004; Jiang et al., 2012). Reportedly, alfalfa contains 17.5% CP, 24.1% CF, and 1,200 kcal/kg metabolizable energy (National Research Council, 1994). Wang et al. (2018) indicated that the growth of pigs on alfalfa pastures produces natural and good quality pork, which is currently gaining more attention in Europe and North America. Interestingly, for the production of better quality pork, alfalfa is used as a fresh fodder in some traditional style pig production systems in China (Wang et al., 2018). Alfalfa fibre is a high-quality protein feed hence increasing its supplementation may improve the nutritional requirement of pigs and improve the growth of piglets. Few studies reported that the supplementation of natural compounds such as flavonoids extracted from alfalfa had insignificant estrogenic impacts, which may increase the production performance, enhance antioxidant, anti-stress induction, and eradicate free radicals from animals (Xie, 2001).

Weaning in piglets is a harsh condition that is mostly associated with a growth disorder and health effects. Weaning piglets are associated with less feed consumption and low nutrient metabolism due to the immature digestive systems, stress as a result of the separation from the dam and littermates, and the sudden change from the easily digestible sow's milk to a less digestible solid feed (Chen et al., 2017). These piglets have limited susceptibility to diseases and infections from enteric bacteria accompanied with frequent diarrhea, stunted growth, low nutrient utilization efficiency, and even mortality (Kick et al., 2012; Che et al., 2018). The supplementation of alfalfa in the diet of pigs has increased in recent years due to the beneficial effects of dietary alfalfa consumption. Dietary alfalfa supplementation increased the short-chain fatty acid concentration in fecal samples of growing pigs (Chen et al., 2013a). Also, alfalfa increased the microbial activities and butyrate levels in the hindgut of the intestinal tract of pigs (Wang et al., 2018).

Therefore, we hypothesize that supplementing alfalfa fibre in the diet of weaning piglets may increase the production performance, blood biochemical composition, and improve the intestinal development and health. Hence, the aim of this study was to investigate the effects of dietary alfalfa fibre supplementation on the growth performance, nutrient digestibility, N metabolism, blood biochemical composition, and intestinal development in piglets.

Materials and methods

Experimental site and location

The animal feeding experiment was conducted from 27th June to 21st August, 2017, involving 7 days of a pre-feeding period and a 48 days' formal test period at the animal breeding station of Jilin Agricultural University, located in Changchun city in the Jilin Province in the People's Republic of China. Jilin is found on latitude 43°42' N and longitude 126°12' E, and Changchun is on latitude 43°88' N and longitude 125°35' E. The annual rainfall ranges between 350-1000 mm (March-August) and the dry season between September – February. Winter ranges between November – March with temperatures between -8 °C (17 ºF) – -20 °C (-4.6 °F) and summer temperatures between 16 °C (61.4 °F) and 28 °C (81.2 °F) around May-July.

Sample preparation

The alfalfa was obtained from the STONE WINGSII, LLC. & SW Forage, LLC, USA. The alfalfa fibre was extracted by crushing it through a 5 mm sieve and the extract was stored in a closed vessel at room temperature prior to being incorporated into the trial diets.

Experimental animals, design and feeding management

A total of 48 crossbred (Duroc × Landrace × Yorkshire) piglets weaned at 28 days old with an average body weight of 8.42 ± 1.88 kg were used in this study (*Fig. 1*). The trials were divided into four treatment groups according to a completely randomized design with each treatment group comprised of four replicates and each replicate contains three piglets. The animals were housed in pens (1.8 × 1.2 m) with a concrete slatted floor each pen contained three piglets. The pens were cleaned on a daily basis to prevent disease outbreak in piglets. The animals were allowed to acclimatize to the diets for a week prior to the beginning of the experiment and lasted for 48 days. Four experimental diets containing 0.00% alfalfa fibre (control group, M0), 6.00% alfalfa fibre (M6), 12.00% alfalfa fibre (M12), and 18.00% alfalfa fibre (M18) were formulated according to the requirements of the National Research Council (2012). The diets contain soybean meal and cracked corn as the main sources of protein and energy respectively (*Table 1*). The piglets were fed twice a day at 08: 30 am and 05:30 pm and had *ad libitum* access to clean drinking water. Feed intake and leftover were recorded daily in the morning for each animal.

M0: 0.00% alfalfa diet, M6: 6.00% alfalfa diet, M12: 12.00% alfalfa diet, M18: 18.00% alfalfa diet

Sample collection

The fecal samples were collected continuously from 08:30 am to 05:30 pm on day 40 to day 45 of the trial period for the determination of nutrient digestibility. The urine was collected within the same time frame as the fecal samples. After each collection, 10% hydrochloric acid was added for fixation of fecal and urine N. The fecal samples were thawed and homogenized within the group, weighed, and dried at 55 °C for 72 h. The dry fecal samples were ground through a 1-mm screen sieve and stored in -20 °C until chemical analysis. The experimental diets were sampled and stored in -20 °C for the DM, CP, and CF analysis. Blood samples were collected from the precaval vein by venepuncture at 8:30 am on day 47 after 12 h of fasting and centrifuged at 1500×g for 30 min at 4 °C. The serum samples were then isolated and frozen at -20 °C until analysis. At the end of the experiment on day 48, all the pigs were electrically stunned and killed by exsanguination. The abdominal cavity was immediately opened to remove the duodenum, jejunum, and ileum. The middle part (5 cm) of the duodenum, jejunum, and ileum was collected and fixed in 10% formalin solution for intestinal morphological

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22752295

analysis. The sample of mucosa scraped obtain from the duodenum, jejunum, and ileum was immediately frozen in liquid N, then stored in -80 °C until biochemical analysis (Wu et al., 2018).

Determination of growth performance

The piglets were weighed early in the morning prior to feeding on the first and last days of the feeding trials. The average daily feed intake (ADFI) was determined by estimating the total feed consumption per day. The average daily gain (ADG) was calculated by subtracting the initial body weight from the final body weight and divided by the days of the experiment. Feed conversion ratio (FCR) was determined by dividing the feed intake by the body weight gain.

Determination of nutrient digestion

The feed and fecal samples were analyzed for CP, CF, and DM digestibility according to the procedures described by (Hassanat et al., 2017; Che et al., 2018). Briefly, the DM content was estimated by drying feed and fecal samples in a vacuum oven at 100 °C overnight (AOAC, 1990; method 934.01). The CP (N × 6.25) was estimated using the macro-Kjeldahl procedure (AOAC, 1990; method 990.03) and the CF was determined using the procedures adapted for use in an Ankom200 Fiber Analyzer (Ankom Technology Corp., Fairport, NY).

Determination of nitrogen metabolism

The N content of all the samples was analyzed using the KjeltecTM 8400 automated Kjeldahl analyzer (PT Haes Brothers, Laboratory & Scientific Equipment). The following formula (*Eqs. 1-6*) was used to estimate the N metabolism in the diet, urine, and fecal samples.

$$\text{The N intake (g)} = \frac{daily\ feed\ intake \times CP\%\ in\ the\ diet \times 15.67}{100} \quad \text{(Eq.1)}$$

$$\text{N in feces (g)} = average\ daily\ fecal\ DM(g) \times fecal\ N(\%) \quad \text{(Eq.2)}$$

$$\text{N in urine (g)} = average\ daily\ urine\ (mL) \times N\ in\ urine\ (\%) \quad \text{(Eq.3)}$$

$$\text{N deposition (g)} = N\ intake\ (g) - fecal\ N(g) - N\ in\ urine \quad \text{(Eq.4)}$$

$$\text{Apparent N digestibility (\%)} = \frac{N\ intake - fecal\ N}{N\ intake} \times 100 \quad \text{(Eq.5)}$$

$$\text{N utilisation} = \frac{N\ intake - fecal\ N - N\ in\ urine}{N\ intake} \times 100 \quad \text{(Eq.6)}$$

Determination of blood biochemical composition of piglets

The albumin, globulin, blood glucose, urea N, triglyceride, cholesterol, aspartate aminotransferase, and alanine aminotransferase in the serum were determined by an automatic blood analyzer (7020 Clinical Analyzer, https://www.hitachi-hightech.com/global/) according to the manufacturer’s instruction.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22752295

Piglet's intestinal morphological analysis

The intestinal segments such as the duodenum, jejunum, and the ileum was analyzed for the VH, CD, and VH - CD ratio using paraffin sectioning and the procedures described by Wu et al. (2018). Briefly, the paraffin sections were made by 1. Flushing: The trimmed tissue samples were wrapped in gauze and rinsed under running water for 24 h. 2. Dehydration: The washed tissue samples were taken out and placed on alcohol for dehydration. The concentration of alcohol as a dehydrating agent is gradually increased from 30% so that the tissue sample is gradually dehydrated, and finally dehydrated thoroughly with absolute ethanol. 3. Transparent: The dehydrated tissue sample was soaked in a solution prepared with alcohol and xylene 1:1 to replace the alcohol in the tissue sample for transparent treatment. 4. Immersion wax: After the tissue sample was treated with xylene and alcohol solution, it was preheated in an oven at 57 °C, and then placed in soft wax a, soft wax b and hard wax for 1 h each time, so that the paraffin was fully immersed in the sample. 5. Embedding: The melted paraffin was poured into a carton, the wax-impregnated tissue was placed into it, then cooled in cold water, solidify and cut into cubes. 6 Slices: The embedded wax blocks were placed on a microtome for continuous sectioning and the cut paraffin pieces were placed in hot water to be flatly attached to the glass slides and dried in an oven at about 40 °C. 7. Dewaxing: The dried chips were first placed in a xylene solution for dewaxing and then immersed in absolute ethanol at 95%, 85%, 70% and 50% alcohol in each 2 min, and finally rinsed with distilled water. 8. Hematoxylin and Eosin (H & E) staining: The dewaxed sections were first immersed in hematoxylin dye for 10 min, then rinsed with distilled water, and placed in hydrochloric acid for 5 seconds. The sections were taken out and rinsed with tap water. Put it in 50%, 70%, 85%, 95% alcohol for 2 min, and finally dye with 0.5% eosin alcohol. 9. Dehydrated and transparent: The stained slices were dehydrated by placing alcohol in different solubility and then placed in a xylene solution for transparent treatment. 10. Sealing: Neutral resin is dropped on the slice, then covered with a cover glass, and the sealed slice was observed under a microscope.

Data analysis

The data were analyzed using a one-way analysis of variance ANOVA procedure of SPSS software version 20.0 (SPSS Inc., Chicago, IL, USA). A probability value of p valve <0.05 was considered statistically significant and were differences between means was noticeable, Duncan multiple range tests (DMRT) was employed to ascertain the difference among the treatments.

Results

Growth performance of weaning piglets

As shown in *Table 2,* the addition of the M6 and M12 alfalfa fibre to the diet increased the ADG in piglets. However, there was a decrease in the ADG at M18 alfalfa fibre supplementation. There was no significant difference ($P > 0.05$) between the M0 and the other treatment groups however the M18 group was significantly lower ($P < 0.05$) than the M6 and M12. The ADFI of the M6 group was higher than that of the other treatment groups. The ADFI of the M6 group was significantly higher ($P < 0.05$) than the M0 group and the M18 group, but not significantly different ($P > 0.05$) from the M12 group ($P < 0.05$). There was no significant difference ($P > 0.05$) in the FCR

DOI: http://dx.doi.org/10.15666/aeer/1702_22752295

between the M0 group and the other treatment groups. The M6 group recorded the highest FCR and the M12 group had the lowest FCR.

In the same row, values with different small letter superscripts mean a significant difference (P < 0.05), while with the same or no letter superscripts mean no significant (P > 0.05). ADG: average daily gain, ADFI: average daily feed intake, FCR: feed conversion ratio. M0: 0.00% alfalfa diet, M6: 6.00% alfalfa diet, M12: 12.00% alfalfa diet, M18: 18.00% alfalfa diet.

Nutrient digestion of weaning piglets

The effect of dietary alfalfa fibre supplementation on nutrient digestibility of piglets was shown in *Table 3*. The digestibility of CP in piglets increased with the increase in the proportion of alfalfa fibre in the diet, but there was no significant effect (P > 0.05) among treatments. The digestibility of CF increases first, and then decreases with the addition of high concentrations of alfalfa to the meal. There was no significant difference (P > 0.05) between the treatment groups. The digestibility of DM in M6 group was higher than the other treatment groups and significantly different (P < 0.05) from the M12 group and the M18 group but not different (P > 0.05) from the M0 group. The M0 group was significantly different from the M12 group.

Table 3. *Dietary supplementation of alfalfa fibre on nutrient digestibility of piglets (%)*

Items	M0	M6	M12	M18
CP	79.72±1.19	80.99±1.12	81.93±2.53	83.15±2.03
CF	47.80±1.70	49.37±0.61	47.72±0.93	46.95±5.10
DM	82.29±0.77^{ab}	82.63±1.30^{a}	79.76±0.82^{c}	80.22±1.39^{bc}

In the same row, values with different small letter superscripts mean a significant difference (P < 0.05) while with the same or no letter superscripts mean no significant (P > 0.05). CP: crude protein, CF: crude fibre, DM: dry matter. M0: 0.00% alfalfa diet, M6: 6.00% alfalfa diet, M12: 12.00% alfalfa diet, M18: 18.00% alfalfa diet.

Nitrogen metabolism of piglets

As shown in *Table 4*, the intake of N in each group varied due to the difference in feed consumption of piglets. The N intake in M12 was higher and significantly different (P < 0.05) from the M18 group but not significantly different (P > 0.05) from the M0 and M12. The fecal N content of piglets decreased with the increase in the concentration of alfalfa fibre in the diet. The fecal N content in the M0 was higher and significantly different (P < 0.05) from the M12 and M18, but not significantly different (P > 0.05) from the M6. The urine N content in the M18 was higher and significantly different (P < 0.05) from the M6 group, but not significantly different (P > 0.05) from the M0 and M12. The apparent N digestibility and N deposition were higher in the M12 in comparison with the other treatment groups. The apparent N digestibility in the M12

Blood glucose (mmol/L)	3.87±0.26	3.75±0.56	3.78±0.55	3.92±0.33
Urea N (mmol/L)	4.64 ± 0.40^{a}	3.39 ± 0.06^{b}	4.08 ± 0.02^{ab}	4.29 ± 0.41^{a}
Triglyceride (mmol/L)	0.60 ± 0.03^{a}	0.56 ± 0.36^{a}	0.47 ± 0.06^{b}	0.58 ± 0.06^{a}
Cholesterol (mmol/L)	2.3±0.06	2.19±0.16	2.06±0.14	2.18±0.32
Aspartate aminotransferase (μ/L)	48.0±3.16	46.0±3.74	47.5±6.45	48.5±7.77
Alanine aminotransferase (μ/L)	42.5±2.89	39.5±2.65	41.25±4.27	40.75±4.5

In the same row, values with different small letter superscripts mean a significant difference (P < 0.05), while with the same or no letter superscripts mean no significant (P > 0.05). M0: 0.00% alfalfa diet, M6: 6.00% alfalfa diet, M12: 12.00% alfalfa diet, M18: 18.00% alfalfa diet.

The albumin concentration in the M12 group was significantly different (P < 0.05) from the other treatment groups. There was no significant difference (P > 0.05) in the globulin and total protein levels between the treatment groups. However, the highest globulin concentration was recorded in the M6, while the highest total protein level was registered in the M12. There were no significant differences (P > 0.05) in the blood glucose, cholesterol, aspartate aminotransferase, and alanine aminotransferase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22752295

concentrations between the groups. The highest blood glucose and aspartate aminotransferase concentrations were observed in the M18 group, while the highest alanine aminotransferase was observed in the M0 group. While the highest cholesterol was observed in the M0 group. The concentration of urea N decreased with the addition of alfalfa fibre to the diet and later increased with the increase in the proportion of alfalfa fibre, but not higher than the control. The urea N level in the M6 was significantly lower ($P < 0.05$) in comparison with the M0 and M18, but not significantly different ($P > 0.05$) from the M12 group. The triglyceride concentration in the M12 was significantly lower ($P < 0.05$) in comparison with the other three groups. The M0 recorded the highest triglyceride concentration.

Intestinal development of weaning piglets

As shown in *Table 6* and *Figure 2,* the M12 group registered the highest VH in the duodenum of each treatment group and the VH of the M12 was significantly higher ($P < 0.05$) than the VH in the M18, but not significantly different ($P > 0.05$) from the M0 and M6. The CD of the duodenum was higher in the M18, but there was no significant difference ($P > 0.05$) between the treatment groups. The VH - CD ratio of the duodenum was significantly lower ($P < 0.05$) in the M0 group in comparison with the other groups. From *Table 6* and *Figure 3,* the VH in the jejunum was significantly higher ($P < 0.05$) in the M12 group in comparison with the M0, but not significantly different from the M6 and M18. There was no significant difference ($P > 0.05$) in the CD of the jejunum between the treatment groups. However, the M12 recorded the highest CD. The VH - CD ratio of the jejunum was significantly higher ($P < 0.05$) in the M18 in comparison with the M0 and M6, but not significantly different ($P > 0.05$) from the M12. From *Table 6* and *Figure 4,* the VH of the ileum first increased with the increase in the concentration of alfalfa fibre in the diet and later decreased at higher dietary alfalfa fibre levels. However, there was no significant difference ($P > 0.05$) between the treatment groups. The CD of the ileum was significantly higher ($P < 0.05$) in the M12 in comparison with the M0 and M6, but not significantly different ($P > 0.05$) from the M18. The VH - CD ratio of the ileum was higher in the M6, but there was no significant difference ($P > 0.05$) between the treatment groups.

Discussion

Growth performance of pigs

The current study showed that the addition of different dietary concentrations of alfalfa fibre to the diet of piglets promotes their growth performance. However, at higher concentrations, there was a downward trend in the growth performance of piglets. These findings indicated that supplementing the optimum concentrations (6.00-12.00%) of alfalfa fibre to the diet of piglets will significantly promote the growth and development of piglets. Our results were in agreement with the findings of (Che et al., 2018; Adams et al., 2018a; Wang et al., 2010; Yuan et al., 2006). In supplementing *Astragalus membranaceus* fibre to the diet of weaning piglets (Che et al. 2018) and Adams et al. (2018a) observed an increase in the growth performance of piglets weaned at 28 days old. Similarly, Yuan et al. (2006) observed an increase in the growth performance of piglets after feeding on Astragalus polysaccharides. Also, after feeding on both *Astragalus membranaceus* roots powder and Astragalus polysaccharide, Wang et al. (2010) observed an increase in the growth performance of broiler chicks. Wang et al. (2016) reported an increase in the growth performance of weaning pigs fed with sugar beet pulp. Chen et al. (2016) reported that adding alfalfa flavonoid to the diet of Yangzhou geese increased their growth performance. However, supplementing higher concentration (18.00%) of alfalfa fibre will have a detrimental effect on the growth performance of weaning piglets. This is because weaning piglets cannot utilize the high fibre content present at the maximal concentrations of alfalfa fibre due to the immature gastrointestinal tract and less gut microbial composition and diversity (Che et al., 2018). Similarly, Chen et al. (2017) and Adams et al. (2018b) indicated that piglets have immature gastrointestinal systems and adapting to a less digestible solid feed such as dietary fibre seems challenging. The supplementation of dietary fibre to the diet of piglets promotes the growth and health of piglets, as these fibre components can be fermented by microorganisms in the intestinal tract to produce large volumes of short-chain fatty acid, that serves as the main energy source for weaning piglets (Christensen et al., 1999; Che et al., 2018), reduce the population of enteric bacteria in the gut that causes piglet diarrhea during weaning (Li et al., 2011; Che et al., 2018). In contrast to our findings, Wellock et al. (2008) observed a decrease in the growth performance of piglets after feeding on a dietary fibre supplemented diet. In addition, there was no effect on the growth performance of lambs after feeding on a diet supplemented with sugar beet pulp and roasted canola seed (Asadollahi, et al., 2018). Also, Jin et al. (2018) observed no change in the growth performance of growing lambs after feeding on a dietary *Urtica cannabina* supplemented diet. Moreover, dietary supplementation of alfalfa saponins had no effect on the growth performance of lambs (Liu et al., 2018). Furthermore, Wang et al. (2018) observed no effect on the ADG and ADFI in piglets after feeding on alfalfa containing diet. Jiang et al. (2012) observed no change in the growth performance of ducks fed with alfalfa meal. The difference between our findings and these studies may be due to the difference in animal species and the fibre source or alfalfa plant concentration applied. Therefore, dietary inclusion of alfalfa fibre at an optimum level can positively promote the growth performance of piglets.

Nutrient digestion of piglets

Che et al. (2018) indicated that the main importance of any nutritional supplement added to an animal's diet was as a result of its ability to be utilized by the animal.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22752295

Hence, the digestibility of nutritional components of a dietary supplement is a vital parameter in evaluating its inclusion in the diet. The findings of this study indicated that the supplementation of alfalfa fibre to the diet of piglets increased their nutrient digestibility. This study showed that the digestibility of CP increased with the increase in alfalfa fibre concentrations in the diet. Also, the CF and DM digestibility first increased with the addition of alfalfa fibre and then decreased as the concentration increases. Similarly, Jin et al. (2018) observed an increase in the CP digestibility after supplementing *Urtica cannabina* in the diet of growing lambs. In addition, Lara et al. (2018) observed an increase in nutrient digestibility in wethers after feeding on corn silage inoculated with *Lactobacillus plantarum* and *Bacillus subtilis*. Moreover, the supplementation of dietary alfalfa saponins in the diet of lambs increased their nutrient digestibility. Furthermore, Ebrahimi et al. (2018) reported a decrease in the nutrient digestibility of neonatal calves after feeding on *Trachyspermum ammi* and *Thymus vulgaris* oils in their diets. The supplementation of alfalfa fibre promotes the development of piglets' intestinal tract and increase the digestive function of piglets. The alfalfa fibre is a high-quality protein feed hence increasing its supplementation may increase the nutrient digestibility of piglet, especially CP digestibility. However, higher fibre content in the diet may decrease the bioavailability of some key nutritional components such as some minerals and vitamins (Adams et al., 2018b) and reduce the proportion of digestible substances in food and digestive energy (Adams et al., 2018c). In contrast to our findings, Che et al. (2018) reported a decrease in nutrient digestibility after feeding *Astragalus membranaceus* fibre to weaning piglets. Wang et al. (2016) reported a decrease in nutrient digestibility in weaning piglets after feeding on a sugar beet pulp. Also, Jørgensen et al. (1996) reported a low nutrient digestibility in pigs fed with high fibre concentrated diet. In addition, Dilger et al. (2004) fed high soy hull fibre to pigs and observed low DM digestibility. Furthermore, dietary fibre affects the function of the gastrointestinal tract, as indicated by low nutrient digestibility and accessibility of feeds with high-fibre levels (Bikker et al., 2006; Adams et al., 2018c). Pinheiro et al. (2018) reported that dietary supplementation of higher alfalfa concentrations in the diet of European adult rabbits had no effect on the digestibility of dietary components. Moreover, dietary fibre intake impacts the various methods in nutrients absorption and digestibility and this may lead to a delay in the glycemic response (Adams et al., 2018b). As reported in a review by Adams et al. (2018b, c), dietary fibre and prebiotics impact the health of the host animal by regulating blood glucose or insulin levels, stool bulking effects, enhancing the acidity of the gut, short-chain fatty acids synthesis, reducing intestinal transit time, inspiring the growth of intestinal microbes, and increase the production of blood biochemical components. Therefore, the effects of dietary fibre on nutrient digestibility may depend on the dietary fibre source or form, the nutritional component, the age of the animal, and the health of the animal.

Nitrogen metabolism and blood biochemical parameters in piglets

The difference in dietary feed consumption influence the rate of N metabolism in animals. The results of this study showed that dietary supplementation of alfalfa fibre increased the N metabolism in piglets. The piglets that were fed with 12% of alfalfa fibre (M12) had the highest N intake. Meanwhile, the fecal N content in piglets decreased with the increase in the concentration of alfalfa fibre in the diet. The highest urine N content was observed in the M18 group while the apparent N digestibility and N

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22752295

deposition were observed in the M12 group. According to the test results, we observed that the addition of alfalfa fibre to the piglet's diet maintained the normal growth performance of piglets. Therefore, optimum dietary fibre concentration can promote the N utilization in the body, but the excessive concentration of alfalfa may reduce the time during which the chyme stays in the intestine hence reduce the N utilization rate. In addition, urinary urea levels may rapidly decompose to ammonia by exposing to the environment (Aarnink and Verstegen, 2007), causing environmental pollution. In this experiment, the addition of alfalfa fibre reduced the emission of fecal N and urinary N, hence reduced environmental pollution. Therefore, improving the fibre levels of the diet may be an important means of reducing the N emissions from pig farms.

Blood contains various proteins, sugars, lipids, and other metabolic substances such as enzymes and hormones which affect the growth and metabolism of nutrients in the body. Blood biochemical indicators influence blood levels, animal health, and impacts growth and nutrient regulation in animals. The findings of this study indicated that the supplementation of alfalfa fibre to the diet increased the albumin, globulin, and total protein concentrations in the blood of piglets. The addition of the optimum (6.00-12.00%) alfalfa fibre to the diet of piglets decreased the blood glucose, cholesterol, aspartate aminotransferase, and alanine aminotransferase in piglets, but higher alfalfa fibre increased blood glucose and aspartate aminotransferase concentration. Meanwhile, the triglyceride levels decreased with the addition of alfalfa fibre to the diet. The serum total protein, including albumin and globulin relate to the protein synthesis in the body. It influences protein concentration, synthesis, and functions in immune responses, transportation, and coagulation (Paschke et al., 2010). The results of this experiment indicated that supplementing alfalfa fibre to the diet may increase the total protein levels in pigs. Similarly, Chen et al. (2016) reported that the supplementation of alfalfa flavonoid to the diet of Yangzhou geese has no adverse effects on the total protein metabolism and liver functions. Furthermore, these authors reported that adding 150 to 450 mg/kg alfalfa flavonoids increased serum total protein concentration in geese (Chen et al., 2016). However, when the amount of alfalfa fibre reached 18%, the total protein content of the serum began to decrease. The addition of fibre to the diet has no adverse effects on the metabolic processes in piglets but excess fibre may attenuate the metabolic functions in piglets. Therefore, supplementing the optimum concentration of alfalfa fibre will promote the health and productivity of pigs. Serum urea N is the final metabolite of protein and amino acid catabolism in animals (Chen et al., 2016). Its content can accurately reflect the nutritional status of an animal and the absorption and utilization of protein in the body. Studies have shown that when serum urea N decreases, there may be a decrease in the protein metabolism of the body and increase in the N deposition (Paschke et al., 2010). Also, the findings of this experiment indicated that the urea N composition of the trial groups was lower in comparison with the M0. The M6 group had the lowest urea N content and the highest N deposition. Contrarily to our observation, Chen et al. (2016) observed an increase in the serum urea N after adding alfalfa flavonoid to the diet of Yangzhou geese. Also, Qiu et al. (2009) reported an increase in the serum urea N concentrations after feeding protein diet supplemented with dietary zinc. This further confirms the relationship between serum urea N and N deposition in animals. The blood glucose is mainly metabolized in the hepatic glycogen decomposition and intestinal absorption. It forms the main tissue components and energy metabolic substrates of the body. Therefore, changes in the blood glucose levels may influence the dynamic balance between the sugar absorption,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22752295

transport, and metabolism in the body. The findings of this study further showed that there was no significant effect on the blood glucose concentration in piglets after feeding on alfalfa fibre, this indicates that the rate of energy conversion between the treatment groups maintained a dynamic equilibrium. The cholesterol and triglyceride concentrations in the serum can reflect the total lipid metabolism in the body (Chen et al., 2016). The higher the cholesterol or triglyceride content, the higher the body's ability to metabolize fat. The results of this experiment indicated that alfalfa fibre may reduce the cholesterol and triglyceride concentrations in the blood of weaning piglets, hence indicating that alfalfa fibre has a certain lipid-lowering effect. Similarly, Chen et al. (2016) deemed that the addition of alfalfa flavonoid decreased the triglycerides and total cholesterol levels in Yangzhou geese. Similarly, Zhou (2011) reported that an increase in cholesterol metabolism and a reduction in the cholesterol deposition of the body, thus promoting meat quality parameters. Aspartate aminotransferase and alanine aminotransferase are involved in the metabolism of amino acids in the body and are important indicators for evaluating liver functions (Chen et al., 2016). The addition of alfalfa fibre to the diet had no significant effect on the two transaminase enzymes, hence indicating that high fibre level in the diets had no effect on the amino acid metabolism of the body. Contrarily to our observation, Chen et al. (2016) observed that the addition of alfalfa flavonoid significantly increased the levels of aspartate aminotransferase and alanine aminotransferase in comparison with the control group. Also, there was an increase in the aspartate aminotransferase and alanine aminotransferase level when rapeseeds diet was fed to geese (Wang et al., 2015a) and alfalfa diet fed to sheep (Wang et al., 2015b). The difference between our findings and that of these authors may be due to the form of alfalfa used and the experimental animal involved. Therefore, adding alfalfa fibre may promote the N metabolism, improve biochemical parameter, and no adverse effect on the amino acid metabolism.

Intestinal morphometry of piglets

Studies have indicated that dietary fibre is a valuable nutrient for the prevention of intestinal disorders and improving intestinal health in both humans and animals (Ingvar, 2004). The small intestine is the main site for digestion and absorption of various nutrients in the diet. The villi are the functional units of the small intestine and the height of the villi can affect the nutrient absorption abilities of the small intestines. The villus atrophy occurs when the cells at the top of the villi are detached or the rate of cell regeneration is decreased and the number of mature cells is reduced leading to gastrointestinal inflammatory disease (Geboes et al., 2018). The intestinal glands and its CD reflect the maturation rate of the cells and the deepening of the crypts means that the cell maturation rate decreases, therefore decreasing the rate of transport of substances from the epithelial cells to the top of the villi (Wallig, 2018). The ratio of the VH - CD influence the functions of the small intestine (Hu et al., 2018). The higher the ratio of the VH - CD, the higher the intestinal mucosal functions and the absorption capacity of the small intestine. However, lower VH - CD indicates that the intestinal mucosa is damaged and the absorption capacity of the intestine decreases (Hu et al., 2018). The results of this study showed that the VH of the duodenum, jejunum, and the ileum was higher in the M6 and M12 in comparison with the control group. In agreement with our study was the findings of Xia et al. (2005) who reported that the supplementation of copper-bearing montmorillonite to the diet of weaning piglets significantly increased the VH and the VH - CD ratio in the small intestinal mucosa

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22752295

compared to the control group. Meanwhile, Xia and colleagues observed no significant effects on the small intestinal morphology after supplementing $CuSO_4$ to the diet of piglets (Xia et al., 2005). Similarly, Jiang et al. (2012) reported that there was a significant difference in the VH, CD, and VH - CD ratio in the duodenum, jejunum, and ileum of ducks fed with different concentrations of alfalfa meal. Broiler chickens fed with wet diet had high VH and low CD in the duodenum, jejunum, ileum, cecum, and the colon in comparison with those fed with dry diet (Yasar and Forbes, 1999). High VH was observed in the duodenum after feeding birds with *Bacillus subtilis* (Samanya and Yamauch, 2002) and yeast cell wall (Zhang et al., 2005). Also, Hedemann et al. (2006) observed that feeding pigs with high-insoluble fibre diets may guard the small intestine against pathogenic bacteria by increasing the VH. In addition, Chen et al. (2013b) indicated that piglets that were fed with wheat bran fibre had a higher VH in the ileum than those fed with soybean fibre. These same authors found that the supplementation of wheat bran fibre and pea fibre in the diet of weaning piglets increased the number of mucosal goblet cells in the colon (Chen et al., 2013b). Furthermore, Xu et al. (2003) indicated that feeding fructooligosaccharide (0.4%) to broilers increased the ileal VH, CD, and VH - CD ratio. We observed that the VH of the duodenum and the ileum decreased at higher concentration of alfalfa fibre (M18) in comparison with the other groups. Xia et al. (2005) indicated that the digestive tract accommodates some stresses that relatively causes a deviation in the intestinal mucosa of piglets due to the close proximity of the mucosal surface of the intestinal components. The supplementation of dietary fibre levels in the diet promotes the development of the intestinal villi in piglets, but higher fibre content may lead to atrophy of the villi. The variations in the intestinal morphology such as shorter villus and deeper crypts have been related to the presence of toxins and other chemical agents (Xu et al., 2003). Gerritsen et al. (2012) showed that dietary fibre levels affect the changes in the intestinal morphology of animals, mainly due to the changes in the surface area of the intestines such as the height and number of villi. Kleessen et al. (2003) reported that feeding high fibre diets to pigs increased the VH of the ileum and jejunum, but had no significant effect. Also, the ileal VH - CD ratio in piglets fed with wheat bran fibre was higher than piglets that were fed with maize bran fibre (Chen et al., 2013a). In this study, the ratio of the VH - CD in the duodenum and jejunum increased with the increase in the supplementation of alfalfa fibre in the diet while in the ileum the highest VH - CD ratio was recorded in the M6 group. The above test results showed that a piglet fed diet with alfalfa as the main fibre source can promote the development of the small intestinal villi and improve nutrient digestibility and utilization rate. In contrast to our study, Nabizadeh (2012) reported that dietary supplementation of inulin in the diet of broiler chicks had no effect on VH, CD, and the VH - CD ratio in the duodenum and jejunum on day 42 of age. In addition, cellulose supplementation significantly reduced the VH in both the jejunum and ileum (Chen et al., 2014). However, inulin inclusion significantly increased ileal VH in broiler chickens at 42 days of age (Chen et al., 2014). Studies have shown that the level of feed intake affects the height of the small intestinal villi and the depth of the crypt. The increase in feed intake promotes the development of the small intestine. The reason may be that some fibre components can regulate the composition of microorganisms in the intestine through fermentation to increase the intestinal VH and CD of animals (Jiang et al., 2012). The supplementation of fibre in the diet may stimulate volatile fatty acids produced by intestinal microbial fermentation, while butyric acid promotes the intestinal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22752295

cell production, thereby deepening CD (Gidenne et al., 2002). Early weaning of piglets can cause stress induction in piglets which may cause changes to the intestinal morphology, atrophy of the small intestinal villi, and deepening of the crypts, hence affecting the body's absorption ability and utilization of nutrients and decreased immunity. Therefore, piglets weaning stress may be alleviated by appropriately raising the fibre level of the diet to maintain the intestinal health of piglets.

Conclusion

This experimental study showed that adding 6-12% of alfalfa fibre to the diet of weaning piglets may improve the growth and nutrient digestibility of piglets, reduce N emissions, and improve N utilization in piglets. Also, adding 6-12% of alfalfa fibre to the diet of piglets may promote the utilization of protein and maintain the balance in glucose metabolism. At the same time improve the intestinal morphological structures and improve the digestion and absorption of the small intestine. Therefore, further research is recommended to elucidate the effects of alfalfa fibre on the gut microbial function with reference to nutrient digestibility and N metabolism in piglets.

(Received 19th Oct 2018; accepted 2nd Jan 2019)

Abstract. This study on Silphidae fauna was carried out at different sites forming part of an agricultural landscape. Catches were carried out in two selected habitats (Borek Stary and Widna Góra) in the Subcarpathian region (south-eastern Poland) during three growing seasons (2009-2010 and 2014) using Barber pitfall traps. It included potato, fodder beet and cereal crops (Widna Góra) as well as field margins (Borek Stary and Widna Góra). Four traps were placed at each of the sites studied then were emptied on average every two weeks. As a result of the observations, a total of 5491 beetles from 13 species were collected.
Keywords: *Silphidae, Thanatophilus sinuatus, Nicrophorus vespillo, crop culture, field margins*

Introduction

Most representatives of carrion beetles (Col., Silphidae) are necrophagous and/or predatory. Herbivorous species are a minority (Anderson and Peck, 1985; Sikes, 2008). Alongside ground beetles (Col., Carabidae) and rove beetles (Col., Staphylinidae), beetles from this family are an important component of epigeic entomofauna of agricultural landscape from the ecological point of view (Tischler, 1955). Necrophagous carrion beetles perform important ecological functions, which can be particularly seen in the agricultural aspect.

Biochemical transformations that accompany the decomposition of dead animals lead to an increased amount of mineral nutrients and humus in the soil and, as a further consequence, they affect soil fertility regeneration. Overall, they contribute to the cycling of elements in nature. In the aspect of agricultural crops that are at risk of outbreaks of many pests, among others gastropods (Gastropoda: Pulmonata: Stylommatophora), it is important to notice the positive biological role of carrion beetles. *Silpha carinata* is a predator of gastropods, both shelled snails and slugs (Dekeirsschieter et al., 2011). *P. atrata atrata* and *A. laevigata laevigata*, in which the characteristically elongated head facilitates shell penetration, exhibit a morphological adaptation for hunting shelled snails. Hunting strategies in these species have been described by Heymons and Lengerken (1932), Plate (1951), Linssen (1959), and Barronio (1974).

Agricultural progress and modern industrialization that aim to improve production in the food sector, given the growing human population, do not guarantee the sustainability of ecosystems. What is more, the loss of identity of ecosystems leads to the impoverishment of biodiversity (Wink et al., 2005). Anthropogenic pressure on agricultural landscape, which includes various agronomic practices, the use of fertilizers and crop protection chemicals as well as different plant and animal production systems, exerts an adverse impact on the diversity of zoocenoses occurring in agrarian landscape

DOI: http://dx.doi.org/10.15666/aeer/1702_22972313

(Boone et al., 1999; Stoate et al., 2001; Porhajašová et al., 2015). Invertebrates, especially insects, are an animal group that is particularly sensitive to landscape changes. As a numerous and diverse component of different biocenoses, they perform important functions in ecosystems (Konieczna and Krupa, 2013), and a decline in their numbers may have a negative cascade effect (Coleman and Hendrix, 2000; Nichols et al., 2007).

The impact of agronomic practices on beneficial coleopterofauna has been identified quite well with regard to, among others, ground beetles (Col., Carabide) (Holland and Luff, 2000; Honěk and Jarošík, 2000; O'Rourke et al., 2008; Bukejs and Balalaikins, 2008; Bukejs, 2009; Eyre et al., 2012; Lemic et al., 2017; Schwerk and Dymitryszyn, 2017) and rove beetles (Col., Staphylinidae) (Bohac et al., 1999; Balog and Markó, 2006; Ghahari et al., 2009). As predatory entomophages, these both beetle families are frequently analyzed comprehensively (Andersen et al., 1983; Andresen, 1997; Frank and Reichhart, 2004; Tamutis et al., 2004). It should be indicated that the cited publications are only selected examples. However, as far as carrion beetles of arable fields are concerned, research is fragmentary. The studies conducted in the Czech Republic (Petruška, 1968; Novák, 1961, 1962; Kočárek and Benko, 1997; Kočárek, 1997; Růžička, 1994; Jakubec and Růžička, 2012; Stanovský et al., 2005), Austria (Juen et al., 2003), Luxembourg (Schlechter, 2008), Lithuania (Tamutis et al., 2007), and Poland (Kamińska, 1989; Konieczna et al., 2014) can be considered to be the most important publications presenting the occurrence of Silphidae in agriculturally used areas.

Apart from providing biological pest control, ground beetles (Arus et al., 2012; Renkema et al., 2014) are commonly considered to be bioindicators of environmental changes (Rainio and Niemelä, 2003; Agvin and Luff, 2010). Referring to the definition of McGeoch (1998), not only Carabidae, but also trophically different beetle families (Staphylinidae, Nitidulidae, Scarabaeidae, Scotylidae) can be regarded as indicator organisms (Beroiz et al., 2010). According to a study by dos Santos Fernandes et al. (2011), Silphidae can also be considered as potential biomarkers of environmental quality.

In analyzing the occurrence of beetles in agriculturally used areas, research on both areas that are subject to direct agricultural use (crop fields) and land that is excluded from such agricultural use (field boundary strips, field margins, and adjacent meadows) is worth undertaking. The need to conduct comparative studies was highlighted by Huruk (2006). Their results can be much more interesting and can allow us to infer on the impact of human activity on the natural environment. At the same time, it is worth noting that the negative impact of agricultural practices on organisms seems to be less noticeable in field margins (Marshall and Moonen, 2002). Taking this into account, the aim of this study was the following: (i) to identify the species composition of carrion beetles occurring in arable fields and field margins, (ii) to determine the dominance system of carrion beetles at such sites, and (iii) to compare the structure of assemblages of beetles caught.

Materials and methods

Study sites

This study on assemblages of necrophilous carrion beetles (Col., Silphidae) was conducted in south-eastern Poland in the years 2009, 2010, and 2014 (*Fig. 1*). Catching

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22972313

of entomofauna was carried out in Borek Stary (UTM EA73) and Widna Góra (UTM FA13/FA23). In Widna Góra, the study included the following crops: (i) a mixed cereal crop for animal feeding (at equal proportions of *Avena sativa* L., *Hordeum vulgare* L., and *Triticum aestivum* L.), (ii) fodder beet (*Beta vulgaris* L., semi-sugar type, cv. 'Zentaur Poly'), and (iii) potato (*Solanum tuberosum* L.), including the fields margins adjacent to these crops (iv, v, vi). In Borek Stary, the study was carried out on (vii) a field margin separating a mixed cereal crop for animal feeding (spring cereals: *Avena sativa* L. and *Hordeum vulgare* L.) and pastures (*Fig. 2a-g*).

Methods for describing the study sites

The field margins were characterized based on relevés made using the Braun-Blanquet method. Due to the limited surface area of the field margins, the relevé area was 20 m^2. To determine the cover-abundance of each of the identified species, the Braun-Blanquet seven-point scale was used (1964), in which a value of 5 corresponds to cover above 75%, 4 – 50-75%, 3 – 25-50%, 2 – 5-25%, and 1 – about 5%. The symbol "+"denotes rare species (2-5 specimens), while r – sporadic species (1 specimen) (Pawłowski, 1977; Wysocki and Sikorski, 2014). In the agriculturally used areas (the potato, fodder beet, and mixed cereal crops), due to the homogeneity of the crop stands, cover of layer C was accepted as 100% (100% culture purity).

Catching of carrion beetles

This study was conducted over three growing seasons (2009-2010 and 2014). Beetles were captured using Barber pitfall traps, which were emptied at 14-day intervals. The pitfall traps were made of plastic containers with a diameter of 9 cm, placed flush with the ground level, and filled with ethylene glycol solution to $^1/_3$ of their volume. Four traps were placed at each of the sites studied. They were monitored from the first 10 days of May to the third 10 days of October. Poultry slaughterhouse waste was used as bait. 11 harvests were carried out in 2009, whereas in 2010 and 2014 – 12 in either of these years. The content of one trap from one harvest at one site was treated as one sample. Over the three-year study period, a total of 380 samples were taken for analysis. The captured entomological material was analyzed under laboratory conditions.

Treatments

Basic agronomic treatments, such as ploughing, harrowing, and fertilization, were done in the crop fields included in the entomological survey. In the potato crop field, the soil was fertilized with farmyard manure and a compound fertilizer, NPK(S) 6-20-30-(7). The following foliar herbicides were applied: 70% metribuzin and quizalofop-P-ethyl 50 g/l. To control the Colorado potato beetle (*Leptinotarsa decemlineata* Say), an insecticide containing zeta-cypermethrin was used. A concentrated boron fertilizer was additionally applied before row closure. The soil for the fodder beet crop was fertilized with a compound fertilizer, NPK(S) 6-20-30-(7). To improve the soil nutrient availability, a nitrogen fertilizer with boron was additionally applied. To control weeds, two herbicides were used: S-metolachlor 960 g/l and 43.0% chloridazon. After fodder beet emergence, the following foliar fertilizers were applied: a nitrogen-magnesium concentrate and boron ethanolamine. In the mixed cereal crop, a foliar herbicide containing S-metolachlor 960 g/l was used.

In the field margins separating the crop fields, the only agronomic treatment was single grass cutting after harvest of the crops in the adjacent fields.

Nomenclature and statistical analyses

Beetles were identified using the keys of Mroczkowski (1955) and Šustek (1981). The qualitative and quantitative characteristics of Silphidae caught were analyzed using zoocenological indices such as the dominance index (D), the Shannon-Wiener species diversity index (H'), and the Pielou species evenness index (J') (Shannon and Weaver, 1949; Pielou, 1966; Górny and Grüm, 1981). To evaluate the significance of differences in the number of species and individuals of carrion beetles (Col., Silphidae) trapped at the individual sites, a Chi-squared test was used (χ^2). To determine similarities between the assemblages of beetles caught, the following was used: (i) cluster analysis using the Ward agglomeration method, in which the Euclidean distance was accepted as a measure of similarity, and (ii) faunistic similarity using the Sørensen formula (P) (Magurran, 2004). The level of significance (the maximum allowable probability of type I error) was set at $\alpha \leq 0.05$. The obtained results were statistically analyzed using Statistica v.12 and Excel 2007 software.

Results

Results of investigation of the floral composition

The results of the phytosociological analysis of the field margins are shown in *Table 1*.

Generally, the number of plant species identified in the field margins was high, with the highest number in the field margin located next to the mixed cereal crop in Borek Stary. The percentage of plants in ground cover was there as much as 95%, while 66% of the species can be described as characteristic of hay meadows. These were predominantly the following grasses with varying fodder value: *Festuca rubra, Holcus lanatus, Agrostis capillaris, Dactylis glomerata,* and *Arrhenatherum elatius,* among which the following dicotyledonous herbs were found, among others: *Geranium pratense, Leontodon autumnalis, Plantago lanceolata*, and *Taraxacum officinale.* The percentage of papilionaceous plants was low and they accounted for 11% of the total plant cover.

A- tree layer, B- shrub layer, C- herb layer

The vegetation found in the field margin bordering the potato crop in Widna Góra also showed certain relationships with hay meadows. *Arrhenatherum elatius* and *Dactylis glomerata* were the dominant species there, whereas among dicotyledonous species the following grew most frequently: *Achillea millefolium, Glechoma hederacea*, and *Taraxacum officinale.* The percentage of segetal species in the ground cover of the studied patch was only 13%. These were typical weeds accompanying root crops.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22972313

The vegetation found in the field margins adjacent to the fodder beet and mixed cereal crops in Widna Góra was distinguished by a different floristic composition. There, segetal and ruderal plants were found to have a distinctly higher percentage, both in terms of the number of species and cover. Most segetal species grew in the field margin located in the vicinity of the fodder beet crop, and these were the following, among others: *Elymus repens, Galinsoga parviflora, Chenopodium polyspermum, Ch. album, Fallopia convolvulus, Cirsium arvense, Polygonum persicaria*, and *P. aviculare*. They accounted for as much as 62% of the ground cover of the studied patch. The percentage of plants typical of hay meadows was small and they were primarily represented by *Holcus lanatus.*

The vegetation found in the field margin next to the mixed cereal crop was characterized by the highest presence of ruderal plants. Their percentage in the total number of species was 27%, while in the cover it was as much as 57%. Attention should be paid to *Solidago gigantea*, a species considered to be invasive in Poland, which occurred in large numbers (Tokarska-Guzik et al., 2012; Otręba and Michalska-Hejduk, 2014) and which was accompanied by *Calamagrostis epigejos,* a species that grows in great numbers in set-aside meadows and fields (Barabasz-Krasny, 2011; Kryszak et al., 2006). Among ruderal species, the following occurred: *Urtica dioica, Erigeron annuus, Geum urbanum, Anthriscus sylvestris*, and *Epilobium parviflorum*, while as regards field weeds, the following grew most frequently: *Elymus repens, Convolvulus arvensis*, and *Artemisia vulgaris*. Plants typical of hay meadows were found in small numbers.

Results of investigation of carrion beetles

A total of 5491 beetle individuals belonging to 13 Silphidae species were collected, and the highest number of beetles was found in the field margin in Borek Stary (*Table 2*). Statistically significant differences in the number of individuals trapped were found ($p < 0.05$), but no differences were found in the number of species ($p = 0.8228$). The subfamily Silphinae, with 4035 individuals and 7 species, was represented in greatest numbers. The sites where all identified species were found were the following: the field margin in Borek Stary, the field margin next to the potato crop, and the field margin adjacent to the mixed cereal crop in Widna Góra. At the same time, these were the sites that were characterized by the highest similarity (P = 100.0%). It was also observed that, in faunistic terms, the field margins investigated showed a greater similarity to one another than in the case of the field margin – adjacent crop field system (*Table 3*).

T. sinuatus was the species that was found in all the sampling areas and which dominated the cover-abundance distribution (3229 individuals) (*Fig. 3a*). Another species that was found in large numbers at all the sites was the eurytopic species *N. vespillo* which, likewise *T. sinuatus*, belonged to the eudominant class (*Table 3*; *Fig. 3b*). Moreover, a third eudominant was found to be present in the field margin next to the potato crop and in the margin next to the mixed cereal crop. These species were *S. obscura obscura* and *O. thoracicum,* respectively. *N. sepultor* was a taxon that showed the lowest numbers (11 specimens). The lowest number of identified species was found in the fodder beet crop (8 species).

To evaluate the species diversity, the commonly applied indices were used (*Table 2*). Generally, these coefficients showed higher values for the field margins than for the crop fields adjacent to them. The Shannon-Weaver index exhibits higher values for the less numerous assemblages, but with a good structure. The highest value of this index

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22972313

(H′=0.83) was recorded in the field margin bordering the mixed cereal crop. It was the site where the highest number of species was found (13), but at the same time an even distribution of the dominance class (*Table 4*) and the lowest number of individuals (628 beetles). At this site, the evenness of species distribution also showed the highest value (J′ = 0.22).

Figure 3. *Most numerous Silphidae. 3a- representative of Silphinae - T. sinuatus; 3b- representative of Nicrophorinae - N. vespillo*

In describing the assemblages of beetles, an important element is to analyze the dominance structure (*Table 4*). Among all the study sites, five dominant groups were only found in the field margin in Borek Stary in 2009 and in the field margin next to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22972313

cereal crop in Widna Góra. No dominant class was found at the other sites, except for the fodder beet crop. In turn, the highest number of subdominants was recorded in the mixed cereal crop. These were the following species: *O. thoracicum*, *P. atrata atrata*, *S. carinata*, *S. obscura obscura*, *N. humator*, and *N. interruptus*. Generally, the recedent and subrecedent classes were the most numerous groups as regards the species grouped in them.

The dendrogram of the species composition similarity of the study sites displayed significant differences (*Fig. 4*). Two main agglomerations that grouped the sites from the same localities were distinguished. Evidently, the field margins in Borek Stary distinguished themselves from the other study areas. The fodder beet crop and the field margin adjacent to it were the sites in the agriculturally used area in Widna Góra which were characterized by the greatest similarity.

Discussion

In the case of studies directly focused on the family Silphidae, bait traps are usually used (Novák, 1961, 1962; Petruška, 1968; Kamińska, 1980; Růžička, 1994; Kočárek and Benko, 1997). Due to the trophic structure and reproductive behavior of carrion beetles, such methodology gives better results of catches (Coyle and Larsen, 1998; Kočárek, 2000; Brousseau et al., 2010). This can be confirmed by the catches in the potato crop. 9 Silphidae species, represented by 457 individuals, were recorded in Widna Góra. On the other hand, in a previous cross-sectional study of the Subcarpathian region which was conducted using unbaited traps, a significantly lower number of Silphidae was trapped, both in qualitative and quantitative terms (Konieczna et al., 2014).

In the potato crop (similarly to all the other sites), the eudominant species were *T. sinuatus* and *N. vespillo*. Another important species in the dominance structure was *S. obscura obscura*, which made up the subdominant class (no dominants were found). Juen et al. (2003) found the above-mentioned species to be present in organic potato crops, but with a different order of dominance, since *S. obscura obscura* proved to be the most numerous species. But *T. sinuatus*, whose number was 355 specimens in Widna Góra, showed a very low number (3 ex.) in the study by Juen et al. (2003). In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22972313

total, the above cited authors recorded 4 species in the imaginal stage (104 ex.) and 5 species in the pre-imaginal stage (86 ex. +11 ex. *Thanatophilus* sp.) in the organic potato crop. Both in qualitative and quantitative terms, the results of the investigations carried out in Widna Góra were distinctly different from the results of Juen et al. (2003), which may be associated with the use of bait traps. A publication by Aleksandrowicz (2002), which relates to the effect of spraying with the insecticide Decis on beetle assemblies occurring in potato crops, draws similar conclusions. In this research, *S. obscura obscura* was also the most numerous representative of Silphidae. *N. vespillo*, in turn, which had the status of eudominant in Widna Góra, was classified as a subrecedent in the study by Aleksandrowicz (2002).

In the fodder beet crop site, the lowest number of species (8 taxa) was identified among all the sampling areas. The number of representatives of the genus Nicrophorus was also lowest. The following three taxa were observed: *N. interruptus*, *N. vespillo*, and *N. vespilloides*. Different results were obtained by Novák (1961, 1962) and Petruška (1968). Their research was carried out in Czechoslovakia and related to the genus *Nicrophorus*. Novák (1961) showed 8 species to be present in a fodder beet crop. In a subsequent study, 7 taxa were found (Novák, 1962; Petruška, 1968). Compared to the study conducted in Widna Góra, the three mentioned species were also found in the studies of the above-mentioned authors. Both in the above-mentioned publications and in the present study, the dominant species was *N. vespillo*.

A study on the impact of application of organic fertilizers on beneficial entomofauna in sugar beet crops was conducted by Porhajašová et al. (2015). The Silphidae was the third largest beetle family found in this study (5.23% of the total assemblage), but it was dominated by Carabidae (63.86%) and Staphylinidae (20.07%). In this case, it can also be presumed that the absence of bait was one of the factors determining the catches of carrion beetles.

Among the crop fields studied, the site where the highest numbers of Staphylinidae beetles were found was the mixed cereal crop, where 673 individuals classified in 11 species had been trapped. As far as the number of taxa is concerned, Kamińska (1980) obtained different results. In wheat and barley growing fields, she demonstrated only 3 carrion beetle species (554 individuals). It is worth adding that, similarly to the study done in Widna Góra, in the research conducted by Kamińska (1980) the dominant species were *T. sinuatus* and *N. vespillo*. The same species were the most numerous group in terms of dominance in a study conducted by Tamutis et al. (2007). Their observations were focused on the occurrence of epigeic coleopterofauna in conventional and organic barley crops. This research revealed that, depending on the agricultural production system, the Silphidae catches were different. Under conventional cropping conditions, 6 carrion beetle species were found, represented by 660 individuals. In the organic crops, 5 species were found, but with a twice lower number of individuals (326). In a study carried out by Varvara and Zamfirensu (2009) in a wheat plantation, the trapped Silphidae accounted for 20.62% of the entire assembly of beetles caught, thus constituting the second largest family of this order. Shah et al. (2003), on the other hand, obtained completely different results for winter cereal crops. Only one species was recorded there – *N. vespillo*, represented by 6 individuals.

Monocotyledonous crops are characterized by a high and dense canopy, and mechanical agronomic treatments are limited to soil preparation before seeding and direct harvest. Such a habitat structure can create more favorable living conditions for beetles (even for temporary living). On the other hand, a lower number of individuals

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_22972313

was found at the other crop sites (the potato crop and the fodder beet crop), which may indicate the unattractiveness of the habitat, due to both the nature of cropping (a low crop canopy, monoculture, the lack of floristic diversity, a lower probability of finding food) and the intensity of agronomic operations performed.

As a result of the catches conducted in the field margins, the highest numbers of beetles were shown in the field margin next to the mixed cereal crop in Borek Stary. Over the two-year study period in this area, a total of 2544 specimens representing 13 species were captured. The same number of identified taxa was determined in the field margin adjacent to the potato crop and in the field margin next to the mixed cereal crop in Widna Góra, but with a lower number of individuals.

Field margins that exhibit both floristic and structural diversity promote increased insect biodiversity (Thomas and Marshall, 1999). Field margins, field boundary strips or parts of arable fields excluded from agricultural production are biodiversity refuges, while predatory entomofauna inhabiting there may contribute to biological pest control (Fry, 1995; Wratten, 1998). In the field margins bordering the mixed cereal crop, the faunistic similarity was 100.0% (Borek Stary and Widna Góra). The high numbers of Silphidae trapped at these sites can be associated with the nature of the adjacent crops.

The publications of Růžička (1994) as well as of Kočárka and Benko (1997) can be mentioned among the few studies regarding the occurrence of carrion beetles in field margins. Růžička (1994) described open spaces excluded from agricultural use. His observations were carried out, among others, in a field margin overgrown with *Urtica* and *Cirsium* and bordering a maize crop as well as on an edge of a barley crop bordering a hornbeam (*Carpinus*) coppice. At these sites, a total of 13 species were found, out of which 11 species were common with the species captured in the field margin in Borek Stary as well as in the field margin adjacent to the potato crop and the field margin adjacent to the mixed cereal crop in Widna Góra. The study by Růžička (1994) demonstrated the presence of *Aclypea opaca* (1 ex.) and *Dendroxena quadrimaculata* (1 ex.), which did not occur in this study. On the other hand, in our study two species were recorded which Růžička (1994) did not confirm to occur. These were the following species: *S. obscura obscura* and *S. carinata*.

In a field margin separating a barley crop and a maize crop, in turn, Kočárek and Benko (1997) found the presence of 226 individuals from 10 species, out of which 9 occurred both in Borek Stary and in Widna Góra. In their study, the most frequently occurring species were *T. sinuatus* and *N. vespillo*.

Conclusion

When analyzing the qualitative and quantitative structure of the Silphidae caught in the field margins relative to the crop fields adjacent to them, a general trend was noticed towards the occurrence of a higher number of individuals and a lower number of species at the environmentally poorer sites (the crop fields). In the field margins bordering the crops, on the other hand, lower numbers of individuals were recorded, but a higher number of taxa identified. Such a distribution of beetles confirms Thienemann's biocenotic rule (1920), according to which the increased diversity of a habitat entails a decline in the total number of individuals. On the other hand, the proportion of recedents and subrecedents, that is, individuals that are few in number but which are important in the aspect of biodiversity preservation, increases.

(Received 31st Oct 2018; accepted 11th Jan 2019)

Abstract. The content of total sugars and reducing sugars in potato tubers is one of the most important quality features determining the suitability for direct consumption and for processing into food products. The objective of the study was to determine the effect of the soil conditioner UGmax on total sugars, reducing (simple) sugars and sucrose in potato tubers. Experimental material consisted of tubers of second early table potato grown in a field experiment conducted in central-eastern Poland. Following chemical analyses, statistical calculations were performed and they demonstrated a significant effect − an application of the soil conditioner UGmax contributed to an increase in the tuber content of reducing sugars compared with control potato tubers. The highest simple sugar content was found after three applications of the soil conditioner at the rate of 1.0 and 2.0 dm^3 ha^{-1}. The remaining carbohydrates determined in the study did not respond to UGmax application. Cultivars grown in the study differed significantly in terms of reducing sugar content only, more sugars being accumulated by Tajfun rather than Satina.
Keywords: *cultivars, reducing sugars, Solanum tuberosum, sucrose, total sugars*

Introduction

Plant production intensification and specialisation, which have led to reduced soil tillage, monoculture, intensive chemical protection, use of heavy machines/tools, shortage of natural manures, result in worsened physical, chemical and microbiological soil properties as well as limited availability of nutrients for plants (Malero et al., 2006). Soil environment is impoverished and lower yields are often produced. Due to this, the need arises to reduce the unfavourable influence and seek eco-friendly solutions. The idea of environment and consumer protection is becoming increasingly popular and seems to become a necessity (Mrówczyński and Roth, 2009). The soil conditioner UGmax, produced by 'Bogdan' Trade-Service Co, Ltd., is a microbiological product available on the Polish market and recommended for application in crop cultivation. It is an extract obtained from a special compost and used to enhance soil fertility. Microorganisms contained in the conditioner boost soil biological activity, increase the solubility of mineral compounds which plants find difficult to take up and promote humus formation (Trawczyński and Bogdanowicz, 2007; Dębska et al., 2016). It results in beneficial changes in soil physical and water status-related properties, pH and structure as well as better rooting system development (Kaczmarek et al., 2008; Piotrowska et al., 2012; Dębska et al., 2016) and, in consequence, increased higher

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23152324

quality yields of crops (Dinesh et al., 2010; Kołodziejczyk, 2014; Pobereżny et al., 2015; Kowalska, 2016).

Potato is one of major agricultural plants which is a staple food for people worldwide and a crop which is classified as one of key plants responsible for maintaining food security. Potato is consumed fresh or processed in both developing and developed countries (Camire et al., 2009; Lisińska et al., 2009; King and Slavin, 2013). Potato tubers are highly nutritious as they contain plenty of starch, protein characterised by high dietetic value, vitamin C, B_3, B_6, minerals, in particular potassium, phosphorus, magnesium and iron. The crop is also a valuable source of health-promoting compounds such as dietary fibre, phenols and carotenoids (Slavin, 2013; Andre et al., 2014). Tuber chemical components are cultivar-related but are also affected by agronomic practices, water availability and thermal conditions (Abong et al., 2009; Grudzińska et al., 2014; Ozturk and Polat, 2016). As it has been suggested that plant protection products, fertilisers, biostimulants and microbiological products may cause changes in plant chemical composition, studies have been undertaken to check their effect on the nutritional value of agricultural produce (Sawicka and Pszczółkowski, 2005; Gugała et al., 2013). Hence the present study aimed at determining the effect of the soil conditioner UGmax on total sugars, reducing sugars and sucrose in table potato tubers.

Materials and methods

Experimental and Agronomic Management

Research results were obtained from a three-year field experiment conducted at the Zawady Experimental Farm of Siedlce University of Natural Sciences and Humanities (52°03′N; 22°33′, central-eastern Poland) on a soil classified as Luvisol, whose pH ranged from slightly acidic to acidic (4.81-5.91 pH in KCl) and which was characterised by a high to very high available phosphorus content, moderate to high potassium content and low magnesium content (*Table 1*) (Marcinek and Komisarek, 2011). The experiment was set up as a split-plot arrangement with three replicates.

Table 1. *Selected chemical properties of soil on which the experiment was conducted*

Study years	Acidity (pH in KCl)	Organic matter (g kg^{-1})	Available nutrients (mg kg^{-1} soil)		
			P	K	Mg
2008	4.99	15.4	90.64	124.5	41.0
2009	4.81	16.8	76.12	173.4	34.0
2010	5.91	18.1	73.48	112.1	45.0

The first factor was two mid-early cultivars of table potato – Satina and Tajfun (*Table 2*).

Table 2. *Description of potato cultivars used in the study*

Cultivars	Registration year	Origin	Maturity	Yield (t ha^{-1})	Utilization
Satina	2000	Germany	second early	43.9	canned, frozen, salads, boiled
Tajfun	2004	Poland	second early	49.8	boiled

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23152324

The second factor was five methods of an application of the soil conditioner UGmax:

1. Control object - without the use of UGmax spraying with water.
2. UGmax - application before planting, at a dose of 1.0 $dm^3 \cdot ha^{-1}$.
3. UGmax - application before planting, at a dose of 0.5 $dm^3 \cdot ha^{-1}$ and double foliar application (10-15 cm potato plant height) at a dose 0.25 $dm^3 \cdot ha^{-1}$, (flowering) at a dose 0.25 $dm^3 \cdot ha^{-1}$.
4. UGmax - application before planting, at a dose of 1.0 $dm^3 \cdot ha^{-1}$ and double foliar application (10-15 cm potato plant height) at a dose 0.5 $dm^3 \cdot ha^{-1}$, (flowering) and at a dose 0.5 $dm^3 \cdot ha^{-1}$.
5. UGmax - double foliar application (10-15 cm potato plant height) at a dose 0.5 $dm^3 \cdot ha^{-1}$, (flowering) and at a dose 0.5 $dm^3 \cdot ha^{-1}$.

The conditioner contained: lactic acid bacteria, photosynthetic bacteria, *Azotobacter*, *Pseudomonas,* yeast, actinomycetes as well as the following amounts (mg l) of macroelements and microelements: potassium − 2905, nitrogen − 1200, sulphur − 1000, phosphorus − 220, sodium − 200, magnesium − 100, zinc − 20, manganese − 0.3 - produced by Bogdan, Trade-Service Co., Poland (Trawczyński, 2007; Zarzecka and Gugała, 2013). Farmyard manure was applied at a rate of 25.0 t ha^{-1} in addition to mineral fertilisers used at the following rates: 44.0 kg ha^{-1} P (in the form of 46% triple superphosphate - Group Azoty Chemical Establishments Police SA, Poland), 124.5 kg ha^{-1} K (in the form of 60% potassium salt – Establishments Trading Commodities Siarkopol Sp. z o.o. Tarnobrzeg, Poland) and 100 kg N per 1 ha (in the form of 34% ammonium salt - Group Azoty Nitrogen Establishments Pulawy SA, Poland) applied in spring. Potatoes were planted at the spacing of 0.675 x 0.370 m in mid-April and harvested at physiological maturity in the first half of September. Weeds were controlled by means of a mixture herbicides: chlomazon (Command 480 SC - FMC Chemical sprl, Belgium) at a dose of 0.2 dm^3 ha^{-1} and linuron (Afalon Dispersive 450 SC – Agan Chemical Manufactures Ltd., Israel) at a dose of 1.0 dm^3 ha^{-1} applied 5-7 days prior to potato plant emergence. During the period of crop growth and development, potato blight was controlled using fungicides: metalaksyl-M 3.8% and mankozeb 64% (Ridomil Gold MZ 68 WG - Syngenta Crop Protection AG, Switzerland) – 2.0 kg ha^{-1} and mankozeb (Dithane 455 SC - lndofil Industries Limited, Republic of India) – 3.0 dm^3 ha^{-1}, and Colorado potato beetle was controlled using insecticides: chlotianidyna (Apacz 50 WG - Sumitomo Chemical Takeda Agro Co., Japan) at a dose 0.04 kg ha^{-1} and tiametoksam (Actara 25 WG - Syngenta Crop Protection AG, Switzerland) at a dose 0.08 kg ha^{-1}.

Determination of carbohydrates

Before harvest, tuber samples from 10 plants per plot were collected in all experimental units and used for chemical analyses. The analyses were carried out each year in triplicate, representing a total of 90 samples. Total sugars and reducing sugars were determined after harvest in the fresh matter of unpeeled potato tubers by means of the Schoorl-Luff method (Krełowska-Kułas, 1993). The method involves reduction, under alkaline conditions, of copper sulphate by reducing sugars contained in Luff solution at the boiling temperature. Basic solution (hydrolysate) was prepared. 12.5 g of potato tubers were grated, made up with water and boiled for 3 minutes. After cooling, the solution was transferred to a 300 ml flask and 5 ml potassium ferrocyanide as well as 5 ml aluminium sulphate were added. After stirring, filtration was performed using a soft filter.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23152324

Total sugars were determined by Schoorl-Luff method. 25 ml of hydrolysate was placed in a 300 ml flask, 2.5 ml of concentrated HCl was added and the mixture was heated for 5 minutes at 68-72°C (hydrolysis of sugars to simple sugars occurred). The solution was cooled and, after adding potassium hydroxide KOH until constant pH was obtained in the presence of phenolphthalein, made up to 25 ml. Next, 12.5 ml Luff solution was added and followed by 12.5 ml hydrolysate, 25 ml acetic acid, 12.5 iodine solution and 27.5 ml hydrochloric acid. Then, the excessive iodine was titration titrated using sodium thiosulfate until light blue colour was obtained.

Determination of reducing sugars was performed by Schoorl-Luff method. 12.5 ml Luff solution and 12.5 ml hydrolysate were transferred to a 300 ml flack (no hydrolysis was conducted). Then, the procedure was the same as for total sugars.

Sucrose content was calculated by subtracting reducing sugars from total sugars after hydrolysis x 0.95. Analyses were performed at the Chemical Laboratory of the Department of Agrotechnology, Siedlce University of Natural Sciences and Humanities in Siedlce.

Statistical analysis

The results of the study were subjected to statistical analysis using the analysis of variance, and the significance of differences was assessed using Tukey test at the significance level of P = 0.05. Statistical calculations were performed in Excel using the authors' own algorithm based on the split-plot mathematical model.

Weather conditions

Weather conditions in individual study years, presented in *Figure 1* and *Table 3*, varied. Precipitation was the highest in 2010 when it was higher than the long-term sum by as much as 144.8 mm. The lowest rainfall was in 2009 when it was also unevenly distributed throughout the individual months of the growing season. By contrast, the year 2008 saw the most favourable rainfall pattern whereas 2010 was the warmest. The remaining growing seasons had temperatures similar to the long-term mean.

Results

Total sugars

Statistical analysis of the obtained results demonstrated that total sugar content was significantly affected by the weather conditions throughout the study years (*Tables 4, 5*).

It averaged 6.57 g kg^{-1} fresh matter (0.657%), the value being lower than 1%, which is favourable from the standpoint of consumers. The accumulation of total sugars was the smallestt in tubers harvested in 2009 (6.25 g kg^{-1}) which was optimal in terms of hydrological conditions. In 2008, total sugar content was slightly but insignificantly higher compared with the 2009 growing season. An accumulation of total sugars was the highest in the wet and the warmest 2010, on average 6.98 g kg^{-1}, the differences being significantly higher compared with tubers harvested in 2008 and 2009. The cultivars grown in this experiment contained similar amounts of total sugars. In the study described here, a tendency was observed for tubers harvested from UGmax-treated plots to slightly increase total sugars. However, the values were very small and ranged from 0.03 to 0.05 g kg^{-1}.

Reducing sugars

In the present study, reducing sugars content ranged from 3.41–3.90 g kg^{-1} fresh matter and were significantly affected by cultivars, an application of the soil conditioner UGmax and weather conditions during the study years (*Tables 6, 7*).

Table 6. *Reducing sugars content in potato tubers depending on UGmax and cultivars (g kg^{-1} fresh matter) (mean of years)*

DOI: http://dx.doi.org/10.15666/aeer/1702_23152324

Cv. Tajfun accumulated more reducing sugars than Satina. The soil conditioner promoted an accumulation of reducing sugars, significant differences being detected for treatment 3 and 4, that is when UGmax had been applied three times. Under the weather conditions of 2010, the concentration of these sugars was the lowest and so the most favourable compared with the remaining study years. It was mainly due to the air temperature which was by 2.3 and 1.8°C higher towards the end of the growing season (July and August).

Sucrose

Sucrose content in potatoes was significantly affected by weather conditions in the study years (*Tables 8, 9*). The concentration of this disaccharide was the lowest in 2009 whereas in the remaining years it was significantly higher. Cultivars grown in the present study accumulated a similar amount of sucrose. An interaction of cultivars and soil conditioner application regime was found, which indicates a different response of the cultivars to spraying with UGmax. There was also observed an interaction of UGmax application regime and study years. The least sucrose was recorded in 2009 in tubers harvested from UGmax-treated plots which were sprayed three times at the rate of 2.0 dm^3 ha^{-1}.

Discussion

In potato production, the most important characteristics which determine fresh tuber consumption suitability and processability include: dry matter content, total sugars (glucose + fructose + sucrose) and reducing sugars (glucose + fructose) which are also called simple sugars. Tubers ought to contain 18-22% dry matter and up to 1% total sugars (when this level, is exceeded, tubers taste sweet) (Lisińska et al., 2009). The results of the research showed that the total sugar content depended only on weather conditions. Total sugars and sucrose content were the highest in tubers harvested in 2010 when both precipitation and temperature during the growing period were the highest, the lowest values for both the traits being recorded in 2009 when precipitation was the lowest. A similar response of tubers to weather conditions, in terms of total sugar accumulation, was observed by other authors (Sawicka and Pszczółkowski, 2005; Zarzecka and Gugała, 2009). Cultivars (Satina and Tajfun) grown in the experiment discussed here contained similar amounts of total sugars, which is consistent with results reported by other workers (Gugała et al., 2013) although Bhattacharjee et al. (2014) found significant differences between cultivars being compared as to their tuber content of total sugars. There is no published literature concerning the effect of UGmax on total sugars, reducing sugars or sucrose in potato tubers.

The concentration of reducing sugars in the tubers of potato for processing for foodstuffs is one of the most important qualitative characteristics, and also called a priority. As a result of long-term studies conducted in Poland and worldwide (Coop et al., 2000; Lisińska et al., 2009; Zgórska, 2013; Grudzińska et al., 2014), the following baseline and optimal concentrations of reducing sugars in potato tuber fresh matter have been determined: not more than 0.25% (optimum level: up to 0.15%) for potatoes destined for chips production, not more than 0.50% (optimum level: up to 0.25%) for French fries varieties, and not more than 0.50% (optimum level: up to 0.25%) for dried products and fresh consumption. Tubers of potato which contain increased amounts of reducing sugars (glucose and fructose) turn brown when heated. In the present studies, reducing sugars content depended significantly on the cultivar, soil conditioner UGmax application and moist-thermal conditions during potato vegetation.The effect of potato cultivar on this characteristic was reported by other authors (Abong et al., 2009; Bhattacharjee et al., 2014; Grudzińska et al., 2014). On the contrary, Sawicka and Pszczółkowski (2005), Gugała et al. (2013) found no such influence. Grudzińska et al. (2014) reported that reducing sugar content was primarily affected by the air temperature 10 days before potato harvest. Moreover, the authors (Grudzińska et al., 2014) found, based on correlation coefficients which they had calculated, that the higher temperature was observed 10-20 days before harvest, the lower concentration of reducing sugars was recorded. A statistically significant effect of hydrothermal conditions on an accumulation of reducing sugars was also noted by other authors (Gugała et al., 2013; Brazinskiene et al., 2014). Cultivars grown in the present study accumulated similar amount of sucrose as in the findings reported by other authors (Sawicka and Pszczółkowski, 2005; Brazinskiene et al., 2014; Czerko et al., 2016).

Many authors have shown that the UGmax soil conditioner had a desirable, beneficial effect on the total and commercial yield of potato tubers, tuber weight per potato (Trawczyński and Bogdanowicz, 2007; Kowalska, 2016; Zarzecka and Gugała, 2016), increased starch and vitamin C content (Zarzecka et al., 2018) and improved soil chemical properties (Trawczyński and Bogdanowicz, 2007, Dębska et al., 2016) as compared to the control.

DOI: http://dx.doi.org/10.15666/aeer/1702_23152324

Conclusion

The application of soil conditioner UGmax significantly increased the content only of reducing sugars in potato tubers, whereas the total sugars and sucrose content did not change. However, the largest, significant influence on the content of carbohydrates (total sugars, reducing sugars, sucrose) had weather conditions during the years of research. The cultivars grown in this experiment can be used in direct consumption, for dried products and for processing into French fries and soil conditioner UGmax used did not cause adverse changes in the chemical composition of tubers.

(Received 8th Nov 2018; accepted 11th Jan 2019)

Abstract. The natural habitat of *Juniperus procera* is a unique ecosystem in Saudi Arabia. The ecosystem of Aseer highlands is an important habitat for flora and fauna. Alsouda Highlands, situated in the south-western part of Saudi Arabia, is claimed to be the highest peak in Saudi Arabia. These forests suffered varying degrees of degradation. Juniperus trees in these highlands have experienced widespread decline with substantial dieback for 35 years. The aim of the study is to evaluate the status of *J. procera* dieback in Alsouda natural stands (2400-2950 m). The results showed that >80 % *J. procera* trees within the natural stands had symptoms of dieback but >65% was not severely affected. Tree recovery signs of new lateral shoots, leaves, sprouts and flowering were evidently observed even among the severely affected trees. The plantation showed no symptoms of dieback, but their growth rate was relatively low. The NDVI showed an increasing trend of greenness with time, especially in the seasons with high rainfall. The effect of slope aspect was evident in the severity of dieback and greenness of the vegetation as detected by the NDVI data. The west facing slopes were higher in NDVI values than the east-facing slopes, due to higher precipitation in the west – facing slopes by the southwestern monsoons. The results indicate significant effect of seasonal rainfall with respect to tree health.
Keywords: *African pencil cedar, natural stands, plantations, new regeneration, NDVI, Aseer region*

Introduction

Juniperus procera Hochst. ex. Endl. (Cupressaceae), known as African pencil cedar and Arar in Arabic, is the world's largest juniper, evergreen, dioecious and wind pollinated forest tree species (Farjon, 2005; Couralet and Bakamwesiga, 2007; Negash and Kagnew, 2013). It spreads naturally in the highlands above 1800 m.a.s.l., but can occurs in a broader range of 1000–3500 m.a.s.l., with an average annual temperature range from 5 °C to 20 °C (Couralet and Bakamwesiga, 2007). It is listed in the IUCN red list of the threatened species due to overexploitation and global decline in its populations (Farjon, 2013).

The species is the dominant forest tree in the southwestern highlands of Aseer Region Kingdom of Saudi Arabia (KSA) at elevations from 2000 to 3000 m.a.s.l (El-Juhany et al., 2008; El-Juhany, 2015), and the density decreases in the subsequent lower elevations (El-Juhany and Aref, 2013). In addition to aesthetic values, the Juniper natural stands are important component of the highland ecosystems in Aseer (Aref et al., 2013) as they enhance biodiversity, reduce soil erosion, conserve rainfall water, and provide wood products (Aboulfatih et al., 1989).

Dieback symptoms and low rate of natural regeneration of *J. procera* were observed in Alsouda, Aseer Region during the early 1980's (El-Juhany, 2015). Symptoms were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23252338

up to 50% among trees in some parks, in addition to absence of new regeneration (Barth and Horst Strunk, 2000). It was attributed to climate change (Fisher, 1997), soil erosion and water run (Aref et al., 2013; El Atta et al., 2013), deprived eroded-soil from litter and mycorrhiza (Barth and Horst Strunk, 2000) and human interferences (Gardner and Fisher, 1994). Highlands in Aseer region had experienced warming trends (Krishna 2014) and decreasing annual rainfall (Hosny and Almazroui, 2015). Dieback were reported in Juniper ecosystems in the Arabian Peninsula and south-west Asia (Fisher, 1997), and parts of Africa (Borghesio et al., 2004).

Globally, Forest dieback and decline are significant threat to biodiversity in forest ecosystems with serious economic and aesthetic impacts (McKinneya et al., 2014. Climate and weather stresses were identified prime causes for water stresses and tree declines (Auclair, 1993; Rice et al., 2004; Jurskis, 2005). Climate change was reported to l affect *J. procera* future distribution in northern Ethiopia (Abrha et al., 2018). Natural pests and diseases causes can affect managed- forest condition and stability (Freer-Smith, 2007). Biotic factors are generally considered as contributing secondary factors, however they were primary causes for dieback in English woodlands (Woodward and Boa, 2013), Spruce forest (Kana et al., 2013), and Juniper forests (Borghesio et al., 2004). Study in Ethiopia showed that *J. procera* trees were tolerant and less affected by cypress aphid compared to *cupressus lusitanica* (Demeke, 2018).

The Juniper Forest in Asir is the only dense forest in the Kingdom and is particularly important from the point of view of conservation. Of particular concern is the widespread decline of *Juniperus procera* on exposed lower slopes with some stands consisting mainly of dead or dying trees. Hence, the aim of this study was to evaluate the health status of *J. procera* and extent of dieback in southwestern highlands of KSA. The objectives were to determine the severity of dieback within natural stands and plantations in Alsouda area, and temporal trends of tree health using satellite images in relation to annual rainfall and slope aspects.

Materials and methods

Study area

The study was conducted in Alsouda Area in Aseer Region, in the southwestern highlands of KSA, which is an important touristic area with the richest plant biodiversity in Aseer Region and KSA (Vincent, 2008). The study site is elongated in shape and dissected by small valleys with a total area of 291 km^2 (*Fig. 1*) and dominated by *J. procera* trees. The satellite image of Landsat depicted in FCC (False color composite (RGB) in order to observe the features clearly. The site was delineated based on topography and maximum stocking density of Juniper trees. It is located between latitude of 18° 8' 43.81" N and 18° 27' 32.00" N and longitude of 42° 18' 0.559"E and 42° 28' 58.317"E and elevations 2400 to 2950 m.a.s.l. As part of the Arabian shield in the western part of the Saudi Arabia, the topography is undulating and characterized by natural geological erosion and sedimentation phenomena (Mallick et al., 2014; Youssef et al., 2016). The dominate type of soil classes are loamy sand, sandy loam, and loam (Mallick, 2016). Alsouda receives the highest amount of annual rainfall in KSA by southwestern monsoons, with variable annual patterns (Vincent, 2008). Precipitation is mainly from March to June during spring and summer growing seasons (Wheater et al., 1989), and minimum and maximum temperature are 19.3 °C and 29.70 °C, respectively.

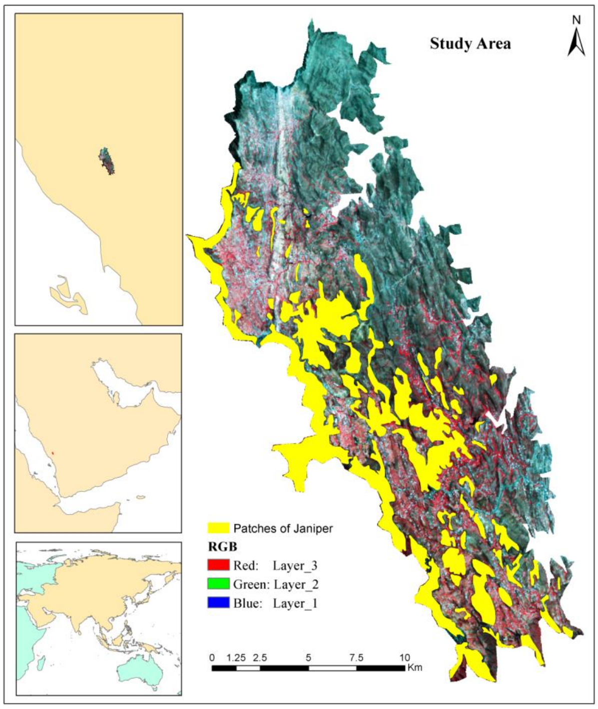

Figure 1. *Study area*

Data collection

Site-based surveys and remote sensing techniques were used as proven valuable tools to vegetation condition across a spatial and temporal range (Vogelmann et al., 2012).

Field survey

Ground surveys were conducted during October 2017 to March 2018 for the *J. procera* natural stands and plantations. According to an initial reconnaissance survey, the natural stands were divided into two aspects as east and west-facing slopes. Systematic random sampling was carried out along six transect lines in each aspect, with a total of 188 trees in the east slope and 201 in the west aspect. Tree dieback was evaluated at sampling point by the first author on ordinal scale from "1" healthy tree without obvious symptoms to "6" severely affected or dead tree (*Fig. 2*). Trees in the four plantation plots, numbered from 1 to 4, were measured for dieback symptoms, tree height and crown width. The nursery raised-seedlings were planted in 2006 with a spacing of about 3 m × 3 m. The number of measured trees 51, 73, 33 and 54 in plots 1, 2,3 and 5, respectively.

Figure 2. *Ordinal scale of 1 to 6 (1= healthy, no signs of dieback and 6 = severe or dying)*

Meteorological data

Rainfall data was obtained from the meteorological station situated within the study area (Al-Sooda Station no. 00028, 18° 15' 08" N (latitude) and 42° 24' 15.7" E (longitude). Whereas temperature data, the meteorological station located towards the 20 km of south-west. (Abha Station no. 41112, 18° 14' 25" N (latitude) and 42° 39' 11" E (longitude). The data related to the rainfall and temperature were operated and maintained by Ministry of Environment, Water and Agriculture and Presidency of Meteorology and Environment (PME), Saudi Arabia respectively. The elevation of both meteorological stations is 2585 and 2125 m from the m.s.l. respectively. The rainfall dataset analysed for the period 1965–2017, whereas temperature datasets for 1978-2017.

Remote sensing data processing

Satellite datasets of LANDSAT TM and LANDSAT-8 level-1TP (Level 1TP product contains systematically, radiometrically, geometrically, and topographically corrected using GCPs) over Aseer region were used for the preparation of the Normalized Difference Vegetation Index (NDVI) and Land use and land cover (LULC) maps. Digital number (DN) data converted to at-sensor radiance for LANDSAT data (https://landsat.usgs.gov/landsat-8-l8-data-users-handbook). ENVI-FLASSH (Fast Line-of-sight Atmospheric Analysis of Spectral Hypercubes) an atmospheric correction module was used to retrieve spectral reflectance.

Conversion of DNs to physical units

At-sensor radiances measured at a wavelength spectrum which captures the image in DNs values, which have no unit and any physical implication; therefore, it is essential to coverts to radiance and reflectance.

OLI and TIRS at sensor spectral radiance

Satellite images were processed in units of absolute radiance using 32-bit floating-point calculations and the values were converted to 16-bit integer values. It was then converted to spectral radiance using the radiance scaling factors provided in the metadata file of LANDSAT-8 (*Eq. 1*):

$$L_\lambda = M_L * Q_{cal} + A_L \quad \text{(Eq.1)}$$

where:

L_λ = Spectral radiance ($Wm^{-2}sr^{-1}\mu m^{-1}$)

M_L = Radiance multiplicative factor for the band (RADIANCE_MULT_BAND_n from the metadata).

A_L = Radiance additive factor for the band (RADIANCE_ADD_BAND_n from the metadata).

Q_{cal} = Pixel value in DN

Atmospheric correction

ENVI-FLASSH (Fast Line-of-sight Atmospheric Analysis of Spectral Hypercubes) an atmospheric correction module was used to retrieve spectral reflectance. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23252338

standard atmospheric (tropical atmosphere) and the geometric parameters (such as aerosol, CO_2, azimuth, zenith angle, square slit, etc.) were calculated using the FLAASH module (Detail could be found in the weblink). The atmospheric parameters (such as water vapor and Aerosol Optical Depth (AOD)) procured from the AERONET (AErosol RObotic NETwork) and incorporated into the FLAASH module.

Normalized difference vegetation index (NDVI)

NDVI is one of the band ratios that are highly correlated with vegetation parameters such as green leaf biomass and green leaf area. It quantifies vegetation by measuring the difference between near-infrared (which vegetation strongly reflects) and red light (which vegetation absorbs). NDVI values ranges from -1 to +1. As shown below, NDVI uses the NIR and red channels in its formula:

$$NDVI = (Infrared – Red)/(Infrared + Red)$$

Moreover, it reduces variation due to surface topography and compensates for variation in radiance as a function of sun elevation for different parts of the scene, which is highly valuable in regional studies. To demonstrate the utility of Landsat data for monitoring vegetation status at the regional scale, random temporal plots are selected and analyzed for the NDVI values. The maximum NDVI is calculated to determine the index of greenness of the vegetation at the time of peak growth season. It is calculated to represent the maximum foliage cover in the study period. Overall, NDVI is a standardized way to measure healthy vegetation, where higher NDVI values indicate healthier vegetation.

Table 1 shows the satellite data acquisition and its related information. The NDVI data were converted into monthly values using the maximum value composite method to reduce cloud disturbance and increase the overall quality of the dataset (Fensholt and Proud, 2012).

Statistical analysis

Trends of annual rainfall and temperature series data were analyzed using Mann-Kendall trend test, and Mann-Whitney U test was used for the dieback ordinal data. Differences among the four plantation plots were analyzed using one-way analysis of variance procedure.

Table 1. *Characteristics of satellite data used in the study*

Satellite/sensor	Date of acquisition	Path/row	Spatial resolution	Information extracted
Landsat TM	1988-06-12	167/47	30 m (Band3 and Band4)	NDVI

Results

Dieback of J. procera in natural stands

Most of the trees in the west and east facing slopes had shown dieback symptoms dieback with varying extent of severity (*Fig 3*). The effect of slope aspect was significant (Pr = 0.03), and the west-facing slopes were less affected than the east-facing slopes. The west-facing slopes had significantly fewer trees with severe dieback symptoms (4%), and more trees without obvious symptoms (17%) compared to the east facing slopes (8% and 11%; respectively) (*Fig. 3*).

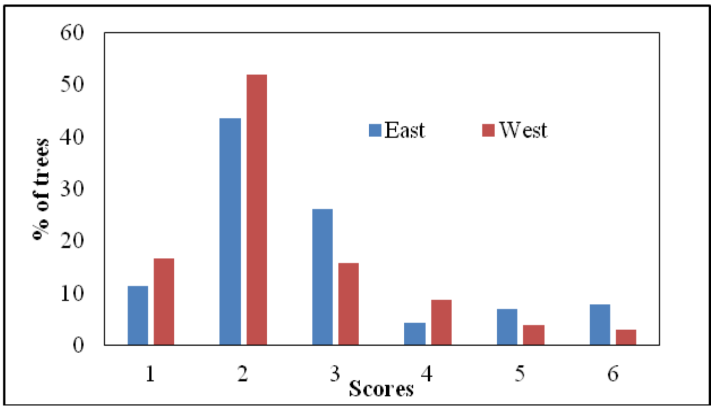

Figure 3. *Percent of J. procera according dieback symptoms in the west and east facing slopes in Alsouda (1 = no symptoms to 6 severely affected dying or dead trees, significant difference between east and west facing slopes Pr = 0.03 using Mann-Whitney U test)*

All of the trees with scores 2 to 5 and some of severely affected trees showed recovery signs and healthy lateral branches. The recovery signs include new lateral shoots, new needles and flowers at different stages (*Fig. 4*). Also, new regenerates were spotted in the well- stocked Juniper stands.

Figure 4. *Recovering J. procera trees from dieback in Alsouda natural stands: A and B) new shoots and leaves C) sprouts and D) new regenerates*

J. procera plantation plots

The 12- year's trees showed no signs of dieback symptoms in the four plantation plots in Alsouda (*Fig. 5*). Difference among the four plots was significant (Pr < 0.001) in height and crown diameter, where plot 2 had significantly shorter trees and smaller crown diameters than the other 3 plots plants (*Table 2*).

Table 2. *Tree height and crown width (cm) of 12-years J. procera plantations in Alsouda, Aseer region*

Plot number	Number of trees	Tree height and SE	Crown width and SE	Dieback symptoms
1	51	254 cm ± 9.5 A	191 cm ± 6.9 A	No symptoms
2	73	193 cm ± 7.6 B	153 cm ± 6.6 B	No symptoms
3	33	234 cm ± 12.3 A	173 cm ± 8.8 A	No symptoms
4	97	246 cm ± 8.5 A	180 cm ± 6.7 A	No symptoms

Figure 5. *Row of planted J. procera from nursery raised seedling in 2006, Alsouda National Park, Aseer Region*

Meteorological data

Total annual rainfall was variable among the years from 1965 to 2017, and the trend was not significant (*Fig. 6a*). However, maximum, minimum, and annual temperature showed increasing trend (Pr < 0.01) during the period of 1978 to 2017 (*Fig. 6b*).

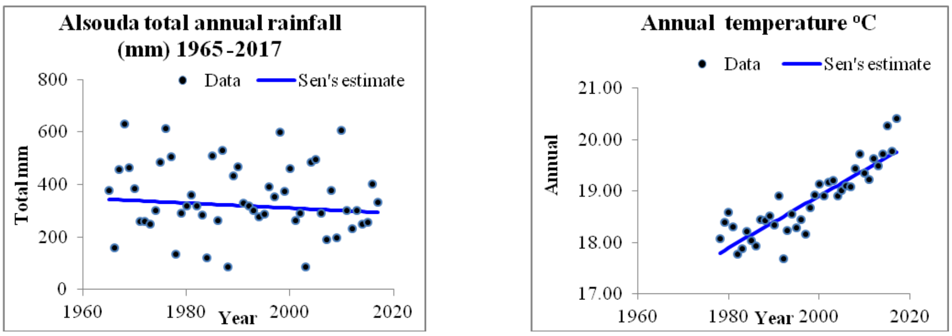

Figure 6. *A) Alsouda annual amount of rainfall during 1965 to 2017 (Pr > 0.05), and B) Abha annual average temperature during 1978 to 2017 (highly significant increasing trend)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23252338

NDVI results

Figures 7 and *8* illustrate an increasing of NDVI values from 1988 to 2016, with a significant drop in 2000 that witnessed drier rainy season. The pattern of NDVI class distribution showed greener narrow western strips *J. procera* (NDVI > 0.51) that extend from south to north with gradual decrease in the NDVI values from west to east. Dissecting the area according to aspect illustrates clear and marked trend of higher values in the west facing slopes (*Tables 3* and *4*).

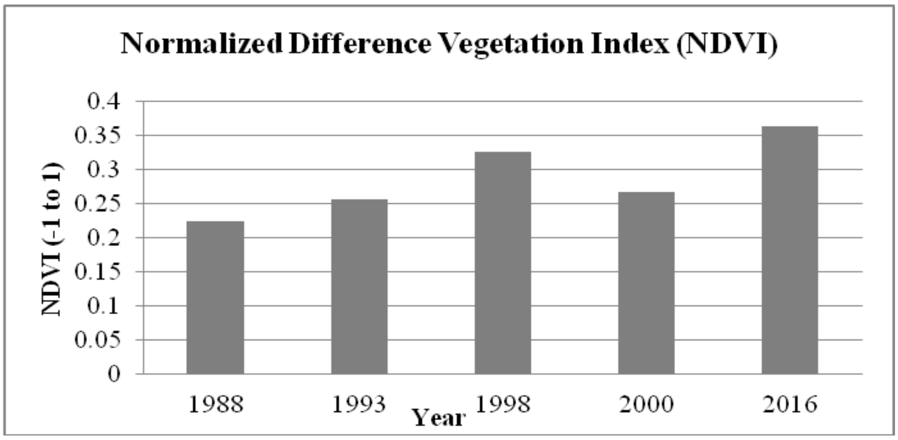

Figure 7. *Mean NDVI value of the study area in 1988, 1993, 1988, 2000 and 2016*

Discussion

J. procera is the most important indigenous tree species in the forest ecosystems of the southwestern highlands (above 2000 m.a.s.l) KSA for its ecological, economically and aesthetic values. It is an essential component in ecotourism attractions of Alsouda, Aseer Region, which is the most frequented touristic site during summer time (June to August) in KSA.

Tree health and stocking density are of vital importance, and dieback is the main problem facing forest ecosystems in KSA. El-Juhany (2015) estimated that 11.5% of the *J. procera* trees in Aseer were affected by dieback. The results of this study showed that many trees have dieback symptoms (84% and 89% in the West and east facing- aspect, respectively). However, the severely affected trees were 7% and 15% in the west and east facing slopes, respectively. Tree recovery signs were in most of the affected trees with new needled, branches, and sprouts. Unlike (Barth and Horst Strunk, 2000), natural regeneration was detected in the well-stocked and remote slopes, indicating the importance of nursing trees (Senbeta and Teketay, 2001). The NDVI pattern and classes confirmed recovering trends Juniper Natural stands.

The 12-year trees in the four plantation plots were free from dieback symptoms, and reached an average height of 2.0-2.5 m and an average crown diameter of 1.7-1.9 m. Tree height is less than the 7-year old plantation in the highlands of Ethiopia (Negash and Kagnew, 2013). This comparatively slow growth may be due low mean annual rainfall of Alsouda (350) compared to 1140 mm in Ethiopia highlands.

Topography and aspect of slopes have significant influences on the microclimate and soil moisture content. Måren et al. (2015) attributed differences in vegetation of *Pinus* and *Juniperus* species to soil characteristics between slope aspects in high altitude of semiarid environments.

In this study, the west-facing *J. procera* had low impact from dieback and had greener vegetation NDVI classes than the east-facing slopes. The west- facing slopes receive higher rainfall higher by the southwestern monsoons precipitation patterns in Alsouda (Vincent, 2008), and consequently higher soil moisture content than the east-facing slopes. Similarly, El-Atta et al. (2013) demonstrated significantly higher leaf water potential (Ψw), chlorophyll content, and net photosynthetic ability of *J. procera* trees under increased soil moisture content in Alsouda.

Conclusions

Extent and severity of dieback was quantified among *J. procera* natural stands in Alsouda, Aseer Region, which was first reported in the early 1980's. Most of the trees have shown symptoms of dieback (> 80%), however they were not seriously affected and showed recovery signs. The recovery signs include new shouts, leaves and flowering even within the severely affect trees. In addition, the new natural regeneration in the well- stocked slopes indicates the importance of tree nursing effect to enhance restoration of Juniper stands. The 12-years plantations showed no symptoms of dieback, but growth rate is relatively low as compared to plantation in other regions that have higher annual rainfall. The meteorological data showed variable rainfall pattern without significant trend over time, while temperature showed significant increasing trends. The effect of slope aspect was evident in the severity of dieback and greenness of the vegetation as detected by the NDVI data. The west facing slopes were higher in NDVI values (greener vegetation) than the east-facing slopes, which may be due to higher precipitation in the west – facing slopes by the south-western monsoons (Vincent, 2008). The tree recovery, new regeneration and absence of dieback in the plantation plots, in spite of the warming trend and variable rainfall, may indicate that climate change is not the prime cause for the dieback phenomenon in the south-western highlands of KSA. The results indicate the importance of annual rainfall in the general health and greenness of the trees. Further studies are needed to quantify differences in rainfall between east and west-facing slopes, and elucidate effect of nursing trees on enhancing natural regeneration of *J. procera.* It is recommended that the plantations efforts should continue, especially among trees within *natural* stands to benefit from the nursing effect.

APPLICATION OF ARTIFICIAL NEURAL NETWORKS AND PARTICLE SWARM OPTIMIZATION FOR TIMBER EXTRACTION WITH CABLE CRANE

ÇALIŞKAN, E.

Department of Forest Engineering, Faculty of Forestry, Karadeniz Technical University 61080 Trabzon, Turkey
(e-mail: caliskan@ktu.edu.tr)

(Received 13th Nov 2018; accepted 11th Jan 2019)

Abstract. The fact that forest areas in Turkey and the world are located at high and steep mountainous areas makes it more difficult to extraction the wood raw material. Therefore, the retreat of forest areas to mountainous areas has brought cable crane to the forefront. Thus, it has become possible to solve complex problems by way of artificial intelligence techniques. The purpose of this study was to determine the impact of factors related with timber extraction via URUSMIII cable crane on total time via Artificial Neural Network (ANN), Particle Swarm Optimization (PSO) and Multiple Regression Analysis (MRA). The data were obtained from oriental spruce timbers which were acquired from spruce stands in the Artvin Forest Directorate, located at NE Turkey. The factors with impact on total time (ground slope, line slope, lateral pull, number of logs, diameter of logs, length of logs, log volume, yarding distance) were measured along with the total time. Determination coefficient (R) and the expressions that indicate error variance (MSE, RMSE and MAE) were taken into consideration for determining the model with the best results. PSO model was determined as the best structure (R = 0.85 MSE = 0.0143, RMSE = 0.1194, MAE = 0.0839): in this study according to the obtained results. The results indicate that PSO had the best performance in the study followed by ANN and finally MRA with the lowest performance. The PSO model can be used for similar conditions on the planning of forest operation, the control of applications and the determination of unit of price for forest workers.
Keywords: *forest operations, timber extraction, total time, artificial neural networks, particle swarm optimization, multiple regression analysis*

Introduction

The need for timber continues to increase in Turkey every day; however forest areas continue to decrease rapidly. The transport stage is quite difficult, expensive and time-consuming in forest management. It is an important issue that the product is extracted with the minimum damage to itself and the environment as well as with minimum loss of quality.

Cable crane systems are used for extraction purposes in many mountainous regions in the world. Since majority of the forests in countries such as Austria, Czech Republic, Japan, Norway and Scotland are located in mountainous areas, cable-crane systems are frequently used for extraction purposes (Russell and Mortimer, 2005; Huber and Stampfer, 2015; Proto and Zimbalatti, 2015)

As is known, forest cable-crane systems are manufactured in whole and are used for carrying heavy forest assets from the air over distances of 300-2000 m. According to yarding distance, these are called as short (< 300 m), middle (300-800 m) and long (800 <) distance skylines (Acar et al., 2005).

URUSMIII cable crane was started to be used in our country during the late 1970s. Although it is not very widespread throughout the country, it is used extensively for timber extraction in the Artvin region (Acar and Şentürk, 2000).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23392355

Cable cranes are quite different in comparison with other extraction methods. The volume is limited for manual extraction. Sliding is one-directional and can be carried out in case the incline is high. Animal-powered extraction cannot be performed from the top to the bottom in steep areas. Whereas for tractor extraction there are various disadvantages such as the issue that transportation cannot be made from the top to the bottom as well as short cable length.

Artificial Neural Networks (ANN) are used as a popular method by many different researchers in different engineering applications. ANN is a structure that based on the learning model of the human brain which contains neurons and is comprised of different layers by combining these neurons using different weights (Haykin, 1999). ANN is a very strong method especially for data modelling when regression coefficients are low (Esteban et al., 2009).

Heuristic optimization is used recently in algorithms in addition to artificial neural networks for improving the success and/or speed of artificial neural networks (Bağış and Çetin, 2009; Liu et al., 2008; Özbeyaz, 2010). Particle Swarm Optimization (PSO) which is one of the heuristic methods has been used successfully in many areas due to reasons such as the ease with which it can be implemented, the low number of parameters that need to be adjusted and the fact that it operates with real numbers. One of these is the training of artificial neural networks (Tamer and Karakuzu, 2006; Delice, 2008; Hema et al., 2008; Gu et al., 2009).

Various studies have been carried out on timber extraction operations during which time studies have been carried out for cable crane URUSMIII (Aykut et al., 1997; Çağlar, 2002; Baldini and Pollini, 1998; Heinrich, 1998; Trzesnowski, 1998; Ledoux and Huyler, 2000; Rieger, 2001; Krpan et al., 2001; Acar et al., 2005; Öztürk and Demir, 2007; Zimbalatti et al., 2009; Zimbalatti and Proto, 2010; Çalışkan, 2015).

The use of Artificial Neural Networks (ANN) and Particle Swarm Optimization (PSO) in timber extraction is at a starting stage in Turkey. Hence, there are no studies in literature which compare the performance of ANN and PSO with other models.

The purpose of this study was to examine the impact of factors related with the interaction of timber extraction with URUSMII cable crane on total time via ANN, PSO and MRA. The data were obtained from oriental spruce timbers from spruce stands in Artvin Forest Directorate, in NE Turkey.

Materials and methods

Study area

This study was carried out in the Ardanuç forest planning unit covering an area of approximately 76817.0 ha of forest with the growing stock 5.9 million m³ in the Artvin province in the northeastern Black Sea region of Turkey. The area was located between 41° 12’ 34” North, and 41° 48’ 55” East. Dominant tree species used for production purposes are natural oriental spruce (*Picea orientalis* Link.), and nordmann fir (*Abies nordmanniana* Stew) and oriental beech (*Fagus orientalis* Lipsky). The climate in Artvin is mild with humid summers. Annual precipitation and temperature averages approximately 700 mm and 13 °C, respectively (Akman, 1990). Felling and delimbing operations were used to be carried out via chainsaws. Cable crane Urus (MIII) is mostly represented as off-road machines and have been widely used (*Fig. 1*). Urus MIII cable crane is generally used in uphill yarding operations, ranging from 500 to 600 m and combining with Mercedes Benz Unimog U1500 truck. Four workers are employed in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23392355

operating the cable crane. The set up duration of cable crane is between 10 and 16 h and pull up duration is between 4 and 8 h depends on terrain conditions. The number of safety ropes ranges between 2 and 4. The basic characteristics of the URUSMIII were given in (Çağlar et al., 2007; Öztürk and Şentürk, 2016).

Figure 1. *Urus MIII cable crane*

Field data collection

Timber extraction was carried out using cable crane. Measured data for the timber operations have been recorded in study forms. Time values for each stage have been measured as 1/100 min (PM) using a chronometer, the amount of work done has been determined in units of m^3, factors that affect the work done (ground slope, line slope, lateral pull, number of logs, diameter of logs, length of logs, log volume, yarding distance) have also been recorded in the study form. No intervention was made on the workers regarding issues such as starting and stopping of work, breaks, pauses, dealing with other operations.

Variables that were considered to have an impact on the work time for skidder timber extraction operations have been evaluated as X_{ii} (X_{11}-X_{18}) and expressed in numerical values. These variables have been briefly explained in *Table 1*.

Repetition time measurement method was used for time measurements and the work phases, total turn time and waiting times were determined using a digital chronometer. The measured time values were obtained for a two person working group in units of 1/100 min. Work phases and related time values have been expressed as Y_{ii} (Y_{11}-Y_{19}) for cable crane timber extraction operations and related time values have been briefly explained in *Table 1*.

Measurements and observations were carried out for timber extraction operations for spruce trees using cable crane (Hauling back of empty carriage (Y_{11}), Descending of bundle hook (Y_{12}), Pulling of hook to logs (Y_{13}), Pulling of loaded hook to carriage (Y_{14}), Moving of loaded carriage to landing site (Y_{15}), Descending of loaded hook to ground (Y_{16}), Unhooking of loads (Y_{17}), Pulling backwards of empty carriage (Y_{18}), Nonworking time (which covers spare and delay time of workers (Y_{19}), Total activity time (y_{fa}).

Total activity time (*Eq. 1*):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23392355

$$y_{fa} = y_{11} + y_{12} + y_{13} + y_{14} + y_{15} + y_{16} + y_{17} + y_{18} + y_{19} \quad \text{(Eq.1)}$$

The ANN-PSO models were generated using Matlab software. Statistical analyses were carried out via “SPSS 21.0” software.

Artificial neural network (ANN)

Artificial neural networks are mathematical models inspired by the structure and behavior of the human brain (Olden et al., 2008). The ANN network includes three main layers: input, hidden and output. These layers are used for data input, data transmission and data output respectively. The hidden layer function is used to transfer the results to the output layer (Fausett, 1994; Haykin, 1994). The output of each neuron can be written as (*Eq. 2*):

$$y_i = f\left(\sum w_{ij} x_i\right) \quad \text{(Eq.2)}$$

where *yi* represents the input that a single node j receives. The function f can be a simple threshold, sigmoid or hyperbolic tangent function. The weights between the nodes i and j are denoted as w_{ij}: x_i represents the output from node i.

Whereas the input layer in this study was comprised of 8 neurons as ground slope, line slope, lateral pull, number of logs, diameter of logs, length of logs, log volume and yarding distance; there was only 1 neuron of Total activity time (y_{fa}) in the output layer. The number of neurons in the hidden layer varies according to the characteristic of the problem.

Back propagation algorithm (BPA) is used for training ANN networks in this study since it is easy to understand and prove mathematically. The back propagation artificial neural network models have already been described and are used widely (Rumelhart et al., 1986; Fausett, 1994; Haykin, 1994; Özçelik et al., 2010).

The hyperbolic tangent sigmoid (tansig) transfer function presented by the following equation was used between the input and hidden layers in the model in this study (Fausett, 1994). A linear (pureline) transfer function was used between the hidden and output layers.

NET: Weighted sum (*Eq. 3*)

$$f\left(NET_i\right) = \frac{1}{1+e^{-NET_i}}\ ,\ f\left(NET_i\right) = NET_i \quad \text{(Eq.3)}$$

BPA uses two parameters that control the speed at which training takes place. The learning coefficient determines the amount of change in the weights. It was observed that values ranging between 0.2 and 0.4 are generally used and that the value of 0.6 yields the most successful results (Öztemel, 2003). The momentum coefficient has an impact on training performance. It was observed that selecting a value ranging between 0.6 and 0.8 would be best (Öztemel, 2003).

Particle swarm optimization (PSO)

Particle Swarm Optimization (PSO) was first developed by Kennedy and Eberhart (1995) inspired by the behaviors of bird swarms when trying to find food. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23392355

population is defined as swarm in this algorithm, whereas each individual is defined as particle. These particles are accepted to be flowing in multi-dimensional space. PSO can be applied successfully in many areas such as artificial neural network training (Zhao et al., 2005; Awad, 2006).

PSO is started with a group of random values (particle swarm) and the optimum solution is tried to be determined by way of iterations. Particle positions are updated according to the best two values in each iteration. The first value includes the coordinates that provides the best solution for that particle until that point. This value is defined as "pbest" and should be stored in memory. Whereas the other best value includes the coordinates that provides the best solution for all particles in that population until that moment. This is the global best value and is denoted as "gbest". For example, let us assume that there are n particles comprised of D parameters.

Every particle has its own position, velocity and best solution. The PSO method can be presented as follows (Elbeltagi et al., 2005; Al_Janabi et al., 2018):

The swarm position in a D space of the *i*th particle can be presented by (*Eq. 4*):

$$X_{\bar{I}} = \left(X_{i1}, X_{i2}, X_{i3}, ..., X_{iD}\right), \quad i = 1,2,3,..,N \quad \text{(Eq.4)}$$

Whereas velocity of each particle can be represented as (*Eq. 5*):

$$V_{\bar{I}} = \left(V_{i1}, V_{i2}, V_{i3}, ..., V_{iD}\right), \quad i = 1,2,3,..,N \quad \text{(Eq.5)}$$

Each particle maintains a memory of its previous best position. The best swarm position is given by (*Eq. 6*):

$$pbest_{\bar{I}} = \left(pbest_{i1}, pbest_{i2}, pbest_{i3}, ..., pbest_{id}\right), \quad i = 1,2,3,..,N \quad \text{(Eq.6)}$$

gbest is unique for all particles in each iteration (*Eq. 7*):

$$gbest_{\bar{I}} = \left(gbest_{i1}, gbest_{i2}, gbest_{i3}, ..., gbest_{id}\right), \quad i = 1,2,3,..,N \quad \text{(Eq.7)}$$

A particle velocity should be updated and the following equation can be used (*Eqs. 8-9*):

$$V_i^{k+1} = V_i^k + c_1 r_1^k.\left(pbest_i^k - x_i^k\right) + c_2 rand_2.\left(gbest_i^k - x_i^k\right) \quad \text{(Eq.8)}$$

$$Fitness = \sum_i \left(Y_i - X_i V\right)^2 \quad \text{(Eq.9)}$$

where the parameters of c_1, c_2 are constants and r_1, r_2 are random numbers ranging between 0–1. $pbest_i$ is the best local solution of the *i*th particle for the iteration number up to the *i*th iteration. The best global solution of all particles is g_{best}. The "inertia weight" w controls the effect of the previous velocity of the particle on the current one. If the value of w is greater than 1, it means that the particle favored searching over exploitation; whereas a w value of less than 1 is an indication that the particle gave more importance to the current best positions (Al_Janabi et al., 2018).

DOI: http://dx.doi.org/10.15666/aeer/1702_23392355

Network architecture, training rate and momentum factor have been determined in our study after examining different combinations. Several different ANN models were developed and tested in order to determine the optimal number of neurons in the hidden layer by trial and error estimates. A single hidden layer was used to significantly reduce the computational time. The general structure of ANN is shown in *Figure 2*.

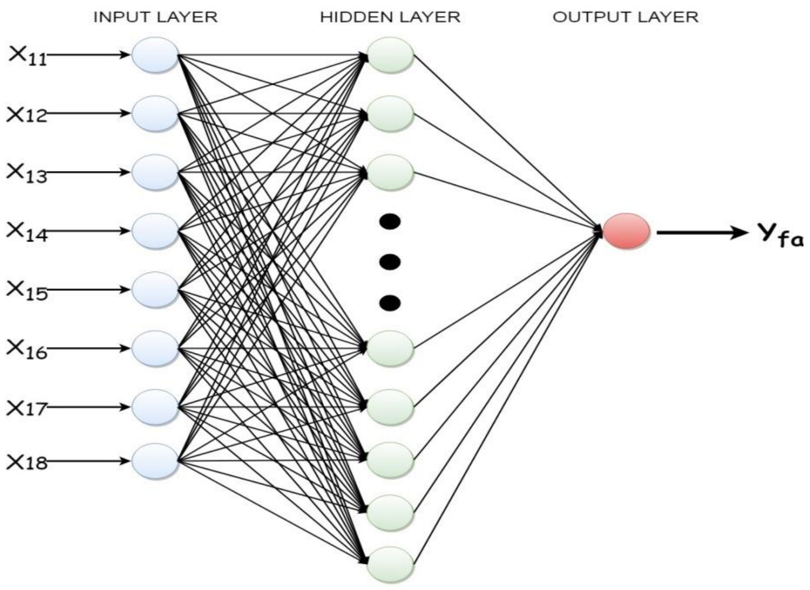

Figure 2. *Schematic diagram of ANN model*

Multiple regression analysis (MRA)

Regression is one of the methods used for testing whether there is a relationship between two or more variables and to express the relationship between the variables by way of linear or curvilinear equations (Öztürkcan, 2009). Regression analysis using more than one independent variable is called multiple regression analysis.

The general structure of the equation in cases when there is more than one independent variable $\left(\text{such as } X_1, X_2, X_3, ...\right)$ (*Eq. 10*):

$$Y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + ... + \beta_n x_n \pm \varepsilon \quad \text{(Eq.10)}$$

where Y: dependent variable, *Xi*: independent variable $\left(i = 1, 2, 3, .., N\right)$ β_i: regression parameters $\left(i = 1, 2, 3, .., N\right)$, ε : random error and *n*: number of unknown parameters.

In this study, ground slope, line slope, lateral pull, number of logs, diameter of logs, length of logs, log volume, yarding distance are selected as the independent variables and total time is selected as the dependent variable.

Statistical calculations on variables that are independent from (x_{ii}) and dependent on (y_{ii}) measurement results have been carried out as:

- Calculation of the average and deviations,
- Examination of the variables that are effective on the actual time spent for each work phase or the unit time value,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23392355

- Examination of the relations between variables,
- And determination of the impact of independent variables on the total time spent for work phases

Model evaluation criteria

In this study, the performance of different predictive models is evaluated by using statistical measures including the; Corrected determination coefficient (R), Mean Squared Error (MSE), Root Mean Square Error (RMSE) and mean absolute error (MAE) were used as criteria for comparing ANN, PSO and MRA. Accordingly, high R and low MSE, RMSE and MAE values indicate the best model. MAE and MSE values were close to 0 and the R value was close to 1, thereby indicating that the predicted value strongly converges to the right (Hocking, 1976; Law, 1999; Cho, 2003; Arıkan, 2014).

a) The correlation coefficient (R) (*Eq. 11*):

$$R = \frac{\sum\left(X_i - \bar{X}\right)\left(Y_i - \bar{Y}\right)}{\sqrt{\sum\left(X_i - \bar{X}\right)^2\left(Y_i - \bar{Y}\right)^2}} \qquad \text{(Eq.11)}$$

b) Mean squared error (MSE) (*Eq. 12*):

$$MSE = \frac{1}{n}\sum_{i=1}^{n}\left(y_i - \hat{y}_i\right)^2 \qquad \text{(Eq.12)}$$

c) Root mean square error (RMSE) (*Eq. 13*):

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n}\left(x_i - y_i\right)^2}{n}} \qquad \text{(Eq.13)}$$

d) Mean absolute error (MAE) (*Eq. 14*):

$$MAE = \frac{\sum_{i=1}^{n}\left(x_i - y_i\right)}{n} \qquad \text{(Eq.14)}$$

where X_i and Y_i are the observed and predicted data, respectively; $\bar{X}$ and $\bar{Y}$ are the mean of the observed and predicted and n the number of observations in the dataset.

Results and discussion

The arithmetic average, standard deviation, max and min values for the actual time values measured in units of 1/100 min as the variables of observed values regarding the work phases via cable crane have been calculated and presented in *Table 1*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23392355

Single input variance analysis was used to examine whether the impact of the correlation matrix indicating the relationship between the variables and x_{ii} groups on the values of y_{ii} was statistically significant or not.

The data were first normalized (0-1) in this study and 70% and 30% of the complete data was used for training and testing respectively. Therefore, 27 testing and 64 training data sets were randomly selected from all land data. The training set adjusts the connection weights and the parameters of the model and the testing set evaluates the trained ANN performance and generalization power (Ghajar et al., 2012a, b).

A network with eight inputs, one hidden layer, and one output was selected in this study. The inputs were: ground slope (x_{11}), line slope (x_{12}), lateral pull distance (x_{13}), extraction distance (x_{14}), diameter of logs (x_{15}), length of logs (x_{16}), number of logs(x_{17}), and log volume (x_{18}); while the output was Total activity time (Cable crane, yfa).

An 8 layer artificial neural network was established in this study and a back-propagation algorithm (BPA) was used as a learning algorithm. The hidden layer and the number of neurons in this layer were determined through trial and error. In this regard, one hidden layer with fifteen (15) neurons was included in the model. Neurons with numbers ranging from 1 to 30 were given to this layer in order to determine the number of neurons that would be included in the hidden layer and each model was tested 10 times to determine the best model for our study. The sigmoid transfer functions were used in input, hidden and output layers in the model. The most suitable model was identified as the model with a network structure of 8-15-1.

Each combination of learning rates and momentum factors were tested for different numbers of hidden neurons. The network was trained in variable epochs via ANN learning algorithm with a learning rate of 0.001 and a momentum coefficient of 0.2. This was the best combination that conducts to the smaller values of R, MSE, RMSE and MAE in *Table 2*. Regression values for the data used in the training and testing of the ANN have been given in *Figure 3*.

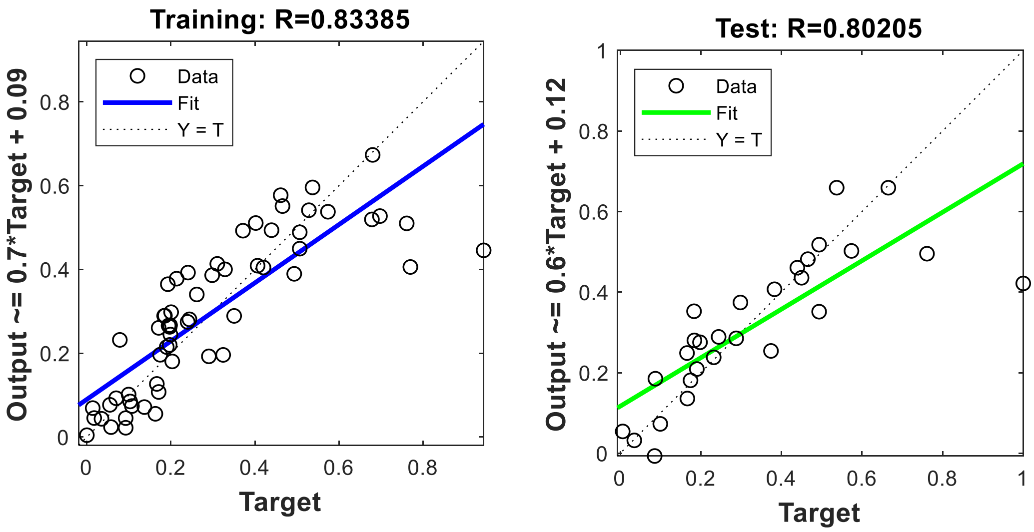

Figure 3. *Training and test, distribution graphs for the ANN prediction model*

Figure 3 shows the R values graph for the training and test stages of the studied model. The values determined were R = 0.8338 for the learning stage and R = 0.8020 for the test stage of the model. *Figures 4* and *5* respectively show the graphs comparing the model predictions and observed values for the ANN model.

It can be observed from *Figures 4* and *5* that the values of the total time during cable crane operations were generally predicted to be close to the observed value.

As mentioned, PSO was used as the artificial neural network algorithm in this study and MSE was applied as a fitness function. The objective of this algorithm is decreasing MSE. The number of data used for training and testing were 64 and 27, respectively.

ANN learning process was started by randomly generating the weights that hold the numerical value of the connections between the layers. These weights express the particle values for PSO. Whereas the number of connections between the layers represents the particle size. The network was setup for each particle and training samples were sent to the network in order. Total error (MSE) was calculated after all values were presented to the network and the obtained value was accepted as the fitness value. This fitness value is determined as the pbest value in the first step; whereas the best fitness value among the particles is determined as gbest. If the fitness value that is the error is not at an acceptable value, the particles are updated with pbest and gbest values. The network was re-established according to the new particle values, the values were resent to the network and fitness value calculation was carried out. These operations are carried out until the best fitness value (gbest) reaches the desired value (very close to 0) or until the maximum number of iterations.

Test process is started if the error is at an acceptable level. This time the network is setup according to the (gbest) particle values, test samples are sent to the input layer in order and the acquired values are provided as the sample output. The last acquired gbest value gives the classification performance of the network when no threshold is applied on the network output.

As a result of the experiments; the optimal parameters for ANN-PSO were determined as; number of hidden neurons = 18, number of particles = 25, number of iterations = 500, (c_1 and c_2 = 2). Particle numbers generally range from 20 to 40 (Tamer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23392355

and Karakuzu, 2006). It was stated in the experiments conducted by the researchers on this algorithm that c1 = c2 = 2 gave good results (Shi and Eberhart, 1998; Liping et al., 2005).

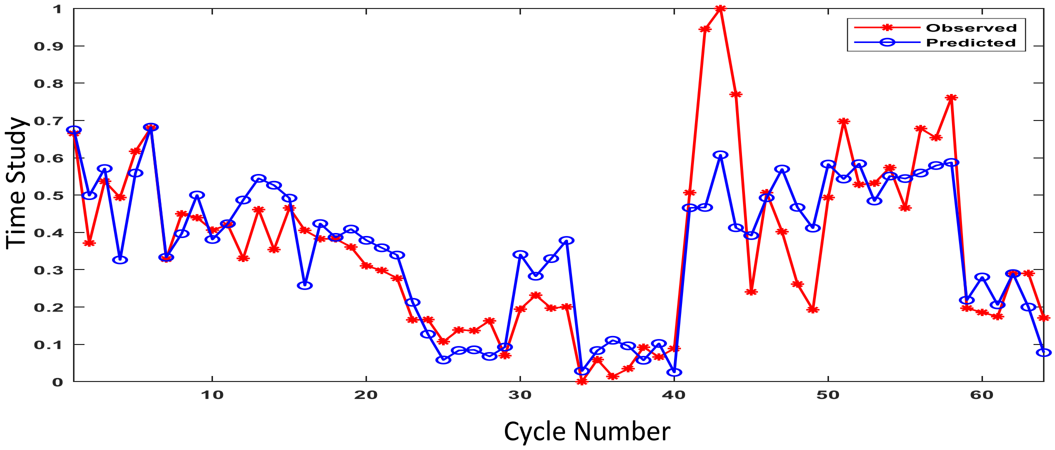

Figure 4. *Comparison of predicted and observed values for training sets using ANN*

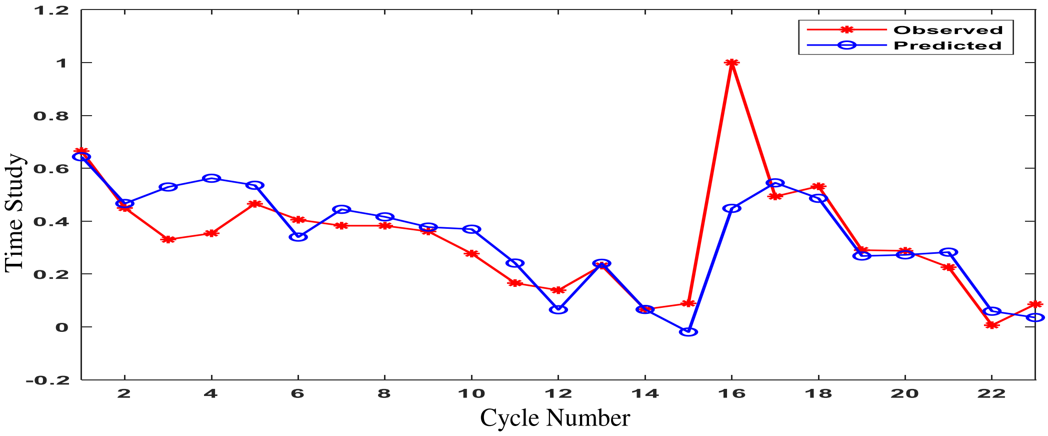

Figure 5. *Comparison of predicted and observed values for test sets using ANN*

This was the best combination that conducts to the smaller values of R, MSE, RMSE and MAE in *Table 2*. *Figures 6* and *7* show the graphs in comparison with the model predictions and observed values for the PSO model.

It can be observed from *Figures 6* and *7* that the values of the total time cable crane operations are generally predicted close to the observed value.

Alternative equalities have been generated via multiple regression analysis. Operations carried out for the timber extraction total activity time with cable crane (y_{fa}) have been given in detail.

Regression equalities based on the $y_{fa} = f\left(X_{11}, X_{12}, X_{13}, X_{14}, X_{15}, X_{16}, X_{17}\right), X_{18})$ relationship have been given in *Table 2*. Consistency of the equation was tested using the coefficients obtained from the regression equation and test data. Graphs that compare the model predictions obtained from the MRA model and the observed values have been given in *Figure 8*.

It can be observed from *Figure 8* that the values of the total time during cable crane operations are generally predicted close to the observed value.

Table 2. *Regression equalities for calculating the total activity time of timber extraction via cable crane*

Nu	Total time	*b*	X_{11}	X_{12}	X_{13}	X_{14}	X_{15}	X_{16}	X_{17}	X_{18}	R-sq
1	y_{fa}	-6.14	0.19	0.39	0.13	0.02	-0.01	0.14	-1.5	-0.21	0.699
2	y_{fa}	-6.23	0.19	0.39	0.13	0.02		-0.14	0.16	-0.22	0.698
3	y_{fa}	13.80	0.18		0.13	0.22		0.14	0.49	-0.21	0.697
4	y_{fa}	11.62	0.16		0.14	0.22		0.19	0.27		0.695
5	y_{fa}	10.66	0.15		0.14	0.22			0.17		0.690
6	y_{fa}	10.63	0.14		0.13	0.22					0.685
7	y_{fa}	-0.11			0.13	0.24					0.677

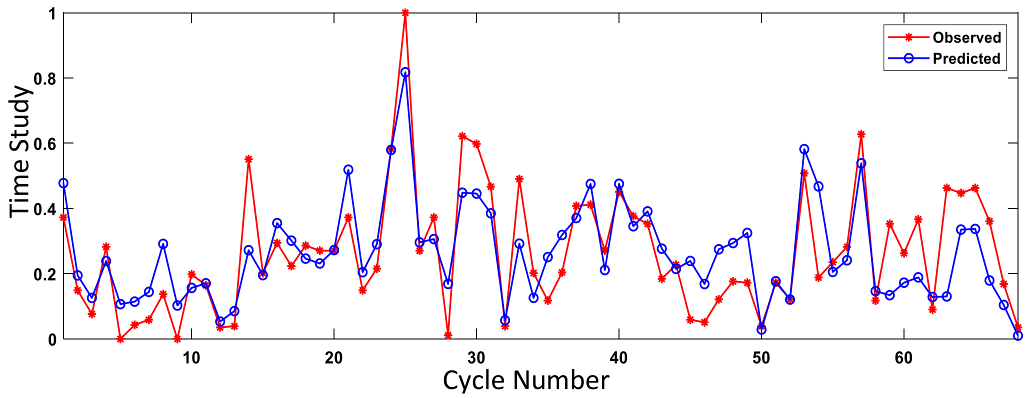

Figure 6. *Comparison of predicted and observed values for training sets using PSO*

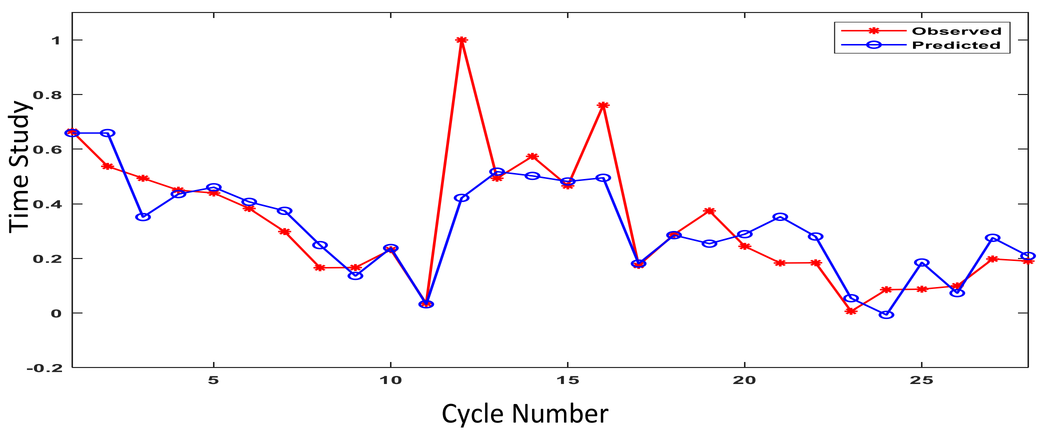

Figure 7. *Comparison of predicted and observed values for test sets using PSO*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23392355

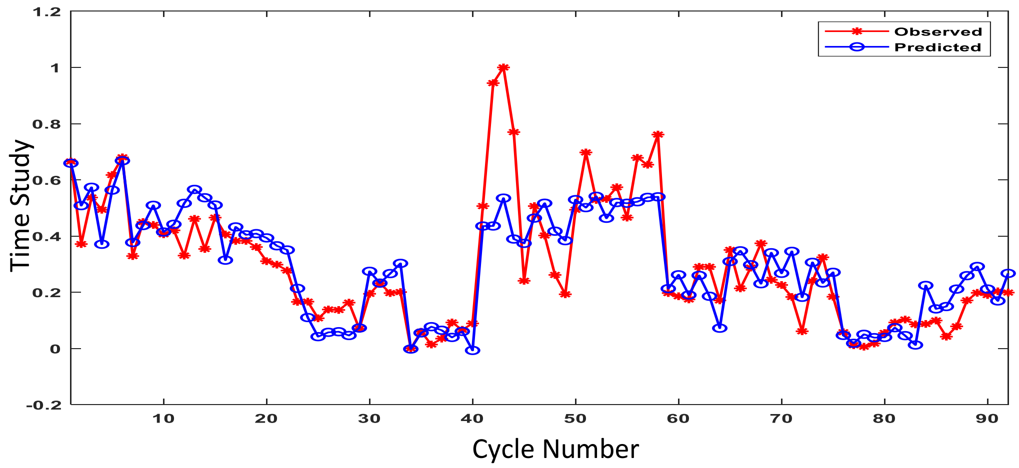

Figure 8. *Comparison of predicted and observed values using MRA*

The performances for predicting total activity time for cable crane are compared using three techniques as ANN, PSO and MRA. The values of performance measures are given in *Table 3*.

Table 3. *A comparison of the ANN, PSO and MRA, models*

Model	R	MSE	RMSE	MAE
PSO	0.85	0.0143	0.1194	0.0839
ANN	0.83	0.0152	0.1232	0.0907
MRA	0.69	0.0194	0.1434	0.1186

Values of R, MSE, RMSE and MAE were compared at the end of the study for determining the algorithm with the best performance. Based on the results obtained from this study, the PSO has been found to be better than the ANN and MRA models, because the PSO has a higher ability in global search than in ANN and MRA models.

ANN and PSO have been applied successfully in the field of forest modeling. Specifically, artificial neural network approach has been carried out for many objectives such as modeling individual tree survival probabilities (Guan and Gertner, 1995), diameter growth based climatic variables (Zhang et al., 2000); wildlife planning issues (Bettinger et al.,2002), forecasting wood demand (Güngör et al., 2004*)* tree volume (Diamantopoulou, 2005a; Diamantopoulou and Milios, 2010; Özçelik et al., 2008, 2010), tree stem diameters (Diamantopoulou, 2005b, 2006; Leite et al., 2011), predicting forest fire burn areas (Cortez and Morais, 2007), forest planning (Pukkala, 2009), tree felling times (Karaman and Çalışkan, 2009), tree heights (Özçelik et al., 2013), prediction of skidding time (Naghdi and Ghajar, 2012), trunk volume estimates ((Bayati and Najafi; 2013), predicted forest fire burn areas (Safi and Bouroumi, 2013), forest feature extraction (Li et al., 2014), prediction of winching time (Bayati and Najafi; 2015), tree diameter increments (Ercanlı et al., 2016) and describing diameter distribution (Bolat et al., 2016), predicting forest fire (Al_Janabi et al., 2018).

Conclusion

In this study, the impact of factors interacting during timber extraction via URUSMIII cable crane on total time was determined by using ANN, PSO and MRA. The data were obtained from oriental spruce timbers from spruce stands in Artvin Forest Directorate located at NE Turkey. In the study, 70% and 30% of the complete dataset were used for training and testing, respectively. Therefore, 27 testing and 64 training data sets were randomly selected from all land data.

Determination coefficient (R) and the expressions that indicate error variance (MSE, RMSE and MAE) were taken into consideration for determining the model with the best results. The R values obtained in the study were determined to vary between 0.85 and 0.83 for PSO and ANN respectively and as 0.69 when MRA was used.

Based on the results obtained from this study, it was determined that the performance of PSO model was better compared to ANN and MRA. The study also indicates that PSO may be used efficiently in forestry operations.

THE RELATIONSHIPS BETWEEN THE LITTERFALL AND THE CANOPY CLOSURE OF ULUDAĞ FIR (*ABIES NORDMANNIANA* (STEV.) SUBSP. *BORNMULLERIANA* (MATFF.)) FORESTS

DUYAR, A.

Department of Forest Engineering, Faculty of Forestry, Karabük University, Karabük, Turkey (e-mail: ahmetduyar@karabuk.edu.tr; phone: +90-370-418-8180; fax: +90-370-418-8181)

(Received 20th Nov 2018; accepted 11th Jan 2019)

Abstract. The litter is the organic layer on the forest ground and has a variety of ecological functions. The litterfall is the main source of litter. The structure of forest canopy affects most ecologic processes such as the net primary production and litterfall in forest ecosystems. This research study focused on the exploration of the changes of litterfall based upon canopy closure of Uludağ fir forests. The study area was selected from Bolu Aladağ forests. Ten litterfall traps were systematically emplaced under the stand. The litterfall accumulated in each trap was collected monthly. The hemisphere photographs of the canopy closures above the stands were analysed with Gap Light Analyzer (GLA) software. The canopy closures were calculated separately for each hemisphere photographs with angles expanded in the multiples of 10° angle of view. The highest correlation coefficient ($r = 0.359$) was found between the amount of total litterfall (333.5 $g \cdot m^{-2} \cdot y^{-1}$) and the canopy closure at 20° angle of view. The canopy closure values observed at 20° angle of view varied between 6.4% and 83.3%. Different mathematical models were developed to estimate the amount of litterfall fractions based on the canopy closure values at 20° angle of view. The coefficients of determination (R^2) for the models developed as part of this study are 0.93 for foliar, 0.82 for seed and 0.83 for wood fraction. Practitioners can estimate the amounts of litterfall components, spreading distances and the accumulating amounts based on the distance by using the mathematical models developed in this study.
Keywords: *Bolu-Aladağ forests, effective closure, hemisphere photograph, litterfall trap, spreadable litterfall*

Introduction

The litter is the organic layer pooled by the dead plant and animal residues on the forest ground. The litter has variety of ecological functions such as soil protection (Enez et al, 2016), water infiltration (Koralay et al., 2015), nutrient deposits (Dündar, 1988), carbon sequestration (Duyar, 2010) and habitat for soil fauna (Duyar and Makineci, 2016) besides some other indirect ecological functions (Sariyildiz and Savaci, 2017). As stated by Dubber et al. (2017), the amount of litterfall is closely related to the net primary production in forest ecosystems. While the litterfall of deciduous trees is predominantly realized in autumn (Pitman et al., 2010), the litterfall of evergreen coniferous trees befalls through the year (Duyar, 2014).

The structure of forest canopy controls both ecologic and ecophysiological processes. The crown width (Duyar, 2014), self-pruning of branches (Mäkinen and Colin, 1999; Wang et al., 2015), the amount of precipitation on the ground (Kiniş et al., 2011), the amount of snowbank (Duyar and Aydın, 2016), and understory vegetation (McDonald et al., 2015; Chandler and McGraw, 2017) are some of the many examples.

Measurements techniques for canopy closure were studied. Various methods were developed (Mailly, 2017) since 1940s as the effects of canopy closure on stand dynamics were pronounced (Garrison, 1949). The most widely used system of today is the Digital Hemisphere Photograph (DHP) of canopy processed with the computers (Chianucci and Cutini, 2013; Macfarlane et al., 2014; Origo et al., 2017). Numerous

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23572372

data such as crown canopy, Woody Area Index (WAI), Leaf Area Index (LAI) and solar radiation penetrating to the stand can be generated with the use of DHP (Liu and Jin, 2017; Mailly, 2017). The litterfall components such as foliar, seed and wood with respect to the stand structure (Liu et al., 2015) and dynamics of decomposition (Zalamea et al., 2012) are estimated based on the established relationships between the canopy data and the ground data obtained from the litterfall collection methods on the ground.

The amount, phenology and the composition (foliar, seed and wood) of litterfall from the trees are under the influence of the mean stand age and height (Atay, 1971), canopy closure (Lopez et al., 2008) and LAI (Liu and Jin, 2017) besides the features of tree species and climate characteristics. The forest practitioners use these data in order to estimate and evaluate the amount, timing and extent of seed cover (Dassot and Collet, 2015) as well as the process of nutrient flow (Magalhães et al, 2014) and carbon sequestration (McGovern and Pasher, 2016) within a stand structure (Leblanc and Fournier, 2017).

Uludağ fir (*Abies nordmanniana* (Stev.) subsp. *bornmuelleriana* (Matff.)) is an endemic subspecies of *Abies nordmanniana* (Stev.) and indigenous to the mountains in the Western Black Sea Region (between Uludağ mount and Kızılırmak river) in Anatolia (Anşin and Özkan, 1997). It occurs at altitudes of 900–2000 m on mountains with the cool and humid weather. Its optimum habitat is about 1550 m (Kantarcı, 1979). The uneven aged management of fir forests (Sıvacıoğlu et al., 2007) create a multiple layered forest structure (Topaçoğlu et al., 2008; Genç et al., 2012) with various sizes of gaps. Fir is a typical shade tolerant tree species (Çalışkan, 1992), and its green crown protrudes up till lower branches (Şevik et al., 2010).

In principle, the litterfall dynamics are critical in the sustainable management of forest ecosystems including the soil properties, nutrient regimes, carbon cycle and some other monitoring studies. Furthermore, litterfall collection method is quite time consuming, exhausting and costly. Developing mathematical models are the most appropriate and an economic method for monitoring studies such as litterfall dynamics and prediction of amount and spreading distances of litterfall components. There are few scientific studies about the dynamics of litterfall in forest ecosystems in Turkey. However, there seems no particular research endeavor designed to investigate the relationships between the amount of litterfall and the canopy closure determined by the DHP in Uludağ fir forest ecosystems. We propose and expect that establishing the relationships between the litterfall collected with the traps and the canopy closure of fir trees determined by the DHP and the exploration of the associated estimation models and methods based on the driven data would contribute to the basic ecological studies in forestry and fill the gaps in the literature as far as fir forest ecosystems are concerned. Thus, the amount and spreading distance of litterfall components will be estimated based on canopy closure ratios in the forest.

This research focuses on the exploration of the changes and the correlation of litterfall in relation to the canopy closure of Uludağ fir forests, determined with the DHP. Based on the results, different mathematical models were investigated for the prediction of the spatial distribution of litterfall, amount of spreadable and collected litterfall.

Materials and methods

The study area

The study was carried out in the Şerif Yüksel Research Forests managed by the Western Black Sea Research Institute in the Aladağ forests located in the southern part of Bolu province in the Western Black Sea Region in Turkey. The research plot lied on a southern aspect with < 5% slope wand an average elevation of 1570 m (40°37'12.2"N and 31°35'59.5"E) (*Fig. 1*).

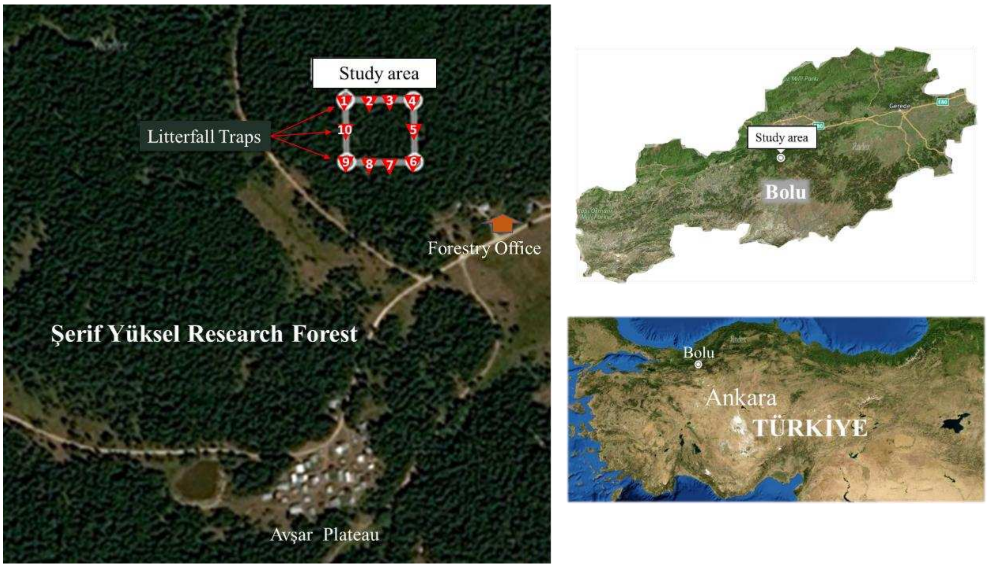

Figure 1. *Map of study site and location of plot (Google earth, 2017)*

The climate of the area

According to Thornthwaite climate classification system (Thornthwaite, 1948), based on the calculations using the long-term data (1960–2012) at Bolu meteorological station (742 m asl), the site had a climate type A C_2' r b'_4 at 1600 m elevation, characterized with (A) a relatively maritime condition, (C_2') without any water shortages or a small shortage, (r) low temperature and (b'_4) high moisture (Duyar, 2014). This plateau sitting at 1600 m of elevation is cooler and rainier compared to the city of Bolu (Tolunay, 1997).

Stand characteristics of the area

The case study area presents multi layered fir stands mixed with relatively few Scots pine (*Pinus sylvestris* L.) trees and managed by uneven aged management system. All of trees on 20 m × 20 m area were measured in the middle of study area, for the determination of the stand characteristics of the study area. The average height of the stand was nearly 21.7 m and the average width or diameter of crown was about 5.1 m (*Table 1*).

Table 1. *The stand characteristics of the study area*

The average diameter at breast height (cm)	Basal area (m²/ha)	Crown diameter (m)	Average height (m)	Dominant height (m)	Number of trees (number/ha)
35.2±12.5	63.5±5.0	5.1±0.9	21.7±6.4	29.0±1.9	608±201

DOI: http://dx.doi.org/10.15666/aeer/1702_23572372

Litterfall sampling

The sampling was conducted between 2011 and 2014 years. Ten litterfall traps were systematically emplaced in an interval of 25 m × 50 m over the one ha of the area (100 m × 100 m) (*Fig. 1*). The litterfall samples were collected once a month by using the 50 cm depth and 0.25 m² (50 × 50 cm) litterfall traps (ICP Forests, 2004) (*Fig. 2*). These are located 1.30 m above the forest floor (Martius et al., 2004). The collected total litterfall ($Total_{Lf}$) biomass was manually separated into three fraction groups; foliar, seed and wood fraction and oven-dried at 65 °C for dry weight determination. The foliar fraction consists of the needles of fir in fir forest ecosystems. Seeds refer to the reproductive organs such as flowers, fruits, seeds, catkins and pieces of cones. Wood fractions are woody pieces thinner than 2 cm in diameter such as twig, branch and bark. It is assumed that branches over 2 cm in diameter are deadwood, not litterfall fraction (Pitman et al., 2010).

Figure 2. *Litterfall traps*

Determining canopy closures with digital hemisphere photographs (DHP)

The canopy DHP over the litterfall traps were taken with a high resolution (12 megapixels) fisheye objective digital camera mounted on the tripod. The default adjustments were selected automatically (Macfarlane et al., 2014). Canopy closures rates were determined with DHP Gap Light Analyzer (GLA) software (Frazer et al., 1999). Each one of the DHP processed with DHP GLA software was sliced into 18 circles with large viewing zenith angles expanded in the multiples of 10°. The largest zenith angle was recorded to be 89°. GLA software computes the percentage of open sky seen (% canopy openness) based on the angles from the hemispherical photographs (Frazer et al., 1999). Thus, the canopy closure ratio (% canopy closure) of each circle is separately determined by dividing the closure area by the circle area (Gonsamo et al., 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23572372

Determination of canopy closure areas

The average stand height is about 21.7 m (*Table 1*) and the height at which the traps are located away from the forest floor is 1.3 m. The distance between the trap and the start of the canopy closure (HD) is 20.4 m. The diameters of canopy cover (CD) viewed from the traps were determined with the tangent (α) values of the perpendicular trap centered zenith angles expanded in the multiples of 10° (*Eq. 1*).

$$CD = HD \times \tan(\alpha) \qquad \text{(Eq.1)}$$

The area of canopy closure viewed from the stated angle was determined with the circle area (A) (*Eq. 2*).

$$A = CD^2 \times \pi/4 \qquad \text{(Eq.2)}$$

The most appropriate correlation was determined at the angle values with the highest correlation based on the angular closure of litterfall components. Then, mathematical models were developed based on the relationships between the amount of litterfall component and the values of canopy closure viewed at the angles above the traps.

Statistical analyses

The litterfall samples and their components collected monthly from the litterfall traps were evaluated in $g \cdot m^{-2}$ unit. The samples were statistically analyzed using IBM SPSS statistics program (SPSS Inc., Chicago, IL, USA). The correlation and the distribution of the samples with respect to the traps and closure are evaluated at $\alpha = 0.05$ confidence level. The ANOVA test was used in order to calculate the statistical distribution of samples and Duncan test was used to determine the differences among the samples.

Results

Distribution of litterfall components

Mean 333.5 (min = 137.8 – max = 526.2) $g \cdot m^{-2} \cdot y^{-1}$ amount of litterfall was accumulated within 10 litterfall traps with different canopy closures. It was found wide variation among the amount of litterfall collected within the traps due to their locations and variations of canopy closure. The foliar litterfall has the largest share (72%) of the total amount of litterfall. The rates of seed and wood litterfall were almost similar to each other (14%). There were significant differences between the amount of $Total_{Lf}$, foliar and wood components accumulated within the traps ($P < 0.01$). The annual amount of collected litterfall components were 2401 $kg \cdot ha^{-1} \cdot y^{-1}$ for foliar, 472 kg $ha^{-1}y^{-1}$ for seed and 462 $kg \cdot ha^{-1} \cdot y^{-1}$ for woody parts (*Table 2*).

Canopy closure

As seen in the hemisphere photographs, some traps coincided with gap areas under loose canopy closure while others coincided with dense areas under high density canopy of trees. There were also differences in perpendicular canopy closures right over the traps. Additionally, the differences in canopy closures were quite distinct from the center of the traps towards outside. Moreover, the amount of energy and sun light

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23572372

penetrating to the crown varies due to the canopy structure of the trees. Such reality influences the size of canopy and the amount of the vegetative and generative organs of the trees. The self-thinning of branches decreased in the trees with plenty of light and located around the large gaps as depicted in *Figure 3*. The green or live canopy starts at a lower height and cover larger areas.

Figure 3. *Hemisphere photos of canopy closure (Traps: a 2; b 3; c 8; d 9)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23572372

Significant differences were found among the average canopy closure rates of the canopy angularly observed above the litterfall traps (P < 0.01) (*Table 3*). The crown rates show an increasing trend from the narrow angle of 10° (40%) towards hemisphere 178° (81%). However, certain differences in crown rates in each hemisphere photos enlarging with 10° zenith angles among the traps were also observed. For example, the average canopy closure (89%) at the narrowest angle (10°) was higher than the canopy closure (85%) at the largest angle (178°) as some traps (trap 6, 3 and 1) coincided with dense canopy closure. The crown rates determined under 10° zenith angles ranged from 0.13% to 93.22% with a Standard Deviation (SD) of 39.82%. Thus, certain differences in the crown rates represented by the traps were also found. The extreme values decreased as the evaluated crown area expanded with respect to the increase of zenith angles. As a result, the crown rates stabilized (mean = 81.4%, SD = 4.87% for 178°) (*Table 3*).

The relationship between canopy closure and litterfall

Based on the relationships between the amount of litterfall for each component of litterfall and the values of canopy closure viewed at the angles above the traps, relatively the highest positive correlation (r = 0.225**) for the woody part was found within the canopy closure at 10° angle of view. In the meantime, the highest correlations for the foliar component (r = 0.285**) and for the seed component (r = 0.136**) of litterfall were attained within the canopy closure at 20° angle of view.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23572372

The levels of correlations show a decreasing trend towards negative values from 30° angle onwards (*Table 4*).

The closer the canopy closure of litterfall is to the traps horizontally, the higher the amount of litterfall collected at the traps is. According to the correlation values indicated in *Table 4,* the amount of litterfall collected in the traps has a limited relationship with the canopy closure viewed at certain angles from the traps. Additionally, *Figure 4* shows that canopy closure values observed within the distance from the center towards the areas viewed until 20° angle of view contribute the highest to the collected litterfall according to the physical and aerodynamic features of litterfall components. However, they indicate decreasing trend after 30° angle.

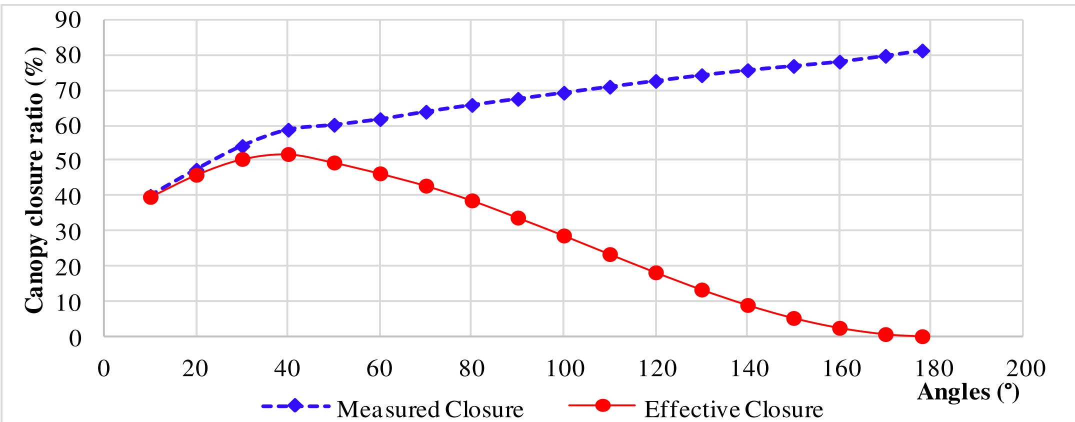

Figure 4. *Measured and the effective canopy closure determined by the angles*

Effective canopy closure for litterfall

The diameter and the area of crown viewed at angular side from the traps were determined with the model developed (*Eqs. 1* and *2*) by the value of zenith angle centered with the traps and the average height of the stand in question (*Table 5*).

Modeling the litterfall with canopy closure

The most appropriate correlation is usually determined at the angle values with the highest correlation based on the angular closure of litterfall components. The amount of woody parts of the litterfall at 10° angular closure is estimated with an exponential function. However, the amount of seed and foliar components as well as the $Total_{Lf}$ at 20° angular closure are estimated with second degree polynomial functions (*Table 6*).

Table 6. *The mathematical models to estimate the litterfall fractions*

Litterfall fractions	Angle of effective closure	Mathematical models	Coefficients of determination (R²)
Foliar	20°	$-0.005x^2 + 0.6976x + 3.1006$	0.93
Seed	20°	$-0.0011x^2 + 0.1422x + 0.7365$	0.82
Wood	10°	$1.0997 \times e^{0.0213x}$	0.83
$Total_{Lf}$	20°	$-0.0051x^2 + 0.8386x + 4.7628$	0.92

The model representing woody parts shows a convex curve and increases gradually with respect to the increase of 10° angular closure values. However, the functions of foliar, seed and $Total_{Lf}$ show a concave curve with respect to the increase in canopy closure values. Thus, the trend of the collected litterfall increases up to a certain point (seed 65%; foliar 70%) and decreases right after that point (*Fig. 5*).

The measured data obtained from the prediction of the spatial distribution of litterfall collected basically from the crown of the trees that are the principle sources of the litterfall were extrapolated. The spatial (horizontal) distribution of litterfall was simulated based on the annual average annually collected litterfall (333.5 $g \cdot m^{-2}$) in an area with 3.6 m in diameter at 20° angle of view. The horizontal sizes were assumed to be the heights of the trees in order to ease the prediction in practice. The $Total_{Lf}$ estimated with the extrapolation of the theoretical sources of the litterfall was distributed to the horizontal areas according to the tree height (TH) criteria. The horizontal distribution of litterfall decreases with respect to the zenith angles $(Cos\alpha)^2$.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23572372

The Amount of Spreadable Litterfall (ASL) model was able to best represent the relationships (*Eq. 3*). It was estimated that the amount of $Total_{Lf} = 13976$ g·y⁻¹ in the litterfall source decreases gradually from the center towards outside further down to the 7-tree heights (7 × 20.4 m = 142.8 m) to 280 g·y⁻¹ (2%).

$$ASL = Total_{Lf} \times (Cos(Arctan(TH)))^2 \quad \text{(Eq.3)}$$

Amount of Accumulative Litterfall (AAL) in a unit area was modelled with an exponential function based on the departure from the center (*Eq. 4*). The amount of litterfall to be collected at two-tree distance (40.8 m) from the litterfall source was estimated to be 0.54 $g \cdot m^{-2} \cdot y^{-1}$ (*Table 7*).

$$AAL = 197.47e^{-2.129AB} \quad \text{(Eq.4)}$$

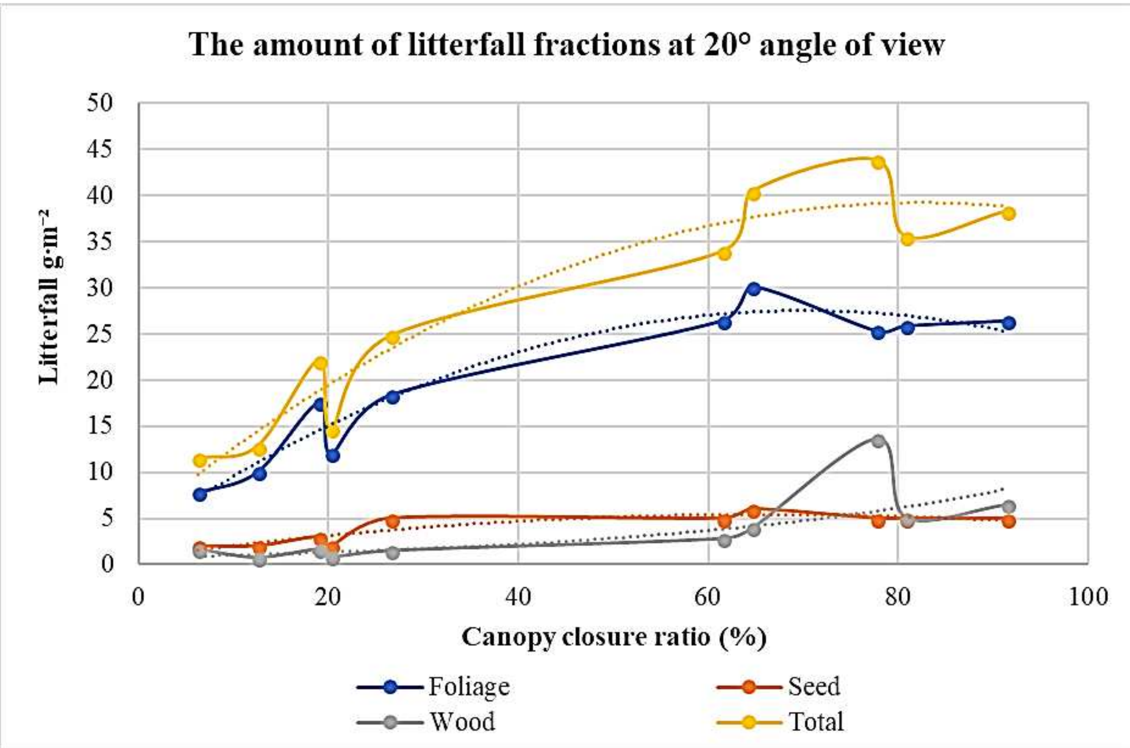

***Figure 5.** The change of litterfall based on the canopy closure*

Discussion

The average amount of litterfall collected yearly in the traps is about 333.5 $g \cdot m^{-2} \cdot y^{-1}$, 72% of which is leaves and the rest (28%) consists equally of seed and woody pats of litterfall fractions. A similar study conducted in China by Yang et al. (1991) in a different Fir stands (*Abies fabric*) indicated that the amount of litterfall was about 286 $g \cdot m^{-2} \cdot y^{-1}$. The 17% of the $Total_{Lf}$ was classified for wood fractions, 73% was for leaves and the rest for the seed fraction. Also, Dündar (1988) found that the amount of litterfall of Scotch pine stands was about 468 $g \cdot m^{-2} \cdot y^{-1}$ in Bolu-Aladağ, in Turkey. Edwards et al. (2017) investigated the proportions of litterfall components and concluded that the rate of foliar is nearly 63.5%, the rate of wood is 27.7% and the rate of seed is about

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23572372

8.8% in northeastern Australia. While the rates of leaves litterfall fraction are similar in both studies, the rates of seed and woody parts differed from each other. The underlying reasons may be attributed to the fact that the parts of trees would be different as well as the frequency or interval of seed-rich years based on the case study period and the time of the seed maturity would be dissimilar to each other. As the firs are cone rich trees, the parts of the cones assumed to be the part of seed contributed to the litterfall as much wood parts as possible. Kucuk et al. (2014) showed that the average 41% of canopy litterfall was allotted to the needle, 13% to the fine branch, 20% to the medium branch, 18% to thick branch and 8% to the very thick branch in young black pine stands.

The collected litterfall did not show a steady increasing linear trend with respect to the values of canopy closure. The amount of collected litterfall was found to be relatively higher in the stands with loose canopy closures over the traps. Chianucci et al. (2014a) warned that one would incline to make more mistakes in the stands with larger gaps compared to the stands with dense canopy closure. The lower degrees of canopy closure cause the lower layers of the stands to have more sun light energy (Lopez et al., 2008). It is believed that the self-thinning of branches starts and proceed slower, and the amount of accumulated vegetative and generative biomass increase as intense light energy penetrates into the stands. Therefore, more energy penetrates into the stands and the carbon sequestration increases. The amount of light energy penetrating inside the canopy decreases in the high dense stands. As a result, self-thinning process accelerates among the trees and the crowns of the trees develop narrower and start from high above the ground. Thus, volume of the crown of the trees around the gaps are quite bigger and the vegetative and generative organs are plenty in the stands with loose canopy closure as compared to the dense stands. Lopez et al. (2008) indicated that such situation is more important in the forest with mostly deciduous stands and the early plant species within the understory of stands are able to find opportunities to store plenty of light energy before the blooming of leaves in the spring season (before the initiation of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23572372

closure). That the rate of canopy closure is relatively lower in the forests with shade tolerant species like fir influences positively the development of seedlings and the maintenance of the multiple layered and un-even aged stand structure.

The rates of the canopy closure above the litterfall traps show a gradual increasing trend with respect to the increase in zenith angle. The same trend was also observed in some other Pinus, Cupressus, Quercus and Carpinus stands (Gonsamo et al., 2013; Chianucci et al., 2014b). A similar decreasing trend of gaps in canopy closure with respect to the increase in zenith angle was also observed by Gonsamo et al. (2013) and Chianucci et al. (2014b)

In this study, while there were significant differences between the canopy closures above the traps in narrow angles (< 40° = 20° zenith angle) in our case study, such differences between the canopy closures are gradually eliminated with the expansion of the angles (40° <). Therefore, it becomes difficult to establish a correlation between the canopy closure and litterfall and develop the associated mathematical models when a study is designed to use larger angle. Thus, it is important to decide at the beginning the appropriate angle interval that allows the best relationships with the litterfall collected manually on a certain interval in order to estimate the litterfall based on the canopy closure of stands. The best correlation was found at 20° angle for foliar and seed and at 10° angle for woody parts of the litterfall. The canopy closure that indicated the best correlation with the litterfall at 20° angle was used as a basis in developing the mathematical models in this study. Based on this reality, the mathematical models were thus developed for each fraction of litterfall at these angles. The R^2 for the models developed as part of the study are 0.93 for foliar, 0.82 for seed, 0.83 for woody fractions and 0.92 for the $Total_{Lf}$. Liu and Jin (2016) showed that rate of the relationships R^2 between the collected litterfall and the LAI determined by the DHP ranges from 0.42 to 0.76 in coniferous forests in China. As well, they developed models to estimate the seasonal amount of litterfall based on the effective LAI determined at 45-60° zenith angles.

Although LAI of forest canopy closure could be determined with optical methods, errors may be encountered due to the storage of leaves and trunk's silhouettes on top of each other based on the viewing angles. Similarly, a certain zenith angle needs to be used, instead of a whole area, in determining the values of LAI as an alternative method to estimate the litterfall. The DHPs were analysed at different zenith angles (0-45°, 30-60°, 45-60° and 0-75°) for effective measurements of LAI in deciduous-coniferous mixed forest. The highest correlation was found with the effective LAI viewed at 45-60° zenith angle based on the litterfall collecting method (Liu et al., 2015). However, errors issuing from the DHP can be removed using appropriate indices (Frazer et al., 2017).

In this study, the effective spreading distance was found to be 7.2 m diameter viewed at 20° zenith angle since the parts of the cones were included with the seed fraction of litterfall. Pamay (1962) indicated that the effective seed spreading distance of the seed trees in the edges of stands is 10-40 m for Anatolian pine (*Pinus nigra* Arnold) and Scotch pine and 20-40 m for Spruce (Picea sp. Mill.). The spreading distance of the seeds are generally dependent on the height of the trees, the weights and the flying capabilities of the seeds. However, the dry, hot and windy weather conditions help increase the flying distances of the seeds. In the meantime, the flying distance of the seeds can reach up to 400 m in Anatolian pine, 480 m for Scotch pine and 200 m in fir

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23572372

trees according to (Atay, 1971). These flying distances include the wing shaped seeds detached from the carpel and cones.

Understanding the litterfall dynamics within the forest ecosystems are critical in the sustainable management of forest ecosystems including the nutrient cycle, carbon sequestration and some other monitoring studies. However, litterfall collection is quite time consuming, laborious and expensive process. One of the most appropriate, practical and economic methods in determining the amount of litterfall and its spreading distances is to develop mathematical models. In this study, we have developed some mathematical models based on canopy closure of the stands using the data obtained from the litterfall collection in Uludağ fir stands. However, the developed models can be rectified with the further data to accommodate various site conditions. Besides, new studies may need to be designed in order to determine the amount and the spreading distances of $Total_{Lf}$ and its fractions in the gaps of the edges of the stands. The necessary mathematical models can be developed for the other commercial trees in our forest ecosystems based on the sampling method and the models developed in this study.

Conclusions

In conclusion, this study has developed statistical relationships for estimating canopy cover based on the litterfall in Uludağ fir forest stands. These results obtained in Bolu-Aladağ (Turkey) can also be used for similar ecological conditions of Uludağ fir. The main findings indicated that the highest correlation was found between the amount of $Total_{Lf}$ and the canopy closure at 20° angle of view (a circle with the diameter of 1/3 tree height at horizontal) using DHP. The amount of litterfall, spreading distance and the collecting amount based on the distance were estimated by the mathematical models developed as part of this study.

The data of fall and spread of the litter are very important for forestry sciences such as ecology, silviculture and management. Therefore, it would be necessary for similar studies to be carried out for other broad-leaved and coniferous tree species in all forest ecosystems. But, litterfall collection studies are long-term and effortful. Due to these reasons, the planed litterfall researches should be designed appropriate for mathematical modeling in the future. Thus, it may be possible to use the obtained results in wider areas. Practitioners can estimate the amounts of litterfall components, spreading distances and the accumulating amounts by using these mathematical models.

Abstract. Water resources planning requires very good data set and accurate analyses, one of which is a trend identification procedure. Different trend analyses are available in the literature and one of the most commonly used one is the Mann-Kendall trend analysis. The biggest problem of this analysis is that trends change with the selection of different time periods. Although many researchers have tried to find different solutions to this problem, in this study, trends are set for all combinations of the available data to cover at least 10-year periods and the results are displayed on a 3-dimensional checkerboard. For the application precipitation and temperature data are considered from 5 meteorology stations in the Akarçay, Turkey.
Keywords: *Afyon, period, trend, rainfall, temperature*

Introduction

Rapid population growth and industrialization have a huge impact on global climate. Particularly in recent decades, the concept of climate change has received growing attention among the researchers. Studies especially address the amount of precipitation (Paul et al., 2017), precipitation intensity (Olive et al., 2017), mean temperature (Khan et al., 2017), extreme temperature conditions (Zhao et al., 2017), amount of evaporation (Xu et al., 2007), stream flow (Saplioglu et al., 20014) and groundwater level fluctuations (Gebert et al., 2007). These are also mathematical (Sing et al., 2016), statistical (Zeleňáková, 2017; Kristo et al., 2017; Onyutha, 2016) and graphical (Cui et al., 2017; Sen, 2012) description studies about trend analysis.

Statistical models are crucial for trend detections. Many researchers conducted statistical studies on trends and proposed different methods (Saplioglu, 2015). One of the most widely used methods is the Mann-Kendall test, which has been employed to analyze seasonal and annual precipitation trends in Bangladesh (Baria et al., 2016), precipitation and drought trends of the Aegean region, Turkey (Bacanli, 2016), precipitation trends in Sicily (Cannarozzo et al., 2006), around the Nile River (Onyutha et al., 2016), in Turkey (Partal and Kahya, 2006), Florya, Istanbul (Guclu et al., 2018), Córdoba, Argentina (Casaa and Nasello, 2010), in the Iberian peninsula (Bustins, 2008), in three different regions of Japan (Yue and Hashino, 2003), in Brazil (Carvalhao et al., 2014), in Sudan (Goanstera et al., 2015), precipitation and temperature trends in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23732384

Northeastern United States (Karmesha, 2012), stream trends and the impact of precipitation and subsurface waters on these trends in India (Kumar et al., 2009), changes in hourly precipitation in Peninsular Malaysia (Syafrina et al., 2018), temporal and spatial precipitation changes and estimation in Mongolia (Kim et al., 2011) and 6-minute precipitation intensity trends in Australia's southern regions (Kamruzamana et al., 2016).

Some researchers have applied the Mann-Kendall test for different time periods and observed that the results were different. For example, Baria et al. (2016), analyzed 50-year data in northern Bangladesh and observed no trends except for one station. They also found different downward trends in all stations for 1990 and beyond. Cannarozzo (2006) conducted a study on 247 stations leading to different trends for three different periods as 1921-2000 (170 trends), 1931-1960 (65 trends) and 1961-1990 51 trends. Although Carvalhao et al. (2014) identified a significant trend from 1899 to 1970 they did not detect any trend from 1970 and beyond. Goanstera et al. (2015), investigated precipitation amount to identify trends from 1950 to 2009 and 1970 to 2009. They observed statistically significant trends during the former part of the records, but no statistically significant trends along the latter part. Seo et al. (2012), used the Mann-Kendall test for different time periods and displayed the confidence intervals of the trends on a checkerboard. Studies suggest that using the Mann-Kendall test for different periods yields different results.

In this study of temperature and precipitation trends are analysed in which is one of Turkey's 25 sub-basins Akarçay. The Mann-Kendall test was used for trend analysis. However, the entire data set was scanned at least 10 years during this process. The results are presented as 3D graphics. The most important aim of the study is to show that the trends may change when the period of the selected period changes rather than determining the current trend.

Materials and methods

This study investigates possible precipitation and temperature trends in Akarçay basin, Turkey.

Akarçay basin features

Akarçay is one of the 25 basins in Turkey and it has a total drainage area of 7,337 km^2 along the closed depression basin extending between Uşak-Banaz in the West and Konya-Doğanhisar in the East. It length is parallel to the tectonic line between the Taurus Belt and Afyon Metamorphics with orientation along 38.7380-39.0098 NW-30.5604-31.4217 SE direction its length – 160 km with 70 km width (*Fig. 1*).

Tables 1 and *2* present statistical parameters of annual homogenized precipitation records and temperature records, respectively

Methods

It is emphasized in this study that the start and end years are crucial in the classical Mann-Kendall tests. In any analysis, trends vary according to start and end years. In the same time series record there may be more than one trend subsequently with different slopes. For this reason, data set is sub-divided into minimum 10-year periods and the

DOI: http://dx.doi.org/10.15666/aeer/1702_23732384

Mann-Kendall test is performed on each period and the results are presented on 3D checkerboard graphics.

Mann-Kendall test statistic

The Mann-Kendall test (Mann, 1945; Kendall, 1970) is a nonparametric procedure, which does not make any assumption regarding the data distribution. The aim of the Mann-Kendall test is to verify whether a trend exists in a time series. If the hypothesis is rejected, it means that there is a trend. During any analysis, time series are divided into two groups; x1, x2, ..., xn, (xi, xj). If i < j for each xi < xj, then P value is increased by one, in the opposite case, that is, for … xi > xj, M value then the test statistics, S = P – M, is defined (Saplioglu et al., 2017).

Kendall correlation coefficient for n > 10 is calculated as follows (*Eqs. 1-2*).

$$\mu_s = 0 \; ve \; \sigma_s = \sqrt{n(n-1)(2n+5)/18} \quad \text{(Eq.1)}$$

$$z = \left.\begin{matrix} \frac{s-1}{\sigma_s} & s > 0 \\ 0 & s = 0 \\ \frac{s-1}{\sigma_s} & s < 0 \end{matrix}\right] \quad \text{(Eq.2)}$$

If the Z-score is less than α corresponding to Z/2 in a normal distribution, then the hypothesis is accepted, indicating that there is no trend. If the Z-score (*Eq. 2*) is greater than α corresponding to Z/2, then the hypothesis is rejected, suggesting that there is a trend. If S is positive, then it is an upward trend, on the other hand, if S is negative, then it is a downward trend. The Mann-Kendall test method is practical as it does not make any assumption regarding the data distribution (Saplioglu et al., 2014).

Applied method

The Mann-Kendall test statistic generally analyzes trends in series between a start and end points. This method iteratively arranges the start and end points and allows one to calculate trends in different periods (at least 10 years). These trend changes are displayed on a checkerboard. The x axis represents the start years, the y axis is for end years and the z axis stands for the confidence interval of the trend, and hence, this axis assumes values between -1 and 1. The range from 0 to 1 indicates a downward trend while from -1 to 0 is for an upward trend. Generally at a confidence interval of 95%, the results are considered as statistically significant indicating the presence of a trend. The blue color scale (-1-0) shows a downward trend while the red color (0-1) implies an upward trend. Software was generated using MATLAB in order to apply the method quickly and automatically (*Fig. 2*). This software was generated embedding the Mann-Kendall statistical subprogram (*Fig. 3*) into MATLAB.

Results and discussion

In the Akarçay basin, stations with data set suitable for the Mann-Kendall test (5 for precipitation and 5 for temperature) were selected and analyzed.

Precipitation trends

Mann-Kendall tests are performed in at least 10 different combinations on the precipitation data set for 5 stations. All results are summarized in tables and graphs. In the classic Mann-Kendall tests, only one analysis is performed at the start and end times of a data set. 2628,

DOI: http://dx.doi.org/10.15666/aeer/1702_23732384

1830, 990, 561 and 1176 Mann-Kendall tests are performed for Afyon, Akşehir, Bolvadin, Çay and Emirdağ, respectively (*Table 3*).

DOI: http://dx.doi.org/10.15666/aeer/1702_23732384

Table 3. *Trend statistics for precipitation data*

	Iteration	Negative trend	Negative rate	Positive trend	Positive rate
Afyon	2628	524	19.94	112	4.26
Akşehir	1830	446	24.37	235	12.84
Bolvadin	990	3	0.30	2	0.20
Çay	561	42	7.49	1	0.18
Emirdağ	1176	46	3.91	64	5.44

Trend analyses for different periods are visually presented on the checkerboard. Out of 2,628 Mann-Kendall tests applied to the Afyon precipitation data, 524 revealed a negative trend while 112 indicated a positive trend (*Fig. 4*). All data between the initial and final points indicate the presence of a negative trend. However, this can sometimes be misleading. For example, the analysis of Afyon station data over the period from 1929 to 2009 shows a trend at a confidence interval of 95%, however, no trend is observed in the analysis of the data over the period from 1929 to 2008 or from 1930 to 2009. Similar examples can be found in the literature (*Fig. 4*).

On the other hand, out of 1,830 Mann-Kendall tests on the Akşehir precipitation data (1941-2011), 446 (24.37%) had a negative trend, whereas 235 (12.84%) with a positive trend. Most of the positive trends are concentrated in the upper left corner of the figure, indicating an upward trend (*Fig. 5*).

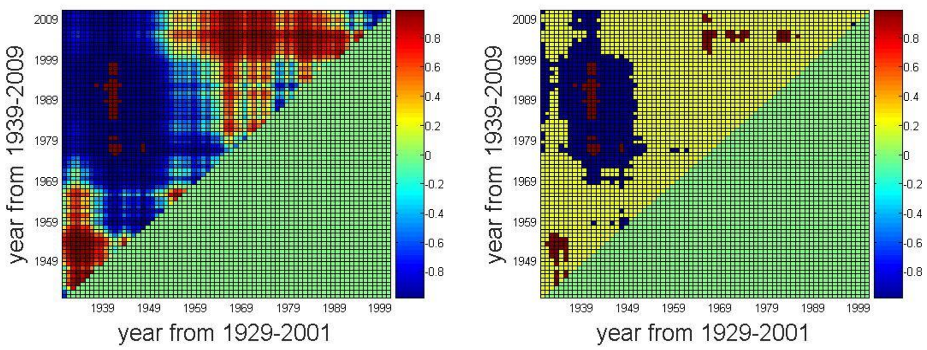

Figure 4. *Afyon precipitation trend analysis results a-) all confidence intervals b-) 95% confidence interval*

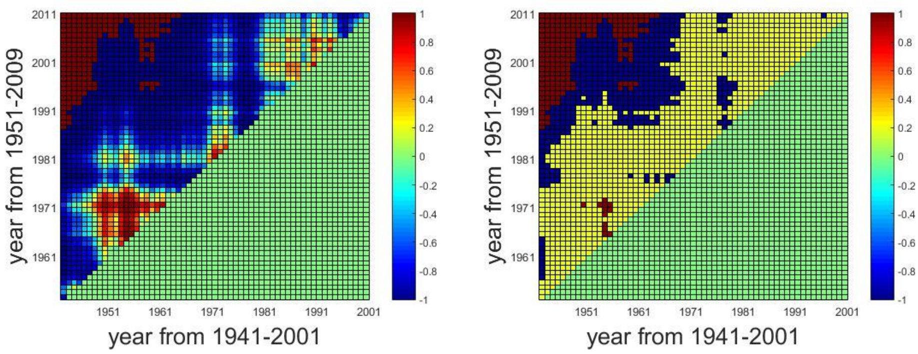

Figure 5. *Akşehir precipitation trend analysis results a-) all confidence intervals b-) 95% confidence interval*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23732384

Mann-Kendall tests conducted 990 times on the Bolvadin precipitation data (1957-2009), 3 (0.30%) exhibited a negative trend and 2 (0.20%) exhibited a positive trend, with the remaining cases no trend (*Fig. 6*).

Out of 561 Mann-Kendall tests performed on the Çay precipitation data (1964-2006), 42 (7.49%) showed a negative trend while 1 (0.18%) showed a positive trend. Most of the negative trends are concentrated in the upper left corner of the figure, suggesting that although the number of trends is low, the negative trend has accelerated in recent years (*Fig. 7*).

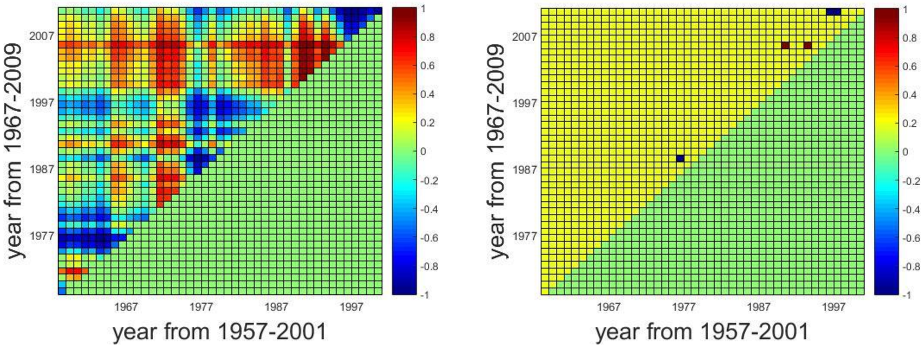

Figure 6. *Bolvadin precipitation trend analysis results a-) all confidence intervals b-) 95% confidence interval*

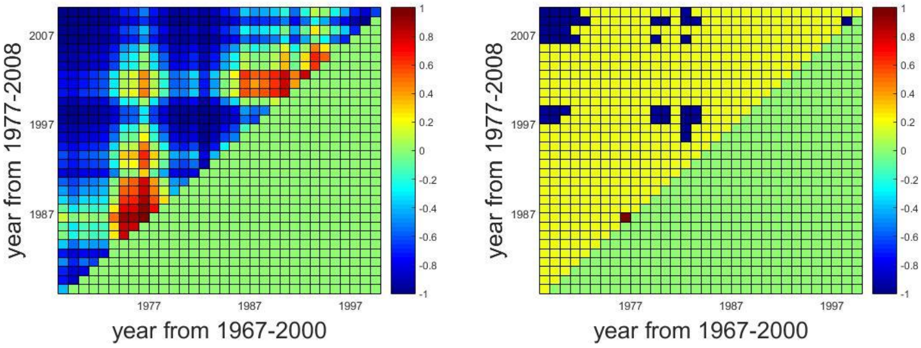

Figure 7. *Çay precipitation trend analysis results a-) all confidence intervals b-) 95% confidence interval*

Temperature trends

Mann-Kendall tests are also performed at least for 10 different combinations on the temperature data set at 5 stations. In the classic Mann-Kendall tests, only one analysis is performed at the start and end times of a data set. 2628, 1941, 528, 528 and 666 Mann-Kendall tests are performed for Afyon, Akşehir, Bolvadin, Çay and Emirdağ, respectively. Trend statistics are given in *Table 4.*

Similarly, 1,176 Mann-Kendall tests carried out on the Emirdağ precipitation data (1953-2009), 46 (3.91%) had a negative trend, whereas 64 (5.44%) showed a positive trend. The positive trends are concentrated in the lower left corner of the figure, while the negative ones are in the center of the figure, indicating that there has been no trend in recent years (*Fig. 8*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23732384

Table 4. *Trend statistics for temperature data*

	Iteration	Negative trend	Negative rate	Positive trend	Positive rate
Afyon	2628	245	9.34	94	3.58
Akşehir	1941	11	0.57	79	4.07
Bolvadin	528	0	0.00	153	28.98
Çay	528	0	0.00	32	6.06
Emirdağ	666	33	4.95	46	6.91

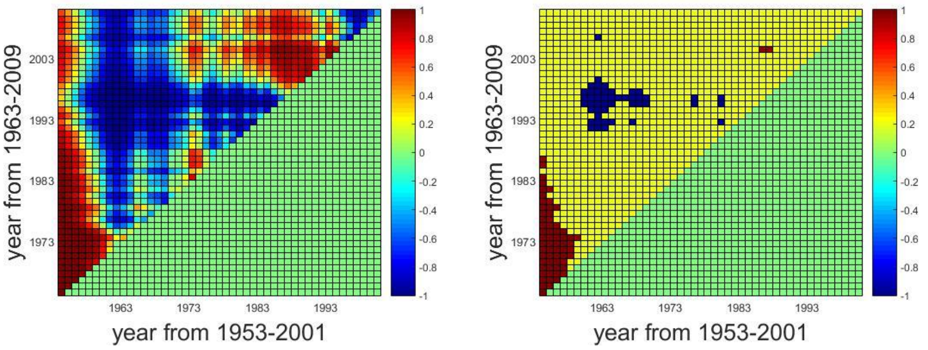

Figure 8. *Emirdağ precipitation trend analysis results a-) all confidence intervals b-) 95% confidence interval*

Trend analyses performed for different periods are visually presented on the checkerboard. Out of 2,628 Mann-Kendall tests on the Afyon temperature data, 245 (9.34%) had a negative trend, while 94 (3.58%) had a positive trend (*Fig. 9*).

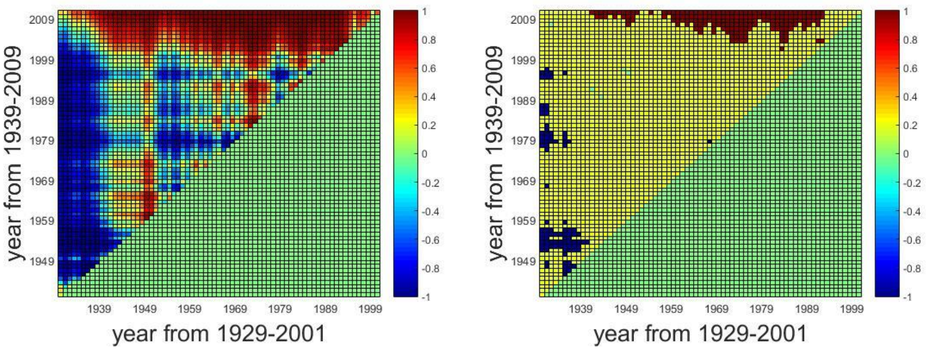

Figure 9. *Afyon temperature trend analysis results a-) all confidence intervals b-) 95% confidence interval*

On the other hand, 1941 Mann-Kendall tests performed on the Akşehir temperature data (1953-2009), yielded 11 (0.57%) negative trends and 79 (4.07%) exhibited a positive trend. The lack of positive trends, especially on the left side of the figure, indicates that the trend in this region is not pronounced (*Fig. 10*).

Similarly, out of 528 Mann-Kendall tests conducted on the Bolvadin temperature data (1969-2009), 0 (0%) had a negative trend with 153 (28.98%) positive trend. The concentration of positive trends at the top of the figure suggests that trends in this region

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23732384

have increased. However, when the classical Mann Kendall test is applied, only one value would be expected to be as 0.05 (the only cell in the upper left corner of the figure, and therefore, no trend would be reported (*Fig. 11*).

Additionally, out of 666 Mann-Kendall tests carried out on the Çay temperature data (1969-2009), 33 (4.59%) and 46 (6.91%) exhibited a negative and positive trend, respectively. The distribution of cells on the figure does not suggest that there is no trend (*Fig. 12*).

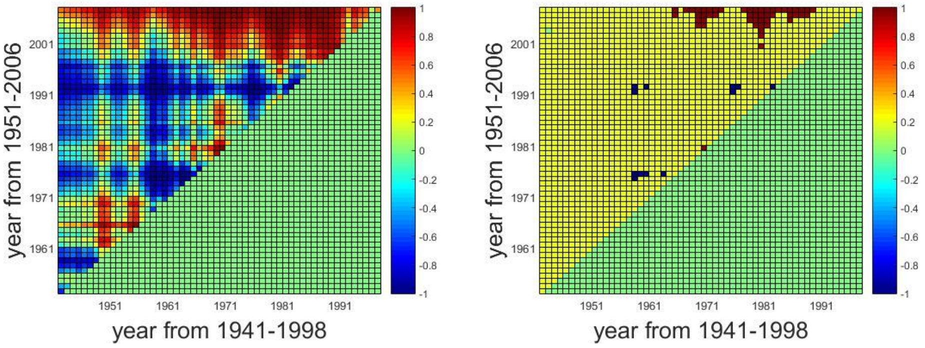

Figure 10. *Akşehir temperature trend analysis results a-) all confidence intervals b-) 95% confidence interval*

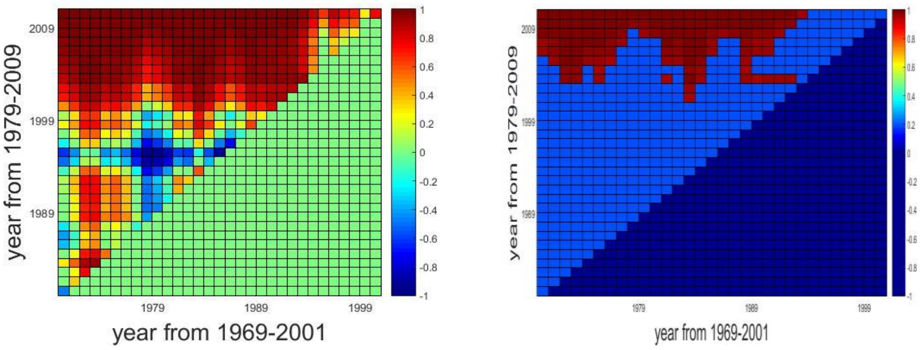

Figure 11. *Bolvadin temperature trend analysis results a-) all confidence intervals b-) 95% confidence interval*

DOI: http://dx.doi.org/10.15666/aeer/1702_23732384

Finally, out of 666 Mann-Kendall tests applied to the Emirdağ temperature data (1965-2009), 46 (3.91%) revealed a negative trend with 64 (5.44%) positive trend. *Figure 13* shows that all the negative trends are associated with the 1965-1995 data and that recent data do not indicate the presence of a trend (*Fig. 13*).

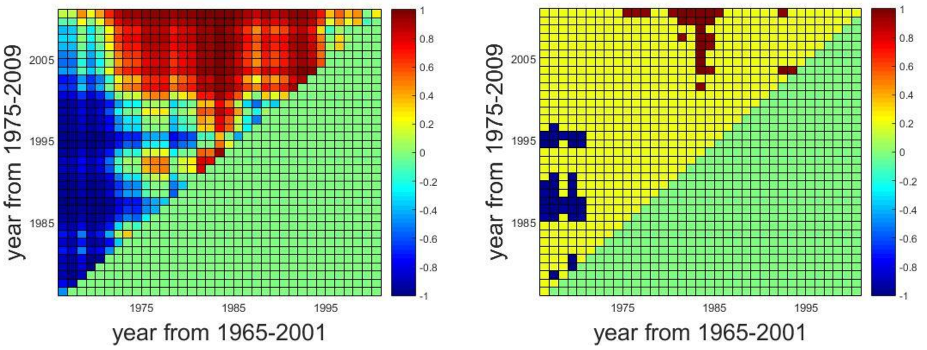

Figure 13. *Emirdağ temperature trend analysis results a-) all confidence intervals b-) 95% confidence interval*

In many studies, the initial and end values of the data are available (Saplioglu et al., 2014; He et al., 2017; Quan et al., 2018). These dates are the dates when records started and records were reached. In this study, it was tried to get answers to questions such as how different the trend would be if the record started to be recorded at a later date than the records started to be recorded, or whether the study would affect the trend values that were made n years ago or n years later. (n-10) (n-9) / 2 studies are possible since a minimum period of 10 years is selected. In this study, all possibilities for all stations are found and shown on checkerboard. For example, the first data from the Emirdağ temperature station were taken in 1973, and in 2008 the researcher who was working did not observe the trend formation, but in 2009, another researcher in the researcher determined the positive trend.

Conclusion

Trend identification is as important as data analysis for the assessment of water resources. The Mann-Kendall test is one of the most commonly used methods for trend analysis. However, changing the start or end time of a period can result in different trend values. In this study, Mann-Kendall tests are performed on all subsets (each having 10 or more year’s data). Confidence intervals of z values are determined and displayed three-dimensionally on a checkerboard.

Data from five precipitation and five temperature stations on Akarçay basin in Turkey, are evaluated and their trends are presented on the checkerboard. Results indicate that the precipitation tends to decrease in Akşehir station and that the temperature significantly increases in Bolvadin station.

This study has eliminated the problem of “time interval selection” for the Mann-Kendall test. For example, Afyon meteorology station precipitation data indicate the presence of a trend between 1929 and 2009 at a confidence interval of 95%. However, no trend is detected in the data if the start year is 1930 or the end year is 2008. Similarly, although the increasing trend in recent years in the Bolvadin temperature data

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23732384

is conspicuous on the checkerboard, the classical Mann-Kendal test fails to detect a trend at a confidence interval of 95%. The analyses in this study are performed for each time interval, and therefore, trend analysis is better analyzed graphically. In addition, using software to analyze the data allowed obtaining individual trend results for all time periods in a very short time. The study is important in terms of showing that different trends can be found in the same station at different periods.

(Received 23rd May 2018; accepted 2nd Jan 2019)

Abstract. The accumulation of selenium by rye at different stages of development depending on the dosages of selenium and pH of soil was investigated. The findings testify that in case of increased selenium content in the soil selenium concentration in the plant also increased. Moreover, it was revealed that in the process of vegetation total selenium content in the rye increases; however the intensity of selenium accumulation by plants decreases. The positive effect of low concentrations of selenium on biomass accumulation of rye plants was found. The total protein content in rye grain was higher by application of selenium. The results of this work show the possibilities of applying of the seleniferous fertilizers for the increasing in the content of micronutrient in the grain plants. The recommended optimal concentrations of selenium additive are 0.01-0.05 mg kg^{-1} of soil.
Keywords: *cereals, seleniferous fertilizers, microelement, yield, proteins*

Introduction

Rye (*Secale cereale* L.) is one of the most important cereals in middle, eastern, and especially north Europe. Among the cereals, rye can be grown under extreme climatic and poor soil conditions. On a global scale rye is a minor crop, its production being about 5% that of wheat or rice (Korzun et al., 2001). However, recently, interest in this crop has increased because of its dietary value. Rye is especially rich source of phytochemicals such as phenolic acids, lignans, alkylresorcinols and benzoxazinoids (Pihlava et al., 2018).

So far scientists do not know for certain whether selenium is an essential microelement for growth and development of plants. Some researchers admit necessity of selenium for plants others believe that selenium is not an essential element for normal life history of vegetative organism. However, there are a number of facts confirming positive influence of selenium on various life processes. Thus, it has been established that selenium increases antioxidant potential and stress-resistance of plants, stimulates their growth in the conditions of oxidation stress caused by UV-radiation (Hartikainen and Xue, 1999; Xue and Hartikainen, 2000; Pennenen et al., 2002; Germ et al., 2007; Golob et al., 2018), herbicides, hypothermia (Seppaenen et al., 2003; Xu et al., 2003), drought stress (Nawaz et al., 2015a; Aissa et al., 2018), plant's ageing (Xue et al., 2001; Djanaguiraman et al., 2004, 2005), salt stress (Kong et al., 2005; Diao et al., 2014; Jiang et al., 2017). There has been noted increase of yield level of some plants further to application of low concentrations of selenium (Graham et al., 2005; Thavarajah et al., 2015; Nawaz et al., 2015b). Positive effect of selenium is also

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23852421

revealed in increased germinating capacity and improved survival potential of plantlets in stress conditions (hypo- and hyperthermia, hypoxia, soil salinity and acidulation etc.) In the presence of selenium lipid membrane peroxidation processes in conditions of high light intensity and low temperatures are reduced, testifying to the effect that selenium has an influence on oxidation-reduction cell status (Zhu et al., 2009).

Selenium intake by plants from soil depends on many factors, for instance, on soil pH, humus content, chemical form of selenium (Zhao et al., 2005; Hawrylak-Nowak et al., 2015). Other important factor able to influence selenium quantity in plants is plant species. There are certain selenium accumulating plants, which accumulate from 100 to several thousand mg Se per kg of dry substance, in other plants including cereals selenium content is 0.01-1.00 mg kg^{-1} on the average (Terry et al., 2000; Wangeline et al., 2011; Pilon-Smits, 2017). Lyons et al. (2005) showed that the main reason for variability in the content of selenium in some cereals (wheat, barley, rye) is the selenium concentration in the soil, but not genotypic variation. Similar findings were also obtained in studies with three varieties of wheat (Sharma et al., 2015).

Analysis of selenium accumulation pattern is very important both for study of biochemical role of this microelement for plants and to study application potential of selenium-containing fertilizers in order to increase selenium supply of animals and humans.

Purpose of this paper was to study selenium accumulation by rye (*Secale cereale* L.) at various ontogenesis stages subject to application of selenium additive to the soil and the impact of this on the yield and grain quality.

Materials and methods

Plant cultivation

The pot experiment was conducted in Kaliningrad, Russia (54°43'N, 20°30'E), from 12 April till 17 July, 2015, in a glass covered greenhouse of the Institute for Chemistry and Biology at Immanuel Kant Baltic Federal University. The greenhouse was not heated and we followed the natural light cycle, no additional lighting was supplied. Common rye (*Secale cereale* L.) cv. Pukhovchanka was used for experiments. The rye was grown in culture pots in permanent-set soil having pH 5.4 and pH 6.6. The dimension of pot was 29 × 20 cm (height × radius) and each pot contained 10 kg of soil. Selenium was applied in the soil in the form of a sodium selenate solution (Na_2SeO_4) in concentrations 0.01 mg, 0.05 mg, 0.1 mg, 0.5 mg (in terms of 1 kg of the soil). Selenium effect on the plants was compared to control treatment (without selenium supplementation). Initial selenium content in the soil was 0.084 mg/kg. Moreover, following basic fertilizers were applied: 0.17 g of nitrogen in terms of ammonium nitrate, 0.13 g of P_2O_5 in terms of potassium hydrophosphate, 0.28 g of K_2O in terms of potassium hydrophosphate and sulfate and 0.044 of MgO in terms of magnesium sulfate per kg of the soil. Solutions of fertilizers and sodium selenate were applied in such manner so that they cannot mix with each other. First in extreme points of soil surface square basic microelements were applied, whereas sodium selenate was applied in the central point. After the soil dried out it was mixed and the rye was planted. Into each pot were planted 20 plants. During experiments the plants were watered with distilled water.

The analysis of plant were performed at three plant growth stages (GS): at tillering stage (GS 26, main shoot and 6 tillers), booting stage (GS 45, mid-boot stage: boots just

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23852421

visibly swollen) and milk development stage (GS 75, medium milk) according to Zadoks' scale (Zadoks et al., 1974).

Four replications for each treatment (selenium suplements, soil pH, and stage of development) were condacted. There were 120 pots in total.

Plant analysis

Selenium was determined by atomic absorption spectrometry (Unicam M Series, Software Solaar, Thermo Scientific) with mineralization of vegetative samples through autoclave decomposition under pressure (Kurkova et al., 2008).

The extraction of reserve proteins was performed by deionized water (for albumin), 5% NaCl (for globulin), 60% ethanol (for prolamin), and 0.4% NaOH (for glutelin). Protein concentration was determined according to Bradford, using BSA as the standard (Bradford, 1976).

Statistical analysis

Statistical analysis was performed using the SigmaPlot 12.3 (Systat Software GmbH, Erkrath, Germany). The mean of four independent samples were taken to represent the result of each replicate. The results were reported as mean ± standard deviation (SD). To identify the difference in means the one-factorial ANOVA was conducted for each factor (selenium application, growth stage, pH of soil, organs of plant) separately Difference among means were determined by Tukey's test at a significance level of $p \leq 0.05$.

Results

Accumulation of selenium in rye at different stages of development

In order to study selenium accumulation by the rye the plants were grown in the soil enriched with this microelement in concentrations 0.01–0.5 mg Se kg^{-1} of soil. Findings on selenium content in vegetative specimen were compared to the plant without selenium supplementation. Initial selenium content in the soil was 0.084 mg kg^{-1}. Selenium was identified in above-ground part of the plant at three stages of vegetation. Results of study of relation between selenium content in all plant and quantity of selenium applied in the soil at different stages of the plant ontogenesis are shown in *Figure 1*.

The findings testify that in case of increased selenium content in the soil selenium concentration in the plant also increased. Thus, after application of 0.05 mg of selenium per kg of soil, 4.74 ± 0.06 µg of selenium was identified in the plant (at milk development stage), while after application of 0.5 mg of selenium per kg of soil selenium content in the plant was almost 16 times higher – 74 ± 2 µg. Moreover, it was revealed that in the process of vegetation total selenium content in the rye increases, however as it is obvious on the picture intensity of selenium accumulation by plants decreases.

In order to study intensity of selenium accumulation by the rye at different ontogenesis stages total selenium content in the plant was calculated per gram of vegetating mass. Dependence of selenium concentration in the plant on selenium concentration in the soil is illustrated in *Figure 2*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23852421

The study shows that tillering stage was characterized by maximum selenium concentration, as the plant advanced intensity of its accumulation progressively decreased. Maximum selenium concentration in the rye at tillering stage was 59.3 ± 0.4 μg g^{-1}, at booting stage – 31.7 ± 0.3 μg g^{-1} and at milk development stage – only 11.8 ± 0.3 μg g^{-1}.

Influence of soil pH on the selenium accumulation in rye

As seen from the provided data, soil acidity difference being investigated influenced selenium intake by the plant. And considerable difference was obvious for the plants grown in the soil enriched with this microelement (*Table 1*). The significant higher concentration of selenium in rye plant growing on less acidic soil (pH 6.6) was determined. However, at tillering stage in plant growing on soil with pH 5.4 and without selenium supplementation the concentration of selenium was higher. At the later stages of plant development (booting and milk development), no significant difference in the selenium concentrations in plants growing on the soil with different acidity and without selenium additives was found.

At the same time, it was revealed that nature of selenium accumulation by the rye in the process of vegetation does not depend on the soil acidity: at the early stage of development – at tillering stage the microelement was received by the plant intensively, at the same time total selenium content in the plant increased.

Table 1. *Selenium concentration in rye plants (µg g^{-1}) in depending of soil acidity and selenium addition concentration*

Selenium distribution in different organs of the rye plant

Study of selenium distribution in different organs of the rye plant testified that selenium content in the grain was higher than in the stem (*Table 2*). It was particularly evident in case of low selenium content in the soil; in case of higher selenium additives in the soil difference between its content in the stem and in the ear became not so evident. Thus, there was no significant difference between the content of selenium in the stem and grain of plants grown with the addition 0.05 mg selenium per kg soil and by soil acidity of 5.4.

Effect of soil applied selenium concentration on biomass accumulation of rye

This paper studies effect of applied selenium soil addition on accumulation of biomass by the rye plants at various ontogenesis stages (*Table 3*). The findings show that optimal for the rye plant is selenium additive in concentration of 0.01-0.05 mg kg^{-1} of soil (soil pH is 6.6). Under these conditions at all stages of development the plants built up maximum biomass both compared to the reference specimen and to the specimen with higher selenium concentrations. At booting stage positive effect of selenium additive in the form of sodium selenate was fixed for all plants irrespective of concentration of selenium applied in the soil. In the case of soil pH 5.4 selenium effect on the plant was more toxic. Positive effect was fixed at tillering stage after application of 0.01 mg Se kg^{-1} of soil and at booting stage after application of 0.05-0.1 mg Se per kg of soil, whereas at milk development stage selenium effect was purely toxic irrespective of concentration.

Table 3. *Influence of selenium concentration in soil on the biomass (g) of rye plants at different ontogenesis stages*

Stage of ontogenesis	Soil pH	Selenium addition concentration, mg Se kg^{-1} soil

soil pH 6.6 promoted increase of biomass both of the stem and of the ear. At this, for the ear stimulating effect of selenium was fixed for all its concentrations, while maximum ear mass was fixed after application of 0.05 mg Se kg^{-1} of soil. In more acid soil we revealed mass decrease both for the ear and the stem after enriching the soil with selenium.

Influence of selenium on quantitative composition of reserve protein fractions in rye

Quantitative composition of reserve protein fractions was depending on selenium supply concentration to the soil (*Table 5*). The total protein content was higher by application of selenium. However, only the contents of globulin and glutelin in the rye grains increased with increasing Se fertilization. For albumin maximum of content was shown for low selenium concentrations (control and 0.01 mg kg^{-1}). Prolamin concentrations were not affected by selenium concentration in soil.

Discussion

The study of selenium accumulation by the rye plants at different growth stages in depending on selenium soil application in concentrations 0.01 – 0.5 mg Se kg^{-1} was conducted. There are four main methods for selenium application to plants: (1) adding Se to the soil; (2) foliar or fruit spraying; (3) soaking seeds in a Se solution before sowing; and (4) hydroponic cultivation with a nutrient solution containing Se (Puccinelli et al., 2017). The first two methods are most widely used due to their efficient and convenient. Despite a number of advantages of foliar processing, it is important to take into account the structural and chemical characteristics of the plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23852421

leaves. In the case of cereals, it is very difficult to produce true foliar processing, some fertilizer is deposited on the soil and extracted by the plant from there. In addition, the application of selenium into the soil before planting, allows us to estimate its accumulation into the plant at different stages of development.

The findings on selenium accumulation by the rye plants display in general the picture typical for cereals, when some elements (especially those participating in synthesis of labile organic compounds) are absorbed by plants at early ontogenesis stages with a rate exceeding dry substance accumulation. Later, after completion of tillering stage stem starts its intensive growth, which leads to sharp decrease of relative content of these elements in dry substance as a result of “dilution” effect.

The one reason of increased intensity of selenium accumulation by the rye in ontogenesis in the course of our experiment was probably exhaustion of the soil in the culture pot as a consequence of absorption of most part of selenium from the soil at initial stages of the plant development. However, as computation shows selenium content in the soil after tillering stage decreased by 1-2%, while selenium concentration per gram of dry vegetating material decreased by 20%. Therefore, the reason of decreased intensity of selenium accumulation by the plants in vegetation process could not be only soil exhaustion with this microelement.

High selenium content in vegetating material at tillering stage was probably associated first of all with physiological functions of selenium. At tillering stage metabolic processes in nurslings are active resulting in intensive generation peroxides of hydrogen and organic molecules, by-products of many biochemical reactions. Hypothetically selenium microelement in plants, same as in mammal organisms, is an essential component of antioxidant system contributing to cell protection against destructive effect of active forms of oxygen. Antioxidant action of selenium may be explained by its influence on activity of glutathione-peroxidase – ferment having foremost significance in protection of plant cell from continuously generated hydroperoxides (Durán et al., 2016; Wu et al., 2017). Thus, intensive selenium accumulation by rye plants at tillering stage testifies to important role of this microelement for normal growth of rye especially at early stages of the plant development.

Assimilation of selenium by the plant is influenced by the physicochemical factors of the soil, such as redox status, pH and microbiological activity (Mehdi et al., 2013). In the present study the rye plant growing on less acidity soil accumulated more selenium. Increase of selenium content in the plants grown in less acid soil can be explained, on the one hand, by the fact that in the soil of high acidity anionic adsorption increases therefore most part of selenium is in absorbed condition, on the other hand, in case of low soil pH, hexavalent selenium is more prone to restorative process, and consequently in acid soil it is mostly in the form of selenite-ion which is not easily accessible for the plants. Lack of trustworthy difference in selenium intake by the plants depending on soil acidity in the case of small concentrations of the microelement is most probably conditioned by the fact that absorption and restorative processes insignificantly influence total pool of bioavailable selenium in the soil.

The study indicated that selenium predominantly accumulates in the grain, in comparison with the stem of rye. This result conforms to literary facts received earlier for winter wheat (Schulz et al., 1998). Selenium concentration in the grain was conditioned, most of all, by its physiological role in the plant, in particular, by selenium ability to substitute sulfur in most important amino acids (Sors et al., 2005; Reynolds et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_23852421

al., 2017; El Mehdawi, 2018). Moreover, predominant selenium accumulation in the ear may indirectly evidence necessity of this microelement. Such result is also of practical importance and should be taken into account when enriching cereals with selenium in order to increase selenium supply of animals and humans.

One of the peculiar features of selenium microelement is its dual nature, i.e. possible manifestation of both antioxidant and pro-oxidant features. Basic factor conditioning one or another selenium action is its concentration.

Positive effect of selenium on growth processes of the rye may be connected with its antioxidant features, i.e. ability to liquidate excessively accumulated free radicals. Thereupon excessive quantities of selenium, on the contrary, lead to intensification of generation processes of active oxygen forms. Some authors attribute positive effect of selenium on plant growth processes to its influence on hormonal status, in particular, under effect of sodium selenite increase of indoleacetic acid and decrease of abscisic acid were observed (Wang et al., 2018).

Negative effect of high concentrations of selenium on accumulation of biomass by the rye plants may also be attributed to substantial disturbance of the cell amino acid balance. Rye pertains to the plants of the 3rd group, i.e. plants not accumulating selenium, for which excessive substitution of cysteine or methionine in proteins by selenium-cysteine or selenium- methionine is particularly typical. At soil pH 5.4 selenium effect on the plant was more toxic. Toxic effect of selenium for the plants grown on more acid soil may be attributed to the fact that at this pH selenate-ion is more prone to restorative processes and may transform to selenite-ion form being more toxic for plants.

The influence of selenium on protein metabolism has been shown in this work. The content of the total protein was higher by the addition of selenium, in particular by increasing the proportion of globulins and glutelin. Earlier a number of authors also noted that the biological role of selenium in plants can be associated with its effect on the metabolism of nitrogen (Poluboyarinov and Golubkina, 2015; Reis et al., 2018).

Conclusions

The research shows that selenium is more intensively accumulated by the rye plants at initial stage of development, it is mainly concentrated in the plant's ear, and in small concentrations selenium exerts simulating effect on biomass accumulation. Thus, the findings certify to the important biological importance of selenium for growth and development of plants. However, mechanisms of protection effect of selenium in vegetative organisms remain unclarified. One of possible mechanisms of such effect is selenium antioxidant features which were proved in respect with humans and animals.

In addition, this study identified the optimum concentration of selenium supplements (0.01-0.05 mg Se kg^{-1} soil). By these concentrations not only increase of studied plants biomass, but also achieved the necessary level of selenium (100 μg g^{-1}) in cereals, which guarantees the security of this trace element humans and animals were observed. Thus, the data allow more fully uncover the function of this trace element in plants, and thus create the basis for the use of selenium-containing fertilizers is not only to increase the availability of selenium for humans and animals, but also to increase the productivity of crop production.

All pairwise multiple comparison procedures (Tukey Test):

Comparisons for factor:

Comparison	Diff of Means	p	q	P	P<0.050
pH 5.4 vs. pH 6.6	1.840	2	40.639	<0.001	Yes

One way analysis of variance

Data source: Tillering_0.5

Group Name	N	Missing	Mean	Std Dev	SEM
pH 5.4	4	0	56.800	0.700	0.350
pH 6.6	4	0	59.300	0.400	0.200

Source of Variation	DF	SS	MS	F	P
Between Groups	1	12.500	12.500	38.462	<0.001
Residual	6	1.950	0.325		
Total	7	14.450			

The differences in the mean values among the treatment groups are greater than would be expected by chance; there is a statistically significant difference (P = <0.001).

Power of performed test with alpha = 0.050: 0.999

All pairwise multiple comparison procedures (Tukey Test):

Comparisons for factor:

Comparison	Diff of Means	p	q	P	P<0.050
pH 5.4 vs. pH 6.6	2.500	2	8.771	0.001	Yes

One way analysis of variance

Data source: Booting_0

Group Name	N	Missing	Mean	Std Dev	SEM
pH 5.4	4	0	0.0480	0.00400	0.00200
pH 6.6	4	0	0.0510	0.00300	0.00150

Source of Variation	DF	SS	MS	F	P
Between Groups	1	0.0000180	0.0000180	1.440	0.275
Residual	6	0.0000750	0.0000125		
Total	7	0.0000930			

The differences in the mean values among the treatment groups are not great enough to exclude the possibility that the difference is due to random sampling variability; there is not a statistically significant difference (P = 0.275).

Power of performed test with alpha = 0.050: 0.084

The power of the performed test (0.084) is below the desired power of 0.800.
Less than desired power indicates you are less likely to detect a difference when one actually exists. Negative results should be interpreted cautiously.

Comparison	Diff of Means	p	q	P	P<0.050
0.01 vs. 0.5	0.0120	5	6.871	0.002	Yes
0.01 vs. 0.1	0.0110	5	6.299	0.004	Yes
0.01 vs. 0	0.0110	5	6.299	0.004	Yes
0.01 vs. 0.05	0.00500	5	2.863	0.302	No
0.05 vs. 0.5	0.00700	5	4.008	0.080	No
0.05 vs. 0.1	0.00600	5	3.436	0.161	Do Not Test
0.05 vs. 0	0.00600	5	3.436	0.161	Do Not Test
0 vs. 0.5	0.001000	5	0.573	0.994	Do Not Test
0 vs. 0.1	0.000	5	0.000	1.000	Do Not Test
0.1 vs. 0.5	0.001000	5	0.573	0.994	Do Not Test

A result of “Do Not Test” occurs for a comparison when no significant difference is found between two means that enclose that comparison. For example, if you had four means sorted in order, and found no difference between means 4 vs. 2, then you would not test 4 vs. 3 and 3 vs. 2, but still test 4 vs. 1 and 3 vs. 1 (4 vs. 3 and 3 vs. 2 are enclosed by 4 vs. 2: 4 3 2 1). Note that not testing the enclosed means is a procedural rule, and a result of Do Not Test should be treated as if there is no significant difference between the means, even though one may appear to exist.

0.01 vs. 0.1	0.1000	5	0.459	0.997	Do Not Test
0.1 vs. 0	1.400	5	6.424	0.003	Yes
0.1 vs. 0.5	0.200	5	0.918	0.964	Do Not Test
0.5 vs. 0	1.200	5	5.506	0.011	Yes

A result of “Do Not Test” occurs for a comparison when no significant difference is found between two means that enclose that comparison. For example, if you had four means sorted in order, and found no difference between means 4 vs. 2, then you would not test 4 vs. 3 and 3 vs. 2, but still test 4 vs. 1 and 3 vs. 1 (4 vs. 3 and 3 vs. 2 are enclosed by 4 vs. 2: 4 3 2 1). Note that not testing the enclosed means is a procedural rule, and a result of Do Not Test should be treated as if there is no significant difference between the means, even though one may appear to exist.

(Received 5th Oct 2018; accepted 2nd Jan 2019)

Abstract. The cities are also expanding with growth in construction rapidly, depending on the population growth. This development causes a lot of environmental problems. Pollution in water is one of the main problems and the aim of this paper is to evaluate water pollution in the study area. There are some statistical methods developed for the measurement and evaluation of water pollution; heavy metal pollution index (HPI) is one of them. Antalya is, one of the big cities in Turkey, also growing fast; population and settlement in this city are increasing quickly. That is why two streams, Duden and Goksu, are selected to measure the heavy metal pollution. The 24 water samples from Duden Stream and 18 water samples from Goksu Stream were taken systematically in June 2018 and were analyzed by using HPI. The heavy metals, from the highest value to the lowest one, were Sr > Fe > Al > Mn > As > Ni > Cu > Pb > Cr > Se in Duden Stream; and Sr > Fe > Al > Ni > As > Cu > Mn > Pb > Cr > Se in Goksu Stream. The Sr and Al values have exceeded the standard permissible values in both of the streams. The heavy metal pollution index (HPI) was used to evaluate the potential risk. Regarding quality the water samples have been classified as “good” and “poor”, generally. On the other hand, some water samples had heavy metal pollution above standards. Especially, the water of D15 - D19 - D20 and G13 samples were determined as “very poor” according to the standards. As a conclusion, the anthropogenic factors and urbanization may be the cause of the pollution. Living creatures that use water may have health problems and ecological equilibrium may be hampered in these stations. Groundwater may be contaminated in these areas. So, the urbanization needs to be done more carefully.
Keywords: *heavy metal pollution index (HPI), urbanization, statistics, surface water, environment*

Introduction

The urbanization may cause pollution. This question becomes much more important, especially in industrial areas. The quality of environment has been influenced by the diffusion of pollutants in air, water and soil in large areas. The accumulation of pollutants has disturbed the ecological equilibrium, in time (Stoica and Baiulescu, 2008). The reason of the heavy metal pollution in water could be natural or anthropogenic (Zarazua et al., 2006; Mehrabi et al., 2015; Sobhanardakani, 2016). Bhuiyan et al. (2015) reported “The heavy metal evaluation index (HEI) showed strong correlations and provided better assessment of pollution levels with HPI.”

Duden Stream flows in the Lara Region of Antalya Bay and it is an example for pollution (Erdem and Topkaya, 2004). According to Yardimci et al. (2005), the other example is Goksu Stream which is the main source of Bogacay River. It feeds Bogacay River. So, Goksu Stream affects the water quality of the Bogacay River and the water quality changes temporally; the critical level of water quality was determined in summer because of the recreational activities. Cengiz et al. (2017) also evaluated the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24232436

risk potential of metallic pollution in Bogacay River. According to this study, the samples from upstream showed lower risk potentials than those from downstream. Yalcin et al. (2016) also has investigated the contamination of the sediments by heavy metals along the banks of the Bogacay River. Demarco et al. (2018) and Uncumusaoglu et al. (2016) emphasized the importance of heavy metal pollution in streams in terms of environmental contamination and anthropogenic pollution. Besides, the heavy metal pollution in surface sediments has been also studied in the most recent papers (Ye et al., 2019; Sodrzeieski et al., 2018; Omwene et al., 2018).

Antalya, which is at the forefront of Turkey's major tourism centers and called the "Turkish Riviera", is quite rich in terms of water resources. The water is provided from underground waters. However, Antalya is located on tufa which has a karstic structure. Because of that, water moves frequently from the underground to the surface or from the surface to the underground. On the other hand, the population growth is remarkable in the 5th largest city of the country. Parallel to this, settlement areas are also expanding. The western part of the city is the best example of fast construction. The construction and also population growth continues on both sides of the city. Therefore, the protection of the existing water has become more important and the quality and/or quantity of water should be investigated to prevent pollution.

Although some studies have been made on this subject, no data has been obtained on heavy metal pollution in Duden and Goksu streams after the built-up and population growth. The surface water, which is coming out from the Kepez Hydroelectric Power Plant, reaches via two channels to the Mediterranean; one of them is Duden Falls in Lara tourist area, the other one is Bogacay River in Konyaalti district. However, the second one passes Goksu Stream before Bogacay River (Leventeli et al., 2017). In this study, heavy metal pollution in the surface water was investigated and analyzed statistical between Kepez Hydroelectric Power Plant and Duden Falls in Lara tourist area, called Duden Stream and also between Kepez Hydroelectric Power Plant and Bogacay River with Goksu Stream in Konyaalti district. The location map of the study area, including the sampling stations, is given in *Figure 1.*

Experimental

Study area

The study area is located in the city center of Antalya district which is one of the big cities in Turkey. The water which is coming out from the Kepez Hydroelectric Power Plant reaches via two channels to Mediterranean; one of them is Duden Falls in Lara tourist area, the other one is Goksu Stream with a part of the Bogacay River in Konyaalti district. There are agricultural, industrial and residential areas in the region.

Field sampling

The samples were collected from 42 locations in June 2018 based on morphological and land use properties of the study area. 1 L polythene containers are used for the collection according to standard procedures. Because of the dry season, surface water samples have been taken at this time. D in numbers of samples means "taken from Duden Stream", G means "taken from Goksu Stream". Goksu Stream has a 10.5 km length and Duden Stream has 28.5 km length. So, 24 samples were taken from Duden Stream and 18 samples from Goksu Stream. There are natural barriers like barbed wire,

DOI: http://dx.doi.org/10.15666/aeer/1702_24232436

morass, prohibited agricultural areas and so on. The long symbols show the stations of Duden Stream and the round symbols show the stations of Goksu Stream (see *Fig. 1*).

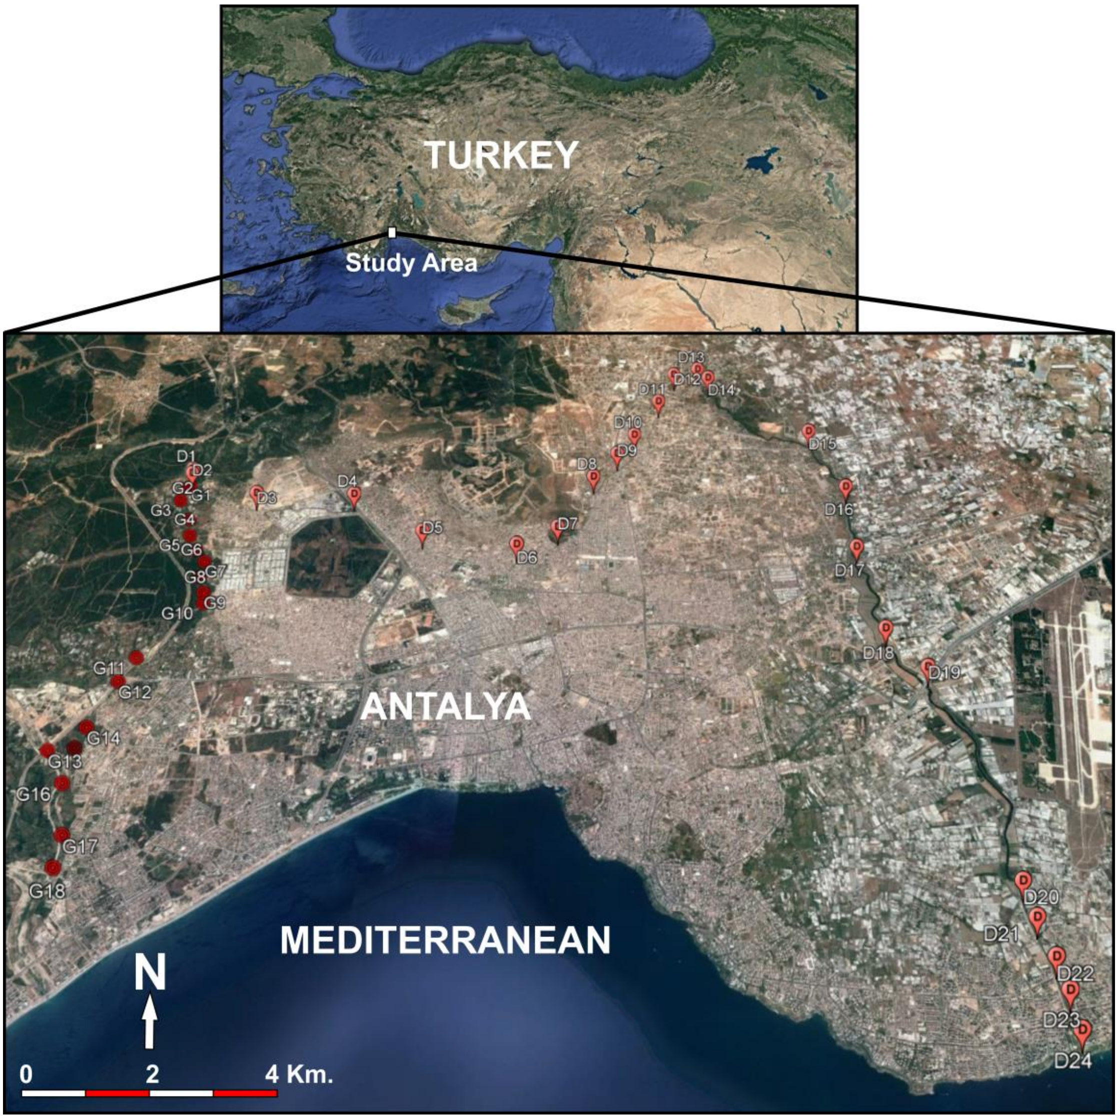

Figure 1. *The location map of the study area shows the sampling stations*

Laboratory methods

Preparation of samples

The experimental studies have been done in the Research Center Laboratory of Akdeniz University. Water samples acidified by adding 5 ml of nitric acid to 1 L polyethylene bottle ISOLAB mark tubes. The biological activities of microorganisms and bacteria that may be in the environment have been terminated in order to prevent the transformation of metals into other forms. The samples were kept in the refrigerator until analysis, and then they were filtered through the filter paper. 2 ml of nitric acid was added after pre-treatment to acidify the samples according to EPA 3005A (1992) method (Rohrbough et al., 1986; ASTM 1985). *Table 1* shows the device parameters of

Inductively Coupled Plasma – Mass Spectrometer (ICP-MS). A certified standard (SPS-SW2 surface water) was used to verify method trueness.

Table 1. *Device parameters of ICP-MS (Perkin Elmer Elan DRC-e)*

Read delay	Time (15), speed (+/- rpm)-20

Statistical methods and heavy metal pollution index (HPI)

The results of the analyses have been given below with calculations and also with assessments have been made using the Descriptive Analysis, Multivariate Statistics Analysis (Correlations, Principal Component, Component Matrix, Hierarchical Analysis) and Heavy Metal Pollution Index (HPI). Multivariate Statistics Analysis has been made using SPSS-23 software. Besides that, EXCEL 2016 software has been used for HPI calculations, according to similar works.

Results and discussions

Chemical data, statistical surveys

The water samples were taken at the same time from the streams to investigate the existence of iron (Fe), lead (Pb), arsenic (As), copper (Cu), manganese (Mn), nickel (Ni), aluminum (Al), cobalt (Co), strontium (Sr), chromium (Cr), selenium (Se), antimony (Sb), mercury (Hg) and cadmium (Cd) elements. The amount of heavy metal elements obtained is given in *Table 2* in ppb (µg / L). However; antimony (Sb), mercury (Hg) and cadmium (Cd) were not detected in any samples. Cobalt (Co) values were below reporting limit. Chromium (Cr) and selenium (Se) values were below reporting limit generally, excepting some samples; Cr values are 1.7 in G1, 2.5 in G2, 1.2 in G3, 4.7 in G9, 4.3 in G10, 2.1 in D12 and 2.9 in D13; Se values are 0.4 in G7, 0.5 G9, 0.3 G10, 2.1 in D12 and 2.9 in D13.

Descriptive statistics of metal concentration are presented in *Table 3*. The heavy metals were arranged from the highest value to the smallest one as Sr > Fe > Al > Mn > As > Ni > Cu > Pb > Cr > Se in Duden Stream. On the other hand, the order of the metal values from the highest value to the smallest one for Goksu Stream was as Sr > Fe

DOI: http://dx.doi.org/10.15666/aeer/1702_24232436

> Al > Ni > As > Cu > Mn > Pb > Cr > Se. Among these metals, the Sr and Al values have exceeded the standard permissible values in both of tributaries. The values of the other metals were far below standard values.

Significant correlation coefficients between 10 heavy metal behaviours in river water in 42 different stations are shown in *Table 4*. Positive correlation was determined between Pb and Fe, Cu, Ni; between As and Cr, Se; between Mn and Al; between Cr and Se in Duden Stream. The highest correlation between these metals was determined between Mn and Al (0.923 *). The positive high correlation between Mn and Al showed that their potential sources may be the same in Duden Stream. There is a positive correlation between As and Fe; between Mn and Al, Ni; between Cr and Se, between Al and Ni in Goksu Stream. High positive correlation between Mn and Al is determined (0.974 *). Besides, there is a high negative correlation relationship between As and Mn (-0.748*), As and Al (-0.715*) in Goksu Stream. These correlations showed that Mn and Al may be from the same source. However, it can be said that As has a different source than Mn and Al in Goksu Stream.

According to the total variance of heavy metal content, the statistical evaluation of the chemical analysis results was high and calculated as 79.460 % (*Table 5*). The explained total variance analysis is evaluated in two parts. One of them is “Initial Eigenvalues”; the other one is “Extraction Sums of Squared Loadings”. The percentage of explanations of each factor is given in order; the cumulatively highest value gives percentage of explanations of the used data. The numerical data of this ratio, which reaches 100, explain its explanatory rate. Therefore, the cumulative value obtained as 79.460% was stated to be high in the factor analyzes of the article. A total of 4 factors were determined by factor analysis. The first factor was explained by Al, Mn, Ni, Pb. The second, third and fourth factors were respectively represented by Cu, As and Fe (*Table 6*). Factors indicate possible sources. Metals within the same factor can be of similar origin in the first factor except other factors.

From the results of the hierarchical analysis, it is understood that three groups were formed among locations (*Fig. 2*). The first group of locations includes 28, 29 and 15 numbers. The second group of locations includes 1, 24 and 23 numbers. The third one includes total of the all numbers. These groups show similarities between the locations Excessive differences between locations show the excess of natural and anthropogenic factors acting on the streams. The analysis results are consistent with factor analysis and with the Principal Component Analysis.

Heavy metal pollution index (HPI)

The pollution indexes are used to estimate the pollution of the water. Generally, heavy metal pollution index (HPI), heavy metal evaluation index (HEI) and degree of contamination (*Cd*) are used to evaluate water for drinking as well as irrigation purposes (Brraich and Jangu, 2015). Mehrabi et al. (2015) have also used heavy metal pollution index (HPI) to evaluate the level of contamination both in groundwater and in soil in Ahangaran mining area, Iran. They reported that HPI values were less than the critical index limit. Bhuiyan et al. (2015) have studied in Buriganga River, Bangladesh. The results showed that most of the samples exceeded the critical limit and "the intensity of pollution gradually decreased from the source to the downstream part of the river". Yang et al. (2015) have studied during the period 2008-2012 to understand the contamination in terms of heavy metal pollution and also used HPI for that. They had the following result: "The general trend of reduction in HPI appears not to have a seasonal variation and most likely resulted from the continued improvement in heavy metal pollution control strategies implemented by local environmental, agencies combined with a significant improvement in wastewater treatment capacities."

Prasad and Bose (2001) proposed the heavy metal pollution index (HPI) (Nasrabadi, 2015). The analysis results were interpreted based on these papers, in this study. Based on the weighted arithmetic average method, HPI shows the total quality of water compared to heavy metals (Horton, 1965; Mohan et al., 1996). The Heavy Metal Pollution Index (HPI) and the sub-index of each parameter (Qi) are calculated using the following correlations (*Eq. 1*).

$$Q_i = \sum_{i=1}^{n} \frac{(M_i - I_i)}{(S_i - I_i)} \text{x}100 \qquad HPI = \frac{\sum_{i=1}^{n} W_i Q_i}{\sum_{i=1}^{n} W_i} \tag{Eq.1}$$

Wi is the unit weight of the i-th parameter, and Qi is the sub-index of the i-th parameter. n is the number of parameters considered. Mi is the measured value of the parameter i. Ii and Si give the ideal and standard values of the i-th parameter. The HPI calculations are shown in *Table 7*. The average of HPI is 80.38833 for Duden Stream, 60.13997 for Goksu Stream. The graphical representations of the results are presented in *Table 8* with heavy metal pollution index (HPI) values. All values, except values of D15 - D19 - D20 - G13 samples, are below the 100.

Figure 3 shows the distribution of the heavy metal pollution index (HPI) values at the stations in the study area. The critical pollution index value is 100; this and above this value should be considered unacceptable (Prasad and Kumari, 2008; Prasad and Mondal, 2008; Reza and Singh, 2010; Ojekunle et al., 2016). According to Sirajudeen et al. (2014) the status categories of HPI are given in *Table 9*. According to the table there is no water in "very good" category. 14 water samples have been classified as "good" (D1 - D2 - D11 - D14 - D21 - G1 - G3 - G7 - G8 - G11 - G12 - G14 - G15 - G17); 20 water samples as "poor" (D3 - D4 - D5 - D7 - D8 - D10 - D12 - D13 - D16 - D18 - D22 - D23 - G2 - G4 - G5 - G6 - G9 - G10 - G16 - G18) and 8 water samples as "very poor (unsuitable for drinking)" (D6 - D9 - **D15 -** D17 - **D19** - **D20 -** D24 - **G13**). The HPI values of D15 - D19 - D20 and G13 samples were well above the limit.

The high HPI values were due to industrial waste waters, domestic sewage and landfill leachate (Milivojevic et al., 2016).

0-25	Very good	---
26-50	Good	D1, D2, D11, D14, D21, G1, G3, G7, G8, G11, G12, G14, G15, G17
51-75	Poor	D3, D4, D5, D7, D8, D10, D12, D13, D16, D18, D22, D23, G2, G4, G5, G6, G9, G10, G16, G18
Above 75	Very poor (unsuitable for drinking)	D6, D9, **D15**, D17, **D19**, **D20**, D24, **G13**

Conclusions

The metal pollution ratio between the Kepez Hydroelectric Power Plant and the Karpuzkaldiran waterfall, which is defined as the “Lower Duden of the Duden Stream” in Lara and also surface water between Kepez Hydroelectric Power Plant and Bogacay River in Konyaaltı district, named Goksu Stream, were investigated using the HPI method. Firstly, aluminum (Al), lead (Pb), arsenic (As), copper (Cu), manganese (Mn), iron (Fe), nickel (Ni), cobalt (Co), strontium (Sr), chromium (Cr), selenium (Se), antimony (Sb), mercury (Hg) and cadmium (Cd) elements were investigated. Antimony (Sb), cadmium (Cd) and mercury (Hg) were undetectable and cobalt (Co) remained below the reporting limit.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24232436

The mean values of aluminum (Al) and strontium (Sr) concentrations exceeded the permitted standard values, while the concentration of other metals remained well below the permissible standard, according to the descriptive statistics of the metal concentration of Duden Stream. When the relations between 10 heavy metal behaviours in stream water in 24 different stations were examined by multivariate analyses; the correlation between Cu and Pb, Fe and Pb, Ni and Pb, As and Cr, As and Se, Mn and metals were positively correlated, respectively, Cr and Sr have the same values and are highly correlated. The HPI critical value is set at 100 according to the literature. Accordingly, it has been determined that the calculated HPI value in water samples D15, D19 and D20 is well above the predicted critical value. The HPI value was consistent with multivariate statistical analyses.

4 factors influenced to the streams at high level with 79.460%. This value shows that the data used in the statistical analyzes are sufficient to explain the factors. The cumulative value calculated by SPSS shows that the percentage of explanations is high and adequate for 4 different factors.

The chemical similarities between the sampling stations show that there are 3 different locations in the region. According to the hierarchical analysis; 28, 29 and 15 samples have formed their dendrogram among themselves; 1, 24 and 23 samples have formed their dendrogram among themselves and all remaining samples have formed their dendrogram among themselves. The main reason of this grouping is the natural and anthropogenic effects.

The Goksu samples, according to the descriptive statistics of the metal concentration of the surface water, only the mean values of the concentration of strontium (Sr) exceeded the allowable standard values, while the concentration of other metals was far below the permissible standard. When the relationship between 10 heavy metal behaviours in stream water at 18 different stations was examined, it was found that there was a positive correlation between As and Fe, As and Mn, As and Al, Mn and Al, Mn and Ni, Al and Ni, Cr and Se metals respectively. It has been determined that the calculated HPI value in the case of water number G13 is above the predicted critical value.

There is no water in “very good” category. 14 water samples have been classified as “good” 20 water samples as “poor” and 8 water samples as “very poor (unsuitable for drinking)”. The HPI values of D15, D19, D20 and G13 samples were well above the limit. So, it is understood that the main source of pollution is anthropogenic.

Abstract. This study was carried out in order to determine the enzyme activity of the wood vinegar obtained from the hazelnut shells with the potential of bio-pesticide in agro-ecosystem soil, and its effect on the microfungi and heterotrophic bacteria in total. The study was realized in the production seasons of 2014-2015 and 2015-2016, in the ecological conditions of the province Muş (in Turkey) on winter wheat field and with four repetitions according to Randomized Blocks Experimental Design. The treatments within the scope of the experiment were conducted as the six different doses of wood vinegar at 0.5%, 1.0%, 2.0%, 3.0%, 4.0%, and 5.0% mL, and the control treatment which was only provided with tap water. Repeated Measurement ANOVA was used to determine the effect of wood vinegar at different doses, the production seasons and periods (pre- and post-treatment) on relevant features. As based on the statistical inferences, only the Treatment × Year and Period × Year interaction effects in terms of the number of heterotrophic bacteria ($P = 0.000$ and $P = 0.011$); and only the Period × Year interaction effects for the number of microfungi ($P = 0.000$) were found statistically significant. Therefore, the effect of the treatments made on the number of heterotrophic bacteria varied by the production seasons. In a similar way, the effect of the production season and periods on the number of microfungi also changed as based on the term. While the effect of period ($P = 0.000$) and the Treatment × Period interaction ($P = 0.014$) effect were significant for Alkaline Phosphatase activity, Year × Period ($P = 0.001$) and Treatment × Period interactions ($P = 0.000$) were found significant as related to Beta Glucosidase activity. In conclusion, it may be stated that the wood vinegar used at different doses with the purpose of protecting plant and/or crop in wheat agro-ecosystem does not have a negative effect on microbial factors determined in the soil, and especially, the treatment of 3% mL has a positive effect on bacteria number and Beta Glucosidase enzyme activity.
Keywords: *agroecosystem, heterotrophic bacteria, microfungi, soil enzyme activities, wood vinegar*

Introduction

The primary objective of agricultural practices is to obtain abundant and high-quality crops without disturbing ecological balances (Topal, 2011). Within the scope of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24372447

sustainable plant protection studies, herbal products may have a considerable part as stabilizer for synthetic pesticides or effecting the actions of synthetic pesticides in soil (Hagner, 2013). In the production of herbal pesticides, a variety of plants and various technologies have been used (Tiilikkala et al., 2011). Wood vinegar (WV) and other weak pyrolysis liquids are produced as a by-product of carbonization processes, and in the archeological studies carried out so far, it has already been detected that they were used in the Neanderthal's era (Tiilikkala et al., 2010). WV consists of water by 80-90% and the rest amount is of more than 200 organic compounds (Kim et al., 2008). The main components of WV are acetic acid and also organic acids, phenolic, alkane, alcohol and ester compounds (Jothityangkoon et al., 2008). WV is a substance that is toxic or slightly toxic to the non-target organisms in water and soil (Hagner, 2013). It has been detected that WV obtained from *Vitex pubescens* displayed antifungal effect (Orahami and Yoshimura, 2013). Baimark and Niamsa (2009) stated that WV could restrain the growth of fungus, as its involving strong phenolic compounds. Velmurugan et al. (2009) found out that the neutralized WV showed a strong antifungal effect. Jothityangkoon et al. (2008) detected that the contamination decreased, in their studies for the effect of WV on fungi producing aflatoxine. Namlı et al. (2014) stated that the case in which WV is treated as biocide in in-vivo conditions would provide beneficial outcomes, in accordance with the data they have already obtained in in-vitro conditions. Orahami et al. (2018) indicated in their studies that WV has had antifungal effect. Eric et al. (2012) stated that distilled and non-distilled WV had inhibited the bacteria. WV can activate the edaphon number in a short time and at maximum, and also has a promoting role in increasing the number of bacteria especially in the root parts of vegetables (Shi, 2003). Duan et al. (2016) put forth that the four types of WV, which they had involved in their studies, had a strong blocking effect on three sorts of bacteria. In plant protection activities, WV stands for a promising solution in terms of preventing the growth of pathogenic bacteria and fungi (Chalermsan and Peerapan, 2009). Lee et al. (2010), in their studies, pointed out that WV had a strong antimicrobial effect. Additionally, it was stated that the applied WV treatments had increased the phosphatase, protease, urease and invertase enzyme activities (Aleandri et al., 2012). It was also observed that the WV application at different concentration in sandy soil created an effect on microbial biomass and enzyme activity (β-Glucosidase, alkaline phosphatase and dehydrogenase) (Du et al., 2016). Koç et al. (2018) detected that WV was promising in increasing the enzyme activities in some of its applications. We consider that the determination of the most effective and appropriate WV dose is a highly important issue for plant protection activities. In this way, to maintain a pest control process without using any chemical substance will become possible. The objective in this research is to determine the effect of the wood vinegar obtained by means of the carbonization of hazelnut shells in the potential of bio-pesticide on alkaline phosphatase and beta glucosidase enzyme activities, bacteria and microfungi populations in agro-ecosystem soil.

Materials and methods

This study has been carried out in Krasunia odeska wheat field that belongs to BERCE Alparslan Agricultural Administration (height: 1276, lateral: 380 47' 33. 1815", long: 410 32' 45. 700") located at a distance of 12 km to the central part of the province Muş (in Turkey) (*Fig. 1*). The study was made in accordance with the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24372447

Randomized Block Design and with four repetitions. Each parcel in experiment has the size of 25 m^2 and at least a 2-m-gap was spaced out between blocks and parcels (Anonymous, 2016a). The treatments made in the experiment was realized in the way of six different doses of WV at 0.5%, 1.0%, 2.0%, 3.0%, 4.0% and 5.0% mL, and the control provided with tap water only. WV treatments were carried out as to the schedule for fertilizing and agricultural spraying by BERCE Alparslan Agricultural Administration. Treatments were made by means of 16 L backpack sprayer (AnadoluPower APW-16, mode of operation: mechanical/operating by side pressing, filling chamber with filter, having an internal tank stirrer, can spray the liquid up to a maximum distance of 4 m, with an adjustable nozzle at 4 different types, 2.70 kg in weight). The classification by the texture of soil in the experimental area is argillaceous soil with the rate of clay by 63.29%, silt ratio by 25.8% and sand ratio by 10.9% (Koç, 2017). The climatic data of the research area, respectively, the 1st year (2014-2015), the 2nd year (2015-2016) and areal precipitation, average temperature and average relative humidity values of the last decade (long period average) were presented in *Table 1* (Anonymous, 2016b).

Wood vinegar (WV) used in this study has been supplied from an establishment developing bio-coal and wood vinegar products by the gasifier of hazelnut shells (Namlı et al., 2014). Wheat seeds were sown by No-Till method. Inputs used in the treatment: bottom fertilizer (NP 20-20-0, 13.700 g/da) upon sowing on the 16th October of 2014 and height fertilizer in bolting period (46% urea, 10 kg/ha^{-1}) were applied. Furthermore, on the 26th May of 2015, to the parcels for which WV was applied, WV at different doses and to the control parcels only tap water was applied. Upon sowing, on the 12th September of 2015, bottom fertilizer (NP 20-20-0, 13.7 kg/ha^{-1}) and height fertilizer in bolting period (46% urea, 10 kg/ha^{-1}) were applied. Moreover, to the parcels which WV was applied on the dates of April 24th, April 30th, May 8th and June 6th, 2016, WV application at different doses was performed and the control parcels were provided with only tap water. The average humidity (%) content of soil samples in the experimental area was detected (*Table 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24372447

Table 2. *Average amount of moisture (%), according to production seasons in the experimental area*

Years	Sample time	Average moisture (%)
2014-2015	19.05.2015	24.90
	25.06.2015	19.60
2015-2016	21.04.2016	27.97
	25.06.2016	16.27

Soil sampling process involved the soil samples obtained from 8 different parts of each parcel (Yardım, 1996) by means of nematode sampling instrument (from a depth of 10 to 30 cm), and those samples taken were blended well to be aggregated. Samples were collected in sterile polyethylene nylon bags and preserved at +4 °C in the laboratory for further analysis. Treatments were realized once in 2014-2015 and four times in 2015-2016. The determination of humidity percentage in soil samples according to Craze (1990), the detection of total number of microfungi and bacteria according to Benson (2001), and the determination of Beta-glucosidase and Alkaline phosphatase enzyme activities were done according to Naseby et al. (1997). Repeated Measurement ANOVA has been used in analyzing data sets. Analysis results have presented as graphically (*Figs. 2–8*). All statistical analyses have been performed by using IBM SPSS (Ver. 24).

Statistical model used for analyzing data set was:

$$Yijkl = \mu + \alpha i + \beta j + \alpha\beta ij + \pi l(ij) + \gamma k + \alpha\gamma ik + \beta\gamma jk + \alpha\beta\gamma ijk + \gamma\pi kl(ij) + \varepsilon m(ijkl)$$

Yijkl: observed value for the number of heterotrophic bacteria, the number of microfungi and enzyme activity in k period of lth experimental unit of jth year in the ith treatment,
μ: overall population mean,
αi: effects of ith treatment (i = 1, 2, 3, …,7),
βj: effects of jth year (j = 1, 2),
αβij: treatment by year interaction,
π l(ij): random effect of the experimental unit l in ith treatment and jth year,
γk: effect of k th period (k = 1 = before, k = 2 after),
αγik: treatment by period interaction,
βγjk: year by period interaction,
αβγijk: treatment × year × period interaction,
γπkl(ij): experimental unit l by period interaction in ith treatment and jth year,
ε m(ijkl): random error term (Mendeş, 2013).

Results and discussion

Repeated Measurement ANOVA has been used for investigating effect of WV applications on the number of heterotrophic bacteria, the number of microfungi and enzyme activity (Winer et al., 1971; Mendeş, 2013). And the results of the Repeated Measurement ANOVA have been presented below:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24372447

Effect of wood vinegar treatments on the number of heterotrophic bacteria

As based on the repeated measurement ANOVA results, only Treatment × Year and Period × Year interaction effects have been found statistically significant (P = 0.000 and P = 0.011). Therefore, the effects of treatments on heterotrophic bacteria have varied by years (2014-2015 and 2015-2016). Similarly, on the basis of period (pre- and post-treatment), the effect of year on heterotrophic bacteria have also differed. Treatment × Year and Period × Year interaction have been presented in *Figures 2* and *3,* respectively. As is seen in *Figure 2,* it has been determined that WV is effective in the treatments for 2014-2015 in terms of the decrease in heterotrophic bacteria, and however, there have been great differences in the case for 2015-2016.

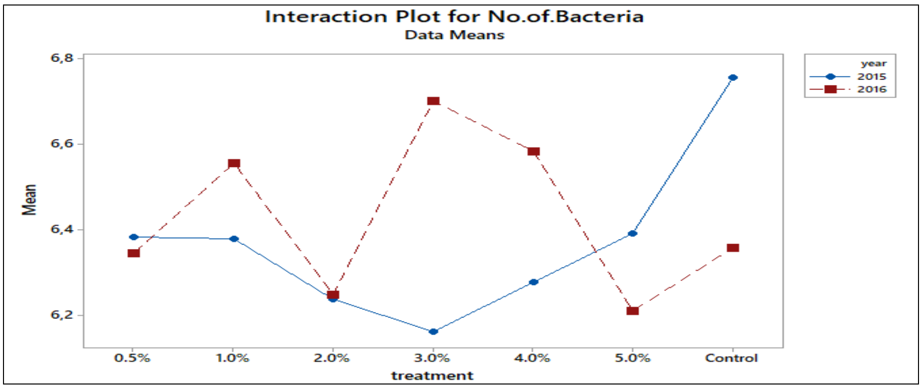

Figure 2. *Interaction plot for treatment by year in terms of number of heterotrophic bacteria*

When the Period × Year interaction plot is analyzed (*Fig. 3*), it is seen that the number of bacteria before the treatment in 2014-2015 is a bit more than the number of bacteria after the treatment. On the other hand, it can be observed that the post-treatment bacteria number in 2015-2016 is considerably more than the number for pre-treatment.

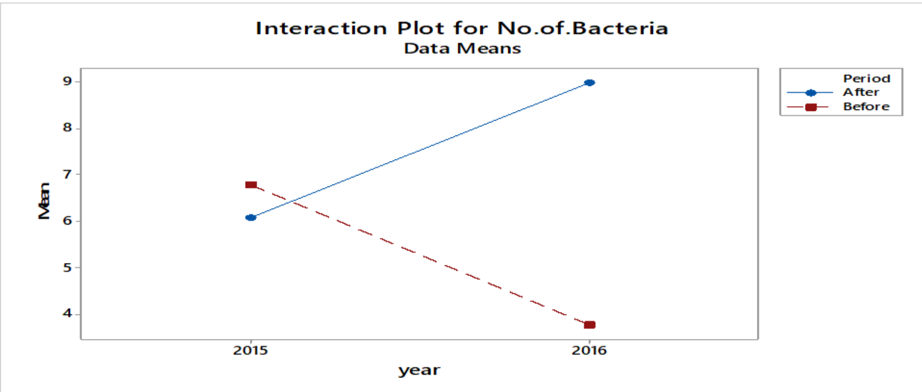

Figure 3. *Interaction plot for period by year in terms of number of heterotrophic bacteria*

Effect of wood vinegar treatments on the number of microfungi

Based on the Repeated Measurement ANOVA results, it has been seen that the only Period × Year interaction effect is statistically significant (P = 0.000). For this reason,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24372447

the effect of year on the number of microfungi has varied by the period (before and after treatment). The Period × Year interaction plot is given in *Figure 4*. As it is seen in this plot, microfungi number in 2014-2015 is rather more, when compared to the period by 2015-2016, independently of treatment number. It is realized that the number of microfungi after treatment in 2015-2016 is greater than it is in 2014-2015.

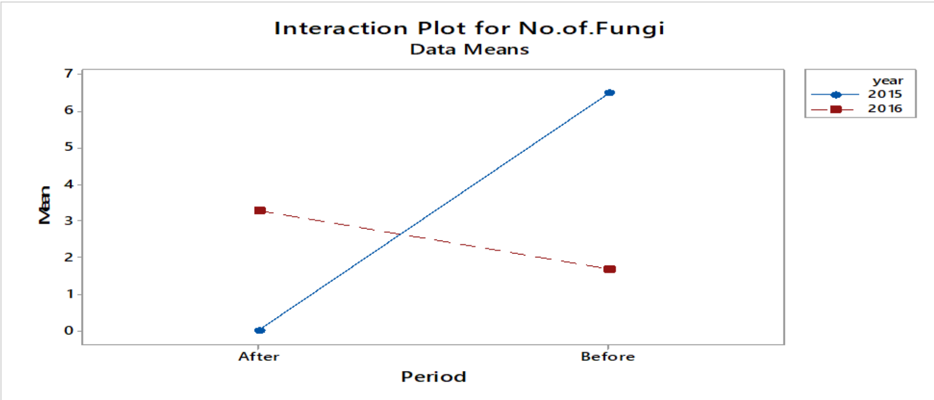

Figure 4. *Interaction plot for period by year in terms of number of microfungi*

Effect of wood vinegar treatments on enzyme activity

Considering the results of statistical analysis, it has been seen that the period effect (P = 0.000) and Treatment × Period interaction (P = 0.014) is significant. Therefore, the effects of treatments on Alkaline Phosphatase activity have varied by period (before and after treatment). Main effect plot for period and Treatment × Period Interaction plot are provided in *Figures 5* and *6,* respectively.

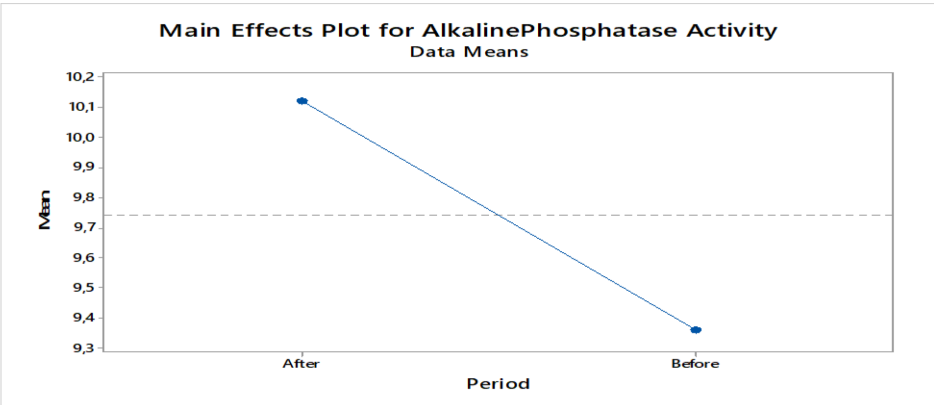

Figure 5. *Main effect plot for period in terms of alkaline phosphatase activity*

As it can be seen in *Figure 5,* the value of Alkaline Phosphatase activity after treatment is significantly higher than before treatment, independently of year and treatments. Treatment × Year interaction effect plot is given in *Figure 6*. When *Figure 6* is considered, the value of Alkaline Phosphatase activity has varied by treatments and years. However, the Alkaline Phosphatase activity at maximum is gained from the WV treatment of 1.0% mL, in 2014-2015. For 2015-2016, the highest value was obtained

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24372447

from the control treatment. As the reason for these results, it has been estimated that the case may be based on the extent, namely the highest, of WV doses used.

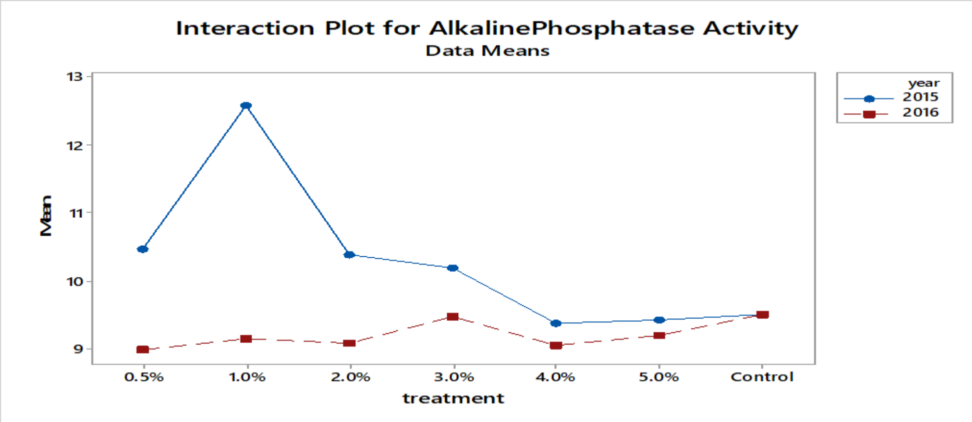

Figure 6. *Interaction plot for treatment by year in terms of alkaline phosphatase*

ANOVA results as related to Beta Glucosidase activity have revealed that Year × Period (P = 0.001) and Treatment × Period interactions (P = 0.000) are statistically significant. Therefore, the effect of year and treatments on Beta Glucosidase activity has varied by period (before and after treatment). Interaction plots for Year × Period and Treatment × Period are presented, respectively, in *Figures 7* and *8*. As it can be seen in *Figure 7,* the difference between pre-treatment and post-treatment is rather obvious, especially in 2015-2016.

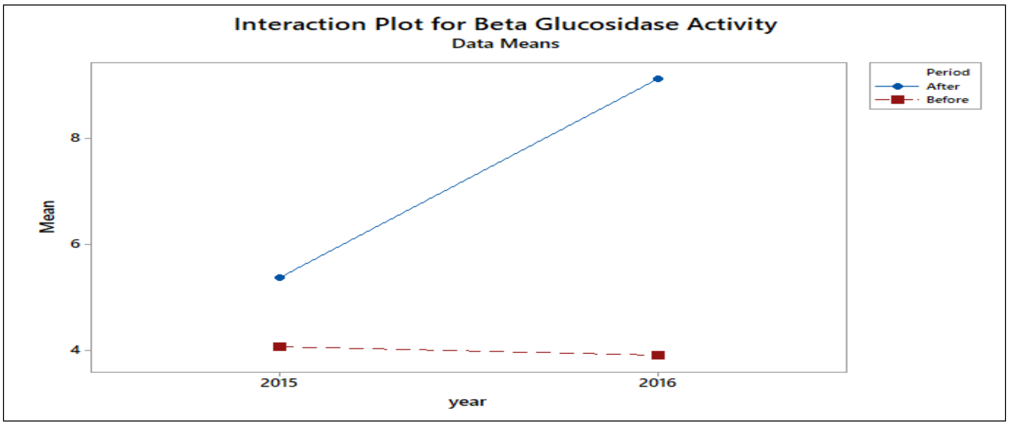

Figure 7. *Interaction plot for period by year in terms of beta glucosidase activity*

When the effect of treatments on Beta Glucosidase activity is considered (*Fig. 8*), it is seen that Beta Glucosidase activity has varied by treatment and years. In addition to this, while the highest value of Beta Glucosidase activity has been gained from the 3.0% mL treatment for the year 2014-2015, the maximum value for Beta Glucosidase activity has been received in the control treatment for 2015-2016. This result, as is in Alkaline Phosphatase activity, is thought to be arisen from that WV doses have been applied at higher levels, as well.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24372447

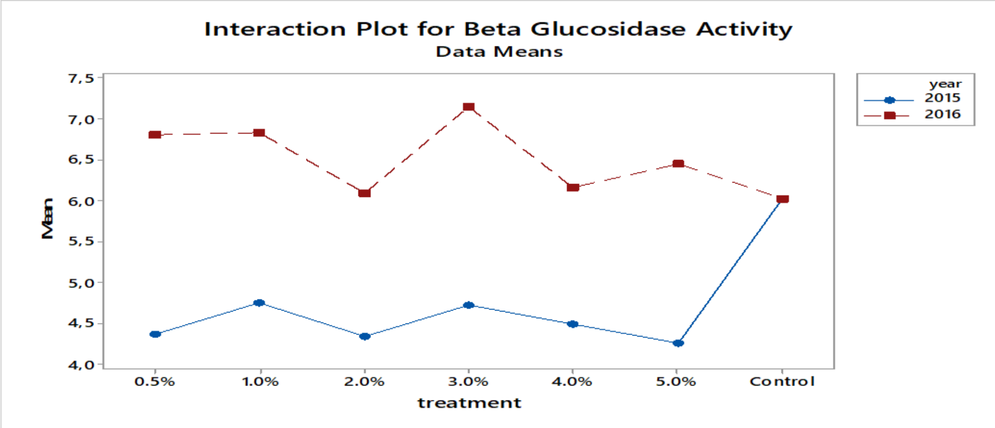

Figure 8. *Interaction plot for treatment by year in terms of beta glucosidase*

The utilization of bio-pesticides in agricultural practices as an alternative to the common pesticides is essential with regard to secure food, preservation of biological diversity and prevention of environmental pollution. In this study, the probable effect of wood vinegar obtained from the carbonization of hazelnut shells having the bio-pesticide potential on some microbial factors in agro-ecosystem soil has been investigated. It is realized that the findings reached at within the scope of this study are supported by the results of some similar studies that have been carried out before. For instance, the obtained findings as being relevant to the number of heterotrophic bacteria share similarity with the results in Shi (2003); however, it has been detected that they indicate some differences compared to the studies carried out by Nurhayati et al. (2005), Chalermsan and Peerapan (2009), Mao et al. (2010), Eric et al. (2012) and Duan et al. (2016). It has been thought that these differences may result from the changes related to the specific conditions, like climatic conditions, in the experimental area. When considered in terms of microfungi, especially in the production season of 2014-2015, it has been determined that WV treatments have effect on the decrease in the number of microfungi. Also, it has been noticed that the results similar to these findings have already been reached in the studies by Jothityangkoon et al. (2008), Baimark et al. (2008), Baimark and Niamsa (2009), Chalermsan and Peerapan (2009), Velmurugan et al. (2009), Lee et al. (2010), Ibrahim et al. (2013), Oramahi and Yoshimura (2013), Saberi et al. (2013), Namlı et al. (2014), Chuaboon et al. (2016), Ahadiyat et al. (2018) and Oramahi et al. (2018). It has been observed that the effect of WV treatments applied in this study on the enzyme activities (Alkaline phosphatase and Beta-glucosidase) varies according to before and after treatment. However, it is understood that the enzyme activities generally increase after WV treatments, and similar results have also revealed in the studies by Aleandri et al. (2012) and Koç et al. (2018). It can be said that WV treatments will be able to affect microbial biomass, as based on the findings obtained from this study, as Du et al. (2016) and Rui et al. (2014) stated before in their researches.

Conclusion

Pesticides which are widely used in agricultural practices harm the food safety and/or security, environment, biological diversity and biological chain. This issue affects soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24372447

productivity and human health in a serious and negative way, and these negative effects become more prominent in time. In accordance with the 2009/128/EC Framework Directives, the usage of pesticides must be minimized, and primarily the low-risk pesticides like bio-pesticides must be taken into consideration. Wood vinegar is a product which has a very low environmental risk and can quickly decay in the soil as a result of microbial activities. At this point, we consider that wood vinegar can be used as a bio-pesticide, i.e. as an alternative to the pesticides. In this study, it has been detected whether wood vinegar used in wheat agricultural eco-system has a negative effect on microbial factors determined in the soil, or not. As based on this, it can be put forth that wood vinegar will be able to be used securely as a pesticide. Additionally, the increase in enzyme activities and productivity may indicate that using WV practically is able to create a positive effect in crop production. Considering wood vinegar treatments, it can be stated that especially its doses and use frequencies have an effect on the microbial factors in soil. It is estimated that the dose of 3.0% mL will especially create a positive effect on the number and activity of biological factors in soil, in general.

Abstract. Fuzzy expert systems search for a solution based on the expertise of people who are experts in a particular field. This could be described as a kind of advisory system edited on computer. The use of natural language on the basis of fuzzy logic and easier understanding of system logs provide this technique to resolve many daily and current problems. In this study, a sample expert system to estimate juice volume in pomegranate was designed, using the fuzzy logic method, which closest to the logic of the human mindset. Recording of data was performed on the private farm of the province of Siirt, Turkey. The Fuzzy Logic Interface of MATLAB Program was used in the designing phase of the system. The evaluation of the model was carried out according to coefficient of determination and coefficient of correlation. The model revealed R^2 = 80% coefficient of determination, and r = 0.89 coefficient of correlation. With more informative parameters, the error rate can be decreased. Fuzzy logic seems one of the useful tools with prediction purposes in horticulture.
Keywords: *fuzzy expert system, Punica granatum L. cv. Zivzik, juice volume, fruit size, irrigation*

Introduction

Pomegranate (*Punica granatum* L.) is a tropical and subtropical fruit species, in the cultivation of which India, Iran and China are the top ranking in the world, followed by Turkey and USA. The annual production of pomegranate cultivation is over 100,000 tons in Turkey, which is available in 48 provinces of the country. Pomegranate is a perennial and drought-tolerant plant. Arid and semiarid zones are popular for growing pomegranate trees (Asgary et al., 2014). The flowering and fruit setting period varies according to low or high altitude conditions. This particularly affects the early or late opening of flowers. It is indicated that the colors and sizes are not normal due to the inadequate temperatures (Onur, 1988; El-Sese, 1988). Pomegranate juice is a good source of fructose, sucrose, and glucose. It also has some of the simple organic acids such as ascorbic acid, citric acid, fumaric acid, and malic acid (Asgary et al., 2014). Morever it is a polyphenol-rich fruit juice with a high antioxidant capacity. This fruit can help preventing or treating several cardiovascular risk factors including hypertension, hypercholesterolemia, oxidative stress, hyperglycemia, and inflammation (Chong et al., 2010; Wang et al., 2014; Sahebkar et al., 2017).

Agricultural production is a complex system requiring knowledge and information from many diverse sources. Agricultural specialist assistance is not always available for the farmer who needs it. In order to support the farmer expert systems were identified as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24492460

a powerful tool with extensive potential in agriculture (Prasad and Vinaya Babu, 2006; Dath and Balakrishnan, 2013; Kolhe and Gupta, 2014).

During the last five decades, the potential of electronic data processing has been used to an increasing degree to support human decision making in different ways. Since the late 1970s and early 1980s decision support systems found their way into management and engineering. Evaluation, diagnosis, prediction could be classified as decision support systems. Even though fuzzy set theory can be used in all three "prototypes" we shall concentrate on "expert systems" only because the need and problem of managing uncertainty of many kinds is most apparent there; hence, the application of fuzzy set theory is most promising and advanced. In operations research the modeling of problems is normally being done by the OR-specialist. The user then provides input data and the mathematical model provides the solution to the problem by means of algorithms selected by the OR-specialist (Zimmermann, 2001). While the typical OR-model or software package normally supports the expert, an expert system is supposed to model an expert and make his expert knowledge available to non-experts for purposes of decision making, consulting, diagnosis, learning, or research (Konopasek and Jayaraman, 1984).

The most relevant approaches of fuzzy expert system (FES) in horticulture is fruit sorting and grading system (May and Amaran, 2011; Nandi et al., 2012; Razak et al., 2012; Teoh et al., 2013; Hasan et al., 2014; Suksawat and Komkum, 2015; Nandi et al., 2016); fruit counting (Kumar et al., 2017; Qureshi et al., 2017), plant watering management (Ge et al., 2013; Ying et al., 2017), plant yield prediction (Srinivasan et al., 2009; Papageorgiou et al., 2013). Brotons et al. (2017) in their study tried to find relation between pomegranate maturity index with to solar net radiation by means of fuzzy approach. As a result of the study, they reported the possibility of prediction the most likely date from which the fruit will be ready for harvest, for a given latitude.

The main purpose of this study was to introduce fuzzy expert systems in estimating the juice volume without requiring any laboratory work by using the pomegranate features such as different harvest time, irrigation amounts, and fruit size.

Materials and methods

Plant material

The plant material of the study is pomegranate (*Punica granatum* L.) cv. Zivzik, obtained from an 8 year-old orchard located at 37° 57’ 17” Northern and 41° 51’ 07” Eastern coordinates, in Kezer region of the Central district of Siirt, Turkey (*Fig. 1*). Experiment was settled with 3 replications according to the design of random blocks.

The irrigation in pomegranate cultivation is one of the important parameters and therefore we have considered it as one of the input parameters. The amount of irrigation water was designed based on the fact that 50%, 75% and 100% of the open water surface evaporation values, obtained from the experimental area, were applied as irrigation water when they reached 80 mm and 120 mm (Aydın et al., 2017). The amounts of irrigation water applied to the treatments were between 292.6 mm (50%), 438.8 mm (75%) and 585.2 mm (100%). In the experiment, during the 4 weeks from the middle of October to the beginning of November, five fruit samples from each Zivzik pomegranate tree were taken weekly and their physical and chemical properties were examined.

DOI: http://dx.doi.org/10.15666/aeer/1702_24492460

***Figure 1.** Zivzik variety of pomegranate: fruit and orchard*

Much of human knowledge is a collection of rules and facts which, for the most part are neither totally certain, nor totally consistent, the storage of these vague and uncertain portions of knowledge by using fuzzy sets seems much more appropriate than the use of crisp concepts and symbolism, "management of uncertainty" of human thinking, when modeled in expert systems, might also increase efficiency, that is, decrease answering time (Zadeh, 1983; Zimmermann, 2001).

The fruit samples used were harvested respectively on October 16, October 23, October 31, and November 6, 2015. The fruits were determined in terms of fruit weight, fruit length, fruit width, aril yield (%), fruit juice ratio, total soluble solids (%), titrable acidity (%), TSS / TA and aril color. Pomological analyzes of these samples were carried out in the laboratory of Siirt University. Fruit size (FS) trait from the analyzed pomological characteristics was used in the prediction.

Fuzzy logic based expert system

An expert system is a computer program that solves problems that heretofore required significant human expertise by using explicitly represented domain knowledge and computational decision procedures (Kastner and Hong, 1984). The general structure of an expert system is shown in *Figure 2*. The Knowledge Acquisition Module supports the building of an expert system's knowledge base. The subject of knowledge acquisition for knowledge-based systems falls conveniently into two parts depending on whether the knowledge is elicited from the experts by knowledge engineers or whether that knowledge is acquired automatically by the computer using some form of automatic learning strategy and algorithms (Graham and Jones, 1988; Zimmermann, 2001).

General structure of FES for juice volume prediction in pomegranate is given in *Figure 3*.

Input and output values and their intervals in established model for the prediction of fruit juice volume (FJL) by means of FL are shown in *Table 1*. As the table shows, harvesting period (HP), amount of irrigation water (AIW) and FS were used as input data, and the output data of fruit juice volume were obtained.

Verbal expressions and fuzzy sets for HP, AIW, FS and FJV are given in *Table 2*. As *Table 2* shows, the verbal expressions established for HP were 1st period, 2nd period, 3rd

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24492460

period and 4th period; for AIW deficit, medium and enough; for FS very small, small, normal, large and very large; and for FJV very low, low, normal, high and very high.

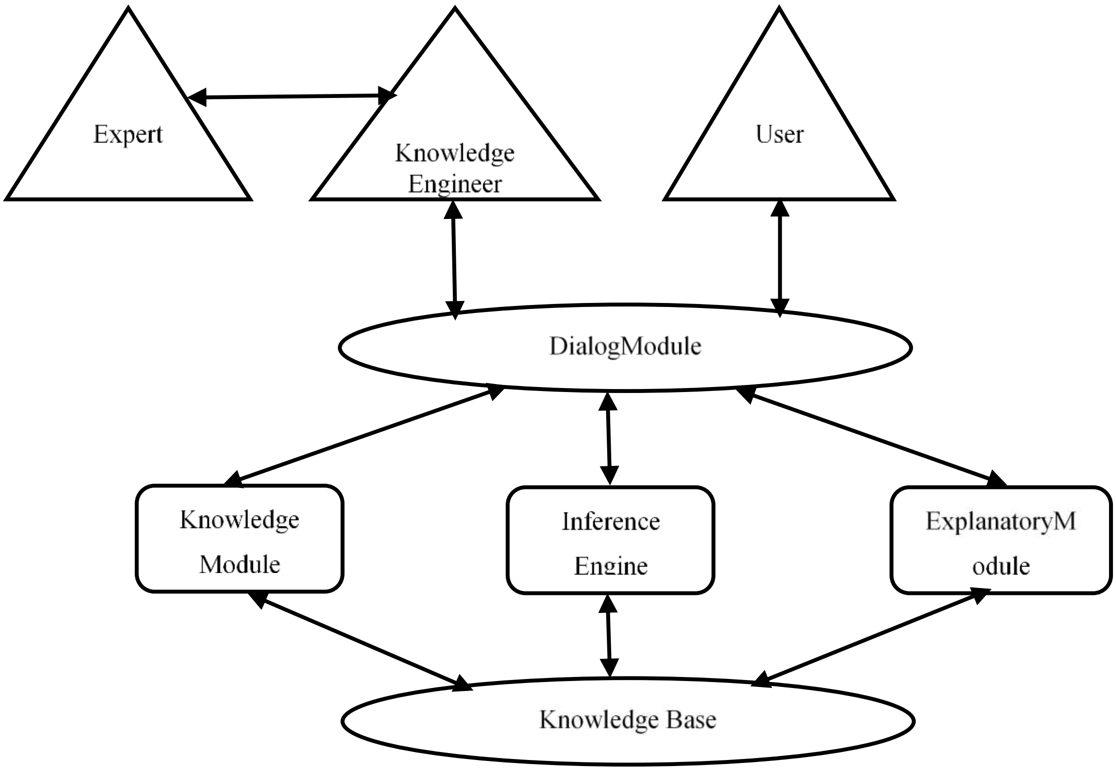

Figure 2. *Structure of an expert system*

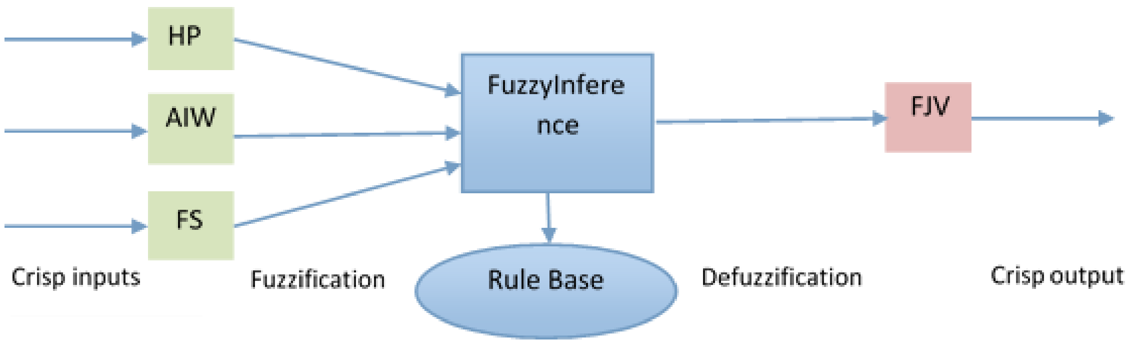

Figure 3. *Scheme of the developed FES*

Table 1. *Input–output values and their intervals*

Input/Output	Trait	Intervals
Input data	HP	0–5 (integer)
	AIW	0–4 (integer)
	FS	76–270 (gr)
Output data	FJV	13–73 (ml)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24492460

Table 2. *Verbal expressions for HP, AIW, FS and FJV*

Trait	Verbal expression	Value intervals
HP	1st period	$0 < x < 2$
	2nd period	$1 < x < 3$
	3rd period	$2 < x < 4$
	4th period	$3 < x < 5$
AIW	Deficit	$0 < x < 2$
	Medium	$1 < x < 3$
	Enough	$2 < x \leq 4$
FS	Very small	$76 \leq x < 110$
	Small	$100 < x < 180$
	Normal	$170 < x < 200$
	Large	$190 < x < 220$
	Very large	$210 < x \leq 270$
FJV	Very low	$13 \leq x < 23$
	Low	$20 < x < 38$
	Normal	$37 < x < 47$
	High	$45 < x < 53$
	Very high	$52 < x \leq 73$

Various functions were used to graph input and output membership. Here, triangular (*Eq. 1*) and trapezoidal (*Eq. 2*) membership functions were used to calculate membership degrees of the input and output values generated (Baykal, 2004).

$$\mu_A(x;a_1,a_2,a_3) = \begin{cases} a_1 \leq x \leq a_2 & then \quad (x-a_1)/(a_2-a_1) \\ a_2 \leq x \leq a_3 & then \quad (a_3-x)/(a_3-a_2) \\ x > a_3 \ \text{ veya } \ x < a_1 & then \quad 0 \end{cases} \tag{Eq.1}$$

$$\mu_A(x;a_1,a_2,a_3,a_4) = \begin{cases} a_1 \leq x \leq a_2 & then \quad (x-a_1)/(a_2-a_1) \\ a_2 \leq x \leq a_3 & then \quad 1 \\ a_3 \leq x \leq a_4 & then \quad (a_4-x)/(a_4-a_3) \\ x > a_4 \ \text{ veya } \ \mathrm{x} < \mathrm{a}_1 & then \quad 0 \end{cases} \tag{Eq.2}$$

Mamdani inference technique was used as fuzzy inference method (Mamdani and Assilian, 1975). A centroid technique method (Cox, 1999) was used for defuzzification of fuzzy data. It finds the point where a vertical line would slice the aggregate set into two equal masses. Mathematically this centre of gravity (COG) can be expressed as:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24492460

$$COG = \frac{\int_a^b \mu_A(x)x\,dx}{\int_a^b \mu_A(x)\,dx} \quad \text{(Eq.3)}$$

A centroid defuzzification method (*Eq. 3*) finds a point representing the centre of gravity of the fuzzy set A, on the interval ab.

Evaluation

In this study, coefficient of correlation and coefficient of determination (*Eq. 4*) (Spiegel et al., 2009) between real estimated and predicted by means of FES were calculated in term of accuracy and efficiency of the system.

$$R^2 = \frac{\sum_{i=1}^{n}(\hat{Y}_i - \bar{Y})^2}{\sum_{i=1}^{n}(Y_i - \bar{Y})^2} \quad \text{(Eq.4)}$$

where: Y_i – observed value, ($\hat{Y}_i$) – predicted value, $\bar{Y}$ – arithmetic mean, n – the total number of observations.

Results and discussion

As a result of analysis of variance, it was determined that there was a significant difference between harvesting periods according to juice volume ($p < 0.05$). A significant positive correlation was found between fruit weight and fruit juice volume ($p < 0.01$).

Descriptive analysis of the data revealed that the average fruit juice volume (FJV) of pomegranate in 4 HP and 3 different irrigation amount (deficit, medium, enough) varied from 18.39 ± 2.73 to 51.33 ± 9.20 ml; fruit weight of pomegranate (FS) from 91.18 ± 10.80 to 226.52 ± 25.80 g respectively.

For the FL realized via the MATLAB program (Mathworks, 2009), 3 inputs (HP, AIW, FS) and 1 output (FJV) were available. The HP graph formed in MATLAB, as illustrated in *Figure 4,* uses the four harvesting period as 4 the conditional fuzzy sets. In FES, however, this input is entered as discrete. The AIW graph formed in MATLAB and containing 3 verbal expressions is illustrated in *Figure 5*. It consists of 3 verbal variables. Since the amount of irrigation water generally changes according to the number of factors such as the amount of irrigation made by the farmer, the amount of rainfall, the amount of evaporation associated with the seasonal temperature, and the soil structure. Just farmer's decision concerning plant irrigation basically can be used. We used this input as the crisp input in our model. For deficit irrigation 1 will be entered, 2 for medium, 3 for enough irrigation. In the FS graph, illustrated in *Figure 6,* for the very small and very large fuzzy sets the trapezoidal membership functions was selected, and for the small, medium and large fuzzy set the triangular function was used. *Figure 7* shows the output graphic FJV. The FJV graph, divides the output data into five ranges as very low, low, normal, high and very high, and shows the verbal expression memberships. For the very low and very high fuzzy sets the trapezoidal membership function was selected; for the normal and high fuzzy sets the triangular function was used.

Rule base of the FES was contained of 25 rules. Rules were formed from the data (HP, AIW, FS) and taking into account the FJV as measured in the laboratory. *Table 3* shows some rules given in our FES.

http://www.aloki.hu • ISSN 1589 1623 (Print) • ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24492460

Table 3. *Some rules from developed rulebase*

Rule 1:	If HP is	'1st Period'	AIW is	'Medium'	FS is	'Small'	Then FJV is	'Normal'
Rule 2:	If HP is	'2nd Period'	AIW is	'Medium'	FS is	'Normal'	Then FJV is	'Low'
Rule 3:	If HP is	'3rd Period'	AIW is	'Enough'	FS is	'Very large'	Then FJV is	'Very high'
Rule 4:	If HP is	'4th Period'	AIW is	'Enough'	FS is	'Very small'	Then FJV is	'Very low'
Rule 5:	If HP is	'2nd Period'	AIW is	'Deficit'	FS is	'Normal'	Then FJV is	'Normal'

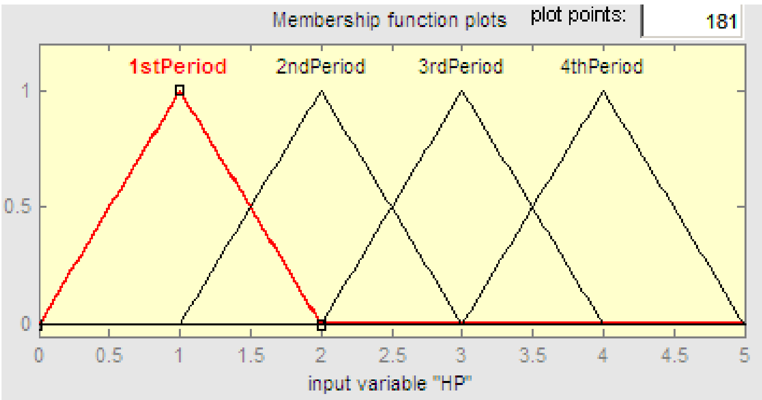

Figure 4. *HP membership function graph*

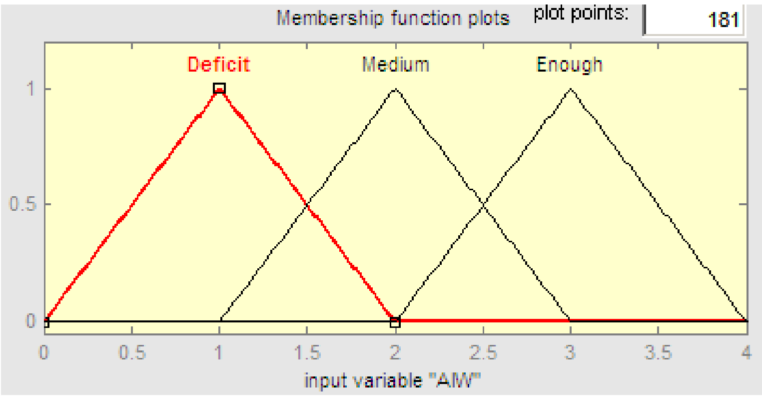

Figure 5. *AIW membership function graph*

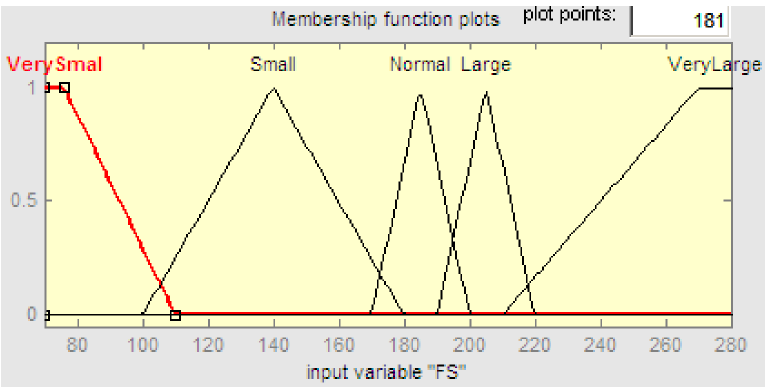

Figure 6. *FS membership function graph*

http://www.aloki.hu • ISSN 1589 1623 (Print) • ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24492460

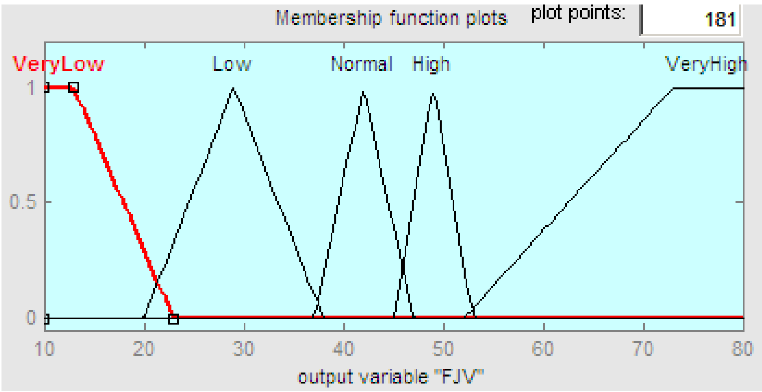

***Figure 7.** FJV membership function graph*

Figures 8 and *9* show the 3-dimensional relationships between the HP, AIW, FS and FS.

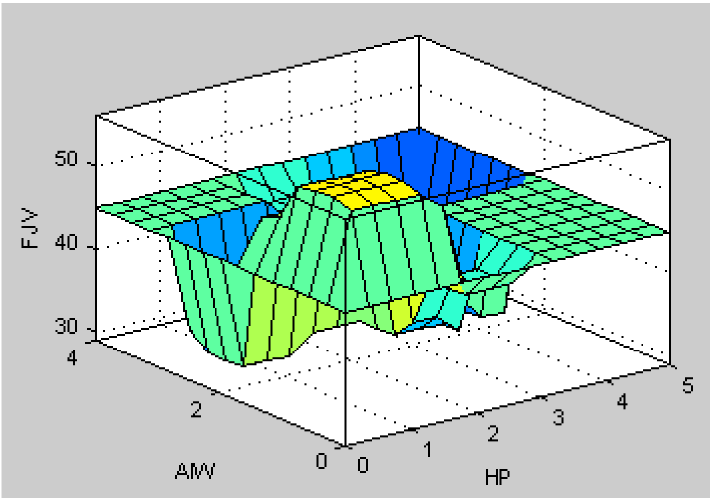

***Figure 8.** 3-D relation between AIW, HP and FJV*

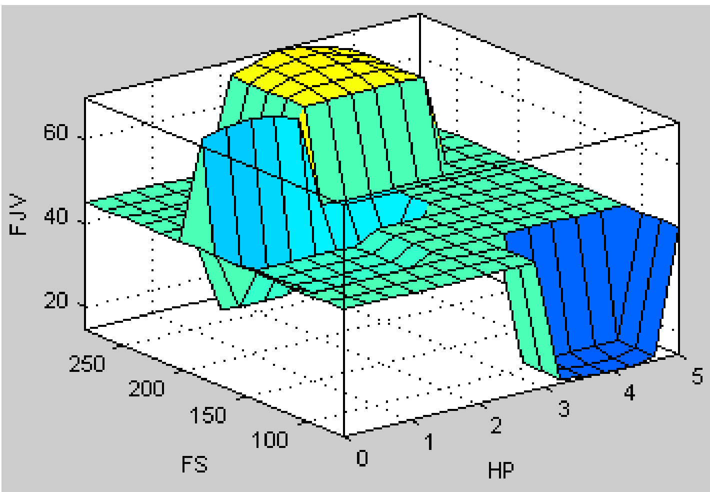

***Figure 9.** Relation between FS, HP and FJV*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24492460

For example, given 1st Period for HP, 2-medium for AIW, and 165 mg for FS, the observed output value appears next to the statement 42 ml for FJV (*Fig. 10a*). Other results can be found by supplying different input data, for example, given HP = 3rd Period, AIW=enough, and FS = 250 mg, the appropriate response for these inputs is FJV = 69.3 ml (*Fig. 10b*).

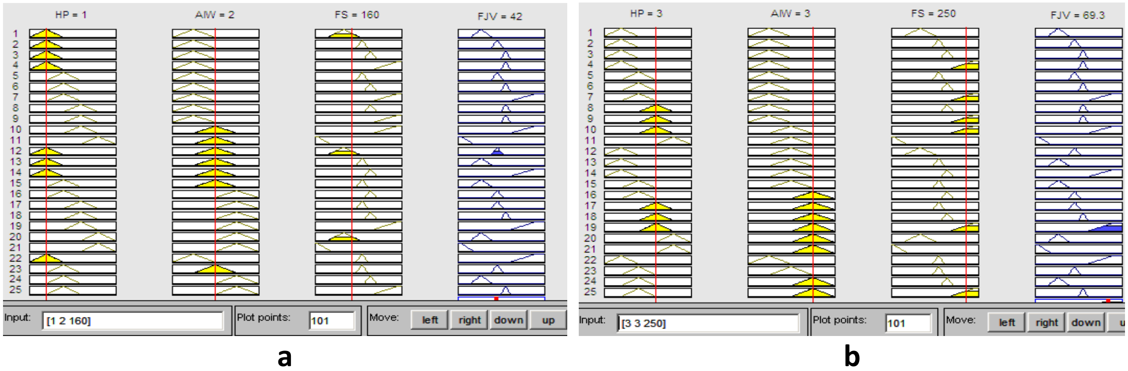

Figure 10. *Simulation results for the given inputs*

As shown in *Figure 10a* and *b,* different rules were fired for the different inputs. Thereafter, all data were run through the FL model, with the results of FJV. The coefficient of correlation between real estimated and predicted by means of FL was 0.89 (*Fig. 11*).

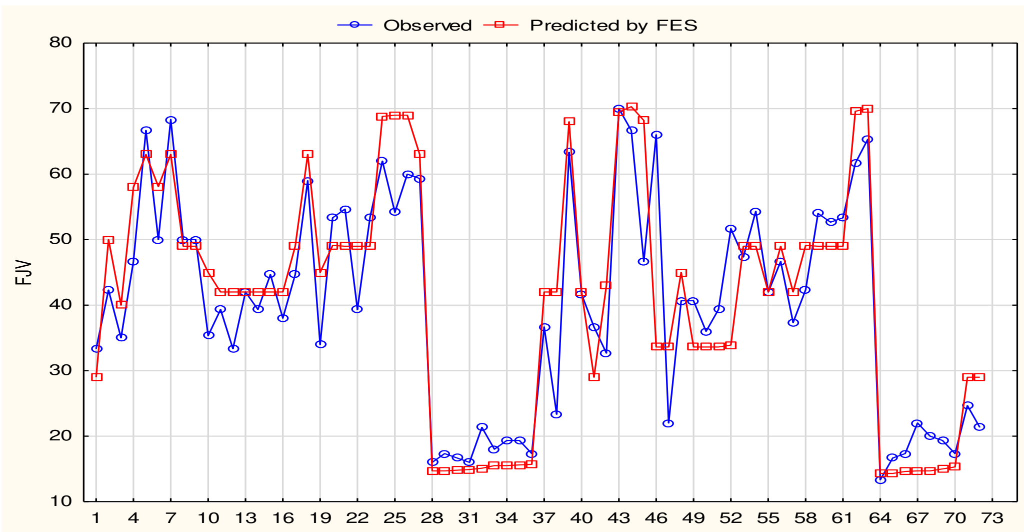

Figure 11. *Relation between FJV measured in laboratory and predicted via FES*

The coefficient of determination was found to be 80%. With the aim of fast, but accurate and easy way of finding volume, weight, and surface area of a crop in the study of Dorvlo et al. (2012) the prediction equation for weight can be used with an appreciable coefficient of determination of 68.89%. Prediction accuracy of the current study was found higher than the study of Dorvlo et al. (2012).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24492460

Conclusion

This paper assayed pomegranate juice volume estimation by means of the FL. Using the input data of HP, AIW and FS model was able to predict fruit juice volume at a level of success. In the end, the study's FL model revealed coefficient of determination rate of 80%. It can be said that a fuzzy expert system can be applied in areas where mathematical modeling is difficult. In addition, the establishment of such expert systems in agriculture using fuzzy logic will help real-time, appropriate and rapid decision-making in land conditions, taking advantage of analytical decision-making capabilities of experts. In the model we build, we can develop an expert system, which gives more definite results in future by further developing and fuzzifiing the other inputs as much as possible, that can guide the producers of pomegranate breeding. Given these results, it is recommended that a prediction system be devised by adding more improved FL model with high sensitivity. Such a system will eliminate the need for intensive laboratory work in lieu of data obtained from farm. Considering all the factors, a more punctual and efficient system can be developed in the future.

Abstract. Invasive non-native parakeet populations are increasing throughout Europe with proved negative impact on native fauna and Turkey is no exception. Rose-ringed and Alexandrine parakeets have established populations in Turkey's large cities but even basic distribution, abundance and breeding behaviour information is missing. This study aims at determining the breeding status and identifying the nest characteristics of Rose-ringed and Alexandrine parakeets in Istanbul's city parks. The study is carried out in 9 city parks during one breeding season. Data on the presence of breeding parakeet species, their nest characteristics and characteristic of suitable cavities on non-nesting trees were collected. Both species were recorded breeding sympatrically in 5 out of 9 city parks with probable breeding in one more park. When nesting, both species preferred high trees with high diameter but Rose-ringed parakeet nests were placed lower than those of Alexandrine parakeet's. Plane (*Platanus* sp.) species were the most used as a nesting tree for both species. This study reveals the first systematic observations on the breeding Rose-ringed and Alexandrine parakeet populations in Istanbul and serves as a basis for further detailed research on both species in Turkey.
Keywords: *invasive species, non-native fauna, nest selection, nest site competition, cavity nesters, environmental change*

Introduction

Invasive non-native species, a human-caused problem, are considered to be amongst the major problems for biodiversity in the Anthropocene (Pievani, 2014). Although there has been a debate on whether invasive species are themselves a cause for ecosystem change or they benefit from already disturbed ecosystems (Didham et al., 2005; Gurevitch and Padilla, 2004; Clavero and García-Berthou, 2005; Davis, 2003) studies show a correlation between invasive species presence and altered local biodiversity. Invasive non-native species can alter the local biodiversity by excluding native species through competition for resources (Mazzamuto et al., 2017), by predation (Wanless et al., 2007), by parasitism (Douda et al., 2017), by disease (Morand, 2017), by hybridization (Kovach et al. 2016) or by causing evolutionary changes (Mooney and Cleland, 2001). All these changes impact ecosystem functioning and therefore creates direct or indirect economic loss (Kaiser, 2006; Dehnen-Schmutz et al., 2004; Schwoerer et al., 2014).

Parakeets, especially the Rose-ringed parakeet (*Psittacula krameri*) are one of the widespread and common invasive bird species with well-established populations in Europe (Pârâu et al., 2016). Rose-ringed parakeets originate from Asia and Africa,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24612471

mostly found around human settlements in Europe and is known to compete for nest-sites (Strubbe and Matthysen, 2009), or for food (Peck et al., 2014) with local species. Alexandrine parakeet (*Psittacula eupatria*), has its native distribution from Afghanistan to Vietnam and is not as widespread and as common as the Rose-ringed parakeet in Europe. Major Alexandrine parakeet populations were reported from Belgium, Germany and Netherlands, all with a couple of hundred individuals (Ancillotto et al., 2016) but Ancillotto et al., (2016) suggested that the number of Alexandrine parakeets is increasing and according to their model its establishment success might be benefiting from the past invasion of Rose-ringed parakeet in Europe.

Rose-ringed parakeet is smaller (40 cm) than Alexandrine parakeet (58 cm) (Juniper and Parr, 2010). In their native ranges both species occur in wide variety of habitats but mainly in woodlands; prefer tree cavities as nest; feed on wild and cultivated seeds, flowers and fruits and considered as serious crop pests (Parr and Juniper, 2010). In its native range, the clutch size of rose-ringed parakeet ranges from two to six (Lamba, 1966).

Two species of invasive non-native parakeets are common in Turkey, Rose-ringed and Alexandrine parakeet (*Psittacula eupatria*). The first observations on the established Rose-ringed parakeet populations in large cities (Istanbul, Ankara and Izmir) were recorded in the 1990s (Boyla et al., 1998). Alexandrine parakeet records, on the other hand, started to increase during the 2000s (eBird, 2012) and probably outnumbered Rose-ringed parakeets in some parts of Istanbul (Sahin, personal observation). Although both species were quickly increased in number in large cities, basic information on their distribution, abundance and breeding status are missing in Turkey.

It is for sure that in order to have a comprehensive understanding of the impact of invasive parakeet species on native biodiversity and to create an effective management plan we first need to understand their distribution, abundance and invasion ecology. Introduction of parakeet species is under strict control by legislation in European Union (European Commission, 2007), however, it is still uncontrolled in Turkey (Per, 2018). Turkey's rich bird diversity is already under various threats due to speed-up in development and urbanisation projects (Şekercioğlu et al., 2011) and the impact of invasive non-native species on native species such as Common starling (*Sturnus vulgaris*, Eurasian nuthatch (*Sitta europaea*), and Syrian woodpecker (*Dendrocopos syriacus*), is probably making it worse in urbanised areas. An immediate research on the topic is needed. This study attempts for the first time to use systematic observations to reveal information about breeding Rose-ringed and Alexandrine parakeets in one of the largest cities of Turkey. The aim of this study is to provide baseline information on the distribution, breeding status and nest preferences of two invasive parakeet species in Istanbul's city parks. Although this study was conducted in 2012, the results are still relevant as both species are present, breeding and moreover, likely to increasing in distribution and abundance in Istanbul according to the number of sightings in global bird-sightings database, e-bird (eBird, 2012). We expect that the baseline information revealed by this study will trigger further studies on the two invasive parakeet species in Turkey.

Material and Methods

Study Area

This study is conducted in Istanbul, one of the largest cities in Turkey. Although two parakeet species can be seen in most parts of the city, especially in densely populated areas, the breeding occurs in parks where a high amount of old trees can be found together (Sahin, personal observation, see “Discussion”). Therefore this study was carried out in the historic parks of Istanbul that are managed by the Istanbul Metropolitan Municipality. Five of these parks (Beykoz (27.9 ha), Buyuk Camlica (12.9 ha), Kucuk Camlica (27.14 ha), Fethipasa (13.4 ha) and Cubuklu (16.3 ha)) are located in Asian and four of them (Emirgan (42.7 ha), Florya (67.5 ha), Gulhane (12.1 ha), Yildiz (39.2 ha)) are located in European side of Istanbul. The location and size of the parks are given in *Figure 1*.

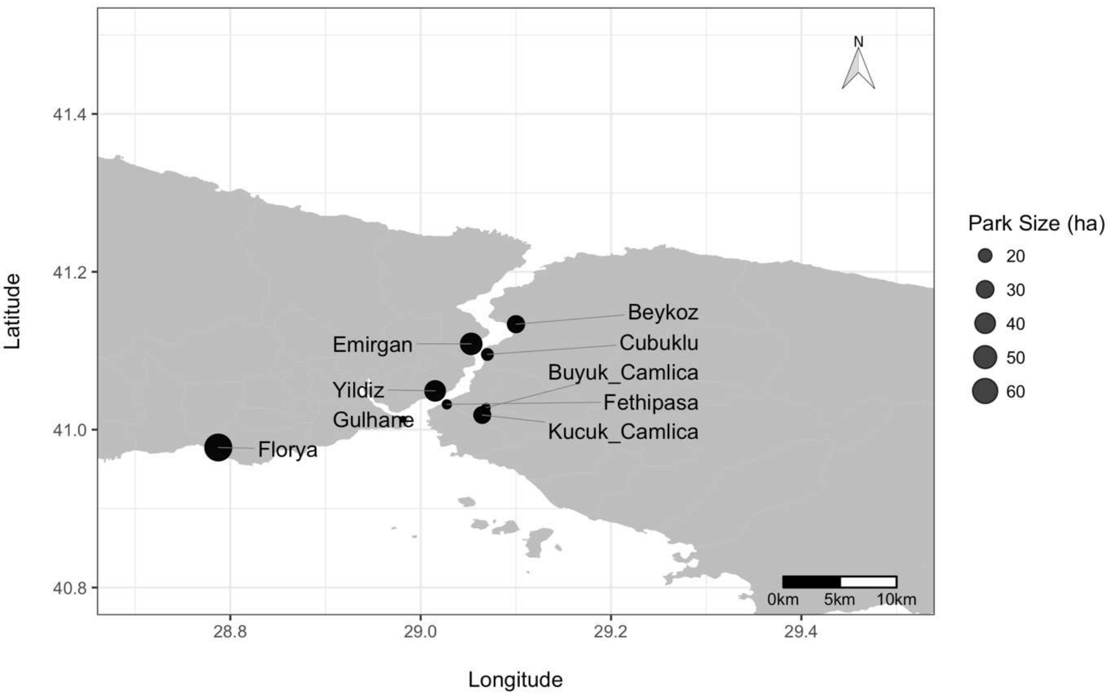

Figure 1. *Location and size of the studied parks in Istanbul. Size of the black circles represents the size of the parks in hectare*

The whole area is a transition zone between the dry Mediterranean and wet Black Sea climate. This impacts the climatic conditions between the northern and the southern part of the city; northern parts get more rain and are colder on average than southern parts.

As all the studied parks are managed, both native and non-native tree species with different ages can be found in these areas. The three most common Gymnosperm genera are *Pinus*, *Cedrus* and *Cupressus* whereas the three most common Angiosperm genera are *Quercus*, *Fraxinus* and *Platanus* for all parks. The total volume of trees belong to these two major classes are given in *Figure 2* and volumes of the most common Angiosperm genera were given in *Figure 3*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24612471

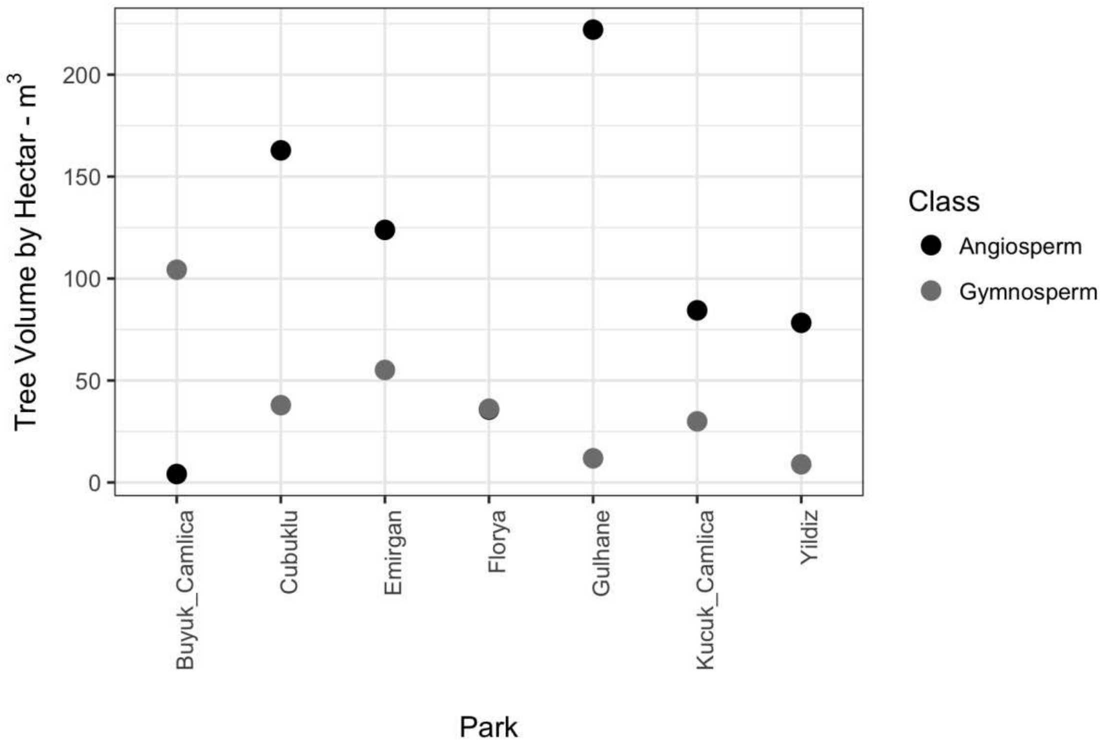

Figure 2. *Volume of Gymnosperm and Angiosperm trees in studied parks. Tree volumes are normalised by hectare for each park*

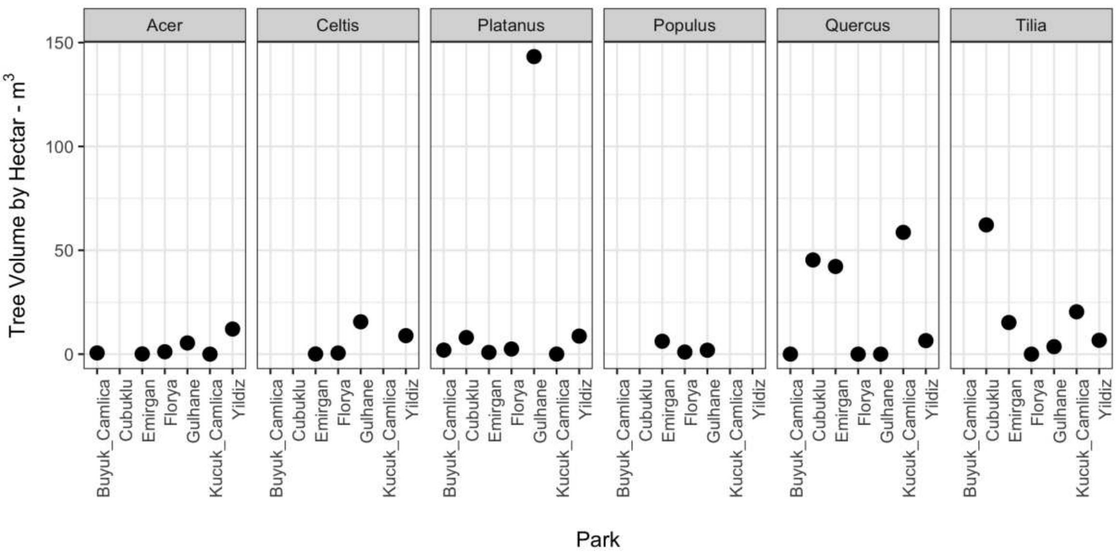

Figure 3. *Volume of the most common Angiosperm trees in studied parks. Tree volumes are normalised by hectare for each park*

The most common passerine species found in almost all parks includes Robin (*Erithacus rubecula*), Blackbird (*Turdus merula*), Great tit (*Parus major*), Blue tit (*Cyanistes caeruleus*), House sparrow (*Passer domesticus*), Chaffinch (*Fringilla coelebs*) among others.

DOI: http://dx.doi.org/10.15666/aeer/1702_24612471

Data Collection

Two visits were made in breeding season between March-May in 2012. In the first (early) visit breeding status and the distribution of two parakeet species were recorded together with the number of adult individuals (recorded as the adult male and adult female / young male) in each park. In this first visit behaviour that indicates breeding (e.g. courtship, nest building etc.) and the location of detected nests were also recorded. In all parks, birds were counted by walking pedestrian paths.

In the second visit, data on nest characteristics were collected for all the nests determined in the first visit. Data on tree species, tree height and diameter, nest height, nest type (natural cavity, old nest for other species or nest box) and the nest orientation were collected. Tree height was measured with the clinometer, the orientation of nests was measured with a compass and the tree circumference was measured with a tape measure from 1.30 m height. Diameter at breast height (dbh) was calculated by dividing tree circumference with Pi number. To identify important factors shaping the nest selection data were collected on trees that have suitable cavities but no parakeet nests. These trees were randomly selected from maps created for forest management plans (Asan et al., 2002).

Statistical Analyses

To determine the factors that have an impact on nest selection, we compared data from nests and non-nest trees. To test within and between species differences among nest height, tree height, nest orientation and tree diameter we used one-way ANOVA tests on SPSS Version 21.0 (IBM Corporations Released 2012).

Results

Breeding Distribution and Abundance

Two species were found sympatrically breeding in 5 out of 9 city parks (*Table 1*). In Beykoz Park, birds were observed in suitable habitat during the breeding season, however, no breeding behaviour or nest were recorded, this area is marked as potential breeding area.

Table 1. *Breeding status of Rose-ringed parakeet (Psittacula krameri) and Alexandrine parakeet (Psittacula eupatria) in studied parks. Possible: species were seen during the breeding season, but no proof for breeding, Certain: active nest(s) were found in the park, No: no proof for breeding or no suitable habitat*

Park	**Breeding Status**

Küçük Çamlıca Park	Certain	Certain
Yıldız Park	Certain	Certain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24612471

In all parks visited and in all visits, Alexandrine parakeet was present during the breeding season where Rose-ringed parakeet was absent in two parks; Büyük Çamlıca and Çubuklu Parks. During the breeding season, the maximum number of individuals recorded for each species are 57 for Alexandrine parakeet in Gülhane Park and 37 for Rose-ringed parakeet in Küçük Çamlıca Park.

A total of 38 nests were found in studied parks during one breeding season, of which 15 belong to Rose-ringed parakeet and 23 belong to Alexandrine parakeet. In parks where both species breed sympatrically, nests of two species found congregated in specific parts of the park rather than scattered away from each other species' nesting area.

Nest Characteristics

The majority of Alexandrine parakeet nests were found on *Platanus* spp trees (especially *Platanus acerifolia* Wild.) followed by *Pinus pinea* and *Celtis australis*. All nests found to belong to Alexandrine parakeet were natural cavities. Similarly, the majority of Rose-ringed parakeet nests were found on *Platanus* spp trees (especially *Platanus acerifolia* Wild.) followed by *Pinus pinea*, *Tilia argantea*, *Populus tremula*, and *Sophora japonica*. Rose-ringed parakeets were observed using cavities that are used by *Dendrocopus* or *Sitta* species in some areas. These cavities were found on *Quercus robur* trees. The relative numbers of nesting trees for both species were given in *Figure 4*.

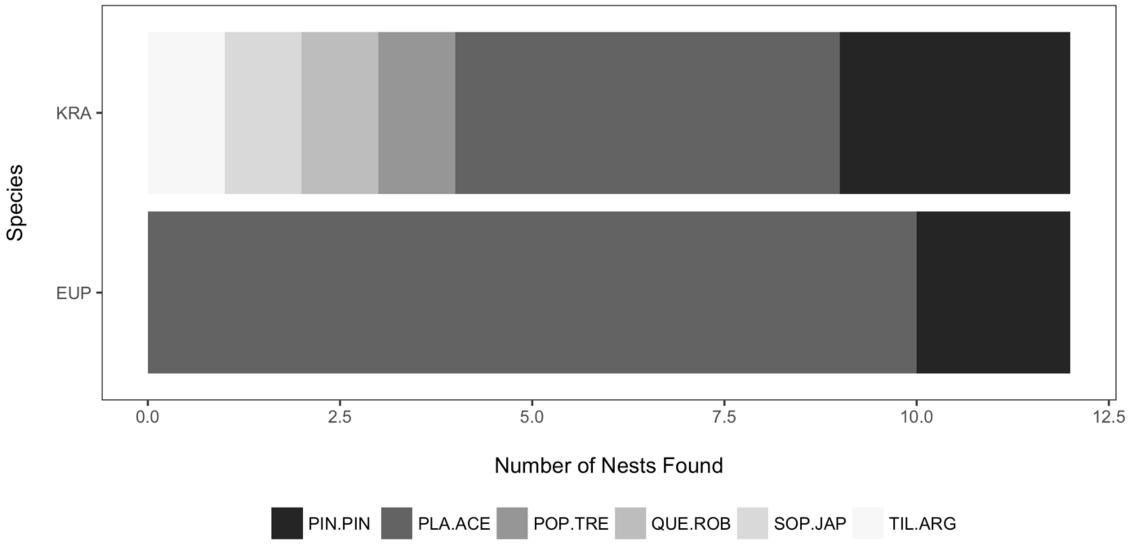

Figure 4. *Number and species of nesting trees for both parakeet species. KRA: Rose-ringed parakeet, EUP= Alexandrine parakeet, PIN.PIN: Pinus pinea, PLA.ACE: Platanus acerifolia, POP.TRE: Populus tremula, QUE.ROB: Quercus robur, SOP.JAP: Sophora japonica, TIL.ARG: Tilia argantea*

12 nests from each species were used in the analysis of comparing nest vs non-nest trees. Data from 24 non-nesting trees were used. For the 12 nests on which measurements were made, Alexandrine parakeet selected cavities placed higher on trees and trees with a wider diameter than Rose-ringed parakeet. The average height of Alexandrine parakeet nests was 8,6±3,6 m and the average tree diameter was 98,8 cm.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24612471

These values were 6,8±1,6 m and 64,58 cm respectively for Rose-ringed parakeet. According to test results, nests were higher and nesting trees had wider diameter than randomly selected non-nesting trees. These measurements were 4,5±2,1 m and 57,92 cm in non-nesting trees.

Comparing nest and non-nest tree characteristics for each species individually revealed that nest orientation (p=0,000; F= 59,668, df= 34) and breast height diameter (p= 0,001; F= 14,693; df= 34) is the important factors in selection of nests for Alexandrine parakeet whereas it is tree height (p= 0,000; F= 20,120; df= 34) and breast height diameter (p= 0,000; F= 99,965; df= 34) for Rose-ringed parakeet.

When both species' nest characteristics evaluated together against non-nesting trees, tree height is not a significant factor (*Figure 5A*) but nest heights were found significantly higher than cavities measured on non-nesting trees (p= 0,000; F= 24,528; df=47, *Figure 5B*). Nesting trees were significantly wider in breast height diameter than non-nesting trees (p= 0,000; F= 15,006; df=47, *Figure 5D*).

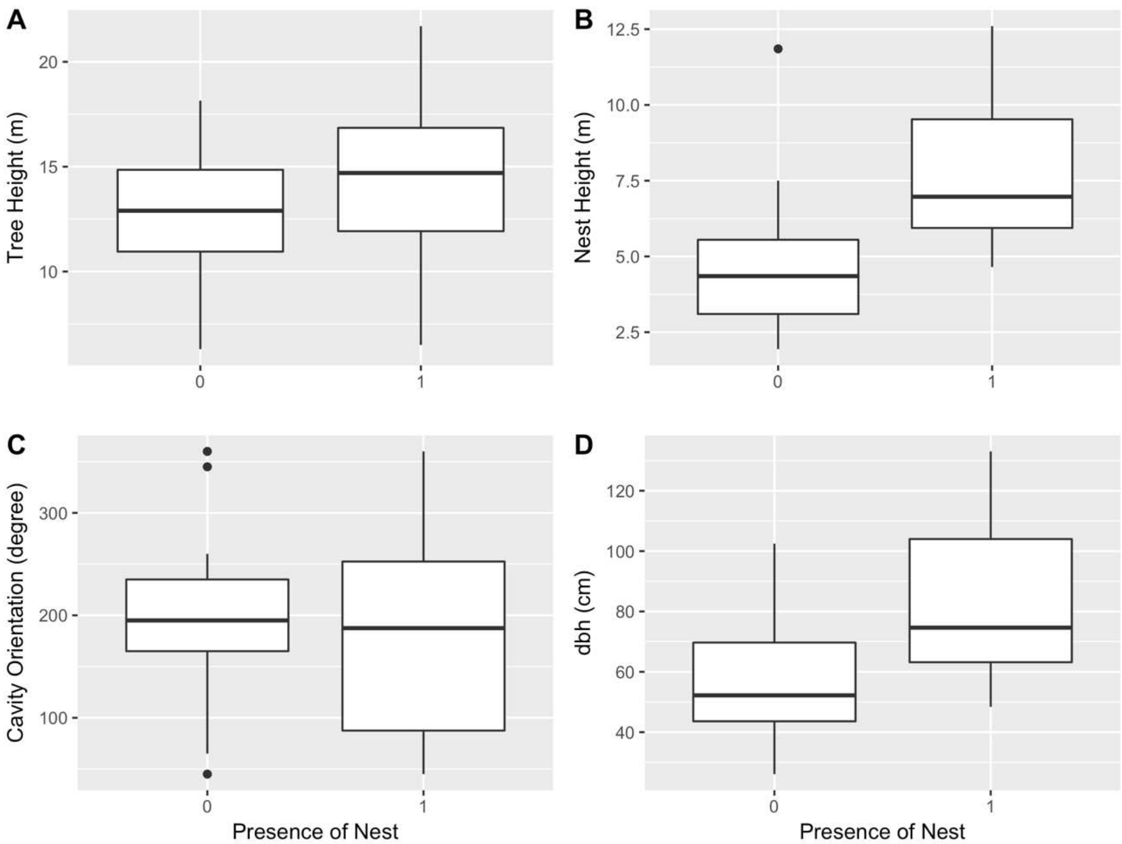

Figure 5. *Comparison of nesting (Presence of Nest =1, n=24) and non-nesting (Presence of Nest= 0, n=24) trees (95% CI). A: height of the tree, B: height of the cavity, C: orientation of the cavity, and D: diameter of the tree at breast height. Both species are evaluated together*

Discussion

This is the first systematic study on the two breeding parakeet species in Istanbul's city parks. The study covered large city parks. A preliminary work has been carried out to check the prevalence of the parakeet breeding sites in İstanbul. Accordingly, sighting data from an online database, e-bird (eBird, 2012), are mapped for both species and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24612471

stratified random selection was applied to the areas outside of large city parks. 6 randomly selected 2 x 2 km squares with different habitats were visited to record the breeding. Although parakeets were observed on old trees in alleys and in open areas no breeding has recorded in these squares. As Pithon (1998); Butler (2003); Strubbe and Matthysen (2011) and Czajka et al. (2011) suggests, European breeding populations of parakeets are concentrated in city parks where there is a high concentration of trees and at the same time anthropogenic activities. According to our preliminary study, breeding parakeets seem to show a similar selection for breeding habitat in Istanbul: both species were recorded breeding in 5 out of 9 city parks investigated in this study. The reason that parakeets are choosing city parks for breeding is probably related with the wide variety of tree species, including exotic ones, which serves as a rich source of food but also a safe breeding habitat relatively isolated from constant human disturbance. In a study carried out in a botanical garden, Claes and Matthysen (2005) found that exotic plant species constitute 36% of the diet of Rose-ringed parakeets. Strubbe and Matthysen (2011) found that male Rose-ringed parakeets, which are responsible for feeding breeding females have a foraging distance a few hundred meters away from the nests. City parks probably provide plenty of suitable nests and food source to both parakeet species during the breeding season.

Strubbe and Matthysen (2007) also found a positive correlation between breeding Rose-ringed parakeet numbers and cavity availability in its breeding areas. In Büyük Çamlıca Park where both species were absent, the majority of the area is covered with pine plantations and therefore does not provide a suitable habitat with many cavities and a wide variety of food resources. In Fethipaşa and Çubuklu Parks, there are less available cavities in comparison to other parks, which might be a reason for the absence of breeding.

In parks where breeding occurred *Platanus acerifolia* were the most preferred nesting tree by both species. Studies on Rose-ringed parakeets found that they most preferred *Platanus* spp. trees in the UK (Pithon, 1998) and Germany (Czajka et al., 2011). In Germany, Czajka et al., (2011) reported that for the Rose-ringed parakeet *Acer* and *Fraxinus* spp. are the most preferred nesting trees, following *Platanus* spp. Strubbe and Matthysen (2007) found that Rose-ringed parakeets prefer habitats that are dominated by *Fraxinus* spp. and that include *Populus* and *Ulmus* spp. in Belgium. In this study, no Rose-ringed parakeet nests were found on *Fraxinus* or *Acer* trees.

To the best of our knowledge, there is no study reporting nest characteristics of Alexandrine parakeet in its non-native range. In this study, we found that the average height of the studied Alexandrine parakeet nests was 8.6 m and average dbh was 98.8 cm. For Rose-ringed parakeet these values were 6.8 m and 64.6 cm respectively. According to Pithon (1998) the average height for Rose-ringed parakeet nests in the UK was 11.1 m and according to Butler (2003), it was 8.1 m. Choosing higher nests probably provides protection from potential predators by making it more difficult to access. In our study, we found that both species prefer higher cavities compared to suitable cavities on non-nesting trees. However, an explanation for the lower average height for Rose-ringed parakeet nests might be the competition between two species for nest cavities. As Alexandrine parakeet is larger than the Rose-ringed parakeet it might be possible that it is taking better cavities and pushing Rose-ringed parakeet to cavities with poorer conditions. This might also have revealed by the nest orientation data we collected. In our study, Alexandrine parakeet nest were mostly south oriented. Given the fact that prevailing winds in Istanbul are northerly, it is possible that Alexandrine

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24612471

parakeets are choosing nests with the south orientation to have a protection from the impact of northerly winds. This competition hypothesis requires a more detailed study.

Recent studies show that increasing parakeet populations are negatively impacting local species (Strubbe and Matthysen, 2009; Mori et al., 2017; Menchetti and Mori, 2014; Yosef et al., 2016). In our study, we observed that the Rose-ringed parakeets were interacting with Eurasian nuthatches *Sitta europaea*, Common starlings *Sturnus vulgaris*, Syrian woodpeckers *Dendrocopos syriacus*; and Alexandrine parakeets were interacting with Western jackdaws *Coloeus monedula*. Although these were only superficial observations, they still have a value in suggesting that competition for resources is probably occurring among invasive non-native parakeets and native species in Istanbul's large city parks. Furthermore, a third invasive bird species, Common myna *Acridotheres tristis* has established breeding grounds in a few of the parks investigated in this study (eBird, 2012). The presence of three invasive species might create complex interactions among invasive and native species (Orchan et al., 2013). This subject definitely requires further investigation. Furthermore, competition between two parakeet species might be affecting these interactions and creates a complex interaction among non-native and native species. These areas require detailed studies.

Conclusion

This is the first study that reports breeding status and nest-characteristics of Rose-ringed and Alexandrine parakeets, two invasive species in Istanbul's city parks and we found that both species breed sympatrically in all parks investigated. Our analyses demonstrated that both species prefer cavities placed higher and on wider trees in comparison to available but not occupied cavities. We could not detect a statistically significant difference between the nest characteristics of two species (not reported here), probably because of small sample size. Although this study was conducted in 2012, the presence and breeding status of both species has not changed in studied parks and moreover two species are seemingly increasing in abundance (eBird, 2012) with a third invasive bird species, Common myna, added to some of the parks. More detailed studies are required on the nest and habitat preferences with higher sample size, potential competition between two parakeet species and their impact on native bird fauna to better inform wildlife managers and protect urban native bird fauna.

Abstract. The main purpose of this study was to evaluate the antioxidant and phytochemical activities and metal contents from leaves, flowers and roots of regional Aak (*Calotropis procera* Ait.) and Hari Boti (*Ajuga Bracteosa* Wall.). Distilled water and acetone solvents were used to extract the antioxidants and phytochemical constituents. Diverse antioxidant and phytochemical activities such as flavonoid, phenolic, and flavonol contents, 2, 2-diphenyl-1-picrylhydrazyl (DPPH), OH°, and H_2O_2 scavenging activities, Fe^{+2} chelating action, ferric reducing antioxidant power (FRAP), ascorbic acid and phosphomolybdenium complex essay were performed by using reported methods. Atomic absorption spectroscopy was used to evaluate the different metals such as Pb, Cd, Zn, Fe, Cu, Mg and K. The flavonoid contents (expressed as rutin equivalents) stated as 12.01-82.56 mg/g dry weight were higher than phenolic contents (expressed as gallic acid equivalents) quantified as 26.60-66.60 mg/g dry weight. *Ajuga bracteosa* extracts exhibited significant DPPH and OH radical scavenging activities. In all the analyzed samples, the highest concentration of iron (27.97 mg/L) was displayed by roots of *Ajuga Bracteosa.* Health risk index (HRI) revealed that level of Cd in roots and flowers of *Calotropis procera* and in flowers of *Ajuga bracteosa* was not safe for the consumption of humans as its concentration exceeded permissible limit.
Keywords: *ascorbic acid, Fe^{+2} chelating action, acetone, ferric reducing antioxidant power*

Introduction

Since old times, people are relying onto medicinal plants for their sicknesses. History for medicinal plants may be longstanding concerning illustration of mankind's historical backdrop. Since the mid of the 19th century diverse categories regarding bioactive compounds have been separated, characterized and identified. Among these, a number of compounds played a prime role in the discovery of new drugs. Many medicines manufactured using plant ingredients possess significant amount of alkaloids, tannins, flavonoids, and phenolic compounds, which play effective role in the cure of a variety of degenerative diseases (Ghias et al., 2012; Ali et al., 2015). Antioxidants help on chain softening responses and free radical searching action as well. All radicals have unpaired electrons and are profoundly breakable, also could extricate electrons starting with other particles to accomplish strength bringing on them harm. An over the top processing about reactive oxygen species (ROS) induces the oxidative stress thereby generating harm to DNA, proteins or lipids, and hampering their normal working (Pham-Huy et al., 2008). These biochemical alterations would involve in the aging process, and additionally in a developing rundown for mankind's diseases, for example, cancerous (Ziech et al., 2011), furthermore Alzheimer's disease (Galindo et al., 2010).

DOI: http://dx.doi.org/10.15666/aeer/1702_24732487

Cancer and cardiovascular diseases are considered main causes of death in United States of America (USA). Approximately, 32% deaths due to cancer could be evaded by nutritional adaptations. Extracts from curative herbs, vegetables, and fruits possess anticancer activity, akin to hormonal cure and chemotherapy (Wang et al., 2018). Oral doses of *Catharanthus roseus* flowers' aqueous extract to rats (diabetic) caused remarkable decrease in blood glucose, and decline in lipid profile. This oral administration also controlled the drop off in body weight (Suja, 2018). Fruits, vegetables and grains hold numerous widespread mixtures of phytochemicals. Antioxidants inferred from plants go about as diminishing operators, metal molecule chelators and also free radical scavengers. In the coming years, exceptional consideration are required to be paid towards exploring natural-based cell reinforcement extraction starting with plants such as, phenols, flavonoids and tocopherols (Wojdyłoa et al. 2007; Katalinic et al. 2006). Toxic metals accumulated in medicinal plants grown on contaminated soil might represent a danger to human wellbeing. Indeed purpose of ongoing research should generally be to lower the levels of contaminates. In national priorities list (NPL) of the substances which are established to cause the potential threat to human health because of recognized or alleged toxicity, arsenic ranks at first. Agency for toxic substances and disease registry (ATSDR) prioritizes substances in light of a mix about their toxicity, possibility of mankind's purposes of presentation and also recurrence. Lead, mercury, and cadmium rank at 2^{nd}, 3^{rd} and 7^{th} positions in the list of toxicants, separately (ATSDR, 2017). Mankind's interaction with metals might happen throughout world related activities principally through inward breath, dermal routes, mining and from water. Furthermore, contaminated food utilization and exposure to polluted air, soil and dust also enhance metal level in humans (Carlin et al. 2016). A thorough survey from claiming phytochemistry, medicinal and universal utilization of *Calotropis procera* (Aak) and *Ajuga bracteosa* (Kauri Boti) may be distributed by Ahmed et al. and Mubashir Hussain et al. separately (Ahmed et al. 2005; Mubashir Hussain et al. 2016). *Calotropis procera* had been used to treat large portions of infections such as ulcers, spoiling about skin, leprosy, piles, bronchial asthma, and illnesses of the liver, abdomen and spleen as well (Kartikar and Basu, 1994). *Ajuga bracteosa* is over 10-30 cm in stature also a prised, medicinal, soft, fragrant and villous herb. Furthermore, goes about similarly as antibacterial, anti-inflammatory, astringent, anthelmintic and antifungal. It can be used to cure intestinal infections, fever, phlegm, gout, palsy, amenorrhea and stiffness (Shen et al., 1993; Kaithwas et al., 2012). Different metals play a vital role in human body. Metals are characterized into two categories; fundamental or key metals and unnecessary or harmful metals. Key metals are copper, iron and Zinc, whereas nonessential or lethal metals are cadmium, chromium, lead and mercury. Key metals also become toxic when taken in high amount (Angelova et al., 2004). Intake of metals through intake of polluted therapeutic plants is related to human wellbeing dangers (Khan et al., 2007). Appraisals of wellbeing dangers to metals are as per the following; Fe is a basic element which limits many body capacities including supply of O_2 in the blood. Fe is also fundamental for giving vitality to the body. Praline hydrolase, ribonucleotide reductase, pyruvate oxidase, mitochondrial cytochrome, and tyrosine are the vital catalysts that entail the iron as a cofactor in the human body (Manore et al., 2009).

Copper assumes a central part in metabolism of energy, amalgamation and assurance of collagen protein. Proteins that oblige the Copper (II) particle as a co-variable in the body are superoxide dismutase and cytochrome-c-oxidase. Raised convergence of Cu in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24732487

human bodies causes many infections like gastrointestinal infection (Turkdogan et al., 2002). High accumulation of lead has troublesome health impacts such as respiratory and dermatogenic issues brought on by ingestion and dermal contacts of polluted soil (Cao et al., 2010; Wang et al., 2009). Abnormal amounts of lead cause hypertension, stomach related and apprehensive clutters, memory and focus issues, muscle and joint torment. Zinc is a critical mineral required for the body. Zinc controls many body functions, similar to resistant and stomach related framework, lessening of stress levels, vitality digestion and curing of wounds. Deficiency of zinc causes numerous infections such as low circulatory strain, development impediment and hindered bone improvement. Cadmium is not viewed as fundamental to human life. Unfriendly wellbeing impacts on individuals are displayed by overabundance cadmium introduction. From 20 to 30 years, cadmium is aggregated in the kidneys for a moderately extensive period and, at high measurements, harm respiratory framework and causes bone sickness. In the study zone these natural plants have been used to cure skin infections, fever, gout and asthma. The point of the available assessment may be to examine the cell reinforcement exercises, furthermore lethal levels for follow metals, additionally assess supplementary metals starting with chosen parts of *Ajuga bracteosa* and *Calotropis procera* developed in the region Bhimber AJK, Pakistan, eventually Tom's perusing utilizing different extraction solvents.

Methods and materials

Instruments/devices used

Double-beam UV-Visible Spectrophotometer, Model UV-1900, Shimadzo, AA-7000 Atomic Absorption Spectrophotometers, Shimadzo, and diamond saw blades (Cutter Diamond) were used in this study.

Reagents and chemicals

Folin-ciocalteu, 2, 2-diphenyl-1-picrylhydrazyl (DPPH), ferrozine, hydrogen peroxide, L-ascorbic acid, and Rutin were purchased from Sigma Chemical Co. whereas H_2SO_4, H_3PO_4, Na_3PO_4, $HClO_4$, HNO_3, $(CH_3)_2CO$, Na_2CO_3, $NaNO_2$, $AlCl_3$, NaOH, CH_3COONa,), CH_3OH, $FeSO_4$, $C_6N_6FeK_3$, $C_2HCl_3O_2$, $FeCl_3$, HO_3P, $C_{12}H_7NCl_2O_2$, $(NH_4)_6Mo_7O_{24}$ were obtained from Merck (Germany).

Sampling area

The district Bhimber is situated at an altitude of 313 meters above sea level. It is located between latitude: 32-48 to 33-34 and longitude: 73-55 to 74-45, and has an area of 1516 km^2. People living in the rural and urban areas of district Bhimbr frequently use extracts of various parts of medicinal plants such as roots, leaves and flowers to cure ailments. Hence, the district was focused for this study (*Fig. 1*).

Sampling of diverse parts of plants

The study was aimed to detect phytochemicals and metals in medicinal plants collected from hilly areas of Bhimber Azad Jammu and Kashmir, Pakistan. Initially, a physical survey was carried out to select the sampling stations. Fresh flower, leaf and root samples (1-1.5 kg wet weight) of the targeted plants were collected separately in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24732487

polythene bags from pre-decided locations during spring season of the year 2018. The samples were authenticated at the Department of Botany, Mirpur University of Science and Technology (MUST), Mirpur-10250 (AJK), Pakistan. The flowers and leafs were plucked with gloved hands whereas the diamond saw blades purchased from local market were used to cut and collect the root samples. Then, to remove soil particles, the collected plants' parts were washed carefully with tap water and distilled water respectively. The plants' parts were cut into small pieces and left to dry them out in mild sunlight for a number of days. The commercial beater was used to convert dried parts of the plants into coarse powder. The dried and powdered samples packed in pre-washed polythene bags were shifted to the lab for wet digestion and metal analysis.

***Figure 1.** Map of district Bhimber, the sampling area*

Digestion of plants' parts for metal analysis

Digestion protocol explained by Sharma et al. (2008) was followed. Various parts of the plant samples (powdered) were digested using the fixed ratio of concentrated H_2SO_4, HNO_3 and $HClO_4$. For this purpose, mixture of conc. sulphuric acid, perchloric acid and nitric acid (1:1:5) was utilised. One g of powdered plant sample taken in beaker was added 15 mL of acid mixture. The sample in beaker was heated for digestion at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24732487

70 °C on hot plate in a fume hood. In order to avoid the evaporation of metal contents, the digestion process was carried out at slow rate. Near to dryness, 10 mL of acid mixture were added again and the temperature was increased slowly upto 90 °C to get around 5-8 mL of clear digested solution. Then, the cooled digested solution in the beaker was added 15 mL of nitric acid (0.05 N) and filtered by using Whatsman filter paper no. 41. The volume of the filtered digest was made upto 30 mL with 0.05 N nitric acid solution and stored at 4 °C in pre-washed, dried polythene bottles for metal analysis (Sharma et al., 2008).

Extraction of the plant samples for analysis of phytochemicals

Two-step extraction procedure was adopted for the investigation of antioxidant activity and phytochemical components. Water and acetone solvents were used in first and second steps for the extraction of hydrophilic and hydrophobic contents respectively.

For water extraction, 1 g powdered plant sample in 10 mL distilled water was centrifuged for 20 min at 6000 rpm and supernatant was shifted to a test tube. The same extraction practice was repeated thrice and each time upper layer was collected in the test tube. The solid residue left after the water extraction was further extracted three times using acetone (1:10 w/v) and the supernatant layer was saved in another test tube. Both the extracts containing phytochemical ingredients were stored at -10 °C to carry out further analysis in the department of Chemistr, Mirpur University of Science and Technology, Mirpur, which is situated at Pakistan country in the cities place category with the GPS coordinates of 73° 45’ 6.3720” E and 33° 8’ 54.2112” N.

Investigation of phenolic contents

The investigation of phenolic contents in water and $(CH_3)_2CO$ concentrates was finished with the assistance of the strategy depicted by Jing et al. (2015). Above all, arranged the ten time’s diluted Folin-ciocalteu by including one mL Folin-ciocalteu, finished the level up to ten mL with distilled H_2O. Around 1 mL of H_2O and $(CH_3)_2CO$ concentrate was mixed with 5 mL of diluted Folin-ciocalteu and 4 mL of 7.5% Na_2CO_3. Before measuring spectrophotometrically the absorbance at 760 nm, left the blend at room temperature to 90 min.

Investigation of flavonoids contents

Recognition of flavonoids was finished with the assistance of strategy altered by Jing et al. (2015). Around 5 mL of H_2O or $(CH_3)_2CO$ concentrates were added into 0.3 mL of 5% $NaNO_2$ for 5 min, and then included 0.3 mL of 10% $AlCl_3$ in the certain blend. Two mL of 1 M NaOH was included the blend to discontinue the response after six min. The surrendered blend was diluted to 10 mL and calculated the absorbance quickly at 510 nm. Rutin was utilized as standard and flavonoids were explained as rutin counterparts.

Investigation of flavonols

Flavonols in the samples were recognized by utilizing the strategy set by Kumaran and Karunakaran (2006). Around 2 mL of H_2O or $(CH_3)_2CO$ concentrate mixed with 2 mL of (50 g/L) CH_3COONa and 2mL of 2% aluminium chloride in the concentrate.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24732487

The blend was permitted to left for 2.5 h and then measured the absorbance at 440 nm. Rutin was utilized as a standard for the detection of flavonols using calibration curve equation y = 0.0007x + 0.3591 (x = concentration of rutin, y = absorbance).

Scavenging activity of DPPH

Scavenging action of DPPH (2, 2-diphenyl-1-picrylhydrazyl) was documented by the strategy portrayed by Yu et al. (2002) and Aoshima et al. (2004). Around 1 mL of the specimen concentrate was added in 2.5 mL of DPPH (0.1 mM in CH_3OH) and held the blend in darkness for 30 min. At 517 nm, vanishing of the shade of DPPH was measured against the clear. The outcomes were measured as *Equation 1:*

$$\% \text{ inhibition} = \frac{\text{A Blank} - \text{A Sample}}{\text{A Blank}} \times 100 \quad \text{(Eq.1)}$$

Scavenging activity of OH°

The scavenging activity of OH° of concentrates of plants in H_2O and $(CH_3)_2CO$ was portrayed by Yu et al. (2004). Around 3 mL of H_2O or $(CH_3)_2CO$ concentrate was mixed in 1 mL of $C_{12}H_8N_2$ (0.04 M), 2 mL phosphate buffer (0.2 M), and 0.04 L of $FeSO_4$ (0.02 M). The reaction was begun by the addition of 0.1 mL of 7.0 mM hydrogen peroxide in the blend, and then measured absorbance at 560 nm. The scavenging activity was evaluated as expressed in *Equation 2:*

$$\text{Scavenging activity} = \frac{\text{A Blank} - \text{A Sample}}{\text{A Blank}} \times 100 \quad \text{(Eq.2)}$$

Scavenging activity of hydrogen peroxide

Aiyegoro and Okoh (2010) reported the method for the measurement of scavenging activity of H_2O_2. The 2.4 mL of hydrogen peroxide solution (4 mM) prepared in 0.1 M phosphate buffer (pH 7.4) was blended with 4 mL extract and incubated for 10 min at room temperature, then measured absorbance at 230 nm against the blank (Reimann and de Caritat, 2005)**.** Scavenging activity was calculated as *Equation 3:*

$$\text{Scavenging activity} = \frac{\text{A Blank} - \text{A Sample}}{\text{A Blank}} \times 100 \quad \text{(Eq.3)}$$

Chelating action of Fe^{+2}

The chelating capacity of Fe^{+2} ions was evaluated via the technique for Dinis et al. (1994). Around 2 mL $FeSO_4$ (0.125 mM) was mixed with 2 mL of water or $CH_3)_2CO$ extracts. Two mL ferrozine (0.3125 mM) was added into the blend to start the reaction and left the blend for ten min. The absorbance was measured at 562 nm against the blank. The accompanying equation was utilized to ascertain chelating action (*Eq. 4*):

$$\text{Chelating Activity} = \frac{(\text{A control} - \text{A Sample})}{(\text{A control})} \times 100 \quad \text{(Eq.4)}$$

Ferric reducing antioxidant power (FRAP)

Hazara et al. described the method for the detection of ferric lessening cancer prevention agent control (Hazara et al., 2008). Around 2 mL of concentrate was blended

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24732487

with the two mL phosphate buffer (0.2 M, pH 6.6) and two mL of 0.1% $C_6N_6FeK_3$ and held the mixture for twenty min at 50 °C. Subsequent to twenty min, the reaction was clogged by two mL $C_2HCl_3O_2$ (10%). The supernants were blended with 2 mL of $FeCl_3$ and 2 mL of H_2O and permitted to remain for 20 min and afterward absorbance was measured at 700 nm aligned with the clear. Ascorbic corrosive was utilized as positive control.

Ascorbic acid determination

Ascorbic corrosive substances were controlled by the strategy as expressed by Klein and Perry (1982). Dry water extract was re-extricated for HO_3P (1%, 10 mL) to 45 min and then filtered. 1 mL filtrate was blended in 9 mL $C_{12}H_7NCl_2O_2$ (0.8 g/1000 mL) and then measured absorbance inside thirty min at 515 nm. Ascorbic substances computed from L-ascorbic acid bend (0. 006-0.1 mg/mL; y = 3. 006x + 0. 007; R^2 = 0. 999), and results were communicated as ascorbic corrosive equivalents.

Phosomolybdenium complex assay

Prieto et al. described the method to measure Phosomolybdenium complex of the extracts spectrophotometrically (Prieto et al., 2006). Quickly 2 mL of sample in H_2O or $CH_3)_2CO$ was mixed in 6.6 mL claiming reagent (28 mol/L Na_3PO_4, 0.6 $molL^{-1}$ sulphuric acid and 4 $molL^{-1}$ $(NH_4)_6Mo_7O_{24}$ topped the mixture and incubated at 95 °C for 90 min. After cooling, the absorbance was measured at 695 nm alongside reasonable holding one mL of reagent and also one mL H_2O rather than extracts and after that subjected to the same exploratory conditions. The outcomes from three examinations, each kept running in triplicate, were communicated as the mean of relative antioxidant action (RAA) compared with that of vitamin-C.

Daily intake of metals (DIM)

Information regarding the daily ingestion of therapeutic plants was gathered during the study. DIM was computed as *Equation 5:*

$$\text{DIM} = \frac{\text{Cmetal} \times \text{CFactor} \times \text{Cfood intake}}{\text{Baverage weight}} \quad \text{(Eq.5)}$$

C_{metal} stands for metal contents in selected samples, C_{Factor} depicts the conversion factor (value is 0.083), $C_{food\ intake}$ utilization of therapeutic plants which is 100 mg per individual per day and $B_{average\ weight}$ corresponds to the normal body weight within review range which is 50 kg.

Health risk index (HRI)

$$\text{HRI} = \text{DIM} / \text{RfD} \quad \text{(Eq.6)}$$

RfD characterizes the reference oral measurement. The value of health risk index less than one represents the protected mode for nearby populace through intake of plants and the other way around (*Eq. 6*).

Results and discussion

Flavonoids, flavonols and total phenol contents of the extracts

It has been identified that flavonoids show cell reinforcement endeavour and their outcomes on ethnical nourishment then wellbeing are impressive. Several recent studies have confirmed that phytochemicals including alkaloids, flavonoids, flavonols, phenols, terpenoids and steroids have colossal antioxidant and free radical scavenging activities. Plant extracts rich in polyphenols and essential phytoconstituents have been shown to display persuasive antioxidant and free radical scavenging activities in diverse antioxidant models (Farhan et al., 2012; Amari et al., 2014).

The flavonoids, flavonols and phenols are important as their hydroxyl groups are accountable for antioxidant effects in plants. Highest flavonoid contents were shown by water extract of leaves of *Ajuga bracteosa* (81.56 mg/g) and least contents (12.01 mg/g) were present in roots of *Calotropis procera* (*Table 1*). Leaves and flowers of *Calotropis procera* showed highest flavonol contents in water and acetone extracts respectively (98.98 mg/g, 60.27 mg/g). Least flavonol contents were present in water and acetone extracts of roots of *Ajuga bracteosa* (82.71 mg/g). Phenolic substance are measured as far as gallic equivalents having highest contents in leaves of *Ajuga bracteosa* (66.60 mg/g) followed by leaves of *Calotropis procera* (*Table 1*).

Table 1. *Phytochemical constituents in leaves, flowers and roots of Ajuga bracteosa and Calotropis procera*

Botanical name of therapeutic plants	Part of the plant taken	Local name	Total phenolic contents (mg/g)		Flavonoid contents (mg/g)		Flavonol contents (mg/g)	
			Water	Acetone	Water	Acetone	Water	Acetone
Ajuga bracteosa	Leaves	Hari Boti	66.60	56.10	81.56	40.77	20.48	15.44

Antioxidant activity

The antioxidants from the leaves, roots and flowers of *Ajuga bracteosa* and *Calotropis procera extracted* in water and acetone are shown in *Table 2*.

The free radical scavenging activity of both hydrophilic and lipophilic antioxidants is estimated by the DPPH radical that is a stable free radical, and has been widely used as a sensitive and rapid tool. DPPH interact with antioxidants that neutralize the free radicals by transferring electrons or hydrogen atoms to DPPH (Archana et al., 2005). Watery extract of flowers of *Ajuga bracteosa* showed highest DPPH scavenging activity (97%) over roots and leaves (96%, 94%). The OH radical has been considered as a highly damaging ROS in free radical pathology, has ability to damage almost every molecule in living cells. The hydroxyl radical scavenging capacity of therapeutic plants is directly related to their antioxidant activity (Uttara et al., 2009). Roots of *Ajuga bracteosa* and leaves of *Calotropis procera* gave the same OH radical and hydrogen peroxide scavenging activity respectively in aqueous extracts (77%), while acetone

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24732487

extracts gave the poor OH radical and hydrogen peroxide scavenging activities. The higher antioxidant yield from leaves and blooms of Ajuga bracteosa and Calotropis procera with water solvent prominently indicate viability of this solvent towards antioxidant components from these materials.

Table 2. *Antioxidant activities in leaves, flowers and roots of Ajuga bracteosa and Calotropis procera*

Metal chelating action

The chelating of Fe^{+2} by different plant extracts is evaluated via the method utilized by Dinis et al. (1994). Different studies revealed that the reducing power of biologically active compounds relative to their antioxidant action is reflected by the electron donation capability. Antioxidants are reducing agents, and inactivation of oxidants by reductants can be described as a reduction–oxidation (redox) reaction, in which one reaction species is reduced at the expense of the oxidation of the other (Gulcin et al., 2010). In the reducing power assay, the presence of antioxidants in the therapeutic plants would cause the reduction of Fe_3^+ to Fe_2^+ by donating the electron. Aqueous extract of leaves of *Ajuga bracteosa* was the most active extract interfered with the formation of ferrous and ferrozine complex, that is connected with redox metal catalysis incorporates chelating in regards to the metal particles before ferrozine followed by chelating activity of roots and flowers of *Ajuga bracteosa,* then, leaves of *Calotropis procera*. Acetone extracts showed less chelating activity towards Fe^{+2} (*Table 3*).

Table 3. *Fe^{+2} chelating activity and FRAP activity in leaves, flowers and roots of Ajuga bracteosa and Calotropis procera*

Botanical name of therapeutic plants	Part of the plant taken	Local name	Fe^{+2} chelating activity (%)		FRAP activity (%)	
			Water	Acetone	Water	Acetone

DOI: http://dx.doi.org/10.15666/aeer/1702_24732487

Table 3 showed the ferric reducing antioxidant power (FRAP) activity in different parts of *Ajuga bracteosa* and *Calotropis procera* in aqueous and acetone extracts. Acetone extracts of *Calotropis procera* showed highest FRAP activity followed by water extracts of *Ajuga bracteosa*.

Phosomolybdenium complex assay and ascorbic acid determination

Phosphomolybdenium assay was expressed as mg AAE/100 g (*Table 4*).

Roots of *Ajuga bracteosa* and flowers of *Calotropis procera* showed significantly higher values in aqueous extract (212.9 mg/g, 207.65 mg/g) respectively. Aqueous extract of flowers of *Ajuga bracteosa* showed the second higher contents (100 mg/g). Lower contents were observed in acetone extracts of flowers of *Ajuga bracteosa* and leaves of *Calotropis procera* (6.0 mg/g, 6.65 mg/g). Significantly differences in ascorbic acid contents among different parts of two plants were recorded (*Table 4*). Flowers of *Ajuga bracteosa* and *Calotropis procera* had the highest and same ascorbic acid contents (0.469 mg/g) followed by roots of *Ajuga bracteosa* (0.379 mg/g). Lower contents were observed in roots of *Calotropis procera* (0.121 mg/g).

Table 4. *Phosomolybdenium complex assay and ascorbic acid contents in leaves, flowers and roots of Ajuga bracteosa and Calotropis procera*

Botanical name of therapeutic plants	Part of the plant taken	Local name	Phosomolybdenium complex assay (mg/g)		Ascorbic acid determination (mg/g)

Distribution of metals

Sources of different metals in soil, plants and water are anthropogenic activities and furthermore from parent materials; however it is hard to assess the ordinary foundation groupings of metals in soil, water and plants (Reimann and de Caritat, 2005). Thus it is surveyed that centralization of metals contains both a trademark geochemical partition and anthropogenic exercises (Acosta et al., 2010). The distribution of metals among selected plants is represented in *Table 5*. Except lead, all metals are present in considerable concentrations. Highest mean level is shown by iron followed by zinc. The decreasing order of concentration of metals is as follows; Fe > Zn > Cu > Ni > Cd > Pb. The relationship study was likewise done to evaluate the shared varieties of chose metals in selected plants.

The correlation coefficients of selected metals in medicinal plants are shown in *Table 6*. Compact disc Fe (r = 0.756) and Fe-Cu (r = 0.633) depicted the positive association. Be that as it may, exceptionally solid positive connection was appeared by Pb-Ni (r = 0.839). Strongest connection was appeared by Zn-Fe (r = 0.869) and Zn-Cd (r = 0.851), showing their conceivable basic starting point.

Cluster investigation of metals was done so as to study the multivariate seizure as appeared as dandrogram in *Figure 2*. Cluster examination gives the huge information on the premise of comparable qualities. Three clusters were observed for selected metals. First cluster exhibited close association of metals (Zn, Fe, and Cd). Cluster of Cu showed mutual relationship with first cluster depicted that the metal concentrations vary because of basic components of the soil minerals and they have lithogenic cause. Third Cluster was appeared by Ni and Pb which also entangled with other clusters revealed that this association may be contributed by the horticultural exercises and additionally dry statement of the suspended particulates.

The quartile circulation of metals in therapeutic plants is shown in *Figure 2*. Symmetric distribution was shown by essential metal i.e. iron. Narrow distribution was shown by Ni, Pb, Cu and Cd. on the ability about dirt towards a multivariable-based cation profession get ready fundamentally liable to physicochemical conditions, for example, pH, temperature and the propinquity of different particles within the dirt structure. Description of health risk assessment is represented in *Table 7*. Health risk index revealed that some metals have safe level in selected plants so that some parts of selected therapeutic plants can be used as drug development and as a supplement to human body. Higher levels of cadmium and iron are investigated by consuming different parts of selected plants.

Conclusion

This study gives an evaluation that chosen plants can be used as cancer prevention agents. Antioxidant properties and phytochemical contents varied among the water and acetone extracts of selected plants. Among these plants, *Ajuga bracteosa* extricate indicated extremely high antioxidant properties and elevated aggregate phenolic substance. It is demonstrated that flavonoid contents are the significant supporter of the cancer prevention agent properties of these plant extracts. The HRI indicates higher levels of cadmium present in roots and flowers of *Calotropis procera* and also in flowers of *Ajuga bracteosa.* The results also indicate that roots of *Calotropis procera* and flowers of both *Calotropis procera* and *Ajuga bracteosa* also exhibit less

phytochemical constituents and antioxidant activity. Based upon the study outcomes, it is proposed that the users should avoid taking roots and flowers of *Calotropis procera* and flowers of *Ajuga bracteosa* to cure ailment. Further study is recommended to find and isolate the potential antioxidants to be used in the drug development

Abstract. This paper aims to estimate the extent of the burned area in ex-Mega Rice Project (MRP) (Block A and Block E), Central Kalimantan and quantify the carbon emission as a result of peat fires in this area. A Synthetic Aperture Radar TerraSAR-X image was the main input in this study. Pre-processing included radiometric calibration, geometric reprojection and speckle filtering (Gamma MAP 7 × 7 kernel size). Maximum Likelihood (ML) classification was used for classifying burned areas. The classification result was validated based on data from the Kalimantan Forests and Climate Partnership report (KFCP). The burned area in 2010 as estimated by the TerraSAR-X satellite image HH/HV polarization was 47.6113 km^2 (4761.13 ha). Main pollutants (carbon dioxide (CO_2), carbon monoxide (CO), particulate matter (PM), black carbon (BC) and organic carbon (OC)) emissions were estimated based on an empirical equation. The average annual carbon releases into the atmosphere from this area were estimated to be 173,019.46 ton CO_2, 11,388.62 ton CO, 1,149.81 ton PM_{10}, 996.50 ton $PM_{2.5}$ 569.43 ton OC and 72.27 ton BC. This study suggests that the methodology proposed based on Earth Observation data can be used to locate burned areas in tropical environment and quantify carbon emissions.
Keywords: *burned area, emission factor, earth observation, forest fire, Ex-mega Rice Project, TerraSAR-X, dual polarization*

Introduction

Peatlands are wetland ecosystems frequently encountered in Southeast Asia. They play a vital role in the biosphere's biogeochemical processes (Immirzi, 1992). At a global scale, they hold an important ecological function as they represent a major store of soil carbon, sink for carbon dioxide and source for atmospheric methane (Strack, 2011); at a local scale they host habitats for several rare and endangered species (Posa, 2011). Page et al. (2011) estimated the volume of tropical peat to be 1758 Gm^3 (~18–25% of global peat volume) with 1359 Gm^3 located in Southeast Asia (77% of all tropical peat). During the last decades, the area of tropical peat swamps has been reduced and degraded due to deforestation, drainage, fires, clearing for agriculture and oil palm plantations and illegal timber harvest (Peace Report, 2018; Koh et al., 2009). From all these causes of environmental degradation, fires are a unique one that can be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24892499

attributed partially to anthropogenic interference, however sometimes they can occur naturally; for instance, it has been demonstrated that fires have been observed during El Niño events as a direct consequence of the extensive drought incurred from the latter (e.g. in 1997, 2002, 2004, 2006 and 2009) (Ballhorn et al., 2009; Putra et al., 2008). Therefore, monitoring of tropical peatlands is crucially important for inventorying the magnitude of carbon stock and estimating the pollutants emitted to the atmosphere.

Deforestation has been a major cause of peatland disturbance; in 2005, 25% of all deforestation in SE Asia was on peatlands according to Rieley et al. (2008). Within Southeast Asia, Indonesia is the country with the largest share of tropical peat carbon stock estimated at 57.4 Gt (Page et al., 2011). In 1996, the Indonesian government initiated the Mega Rice Project (MRP) in the southern parts of Central Kalimantan. The aim of this project was to convert one million hectares of peat swamp forest to rice paddies. Consequently, forest cover decreased from 64.8% in 1991 to 45.7% in 2000, and clearance has continued since then. The MRP project led to frequently large fire occurrences during dry seasons. Approximately 4,740 km^2 in MRP have been damaged from severe fire episodes in 1997 and released 0.19 – 0.23 Gt of carbon to the atmosphere. This huge amount of carbon suggests that severe peat fires occurred in the MRP area (Putra et al., 2008).

Chemical species have long been detected and quantified directly from specialized satellite instruments such as the GOME instrument onboard ERS-2, the MODIS instruments onboard TERRA and AQUA satellites and the SCIAMACHY instrument onboard ENVISAT. Streets et al. (2013) provide a review on emission estimates from satellite retrievals. Another indirect approach to estimate gas emissions is to spatially quantify the phenomenon generating the emissions and then estimate the latter based on empirical relationships or models. This indirect approach is of special interest in land cover applications since Earth Observation has advanced significantly in estimating the spatial extent of deforestation activities and subsequently the calculation of environmental parameters (e.g. Kim et al., 2015; Zeng et al., 2018; Broich et al., 2017; Krasovskii et al., 2018; Joshi et al., 2015; Fawzi et al., 2018; Nugroho et al., 2018; Grinand et al., 2013). For instance, Carlson et al. (2013) estimated high-resolution carbon flux estimates from Kalimantan oil palm plantations based on land cover classification from Landsat data (at spatial resolution of 30 m). In the context of forest fires, an immediate consequence is forest loss and the associated outcome is the pollution emissions during the combustion (Page et al., 2002; Hooijer et al., 2010). Forest fires result to emission into the atmosphere of particulate matter (PM_{10}, $PM_{2.5}$), particulate black carbon (BC), organic carbon (OC) and gaseous emissions (carbon monoxide (CO), carbon dioxide (CO_2), nitrogen oxides, non-methane volatile organic compounds (NMVOC), methane (CH_4), nitrous oxide (N_2O), sulfur dioxide (SO_2) and ammonia (NH_3)) (Shrestha et al., 2013). CH_4 and N_2O emissions from tropical peatlands are low (Strack, 2008). On a global scale, fire impacts the net carbon balance of global terrestrial ecosystems; this impact has been quantitatively assessed by Li et al. (2014). Recent research from Junpen et al. (2018) suggested that emissions from biomass open burning can be estimated based on burned area products derived from satellite data. In a similar context, Hawbaker et al. (2016) mapped the extent of burned area in the Southern Rocky Mountains, USA, subsequently use the LANDFIRE Fuel Characteristic Classification System to assign biomass loads and finally estimate biomass consumption and greenhouse gas emissions based on the CONSUME model. Several other studies have quantified burned area based on satellite data (e.g. Junpen et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24892499

2013; Permadi and Oanh; 2013). A critical aspect in such methodological approach is the spatial resolution of the satellite image which plays an important role in the accuracy of the burned area estimation and subsequently the estimation of pollutants emissions (Belenguer-Plomer et al., 2018; Yun and Pritchard, 2018). For a review of the strengths and limitations of remote sensing in estimating tropical forest biomass, the reader is directed to Mitchard (2015) and Saatchi (2015).

The aim of this paper is to assess the burned area based on fine spatial resolution Synthetic Aperture Radar (SAR) satellite images and field data, and consequently quantify the carbon emissions through empirical relationships that occurred from peat fires in blocks A and E of the MRP.

Materials and methods

Study area

Central Kalimantan, Indonesia is the second largest province of the island of Kalimantan and the third largest province of the country, covering 153,800 km^2. The climate is tropical with a significant amount of rainfall; the drier season usually begins in May and lasts until October while the wetter season covers the period between November and April. The temperature fluctuates between 25-27 °C and the rainfall ranges from 2,776 to 3,393 mm per year with an average of 145 rainy days annually (Moore et al., 2011). The central area of Central Kalimantan is covered by tropical forests while the southern area is swampy with an extensive river network. Peat swamp forest areas in Indonesia are primarily located at low altitudes in the coastal and sub-coastal lowlands of Papau (4.6 Mha), Sumatra (8.3 Mha) and Kalimantan (6.8 Mha) (Page et al., 1999); central Kalimantan contains one of the largest tropical peatland areas in the world. *Figure 1* presents the study area which is part of the MRP.

Satellite data

A SAR image was used in this study as the main input. TerraSAR-X is a high spatial resolution X-band SAR active system operating at 9.65 GHz centre frequency. The satellite was launched in 2007 and provides single, dual or full polarization data at a spatial resolution between 1 m and 16 m depending on the mode of acquisition. A TerraSAR-X Single Look Slant Range Complex (SSC) product in the DLR-defined COSAR binary format and the associated Multi Look Ground Range Detected (MGD) product in GeoTiff format were provided by ASTRIUM GEO-Information. The MGD product is a multi-look product with reduced speckle and approximately square ground resolution cells. The image was acquired in dual polarization (HH/HV) StripMap imaging mode on 05/04/2010 with a 6.6 m spatial resolution and 37.489 incidence angle. The image coordinates are oriented along the flight direction and the ground range. A simple polynomial projection was performed in range to an ellipsoid in order to achieve approximately quadratic pixels. The advantage of this product is the fact that no image rotation to a map coordinate system has been performed and interpolation artefacts are thus avoided.

Satellite image processing

The TerraSAR-X image was preprocessed by applying sequentially radiometric calibration, geometric reprojection and speckle filtering. An absolute radiometric calibration of Sigma Naught (σ0) was performed providing radar reflectivity per unit area at ground range. The simplified approach was followed where Noise Equivalent Beta Naught (NEBN) was ignored. The image was then reprojected onto the Geographic Lat/Lon (WGS 84) Coordinate Reference System (CRS) using the nearest neighbour resampling method. Finally the Gamma MAP filter with 7 × 7 kernel window was applied to reduce the speckle noise of the image as it has been shown to provide the best results in a tropical environment (Nuthammachot et al., 2017).

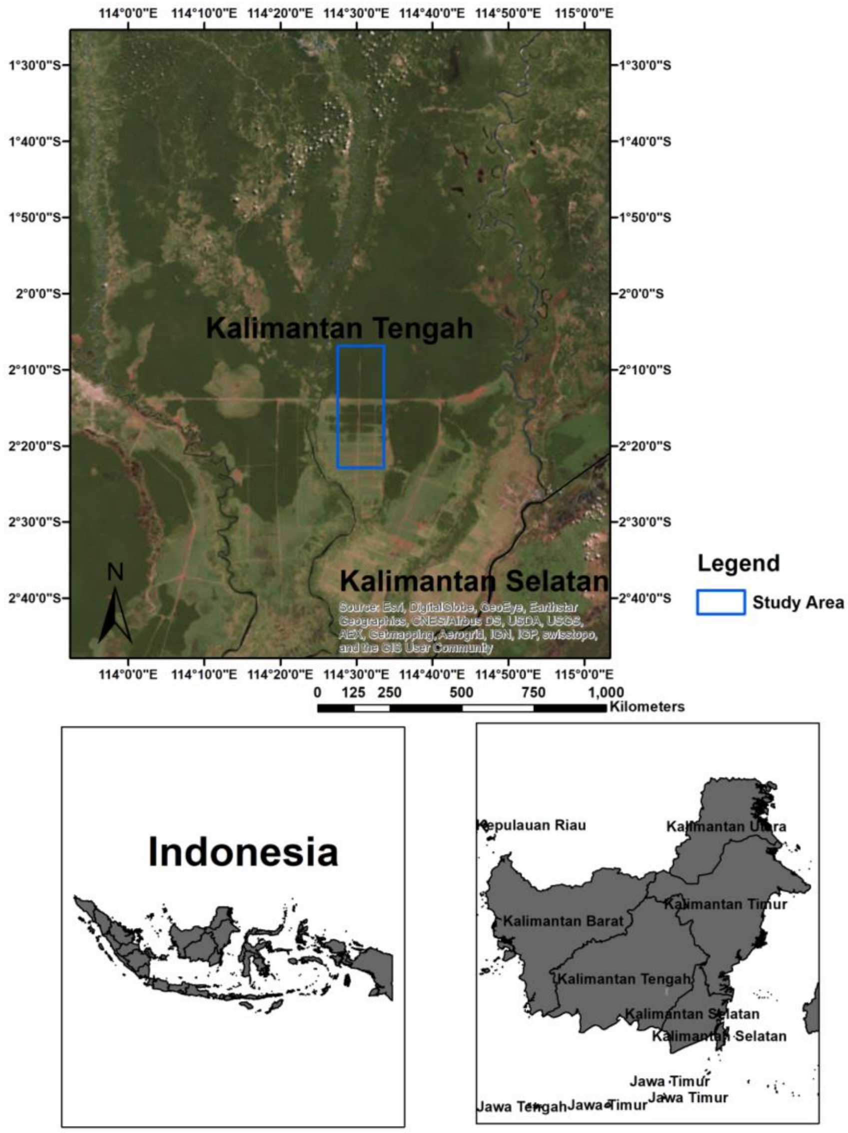

Figure 1. *A true-colour satellite image representation of the study area in Central Kalimantan, Indonesia*

For the detection of the burn areas the Maximum Likelihood (ML) algorithm was used to classify pixels corresponding to burned land as it is one of the most traditional classification algorithms developed, yet has been proven very powerful in a variety of remote sensing challenges. The thematic map produced indicating the burned area as estimated from TerraSAR-X dual polarization (HH/HV) was validated with the field

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24892499

data published in the Kalimantan Forests and Climate Partnership (KFCP) report (KFCP Vegetation Monitoring, 2014). The results of the validation were presented with an error matrix (contingency table) as suggested by Congalton (1991).

Emission estimation

The burned area calculated from the SAR data was used as an input to estimate the emission pollutants in this study area. Particulate matter and trace gas emissions from forest fires can be approximated based on the availability of field data in a given area. Hao and Liu (1994) present a methodology to estimate forest fire emissions (*Eq. 1*) based on which the emission of each pollutant can be quantified.

$$\mathrm{Em}_{\mathrm{i,j}} = \sum_{j} M_j \times \mathrm{EF}_{\mathrm{i,j}} \times 10^{-3} \qquad \text{(Eq.1)}$$

where:
$Em_{i,j}$ = Emission of pollutant i from land cover type j (tonne/yr)
M_j = Amount of burned biomass on land cover type j (tonne/yr)
$Ef_{i,j}$ = Emission factor of pollutant i from land cover type j (g/kg of dry matter)

The amount of biomass burned each year from forest fires was calculated by multiplying the factors burned area, fraction of total area burned annually, dry matter density and burning efficiency as presented in *Equation 2*. Dry matter density ρi and forest burned area fraction fj values were taken from the FAO Forest Resource Assessment (FAO, 2003).

$$M_j = \mathrm{A}_j \times f_j \times \rho_j \times \eta_j \qquad \text{(Eq.2)}$$

where:
A_j = Area of land cover type j (ha)
f_j = Fraction of total area burned annually of land cover type j
ρ_j = Dry matter density (tonne/ha)
η_j = Burning efficiency (oxidized in the combustion)

The emission factors of forest burning in a tropical forest environment were adapted from Andreae and Merlet (2013) and are provided in *Table 1*. The unit of emission factors (g/kg dry mass residue burning) was calculated by the division of the mass concentration of a pollutant (e.g. CO_2) {g} and the dry mass residue before burning {kg}. This parameter is reliable to use for pyrogenic emission factors for pollutants in tropical forest areas. In the literature, most of available CO_2 emission factors from biomass burning especially from forest fires are reported higher than 1,000 g/kg, e.g. Andreae et al. (2001), Chaiyo and Garivait (2014), Shrestha et al. (2013). In case of a complete combustion, the carbon released into the atmosphere would be equal to the carbon in the form of CO_2. As forest fire is frequently an incomplete combustion, the carbon discharged in the form of CO_2 represents more than 90% of the total carbon lose; CO emissions account for less than 5% of the total carbon release and minor carbonaceous compositions comprise of BC and OC (Chaiyo and Garivait, 2014). Consequently, the emission factor for CO_2 is higher comparing to other emission factors.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24892499

Emission factors and other parameters i.e. dry matter density, burning efficiency for determining the biomass burned differ for each vegetation species, geographic location and environmental conditions. At global scale and national level, the estimation of emissions has been based on available guides such as the Intergovernmental Panel on Climate Change (IPCC) report 2006 for greenhouse gases emission inventory and research data or the approach proposed from Andreae and Merlet (2001). However, a country-specific value is needed to apply to Indonesia area for accurate data. In this study, we used primary data from Asian countries to estimate carbon emission. When the default parameters have been unavailable for Asia countries, the others parameters for a simlar climatic conditions and vegetation type have been the first choice (Junpen et al., 2013; Phairuang et al., 2017).

Table 1. *Pyrogenic emission factors for pollutants of interest for the tropical forest environment (adapted from Andreae and Merlet, 2013)*

Pollutant (abbreviation)	Pollutant	Tropical forest (g/kg)
CO_2	Carbon dioxide	1580
CO	Carbon monoxide	104
PM_{10}	Particulate matter less than 10 microns in diameter	6.5-10.5
$PM_{2.5}$	Particulate matter less than 2.5 microns in diameter	9.1
OC	Organic carbon	5.2
BC	Black carbon	0.66

Results and discussion

Burned areas enclosed in the MRP sites at Central Kalimantan, Indonesia were detected using a dual polarization TerraSAR-X image acquired in April 2010. *Figure 2* depicts the burned area as reported by the KFCP report (KFCP Vegetation Monitoring, 2014) and as estimated from the SAR image classification followed in this paper. It is apparent that the spatial distribution of the binary classification results from the classification of the SAR image correspond closely to the results reported by the KFCP. We estimated that the cumulative burned area calculated from the SAR image processing algorithm accounts for 47.6113 km^2 (4761.13 ha). The cumulative burned area reported from the reference map was 50.4128 km^2 (5041.28 ha). It has to be noted that these two datasets refer to two consecutive years. *Table 2* provides the accuracy assessment, with the reference data represented from the KFCP report (KFCP Vegetation Monitoring, 2014). The overall accuracy was 88.26%. The commission error for the burned area was 26.21%, which is attributed to the fact that several very small areas scattered around the image (salt and pepper effect) were classified as burned areas while they have been noise from the SAR image instead. A larger kernel in the speckle filter could have eliminated these pixels and reduce the commission error, however other artefacts would have been introduced in the image by selecting a kernel with a larger than 7 × 7 window size. The omission error was 33.80% and these are areas at the south-east side of the image and further away from the drainage canals; either the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24892499

classifier has underestimated the burned effect in this part of the image, either this was a direct consequence of the difference in date acquisition of the two data sets.

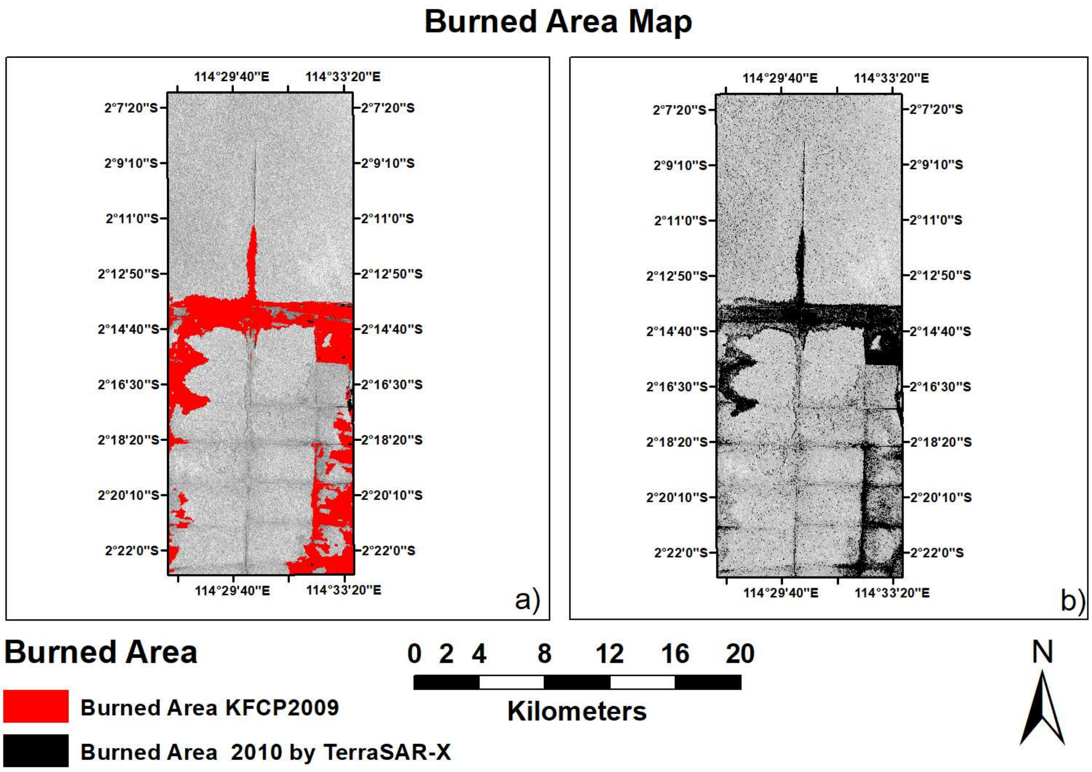

Figure 2. *Burned area map in the location of the MRP site Central Kalimantan, Indonesia: (a) burned area in 2009 by KFCP (KFCP Vegetation Monitoring, 2014); (b) burned area in 2010 by TerraSAR-X satellite image HH/HV polarization*

The estimation of pollutant emissions from burned areas in the area of interest based on the SAR data classification results (*Table 3*) showed that the emission pollutants of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_24892499

CO_2 was 173,019.46 ton, CO (11,388.62 ton), PM_{10} (1,149.81 ton), $PM_{2.5}$ (996.50), OC (569.43 ton) and BC (72.27 ton). These results indicate that CO_2 has the highest annual carbon releases into the atmosphere in this study area while BC are estimated to the lowest value comparably (*Table 3*).

Table 3. *Emission pollutants estimated based on the identified burned areas from the SAR satellite image classification*

Pollutant	Tropical burned forest (tons)
CO_2	173,019
CO	11,388
PM_{10}	1,149
$PM_{2.5}$	996
OC	569
BC	72

Conclusions

In this paper the burned area of a tropical peatland area in Central Kalimantan, Indonesia was estimated based on a very high spatial resolution SAR satellite image and evaluate against field collected data reported from KFCP (KFCP Vegetation Monitoring, 2014). The two results agree spatially in regard to the distribution of burned areas. The burned area estimated from the SAR image was subsequently input in an equation developed to estimate pollution emittance. We found that the average annual carbon release from the area of study into the atmosphere is 173,019.46 ton CO_2, 11,388.62 ton CO, 1,149.81 ton PM_{10}, 996.50 ton $PM_{2.5}$, 569.43 ton OC and 72.27 ton BC. The workflow presented, based on SAR satellite data, can be followed to map the burned area, estimate the cumulative land affected by fire and its corresponding biomass and quantitatively approximate the pollutants emission. The future research direction is a comparative analysis between SAR and other optical satellite images, such as Landsat and Sentinel-2, to improve the accuracy of the results.

Acknowledgements. (Received 3rd Nov 2018; accepted 28th Jan 2019)

Abstract. Butterflies have an important role in the ecosystem of Sangihe Island, North Sulawesi, Indonesia. Currently, data on the diversity of butterflies on the island are still lacking and have not been published yet. Therefore, this study was aimed to analyze the structure of the butterfly community and its diversity in Sangihe Island, North Sulawesi, Indonesia. The research was conducted from March 2018 to May 2018 in Sangihe Island, North Sulawesi. Sampling was performed at three types of habitat: a farm, a forest edge, and bushes. Sampling method used was surveyed with purposive sampling. A collection of butterflies was gathered by the sweeping method using sweep net following the transect line randomly for 500 m long. At each habitat, four transects were set and the collection step was duplicated. Sampling was performed from 8.00 am to 15.00 pm. The collection comprised of 5 families, 39 species, and 944 individuals. The most commonly found family was Nymphalidae, while the most abundant species were *Junonia hedonia intermedia* and *Eurema tominia*. Species abundance, species richness index, species diversity index, and species evenness index were found to be the highest at the forest edge habitat, while the lowest ones were from the bushes. The diversity of the butterflies at the forest edge habitat was higher since host plants were located in the area, and the vegetation served as a food source and shelter for the animals.
Keywords: *forest edge, sweep net, Junonia hedonia, Nymphalidae, host plant*

Introduction

Sangihe Island is one of the most remote islands in the province of North Sulawesi, which directly borders with the Philippines. The Sangihe Island biodiversity involves a variety of plants and animals including butterflies (Shekelle et al., 2008; Central Agency on Statistics, 2015).

Butterflies are part of Lepidoptera, a type of insect with scaled wings. The scales provide beautiful colour patterns such as ribbon, nodes, and circles (Braby, 2004; Arya et al., 2014). The beautiful color patterns make several types of butterflies highly hunted and traded as collection, thus making them declared as endangered species (Coote, 2000). The diversity of butterflies in Indonesia is abundant, which consists of about 1,600 species out of 20,000 species among all species of butterflies worldwide (Alarape et al., 2015). The rich biodiversity in Indonesia could only be rivalled by the tropical countries in South America, such as Brazil and Peru that have about 3,000 species. The king butterfly, *Troides hypolitus*, is mostly found in the western part of Indonesia and Sulawesi, with some species spread in Maluku and Papua. Sulawesi is an island with the highest uniqueness of butterflies in Indonesia. From 557 species of butterflies spread in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25012517

Sulawesi, 239 of them (more than 40%) are endemic and can only be found on the island, such as *Papilio blumei*. Meanwhile, more than 600 species are spread in Java and Bali islands, 40% of which are endemic species (Amir and Kahono, 2008; Nidup et al., 2014).

Butterflies have an important role in maintaining the biodiversity with their function as pollinator that help pollination in plants, thus they help breeding of plants naturally (Plona, 2002; Perveen and Haroon, 2015). Moreover, butterflies are an important food for birds, reptiles, spiders and other predatory insects (Haroon et al., 2013). In terms of conservation of the ecosystem, butterflies are popular as bioindicators of the change of quality of the environment (Patil and Shende, 2014; Arya et al., 2014; Ghosh and Mukherjee, 2016).

Butterflies are often used as a model by scientists to estimate and predict biodiversity due to the effect of local and global climate change, environmental damage, distribution of plants and animals, forest management on the natural ecosystem (Axmacher et al., 2004; Vu et al., 2015). Several research studies have shown that deforestation in tropical countries due to illegal logging, over volume of logging, and clearing of forest area to provide space for farms, all could affect the distribution, structure, and composition of the community, diversity of the species of butterflies (Van Vul and Quang Vu, 2011; Nidup et al., 2014; Widhiono, 2015; Vu et al., 2015; Nkongolo and Bapeamoni, 2018). Butterflies are also affected by environmental variations and changes in the forest structure; moreover, they are also affected by the abundance of plants they feed on (Bora and Meitei, 2014; Castro and Espinosa, 2015). Butterflies are also highly sensitive to climate change (Parmesan and Yohe, 2003). Therefore this study was aimed to analyze the community structure and biodiversity of butterflies at Sangihe Island, North Sulawesi, Indonesia.

Materials and methods

Study area and types of land use

The study was performed from March to May 2018 at Sangihe Island, North Sulawesi, Indonesia (*Fig. 1*). Sampling was done on 3 types of habitat: forest edge, farming area, and bushes. In each habitat, 4 transect lines of 500 m were laid out. On each transect, air temperature, air humidity, canopy closure, altitude, and coordinates, were measured. Measurement of air temperature and humidity was carried out using Thermo-Hygrometer while taking of butterfly samples. The percentage of canopy coverage in each habitat was obtained by making a plot of 20 m x 20 m on each transect so that there were 4 plots in each habitat type. The percentage of canopy coverage in each plot was obtained by vertically projecting tree canopy coverage on the plot. Vertical projection on the flat area of the land was then converted into percentage, with the area of the plot as a denominator, so that the value of canopy coverage will be obtained for each plot in each transect. Altitude and coordinates were measured using a Global Positioning System (GPS) on each transect line.

The forest edge is a habitat that contains variety of plants such as *Ficus* sp (Moraceae), *Alstonia macrophylla* (Apocynaceae) and *Garcinia* sp. (Clusiaceae). At this habitat, there was a river with 8-10 m width. The area had a daily temperature ranging from 28.1-29.9 °C, the humidity of 82-87, canopy coverage of 76-86%, the altitude of 120-201 m above sea level, and it is located at the following coordinates 03°30’05.56” S and 125°31’43.31” E.

DOI: http://dx.doi.org/10.15666/aeer/1702_25012517

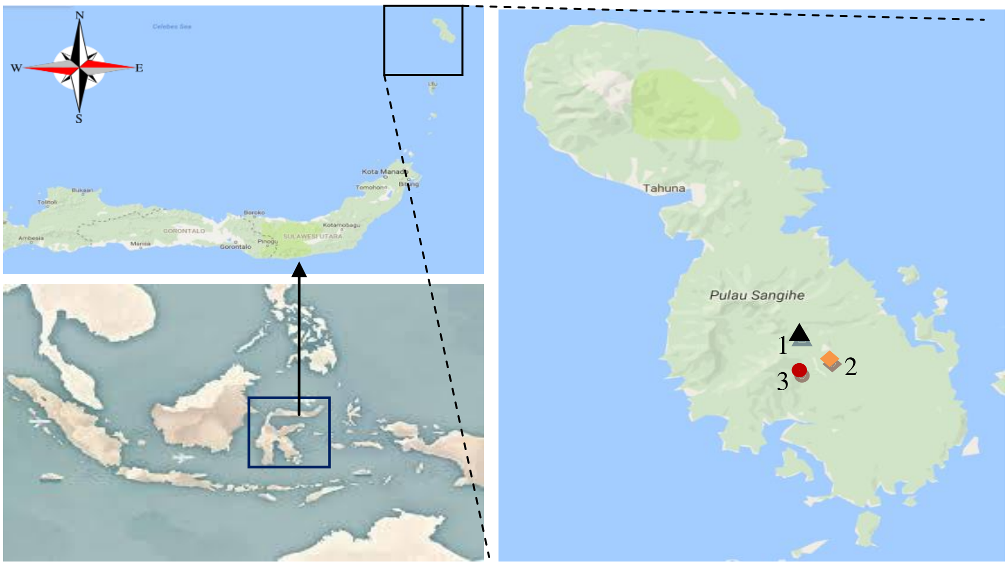

Figure 1. *Map of the study area in Sangihe Islands, North Sulawesi, Indonesia (1. edge forest, 2. farm area, 3. bushes)*

The farm area is an area managed by the local community and planted with a variety of crops such as cloves (*Eugenia aromatica*), coconut (*Cocos nucifera*), banana (*Musa* sp) and cassava (*Manihot utilisima*). The farming area selected in this study had a daily temperature of 29.2-30.3 °C, the humidity level of 79-82, canopy coverage of 70-80%, the altitude of 61-97 m above sea level, and it is located at the following coordinates 03°26’21.27” S and 125°36’01.77” E.

The bushes area selected in this study was formerly a farming area that has been abandoned by the local community and covered with plants such as ferns (Pteridophyta), grass (Poaceae), and bamboo (*Bambusa* sp). This habitat had a daily temperature of 33.0-35.3 °C, the humidity of 51-65, canopy coverage of 40-57%, the altitude of 120-137 m above sea level, and it is located at the coordinates of 03°26’52.73” S and 125°35’42.28” E (*Fig. 2*).

Sampling

Research method used was survey method through purposive sampling. Butterflies were collected with a sweeping method by using a net following transect lines that were set randomly for 500 m length and 5 m width to each side, left and right (Hamer et al., 2003). At each habitat, four transects were prepared and at each transect, sampling was duplicated. The total number of transects was 12. Sampling was performed at 8 am-3 pm (Peggie and Amir, 2006). From every species, only one butterfly was collected. When similar species was found, it was released back to nature. Sampling was performed every month for 3 months. Sampling was done monthly for three months. Butterfly sampling for 3 months was quite representative and can provide information about the diversity of butterflies in the Sangihe Islands. This is because those three months were during the dry season when the weather conditions were sunny. Those conditions were very suitable for butterflies to live. During this period, most nectar-rich plants began to flower (Rizal, 2007), thus providing butterflies food sources and supporting the life and breeding of butterflies.

Figure 2. *Photographs of study sites (a) Sangihe Island, (b) edge forest, (c) farm area, (d) bushes*

Identification of butterfly samples

The process of identifying and classifying the specimens was based on the following identification books: Practical Guide to the Butterflies of Bogor Botanic Garden (Peggie and Amir, 2006), Agricultural entomology (Jumar, 2000), Butterflies of The South East Asian Island, Part I Papilionidae, Part II Pieridae-Danaidae, Part III Satyridae-Lybytheidae, Part IV Nymphalidae (I), Part V Nymphalidae (II) (Tsukada and Nishiyama, 1982, 1981,1982,1985, 1991), and Insect in Halimun Mountain National Park Bagian Barat (Amir et al., 2003).

Data analysis

Data analysis in this study was performed on several parameters: species abundance (n), species richness index (S), species diversity index (H) and species evenness index (E). Species abundance is the number of individual in each species found in each habitat. At all habitats, the indices used were Margalef species richness index (DMg), Shannon species diversity index (H) and Pielou species evenness index (J) (Magurran, 1988).

Species richness index (Dmg) was calculated using Margalefs index to show the number of species in a certain type of habitat (Magurran, 1988), using *Equation 1:*

$$\text{Species richness Indeks (Dmg)} = \frac{(S-1)}{\ln S} \qquad \text{(Eq.1)}$$

where: S = The number of species.; ln = Natural logarithm (natural number).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25012517

Meanwhile, species diversity index was calculated using the Shannon-Weiner diversity index (H) in Magurran (1988) to describe the diversity of butterfly species, using *Equation 2:*

$$\text{Spesies diversity index } (H') = -\sum_{i=l}^{s} (Pi) \ln (Pi) \qquad \text{(Eq.2)}$$

where: Pi = the proportion of each species; ln = natural logarithm (natural number).

At the same time, to show the level of evenness of individual abundance in each butterfly species and as an indicator of species dominance in each habitat, species evenness index was calculated using Pielou's evenness index (Magurran, 1988), using *Equation 3:*

$$\text{Species evenness index (E)} = \frac{H'}{Ln\ S} \qquad \text{(Eq.3)}$$

where: H' = species diversity index; ln = natural logarithm (natural number); S = the number of species.

All indexes were calculated with the help of the program PAST 2.17 (Hammer et al., 2001). Statistical analysis to analyze the difference in species abundance, species richness index, and species evenness index among habitats was performed using the software Statistica version 6, with one-way ANOVA and Duncan test at a confidence level of 95% (StatSoft, 2001; Ohsawa, 2005). To check the relationship between species diversity with other physicochemical parameters in nature, the Spearman correlation was used using the software Statistica version 6 (StatSoft, 2001).

Analysis of similarity between butterfly communities was performed with Sorensen similarity index, by checking the existence and inexistence of certain species of butterfly (Magguran, 1988). The index was calculated using Biodiv 97, macro software in Excel (Shahabuddin et al., 2005). Index of dissimilarity (1 - Sorensen index) was used to do cluster analysis (Krebs, 1999; Ludwig and Reynold, 1988). Cluster analysis of every community was ordered hierarchal in the form of a dendrogram. The dendrogram was prepared using the program Statistica for Windows 6 (StatSoft, 2001). The clustering process was based on unweighted pair group with arithmetic mean and Euclidian distance (Lewis, 2001).

Results

Structure and composition of butterflies

The results found 5 families of butterflies in Sangihe Island, consisting of 39 species and 944 individuals. The families found were Nymphalidae, Papilionidae, Lycaenidae, Pieridae, and Hesperidae. The family with the highest number of species and individuals was Nymphalidae, with 19 species and 508 individuals (53.81%), followed by the family Papilionidae with 8 species and 214 individuals (22.67%). The family Nymphalidae was the most dominant family that was found in all sampling areas. Meanwhile, Hesperidae was the family with the least number of species, with only 2 species and 5 individuals (0.64%). The family Hesperidae was only found at the forest edge and farm and not in the bushes (*Table 1* and *Fig. 3*).

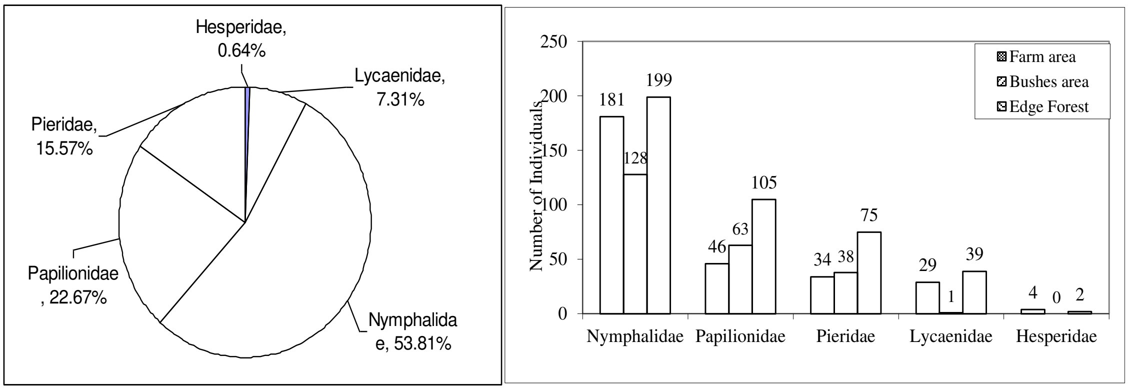

Figure 3. *The abundance of family butterflies found in three types of habitat at Sangihe Island, North Sulawesi*

Junonia hedonia intermedia is a butterfly species with the highest abundance (20.66%) compared to other species, followed by *Eurema tominia* with the abundance of 8.26%. Butterfly species with the lowest abundance with only 1 individual (0.11%) was *Cyrestis acilia* (*Table 1* and *Fig. 4*).

The species of butterflies found in all three habitats were not similar. There were species that were found in all 3 habitats, some were found only in 2 habitats, and some others were found only in 1 habitat. There were 17 species found in all types of habitat and 12 species found in only 2 habitats. Meanwhile, 3 species were found only in farm area while *Papilio helenus* was found only in the bushes. The species found only in the forest edge habitat were 6 species (*Table 1*).

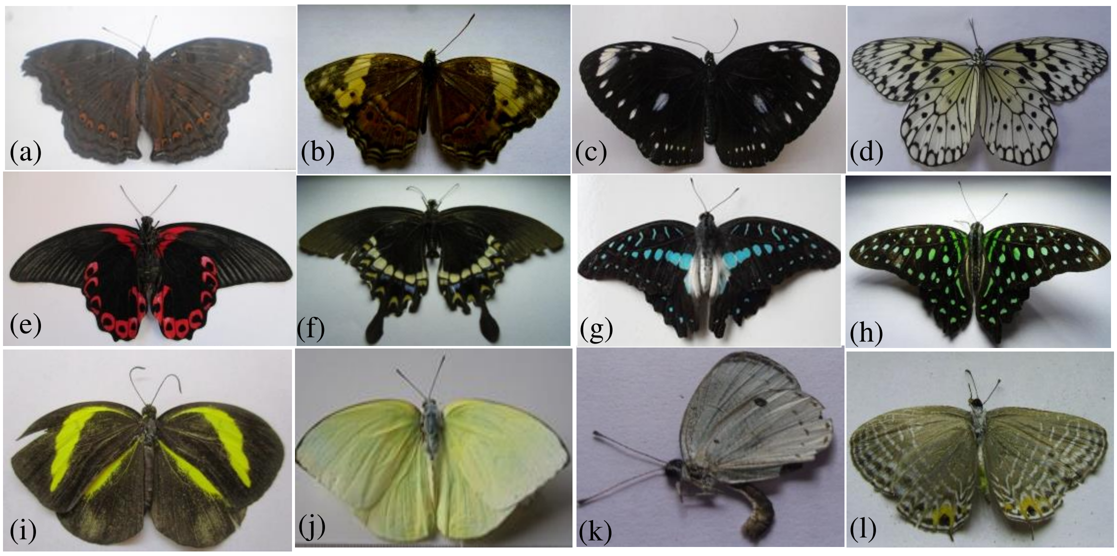

Figure 4. *Several species of butterflies found in the Sangihe Islands. Families Nymphalidae: (a) Brown pansy (J. hedonia intermedia), (b) Heliconians (C. arias), (c) Westwood's king crow (E. leucostictos westwoodi), (d) Paper kite (I. leuconoe); Papilionidae: (e) Red Mormon (P. rumanzovia), (f) Common Mormon (P. polytes), (g) Meyer's Triangle (G. meyeri), (h) Tailed jay (G. agamemnon); Pieridae: (i) Grass yellows (E. tominia), (j) Lemon Emigrant (C. pamona flava); Lycaenidae; (k) Sulawesi Quaker (P. phoenix), and (l) Common Cerulean (J. celeno)*

DOI: http://dx.doi.org/10.15666/aeer/1702_25012517

Butterfly species diversity

The average value of species abundance (118.00 ± 33.46), species richness index (4.52 ± 0.48), species diversity index (2.82 ± 0.14) and species evenness index (0.91 ± 0.02) were found to be the highest at forest edge habitat, while the lowest one was found in the bushes habitat (*Table 2; Fig. 5*). One-way ANOVA and Duncan tests showed that there were significant differences in terms of richness index (ANOVA: F = 15.72; P < 0.05), and diversity index of species (ANOVA: F = 32.96; P < 0.05), among habitats, while abundance (ANOVA: F = 4.05; P > 0.05) and evenness indices (ANOVA: F = 2.04; P > 0.05), were not significantly different. The species richness index and species diversity index of butterflies found in the farm were significantly different with those found in the forest edge and bushes habitats (*Table 2; Fig. 5*).

Table 2. *Species diversity of butterflies in three types of habitat at Sangihe Island, North Sulawesi (Average ± St dev)*

Habitat	Transect	Abundance species	Richness index	Diversity index	Evenness index
Farm area	1	106	4.50	2.72	0.88
Farm area	2	60	3.18	2.35	0.89
Farm area	3	44	3.44	2.35	0.89

Correlation between species diversity and environmental factors

The results of temperature measurements in farm area habitat showed an average value and standard deviation of 29.68 °C ± 0.40, edge of forest showed an average value and standard deviation of 28.58 °C ± 0.77, and bushes habitat showed an average value and standard deviation of 34.20 °C ± 0.83. Average air humidity on farm area was 80.70% ± 1.09, on edge of the forest was 83.50% ± 1.12, and bushes habitat was 57.75% ± 5.26. Canopy coverage on farm area was averagely 74.75% ± 3.56, on edge of the forest was averagely 81.75% ± 4.02, and on bushes habitat was averagely 48.00% ± 6.28 (*Table 3*).

Correlation between the diversity of butterfly species with the environmental factors showed that temperature was negatively correlated with species diversity index (-0.85) and species richness index (-0.77) (*Table 4*). This result shows that the lower the temperature, thus the higher the species diversity and species richness indices of butterflies. Species richness index and species diversity index of butterflies were

DOI: http://dx.doi.org/10.15666/aeer/1702_25012517

positively correlated with humidity and canopy coverage percentage. Meanwhile, the altitude did not give significant effect on species diversity of butterflies.

Community similarity

Composition similarity of butterfly community in Sangihe Island showed that the highest similarity index was between the forest edge and farm habitats (0.85 or 85%). The lowest Sorensen similarity index was found between the forest edge and bushes habitats (0.67 or 67%) (*Table 5*).

A dendrogram was produced using *unweighted pair group method with arithmetic mean* (UPGMA) and it shows that there were 2 groups formed, where forest edge habitat was grouped together with the farm habitat (*Fig. 6*). This result shows that the butterfly community at forest edge habitat was highly similar to that found in the farm habitat.

Table 5. *Matrix about butterfly community similarity among habitats in Sangihe Island*

Habitat	Farm area	Edge forest	Bushes
Farm area	1.00	0.85	0.68
Edge forest	0.85	1.00	0.67
Bushes	0.68	0.67	1.00

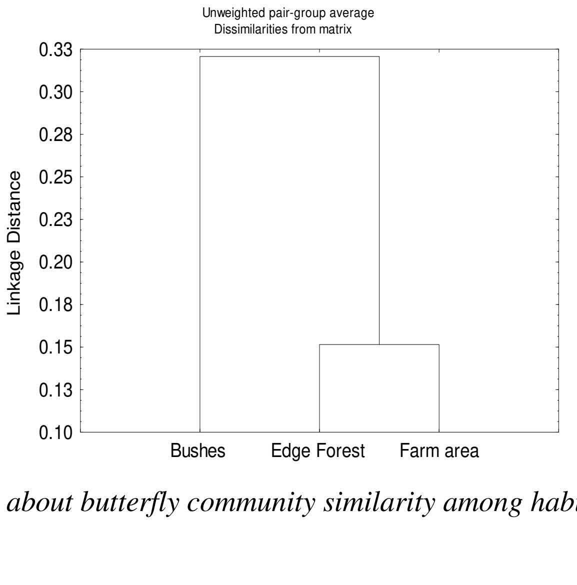

Figure 6. *Dendrogram about butterfly community similarity among habitats in Sangihe Island*

Discussion

The number of butterfly species found in the research was only 0.20% of all species worldwide, 2.23% of species found in Indonesia, and 6.96% of species found in Sulawesi. There are about 19,238 of butterfly species worldwide (Patil et al., 2017),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25012517

1,750 species in Indonesia (Peggie, 2014), and 560 species in Sulawesi (Vane-Wright and de Jong, 2003). The number of butterfly species found in Sangihe Island in this study was lower than the results of several other studies carried out on the mainland of North Sulawesi. Studies in Manembo-Nembo Nature Reserve (Koneri and Maabuat, 2016) and Gunung Tumpa National Park (Tallei et al., 2015), North Sulawesi managed to find 44 and 50 species, respectively.

Several studies in other islands reported a higher number of butterfly species as compared to the current results found in Sangihe Island. Koneri and Saroyo (2012) reported 28 butterfly species in Manado Tua Island, Manado, North Sulawesi, while Lamatoa, et al. (2013) collected 19 species of butterfly in Mantehage Island, North Sulawesi. Moreover, Rosmidi et al. (2017) reported 27 butterfly species found in Perhentian Island and Bidong Island, Terengganu, Malaysia. The difference in the number of species found in each sampling location is affected by sampling area, sampling time, sampling method, habitat's condition and sampling period. The difference in the number of species between an island and the mainland is affected by the island area and distance between the island and the mainland. This result is in accordance with the biogeography theory of islands that mentions small and far islands support a lower number of species compared to bigger and nearer islands (Sumarto and Siahaan, 2012).

The family Nymphalidae was found abundantly in the study since it is a type of butterfly family that can adapt well to environmental conditions, has a large number of family members, and tend to be polyfag. The polyfag characteristic allows Nymphalidae to fulfill its need on host plant although the plant is not available. These reasons cause Nymphalidae exist in a relatively high number of species and individuals in Sangihe Island. According to Rosmidi et al. (2017), this phenomenon could be due to a large number of species in the family as well as their wide variety of selection of food, including flowers, fruits, honeydew, tree sap, rotten materials, and decomposing carcasses; moreover, they also have good adaptation on feeding on a wide range of host plants.

The host plants of Nymphalidae butterflies include Annonaceae, Asteraceae, Verbenaceae, Moraceae, Rubiaceae and Anacardiaceae (Lamatoa, et al., 2013). Plant species that are often found in Sangihe Island include *Ficus* sp (Moraceae), *Mussaenda pubescens* (Rubiaceae), *Garcinia* sp (Clusiaceae), *Lantana camara* (Verbenaceae), *Cananga odorata* (Annonaceae), *Mangifera indica* (Anacardiaceae), *Ficus benjamina* (Moraceae), Citrus sp (Rutaceae) and *Eupatorium inulifolium* (Asteraceae). A distinct difference in terms of the dominant family found in several places is due to the fact that distribution of butterflies is affected by the distribution of the host plant and the ecology (Amir et al., 2003; Panjaitan, 2008). The family Nymphalidae could be found easily all year since they are generalist and some types of this family do not depend only on the availability of flower nectar since they could get their food from rotten fruits or even animal urine (Sarma et al., 2012; Sari et al., 2013).

The species *Junonia hedonia intermedia* was found the most in the study. This species has wings with dark brown colour and orange eye pattern near the edge of the wings. It is able to fly fast and often found standing on the ground or leaves to get sunlight. Several studies reported finding this species standing on the ground or damp stones searching for minerals. This species was abundantly found in the study since it is part of the family Nymphalidae and has polyfag characteristic. Polyfag butterflies could multiply on many types of plants. Their larvae could survive in low diversity of host

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25012517

plants (Helmann, 2002). The high existence of a butterfly species is supported by the availability of plants as sources of food (Yamamoto et al., 2007).

The existence of butterflies in a habitat highly depends on the condition of the habitat and the availability of sources of nectar as well as host plants. Several species of butterflies were found in low frequency and limited only to a type of habitat. Species of butterflies that were found in low frequency with limited distribution are those that are sensitive to the damage of the habitat (Sunduvu and Dumbuya, 2008). Damage to the habitat causes fragmentation and extinction of plants as sources of nectars and host to those butterflies (Hardy et al., 2007).

Species abundance, species richness index, species diversity index, and species evenness index were found to be the highest in the forest edge habitat since this habitat has a variety of plants that can act as a food source as well as host plants for the butterflies. The high species diversity of butterflies in the forest edge habitat could also be due to the existence of a river in the area that can support the life of the butterflies. Butterflies need minerals to survive, which are usually gained from the soil surface, rocks, or riverbank. Riverbank has a variety of vegetations, rocks, sand, mud, and water that attract more butterflies to get water and nutrient from wet rocks, sand, and mud along the riverbank (Van Vu and Quang Vu, 2011).

There was low diversity of butterflies in the bushes habitat since the habitat has a low number of flowery plants and mostly contains grass (Poaceae) and ferns (Pteridophyta). The bushes habitat was originally forest that was converted into farm area. When the farm was abandoned, it turned into bushes. The low species diversity index shows the low availability of food sources and adaptability of the butterflies towards limited environmental factors. Conversion of the forest into farms could reduce natural biodiversity. Several studies have shown that conversion of the natural habitat is the cause of the decline of butterfly species (Chowdhury et al., 2017). Species diversity could decline due to fragmentation of the habitat (Bayero, 1995).

A decrease in species diversity of butterflies was also reported due to deforestation in Kalimantan (Schulze and Fielder, 1998) and in Sulawesi (Fermont et al., 2005). Change of habitat due to change of function of parts of the forest could be a serious threat to the existence of specific species of butterflies in Indonesia. There is a correlation between the diversity of butterflies and their habitat. Larvae and adult butterflies depend on the diversity of host plants. Although butterflies could migrate to new areas, if the plant food is extinct, thus the butterflies also go to extinction. Hamer and Hill (2000) conducted a study on butterfly community in tropical areas and reported that abundance and diversity of butterfly species were higher in forests that have not been used for logging yet compared to forests with logging activity. Their study showed that damage to the forest highly affects species diversity of butterflies. The diversity of butterflies increases when the scale of the habitat and the complexity of the vegetation structure increase (Nkongolo and Bapeamon, 2018). Sharma and Joshi (2009) reported that there was a correlation between the complexity of the habitat structure, shape of vegetation, and diversity of butterflies. High vegetation diversity will increase the diversity of butterflies. The environmental support system such as the availability of habitat, water, mineral, food, temperature, and humidity affect the diversity of butterflies (Mas'ud et al., 2018).

Species evenness index was found the highest at the forest edge habitat. High evenness index shows the lack of dominant species of butterflies. The smaller the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25012517

species evenness index, thus the less equal the species distribution is and there is a domination by certain species of butterfly (Magurran, 1988).

Species richness index and species diversity index of butterflies were found to be positively correlated with humidity and vegetative canopy, but negatively correlated with the air temperature. Temperature highly affects the activity of butterflies, their distribution, growth, and breeding. The temperature at the bushes habitat was higher than the forest edge habitat and the farm area. High air temperature causes a decrease of the volume of nectar secretion in flowers (Efendi, 2009), thus butterflies reduce their activity in the area and move to the forest area that is warm in order to save their energy and reduce evaporation of moisture from their body. This phenomenon causes low species diversity and number of individuals of butterflies found in the bushes habitat.

Rajagopal et al. (2011) reported that species richness index of butterflies is affected by air temperature and humidity. Moreover, Kunte (2001) and Pandhye et al. (2006) also reported that temperature and rainfall are two important factors that directly affect richness and population of butterflies. Tree canopy highly affects the diversity of butterfly species since they can provide protection and food source for the butterflies. There are several species of butterflies that live in a habitat with thick forest canopy, but on the other hand, there are also species that live in a habitat with less forest canopy.

Species similarity among habitats could be measured with similarity index or species similarity coefficient. Similarity index is also used as a basis for cluster analysis. The highest similarity index was found between the forest edge and farm habitats. This shows that there is a high similarity of butterfly species found in the forest edge and in the farming area. This phenomenon could be due to the fast movement of butterflies from one habitat to another and the variety of vegetation in habitats, thus affecting the existence of butterflies. Kendeigh (1980) reported factors that cause similarity of species between two habitats to include a short distance between the two habitats, a similar composition of vegetation, and others.

Conclusions

Butterfly species found in Sangihe Island consisted of 5 families, 39 species, and 944 individuals. Nymphalidae is the most abundant family with the highest number of species when compared to other families, since the family can adapt well to the environmental condition, has the most number of family members, and tend to be polyfag. The polyfag characteristic allows the Nymphalidae to fulfill its need for host plan although the host plant is not available. Based on the type of habitat, the highest species richness index, species diversity index, and species evenness index were found in the forest edge habitat, while the lowest ones were found in the bushes habitat. The difference in the diversity of butterflies among habitats was due to the different structure and complexity of the vegetation in each habitat. High vegetation diversity will increase the diversity of butterflies. Availability of resources such as habitat, water, mineral, food, temperature, and humidity affect the diversity of butterflies. Meanwhile, environmental factors such as temperature and humidity highly affect the activities, distribution, growth, and breeding of butterflies. The temperature at the bushes habitat was higher than the other two habitats. Therefore, the volume of nectar secretion in flowers decreases, so the butterflies reduce their activities in the area or move to the warm forest edge area.

Based on the results of this study, it is recommended to conduct further research on plant species which have an ecological role and function as food sources and hosts for butterflies. The time period of research might be also extended so that the research can be conducted during the rainy season as well. The use of herbicide to kill grasses and weeds should be carefully monitored because it can kill butterflies too. Agroforestry system can be implemented in forest areas to increase vegetation diversity, and consequently to add more host plants and food sources for butterflies.

(Received 4th Nov 2018; accepted 11th Jan 2019)

Abstract. Surplus-production models were used for estimating the sustainable exploitation of *Labeo calbasu* fish stock in Kaptai reservoir, Bangladesh. The annual catch and effort data of 14 years (2001-2014) were analyzed to estimate the Maximum Sustainable Yield (MSY) using software packages CEDA and ASPIC. The average production was found 156 mt while the topmost and undermost catch was 263 mt (in 2009) and 108 mt (in 2003) respectively MSY and CV of Fox model for normal, log normal and gamma assumption were 87 mt (0.339), 65 mt (0.464) and 67 mt (0.551) respectively whereas values from Schaefer model were 139 mt (0.055), 130 mt (0.055) and 137 mt (0.064) and 139 mt (0.059), 130 mt (0.056) and 137 mt (0.064) in Pella-Tomlinson models. As regards, ASPIC estimated MSY and CV values for Fox and Logistic models were 127 mt (0.054) and 133 mt (0.057) respectively. Higher R2 values (above 0.879) in ASPIC in contrast with CEDA (0.71-0.818) represent its better fitting to data. To be conservative, we choose the MSY of 80-100 mt which indicates overexploited condition of *L. calbasu* in Kaptai reservoir and actions should be taken for sustainable management.
Keywords: *population dynamics, CEDA, ASPIC, maximum sustainable yield, exploitation, management*

Introduction

Fishery is one of the lion's share consequential sources of revenue and socio-economic industry in Bangladesh as the country is glorified with hundreds of rivers and ditches, large coastal waterbody, a huge portion of wetlands, oxbow lakes, Bay of Bengal etc. Kaptai reservoir locally known as Kaptai Lake (latitude 22°22'-23°18' N; longitude 92°00'-92°26' E, *Fig. 1*) is the largest artificial freshwater resource of South-East Asia (Fernando, 1980; Haldar et al., 1991). It was constructed for hydro-electrical power generation damming the river Karnafuli situated in the Chittagong hill tracts in 1961. However fisheries, flood control, drainage and irrigation are considered as secondary option. The total outer area and average deepness of water is about 68,800 ha

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25192532

and 9 m respectively containing the highest depth of 32 m (Alamgir and Ahmed, 1986; Haldar et al., 2003). The significant role of Kaptai reservoir in fishery production and socio-economic sectors has made this reservoir one of the most potential fisheries support of Bangladesh.

Kaptai reservoir constitutes a major portion of inland water resources. According to the report of Ahmed (1999) it comprises about 46.8% of the entire pond area of Bangladesh offering a huge potential for fish production. The major fish landing sites of the reservoir are shown in *Figure 1*. Ahmed et al. (2001) stated that during their study in this lake, fishery has been found to contribute around 6000 mt annually and the number of engaged fishers were estimated as 5560. Mesbahuddin (1966) documented that a small scale fishers group first started fishing here in 1963 using gill nets, seine nets, hooks and lines. About 74 freshwater species produce around 6000 mt of fish every year (Ahmed et al., 2001; Chakma, 2007). But according to the recent production records, a declining trend has been found in the productivity of high-value fish with the courses of time.

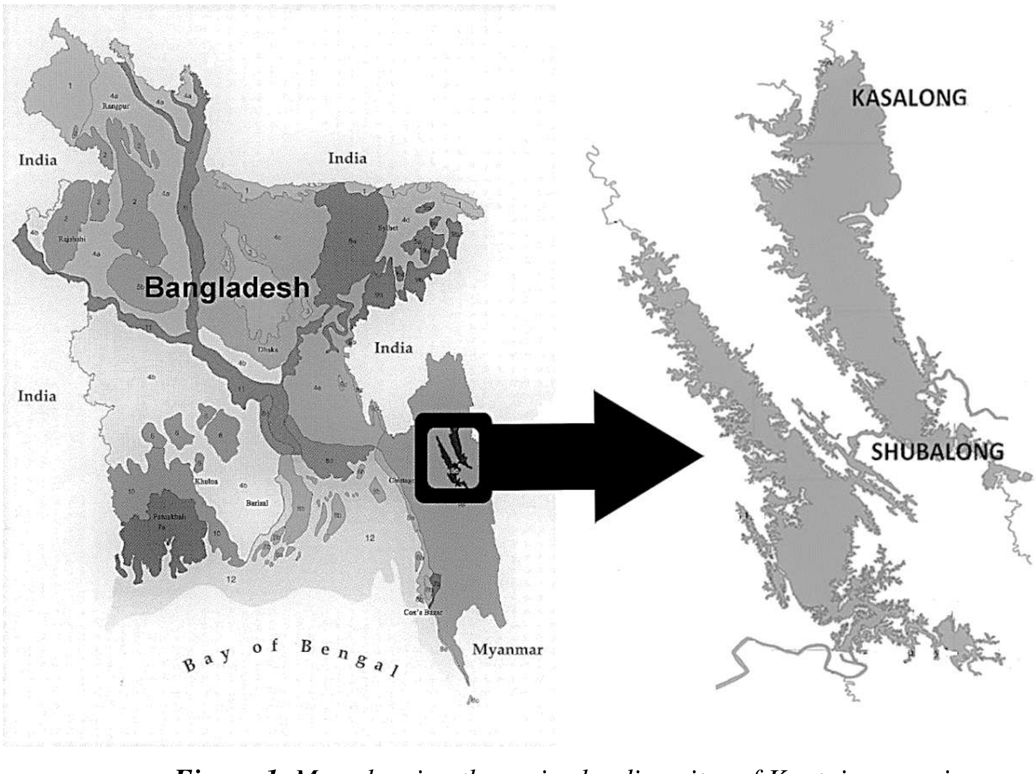

Figure 1. *Map showing the major landing sites of Kaptai reservoir*

Borre et al. (2001) stated that it could happen because the world's lakes suffer from some crucial threats for example quick eutrophication, invasive species, noxious pollution, excess fishing, alteration in water direction, acidic water and altered climate. Remarkably, Kaptai reservoir is also troubled by invasive species, overfishing of certain species and water diversion issue due to regulating electricity. Thus the performance of Kaptai reservoir has been suffering from a host of environmental, socioeconomic and management constraints as well affecting its potential.

Productivity record says that highly commercial important carps such as *Labeo rohita*, *Catla catla*, *Cirrhinus cirrhosis*, *L. calbasu* and *Tor tor* were found to show a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25192532

dramatic decrease and it has been noted that the carp production was about 81% of the total production in 1965/66 while now it is only 5% (Alamgir and Ahmed, 1986). *L. calbasu* is an important profit-making omnivorous fish found in slow running rivers, ponds and lakes and normally attains a length of about 90 cm and weight of 5.5 kg. It is available throughout India except in Kerala (Jayaram, 1999), Bangladesh, Pakistan, Nepal, Myanmar, Burma, Thailand, Yunnan and also South China. Moreover, being a profitable species it is often cultured in South Western China (Jhingran, 1982). The productivity record of 2001-2014 reveals that the annual average yield of carp was about 415 mt while the average production of *L. calbasu* per annum comprises 156 mt (37.6% of total carp production) in this reservoir.

Hitherto, the orange fin *Labeo* along with other species have suffered from blind commercial fishing, dreadful conditions of ecosystem, destruction of habitat, lack of policy implementation, reduction of water level, toxic waste, using of unconstitutional fishing gears, deterioration of breeding ground, catching of juveniles etc. In this regard, the understanding of population dynamics of aquatic resources is essential for getting the maximum benefit and protecting water resources. Undoubtedly, the principal management approaches of a species are to assess its stock. The aim of this assessment includes the understanding of fish population dynamics (Jennings et al., 2001) predicting the fish population for alternative management approaches if needed (Hilborn and Walters, 1992).

In accordance with fish population ecology and economics, MSY (maximum sustainable yield MSY) is the largest harvested sustainable catch from a species' stock under the privileges of current ecological conditions where non-equilibrium biomass production models (BDMs) (also known as surplus production models, SPMs) could be used to assess the MSY value for a fish stock. The stereotyped SPMs which has been used to assess fishery resources have got universality as it is easier to run. MSY parameters can be determined directly from catch and effort (CPUE) data (Polacheck et al., 1993). In spite of being questioned the MSY, estimated from surplus production models has kept increasing its popularity as fishery management target biological reference points (Ricker, 1975; Pitcher and Hart, 1982; Hilborn and Walters, 1992; Prager, 1994; Quinn and Deriso, 1999; Maunder et al., 2006). Nevertheless, the MSY reference points B_{MSY} (biomass at giving MSY, B_{MSY}) and F_{MSY} (fishing mortality rate at MSY, F_{MSY}) are frequently considered as management benchmark (Jacobson et al., 2002).

However, past works have been done focusing on the biological and limnological aspects of Lake Fishery (Chowdhury and Mazumder, 1981; Azadi, 1985; Mahmood, 1986; Hye and Alamgir, 1992; Ahmed et al., 1994) and on its socioeconomic aspects (Ahmed, 1999; Hye, 1988). Although some studies have been done on conservation *L. calbasu* of Kaptai lake (Alam et al., 2000; Haroon et al., 2002; Nahiduzzaman et al., 2012; Hasan et al., 2013; Kabir and Quddus, 2015) but no work has been done yet neither to estimate the sustainable yields nor to assess the stock size of *L. calbasu* in Kaptai reservoir using surplus production models. Studies on population dynamics and assessment of any fishery are of great importance in management. Therefore, it is crucial that fisheries experts deliver a dependable diagram of stock dynamics and stock status to the authorities (Lynch et al., 2012). Thus, different production models have been used in this study aiming at the estimation of the size of mentioned fish production. The study has been performed to draw the required management accesses for its sustainable exploitation which may help fishery administrators and fishery

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25192532

biologists to achieve the target. Therefore, the aim and scope of the article was to provide new perspective of surplus production models for the sustainable exploitation of the high value *L. calbasu* stock in Kaptai lake estimating its MSY.

Materials and methods

Data assemblage

The catch and effort data of Orange fin *Labeo* from 2001 to 2014 were obtained from the data documented by Fisheries Statistical Report of Bangladesh compiled by FRSS (Fisheries Resource Survey System, FRSS), DoF (Department of Fisheries, DoF). The catch data has been presented in weight (mt) while the CPUE in the form of catch captured per boat. The non-equilibrium models have been used to analyze the data. The reservoir is dominated by multi-species fishery and one gear can be used to catch different fishes at a time. Professional, seasonal professional and subsistence fishers use traditional fishing methods and artisanal gears such as seine net, cast net, gill net, lift net, hooks and lines and one type of fish aggregating device (FAD). Mostly Gill net and Sein Net are used with mechanized and non-mechanized vessels engaging for fishing. The mechanized crafts spend 8 to 12 h a day in each voyages, while non-mechanized are operated on daily basis where duration of operation is not fixed. The number of fishing boat fluctuated from 634 to 1702 in the study period. Use of fishing gears and its operating time vary depending on water depth, weather condition, fish abundance, type of fishing grounds, fisherman and vessels as well. Thus, the efforts were taken as fish captured by mechanize and non-mechanized boats per day. However, generally the fishing duration of seine net, gill net, cast net, lift net and FAD are 12 h, 13 h, 4 h, 12 h and 8 h per day, respectively (Roy et al., 2018).

Biomass production models

The available fishery census of *L. calbasu* were analyzed by CEDA (catch and effort data analysis) and ASPIC (a stock production model incorporating covariates) (Hoggarth et al., 2006; Prager, 2005). The Biomass Dynamics Models (BDMs) consist of Schaefer, Fox, and Pella-Tomlinson models.

The most frequently used Schaefer model (Schaefer, 1954) is established on a logistic population growth model (*Eq. 1*):

$$\frac{\mathrm{d}B}{\mathrm{d}t} = rB(B_\infty - B) \qquad \text{(Eq.1)}$$

Later on, considering the Gompertz growth equation Fox suggested the following analysis (*Eq. 2;* Fox, 1970):

$$\frac{dB}{dt} = rB(1nB_\infty - 1nB) \qquad \text{(Eq.2)}$$

However, the final generalized equation (*Eq. 3*) was stated by Pella and Tomlinson (1969):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25192532

$$\frac{dB}{dt} = rB(B_{\infty}^{n-1} - B^{n-1}) \quad \text{(Eq.3)}$$

where B = the biomass, t = time, B_{∞} = carrying capacity, r = intrinsic growth rate

CEDA (version 3.0.1)

The computer package CEDA version 3.0.1 has been built based on non-equilibrium surplus production models (Schaefer, 1954; Pella and Tomlinson, 1969; Fox, 1970). It follows the standard dynamics of the fish production models. Moreover, it also expresses three error assumptions named normal, log-normal and gamma. *CV* (coefficient of variation) of the estimated MSY could be calculated from the output confidence interval. CV of *Tables 2* and *3* were determined by bootstrapping method.

ASPIC (version 5.0)

The ASPIC package denotes the association of both Logistic (Schaefer) and Fox (a special case of GENFIT) production models. This package permits the bootstrap estimation of variability and is efficiently adaptable in case of handling different fishing patterns. Both the CEDA and ASPIC packages require an input value of initial proportion that is IP. Initial proportion defines the progressive fishery data series. IP equal to zero or near to zero implies that the fishery started from maiden state while the value of IP close to one refers to the fishery started from a heavily exploited population. The primary production was about 73% of the maximum catch so IP = 0.7 was used in this study for both CEDA and ASPIC computer packages. R^2 values determine the goodness-of-fit of the model to data.

Results

The observed highest and lowest catch were in 2009 (263 mt) and in 2003 (108 mt) respectively while the average yield was 156 mt in this period. The topmost and undermost values of CPUE were found as 0.255 mt/boat (in 2001) and 0.066 mt/boat (in 2014) respectively (*Table 1*) containing the average CPUE 0.148 mt/boat. It shows the increasing trend of effort causes decreasing rate of catch and CPUE with a slight fluctuation in courses of time.

CEDA result

CEDA has been found to be sensitive towards different IP values. Consequently, it has produced different outputs MSY estimations for different IP inputs (*Table 2*). In some cases, gamma error assumption has been found to exhibit minimization failure in different models (for IP = 0.1, 0.8 and 0.9). However, minimization failure was also observed in Fox model for IP = 0.8. *Table 3* shows the computed parameters for IP = 0.7. According to Fox model the R^2 values of normal, log normal and gamma assumption were 0.71, 0.75 and 0.734 respectively while IP = 0.7 (*Table 3*). On the other hand, the R^2 values calculated by Schaefer and Pella-Tomlinson for all error assumptions remained the same as 0.81, 0.818 and 0.815 orderly.

K: carrying capacity; *q*: catchability coefficient; *r*: intrinsic population growth rate; MSY: maximum sustainable yield; *CV*: coefficient of variation; R^2: coefficient of determination; *B*: current biomass; B_{MSY}: biomass at giving MSY

Fox model determined the values of MSY and CV for normal, log normal and gamma assumption as 87 mt (0.339), 65 mt (0.464) and 67 mt (0.551) respectively whereas values of these parameters were 139 mt (0.055), 130 mt (0.055) and 137 mt (0.064) in Schefer and 139 mt (0.059), 130 mt (0.056) and 137 mt (0.064) in Pella-Tomlinson models in that order. The estimated values of carrying capacity K were higher while the values of catchability coefficient q and intrinsic population growth rate r were lower in Fox model than Schaefer and Pella-Tomlinson models.

The graphical demonstration of observed and expected annual catch values has been shown in *Figure 2*. It illustrates an adjacent relationship between observed and estimated catch values for all the error assumptions used in every model.

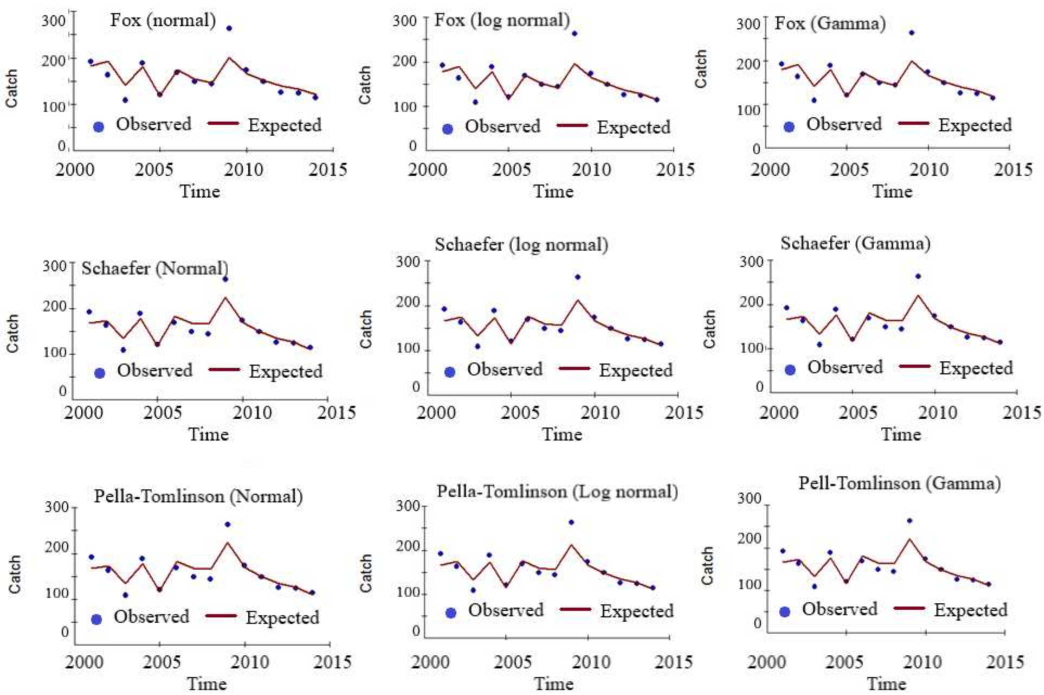

Figure 2. *Annual expected (lines) and observed (dots) catches (mt) using IP = 0.7 from three production models (Fox, Schaefer and Pella-Tomlinson models) and three error assumptions (normal, log normal and gamma) from the CEDA computer package for Labeo calbasu fishery of Kaptai reservoir*

ASPIC results

Table 4 shows the calculated parameters for IP = 0.7 where MSY and CV values for Fox and Logistic models were 127 mt (0.054) and 133 mt (0.057) respectively. The R^2 value for Logistic model (0.887) was higher than the Fox model (0.879). This result discloses its better fit to data than Fox model. According to Fox model the estimated values of F_{MSY} (fishing mortality rate at MSY, F_{MSY}), B_{MSY} (stock biomass at giving MSY, B_{MSY}) and K were 0.152, 832 mt and 2260 mt respectively while those values for Logistic model have been found as 0.281, 472.7 mt and 945 mt respectively.

q (Catchability coefficient), K (carrying capacity), F_{MSY} (fishing mortality rate at MSY), B_{MSY} (stock biomass giving MSY), CV (coefficient of variation) and R^2 (coefficient of determination)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25192532

The ranges of MSY was 126 mt– 277 mt in ASPIC whereas it was 3 mt – 39500 mt for CEDA which depicts the lesser sensitivity of ASPIC to IP values. Again, the higher value of R^2 using ASPIC software provides its evidence to be better fit than CEDA. ASPIC estimated values of fishing mortality (*F*) and biomass (*B*) of *L. calbasu* for IP = 0.7 have been shown in *Table 6*. It shows an upward trend of fishing mortality rate and descending rate of biomass which has ultimately caused the increasing of F/F_{MSY} and decreasing of B/B_{MSY} in the long run of time. However, the changes in F/F_{MSY} and B/B_{MSY} defines that the overexploitation was being done consistently for the last years.

Table 6. *Fishing mortality (F) and biomass (B) from ASPIC (IP = 0.7) from 2001 to 2014*

F= fishing mortality, *B*= biomass, F/F_{MSY}= ratio of fishing mortality to F_{MSY}, B/B_{MSY}= ratio of biomass to B_{MSY}

Discussion

Study on population dynamics is of great importance since the sustainable management policy of capture fisheries depends on the stock assessment outcomes. The main objective of this study was to estimate the MSY of *L. calbasu* in Kaptai reservoir, Bangladesh through non-equilibrium surplus production models using CEDA and ASPIC software packages. MSY from surplus production models is the reflector of a fishery stock in a certain area and thought as a biological reference point for attaining the sustainable production target (Hilborn and Walters, 1992; Prager, 2002; Musick and Bonfil, 2004). Greater MSY than the recent catch projects mushrooming fishery stock which permits more fishing till the estimated MSY while MSY lesser than current catch determines the resource as overexploited where conservation is must for feasible production. Equal figures for both parameters define the equilibrium status of the fishery. Based on the analysis in *Tables 2–6,* the estimated MSY for Fox model ranged 65-87 mt while Schaefer and Pella- Tomlinson determined ranging 130-139 mt which supports Fox model being more conservative than others.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25192532

On the other hand, the ASPIC estimated value of MSY (127-133 mt) is above than the recent catch (113 mt). Ewald and Wang (2010) has already reported about this uncertainty of MSY. Besides maximum sustainable yield, F_{MSY} and B_{MSY} also play role in sustainable fisheries management. The values of F/F_{MSY} had an upward trend meanwhile values of B/B_{MSY} decreased in the passage of time. Moreover, R^2 values from ASPIC (above 0.879) is higher than that of CEDA (0.71-0.818) which may pinpoint it is better fitting to the computed data. To be conservative we choose the MSY of 80-100 mt in this study, because the latest catch is higher than the MSY value, we found the overexploited condition of *L. calbasu* in Kaptai reservoir and managerial actions for its conservation are required.

Even though MSY is commonly used as biological reference point but when the unexplored CPUE data in indexing fish population abundance is used the interpretation, usage of derived population and management keys should be done carefully (Panhwar et al., 2012). The catch and effort data are required for surplus production models to appraise the status of stock (Mehanna and El-Gammal, 2007). In fact, in fish population and dynamics these models are the first conventional methodical tools of assessing an exploited fish stock when the data consists of year wise catches and some abundance index as well. Although these are not realistic as age-structured models but useful in representing yield policies (Jensen, 2002b). Not only that sometimes they could even produce better estimation of BRP (biological reference points) than age-structured models (Prager, 2002) and comparatively more suitable for management purposes at very practical cost (Haddon, 2011). Statistically the fluctuation in the data of catch, effort or CPUE indicates the changes of stock status. Contradictory relation between effort and catch suggest the swift downturn of fish stock. In some studies on marine fishery show the increasing rate of catch in spite of higher rate of effort (Balli et al., 2011; Kumar et al., 2012; Panhwar et al., 2012; Panhwar et al., 2013; Kalhoro et al., 2013; Mohsin et al., 2017; Karim et al., 2018). Remarkably, in our study greater rate of effort caused the catches to be reduced. The reason behind this consequence is the confined nature of reservoir. So, there is neither migration of fishes from other sources nor as a result lesser recruitment occurs there.

This study examined the current status of orange fin *Labeo* fishery stock of Kaptai reservoir using non-equilibrium SPMs which clearly projects that this fishery is in overexploited condition. In general, surplus production models comprise some unavoidable assumptions, many of which are not met in nature. These assumptions consist of interaction less species, independent r (intrinsic growth rate) over age composition, environmental factors free population, constant catchability coefficient, single stock unit, simultaneous fishing and natural mortality, accurate catch and effort statistics and consistent gear or vessel efficiency. In spite of having above mentioned assumptions its critical usage has made it as a powerful tool for fish stock assessment (Musick and Bonfil, 2005). Ahmed and Hambrey (1999) documented that the use of unlicensed fishing gears as well as non-permissible mesh size and brush shelters causes fingerlings reduction during the post-stocking period. Although every year, the authorities impose a ban on fishing from May 1 to July 31 considering the safety fish breeding and sound production in reservoir but subsistence fishermen and tribal people continue catching fish for home consumption and illegal marketing**.**

In light of the above, the following conservation schemes are suggested:

1. Addressing special legislative framework for Kaptai reservoir fisheries management as well as unbiased enforcement of this constitution

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25192532

2. Restricting illegal gears and mesh size
3. Boycotting undersized fish harvest
4. Improving the ecological condition for providing the fishes a healthy home
5. Introducing sanctuary for better and safe growth

In brief, considering the excessive fishing pressure the existing lake fishery should be investigated further wisely for appropriate management.

Conclusion

This is the first attempt to use non-equilibrium SPMs for stock assessment in the reservoir fishery of Bangladesh. The estimated outputs of both CEDA and ASPIC computer packages exhibit that the influential money earning *Labeo calbasu* fishery in Kaptai reservoir is overfished. Uncertainty in determining MSY could happen because of commercial data collection drawback as well as for the apprehensive reliability of CPUE data set. Moreover, there is not enough independent information to test its reliability. Therefore, during the time of interpretation and usage of derived population as well as management parameters obvious tentative steps should be considered. In the light of uncertainties of fisheries science further studies could be done to assess the fish stock accurately along with the studies of the improvement of artificial breeding techniques, modification in genes to increase its adaptability in adverse environmental condition, implementation of different culture techniques etc. This study is to provide an initial concept of stock assessment of *L. calbasu* fishery through surplus production models.

Abstract. The aim of this study was to evaluate the changes in forest road pavement bearing capacity (PBC) depending on meteorological conditions, traffic effects and horizontal curve parameters for a year on a monthly basis. Within this context, two different roads were investigated and measured with dynamic cone-penetrometer. The total number of the measurement points was 265 for traffic-restricted road (road no: 001-RN1) and 315 for open traffic road (road no: 005-RN2). In the study, three multiple regression models were developed to estimate PBC values on forest road. According to Model1, which was developed to estimate PBC values depending on vehicle traffic and on meteorological factors for alignment section of the RN2, the adjusted R^2 was found to be 0.635. In Model2 for the curve section of the RN2, the adjusted R^2 was found to be 0.711. Model3 for RN1 depending on meteorological factors demonstrated that the accuracy of PBC estimation had a high adjusted R^2, which was 0.952. In conclusion, PBC values can be estimated at high accuracy. Furthermore, traffic load has a strong effect on PBC. On the other hand, temperature has an important negative effect on the variation in PBC on RN1.

Introduction

Roads provide access for people to work, enjoy, or consider natural ecosystems (Demir, 2007). Forest road ecosystem includes both the paved and unpaved rights of way and adjacent structure, including other infrastructure, ditches, drainage features, and other components that provide the means for vegetation to establish and provide habitat for associated plants and animals (Lugo and Gucinski, 2000). Forest roads have several functions with respect to the management of forestry activities (Acar, 2016; Demir and Hasdemir, 2005). One of these main functions is the transport of timber from its point of felling to the mill. It accounts for a high proportion of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25332550

costs to the industry (Dawson, 2001). For that reason, different heavy vehicles operate on forest roads to manage forestry activities and forest operations. On the other hand, therefore, so as to fulfil these functions, pavement is an important element on forest roads (Akay et al., 2018). However, land degradation and pavement deteriorates in time depending on climate factors, traffic load, maintenance works, slope degree, canopy closure and other factors (Haas, 2001; Tighe et al., 2003; Akgul et al, 2017; Akgul and Hasdemir, 2018; Gokbulak et al., 2018; Sheikh et al., 2017; Yurtseven et al., 2019). Also, pavement deterioration occurs depending on pavement surface compaction rate. Pavement deterioration is the most important factor for traffic safety and safe drive of vehicles. Pavement performance changes depending on deterioration (Akgul et al., 2016).

Pavement deterioration can be slowed down or stopped with proper maintenance. For this reason, it is essential to evaluate the structural condition of a pavement, for example its bearing capacity (Domitrovic and Rukavina, 2013). On the other hand, Kiss et al. (2016) emphasized that in order to prevent significant road deterioration, high bearing capacity is required for the roads which are intensively used by the vehicles. The bearing capacity of a pavement system is defined as the number of wheels passages that it can support before it reaches structural distress (O'mahony et al., 2000). Direct measurement of the bearing capacity is not possible. Instead, the deflection caused by a known load can be measured, and then the bearing capacity can be calculated (Primusz et al., 2015). Most of the devices used to measure the bearing capacity of forest roads express the measurement results with regard to elastic modulus (Kaakkurivaara et al., 2015)

The bearing capacity of a pavement mainly depends on its structure (Trzcinski and Kaczmarzyk, 2006). Besides, the diversity of traffic load and extreme meteorological conditions affect pavement structure, for example its bearing capacity (Bocz, 2009). The stresses caused by traffic load affect each pavement layer differently. For example, it causes deformations and structural changes in the pavement. Climate conditions significantly affect pavement stiffness and bearing capacity (Szentpeteri, 2013). In spring, the bearing capacity of pavement decreases because of the increase in the amount of moisture on subgrade (Charlier et al., 2009; Vestin et al., 2018). The bearing capacity of pavement is easily determined by a Dynamic Cone Penetrometer (DCP). On the other hand, DCP is a simple testing device for measuring in situ compaction, density, strength or stiffnes (Wu and Sargand, 2007; Puppala, 2008).

The objective of the study was to monitor the changes in forest road pavement bearing capacity (PBC) on two different forest roads depending on meteorological conditions, traffic effects (vehicle passages, traffic load, vehicle tonnage etc.) and road sections (horizontal curve and alignment).

Material and methods

Study area

The research area is located in the northern part of Istanbul University's Education Research and Practice Forest close to Sariyer, Istanbul. The research field is at Thracian side of the Marmara Region between 28° 59' 17" – 29° 32' 25" east longitudes and 41° 09' 15" – 41° 11' 01" north latitudes according to Greenwich. Within the scope of the study, two different forest roads [road no: 001 (RN1) and road no: 005 (RN2)] were selected as study areas (*Fig. 1*).

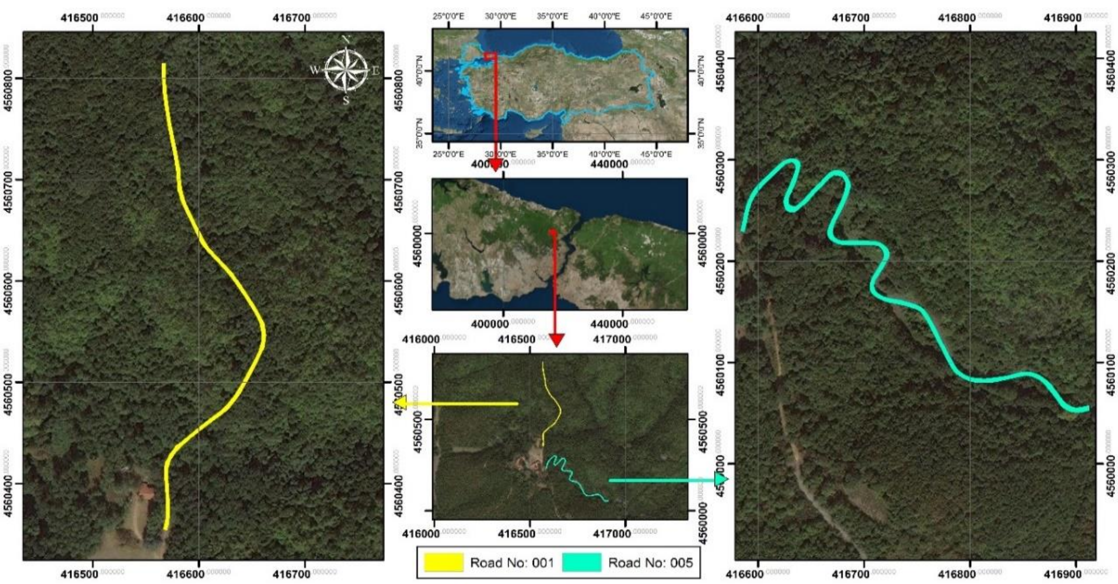

Figure 1. *Location map of the study area*

The RN1 and RN2 were classified as Normal Type-B forest road with 4-m platform width. The total length of the RN1 was 530 m while the total length of the RN2 was 684 m. The average slope of the RN1 was 8%, while the average slope of the RN2 was 12%. The RN1 was composed of nine horizontal curves while RN2 was composed of eleven horizontal curves. The minimum curve radius was 9.0 m while maximum curve radius was 200 m for RN1, and the minimum curve radius was 6.8 m while maximum curve radius was 50.3 m for RN2 (*Table 1*).

Meteorological data (weather conditions)

Weather data was continuously recorded at the adjacent weather station at the Green Roof Research Site located in Istanbul University Faculty of Forestry. Weather data was measured by an automated weather station (DeltaOhm HD2003). Precipitation measurements (hourly basis) were performed using a rain gauge (DeltaOhm HD2003 tipping bucket, measurement accuracy ±1%). Also, weather data recorded during study period were compared to long term meteorological data between 1929 and 2017 for the research field which were listed in *Table 2* (General Directory of Meteorology-GDM, 2018).

Data collection for traffic characterization

Within the scope of the study, camera traps were installed to observe traffic characterization of the RN2. The RN1 was restricted to vehicle passages for one year. The camera traps (Bushnell Trophy Cam, 8MP) were positioned on tree trunks at both the start and end section of the RN2. The camera traps were programmed to take photo at 1 sec interval. The pictures taken by the camera traps were controlled on a monthly basis from September 2015 to September 2016. Vehicle tonnages were calculated in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25332550

four groups (automobile, crossover & SUV, minibus, pickup) according to vehicle types.

Measurement of PBC and data collection

In this study, in order to measure PBC, 53 measurement lines (30 lines in curve section; 23 lines in alignment section) at 10-m intervals were determined along the RN1 while 63 measurement lines (29 lines in curve section; 34 lines in alignment section) at 10-m intervals were determined along the RN2 (*Fig. 2*).

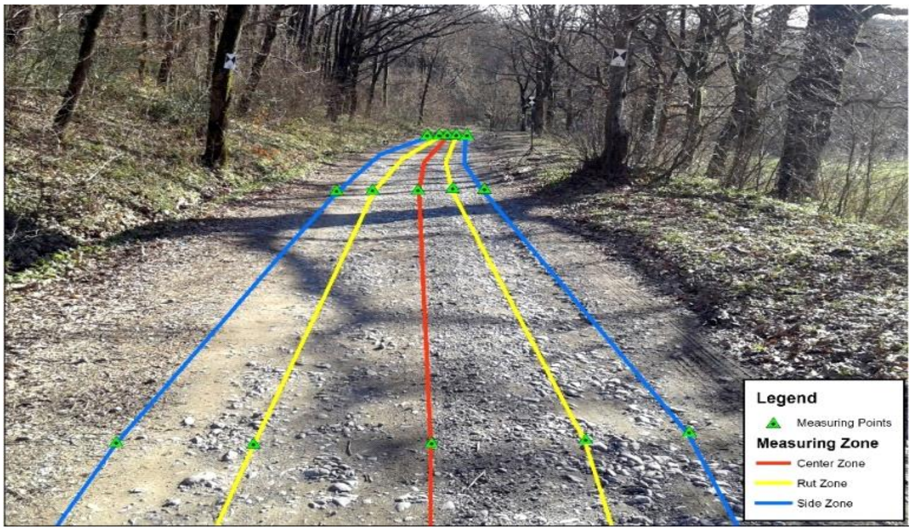

Figure 2. *Penetrometer measuring points*

Five penetrometer measurement points were set on each measurement line with a right angle to the road platform. In total, 265 measurement points (150 points in curve section; 115 point in alignment section) were established for the RN1 and 315 measurement points (145 points in curve section; 170 points in alignment section) were established for the RN2.

The measurement points were fixed with nails (20 cm length). The coordinates of each measurement point were measured by Pentax W800 total station in UTM ED1950 coordinate system (*Fig. 3*).

Figure 3. *Establishment of measurement points*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25332550

PBC was measured using a penetrologger (Eijkelkamp Agrisearch Equipment, the Netherlands). Thirty-degree cones were used with a cone basal surface area of 1 cm^2 (nominal diameter 11.28 mm) (*Fig. 4*). Data collection was conducted from October 2015 to September 2016 on a monthly basis.

Figure 4. *Data collection*

Statistical analysis

All statistical analyses were performed using SPSS 23.0 statistical package. In order to estimate the effects of road geometrical properties on PBC, two different multiple regression models were developed for both road alignments and curves on the RN2. Moreover, multiple linear regression model was developed for the in RN1 to estimate the effects of meteorological parameters on PBC. To evaluate the accuracy of the mathematical model by regression analysis, 80% of the total number of the variables ($N = 1668$ for alignment section of RN2; $N = 1371$ for curve section of RN2; $N = 2540$ for RN1) were randomly selected and used as calibration data, while 20% of them ($N = 432$ for alignment section of RN2; $N = 369$ for curve section of RN2; $N = 640$ RN1) were also used as testing data. Furthermore, paired sample *t*-Test and correlation analysis were used to calculate the significance level of the models.

Results and discussion

Results of meteorological data

According to the meteorological data, the minimum average temperature was measured in February as 6.50 °C while the maximum was measured in August as 24.52 °C. The maximum total precipitation was measured in February as 130.1 mm while the minimum was measured in September as 9.6 mm (*Table 3*).

Results of traffic characteristics

According to the camera traps, 4598 vehicle passages were observed from September 2015 to September 2016 (*Table 4; Fig. 5*). The minimum total vehicle passages were in January as with 80 passages while the maximum total vehicle passages on monthly basis was in September 2016, which reached 1604 passages. Moreover, the average speed of vehicles was calculated as 30 km/h for this road.

Results of PBC on monthly basis

PBC values measured monthly were calculated as mean values and are listed in *Table 5*. It was divided into two main columns as curve section and alignment section for monitoring PBC differences between the RN1 and RN2. The table demonstrates that the measured PBC values of the RN1 were lower than those of the RN2. Furthermore, the measurement results showed that PBC values of the curve sections were relatively lower than those of the alignment sections on the RN2. A comparison of PBC values between the curve section of the RN1 and that of the RN2 revealed that PBC values of the RN2 was almost two times higher than those of the RN1 (*Fig. 6*).

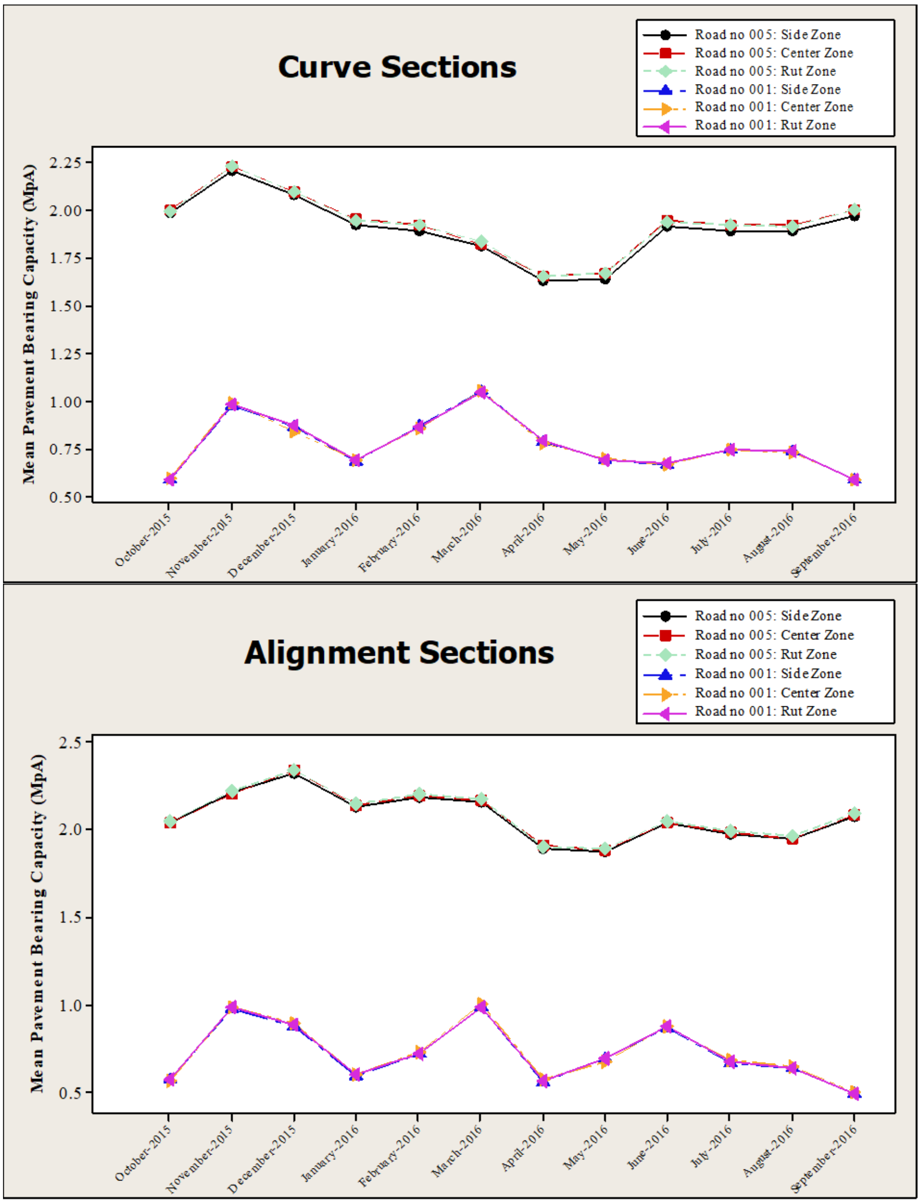

Figure 6. *Mean bearing capacity on curve sections and alignment sections of RN1 and RN2*

Besides, PBC values of the alignment section on the RN2 were found as three times higher than those on the RN1 (*Fig. 7*). PBC values were also observed to be lower in spring than in other seasons.

Results of statistical model

The descriptive statistics of the calibration data used in multiple regression model for the curve section ($N = 1371$) of the RN2 are listed in *Table 6,* while they are presented in *Table 7* for the alignment section ($N = 1668$) of the RN2. The descriptive statistics of the calibration data ($N = 2540$) for the RN1 are listed in *Table 8.*

In order to estimate the effects of road geometrical properties on PBC, two different multiple regression models were developed for both road alignments and curves on the RN2. Moreover, multiple linear regression model was developed to estimate the effects

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25332550

of meteorological parameters on PBC on the RN1. In all regression models, PBC was considered as the dependent variable. In the regression model for the alignment section of the RN2; road zone (Z), total precipitation (Tp), tonnage (Tn), passages (Ps) were considered as independent variables, in the regression model for the curve section of the RN2; road zone (Z), curve radius (CuR), total precipitation (Tp), precipitation intensity (Pi), passages (Ps), tonnage (Tn), curve length (CuL), while in regression model for RN1 road zone (Z), total precipitation (Tp), temperature (Tm), pressure (Prs) were considered as independent variables.

At the stage of testing the statistical relationship between the variables for the curve section of the RN2, the results of Pearson's correlation coefficients and their significance levels ($p < 0.01$) and correlation analysis are shown in *Table 9*. It was found that there was a strong positive relationship between PBC and ln(Z), (Z).

Also, according to Pearson's correlation coefficients and their significance levels ($p < 0.01$), a strong positive correlation was found between PBC and ln(Z), (Z) (*Table 10*).

Table 10. *Correlations between variables for alignment section of RN2*

F test and adjusted R^2 statistics of the multiple linear regression models indicated that all three models were effective predictors of PBC. According to model 1, which was developed to estimate PBC values depending on vehicle traffic effects and meteorological factors for the alignment section of the RN2, adjusted R^2 was found as 0.635. Moreover, in Model 2 developed to estimate PBC values depending on vehicle traffic effects, curve parameters and meteorological factors for the curve section of the RN2, adjusted R^2 was found as 0.711. Model 3, which was developed to estimate PBC values for all sections of the RN1 depending on meteorological factors, adjusted R^2 was found as 0.952 (*Tables 12* and *13*).

As it is seen in *Table 12,* according to results of RN1's adjusted R^2 it was possible to closely estimate PBC without traffic effects on forest road.

Also, in the study, developed regression models validated with test data (observation data). Scatter plot for model 1 had a linear correlation with $R^2 = 0.57$ between the observed and predicted PBC ($N = 432$), scatter plot model 2 had a linear correlation with $R^2 = 0.59$ between the observed and predicted PBC ($N = 369$) while scatter plot for model 3 had a linear correlation with $R^2 = 0.96$ between the observed and predicted PBC ($N = 640$) (*Figs. 8, 9,* and *10*).

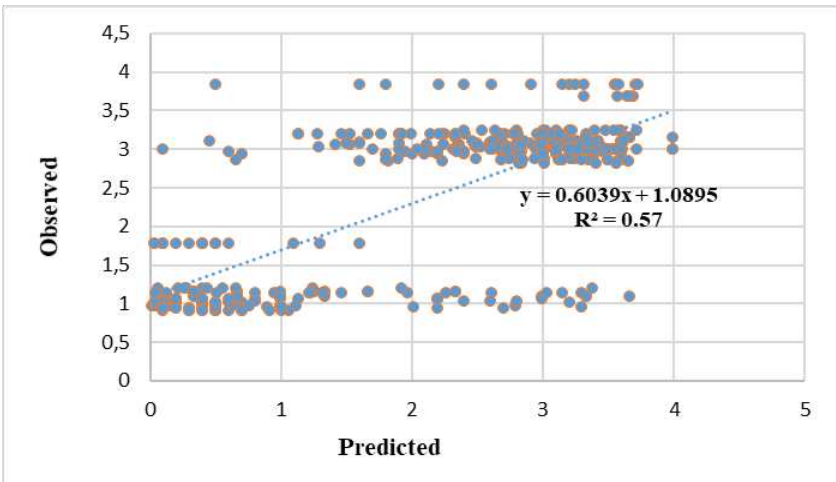

Figure 8. *Validation of predicted and observed PBC values for model 1*

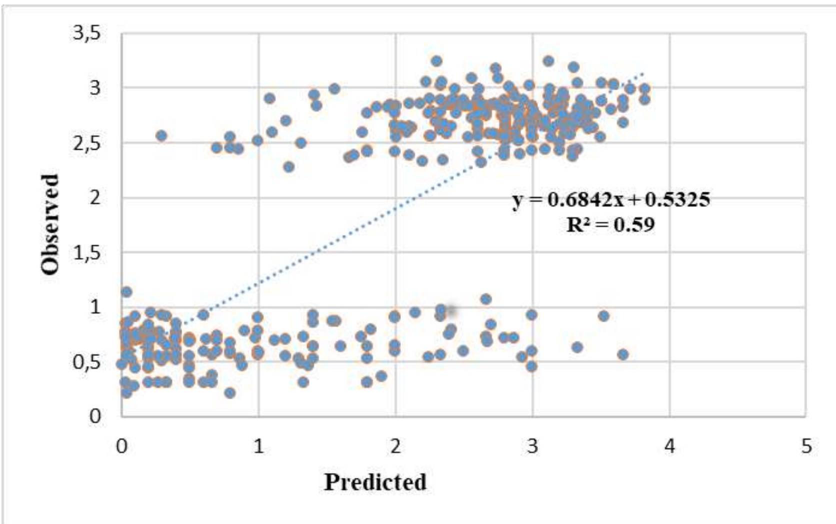

Figure 9. *Validation of predicted and observed PBC values for model 2*

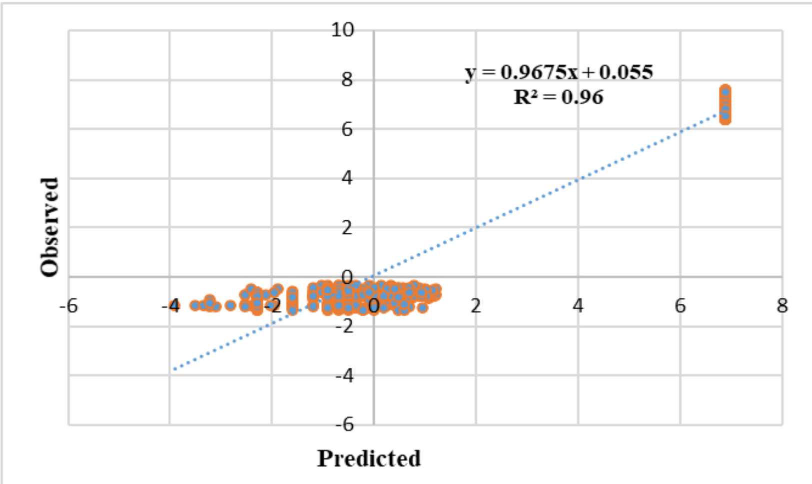

Figure 10. *Validation of predicted and observed PBC values for model 3*

Within the scope of the study, two different forest roads were investigated for monitoring the changes in PBC in one year. One of these roads was restricted to vehicle passages during the study. Hence, on this road (RN1); the effects of meteorological factors on PBC were investigated. Furthermore, on the other road (RN2), the changes in PBC were monitored depending on road sections, traffic effects and meteorological effects.

A comparison of the mean PBC between two roads, it was observed that PBC values on the RN2 were almost two or three times higher in the RN1. The most likely reason might be traffic load on the RN2. Similarly, Săceanu (2012) found a strong correlation between PBC and vehicle passages and tonnage. Our results showed that traffic load (vehicle passages and tonnage) was an important factor. In addition, during the measurement period on the RN2 which is open to traffic, there is a general decrease in the overall PBC values caused by the traffic load. In this regard, Salour (2015) stated that the combination of environmental factors and intensive vehicle traffic increased the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25332550

deterioration of the road structure. The PBC values of the curve sections that we found were relatively lower than those of the alignment sections on the RN2. The possible reasons for that difference might include the changes (braking, accelerating) in the speed of the vehicles in the curve and alignment regions and lateral shifts of vehicles. Moreover, Das et al. (2016) reported that vehicle of placement in curve was different when compared to alignment, and the radius of curve also affected the lateral position of the vehicle.

PBC values were observed to be lower in spring than in other season. In order to explain the reason for this, Charlier et al. (2009) emphasized that the PBC decreases in spring because of the increase in the amount of moisture on subgrade. On the other hand, in connection with this, Yoshida et al. (2016) mentioned the need to have adequate drainage facilities to maintain the sustainability of the bearing capacity. Adlinge and Gupta (2013) also stated that moisture significantly reduced the strength of subgrade. Demir et al. (2012) and Erdem et al. (2018) stated that there is a parallel relationship to between monthly precipitation and sediment production. Monthly sediment production from unpaved forest road was significantly higher than that of paved forest road and undisturbed area. It clearly shows that a stabilizing cover on a forest road led to less sediment production and more soil protection (Demir et al., 2012; Erdem, 2018). The results of previous studies are similar to ours (Kaakkurivaara et al., 2015; Salour, 2015; Grajewski, 2016).

According to the correlation of the results, PBC values had a high negative correlation with Temperature (Tm) on RN1. Similar to these results, Pan et al. (2015) and Motiejūnas et al. (2010) reported that the increase in temperature on asphalt roads led to a decrease in the PBC. On the RN2, there was a strong relationship between PBC and road zone (Z) values both in the curves and alignments. On the RN1, however, there was a weak relationship between PBC and zone (Z). This might be probably because there was no traffic load on the RN1 while there was traffic load on the RN2. According to the correlation results, PBC values had a high correlation with road zone. We have the impression that it was possibly due to the wheel track.

Conclusions

Road surface stability is an important factor on sustainability of forest operations in all seasons. In this context, the PBC value is an indication of the continuity of forest operations. Also, these values and models can be useful to managers for decision making stage in forestry activities.

So, traffic load, especially vehicle tonnage had a strong effect on PBC. On the other hand, temperature had a significant effect on the variation in PBC on the RN1. However, three multiple regression models were developed to estimate PBC values. According to the regression models, PBC values could be estimated at high accuracy. These models will also provide useful results to managers for decision-making in the future. Moreover, fixed measurement points constituted in study can be used to generate pavement compaction maps, PBC changes map etc. for future studies.

(Received 11th Nov 2018; accepted 16th Jan 2019)

Abstract. In maize soybean intercropping-system maize plants significantly increase the shade density at soybean canopy, and few people studied the threshold level of shade for sustainable production of soybean in this system. This experiment was started to determine the effect of four different shade treatments T_{75} (75%); T_{50} (50%); T_{25} (25%); T_0 (0%, control) on morphology, physiology and yield of soybean plants. Relative to T_{75}, treatments T_{25} and T_0 significantly increased the stem diameter and stem breaking strength while plant height was decreased. The chlorophyll a, chlorophyll b, and chlorophyll a + b, photosynthetic and chlorophyll fluorescence characteristics were improved as shade decreased, and maximum values were observed in T_{25} and T_0. Similarly, enzymatic activity of Rubisco was accelerated from T_{75} to T_0. However, genes related to sucrose synthesis (SS and SPS) were down-regulated by increasing shade (T_{75}). Importantly, non-significant differences were measured for seed-yield between T_{25} and T_0, and the plants of soybean under T_{25} produced 88% of T_0 yield. Overall, these results implied that agronomist should develop an appropriate intercropping planting pattern where the maximum shade density ranges from 20 to 30 % to obtain higher seed yield of soybean crop under intercropping-system.
Keywords: *Rubisco, intercropping, chlorophyll fluorescence characteristics, sucrose synthesis, seed-yield*

Introduction

Sun radiations are among the most important abiotic factors for agricultural production (Yang et al., 2014, 2018a). For most crop plants, even a slight increase or decrease in light intensity leads to considerable changes in photosynthetic characteristics (Wu et al., 2017). Light intensity affects the central processes of crops such as physiology, biochemistry and cell division (Kong et al., 2016; Yang et al., 2018b; Wu et al., 2018). Indeed, the numerous plant processes impair with decreasing light intensity which bring dramatic developmental and physiological changes, leading to a rapid decrease of these processes (Yang et al., 2015; Wu et al., 2016). Shading conditions could affect carbon balance of crop plant because the carbohydrate (sugars) demand increases while its production decreases: rates of physiological processes rise while the photosynthetic yield reduces (Yang et al., 2018a). Accordingly, tolerance to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25512569

shade stress reduced at low photosynthetic rate in C_3 plants (Su et al., 2014). Moreover, the pattern of carbohydrates (Sugars) into expensive processes, like the biosynthesis of defense proteins (notably light-harvesting chlorophyll protein) raises with increasing shade (Yang et al., 2018a). The photosynthetic rate is the major driver of crop plant carbon balance, optimum and continuous availability of light should also be considered into account to study the plant responses to shade stress.

Crop growth as dry matter production is largely dependent on current photosynthesis and, therefore, one of the main important changes by shade stress in crop growth is ascribed to its huge reduction of net photosynthesis (Yang et al., 2018b). Reductions in photosynthesis could occur thanks to two main principle mechanisms (Yang et al., 2017): (i) decrease CO_2 diffusion into leaves, since the decrease internal and stomatal conductance (g_i and g_s, respectively), and (ii) metabolic potential inhibition for photosynthesis by inhibiting the leaf growth and enlargement by controlling the cell proliferation (Wu et al., 2017, 2018). However, further investigations are needed due to the relative significance of such mechanisms is debatable. The amount and activity of important enzymes involved in CO_2 fixation and regeneration of rubisco-1, 5-bisphosphate (RuBP) determined the metabolic potential of photosynthesis in plants under different conditions (Seemann and Sharkey, 1986; Delfine et al., 1999; Redondo-Gómez et al., 2007) as well as the activity and content of light capturing components, electron transport fragments, and energy transferring enzymes (Kao et al., 2003; Ranjbarfordoei et al., 2006; Stepien and Klbus, 2006). In photosynthesis Rubisco (RuBP carboxylase or oxygenase) catalyzes the process of CO_2 fixation (Mauser et al., 2001), which is directly involved in the first phase of Calvin Benson cycle and accounting for 12 to 35 percent of the leaf protein especially in C_3 crop plants (Evans and Seemann, 1989). In past reports, it has been revealed that the main biochemical restraint involved in shade-associated down regulation of net photosynthetic rate was reduction in the amount or activity of Rubisco (Evans and Seemann, 1989).

In past few years, chlorophyll fluorescence measurements have been known as an informative and useful indicator characterizing different light responses of photosynthesis. Considerable attention was paid to investigate and to determine the important characteristics of this technique (Schreiber et al., 1995). Chlorophyll fluorescence mainly and effectively used to measures the quantum yield of photosystem II and photo-inhibition by determining the potential quantum yield under prevailing light and shade conditions (Rascher et al., 2000). Shade significantly affected the performance and structure of the photosynthetic apparatus (Yao et al., 2017). It blocks the energy transport from PSII to PSI, reduces the leaf thickness, palisade and spongy tissues which results in low chlorophyll fluorescence (Wu et al., 2017; Yao et al., 2017). Thus, in this present study we aim to investigate the chlorophyll fluorescence parameters of soybean plants in response to different shading conditions because plant photosynthetic characteristics are directly dependent on the net performance of chlorophyll fluorescence parameters.

Maize (*Zea mays* L.) soybean (*Glycine max* L. Merr.) intercropping system is the main planting pattern for cereal and legume production (Rahman et al., 2017). Within the maize-soybean intercropping system – described here as the deliberate sowing of soybean crop within the intercropping strip area of maize planting – the presence of maize crop adds a level of complexity in terms of light environment dynamics for resource-use. Importantly, intercropping system of maize and soybean is used extensively in many parts of China and farmers are achieving a land equivalent ratio of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25512569

1.3-1.4 that is much higher than other relay-intercropping systems in the world (Liu et al., 2018). However, soybean plants are extremely sensitive to shading conditions (Wolff and Coltman, 1990; Feng et al., 2018) and in this system soybean plants suffered from severe maize shading during their vegetative growth period from germination to maturity that increased the seedling height of soybean plants and it became more susceptible to lodging as the intensity of shade increases (Li et al., 2014a,b). Physio-morphological responses of soybean plant under shade conditions have also been considered. A number of studies have shown the significant reduction in stomatal conduction, photosynthetic rate, number of nodes, number of seeds and eventually seed yield (24~50%) under shade conditions (Yang et al., 2017). Therefore, great emphasis is placed on crop management with an aim to make plants more efficient in light use and enhance yield under shade conditions. However, the comprehensive understanding of physiology, morphology and gene expression related to carbon metabolism (SS and SPS) is still unclear because they are highly influenced by environmental factors under changing conditions especially intercropping systems.

To investigate the role of shading in regulation of soybean morphology and reproductive development, studies of shade treatments on soybean plants were carried out to (i) determine the impact of different shade treatments on morphological characteristics of soybean plants, (ii) study the effect of different shade treatments on photosynthetic and chlorophyll fluorescence parameters of soybean plants, and (iii) to suggest the threshold level of light intensity required by soybean plants for utilizing the available resources adequately to produce higher soybean seed yield under intercropping conditions. Overall, the main objective of this paper is to provide information for agronomists to develop appropriate planting patterns in which soybean plants receive optimum light intensity for their growth.

Materials and Methods

Plant Material and Growth Condition

Pot experiment was conducted at the greenhouse characterized by a 12 h dark/12 h light photoperiod, 28°C day and 25°C night temperature and approximately 60% relative humidity (in 2018). Experiment was complete randomized design with shade tolerant cultivar of soybean (*Glycine max* L.) Nandou-12 bred by NAAS (Nanchong Academy of Agricultural Sciences) was selected from 30 soybean varieties recognized on the basis of shade tolerance. The ten seeds were sown in pots with dimension of (30 cm diameter, 20 cm height). Soil was collected from the tillage layer of 0-10 cm depth at farm land located in Wenjiang, China. Soil textural class is silty clay loam or silty clay. Chemical properties were: 29.0 g kg^{-1} of SOC, 2.10 g kg^{-1} of total N, 0.78 g kg^{-1} of total P, 16.0 g kg^{-1} of total K, 154 mg kg^{-1} of available K and 7.11 of pH (1 : 5 v/v). The soil was air-dried and sieved through a 4-mm sieve. Basal nutrients were applied at the following rates (mg kg^{-1}): 210 urea, 215 KH_2PO_4, 160 $CaCl_2.2H_2O$, 45 $MgSO_4.7H_2O$, 8 Fe-EDTA, 7 $ZnSO_4$ and 4 $CuSO_4$, 0.8 H_3BO_3, 6.8 $MnSO_4.H_2O$, 11 $ZnSO_4.7H_2O$, 3 $CuSO_4$ .5H_2O, 0.5 $CoSO_4.7H_2O$, 0.4 $Na_2MoO_4.2H_2O$. All the plant-nutrients were mixed thoroughly with sand and soil. After the germination of soybean seeds, three plants per pot were maintained up to maturity and every treatment had 15 pots. In addition, when the first trifoliate leaves developed the soybean seedlings were transferred to four different shade treatments (Shao et al., 2014): T_{75} (75% shade); T_{50} (50% shade); T_{25} (25% shade); T_0 (0% shade, normal sunlight) and the shaded

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25512569

conditions were provided by a covering the pots with black nylon net. The experimental period duration was 110 days. Plants were harvested at maturity and seeds were air-dried for seed yield and yield related parameters.

Measurements and Sampling

Plant Morphological Traits

Plants were collected from each replicate for morphological measurements, the plant height; stem diameter and plant biomass were measured at stages V_4 (four trifoliate of vegetative growth), R_1 (flower initiation at the start of reproductive growth) and R_5 (seed filling at the start of seed formation) of soybean because these are the critical stages which determines the growth and development of soybean. All the plant samples of soybean plants were placed to 105°C for 1 hour and dried to constant weight at 75°C plant biomass. Leaf area was measured by using (CI-203 CID Bio-Science Portable Instruments for Precision Plant Measurement Inc. 1554 NE 3rd Ave, Camas, WA USA). The basal internode (first internode) was used to determine the stem breaking strength of soybean plants by using the digital plant lodging tester (YYD-1, Zhejiang Top Instrument Co. Ltd., Hangzhou, China) according to the previously described method (Liu et al., 2016).

Photosynthetic Pigment Concentration

Latest fully expanded leaves from each treatment were sampled. Chlorophyll (Chl a, Chl b, and Chl a + b) was extracted by grinding samples with chilled mortar and pestle in 10 ml of 80% acetone and centrifuged 1000 rpm for 3 min at 4°C. The samples were placed in ice-cold 10 ml of 80% aqueous acetone solution in the dark for 24 h at room temperature. The supernatant was then separated and analyzed by spectrophotometer (UV-2250, Kyoto, Japan) at wavelengths of 663, 645, and 470 nm as described by Fan et al. (2018) to evaluate the Chl a, Chl b, and Chl a + b content, respectively (Fan et al., 2018).

Photosynthesis

Three fully expanded leaves of soybean plants from each treatment were selected at V_4, R_1 and R_5 stages of soybean. Photosynthetic parameters including net photosynthetic rate (P_n), transpiration rate (T_r) and intercellular CO_2 concentration (C_i) were measured with the help of portable photosynthesis system (*Model LI-6400, LI-COR Inc.,* Lincoln, NE) between 10:00 and 11:00 am. The following settings were used: PARi = 1,000, stomatal ratio = 0.5, flow = 500 µmol mol^{-1} and reference CO_2 concentration = 400 µmol mol^{-1}.

Chlorophyll fluorescence measurements

Chlorophyll fluorescence measurement was taken by using Fluor Technologia operated using the Fluor Images software. Fully expanded leaf samples from each treatment were taken and immediately preserved in plastic bags and placed in ice box preventing from the direct light. Then by using above mention software, samples were passed to fluorescence analyzing device. We examined maximum quantum yield (Fv/Fm), effective quantum yield of photosystem (ϕPSII), photochemical quenching (qP) and electron transport rate (ETR) by placing 20 min under light and dark

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25512569

conditions. Previously published method was followed by using FluorImager software, Technologia LTD version 2.2.2.2 (Pan et al., 2017).

Rubisco Analysis

For the measurements of Rubisco activated enzyme, frozen leaf samples (1 g) of soybean plants were ground with a mortar and pestle in an ice box and 2 ml of extraction buffer solution was used. The extracted solution was centrifuged 7000 rcf at 4°C for 15 min. Double antibody sandwich method was used to determine the level of plant Rubisco activase (RCA).The Rubisco activase (RCA) antibody was encapsulated by the micropore plate to form solid phase antibody, which was added to the micropore of the monoclonal antibody successively. 40 µl of sample diluent was added first and then 10 ml of sample solution in the micropore plate. The micropore plate was sealed with a plastic film for incubation at 37°C for 30 min and this incubation was repeated 5 times. Body - antigen - enzyme - labeled antibody complex, after thorough washing and substrate TMB color. TMB is transferred under the catalysis of HRP enzyme. Turn it into blue and turn it into the final yellow color under the action of an acid. After adding the stop solution, the absorbance (OD value) was measured within 15 min at 450 nm wavelength by enzyme marker and the sample was calculated by standard curve. The Rubisco activity was expressed as U/g (Seemann, 1989).

Biomass Accumulation and Distribution

For plant biomass accumulation and partitioning in different soybean plant organs, six soybean plants of two pots, were destructively sampled at V_4, R_1 and R_5 stages of soybean. Then all the collected soybean plants were separated into root, stem, leaves, and pod, and placed in oven for one hour at 105°C to kill the fresh-tissues and then dried the samples at 65°C to measure the constant weight before weighing of each plant organ of soybean for total biomass accumulation and partitioning analysis.

Carbon Status and Real-time Quantitative PCR Verification

To measure the starch and soluble sugar content soybean leaves were collected at V_4 stage at the end of the day and analyzed by following the previous method (Cross et al., 2006). Meanwhile, the expanding leaves of soybean plants at V_4 from all the treatments were collected for the determination of RNA abundance. All the leaves were labeled and frozen in liquid nitrogen immediately. Total RNA was extracted with RNAiso Plus (Takara, Japan). Reverse transcription and amplification of cDNA were performed using SuperScript II First-Strand Synthesis for qRT-PCR (Takara, Japan). Real-time quantitative PCR was conducted in CFX 96™ Real-Time System (Bio-Rad, USA) and $2^{-\triangle\triangle CT}$ method used for data analysis.

Seed Yield and Yield Parameters

In the current experiment, all the remaining pots (9 pots, 27 plants) were collected from every treatment at maturity. All these collected sampled were utilized to measure the seed yield and yield components. All the sampled plants were dried in sun-light for seven days, threshed by hand and weighed to measure the seed yield of every treatment and then converted into g plant^{-1}. The seed number plant^{-1} was counted for all the sampled plants and average seed number plant^{-1} was calculated. Three lots of 100 seeds were collected from bulk seed lot of every treatment and dried in oven at 65°C till

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25512569

constant weight achieved, and then seed weight (mg) was measured by using an electrical balance and mean weight was calculated.

Statistical Analysis of Data

All the data recorded for every parameter was analyzed using computer software Statistix (version, 8.1. Statistix, USA) (Raza et al., 2018a). Analysis of variance (ANOVA) technique and least significance difference (LSD) test were employed to assess the effect of shading treatments on measured parameters, and all the means were compared at 5% probability level. Moreover, Microsoft Excel program was used for the graphical presentation of data using standard error (± SE).

Results

Morphological Characteristics

Different light treatments considerably changed the morphological characteristics of soybean plants at all growth stages (V_4, R_1, and R_5). *Figure 1* shows the morphological characteristics of soybean plants under different light treatments.

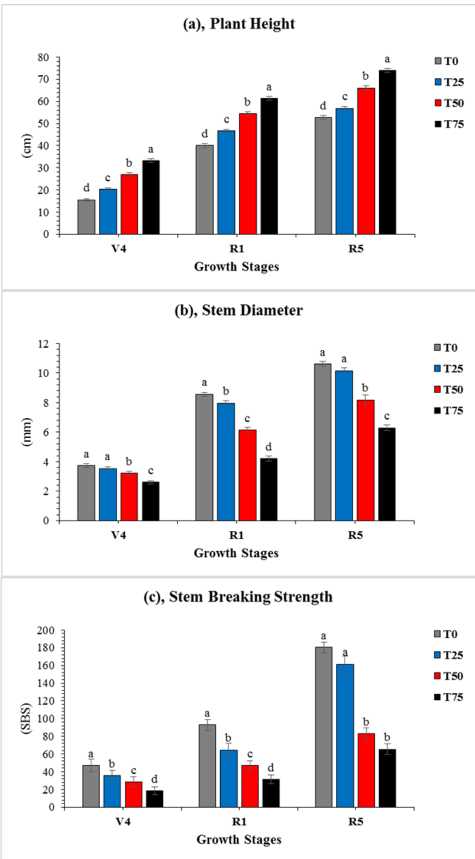

Figure 1. *Changes in plant height (a), stem diameter (b), and stem breaking strength (c) of soybean plants as affected by different photosynthetically active radiations treatments at V_4 (four trifoliate stage), R_1 (flower initiation stage), and R_5 (seed formation stage). T_{75}, T_{50}, T_{25}, and T_0 refer to 75%, 50%, 25%, and 0% shade, respectively. Means are averaged over three replicates. Bars show ± standard errors, (n = 3). Within a bar, different lowercase letters show a significant difference (p ≤ 0.05) between treatments*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25512569

In our study, different light treatments had a significant ($P < 0.05$) impact on plant morphological parameters, the plant height (PH) of soybean plants were substantially increased from T_0 to T_{75} at all growth stages. Specifically, the highest PH 33.2, 61.3, and 73.9 cm of soybean plants were recorded under T_{75}, and the lowest PH 15.6, 40.0, and 52.7 cm were measured in T_{75} at V_4, R_1, and R_5, respectively. Meanwhile, opposite findings were measured for stem diameter (SD) and stem breaking strength (SBS). Compared with T_{75}, SD and SBS significantly increased under T_{25} and T_0, and the SD and SBS of T_{25} and T_0, respectively improved by 41% and 60%, and 38% and 64% at R_5, than those in T_{75}. Importantly, our findings show that the shade from 25% (T_{25}) to 0% (T_0) significantly improves the morphology of soybean plants by increasing the SD and SBS.

Chlorophyll Content

In our experiment, the different light treatments significantly ($P < 0.05$) affected the chlorophyll (Chl a, Chl b, and Chl a + b) content of soybean leaves at all stages. The contents of Chl a, Chl b, and Chl a + b of soybean leaves under T_{75}, T_{50}, T_{25}, and T_0 were measured, as presented in *Figure 2*.

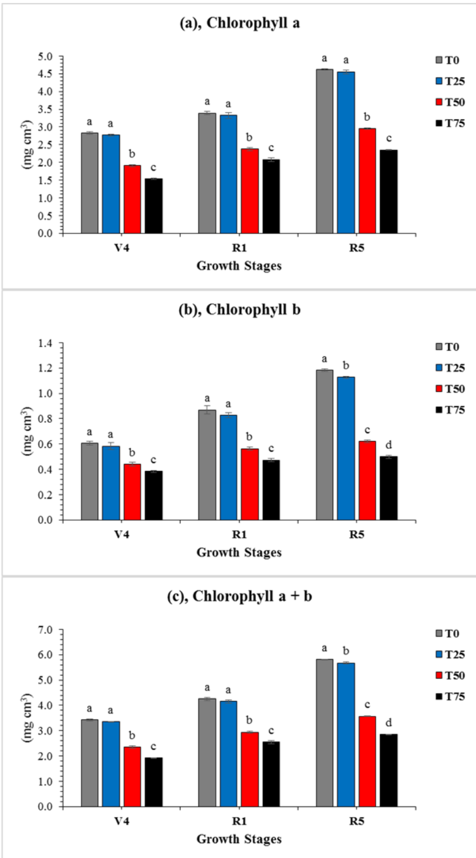

Figure 2. *Changes in chlorophyll a (a), chlorophyll b (b), and chlorophyll a +b (c) content of soybean plants as affected by different photosynthetically active radiations treatments at V_4 (four trifoliate stage), R_1 (flower initiation stage), and R_5 (seed formation stage). T_{75}, T_{50}, T_{25}, and T_0 refer to 75%, 50%, 25%, and 0% shade, respectively. Bars show ± standard errors, (n = 3). Within a bar, different lowercase letters show a significant difference ($p \leq 0.05$) between treatments*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25512569

We observed that decreasing shade from T_{75} to T_0 increased the Chl a, Chl b, and Chl a + b contents at all measured growth stages. Interestingly, the Chl a, Chl b, and Chl a+b contents of soybean leaves were found non-significant between T_{25} and T_0 treatments, but the contents of Chl a, Chl b, and Chl a+b were always found higher under T_{25} and T_0 than those of in T_{75} treatment. Overall, at R_5, the Chl a, Chl b, and Chl a+b contents increased by 48%, 56%, and 50%, under T_{25} in comparison with T_{75}, respectively, suggesting a direct link of chlorophyll contents with the changes in available light intensity.

Photosynthetic and Chlorophyll Fluorescence Characteristics

Table 1 presents the photosynthetic characteristics of soybean plants in response to different light treatments. Relative to T_{75} treatment, photosynthetic rate (Pn) and transpiration rate (Tr) enhanced considerably from T_{50} to T_0 treatments, while stomatal conductance (Gs) and intercellular CO_2 concentration (Ci) of soybean plants were reduced at all V_4, R_1, and R_5 (*Table 1*). The Pn of T_{50}, T_{25}, and T_0 respectively improved by 12%, 31%, and 32% at V_4, 11%, 27%, and 28% R_1, and 7%, 17%, and 22% at R_5 as compared to those under T_{75}. Additionally, all the photosynthetic parameters of soybean plants at R_5 followed the same pattern to that of V_4 and R_1. Importantly, at V_4 and R_1 soybean plants exhibited the non-significant differences for photosynthetic characteristics under T_{25} and T_0, suggesting that shade of 25% to 0% was enough to maintain the optimum photosynthetic rate for better growth and development.

Table 1. *Effect of different photosynthetically active radiations treatments on photosynthetically characteristics and enzymatic activity Rubisco of soybean plants at V_4 (four trifoliate stage), R_1 (flower initiation stage), and R_5 (seed formation stage)*

The fate of absorbed solar energy in leaves of soybean at three different growth stages was investigated under changing light conditions, and shows in *Table 2*. In the present study, the chlorophyll fluorescence parameters including F_v/F_m, Φ_{PSII}, qP, and ETR were changed significantly under different light treatments. The F_v/F_m, Φ_{PSII}, qP,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25512569

and ETR of soybean leaves in T_{25} and T_0 were found significantly higher than those under T_{75}. Moreover, treatment T_{25} and T_0, at R_5 significantly increased the chlorophyll fluorescence values of F_v/F_m, Φ_{PSII}, qP, and ETR by 4% and 5%, 17% and 21%, 11% and 13%, and 17% and 21%, respectively, as compared to T_{75} treatment, indicating that adequate light intensity (T_{25} and T_0) plays the fundamental role in improving the chlorophyll fluorescence parameters and photosynthetic capacity of soybean plants, which can help to maintain optimum growth and development under changing light conditions. In addition, the dynamics of chlorophyll fluorescence parameters at V_4 and R_1 stages under different light treatments showed the consistent pattern with those of at R_5 stage.

Carbon status, Rubisco Activity and Gene Expression

To further study the impact of shade treatments on soybean growth, we measured the total soluble sugar and starch content of soybean root and shoot at the end of day. As expected, total soluble sugar and starch content were considerably increased with decreasing shade treatments (from T_{75} to T_0) in both root and shoot. The highest total soluble sugar content 2.45 mg g^{-1} and 6.47 mg g^{-1}, and starch content 0.37 mg g^{-1} and 0.69 mg g^{-1} were determined under treatment T_0 followed by T_{25} (total soluble sugar content 1.95 mg g^{-1} and 6.25 mg g^{-1}, and starch content 0.32 mg g^{-1} and 0.65 mg g^{-1}) in root and shoot, whereas minimum total soluble sugar and starch content were measured in T_{75} treatment (*Figure 3*). In this experiment, a significant difference in Rubisco activity was measured in all treatments. Acceleration in the activity of Rubisco occurred in all treatments from T_{75} to T_0, the amplitude of increase was higher under T_0 than T_{75}, T_{50}, and T_{25} treatments. However, non-significant differences were observed between T_{25} and T_0 treatment for Rubisco activity. Overall, the Rubisco activity of soybean plants under T_{25} was increased by 39%, 40% and 42% at V_4, R_1, and R_5, respectively

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25512569

with respect to those under T_{75} treatment. These results indicate that the activity of Rubisco under T_{25} and T_0 showed the similar trend and shade of 25% can be effective at the enzymatic activity of Rubisco. Homologues of soybean sucrose phosphate synthase (GmSPS1*T1* and GmSPS2*T2*) and sucrose synthase (*GmSS*) were selected after blast against Arabidopsis to determine gene expression under different treatments. All three genes for sucrose phosphate synthase and sucrose synthase were up-regulated with increasing light at V_4 stage. Relative to T_{75} treatment, the expression of GmSPS1T_1 and *GmSPS2T2* were increased by 0.34 and 0.42 folds in T_{25}, respectively. While the expression of *GmSS* was enhanced by 2.3 folds in treatment T_{25} than T_{75} *Figure 4*.

Biomass Accumulation and Distribution

Changing light conditions significantly affected the total biomass accumulation (TBA) (g $plant^{-1}$) of soybean plants at various stages. In our study, the maximum TBA was 6.7, 22.4, and 35.5 under treatment T_0, while minimum TBA 4.1, 8.5, and 19.4 was observed in T_{75} treatment at V_4, R_1, and R_5, respectively (*Table 3*). However, soybean plants under T_{25} produced 86%, 76%, and 85% of the T_0 soybean biomass at V_4, R_1, and R_5, respectively. Furthermore, we also measured the biomass distribution among root, stem, leaves, and pods at different growth stages of soybean in response to changing light conditions (*Table 3*). At V_4 and R_1 stages of soybean, the maximum biomass partitioning (g $plant^{-1}$) was recorded in stem (3.8 and 13.4) followed by leaves (2.7 and 8.3) and root (0.25 and 0.65) under T_0, while at R_5 biomass distribution pattern was changes and the highest biomass was found in leaves (16.2) followed by stem (14.9), pods (2.6) and root (1.7) in T_0 treatment. Compared with T_{75} treatment, soybean plants under T_{25} and T_0 treatments, respectively obtained 40% and 35% higher pod biomass at R_5 stage.

Yield and Yield Components

In our study, there was a significant impact of different light treatments on seed yield of soybean plants *Figure 5*. The highest seed yield, 15.1 g plant^{-1}, was recorded in T_0 treatment. Relative to T_{75}, soybean plants under T_{25} and T_0 produced the 22% and 31% higher seed yield. Yield parameters also varied among different light treatments. The effects of light treatments on pod number (plant^{-1}), seed number (plant^{-1}) and seed weight (mg) were significant, and pod number and seed number under T_0 treatment were found significantly higher than that in T_{75}, T_{50}, and T_{25}. Meanwhile, seed weight was found considerably heavier in T_{75} as compared to treatment T_0. Overall, light treatment T_{25} and T_0 increased the pod number and seed number by 37% and 44%, and 38% and 45% as compared to treatment T_{75}, respectively, while T_{75} treatment enhanced the seed weight of soybean seeds by 21% than T_0 treatment *Figure 5*.

Discussion

The plant morphology has certain manipulability, and corresponding adaptation mechanisms present in changing environmental conditions (Gong et al., 2015). Use of higher planting density is the effective method for enhancing seed yields (Liu et al., 2015a). However, this practice is typically obstructed by impair light conditions (Li et al., 2014a). Numerous experiments have reported that shading conditions favor the upward growth of stem while reducing the stem breaking strength and stem diameter (Kurepin et al., 2007; Gommers et al., 2013; Yang et al., 2014). However, very few studies have Paidattention on the effect of changing shade treatments on soybean morphology to understand the threshold level of shade which will not affect the optimum soybean growth. In this study, a gradual decrease in shade (from T_{75} to T_0) significantly increased the stem diameter and stem breaking strength by maintaining the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25512569

optimum plant height of soybean plants (*Figure 1*). These findings showed that any variation in available light at soybean canopy directly affect the morphological characteristics of soybean plants and improved light availability positively improved the soybean growth by enhancing stem breaking strength which reduced the soybean lodging (Liu et al., 2016). Importantly, soybean plants under treatment T_{25} obtained superior morphological characters than T_{75} and T_{50}, suggesting that under 25% of shade soybean plants can maintain their optimum growth. Sun-light stimulates the plant growth and development; by photosynthesis process, plants use sun-light to convert H_2O and CO_2 into carbohydrate, photosynthetic pigments (Chl a, Chl b, and Chl a+b) playan important role in changing the solar energy to chemical energy (Liang, 2000; Yuncong et al., 2007). In changing light conditions, the study of Chl a, Chl b, and Chl a+b helps as an indices for sun-light absorption (Fan et al., 2018). In past reports, researchers have confirmed that Chl contents significantly affected by changes in light availability and decrease with the reduction in light (Li et al., 2014a,b). Similarly, significant variations were measured for Chl a, Chl b, and Chl a + b contents in all shade treatments, and chlorophyll contents were enhanced from 2.4 to 4.6 mg cm^3 with the decrease in shade from T_{75} to T_0, respectively, our results are consistent with previously reported results (Wittmann et al., 2001; Fan et al., 2018). On the other hand, several scientists have claimed that Chl a, Chl b, and Chl a + b contents increase with the increase in shade, especially Chl b contents (Li et al., 2014a).

In addition to the impacts of changing light conditions on morphology and chlorophyll contents our results showed that deleterious effects of increase shade eliminated by adequate light availability (treatment T_{25} and T_0). There are many causes why soybean plants under high shade conditions produced less carbohydrate. For instance, researchers have concluded that assimilate demands of soybean plants increased while photosynthetic rate decreased under increased shade conditions (Su et al., 2014; Yang et al., 2017). In this experiment, optimum light (T_{25} and T_0) at soybean canopy led to increase the photosynthetic rate and transpiration rate while stomatal conductance and intercellular carbon dioxide levels were decreased. Therefore, this showed that the enhanced photosynthetic characteristics increased the carbon gain and improved the soybean growth (Liao et al., 2005). Moreover, these findings indicating that the increased photosynthetic rate under T_{25} and T_0 treatments may be associated with the higher chlorophyll contents (i.e. higher Chl a, Chl b, and Chl a+b contents at V_4, R_1, and R_5, (*Figure 2*) of soybean leaves (Feng et al., 2018). Improved photosynthetic capacity is always accompanied with high quantity of electrons passing through PSII (Yao et al., 2017). Chl fluorescence parameters are one of the major factors in regulation of photosynthesis and crop responses to environmental conditions because of its sensitivity and convenience (Dai et al., 2009). In addition, total soluble sugar and starch content are the direct measure of high photosynthetic rate (Iqbal et al., 2018a). Crops translocate carbohydrate from source leaves to different plant parts that decides the plants fitness under changing environments (Amiard et al., 2005). Numerous previous experiments confirmed the role of light intensity for the production of total soluble sugar and starch content in plants (Preiss, 1982; Michalska et al., 2009). Similarly, we found that the total soluble sugar and starch content were considerably improved by 33% and 144% in T_0 than T_{75}. These results were in agreement with past reports (Pilkington et al., 2015). Previous experiments have confirmed that heavy shade results in reduce photosynthesis due to the decrease in qP, PSII and ETR (Huang et al., 2011; Yao et al., 2017; Feng et al., 2018). In this experiment, similar results were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25512569

obtained, however, improved Chl fluorescence characteristics were measured under T_{25} and T_0 treatments. These results reveals that optimum light intensity (treatment T_{25} and T_0) improves the efficiency of PSII and ETR that could enhance the photosynthetic capacity of soybean plants by improving the energy transport from PSII to PSI, our results are consistent with previously reported results (Yang et al., 2018a). The loss of rubisco activity was recognized to be very early and fast response of crop plants to shade stress (Servaites et al., 1986). While, at R_5, in current research the activity of rubisco was significantly accelerated in T_0 (0.38 μmol CO_2 g^{-1} FW min^{-1}) and T_{25} (0.36 μmol CO_2 g^{-1} FW min^{-1}) as compared to T_{75} (0.19 μmol CO_2 g^{-1} FW min^{-1}) (*Table 1*), our findings are consistent with past reports (Carmo-Silva and Salvucci, 2013). This higher rubisco activity under decreased shade treatments (T_{25} and T_0) exhibited that the higher photosynthetic rate of soybean plants directly correlated with rubisco activity under changing environments (Zhang et al., 2002).

This study provides the important data on biomass accumulation in soybean plants in different shade treatments (*Table 3*). Increased photosynthetic rate is one of the main factors for plant biomass production (Raza et al., 2018b). Previously, researchers have found that biomass accumulation is directly associated with the availability of light intensity (Kiniry et al., 2004) and reductions in light decreased the biomass production (Maddonni and Otegui, 2004). Our findings proposed that an adequate light availability (T_{25} and T_0) at soybean canopy can increase biomass accumulation by capturing and utilizing sun-light for their biochemical and physiological processes which in turn increased availability of carbohydrates for seed formation and this finding was similar to previous result (Liu et al., 2015b). Moreover, the accelerated dry matter production in soybean may be related to the utilization of major nutrients (Raza et al., 2018a) as the nutrient uptake ability of crops increased with improve light conditions (Yang et al., 2017). Additionally, we also measured the biomass partitioning in leaves, stem, pods, and seed of soybean plants in response to different shade treatments (*Table 3*). The dry matter partitioning changed considerably at V_4, R_1, and R_5 in soybean in all treatments. At V_4 and R_1, when reproductive parts were the weak sink the highest allocation of plant-biomass was determined in stem followed by leaves (Jasdanwala and Khan, 1988; Srinivasan et al., 2017). After that, at R_1 and R_5, the plant-biomass distribution changed and the most of plant-biomass assimilated to the leaves and pods in all treatments (Couch et al., 2017). Similar to our findings researchers have reported that optimum light intensity increased the assimilation of plant-biomass to economic parts, while decreased the dry matter partitioning to vegetative organs (Jasdanwala and Khan, 1988). Nevertheless, severe shading conditions (T_{75} and T_{50}) increased the retention of plant-biomass in stems (Wu et al., 2017) which did not promote the seed formation process and decreased the seed yield (*Figure 5*). These findings of plant-biomass partitioning demonstrated that accelerated translocation of photo-assimilates from the stem for pod formation occurred in soybean plants of treatments T_{25} and T_0, while severe shading conditions was not favorable to plant-biomass partitioning to pod.

Previously, it has been found that severe shading conditions significantly decreased the soybean yield and yield components (Wu et al., 2016; Iqbal et al., 2018b). Similarly, in our study, treatment T_{75} (severe shading) had significant negative effect on seed yield and yield related parameters, and minimum pod number (29.9 $plant^{-1}$) and seed number (36.4 $plant^{-1}$), and seed yield (10.4 g $plant^{-1}$) of soybean were noticed in T_{75} treatments. This is might be due to the lower photosynthetic rate and biomass accumulation, similar to our results in another study of relay-intercropping scientist has reported that soybean

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25512569

seed yield of soybean plants significantly decreased in severe shading conditions as compared to normal conditions (Yang et al., 2017). Moreover, light enrichment treatments significantly increased the pod number and seed yield of soybean. Hence, pod number (52.4 and 46.9 plant^{-1}) and seed number (66.7 and 59.1 plant^{-1}) of soybean plants might be improved in adequate light (T_{25} and T_0, respectively), these results implied that optimum light availability at soybean canopy can significantly improve the morphological parameters, photosynthetic and chlorophyll florescence characteristics which in turn considerably increased the seed yield of soybean plants by increasing the pod number and seed number.

Conclusion

The significant impacts of shade treatments on soybean have been studied previously, but rarely researchers have investigated the effects of different shade treatments on soybean plants to understand the threshold level of shade for the better growth and development. In this experiment, we showed that by selecting the shade tolerant variety soybean plants can cope shade up to 25% (T_{25}). Increased shade (T_{75}) considerably impaired the morphological characteristics (*Figure 1*), enzymatic activity of key enzyme (Rubisco) by down-regulating the important sucrose-synthase-genes (*Figure 4*). In addition, as compared to T_{75}, treatment T_0 and T_{25} significantly improved the photosynthetic and chlorophyll florescence characteristics of soybean plants especially quantum yield of PSII which in turn considerably increased the seed yield and yield-components (*Figure 5*). Overall, these results implied that agronomist should have to develop an appropriate intercropping planting pattern where the maximum shade density ranges from 20 to 30% to obtain higher seed yield of soybean crop under intercropping-system. This could be achieved by developing the narrow-wide row planting pattern in which maize plants can grow under narrow rows and soybean plants can grow in wide rows by maintaining the appropriate distance in which soybean plants can receive enough light for their optimum growth. In addition, developing the long term and environment friendly agronomic approaches to improve the seedling growth of soybean under intercropping systems by reducing the shade density in maize soybean intercropping system is an important direction for future research.

Abstract. This paper examines the effects of selected heavy metals: zinc, nickel, copper, cadmium and lead, on the growth of three species of entomopathogenic fungi of the genus *Isaria* Pers.: *I. farinosa* (Holmsk.), *I. fumosorosea* Wize, and *I. tenuipes* Peck. Ions of metals were added to the Sabouraud medium in three concentrations: 1× - concentration corresponding to the natural content of the given metal in Polish soils; 10× - concentration 10 times higher, and 100× - concentration 100 times higher than the natural content. Heavy metal ions in concentration 1× did not significantly restrict the growth of fungus colonies, and in some cases caused a slight growth stimulation. The greatest toxic effect of heavy metal ions on the entomopathogenic fungi was observed when their concentration was 100 times higher than the natural content. Nickel had the greatest inhibitory effect on the growth of fungal colonies, while lead showed the least effects. The fungal species most sensitive to the presence of heavy metals in the medium was *I. tenuipes*, while *I. fumosorosea* had the highest tolerance.
Keywords: *insect-pathogenic fungi, metal-resistance, mycelial growth, Hypocreales, soil*

Introduction

Heavy metals are considered one of the most dangerous environmental pollutants created as a result of human economic activities, both agricultural and non-agricultural (Kabata-Pendias and Pendias, 2001; Goyer, 2001; On et al., 2005; Micó et al., 2006). In the soil they react with other chemicals, accumulating in different forms with differentiated bioavailability to plants (Singh and Kalamdhad, 2011).

The solubility of heavy metals in soil, and hence their biological effects, decreases with increasing content of organic matter or clay minerals, and increases under higher acidity (Kabata-Pendias and Pendias, 1999, 2001). Metals in natural concentrations are often essential in the functioning of living organisms, but often have toxic effects when present in excessive amounts (Badura and Piotrowska-Seget, 2000; Singh and Kalamdhad, 2011). Additionally, their presence in soil has a major impact on cellular structures, growth and development, and biological activity of soil microorganisms (Badura and Piotrowska-Seget, 2000; Tscherko et al., 2007; Hassn et al., 2014).

Although heavy metals naturally occur in the soil environment, presently there are many factors significantly contributing to their increase such as industrial activities, and perhaps most importantly, the intensification of agricultural production using chemical-dependent farming methods (Lenart and Wolny-Koładka, 2013). The European Parliament and Council Regulation (EC) No 1107/2009, states the use of integrated plant protection natural alternatives should be considered a priority instead of the use of chemical ones (Tomalak, 2010). The use of products with biological origin based on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25712582

micro-organisms such as entomopathogenic fungi are becoming increasingly important (Sheeba et al., 2001; Meyling and Eilenberg, 2007; Tkaczuk, 2008; Batta et al., 2011; Schemmer et al., 2016; Showket et al., 2017).

Entomopathogenic fungi are a very important component of the environment and infect many species of arthropods causing disruption of physiological processes in the host followed by mortality (Hajek and Leger, 1994; Chandler et al., 2000; Quesada-Moraga et al., 2007). They occur primarily in the soil and constitute an essential part of the organic biomass (Ferron, 1981; Keller and Zimmermann, 1989; Tkaczuk, 2008). Soil often provides the substrate for the maintenance of a natural reservoir of many entomopathogenic fungi. Soils can be inoculated with these fungi either by an infected insect entering the soil or by the deposition of spores on the soil surface by natural dispersion mechanisms (Hajek, 1997). Presence and pathogenicity of many entomopathogenic fungi depend on interactions with host organisms, prevailing climatic conditions, and other biotic and abiotic factors.

Laboratory studies have shown that heavy metals impact the growth, metabolism, and pathogenicity of entomopathogenic fungi (Ropek and Para, 2003; Baldrian, 2003; Pečiulytė and Dirginčiutė-Volodkienė, 2012; Hassn et al., 2014). Ecotypes of specific species of entomopathogenic fungi accumulate heavy metals in different amounts leading to diverse effects on growth and pathogenicity (Popowska-Nowak et al., 2004; Tkaczuk, 2008).

Some of the hypocralean fungi most commonly found in the soil environment that are highly parasitic to insects include species of the *Isaria* Pers. genus (Zimmermann, 2008; Ropek et al., 2014). *Isaria farinosa* (Holmsk.) is frequently responsible for natural epizootics among butterflies overwintering as pupa especially in soil and forest litter (Vänninen, 1996; Chandler et al., 1997). *Isaria fumosorosea* Wize is used to produce a bio-insecticide to control whiteflies infesting greenhouse production plants (Gonzales et al., 2016). *Isaria tenuipes* Peck. causes epizootics of larval and pupal stages of several lepidopterous pests. After the death of the host, the fungi produces fascicles of hyphae, referred to as synnemata, which emerge from the cadaver and produce great amounts of conidia (Fukatsu et al., 1997).

The purpose of this paper is to investigate the effect of selected heavy metal ions on the growth of entomopathogenic fungi of the *Isaria* genus under laboratory conditions.

Materials and methods

Fungal isolates

Laboratory tests examined the effects of five selected heavy metal ions: zinc, nickel, copper, lead, and cadmium, on the growth of *Isaria farinosa, I. fumosorosea*, and *I. tenuipes*. The fungal material was obtained from stock collections maintained at the Department of Plant Protection and Breeding, Siedlce University of Natural Sciences and Humanities, Siedlce, Poland.

Initial isolates of *I. farinosa* and *I. tenuipes* were obtained from infected pupae of an unidentified butterfly species found in leaf litter of mixed woods in the vicinity of Siedlce. The isolate of *I. fumosorosea* was obtained from the soil of cultivated fields and collected using the ‘insect bait’ method.

The fungi were identified on the basis of morphological characteristics, using identification keys (Inglis et al., 2012; Humber, 2012). Prior to treatments, isolates were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25712582

applied to Petri-plates with Sabouraud medium and maintained at 20 ± 2 °C for 7 days in total darkness.

Preparation of media with metal ions

Heavy metal ions were added to sterile Sabouraud medium in three concentrations: 1× - concentration corresponding to the mean content of that metal in Polish soils, 10× - concentration 10 times higher and 100× - 100 times higher than the natural content. Treatment concentrations are listed in *Table 1*. Metal ions were added to the culture media in the form of various salts.

Table 1. *Characteristics of heavy metal salts used in the experiment*

Ion	Salt used	Concentration of ion corresponding to the natural content in soil (mg/l)
Cu	$CuSO_4 \times 5H_2O$	6.5
Zn	$ZnSO_4 \times 7H_2O$	33.0
Ni	$Cl_2Ni \times 6H_2O$	6.5
Pb	$Pb(NO_3)_2$	13.8
Cd	$CdCl_2 \times 2H_2O$	0.22

The Sabouraud medium was treated with $H_2PO_4^-$ and HPO_4^{2-} as a buffer to maintain pH of 6.4. Plates were centrally inoculated with a mycelial disc of 3-4 mm in diameter, and were stored in darkness at 20 °C. The colony diameter was measured 5, 10, 15 and 20 days after inoculation. Each experimental combination and the control with no metals were replicated four times. All laboratory experiments were achieved at the Siedlce University of Natural Sciences, Department of Plant Protection and Breeding, Siedlce, Poland in 2017.

Statistical analysis

Size of fungus colonies, expressed as a percentage in relation to the control, were treated as variables. The results were processed statistically using the Statistica 12 program. Tukey's test and single-factor analysis of variance at a significance level of $\alpha = 0.05$ were used to compare group means.

Results

Metal ions of zinc, nickel, copper, lead, and cadmium affected the growth of *Isaria* genus in various ways, with the reaction dependent on the type of metal as well as concentration. Levels of zinc, copper, and cadmium at the levels found in native Polish soils caused a slight stimulation of colonies of *Isaria farinosa* (*Table 2*).

After 20 days all colonies *I. farinosa* on the media with 1×, 10×, and 100× heavy metal concentrations grew, respectively, 110.8%, 115.8%, and 102.8% of the control colony diameter. Twenty days after the application of ionic cadmium and lead with the concentration 10 times higher than the natural content (10×) that the diameter of the *I. farinosa* colony was 32.9% smaller than the control for cadmium and 30% smaller for lead. Other heavy metals added to the media at 10× concentration did not significantly affect the growth of the colonies. Of all the heavy metals cadmium and nickel ions at

DOI: http://dx.doi.org/10.15666/aeer/1702_25712582

the concentration 100 times higher than natural the most strongly inhibited the growth of the *I. farinosa* cultures.

Con[1] - concentration; 1× - the concentration corresponding to the natural content of the metal in the Polish soils; 10× - the concentration of 10-times higher than the natural content; 100× - the concentration of 100-times higher than the natural content; means in columns fallowed by different letters within the given metal differ significantly at $P < 0.05$

After 20 days of incubation fungal colonies on the media with ions of those two metals were, respectively, 54.6% and 75.8% of the control diameter. In the case of the other heavy metals: lead, copper, and zinc, those values were 85.7%, 91.7%, and 100.5%, respectively.

The ions of heavy metals at the concentration of 1× and 10× did not influence significantly the growth of *Isaria fumosorosea* colonies (*Table 3*). Only cadmium and lead ions reduced the growth by 6.6% when compared to the control. With respect to cadmium ions this difference was statistically significant. Other ions of heavy metals at both 1× and 10× concentrations slightly stimulated the development of *I. fumosorosea*.

Ions of nickel and zinc added to the medium at the concentration 100 times higher than the natural content in Polish soils limited fungus growth after 20 days the most, by 20.3% and 15.3%.

Con[1] - concentration; 1× - the concentration corresponding to the natural content of the metal in the Polish soils; 10× - the concentration of 10-times higher than the natural content; 100× - the concentration of 100-times higher than the natural content; means in columns fallowed by different letters within the given metal differ significantly at $P < 0.05$

This difference was statistically significant. It was found that cadmium 100× concentration did not affect adversely the development of the *I. fumosorosea* colony, while in the case of lead and copper the colonies were only about 5.9% and 9.7% smaller than the control.

Discussing the experiment findings it should be noted that so far there have been no studies on the effects of heavy metal ions on the growth of *Isaria tenuipes*. This paper, therefore, is the first one in scientific literature devoted to the subject. The experiment showed that 20 days after heavy metal ions were added to the media at the concentration corresponding to their natural content in the Polish soils (1×) and 10-times higher (10×), they did not significantly inhibit *I. tenuipes* growth (*Table 4*). It was found that only in the presence of nickel were the diameters of fungus colonies around 10% smaller than the control, while in the case of them growing on the medium with cadmium and lead there was even a slight growth stimulation. With the concentration 100 times higher than their natural content in Polish soils, zinc, nickel, and copper ions were the most toxic to *I. tenuipes*. Within the first 5 days of the experiment the culture with nickel ions had not grown, and within 10 days the *I. tenuipes* colony had reached only 16.1% of the control diameter. 20 days after the experiment had started fungal colonies on media

containing zinc, nickel, and copper at their highest concentration (100×) were, respectively, 29.5%, 33.8% and 69.1% of the size of the control culture.

Con[1] - concentration; 1× - the concentration corresponding to the natural content of the metal in the Polish soils; 10× - the concentration of 10-times higher than the natural content; 100× - the concentration of 100-times higher than the natural content; means in columns fallowed by different letters within the given metal differ significantly at $P < 0.05$

With respect to the fungi *I. farinosa* and *I. fumosorosea* this difference was statistically significant. However, after 20 days the presence of cadmium in the medium only to a low degree decreased the size of the *I. tenuipes* colony, by 8.7%, while lead ions stimulated its growth. It should be noted that out of the entomopathogenic fungi of the *Isaria* genus, *I. tenuipes* proved the most sensitive to the presence of zinc, nickel and copper ions used in the concentration 100 times higher than their natural content in Polish soils (*Table 5*).

Discussion

Heavy metals are highly toxic to living organisms. They contribute to the deterioration of soil chemical properties and restrict the number of soil microorganisms (Kabata-Pendias and Pendias, 2001; Šmejkalová et al., 2003; Ahmad et al., 2005; Tscherko et al., 2007; Lenart and Wolny-Koładka, 2013).

Studies performed in vitro suggest certain species of entomopathogenic fungi, and as well as individual strains within species, exhibit different sensitivity to heavy metal ions (Jaworska et al., 1996; Ropek and Para, 2003; Keller et al., 2003; Tkaczuk, 2003, 2005; Gorczyca, 2005; Quesada-Moraga et al., 2007; Pečiulytė and Dirginčiutė-Volodkienė, 2012; Hassn et al., 2014). Some of the metals are inhibitory, while others, such as lead or zinc, can stimulate biomass growth of entomopathogenic fungi at certain levels (Bajan et al., 1998).

Our studies showed the presence of zinc, copper, and cadmium in a medium with concentrations similar to the natural content in Polish soils caused a slight stimulation of *I. farinosa* colony growth. Those findings were confirmed by the studies of Popowska-Nowak et al. (2000), who found that zinc ions added to a medium had stimulating effects in the initial phase of *I. farinosa* fungus growth. By examining various species of entomopathogenic fungi in the soil of Sweden Arnebrandt et al. (1987) and Nordgren et al. (1985) observed that two species: *I. farinosa* and *B. bassiana,* had the greatest tolerance to soil contaminated with copper and zinc. El-Sharouny et al. (1988) found in their study that *Isaria* and *Metarhizium* Sorokin were resistant to high content of zinc in the soils of Egypt. Hassn et al. (2014) studied the effect of metal ions on the growth of *Isaria javanica* (Bally) Samson and Hywel-Jones (= *Paecilomyces javanicus*) found that zinc, copper, and cadmium in amounts corresponding to their natural content in soils, as well as cadmium in concentration 10 times higher than the natural content, did not affect colony growth of this fungus significantly. Other species of entomopathogenic fungi have been shown to be tolerant and resistant to high contaminations of the soils, by heavy metals (Arnebrandt et al., 1987; Fomina et al., 2007). Trevors et al. (1986), Gaad (1993), and Zimmermann and Wolf (2002) found that entomopathogenic fungi display relatively high resistance to heavy metals, or produce mutations capable of tolerating high concentration. Additionally, Popowska-Nowak et al. (2004) observed that entomopathogenic fungi can employ adaptive mechanisms in areas heavily contaminated by heavy metals. Pečiulytė and Dirginčiutė-Volodkienė (2012) also

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25712582

observed higher concentration of copper ions added to a medium stimulates the number of infectious units produced by *Peacilomyces inflatus* (Burnside) J.W. Carmich. They also found by extending the breeding time, tolerance to copper and zinc increased, with some species starting growth on the first day of the experiment, and others as late as after 57 days. Fungus species belonging to *Beauveria, Isaria* or *Metarhizium* genus are among entomopathogenic fungi with the highest tolerance to high concentrations of heavy metals in soils, having an ability to accumulate them (Kameo et al., 2000; Fomina et al., 2007; Tkaczuk, 2008). Gorczyca (2005) reported selected metal ions, including cadmium, lead, copper, manganese, magnesium, and zinc stimulated fungal biomass growth of *B. bassiana* (Bals.) Vuill. strain Bb5.

Heavy metals in high concentrations, can significantly limit growth, spore germination, and pathogenicity of fungi for in vitro studies. Lead has a great capacity to accumulate in the environment can be particularly toxic to fungus cells (Ropek and Para, 2003; Jaworska and Gorczyca, 2004; Tkaczuk, 2005; Hassn et al., 2014). Ropek and Para (2003) observed that the heavy metals they used restricted the growth of *Paecilomyces farinosus* (= *Isaria farinosa*) significantly, and the ions of lead, cadmium, zinc, and copper had the most toxic effects on this fungus isolate.

In our studies concentrations of cadmium and lead at levels 10 times higher than the natural content in Polish soils showed an inhibitory influence on the growth of the *I. farinosa*. Levels of cadmium and nickel at 100 times higher than the natural soil content greatly reduced fungal growth. Tkaczuk (2005) showed nickel had the greatest inhibitory effects on the germination of spores of *Pandora neoaphidis* (Remaud and Hennebert). Hassn et al. (2014) reported that cadmium, copper, and zinc ions at the concentration 100 times higher than the natural content in the soils of Iraq, regardless of the period of observation, completely inhibited the growth of an *I. javanica*. Tkaczuk (2008) reported that cadmium was only slightly toxic to entomopathogenic fungi *B. bassiana* and *M. anisopliae* tested in vitro studies, but significantly reduced the number of colony forming units (CFU) of these fungi in soil. Jaworska and Gorczyca (2004) observed that only very high soil contamination with heavy metals (321 mg Cd, 1294 mg Cu, 1974 mg Pb and 3427 mg Zn × kg^{-1}) caused a decrease in *I. farinosa*, *B. bassiana* and *M. anisopliae* pathogenicity to *Galleria mellonella* larvae.

Heavy metal ions added to the medium at the concentration corresponding to the natural content in Polish soils and 10 times higher did not affect significantly the growth of *I. fumosorosea.* The relatively high resistance of *I. fumosorosea* to the effects of some heavy metals is confirmed by research of Gorczyca and Ropek (2000), Tkaczuk (2003, 2008), and Pečiulytė and Dirginčiutė-Volodkienė (2012).

We have shown that cadmium and lead in the highest concentration caused only a small reduction in the growth of the *I. fumosorosea.* Our results that indicated growth of the *I. fumosorosea* was inhibited by high levels of nickel and zinc were similar to studies of Jaworska et al. (1996) and Tkaczuk (2003). It is worth noting that in our studies cadmium ions showed no significant inhibitory effect on the growth of this fungus. Our results were confirmed by Tkaczuk (2008), who concluded that cadmium used for in vitro studies showed low toxicity to *Isaria* fungi. However, Gorczyca and Ropek (2000) reported that adding cadmium to a medium not only limited the growth of *P. fumosoroseus* (= *I. fumosorosea*), but also reduced the amount of its biomass. They further reported that zinc and copper has limited negative effects. Gorczyca and Ropek (2000) reported the accumulation of metal ions was up to 3 to 5 times higher in *P. fumosoroseus* biomass than in the culture medium.

Heavy metals affect growth, morphology or metabolism of soil organisms (Niklińska and Chmiel, 1997). Pečiulytė and Dirginčiutė-Volodkienė (2012) reported fungi with the greatest resistance to heavy metals do not accumulate them in their biomass but bind them to the surface of their cells. It is known that fungi can accumulate significant amounts of metals. The cell walls of fungi are composed of polysaccharides, proteins and lipids which contain functional groups with potential metal complexing capacities (Trevors et al., 1986; Gaad, 1993).

Metals in soil are present as free metal ions, soluble metal complexes, exchangeable metal ions, organically bound metals, precipitated or insoluble compounds such as oxides, carbonates and hydroxides (Leyval et al., 1997). The mobility of metals in soil is dependent of their speciation, which is controlled by hydrochemical variables (pH, redox potential, presence of complexing inorganic and organic an-ions, ionic strength) as well as by their interactions with solid surface. The toxicity of metals in soil depends on their bioavailability, which, according to Berthelin et al. (1995), is a function not only of their total concentration but also of physico-chemical and biological (e.g. biosorption, bio-accumulation and solubilization) factors. The negative effects of heavy metals on entomopathogenic fungi on metabolism, growth, germination and differentiation may vary, depending on the fungal species, metal concentration, and other physico-chemical factors such as soil organic matter and clay content (Gaad, 1993; Tobin et al., 1994).

Conclusions

Heavy metal ions added to fungal culture medium in concentrations corresponding to the natural content found in soils of Poland did not significantly affect the growth of cultures of *Isaria* ssp. When compared to control cultures, slight increases were noted. At a concentrations 10 times higher than the natural content in Polish soils, heavy metal ions had little influence on the growth of the *Isaria* fungal colonies. Cadmium and nickel has the highest inhibitory effects *Isaria.* Heavy metal concentrations of 100 times greater than levels found naturally had the greatest toxic effects. Nickle was the most toxic and lead was the least toxic. *Isaria tenuipes* showed the greatest sensitivity to heavy metals *I. fumosorosea* having the highest tolerance. Strong pollution of soil by some heavy metals could be a restrictive factor of development of entomopathogenic fungi in the environment. Further studies on heavy metal resistance of different isolates within the particular genus of these fungi can be performed to search of virulent strains to be applied as biopesticides.

SYNTHESIS, CHARACTERIZATION AND INVESTIGATION OF ANTIMICROBIAL ACTIVITY OF SILVER NANOPARTICLES FROM *CYDONIA OBLONGA* LEAF

BARAN, M. F.

Medical Laboratory Techniques, Vocational Higher School of Healthcare Studies, Mardin Artuklu University, 47200 Mardin, Turkey
(e-mail: mfiratbaran@gmail.com)

(Received 12th Nov 2018; accepted 16th Jan 2019)

Abstract. In this study, leaf extract of *Cydonia oblonga* were used to synthesize silver nanoparticles. Silver nanoparticles have been successfully synthesized by environmentally friendly and economical methods. Characterization of synthesized AgNPs used UV-visible spectroscopy (UV-Vis.), thermogravimetric and differential thermal analysis (TGA-DTA), X-ray diffraction spectroscopy (XRD), scanning electron microscopy (SEM), electron diffraction X-ray (EDX), Fourier transform infrared spectroscopy (FT- IR). XRD results demonstrated that the crystal structure of AgNPs was cubic and had a size of 27.30 nm. AgNPs were found to be spherical in SEM images. The element composition was also revealed by EDX. Antimicrobial activity of silver nanoparticles; Gram-negative *Escherichia coli* was tested on gram positive *Staphylococcus aureus* and *Candida albicans* yeast. The concentration values of 0.0552, 0.1535 and 0.0383 mg L^{-1} were determined as MIC (minimum inhibitory concentration), respectively. It was evaluated that the commercial antibiotics used were more effective at low concentrations compared to colistin, vancomycin and fluconazole.
Keywords: *XRD, SEM, TGA-DTA, silver nanoparticles, Cydonia oblonga*

Introduction

Particles with a size of 1-100 nm are called nanoparticles. These particles can be obtained by biological, physical and chemical means. They are used in different areas such as energy, pharmacology, biomedical, cosmetics, textiles, food and agriculture etc. (Chaudhry et al., 2018). Compared to physical and chemical methods, the advantages of biological methods such as ease of application and control, eco- friendliness and lack of toxic chemicals make this method important (Pantidos and Horsfall, 2014). Due to the fact that it is cheap and easy to obtain, the use of vegetable resources for synthesis is becoming increasingly common. In the synthesis of silver nanoparticles, phytochemicals in plant leaf extracts form AgNPs by reducing the Ag^+ ions in the media to the Ag^o form, and these phytochemicals also provide stability (Prakash et al., 2013). Silver nanoparticles (AgNPs) were synthesized using plant extracts and these particles showed good antimicrobial activity (Ahmed et al., 2018).

In this study, AgNPs were obtained in a very short time with stable, energy-free and room conditions with *Cydonia oblonga* leaf extract and without any additional chemicals/and or physical steps. The resulting nanoparticles showed a strong antimicrobial effect. In this study a simple and rapid green synthesis of AgNPs is presented.

AuNPs using leaves extract of R. rugosa have been reported. Silver and gold nanoparticles can be prepared with lower amounts of leaf extract and without any additional chemicals/and or physical steps. The effect of leaf extract quantity and concentration of metal solution were also evaluated to optimize the synthesis route producing the metal nanoparticles.

Materials and methods

Silver nitrate ($AgNO_3$) 99.98% was obtained from Sigma-Aldrich. Vancomycin, fluconazole and colistin were commercially purchased for antimicrobial applications.

Preparing Cydonia oblonga leaf extract

The leaf extract of *Cydonia oblonga* was washed with distilled water and dried at room temperature. 25 g was taken and the size reduced. It was mixed with 500 ml distilled water and boiled at 85 °C. The extract was filtered through Whatmann No.1 filter paper and cooled to room temperature. Stored at 4 °C for use in the study.

Synthesis of AgNPs

1 mM $AgNO_3$ aqueous solution was used for silver nanoparticles synthesis. It was left to react at room temperature with 125 ml of plant extract and 500 ml of silver nitrate solution was added to 1000 ml of flask and allowed to react under room conditions. AgNPs formation was monitored primarily with a macroscopic method depending on the change of colour and was determined according to time with spectrophotometric measurements (Pugazhendhi et al., 2018). Composed dark colored solution was obtained with centrifuge (7500 rpm, 10 min). The top, liquid portion was removed, while the remaining solid segment was washed with distilled water. The resulting AgNPs were left to dry at 65 °C and stored in the dark until use in the characterization process.

Characterisation techniques

Synthesised silver nanoparticles (AgNP) UV-Vis. Specrtrums were obtained on a spectrophotometer (UV-1601 220 V SHIMADZU). Scanning electron microscope (EVO 40 LEQ) was used to measure AgNPs dimension and morphology of AgNPs crystal construction was analysed with X-ray diffractometer (RadB-DMAX II) between $3° \leq 2\theta \geq 80°$ spaces. SEM- energy dispersive X-ray (EDX) spectroscopy was used to demonstrate AgNPs existence and morphology. FTIR (Perkin Elmer ATR-FTIR) analysis was used to determine those functional groups that has a role in the reduction in the plant extract in the range of 4000-400 cm^{-1}. Thermogravimetric analysis (TGA SHIMADZU DTG-60H) reported the degradation temperatures of AgNPs under the atmosphere of nitrogen gas at 25 °C min^{-1} and the atmosphere of nitrogen gas at constant heating rate.

Antimicrobial activity of AgNPs

The effects of the obtained particles on gram negative Escherichia coli ATCC 25922, gram positive Staphylococcus aureus ATCC 29213 bacteria and Candida albicans yeast were investigated. Minimum Inhibitory Concentration (MIC) was determined by microdilution method. In practice, the muller Hilton medium was added to the microplate wells and incubated overnight at 37 °C by addition of an appropriate amount of the microorganism mixture and the AgNP solution adjusted to 0.5 in turbidity according to the Mc Farland standard (El-Batal et al., 2018; Vishwasrao et al., 2018; Dhand et al., 2016). The next day the MIC was determined by the well in which the reproduction ended. In addition, vancomycin, colistin and fluconazole commercial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25832592

antibiotics and 1 mM $AgNO_3$ solution were used for *S. aureus*, *E. coli* and *C. albicans* to compare the effects of AgNPs.

Result and discussion

XRD analysis with X-ray diffraction

The evaluation of the analysis of AgNPs XRD phase and crystal structure was shown in *Figure 1,* which was synthesised with green method. Crystal structures of silver nanoparticles' reflections (111), (200), (220) and (311) were calculated with the values 2θ (37.38°, 44.78°, 64.81° and 77.50°) on XRD analysis (*Fig. 1*). It was determined that AgNPs were of elemental (Ag^o) and cubic crystalline structure. The crystalline particle size of the AgNPs was calculated according to the Debye-Scherrer equation and found to be approximately 27.30 nm.

The Debye-Scherrer equation is (Narayanan and Sakthivel, 2011; Banala et al., 2015; Rolim et al., 2019):

$$D = K\lambda / (\beta \cos\theta)$$

Here, D is the crystal size of AgNPs (nm), k = Scherrer's constant, (0.90), λ = X-ray wavelength (1.5406° A), β = FWHM (full width at half maximum) of the peak located at 2θ = 37.38°, θ = Bragg's angle of diffraction.

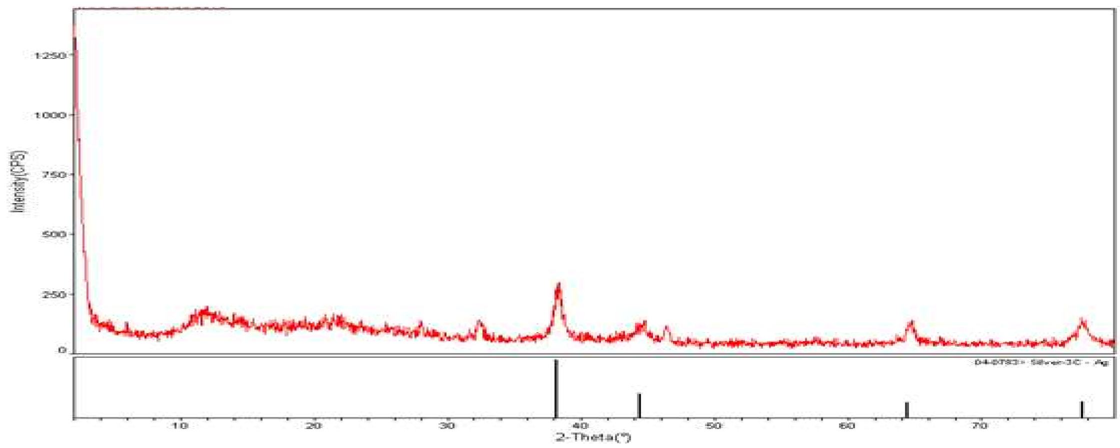

Figure 1. *XRD measurements of AgNPs confirming the cubic crystalline structure of AgNPs*

Analysis of UV-vis spectroscopy

In UV-vis spectroscopy analysis silver nanoparticles' formation was observed with samples taken at different times at 0, 5, 10, 15, 20, 25, 30 and 45 min. The color change to dark brown, which shows the formation of AgNPs, was observed very quickly. At about a maximum of 441.58 nm a sharp plazmon resonance indicated appropriately synthesised AgNPs (*Fig. 2*) Similarly, some other researchers which were near to our research found different spectrum values at 390-500 nm surface plazmon resonance (Al-Bahrani et al., 2017; Kalimuthu et al., 2008; Anbu et al., 2018; Khan et al., 2018; Rajakumar et al., 2017).

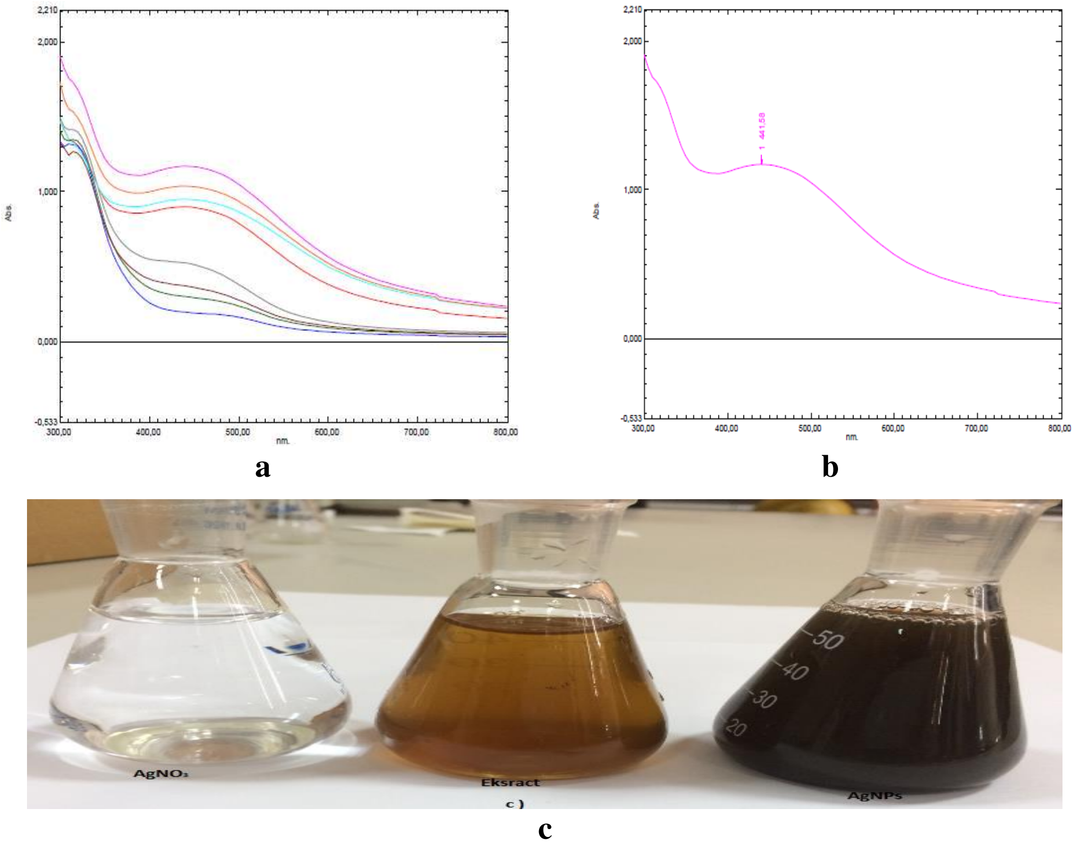

***Figure 2. a** The UV–Vis spectra of AgNPs synthesized by Cydonia oblonga leaf aqueous extract. **b** On UV-Vis spectroscopy maximum absorbance value synthesised AgNPs. **c** AgNPs stepwise thematic representation of the synthesis carried out*

Fourier transform infrared spectroscopy (FTIR) spectroscopy analysis

FT-IR spectrum provided information on which functional groups the reaction occurs in by comparing *Cydonia oblonga* leaf extract and synthesised AgNPs (*Fig. 3*). The characteristic peaks appeared at 3291 cm^{-1} and it represents the -OH stretching vibrations of free and hydrogen bound hydroxyl groups present in *Cydonia oblonga* extract. The peak obtained at 2081 cm^{-1} is due to -CH stretching vibrations of methylene groups, and furthermore, the sharp peak present at 16365 cm^{-1} can be assigned to non-hydrated C=O groups and it revealed that the asymmetric and symmetric stretching vibrations of carboxyl groups.

FTIR spectrum measurements which were synthesised on different studies showed the existence of intense band on 3314, 2119 and 1636 cm^{-1} (Pugazhendhi et al., 2018; Baran et al., 2018).

Analysis results of silver nanoparticles SEM and EDAX

Morphological specifications of AgNPs' which are obtained from leaf extract of *Cydonia oblonga* were examined by using electron microscope (SEM), shown in *Figure 4*. The results have shown the presence of silver nanoparticles (AgNPs). Morphological specifications which were obtained from leaf extract of *Cydonia oblonga* were examined by using electron microscope (SEM), shown in *Figure 4*. The results have

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25832592

shown us clearly the existence of spherical shaped silver nanoparticles (AgNPs') under 100 nm. It was seen on XRD calculation that particles size was about 27.30 nm. Similarly, SEM analysis provided supplementary information about AgNPs size and morphological specifications (De Jesús Ruíz-Baltazar et al., 2017; Prakash et al., 2013; Jha and Shimpi, 2018).

Energy distributed spectrums of acquired AgNPs from EDX analysis have shown that there have been pure silver pieces (*Figure 5)*. The results obtained with AgNPs in other scientific studies support our findings (Veisi et al., 2018; Kumar et al., 2016; Ramkumar et al., 2017).

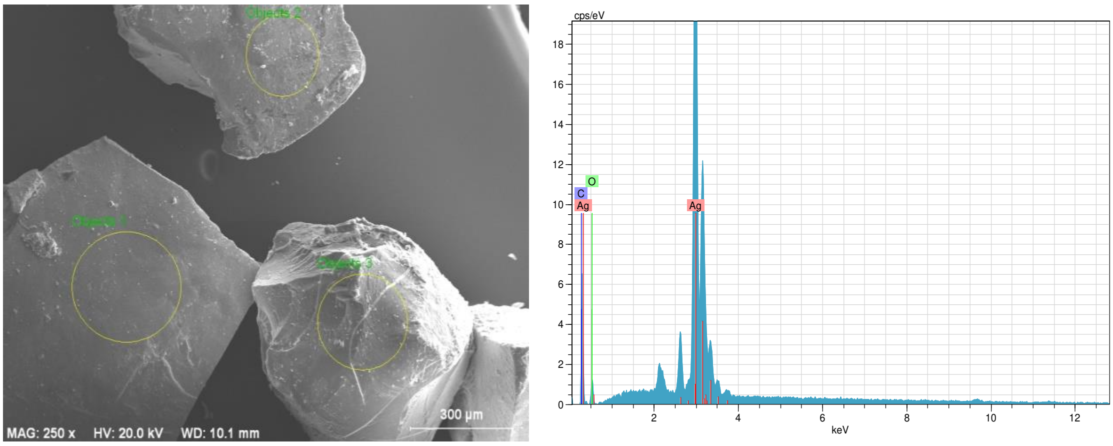

Figure 5. *EDX profile of AgNPs showing its elemental composition*

TGA-DTA findings

Nanoparticles which were prepared with green synthesis were analysed with the flow rate of 20 mL min^{-1} in N_2 (g) atmosphere with 10 °C min^{-1} heating rate between 31-900 °C TGA and DTA data. TGA bent shows specimen mass loss for thermal degradations. DTA bent determines maximum heat of dissociation at every stage of degradation (Baran et al., 2018).

It has been seen in *Figure 6* that at 31-257 °C mass loss is derived from moisture, at 257-333 °C there is a mass loss which is derived from cellulosic materials, at 333-900 °C the mass loss is derived from plant extract phytochemicals. TGA data were reported on the study about AgNPs synthesised mass loss. Similar studies support the results in this aspect (Baran et al., 2018).

Antimicrobial activity of synthesised AgNPs

Microorganisms are more and more resistant to the antibiotics used, which causes the struggle with them to fail. Therefore, the search for antimicrobial agent is more

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25832592

interested in combating infection. Antimicrobial activity studies with AgNPs may be a serious alternative to this condition. AgNPs increase the formation of reactive oxygen species (ROS) and disrupt the wall structure. These (ROS) to the affinity of the membrane structure and function changes are produced. They have an antimicrobial effect because they form a repressive process (Wang et al., 2017).

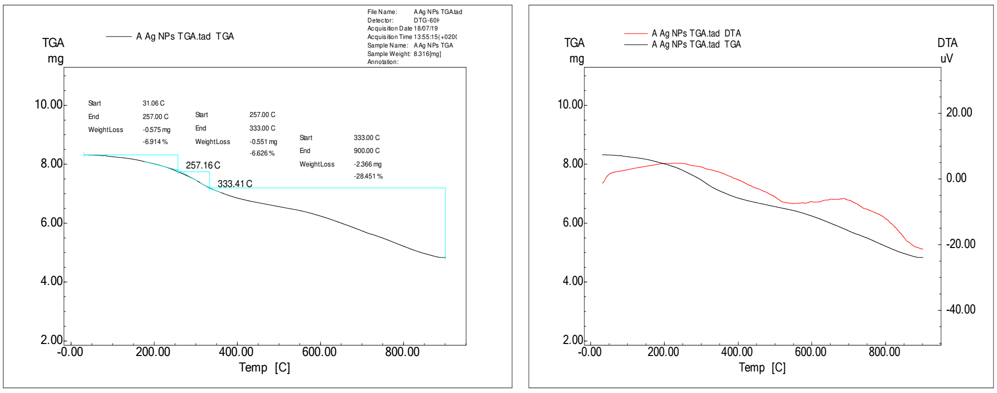

Figure 6. *TGA-DTA analysis result of synthesised silver nanoparticles*

In our study, the effect of AgNPs' antimicrobial effect is searched which are obtained from leaf extract of *Cydonia oblonga* by MIC method. Antifungal activities of AgNPs were studied on *C. Albicans* and probable antibacterial effect on gram positive *S. aureus ATCC 29213* and gram negative *E. coli ATCC 25922*. MIC worths were determined of AgNP and 1 mM silver nitrate. In our study, fluconazol, vancomisin and Colistin antibiotics were used. The synthesized silver nanoparticles have been shown to have a strong antimicrobial effect. The MIC of the AgNPs on *E. coli ATCC 25922*, *S. aureus ATCC 29213* and *C. albicans* was determined as 0.0552, 0.1535 and 0.0383 mg mL^{-1}, respectively. From the acquired results, which have been shown in *Table 1,* it is clear that AgNPs are more effective than antibiotics and 1 mM silver nitrate solution.

In order to determine the antimicrobial activity of AgNPs, in the other scientific studies, 53, 15 and 40 µg mL^{-1} MIC values were found for *E. Coli* (Sinsinwar et al., 2018; Rolim et al., 2019; Hemmati et al., 2019). Values of 100 and 11.60 µg mL^{-1} were calculated for E. coli (Ananda et al., 2019; Shao et al., 2018).

Table 1. *MIC values of synthesized silver nanoparticles (AgNPs) (mg mL^{-1}), silver nitrate and S. aureus, C. Albicans, vacomycin, fluconazole, colistin antibiotics for E. coli, respectively*

Organism	AgNPs	Silver nitrat	Antibiotic
S. aureus ATCC 29213	0.1535	0.500	0.50
C. albicans	0.0385	0.500	0.50
E. coli ATCC25922	0.0552	1.000	0.125

Conclusions

As a result, silver nanoparticles were characterized by UV-visible spectra, TGA-DTA, FTIR, SEM-EDX and XRD measurements. The nanoparticles were obtained by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25832592

eco-friendly synthesis method with the use of *Cydonia oblonga* leaf aqueous extract, which does not involve simple, easy and toxic chemicals. In the case of waste, the use of the leaves as a vegetable source for synthesis provides a great advantage both for the recycling of the waste and for the cheap and easy production of the raw material for synthesis. AgNPs obtained by environmentally friendly methods can act as a powerful antimicrobial agent and their contribution to human health in medical industry can be a serious factor. The utilization of the leaf in waste form in this way and the synthesis will be quite interesting considering the transfer of the recycling to the industry. These nanoparticles can also be used for dye removal and bioremediation of waste water.

Abstract. Due to industrial growth and urbanisation, excessive usage of groundwater resulted in a problem of saltwater intrusion in Tuticorin, India where control and management is very much essential. In the present study, groundwater samples are collected and analysed from 38 observation wells in years 2014 and 2018. Thirteen parameters namely pH, Electrical Conductivity (EC), Total Dissolved Solids (TDS), Total Hardness (TH), Calcium (Ca^{2+}), Magnesium (Mg^{2+}), Sodium (Na^{+}) Potassium (K^{+}), Bicarbonate (HCO_3^-), Chloride (Cl^-), Sulphate (SO_4^{2-}) Nitrate (NO_3^-) and Fluoride (F^-) are determined and considered in calculating the Water Quality Index (WQI) based upon weighted arithmetic index method. Geographical information system (GIS) is used to interpolate water quality data by inverse distance weighted method. Experimental investigation indicates saltwater intrusion in the coastal aquifer of Tuticorin is due to excessive withdrawal of groundwater. Potential intrusion of saltwater is studied with respect to distance of observation wells from seashore. Finite Element Modelling of Flow (FEFLOW) is used to select the optimum pumping and recharge rate to control saltwater intrusion. A model is calibrated with hydraulic head measured using piezometer in the observation well, as well as salt concentration. The model is simulated using three different groundwater scenarios such as Abstraction, Recharge and combined Abstraction, Desalination Recharge (ADR) method. The simulation results depicted that the planned ADR system accomplishes significantly better than using abstraction or recharge well.
Keywords: *GIS, groundwater management, FEFLOW, hydraulic head, water quality index*

Introduction

Groundwater extraction is required in several coastal areas where the freshwater supply from surface sources is not sufficient. However, extreme groundwater abstraction may lead to intrusion of saltwater into the aquifer, henceforth salinity increases making the groundwater unfit for human intake (Rao et al., 2004). Saltwater contamination arises due to vertical movement across interconnected aquifers through open well or bore well (Barlow and Reichard, 2010). Jebastina and Prince Arulraj (2016) analysed groundwater and determined the quality changes due to silicate weathering and dissolution of carbonate. Assessment of groundwater quality plays a vital role in our society, predominantly concerning health (Sener et al., 2009). One of the important and easy methods for evaluating intrusion of saltwater in coastal areas is periodic analysis of groundwater chemistry (Todd, 1980). The information of hydrochemistry is significant to assess the groundwater quality in Coimbatore in which the groundwater is used for drinking, agriculture, and industrial purposes (Jebastina and Prince Arulraj, 2017). In recent years water quality index (WQI) has become an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

essential method to assess the quality of groundwater. Tavassoli and Mohammadi (2017) assessed the vulnerability of groundwater based on WQI values. WQI method handles complex data of water quality parameter and provides simplified output to understand water quality problem. Idowu et al. (2016) used geographical information system (GIS) as a prevailing tool to assess vulnerability of seawater intrusion and effective management of Groundwater.

Todd (1974) discussed various methods of preventing saltwater from polluting groundwater sources including; decrease of pumping rates, repositioning of extraction wells, use of sub-surface walls, recharge of water by natural and artificial methods, abstraction of saline groundwater and any combination of above techniques. El Mokhtar et al. (2018) developed model for planning and management of sustainable use of groundwater resources in the coastal aquifer of Fum Al Wad, Morrocco. Groundwater model evidenced that pumping of saline water from coastal aquifers would mitigate the rate at which saltwater flows into the aquifer so that quality of water improved. Hussain et al. (2015) suggested continuous Abstraction of brackish water, desalination and recharge techniques control saltwater intrusion effectively in coastal aquifers. Thomas et al. (2016) used simulation model to determine proper pumping strategy for the management of Coastal aquifers. Finite Element Modelling of Flow (FEFLOW) is a software used for groundwater modelling capable of simulating flow.

The main objective of this study is to evaluate the quality of groundwater using WQI in Tuticorin, India and thematically denote it using Geographical information system (GIS) for the better understanding of the current scenario at a glance. An effort has been made in the coastal aquifers of Tuticorin to protect the wells from seawater intrusion by FEFLOW code, using hydrogeological and hydro chemical data.

Location of the study area

The study area Tuticorin is situated in the southeast shoreline of Tamil Nadu, India and is positioned between 8° 19′ to 9° 22′ N latitude and 77° 40′ to 78° 23′ E longitude. The area is bound by the Gulf of Mannar in the east and Tirunelveli district, Tamil Nadu in the west. The main occupation of the people is agriculture. Many chemical industries, food processing industries, salt industries are situated in Tuticorin. Many industries are established after the construction of the port and Tuticorin became a district in the year 1986. After the formation, the economic development has been boosted and began to develop rapidly. Therefore, the urban expansion acquired in various areas of the district. The slope of the terrain is mild in the western part and flat in the eastern part. The location map of the study area is shown in *Figure. 1*.

Methodology

Sample collection

A total of 38 groundwater samples are collected from open and bore wells. The location of observation wells is shown in *Figure 2*. Each sample is collected in 1000 mL acid-washed polyethylene HDPE bottle. The bottle is fully filled with water such that no air bubble is stuck within the water sample. To avoid evaporation, the bottles are closed with double plastic caps. Precaution is also taken to prevent agitation of sample during transfer from field to the lab.

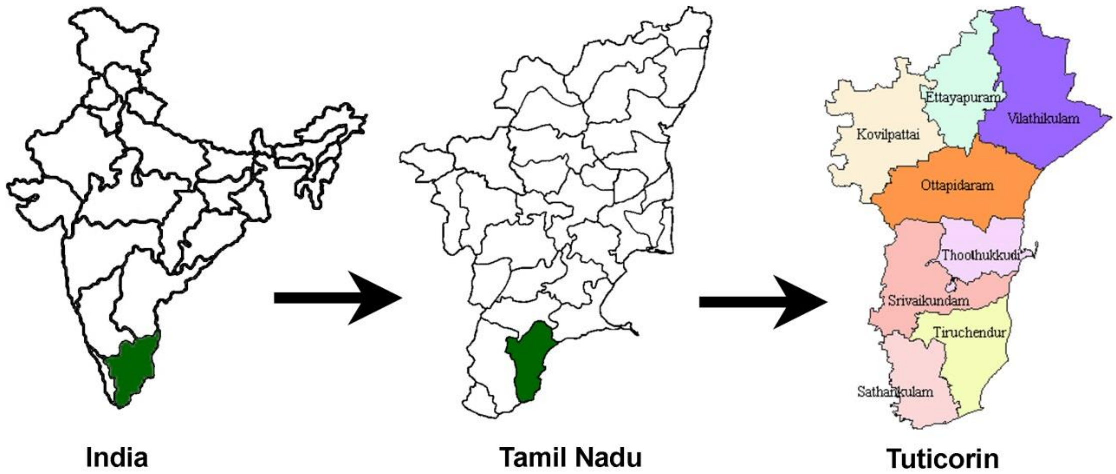

Figure 1. *Location map of study area*

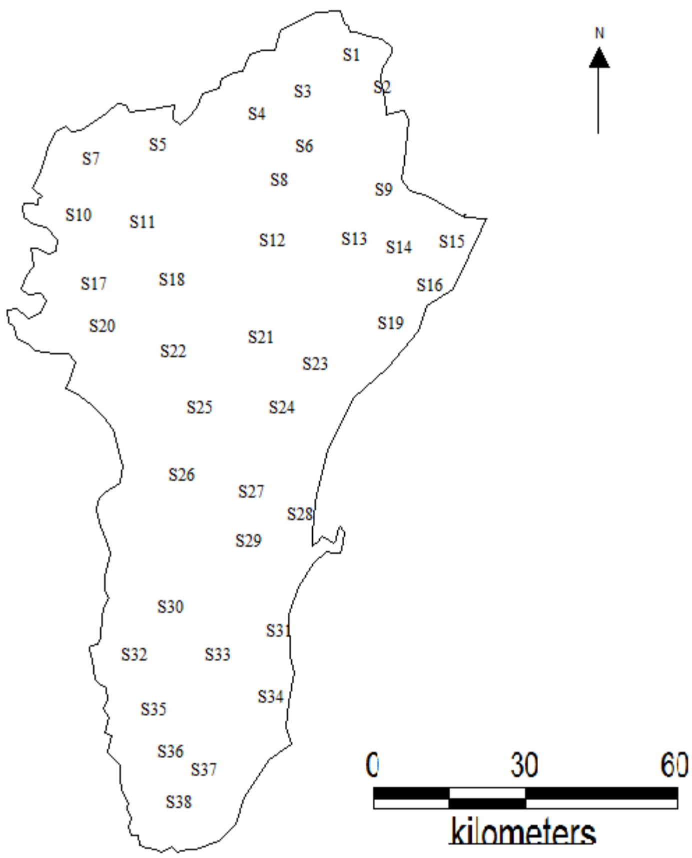

Figure 2. *Location of observation wells*

Laboratory measurements

The physico-chemical analysis was conducted using following methods and equipment as shown in *Table 1*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

Table 1. *Method and instrument used in water quality analysis*

S.No	Parameter	Method	Instrument/equipment
1.	pH	Electrometric	pH meter
2.	EC (electrical conductivity)	Electrometric	Conductivity meter
3.	TDS (total dissolved solids)	Electrometric	Conductivity meter
4.	TH (total hardness)	Titration by EDTA	-
5.	Ca^{2+} (Calcium)	Titration by EDTA	-
6.	Mg^{2+} (Magnesium)	Titration by EDTA	-
7.	Na^{+} (Sodium)	Flame emission	Flame photometer
8.	K^{+} (Potassium)	Flame emission	Flame photometer
9.	HCO_3^- (Bicarbonate)	Titration by H_2SO_4	-
10.	Cl^- (Chlorine)	Titration by $AgNO_3$	-
11.	SO_4^{2-} (Sulphate)	Use wavelength of 420 nm	UV–VIS spectrophotometer
12.	NO_3^- (Nitrate)	Use wavelength of 220 nm	UV–VIS spectrophotometer
13.	F^- (Fluoride)	Ion-selective electrode (ISE)	pH meter

All concentrations are denoted in milligrams per litre (mg/L), excluding the pH and EC

Determination of water quality index (WQI)

To calculate WQI, thirteen parameters namely pH, EC, TDS, TH, Ca^{2+}, Mg^{2+}, Na^{+} K^{+}, HCO_3^-, Cl^-, SO_4^{2-} NO_3^- and F^- are considered into account. The following few steps are followed in calculating WQI.

Parameter selection

The selection of parameters depends on several aspects, such as the purpose of the index, the importance of the parameter, and the availability of data (Stigter et al., 2006). For the assessment of drinking water quality, priority should be given to those parameters which are known to be important to health and to be present in significant concentrations in the water source (Ramesh et al., 2010). *Table 2* gives the details of the weights and relative weights assigned to various parameters.

Table 2. *Weights for various parameters*

Water quality parameter	Units	WHO (2017)		Weight (W)	Relative weight (W_R)
		Most desirable limit	Maximum allowable limit		
pH	-	6.5	8.5	4	0.09
EC	µs/cm	780	3125	-	-
HCO_3	mg/L	-	300	1	0.03
TDS	mg/L	500	1500	5	0.11
F	mg/L	-	1.5	5	0.11
Cl	mg/L	200	600	5	0.11
NO_3	mg/L	45	-	5	0.11
SO_4	mg/L	200	400	5	0.11
Na	mg/L	-	200	4	0.09
Ca	mg/L	75	200	3	0.07
Mg	mg/L	30	150	3	0.07
K	mg/L	-	10	2	0.05
TH	mg/L	300	600	2	0.05
				$\sum W = 44$	$\sum W_R = 1$

Drinking water quality standards given by the World Health Organization (WHO, 2017)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

Weight assignment

The assignment of weight to water quality parameters is to represent the importance of each parameter in the overall water quality. Higher weightage implies greater importance of the variable with respect to public health (Song and Kim, 2009). Therefore, each of the selected parameters has been given a weight (W) 1 to 5, depending on their importance. The chosen weights are tabulated in *Table 2*. These weights are assumed based on the data available from previous studies (Serrekawo and Karoppannan, 2018; Ramakrishnaiah et al., 2009; Gebrehiwot et al., 2011; Kalpana et al., 2014).

Relative weight calculation

Relative weight (W_R) can be determined by dividing the individual weight of each parameter (W_I) by the sum of weight of all selected parameters (*W*) shown in *Equation 1*.

$$W_R = \frac{W_I}{W} \quad \text{(Eq.1)}$$

where W_R is the relative weight, W_I is the weight of the parameter under consideration.

Quality rating calculation

The fourth step is the calculation of quality rating (Q_I) for each parameter, is given in *Equation 2*.

$$Q_I = \frac{C_I}{S_I} \times 100 \quad \text{(Eq.2)}$$

where Q_I is quality rating, C_I (mg/L) is the concentration of each parameter in water sample, and S_I (mg/L) is the Bureau of Indian standard for chemical parameter.

Sub-index calculation

The sub-index for each chemical parameter is determined using *Equation 3*.

$$S_I = W_R \times Q_I \quad \text{(Eq.3)}$$

S_I is the sub-index of the *i*th parameter. It combines its quality rating as well as its assigned weight.

Calculation of water quality index

The overall WQI is calculated by summation of all sub index values of each groundwater sample as follows (*Eq. 4*):

$$WQI = \sum S_I \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

Classification of water quality index

Higher WQI values indicate worse water quality, and lower values indicate excellent water quality. The detail description of WQI range and its classification is given in *Table 3*.

Table 3. *Classification of WQI values*

WQI range	Category of water
<50	Excellent
50–100	Good
100–200	Poor
200–300	Very poor
>300	Unfit for drinking purpose

GIS analysis

GIS is an effective method for spatial analysis and integration of the data to derive needed outputs and modelling. GIS can be beneficial for taking fast conclusions as graphical illustration would make visualization easy for policy makers. The study area of Tuticorin district is digitized from the survey of India toposheet using QGIS. The exact locations of observation wells are determined in the field using GPS and the precise longitudes and latitudes of observation wells are imported in GIS platform. Inverse Distance Weighted (IDW) interpolation method was used for spatial modelling of WQI and the parameter values are classified according to *Table 3*.

Model development (FEFLOW)

The first step in FEM analysis is the generation of mesh that fills the envisioned model domain with elements as shown in *Figure 3*. Based on the finite-element mesh, initial hydraulic head, boundary conditions and material properties are defined as given in *Table 4*.

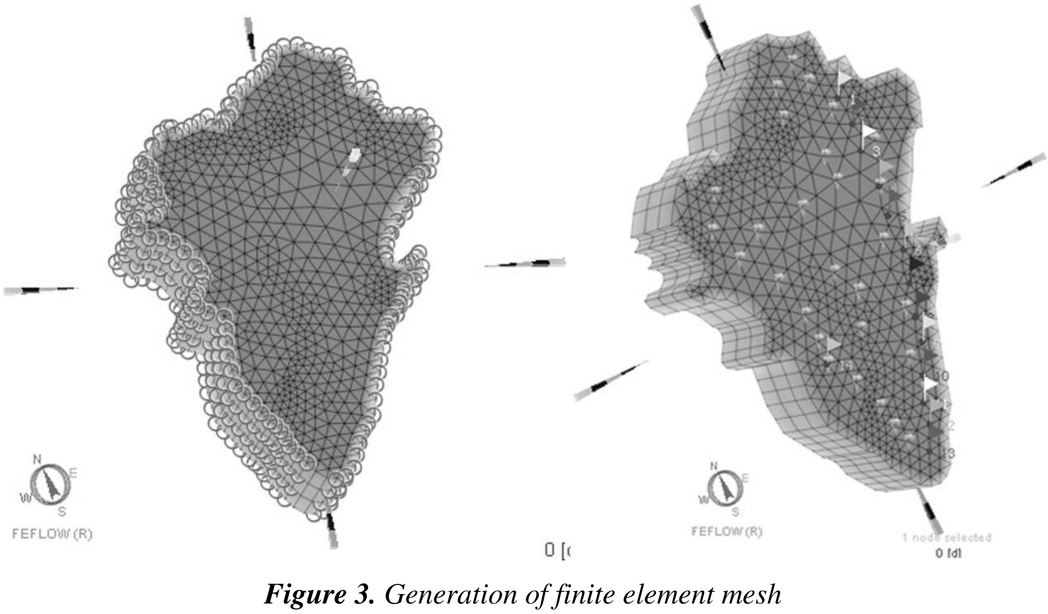

Figure 3. *Generation of finite element mesh*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

Table 4. *Data used for model development*

Parameter	Value
Physical parameters	
Mesh	
Element type	Triangle prism
Mesh element	3351
Mesh node	2496
Number of layer	1
Number of slice	2
Total model boundary areas	4621 km^2
Materials properties and boundary conditions (BC)	
Hydraulic conductivity K_X, K_Y, K_Z	4.5 × 10^{-4} m/s, 4.5 × 10^{-4} m/s, 1.5 × 10^{-4} m/s
Specific storage (fluid flux)	.002
Total porosity	.35
Longitude dispersivity	1
Transverse dispersivity	0.1 m
Density ratio	1025 kg/m^3
Constant head	0 m
Recharge concentration	0 mg/L
Constant head concentration	35000 mg/L
Initial concentration	20.22
Initial head	1.011 m

The model is calibrated by changing the aquifer properties and the boundary conditions in order to obtain a model appropriate to simulate the groundwater flow and the mass concentration distribution, within the calibration target. In the calibration process, a trial and error technique is carried out in order to reduce the variance between the simulated and the measured values. Once the model is calibrated; it is run to verify various scenarios as shown in *Table 5* where the extrapolative simulations are performed to minimize saltwater intrusion in the unconfined aquifer.

Table 5. *Three scenarios used for model simulation*

Simulation	Description
Scenario A	Abstraction of saline water 1000 m^3/day
Scenario B	Recharge of treated water at the rate of 500 m^3/day
Scenario C	Abstraction of saline water 1000 m^3/day, desalination and recharge of treated water at the rate of 500 m^3/day

Results

Laboratory measurements

The water quality characteristics of the groundwater samples during the year 2014 and 2018 are determined and the values are given in *Tables 6* and *7*.

SO_4	mg/L	200	400	2	5
Na	mg/L	-	200	15	16
Ca	mg/L	75	200	3	1
Mg	mg/L	30	150	1	3
K	mg/L	-	10	20	16
TH	mg/L	300	600	5	8

pH

A pH value 7 indicates neutral. If the value is lower than 7 it indicates acidity and higher than 7 indicates alkalinity. The values of pH ranges from 7.5 to 8.8 and 7.4 to 8.8 during 2014 and 2018 which specifies that the groundwater is alkaline in both 2014 and 2018 and some of the samples exceed the maximum permissible limits of WHO standards. The slight alkalinity is due to the existence of bicarbonate ions, which are formed by the free combination of CO_2 in water with the carbonates from the aquatic life, which affects the pH of the water (Azeez et al., 2000). The spatial distribution of pH is shown in *Figure 4* indicates all the samples are within the permissible limit of 6.5-8.5., except two samples in 2014 and six samples in 2018.

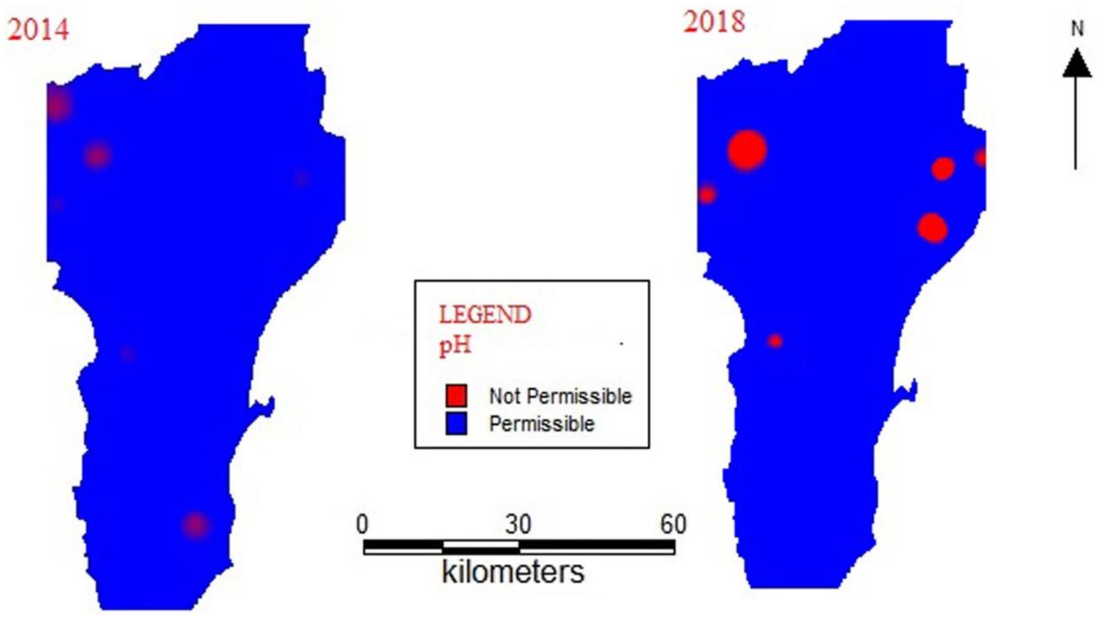

Figure 4. *Spatial distribution of pH*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

Electrical conductivity

Electrical conductivity is the most significant parameter to delineate salinity hazard and suitability of water for irrigation purpose. The EC vary from 250 to 4180 µs/cm and from 120 to 9310 µs/cm during the years 2014 and 2018, respectively. The spatial distribution of EC is shown in *Figure 5*. Higher value of EC were noted during 2018 when compared to that of 2014. The classification of water salinity based upon Electrical conductivity shows that 45% in 2014 and 50% in 2018 falls within the permissible limit. To determine the salinity of groundwater, it is important to categorize the groundwater based on their EC values (Handa, 1969), which are represented in *Table 10*.

Table 10. *Classification of waters based on EC (Handa, 1969)*

EC (µs/cm)	Water salinity	2014		2018	
		Number of samples	Percentage of samples	Number of samples	Percentage of samples
0–250	Low	1	3	3	8
251–750	Medium	9	24	6	16
751–2250	High	17	45	19	50
2251–6000	Very high	11	20	8	21
6001–10000	Extremely high	-	-	2	5
10001–20000	Brines weakly concentrated	-	-	-	-
20001–50000	Brines moderately concentrated	-	-	-	-
50001–100000	Brines highly concentrated	-	-	-	-
>100000	Brines extremely highly concentrated	-	-	-	-
Total		38	100	38	100

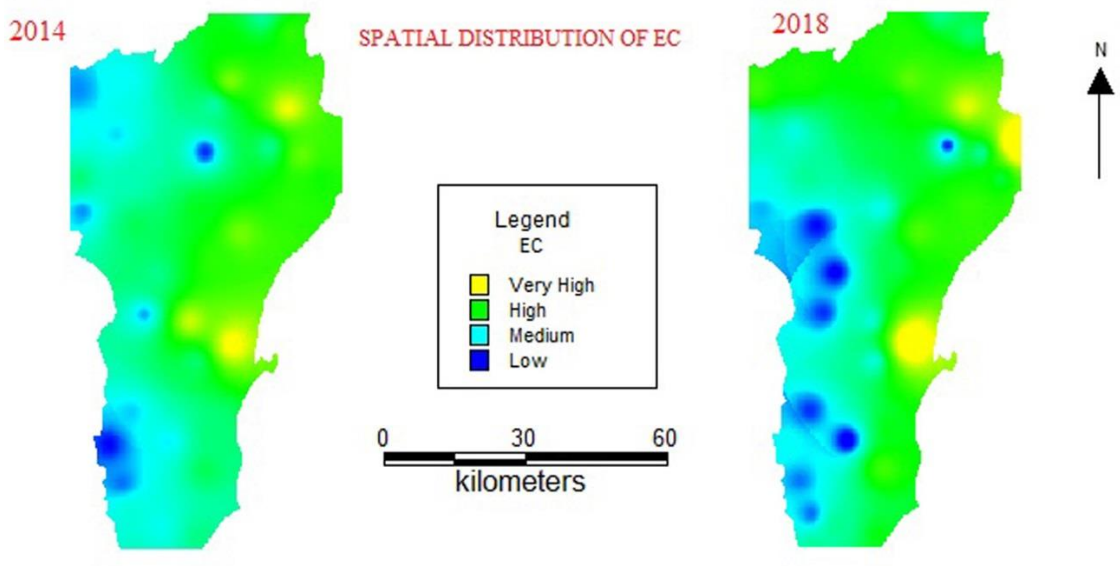

Figure 5. *Spatial distribution of EC*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

Total dissolved solids

TDS of the groundwater are found to vary from 145 to 2503 mg/L during 2014 and 73 to 5581 mg/L during 2018. The Spatial Distribution of TDS is shown in *Figure 6*. Some groundwater samples having high value of TDS are may be due to presence of excess salts in the soil and also by manmade activities. Sewage waste from household may penetrate into the groundwater which also leads to raise in TDS values. To ascertain the groundwater, it is essential to categorize the groundwater based on their TDS values, which are presented in *Tables 11* and *12,* respectively.

Table 11. *Classification of groundwater based on TDS (Davis, 1966)*

Total dissolved solids (mg/L)	Classification	2014		2018	
		Number of samples	Percentage of samples	Number of samples	Percentage of samples
<500	Desirable for drinking	12	32	11	32
500–1000	Permissible for drinking	10	26	10	26
1000–3000	Useful for irrigation	16	42	14	37
>3000	Unfit for drinking and irrigation	0	-	3	8
Total		38	100	38	100

Table 12. *Classification of groundwater based on TDS (Freeze and Cherry, 1979)*

Total dissolved solids (mg/L)	Classification	2014		2018	
		Number of samples	Percentage of samples	Number of samples	Percentage of samples
<1000	Freshwater	16	42	15	39
1000–10000	Brackish water	22	58	23	61
10000–100000	Saline water	-	-	-	-
>100000	Brine water	-	-	-	-
Total		38	100	38	100

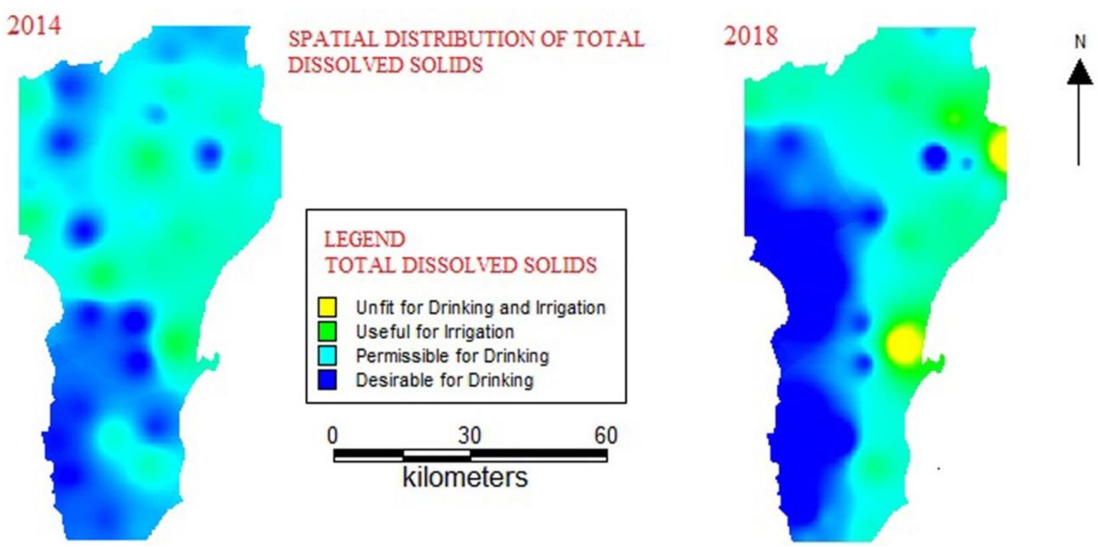

Figure 6. *Spatial distribution of TDS*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

Total hardness

Total hardness is found to vary from 95 to 1320 mg/L with a mean value of 401.71 mg/L during 2014 and 40 to 2120 mg/L during 2018. According to WHO, the allowable limit of TH for drinking is 600 mg/L and the desirable limit is 300 mg/L. The Spatial Distribution of TH is as shown in *Figure 7*. The Total Hardness of the groundwater sample in the study area fell in the hard and very hard water category. Total Hardness means both temporary and permanent hardness. Hardness is a significant parameter in determining the need for industries and domestic purposes. Hard water does not produce much bad effect but it requires more detergent for cleaning and in some cases very hard water might be the reason for heart disease (Schoeller, 1965). The TH in mg/L is determined by *Equation 5* (Todd, 1959):

$$TH\,(mg\,/\,L) = 2:497Ca2^{+} + 4:115Mg2^{+} \quad \text{(Eq.5)}$$

Based on hardness groundwater is classified (Sawyer and McCarthy, 1967) and is presented in *Table 13*. In the study area, 22 samples were found in very hard class in 2014, whereas in 2018, 19 samples were found in very hard class. This reveals that Tuticorin experiences very hard water during both the years. High levels of hardness may affect water supply system, excessive detergent consumption and also health problem (Bhawan and Nagar, 2008).

Table 13. *Classification based on hardness (Sawyer and McCarthy, 1967)*

Total hardness as CaCo3 (mg/L)	Classification	2014		2018	
		Number of samples	Percentage of samples	Number of samples	Percentage of samples
<75	Soft	0	0	1	3
75–150	Moderately high	3	8	8	21
150–300	Hard	12	32	9	24
>300	Very Hard	22	58	19	50
Total		38	100	38	100

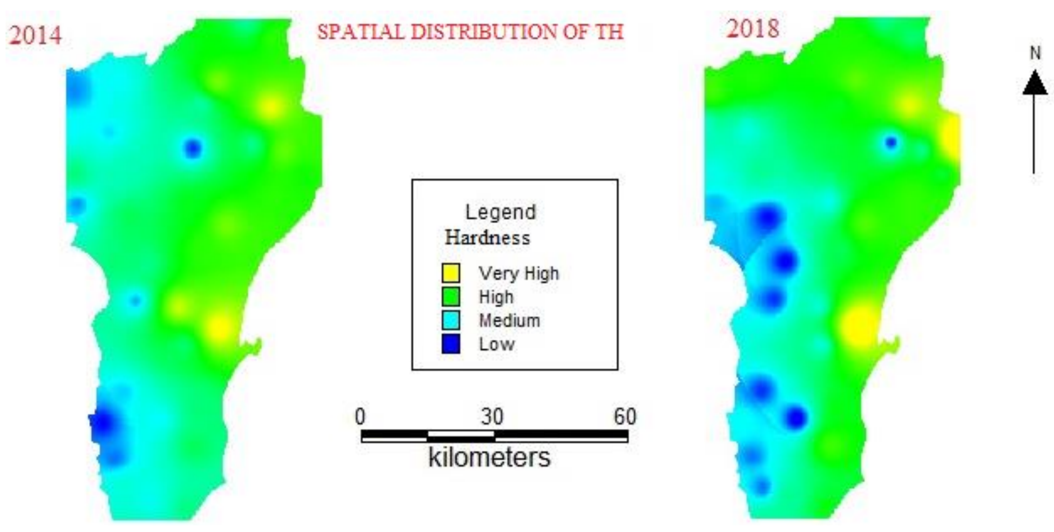

Figure 7. *Spatial distribution of TH*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

Calcium

Calcium concentration is found to vary between 8-360 mg/L with a mean value of 74.53 mg/L for 2014 water samples and 8-272 mg/L with a mean value of 64.79 mg/L for 2018 samples. The allowable limit of calcium in groundwater is 200 mg/L as per WHO (2017). The Spatial Distribution of Calcium is shown in *Figure 8*. In 2014, 92% and in 2018, 97% of samples are up to the standard and only 8% samples exceed the permissible limit in 2014 and 3% samples exceed the permissible limit.

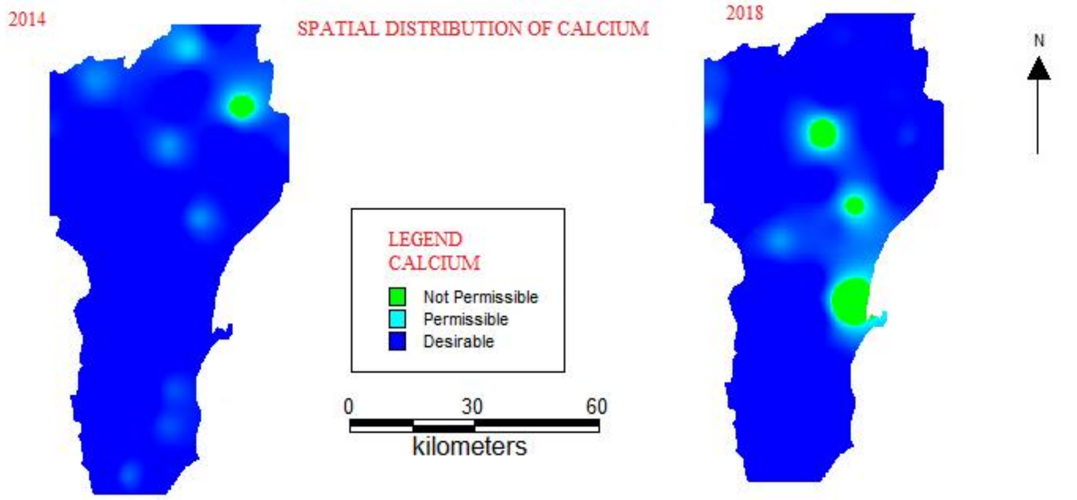

Figure 8. *Spatial distribution of calcium*

Magnesium

Magnesium vary from 10 to 175 mg/L with a mean value of 52.34 mg/L during the year 2014 and 5 to 493 mg/L with a mean value of 62.32 mg/L during the year 2018. The maximum allowable limit of magnesium in groundwater is 150 mg/L as per WHO (2017). The Spatial Distribution of Magnesium is shown in *Figure 9*. In 2014, only 3% of sample exceeds the permissible limit while in 2018 the 3% increased to 8% which revealed changes in water quality.

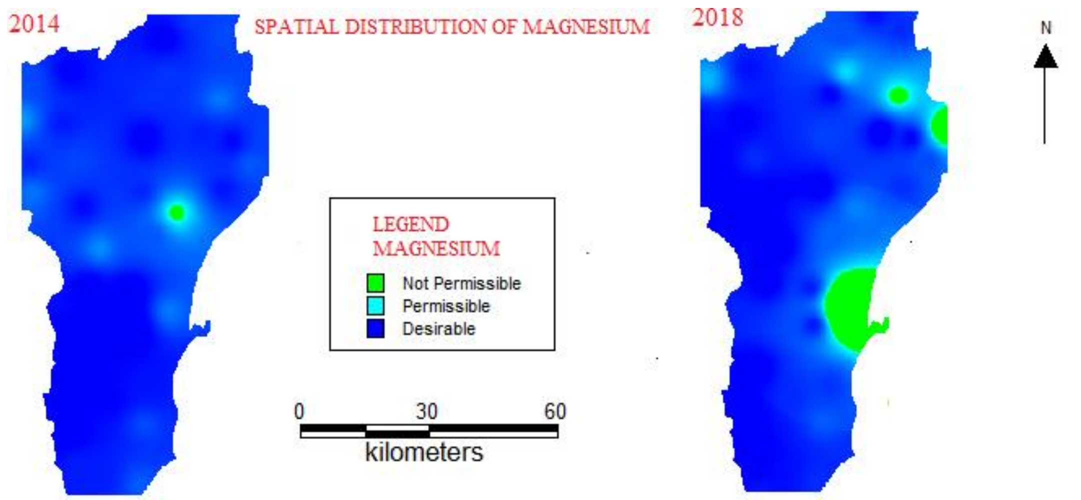

Figure 9. *Spatial distribution of magnesium*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

Sodium

Sodium is found to vary from 10 to 552 mg/L with a mean value of 196.18 mg/L during the year 2014 and 7 to 1610 mg/L with a mean value of 265.55 mg/L during the year 2018. Sodium causes an increase in the hardness of soil as well as decrease its permeability (Tijani, 1994). The spatial distribution of sodium is shown in *Figure 10*. In 2014 and 2018 the high concentration of sodium is observed which may be due to saltwater intrusion.

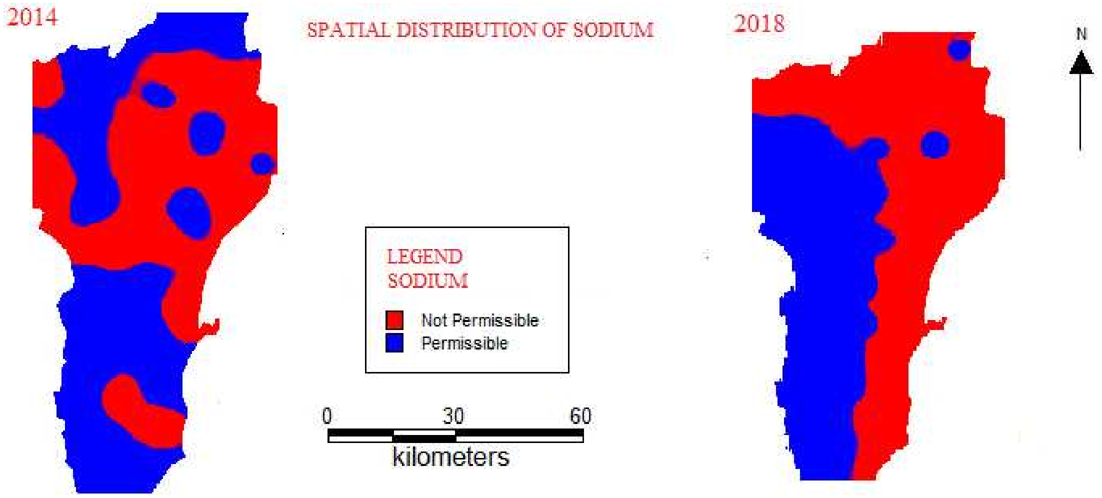

Figure 10. *Spatial distribution of sodium*

Potassium

Potassium ranges vary from 5 to 121 mg/L with a mean value of 24.84 mg/L during the year 2014 and 1 to 63 mg/L with a mean value of 14.71 mg/L during the year 2018. As per WHO (2017) standards, the allowable limit for potassium is 10 mg/L. The Spatial Distribution of Potassium is shown in *Figure 11*. Due to Salt pans, chemical fertilizer industries potassium concentration may be increased in the groundwater.

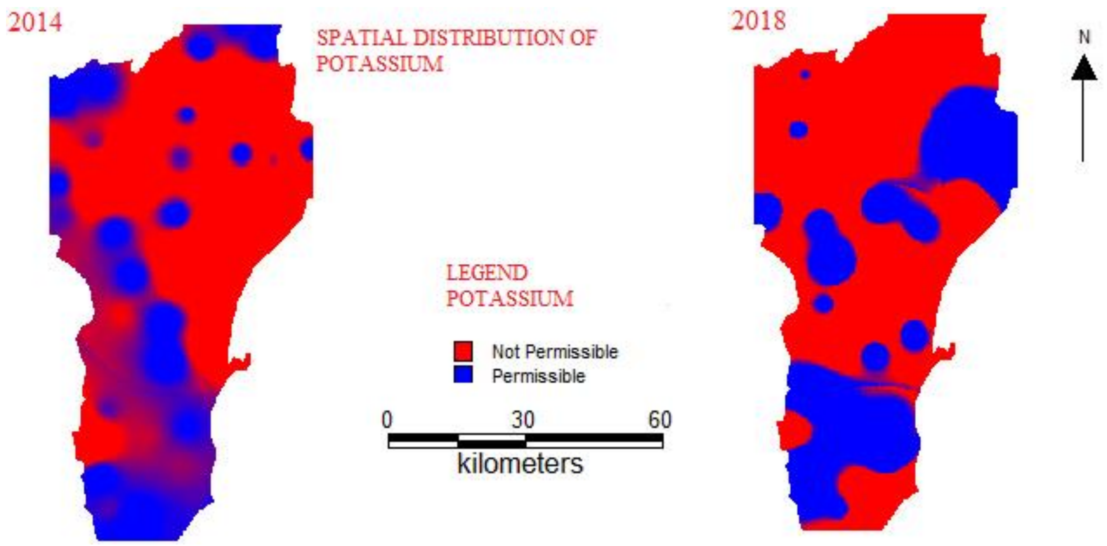

Figure 11. *Spatial distribution of potassium*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

Bicarbonate

Bicarbonate ranges from 54 to 702 mg/l with a mean value of 311.63 mg/L during the year 2014 and 35 to 732 mg/L with a mean value of 378.93 mg/L during the year 2018. Bicarbonate concentrations are somewhat higher in the year 2018 compared to the year 2014 indicating the influence of carbonate due to weathering processes. There is a major variation observed in the spatial distribution of bicarbonate as shown in *Figure 12* which may be due to saltwater intrusion (Selvam et al., 2013; Srinivasamoorthy et al., 2011).

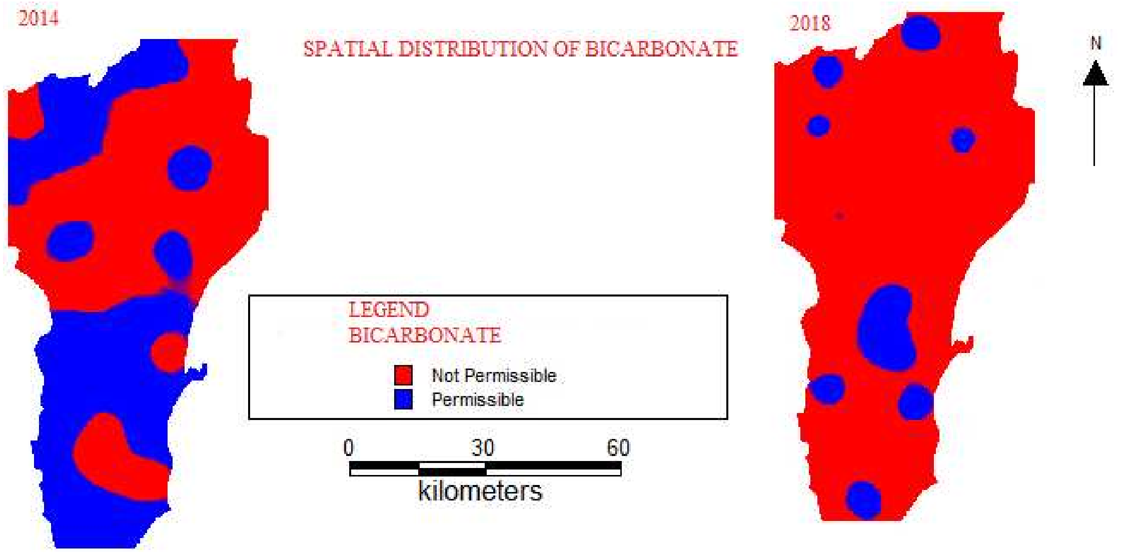

Figure 12. *Spatial distribution of bicarbonate*

Chloride

Chloride ranges from 7 to 865 mg/L with a mean value of 253.03 mg/L during the year 2014 and 7 to 1914 mg/L with a mean value of 328.34 mg/L during the year 2018. The allowable limit of Chloride is 600 mg/L. In Tuticorin 11% of sample exceed the permissible limit of chloride concentration in 2014. But in 2018 the percentage increases to 13%. Thus, high concentration of sodium and Chloride ions in groundwater may show a substantial effect of saltwater intrusion (Mondal et al., 2010). The Spatial Distribution of Chloride is shown in *Figure 13*. Higher concentration is noted during 2018 when compared with 2014 indicating domination of industrial activity and saltwater intrusion to the groundwater. High concentration of Chloride may be harmful to persons suffering from sicknesses of the heart and kidneys (Bhawan and Nagar, 2008).

Sulphate

Sulphate concentration vary from 10 to 624 mg/L with a mean value of 145.63 mg/L during the year 2014 and 6 to 1440 mg/L with a mean value of 194.08 mg/L during the year 2018. If the sulphate concentration exceeds allowable limit of 400 mg/L it will affect human organs. The sorting of groundwater based on sulphate is specified in *Table 2* and it is found that 5% of samples exceeded permissible limits during the year

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

2014 and 13% of samples are found to be exceeded the limits during the year 2018. Sulphate concentration in groundwater increases due to dissolution minerals and anthropogenic sources. The Spatial Distribution of Sulphate is shown in *Figure 14*.

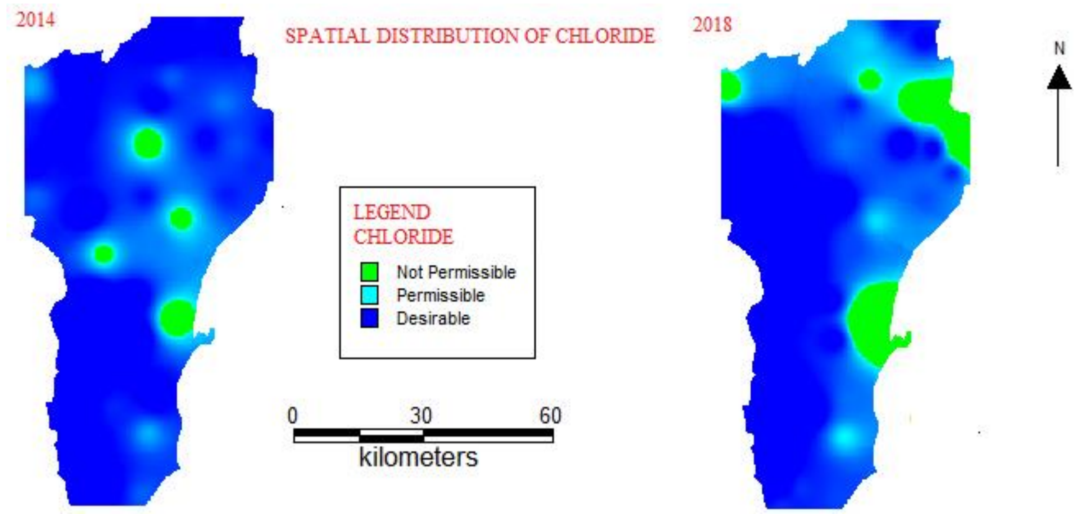

Figure 13. *Spatial distribution of chloride*

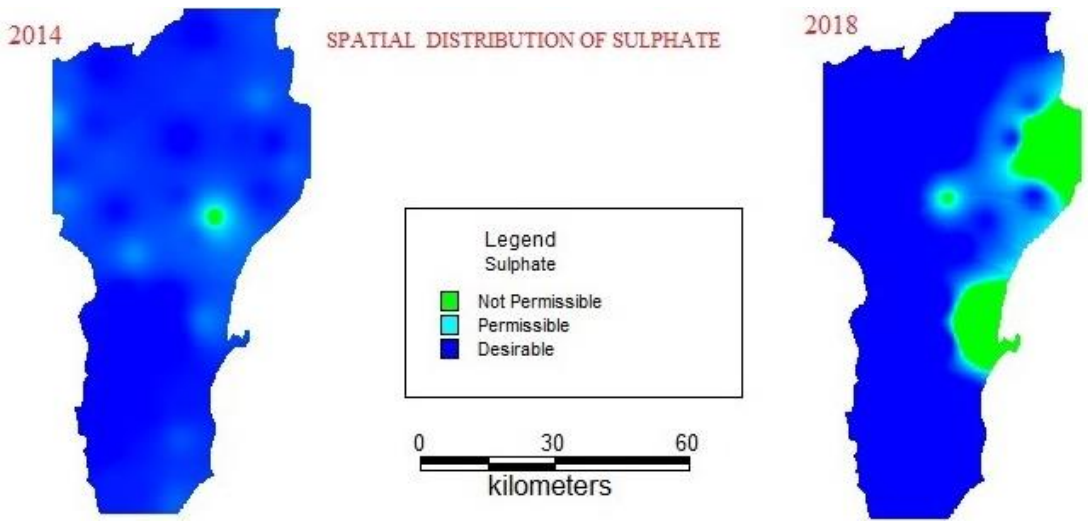

Figure 14. *Spatial distribution of sulphate*

Nitrate

Nitrate concentration vary from 1 to 73 mg/L with a mean value of 45.55 mg/L during the year 2014 and 1 to 55 mg/L with a mean value of 43.55 mg/L during the year 2018 allowable nitrate in drinking water as per WHO standards are 45 mg/L. The spatial distribution of nitrate is shown in *Figure 15*.

Fluoride

Fluoride concentration varies from 0 to 2 mg/L with a mean value of 0.64 mg/L during the year 2014 and 0 to 1 mg/L with a mean value of 0.46 mg/L during the year

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

2018. Allowable fluorides in drinking water as per WHO standards are 1.5 mg/L. Concentrations higher than allowable limit create many health problems (WHO, 2017). The spatial distribution of fluoride is shown in *Figure 16*.

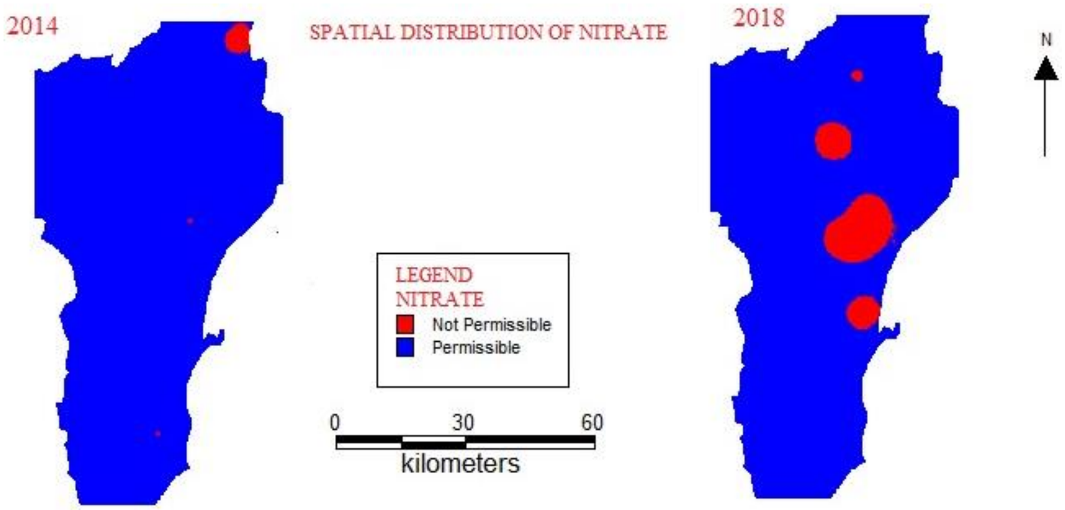

Figure 15. *Spatial distribution of nitrate*

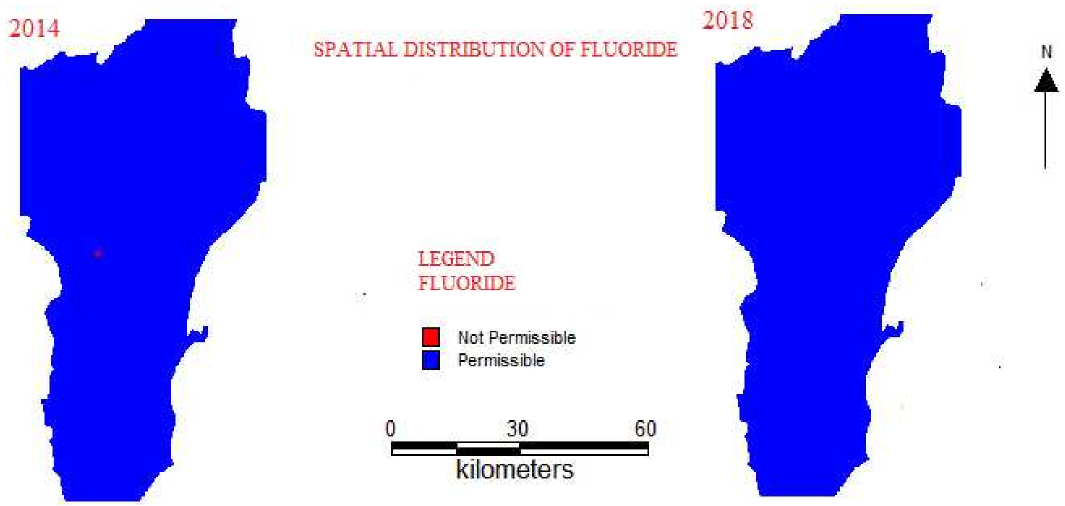

Figure 16. *Spatial distribution of fluoride*

According to salt concentration cations are characterized in ascending order as follows $Na^+ > K^+ > Mg^{2+} > Ca^{2+}$. From the above sorting it is clearly understood that Sodium and potassium concentration is prominent than the magnesium and calcium.

According to salt concentration anion are characterized in ascending order as follows $HCO^{3-} > Cl^- > SO_4^{2-} > F$. From the above sorting, Cl and HCO_3 showed a prominent role in Tuticorin than the concentrations of NO_3 and F.

Piper plot

Statistical diagram such as Piper plot is used to understand about hydro chemical processes functioning in the groundwater. The Piper diagram is used to recognize

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

problems concerning the hydrogeochemical development of groundwater. The piper plot has three portions like two triangular portion and a diamond-shaped portion (Piper, 1944). The overall water quality is represented in the diamond-shaped field by extending the position of the plots in the triangular portion. Groundwater can be notable by their location, occupying certain spaces of the diamond-shaped portion. The experimental data obtained from the groundwater samples are plotted on a Piper trilinear diagram to understand the hydrogeochemical pattern in Tuticorin during the years 2014 and 2018.

The geochemical characteristics can be studied using Piper plot, which is separated into six sub groups (1) (Ca-HCO3 type); (2) (Na-Cl type); (3) (mixed Ca-Na-HCO3 type); (4) (mixed Ca-Mg-Cl type); (5) (Ca-Cl type) and (6) (Na-HCO3 type). The diagram *Figure 17* exposed that the samples during 2014 found in the group of Na-Cl and mixed Ca-Mg-Cl type. But during 2018, Ca-HCO3 type of water prevails in Tuticorin. Ca-Mg-Cl type of water falls under both years. It is detected that the alkalis (Na^+ and K^+) exceed the alkaline (Ca^{2+} and Mg^{2+}) and strong acids exceed weak acids. During 2014 and 2018, strong acid dominant over weak acid and HCO^{3-} and Cl^- have influence equal to Na^+, which indicates the severe saltwater intrusion occurred in Tuticorin.

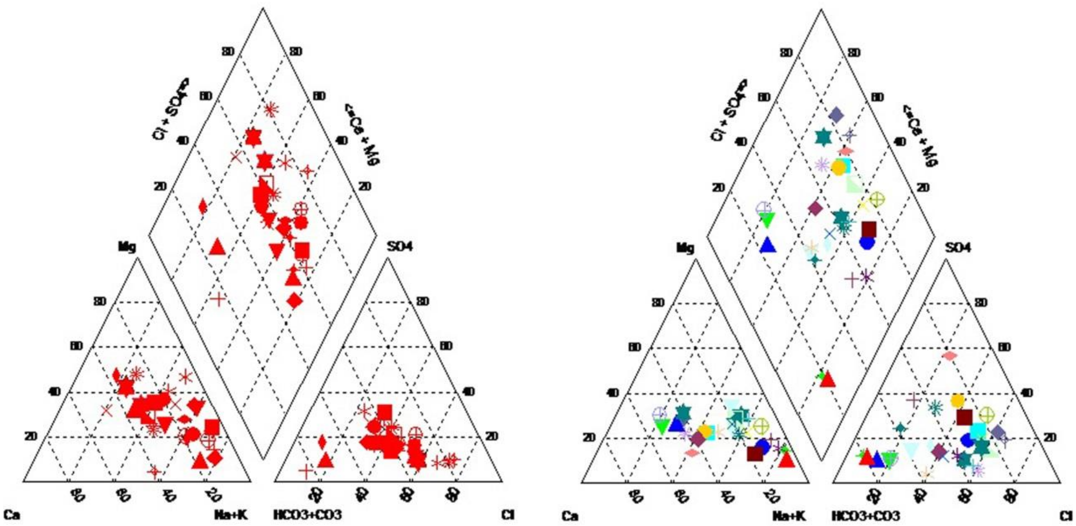

Figure 17. *Piper plot during the years 2014 and 2018*

Water quality index

The WQI for groundwater samples is exposed in *Tables 6* and *7*. Water collected from 38 observation wells are analysed for WQI. From the WQI value, it is found that villages like Keelairal, Kulathurterkku, Ottapidaram, Padanthapuli, Puthiyamputhur, Vilathikulam, Singathakuruchi, Vedanatham, Kachanavilai, Palangulam, Ariyanayagipuram, Srivaikundam, Thirukalur have showed improved water quality in 2018 compared with 2014. Water quality improvement may be due to the less withdrawal fresh groundwater and the rehabilitation of tanks. These villages located in the Taluk of Vilathikulam, Kovilpatti, Satankulam, Ettayapuram, Ottapidaram and Srivaikundam. The sample collected in villages present in Tuticorin Taluk like Melathattaparai, Marthadampatti have showed severe water quality deterioration

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

occurred from 2014 to 2018. Since the fresh groundwater extraction is more in Tuticorin due to industries saltwater intrusion occurs in the coastal aquifer. It is clearly portrayed from WQI method that the saltwater intrusion mainly in the coastal belt of Tuticorin and moves inward.

The spatial and attribute data are integrated for the creation of the spatial WQI map. The WQI Maps for the year 2014 and 2018 are depicted in *Figure 18*.

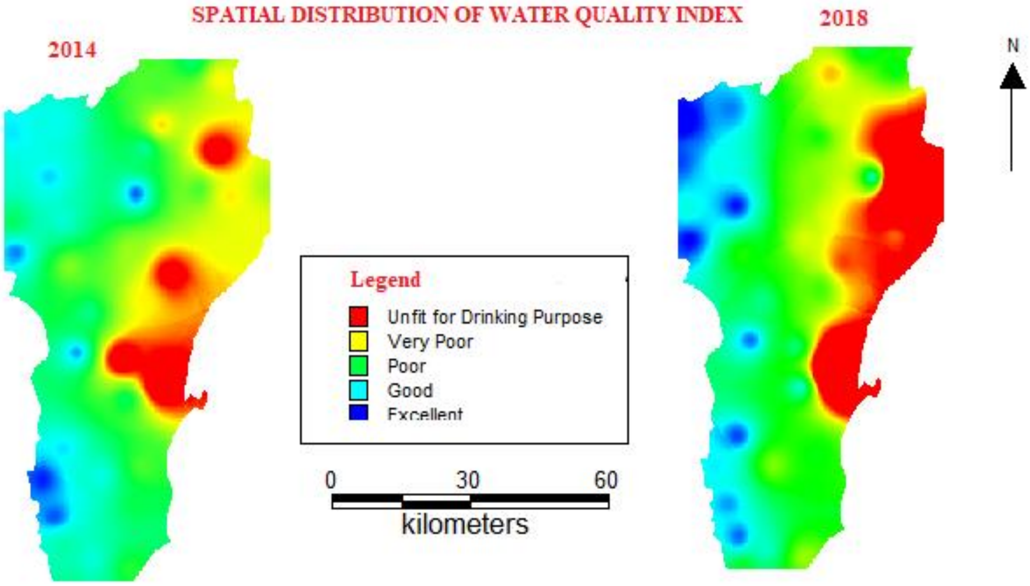

Figure 18. *Water quality index map for the year 2014 and 2018*

Comparison of WQI with the distance from sea

The computed WQI with respect to the distance of observation well from the sea is shown in *Figure 19*. From the figure it can be seen that water quality is poor in the observation wells found with in 15 km from sea shore during the year 2018 where as in 2014, observation wells found within 9 km are only affected. Similarly, in 2018 observation wells found with in 7 km is unfit for drinking. Hence the saltwater intrusion has moved inward from the seashore to the distance of 15 km during 2018.

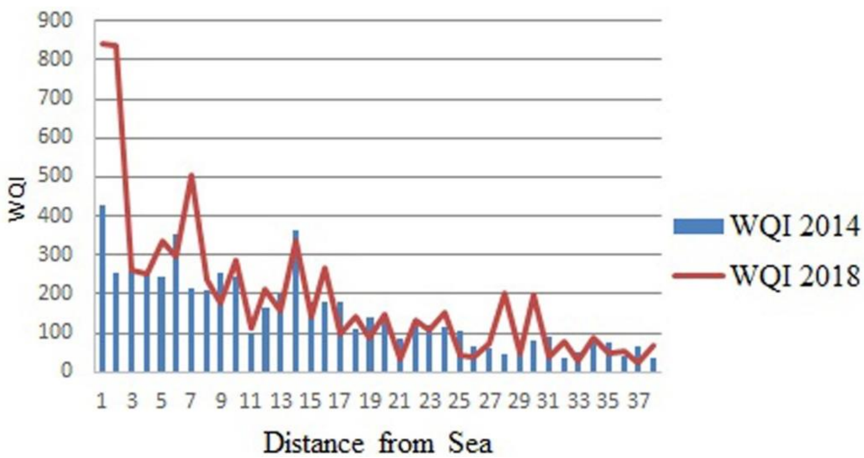

Figure 19. *WQI with respect to the distance from sea*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

Model calibration

The model is calibrated for steady state and then for transient state. In a steady state calibration hydraulic conductivity and the recharge concentration are adjusted until hydraulic head measured using piezometer in 15 observation wells in April 2018 become close to the computed hydraulic heads. The calibrated results are depicted in *Figure 20*. Good match is found between observed and computed hydraulic head. For transient state calibration longitudinal and transverse dispersivity are changed to match observed salt concentration with computed salt concentration. Final calibrated value of longitude dispersivity is 30 m and transverse dispersivity is 4 m.

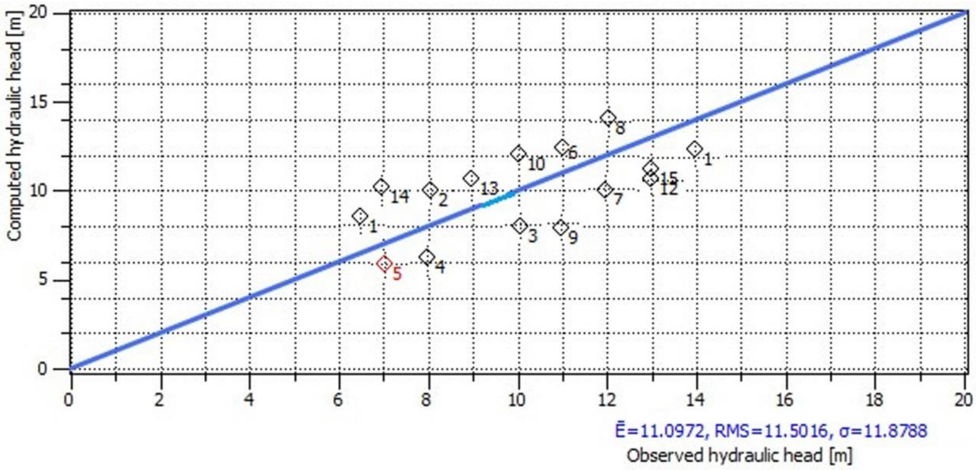

Figure 20. *Comparison of measured and computed hydraulic head*

Model verification

The Model developed is validated during the years 2000 to 2018 for the well located in Tuticorin by using data of salt concentration obtained from State Ground and Surface Water Resources Data Centre, Tamilnadu, India. A good match is found between the observed and simulated salt concentration in Tuticorin as shown in *Figure 21*.

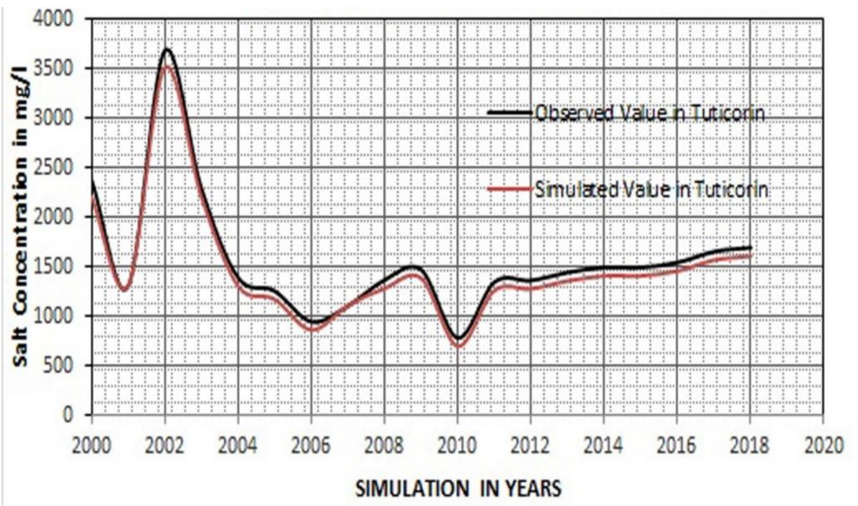

Figure 21. *Model verification for the well in Tuticorin*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

Model simulation

The effect of Scenario A (Abstraction) Abstraction of saline groundwater using 15 pumping wells at a withdrawal rate of 1000 m^3/day per well at a short distance of 1500 m from the shoreline is showed a significant change in salt concentration in Tuticorin as shown in *Figure 22*.

The effect of Scenario A (Abstraction) Abstraction of saline groundwater using 15 pumping wells at a withdrawal rate of 1000 m^3/day per well at a short distance of 1500 m from the shoreline is showed a significant change in salt concentration in Tuticorin as shown in *Figure 22*. Simulated results of Scenario A (Abstraction) in the well in Tuticorin showed a decrease in groundwater salt concentration from 1600 mg/L in the year 2019 to 900 mg/L in the year 2030.

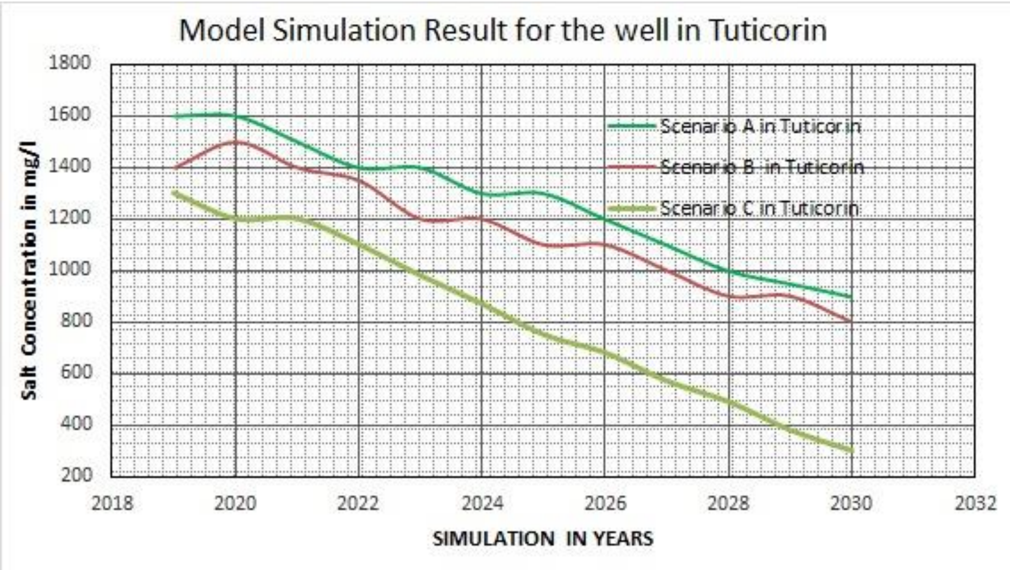

Figure 22. *Simulation result for the well in Tuticorin*

The Scenario B is the recharge of aquifer with treated saline water at the rate of 500 m^3/day, showed to have significant impact than the pumping Scenario A as depicted in *Figure 22*. Simulated results of Scenario B (Recharge) in the well in Tuticorin exhibited a decrease in groundwater salt concentration from 1400 mg/L in the year 2019 to 800 mg/L in the year 2030.

But in Scenario C abstracting saline groundwater 1000 m^3/day and recharge treated water at the rate of 500 m^3/day showed good control over the salt water intrusion in Tuticorin as revealed in *Figure 22*. Simulated results of Scenario C (ADR) in the well in Tuticorin exposed a steady decline in groundwater salt concentration from 1300 mg/L in the year 2019 to 300 mg/l in the year 2030.

From the simulation result it is understood that ADR method is good to control water quality in the well from saltwater intrusion.

Discussion

From the Spatial analysis of water quality parameters, WQI method, Piper plot diagram, it is understood that the severe saltwater intrusion is occurred in Tuticorin. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_25932617

current pumping rate would further decline the water quality and can lead to the destruction of groundwater resources.

An attempt is made in the study to determine the distance of seawater intrusion based on WQI. The analysis results give better knowledge of zone of dispersion. Water Quality became very poor in the observation wells found with in 15 km from sea shore in 2018. Hence the saltwater intrusion has moved inward from the seashore to a distance of 15 km. Pumping saline water from the zone of dispersion can reduce saltwater intrusion.

Several studies like Selvam et al. (2013) analysed the water quality parameter but the control measures not provided. In this research groundwater model is developed and three scenarios were applied to find the best method to minimise the seawater intrusion. The simulation results showed that ADR method is good to control from saltwater intrusion.

From the study, it is clearly depicted 15 pumping wells at a withdrawal rate of 1000 m^3/day per well at a short distance of 1500 m from the shoreline and Recharge treated water at the rate of 500 m^3/day required for the reduction, or displacement of the saline water towards the coast to eventually maintain or push the dispersion zone towards the coast is very important.

Conclusions

The effect of saltwater intrusion in coastal aquifer necessitates systematic investigation, especially when the extraction of groundwater in the coastal aquifer increases. The spatial analysis of groundwater using GIS, Water Quality Indices method, Piper plot diagram shows that the coastal aquifer is severely affected by saltwater intrusion. Potential intrusion of saltwater is studied with respect to distance of observation wells from seashore. In 2018 water quality in the observation wells located with in 15 km from the Seashore is very much affected. Three different simulation scenarios namely Abstraction, Recharge and a combination of system were applied to the observation well located in Tuticorin to reduce the seawater intrusion. FEFLOW model was used to evaluate these methods adopted to reduce seawater intrusion. The simulation results of FEFLOW show that the method ADR performs better than using abstraction or recharge wells. Integrating field study with developed model to determine the site selection of recharge well is a possibility for future work.

Abstract. Several investigations have demonstrated the advantageous role that plants have in the phytoremediation of soils and waters contaminated by heavy metals. Therefore, under the present investigation, *Chrysopogon zizanioides* and *Typha latifolia* plants were tested for their effectiveness in absorbing 17 heavy metals (Al, B, Ba, Be, Co, Cr, Cu, Fe, Mg, Mn, Ni, Pb, S, Se, Tl, V and Zn) coming directly from a landfill leachate. The translocation factor was quantified in both species, where *T. latifolia* recorded a FT >1 % of the metals V, Ni, Mn and B. While in *C. zizanioides*, the metals Tl, Se, Co and B obtained a FT >1 %. In general, extraction was achieved without noticeable toxicity despite the excessive level of metals. These results demonstrate the suitability of these hyperaccumulator plants and establish them as a comfortable and inexpensive alternative to reduce water and soil pollution problems.
Keywords: *leachate, plants, translocation factor, extraction, hyperaccumulator, pollution*

Introduction

The continuous industrial and commercial growth in many countries around the world, in the last decade have been accompanied by a rapid increase in the production of both municipal and industrial solid waste (Renou et al., 2008), encouraging the search for alternative methods for the final disposal or confinement of waste (Białowiec, 2011), with the sanitary landfill being one such large-scale method, especially for municipal solid waste (Del Moro et al., 2014; Koda et al., 2016; Wong et al., 2015; Remmas et al., 2017) and urban solid waste (Renou et al., 2008).

Landfilling involves particular methods and engineering works that control leachate leakage (SEMARNAT, 2012). Leachate is defined as the aqueous effluent generated as a result of the filtration of rainwater through the wastes and the inherent water content of the wastes themselves deposited in landfills (Renou et al., 2008; Zapata and Zapata, 2013). They are generally high in contaminants (Roongtanakiat et al., 2003), especially heavy metals and organic and inorganic matter (Bulc, 2006) that can contaminate groundwater and surface water in the area near the landfill (Khattabi and Aleya, 2007; Öman and Junestedt, 2008).

The effects on human health and ecosystems associated with heavy metal pollution (Vaverková et al., 2018) become even more worrying given their tendency to accumulate and magnify along trophic levels (Anning and Akoto, 2018). For example, due to their bioaccumulation they can have toxic effects on living organisms when they exceed a certain concentration (Nriagu et al., 1991; Gusiatin et al., 2013; Mahmoud et al., 2014; Sas et al., 2015), representing a risk to human health when transferred thought the food chain (Kelly et al., 1996; Mazur et al., 2013; Radziemska et al., 2013; Mahmoud et al., 2014; Roy and McDonald, 2015).

Faced with this problem, phytoremediation is an energy-efficient, cost-effective and aesthetically pleasing alternative to remediation sites with low to moderate levels of pollution (Mojiri et al., 2015). It is a set of technologies that reduce in situ or ex situ the concentration of various compounds from biochemical processes carried out by plants and associated microorganisms (Kelley et al., 2001; Cherian and Oliveira, 2005; Eapen et al., 2007; Cho et al., 2008). Some of the plants widely used in phytoremediation are *Chrysopogon zizanioides* and *Typha latifolia*, both of which are widely distributed around the world.

Chrysopogon zizanioides, commonly known as vetiver, is a perennial herb of the Poaceae family, originally from India (Truong et al., 2009). It has a high tolerance to elevated concentrations of heavy metals such as As, Cd, Cu, Cr, Pb, Hg, Ni, Se and Zn, showing its unique physiological characteristics (Truong, 2002; Chomchalow, 2003; Shu, 2003; Danh et al., 2009; Truong et al., 2010; Vargas et al., 2016). *C. zizanioides* is considered efficient in purifying leachate from a landfill (Xia et al., 2000). In terms of its morphological characteristics, vetiver has a complex root system that can grow between 3 to 4 m per year, so the root can penetrate much deeper into the soil and water. This massive root system can reduce and prohibit deep drainage, improve soil stability and nutrient uptake (Danh et al., 2009; Truong, 2000).

Regarding *Typha latifolia* (common cattail) of the Typhaceae family, it is an aquatic, rooted, perennial herbaceous plant that grows extensively in tropical and warm regions, measuring 1.6 to 2.2 m high (Ye et al., 1997; Bonilla and Arauz, 2012). This species is expansive and widespread both in shallow lowland waters and in lower mountainous regions (Klink et al., 2013). It is characterized by high biomass production and a high rate of decomposition (Podbielkowski and Tomaszewicz, 1982). *T. latifolia* is used in phytoremediation because of its ability to remove heavy metals from impacted sites and accumulate them mainly in its roots (Hernández et al., 2014) which has suggested that root tissue cells can tolerate high concentrations of metals (Carranza-Álvarez et al., 2008; Alonso-Castro et al., 2009; Leura-Vicencio et al., 2013).

In the present study, the phytoremediation capacity of *Chryzopogon zizanioides* and *Typha latifolia* in leachate from a municipal landfill was evaluated, determining the concentration of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26192630

heavy metals, Aluminum (Al), Boron (B), Barium (Ba), Beryllium (Be), Cobalt (Co), Chromium (Cr), Copper (Cu), Iron (Fe), Magnesium (Mg), Manganese (Mn), Nickel (Ni), Lead (Pb), Selenium (Se), Thallium (Tl), Vanadium (V) and Zinc (Zn), by optical emission spectrometry with inductively coupled plasma (ICP-OES), and the translocation factor was calculated. The objective of the present study is to identify and measure the metals present in the heterogeneous mixture of the landfill leachate and to compare an introduced species that is *C. zizanioides* with *T. latifolia* native to Mexico. The originality of this work is centred on the type of contaminant in which the leachates are being used because most of the research focuses on a single metal or some metals in laboratory conditions without exploring how these metals would behave when they are in such a complex mixture as leachates without mentioning some other variants such as the type of soil being used. It is a pioneering work because the company opens the way for us to do research on these and other species found in the landfill.

Materials and methods

Samples

Collection of plants by simple random sampling of soil (contaminated and uncontaminated) as well as leachate was carried out at the sanitary landfill located in Leon, Guanajuato, Mexico (21°10’30.12” N, 101°46’29.25”). According to INEGI, 43% of the region’s surface is represented by dry and semi-dry climate, mainly in the northern region; 33% of the surface, towards the southwest and east, is sub-humid warm climate and the remaining 24% has sub-humid temperate climate. The average annual temperature is 18 °C. The rains are presented in summer, mainly in the months of June to September, the average precipitation of the state is approximately 650 mm annually. The collection of samples was during the month of October, in the dry period. The contaminated plants were taken from the landfill cells where they are irrigated with leachate that results from the decomposition of the deposited waste. The control plants were collected from the nursery located in the landfill facilities. At the collection points, 1 kg of rhizospheric soil and 300 mL of leachate from the leachate lagoon were also collected. They were stored at 4 °C until analysis.

Analysis of samples

The plants were washed and dried at room temperature. The shoots were separated from the roots, then cut and crushed in a mortar to obtain a particle size less than 2.0 mm (Farago et al., 1998). Subsequently, they were digested with 7 mL of HNO_3 and 3 mL of tridestilled H_2O. On the other hand, soil samples were placed under shade to remove excess water, ground in a mortar and sieved using stainless steel meshes of 9.51 mm and 2 mm in diameter. They were digested in tridestilled H_2O and 500 mL HNO_3 (1:1, v/v). Leachate was filtered using a 0.45 m filter (Farago et al., 1998) to remove particles that may interfere with the analyses. They were then digested with tridestilled H_2O and HNO_3, and a final volume of 25 mL with tridestilled H_2O was measured.

All previously digested samples were analyzed by means of an optical emission spectrometer with inductively coupled plasma (IRIS Advantage, Thermo Jarrell Ash Co.), with the software. A multi-element calibration curve was used including 16 chemical elements: Al, B, Ba, Be, Co, Cr, Cu, Fe, Mg, Mn, Ni, Pb, Se, Tl, V, Zn, prepared from a commercial standard Sigma Aldrich solution.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26192630

Three repetitions per sample were made for the analysis of metals in plants, soils and leachate.

Translocation factor

The translocation factor (TF) is an indication whether or not a plant can be considered as a hyperaccumulator of chemical elements, it was determined based on the concentrations of metals in plants, soils and leachate, as well as their respective controls, according to the following formula (Mendieta and Taisigue, 2014) as shown in *Equation 1:*

$$\text{Translocation factor} = \frac{\text{Concentration of metals in shoots}}{\text{Concentration of metals in roots}} \qquad \text{(Eq.1)}$$

Statiscal analysis

An analysis of variance (ANOVA) was made using the statistical program SPSS 12 for Windows, used to discriminate between the means the procedure of Honestly Significant Difference (HSD) of Tukey, with a level of significance $\alpha = 0.05$.

Results

Concentration of heavy metals in the leachate

The concentrations of heavy metals in the leachate are presented in (*Table 1*) (average of the replicas performed) where the results are compared with those from a study carried out by Öman and Junestedt (2008) on leachate from Swedish municipal landfills.

Table 1. *Heavy metal concentrations (µg/L) of leachate of the site studied and the corresponding threshold limit values*

Metal	Concentration	Threshold Limit
Al	1.09 (± 0.0)	209
B	133.3 (± 86.0)	2580
Ba	810.8 (± 343.5)	280

Concentration of metals in biomass of species

A statistically significant difference ($p < 0.05$) was recorded in the absorbed concentration of each metal between the plants, as well as in their evaluated parts (shoots and roots). The concentration of metals was observed in the roots and in the shoots as shown in *Figures 1* and *2*.

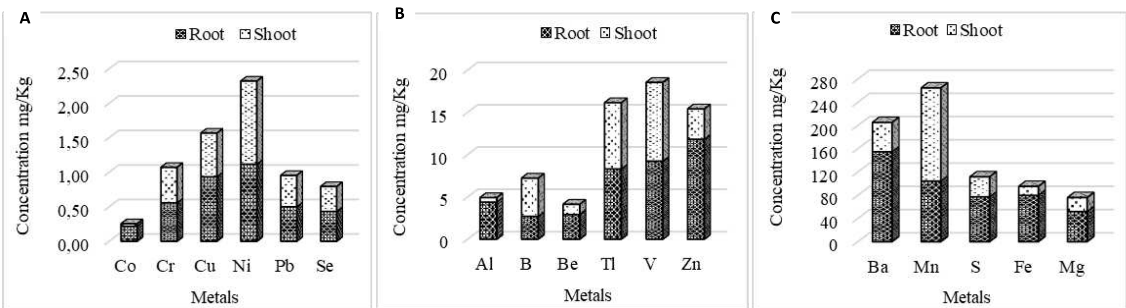

Figure 1. *Concentration of metals in cattail biomass*

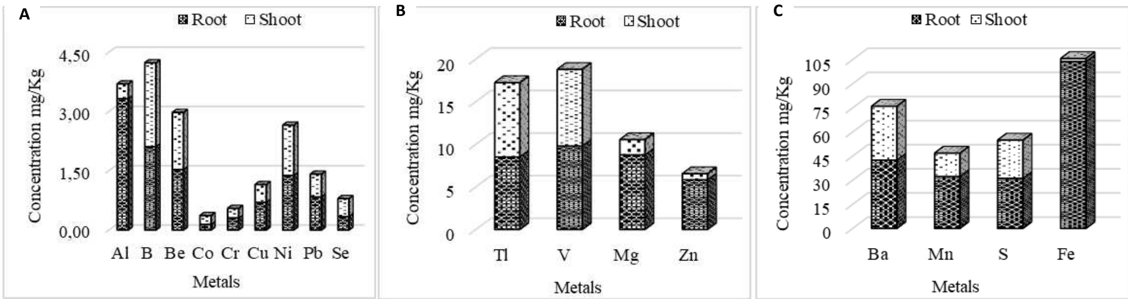

***Figure 2.** Concentration of metals in vetiver biomass*

Translocation factor

Successful phytoremediation evaluates results by emphasizing the ability to accumulate and transfer metals. While plant species may naturally accumulate heavy metals in their roots, a chemical amendment may be necessary to achieve effective translocation of such metals in plant shoots (Anning and Akoto, 2018). Baker (1981) points out that an FT above 1% indicates that a translocation from the root to the aerial part of the plant occurs. Plants with FT > 1 are considered accumulators or hyperaccumulators (if concentrations exceed 0.1%) (Mendieta and Taisigue, 2014), indicating that they are capable of accumulating excessive amounts of heavy metals.

Translocation factor (FT) values for all metals in cattail and vetiver are shown in *Figures 3* and *4.*

Discussion

Concentration of heavy metals in the leachate

Concentrations of heavy metals in the leachate exceeded the limits of the standard threshold *Table 1*. The threshold limits for metals come from a study conducted by Öman and Junestedt (2008) on leachate from Swedish municipal landfills. Heavy metal concentrations (µg/L) of leachate from the site studied and corresponding threshold limit values.

Seventeen heavy metals were identified: S, Ba, Fe, Tl, V, Mg, Zn, Mn, B, Ni, Cr, Se, Be, Co, Pb, Cu and Al, in descending order of concentration (µg/L). As can be seen, S is the metal with the highest absorption, with a concentration of 825.9 µg/L. But it failed to exceed the threshold concentration with a value of 90.800 µg/L. Aluminium was the least abundant metal with a concentration of 1.09 µg/L and differed with the reference site (209 µg/L). On the other hand, some metals (Ba, Be, Co, Cr, Ni, Pb, Tl, V and Zn) obtained a higher concentration than the threshold level. Ba obtained a concentration of 810.8 µg/L while the threshold level concentration was 280 µg/L. The concentration of Be (12.5 µg/L) and Co (12.5 µg/L) were higher than the threshold concentrations (0.065 and 7.7 µg/L respectively). In contrast, Tl, V and Zn showed relatively high concentrations (223.9, 210.9 and 202.5 µg/L respectively) compared to the corresponding threshold levels of 0.12, 16 and 66 µg/L. Ni reached a concentration of 36.01 µg/L, just above the threshold level (31 µg/L). The threshold concentrations of Cr and Pb were 15.3, 31 and 4.4 µg/L respectively, while the concentrations obtained in the study area were 27.34 and 8.5 µg/L respectively.

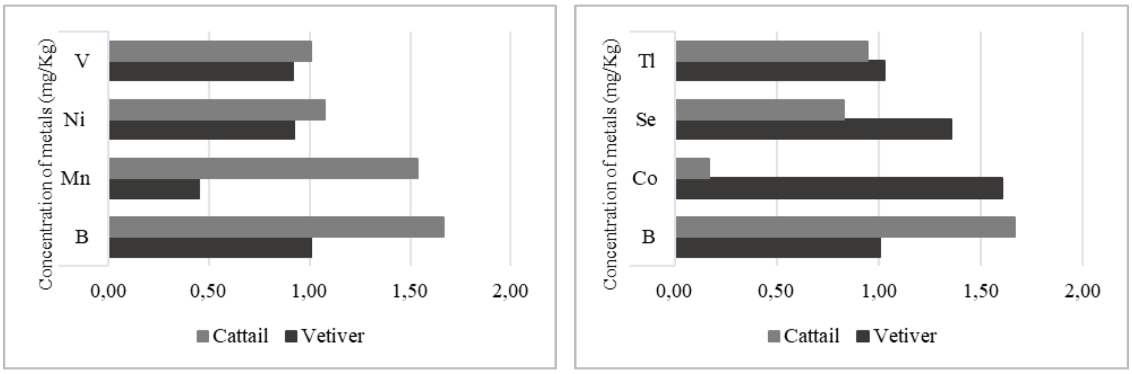

***Figure 3.** Translocation factor >1% of heavy metals in cattail and vetiver*

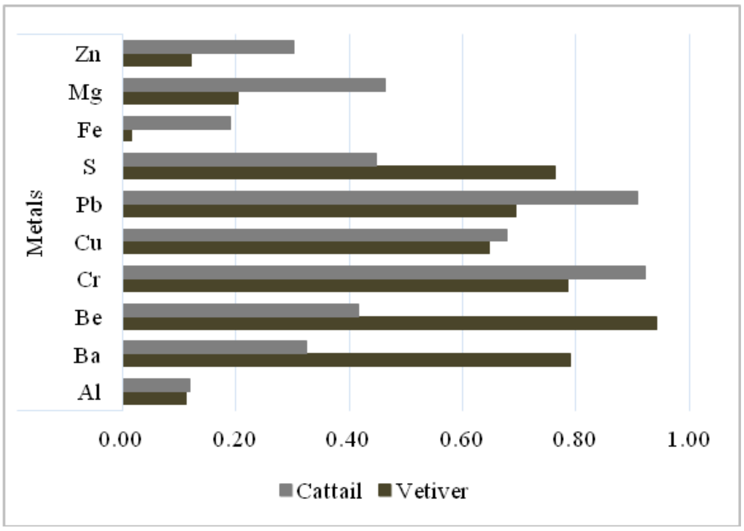

***Figure 4.** Translocation factor <1% in heavy metals in cattail and vetiver*

According to Méndez et al. (2004), the composition of a leachate from a sanitary landfill depends on factors such as: the initial degree of humidity of the residues, rainfall, atmospheric humidity, temperature and evaporation. It generally has a high content of pollutants, especially heavy metals and other harmful substances that become pollution in the area around landfills and in groundwater if they infiltrate (Roongtanakiat et al., 2003). As already mentioned, heavy metals are very harmful to the environment and human health due to their toxicity, persistence and non-degradability. These effects can be particularly problematic, requiring environmentally friendly and cost-effective remediation measures, such as phytoremediation (Ghosh and Singh, 2005; Ali et al., 2013).

Uptake of heavy metals in T. latifolia and C. zizanioides

In both plant species the 17 heavy metals also present in the previously analyzed leachate were identified. In the contaminated samples almost null concentrations (<1 mg/kg) up to high concentrations (>200 mg/kg) were detected. However, in both controls no values were recorded for Co, Cr and Cu, nor for S and Tl in cattail and vetiver, respectively. The highest uptake was in the cattail plant was for heavy metals:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26192630

Mn, Ba, S, Mg, Zn, B, Al, Be, Cu and Cr, in descending order of concentration, and in vetiver were Fe, Tl, Ni, Pb and Co. For Se and V showed very similar concentration values in both contaminated plants analyzed.

Considering the relationship between the concentration present in the contaminated plant and its control, it was observed that vetiver had the highest uptake of Al, Fe, Ni, Pb and V; and for cattail the ones with the highest uptake were B, Ba, Be, Mg, Mn, Se, Tl and Zn. The analysis of variance showed a statistically significant difference ($p < 0.05$) between the concentration of each metal present in the contaminated plant and its respective control.

It is necessary to mention that some are essential elements, and are essential for the maintenance of the biochemical systems of all individuals (Yaman and Akdeniz, 2004). Several elements are essential for the growth, reproduction and/or survival of living organisms; others are of great economic and industrial importance and, from a toxicological point of view, their importance is enormous, presenting a multiplicity of toxic effects.

Based on the results, the cattail can be considered as an accumulator plant, reaching a higher uptake of heavy metals with respect to its control and vetiver. It has been reported the effectiveness of the cattail to capture Al, Cu and Zn (Margalef, 198 and Syukor et al., 2016,), as well as Mg, Cr and Mn (Sarkar et al., 2017), but not the uptake of Ba, S, Fe, V, Tl, B, Be, Ni, Pb, Se and Co.

With respect to vetiver, it seems to be a more effective accumulator of S, Fe, Ni, Pb, V, Al, Tl, Cu, Co and Cr. Truong (2000) reported for vetiver the uptake of Co, Ni and Se (50-100, 100, >74 mg/kg, respectively), in concentrations higher than those obtained in the present work (0.37, 2.65 and 0.8 mg/kg, respectively). The concentrations of Fe and Pb were higher (105.67 and 1.41 mg/kg, respectively) than those reported by Suelee et al. (2017) (0.08 and 0.31 mg/kg, respectively). It should be noted that the metals V and Tl have not been reported in investigations carried out in vetiver as a phytoremediation plant, being two of the elements with higher concentration (18.79 and 17.23 mg/kg, respectively) with respect to all those identified in this plant.

Concentration of metals in biomass of species

The highest concentration of metals was observed in the roots as shown in *Figures 1* and *2*. The metals with the highest concentration in the roots of both species evaluated were: Al, Ba, Be, Cr, Cu, Pb, S, V, Fe, Mg and Zn, with those of cattail showing the highest uptake of metals (Al, Ba, Be, Cu, Mg, S and Zn), compared to the roots of Vetiver (Fe, Ni, Pb and V). In the leaves the elements with the highest concentration were B, Co, Mn, Ni, Se and Tl. The belfry B, Mn and Ni, obtained higher concentrations in the leaves (4.51, 160.42 and 1.20 mg/kg). Vetiver leaves had higher concentrations of Co, Se and Tl (0.23, 0.46, 8.73 mg/kg, respectively).

Translocation factor (FT)

Successful phytoremediation evaluates results by emphasizing the ability to accumulate and transfer metals. While plant species may naturally accumulate heavy metals in their roots, a chemical amendment may be necessary to achieve effective translocation of such metals in plant shoots (Anning and Akoto, 2018). Baker (1981) points out that an TF above 1% indicates that a translocation from the root to the aerial part of the plant occurs. Plants with TF > 1 are considered accumulators or

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26192630

hyperaccumulators (if concentrations exceed 0.1%) (Mendieta and Taisigue, 2014), indicating that they are capable of accumulating excessive amounts of heavy metals. The translocation factor (TF) values for all metals in cattail and vetiver are shown in *Figures 3* and *4*.

In general, the translocation values of metals in plants presented a statistically significant difference ($p < 0.05$) between plants. The cattail recorded a TF >1% for V (1.01%), Ni (1.08%), Mn (1.54%) and B (1.66%), being higher for the latter. In the case of vetiver the metals that obtained a TF >1% were: B (1.01%), Tl (1.03%), Se (1.36%) and Co (1.60%). As can be seen in *Figure 3,* B presented 1.66 in the cattail and 1.01 in the vetiver.

The rest of the metals presented a FT <1%, for both evaluated plant species. According to Mendieta and Taisigue (2014), TF values between 0.1 and 1% indicate that plants are considered tolerant of these metals.

From the current results, the cattail seems to be a more effective accumulator and, to some extent, a translocator of V, Ni, Mn and B than the vetiver, which apparently has a greater affinity for Tl, Se, Co and B.

Research has established that both plants are able to absorb heavy metals from landfill leachate (in situ). Being the cattail, the species that achieved a higher concentration of heavy metals, specifically in their roots. As for vetiver, it successfully captured the metals, however, its concentrations are 10% lower than those of the cattail.

Conclusions

This study showed that the composition of the leachate analyzed from a sanitary landfill in Mexico, which due to its heavy metal content poses a risk to human health and the environment, therefore successful mitigation measures are required. The two plants, *T. latifolia* and *C. zizanioides*, studied in the phytoremediation of different heavy metals present in the previously characterized leachate, proved to be highly effective in capturing seventeen heavy metals present in the previously characterized sanitary landfill, which was supported by the TF values that were used as an indication of the suitability of these plants for phytoremediation. The use of these species indicates that it could be cosmopolitan due to its attributes of remediation of diverse pollutants being economic resources and of easy access. The results obtained will allow progress in the management of degraded spaces and their restoration through innovative phytoremediation techniques.

Recommendations based on the results, considerations should be taken, such as applying the process of phytoextraction assisted by chelating agents in situ, to evaluate and quantify the effect that these chelating agents have on the availability of metals in plant species. As well as to study the autochthonous microorganisms of the rhizospheric soil that participate during the removal of metals. On the other hand, to evaluate the relation plant-soil-microorganisms and to characterize the exudates that are produced in a natural way, for these conditions to define if these compete with organic acids of reactive grade.

Acknowledgements. This study was financed by Promotora Ambiental S.A.B. de C.V. Directed by Dr. Sugey López Martínez. I am also grateful for the scholarship granted by the National Council for Science and Technology (CONACyT) with scholarship No. 430983 during my postgraduate studies in Master's in Environmental Sciences (PNPC).

(Received 14th Nov 2018; accepted 16th Jan 2019)

Abstract. In the context of global warming, extreme drought climate events show a trend of frequent occurrence. Studying the relationship between climate change and drought disasters by using the performance characteristics of climate change has become a new strategic focus of global change science. In this paper, we collected meteorological data from 14 meteorological stations from 1956 to 2015 in Heilongjiang Province and used a standard precipitation index (SPI) of meteorological drought to analyze temporal and spatial characteristics of droughts in the province. Multiple methods such as Linear regression analysis, Mann-Kendall trend test and Kriging interpolation were applied and analyzed to reveal temporal and spatial distribution patterns of drought frequency and drought intensity in different parts of the province. The results show that: (1) the precipitation in Heilongjiang Province has shown a downward trend in the past 60 years and the correlation between the monthly average precipitation and the monthly mean temperature is also apparent. (2) Since 1990s, the intensity of higher drought has escalated in the whole province and has gradually strengthened from south to north. (3) The frequency distribution of drought is the lowest in the central and southern regions, and the highest in the west. (4) The uneven precipitation, sandstorm and uneven distribution of evaporation caused by the monsoon in Heilongjiang Province are the main meteorological factors for the formation of drought in the province.
Keywords: *Heilongjiang Province, drought, spatial-temporal variation, standardized precipitation index (SPI)*

Introduction

Drought is one of the most complex and recurring natural disasters that is caused by intense and persistent shortage of precipitation. Precipitation is the main parameter that treats some environmental disasters as drought, and many other factors such as temperature, high winds, and low relative humidity also play a significant driving role in the occurrence of drought. Drought is considered to be one of the most serious natural disasters in the world because of its large spatial range and long duration, resulting in frequent occurrence of large-scale and intensive droughts around the world (Koutroulis et al., 2011; Okonkwo et al., 2013; Ngetich et al., 2014; Potop et al., 2014; Blauhut et al., 2015; Kazemzadeh and Malekian, 2016). China is deeply affected by the monsoon climate and topography, resulting in uneven distribution of water and heat leads to frequent droughts (Bi, 2007; Wang, 2007). Since 1950s, the drought disaster in northern China has been expanding and accelerating. According to the statistics, average area affected by drought in China is 1873.1 hm^2, with a disaster rate of 43%; the grain output reduced by 25-30 billion kg, accounting for more than 60% of the total

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26312650

losses caused by various natural disasters. Drought brings huge economic losses to China's national economy, especially agricultural production (Jiang and An, 2011).

The problem of aridification in northern China has always been the focus of academic circles. In particular, research on two typical arid regions in North China and Northwest China has received much attention (Sun and Gao, 2000; Li et al., 2007; Hao et al., 2010; Yi et al., 2012). The study on drought in northern China has mainly concentrated on the characteristics, causes and aridification of drought evolution. For example, Spinoni et al. (2014) conducted a statistical analysis of the frequency, duration and intensity of drought events worldwide based on the SPI index. Lu et al. (2010) based on the run-length theory, extracted the drought duration and drought intensity from the comprehensive meteorological drought index sequence, and established the joint distribution of the two copula functions. Corti et al. (2011) constructed a regional drought loss assessment model. At present, the research has mostly evaluated drought and set drought research indicators from the perspective of the causes and mechanisms of drought, and the main indexes involved are standardized precipitation index (SPI), Z index, standardized precipitation evapotranspiration index (SPEI), Palmer drought index (PDSI), surface water supply index (SWSI), Wald Wasser Haushalts Modell (WAWAHAMO), water deficit index (WDI) and meteorological drought index (CI) (Mishra and Singh, 2011). Due to the complexity of the drought itself, there is currently no drought index that can comprehensively describe the changing characteristics of different types of drought. The several drought indices mentioned above have relative rationality in different geographical areas and specific timescales. Among them, the standardized precipitation index (SPI) has been accepted by meteorological scientists all over the world because of its simplicity and multi-scale advantages based only on precipitation data. It has been widely used in drought analysis and assessment work in various places (Patel et al., 2010; Kumar et al., 2016; Sujitha and Shanmugasundaram, 2017; Yang et al., 2017; Guhathakurta et al., 2018). In recent years, due to the influence of multiple factors, the frequency of drought in Heilongjiang Province has increased, and the scope of drought has expanded, spreading from the Mudanjiang area to the whole province. Except for the Heilongjiang River coast and the Greater Xing'an Mountains, most of the counties and cities have experienced different degrees of drought (Zhang et al., 2014). However, most of the studies on drought in the north have been analyzed of a regional perspective, while there are few studies on the analysis of local drought from smaller scales. In the Heilongjiang region, especially on higher latitudes, analysis of annual and seasonal drought characteristic is very infrequent. Based on the standard precipitation index (SPI), this paper implemented data analysis or geographic interpolation from interannual, interdecadal, monthly, seasonal, and abrupt changes by calculating drought frequency and drought intensity, and analyzed the spatial and temporal distribution characteristics and formation mechanism of drought in Heilongjiang Province. Through these efforts, we hope to provide a theoretical reference for the scientific understanding of regional drought characteristics and effective defense against drought disasters.

Study area

Heilongjiang Province is located in the northeastern part of China, and the total land area is 473000 km^2. It is an important passage from the Asia-Pacific region to the Russian Far East and the European continent (*Fig. 1*). The Heilongjiang River Basin is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26312650

mainly composed of four major river systems: Heilongjiang, Songhua River, Wusuli River and Suifen River. Regarding topography, the northwest, north and southeast of the province are relatively high, while the northeast and southwest are relatively low. Heilongjiang Province belongs to temperate continental monsoon climate with an annual average temperature between -5 and 5 °C, decreasing from south to north, roughly the 0 °C contour of Nenjiang and Yichun lines (Zhang et al., 2014). The annual precipitation is mostly between 400 and 650 mm, with more precipitation in the central mountainous area, less precipitation in the western and Northern regions, and precipitation resources are relatively stable. As an important province in Northeast China, Heilongjiang Province has a dense population and a large number of large and medium-sized cities, and it has a significant strategic position in China’s political economy. However, the frequency of drought in Heilongjiang Province is at the forefront of China, and the problems caused by drought have seriously restricted the social and economic development of Heilongjiang Province.

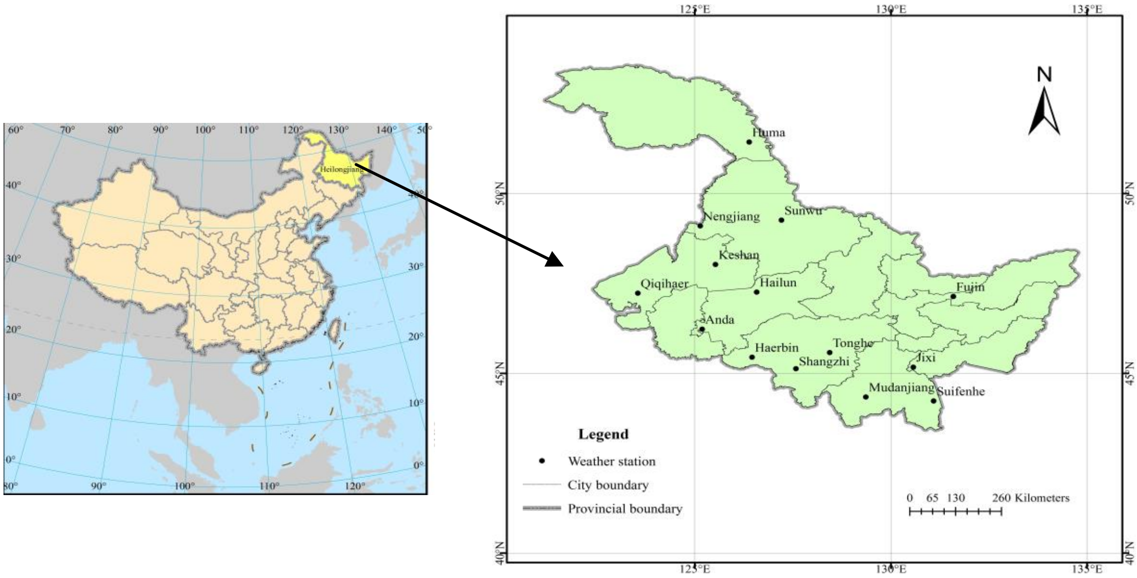

Figure 1. *Location of Heilongjiang Province and distribution of typical weather stations*

Materials and methods

Data

The meteorological data is provided by the China Ground International Exchange Station of China Meteorological Data Network about 14 Station which was used 1950-2015 monthly site data, including precipitation, maximum temperature, minimum temperature, average temperature, sunshine hours, wind speed and relative humidity, as well as latitude and longitude and elevation. Because bound by the site incomplete data due to site changes and lack of measurement caused by some reasons, 14 stations of Heilongjiang which has complete data were selected (*Fig. 1*). All data have undergone rigorous quality control and error correction. The GDEMV2 30M resolution digital elevation data used in this paper is from the Geospatial Data Cloud website. China’s basic administrative divisions and water system map data come from the Resource and Environmental Science Data Center of the Chinese Academy of Sciences.

Study methods

Linear regression analysis

Linear regression analysis describes the linear dependence between the dependent variable *y* and the independent variable *x*. If the independent variable has only one *x*, then this linear regression is called a one-way linear regression. The task of unary linear regression is to find a linear regression equation describing the two variables *x*, *y* based on several observation points (x_i, y_i) (*i = 1, 2, 3...n*). When judging the goodness of fit of a regression equation, the R^2 decision coefficient is a significant indicator. The calculation formula of the correlation coefficient *r* of the regression equation is (*Eq. 1*):

$$\mathrm{r} = \frac{\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i - \bar{x})^2}\sqrt{\sum_{i=1}^{n}(y_i - \bar{y})^2}} \qquad \text{(Eq.1)}$$

The closer the absolute value of the correlation coefficient *r* is to 0, the worse the correlation between the two variables. Conversely, the closer the absolute value of the correlation coefficient *r* to 1, the better the correlation between the two variables *x* and *y*, and the closer the linear regression equation to a flat line parallel to the x-axis.

Standardized precipitation index (SPI)

The standardized precipitation index was proposed by Mckee in 1993 when studying the drought conditions in Colorado, USA. By first calculating the Γ distribution probability of precipitation in a certain period, and then normalization, the cumulative precipitation frequency distribution is used to divide the drought level. Due to the standardized treatment, the SPI index eliminates the spatial and temporal distribution of rainfall, has multiple time scale characteristics, is sensitive to drought response, and can effectively reflect drought and flood conditions in different regions and different time periods (Yuan and Zhou, 2004; Kim et al., 2015). The SPI calculations for this study used the computational procedures of the University of Nebraska approved by the World Meteorological Organization. After calculating the SPI index, we can classify the drought level according to *Table 1*. The SPI level is above the light drought (including light drought), indicating that the drought occurred in the area.

Drought evaluation indicators

1) Drought frequency

Drought frequency refers to the ratio of the number of times the drought occurs (the level corresponding to the SPI index is above light drought) to the total number of observations during that period (Song and Singh, 2010). The calculation formula is as follows (*Eq. 2*):

$$P_i = \frac{n}{N} \times 100\% \qquad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26312650

where: N is the total time point (year, season, month) of observation data at a station, and n is the number of time points (year, season, month) when drought occurs (SPI drought level is above light drought).

Table 1. *Classification of standardized precipitation index drought level*

Grade	Type	Value of SPI	Extent of the effects of drought
1	No drought	-0.5<SPI	Precipitation is normal or higher than normal years; moist surface, no signs of drought
2	Light drought	-1<SPI≤-0.5	Precipitation is less than normal years; the surface air dry, the soil appear moisture mild deficiencies
3	Moderate drought	-1.5<SPI≤-1.0	Precipitation continued below normal years; soil surface is dry, soil water shortage, surface of plant leaves daytime wilting phenomenon
4	Serious drought	-2.0<SPI≤-1.5	Soil appeared sustained severe lack of moisture, Soil appear thicker dry soil, wilting plants, dry leaves and fruit shedding, cause a serious impact on crops and ecological environment and industrial production, drinking water
5	Special serious drought	SPI≤-2.0	Soil appeared a serious shortage of water for a long time, surface plant withered or death, cause a serious impact on crops and ecological environment,, have a greater impact on drinking water and industrial production

SPI: standardized precipitation index

2) Drought intensity

Drought intensity is the average of the absolute values of the SPI index at a site or time period in which drought (above SPI drought levels are above light drought) occurs over a certain period of time (Chang et al., 2012). Calculated as follows (*Eq. 3*):

$$I = \frac{1}{m}\sum_{i=1}^{m}\left|SPI_i\right| \qquad \text{(Eq.3)}$$

The drought intensity was not obvious when $S_{ij} < 0.5$; $1 > S_{ij} \geq 0.5$ was a mild drought; when $1.5 > S_{ij} \geq 1$, it was a moderate drought; when $S_{ij} \geq 1.5$, it was severe drought.

Kriging interpolation

The Kriging interpolation method was first proposed by South African mining engineer D. G. Krige in 1951 and later developed by the famous French geographer G. Matheron. Based on the spatial autocorrelation, the Kriging method uses the original data and the semivariance function as the structure to perform unbiased optimal estimation of the unknown sample points of the regionalized variables (Li et al., 2013). The Kriging method not only considers the distance, but also considers the spatial distribution of known sample points and the spatial orientation relationship with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26312650

unknown samples through variogram and structural analysis. The interpolation formula is (*Eq. 4*):

$$z(x_0) = \sum_{i=1}^{n} \lambda_i z(x_i) \quad \text{(Eq.4)}$$

where: $z(x_0)$ is the estimated value at x_0, $z(x_i)$ is the observed value at x_i, λi is the Kriging weight coefficient, and n is the number of observation points.

Mann-Kendall test

The Mann-Kendall test can be used to determine if there is an anomaly in the hydrometeorological data arranged in time series and to determine the time of the mutation. It is often used for the detection of precipitation and drought trends affected by climate change (Luo et al., 2008). Its calculation method is:

1) Calculate the order column S_k of the sequential time series and calculate UF_k according to the equation.

The order of the time series x with n sample sizes is listed as (*Eq. 5*):

$$s_k = \sum_{i=1}^{k} r_i \quad r_i = \begin{cases} 1, x_i > x_j \\ 0, x_i \le x_j \end{cases} \quad j = 1,2,\cdots,i \quad \text{(Eq.5)}$$

It can be seen that the order column S_k is the cumulative number of the number of values at the *i*-th time when the value is greater than *j*. Assuming the time series are randomly independent, the statistics are defined (*Eq. 6*):

$$UF_k = \frac{s_k - E(s_k)}{\sqrt{Var(s_k)}} \quad k = 1,2,\cdots,n \quad \text{(Eq.6)}$$

where: $UF_1 = 0$, $E(s_k)$, $Var(s_k)$ are the mean and variance of the cumulative number S_k, respectively. When $x_1, x_2, ..., x_n$ are independent of each other and have the same continuous distribution, they can be calculated by (*Eq. 7*):

$$E\ (s_k) = \frac{n(n+1)}{4} \quad Var(s_k) = \frac{n(n-1)(2n+5)}{72} \quad \text{(Eq.7)}$$

2) Calculate the order column S_k of the reverse sequence of time, and calculate UB_k according to the equation.

Repeat the process in 1) by the time series x reverse order x_n, x_{n-1}, ..., x_1, while making $UB_k = -UF_k (k=n, n-1,...,1)$, $UB_1 = 0$. Given a significance level of $\alpha = 0.05$, the critical value $U_{0.05} = \pm 1.96$. The two statistical sequence curves UF_k and UB_k and ±1.96 two critical lines are plotted on the same graph. If the value of UF_k or UB_k is greater than 0, it indicates that the sequence has an upward trend. Conversely, if the value of UF_k or UB_k is less than 0, it indicates that the sequence has a downward trend. If there is an intersection between UF_k and UB_k, and the intersection is between the two critical lines, the time corresponding to the intersection is the moment when the mutation starts. If the two curves exceed the critical value, it indicates that the trend of rising or falling

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26312650

is significant, and the range exceeding the critical line is the time zone in which the mutation occurs.

Results

Characteristics of drought time in Heilongjiang Province within the year

Analysis of monthly drought characteristics

The monthly temperature and precipitation data of 14 meteorological stations in Heilongjiang Province were statistically analyzed, and the correlation curves of monthly mean temperature and monthly mean precipitation in Heilongjiang Province were plotted (*Fig. 2a*).

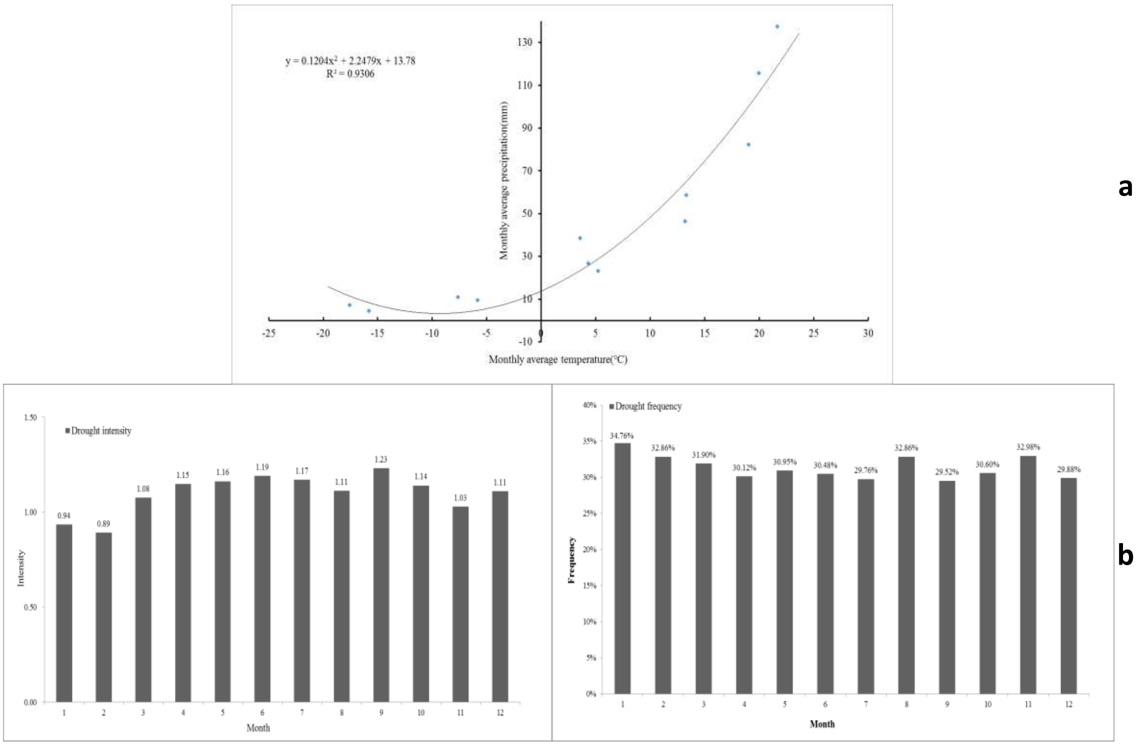

Figure 2. *(a) Analysis curve of monthly mean temperature and monthly mean precipitation in Heilongjiang Province. (b) Monthly drought frequency and intensity histogram of Heilongjiang Province*

It can be seen from the figure that there is a very obvious correlation between temperature and precipitation in Heilongjiang Province, and the R^2 value of the correlation analysis curve reaches 0.9417. This shows that in the global warming environment, the precipitation in Heilongjiang Province is greatly affected by the temperature and even changes with the temperature. Calculate the corresponding SPI index, and classify the data. It can be seen that the monthly drought frequency in Heilongjiang Province is not much different, and fluctuates around 31%. The month with the lowest frequency of drought is September, and the month with the highest frequency of drought is January. The annual intensity of the drought is relatively stable, and fluctuates between light and moderate levels. Among them, the intensity in January

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26312650

and February is 0.5~1, which is light drought. From March to December, it is between 1 and 1.5, all of which are in the middle drought. The month with the highest drought intensity is September, with a value of 1.23. The month with the lowest drought intensity was February, with a value of 0.89 (*Fig. 2b*). It can be seen that the drought in Heilongjiang Province is common during the year, but the intensity is relatively light and stable.

Analysis of seasonal drought characteristics

The precipitation in the four seasons of Heilongjiang Province varies greatly, showing typical monsoon precipitation. In winter, the icing period has adversely affected the water cycle of the four major river systems. Together with the combination of the northwest monsoon, the phenomenon of low precipitation in winter and high frequency of drought occurred in Heilongjiang Province. Comparing *Figure 3,* the seasonal drought frequency and drought intensity in Heilongjiang Province showed a reverse trend. The summer drought frequency is the lowest, but the drought intensity is the highest; the winter drought frequency is the highest, but the drought intensity is the lowest. This is due to the abundant precipitation in summer, which leads to a low frequency of drought. However, the terrain and water system in Heilongjiang Province are complex, and the summer is susceptible to the southeast monsoon, which is fragile and sensitive to drought. Moreover, global warming has caused frequent high temperatures in Heilongjiang in summer, greatly increasing the intensity of drought. Therefore, in summer, compared with winter, it is more susceptible to high temperature and forms a greater drought intensity.

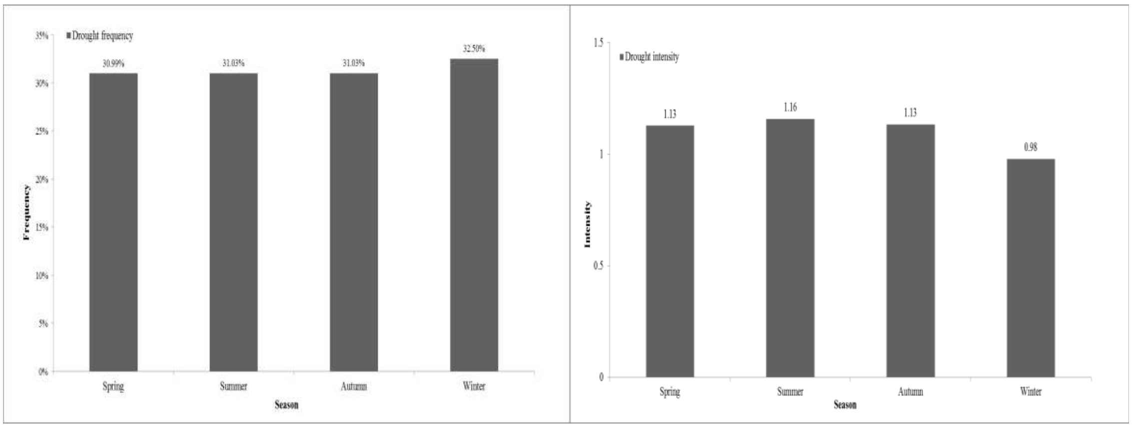

Figure 3. *Heterogeneous frequency and intensity histogram of four seasons in Heilongjiang Province*

Analysis of interannual and interdecadal drought characteristics in Heilongjiang Province

Time change trend analysis

Using linear regression method to analyze the trend of annual average precipitation in Heilongjiang Province, it can be seen that the precipitation in Heilongjiang Province showed a downward trend in the whole 60 years, and maintained a fluctuation of about 500 mm, but it did not pass the significance test ($P > 0.05$). The results show that the R^2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26312650

value is only 0.0103, which indicates that the downward trend is not significant, and the overall precipitation is relatively stable. The decadal trend map of precipitation (*Fig. 4a*) shows that during the ten years from 1956 to 1965, Heilongjiang Province had abundant precipitation, and the average precipitation was 572.07 mm. However, in the 20 years after 1966, the precipitation decreased sharply, and the average precipitation between 1966 and 1975 was only 501.6 mm. In these 20 years, the precipitation was low and lasted for a long time, which was very likely to lead to drought, and the most typical example was the national drought that occurred in 1978~1983. From 1986 to 1995, the precipitation increased and reached to 557.76 mm. During the ten years between 1996 and 2005, interdecadal precipitation ushered in a sharp drop and fell to the lowest point in 60 years (495.81 mm). This is closely related to the severe drought that lasted for 4 to 5 years in North China and Northeast China around 1997. In 2006~2015, the precipitation has rebounded (529.55 mm), but compared with the previous stage, it still shows a downward trend.

By analyzing the variation trend of annual mean temperature in Heilongjiang Province in the past 60 years, it can be seen that the temperature in Heilongjiang Province has been fluctuating and rising in general during the past 60 years, but it did not pass the significance test ($P > 0.05$). The R^2 value is 0.472, reflecting a relatively significant upward trend in temperature (*Fig. 4b*). Affected by global warming, the annual average temperature in Heilongjiang Province has gradually increased over the past 60 years, making the intensity of drought increasingly intensified. It can be seen from *Figure 8* that in the 30 years from 1956, the annual average temperature rose slowly at a lower rate; by the decade 1976-1985, the annual average temperature has increased to 1.98 °C. In the next ten years, the temperature increased significantly at a higher rate. The average temperature in the decade from 1986 to 1995 reached 2.87 °C. After that, the growth rate has slowed down noticeably. In the 20 years after 1996, the temperature in Heilongjiang Province has reached a state of constant stability, with an average temperature of 3.19 °C in two decades.

c

Figure 4. *(a) Trends in annual average precipitation in Heilongjiang Province; (b) trends in interdecadal precipitation in Heilongjiang Province; (c) trend pattern of decadal precipitation in Heilongjiang Province*

By calculating the SPI index, the drought frequency and drought index since 1956 in Heilongjiang Province were classified and calculated. It can be seen from *Figure 5a* that the drought frequency always had large fluctuations, but it was basically the same as the overall trend of 60 years. In 1957 and 2013, there were less than 12% of the frequency, and in 1971 and 2011 there were nearly 50% of the high frequency. It can be obviously seen from *Figure 5b* that the intensity of drought in Heilongjiang Province has fluctuating upward in 60 years, and passed the significance test ($P > 0.05$). The intensity was between light drought and moderate drought. This was related to the persistently high temperature in Heilongjiang Province in the past 20 years and was also a response to the deterioration of the global climate.

Mutation analysis

Using the Mann-Kendall test to test the precipitation sequence from 1956 to 2015 in Heilongjiang Province, we can find that the UF curve is greater than 0 in 1956~1957 and 1959~1961, but all passed the $\alpha = 0.05$ significance test, which indicates that during these two time periods, the precipitation in Heilongjiang Province has increased, but it is not significant (*Fig. 5c*). Between 1957 and 1959, the UF curve and UB curve intersected, and both of them were between the significant horizontal line of alpha = 0.05. This indicates that the precipitation in Heilongjiang Province showed two abrupt changes in the trend of rising-falling-rising between 1956 and 1961. In 1961, the UF curve intersected the UB curve again, after which the UF curve began to fall less than 0 and continued to fall. In 1974, it broke the $\alpha = 0.05$ significance test horizontal line, and then returned to the $\alpha = 0.05$ significance test level line in 1984. This showed that 1961 was an extremely important drop point in the precipitation sequence. From 1961, the annual average precipitation in Heilongjiang Province began to decline, and the decline between 1974 and 1984 was very significant. After 1984, the UF curve was still less than zero but rising. This showed that after 1984, the precipitation in Heilongjiang was decreasing, but its rate gradually slowed down. In 1993-1995, the UF curve exceeded zero again, and the precipitation increased. However, after 1995, the UF curve continued to decrease from zero again, which represents a decreasing trend of precipitation. This drop in precipitation for the Northeast region has brought about a drought lasting about five years, the Northeast people’s production and life has brought serious impact.

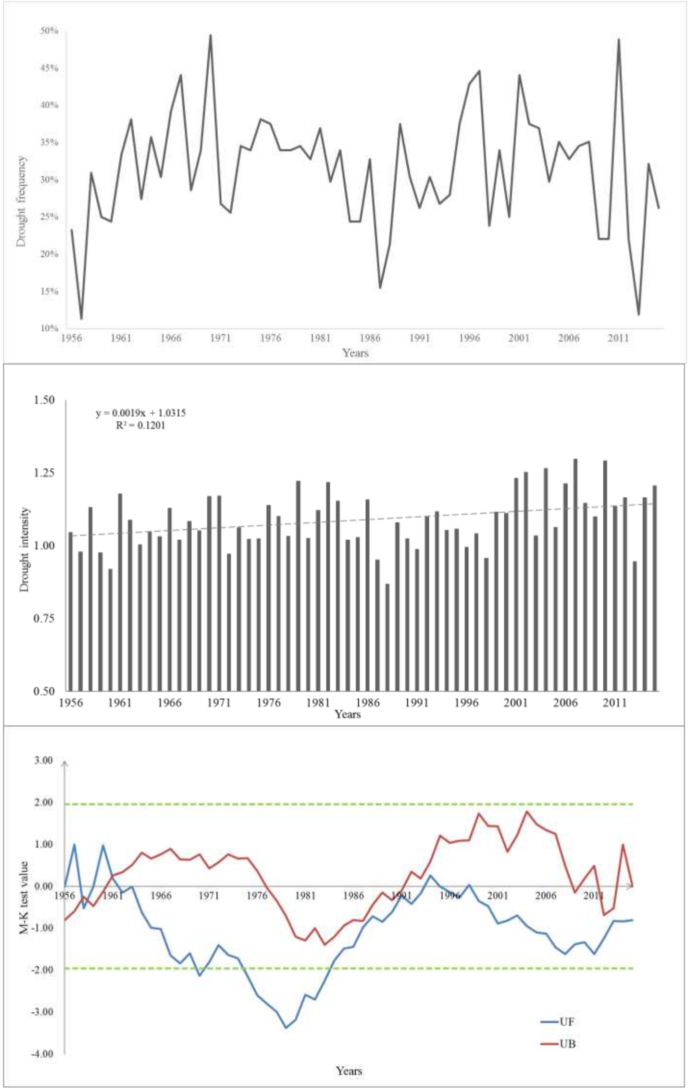

Figure 5. *(a) Trend pattern of drought frequency in Heilongjiang Province from 1956 to 2015; (b) trend pattern of drought intensity in Heilongjiang Province from 1956 to 2015; (c) annual average precipitation M-K test curve in Heilongjiang Province*

Analysis of spatial characteristics of drought in Heilongjiang Province

Interannual drought spatial distribution

According to the SPI index of 14 weather stations, the drought frequency and drought intensity in 60 years were calculated. According to the analysis of *Figure 6,* the highest drought frequency in the province was centered on Qiqihaer and has spread to Anda and Harbin, with values of 33.61%, 32.22% and 31.94%, respectively. Because of the existence of Zhangcailing and Mudanjiang in the south-central region, the drought frequency in the region centered on Tonghe River was less than 29.86%. The drought frequencies in the west of Jixi and Suifenhe were 32.36% and 32.08%, respectively. The variation of drought intensity in Heilongjiang Province was contrary to that of drought frequency. The drought intensity was small in areas with high drought frequency, but large in areas with low drought frequency. Drought events with high intensity were often rarer than those with small intensity.

DOI: http://dx.doi.org/10.15666/aeer/1702_26312650

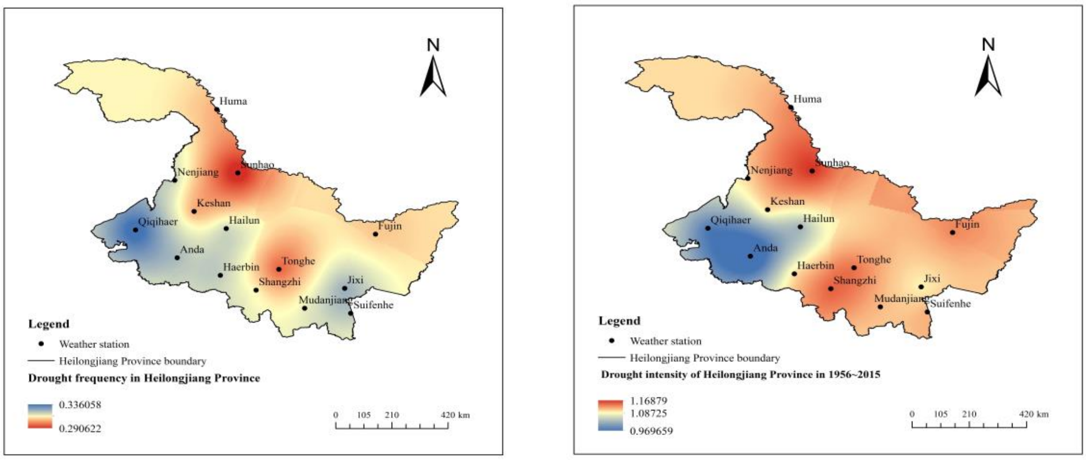

Figure 6. *Drought frequency and intensity distribution map of Heilongjiang Province*

Spatial evolution of interdecadal drought

According to the analysis of *Figure 7a,* in the 1956-1965 period, the Suifenhe River in the west and the Suifen River in the southeast formed the two most intense central points. In the 1966-1975s, one of the centers of gravity shifted, forming the central point of the Tonghe River in the south-central part and the Suifen River in the southeast. The overall drought intensity was characterized by weak southwest and strong southeast. From 1976 to 1986, the two central points of drought intensity were distributed on both sides of the East and West again, which was similar to the distribution from 1956 to 1965, but their scope was obviously expanded. The center of drought intensity in the West changed from one point of Nenjiang River to a larger enclosure formed by Nenjiang River, Sun Wu and Keshan, occupying the northwest of Xiaoxing'an Mountains. Moreover, the northern part of the Greater Khingan Range was also affected by the encirclement. The drought center in the south of China shifted from Suifen River to Mudanjiang area, which was not far from the southwest of Suifen River. In the 1986~1995 era, the southern drought intensity center continued to move westward to Harbin. The other drought intensity center moved from the northwest of the Xiaoxing'an Mountains in the last decade to Fujin in the eastern part of Heilongjiang Province, and almost covered the whole Sanjiang Plain area with Fujin as the center. Since 1996, global warming has caused long-term persistence in the Heilongjiang region to be affected by high temperatures, and the spatial distribution of drought intensity has changed significantly. In the decade from 1996 to 2005, the lowest drought intensity in Heilongjiang Province jumped from the previous drought to moderate drought, and formed the two major centers of Sun Wu and Tonghe. The high drought intensity ranged over the severe situation in central Heilongjiang Province. In the 2006-2015 period, the high drought intensity distribution area of Heilongjiang Province has spread throughout the province, gradually increasing from south to north. Different from the local point distribution in the previous high-intensity intensity areas, during this period, the drought intensity was generally above the moderate drought, and the higher drought intensity range has been extended to the province. The drought frequency distribution (*Fig. 7b*) of 14 meteorological stations in Heilongjiang Province from 1956 to 2015 was relatively stable, basically fluctuating around 30%, and the drought frequency of 14 stations showed similar distribution patterns in each age.

DOI: http://dx.doi.org/10.15666/aeer/1702_26312650

Spatial distribution of seasonal drought

It can be seen from *Figure 8a* that the intensity of drought in Heilongjiang Province was generally large and the distribution was the widest. The areas with high drought intensity were mainly concentrated in the central and southeastern mountainous areas, the Daxing'an Mountains in the north and the west of Nenjiang River. The plains have alleviated the drought to some extent due to the pooling of rivers and snow and ice. The two major centers with higher drought intensity in summer were Sun Wu in the north of Xiaoxing'an Mountains and Fu Jin in the north of Sanjiang Plain, and the drought intensity was strong in the north and weak in the southeast. This was due to the influence of the southeast monsoon in Heilongjiang Province in summer, which lead to more precipitation in Southeast China. The Wanda Mountain in the East and the mountains in the middle of Heilongjiang Province blocked the intrusion of warm and humid air currents, which formed a typical monsoon precipitation distribution in summer. The distribution pattern of drought intensity in autumn in Heilongjiang Province was similar to that in the past 60 years. Nenjiang-Sunwu-Keshan and Mudanjiang-Suifenhe were the two high drought intensity centers, which were moderate drought, and other areas were light drought. The distribution of drought intensity in Heilongjiang Province in winter was closely related to the 60-year average precipitation distribution. The drought intensity of the Shangzhi-Tonghe area with large precipitation was large, while the Qiqihar-Anda area with less precipitation had less drought intensity. This was due to the cold weather in Heilongjiang in winter, which caused the river to freeze, affecting the water cycle, and the precipitation was also reduced to the lowest in the four seasons. The Heilongjiang region was sensitive to drought due to its complex topography and water system. The area with more average precipitation had more water demand, so it was more sensitive to the lack of water and formed a higher drought intensity. It can be seen from *Figure 8b* that the drought frequency distribution of the four seasons in Heilongjiang Province was relatively uniform, and the drought frequency of the four stations in the four stations was stable at around 30%.

Discussion

Impacts of topography and basic meteorological elements on the formation of drought

The uneven precipitation, sandstorm and uneven distribution of evaporation caused by the monsoon in Heilongjiang Province are the main meteorological factors for the formation of drought in the province. The precipitation in Heilongjiang Province is greater in the east than that in the west, but the sand and evaporation are both greater in the west than those in the east. This is affected by the temperate continental monsoon climate of Heilongjiang Province. The humid monsoon in the southeast of summer is blown in from the southeast, but it cannot be penetrated inland by the middle and southern mountains (Zhou et al., 2011). In the winter and spring, the dry monsoon from south of Siberia carries the sands of Mongolia from Songnen Plain to the west of the central mountains. This has led to an increase in evaporation and increased drought in the western region. Based on the above factors, the overall drought frequency in Heilongjiang Province is higher than that in the east.

Interannual climate anomaly signals affecting drought in northern China

There are many complex factors which affect the climate change in northern China. Since summer precipitation in most parts of China accounts for the majority of total annual precipitation, the interannual anomaly signals affecting summer precipitation in China are discussed. Analysis of factors affecting summer precipitation include sea surface temperature (ENSO phenomenon), snow cover, ground temperature and other underlying surface thermal factors and Asian monsoon, tropical convection, equatorial convergence, cross-equatorial flow, Qinghai-Tibet high, western Pacific subtropical high, Mid-latitude block high pressure, polar vortex, teleconnection type, quasi-two-year oscillation (QBO), three major oscillations and other atmospheric activity centers or atmospheric circulation systems, as well as solar activities, astronomical factors, geophysical factors, etc. (Chen et al., 2001; Wang et al., 2005; Sha et al., 2013; Feng et al., 2014). These factors cover a wide range of aspects, including not only the Earth system ocean circle, the ice and snow circle, the atmosphere, the lithosphere, but also the solar activities outside the Earth system.

Impacts of climate warming and atmospheric circulation on drought

Studies have shown that precipitation in a particular place has a certain relationship with changes in atmospheric circulation (Yan and Zhang, 1994; Salinger and Mullan, 1999; Ramadan and Beighley, 2012). From the atmospheric circulation situation, it can be seen that there are significant differences between the rainy and rainy periods. During the rainy period, in the middle and high latitudes of East Asia, the westerly winds of the westerly winds are large, the high pressure of Yakutsk is strong and stable, and there is a clear north ridge in the eastern part of Lake Baikal, so that the eastern part of the northeast is at the front of the average trough of the south branch. Frequent low pressure and cold vortex move eastward, forming rainy weather and increasing precipitation. On the contrary, there is less precipitation (Sun and Zhou, 2010; Hanssen-Bauer, 2015).

The precipitation in Heilongjiang showed a significant downward trend in the 60 years of 1956~2015. After 1990s, there was a sharp decline in large-scale drought. The persistent drought in these years is closely related to the background of global warming. Global warming is an important reason for the frequent drought in Heilongjiang after the 80s of last century. Sustained high temperature makes the arid area enlarged; the surface evaporation increased; the soil organic matter decreased; the wetland area narrowed, destroyed the ecological diversity and stability of Heilongjiang Province, made the ecological climate environment of Heilongjiang Province fragile, land desertification, salinization, desertification greatly aggravated. Therefore, Heilongjiang is more vulnerable to drought. In addition, the precipitation in Heilongjiang Province has almost the same interdecadal oscillation trend with atmospheric circulation, vorticity field and divergence field. Since the 1980s, the East Asian westerly circulation affecting Heilongjiang Province has a strong latitude, the Yakutsk high is weak, there is no polar vortex center in the eastern Ural Mountains, and the eastern part of Heilongjiang Province is under the Northwest Airflow behind the ridge-trough, which often leads to high temperature and drought weather. At this time, the north of China is in the situation of weakening the convergent updraft caused by the weakening of positive vorticity and stronger divergent subsidence caused by the weakening of divergence, which is not conducive to the formation of precipitation.

DOI: http://dx.doi.org/10.15666/aeer/1702_26312650

The mechanism for the formation of the drought are complex, there are a lot of factors that impact worthy of further study, such as El Nino phenomenon, sunspot activity and Heilongjiang drought pending further analysis. Warm and cold years the drought disasters variation and related mechanism need to be further clarified.

Conclusion

1) The correlation between monthly mean precipitation and monthly mean temperature in Heilongjiang Province is apparent. The drought in Heilongjiang Province occurred during the year, but its intensity was relatively light and it was relatively stable. The seasonal drought frequency in Heilongjiang Province was negatively correlated with drought intensity.

2) The precipitation in Heilongjiang Province in the whole 60 years showed a downward trend, but the downward trend was not significant, and the overall situation was relatively stable. Interdecadal precipitation fluctuated greatly, with two large declines in the 1960s and 1990s, and a very significant drop in 1961. Although the frequency of drought has been fluctuating greatly, the overall trend of 60 years has remained basically the same. The intensity of drought is fluctuating and the intensity is between mild drought and moderate drought.

3) The distribution of drought frequency in Heilongjiang Province is the lowest in Xiaoxing’anling in the central part and the Songhua River and Mudanjiang in the south, the highest in the Songnen Plain in the west. The spatial distribution of drought frequency in Heilongjiang Province is relatively stable in 60 years, and it basically fluctuates around 30%. The interdecadal drought intensity shows a periodical cycle of localized point-like distribution with strong intensity in the eastern and western regions in the previous decade and strong intensity in the eastern part of the decade. Since the 1990s, the intensity of drought in the entire central region has increased. After entering the 21st century, the distribution of higher drought intensity has spread throughout the province, and the lowest intensity has reached moderate drought, and gradually increased from south to north.

4) The intensity of drought in Heilongjiang Province is generally large and the distribution is the widest. In the other three seasons, only local areas have greater drought intensity. The drought frequency distribution of the four seasons in Heilongjiang Province is relatively uniform, and the drought frequency of the four weather stations in the four seasons is stable at around 30%.

5) The uneven precipitation, sand and evaporation distribution caused by the monsoon in Heilongjiang Province are the main meteorological factors for the formation of drought in the province. Global warming is an important reason for the frequent drought in Heilongjiang after the 1980s. Heilongjiang Province is prone to high temperature and dry weather due to the influence of the East Asian Westerly circulation, the Yakutsk high pressure and the northwest airflow. Moreover, the weaker positive vorticity caused by the weaker positive vorticity in Heilongjiang Province and the weaker divergence caused by the divergent downdraft flow are not conducive to the formation of precipitation.

The climate of Heilongjiang Province has the typical characteristics of the northeast region. Its temperature change and extreme weather events in recent years have been some change, and its causes are still unable to be defined. The aim of research in the

DOI: http://dx.doi.org/10.15666/aeer/1702_26312650

future is seeking the regional disaster response to the global climate change and mechanism between them.

Abstract. Determination of the change in groundwater level in terms of planning and managing resources is important**.** In this study, the groundwater level of Reyhanlı region in Turkey was predicted using multi-linear regression (MLR), adaptive neural fuzzy inference system (ANFIS), Radial basis neural network (RBNN), support vector machines with radial basis functions (SVM-RBF) and support vector machines with poly kernels (SVM- PK) methods. Models were carried out using 192 data of monthly ground water level, monthly total precipitation and monthly average temperature values measured for 16 years between 2000 and 2015. Comparisons revealed that the SVM–RBF and SVM-PK models had the most accuracy in the groundwater level prediction.
Keywords: *groundwater level prediction, multi-linear regression, support vector machines, adaptive neural fuzzy inference system, radial basis neural network*

Introduction

Groundwater level (GWL) drops due to excessive water withdrawal are serious threats to the sustainability of drinking water basins. Due to global warming and the growing population, the increase in agricultural activities negatively affects the groundwater especially in rural areas. In Turkey, many basins are experiencing problems in terms of the groundwater potential. Increasing water demand, adverse conditions created by climate change and lack of planning related to underground water management in the basin have increased these problems. There are a number of studies that have examined groundwater level reductions due to various reasons. In the field of hydrology, models of groundwater level require knowledge or estimation of the hydrologic parameters of the basin. Prediction of groundwater level is important for effective planning and sustainable groundwater management.

In recent years, artificial intelligence approaches have been widely used in water resource management and hydrological projects (e.g., Kaya et al., 2011, 2016; Mohanty et al., 2013; Li et al., 2012; Shiri et al., 2013; Demirci and Baltaci, 2013; Üneş et al., 2015a, b, 2017; Demirci et al., 2015a, b; Tasar et al., 2017, 2018; Feng and Tian, 2018; Yılmaz et al., 2018; Kankal et al., 2018; Nacar et al., 2018; Wunsch et al., 2018).

Many investigations have been also conducted to predict groundwater level fluctuations with using artificial intelligence techniques. Emamgholizadeh et al. (2014) studied the potential of artificial neural network (ANN) and adaptive neural fuzzy inference (ANFIS) for the groundwater levels (GWL) predictions. Heesung et al. (2011) studied two nonlinear time-series models for predicting the groundwater level (GWL) fluctuations using ANNs and SVM. Nourani et al. (2015) used feed-forward neural network (FFNN), Auto Regressive Moving Average (ARIMAX) models for GWL forecasting of the plain of

DOI: http://dx.doi.org/10.15666/aeer/1702_26512663

Ardabil, Northwestern Iran. Guzman et al. (2015) used Artificial Neural Networks (ANN) and Support Vector Regression (SVR) in daily groundwater levels predictions. According to their results ANN and SVR have good accuracy to predict daily groundwater levels. Yoon et al. (2016) used a weighted error function approach to improve the performance of artificial neural network (ANN)- and support vector machine (SVM)-based recursive prediction models for the long-term prediction of groundwater levels in response to rainfall. Zhou et al. (2017) proposed a data-driven prediction model combining discrete wavelet transform (DWT) preprocess and support vector machine (SVM) for groundwater depth forecasting. Ebrahimi and Rajaee (2017) investigated the effect of wavelet analysis of ANN, MLR and SVR approaches using GWL data which recorded over in the Qom plain, Iran. Zare and Koch (2018) used new hybrid Wavelet-ANFIS model with several combinations of inputs and mother wavelets to simulate and predict GWL-fluctuations in the Miandarband plain, Iran. The results showed that all model approaches could be used with acceptable accuracy. Other authors also found that artificial neural network in general are exceptionally well suited to predict groundwater levels for different geological settings (Coulibaly et al., 2001; Nayak et al., 2006; Mohammadi, 2008; Sreekanth et al., 2009; Adamowski and Chan, 2011; Trichakis et al., 2011; Chitsazan et al., 2015; Khalil et al., 2015; Chang et al., 2016; Bargezar et al., 2017; Yu et al., 2018).

The main purpose of the present study is to analyze the performance of the MLR, ANFIS, RBNN, SVM-RBF and SVM-PK techniques in monthly groundwater level forecasting using the Monthly Mean Precipitation (MP), Monthly Average Temperature (MT), Monthly Ground Water Level (GWL+1) data. The predictions of the models were compared with those of observed values using te statistical analysis. The monthly groundwater level data measured from DSI (Turkish General of State Hydraulic Works) between 2000 and 2015 and the monthly total precipitation and monthly average temperature data recorded by Antakya Meteorological Station were used to determine groundwater level.

Material and methods

Study area

In this study, groundwater level of Reyhanlı region on Amik plain is studied (*Fig. 1*). Amik plain is the most efficient plain of Turkey in terms of productivity. It is covered with thick alluvial soil layer and is known as the most efficient basin in terms of agricultural potential. It forms the largest flat land of Hatay Province. Amik Plain nourishes its soil primarily with Asi River, Afrin and Karasu Stream. The plain which locates in the basin of Asi has an area of approximately 65 000 ha. The groundwater level in Amik Plain reduces by approximately 5-6 m each year. Due to drying of Amik Lake, global climate changes and unconscious irrigation, there is a very serious water shortage in the plain which lead to several problems especially for farmers. For these reasons, using existing water resources more effectively has become inevitable.

The DSI observation-well with number 15768 used in the present study is in Reyhanlı region and located at 36.2685 latitude and 36.5676 longitude. It has a depth of 50 m. The monthly groundwater level data taken from DSI (Turkish General of State Hydraulic Works) data and the monthly total precipitation and monthly average temperature data recorded by Antakya Meteorological Station were used to determine groundwater level. Models were carried out using 192 data of monthly ground water level, monthly total precipitation and monthly average temperature values measured for 16 years.

DOI: http://dx.doi.org/10.15666/aeer/1702_26512663

Figure 1. Location of Reyhanlı region

The monthly groundwater level fluctuation between the years 2000 and 2015 is shown in *Figure 2*. In the Reyhanlı region, generally, high precipitations occur in early and end of spring. However, drought is observed in the summer months. It is observed that consequent groundwater level fluctuations are entirely dependent on meteorological conditions, which affect the drainage basin. It can be seen from this figure that the vertical axis of *Figure 2* shows well gauge readings located in Amik region and the level fluctuations range in the order of 27 m.

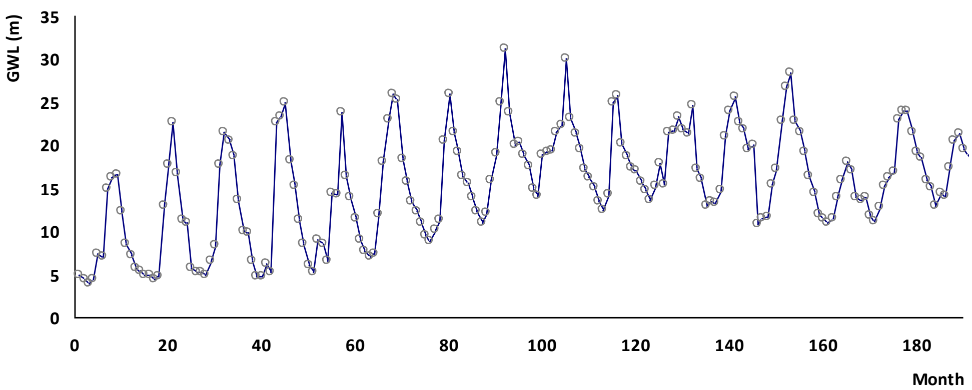

Figure 2. *Groundwater level fluctuations of Reyhanlı region between the years 2000 and 2015*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26512663

In all of the models, Monthly Mean Precipitation (MP), Monthly Average Temperature (MT), Monthly Groundwater Level (GWL+1) were used for estimating of the Ground Water Level fluctuations. The models are first trained by using the first set of data, namely training data comprising the first 144 data of 192 months' observations. Once the training stage was completed, the models were applied to the testing data which comprise the last remaining 48 months' observations. For applied each model, the mean square error (MSE), mean absolute error (MAE), and the determination coefficient between the model estimations and the observed values are computed. The results are used to compare the performance between model prediction and observed well data. The MSE and MAE are given as in *Equations 1* and *2:*

$$MSE = \frac{1}{N}\left(\sum_{i=1}^{N} Yi_{observed} - Yi_{forecast}\right)^2 \tag{Eq.1}$$

$$MAE = \frac{1}{N}\sum_{i=1}^{N}\left|Yi_{observed} - Yi_{forecast}\right| \tag{Eq.2}$$

where N and Yi denote the number of data sets, groundwater level data respectively. Different number of input combinations were tried for the best performance of using models were compared with each other.

Multiple-linear regression (MLR)

This method is used to find out how much a dependent variable is affected and the value of the independent variables in which it is affected and associated.

In multiple regression analysis, dependent variable y indicates the relationship between independent variables $x_1, x_2, ..., x_p$ and it can be written as in *Equation 3:*

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + ... + \beta_j x_j + ... + \beta_p x_p + \varepsilon \tag{Eq.3}$$

Here, β_0, β_1, β_2, β_j, .., βp are called the regression coefficients. Any βj regression coefficient gives the expected change in the y variable versus a unit change in the xj variable when other variables are kept constant (when the effect of the other variables is eliminated).

Adaptive neural fuzzy inference system (ANFIS)

Fuzzy rules are expressed in form of if-then statements between system inputs and outputs depending on the linguistic variables. ANFIS was first represented by Jang (1993). ANFIS works by a learning algorithm derived from neural network functional rules. The parameters of the fuzzy inference system are determined by the neural network learning algorithms in a fuzzy rule-based system. Fuzzy Inferences System can be classified into two types; Mamdani's system and Sugeno's system. ANFIS techniques are based on the Sugeno's system. ANFIS with Sugeno type works according to "If-Then" rule and the ANFIS structure uses the Sugeno-Fuzzy rules.

The Sugeno NF system, generated by two rules using three inputs, is shown in *Figure 3a*. Where, w_1 or w_2 is obtained by weighted mean of individual rule outputs. NF

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26512663

structure is shown in *Figure 3b*. NF is connected via directional links and contains several nodes. Every node has a node function that can be constant or adjustable parameters. In the figures, A_1, B_1, C_1 and A_2, B_2, C_2 are linguistic labels (such as “low”, “medium” or “high”), f_1 and f_2 denote, respectively, output functions of 1. and 2. rule, $\{p_i, q_i, r_i, s\}$ specified as result parameters. Sugeno’s system is more compact and computationally more efficient (Jang, 1993). For more information, it can be looked at Jang (1993).

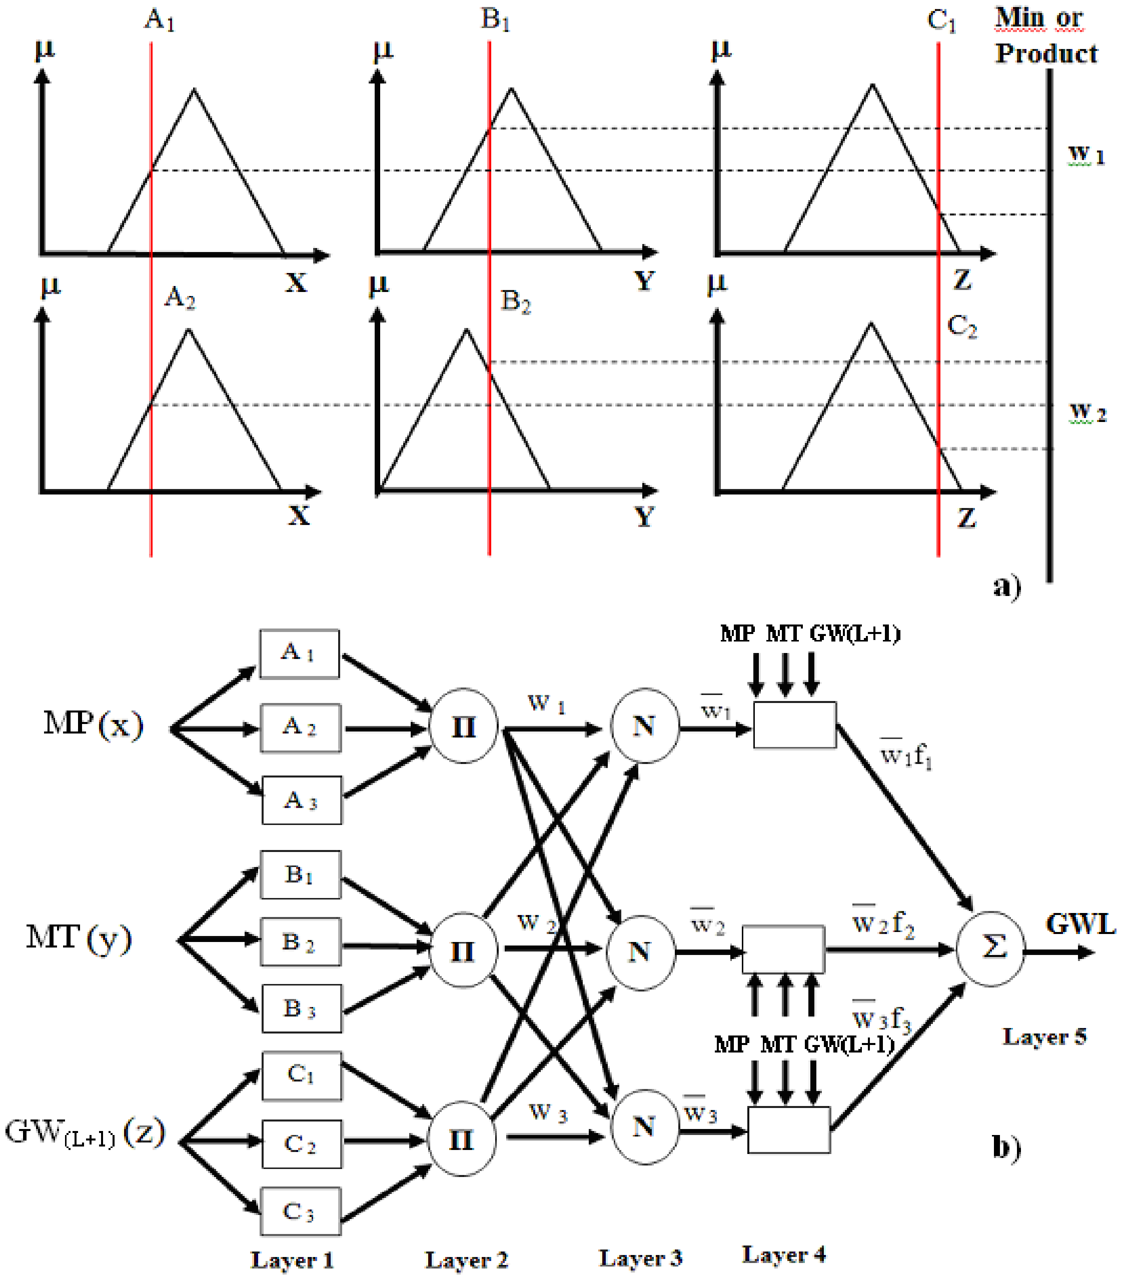

Figure 3. a *Sugeno type fuzzy model.* ***b*** *Neuro-fuzzy (NF) system structure for three inputs. In this presented fuzzy model, input data were taken as monthly mean precipitation (MP), monthly average temperature (MT), monthly ground water level (GWL+1), and ground water level (GWL) were estimated as output data*

Radial basis neural network (RBNN)

Radial basis neural network was first presented into the ANN literature by Broomhead and Lowe (1988). The RBNN models consist of two layers whose output nodes form a linear combination of the basis functions. The learning scheme of RBNN is fundamentally different from that of the feed-forward ANN. The RBNN assumes a radially symmetric function, typically the Gaussian function, for its hidden units. The relation between inputs and outputs is demonstrated in *Figure 4*. Detailed information about RBNN theory can be found in the works of Haykin (1998).

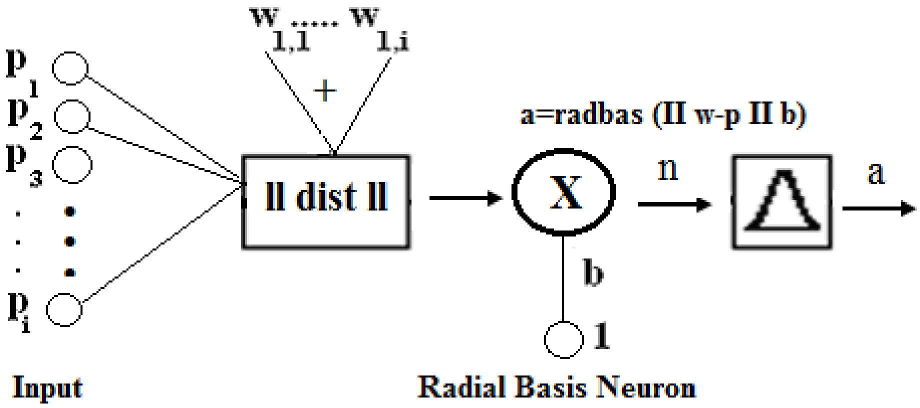

Figure 4. *Schematic representations of RBNN*

In *Figure 4,* the net input to the radbas transfer function is the vector distance between its weight vector w_i and the input vector p_i, multiplied by the bias b. The || dist || box in this figure accepts the input vector p and the single row input weight matrix, and produces the dot product of the two. The radial basis function has a maximum of 1 when its input is 0. As the distance between w and p decreases, the output increases. Thus, a radial basis neuron acts as a detector that produces 1 whenever the input p is identical to its weight vector w. The transfer function for a radial basis neuron is given as *Equation 4:*

$$radbas(n)= e^{-n^2} \quad \text{(Eq.4)}$$

Support vector machines (SVM)

The SVM has become a relatively novel and promising estimator in data-driven research fields, of which basic concept and theory have been introduced by Vapnik (1998). The generalization ability of the SVM is considered to be better than ANN, in the sense that it is based on the structural risk minimization rather than the empirical risk minimization of ANN. The main process of SVM model building consists of selecting support vectors which support the model structure and determining their weights. *Figure 5* shows the SVM models schematic representations. The idea behind SVM is to find a hyperplane that separates two classes in the transformed feature (input) space with a maximum distance. SVM aims to find the optimal regression hyperplane, that all training samples lay within an ε-margin around it and is also as flat as possible (Schölkopf and Smola, 2002). SVM models are closely related to artificial neural

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26512663

networks and use a sigmoid kernel function while having a two-layer, forward-feed artificial neural network (Haykin, 1998).

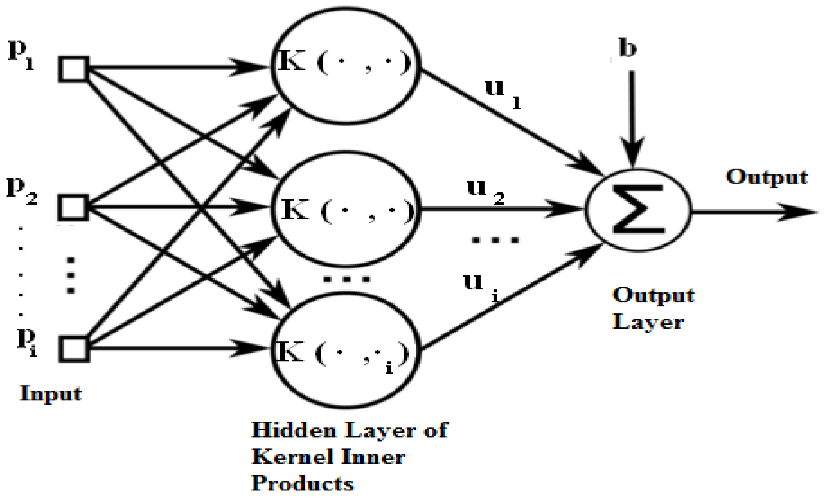

Figure 5. *Schematic representations of SVM*

An interesting feature of SVM is that by minimizing the average error rate on the data set from the empirical risk minimization principle derived, statistical learning can be achieved.

SVM defines how to draw this boundary between variable groups. SVM studies according to statistical learning theory. A set of training data [(p_1, y_1), (p_2, y_2),..... (p_n, y_n)], where "p_i" value indicates the input space of the sample and has a corresponding target "y_i" value.

The SVM function is expressed as in *Equation 5:*

$$y = (K_{pi}.W_{jk}) + b \qquad \text{(Eq.5)}$$

where the Kernel function is K_{pi}, b is bias term of SVM network and W_{jk} is called as the Lagrange multipliers that obtain the significance of the training data sets for the output data. The kernel function of non-linear radial basis (Hsu et al., 2003) is in *Equation 6:*

$$K_{xi} = e^{-\gamma \|p_i - y_i\|^2} \qquad \gamma > 0 \quad \text{and} \quad i = 1,2,3,...n \qquad \text{(Eq.6)}$$

where γ is a user-defined parameter. The kernel function of polynomial (Hsu et al., 2003) is in *Equation 7:*

$$K_{xi} = (p.y + c)^d \qquad i = 1,2,3,...n \qquad \text{(Eq.7)}$$

SVM differs from the other classification methods significantly. Its intent is to create an optimal separating hyperplane between two classes to minimize the generalization error and thereby maximize the margin. SVM is an approximate implementation of structural risk minimization approach. Structural risk minimization method described that the error rate of learning machine on test data is bounded by the sum of training error rate and a term that based on Vapnik–Chervonenkis dimension (Haykin, 1998).

Results and discussion

In order to demonstrate the models capability for predicting groundwater level variations, this section will discuss the validation process of the optimal MLR, RBNN, RBNN, SVM-PK and SVM-RBF models. The correlation coefficient (R), mean square error (MSE) and absolute mean error (MAE) for the performance evaluation of all models are calculated. Comparison parameters of MSE, MAE and R obtained from testing data are shown in *Table 1*. Results are used to compare the performance of model prediction and the observation data.

In *Figure 6a,* results of MLR model shows that the correlation coefficient is high and the groundwater level estimate is closer to the actual values. MLR models performed less efficiently than the other models based on MSE, MAE and R (5.44-1.73-0.84) criteria shown in *Table 1*.

For RBNN model, the distribution and scatter graphs are shown in *Figure 6b*. When scatter graphs for testing data are analyzed, RBNN model results also showed a good performance. RBNN estimated values are close to the actual values. Correlation coefficient was obtained as R = 0.88. According to the MSE, MAE and R (4.64, 1.62, 0.88) criteria, compared to MLR model, the RBNN model results showed better performance.

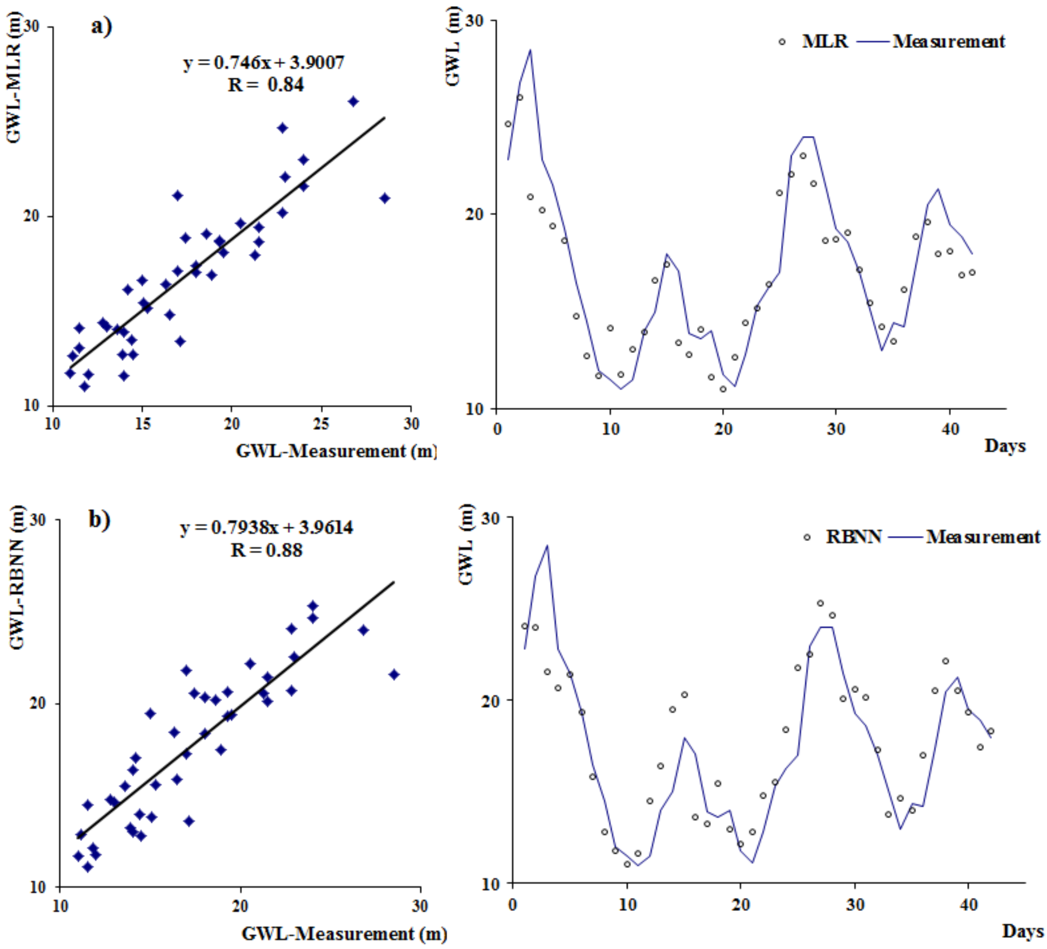

Figure 6. ***a*** *Measurement and MLR model scatter and distribution.* ***b*** *Measurement and RBNN model scatter and distribution*

16 years data were evaluated for ANFIS model, and the results are defined as follows. In ANFIS models, distribution and scatter graphs for testing data are shown in *Figure 7a*. Correlation coefficient were obtained as R = 0.87. When distribution and scatter charts are analyzed, estimated values are close to the actual values and ANFIS results showed similar results according to RBNN results. When we looked MSE, MAE and R (4.82-1.63-0.87) criteria values shown in *Table 1,* The ANFIS estimated values gave better results than the MLR values

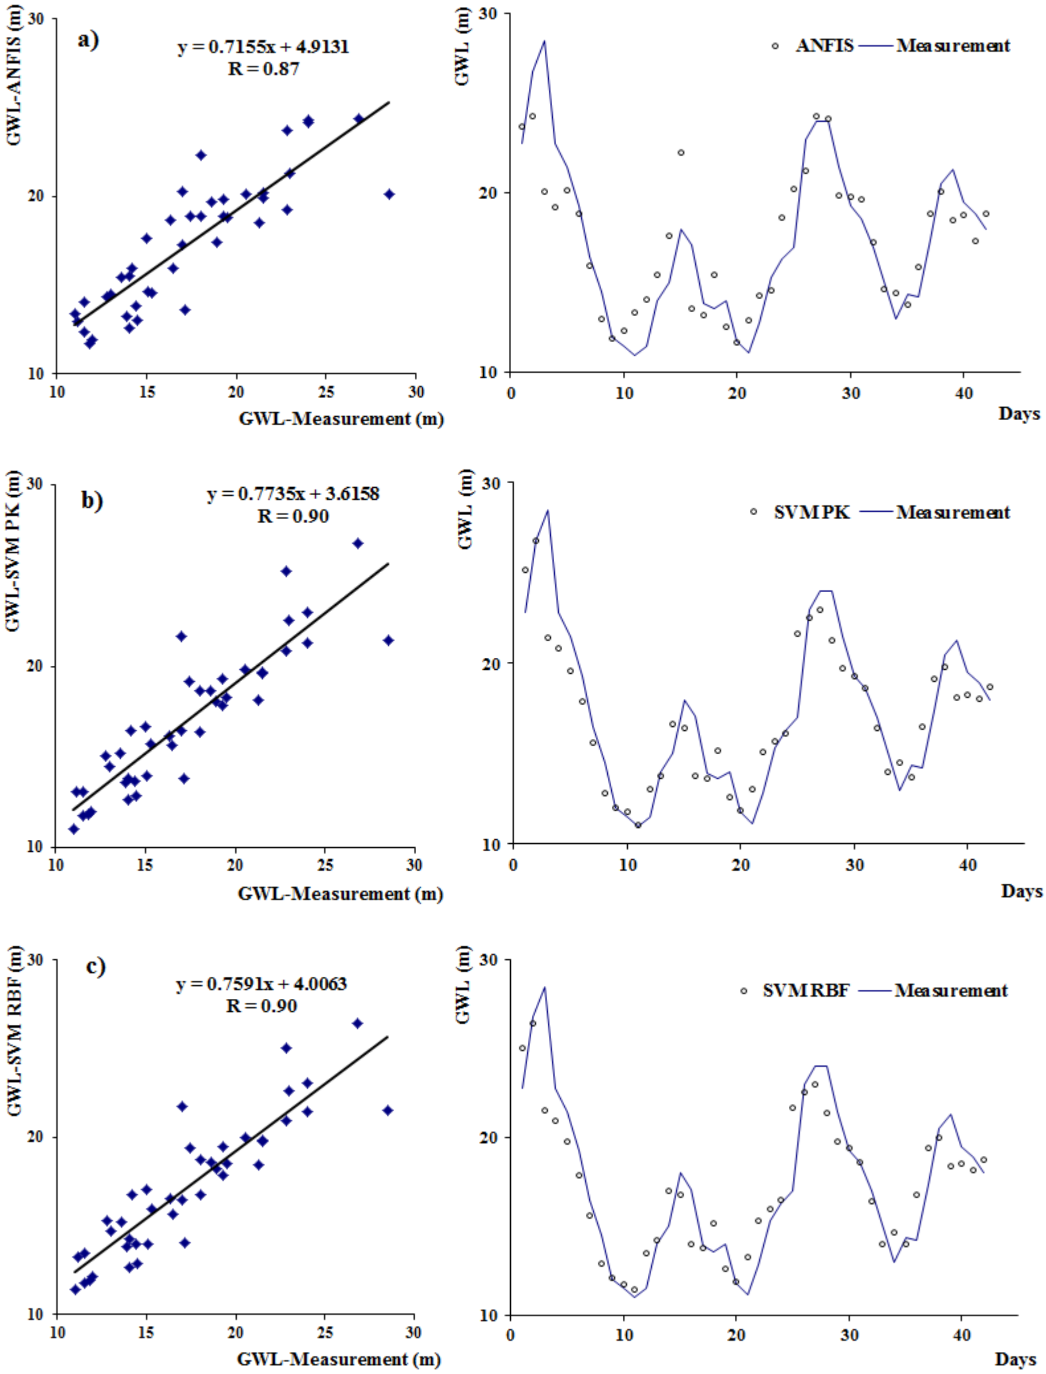

Figure 7. ***a*** *Measurement and ANFIS model scatter and distribution.* ***b*** *Measurement and SVM-PK model scatter and distribution.* ***c*** *Measurement and SVM-RBF model scatter and distribution*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26512663

Table 1. *Model results according to statistical criteria*

MODELS	INPUTS	MSE	MAE	R
MLR	MP,MT, GWL(L+1)	5.44	1.73	0.84
RBNN	MP,MT, GWL(L+1)	4.64	1.62	0.88
ANFIS	MP,MT, GWL(L+1)	4.82	1.63	0.87
SVM-PK	MP,MT, GWL(L+1)	3.81	1.41	0.90
SVM-RBF	MP,MT, GWL(L+1)	3.78	1.42	0.90

MSE: mean square error, MAE: mean absolute error, R: correlation coefficient, MP: monthly mean precipitation, MT: monthly average temperature, GWL+1: monthly groundwater level

The SVM Poly Kernels (SVM-PK) and SVM Radial Bases Function (SVM-RBF) models were also applied to estimate the ground water level. Estimated testing results for SVM models are shown in *Figure 7b* and *c*. The SVM Poly Kernels (SVM-PK) and SVM Radial Bases Function (SVM-RBF) estimated values gave closer results according to the RBNN values. The correlation coefficient was obtained for both model to be R = 0.90 as seen in *Figure 7b* and *c*. SVM model results data are close to the actual values shown in figures. As seen from the scatter plots, the SVM model estimates are less scattered in relation to the other models.

According to MSE, MAE and R, the MLR (5.44-1.73-0.84) model has the lowest success rate. ANFIS approach (4.82-1.63-0.87) and RBNN approach (4.64-1.62-0.88) have the higher success rate than the MLR model. SVM-PK (3.81-1.41-0.90) and SVM-RBF (3.78-1.42-0.890) models were found to perform better than the other models at all performance evaluations.

Conclusions

In this study, groundwater level fluctuations of Reyhanlı region in Turkey were predicted with using MLR, ANFIS, RBNN, SVM-RBF and SVM-PK approaches.

The accuracy of all models in groundwater level estimation was also investigated, and the results were compared with each other model. Comparisons revealed that the SVM –RBF and SVM-PK had the closer accuracy in the groundwater level prediction. In general, MLR model has the smaller lowest success rate. ANFIS and RBNN models gave better results than the MLR model. According to the MSE, MAE and R criteria, the best results were obtained in SVM-RBF and SVM-PK models. The results of the case study are satisfactory and demonstrate that SVM-RBF and SVM-PK models can be a useful prediction tool in the area of groundwater hydrology.

It is recommended for future studies that authors should study the use of new methods of artificial intelligence techniques in daily, weekly, or yearly groundwater level forecasting for different geographical regions.

(Received 22nd Nov 2018; accepted 25th Jan 2019)

Abstract. This study was conducted to determine the effect of Phosphorus (P) i.e. (P_0= Control, P_{40}= 40, P_{80}= 80, and P_{120}= 120 kg ha^{-1}) and Zinc (Zn) i.e. (Zn_0= Control, Zn_{05}= 5, Zn_{10}= 10, and Zn_{15}= 15 kg ha^{-1}) on yield and on some agronomic characteristics of cotton (*Gossypium hirsutum* L.) Adiyaman, Turkey. The field experiments were arranged in a randomized complete block with a split plot design with three replications in years of 2011 and 2012. P and Zn treatments were applied in main and sub-plots, respectively. Cotton cultivar of Stoneville-453 was used in the experiment. Based on the results, phosphorus and zinc applications increased the seed cotton yield. The highest plant height was obtained from the interaction of P_{80} x Zn_5 and the highest number of bolls was taken from the interaction of P_{80} x Zn_{10}. In terms of the number of monopodial branches, statistically significant differences were found in both years, but this significance was not stable over the years. It was concluded that the combined treatments of phosphorus and zinc did not have a significant effect on the boll weight, boll seed cotton weight and ginning outturn. The effect of fertilizers on the number of sympodial branches and 100 seed weight were significant in the first year but not significant in the second year.
Keywords: *sympodial branch, agronomic traits, ginning, interaction, replications*

Introduction and literature review

In addition to being the main source of natural fiber, cotton is a plant that has an important place in global agriculture and trade with its oil, meal, and other by-products obtained from its seed. Cottonseed pulp is also used in animal nutrition. Along with the developing textile industry, the importance of cotton production in the world economy is increasing gradually. Fertilizer is an important input in cotton production and it has become a necessity for farmers to use for a profitable production. An important component of profitable cotton production is an adequate and balanced fertilization. In the case of cotton and most plants various yields are obtained due to the various growing conditions in different regions. It is necessary to apply cultural measures such as fertilization, tillage, and diseases and pest control as well as sowing, seedbed preparation, and other managements for higher yielding.

Today, the most applied fertilizer of cotton plant is nitrogen, the second one, phosphorus (P) is also one of the essential elements for plant development. Zinc and Phosphorus are important plant nutrients affecting plant growth directly. Phosphorus increases boll development by affecting the flower formation and fertilization biology in cotton. Despite the continuous addition of phosphorus from the organic and inorganic sources to the heavily cultivated soils, the phosphorus level of the soil is insufficient for profitable crop production. P is an essential element for metabolic functions and vital structures in plants. It is especially vital in early root development, photosynthesis, cell division, energy transfer, early boll development and early maturity (Stewart, 1998).

Phosphorus deficiency leads to deterioration of plant membranes and decreases energy transfer in the plant (Oosterhuis et al., 2007). P deficiency is one of the most

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26652676

important factors limiting the yield in plant production, especially in calcareous alkaline soils. Particularly above pH 7, phosphorus in the soil is fixed by cations such as calcium in the soil to form insoluble salts (Zhou et al., 2001). The phosphorus, which turns into salt, becomes useless for the plants (Castro and Torrent, 1995).

Phosphorous fertilizers, unlike nitrogen fertilizers, are fixed very tightly in the soil. Plants rarely intake more than 20% of the applied phosphorus. However, this rate is as high as 60% in nitrogen. Phosphorous fertilizers turn out to be beneficial for plants faster in soils with a pH of 5.5-7. The plant cannot sufficiently utilize it, as it is fixed too tightly under these pH degrees. These fertilizers are more beneficial when supplied with lime to acidic soils. As the lime prevents phosphorus to be fixed by minerals like iron and aluminum (Aydemir, 1982).

Phosphorous fertilizers can affect significantly the increase of the number of flowers and bolls, the size of bolls, and early maturity rather than the vegetative growth of cotton. It is claimed that phosphorus helps blooming, bearing fruits, and increases the yield in cotton, and that phosphorus deficiency in the soil results in the reduction of plant height as well as seed cotton yield by 30% (Şenel, 1980).

Crop yield is limited by the low levels of micronutrient minerals such as zinc (Zn) especially in arid and semi-arid regions of calcareous soils (Cakmak et al., 1999). Zinc is the most preferred micronutrient element to cotton. That is important in regulating the chlorophyll content and assimilation rate of the cotton leaf (Weir et al., 1996). Zinc plays an important role in some enzyme systems and catalyzes the process of disintegration in the plant cell. Moreover, it is also vital in the structural change of carbohydrates, chlorophyll formation and growth-promoting substances. Zinc also prevents withering by promoting water intake (Price, 1970). It was reported that the critical limit of zinc in the field soil is 0.5 ppm (Linsday and Norwel, 1978), and application of zinc as $ZnSO_4$ increases seed cotton yield significantly comparing non-applied control plot and a 25 kg ha^{-1} $ZnSO_4$ application gives the highest yield (Sharma and Gupta, 1988), furthermore, NPK+Zn application significantly increases the seed cotton yield and the number of bolls (Prasad and Prasad, 1994). 44 and 75 kg ha^{-1} phosphorous fertilization with 40 ppm foliar zinc application 75 and 90 days after sowing resulted in an increase in the number of bolls, boll weight, 100 seed weight, and seed cotton yield in cotton plants (Sawan et al., 1997). In addition, Soomro et al. (2000) also reported that due to a 5 kg ha^{-1} zinc sulfate application the cotton increased the number of bolls, boll weight, seed index, and seed cotton yield compared to the control. Zinc treatment was reported to increase the cotton yield compared to the control (Sawan et al., 2001) and phosphorus and zinc applications increase100 seed weight, seed cotton yield, and fiber yield (Elwan et al., 2002). Nevertheless, it was also stated that zinc application increased plant height the same treatment in soil with high pH and phosphorus content did not affect the yield (Ören and Başal, 2006). Panayotova et al. (2017) observed that 0, 40, 80, 120, and 160 kg ha^{-1} P applications, increased the seed cotton yield from 5.02 to 11.71%, the number of bolls from 3.0 to 25.9%, and plant height significantly.

Foliar zinc application twice i.e. (0 and 58 g ha^{-1}) 70 and 85 days after sowing, and the foliar phosphorus application twice i.e. (control, 576, 1152, and 1728 g ha^{-1}) 80 and 95 days after sowing increased seed cotton yield, number of bolls, 100 seed weight, and fiber yield (Sawan et al., 2008). Zinc treatments of the 0, 5, 7.5, 10, and 12.5 kg ha^{-1} doses a 7.5 kg ha^{-1} was stated to be the most effective zinc dose, and this zinc ratio increased 100 seed weight and seed cotton yield (Ahmed et al., 2010).

This study aimed to assess the effect of phosphorus and zinc applications on the yield and agronomic characteristic of cotton in South East Anatolia.

Materials and methods

Field trials were carried out in zinc deficient soils of Old Hosni Mansur (Eskihüsnümansur) village of Adiyaman in Turkey in 2011 and 2012 growing seasons. Stoneville 453 cotton cultivar was employed as plant material.

Field trials were set up at the same location in both years, but on the different parts of experimental field showing Zn deficiency. Some soil properties of the experimental area were given in *Table 1*.

Table 1. *Soil properties of the field*

Soil properties	2011	2012

Adiyaman is located at the transitional zone between coastal and continental climate conditions. Adiyaman province is located at 37°45’ north latitude and 38°16’ east longitude with an altitude of 672 m. Field trials were located at 37°41’47’ north latitude 38°20’55’ east longitude with a 547 m altitude from sea level (*Figure 1*).

Anonymous, 2012b

In the field trials, phosphorus (Triple Super Phosphate), and zinc sulfate heptahydrate ($ZnSO_4.7H_2O$) (22%) were used as treatments. The experiments were carried out by split plot in randomized complete blocks with 3 replications. P doses i.e. (P_0= Control, P_{40}= 40, P_{80}= 80, and P_{120}= 120 kg ha^{-1}) formed main plots and Zn treatments i.e. (Zn_0= Control, Zn_{05}= 5, Zn_{10}= 10, and Zn_{15}= 15 kg ha^{-1}) formed sub-plots. Each plot had a length of 12 m and consisted of 6 rows. There were 2 m alleys between plots, and 3 m between blocks 70 cm inter rows and 15 cm intra row spacing were allowed. Sowing was practiced on 22nd April in 2011, and 27th April in 2012, by a pneumatic drill. In total, a 160 kg ha^{-1} pure nitrogen was applied. Half of the nitrogen was given during the sowing and the remaining half was given by the lister tool just before the first irrigation. All of the phosphorus was given during the sowing by drill and the Zinc sulfate heptahydrate ($ZnSO_4.7H_2O$) was manually given into neighboring rows located 5-6 cm apart and depth from cotton seeded rows.

Irrigation was practiced seven times in 2011 and 8 times in 2012 applying 840 mm and 960 mm for consecutive years, respectively. Furrow irrigation method was performed. Agronomic managements were carried out based on common practices employed in the region. No spraying was carried out against pests in either year.

Seed cotton harvests were done manually (handpicking) on 23th September 2011 and 17th September 2012, respectively. Seed cotton yield (kg plot^{-1}) was scored taking into account two rows in the middle of 10 meters in each plot (10 m x 1.4 m = 14 m^2) excluding the one-meter area from both ends of the plot. The ginning outturn (%) was determined by the ginning of 0.5 kg of seed cotton collected from each plot. Plant height (cm), number of monopodial branches (per plant^{-1}), number of sympodial branches (per plant^{-1}), and number of bolls (per plant^{-1}) were calculated by scoring in 10 randomly selected plants in each plot. Boll weight (g), boll seed cotton weight (g) and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26652676

100 seed weight (g) were scored by employing 35 boll samples randomly selected from plots just before harvest (Worley et al., 1976).

The data obtained from the experiment was analyzed by using the MINITAB 18 (Minitab Inc., USA) statistical software and analysis of variance was performed according to the split plot test in randomized complete block design and the means were grouped by the Tukey HSD ($p \leq 0.05$) test.

Results and Discussion

In the analysis of variance (ANOVA) according to the combined years of the properties examined in the trial, statistical differences were found between years. Due to that the results of each year were analyzed separately.

F values obtained from the analysis of variance of the traits under study in the experiment were given in *Table 3*.

Table 3. *Statistical significance (F) of some traits in the ANOVA*

Seed cotton yield (kg ha^{-1}), plant height (cm), number of monopodial branches (no. $plant^{-1}$), number of sympodial branches (no. $plant^{-1}$), number of bolls (no. $plant^{-1}$), boll weight (g), boll seed cotton weight (g), ginning outturn (%) and 100 seed weight (g) were given in *Tables 4, 5 and 6*.

Seed Cotton Yield (kg ha^{-1})

Table 4 showed that the lowest seed cotton yield in 2011 was obtained from the control plot of P_0 x Zn_0 with as 3401 kg ha^{-1} and the highest yield was provided by the P_{120} x Zn_{15} interaction with 4595 kg ha^{-1}, while the lowest seed cotton yield in 2012 was again obtained from the control plot, of P_0 x Zn_0, with 2993 kg ha^{-1} and the highest yield was provided by the P_8xZn_1 interaction with 4189 kg ha^{-1}.

The lowest yield provided by the control plots in both years showed that phosphorus and zinc had some positive effects on yield. However, the highest yield varied in both years, and this fluctuation was based on various climatic and soil factors.

Sawan et al. (2006) found that phosphorus application at three concentrations (i.e. 600, 1200, and 1800 ppm P) significantly increased the seed cotton yield compared to control (9.49% -17.12%). Meanwhile, Singh et al. (2013) indicated that phosphate deficiency decreased plant growth and photosynthesis, thereby reduced biomass

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26652676

accumulation and yield. Russell (2001) claimed that phosphorus, as part of the cell nucleus, was important for cell division and the development of meristematic tissue, and therefore had a stimulating effect to increase the number of bolls and flowers per plant.

*Means followed by different letters within columns are significantly different ($p \leq 0.05$)

Zinc might have a positive effect on the photosynthetic activity of leaves (Welch, 1995), which enhances the mobilization of photosynthetic assimilates and directly affected the boll weight. In addition, zinc was required for the synthesis of tryptophan, a precursor of indole-3-acetic acid (Oosterhuis et al., 1991). This is the main hormone that prevents the separation of bolls and bract leaves of the plant. Thus, this increases the number of bolls in the plant, consequently, the seed cotton yield (Rathinavel et al., 2000).

Similar findings suggested that zinc and phosphorus applications increased the seed cotton yield (Sharma and Gupta, 1988; Sawan et al., 1997, 2001; Soomro et al., 2000; Elwan et al., 2002; Mamatha, 2007; Ahmad et al., 2009; Ahmed et al., 2010; Saleem et al., 2010; Emara, 2016; Sawan, 2018).

Plant Height (cm)

Table 4 showed that the lowest plant height in 2011 was obtained from the control plot of P_0 x Zn_0, with 74.4 cm and the highest plant height was provided by the P_{80} x Zn_5 interaction with 82.4 cm, while the lowest plant height in 2012 was obtained from the plot P_{80} x Zn_0 with 64.2 cm and the highest plant height was provided by the control plot of P_0 x Zn_0 and the plot of P_{80} x Zn_5 interaction with 73.8 cm and 73.3 cm, respectively.

The results revealed that phosphorus and zinc had a statistically significant effect on plant height. The P_{80} x Zn_5 interaction taking the first rank in both years indicated that this treatment increased plant height. This result is supported by the Neilsen and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26652676

Hogue's (1986) finding claiming that in phosphorous-rich soils phosphate had low solubility forms, such as the compound $Zn_3(PO_4)_3$ which prevents the transport of zinc to the above-ground organs of the plant, hence, the growth decreases due to the lesser amounts of Zn in the plant tops. Ören and Başal (2012) and Mamatha (2007) observed that zinc applications and Saleem et al. (2010) observed that P applications increased plant height compared to control.

Monopodial Branches (Per Plant)

Table 4 showed that some statistically significant differences were found in both years of experiment in terms of the number of monopodial branches. In 2011, the lowest number of monopodial branches was in P_{80} x Zn_{15} (0.7 per plant) interaction and the highest number was in P_{80} x Zn_{10} (1.4 per plant) and P_{120} x Zn_5 (1.4 per plant). In 2012, the lowest number of monopodial branches was obtained from P_0 x Zn_5 (0.1 per plant) interaction, while the highest number of monopodial branches was obtained from P_0 x Zn_0 (0.5 per plant) interaction.

In terms of the number of monopodial branches, statistically significant differences were found in both years of experiment. Nonetheless, this difference was not stable but varied depending on years. The difference between the experimental years might be due to soil properties and climatic conditions in the experimental years. Saleem et al. (2010) reported that 90 kg ha^{-1} P application decreased the number of monopodial branches compared to the control.

Sympodial Branches (Per Plant)

Statistically significant differences were in 2011, but no difference was found in 2012. The lowest number of sympodial branches in 2011 was from the P_{40} x Zn_0 (11.5 per plant), while the highest number of that was from the P_{120} x Zn_{15} (14.77 per plant) and P_0 x Zn_5 (14.4 per plant) interactions, whereas in 2012, the lowest number of sympodial branches was obtained from the interaction of P_0 x Zn_5 (7.1 per plant), while the highest number of sympodial branches was obtained from P_8 x $Zn_{0.5}$ and P_8 x Zn_1 (11.2 per plant) interactions (*Table 5*).

The results indicated that phosphorus and zinc applications were important in 2011 but they were non-significant in 2012 for sympodial branches, and this difference derived from climate and soil conditions. This showed that there was no stability derived from the effects of phosphorus and zinc on the number of sympodial branches. Ahmad et al. (2009) and Mamatha (2007) reported that zinc applications, both 34 kg ha^{-1} and 50 kg ha^{-1} increased the number of sympodial branches per plant compared to control.

Number of Bolls (Per Plant)

From *Table 5*, it is evident that the lowest number of bolls occured from P_{40} x Zn_0 (12.7 per plant) interaction and the highest number from P_{80} x Zn_{10} (17.7 per plant) interaction in 2011, while in 2012, the lowest number of bolls was obtained from P_{40} x Zn_5 (8.8 per plant) interactions and the highest number was obtained from P_{80} x Zn_5 (11.40 per plant) and P_{80} x Zn_{10} (11.0 per plant) interactions.

These results revealed that phosphorus and zinc interaction had a statistically significant effect on the number of bolls and the highest effect was obtained from the interactions of P_{80} x Zn_5 and P_{80} x Zn_{10}. Phosphorus and zinc applications can lead to an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26652676

increase in the number of bolls by having a positive effect on flower formation and fertilization biology. The results in the current study number of bolls was similar to that from Prasad and Prasad (1994), Sawan et al. (1997), Soomro et al. (2000), Sawan et al. (2008), and Emara (2016). Furthermore, Ahmad et al. (2009) reported that phosphorus application of 34 kg ha^{-1} increases the number of bolls and Mamatha (2007) showed that 50 kg ha^{-1} of zinc application increased the number of bolls by 18.88% compared to control.

Boll Weight (g)

In 2011 and 2012, no significant effect of phosphorus and zinc on the weight of bolls was found (*Table 5*). Boll weights ranged from 5.9 to 6.4 g in both years of experiment. Therefore, it can be concluded that phosphorus and zinc had no significant effect on the weight of bolls in the present study.

Nonetheless, these results in terms of boll weight contradict partially with that of Soomro et al. (2000), Mamatha (2007), and Emara (2016) regarding zinc applications increase the weight of bolls. This may be due to the various cultivars employed in the study and zinc and phosphorus doses used in the trials.

Boll Seed Cotton Weight (g)

In both years, no statistically significant effect of phosphorus and zinc applications on the weight of boll seed cotton was found (*Table 6*). Boll seed cotton weights varied from 4.8 g to 5.4 g. These results showed that phosphorus and zinc had no significant effect on the weight of boll seed cotton.

DOI: http://dx.doi.org/10.15666/aeer/1702_26652676

Ginning Outturn (%)

From *Table 6*, no statistically significant effect of phosphorus and zinc on ginning outturn was found in 2011 and 2012. The ginning outturn in 2011 and 2012 varied from 40.8 to 42.3%. These results revealed that phosphorus and zinc had no a significant effect on ginnıng outturn.

Table 6. *Means and the groups of boll seed cotton weight (g), ginning outturn (%) and 100 seed weight (g)*

Similar results were reported by Emara (2016) that zinc had no significant effect on ginning outturn. However, Mamatha (2007) observed that zinc application increased the ginning outturn while Ahmad et al. (2009) reported that phosphorus had little effect on ginning outturn. This might be due to the differences in the plant material and the doses of zinc and phosphorus used in the experiments. In addition, climatic conditions might affect the formation and development of fibers and might influence the formation of various Zinc and P ginning outturns.

100 Seed Weight (g)

It was observed in *Table 6* that there were differences among factors affecting 100 seed weight only in 2011 but not in 2012. In 2011, the lowest 100 seed weight was obtained from the interaction of P_{80} x Zn_0 (9.4 g) and the highest 100 seed weight from the interaction of P_{120} x Zn_{15} (10.7 g). In 2012, the 100 seed weight varied from 9.5 g to 10.6 g. The presence of the difference between the years might be due to climate and soil factors. Sawan et al. (2001) and Emara (2016) reported that Zn applications increased 100 seed weight. In this case, the increase in 100 seed weight might be due to increasing photosynthesis activity by Zn application (Welch, 1995).

Conclusion

Mineral nutrients are one of the most important factor affecting plant growth by contributing the formation of dry matter by affecting the biochemical processes occurring in plants. It was found that phosphorus and zinc management had a significant effect on seed cotton yield, plant height, number of bolls, and number of monopodial branches in both years of the experiment. Both plant nutrients had significant effect on the number of sympodial branches and 100 seed weight only in the first year but not in the second year. These inputs had no significant effect on boll weight, boll seed cotton weight, and ginning outturn in both years.

It was concluded that, depending on the distribution of plant nutrients in the soil, 80-100 kg of phosphorus and 10-15 kg of Zinc applications per hectare can increase in seed cotton yield. Validity of these results must be verified via multi location tests in future studies.

Abstract. This paper presents changes in basic energy parameters of fodder galega (*Galega orientalis* Lam.) cultivated for five years as a potential energy crop under the effect of mineral fertilization. Additionally, the chemical composition of ash obtained after burning the fodder galega biomass was examined for its possible use as a liming agent. The field experiment was conducted between 2005 and 2009 in the experimental plots of the Soil Science and Plant Nutrition Department at the Siedlce University of Natural Sciences and Humanities, Poland (52°17′N and 22°28′E). Five levels of fertilization were included in the study: without fertilization, NP, NK, PK, NPKCa (0 – control, N–20, P–50, K–150, Ca–150 $kg \cdot ha^{-1}$). Significantly highest values of heat of combustion (18.95 $MJ \cdot kg^{-1}$) and calorific value were found for galega fertilized with nitrogen (20 $kg \cdot ha^{-1}$) and potassium (150 $kg \cdot ha^{-1}$). The highest dry matter yields and the highest yield energy value, as well as the most amount of ash obtained from biomass combusting were found for galega harvested from objects fertilized with NPKCa (20; 50; 150; 150 $kg \cdot ha^{-1}$). The content of macroelements in galega ash followed a decreasing sequence of: Ca > K > P >Mg > S > Na.

Keywords: *Galega orientalis Lam., heat of combustion, calorific value, ash, macroelements*

Introduction

In recent years, a great interest in new species of energy crops has been observed all over Europe (An et al., 2018; Drazic et al., 2017; Haines et al., 2015; Jureková et al., 2015; Kalembasa and Symanowicz, 2003; Maw et al., 2017; Tumminello et al., 2018; Wang et al., 2018).

According to the EU Climate and Energy Package of 17.12.2008, by 2020, Member States should reach the level where 20-30% of all energy obtained is from renewable energy sources (Zegada-Lizarazu et al., 2010). The research conducted in central-eastern Poland, concerning adaptation of fodder galega (*Galega orientalis* Lam.), a plant originating from the Caucasus, demonstrated the multi-directionality of its cultivation. It can be cultivated for animal fodder in the form of green forage, silage, dried feed, hay or protein concentrate. This is a perennial, leguminous plant (cultivation for even 16-18 years), rich in macro- and microelements. Biomass of the species can also be co-fired with coal (Brodowska et al., 2018).

The research conducted in the Podlasie region (Kalembasa and Symanowicz, 2003), with the application of ^{15}N isotope, proved the high possibilities demonstrated by fodder galega to biologically reduce atmospheric nitrogen (380 $kg \cdot ha^{-1}$). Preliminary research

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26772687

also showed the possibilities of cultivating fodder galega as an energy crop. Therefore, the introduction of an additional plant, apart from *Miscanthus sacchariflorus, Miscanthus x giganteus* (Jeżowski et al., 2011; Maksimović et al., 2016); *Sweet Sorghum, Maize, HBS* (Maw et al., 2017); *Sorghum hybrids* (Pannacii and Bartolini, 2016); *Salix spp*., (Stolarski, 2008) and *Sida hermaphrodita* (Krzyżaniak et al., 2015) is recommended and related to the possibility of increasing biomass production, with a view to binding atmospheric N_2. An additional benefit is the possibility of using ash from biomass combustion as a liming agent in agriculture. To evaluate the usefulness of biomass for energy purposes, the following values must be examined: moisture, ash content, sulphur content, heat of combustion and calorific value coal (Brodowska et al., 2018). The calorific value of biofuels is 5-8 $MJ \cdot kg^{-1}$ for biomass of 50-60% moisture content, 15-17 $MJ \cdot kg^{-1}$ for pre-dried biomass (15-20% moisture content) and about 20 $MJ \cdot kg^{-1}$ for completely dried biomass.

The potential of biomass production is enormous and is of importance for bioenergy in the future. Eastern galega provide a relatively anknown input feedstock for conversion of biomass into biofuel especially when grown on marginal lands. Field studies carried out 10 years ago are still valid. The search for new potential energy crops, especially perennial with low crop costs, continues (Foster et al., 2017).

The aim of this paper was to determine the optimum conditions for cultivating fodder galega in terms of usefulness for energy purposes and the fertilizing value of ash obtained after biomass combustion.

Material and methods

In the years between 2005 and 2009 the field experiment was set up with a completely randomized method in three replications, on the experimental plots of the Soil Science and Plant Nutrition Department at the Siedlce University of Natural Sciences and Humanities, Poland - 52°17′N, 22°28′E (*Figure 1*).

Figure 1. *Location of the study area [https://contour maps.com.pl] in the own modification*

Five levels of fertilization were included in the study: without fertilization, NP, NK, PK, NPKCa. The field experiment was conducted on loamy sand soil containing 31.5 $g \cdot kg^{-1}$ of carbon compounds, 1.66 $g \cdot kg^{-1}$ of total nitrogen, and pH in KCl $mol \cdot dm^{-3}$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26772687

– 6.6. The content of available forms of phosphorus and potassium in soil determined with the Egner-Riehm’s method was high (80 mg·kg^{-1} P and 140 mg·kg^{-1} K) and the content of magnesium determined with the Schachtschabel’s method was average (50 mg·kg^{-1} Mg). According to the IUSS World Reference of Soil resources (2014), the soil on which the field experiment was carried out was classified as *Hortic Anthrosol*. The fodder galega seeds was sown in the amount of 24 kg·ha^{-1} (300-500 plants per 1 m^2). The germination was 45-60% and the 2.4 grams was TGW. Mechanically scarified seeds were sown into soil inoculated with *Rhizobium galegae* bacteria. In the subsequent years, the following fertilization scheme was implemented: N – 20 kg·ha^{-1} as 34% ammomium nitrate applied in early spring; P – 50 kg·ha^{-1} as triple superphosphate applied in autumn; K – 150 kg·ha^{-1} as 60% potassium salt at two doses: dose I (100 kg·ha^{-1} K) applied in early spring, dose II (50 kg·ha^{-1} K) applied after the first swath; Ca – 150 kg·ha^{-1} as dolomite calcium applied in autumn. During vegetation, agricultural procedures such as weeding were performed. The three swaths of fodder galega were harvested at budding in each,subsequent crop year (*Figure 2*).

***Figure 2.** Fodder galega (Galega orientalis Lam.) – budding phase*

In the samples marked plant analytical moisture, ash and combustion heat in accordance with Polish Norm PN-81/G-04513. The calorific value (according to Szyszlak-Bargłowicz and Piekarski, 2009) and energy value were calculated.

$$H_c = \frac{h_{cc}(t_h - t_l) - h_{rw} \cdot w_{rw}}{m_p} \quad \text{(Eq.1)}$$

H_c – heat of combustion value (MJ·kg^{-1});
h_{cc} – heat capacity of the calorimeter;
t_h – highest temperature of the main measurement period;
t_l – lowest temperature of the main measurement period;
h_{rw} – heat of burning the resistance wire;
w_{rw} – weight of the resistance wire;
m_p – mass of the plant sample.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26772687

$$C_v = H_c - h_{vw} \cdot (m_a + f_{h/w} \cdot h_c) \quad \text{(Eq.2)}$$

C_v – caloric value ($MJ \cdot kg^{-1}$);
H_{vw} – heat of vaporization of water at 25°C;
m_a – analytical moisture;
$f_{h/w}$ – conversion factor of hydrogen to water (8.94);
h_c – hydrogen content in the analytical sample.

$$E_v = Y_b \cdot C_v \quad \text{(Eq.3)}$$

E_v – energy value ($MJ \cdot ha^{-1}$);
Y_b – yield of biomass;
C_v – caloric value.

The content of total macronutrients was determined with the ICP-AES method (Spectrometer Optima 3200RL, Perkin Elmer, Waltham, USA) in plant material after drying, comminution and dry mineralization (550°C).

The results obtained were subjected to statistical analysis using the analysis of variance ANOVA (Statistica 12 PL, Statsoft, Inc., 2018). The least significant difference (LSD) determined by the Tukey's test. The criterion for significance was set at $P \leq 0.05$. The linear regression equations and correlation coefficients between selected features were determined (Statistica 12 PL, Statsoft Inc., 2018).

The atmospheric conditions in the year 2005-2009 exerted a large impact on the content of total NPKCa in the sub-surface horizon (Ap) of the soil profile and on its uptake by the test plant (*Table 1*). Excessively high temperatures limited the uptake of macroelements whereas a large volume of precipitation caused extensive washing-out of these elements deep into the soil profile.

Results and discussion

Changes in the basic energy parameters of fodder galega (a potential energy crop) are presented in *Table 2*. The determined analytical moisture of fodder galega harvested from fertilized objects ranged from 6.33 to 6.49%. Fertilization applied and years of research did not significantly differentiate this parameter.

Mineral fertilization and years of research significantly differentiated ash content in the fodder galega biomass. The significantly highest amount of ash in biomass was found for the galega harvested from the control object (without fertilization) as compared to the fertilized objects under analysis. The significantly highest ash content was found for the biomass of fodder galega harvested in the fourth year of the research. The energy value of 1 kg of dry matter of entire fodder galega plants, obtained according to PN-81/G-04513, designed to determine heat of combustion in the analytical state, ranged from 16.88 to 18.95 $MJ·kg^{-1}$. The significantly highest values of heat of combustion were determined for fodder galega fertilized with nitrogen (20 $kg·ha^{-1}$) and potassium (150 $kg·ha^{-1}$). Similar values of heat of combustion (17.8-18.2 $MJ·kg^{-1}$) were determined in studies on *Miscanthus* fertilized with sludge in the doses of 0, 10, 20, 40, 60 $Mg·ha^{-1}$ dry matter (Kołodziej et al., 2016). In studies on sorghum hybrids fertilized 75 kg N and 75-80 kg K_2O the average values of HHV elevate 17.7-18.4 $MJ·kg^{-1}$d.m. (Pannacci and Bartolini, 2016). According to Pilon and Lavoie (2013) switchgrass calorific value was on the level 18.0-19.5 $MJ·kg^{-1}$. The amount of energy (higher and lower heating value) as well as the thermophysical and chemical composition of biomass (carbon, sulphur, hydrogen, nitrogen as well as ash and moisture content) are very important characteristics of biomass used for energy purpose and production of biomaterials. For example, ash formed in the process of biomass combustion (responsible for particulate emission and corrosion), affect the operation of boilers, installation safety and its later use or utilization. The composition of feedstock also influences the quality of bio-products obtained by thermochemical conversions (Wilson et al., 2013).

It should be assumed that for cultivation of leguminous plants intended for energy purposes, harvested in the budding phase, intensive fertilization with nitrogen and phosphorus is not necessary. Leguminous plants are able to biologically reduce atmospheric N_2 as a result of their symbiosis with bacteria of the *Rhizobium* genus. The highest values of combustion heat were obtained for fodder galega cultivated in the fifth year of research. The calorific value presented in *Table 2*, calculated on the basis of formulas (Szyszlak-Bargłowicz and Piekarski, 2009), was about 0.89% smaller than the heat of combustion determined. To obtain maximum total dry matter yield (3 crops during the vegetation period) of fodder galega (16.25 $Mg \cdot ha^{-1}$), it is necessary to supply soil with NPKCa. In the studies with *Miscanthus*, lower dry matter yields were obtained in the first year of research (Kohle et al., 2001; Jeżowski, 2008). The average dry weight of biomass sorghum was on the level 13.5-21.7 $t \cdot ha^{-1}$ after 141 days after emergence and 22.0-27.3 $t \cdot ha^{-1}$ after 127 days after emergence (Pannacci and Bartolini, 2016). In our own research conducted, the optimum balanced dose of mineral fertilizers was as follows: N-20, P-50, K-150, Ca-150 $kg \cdot ha^{-1}$. In subsequent years of cultivation, the dry matter yield of fodder galega significantly increased. It was related to a strongly developed root system, an increased process of biological reduction of molecular nitrogen due to soil infection with *Rhizobium galegae* bacteria and supplying basic nutrients to soil. Comparing the yield of fodder galega with its energy value in subsequent years demonstrates that the dry matter yield contained significant amounts of energy. The amount of energy obtained from 1 ha was directly proportional to the volume of the yield obtained. Total amount of energy obtained after five years of the experiment amounted to 1176.24 ($MJ \cdot ha^{-1}$). The energy value of the yield obtained under the effect of fertilization with NPKCa was over twice as high as the values obtained for the yield of fodder galega obtained in objects without fertilization. The energy value of the fodder galega yield under the effect of fertilization with NPKCa was 33% higher than the value obtained for *Miscanthus* fertilized with 20 $Mg \cdot ha^{-1}$ of dry matter sludge (Kołodziej et al., 2016). Based on the research conducted, significant relations were found between the calorific value (C_v) and heat of combustion (H_c) and between energy value (E_v) and dry matter yield of fodder galega (Y_b) for the fertilization applied (*Figure 3a and 3b*).

A statistical analysis also demonstrated a significant relation between dry matter yield (Y_b) of fodder galega and analytical moisture (M_a) for the years of research. The mean energy value (E_v) calculated for individual years of research was also correlated with analytical moisture (M_a). A positive correlation between heat of combustion (H_c) and calorific value (C_v) was demonstrated for the years of research and energy value (E_v) and dry matter yield of fodder galega (Y_b)obtained in subsequent years of research. The obtained results of our own research were at a similar level in comparison to the previous research carried out in the soil abundant in available nutrients (Kalembasa and Symanowicz, 2003).

The average content of macroelements in ash obtained after combusting fodder galega biomass followed a sequence of decreasing values: Ca > K > P > Mg > S >Na (*Table 3*). The fertilization applied and years of research significantly differentiated the content of phosphorus, potassium, calcium and sulphur in ash. Higher total amounts of macroelements were determined in ash obtained from fodder galega fertilized with NK and NPKCa and in the fourth year of research.

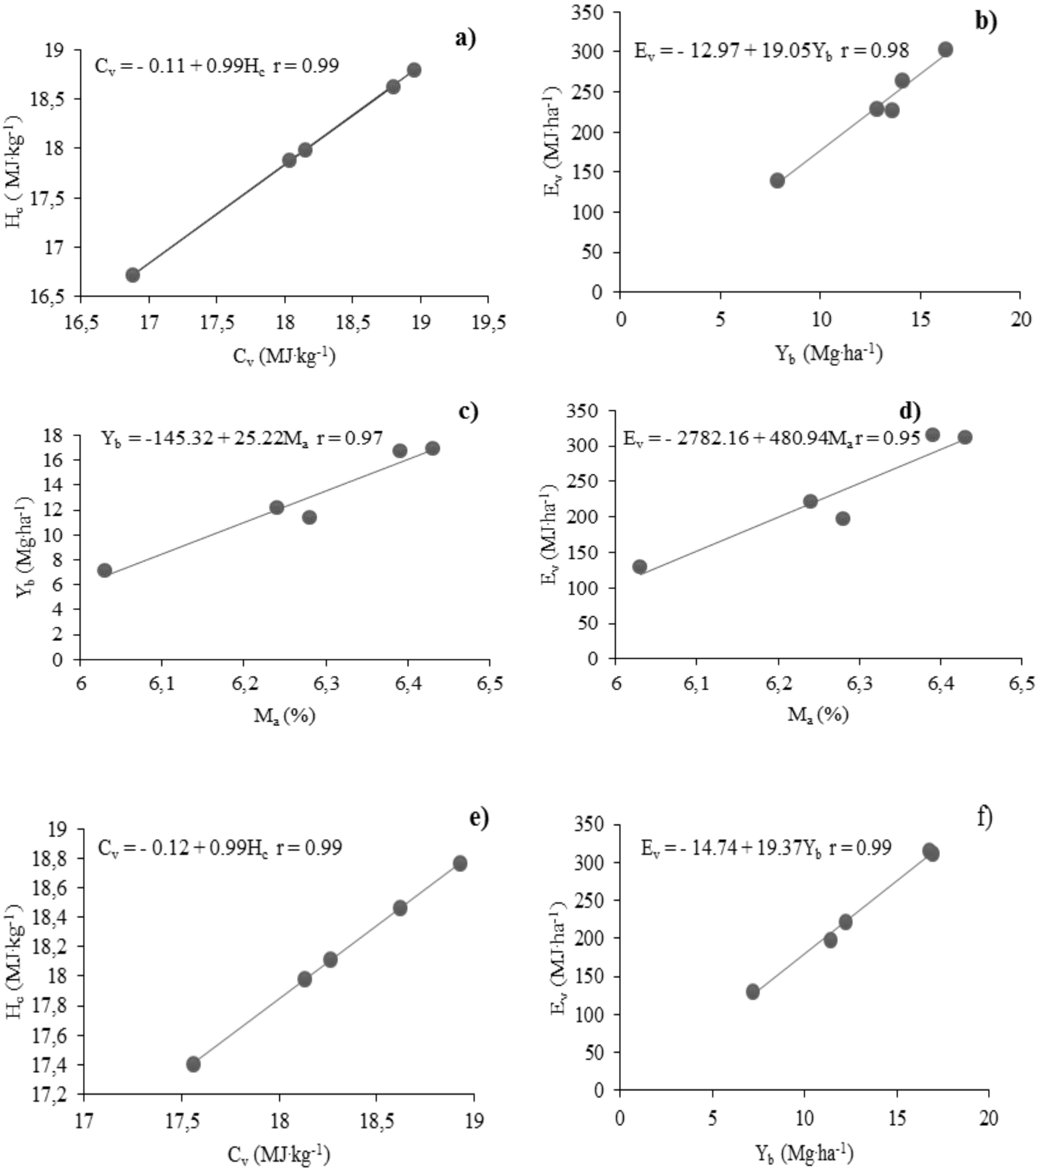

Figure 3. *The relations between heat of combustion (H_c), calorific value C_v), energy value (E_v), dry matter yield of fodder galega (Y_b), analytical moisture (M_a) for the fertilization applied – Fig.1a,b and for the subsequent years of research – Fig. 1c,d,e,f*

The amount of ash obtained after the combustion of the total yield of fodder galega biomass, and the amount of phosphorus, potassium, calcium, magnesium and sulphur was significantly differentiated for fertilizing objects and years of research (*Table 4*). The significantly highest amounts of the analysed parameters (ash, phosphorus, potassium, calcium, magnesium, sulphur and sodium) were obtained for fodder galega fertilized with NPKCa. Similar values of ash were obtained in the research with sugar miscanthus, while the content of macroelements determined in ash obtained after combusting sugar miscanthus was at a low level (Borkowska and Lipiński, 2007). In examining subsequent years of research, the highest percentage share of calcium, potassium, phosphorus and magnesium was found in the fourth year of research, and the highest share of sulphur and sodium was found in the fifth year.

The results obtained were lower than those obtained in the research with other energy crops - miscanthus sinensis, virginia mallow, basket willow (Stolarski, 2008; Stypczyńska et al., 2017). The harvesting date of energy crops significantly affects the content of macroelements (in particular, of potassium) in biomass and ash. The diversified content of macroelements in energy crops is shown in studies, in which 5 times less sulphur was determined in the biomass of basket willows in comparison to our own research. The ash obtained from the combustion of fodder galega biomass, containing large amounts of alkaline elements, can be used for deacidification of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_26772687

medium and heavy soils (Regulation Commission UE, 2013). The possibility of using ashes to increase soil alkalinity, to improve the properties of heavy soils and to increase the content of macroelement in soils was indicated in the research by other authors (Kowalczyk, 2017; Stypczyńska et al., 2017; Symanowicz et al., 2018).

Conclusions

A strong interest in alternative energy sources indicates the possibility of using fodder galega biomass as a source of renewable energy which does not produce such high SO_2 and NO_x emissions, as is the case while combusting hard coal.

The calculated calorific value of 1 kg of fodder galega dry matter, ranging from 16.72 to 18.79 MJ, is comparable to the data concerning of sweet sorghum, switch grass, *Miscanthus,* straw, bark and lignite.

Additionally, the waste by-product created in the process (ash) can be used for agricultural purposes as a liming agent of balanced chemical composition.

The highest dry matter yields and the highest yield energy value, as well as the most amount of ash obtained from biomass combusting were found for galega harvested from objects fertilized with NPKCa (20; 50; 150; 150 $kg \cdot ha^{-1}$).

Abstract. *Bacillus velezensis* W1, isolated from two-spotted spider mites that had died naturally, is a patented strain with strong capability to cause mortality of the phytophagous mite *Tetranychus urticae*. The whole genome of W1 was completely sequenced with a combination of an Illumina Miseq platform (400-bp paired-end) with 2 × 250 bases and a Pacific Biosciences (PaBio) RS II Single Molecule Real Time (SMRT) sequencing platform using a 20 kb SMRTbell™ template library. Here, we report the complete genome sequence of *B. velezensis* W1, including one circular chromosome of 4,237,431 bp encoding 4,352 genes with GC content of 45.84%, providing insights into the genomic basis of its acaricidal activity and facilitating its application in red spider mite biocontrol.
Keywords: *Bacillus, two-spotted spider mite, biocontrol, whole genome, Acaricides*

Introduction

The two-spotted spider mite, *Tetranychus urticae* Koch, is one of the most polyphagous arthropod herbivores and feeds on more than 1,100 plant species belonging to more than 140 different plant families including species known to produce toxic compounds. It is a major pest in field crops, destroying both annual and perennial crops (Grbic et al., 2011). The use of chemical insecticides and acaricides are currently the primary control method of *T. urticae* (Jafari et al., 2016). The frequent application of these chemicals, paired with several biological aspects of this species, such as its short life cycle, high fecundity and arrhenotokous reproduction, has led to the mites developing resistance to the most pesticide groups (Minazzi et al., 2016). Additionally, chemical pesticides can have unintended consequences, impacting environmental quality, food safety, human health, and biodiversity (Yang et al., 2016).

Recently, biological control agents in the form of parasites, predators and pathogens have gained a lot of attention. Biological control of spider mites using predators or parasites is widely practiced, particularly the use of phytoseiid mites, which are currently sold worldwide (Funayama et al., 2015). Entomopathogenic fungi or entomogenous fungi such as *Hirsutella thompsonii* Fisher (El-Sharabasy, 2015), *Neozygites floridana* Weiser and Muma (Klingen et al., 2008), *Beauveria bassiana*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

(Balsamo) Vuillemin (Ullah and Lim, 2015), *Verticillium lecanii* (Zimm.) (Seiedy, 2015), and *Isaria cateniannulata* (Zhang et al., 2016) are currently the most studied biological control agents of spider mites. Few bacteria, however, have been reported as biological control agents of spider mites owing to the piercing-sucking mouthparts of the mites, which make it difficult for bacteria to infect them. In recent years, researchers have concentrated on intracellular organisms such as *Wolbachia* that may cause distorted sex ratio in the mite offspring, thereby impacting population (Chen et al., 2016), and toxin-producing bacteria such as *Bacillus thuringiensis* that can produce crystal proteins called δ-endotoxins that are commonly used as a biological acaricides (Neethu et al., 2016). Additional research has been carried out on potential acaricide producing strains such as *Pseudomonas putida* (Aksoy et al., 2008).

Bacillus velezensis W1 (W1 hereafter), isolated from two-spotted spider mite that had died naturally, is a patented strain (Patent no; ZL201610096541.8) that has a strong capability to cause mortality of the phytophagous mite *T. urticae* (Li et al., 2018). This strain has the potential to be a safe and eco-friendly acaricide. To further explore its biocontrol ability and to reveal its acaricidal activity mechanism, we carried out the complete genome sequencing and analysis of W1.

Materials and methods

Bacterial strain and culture condition

B. velezensis W1 is a Gram-positive rod shaped bacterium averaging 2.5 µm in length and 1 µm in width (*Fig. 1a*). W1 spores are centrally located and average 1.3 µm in length (*Fig. 1b*). The bacteria could grow rapidly in Luria Bertani (LB) liquid medium reaching the stationary phase after 12 h at 35 °C. By comparison, the growth rate in LB solid medium was much slower with the stationary phase attained at 24 h. Optimum growth occur at a temperature 35 °C and pH 8.0 (*Table 1*). The colony morphology of strain W1 grown in solid LB medium is circular convex with undulate beige-opaque margins (*Fig. 1c*).

Phylogenetic analysis

Phylogenetic tree of the *B. velezensis* W1 and other related taxa was constructed with MEGA 7.0 (Kumar et al., 2016) using Neighbor-Joining method (Saitou and Nei, 1987) based on *gyrB* gene, and the distances were computed using the Maximum Composite Likelihood method (Tamura et al., 2004), with 1000 replications in the bootstrap test. Bootstrap confidence levels > 30% are indicated at the internodes. The scale bar indicates nucleotide substitutions per nucleotide position.

Genome sequencing information

Genome project history

Strain W1 was selected for sequencing due to its ability to cause mortality of the phytophagous mite, *Tetranychus urticae*. The whole genome was deposited in GenBank under the accession number CP028375. Genome sequencing and assembly was performed at the Wuhan Genoseq Technology Co., Ltd, Wuhan, China. The summary of the project information is shown in *Table 2*.

Growth conditions and genomic DNA preparation

The genomic DNA of W1 was extracted using a QIAamp DNA mini kit (Qiagen, USA), according to the manufacturer's protocols.

Genome sequencing and assembly

The whole genome of W1 was completely sequenced with a combination of an Illumina Miseq platform (400-bp paired-end) with 2 × 250 bases and a Pacific Biosciences (PaBio) RS II Single Molecule Real Time (SMRT) sequencing platform using a 20 kb SMRTbell^{TM} template library. Approximately 1,385.26 Mb with 4,661,344 reads were generated from the Illumina Miseq and PacBio sequencings, respectively. The quality of these reads was assessed by the FastQC tool (http://www.bioinformatics.babraham.ac.uk/projects/fastqc) and low quality reads were filtered by Quake (Kelley et al., 2010) and AdapterRemoval (version 2.1.7) (Lindgreen, 2012). The clean reads were *de novo* assembled into a single contig with a genome coverage of 305 folds using A5-miseq version 20150522 (Coil et al., 2015), Canu v1.4 (Koren et al., 2017) and pilon v1.18 (Walker et al., 2014). Glimmer 3.02 (Delcher et al., 1999) was used to predict the open reading frames (ORFs).

Genome annotation

Software packages tRNAscan-SE v. 1.3.1 (Lowe and Eddy, 1997) and RNAmmer v. 1.2 (Lagesen et al., 2007) were used to predict tRNA and rRNA, respectively. The gene function annotations were based on BlastP similarity searches (E-Value < 10^{-6}) against 5 databases: evolutionary genealogy of genes: Non-supervised Orthologous Groups (http://eggnogdb.embl.de/), Kncyclopedia of Genes and Genomes (http://www.genome.jp/kegg/), Non-Redundant GenBank Protein Database databases (www.ncbi.nlm.nih.gov/protein), Swiss-Prot (http://www.uniprot.org/), Gene Ontology Database (http://www.geneontology.org/). Circular genome map was created by cgview (Stothard and Wishart, 2005) with COG function annotation.

Results and discussion

Sequence analysis using gyrB

The phylogenetic analysis based on *gyrB* gene sequences using MEGA 7.0 [14] showed that *B. velezensis* W1 is evolutionarily positioned between *B. velezensis* and *B. amyloliquefaciens* (*Fig. 2*). In recent studies of genome sequencing and comparative genomics of *B. velezensis* NRRL B-41580, *B. methylotrophicus* KACC 13015 and *B. amyloliquefaciens* subsp. *plantarum* FZB42, it was established that these last two strains are heterotypic synonyms of *B. velezensis* (Dunlap et al., 2016), and based on our results, the classification of strain W1 was confirmed as a member of the species *B. velezensis*. The complete genome sequence of strain *B. velezensis* W1 is deposited at GenBank under accession number CP028375. The strain is available from China General Microbiological Culture Collection Center (CGMCC No. 11949).

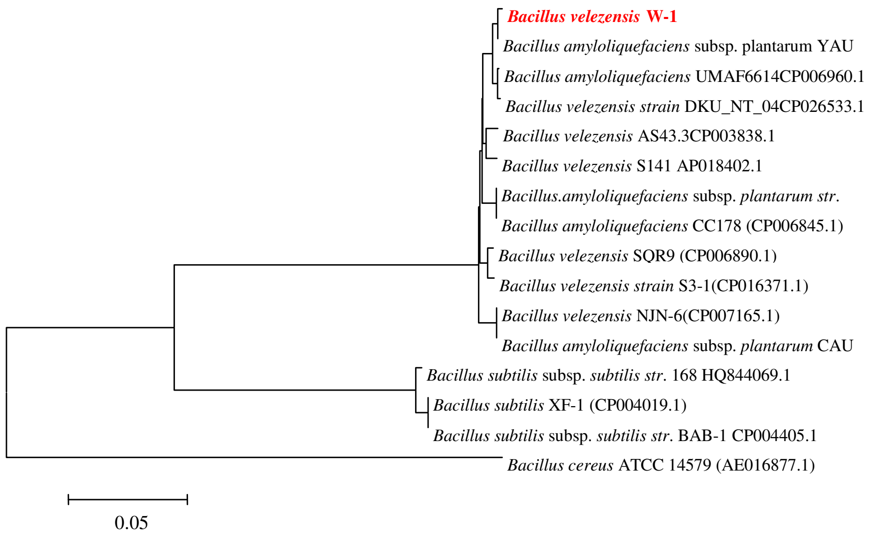

Figure 2. *Phylogenetic trees of the B. velezensis W1 and other related taxa*

Genome properties

The complete genome of W1 consisted of one 4,237,431 bp circular chromosome with an average GC content of 45.84% without a plasmid. Totally, 4,404 protein-coding genes were predicted (*Table 3; Fig. 3*), along with 85 tRNA genes and 27 rRNA genes (*Table 4; Fig. 3*). Among these 4,404 protein-coding genes 4,352 ones (98.82%) were annotated with predicted function (*Table 5*). There were 2879 (65.37%) genes assigned to COG database (*Table 6*).

Insights from the genome sequence

The virulence factors of pathogenic bacteria (VFDB) of W1 were predicted using BLAST similarity searches (E-Value < 10−6) in Virulence Factors Database (http://www.mgc.ac.cn/VFs/) (Chen et al., 2012). W1 comprises several virulence factors (*Table 7*) which might all contribute to acaricidal activity, such as clpC, clpE, clpP, gale, lplA1, acpXL, bslA/yuaB, cps4I, and ureB.

There is a cluster of three collagen-related structural motif genes found in the genome, i.e., clpC, clpE and clpP. The genes of collagen-like proteins (clPs) have been identified in a broad range of bacteria, including some human pathogens and non-human pathogenic strains such as *B. cereus* and *B. amyloliquefaciens* which are reported to use as biocontrol agents (Zhao et al., 2015). The clPs are important for biofilm formation and bacterial adhesion to host cells and swimming motility (Zhao et al., 2016). In low-GC Gram-positive bacteria, the clpP protease is the main system involved in protein degradation (Vaz Cassenego et al., 2016), and play a role in both virulence and environmental adaptation, and acyldepsipeptides activated by ClpP core were effective in killing persister cells (Springer et al., 2016).

Biofilms are surface-associated bacterial aggregates, in which bacteria are enveloped by polymeric substances known as the biofilm matrix. Biofilms of biocontrol strains were considered as some significant biocontrol properties, which provide the necessary proximity to the host so that the secretion of secondary metabolites featuring biocontrol activity from biofilm forming cells may act directly on the target (Kröber et al., 2016; Vlamakis et al., 2008). *B. amyloliquefaciens* is a Gram-positive bacterium that forms biofilms, which are created by a heterogeneous population of motile, matrix-producing and sporulating cells. One characteristic feature of biofilms is the extracellular matrix built from EPS combined with macromolecules like proteins and nucleic acids (Kröber et al., 2016). The bslA/yuaB was considered to stand for biofilm surface layer protein and be responsible for the hydrophobic layer on the surface of biofilms (Kobayashi and Iwano, 2012).

The chromosome encodes six chitin deacetylases (chr_orf00199, chr_orf01107, chr_orf03856, chr_orf05798, chr_orf01368, chr_orf02151), which are insect chitin degradation enzymes that catalyze the deacetylation of chitin to form chitosan, and enable the degradation of chitin in the midgut peritrophic membrane of many insects and have been identified as insect virulence factors (Yang et al., 2018; Yu et al., 2016).

Table 7. *Predicted virulence factors of B. velezensis W1*

Conclusions

This report described the complete genome sequence of *B. velezensis* W1. The species has biotechnological potential due to its capability to cause mortality of the phytophagous mite, *Tetranychus urticae*. Its acaricidal activity might be related to function of the virulence factors of pathogenic bacteria, like clpC, clpE, clpP, gale, lplA1, acpXL, bslA/yuaB, cps4I, and ureB, as well as collagen-related structural motif genes clpC, clpE and clpP. Biofilm and chitin deacetylases have been identified as biocontrol properties and insect virulence factors. Moreover, this bacterial strain can be used as microbial acaricides to control more and more acari in the field and greenhouse.

(Received 28th Nov 2018; accepted 28th Jan 2019)

Abstract. This study investigates the effects of increasing doses of sewage sludge with *Rhizobium* inoculation on lentil (*Lens culinaris* Medic.) straw and grain macro, micro and heavy metal contents in 2003-2004 and 2004-2005 growing seasons. Experiment was conducted as a randomized complete block design with 3 replications. At the end of the study, it was seen that *Rhizobium* inoculation affects the N, Mg, and Pb contents of the lentil straw on by P<0.05, P and Ca contents by P<0.01 in the first year; the N, Fe, and Zn contents on P<0.05 level, on the Pb content P<0.01 level in the second year. Lentil grains were affected only on the K, Fe, Pb, and Cd contents by P<0.05. Sewage sludge applications were used to detect the effects on the N, Mg, Fe, Mn and Cu contents of the lentil straw by P<0.01, Co content by P<0.05, and Pb content by P<0.01 in first year; on the N, K, Zn and Pb contents by P<0.01, P and Mn contents by P<0.01, on the Mg, Fe, Cu, and Co contents by P<0.05 in the second year. Effects received by the lentil grains are as follows: The N, K, and Cu contents by P<0.01, on the Pb, Fe, P, and Mg contents by P<0.01, on the Ca and Zn contents by P<0.05 in the first year; on the P, K, Ca, Mg, Fe, Mn, Zn, Cu and Co contents by P<0.01, on the Pb content by P<0.05 in the second year. The effects of inoculation on the lentil straw and grain, regarding the nutrient and heavy metal contents were determined to be insignificant. This result may be a result of weak inoculation application and the heavy metal content of the sewage sludge, as well as the negative effects of *Rhizobium* inoculation.
Keywords: *Cadmium, macro nutrients, legume, Rhizobium, municipal waste sludge*

Introduction

One of the preferred methods to remove sewage sludge in industrialized and populous countries is to use sewage sludge in agricultural production under controlled conditions. Particularly, sewage sludge derived industrial waste cause health problems because of the potential toxic substance like heavy metals, phenolics (Mueller et al., 1989; Van Assche and Clijsters, 1990). Moreover, the organic substance of soils is low. In order to achieve steady agricultural production, and taking into account the limited organic fertilizer resources – used for preserving or increasing the organic substance content of soils – scientists have been using sewage sludge.

High or low of organic substance extent of soils have effects on physical, chemical and biological specification directly and indirectly. The organic fertilizer source used includes nutrient elements (stable manure, poultry manure, refuse compost, sewage sludge) and the content of potential toxic elements affect the frequency of application in agricultural production. In addition, the pH of the soil affects the amount and place of application of the sewage sludge (Logan and Chaney, 1983).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27012717

Generally, it is preferred that sewage sludge is applied to the soil which has 6 pH or more. Because sewage sludge contains elements especially like Cd, Zn and Ni. These have high activity on acidic soils. Using sewage sludge in agricultural production improves physical characteristic of the soil and it functions as a source of nutrition elements for plants (Smith, 1996). The important thing here is that we should be careful in the harvest period after sewage sludge applied. Because after sewage sludge is applied, there should be a delay period before harvesting and therefore, sewage sludge applications must be done considering the harvest periods (Lovell et al., 1995).

As sewage sludge includes potential toxic substances, it has serious effects on macro and micro flora of soils (Sterritt and Lester, 1980; Brynhildsen and Rosswall, 1997; Athar and Ahmad, 2002). So, some researchers had investigated and found out what the sewage sludge effects on the soil development and soil microorganism are (Sönmez, 2003; Tüfenkçi et al., 2006a). According to the research, microorganisms had developed some mechanism against the toxic substances, but *Rhizobium* bacteria (Haferburg and Kothe, 2007), was discovered to be especially vulnerable to them (Chaudri et al., 1993, 2000). Therefore, soil organisms especially *Rhizobiums* where sewage sludge are applied face some important problems. In the area where sewage sludge is applied, heavy metal loading in different organs of plants has been monitored (Xian, 1989; Nellesen and Fletcher, 1993; Yürük and Bozkurt, 2006). The legumes used in the rehabilitation of contaminated areas with heavy metals (Zribi et al., 2012), and especially the presence of microbial density produced by plants in the rhizosphere and root exudates are very important (Glick, 2004). It has been reported that it has a negative effect on the inoculation of cadmium, copper and zinc *Rhizobium* in areas where treatment sludge has been applied for many years (Charlton et al., 2016).

In this study, we aimed to determine the effects of *Rhizobium* budding on the nutrition element of the straw and grain and monitor the changes on the heavy metal content after the application of sewage sludge on the lentil plant.

Materials and Methods

This study was carried out on the experiment area of Van Yüzüncü Yıl University in Eastern Anatolia in Turkey (between latitudes 35° 57’ 84 N and longitudes 42° 74’ 61 E at an elevation of 1725 m) in 2003-04 and 2004-05 growing seasons using one red-seeded nationally registered lentil cultivar (cv. Sazak-91) with 1000-seed weight of 30 g. Annual amounts of rainfall were 349.7 mm and 421.2 mm in 2003-04 and 2004-05, respectively. Average temperatures were 9.9^{0}C in 2003-04 and 9.6^{0}C in 2004-05 (*Table 1*). The results of the elemental analysis of the treatment area soil and the sewage sludge used in the experiment were given in *Table 2*.

Seeds were inoculated using peat inoculants which included a mixture of nodule-forming strains of *Rhizobium leguminosarum biovar viciae* specific to lentil. Peat inoculant was prepared with commercial peat cultures provided by the Soil and Fertilizer Research Institute, Ankara, Turkey, according to the method of Somesagaran and Hoben (1994). Peat inoculants were kept in a refrigerator at +4 ^{0}C until they were used. It was separately provided from the Soil and Fertilizer Research Institute in 2003-04 and 2004-05 winter seasons. Content and activity of peat inoculants were checked before the trials in 2003-04 and 2004-05. Peat inoculants was used after cell count was adjusted to 1 x 10^8 *Rhizobium* cells g^{-1} so the content of peat culture was standardized by diluting peat inoculants. The most probable number (MPN) method was used for estimating viable cells of *Rhizobium* (Somesagaran and Hoben, 1994).

*LTA = Long-term average (1979-2006)

Four doses of trial sewage sludge (SS0; 0 (control), SS10; 10, SS20; 20 and SS40; 40-ton ha^{-1}) were applied as inoculated and non-inoculated in parcels with 3 repetitions. Sowing was done by hand with 30 cm row spacing during late October in both years (20 October 2003 and 25 October 2004). The seeding rate was 140 kg ha^{-1} with the large-grained Sazak 91. A basal dose of 140 kg ha^{-1} di-ammonium phosphate (DAP) was given to each parcel at the time of sowing. Seeds were inoculated with *Rhizobium leguminosarum biovar viciae* bacteria at the predetermined rates before sowing in all parcels, except for the uninoculated control (Vincent, 1970). Application of the peat inoculant on the seeds was conducted using water which contains 2% sugar. The parcel size was 1.5 x 5 m. The experiment was carried out as rain fed. Parcels were hand-weeded twice each season. Plants were harvested during late June in both years (22 June 2004 and 27 June 2005).

The levels of nitrogen (N), phosphorus (P), potassium (K), magnesium (Mg), calcium (Ca), iron (Fe), manganese (Mn), zinc (Zn), copper (Cu), cobalt (Co), cadmium (Cd) and lead (Pb) were analyzed in dried and grinded samples that straw and grain extracts were obtained from each repetition to be in two parallel according to the methods reported by Kacar and İnal (2008) (*Table 3*).

At the end of the experiment, as in Jackson (1958), soil samples were taken from 0-20 cm depth on each repeating and brought to the laboratory and analyzed. The rest was done as follows: Texture, (Bouyoucous, 1951) soil reaction, (Jackson, 1958); total salt, (Richards, 1954): lime, (Hızalan and Ünal, 1966); organic substance, according to modified Walkley Black Method (Walkley, 1947); nitrogen, according to Kjehldahl Method (Kacar, 1994); available phosphorus, according to sodium bicarbonate method (Olsen et al., 1954); exchangeable potassium, calcium and magnesium, according to Thomas (1982) with 1 N ammonium acetate; micro elements and heavy metals found in soil samples were retrieved after shaking with 0.05 M DTPA (Diethylene Triamine Penta Acetic acid) adjusted to pH 7.3 (Lindsay and Norvel, 1978). These residuals were specified in Atomic Absorption Spectrometer. The values obtained at the end of the experiment were analyzed with Costat statistics program (Düzgüneş et al., 1987).

Results

Effects of the application in the content of straw and grain macro elements

As it can be seen in *Table 4*, inoculation had a significant effect on both the first and the second year lentil straw N ($p<0.01$) and Ca ($p<0.01$) values, while it had a significant effect on P and Mg ($p<0.01$) values only on the first year. Its effect on potassium was found to be insignificant in both years. It was seen that while the sewage sludge affected the nitrogen ($p<0.01$) on both years, it was discovered that it affected P, K and Ca ($p<0.01$) only on the second year and Mg ($p<0.01$) only on the first year. It was observed that the interaction only affects nitrogen with a value of $p<0.05$ in both years (*Table 4*). While the sewage sludge application on the grain nitrogen content had a significant effect on the first year ($p<0.01$), it had a significant effect on the P, K, Ca, and Mg elements in both years, respectively as $p<0.01$, $p<0.01$, $p<0.05$ / $p<0.01$ and $p<0.01$. Inoculation had a significant in grain nitrogen and phosphorus in both years ($p<0.01$ and $p<0.05$), in potassium and calcium ($p<0.01$ and $p<0.05$), it had a significant effect only in the first year. It was detected that the interaction affected the K and the Mg content of the grain macro nutrients on the second year with a level of $p<0.05$ (*Table 5*).

When the change in the content of straw macro element of lentil at sewage sludge application was investigated, it was seen that the contents of N, P, K, Ca and Mg increased considerably in both years according to control. The highest N, P, K, Ca and Mg values were reached respectively as 1.402%, 1578 mg kg^{-1}, 2.597%, 4.48% and 3.578% at the application of 40-ton ha^{-1} of sewage sludge in the first year (*Table 4, Figure 1*).

Same results were reached also in the second year, but only the content of Mg value was reached as 2.687% at application of 20-ton ha^{-1} of the sewage sludge. At the application of 40-ton ha^{-1} of sewage sludge, the highest values of N, P, K, Ca and Mg were determined as 1.728%, 1907 mg kg^{-1}, 2.931%, 5.48% and 2.569%, respectively. The lowest value of both years was determined in control parcels (*Table 4, Figure 1).*

After statistical analyses, straw macro element of lentil in inoculated parcels increased in both years as compared to non-inoculated parcels. It was seen that N content in this increase was significant in both years; P, Ca and Mg are significant only in the first year. Increase in potassium content was not significant (*Table 4*). Inoculation resulted in significant increases in the nitrogen, phosphorus, calcium and magnesium content of lentils. A significant increase was detected for N in both years; for P, Ca and Mg it was only detected in the first year. It was seen that the decrease and increase in potassium content was statistically insignificant (*Table 4, Figure 1*).

At the application of 40-ton ha^{-1} of sewage sludge, the highest value was reached in both years. The lowest value in both years was determined in control parcels. The highest value on grain of N, P, K, Ca and Mg elements were respectively detected as 4.629%, 0.599%, 1.463%, 0.142% and 0.254% in first year, as 4.170%, 0.583%, 1.846%, 0.159% and 0.157%, respectively in second year (*Table 5, Figure 1*).

The effect of application to the straw and grain micro element content of lentil

The results of variance analysis and the results of the averages of the effect of straw and grain micro element content of lentil and *Rhizobium* applications are given in *Table 5, 6* and *Figure 2*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27012717

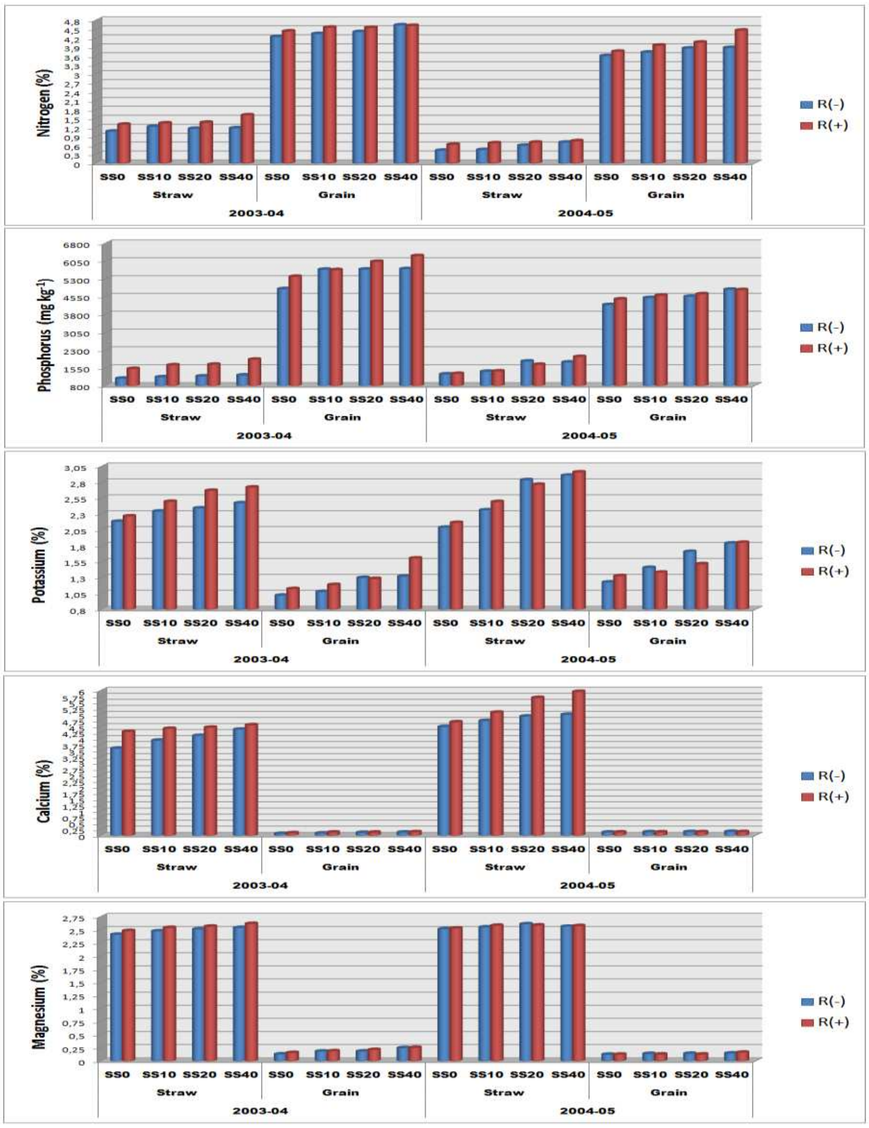

Figure 1. *Effects of applications on lentil straw and grain macro element contents SS0: 0 ton ha^{-1}, SS10: 10 ton ha^{-1}, SS20: 20 ton ha^{-1}, SS40: 40 ton ha^{-1}, R-: Rhizobium non-inoculation, R+: Rhizobium non-inoculation*

The application of sewage sludge affected the content of straw iron value of lentil by P<0.01 in first year, by P<0.05 in the second year. It affected the manganese content by P<0.01 in both years; zinc content by P<0.01 in the second year while it was insignificant in the first year. Copper content was affected by P<0.01 in the first year, by P<0.05 in the second year. Inoculation affected the content of manganese and copper in both years, while it affected the content of iron and zinc by P<0.05 in the second year. It was seen that its effect on iron and zinc application in the first year was insignificant (*Table 6*).

Inoculation effect on the grain micro element content was significant for Fe and Zn (p<0.01) in both years and for Mn in the second year (p<0.01). The sewage sludge application was significant for Fe, Zn and Cu (p<0.01 / p<0.05) in both years and for Mn (p<0.01) in the second year. The effect of the interaction was detected as significant in the second year only in Mn (p<0.01) (*Table 7*).

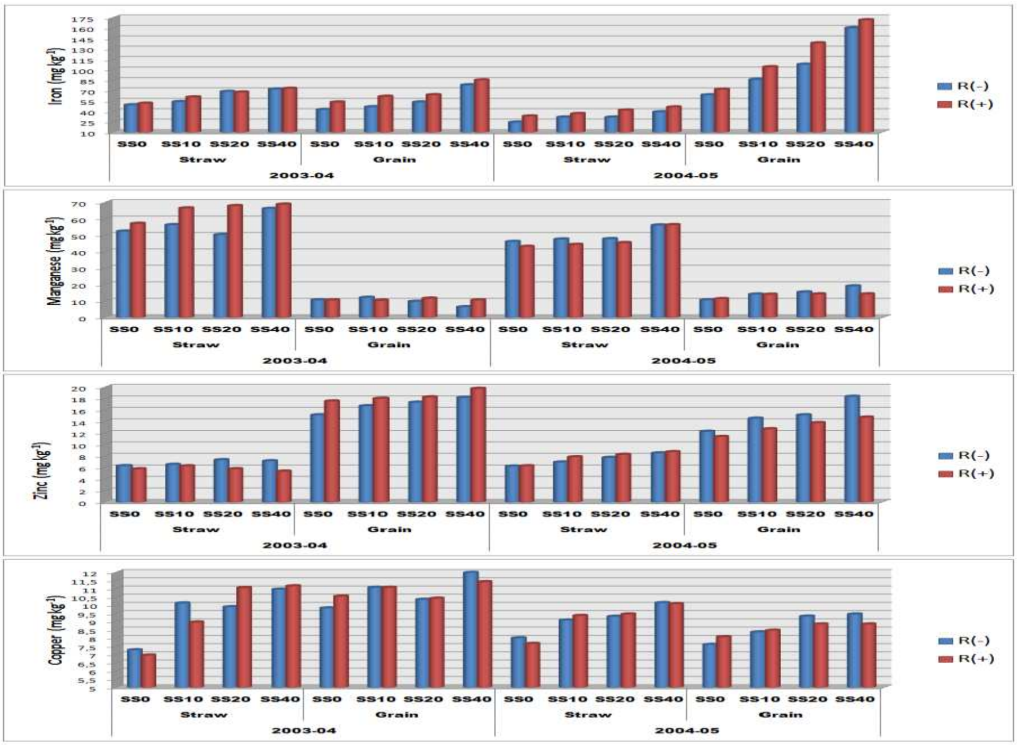

***Figure 2.** Effects of the applications on straw and grain micro element contents of lentil SS0: 0 ton ha^{-1}, SS10: 10 ton ha^{-1}, SS20: 20 ton ha^{-1}, SS40: 40 ton ha^{-1}, R-: Rhizobium non-inoculation, R+: Rhizobium non-inoculation*

The highest value of straw content of Fe, Mn, Zn and Cu were reached at the application of 40-ton ha^{-1} of sewage sludge in both years and the lowest value level was detected at control parcels. The highest value was reached as 72.9 mg kg^{-1}, 67.7 mg kg^{-1}, 6.57 mg kg^{-1} and 11.07 mg kg^{-1} respectively in first year; as 42.9 mg kg^{-1}, 56.3 mg kg^{-1}, 8.66 mg kg^{-1} and 10.12 mg kg^{-1} respectively in second year. The alteration in content of straw micro element depending on inoculation was variable. Others were found to be insignificant while only iron was insignificant in the second year (*Table 6, Figure 2*).

Even though inoculation had insignificant effects on the grain micro element content of lentil in both years, except for Fe, it was seen that sewage sludge had very important effects on Fe, Zn and Cu in both years, on Mn in the second year only (*Table 7, Figure 2*).

According to control, depending on applications of sewage sludge, Mn increased only in the second year, while Fe, Zn and Cu increased highly in both years. The highest value was reached at the application of 40-ton ha^{-1} of sewage sludge as 81.8 mg kg^{-1}, 18.98 mg kg^{-1} and 11.70 mg kg^{-1} respectively in the first year and 166.2 mg kg^{-1}, 16.7 mg kg^{-1}, 16.57 mg kg^{-1} and 9.16 mg kg^{-1} respectively in the second year (*Table 7, Figure 2*).

The effect of the applications to the straw and grain heavy metals content of lentil

The results of variance analysis and the results of the averages of the effect of sewage sludge and *Rhizobium* applications on the straw and grain heavy metal contents of lentil are given in *Table 8, 9,* and *Figure 3*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27012717

Rhizobium application had a significant effect on the straw Co content of the lentil in the second year ($p<0.05$) and on the Pb content in both years ($p<0.01$). The effect of the sewage sludge application and interaction was significant only on Pb content in both years ($p<0.01$). While the inoculation on grain heavy metal content of lentil had a significant effect on the content of Pb ($p<0.01$) and Cd ($p<0.05$) in the first year, the sewage sludge application had a significant effect on Co in the second year ($p<0.05$) and on Pb ($p<0.01$/$p<0.05$) in both years. The effect of interference on grain heavy metal content was found to be insignificant (*Table 8, 9*).

As the doses of sewage sludge are increased, the content of straw heavy metal of lentil also increased. The highest value in Co, Pb, and Cd contents were reached at the application of 40-ton ha^{-1} of sewage sludge in both years as 2.714 mg kg^{-1}/0.999mg kg^{-1}, 0.618 mg kg^{-1}/0.602 mg kg^{-1}, 0.201 mg kg^{-1}/1.027 mg kg^{-1} respectively, and the lowest value was reached at control parcels. Inoculation only affected Pb content. Lead content decreased in the second year while it increased with inoculation in the first year (*Table 8, Figure 3*).

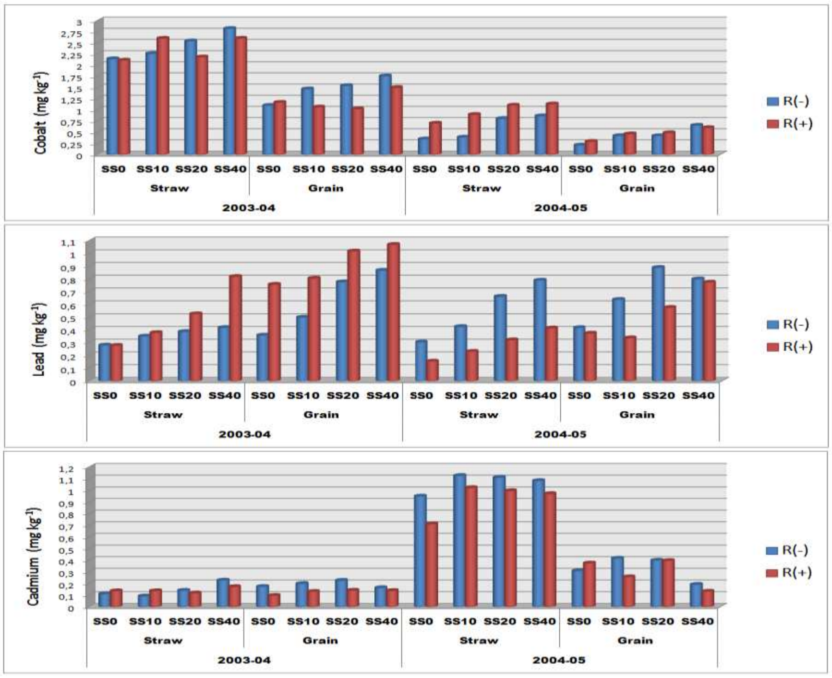

Figure 3. *Effects of the applications on straw and grain micro element contents of lentil SS0: 0 ton ha^{-1}, SS10: 10 ton ha^{-1}, SS20: 20 ton ha^{-1}, SS40: 40 ton ha^{-1}, R-: Rhizobium non-inoculation, R+: Rhizobium non-inoculation*

It was seen that sewage sludge had a statistically important effect on the grain heavy metal content of lentil with regards to Co in the second year and Pb in both years but its effect on Cd was insignificant (*Table 9, Figure 3*).

Co and Pb content increased significantly with the application of residual sewage sludge according to control in both years. The highest value was reached as 1.631 mg kg^{-1} and 0.968 mg kg^{-1} respectively in the first year; as 0.628 mg kg^{-1} and 0.686 mg kg^{-1} respectively in the second year. *Rhizobium inoculation* decreased the taking of Cd, while it increased the taking of Pb seed in the first year (*Table 9, Figure 3*).

Discussion

In our study, it was determined that the increasing applications of sewage sludge increase the amount of lentils' straw and grain macro, micro and heavy metal contents in both years. The highest values were reached in 40-ton sewage sludge ha^{-1} applied parcels. Increases in N, P, K, Ca, Mg, Fe, Mn, Cu, Co, and Pb contents of the lentil straw in the first year were respectively 17.9%, 19.7%, 16.8%, 13.4%, 5.4%, 44.1%, 23.5%, 55.5%, 27.5%, 120.7 and in the second year they 12.7%, 47.7%, 37.8%, 19.1%, 3.0%, 48.4%, 25.9%, 29.1%, 90.7%, 161.7%, respectively. The straw zinc content increased by 37.7% in the second year and the cadmium content increased by 62.1% in the first year. The first and second year increases in the grain nutrient and heavy metal contents were respectively N; 6.7%-13.3%, P; 16.5%-9.8%, K; 36.5%-44.6%, Ca; 52.7%-16.1%, Mg; 75.2%-24.6%, Fe; 70.1%-144.8%, Mn; 51.8%, Zn; 15.9%-39.8%, Cu; 14.9%-16.7%, Co; 43.9%-148.2% and Pb; 73.5%-100.3%. Even though there was a decrease in the grain Cd content, this was found to be statistically insignificant (*Table 4, Table* 5, *Figure 1*).

In similar studies, it has been reported that plants' nutrient and heavy metal contents go up as a result of increasing sewage sludge applications (Sönmez and Bozkurt, 2005; Tüfenkçi et al., 2006b; Yürük and Bozkurt, 2006; Singh and Agrawal, 2010). This is probably because of the changes in the nutrient element composition of soils with sewage sludge. Indeed, Antolin et al. (2005) reported in their study that with the addition of long-term sewage sludge, there is a decrease in the pH of the soil and increase in the total organic carbon and DTPA extractable heavy metal content. In other relevant studies, it was reported that there was an improvement in the physical and chemical properties of the soil with the addition of sewage sludge. The amount of product and the nutrient element contents increased too (Barzegar et al., 2002; Speir et al., 2003; Sönmez and Bozkurt, 2005; Tüfenkçi et al., 2006b). With a high rate of sewage sludge addition, the cation exchange capacity (CEC) of soils increases (Soon, 1981) and the bioavailability of heavy metals become limited (Kladivko and Nelson, 1979; Kim and Kim, 1999).

With *Rhizobium* inoculation; the phosphorus, potassium, calcium and magnesium contents of straw and grain nitrogen have increased within the years. These increases were 21.3%-9.4%, 44.1%-1.9%, 8.9%-1.8%-10.5%-11.9% and 2.6%-0.3% respectively in lentil straw and 2.9%-7.6%, 6.2%-2.0%, 10.3%-2.6%, 20.2%-3.4% and 8.5%-1.5% respectively in lentil grain (*Table 4, Table 5, Figure 1*). It is reported by some researchers that *Rhizobium* inoculation provides significant increases, especially in the nitrogen content, as well as in plant growth (Marschner, 1995; Al-Karaki, 1999; Kacar and Katkat, 1999; Soumaya et al., 2016; Tüfenkçi et al., 2006a). The physical and chemical properties of soils have a significant effect on microorganism activities (Ham, 1980; Lowendorf, 1980; Haktanır and Arcak, 1997). In addition to being a good source of organic fertilizers with high organic matter and nutrients, sewage sludge should be used with caution due to the high amount of heavy metals they contain (Fernandes, 2005; Bozkurt et al., 2006; Carbonell et al., 2009; Fernandez et al., 2009). Applied sewage sludge affects the physical, chemical and biological properties of soil and therefore affects the microorganism activities. This is also seen in the results reported by some researchers (Chaudri et al., 2008; El-Azhari et al., 2012; Charlton et al., 2016). As a matter of fact, Mattanaa et al. (2014) reported that the effects of sewage sludge on soil microorganisms are different according to the methods applied to the sludge before.

DOI: http://dx.doi.org/10.15666/aeer/1702_27012717

Antolin et al. (2010) stated that the addition of sewage sludge has no significant effect on nodulation.

The effect of inoculation on grain and straw micro element content compared to non-inoculated plants is evident in iron values. Manganese and zinc were detected only in the grain in the second year. Iron increases in the first and second year straw and grain are respectively 3.8% -24.5% and 19.5% -16.4%. In the second year, 10.4% increase in grain manganese and 14.6% decrease in zinc were determined. It was seen that inoculation in copper did not make a significant difference (*Table 6, Table 7, Figure 2*). Zribi et al. (2012) reported that *Medicago sativa-sinorhizobium* symbiosis could be used for phytoremediation in medium polluted areas with Cd, Cu, Pb and Zn.

The significant effect of *Rhizobium* inoculation on the heavy metal content was determined as an increase in the cobalt content of the lentil straw in the second year and lead in both years by 59.0%, 39.3% and 94.3%, respectively. The effect of inoculation on the grain heavy metal content of lentil is designated in lead and cadmium contents. Despite the increase in lead content in both years, it was seen that only the first year was important. It was seen that there was an increase of 45.9% compared to non-inoculated plants. The cadmium content was decreased with inoculation by 49.2% in the first year and 13.4% in the second year. The decrease with inoculation in the cobalt content during the first year was 23.6%, but this decrease was deemed insignificant (*Table 8, Table 9, Figure 3*). Akhtar et al. (2018) reported that *Rhizobium* inoculation has a positive effect on metal contaminated areas. Ghnaya et al. (2018) reported that *Rhizobium* inoculation in cadmium-contaminated environments increased the root cd content of *Medicago sativa* L. and increased the transport to the surface of the plant.

Conclusion

Rhizobium inoculation is particularly recommended in legumes. Due to rapid population increase and technological developments, the amount of treatment sludge is increased. It is currently being investigated for the disposal of sewage sludge, which is an important problem for use in agricultural areas. In this study, the efficiency of treatment sludge use and *Rhizobium* inoculation in legumes was investigated. As a result, *Rhizobium* inoculation has been found to have a positive effect on both the lentil and the nutrient element content.

In increasing applications of sewage sludge, *Rhizobium* inoculation has been shown to have a more pronounced effect on the straw element content of lentils, especially in the first year trials than in *Rhizobium* non-inoculation.

The most important disadvantage of the use of sewage sludge is the risk of heavy metal contents of soil and plant. In this study, *Rhizobium* inoculation has been shown to have a negative effect on the absorption of heavy metals against increasing sludge applications. The chemical composition of the treatment sludge to be used in such studies should be considered and accordingly the application dose should be adjusted.

As a result, we have determined that the use of sewage sludge is not a risk for heavy metal in terms of both soil and plant and it can be used with *Rhizobium* inoculation.

RAINFALL EROSIVITY IN NORTH-CENTRAL ANATOLIA IN TURKEY

OĞUZ, I.

Department of Soil Science and Plant Nutrition, Gaziosmanpaşa University, Tokat, Turkey
(e-mail: irfan.oguz@gop.edu.tr)

(Received 25th Jul 2018; accepted 4th Feb 2019)

Abstract. This study was performed by the reevaluation of historical Universal Soil Loss Equation using field experiment data that was obtained between 1978 and 1995 in Tokat, Turkey. In the study area, the annual average rainfall was 452 mm and about 50% of erosive rainfall events were less than 10 mm. The duration of average erosive rainfall event was 6 h and the average event intensity was 3.83 mm h^{-1}. The average erosive rainfall time in daylight (06:00-18:00), night (18:00-06:00) and mix rainfall conditions were 223.1 and 191.6, 450.2 min, respectively. The maximum rainfall amount, event intensity, storm erosivity, the maximum intensity of 10 min (IM10), the maximum intensity of 15 min (IM15), the maximum intensity of 30 min (IM30) were mostly occurred in daylight erosive rainfalls. But the maximum soil loss and runoff produced by night erosive rainfall. This situation was attributed to the short-term effect on soil erodibility of day and night temperature differences in spring which is rainfall erosivity is high for the region. Higher correlation is observed between soil loss and IM10 compared to IM30. USLE R-factor showed a good correlation with Modified Fournier Index (MFI) for the region. The Mann–Kendal and Theil–Sen Slope estimator statistics to detect the direction and magnitude of an available monotonic trend in some erosivity parameters as well as soil loss and runoff. Trend analysis showed monotonic decreasing of all rainfall physical properties, soil loss and runoff.
Keywords: *rainfall erosivity, modified Fournier index, erosion index, trend analysis, soil loss, runoff, Turkey*

Introduction

Erosion is the most severe and widespread environmental problem in Turkey, as well as in worldwide. In the water erosion, the rainfall erosivity is the major factor for soil loses. The universal soil loss equation (USLE) was the most common prediction model and conservation planning tool in the United States and worldwide (Wischmeier and Smith, 1978; Beasley et al., 1986; Young et al., 1989; Sharpley and Williams, 1990). The rainfall erosivity factor (R) is the one of USLE factors and represents the multiplication of rainfall energy and maximum 30 min intensity (EI30) by erosive rainfall events in a year. This rainfall erosivity index is widely used for empirical soil loss prediction. Its calculation, however, requires high temporal resolution rainfall data that are not readily available in many parts of the world (Xie et al., 2014).

Rainfall erosivity is influenced by the rainfall type, amount, occurred time and intensity of storm. In many parts of world, pluviograph records are not sufficiently available in rural areas to calculate erosivity (Renard and Freimund, 1994; Yu and Rosewell, 1996a). This limitation has, however, been met by the estimation of R values from rainfall amount (Ferro et al., 1991; Salako et al., 1995). Several empirical equations such as the KE > 25 (Hudson, 1971), the AI_m (Lal, 1976), the Fournier index (Fournier, 1960), the Modified Fournier Index (Arnoldus, 1977) and the physically-based A index (Sukhanovski et al., 2002) have been setting to handle R factor values from rainfall amount (Richardson et al., 1983; Renard and Freimund, 1994; Yu and Rosewell, 1996b; Salako, 2008).

DOI: http://dx.doi.org/10.15666/aeer/1702_27192731

In a study conducted in Santa Catarina, Brazil, daily precipitation graphs between 1989 and 2012 were used to calculate the various indices of precipitation erosion. The indices were correlated with the respective soil losses from the standard plot of USLE and the 30 min erosivity index (EI30) of rainfall recommended for the region (Jefferson et al., 2014).

Renard and Freimund (1994) suggest the use of the MFI for areas where long term data is not available. The Fournier index has been used to describe erosivity, in several countries, e.g. Germany (Sauerborn et al., 1999), Argentina (Busnelli et al., 2006), Spain (Angulo-Martínez and Beguería, 2009), Jordan (Eltaif et al., 2010), Cape Verde (Sanchez-Moreno et al., 2014), Greece (Efthimiou, 2018).

Despite the importance of the effect of rainfall characteristics (duration, occurrence time, etc.) on erosion occurrence and sediment delivery process, studies conducted on this subject have been limited in the past decades. In a study, the role of rainfall variability and extreme events were studied in long-term landscape development. The result showed that low-intensity rainfall events with long durations, large magnitudes and less return periods, contribute significantly to total soil erosion (Baartman et al., 2013). Rainfall duration is among the most effective characteristics of erosivity factor on runoff, splash and soil loss (Katebikord et al., 2017). In Masse (Central Italy) rainfall data were used to determine of erosive characteristics of the region between 2008-2012 years. Within the data period, the rainfall total durations varied from 0.3 to 97.3 h. A total of 228 single rainfall events was identified $p \geq 1$ mm 60 of them were named erosive events and the other 168 have not produced runoff and soil loss and were named non-erosive events. In the study, rainfall depth P, and duration D were determined in detail. In the 58 erosive storms have a range of P, and D, respectively of $7.6 \leq P \leq 148.6$ mm, and $0.4 \leq D \leq 97.3$ h, and the 51 non-erosive storms have a range of $1 \leq P \leq 19$ mm, and $0.3 \leq D \leq 19.01$ h. The rainfall of the region were defined certainly erosive if $D > 24$ h and $P > 20$ mm (Todisco, 2014).

The 30 min maximum intensity (IM30) value of individual rainfall event is widely used in various calculations. However, the effects of different rainfall intensity values on runoff and soil losses are investigated. In a study in Iran, the 18 erosion plots were placed on rangeland hill slopes and measured of runoff and soil loss from 2010 to 2011. Thirteen maximum rainfall intensities were calculated and some of them are presented as maximum intensity in 10, 20, 30, 40, 50, 60 and 90 min. The kinetic energy of storms was computed by USLE R factor computation procedure (Wischmeier and Smith, 1978). The relationship between rainfall intensity and soil loss were varied across intensities. In low rainfall intensities a linear function is fitted to soil loss-rainfall intensity, and in high rainfall intensities nonlinear functions are fitted to soil loss-rainfall intensity (Mohamadi and Kavian, 2015).

Runoff plot observations under natural rainfall conditions represent the primary method for conducting water and soil conservation studies (Araya et al., 2011; Phan et al., 2012). However, performing plot observations experiments is a time-consuming and resource-intensive process (Cerdan et al., 2010). In Turkey, a project was carried out to determine some factor values of USLE in 15 locations has different soil and climatic conditions. The research results of all study locations were reported in a guide (Oğuz et al., 2006). Since erosivity varies significantly from year to year, at least 15 years of data are required to obtain representative estimates of annual erosivity (Foster et al., 2003). In the project, the study duration were chosen about 20 years to better represent the climate and soil conditions of study locations. Therefore, the effect of humid, dry and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27192731

normal climatic conditions on soil and water losses is considered to be sufficiently represented. Tokat region was one of the study locations of this national project. Soil losses and runoff records by erosive rainfall of the natural erosion plots were kept regularly between 1978-1995 years. The purpose of that study was only determine some USLE factor values of study locations so only a limited part of the data were presented. It was thought that the reevaluation of this long period natural erosion plot data could contribute to the solution of the current erosion problems of Tokat region. For this purpose this article is structured in three sections. The first part of this research we present rainfall characteristics of the study area such as several times maximum intensities, erosive rainfall duration and amounts, occurrence times of soil and runoff loss, and the correlation between soil loss, runoff and some several time maximum intensities.

Secondly, comparison of the Modified Fournier Index (MFI) and USLE R factor values for individual rainfall events.

Finally, we analyzed the trend of some rainfall characteristics, soil loss and runoff amounts and estimated the steepness of the slope used the Mann-Kendall for testing trend and Sen’s slope estimator to determine trends of variables in Tokat region for the study period.

Materials and methods

The study was based on reevaluated historical natural Universal Soil Loss Equation plot data between in 1978 and 1995 in Tokat, Turkey (40°18’N, 36°34’E). Tokat is located in North Central Anatolia and lies at an average altitude of 600 m. It is situated in the area of transition from Central Anatolia to the Middle Black Sea region. The study area contains plain to moderately steep area with high vegetation entities and/or under cultivation. The major vegetation types in plain area are vegetable, sugarbeat, potato and wheat. Where, orchard and wheat are common in mild steep areas, and grassland with Graminea and Fabaceae as dominant species in the moderate steep areas, other types being shrub and meadow. The mean annual temperature is 12.6 °C and the annual precipitation is 452 mm.

Study is conducted in Akis Soil Series, Typic Ustorthent which are moderate to well drained soils, and with standard USLE conditions at a site with the standard slope steepness of 9% and slope length of 22.13 m. Runoff plot was framed with a 20 cm high border, to keep precipitation and runoff within the plot area. The plot had a collecting tank and a container tank (0.56 m diameter and 1.00 m deep) at the lower end of the slope to catch runoff and sediment.

Hourly rainfall data were collected using a tipping bucket rain gauge with totals recorded every 24 h from 1978 to 1995. The rainfall charts from 1978 to 1995 were used to handle a data set of some rainfall characteristics such as amount (mm), duration (min) and time of occurrence (the 24 h day was separated as 06:00-18:00 h (daylight), 18:00-06:00 h (night) and if the rains occurred during both period we called mix). The maximum intensities of 10 (IM10), 15 (IM15) and 30 (IM30) min for each erosive rainfall were calculated from rain charts. Rainfall erosivity is computed using USLE-R Factor calculation procedure (Wischmeier and Smith, 1978) with the help of erosion index values of 30 min only (EI30). About 373 rainfall charts were analyzed for this purpose.

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 17(2):2719-2731.
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27192731

Rainfall erosivity was evaluated with USLE-R factor and Modified Fournier Indices. The R factor is calculated with the help of *Equations 1–4*.

$$E_u = 0{,}119 + 0.0873\, log\, log\, I \quad \text{(Eq.1)}$$

where I: Intensity, mm h^{-1}; E_u: Rainfall energy per unit of rainfall, MJ ha^{-1} mm^{-1}.

$$E_g = E_u * h \quad \text{(Eq.2)}$$

where E_g: Storm energy, MJ ha^{-1}, h: Rainfall amount, mm.

$$EI = E_g * IM30 \quad \text{(Eq.3)}$$

where EI: Single storm erosivity, MJ mm ha^{-1} h^{-1}; IM30: the maximum 30 min intensity, mm h^{-1}.

$$R = \sum (E_g * IM30) \quad \text{(Eq.4)}$$

where R: Annual erosivity which occurred within in a year (R factor), MJ mm ha^{-1} h^{-1} y^{-1}.

Fournier is developed an erosivity index (Fournier, 1960) and this index was modified by FAO (FAO, 1977) as follows (*Eq. 5*):

$$MFI = \sum_{i=1}^{12} \frac{pi^2}{P} \quad \text{(Eq.5)}$$

where pi is the rainfall in a month, mm and P is the annual rainfall, mm.

In the meteorological variables, parametric and non-parametric approaches have been used over years. The most frequently used tests for identifying the variations in meteorological variables have been nonparametric. The most popularized approach among them is Mann–Kendal test (Kendall, 1975; Mann, 1945). The Mann-Kendall nonparametric test was used to test for trend. This test is calculated as *Equation 6* (Mohtar et al., 2015; Yurekli, 2015):

$$S = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} \mathrm{sgn}(x_j - x_i) \quad \text{(Eq.6)}$$

where n is the number of event, x_j and x_i are the observed events, and sgn is the sign function.

The variance is given by *Equation 7:*

$$\sigma_S^2 = 18^{-1}\left[n(n-1)(2n+5) - \sum_{i=1}^{m} t_i(t_i - 1)(2t_i + 5)\right] \quad \text{(Eq.7)}$$

where n is number of events, m is the number of tied events, ti is the number of events that are tied. For sample size greater than 10 the test can be given in *Equation 8:*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27192731

$$Z_{MK} = \begin{cases} \frac{S-1}{\sqrt{\sigma_S^2}} & \text{if } S > 0 \\ 0 & \text{if } S = 0 \\ \frac{S+1}{\sqrt{\sigma_S^2}} & \text{if } S < 0 \end{cases} \quad \text{(Eq.8)}$$

For increasing rainfall trends, the values of Z_{MK} is positive and for decreasing trend the value of Z_{MK} is negative.

Sen's estimator for slope is a nonparametric test for the steepness of the trend. For N pairs of data (*Eq. 9*):

$$Q_k = \frac{x_j - x_i}{j - i} \text{ for } k = 1, ..., N \quad \text{(Eq.9)}$$

where Xj and Xk are the values at times j and k (j > k), respectively. The N values of Qk are ranked from smallest to largest. According to condition that N is odd or even, the median concerning with total N values of is calculated by *Equation 10:*

$$Q_{med} = \begin{cases} Q_{\left[(N+1)/2\right]} & \text{if N is odd} \\ 2^{-1}\left\{Q_{\left[(N)/2\right]} + Q_{\left[(N+2)/2\right]}\right\} & \text{if N is even} \end{cases} \quad \text{(Eq.10)}$$

The confidence interval for Q_{med} was obtained to determine the significance of the slope.

Results and discussion

Rainfall distribution: The mean monthly rainfall and the coefficient of variation of the rainfall were recorded from 1978 to 1995 (*Table 1*). The annual average rainfall was 452 mm, the minimum rainfall occurred in August and the maximum in May. The maximum and minimum annual average rainfall occurred in 1993, with 604.5 mm and in 1994 with 311.7 mm, respectively.

The monthly rainfall was divided into 13 groups considering the frequencies. Monthly storm amount distribution between 1978 and 1995 in Tokat is given in *Figure 1,* which shows that about 78% of monthly rainfall amounts were less than 60 mm and only about 22% of monthly rainfall exceeded 60 mm. In the region, the monthly rainfall exceeding 70 mm was relatively low. 90-100 mm and 120-130 mm monthly rainfall amount group was observed quite low frequency. No frequency was observed in the 110-120 mm monthly storm amount group.

In the study period, totally 373 erosive single storm were occurred. Erosive single rainfall events distribution between 1978 and 1995 in Tokat is given in *Figure 2*. As shown in *Figure 2,* about 50% of erosive rainfall event were less than 10 mm and about 30% of erosive rainfall events were 20 mm. Only about 20% of erosive rainfall events

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27192731

were between 30 mm to 130 mm. There is a negative correlation between erosive rainfall amount and frequency. This result showed that the erosive rainfall events of Tokat region is generally occurs in low amounts.

Rainfall duration, event intensity and time of occurrence: The average erosive rainfall event duration was 6 h and the average erosive event intensity (amount for an event/total duration) was 3.83 mm h^{-1}. Erosive rainfall was separated according to daylight, night and mix as presented in *Table 2*, where differences between rainfall characteristics and soil loss and runoff in different erosive rainfall time of occurrence, are shown. In the study period, the number of the erosive rainfall occurred in daylight, night and mix conditions were 74, 73 and 226, respectively.

Average erosive rainfall duration in daylight, night and mix rainfall conditions were 223.11, 191.58, and 450.18 min, respectively (*Table 2*). The average night erosive rainfall duration was observed shorter than the other types. Mix rainfall has been found having the longest rainfall duration. Jingi et al. (2011) studied the effect of rainfall duration (5, 10, 15, 20, 25, and 30 min) on separation of soil grains and splash erosion using splash collecting container, and their results indicated significant positive effect of rainfall duration on soil splash. But under natural rainfall conditions, an erosive rainfall has usually variable intensities. When a rain takes place in a prolonged period of time, it generally causes the variables intensities of this rain to achieve lower energy levels. Therefore, the long erosive rainfall duration mostly causes less soil loss and runoff than shorter erosive rainfall duration. The erosive rainfall duration of daylight took place between erosive rainfall duration of mix and night conditions. The average night erosive rainfall amount was also at the lowest levels. The daylight was moderate, and the mix had maximum rainfall amount.

Average erosive event intensity in daylight, night and mix rainfall conditions were 6.92, 4.51, 2.60 mm h^{-1} respectively. Maximum event intensity took place in daylight erosive rainfall and minimum was in mix rainfall. Likewise storm erosivity (EI) was 35.72, 23.80 and 18.65 respectively in daylight, night and mix rainfall (*Table 2*).

In the study, maximum rainfall intensities (IM10, IM15 and IM30) of each erosive rainfall are grouped for different time occurrences (daylight, night and mix rainfall conditions) and we observed the maximum average values in daylight rainfall (*Table 2*). Average erosive rainfall intensities (IM10, IM15 and IM30) were occurred the second in night and the third in mix rainfall.

Soil losses and runoff values are grouped for three different time occurrences (*Table 2*). The maximum soil loss and runoff are occurred in night rainfall. Even though in night erosive rainfall had less storm erosivity, event intensity and several time maximum intensities (IM10, IM15 and IM30) than daylight erosive rainfall, the most soil loss and runoff was observed. This result might be caused by day and night differences in soil conditions like infiltration, evaporation, etc. On the other hand, because of the longer mix rainfall duration more rain infiltrated in the soil by decreasing the runoff eventually the soil loss. Various rainfall properties such as the duration, intensity and its energy have more impact on the erosion compared to the rainfall amount. Although, the average erosive night rainfall amount is less than the mix erosive rainfall amount, the maximum runoff occurred in night rainfall because of soil hydraulic conditions.

The study showed that mix erosive rainfall characteristics were common in the Tokat region. However, because these rainfalls have lower event intensity, storm erosivity and several time intensities, they presented lower erosion risk. Interestingly, daylight rainfalls which have higher erosivity parameters (event intensity, storm erosivity and several time intensities) compared to night erosive rainfalls caused less soil loss. It is believed that this situation was caused by the day and night time temperature

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27192731

differences causing short time changes in the soil erodibility. As a matter of fact, erosive rainfalls are widely observed during April, May and June, when the day and night time temperatures are quite high.

Table 2. *The relation between some properties of the erosive rainfalls and soil losses and runoff in Tokat*

Correlations between soil loss, runoff and several time maximum intensities (IM10, IM15 and IM30): Some descriptive statistics for soil loss, runoff and several maximum time intensities are presented in *Table 3*, which reveals that, the higher CV of variables occurred in IM10, IM15, IM30, soil loss and runoff respectively. When the maximum intensities are compared, the CV values of IM10 and IM15 are more changeable than IM30.

Table 3. *Descriptive statistics of soil loss, runoff and several time maximum intensities*

Properties	Min.	Max.	Mean	St. dev.	Variance	CV
Soil loss, ton ha^{-1}	0.0003	27.51	2.20	4.88	24.28	221.66
Runoff, mm	0.01	15.92	2.00	3.50	12.38	174.64
IM 10, mm h^{-1}	0.42	199.80	13.10	18.22	332.76	139.01
IM 15, mm h^{-1}	0.42	134.00	10.53	12.95	168.27	123.07
IM 30, mm h^{-1}	1.00	78.80	7.43	8.45	71.57	113.77

The correlations between soil loss, runoff, IM10, IM15 and IM 30 are presented in *Table 4*. According to correlation analyses, there is strong positive correlation between properties (soil loss and runoff) and IM10, IM15 and IM30 values. The IM30 parameter has been shown to be a better predictor of sediment yield than rainfall depth (Foster et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27192731

al., 1982). Even though IM30 is widely adopted in the empirical estimation of event soil loss (Bagarello et al., 2013; Kinnell, 2010), in our study, we found the maximum correlation between soil loss and IM10 values. This may result IM10 values to describe erosivity as a better parameter than IM30 for the region. IM15 values are medium correlated between soil loss and IM15 values, while runoff and IM30 parameters showed maximum correlation.

Table 4. *Correlation coefficients between soil loss, runoff, IM10, IM15 and IM 30*

Properties	IM10, mm h^{-1}	IM15, mm h^{-1}	IM30, mm h^{-1}

Runoff, mm	0.805^{**}	0.781^{**}	0.815^{**}

$^{**}p < 0.01$

Trend and slope analyses: Trend analysis gave appropriate data to describe trend and slope of some rainfall characteristics, MFI index, soil loss and runoff for the region. The Mann-Kendall test and Sen's slope estimator were used for this purpose. The Mann-Kendall statistics for trend and Sen's slope estimator is given in *Table 5* for Tokat city. The Mann-Kendall statistics showed significant trend for all parameters. The Sen's slope estimator had negative slope for research period for all parameters. The calculated p values are smaller than the critical p value from the table of the standard normal distribution. The Ho hypothesis related to no monotonic trend was rejected for all data sets.

Rainfall erosivity is the ability of rainfall to cause erosion due to the function of erosive characteristic of rainfall (Mikhailova et al., 1997). In Tokat region, some physical characteristics of rainfall which is related to rainfall erosivity showed decreasing trend whole study period. Likewise, similar trends exist for soil losses and runoff.

Table 5. *Trend and slope results for study area for study period (1978-1995)*

Parameters	z	p-value	Sen	CI for Sen
Daily rainfall, mm	-3.50	0.00	-0.063	(-0.085, -0.044)

Runoff, mm	-3.50	0.00	-0.063	(-0.085, -0.044)
Soil loss, ton ha^{-1}	-2.47	0.01	-0.018	(-0.035, -0.004)

Comparison of R factor with Modified Fournier Index for the region: Computation of the erosion index (EI), which is basic for the determination of the R factor (Rain Factor) of Universal Soil Loss Equation (USLE) is tedious and time consuming and requires continuous records. Although there is pluviometer data in some rural areas but

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27192731

pluviograph data is not available in most areas. To handle this handicap some researchers have introduced various indexes or models. The Modified Fournier Index (MFI) is one of them. Several studies (Renard and Freimund, 1994; Diodato and Bellocchi, 2007; Lee and Heo, 2011; Taguas et al., 2013; Yue et al., 2014) have shown a high correlation between the R factor and rainfall parameters such as the MFI. In this study we used Modified Fournier Index (MFI) and R factor of USLE to estimate and compare each method to describe erosivity. To have a better understanding of MFI performance, 216 monthly MFI values and R factor values were compared. A strong correlation between them (r = 0.516**) was obtained. Monthly correlation coefficients and some descriptive between R and MFI values are given in *Table 6*. Both methods presented good correlation. The best correlations and maximum coefficient of variance were found in summer session.

Table 6. *Monthly correlation coefficients and some descriptive between R and MFI values*

Conclusion

The rain gauge data from 1978 to 1995 were analyzed for Tokat, located in the middle Black Sea region in Turkey, in order to characterize rainfall erosivity. The annual average rainfall was 452 mm. The EI values of the erosive rainfalls during the research period generally were low. A significant portion of the erosive rainfalls is lower than 10 mm. Erosive rainfalls usually took place during April, May and June. The highest EI values observed during the daylight erosive rainfalls, however with the temperature increasing during the day soil presented lower erodibility. It is assumed that this situation is linked to the higher soil temperature observed during the daylight rainfalls increasing the infiltration and evaporation, causing lower levels of runoff. Taking this result into consideration, it is recommended to carry out rainfall erosivity studies considering the soil losses and runoff as well. Rainfall erosivity studies carried out supported by soil losses and runoff will provide more reliable results.

Night erosive rainfalls which presents highest soil loss and runoff, created only 19.57% of all the erosive rainfalls. Although they have lower EI value than the daylight rainfalls, night erosive rainfalls caused more soil loss and runoff. Night erosive rainfalls almost created twice the soil loss compared to daylight rainfalls.

The Modified Fournier Index (MFI) was calculated using long term monthly data between 1978 and 1995. The MFI and R factor of USLE was compared and presented a strong correlation between them. This result shows MFI is useful an index to estimate rainfall erosivity which is not available pluviograph data for Tokat region.

According to trend analysis test results, the revealed findings indicated that the negative trends of all test parameters for the region. Considering to this result, a decrease tendency was determined in the erosion parameters of the region over time.

Tokat region rainfalls presented low erosivity. Mostly mix erosive rainfalls were occurred in study period. Mix erosive rainfalls have longer event duration but lower energy. Therefore, these rainfalls have lower erosion risk. Erosive rainfalls form almost 61% of the erosive rains. Although daylight and night erosive rainfalls have higher erosion risk, being low in ratio decreases the erosion risk. Soil losses can be taken under control by applying cultural practices on individual farmer basis, such as contour farming, no tillage, forage crop farming etc. Taking these precautions for sustainable farming does not create high levels of costs.

(Received 6th Dec 2018; accepted 4th Feb 2019)

Abstract. This study was conducted to determine the effect of different harvest aid chemicals on the yield and yield components of cotton in the experimental area of Osmanbey Campus in Harran University. The method employed in the study was the randomized complete block design with three replications in growing seasons in 2012 and 2013. The Stoneville-453 cotton cultivar was the subject of the study. Commercial names and compounds of the chemicals used in the experiment were as follows: Sonround (480 g/l Glyphosate), Efhun (Ethephon) (480 g/l Ethephon), Drop Ultra (120 g Thidiazuron + 60 g Diuron), Finish (480 g Etephon + 60 g Cyclanalide), and Appeal (54 g Fluthiacet-Methyl). Including the control plots, 10 treatments were performed when the bolls were 60% open. It was concluded that while the highest seed cotton yield was obtained from the Drop Ultra 600 cc ha^{-1} (5422.7 kg) and Appeal 75 ml ha^{-1} + Efhun 3000 ml ha^{-1} (5382.3 kg) applications in 2012, it was Sonround 3000 ml ha^{-1} (4150.7 kg) that produced the highest yield in 2013. On the other hand, the highest earliness ratio was obtained from the Drop Ultra 300 cc ha^{-1} + Efhun 3000 ml ha^{-1} treatment (96.30% and 96.30%) in both years. In the second year of the experiment, seed cotton yield and the number of bolls were lower when compared to the first year. The combination and single mixture treatments had different effects on examined properties.
Keywords: *Gossypium hirsutum L., defoliant, earliness ratio, boll weight, open boll percentage*

Introduction

Since cotton has a perennial and indeterminate growth property, it continues its vegetative growth as long as the conditions are appropriate. Thus, maturation is delayed (Stewart et al., 2000; Bondada and Oosterhuis, 2001). It is therefore important to harvest quality cotton on time. If a clean seed cotton harvest and higher harvest efficiency are desired, cotton must be defoliated before harvest either by hand or machine. Defoliation can shorten boll opening time by as much as 1-3 days, and provide an earliness ratio ranging between 1% and 20% in the first-hand seed cotton harvest (Oğlakçı and Gençer, 1992; Du et al., 2013).

Defoliation can be defined as the process of removing leaves when they become physiologically matured. Defoliation occurs when a release layer is formed at the point where the leafstalk (petiole) is attached to the plant stem (Görmüş, 2014). In order for the separation to come up in the leaves, certain conditions such as water stress (excess water or dehydration) need to be eliminated (Silvertooth, 2001). Separation of leaves, square, and bolls starts only when stress conditions are eliminated. However, separation can also take place within 24 hours after irrigation is applied to the dehydrated plants. In this case, defoliation takes place within 4-6 days (Osborne, 1974). For this reason, defoliation should not be delayed more than 4-5 weeks after the last irrigation.

Defoliants increase the synthesis of ethylene in the cotton plant. By creating an extra layer and encouraging the formation of a release layer at the point where the leafstalk joins the branch or main stem, they cause the leaf to break off. Meanwhile, the increase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27332743

of ethylene in plant tissues causes the rise of the auxin hormone, which promotes the opening of bolls (Morgan et al., 1977; Cathey, 1985; Suttle, 1988).

In addition to assisting the harvest, defoliation provides unspotted fiber, which results in better grades, faster and more efficient picking, faster drying of the dew, and thus early picks. It also helps delay the seed coat decay and encourage the boll opening (Edmisten, 1998). Therefore, it is necessary to use defoliants in order to accelerate the opening of the bolls before harvest, to increase harvesting efficiency, to reduce the seed cotton moisture, fiber contamination, and negative effects of pest and diseases populations (Oğlakçı, 1992). A plant, to which a defoliant or harvest-aid chemicals were applied, might have immature bolls on its top. As a general rule, the maturation of the first boll, placed at the 4^{th} or 5^{th} node downwards from the top boll on the plant to be collected, was used as a main determinant for the defoliant application time (Oğlakçı and Kaynak, 1992; Larson et al., 2005; Çopur et al., 2010). In defoliant applications, obtaining an optimum usage experience and desired result depends on when the farmers apply these defoliants rather than which chemicals they use (Edmisten, 1998). For this reason, the most suitable time of defoliation should be determined by considering genotype properties and region conditions (Çopur et al., 2010).

As a result of early defoliation, the yield is reduced and the fiber quality is negatively affected (Snipes and Baskın, 1994). Similarly, in the case of late defoliation, adverse weather conditions can be a problem (Kerby et al., 1992), and due to low temperature conditions, defoliation cannot be achieved sufficiently. However, late defoliations enable the development of immature bolls, thereby increases the yield. Defoliant timing has also a significant influence on the fiber quality. Too early or too late defoliation affects the fiber quality adversely (Samani et al., 1999; Wright et al., 2014). Early defoliation can be critical for maximum yield. On the other hand, the risk of yield loss as a result of the rain and early frost damages in winter season might be increased when defoliation is delayed (Bange and Milory, 2001).

Many researchers used defoliants and boll-opening chemicals that assist harvesting in their studies (Snipes and Baskın, 1994; Çopur et al., 2010; Du et al., 2013; Singh et al., 2015; Tashaev et al., 2016). Ethephon is a boll opener that is widely used as a chemical aid during the harvest. It increases the yield by increasing the number of opened bolls (Gwathmay and Hayes, 1997; Du et al., 2013; Singh et al., 2015).

While some researchers used a single chemical, others employed a mixture to achieve better results in harvest. If one or more defoliants and boll openers are mixed in the combinations, the activity and response of the defoliant increase positively (Snipes and Cathey, 1992; Gwathmay and Hayes, 1997; Du et al., 2013).

The joint use of defoliant and Etephon increases the rate of first-hand seed cotton yield significantly. But it does not have any effects on the boll weight, ginning outturn, and fiber properties (Du et al., 2013). Moreover, defoliant mixture and Ethephon (Thidiazuron+Ethephon and Thidiazuron-Diuron+Ethephon) can increase the number of opened bolls and enhance defoliation efficiency. They also increase the first-hand seed cotton yield more than a single defoliant and boll opener usage (Du et al., 2013).

Many studies have been carried out on defoliants and boll openers. In their study with different defoliants (Dropp Ultra and Round Up) and different application times (60, 75, and 90 days after flowering), Çopur et al. (2010) found out that Dropp Ultra treatment, applied 60 days after flowering, decreased the seed cotton yield, the number of bolls, boll weight and fiber index. However, they also pointed out that the delayed defoliant application increased the number of bolls, seed cotton yield and boll weight,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27332743

and that neither of the treatments had any effects on ginning outturn or fiber quality. On the other hand, Awan et al. (2012) reported that the defoliant treatments resulted in a twenty-five-day earlier harvest and provided a better seed cotton yield when compared to the control plots. In addition, they also argued that the treatments had significantly affected fiber fineness and uniformity, but had no significant effects on fiber strength. In a similar study, Singh et al. (2015) suggested that, after using the defoliants Dropp Ultra and Ethrel (Ethephon), the lowest yield was obtained from the highest dose (Dropp Ultra 225 ml ha^{-1}) while the highest yield was from the Dropp Ultra 200 ml ha^{-1} dose. Moreover, they claimed that the defoliants, applied 150 days after sowing, resulted in a more seed cotton yield when compared to the defoliants applied 140 days after sowing. They also stated that Dropp Ultra defoliant contributed better to the boll opening.

The Harran plain, where the study was conducted, is one of the most important cotton production centers in Turkey. The size of cotton sowing areas and the volume fibre production have increased significantly because of the increase in the number of irrigated lands following the GAP (Southeastern Anatolia Project).

However, in some years, the harvest is significantly delayed due to early autumn rainfalls. Seed cotton harvesting in this region is mostly performed with combine. Therefore, defoliation and boll opening are of great importance for increasing the combine harvest efficiency and a cleaner cotton harvest.

This study was carried out to determine the most appropriate dose or doses of different harvest-aid chemicals (single or mixture) and their effects on the yield and yield components of cotton.

Material and methods

The study was conducted in the experimental area of Osmanbey Campus in Harran University in accordance with randomized complete block design with three replications in 2012 and 2013 growing seasons. The experimental field is located in Harran Plain (altitude: 465 m; 37°08' North and 38°46' East) near the Turkish-Syrian border (*Figure 1*).

Figure 1. *The experimental field*

Stoneville-453 cotton cultivar was used as the study subject. ST-453 cotton cultivar Stonoville pedigreed seed co. was developed and registered in 1988 (Calhoun et al., 1997). In our region it was certificated in 1995 and has been widely used since then.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27332743

Especially earliness at an intermediate level, high yield and 42% gin outturn were the main reasons for farmers' preferring this cotton cultivar (Harem, 2010).

In the experiment, each plot was established with a length of 12 m, 6 rows, 70 cm inter-rows and 15 cm intra-rows spaces (*Figure 2*). Sowing was done on 14th April in 2012, and on 22th April in 2013 with a pneumatic sowing machine. During the experiment, half of the pure nitrogen (N) and all of the pure phosphorus (P) were applied. The N and P were applied as 70 kg ha^{-1} N and 70 kg ha^{-1} P_2O_5 respectively from a 20.20.0 composed fertilizer at the sowing time. The remaining pure nitrogen was given with the lister tool as 90 kg ha^{-1} just before the first irrigation.

Figure 2. *A photography from the experimental field*

Total irrigation amount during growing seasons (surface irrigation) was about 1100 mm. The first irrigation was applied 3 weeks after sowing and the second one was 3 weeks after that. Thereafter, the plots were irrigated every 2 weeks until the end of the season, thus providing a total of ten irrigations.

The experimental area was a flat and nearly flat land, and its calcium content was 32%. All soil profiles had high clay content (60%) and pH was from 7.3 to 7.4. The organic and salinity level was 0.8% and 0.08%, respectively. It had a high cation exchange capacity of 57.1 meq/100 g. Na content in the 0-150 cm profile was 1.4. The soil belonged to Ikizce soil series and is classified as vertic calciorthid aridisol (Dinç et al., 1988).

The average temperature during the cotton growth period (from April to October in 2012 and 2013) ranged between 19.3-18.4°C in April, 22.4-22.9°C in May, 30.6-29°C in June, 33.3-32°C in July, 32.3-31.6°C in August, 28.4-26.6°C in September, and 21.0-19.3°C in October (*Table 1*). The total precipitation was between 0.2 and 42.3 mm with a monthly average of 18.17 mm in 2012 (April-October), and between 0 and 56.2 mm with a monthly average of 12.17 mm in 2013. In addition, during the experiment period in summer, there was no rain in June, July, August, September, and October in 2013 (Anonymous, 2013).

(Anonymous, 2013)

The compounds of the chemicals applied in the experiment are as follows:

1) Sonround (480 g/L Glyphosate),
2) Efhun (Ethephon) (480 g/L Ethephon),
3) Drop Ultra (120 g/L Thidiazuron + 60 g/L Diuron),
4) Finish (480 g/L Etephon + 60 g/L Cyclanalide),
5) Appeal (54 g/L Fluthiacet-Methyl).

In both years, chemicals were applied as defoliants in accordance with the recommendations by manufacturers. Both chemicals were mixed with water (300 L ha^{-1}) and applied by using a backpack sprayer with a pressure set to 4.22 kg cm^{-2}. The sprayers were calibrated for a 4.80 km h^{-1} walking speed before each treatment.

Ten defoliant treatments were tested as follows:

T_1 : Sonround (3000 ml ha^{-1})
T_2 : Efhun (3000 ml ha^{-1})
T_3 : Drop Ultra (600 cc ha^{-1})
T_4 : Drop Ultra (300 cc ha^{-1}) + Finish (2500 cc ha^{-1})
T_5 : Drop Ultra (300 cc ha^{-1}) + Efhun (3000 ml ha^{-1})
T_6 : Appeal (1500 ml ha^{-1})
T_7 : Appeal (750 ml ha^{-1}) + Efhun (3000 ml ha^{-1})
T_8 : Appeal (750 ml ha^{-1}) + Finish (2500 cc ha^{-1})
T_9 : Finish (2500 cc ha^{-1})
T_{10} : Water spray (control plot)

Harvest aiding chemical treatments were applied on September 13 in 2012, and on September 10 in 2013 (when the bolls were opened at 60% ratio) (Silvertooth, 2001; Edmisten, 2006; Mrunalini et al., 2018). Harvest was made 15 days after the treatments in an area that includes middle two rows of each plot (10 m x 1.4 m = 14 m^2), excluding the 1-meter length from both sides of the plots. The first-hand harvest was done on September 28 and the second-hand harvest on October 27 in 2012, whereas the first-hand harvest was done on September 24 and the second-hand harvest on October 27 in 2013. Twenty plants were randomly chosen from the central row of each plot to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27332743

determine plant height, the number of opened bolls per plant, boll weight (g seed cotton boll^{-1}), seed cotton yield (g plant^{-1}), and plant height (cm). Earliness as percentage of the yield harvested in the first picking was calculated as follows: seed cotton yield in first picking was divided by the total seed cotton yield and multiplied by 100. Total seed cotton yield of each plot (including the twenty plant sub samples) was ginned on a laboratory roller gin stand to determine lint yield (kg lint he^{-1}), lint percent, seed index (g per 100 seeds), and lint index (g of lint per 100 seeds) (Sawan, 2016). Statistical analysis was performed by using the JMP 11 statistical program (SAS Inc.). Means were separated by Fisher's protected least significant differences (LSD) test and $p \leq 0.05$ was denoted as the significance level.

Results and Discussion

Seed Cotton Yield (kg ha^{-1})

Different results were obtained from different defoliant treatments in 2012 and 2013 years. The highest seed cotton yields (5422.7 and 5382.3 kg ha^{-1}) were obtained from the applications of T_3 (Drop Ultra 600 cc ha^{-1}) and T_7 (Appeal 75 ml ha^{-1} + Efhun 3000 ml ha^{-1}) in 2012, and T_1 (Sonround 3000 ml ha^{-1}) application provided the highest seed cotton yield (4150.7 kg ha^{-}1) in 2013 (*Table 2*).

* Means in each column followed by the same letter are not significantly different ($p<0.05$)

If one or more defoliants and boll openers are mixed in the combinations, the activity and response of the defoliant increase positively (Snipes and Cathey, 1992; Gwathmay and Hayes, 1997; Awan et al., 2012; Du et al., 2013). This idea is partially confirmed with an increase in treatments when compared to control plots. Thidiazuron accelerates boll dehiscence by increasing ethylene level in cotton leaves (Suttle, 1985). Light penetration is also improved by leaf removal. These crop conditions lead to early maturity and opening of bolls (Malik et al., 1991). Kerby (1988) stated that with stimulation of defoliation process, leaves transport most of their nutrients and metabolites to developing bolls. Results from this study also indicate that defoliants did not cause yield loss or deterioration in fibre quality in a physiologically matured crop.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27332743

In the second year of the experiment, it was observed that there was a decrease in the seed cotton yield in all treatments, which can be associated with the environment and climate conditions. When the climate data of the year 2013 are examined, it is seen that during the growing period (April-October) the weather (*Table 1*) was very dry, evaporation was intensive, and precipitation was too low (Anonymous, 2013).

Earliness Ratio (%)

In both years of the trial, statistically significant differences have been seen among all treatments in terms of earliness ratio. Of all treatments, the best earliness ratio results were obtained from the T_5 subject (Drop Ultra 300 cc ha^{-1} + Efhun 3000 ml ha^{-1}) (96.30 and 96.30%, respectively) (*Table 2*) in both years. Our findings were compatible with the results of Du et al. (2013) who obtained the highest seed cotton yields in earliness ratio from the defoliant and boll opener Thidiazuron+Ethephon and Thidiazuron-Diuron+Ethephon treatments (83 and 87%). Meanwhile, the lowest earliness ratio was obtained from the T_1 (Sonround 3000 ml ha^{-1}) and T_4 (Drop Ultra 300 cc ha^{-1} + Finish 2500 cc ha^{-1}) in 2012, and T_9 (Finish 2500 cc ha^{-1}) in 2013 (*Table 2*).

Number of Bolls (no. plant^{-1})

Different groups were formed among all treatments in terms of the number of bolls in both years. As in seed cotton yield, more boll numbers were obtained in 2012 than in 2013. When the climate data of 2013 is analyzed, it is seen that during the growing period (April-October) the weather was very dry and evaporation was very intensive (Anonymous, 2013).

Whereas, in 2012, T_1 (Sonround 3000 ml ha^{-1}), T_2 (Efhun 300 ml ha^{-1}), and T_6 (Appeal 150 ml ha^{-1}) produced the highest number of bolls, in 2013, T_9 (Finish 2500 cc ha^{-1}) and T_{10} (Control) gave the highest number of bolls (*Table 2*). Similarly, while Çopur et al. (2010) reported that the highest number of bolls were obtained from the both late defoliant application and no defoliant application plots, Görmüş et al. (2017) suggested that the highest number of bolls were obtained from the control plots in the second year. These results are also compatible with our findings. The reason for this situation is that the leaves of the plants in the control plots continue to exist with their vitality and they keep producing photosynthesis on the plant.

Number of Open Bolls (no. plant^{-1})

In both years, statistically different groups were formed in terms of the number of open bolls. In the first year of the experiment, the highest number of open bolls (18.60 per plant) was taken from the T_2 subject (Efhun 3000 ml ha^{-1}) (*Table 3*). However, in the second year of the experiment, T_{10} (Control) formed the highest number of open bolls (12.40 per plant) in all treatments. When the climate data were taken into consideration (Anonymous, 2013), it can be said that since the summer was dry, the plants in the control plots were bent to open more bolls and to be matured.

Number of Unopened Bolls (no. plant^{-1})

As shown in *Table 3*, statistically different groups were formed in terms of the number of unopened bolls in both years. T_{10} (Control) formed a greater number of unopened bolls (1.83 no. $plant^{-1}$) than other treatments in 2012. On the other hand, T_5 (Drop Ultra 300 cc ha^{-1} + Efhun 3000 ml ha^{-1}) mixture yielded the best result

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27332743

(0.83 no. plant^{-1}). The result of Singh et al. (2015) illustrates that Dropp Ultra defoliant promotes the boll opening better. This is consistent with our study. For, T_9 Finish (2500 cc ha^{-1}) gave the highest number of unopened bolls (1.83 no. plant^{-1}) in 2013. The best results (0.80 no. plant^{-1}) was taken from the T_1 (Sonround 3000 ml ha^{-1}) application.

% CV	1.64	3.07	9.65	10.49	2.82	1.50

*Means in each column followed by the same letter are not significantly different ($p<0.05$)

Boll Weight (g)

The highest boll weight (6.73 g) was obtained from the T_1 (Sonround 3000 ml ha^{-1}) in 2012 and from the T_4 (Drop Ultra 300 cc ha^{-1} + Finish 250 cc ha^{-1}) (6.67 g) in 2013. Defoliant and boll-opening treatments gave better results when compared to the control plots (*Table 3*). This situation reveals that defoliant and boll openers increase boll weight. In parallel with our study, Awan et al. (2012) report that the defoliant and sulfur doses gave better results than control plots in terms of boll weight.

Boll Seed Cotton Weight (g)

Statistically significant different groups were formed among all treatments in terms of the boll seed cotton weight in both years (*Table 4*). The highest boll seed cotton weight (5.03 g) was obtained from the T_1 (Sonround 3000 ml ha^{-1}) in 2012 from the T_4 (Drop Ultra 300 cc ha^{-1} + Finish 250 cc ha^{-1}) (4.20 g) in 2013. Awan et al. (2012) claim that the defoliant and sulfur doses gave better results than control plots in terms of boll seed cotton weight. This is confirmed in our study, as well.

Ginning Outturn (%)

In terms of ginning outturn, there were statistically significant differences between the treatments only in 2012. The highest ginning outturn was obtained from the T_8 (Appeal 75 ml ha^{-1} + Finish 2500 cc ha^{-1}) (41.97%) in 2012 (*Table 4*). These differences between years may be resulting from differences in climate factors. However, in their studies, Denizdurduran and Efe (2009), Çopur et al. (2010), Du et al. (2013), and Tülemen (2016) state that the ginning outturn differences are not significant.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27332743

Seed Index (g)

Different groups were formed among all treatments in terms of 100 seed weight in both years. In 2012, while the highest seed index weight (8.73 g) was obtained from the T_7 (Appeal 75 ml ha^{-1} + Efhun 300 ml ha^{-1}) and the lowest value was received from the T_{10} (Control) (7.83 g) treatment. All treatments formed more seed indexes than control plots (Awan et al., 2012). On the other hand, T_1, T_2, T_5, T_8, T_9 and T_{10} (control) had the highest seed indexes (*Table 4*) in 2013. This variability between years can be attributed to changing of climatic conditions (Anonymous, 2013).

Table 4. *Boll seed cotton weight, ginning outturn, and seed index in cotton with different harvest aid chemical treatments, and groups formed according to the LSD test*

Conclusion

While the T_3 (Drop Ultra 600 cc ha^{-1}) (5422.7 kg) and T_7 (Appeal 750 ml ha^{-1} + Efhun 3000 ml ha^{-1}) subjects gave the highest seed cotton yield (5382.3 kg ha^{-1}) in 2012, T_1 (Sonround 3000 ml ha^{-1}) gave the highest seed cotton yield (4150.7 kg) in 2013. In both years, the best results were obtained from the T_5 (Drop Ultra 300 cc ha^{-1} + Efhun 3000 ml ha^{-1}) in terms of earliness ratio (96.30 and 96.30%, respectively). Furthermore, the seed cotton yield and the number of bolls were observed to be lower in the second year when compared to the first year. T_1 (Sonround 3000 ml ha^{-1}) (5.03 g) in 2012 and T_4 (Drop Ultra 300 cc ha^{-1} + Finish 250 cc ha^{-1}) (4.20 g) in 2013 provided the best results in terms of boll weight. Different groups were formed among all treatments in terms of seed index in both years. In the study, combination and single mixture treatments had shown different effects on the examined properties. In addition, according to the results of the present study, it was found that the increase in combine harvesting has contributed to a clean and timely picking of cotton in recent years. Therefore, it becomes compulsory to use harvest aiding chemicals. In conclusion, although defoliants and boll openers increase the yield slightly, we recommend the farmers to use them since they have no negative impacts on the plants.

(Received 11th Dec 2018; accepted 4th Feb 2019)

Abstract. The main aim of this study is to investigate the compaction pressure and density profile, and to determine the effectiveness of the compaction process applied to the pile-type silos. Chopped material was compacted into a pile-type silo. Pressure-sensing rubber globes were placed at the measuring points to determine the compaction pressure, during the silo filling. The compaction pressure and compaction time were acquired by the pressure measurement system. Data were stored by a recorder. The density measurements were made at pre-determined measurement points in each layer after the compaction process. The results showed that there was a significant relationship ($R^2 = 0.919$, $P < 0.01$) between the compaction pressure applied to silage and the density of silage under field condition. Pressure and density profile were found to be highly variable in the silo. The highest density (535.0 Kg m^{-3}) and pressure (0.46 bar) were at the bottom layer of the silo while the lowest density (206.6 Kg m^{-3}) and pressure (0.21 bar) were at the top layer of the silo.
Keywords: *silage, pile silo, pressure sensor, pressure measurement system, silage density*

Introduction

The compaction process is the most important process in silage making. This process is necessary to increase the density and remove oxygen from inside the silage as much as possible. Higher silage density and quality can be achieved by applying more compaction on the silage. It was indicated in the literature that the density of silage was variable in silage silos (Muck and Holmes, 2000; Roy et al., 2001; Tan et al., 2018). Latsch (2014) stated that the heterogeneous density occurring in silos was a major problem.

The efficiency of compaction is affected by the weight of equipment used (Darby and Jofriet, 1993; Muck et al., 2004), the layer thickness, the number of layers, the silo height (D'Amours and Savoie, 2005), the applied pressure (Savoie et al., 2004), the compression time (Roy et al., 2001), and the operator experience (Tan et al., 2018) while compaction pressure has an effect on silage fermentation (Tan et al., 2017). Toruk et al. (2010) reported that fermentation characteristics of the silage were positively affected by the increasing compaction pressure. Savoie et al. (2004) found that the density of corn silage was affected by pressure and layer thickness. In Turkey, the most common types of silos used for silage are the bunker silo and the pile-type silo. The use of pile-type silos is much more common in small livestock farms. However, determination of silage density and silage quality are significant problems for small livestock farms. Previous studies were generally conducted in laboratory conditions (Hoffman et al., 2013; Savoie et al., 2004), and studies to determine the compression

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27452754

pressure in the silo under the field conditions are limited. Therefore, this study aimed to determine the relationship between density and compaction pressure in pile-type silo under field conditions.

Materials and methods

Experimental conditions

The second crop of maize (Pioneer ® P2948W) was harvested at 32% dry matter (DM) on November 2nd, 2017. The chopped material was ensiled in the pile-type silo within a day. The mean particle length of the chopped material was 12 mm. A single tractor (John Deere 6230) was used to compact the silage material. A mass of the compaction tractor was 4.6 tons. The tractor had a pressure of 2 bar at the front tire (380/85R24) and pressure of 2.3 bar at the rear tire (420/85R38). The transversal way has been used by the tractor to pack the silo. The compaction pressure applied during the packing of the pile-type silo in small livestock farm was also recorded. The densities of the material were calculated in the samples taken from predetermined measuring points. Before filling silo, a sample of fresh material was put aside to determine the dry matter content by oven drying at 103 °C during 24 h according to standard S358.2 (ASAE, 2002).

Pile silo and measurement points

The pile-type silo was 4.5 m wide, 12 m long, and 1.6 m high (theoretical volume of 86.4 m^3). The silo was divided vertically into three regions (north-N, center-C and south-S), and horizontally into three positions (1, 2 and 3) and three layers (top, middle, bottom). The height of layers in the silo was equal. The height of each layer is approximately 0.4 m. *Figure 1* shows the pressure and density measurement points and the location of pressure sensors.

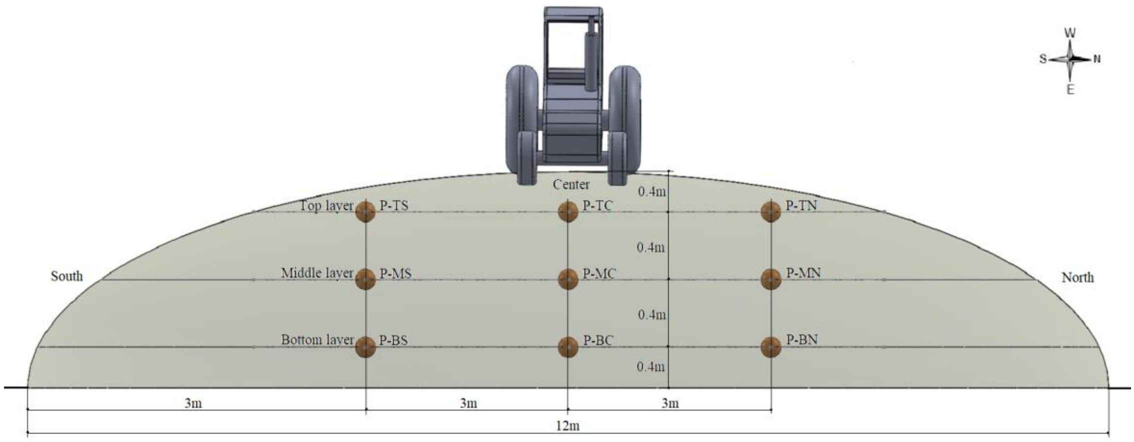

Figure 1. *Pressure measurement points in the pile silos*

Pressure measurement

The compaction pressure was acquired by the pressure measurement system. The measured pressure values were recorded by a data logger of the pressure measurement

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27452754

system throughout the entire process. Pressure values were recorded as one data per second (1 value/second). The lowest pressure (Min.), maximum pressure (Max.) and residual pressure (RP) values measured during the compaction process were evaluated. The residual pressure was the total pressure remaining on the material after the compaction process.

The pressure measurement system has mainly three units (*Figure2*). These are data collection and recording (1), pressure sensors (2), and pressure-sensing rubber globes (3).

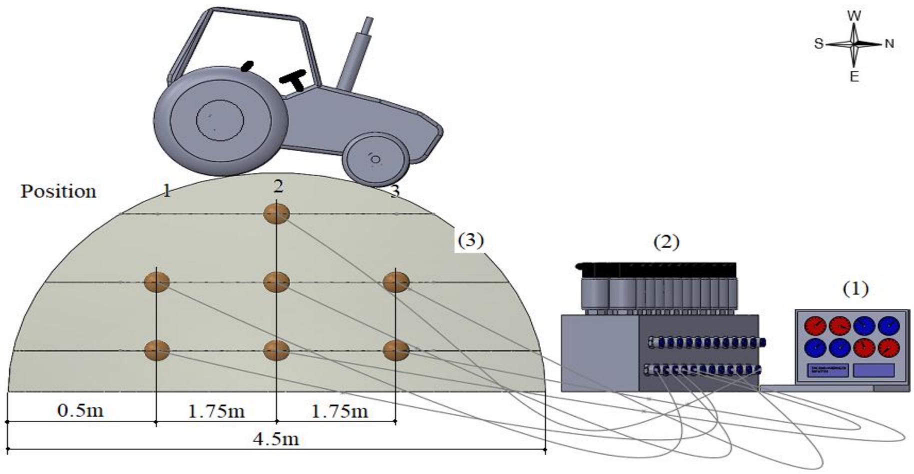

Figure 2. *Pressure measurement system; (1) data collection and recording, (2) pressure sensors, and (3) pressure sensing rubber globes*

The pressure-sensing rubber globes (PS) were installed into the silo to characterize the general condition of the silo and to measure the pressure during the ensiling stage. Pressure measurements were done by 27 PS. The pressure sensors were connected to the PSs via hydraulic hoses (Turner and Raper, 2001; Tan et al., 2018). The sensors (MPS500 series) used in the system had a measurement range of 0-25 bar, 4-20 mA output signal and a temperature range from -40 °C to +125 °C. The sensors were connected to NI DAQ measurement and storage system. The data (NI cDAQ-9184) were stored in an MS Excel file on the computer by using a user interface created with a NI Labview software (Tan et al., 2018). In order to determine whether the output values of the pressure sensors used in the measurement system were correct and reliable, especially under the dynamic conditions, two different calibration curves were created (Dalmıs, 2006; Akıncı, 1994). The pressure distribution was analyzed as a function of the three position factors (region, position, and layer).

Density measurement

The density measurements were made at each pressure measurement point after the compaction on each layer during the ensiling stage. The density distribution was also analyzed as a function of the three position factors (region, position and layer). The density of the silage was determined by taking the cylinder volume into consideration. The silage samples taken with the cylindrical container were then weighed (*Eq. 1*). The volume and weight of the silage materials were then used to calculate the density of the silage in kg m^{-3}:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27452754

$$\rho = \frac{m}{v} \quad \text{(Eq.1)}$$

where ρ is the ensiling material density, kg m^{-3}, m is the mass of the ensiling material filling, kg, and v is the cylinder volume, m^{-3} (Hoffmann et al., 2013; Wang, 2012).

Compaction time measurement

The compaction time was measured by the pressure measurement system. The measured time values were recorded by a data logger of the pressure measurement system throughout the entire process. The total compaction time measured during the compaction process was evaluated. The compaction time (hour/min) of packing tractor was recorded to estimate total compaction time on each layer.

Statistical analysis

In this study, to evaluate statistical significance between the compaction pressure and density in a pile-type silo, the data were analyzed by using the one-way ANOVA employing SPSS (version 18.0) software in a 3 x 3 x 3 factorial design. The minimum level of significance was 5%. Means were compared by the Tukey HDS test. A correlation test was performed among all parameters. The model statement included the effect of treatment, region, layer, position and interaction treatment (Eq.2).

The mathematical model used was;

$$y_{ijkl} = \mu + r_i + l_j + p_k + (rl)_{ij} + (rp)_{ik} + (lp)_{jk} + (rlp)_{ijk} + e_{ijkl} \quad \text{(Eq.2)}$$

in which y_{ijkl} = observed value of the variable that received the level of region i, layer j, position k, μ = overall mean; r_i = region effect, l_j = layer effect, p_k = position effect, interactions and e_{ijkl} = random error associated with each observation.

Results

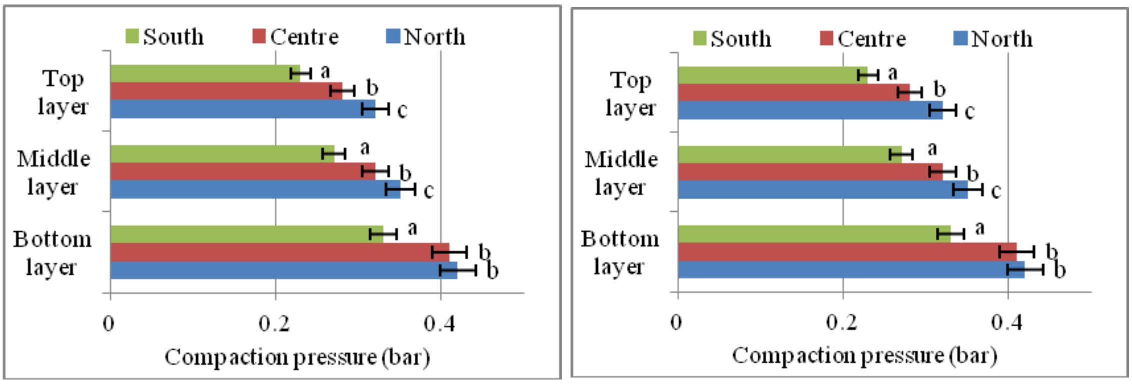
The compaction pressure (a) and the density (b) measured in different layers according to the north-south regions of the silo are given in *Figure 3*. Compaction pressure and density values were increasing from the top layer to the bottom layer in all regions of the silo. The average values of the compaction pressure (a) and the density (b) measured in different layers according to the position are given in *Figure 4*.

The density of the silage and the residual pressure, the minimum and maximum compaction pressure measured in different layers during the ensiling stage are given in *Table 1*. When the values of compaction pressure between three layers were compared to each other, the top layer data were lower than the middle and the bottom layers. The bottom layer had the highest average compaction pressure compared to the other layers. Different results were obtained for the pressure. Compared to the other points, at the B-N_3 (0.46 bar) point, residual pressure was the highest, and at the T-S_1 (0.21 bar) point the lowest residual pressure was measured.

The applied compaction pressure varied from the northern (N) region of the silo to the southern (S) region. The highest pressure was measured in the northern region of the silo. B-$N_{1,2,3}$ were 16.67% and 24.77% higher than the C-$N_{1,2,3}$ and S-$N_{1,2,3}$, respectively. This indicates that the operator spent more time in the northern region of the pile-type silo than other regions. The effects of the compaction pressure have been

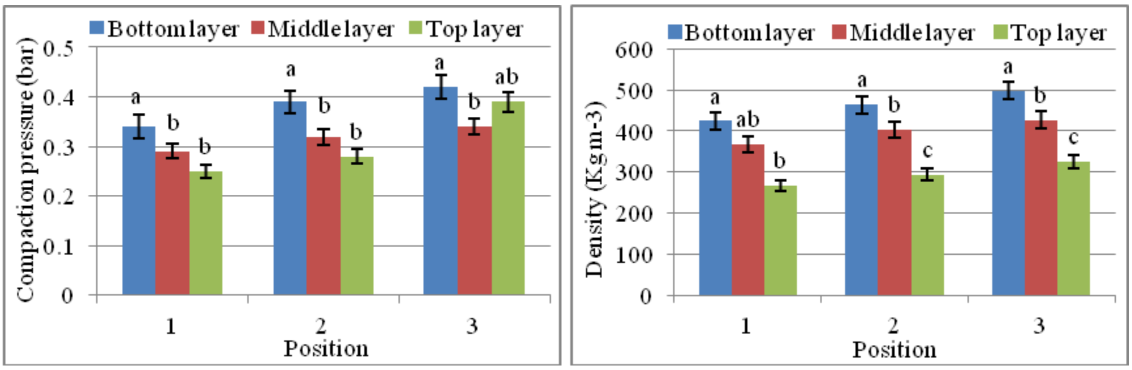
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27452754

found statistically significant in the region and position ($P < 0.05$). The lowest mean compaction pressure was at position-1 (0.29 bar), and the highest compaction pressure was at position-3 (0.35 bar), which was 16.72% higher than the one at position-1.



a b

Figure 3. *The compression pressure (a) and density (b) measured in different layers according to the regions. Column with different letters within regions are statistically significant at P = 0.05 (n = 9)*



a b

Figure 4. *The compaction pressure measured (a) and density (b) in different layers according to the positions (positions 1, 2 and 3 have been shown in Figure 2). Column with different letters within regions are statistically significant at P = 0.05 (n = 9)*

The density of fresh matter increased from top to bottom in the pile-type silo. The bottom layer had the highest average fresh matter density compared to other layers. The average silage density of the top layer was the lowest and bottom layer had the highest silage density among the three layers. The compaction pressure applied to the silo is not equal which causes density differences. For this reason, the compaction time in the top layer of the silos should be higher than the other layers. The highest density was measured in the N-region of the silo. There was a difference among the regions according to the densities. B-$N_{1,2,3}$ were 15. 85% and 37.73% higher than the M-$N_{1,2,3}$ and S-$N_{1,2,3}$, respectively. The fresh matter density measured at position-3 of the silo in all layers was much higher than position-1 and position-2 of the silo. The effects of the density and the compaction pressure on the regions, layers, and positions are shown in *Table 2*.

MP: the measurement point defined for density and pressure; Min.: the lowest pressure value measured at the specified point; Max.: the highest pressure value measured at the specified point; RP: the residual pressure on the material after compression

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27452754

The density was the lowest at T-S_1 position with 206.6 Kg m^{-3} and the highest at T-N_3 position with 345.1 Kg m^{-3}. The main reason for this is that there was a shelter near the right side of the silo. This was a problem for the quality of the compaction process. The density also increased with the increasing pressure. The densities obtained in our study were similar to several studies in the literature. In the present study, the density in the regions ranged from 337.32 Kg m^{-3} to 420.98 Kg m^{-3} (*Table 2*).

The highest density and pressure changes were calculated between the layers, which are 36.16% and 27.15%, respectively. The lowest density and pressure changes were calculated between the positions, which are 15.27% and 16.72%, respectively. The density and residual pressure in the northern and center region of the silos were higher than the southern region of the silos. The layers had significant effects on the density and pressure ($P < 0.05$). The highest values were measured at the bottom layer. In the present study, the density of the pile-type silo ranged from 294.77 Kg FM m^{-3} to 461.7 Kg FM m^{-3}. The compaction time was the lowest at the top layer and the highest at the bottom layer. The positions had also significant effects on the density and pressure (*Table 2*). The average residual compaction pressure on the material after compaction in the pile-type silo was calculated as 0.33 ± 0.62 bar, and the average density was calculated as 385.178 Kg m^{-3}.

Table 2. *The effects of density and compaction pressure on the regions, layers and positions*

Regions	D	RP	Layers	D	RP	Positions	D	RP
North	420.98^{a}	0.362^{a}	BL	461.71^{a}	0.383^{a}	1	352.77^{a}	0.294^{a}
Centre	397.22^{a}	0.338^{a}	ML	399.05^{b}	0.317^{b}	2	386.45^{ab}	0.331^{ab}
South	337.32^{b}	0.279^{b}	TL	294.77^{c}	0.279^{c}	3	416.30^{b}	0.353^{b}
RP				$R^2 = 0.989$				
Region*Layers				F = 9.412			$P < 0.05$	
Region*Position				F = 7.765			$P < 0.05$	
Layers*Positions				F = 17.353			$P < 0.05$	
Region*Layers*Positions				F = 5.397			$P < 0.05$	
D				$R^2 = 0.996$				
Region*Layers				F = 32.147			$P < 0.05$	
Region*Position				F = 31.291			$P < 0.05$	
Layers *Positions				F = 4.919			$P < 0.05$	
Region*Layers*Positions				F = 20.426			$P < 0.05$	

*Mean values in the same column with the same superscript do not differ significantly at ($P < 0.05$)
D: Density; RP: is the residual pressure on the material after compression

The correlations amongst all parameters are shown in *Table 3*. The correlation results showed that the fresh matter density of the silages and the compaction pressure were strongly ($R^2 = 0.919$, $P < 0.01$) correlated (*Table 3*).

The density of the silage in the pile-type silo was positively affected by the increasing compaction pressure. The pressure and density of the silage showed positive correlations with the regions and positions, whereas they were negatively correlated with the thickness of the increased layers. This indicates that the thickness of the layers, the compaction times reserved for the layers, and the movement of the compaction equipment is important in silo management.

Discussion

In our study, the density and pressure values in some regions of the silo are higher than the other regions. However, according to Latsch (2014), there are no significant differences between the bulk density in compact areas. In position 1, compacting time was found a bit longer than in position 2 and 3. In the present study, compaction time was the lowest at the top layer and the highest at the bottom layer. This indicates that the operator spent more compaction time in some layers than the other ones. Similar results were reported by Latsch (2014), Tan et al. (2018), and Muck et al. (2004).

There is no literature on compression pressure measurement in the ensiling process performed under field conditions. Compaction efficiency has been described in relation to silage density in many studies. In this study, the compression pressures and silage density measured in the field conditions have been explained together. As a result of the study, it was observed that the densities related to the measured pressure values were consistent with the literature. As a result, it was seen that the compaction pressure applied in the pile-type silo meets the recommended density values in the literature.

In the present study, the density of the pile-type silo ranged from 294.77 Kg FM m^{-3} to 461.7 Kg FM m^{-3}, which are similar to those found by Muck and Holmes (2000) and Roy (2001). These values are higher than the ones (205.03-376.43 Kg m^{-3}) expressed by Norell et al. (2013) and (129-302 Kg m^{-3}) expressed by Oelberg et al. (2006). These results can be explained by the fact that they are not average value.

In our study, it was determined that the silo density and pressure increased from the top layer to the bottom one. This can be explained by the increase in the layer thickness and the weight of the mass. Huhnke (1995), Muck and Holmes (2000), D'Amours and Savoie (2005), and Oelberg et al. (2005) also observed that the density at the top of the silo was lower than the density measured at the bottom. However, the data about the compaction pressure were not determined in the literature. D'Amours and Savoie (2005) reported that the density in the silo was quite variable and was affected by the pressure. According to Tan et al. (2017), the highest compaction pressure measured in the bunker silo is 0.34 bar. In our study, the measured residual pressure was 0.46 bar, which was higher than the value reported by Tan et al. (2017). Although average residual pressure was 0.33 bar, the maximum pressure measured instantaneously was0.726 bar during the ensiling.

There was a strong and positive relationship between the silage density and the compaction pressure applied to the corn silage in a pile-type silo. The results showed a positive correlation with regions and position, whereas they were negatively correlated with increasing layers thickness. According to Tan et al. (2017), there was a relationship between the compaction pressure applied to silage and temperature. The relations between density and pressure were not reported in those studies conducted in field conditions in the previous studies.

Conclusion

Pressure and density values in the silo were found to be quite variable for regions, positions and layers. The differences could be largely explained by different compaction times and tractor mass for regions, the way used by the tractor to pack the silo for positions and the increasing material mass for layers. At small farms, very heavy compaction equipment is not available. For this reason, it may be advisable to make more compaction time for packing or more passages on a thinner layer to achieve high density in these farms.

Results indicated that it is important to select areas that will not restrict tractor movements when locating the silo. This situation causes differences in silo compaction pressures due to restrictions on tractor movements. The effects of measured exact regional compaction time on the quality of silage and silage compaction pressure can be worked for future works.

DETERMINATION OF HEAVY METAL ACCUMULATION IN AIR THROUGH ANNUAL RINGS: THE CASE OF *MALUS FLORIBUNDA* SPECIES

YIGIT, N.

Department of Forest Engineering, Faculty of Forestry, Kastamonu University Kastamonu Turkey
(email: nyigit@kastamonu.edu.tr; phone: +90-366-280-1747; fax: +90-366-280-1700)

(Received 6th Dec 2018; accepted 4th Feb 2019)

Abstract. Air pollutants can be observed all over the world. Sulfur dioxide and nitrogen oxides are the most worrying ones among them. The growth rates of many forested areas in the world decrease at high altitudes, and air pollutants are more abundant as the cause of this. The leaf surface constitutes the interface between plants and the worsening atmospheric environment. Therefore, it is the first point of contact between plants and air pollutants and constitutes an effective barrier to the pollutant input. The outer surfaces of leaves are covered with a thin membrane called the cuticle. This membrane layer has many basic functions, such as preventing the excessive water loss of the plant, regulating the intake of dissolved substance and protecting photosynthetic tissues, preventing of harmful irradiation, such as improved UV-B caused by stratospheric ozone depletion. The wood structure also provides us with information on the pollutants to which they are exposed to and their levels due to the fact that trees are stationary. In this study, the accumulations of Co, Cu, Cd, Pb, Ni, Cr, Mn, Fe, Al, Zn, Na, Ca, Ba, Mg, and As elements, accumulated on the annual rings of *Malus floribunda* species in Ankara-Yenimahalle between 1962 and 2017, by years were determined using the GBC Integra XL–SDS-270 ICP-OES device. In conclusion, it is observed that amounts of all elements in the wood in different age ranges are statistically different at a confidence level of at least 99.9%.
Keywords: *wood, air pollutant, tree species, bioindicator, elements*

Introduction

Toxic pollutants have increased considerably in the last century and adversely affect the lives of most living beings around them (Wolz et al., 2003; Tang et al., 2013). Trees in the settlements contribute to preventing air pollution; reducing noise, wind, dust and greenhouse effect; balancing temperature; providing energy savings and moisture; and creating habitats for fauna and flora (Cetin, 2018a, b, c, d). Environmental pollution includes the mixture of organic and inorganic compounds. Although organic components decompose harmlessly and as fully mineralized, the separation of inorganic compounds from the medium is technically difficult since do not change with a physical process (Meagher, 2000). Inorganic pollutants are basically heavy metals, such as As, Ag, Hg, Sb, Cd and Pb, containing the elements with biological functions (such as Fe, Mo, Mn, Zn, Ni, Cu and Co), which are harmful when they are present in excessive amounts and which do not play a known role in living organisms (DalCorso et al., 2013). Inorganic pollutants may arise from natural conditions such as the exposure of rocks to weather conditions, soil erosion, and volcanic activities or human-induced factors such as industrial or agricultural activities (Fasani et al., 2018).

Human-induced factors can be defined by the high concentration of primary pollutants such as SO_2 in the air and initiate local pollution. These activities can be the cause of tree deaths, and the high level of air pollutants in neighboring areas (Garrec, 1993).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27552764

Secondary pollutants are characterized by physiological effects, such as the yellowing of leaves and a decrease in the viability of trees as a result of the interaction of secondary pollutants with trees. These pollutants, usually along with climatic stress, initiate forest decline with a very irregular localization on a regional scale. It is necessary to consider the nature and level of these pollutants to determine the plant stress caused by air pollution. As an example of this, a summary of the scientific literature on the effects of air pollutants on epidermis characteristics during two periods was created (*Table 1*) (Garrec, 1993).

Table 1. *The effects of air pollutants on epidermis characteristics from the scientific literature*

Air pollutant	**Cuticular characteristics**				
	Wax erosion	**No wax erosion**	**Increasing wax amount**	**Decreasing wax amount**	**No effect on wax amount**
SO2	*******	****	**	**	**
O3	*****	*****		**	**
Acid rain	******	***	*	*	**
Acid mist	**	**			**
NH3	**	**			

*Shows the density of pollutants

The data presented in *Table 1* show the variability of the response of the plant surface and/or the inhomogeneity of the action of these pollutants. Nevertheless, based on these data, primary air pollutants such as SO_2 are likely to have a detrimental effect on the epidermis. Unlike the concentrated primary pollutants, secondary air pollutants such as O_3 or acid deposits seem to have a less significant effect on the cuticle layer. In fact, most of the results show that the effect of these less concentrated secondary pollutants is similar to the aging process and does not have a polluting characteristic (Gunthardt-Goerg and Keller, 1987; Lutz et al., 1990).

Trees are regarded as the sensors that record environmental disturbances since they live for a long time, that remain in the same place throughout their lives and thus display chronology, and that are geographically common (Kord et al., 2009; Balouet et al., 2007). The fact that trees accumulate the heavy metals they receive from the air with the components in and above the soil makes them good indicators. Therefore, various organelles such as trunks, branches, and leaves of trees have been used for many years to determine the concentration of heavy metals in them. Leaves are the most commonly used organelles. The main reasons for this can be listed as the fact that leaves incorporate heavy metals through their stomata during photosynthesis and accumulate them, the fact that the collection of leaves does not cause permanent damage to the tree, and the fact that how long the accumulated heavy metal accumulates is known since the ages of leaves are known. Furthermore, herbarium collections (Herpin et al., 1997), the annual growth rings of trees (Watmough, 1999) also provide historical examples for bio-analysis. In fact, trees are not better indicators compared to fungi, algae, and moss. However, the use of trees throughout cities and the fact that they live longer compared to other indicator plants provide more information to scientists about the increase in heavy metal pollution in the air from past to present in the studies carried out on them (Sawidis et al., 2011; Turkyilmaz et al., 2018a; Shahid et al., 2017; Shcerbenko et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27552764

2008). In recent years, many authors have reported the temporal and spatial reconstructions of heavy metals recorded on tree rings of different tree species (Aznar et al., 2008; Lageard et al., 2008; Nabais et al., 1999; Orlandi et al., 2002; Vives et al., 2005; Türkyılmaz, 2018b).

Materials and methods

The study was carried out on the wood materials obtained from *Malus floribunda* tree located in Yenimahalle region, which is one of the regions of Ankara province with the heaviest traffic. Ankara province has an area of 26.897 km^2 and is located between 39.57 N latitude and 32.53 E longitudes. Its altitude above sea level is approximately 890 m. Ankara province is located in B4 square (Grid) according to P. H. Davis's Turkey map grid system (Davis, 1965-1985). In terms of biogeography, it is located in the Irano-Turanian floristic region. The Irano-Turanian floristic region covers the central and eastern Anatolia regions of Turkey. These regions are cold and snowy in winters and usually dry and without rain in summers (Atalay and Efe, 2014; Saya and Güney, 2014). The average temperature on a provincial scale is 11.7 °C, and the annual average precipitation is 389.1 mm. The highest and lowest temperature values were determined to be 40.8 °C and -24.9 °C, respectively. Upon examining the provincial center and the wind status of stations in general, the dominant wind is observed to vary depending on the land structure. Accordingly, the dominant wind blows in the northeast direction in Ankara (center), Esenboğa and Yenimahalle districts where the study area is located. The highest wind speed determined in Ankara is 29.2 m/s (URL 1) (*Fig. 1*).

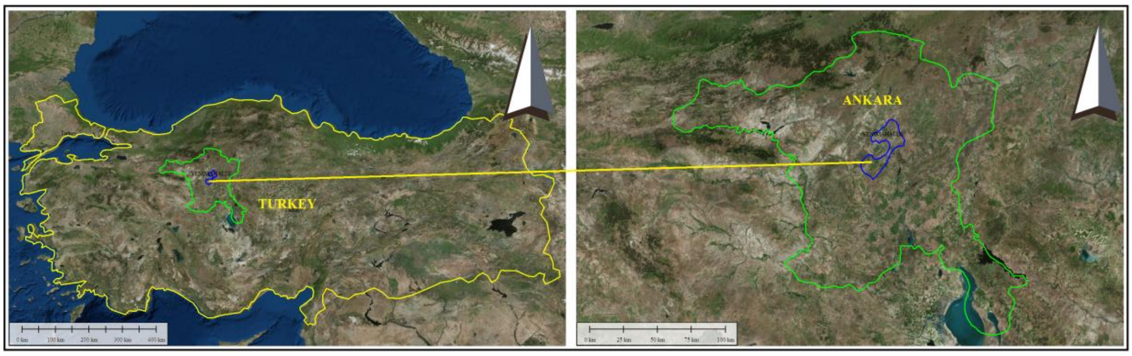

Figure 1. *A map of Ankara*

The samples were cut from *Malus floribunda* in Ankara-Yenimahalle (Turkey) in December, when the vegetation season ends, in 2017. The cut samples were brought to the laboratory and separated into pieces in the form of 1 cm-thick discs in the laboratory environment. The sectional surfaces were made smooth by sandpapering so that annual rings could be observed clearly. During the macroscopic observation, it was determined that the tree was 55 years old, and it was decided that it was appropriate to perform grouping into five age ranges by considering the widths of annual rings. The annual rings were divided into five-year sections, and the samples taken from two opposite sides of the tree were classified. Thus, 11 samples including five-year annual rings and barks were obtained.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27552764

The wood samples were shredded and turned into sawdust. During these processes, attention was paid to not using any tool made of the elements discussed in the study. The wood samples were first kept for 30 days until they became dry. Then, they were dried in the drying oven at 50 °C for one week. 0.5 g of the dried samples were taken, 6 ml of 65% HNO_3 and 2 ml of 30% H_2O_2 were added to them, and they were placed in a microwave oven. The program of the microwave device was set to 15 min at 200 °C. After burning the samples in the microwave oven, the samples which were dissolved into solution were taken into balloons and completed to 50 ml with ultrapure water and made ready for Fe, Co, Ni, Zn, Cd, Hg and Pb analyses with the GBC Integra XL–SDS-270 ICP-OES device (GBC Scientific Equipment Pty Ltd., Melbourne, Australia) For the analysis of the samples, the plasma of the ICP device was burned, and ultra-pure water was passed through the system for 15 min to equilibrate. The calibration chart was created by preparing standard solutions according to the elements to be analyzed. After constructing the calibration chart, the samples were given to the system and read. Since the sample was taken by 0.5 g and completed to 50 g with water, the analysis results were multiplied by 100. Different calibration charts were created at the ppm or ppb level according to the analysis results that did not fall into the calibration chart, and reading was performed again. The detection limits for the GBC device were determined to be (Pb---> 0.377 ppb, Cu---> 0.639 ppb, Ca---> 0.00208 ppm, Mg--->0.00758 ppm, Cd---> 0.063 ppb, Cr---> 0.311 ppb, Ni---> 0.171 ppb, Fe---> 0.00068 ppm, Mn---> 0.00015 ppm, Zn---> 0.00634 ppm). In the study, all measurements were performed in three replicates. Then, the data were evaluated by the analysis of variance, Duncan's test, and correlation analysis using SPSS package program (Anonim, 1998; Eymen, 2007).

Results

A total of 15 elements were discussed for the determination of heavy metal accumulations in the wood and bark. The analysis of variance and Duncan's test were applied to the results obtained in terms of the studied elements. The average values obtained for wood and bark and the F values calculated as a result of the analysis of variance are presented in *Table 2*.

Based on the results summarized in *Table 2,* it was determined that there was no significant difference among Cu, Fe, Ca and As values at a confidence level of at least 95%. For the rest of the elements, statistically significant differences were found between the wood and bark. According to the F values calculated, the values obtained for bark and wood were significantly different at a confidence level of 99.9% for all elements (*Table 2*). However, Duncan's test was not applied to determine the homogeneous group since it was performed on 2 characters including bark and wood.

The analysis of variance was performed using SPSS according to all the elements studied on annual rings in the wood sample, and the analysis result, F value, and Duncan's test results are presented in *Table 3*.

Upon examining *Table 3,* it was observed that there were significant differences at a confidence level of at least 99.9% in terms of all the characters subjected to the analysis of variance. It was determined that Cu value was divided into 9 different homogenous groups and that the highest value (26674.13) was reached between the years 1967-1972. Similarly, it was determined that Ni (1907.5), Al (2327.9), Mg (907.56) and Zn (14033.33) also had the highest values between those years. It was determined that As

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27552764

value was divided into 2 different homogenous groups and that Na, Ba, and B values were divided into 10 different homogenous groups. Na value was determined to be the highest (2016.6) between the years 2000 and 2005. It was determined that Mg element reached its highest value between 1955 and 1960.

The graphics, which were prepared to make the changes associated with heavy metals according to the ages more clearly understandable, are presented in *Figure 2*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27552764

Figure 2. *Annual changes in heavy metal concentrations over years (A changes in Co concentrations, B changes in Cu concentrations, C changes in Cd concentrations, D changes in Pb concentrations, E changes in Ni concentrations, F changes in Cr concentrations, G changes in Mn concentrations, H changes in Fe concentrations, I changes in Al concentrations, J changes in Zn concentrations, K changes in Na concentrations, L changes in CA concentrations, M changes in Ba concentrations, N changes in Mg concentrations, O changes in As concentrations*

As seen in *Figure 2,* especially Pb, Cu, Co, Mg and Ba elements were found to decrease after 1979-1984 years. One of the reasons for this could be the use of natural gas in Ankara since the 1980s.

As a result of the study, correlation analysis was performed to determine the relationships between the elements and the results are presented in *Table 4*. The studied relationship that was not measured in the correlation analysis is related to the linear part of the relationship between the variables. The correlation coefficient calculated as a result of the correlation analysis is indicated with r and takes values between –1 and +1. The fact that the coefficient is close to +1 indicates that there is a good correlation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27552764

between the two variables, and the fact that it is close to -1 indicates that there is a good but inverse correlation; in other words, one of the variables increases while the other one decreases. Upon evaluating the results in this respect, it is observed that the level of relationship between some elements is really high.

Na ppm											-.392*	-.312	-.370*	-.429**
Ca ppm												.603**	.671**	.674**
Ba ppm													.961**	.745**
Mg ppm														.815**

Upon examining *Table 4,* it is observed that there is a positive correlation in general with respect to the measured characters. When the results are examined in this context, the relationship between some elements is observed to be quite high. For example, the correlation coefficients between Cr and Al (0.986), Mn and Al (0.998) and Cr and Mn (0.979) are quite high. Similarly, the correlation coefficient calculated between Na and As (-0.429) is negative but very strong. Furthermore, very strong relationships were observed among many elements (*Table 4*).

Discussion and conclusion

The results of the study reveal that the concentration of all heavy metals that adversely affect human health increases with age. It can be said that the increase in the amount of heavy metals in tree rings is due to the morphological structure of the tree and ecological impacts, which does not exhibit a linear increase, high in some years and low in other years. The morphological structure of the epidermis layer varies by age and polluted air (Huttunen and Laine, 1983; Mengel et al., 1989; Turunen and Huttunen, 1990). Similar results were also obtained in the studies carried out on different species (Beramendi-Orosco et al., 2013; Türkyılmaz et al., 2018c, 2019). In the study carried out by Beramendi-Orosco (2013): on *Prosopis julifora* annual rings, the researchers ported that the amount of Cu, which was 1.09 ppm during 1988-1992, was 1.27 ppm during 2003-2007 and that the amount of Pb, which was 0.35 ppm during 1998–2002, was 0.46 ppm during 1993-1997. Similar results were also obtained in the studies in which changes were determined by months (Norouzi et al., 2015).

When tree annual rings were examined, it was determined that heavy metal accumulation was intense in the early years in elements such as Cd, Pb, Al, Zn, Mg, Ca and B. However, there is no clear evidence on whether this intensity was due to the accumulation during the first years of the tree or the accumulation of all years. As seen

DOI: http://dx.doi.org/10.15666/aeer/1702_27552764

in *Figure 2,* especially Pb, Cu, Co, Mg and Ba elements were found to decrease after 1979-1984. One of the reasons for this could be the use of natural gas in Ankara since the 1980s.

Although some elements such as K, S, Mg, CI, and P can be transported to the plant's metabolic activities, the transport of certain elements in the phloem (B, Ba, Ca, Cu, Fe, Li, Mn, Mo, and Zn) is more limited (Perone et al., 2018). In recent years, the nature and intensity of the concentration of elements in nature have increased due to the increase in human effects and vehicle traffic. Some data indicate that climate change is affected not only by the traces of pollution but also by plant metabolism and by the distribution of elements in plants (Cui et al., 2013; Li et al., 2004). Nowadays, in the world, motor vehicles exhausts, industrial activities, mineral deposits and enterprises, use of urban wastes as fertilizers, chemical fertilizers and pesticide applications, and reach a significant amount of heavy metal soil. The accumulation of heavy metals in the soil not only affects soil fertility and ecosystem activities, but also affects many metabolic events such as photosynthesis, respiration, growth and development within the plant and therefore affects animal health and human health significantly due to deteriorated food chain. In the soils where heavy metal accumulation is observed, heavy metals reach the human body through the skin contact of people, breathing, growing vegetables and fruits. For this reason, heavy metal that can be harmful to human health, etc. the means of transmission and prevention of all kinds of substances should be investigated.

Abstract. Similarity Indices are widely applied in the field of ecology to measure species diversity as well as to map patterns of conservation and monitor threats to biodiversity. Among the known, Jaccard's and Sorensen's indices are the most frequently employed similarity Indices. Here, we propose a new and efficient statistical approach in the field of ethnobiology and validate its efficacy by comparing the results with predefined similarity Indices used in previous studies. The core objective was to propose a new index for quantitative ethnobiological analyses and to find out solutions for sorting the plants having similar ethnobiological uses in allied, aligned, national and global regions; as the pre-existing indices like Jaccard's and Sorensen's indices provides best estimates in the field of ecology but not in ethnobiological studies. In comparative ethnobiological studies, ethnobiologists use conventional ecological tools for evaluation of similarities and dissimilarities. Our proposed similarity index is based on the quantification of similar uses of common medicinal plants via comparing present study with previously published reports from various areas where, the author(s) have used the Sorensen's index and/or Jaccard's index. To assess the significance and validity of this newly developed index, similarities and differences in ethnomedicinal studies on medicinal plants in different regions were evaluated. Data regarding medicinal plants usage here was compared with 20 previously published studies and then analyzed through pre-existing indices as well as Rahman's index to examine the novelty in the study. Our preliminary results revealed noteworthy coherence with the existing similarity indices, albeit, the new index was more efficient than the previous. Our comparison revealed, that as far as common vegetation and floral levels are concerned, the existing ecological coefficients of similarity are efficient and precise; but for similarities in the field of medicinal plant studies certain constraints are overcome by the proposed similarity index. Inferences derived from Rahman's similarity index (RSI) are as reliable as the previously known and well-established similarity indices. Further, RSI specifically targets the ethnobiological similarities, a limitation in Jaccard's and Sorensen's indices. Thus, RSI would be a useful tool/index in the assessment of rigorous quantitative ethnobiological data.

Keywords: *similarity index, novel uses assessment, quantitative ethnobiology, ethnomedicine, cultural use similarities*

List of abbreviations: RSI: Rahman's similarity index; JI: Jaccard's similarity index; QS: Sorensen's similarity index; AJK: Azad Jammu and Kashmir

Introduction

What are quantitative similarity indices?

For comparing two populations, a similarity index provides a quantitatively based measurement, analogous to the application of similarity for DNA-fingerprinting (Lynch, 1990; Chuang, 2012). Similarity indices are also been widely used in ecology (Hubalek, 1982; Chao et al., 2006). Johnston (1976) investigated the characteristics of 25 similarity indices. Among these indices, the Jaccard's index (Jaccard, 1902) and Sorensen index (Sorensen, 1957) are often applied in the ecological studies. These indices are used to note the species-diversity for nature and natural protection (Higgs and Usher, 1980; Legendre and Legendre, 1998). The Jaccard's index is defined as the number of shared species divided by a total number of distinct species in two communities. The Sorensen index is the ratio of the number of shared species to the average number of total species in two communities. The definitions of the Jaccard's and Sorensen's indices are constructed on the numbers of species in two populations (Chuang, 2012).

Why is an ethnobiological similarity index needed?

It is desirable to make comparisons between floral or faunal samples taken at different times, different places, or by different techniques. Such comparisons seem profitable and take advantage of the existence of similarity indices, many of which have been developed earlier in this century. Some of these indices merely take into account the presence or absence of species in the samples, while others integrate information on the relative abundance of the species. The desirable index depends on the questions asked and the kind of data available in a given case (Wolda, 1981). In ethnobotanical studies, researchers also may wish to integrate information about the reported uses of a species. The calculation of diversity indices is a very useful tool for ethnobotanical studies, which helps researchers to ask questions and analyze data obtained through this method, besides permitting comparisons among different communities in different or similar environments (Höft et al., 1999).

Jaccard's and Sorensen's similarity indices are widely applied in the ethnobotanical studies from national and global areas, i.e. Alpine and Sub-alpine regions of Pakistan (Kayani et al., 2015), Thar Desert (Sindh), Pakistan (Yaseen et al., 2015), Abbottabad, Pakistan (Ijaz et al., 2016), Mansehra, Pakistan (Rahman et al., 2016a, b, c), Azad Kashmir, Pakistan (Ahmad et al., 2017; Amjad et al., 2017), Dindigul district, Tamilnadu, India (Faruque et al., 2018), Bandarban District of Bangladesh (Sivasankari et al., 2014), central East Shewa of Ethiopia (Feyssa, 2012), Republic of Benin (Laleye et al., 2015), Kembatta Tembaro (KT) Zone, Southern Ethiopia (Maryo et al., 2015), Brazilian Pampa Teixeira et al., 2016), but they are not amenable to comparative Ethnopharmacology (Weckerle et al., 2018).

Here, we propose a new and efficient statistical approach in the field of ethnobiology and validate its efficacy by comparing the results with predefined similarity indices used in previous studies.

Material and methods

Study area

Manoor Valley is remote area of District Mansehra (Rahman et al., 2016a), situated on north side about 50 km from main Kaghan road at ‘Mahandri’ in the Lesser Himalayas of Pakistan (*Fig. 1*).

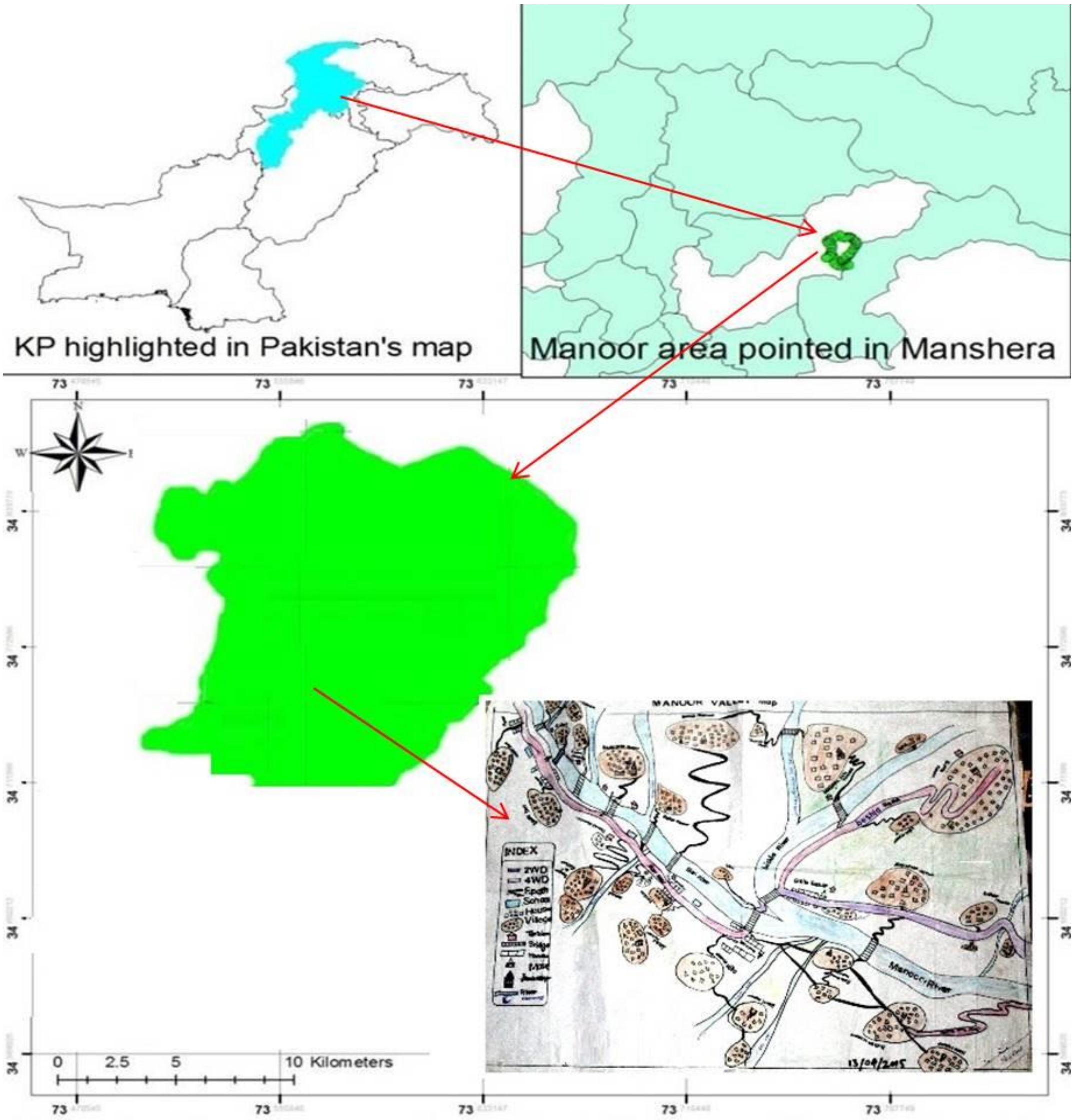

Figure 1. *Map of the study area*

Collection and identification of medicinal plants

Frequent field surveys were undertaken during the early, mid and late summer season of 2016. Plant specimens were collected, tagged and pressed. For botanical information, local informants and traditional healers were interviewed for cultural uses for various diseases. The plant specimens were identified with the help of available literature (Nasir and Ali, 1971-1994; Ali and Qaiser, 1995-2004) and submitted to the Herbarium, Department of Botany, Hazara University Mansehra, Pakistan (HUP).

Similarity indices

There are a number of indices that calculate similarities in plant species and used in the field of ecology such as; Jaccard's and Sorensen's similarity indices, but no index to date has been designed for evaluation of ethnobiological similarities. So, in comparative ethnobiological studies, the ethnobiologists mostly use conventional ecological tools for evaluation of similarities and dissimilarities. We propose a similarity index named as Rahman's similarity index (RSI), based on the quantification of similar uses of common medicinal plants by comparing current study with previously published documentations from various areas. To evaluate the significance of this newly developed index and its validity in similarities and differences in ethnobiological studies of different regions, the data regarding medicinal plants usage from the current project was taken and compared with 20 previously published studies. Further, we then analyzed this data set through pre-existing indices and Rahman's index to examine the novelty in the study.

Jaccard's similarity index (JI%)

Jaccard's similarity index (JI%) is calculated by comparison of previously published studies from aligned, regional and at global countries by analyzing the percentages of quoted species and their medicinal uses by using the following formula:

$$\mathrm{JI} = c \times \frac{100}{a + b - c}$$

where, a = number of species unique in site A, b = number of species unique in site B. c = number of species common to A and B (Jaccard, 1902; Kayani et al., 2015).

Sorensen's similarity index (QS%)

Sorensen's similarity index (QS%) was developed by a botanist Thorvald Sorensen and published in 1948. The comparison with previously published data collected from different regions was performed by evaluating percentages of the quoted species and their medicinal uses by applying Sorensen similarity index formula (Sorensen, 1948; Wolda, 1981).

$$\mathrm{QS} = \frac{2c}{a + b} \times 100$$

where, a = number of species unique in an area A, b = number of species unique in an area B and c = number of species common to area A and B.

New ethnobiological similarity index

Rahman's similarity index (RSI)

Rahman's similarity index (RSI) is proposed by Inayat Ur Rahman and Farhana Ijaz. RSI is calculated as "by comparison of the present study with the studies previously published from allied, regional, national and global level through the percentages of plant species analyzed and commonly cited with same cultural medicinal uses". The formula used as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27652777

$$RSI = \frac{d}{a + b + c - d}$$

where, “a” is the number of species unique in an area A, “b” is the number of species unique in an area B, “c” is the number of common species in both A and B areas and “d” is the number of common species used for similar ailment in both A and B areas. While a & b ≠ 0 and c & d ≥ 0.

To find out the percentage of common uses between two areas, the formula can be written as

$$RSI = \frac{d}{a + b + c - d} \times 100$$

The probability was calculated (number of events divided by number of possible outcomes) by using the discrete random variables; a = number of common species used for similar ailments in data set A, b = total number of possible species in data set A, a’ = number of common species used for similar ailments in data set B, b’ = total number of possible species in data set B). To quantify the strength of evidence, we advocated 5% significance as a standard level for concluding that there is evidence against the hypothesis tested (Dahiru, 2008).

Results

In present study, the local inhabitants and traditional healers were using 27 medicinal plant species belonging to 19 families for treating 42 different diseases. Traditional medicinal uses of plants mentioned in *Table 1* are compared with 20 published ethnomedicinal documentations of allied, regional, national and at global level *Table 2*.

Critical comparison of JI and QS with RSI

Comparative analysis of the present study and previously published investigations reveals the similarity index of 27 reported medicinal plants ranging from 0% to 15.69% (JI%), 0% to 27.12% (QS%) and 0% to 6.78% (RSI%) as shown in *Table 2*. The analytical approach of Jaccard’s and Sorensen’s similarity indices both determines only the common floral similarity by comparison of a case study with previous documentations. They don’t address the common plants with similar use(s) (*Table 2*). The Jaccard’s index derives similarity of community ecology but now it is frequently used for assessing the similarity of pharmacopoeias and medical floras. Imagine two datasets (medicinal flora) with sample a = 100 and sample b = 100 and an overlap of similar plant species is c = 50; out of these, 25 plants are with similar usage. While JI delivers a similarity index of 20%, the actual overlap is 25% (plant species with similar usage). When we employ QS on the same datasets, it delivers a similarity index of 33%, the actual overlap is 25% (plant species with similar usage). While, the proposed similarity index (RSI) shows the cultural similarities between ethnic communities of different areas by calculating particular plant species, same medicinal usage. Imagine same datasets (medicinal flora) with sample a = 100 and sample b = 100 and an overlap of plant species is c = 50 but out of these, 25 plants are with similar usage d = 25 for RSI. It delivers a similarity index of 25% which is the actual overlap (plant species with similar usage). Upon comparison with pre-existing similarity indices (JI and QS), new medicinal use reports of plant species are more accurately determined by the proposed similarity index (RSI).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27652777

Cross-cultural analysis of the reported species assessed through the newly developed similarity index (RSI) revealed new medicinal uses for *Ajuga integrifolia, Dysphania ambrosioides, Cichorium intybus, Convolvulus arvensis, Indigofera heterantha, Malva parviflora, Plantago major, Medicago sativa*, *Portulaca oleracea, Punica granatum, Taraxacum officinale, Trachyspermum amii, Trifolium repens, Xanthium strumarium* and *Zanthoxylum armatum* for the first time, but not indicated by the JI or QS indices. These results indicate that as far as common vegetation and the floral levels are concerned, these ecological similarity coefficients are accurate and precise but for medicinal similarities, both pose limitations. To overcome these limitations, we propose this new index, which could address the similarity between two regions/sites on the basis of common plant/animal species with respect to their uses.

Table 1. *Randomly selected medicinal plants from the first author PhD study, a supposition for comparison with other documentations from different regions for similarities to show differences in results of two well-known indices with our newly developed one, documentations of shared species are mentioned in the column 'literature comparison'*

Discussion

In present study, 27 plant species belonging to 19 families were reported by the local informants for 42 various health issues. The ethnomedicinal uses reported in the present study (*Table 1*) were compared with 20 published ethnomedicinal studies from allied, regional, national as well as at global level (*Table 2*). Comparative analysis of present study with previous documentations revealed that the similarity index of 27 reported medicinal plants ranged from 0% to 15.59% (JI) and 0% to 27.12% (QS) (*Fig. 2*). Highest degree of similarity index was found with studies conducted by Qureshi et al. (2008); Akhtar et al. (2013); Ijaz et al. (2016), Matin et al. (2001) and Khan et al. (2013) with JI (15.69%, 15.22%, 13.89%, 10.78% and 10.10%) respectively and QS (27.12%, 26.42%, 24.39%, 19.47% and 18.35%) respectively. Furthermore, three more international documentations having the common species with the present study, due to which JI and QS shows similarity percentage with the study area, but interesting thing is that all of them were used for different medicinal purposes which clearly means that Jaccard's and Sorensen's similarity indices both targets only the common medicinal plant species in both areas but not its common medicinal uses (*Table 1*). *Table 1* shows three different values which are of species enlisted only in the study area, common species with similar uses and common species with dissimilar uses. But JI and QS shows the results by combining both common species with similar uses and common species with dissimilar uses in similarity. This simply reveals that either the common plant species is similar or different in medicinal use but it is in similarity by JI and QS. In comparison, we found Jaccard's similarity index and Sorensen's similarity index value 0% with 3 studies from Siran Valley, (Mansehra), Pakistan (Ahmad et al., 2009), Deosai Plateau, Gilgit Baltistan, Pakistan (Bano et al., 2014) and Aladaglar, Nigde-Turkey (Ozdemir and Alpınar, 2015). But in this case, no single common plant species has been found that is why JI and QS also showed 0% similarity (*Fig. 2*).

Table 2. *Comparison of the present study with previous studies at regional, neighboring and global level*

NRSAA: Number of recorded plants species of aligned areas, **TSCBA:** Total species common in both area, **SEOAA:** Species enlisted only in aligned areas, **SEOOA:** Species enlisted only in our study area, **CSSU:** Common species with similar uses, **CSDU:** Common species with dissimilar uses, **JI:** Jaccard's similarity index, **QS:** Sorrenson's similarity index, **RSI:** Rahman's similarity index, **Sign.:** Significance level

Applications of Rahman's similarity index (RSI)

The similarities and differences in ethnomedicinal studies seem to target the importance of traditional knowledge on medicinal plants in different regions (Ijaz et al., 2016). The proposed similarity index (RSI) shows the cultural similarities between ethnic communities of different areas by calculating particular plant species, same medicinal usage. Traditional medicinal uses of plants mentioned in *Table 1* are compared with 20 published ethnomedicinal documentations of allied, regional, national and at global level (*Table 2*). Review of the literature indicates the medicinal similarity index uses ranges from 0% (Ahmad et al., 2009, 2012; Ajaib and Khan, 2014; Bano et al., 2014; Tariq et al., 2014; Ullah et al., 2014; Ozdemir and Alpınar, 2015; Rashid et al., 2015; Kichu et al., 2015; Ahmad and Pieroni, 2016) to 6.78% (Qureshi et al., 2008). The highest degree of similarity index of the present study was found with a study conducted in Abbottabad, Pakistan by Qureshi et al. (2008) with RSI = 6.78% (*Fig. 2*). In comparison, we found RSI value 0% with 10 previous studies and out of these seven studies had common plant species but no single common plant species has been cited for common medicinal use(s) that is why RSI showed 0% similarity (*Fig. 2*). These results indicate that the new index (RSI) could address the similarity between two regions/sites on the basis of common plant/animal species with respect to their uses. Medicinal uses comparative analysis reveals that maximum variation in RSI might be due to cultural/ethnic or traditional differences between the current study area and previously documented studies in allied, regional, national and global levels. Distance

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27652777

between study area and other regions also support the variation in results as it directly correlates the vegetation of an area due to the differences in their edaphic factors (Coughenour and Ellis, 1993; Witkowski and O'Connor, 1996) and physiographic because each area has specific surface features and their form (Barnes et al., 1998). RSI shows the cultural similarities between ethnic communities of different areas by calculating particular plant species similar medicinal usage. RSI focuses on similar uses of common medicinal plants (*Table 2* and *Fig. 2*). Upon comparison with both the similarity indices, new medicinal use reports of plant species are more accurately determined by the proposed similarity index (*Fig. 2*).

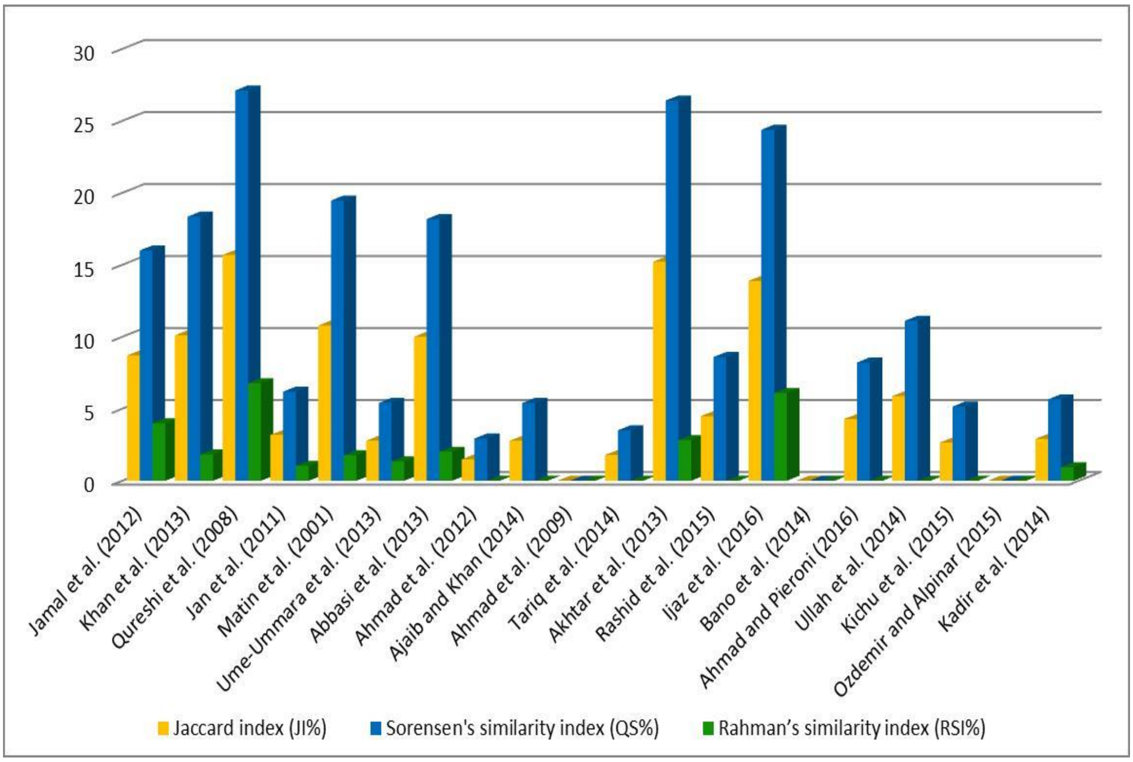

Figure 2. *Comparison of the case study with previous studies at regional, national and global level through Jaccard's, Sorensen's, Rahman's similarity indices*

Similarity indices and significance level

Comparative analyses of the present study with Matin et al. (2001) revealed that in total 27 reported medicinal plants; two species were common in medicinal usage to both areas. The JI is consequently 10.78% and QS is 19.47%, but newly proposed index (RSI) showed 1.77% similarity. Whereas the results of RSI are also supported by significance test (5%), as the level of significance between present study and Matin et al. (2001) indicating the significance value of 0.13. We found RSI value of 0% while comparing with previously done 10 ethnobiological studies (Ahmad et al., 2009, 2012; Ajaib and Khan, 2014; Bano et al., 2014; Tariq et al., 2014; Ullah et al., 2014; Ozdemir and Alpınar, 2015; Rashid et al., 2015; Kichu et al., 2015; Ahmad and Pieroni, 2016), and out of these 7 studies had common plant species but no single common plant species has been cited for common medicinal use(s) that is why RSI showed 0%

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27652777

similarity. The level of significance also strongly supports these results by indicating the highest level of significance (0.00%) (*Table 2*). The threshold level of significance for RSI is >1% (more than 1), as this is the border line of significance level at 5% ($p = 0.05$). Furthermore, with 2 previous studies (Ijaz et al., 2016; Qureshi et al., 2008) maximum RSI (6.1% and 6.78%) was found and following these results the significance level was also increased (1.25% and 1.26%) respectively in comparison with other studies. Our results are in accordance with Goodall (1966) who reported that a lower value of the similarity index may often correspond with a less probable degree of similarity and vice versa.

Conclusion, novelty and future impact

After analytical comparison, some new medicinal uses of *Ajuga integrifolia, Bauhinia variegata, Dysphania ambrosioides, Convolvulus arvensis, Indigofera heterantha, Malva parviflora, Plantago major, Salvia moorcroftiana, Taraxacum officinale, Xanthium strumarium, Medicago sativa, Portulaca oleracea, Punica granatum, Trachyspermum ammii, Trifolium repens* and *Zanthoxylum armatum* were recorded for the first time for the current reported medicinal uses from the study area. These novel/new medicinal use reports of plant species were pinpointed by the newly developed similarity index (RSI) but not indicated by the JI or QS indices. Inferences derived from RSI are reliable and upon comparison can lead to novel findings and new medicinal use reports of plant species more accurately. Further, RSI specifically targets the ethnobiological similarities and would be a useful tool/index for future studies in the assessment of rigorous quantitative ethnobiological data.

Acknowledgements. First author would like to thank Higher Education Commission (HEC), Pakistan for granting scholarship under International Research Support Initiative Program (IRSIP) to conduct a research work at Missouri Botanical Garden, USA. The authors gratefully acknowledge Dr. Robbie Hart (Missouri Botanical Garden, P. O. Box 299, St. Louis, MO 63166-0299, USA) for his confirmatory input in the index. We are thankful to Dr. Shahzad, Head Department of Mathematics, Hazara University Mansehra, Pakistan as well for. helping us in statistical work. The authors would like to extend their sincere appreciation to the Deanship of Scientific Research at King Saud University for its funding to the Research Group number (RG-1435-014).

Author contributions. IUR designed and conceived the study. IUR and FI developed the formula, gathered relevant literature and analyzed the data. IUR wrote the manuscript and NA helped in writing. AA, ZI and RH supervised the work, RH and SMK helped in the data analysis, RBU, EFA and AAA critically reviewed the manuscript. IUR and NA revised the manuscript, MSA helped in revision. All the authors have read and approved the final manuscript.

Ethical approval. This ethnomedicinal study was approved by the “Advanced Studies Research Board, Hazara University Mansehra, Pakistan”. A semi-structured questionnaire (written consent) was developed and filled during interviews with local informants and traditional healers.

Conflict of interests. The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interests.

(Received 9th Sep 2018; accepted 22nd Nov 2018)

Abstract. A field experiment was carried out in 2013-2016 in the Agricultural Experimental Station – Zawady of the University of Natural Sciences and Humanities in Siedlce, Poland. The examined factors included: I – three morphotypes of winter rape: population cultivar (Monolit), hybrid semi-dwarf (PR44D06) cultivar, restored hybrid cultivar of conventional growth type (PT205); II – two sowing methods: row spacing of 22.5 cm, row spacing of 45.0 cm; III – four types of applied biostimulators: control variant (without application of biostimulators), Tytanit® biostimulator, Asahi®SL biostimulator and Silvit® biostimulator. The aim of the research was to determine the effect of natural plant preparation on the yield of four cultivars of winter rape. It was found that biostimulators applied in the experiments increased the thousand-seed weight on average from 0.03 to 0.1 g in comparison to the control variant. The highest value of this feature was obtained in the variant with Asahi®SL treatment and significantly lower in plots treated with Silvit® and Tytanit® bioregulators. A significant increase in seed yielding was observed as the effect of natural growth stimulators. The highest value of this feature was observed in all cultivars after the application of Asahi®SL and Silvit®.
Keywords: *Brassica napus, biostimulator, morphotype, seed yield, straw yield*

Introduction

Unfavourable soil conditions and stress related to drought are one of numerous factors affecting a decrease in the quantity and quality of yield. Strong stress causes a disturbance of the cell structure and metabolism and, as a result, results in stopping the photosynthesis and disturbing plant metabolism. In the opinion of Sharm et al. (2014), the application of natural growth stimulators increases plant resistance to the unfavourable effects of various stress factors, including pathogens. Van Oosten et al. (2017) believe that biostimulators have a beneficial effect on the growth and productivity of plants, which is why they are gradually becoming elements of standard agrotechnics in the field cultivation. The composition of biostimulators usually include one or more biologically active organic compounds, such as: amino acids, vitamins, enzymes, plant hormones and macro and microelements, while a separate group consists of biopreparations produced with the participation of live microorganisms containing various types of bacteria and fungi.

Asahi SL, also known as Atonik or Chaperone, is the most often applied biostimulators in farming and horticulture. Asahi SL contains phenolic compounds: sodium o-nitrophenolate and sodium p-nitrophenolate and sodium 5-nitroguaiacolate, which naturally occur in plant cells and take part in biochemical and physiological plant processes. Phenols increase plant tolerance to all harmful stimuli from the environment, especially drought. Additionally, they reduce the decrease in auxins concentration in plants caused by water shortage, and control plant growth and development (Matysiak et al., 2011). Titanite is a mineral growth stimulant containing titanium ions that are organically complexed and are well absorbed by plants. Titanium is considered an essential element for the growth and development of plants. The application of even a small amount of titanium affects the growth of plants and increases their resistance to stress factors. It increases the activity of enzymes and thus increases the durability of mineral uptake in the soil.

Silvit is a natural growth stimulant containing the active silicon that is fully absorbed by plants. This bioregulator limits the physical penetration of tissues by pests, because cell walls become more resistant to enzymes produced by pathogens (fungistatic effect), increases plant tolerance to low temperatures, reduces transpiration during drought, intensifies photosynthesis in low light conditions, reduces the impact of high salinity for plant growth and phosphorus deficiency by regulating its uptake and eliminating toxic effects of aluminium on root growth.

The study assumed the research hypothesis that the application of natural plant preparations can contribute to an increase in winter rape (*Brassica napus* L.) yielding. Due to scarce research concerning the effect of this factor, a study was undertaken to determine the effect of the Tytanit®, Asahi®SL and Silvit® biostimulator on the thousand-seed weight, seed yield, straw yield and harvest index of three winter rape cultivars.

Materials and Methods

Field experiments were conducted in three growing seasons: I – from 13.08.2013 to 11.07.2014; II - 11.08.2014 to 17.07.2015; III - 14.08.2015 to 14.07.2016 in the Agricultural Experimental Station – Zawady (52º03'N and 22º33'E) of the University of Natural Sciences and Humanities in Siedlce, Poland. The experiment was established at the random sub-blocks design (split – split – plot), in three replications. The surface of one plot for harvest was 18 m^{-2}. It involved examination of the following factors: rape cultivars, sowing methods and types of biostimulators applied. With regard to the main experimental factor, three cultivars were sown, representing three cultivation types: population cultivar – Monolit, restored hybrid cultivar of a semi-dwarf growth type –

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27792789

PR44D06, restored hybrid cultivar of a conventional growth type – PT205. The secondary factor included two sowing methods: row spacing of 22.5 cm (row sowing – density sowing of 60 seeds per 1 m^{-2}), 45.0 cm planting space (precision sowing – sowing density 40 seeds per 1 m^{-2}). With regard to the tertiary factor, three types of biostimulators were applied against the control variant, cultivated without biostimulator application. Tytanit® biostimulator (active substance – titanium) was applied in autumn at the 4-8 leaves unfolded stage (BBCH 14-18) at the dose of 0.20 $dm^3 \cdot ha^{-1}$ (date I), in spring after vegetation started: beginning of side shoot development at the dose of 0.20 $dm^3 \cdot ha^{-1}$ (date II), at the stage of flower bud development (inflorescence emergence) – beginning of flowering at 0.20 $dm^3 \cdot ha^{-1}$ (date III). Asahi®SL biostimulator was applied on three dates: in autumn at the BBCH 13-15 stage at the dose of 0.60 $dm^3 \cdot ha^{-1}$, in spring, after vegetation started at the dose of 0.60 $dm^3 \cdot ha^{-1}$, two weeks after performing the second procedure (0.60 $dm^3 \cdot ha^{-1}$). Silvit® biostimulators containing active silicon were applied three weeks after emergence at the dose of 0.20 $dm^3 \cdot ha^{-1}$, in spring, after vegetation started at the dose of 0.20 $dm^3 \cdot ha^{-1}$ and two weeks after the second procedure, at the dose of 0.20 $dm^3 \cdot ha^{-1}$.

The experiment was carried out on soil classified in the order of soils with clay translocation, type – Luvisols, subtype – Albic Luvisols. This soil was classified as IVa bonitation class soil, of very good rye complex for agricultural use. During the years of the experiment, soil pH (in 1n KCl) was slightly acidic, ranging from 5.68 to 5.75. The soil was characterized by a low total content of nitrogen (on average 0.85 $g \cdot kg^{-1}$), phosphorus (on average 0.44 $g \cdot kg^{-1}$), potassium (on average 0.65 $g \cdot kg^{-1}$) and calcium (on average 0.83 $g \cdot kg^{-1}$) and the medium content of magnesium (on average 0.42 $g \cdot kg^{-1}$) and sulphur (on average 0.13 $g \cdot kg^{-1}$). It demonstrated low content of available phosphorus forms (on average from 75 to 80 $mg \cdot kg^{-1}$) and medium content of available forms of potassium (on average from 200 to 205 $mg \cdot kg^{-1}$) and magnesium (on average from 59 to 61 $mg \cdot kg^{-1}$). The forecrop for winter rape in the first year of research was spring wheat and in subsequent years it was winter triticale. After forecrop harvest, a set of post-harvest procedures was carried out using the ploughing aggregate + open cage roller, and then two weeks after the first procedure, pre-sow ploughing at the depth of 20.0 cm was carried out, using a ring roller at the same time. To prepare the soil for sowing and to mix fertilizers, a complex soil tillage unit was used. Before sowing, phosphorus-potassium fertilization was applied at the dose of 40 kg $P \cdot ha^{-1}$ and 110 kg $K \cdot ha^{-1}$ and the first dose of 40 kg $N \cdot ha^{-1}$. Fertilization was applied in the form of Lubofos at the dose of 600 kg. Fertilizing doses were supplemented with 55.9 $kg \cdot ha^{-1}$ of ammonium nitrate (19 kg $N \cdot ha^{-1}$), 29.6 $kg \cdot ha^{-1}$ triple superphosphate (13.6 kg $P \cdot ha^{-1}$) and 29 $kg \cdot ha^{-1}$ potassium salt (17.9 kg $K \cdot ha^{-1}$). The second dose of nitrogen in the amount of 100 $kg \cdot ha^{-1}$ was applied in spring, before vegetation started (BBCH 28-30) applying ammonium nitrate at the dose of 255.5 $kg \cdot ha^{-1}$ (86.9 kg $N \cdot ha^{-1}$) and ammonium sulphate at the dose of 62.5 $kg \cdot ha^{-1}$. The third dose of ammonium 60 $kg \cdot ha^{-1}$ was applied at the inflorescence emergence (BBCH 50), by applying ammonium nitrate at the dose of 176.5 $kg \cdot ha^{-1}$ (60 kg $N \cdot ha^{-1}$). Winter rape was sown in two row spacing widths: 22.5 cm and 45.0 cm, maintaining the density of 60 $pieces \cdot m^{-2}$ and 40 $pieces \cdot m^{-2}$, respectively. The sowing was done at the optimal time recommended for this region (in 2013 – August 13, 2014 – August 11, and in 2015 – August 14). Directly after sowing, herbicide Command 480 EC at the dose of 0.25 $dm^3 \cdot ha^{-1}$ was applied to carefully cultivated soil. Next, at the stage of BBCH 13-14, Fusilade Forte 150 EG at the dose of 2.0 $dm^3 \cdot ha^{-1}$ was applied. At the 4-8 leaves unfolded stage (BBCH 14-18)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27792789

fungicide Horizon 250 EW was applied (0.75 $dm^3 \cdot ha^{-1}$). At the stem elongation stage (BBCH 30), flower bud emergence stage (BBCH 50-58), flowering (BBCH 60-69) – Proteus 110 OD insecticide was applied at the dose of 0.6 $dm^3 \cdot ha^{-1}$. At the beginning of flowering (BBCH 61) – Propulse 250 SE fungicide was applied at the dose of 1.0 $dm^3 \cdot ha^{-1}$. At the stage of first petals falling – Mondatak 450 EC was applied at the dose of 1.0 $dm^3 \cdot ha^{-1}$. Rape was collected in two stages, in the first and second decade of July (I year: 11.07.2014; II year: 17.07.2015; III year: 14.07.2016).

The thousand-seed weight was specified for two samples of 500 seeds, collected from purified yield from each plot. The volume of seed yield from each plot was determined by weight after threshing, and then, after adjusting to the normative humidity (9.0% of water content in seeds), it was converted to the area of 1 ha.

The value of harvest index was calculated according to the formula:

$$HI = \frac{Pn}{Pn + Ps} * 100\% \qquad \text{(Eq.1)}$$

where:
HI – harvest index (%)
Pn – seed yield ($Mg \cdot ha^{-1}$)
Ps – straw yield ($Mg \cdot ha^{-1}$).

The results of the study were statistically analysed with the use of the analysis of variance. The significance of variation sources was tested with the "F" Fischer-Snedecor test, and the assessment of significance at the significance level of p=0.05 between compared means – with Tukey's range test.

Weather conditions were diversified in the years of the research (*Table 1*).

Table 1. *Characteristics of weather conditions in the years 2013-2016 (Zawady Meteorological Station, Poland)*

In the growing season 2013-2014 the total annual precipitation was by 60.0 mm higher in comparison to the average total precipitation from the multiannual period, and the mean air temperature was by 0.8°C higher. The highest annual total precipitation (on average 599.2 mm) and the lowest mean annual air temperature (on average 8.8°C) were recorded in the vegetation season of 2014-2015. The total annual precipitation in this period was higher by 171.7 mm in comparison with the total precipitation from the multiannual period. The 2015-2016 growing season was the warmest and most dry. The total annual precipitation was 43.8 mm lower than the multiannual average, and the average annual air temperature was 1.3°C higher in comparison to the mean of 1996-2010.

Results and discussion

The research demonstrated that Asahi SL, Silvit and Tytanit biostimulators significantly increased the thousand-seed weight on average from 0.03 to 0.1 g in comparison to the control variant (*Table 2*). The highest value of this feature was obtained in the variants where Asahi®SL was applied – on average 5.64 g, and significantly lower in plots treated with Silvit® and Tytanit® bioregulators (on average 5.58 g and 5.57 g). This is consistent with previous research by Harasimowicz-Hermann and Borowska (2006), who found that the thousand-seed weight was also higher by 18.0% in comparison to the control variant as a result of applying Asahi SL biostimulator.

Table 2. *The weight of one thousand seeds (g) depending on factors of experience*

Year	Cultivars			Ways of sowing		Types of biostimulators used				Mean

On the other hand, Malarz et al. (2008) and Słowiński and Jarosz (2008) did not demonstrate a significant effect of biostimulators on thousand-seed weight. Matysiak et al. (2011) after the application of Asahi SL at the BBCH 28-30 stage obtained only a slight increase in thousand-seed weight and only in one research season, while Budzyński et al. (2008) after applying the same bioregulator, demonstrated only a trend towards an increase in the value of this feature. The thousand-seed weight of the semi-dwarf cultivar PR44D06 was on average higher by 0.12 g than for the conventional form PT 205, while the lowest (on average by 5.43 g) was found for the line cultivar (Monolit). A similar trend was reported by Mekki (2013) and Czarnik et al. (2015). The authors obtained higher thousand-seed weights in heterotic cultivars than in population cultivars. On the other hand, Jankowski and Budziński (2007) recorded lower thousand-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27792789

seed weight, on average by 8.0%, in heterotic cultivars Kaszub and Kronos, as compared to population cultivar Contact. The thousand-seed weight was not significantly diversified in relation to the sowing method. The absence of a significant effect of this factor was also demonstrated by Ozera (2003), Shahin and Valiollah (2009), Uzun et al. (2012) and Krcek et al. (2014). On the other hand, Różyło and Pałys (2011) reported a slight trend to increase the thousand-seed weight for the 33.0 cm spacing in comparison to 25.0 cm spacing. The thousand-seed weight of the examined cultivars significantly depended on weather conditions in individual years of the experiment. Restored hybrids PR44D06 and PT205 demonstrated the highest thousand-seed weight in the first year of the research, characterized by excessive precipitation in June and in the first decade of July, and lower values were obtained in the third year of research, with precipitation shortage occurring in May and June, and the average temperature in those months higher than the multiannual average. On the other hand, in that season, the population cultivar Monolit demonstrated the highest value of this feature in comparison to the initial years of the research. The types of applied biostimulators significantly affected the seed yield in the examined cultivars (*Table 3*).

The highest value of this feature in all cultivars was observed after the application of Asahi®SL – on average 4.13 Mg·ha^{-1} and Silvit® – on average 3.96 Mg·ha-1. Similarly, Matysiak et al. (2011, 2012) found that Kelpak and Asahi SL bioregulators increased the volume of the seed yield on average by about 25%. Harasimowicz-Hermann and Borowska (2006) depending on the vegetation season, found an increased yield in the range of 9.0 to 19.0% in comparison to the variant without natural growth stimulators. Budzyński et al. (2008) and Matysiak and Kaczmarek (2008) obtained the best yield producing effect in the variants where a single application was used at the BBCH 30 stage or later (BBCH 50). The authors found that single application resulted in a yield increase on average by 3.0% (140 kg), and double application (on average by 5.0% (220 kg)). The effect of the genetic factor on seed yield was demonstrated by Zhang et al. (2011), Mekki (2013) and Nowosad (2016). In own research, the highest seed yield (on average 4.20 Mg·ha^{-1}) was found for the long-stem cultivar PT205, significantly lower (on average 4.04 Mg·ha^{-1}) for PR44D06, and the lowest (on average 3.61 Mg· ha^{-1}) for the population cultivar Monolit. This is in line with the research results obtained by Jankowski and Budzyński (2007), El-Habbasha and El-Salama (2010) and Wójtowicz and Jajor (2010), who also emphasized that heterotic varieties demonstrated higher

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27792789

yielding potential than conventional ones. A higher seed yield in restored hybrid (DK Exquisite) of a conventional growth type was documented in Krcek et al. (2014). Jankowski et al. (2016) also recorded higher seed yields (on average 4.73 $Mg \cdot ha^{-1}$) in the conventional morphotype of the Visby cultivar in comparison to semi-dwarf cultivars PR445D03 and Avenir. On the other hand, Kotecki et al. (2004) obtained the highest value of the analysed feature in the population morphotype (Lirajet and Lisek). The statistical calculations did not show any significant interaction between the varieties of biostimulators used. Increasing sowing density from 40 to 60 seeds per 1 m^{-2} significantly affected an increase in seed yield (on average by 0.78 $Mg \cdot ha^{-1}$). No interaction was proven between cultivars and methods of sowing. This shows that similar cultivars responded in a similar way to row spacing and sowing density. Similar results were obtained by Cheema et al. (2001), Ozera (2003) and Champiri and Bagheri (2013). Those authors found a higher value of the discussed feature in narrow row spacing in comparison to cultivation at 30.0 and 45.0 cm. This regularity was also confirmed by Uzun et al. (2012), Różydło and Pałys (2014) and Kutcher et al. (2015). Different research results were obtained by Krcek et al. (2014) who, based on one-year studies, did not reveal significant differences in the seed yield for narrow (12.5; 25.0 cm) and wide (35.0; 45.0 cm) row spacing. The analysis of variance did not show any significant interaction of varieties with the sowing methods, which indicates that the studied varieties reacted in the same way to changing the inter-row spacing. Yana and Hunta (1998) provide that humidity and thermal conditions in 80% affect the yield. In own research, the highest precipitation in September at the level of 94.3 mm, more than twice as high as the multiannual average, occurred in the first year of the research. In that season, characterized by an annual total precipitation at the level of 487.5, the highest seed yield was recorded. Similar research results were obtained by Kotecki et al. (2004), who found the highest value of the analysed feature in the years of the total annual precipitation of 520 mm. Our own research demonstrated that cultivars were characterized by varied seed yield in individual years of the research. In the season characterized by the highest average air temperature and the lowest total precipitation, significantly the highest value of the analysed feature was recorded in restored hybrid morphotypes. Gehringer et al. (2007) found that heterotic cultivars also demonstrated a higher ability to adapt to unfavourable weather conditions. The types of applied biostimulators significantly affected the straw yield and harvest index (*Tables 4, 5*). The highest values of those features were obtained in the variant treated with Asahi SL biostimulator (on average 6.41 $Mg \cdot ha^{-1}$, on average 38.8%). Other biostimulators increased the straw yield (on average by 0.10 $Mg \cdot ha^{-1}$) in comparison to the control variant and harvest index (on average by 3.8%). The straw yield of semi-dwarf cultivar PR44D06 was lower on average by about 4.0% in comparison to other winter rape cultivars. The by-product yield was not conditioned by weather conditions in the years of the experiment. The statistical calculations did not show any significant interaction of the studied varieties with the climatic conditions prevailing in the years of conducting the experiment, which means that varieties reacted in the same way to weather conditions in individual years of research. The seed yield to the biomass yield ratio (harvest index – HI) was more favourable in heterotic cultivars than in the population cultivar Monolit. Different results were obtained by Zając et al. (2013). Those authors statistically found insignificant differences between the population morphotype Poznaniak and the restored hybrid Adam. Our own research demonstrated that the by-product yield of the analysed cultivars increased significantly along with an increase in

DOI: http://dx.doi.org/10.15666/aeer/1702_27792789

sowing density. Statistical calculations did not show any significant interaction between the studied varieties and the sowing methods. Similarly, the harvest index assumed more favourable values in conditions of reduced row spacing. The highest by-product yield in the three-year research cycle (on average 7.19 $Mg \cdot ha^{-1}$) was obtained in the vegetation period of 2014-2015, which was characterized by varied humidity and thermal conditions during the phase of plant growth and development, significantly lower – (on average 6.89 $Mg \cdot ha^{-1}$ in 2013-2014) was characterized by optimum weather conditions during the vegetation season and winter rest and the lowest (on average 4.86 $Mg \cdot ha^{-1}$) was in 2015-2016, where significant frost damage to plants occurred and a precipitation shortage was recorded in April, May and June. In the first year of the research, characterized by average precipitation (487.5 mm), the highest value of harvest index was obtained and the lowest (on average 35.4%) was obtained in the vegetation season of 2015-2016 with the significantly lowest precipitation (383.7 mm).

Conclusions

1. Biostimulators applied in the experiment had a significant effect on the thousand-seed weight, the main yield, the by-product yield and the seed yield to biomass yield ratio (HI) of the examined winter rape morphotypes. The strongest stimulating effect was found after the application of Asahi SL biostimulator.

2. The highest yielding was found for restored hybrids PT205 and PR44D06. It was demonstrated that their yield was on average 43 to 59 Mg·ha^{-1} higher in comparison to the conventional cultivar.
3. In the examined winter rape morphotypes, under the effect of increased row spacing and decreased sowing density, a reduction of seed yield was found, on average from 0.63 to 0.95 Mg·ha^{-1}. The lowest main yield resulting from a factor change was demonstrated in the line cultivar Monolit.
4. Weather conditions in the year of the experiment had a significant effect on the value of the examined parameters. The highest seed yield was observed in the vegetation season of 2013-2014, characterized by the best pluvio-thermal conditions during the spring-summer development of winter rape.

SACCHARIDE CONTENT IN POTATO TUBERS TREATED WITH BIOSTIMULATORS

MYSTKOWSKA, I.

State School of Higher Education, Sidorska 95/97, 21-500 Biała Podlaska, Poland
(e-mail: imystkowska@op.pl)

(Received 18th Sep 2018; accepted 22nd Nov 2018)

Abstract. Field research was carried out in 2015-2017 on an individual farm in Międzyrzec Podlaski (51°59' N and 22°47' E) in Poland. The aim of the study was to determine the effect of the type of biostimulators used (Kelpak SL, Titanit, GreenOk, BrunatneBio Złoto Cytokininy) on the saccharides content in tubers of three edible potato varieties (Honorata, Jelly, Tajfun). Potato plants were treated three times with biostimulators (starting from the BBCH 39 phase, every 10-14 days) with the potato plants sprayed with distilled water as the control object. The experiment was based on the split-plot method. A large amount of precipitation –325.4 mm and the lowest average air temperature –14.6 °C in 2017 contributed to the increase in the content of reducing sugars in potato tubers. Tubers of plants treated with the GreenOk preparation were characterized by the highest total sugar content compared to plants from the control object. The content of saccharides in tubers was significantly differentiated by the genotype of the variety. The largest amount of sugars was collected by the Honorata variety, and the least of the Tajfun variety.
Keywords: *Solanum tuberosum L., varieties, total sugars, reducing sugars, sucrose, types of bioregulators*

Introduction

One of the important characteristics of potato (*Solanum tuberosum* L.) determining the suitability of varieties for direct consumption and for processing is the content of reducing sugars, called monosaccharides (glucose + fructose) and the sums of sugars, or the total sugar (reducing sugars + sucrose). The content of reducing sugars in potato tubers is about 0.3%, and the total sugar to 1.0% in fresh tuber mass. Higher concentration of monosaccharides increases the intensity of Maillard reactions (Copp et al., 2000; Edwards et al., 2002), and causes darkening of the pulp during thermal processing (such as frying and drying) and deterioration of taste and smell, and in the final frying phase the formation of acrylamides (Hebeisen et al., 2005; Saraiva and Rodrigues, 2011; Shepherd et al., 2010). Aspargins and acrylamides derived from reducing sugars are dangerous to health and have been classified by the World Health Organization (WHO) as carcinogens for humans and animals (Keijbets, 2006; Tajner-Czopek, 2011). The use of raw material with low (0.1–0.2%) concentration of reducing sugars is considered the basic factor inhibiting the formation of acrylamide (Biedermann-Brem et al., 2003; De Wilde et al., 2006). In limiting the amount of acrylamide formed it may be helpful to soak and blanch French fried before frying, which reduces the content of reducing sugars in the fries (Pedreschi et al., 2007). The high sugar content (above 1% in fresh mass) decreases the taste properties, as tubers become sweetish and darken the pulp (Boguszewska, 2007; Kraska, 2002; Leszczyński, 2000; Zgórska et al., 2006a). Biostimulators control mineral metabolism, increase plant resistance to stressful environmental conditions (Sawicka and Mikos-Bielak, 2002; Wierzbowska et al., 2015), affect chemical composition, as well as increase resistance to attacks from diseases and pests (Grzyś, 2012). The content of reducing sugars and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27912797

sucrose in the potato is influenced by the genetic factor, types of biostimulators and weather conditions.

Due to the few studies on the beneficial effects of biostimulators on the content of sugars, reducing sugars and sucrose, studies were undertaken to determine the effect of biostimulators (Kelpak SL, Titanit, GreenOk, BrunatneBio Złoto Cytokininy) on the saccharides content in tubers of three edible potato varieties (Honorata, Jelly, Tajfun).

Materials and methods

The experimental site

The potato tubers from a three-year field experiment carried out in 2015-2017 on an individual farm in Międzyrzec Podlaski (51°59’ N i 22°47’ E), Biała Podlaska county, Lublin voivodeship, in Poland were the material for studies. The experiment was established in three replications using the split-plot method, on the soil included in the very good rye complex, class IVa.

In individual years of research, soils differed in the content of organic matter and absorbable macro-elements. In 2015 and 2016, the soil was characterized by slightly acidic reaction, and in the last year of research, alkaline. The content of organic matter ranged from 15.0 to 18.7 $g \cdot kg^{-1}$. The content of absorbable phosphorus (P) was from high to very high, potassium (K) from medium to very high, and magnesium (Mg) was high. The first factor were three moderately early varieties of edible potato: Honorata, Jelly and Tajfun, and the second one, four types of biostimulators used in three dates (beginning of flowering, fully flowering and after flowering of plants):

1. Control object – without the use of biostimulators spraying with distilled water
2. Biostimulator Kelpak®SL (active substance - *Ecklonia maxima* algae extract), containing plant hormones: auxin – 11 $mg \cdot l^{-1}$ and cytokinin – 0.031 $mg \cdot l^{-1}$, at a dose of 0.20 $l \cdot ha^{-1}$
3. Biostimulator Tytanit® (active substance – titanium) at a dose of 0.20 $l \cdot ha^{-1}$,
4. Biostimulator GreenOk® (active substance – humus substances 20 $g \cdot l^{-1}$) at a dose of 0.20 $l \cdot ha^{-1}$
5. Biostimulator BrunatneBio Złoto (active substances – plant hormones: auxin – 0.06 $mg \cdot l^{-1}$ and cytokinin – 12 $mg \cdot l^{-1}$) at a dose of 0.20 $l \cdot ha^{-1}$

The forecrop for potato in particular years of research was winter wheat. After harvesting the forecrop, a team of post-harvest crops was made. In autumn, each year preceding planting, natural fertilization in the form of manure in the amount of 25.0 $t \cdot ha^{-1}$ and mineral fertilization with phosphorus-potassium in the amount of P – 44.0 (100 $P_2O_5 \cdot 0.44$) $kg \cdot ha^{-1}$ (lubofos for potatoes 7%) and K – 124.5 (150 $K_2O \cdot 0.83$) $kg \cdot ha^{-1}$ (lubofos for potatoes 25%) was applied. These fertilizers were plowed pre-season plowing. Nitrogen fertilizers were sown in the spring in an amount of N 100 kg/ha (nitro-chalk 27%) and mixed with the soil using a cultivator. Potatoes were planted manually under the marker at a spacing of 67.5 × 37 cm, in the third decade of April (24 April 2015, 30 April 2016, 22 April 2017). Each plot consisted of five ridges. Cultivation and care treatments were carried out in accordance with the requirements of correct agrotechnics and methodological assumptions of the experiment. During the growing season, observations of the most important phases of potato development were carried out on each object: emergence, flowering buds, flowering, maturation of plants. Potato plants were treated three times with biostimulators (starting from the BBCH 39

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27912797

phase, every 10-14 days) with the potato plants sprayed with distilled water as the control object. Prior to harvest, random samples of tubers were collected from ten potato plants (excluding the marginal crops) each plot and used for chemical analysis and assessment of consumption-related characteristics of the tubers. The harvest was made during the technological maturity of tubers, in the first decade of September (02 September 2015, 03 September 2016, 05 September 2017).

Chemical analysis methods

For the tests, 5 kg of potato samples were taken from each variety and combination. The tubers were homogenized by in-depth mixing of the pulp and samples were taken for laboratory determinations for the content of reducing sugars and total. The content of reducing sugars and total sugar was determined in fresh weight of unpeeled tubers with the Luff-Schoorl method. This method is based on the reduction reaction in the alkaline medium at the boiling temperature of the copper salts in the Luff solution by the reducing sugars contained in the solution (Krełowska-Kułas, 1993). The sucrose content was calculated from the difference of the total sugar after hydrolysis and reducing sugars × 0.95.

Meteorological conditions

The weather conditions in the potato growing years were shown by means of precipitation sums and average air temperatures in *Table 1*. The growing season of 2015 had the average air temperature of 15.2 °C, higher by 0.2 °C than the long-term mean and rainfall at 295.1 mm, but unevenly distributed throughout the growing season. The highest average air temperature was recorded in 2016 and amounted to 15.8 °C, it was higher than the long-term average by 0.8 °C, while this year was characterized by the lowest amount of precipitation – 200.9 mm, lower by 134.5 mm from the long-term sum, was one of the least favourable years, with a high rainfall deficit in the period of June-August, decisive for yield accumulation. The highest number of rainfall was recorded in the growing season 2017 –325.4 mm and the lowest average air temperature –14.6 °C (*Table 1*).

means was tested using the multiple comparison Tukey's test at the significance level of P = 0.05. Statistical calculations were performed in Excel using the authors' own algorithm based on the split-plot mathematical model.

Results and discussion

Based on a three-year study, the level of total sugars, reducing sugars and sucrose was determined in three varieties of edible potato tubers, and it was up to 1% in the fresh weight of tubers. These results were confirmed by the studies of Zgórska et al. (2006a). Chemical analyses have shown, and statistical calculations have confirmed the significant impact of varieties, types of biostimulators, as well as weather conditions in the years of research on the saccharides content in potato tubers. In own studies, the average content of total sugars in edible potato tubers was 6.72 $g{\cdot}kg^{-1}$, reducing sugars 3.25 $g{\cdot}kg^{-1}$, sucrose 3.30 $g{\cdot}kg^{-1}$ (*Tables 2, 3* and *4*). The research presented shows that the genetic factor had an effect on the sum of sugars, reducing sugars and sucrose in potato tubers. The variety that contained the most sugars in total was Honorata, then Jelly and Tajfun. The varieties compared were different in terms of the accumulation of the component in question. The highest amount of sugars was accumulated by the Honorata variety – on average 6.94 $g{\cdot}kg^{-1}$, Jelly – on average 6.70 $g{\cdot}kg^{-1}$, and the least by Tajfun – on average 6.54 $g{\cdot}kg^{-1\cdot}$ Among the tested varieties, the most reducing sugars in tubers was accumulated by the Tajfun variety, significantly lower content was found in Jelly tubers, while the smallest amounts were found in the tubers of the Honorata variety. In reference to sucrose, it was found that significantly most of this saccharide was found in tubers of the Honorata variety, and significantly least was found in the tubers of the Tajfun variety. In this study, varietal differences in the content of reducing sugars and sucrose in potato tubers have been demonstrated, which was the subject of research by Grudzińska and Zgórska (2008). These results were confirmed by Gugała et al. (2013), Sawicka and Pszczółkowski (2005). According to these authors, the content of reducing sugars and sucrose is a feature directly related to the genotype of a given variety. Grudzińska et al. (2016), Zgórska and Grudzińska (2012) showed a significant effect of the genetic factor on the content of reducing sugars in edible potato tubers. It was observed that the biostimulators had a significant influence on the content of reducing sugars. Under the influence of biostimulators used, there was a slight increase in the saccharides content compared to tubers from the control object – on average from 0.4 to 1.3%. Tubers of plants treated with the GreenOk preparation were characterized by the highest content of sugars - 6.78 $g{\cdot}kg^{-1}$, in comparison to plants from the control object, while reducing sugars from 2.71 $g{\cdot}kg^{-1}$ to 3.51 $g{\cdot}kg^{-1}$, respectively. With regard to sucrose, the minimum content was from 3.2 $g{\cdot}kg^{-1}$ on the object, where Kelpak SL was used, and the largest on the object where the BrunatneBio Złoto biostimulator 3.5 $g{\cdot}kg^{-1}$ was used. However, not all biostimulators have been statistically proven. In studies by Czeczko and Mikos-Bielak (2004), the Asahi SL biostimulator used increased the concentration of sucrose, but these changes have not been statistically proven. The random factor, i.e. the conditions prevailing in the years of research, resulted in the diversification of the sum of sugars in potato tubers. The highest content of total sugars and sucrose was determined by tubers harvested in 2015 and 2016, which were characterized by high air temperature of 15.2 °C and 15.8 °C and precipitation of 295.1 mm, and the lowest total sugars and sucrose level was accumulated by tubers harvested in 2017, which was distinguished by favourable weather conditions during the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27912797

growing season (*Table 1*). Grudzińska (2012) also confirmed the significant impact of weather conditions on the level of total sugars in edible potato tubers. The highest content of reducing sugars 3.46 g·kg^{-1} was characteristic of tubers harvested in `hich was characterized by the highest rainfall and the lowest average air temperature – 14.6 °C and longer vegetation period. The prolongation of the growing season resulted in the accumulation if simple sugars, but in a quantity not lowering the technological value of potato tubers. Variable atmospheric conditions in the years of conducting the experiment resulted in significant interactions: years × variety, years × types of biostimulators and years × varieties × types of biostimulators. The proven interaction between the studied factors documents the varied response of cultivated varieties and their combination with plant growth biostimulators. Mazurczyk and Lis (2001) and Zgórska and Frydecka-Mazurczyk (2002) found that high temperature and low soil moisture limited the accumulation of sugars regardless of the variety. In contrast, Antonious et al. (2001) found the effect of weather on the concentration of reducing sugars. The prolongation of the growing season resulted in the accumulation of simple sugars but in the amount not lowering the technological value of potato tubers. The highest content of sucrose was characterized by tubers harvested in the growing season with low temperature at harvest time and with a lot of rainfall. Such climatic conditions could have caused secondary tuber growth and subsequent maturation. At high temperatures and a very small sum of precipitation, all tested varieties were characterized by the lowest content of

Conclusions

Under the influence of the biostimulators used, there was a slight increase in the total sugar content and sucrose, a reduction in reducing sugars compared to tubers from the control object. Tubers of plants treated with the BrunatneBio Złoto Cytokiny preparation were characterized by the highest content of sucrose and the smallest content of reducing sugars. While tubers of plants treated with the GreenOk biostimulator were characterized by the highest content of total sugars, in comparison to plants from the control object.

Abstract. The present study reports ethnobotanical information about plants, which were used by indigenous communities of two union councils of district Kotli AJK. The present study is first report of quantitative ethnobotany from study area. Rajh Mehal and Goi are representative union councils of district Kotli, Azad Jammu and Kashmir having large ranges diversity in habitat and climatic conditions. This district is naturally blessed with highly medicinal plants but unfortunately ethno-botanical information is sporadically known. The study area was surveyed for two consecutive years during moon soon period and ethnobotanical data was collected from 112 local inhabitants using a semi-structured, open ended questionnaire and by free listing method. Several quantitative indices including Informant Consensus Factor, Use Value, Frequency of Citation, Relative Frequency of Citation and Relative Importance Index were used to determine relative usage, benefits and coverage of ethno-medicine. The agreement of homogeneity between the present and previous studies and among the indigenous communities was evaluated using the Jaccard Index. The summary statistics and correlation between use value and relative frequency of citation was calculated in SPSS v 16. The data from free listing method was analyzed by using ANTHROPAC package in R software. Comparison of indigenous knowledge among different genders and age groups was made using Spearman correlation test, the result showed that men had higher information (14.05) about plant uses than females (8.55) in the study area. Male informants reported 63.8% (±10.18) of total recorded species and 76% (±4.13) uses while female informants reported 38.8% (±6.06) species and 68% (±3.65) uses. Smith's Salience analysis indicates that most of the plants in the study area were useful against abdominal pain and worms, constipation and pain. Diseases were classified into twelve different disease categories based on International Classification of Diseases (ICD) classification, with Skin and related symptoms (S00-T98) had highest value (0.91) of Informant's Consensus Factor (IC) followed by Circulatory problems (I00-I99) and Diabetes (E10-E14) each having IC value of 0.90. Aerial parts of 21 plant species were utilized in herbal preparations followed by leaves (20 spp.) and oral mode of admiration was most common among inhabitants. Among all the studied species *Zanthoxylum alatum* was found highly important with a relative importance value of 93.75 followed by *Adhatoda zeylanica* with an importance value of 91.67. High dependency of local inhabitants on traditional medicines was confirmed by higher values of informant consensus factor, which showed that people in study area still use herbal medicines as a primary source of their health care. The present study indicated that area was rich in medicinal plant knowledge and there is a need to exploit this information for drug development and pharmacological activities in addition of conservation and management of this valuable plant resource of the area.
Keywords: *ANTHROPAC, frequency of citation, relative importance, informants consensus factor, medicinal importance*

Abbreviations: prior informed consent (PIC), informant consensus (IC), use value index (UV), relative frequency of citation (RFC), medicinal importance (MI), number of use-reports (Nur), number of species cited (Nt), frequency of citation (FC), international plant name index (IPNI), international classification of diseases (ICD), relative pharmacological properties (PH), relative body system treated (BS), relative importance (RI), oral (Or), tropical (Tr)

Background

One of survey by World Health Organization estimates that about 80 percent of world population depends upon herbal medicines made from approximately 50,000 flowering plants of total world flora (Govaerts, 2001; Schipmann et al., 2002). Effectiveness of plants to cure various aliments is known to humans right from their origin and many herbal drugs are still being utilized in current day herbal system effective against various diseases (Goyal et al., 2014). Indigenous knowledge about plants is an important asset that is gathered from countless activities involving empirical observation, 'trial and error' by the indigenous peoples seeking a cure for an ailment (Locher, 2013). Traditionally, ethnobotanists are interested in exploring the effect of different demographic factors, i.e. age, gender, ethnicity and other attributes of indigenous knowledge coupled with quantitative ethnomedicinal documentation of traditional knowledge by employing different statistical tools (Ullah et al., 2013).

Ethnobotanical knowledge is considered to be an integral part of the knowledge for the drug development. It either helps in identifying new drugs or refocusing on the plants earlier reported to have bioactive components (Mahwasane et al., 2013). The indigenous communities residing in Pakistan mostly use herbal therapies to cure their ailments. Resultantly various studies significantly contributed ethno-pharmacological inventories. With reference to Azad Jammu and Kashmir, some ethnomedical studies have been reported from various areas such as Neelum (Mahmood et al., 2011), Poonch valley (Khan et al., 2010, 2012) and Sudhnoti (Ishtiaq et al., 2015). Few papers have been written on ethnobotanical aspects form the District Kotli (Ajaib et al., 2010; Amjad et al., 2015; Amjad and Arshad, 2014); however, these studies are superficial and lack of novelty in terms of quantitative data in addition to traditional phytotherapies. Therefore, the present study was aimed to:

1. Record and discuss knowledge on medicinal plant uses in the local traditional practices including method of preparation and use of plants as herbal medicine
2. The differential distribution of knowledge about plants and medical properties among sectors of the society
3. Identifying novel uses of plants compared to previously reported work
4. Analysis of ethnobotanical data by using different quantitative indices

Methods

The study was organized into three stages (*Fig. 1*).

a) Field work

The study area lies near line of control and is diversity hotspot due to frequent rain and pleasant weather conditions. Being remote and having less literacy rate people in area still depend upon herbal medicines but documentation of this traditional knowledge is very rare. The present study was conducted by interviewing 112 local inhabitants

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27992829

with age ranges between 40 to 75 years, including herbalists, midwives (*Daai*) and local peoples (male, female). Legal permission was taken from representatives of the municipality for conducting interviews and collection of ethnobotanical data. All respondents were asked to sign a prior informed- consent (PIC) form after the objectives and possible consequences of the study had been explained. The prior informed consent (PIC) form was translated into the local *Pahari* language. The study area was explored for three years (July 2015–September 2016), plant samples were collected and information was gathered by group discussions, interviews and field visits. Sample size was determined by using method developed by Kadam and Bhalerao (2010).

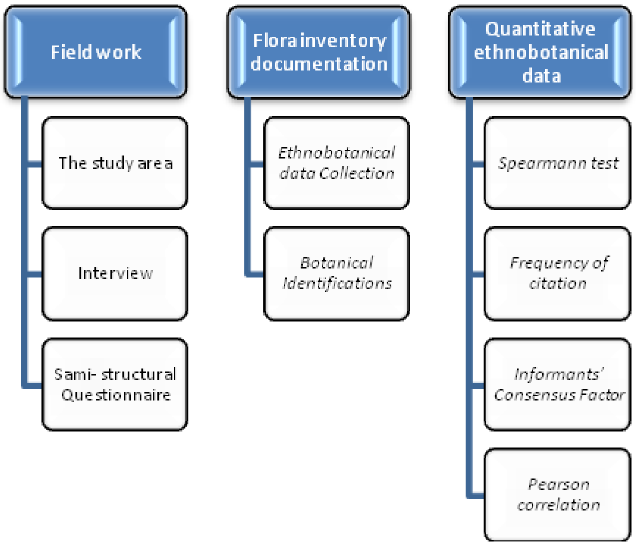

Figure 1. *Experimental design for the collection of data*

b) Floral inventory documentation

Ethnobotanical information collected through interviews was recorded in a semi-structured questionnaire. Information obtained was cross-checked and compared with existing available literature. Furthermore, the indigenous learning about the plant assets, religious and social perspective, for example, populace density was additionally recorded. The Minimum Standards of Reporting Checklist contains details of the experimental design, and statistics, and resources used in this study. During field surveys, the local/common names of plants were recorded with the help of a local guide or local informants. For taxonomic confirmation of plant was done using different Floras and monographs of the different areas of Pakistan, whereas the International Plant Name Index (IPNI) (www.ipni.org) was also used to obtain the correct botanical name confirmation.

c) Quantitative analyses of ethnobotanical data

Frequency of citation (FC)

The result of FC presented as %age and proportions. Each plant reported by informants with respect to the native use was calculated as frequency of citation (FC). The collected ethnomedicinal information was quantitatively analyzed using relative frequency citation index (RFC) after Vijaykumar et al. (2015) as follows:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27992829

$$RFC = FC / N$$

where FC is frequency of citation N is number of informants.

Informants' consensus factor (F_{IC})

IC is utilized to build up the consistency of learning among the sources for each sickness treated and diverse illness categories (Heinrich et al., 1998). Informant consensus factor was drawn to search agreements of the informants against the cures for each diseases category. For this purpose, following formula was used:

$$F_{IC} = \frac{Nur - Nt}{Nur - 1}$$

where *Nur* is the number of use-reports in each group of disease; *Nt* is the number of species cited for the particular disease by all the informants. The F_{IC} values are ranged between 0 and 1, in which '1' shows the maximum level of consensus. Consequently, high F_{IC} can be used in identifying important plants for searching novel bioactive molecules (Carrió and Vallès, 2012).

Medicinal importance (MI)

The MI was figured out by utilizing following equation after Baydoun et al. (2015).

$$MI = \frac{\text{No. of use reports for disease category}}{\text{No. of species used}}$$

Use value index (UV)

The use value was calculated by using following formula (Vijayakumar et al., 2015):

$$UV = \sum Ui / N$$

Ui is the number of uses stated by each informant for a given species and N is the total number of sources (informants).

Relative importance (RI)

RI was determined by the formula

$$RI = \frac{\text{Rel PH} + \text{Rel BS x 100}}{2}$$

$$\text{Rel PH} = \frac{\text{PH of a given plant}}{\text{Maximum PH of all reported plant species}}$$

where PH is pharmacological attributes of the each provided plant and Rel PH is the relative number of pharmacological properties for an individual plant.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27992829

$$BS = \frac{\text{BS of a given Plant}}{\text{Maxi. BS of all reported plant species S}}$$

BS is the number of body system healed by single species and Rel PH is relative number of body system treated by a single species.

Smith's salience analysis (SS)

The analysis of agreement and variation in free-lists using cultural domain analysis is described and justified in detail by Puri (2010), Quinlan (2005), Weller and Baer (2002), and several statistical software packages, including ANTHROPAC, can manage and analyze data in this way. The cultural domain analysis using ANTHROPAC was performed using Borgatti's (1996) Methods Manual. The main steps can be briefly summarized free-lists are compiled in an informant by disease matrix, which indicate both the rank order and the presence or absence of items in each informant's list from this, the frequency of items, their average rank in the list, and a measure of salience (based on Smith, 1993) can be calculated. This is essentially a weighted average of the (inverse) rank of an item across multiple free-lists, where the number of items in the list weights each list.

Pearson correlation

Pearson correlation analysis was calculated in order to access the linear relationship b/w the RFC and Use value index (UV) by using SPSS ver. (16, the r^2) also estimated to measure cross species variability in RFC that was described by variance in UV. The r^2 was computed simply taking square of r (Amjad et al., 2017).

Spearman test

To decide if a statistically significant correlation exists between the number of plants mentioned and the age of informant, we used the Spearman test. The Mann-Whiney U and Kruskal-Wallis tests were used to find significant differences among two and 5 groups related groups, respectively, all values set at 0.5 alpha level of significance (Bruschi et al., 2011; Shaheen et al., 2017a).

Results

Demographic data

Ten field visits (to complete regular varieties) were done to accumulate ethnobotanical information related to use of medicinal plants. The aggregate length of the field work was roughly about 3 years i.e. from July 2015 to September 2016 and data was recorded form 112 informants (male 67 and females 45). The informants were divided in to four categories based on their gender, age group, education and profession. Mostly herbalists were present in the age group range between 51-60 while least number of informants had age more than 60 years. Literacy rate of study area was very low as most of informants (about 26.7%) were uneducated and only 5 informants which is 4.46% of total informants had higher education. On average male informants had more information about the plant uses than female informants, male informants on average know 14.05 species than female who know 8.55 species. Similarly uses known

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27992829

by male and female were different, on average males report 6.12 uses of plant while female reports 5.82 uses of the plant (*Table 1*). Informants of age between 41 and 50 know most plants than other age groups but information about plant use was provided most by informants with age between 51-60 years and more than 60 years as they on average report 6.25 and 9.91 uses of plants. Among educated informants, those having middle (secondary school) education know most of the plant species (20.38) and people with intermediate education (Higher secondary school) know most uses of plant species (7.30) among different professionals' traditional health practitioners know most of the species (23.08 on average) and also reported multiple uses (on average 9.60) of recorded species (*Table 1*). Many examinations have demonstrated that age and sex are two vital variables to be considered while assessing the appropriation of information inside a gathering of sources (Torres-Avilez et al., 2016; Albuquerque et al., 2011). In any case, not many investigations have broken down the impact of these factors on the appropriation of ethno-medicinal information in Pakistan and none of them utilized factual examinations for approval of the gathered information (Ahmad et al., 2014). Spearman's correlation analysis showed significant positive differences between the age and the number of both mentioned species ($rs = 0.24$; $p < 0.05$) and different uses ($rs = 0.35$; $p < 0.05$), indicating that there is a trend of older people being more knowledgeable than younger people.

Ethno floral diversity

During the ethnobotanical survey, 80 plants were explored, which belonged to 69 genera and 50 families. The detailed inventory of medicinal plants along with related information is presented in *Table 2*. Family Asteraceae contributed maximum to ethno-flora with 9 species, followed by Lamiacea, Rosaceae and Solanaceae (4 species each) (*Fig. 2*). The greater diversity of a family from study area was related to high occurrence of its members, familiarity of local people with its species and presence of active ingredients in its members which are being utilized to treat various ailments (Arnold, 2015; Mouterde, 1966, 1978, 1983). These results are in accordance with the different studies carried out in different regions of Pakistan and world (Bibi et al., 2014; Khan et al., 2014; Lulekal et al., 2013).

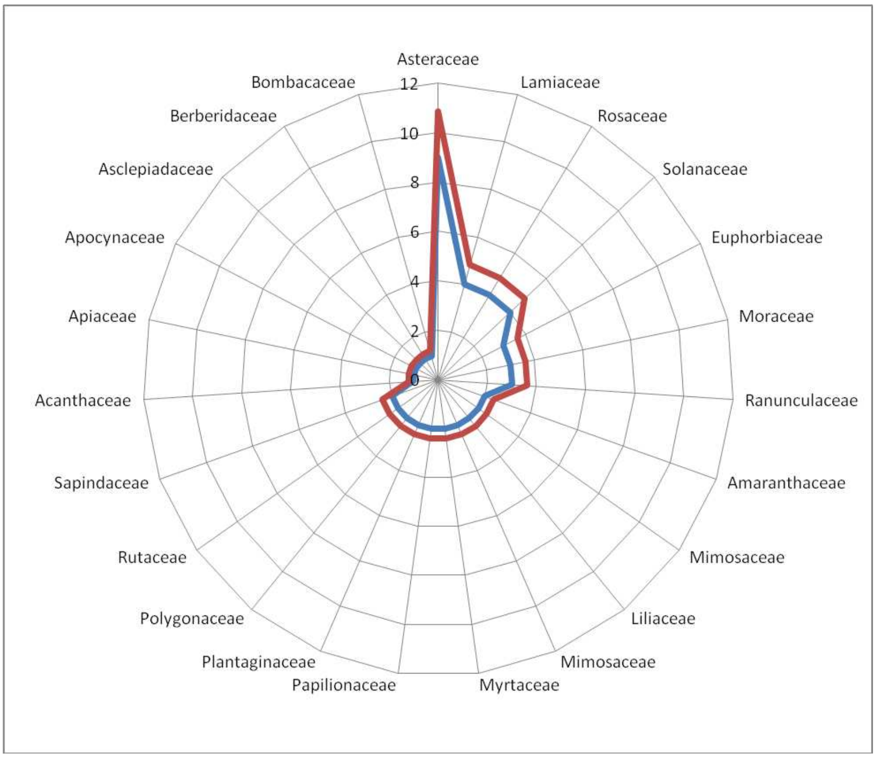

Figure 2. *Contribution of major families in the ethnoflora of the study area*

Medicinal usage

In this survey, fifty-three diseases/ailments were treated by 80 plant species with maximum 16 species (30% of total) were used abdominal pain and constipation which were common and prevailing problems of the area, followed by pain (11 spp., 20.1%), sexual dysfunction (10 spp., 18.84%), tooth problems and wounds (9 spp., 16.9% each) (*Fig. 3*). The documented uses of ethnomedicinal plants were compared with recently published literature (Ishtiaq et al., 2015; Amjad et al., 2017; Shaheen et al., 2017b) to seek the novelty of uses. Most of the documented species possessed similar uses; however, 16 species possessed novel uses (*Fig. 4*), which were not previously reported in literature. The main reason for the similarity among these studies was the same climatic conditions which resulted into the same floristic composition as well as the dissemination of information related to the use of plants among the informants of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27992829

different areas. The reason for less similarity among the studies may be due to the existence of different cultural values in communities inhabiting the areas so they use plants differently for their healthcare needs. (Baydoun et al., 2015; Panyaphu et al., 2011). However, the informants were unaware of such concern and they informed only beneficial effects of plants without pointing out any side effects. Different parts were used for preparing herbal recipes. Leaves (31%) were the most used plant part, followed by aerial parts (17%), fruit (14%), roots (12%), bark (8%), flower (6%) and bulb, cone branches, pulp, resins (1% each) (*Fig. 5*). The preference of leaves in preparing herbal preparations may be due to storage of most of the active ingredients in leaves in order to attain resistance from the herbicides and insects. Furthermore, they are accessible and easy to collect (Panyaphy et al., 2011; Mesfin et al., 2013; Ahmed et al., 2013).

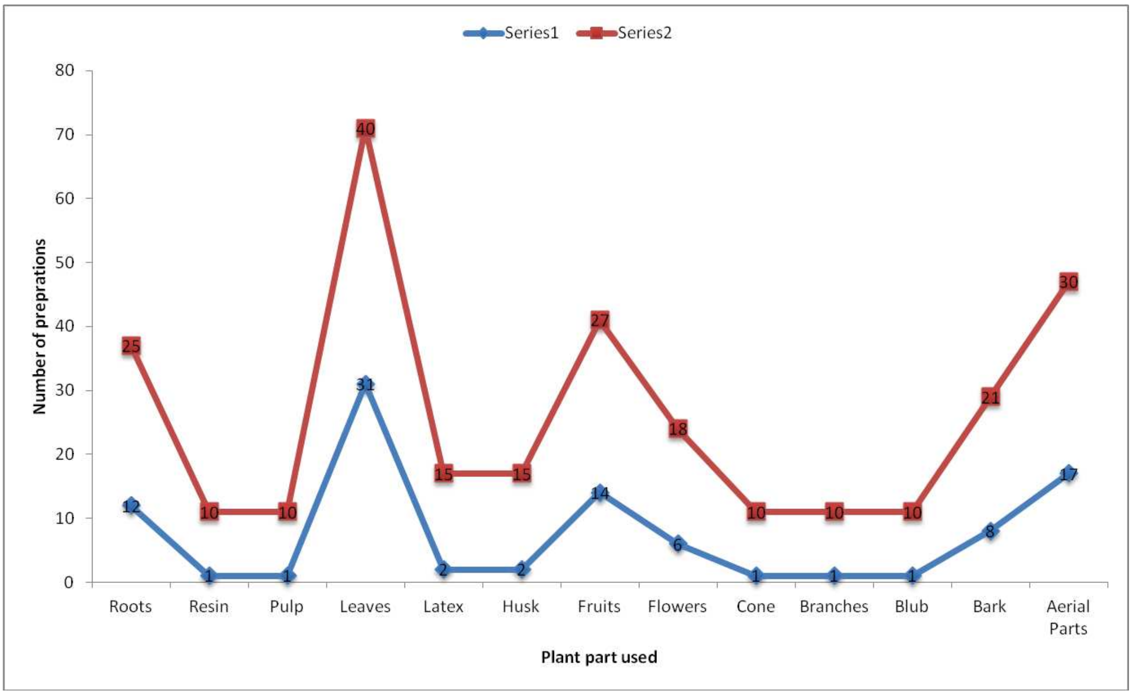

Figure 5. *Different plant parts used in herbal preparations*

Methods of preparation and administration

Different herbal recipes were prepared from the medicinal plants and method of preparation and application vary based on type of disease treated and actual site of application (*Fig. 6*). The most herbal recipes were prepared by grounding plant parts into powder about 16.4%. Other methods of preparation and administration include: juice (15%), paste (14%), decoction (11%), chewing (6.3%), potherb (5.7%), infusion (3.8%), extract (3.16%), boiling, smoking, poultice, latex and wrapping (2.53% each), cooking and oil (1.9% each), rubbing (1.27%), herbal bath, smelling and tea (0.63% each). Although most of the preparations were made from a single plant few were made from mixture of more than one plants, for example, seeds of *Leucaena leucocephala* were grounded and mixed with equal amount of powdered seeds of *Albizia lebbeck* to treat sexual debility. Similarly, roasted fruit of *Papaver somniferum* was ground with *Terminalia chebula, Foeniculum vulgare* and black salt for the treatment of abdominal pain and sleeplessness. With regard to the method of preparation, the undertaken study was in accordance with the work carried out by Mouterde (1983). Most of the preparations were administered orally (57.58%), followed by tropical (39.62%) and inhalation (2.8%). These results were in accordance with Vijayakumar et al. (2015).

Therapeutic indications

Informant's consensus factor (F_{IC})

In order to check the agreement of informants about the knowledge of plants uses, the recorded 90 diseases were grouped into 12 different disease categories according to IDC. The Informants Consensus Factor (F_{IC}) values ranged from 0.80 to 0.91, showed much homogeneity in nearly all the described disease categories (*Table 3*). Generally, F_{IC} values range from 0 to 1, in which the high values are good indicator of high

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27992829

informant consensus on the species used in the treatment of a particular category of illness (Heinrich et al., 1998; Trotter and Logan, 1986). The Informants Consensus Factor (F_{IC}) analysis indicated that among the 12 disease categories skin and related symptoms had the highest F_{IC} values (0.91), treated by a large number of taxa (10 species) and 96 use reports. It was followed by circulatory problems (0.90), diabetes (0.90). The highest value of F_{IC} suggests increased data about the usefulness of plants to cure a specific disease. The most commonly used plants to treat these diseases were *Pinus roxburghii, Ranunculus arvensis Albizia lebbeck, Lepidium sativum, Chenopodium album, Otostegia limbata, Berberis lyceum, Medicago polymorpha* and *Adhatoda zeylanica*. Although the F_{IC} for gastrointestinal disorders (0.88) was less compared to some other ailment categories, however, a maximum number of plants (66 species) were recorded under this category. This category contains wide range of ailments such as abdominal pain, abdominal worms, piles, cholera, constipation, diarrhea, dysentery indigestion, flatulence, stomach disorder, intestinal problems, lack of appetite, nausea, vomiting and stomach pain (Afolayan et al., 2014; Abe and Ohtani, 2013). The plants with high F_{IC} value might contain the high amount of bioactive compounds and can be subjected to further biochemical and pharmacological analysis.

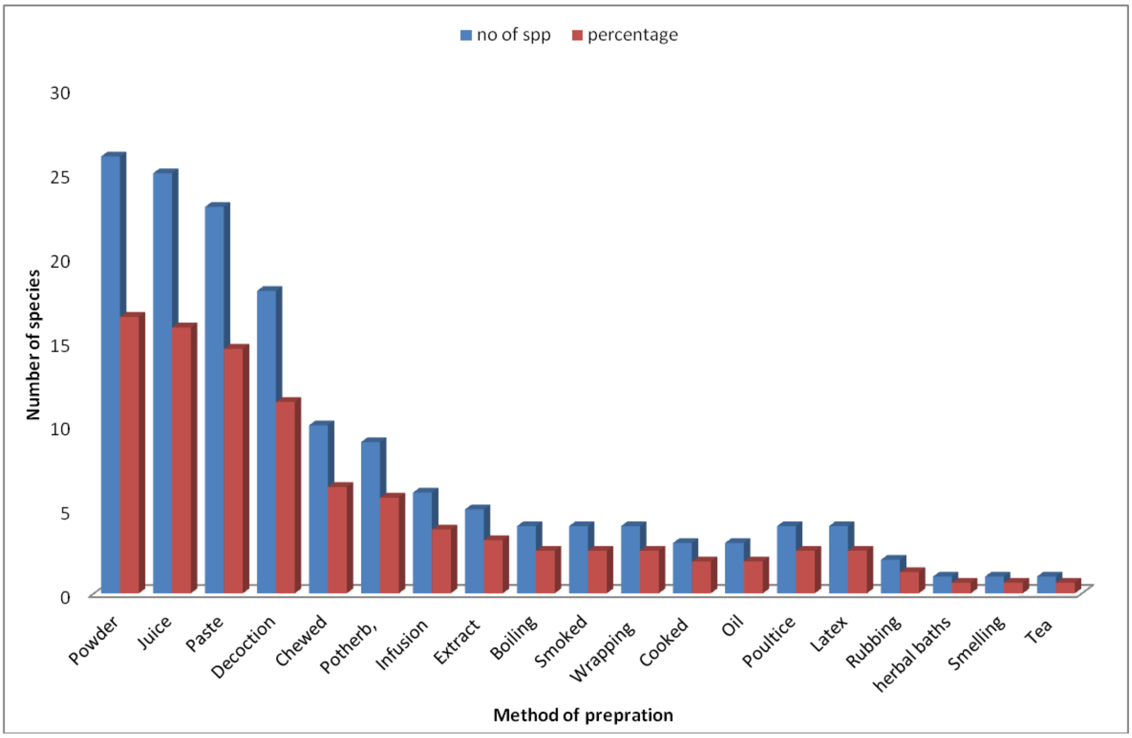

Figure 6. *Various herbal preparations/formulations from the native flora of Rajh Mehal*

Medicinal importance (MI)

The medicinal importance (MI) values can be used as a sign of the relative medicinal relevance of mentioned plant species (*Table 3*). These values can be used in finding variability among the pharmacological, environmental and cultural determinants between the investigated species and areas (Baydoun et al., 2015). The MI and F_{IC} values were higher for skin and related symptoms (9.6) because weather conditions in study area quit severe dry and prolong winter; that is why people in the study area suffer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_27992829

skin problems very commonly. After skin diseases circulatory problems (8.93) were common, then diabetes (8.8) and digestive system problems, mouth, ear and oral disease (8.45). These values were closer to the findings of Baydoun et al. (2015) and higher than the MI values reported by Carrió and Vallès (2012).

Relative importance (RI)

The highest RI value was obtained for *Adhatoda zeylanica* (93.75) *Zanthoxylum alatum* (91.67), *Berberis lyceum*, *Juglans regia* (87.50 each) *Punica granatum, Olea ferruginea* (83.33 each), and *Solanum surattense* (79.17) which indicated that these plants possess strong pharmacological properties and are used more frequently in the study area. The important and most commonly cited plants belonged to Asteraceae, Lamiaceae, Solanacea and, Rosaceae. Theses finding agrees with the early reports by Carmen Juárez-Vázquez et al. (2013), Yaseen et al. (2015) and Alonso-Castro et al. (2012).

Smith's salience analysis (SS)

Salience analysis (Smith, 1993) accounted for frequency of mention; on an average 60 illnesses were listed. In free-listing we interview 112 informants but for Salience analysis and ranking of illness 10 most informative informants were chosen. The *Table 4* shows salience estimates for each illness, indicating both the number of people who mentioned the illness and the order of their responses. In Smith's Salience analysis abdominal pain and worms had the highest overall salience index, mentioned by 73.21% of informants. Constipation was the second most salient illness had 70.54% of informants and Pain was the third most cited illness treated by the plants in the study had 67.8% frequency. Sleeplessness, uterus disease, weak eyesight and bleeding gonorrhea were the less salient diseases. Composite Salience was another step to reinforcement the results of Smith's Salience by narrow down the informant numbers, result was draw the on the base of ten key informants.

Use value index (UV) and relative frequency of citation (RFC)

The use value (UV) shows the range to which a species can be used and the species with high UV values were mostly exploited in the area to cure a specific aliment. *Zanthoxylum alatum* (1.19), *Olea ferruginea* (1.11), *Solanum surattense* (1.05) and *Juglans regia* (1.04) possessed the higher use values. *Table 2* showed high values of UV and RFC of different plant species. It is evident from the results that *Adhatoda zeylanica,* (0.79) *Berberis lyceum* (0.77), *Juglans regia* (0.75) and, *Punica granatum var. nana* (0.73) and *Zanthoxylum alatum* (0.72) were the most cited species in the research area. On the bases of RFC and UV we concluded, since these species are very commonly available in the area, therefore the inhabitants mostly cited these. Moreover, these species were native to that area and were present for decades, so their properties to cure different disease got popularized among the indigenous peoples. A strong significant and positive correlation ($r^2 = 0.60$) was recorded between UV and RFC showing that by increase in number of informants the knowledge about plant use in herbal medicine will also increase. These results indicate that the study can make a significant contribution to folk knowledge on the use of medicinal plants and further laboratory-based investigations could help in identifying the active ingredients of the most commonly exploited plants. The variation in data can be explained by coefficient of determination and in present study the value of R^2 was 0.36 reflecting that 33% variation in use value can be explained in terms of relative frequency of citation (*Table 5*).

Table 5. *Pearson correlation between UV and RFC*

		UV	RFC	Mean ± std. deviation
UV	Pearson correlation	1	0.606**	0.6034 ± 0.23249
	Sig. (2-tailed)		0.000	
	N	80	80	
RFC	Pearson correlation	0.606**	1	0.4250 ± 0.19266
	Sig. (2-tailed)	0.000		
	N	80	80

Discussion

This study documented the good diversity of medicinal plants coupled with their therapeutic use and medicinal importance in the indigenous communities of Rajh Mehal, AJK. The ethnobotanical inventory consists of an ample therapeutic indication of 80 medicinal plants distributed in 12 disease categories that revealed a good picture of the health disorders of the native population. The natives mostly prefer single species based preparations instead of mixtures. The high Informant Consensus (F_{IC}) suggests that current use and knowledge of medicinal plants are still strong and local inhabitants have a high dependency on medicinal plants in meeting their primary health care. Many novel uses of plants were documented after comparing with the previously published literature. Most of the documented species possessed similar uses; however, 16 species possessed various novel uses which were not previously recorded. These include: *Conyza bonariensis* (Wound), *Carthamus tinctorius* (Pneumonia), *Celtis australis* (Smallpox, anti-allergic), *Dodonaea viscosa* (Toothache, diabetes), *Ipomoea carnea* (Athlete foot), *Launaea taraxacifolia* (Diabetes, pain), *Leucaena leucocephala* (Sexual debility), *Olea ferruginea* (Mouth ulcer, throat pain), *Pinus roxburghii* (Diabetes), *Plectranthus rugosus* (Mouth infection), *Rosa brunonii* (General weakness), *Rubia cordifolia* (Amenorrhea), *Rubus ellipticus* (Cool demulcent), *Rumex nepalensis* (Edema, weakness), *Thalictrum aquilegifolium* (Sunstroke) and *Zizyphus oxyphylla* (Fever, abdominal pain). In Smith's Salience analysis indicated that abdominal pain and worms had the highest overall salience index, mentioned by 73.21% informants. Constipation was the second most salient illness had 70.54% of informants and Pain was the third most cited illness treated by the plants in the study had 67.8% frequency but Sleeplessness, uterus disease, weak eyesight and bleeding gonorrhea were the less salient diseases. Composite Salience was another step to reinforcement the results of Smith's Salience by narrow down the informant numbers, result was draw the on the base of ten key informants. On the bases of RFC and UV we can say that, these species are very commonly available in the area, therefore the inhabitants mostly cited these. Moreover, these species were native to that area and were present for decades, so their properties to cure different disease got popularized among the indigenous peoples.

Conclusion

The present study can serve as best baseline study to search active ingredients of plants which are being utilized as herbal medicine in the study area, particularly plants with novel uses. These plants might be subjected to further lab and clinical analysis for validation of results from present study. This traditional knowledge together with scientific studies can lead to powerful discovery for newer, safer and affordable medicines. Furthermore, this study could be helpful in the conservation of the traditional knowledge of medicinal plants of the remote areas like Rajh Mehal for the uplift of a good life standard and livelihood of the local communities is indispensable. High dependency of local communities on local flora is resulting in extinction of medicinal plants, so step should be taken for conservation and management of these valuable plant resources of this territory.

Acknowledgements. We are enormously thankful to the local inhabitants/informants of the study area for their assistance and knowledge sharing, without which such study is unfeasible. I want to acknowledge

COMSATS Institute of Information Technology, Islamabad, English language department for language editing.

Author's contributions. MFQ and RQ designed experiments, field data were collected by QFM, MSA and WA, analytic analysis was also done by QFM and AS, HS, MFQ wrote first draft of manuscript, RQ reviewed and made amendments in original draft of manuscript.

Conflict of interests. We declare that we have no conflict of interests.

Ethics approval. Before initiating of our survey ethical approval for the study was obtained from the COMSATS Institute of Information Technology Ethics Committee. Legal permission was taken from representatives of the municipality for conducting the interview. All respondents were asked to sign a prior informed- consent form after the objectives and possible consequences of the study had been explained. The prior informed consent (PIC) form was translated into the local Pahari language.

(Received 26th Oct 2018; accepted 7th Jan 2019)

Abstract. Comparison of twelve conifer species (*Abies alba, A. concolor, A. nordmanniana, A. pinsapo, Cedrus atlantica, C. deodara, Picea abies, P. omorika, P. pungens, Pseudotsuga menziesii, Taxus baccata*, and *Pinus nigra*) in the sense of needle morpho-anatomy and pollen morpho-physiology, in correlation to air pollution, was performed for the first time. Analyzed properties of species were also compared with literature sources. Listed conifers were investigated in five Belgrade parks, characterised by different degrees of air pollution, especially CO_2. Their rank, I-V, was performed from non-polluted to heavily-polluted parks. Ranking in the sense of needle morpho-anatomy and pollen morpho-physiology did not match expected ones, but park V remained the worst for many analyzed species. Trees with shorter needles had greater stomatal density, which was particularly prominent in *A. alba, A. nordmanniana, P. abies, P. omorika, P. nigra* and *T. baccata*. The pollen grains of *C. atlantica* and *T. baccata* were the most sensitive to air pollution. In some analyzed species distance of particular trees close to the heavy traffic also was in correlation with needle dimensions (*P. omorika, A. concolor, A. nordmanniana, P. nigra*), stomatal density (*A. alba, P. abies, P. omorika, P. pungens) and pollen vitality (A. pinsapo, C. atlantica, P. menziessi, P. nigra,* and *T. baccata*).
Keywords: *cedar, fir, pine, spruce, yew*

Introduction

The increasing content of air pollutants, such as CO_2, SO_2, nitrogen oxides, soot, dust, etc. is always present in urban habitats and produces an adverse impact on growth and health of the living world. Since plants absorb chemicals and deposit solid particles, green areas, such as parks, are essential for the quality of life in cities. In addition, plants suffer changes which lead to their slow development, to diminished resistance to disease and pest attacks and, ultimately, to their death. These changes could be visible

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28312848

(macro-changes) or less visible (micro-changes). Both of them are reliable indicators of the level of vulnerability of urban habitats.

Many scienticists tried to imitate polluted habitats and trees response to them. Fumigation of *Picea omorika'*s pollen with SO_2 resulted in reduced seed production (Krug, 1990). Fumigation of the needles of seedlings of Scots pine (*Pinus sylvestris*) and Norway spruce (*Picea abies*) with SO_2, O_3 and combination of these two gases greatly reduced soluble carbohydrates in the needles taken from *P. sylvestris*, but to a lesser content in case of needles taken from *P. abies* (Peace et al., 1995). Furthermore, when field with needles of 3-year-old seedlings of Scots pine was fumigated with relatively low concentration of SO_2, their needles emitted H_2S. This emission depended of light and SO_2 concentration (Hällgren and Fredrikson, 1982). On the other hand, some investigations showed that conifer species (Austrian pine, cypress and larch) influenced the lowest level of NO_2, O_3 and NH_3 in the air (Donovan et al., 2005). Conifers also delay ultra-fine dust particles more effectively than broadleaved trees (Freer-Smith et al., 2005). Furthermore, it should be noted that only evergreen and conifer species delay leaves and transpire throughout the whole year. Their transpiration is important especially in winter, when the level of air pollutants is extremely high, or following heavy air pollution (in the period of defoliation of deciduous trees). There are four main ways that urban trees affect air quality: (1) temperature reduction and other microclimatic effects, (2) removal of air pollutants, (3) emission of volatile organic compounds and tree maintenance emissions, and (4) energy effects on buildings (Nowak, 2002).

The purpose of the study is to evaluate, for the first time, the degree of vulnerability of twelve conifer species from five parks to air pollution by means of investigation of both morpho-anatomic leaf properties and morpho-physiological pollen traits. Furthermore, the influence of distance of trees from traffic was also taken into account. Increased content of CO_2 leads to a decrease of stomatal density (Lin et al., 2001) and number of stomata (Woodward and Bazzaz, 1988). In *Pinus crassifolia* (Qiang et al., 2003) their positive correlation (r = 0.63) were found. In one-year old needles of *P. douglasii*, Apple et al. (2000) reported that CO_2 and temperature did not influence stomatal density. They stated that effects could be more visible later (after three years) and genetic influence is very strong, so stomatal density depends on needle elongation.

Materials and methods

Plant materials, selected parks and trees

Five Belgrade parks in Serbia (Europe), exposed to different levels of air pollution, were selected in 2015 (*Fig. 1*). Listed parks were ranked from non-polluted to very heavily-polluted Popović et al. (2016).

For needle and pollen studies twelve and nine tree species were used (*Tables 1* and *2,* respectively).

Processing morpho-anatomic properties of needles

Well-developed one-year old leaves (needles) of twelve conifers were collected for laboratory testing: morpho-anatomic analyses of needles, where length, width, shape, dry mass and stomatal density were measured. For the purpose of morpho-anatomic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28312848

analyses, needles all around a tree crown were collected (ca. 20 needles). Stomata rows from abaxial needle side were obtained by the 'Kolodium method' (Wolf, 1950).

Processing morpho-physiological properties of pollen grains

Pollen was extracted from ripe strobili from nine trees in parks or extracted in laboratory after immersing twigs with half-ripe strobili in water. Observations of needle stomatal density and morpho-physiological analysis of pollen were performed using a light microscope (*Leica Galen III*) and included measurements of length and width of pollen grains, as well as their germinability and length of pollen tubes at 10% of sucrose. Measurements were carried out on 50 pollen grains per tree. The needle and pollen shape coefficient were calculated by the formula: 100*width/length.

Statistical analyses

Mean values and differences between parks (at 95% level), as well as analysis of variance were calculated in *Statgraphics Centurion* XVI, Version 16.1.11. Coefficient of correlation (r) by linear regression analysis for all measured properties was performed.

Results

Morpho-anatomic properties of needles

Ranking of parks in *Tables 3* and *4* were performed from heavily-polluted (V, IV) to moderate polluted (III, II) and non-polluted areas (I). The needles of *A. alba*, *A. concolor*, *P. abies* and *P. pungens* were significantly shorter in the park V (*Table 3*). Consequently, trees with shorter needles had greater stomatal density, which is particularly prominent in *A. alba, A. nordmanniana*, *P. abies*, *P. omorika*, *P. nigra* and *T. baccata* (*Table 3; Fig. 2*). Needles of *P. omorika* and *P. nigra* were significantly larger in the park IV (*Table 3; Figs. 3* and *4*). The needles of *Taxus baccata*, predominantly collected in the proximity of traffic crossroads in the park IV were shorter than in other parks (*Fig. 4*). Interestingly, the needles of *Pseudotsuga menziesii* were larger in the park V than in the park III (*Table 3*). Larger needles very often had a larger leaf-area, perimeter and dry mass. As presented in *Table 3,* especially with respect to morphology of needles, the parks are ranked as follows (from the best to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28312848

worst results): IV, II V, III and I. This ranking does not correlate to the ranking in terms of park pollution (I-V, from the best to the worst results). As a consequence, we could not conclude that morphological parameters of conifers are reliable indicators of air pollution. However, some species, such as *P. omorika, P. pungens, P. nigra and T. baccata* had larger needles when situated deep inside the park (far from the heavy traffic). Furthermore, *A. alba* and *P. abies* also produced better results in parks with moderately polluted air than in heavily-polluted parks. With respect to stomatal density, the greatest differences between parks were observed in case of *A. alba*, *A. concolor*, *C. atlantica* and *T. baccata*. Many species had the greatest stomatal density in the most polluted parks (V and IV), but we could not generally conclude that stomatal density of conifers is a dependable indicator of air pollution.

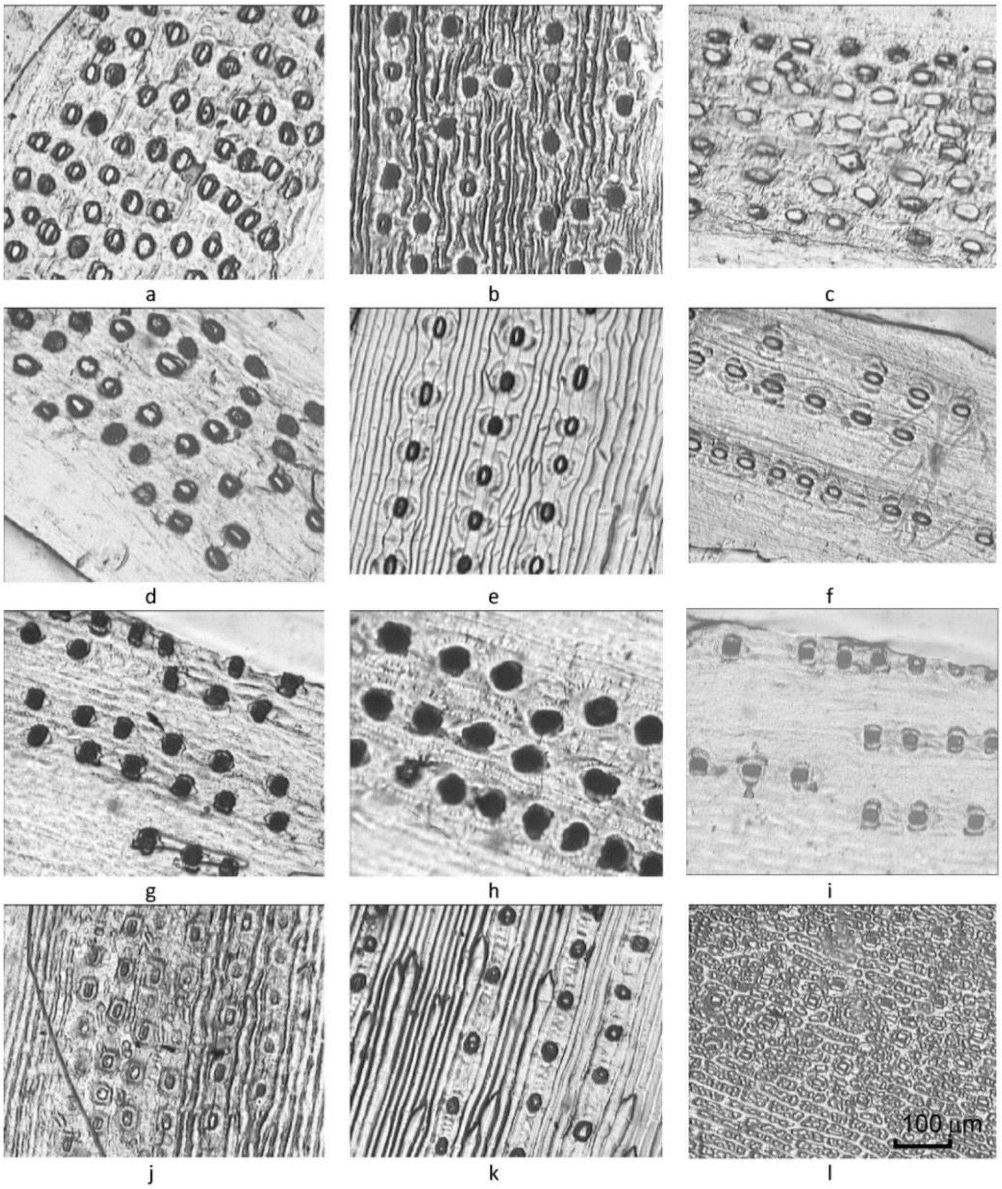

Figure 2. *Rows of stomata on the abaxial needle side (objective 10x): Abies alba - V (a), A. concolor - III (b), A. nordmanniana - I (c), A. pinsapo - IV (d), Cedrus atlantica - III (e), C. deodara - II (f), Picea abies - V (g), P. omorika – IV (h), P. pungens – IV (i), Pseudotsuga douglasii – III (j), Pinus nigra - III (k), Taxus baccata - V (l)*

*Significant differences ($p < 0.05$)

Morpho-physiological properties of pollen grains

Morpho-physiological pollen properties are presented in *Table 4* and *Figures 5* and *6*. The impact of air pollution was calculated and graphically presented in four tree species: *Cedrus atlantica*, *Picea omorika*, *Taxus baccata* and *Pinus nigra* (*Fig. 6*). These four species were selected because they belong from different genera and simultaneously were present in two or more parks. The best results were obtained in the park IV (in case of *P. omorika*, *T. baccata* and *P. nigra*). The largest amount of pollen of *C. atlantica* was found in the park II, but its vitality (pollen tube length) was the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28312848

highest in the park III. The parks were ranked as follows (from the best to the worst results with respect to morpho-physiological pollen properties): IV, II, III, I (only for *T. baccata*) and V. This ranking of parks is not similar to the rankings obtained by the analysis of morphometric values of tree needles (statistic results are not presented). However, we could generally conclude that the analysed conifers have the smallest pollen grains and the lowest pollen vitality in the park with the heaviest air pollution (V) (*Fig. 5*). The pollens of *T. baccata* and *C. atlantica* were most sensitive to air pollution (*Table 4; Fig. 5*). Furthermore, *P. omorika* and *P. nigra* showed better results when situated far from the traffic zones. Small, abnormal and non-vital pollen grains lead to lower germinability and energy of pollen germination (manifested in form of small pollen tubes) (*Fig. 5*). The most drastic examples of changes of pollen grains were observed in the park III, in case of *Cedrus atlantica* and *Picea omorika,* and in the parks IV and V, in case of *P. nigra* (*Table 4; Fig. 6*).

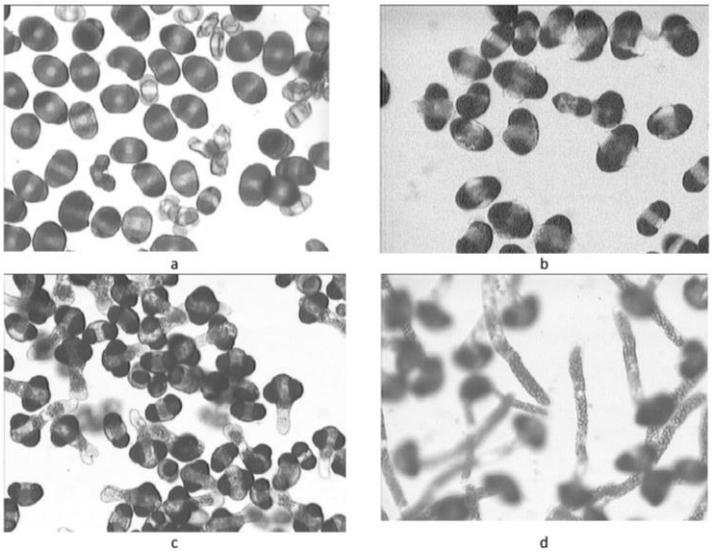

Figure 5. *Small, abnormal and non-vital pollen grains of Cedrus atlantica – V (a) and Picea omorika – V (b). Good germinability of Pinus nigra – IV (c) and C. atlantica – III (d) pollen grains*

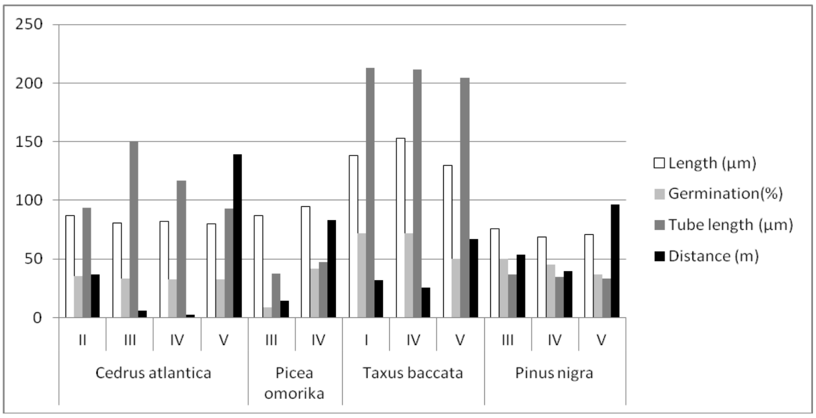

Figure 6. *Graphical illustration of average values of pollen grains length, length of pollen tubes and distance from traffic in Cedrus atlantica, Picea omorika, Taxus baccata, and Pinus nigra*

In some analyzed species distances of particular trees from heavy traffic also were in significant correlation with needle dimensions (*A. concolor*, *A. nordmanniana and P. omorika*, r = -0.93, 0.99, and 0.56, respectively, *Fig. 7*), stomatal density (*A. alba*, *P. abies*, *P. omorika*, *P. pungens*, r = -0.99, 1.0, -0.70, and 0.71, resp., *Fig. 8*) and pollen vitality (germinability: *C. atlantica*, r = 0.73, *P. nigra*, r = 0.57 and *T. baccata*, r = 0.68, *Fig. 9;* length of pollen tubes: *A. pinsapo*, r = 0.99 and *P. menziesii*, r = 0.95, *Fig. 10*).

Discussion

Conifer foliage is a useful indicator in bio-monitoring of air pollution (*Pinus ponderosa*). Several of investigated species Vukićević (1987) considered resistant to urban conditions (*A. concolor*, *A. nordmanianna*, *A. pinsapo*, *C. atlantica* and *P. omorika*). The average needle length and width for all twelve investigated species are in agreement with the published results of Vidaković (1982) and Vukićević (1987). The needle length and width of *A. alba* from park V also agree with previous results obtained by Pawlaczyk et al. (2005) and Pawlaczyk and Bobowicz (2008). The average needle length and width of *P. omorika* are also in agreement with the results obtained in natural habitats (Milovanović et al., 2005; Radovanović et al., 2014; Nikolić et al., 2015). Furthermore, dimensions of *Pinus nigra* from park V are in agreement with the results obtained by Matziris (1984) and Borzan et al. (2002). The values of needle length and leaf area in our *A. pinsapo* from park IV are higher than those already reported by Sękiewicz et al. (2013). The needle length of *Cedrus atlantica* also agrees with the results obtained by Jasińska et al. (2013), while needle width was about 25% higher. Needle width of *Pinus sylvestris* was higher in CO_2 polluted air, as a result of an increase of messophyl tissue (Lin et al., 2001). In some other conifers, air-polluted needles are shorter, with lower number of stomata (*Pinus pinaster*, Wahid et al., 2006). Effects of drought could be found even at the level of needle anatomy, where stomatal density increased as needle length decreased (*Pinus canariensis*, Grill et al., 2004).

Dimensions of trees and their leaves could depend on soil nutrition. Addition of nitrogen increased length, width and number of needles per shoot in *P. menziesii* (Brix and Ebell, 1969).

In *A. alba*, *A. nordmanniana* and *A. pinsapo* stomatal density was higher (*Table 1*) than in literature (Robakowski et al., 2004; Meidner and Mansfield, 1968; Sancho-Knapik et al., 2014, resp). The same situation was found in *P. abies* and *P. pungens* (Dixon et al., 1995 and Meidner and Mansfield, 1968, resp.). In *T. baccata* stomatal density is lower in park V than in other investigated parks, but similar with literature results (Stefanović, 2015).

Our results of pollen length of *P. abies* and *P. omorika* were slightly higher than those reported by Jia et al. (2014), but germination was significantly low, especially of *P. omorika* in park III (*Table 2*). In our previous investigations germination of *P.*

omorika pollen was 54-68% (max. 94%) (Batos and Nikolić, 2013). In case of *P. menziesii,* the average values of pollen size were similar to those reported in the literature (Ho, 1968). The air pollution changed the properties of leaves and pollen grains through chemical changes. An increased content of lead in the air influenced lower pollen germination and pollen tube growth in *Pinus strobus* and *P. resinosa* (Cox, 1988). In case of *Abies alba,* contaminated pollen decreased vitality and germination up to 50%, which depended on genotype-specific response to air pollution (Kormuťák, 1996 and refs. cited therein). The same situation is found in our results of *A. alba* (*Table 2*), where decreased germinability and length of pollen tubes was also up to 60% and 50 μm, respectively. Furthermore, in some species (*P. omorika, P. nigra*, etc.) we found some abnormalities in dimensions, shape and vitality of pollen grains, which occurred slightly more frequently in more heavily contaminated parks (case of *C. atlantica*, *P. omorika*, etc., *Table 2, Figs. 5* and *6*).

We have to underline that presented results of morpho-anatomical and pollen propertiesof conifers in urban area have never been explored so detailed in the past.

Conclusions

Based on the presented results of morpho-anatomical and morpho-physiological characteristics of conifer needles and pollen, respectively, it can be concluded that the consequences of air pollution are more apparent in case of pollen. In city parks with heavy traffic (V, IV, III), pollen grains of trees were smaller and less vital. Very often results were in correlation with distance of trees from traffic. Some of examined conifer species are especially sensitive to air pollution caused by vehicles (*Picea omorika, Cedrus atlantica, Taxus baccata, Pinus nigra*), especially in pollen properties. The level of air contamination, as well as other atmospheric conditions (temperature, humidity, wind direction and strength, etc.) could vary among different years, too. All the above factors and their influence on growth, development and blooming of trees, should be taken into consideration in landscape architecture and horticulture works in future.

Abstract. A distributed hydrological model (SWAT), which is widely used both domestically and internationally, was selected to quantitatively analyze the impact of land use and climate change on runoff in this paper in Dawen River Basin, China. The calibration and validation results obtained at Daicunba and Laiwu hydrological stations yield R^2 values of 0.83 and 0.80 and 0.73 and 0.69 and the Ens values of 0.79 and 0.76 and 0.71 and 0.72, respectively. Taking 1980-1990 as the reference period, the annual runoff increased by 288 million m^3, which was caused by changes in the land use of basin from 1991 to 2004, whereas the annual runoff decreased by 132 million m^3 due to climate change. Land use changed from 2005 to 2015, which resulted in an increase in annual runoff of 13 million m^3, and annual changes in climate caused a decrease in annual runoff of 61 million m^3. An extreme land use scenario simulation analysis shows that, compared to the current land use simulation in 2000, the runoff of cultivated land scenarios and forest land scenarios was reduced by 38.3% and 19.8%, respectively, and the runoff of grassland scenarios increased by 4.3%. Climate change simulation analysis revealed that there was a positive correlation between runoff changes and precipitation changes in the river basin. The annual total runoff in the basin decreases with rising temperatures and decreases with decreasing temperatures, which showed that the impact of precipitation variability was stronger than that of change in air temperature.
Keywords: *SWAT model; arbitrary scenario method; calibration and validation; runoff simulation*

Introduction

Climate and land use are two important factors that influence the hydrological responses of a river. Climate variability can impact flow routing time, peak-flows and volume by affecting the amount and distribution of regional precipitation and temperature (Sahoo et al., 2018; Kalogeropoulos and Chalkias, 2013; Zuo et al., 2015a), whereas land-use changes can cause changes in baseflow, annual mean discharge, and flood frequency and severity (Lin et al., 2015; Anand et al., 2018; Memarian et al., 2014). In the context of climate change, drastic human activities have a great influence on watershed hydrology. Among these activities, land-use change is the most direct manifestation of human impact (Zou et al., 2018; Zeng et al., 2015). The impact of climate change on hydrology has become more and more serious in recent years, including quantity, quality, spatial and temporal distribution of water resources, and the degree of development and utilization of water resources. The impact of climate change on water resources has been the focus of a significant amount of current research (Sunde et al., 2018). The distributed hydrological model not only considers spacial heterogeneity but also has the advantage of portraying hydrological and physical processes (Uniyal et al., 2015; Zhang et al., 2018). In recent years, distributed hydrological models have been widely used to evaluate the hydrological effects of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28492863

climate and land use changes. In many distributed hydrological models, the SWAT (Soil and Water Assessment Tool) model has been widely used in the simulation of basin water balance, long-term surface runoff and daily average runoff (Gyamfi et al., 2016). A large number of domestic studies have adopted models to simulate the effects of climate and land-use changes on the hydrological cycle of a river basin; in particular, these models have provided a basis for large-scale complex basin applications (e.g., the Haihe River Basin (Zhang and Chen, 2009), Yellow River Basin (Wang and Zheng, 2014), and Huaihe River Basin (Yang and Chen, 2017).

International research on climate change in the hydrological field began in the 1970s (Bull and Schick, 1979; Ruddiman et al., 1977; Lettenmaier and Burges, 1978), and studies on the impact of climate change on the water cycle began in the late 1980s in China (Wu et al., 2016; Lin et al., 2015; Zeng et al., 2013; Zhang and Yang, 2014). Based on global meteorological data from 1900 to 1998 and using RS and GIS technologies, Sanjay K. Jain conducted a simulation study on the effects of land-use/cover changes on the process of runoff and sediment production in the Satluj Watershed in the Himalayas (Jain et al., 2010). Prokop found that land-use change was an important factor of hydrological changes in the Himalayas from 1930 to 2010 (Prokop and Sarkar, 2012). Wei Chao quantitatively studied the dynamic change of land use in Taian based on RS technology (Wei et al., 2016). In this paper, the SWAT model is used to simulate runoff in Dawen River Basin. Through the simulation of watershed runoff in a changing environment, the tendency and rules of runoff under the background of climate change and land use are discussed, and the impacts of climate change and land use change on water resources in the river basin can be assessed. The results of the research provide effective means for the simulation, evaluation and analysis of water resources in the basin and the optimal allocation of water resources, which is of great significance for regional economic development and sustainable development.

Materials and methods

Study area

The Dawen River is located between 35°37′30″-36°32′30″N and 116°11′15″-118°0′0″E in Shandong Province, China. The Dawen River flows from east to west and passes along Laiwu, Taian, Pingyin, and Wuyuan. The northern part of Dawen River Basin is mainly constrained by the Taishan Mountain Range and the Xiaoqing River; the eastern part is bounded by Lushan; the south is bordered by Mengshan, Yumai and Huaihe River basins; and the west is bordered by the Yellow River Basin. The east-west distance of the Dawen River Basin is approximately 176.6 km; the north-south distance is approximately 102 km; and the basin area is approximately 8726 km^2 (*Fig. 1*).

The SWAT hydrologic model

The SWAT model is a basin-scale model that was developed by the Agricultural Research Service (ARS) of the United States Department of Agriculture (USDA). It is mainly used for the simulation of water quantity and quality of surface water and groundwater (Kiniry et al., 2005). This model has been widely used in different regions around the world and mainly used for the direct evaluation of the effects of human

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28492863

activities, climate variability or other factors related to large-scale precipitation (Wang et al., 2015).

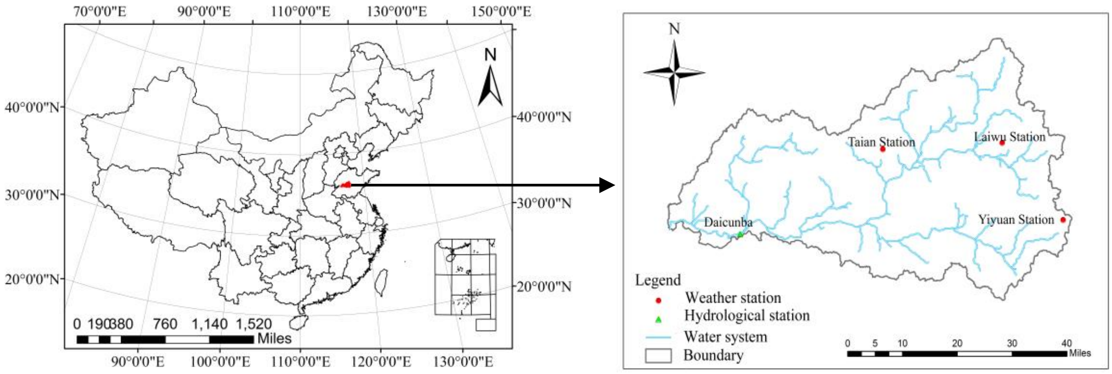

Figure 1. *Dawen River Basin location map*

The SWAT model partitions a watershed into sub-basins connected by a stream network and further delineates hydrologic response units (HRUs). By using data such as precipitation, soil properties, topography, land cover, and management, the surface runoff generated from each HRU can be calculated in each sub-watershed. The hydrologic cycle, as simulated by SWAT, is based on the water balance equation (*Eq. 1*), and the simulated processes include vadose zone processes and groundwater flow (Zhang et al., 2017).

$$SW_t = SW_o + \sum_{i=1}^{t} (R_{day} - Q_{surf} - E_a - W_{seep} - Q_{gw})_i \quad \text{(Eq.1)}$$

where SW_t is the final soil water content, SW_0 is the initial soil water content, t (days) is the time, R_{day} is the precipitation on day i, Q_{surf} is the surface runoff on day i, E_a is the evapotranspiration on day i, W_{seep} is the amount of water entering the vadose zone from the soil profile on day i (soil interflow), and Q_{gw} is the amount of return flow on day i.

The hydrologic model of the Dawen River Basin

SWAT model and database establishment

The topographic, soil, land use and hydro-meteorological data were collected or generated as follows (*Table 1*). The 90*90 DEM downloaded data is geometrically corrected by using a binomial formula. The error must be less than 0.5 pixel units to meet the requirements of the model river network division and sub-basin extraction. The soil data were sourced from the soil database of the Harmonized World Soil Database (HWSD) and the HWSD by using the USDA standard. The soil data was corrected and interpreted by ENVI 5.1. The land use map obtained by processing the classification is converted into a land use type map in a format supported by the SWAT model, get the land use map of the study area in 1985 and 2000 and 2015 (*Fig. 2*). This study used the weather observation data of three traditional meteorological stations from 1980 to 2015 (the Taian, Yiyuan and Laiwu stations).

SWAT calibration and validation

Based on the land use data and meteorological data in 2000 and the meteorological data from 1980 to 2015, the global sensitivity analysis module in SWAT-CUP was used to analyze the sensitivity of the parameters. The value of T provides the degree of sensitivity; the greater the absolute value is, the more sensitive it is. The P value indicates that the closer the significance value of sensitivity is to 0, the more significant it is. Based on the measured data of the hydrological station, the sensitivity analysis of the parameters was performed, and parameters with strong sensitivity were selected to adjust the parameters. By using the official SWAT-CUP software, the parameters were adjusted (Khalid et al., 2018; Zhang et al., 2013). The SUFI-2 algorithm was used to determine the optimal value of the parameters by iteration (Zhang et al., 2013), and the best values of the parameters were introduced to the model through the internal tuning parameters of SWAT modelfor simulation verification. In this paper, the effective evaluation method defined by Karuse (Krause et al., 2005) is used to applicability of the simulated value of the SWAT model in Dawen River Basin was evaluated by using two indicators of correlation coefficient (R^2) and Nash-Sutcliffe efficiency coefficient (Ens). Scenarios were established to quantitatively analyze the impact of both of these indicators on river basin runoff and to separately analyze the impact of single land use type and different climate change scenarios on the runoff of the river basin. This provided an important scientific basis for water resource management and land-use planning under the influence of climate change and human activities. Relevant studies have suggested that simulations have significant effects when $R^2 > 0.6$ and Ens > 0.5 (Zuo et al., 2015b; Lotz et al., 2017).

Scenario development and model analysis

After verifying the accuracy of the model simulations, the response of the Dawen River basin to land use and climate change was analyzed by establishing five scenarios. The specific settings of these scenarios were presented in *Table 2*. In the simulation process, the parameters of the vegetation module and the soil hydraulic parameters were changed accordingly: Scenario 1 was used as the base period and compared to scenarios 4 and 5 to obtain the impact of both land use and climate change on production flows. Scenarios 2 and 3 were compared with scenario 1, and the impact of climate change on production flow was obtained. Then, scenarios 4 and 5 were compared with scenarios 2 and 3, respectively, to obtain the impact of land-use change on production flow during the corresponding period. Finally, the impact of land use and climate change at different periods on the runoff of the entire river basin were quantitatively analyzed.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28492863

Table 2. *Model simulation scenario settings*

Scenarios	Land use	Climate data
1	1985	1980-1990
2	1985	1991-2004
3	1985	2005-2015
4	2000	1991-2004
5	2015	2005-2015

Based on the land use data in 2000, all of the land use types in the basin were set to farmland, forest land and grassland scenarios, and the corresponding soil hydrological parameters and vegetation module parameters were changed. The annual runoff under different land use scenarios was simulated from 2000 to 2015.

Based on a hypothetical climate plan (Yao et al., 2017), land use in 2000 and the possible scope of climate change, the values of the precipitation and temperature changes were obtained by using any scenario approach, and under the conditions of constant temperature and precipitation, the temperature increased by 1 °C and 2 °C, and decreased by 1 °C and 2 °C, respectively, the precipitation changes increased by 10% and 20% and decreased by 10% and 20%, respectively. 25 climate change scenarios were established. The response of runoff to climate variability was simulated through different climate variability schemes. The annual change in runoff b is solved as follows (*Eq. 2*):

$$b = (y_i - y_0) / y_0 \times 100\% \quad \text{(Eq.2)}$$

where y_i is the average annual runoff under the i climate scenario (m^3/s); and y_0 is the annual average runoff under a real scenario (m^3/s).

Results and analysis

Correction and verification results

According to the natural river network and topography of the basin, the study area was divided into 35 sub-basins, as shown in *Figure 3*. To obtain a reasonable resolution to assess soil properties, land uses, and management practices, the threshold values of land use, soil type and slope were chosen as 10%, 15% and 10%, respectively. These sub-basins were then further divided into 326 HRUs.

Through analysis, the first six sensitivity parameters were selected to adjust the parameters (*Table 3*). At the calibration period (*Table 4; Figs. 4, 5* and *6*), the simulated peak values in the flood season were lower than the measured values in 1999 and 2002, and higher than the measured values in 2000, 2005, and 2007; the R^2 and Ens values in Daicunba were 0.83 and 0.79, respectively. The simulated peak values in the flood season were lower than the measured values in 1985 and 1991, and higher than the measured values in 1982, 1987, 1988, and 1992; the R^2 and Ens values in Laiwu station were 0.73 and 0.71, respectively. The runoff simulation values of the two stations during the correction period have high precision.

Period	Site	R^2	Ens
Regular rate	Daicunba	0.83	0.79
	Laiwu Station	0.73	0.71
Verification period	Daicunba	0.80	0.76
	Laiwu Station	0.69	0.72

During the verification period (*Table 4; Figs. 4, 5* and *6*), the simulated peak value in the flood season was lower than the measured value in 2013, and higher than the measured values in 2009, 2012 and 2015; the R^2 and Ens values in Daicunba were 0.80 and 0.76, respectively. The simulated peak values in the flood season were lower than the measured values in 1999, and higher than the measured values in 1996 and 2001; the R^2 and Ens values in Laiwu Station were 0.69 and 0.72, respectively. The accuracy of the runoff simulation values at the two stations during the verification period is thus adequate.

For the determination and verification of monthly runoff, the deterministics coefficient of the measured and simulated values of runoff are $R^2 > 0.6$ and Ens > 0.6. This shows that the measured values of runoff are in good agreement with the simulated values and that the SWAT model has good applicability in the study area.

Simulation scenarios

Responses of streamflow to different land use scenarios

To understand the impact of land-use changes on streamflow in this basin, the calibrated SWAT model was run under scenarios S1 S4 and S5. The percentages of land-use change rates and the changes in land use area in kilometers under these three scenarios are shown in *Figure 7* and *Table 5*. In scenario S1, the status of land use in Dawen River was mainly meadow (27.69%), forest land (19.07%), cultivated land (28.18%), and building land (12.17%). Compared to scenario S1, the area of forest land increased by 23.66%, the area of building land increased by 11.08%, and the area of cultivated land and unused land decreased by 24.38% and 6.93%, respectively, in scenario S4. Compared to scenario S4, the area of forest land decreased by 27.66% and that of unused land decreased by 3.57%, the area of the meadow increased by 10.64%, and the area of building land increased by 17.27% in scenario S5. From 1985 to 2015, the meadow area increased by 17.85% and the cultivated land area decreased by 18.3%. The water area did not change much.

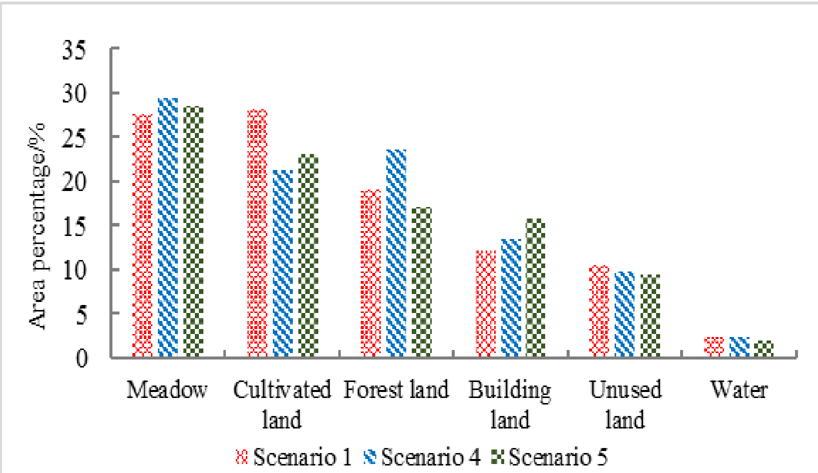

***Figure 7.** Percentages of land uses under three scenarios*

***Table 5.** Proportion of land use in the Dawen River Basin in 1985, 2000 and 2015*

Year	Meadow (%)	Cultivated land (%)	Forest land (%)	Building land (%)	Unused land (%)	Water (%)
1985	27.69	28.18	19.07	12.17	10.56	2.33
2000	29.49	21.31	23.59	13.51	9.83	2.27
2015	28.51	23.02	17.06	15.85	9.48	1.96

Based on the situational settings, a quantitative study was conducted on the runoff response to land use and climate change in Dawen River Basin (*Table 6*). The results

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28492863

show that the average annual runoff values in scenarios 1, 2, 3, 4 and 5 are 9.21, 7.89, 7.28, 8.17, and 7.41 million m^3, respectively. Scenarios 2 and 3 are compared to Scenario 1. Climate change caused an annual average runoff reduction of 1.32 and 0.61 million m^3. The comparison between Scenario 2 and Scenario 4 results in an increase of 28 million m^3 in average annual runoff due to the change in land use. The comparison between Scenario 3 and Scenario 5 results in an increase of 13 million m^3 in average annual runoff due to land use change.

Table 6. *Simulation results of land use and climate change impact on runoff in the Dawen River Basin*

Scenario	Annual precipitation (mm)	Annual average temperature (°C)	Average annual flow (10^9m^3)	Impact of land use change on runoff (10^9m^3)	Impact of climate change on runoff (10^9m^3)
1	-	-	9.21	-	-
2	755.7	13.4	7.89	-	-1.32
3			7.28	-	-0.61
4	-	-	8.17	0.28	-
5	-	-	7.41	0.13	-

Annual average runoff changes under different extreme land use scenarios

The runoff variation under three different extreme scenarios was compared to simulated runoff under the land use scenario in 2000 (*Fig. 8*). The runoff in the cultivated land scenario decreased by 38.3%, and the runoff decreased by 19.8% in the forest land scenario. However, the runoff increased by 4.3% in the grassland scenario. These results show that grassland can increase the runoff and water supply in the basin to conserve water resources. The increase in cultivated land will lead to a large reduction in runoff. Because cultivated land has the effect of inhibiting the increase of runoff, human activities have a greater impact on hydrology.

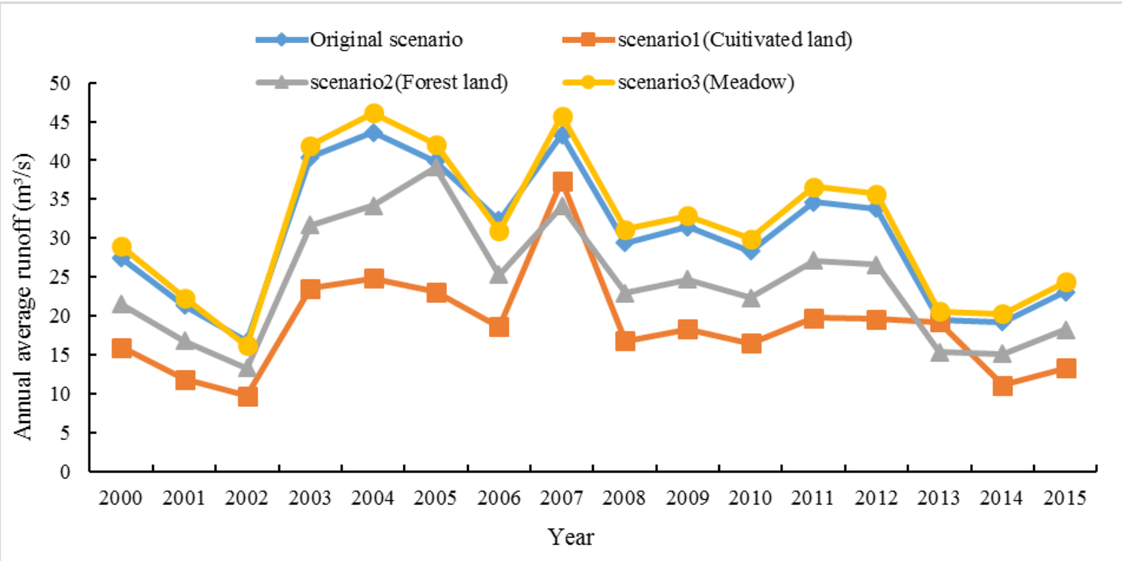

Figure 8. *Simulated runoff changes in extreme land use scenarios*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28492863

Influence of temperature and rainfall on average runoff in the basin

It can be seen from the annual average temperature and precipitation cumulative anomaly curve in the Dawen River Basin (*Fig. 9*). From 1990 to 1995, the temperature accumulation anomaly curve showed a downward trend, which was a period of low temperature. From 1995 to 2009, the temperature accumulation anomaly curve showed an upward trend, which was a period of higher temperature. Then, the temperature accumulation anomaly curve began to rise after a short decline until 2015, and the overall situation was relatively stable. The average temperature over 26 years is approximately 13.4 °C and is growing at a speed of 0.47 °C/10a. The cumulative anomaly curve of precipitation in the Dawen River Basin from 1990 to 1998 showed a downward trend, which was a period of low rainfall. The cumulative anomaly curve of precipitation in 1998-2002 experienced a short stage of rising and falling, and the overall situation was relatively stable. From 2002 to 2015, the cumulative anomaly curve of precipitation showed an upward trend, which was a rainy period. According to this analysis, the average precipitation in Dawen River Basin during the past 26 years is 755.7 mm, and the annual average precipitation has decreased overall. The reduction rate is approximately 54.9 mm/10a.

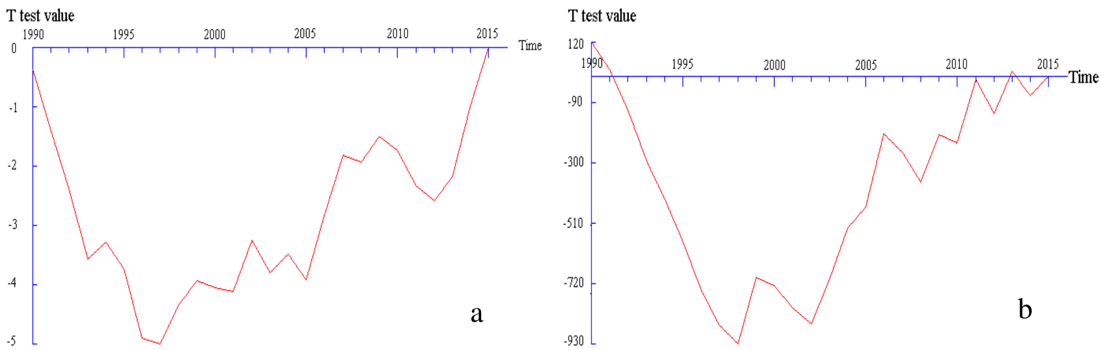

Figure 9. *Cumulative anomaly curve. a: Temperature; b: Precipitation*

It can be seen from *Figure 10* and *Table 7* that the multi-year average runoff variation in Dawen River Basin is mainly related to rainfall and temperature in the basin. First, the annual total runoff of the basin decreases with increasing temperature and decreases with decreasing temperature. The annual runoff decreased by 4.1% when the temperature increased by every 1 °C; the annual runoff decreased by approximately 3.0% when the temperature decreased every by 1 °C. This indicates that temperature is one of the main sensitive factors affecting runoff in the basin. Second, there is a positive correlation between rainfall and annual runoff in the basin. The annual runoff of the basin increases with the increase in annual rainfall, and the increase in runoff is greater than the increase in rainfall. When the annual rainfall in the basin increases by every 10%, the annual total runoff increases by approximately 18.3%. The average annual runoff of the basin decreases with the decrease of precipitation, but its reduction of rainfall is smaller than its increase of rainfall. When the annual rainfall decreases by every 10%, the annual average runoff decreases by 15.1%. Precipitation is an important factor affecting runoff in the basin. Compared to the change of temperature, the annual runoff of the basin is more affected by rainfall.

Conclusion

In this paper, the distributed hydrological model (SWAT) is applied to quantitatively simulate the impact of land use and climate change on water production in Dawen River Basin through multi-site calibration and verification. The results are shown as follows:

(1) The calibration and validation at two hydrological stations showed that the R^2 values were 0.83 and 0.80 and 0.73 and 0.69, and the Ens values were 0.79 and 0.76 and 0.71 and 0.72, respectively, which satisfied the SWAT model simulation accuracy evaluation criteria. Therefore, the SWAT model was suitable for this research basin. The parametric model can be applied directly to the actual situation in the basin.

(2) Land use and climate change in different periods have different effects on water yield in the basin. Scenarios 2 and 3 are compared to Scenario 1, indicating that climate change caused annual average runoff reductions of 1.32 and 0.61 billion m^3, respectively. The comparison between Scenario 2 and Scenario 4 results in an increase of 28 million m^3 in annual average runoff due to the change in land use. The comparison between Scenario 3 and 5 shows an increase of 13 million m^3 in average annual runoff due to land-use change.

(3) The simulation results of different land use types showed that the runoff in cultivated land decreased by 38.3%, the runoff in forest land decreased by 19.8%, and the runoff in grassland increased by 4.3%. Therefore, in the future watershed management process of Dawen River Basin, the type of land use will be adjusted to meet the water demand in the basin, increase the water output of the basin and ensure water use downstream of the basin.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28492863

(4) By analyzing the rate of runoff change in the basin under various climate scenarios, the annual total runoff in the basin decreases with the increase of temperature, and decreases with the decrease of temperature. The annual runoff increased with the increase of annual rainfall and the increase of runoff was greater than the increase of rainfall. The annual average runoff of the basin decreased with the decrease of precipitation, but its degree of decrease of rainfall was smaller than its degree of increase of rainfall.

(5) Runoff is not only affected by changes in land use but also by climate change. If the change in runoff is mainly caused by land use, the water resources planning and management policy can still be formulated based on current hydrology and meteorological data; If the main factor causing the change in runoff is climate change, then it is necessary to focus on the impact of future climate change on hydrology and water resources, and the research can also provide a reference for water resources planning management.

Acknowledgements. We express our sincere appreciation to the anonymous reviewers for their constructive suggestions. The work was supported by the special program for the National Natural Science Foundation of China (41471160). The authors would also to thank the reviewers for their very valuable comments, which greatly improved the quality of the paper.

Abstract. The NASA global inventory modeling and mapping studies released one year and a half month maximum synthetic of global dat, based on which the authors analyzed data originated from the Chinese meteorological data sharing service science and data pertaining to northwest air temperature and precipitation, climate, month and year value data sets, etc throughout the period of 1982 to 2013. The Normalized Difference Vegetation Index (NDVI) was analyzed in terms of vegetation spatial analysis, using linear regression analysis, standard deviation, the Hurst index, and the partial correlation analysis methods. The results showed that from 1982 to 2013, the overall NDVI in China, South Asia, and Southeast Asia had an increasing trend. During the 1990s, the vegetation volatility was higher in China, South Asia, and Southeast Asia. Additionally, in the three areas, the NDVI change increased dramatically after 2008, but subsequently decreased in 2010. From 1980 to 2013, the ecological environment of the eastern part of China, the northeast and the south, East Asia, Southeast Asia, India, Thailand, Bangladesh, and the eastern part of Pakistan are generally good. In Western and Northwest China and in other Southeast Asian countries, in South Pakistan, the South and back, the eastern, southern and southwestern parts, the state of the ecological environment are generally poor. From 1998 to 2005, in China, Southeast Asia, and South Asia, the NDVI is reduced. From 2006 to 2013, in China, Southeast Asia, South Asia, the NDVI increased significantly.

Introduction

Vegetation is connected to the atmosphere, water, and soil, comprising the core of the land surface in the earth's ecosystem. Since photosyntheses is related to the degree of vegetation coverage, changes in vegetation coverage exert a significant goal impact, as they influence the properties of the land surface, soil and water conservation, climate regulation, and overall stability of the ecosystem (Meyer et al., 1992; Sun et al., 1998).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28652879

Within the interaction between the earth spheres, the hydrological processes and the soil–vegetation–atmosphere interactions and on global and regional climate and ecosystem of their feedback is the most basic frontier issue (Cao et al., 2011; Chang et al., 2011). Therefore, climate and vegetation share an inseparable relation, manifested mainly in two aspects: vegetation adaptability to climate and vegetation feedback effect on climate (Fung et al., 2000; Chen et al., 2015). Changes in vegetation influence the properties of soil surface such as moisture, which in turn will affect regional climate (Justice et al., 1986; Zhang et al., 2003). On the other hand, climate changes affect vegetation's growth; thus, the climate is the main factor influencing the distribution of the biological community, and its changes alter the structure of vegetation communities, composition, and biomass, thus shaping the forest ecological system and simultaneously decreasing biological diversity (Zhang et al., 2001; Cui et al., 2009). The Normalized Difference Vegetation Index (NDVI) characterizes surface vegetation and is sensitive to measure vegetations' growth parameters, thus comprising an effective index for quantitative characterization of vegetation growth (Yang et al., 2004; Yaşar et al., 2018). As such, the NDVI has been widely used in several areas such as agriculture, ecology, and environment. Recently, the association between NDVI and climate response has been studied by researchers of different areas (Zhang et al., 2007; Mr et al., 2017).

President Xi Jinping brought up the “One Belt And One Road” to promote close cooperation among different countries, including hazard-prone areas, such as China, South Asia, and Southeast Asia where natural disasters occur most frequently. Investigating the ecological environment of these countries may improve the prevention of regional disasters and the capacity to mitigate their effects. Additionally, it may improve the accuracy of climate change research in other areas, thus promoting the “One Belt And One Road” for an improved cooperation between countries (Wagner et al., 2014; Lu et al., 2016).

Materials and Methods

Study Area

The geographical scope of this research (*Figure 1*), followed the “One Belt And One Road” strategy, including China's south and southeast bordering countries, as follows: South Asia, including Afghanistan, Bangladesh, Bhutan, India, Nepal, and Pakistan; and Southeast Asia area including Cambodia, Laos, Myanmar, Thailand, and Vietnam (Wang et al., 2008).

Data sources

The GIMMS NDVI3g dataset was downloaded from the NOAA-Advanced Very High Resolution Radiometer (AVHRR) for the period from 1982 to 2013. GIMMS NDVI3g (http:// data.cma.cn/) has a spatial resolution of 1/12° and a temporal resolution of 15 days (Fensholt and Proud, 2012; Guay et al., 2014). The GIMMS NDVI3g dataset has been optimized to minimize the effects of the differences in sensor design between the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28652879

AVHRR/2 and AVHRR/3 instruments as well as volcanic eruptions (Pinzon and Tucker, 2014; Liu et al., 2015a, b). To further eliminate the interference of factors such as atmosphere, clouds, and angle of the sun (Hou, 2001), the maximum synthesis MVC (maximum value composites) is used to obtain the monthly and annual NDVI values. The monthly NDVI is calculated according to the following formula:

$$MNDVI_i = Max(NDVI_1, NDVI_2) \quad \text{(Eq.1)}$$

In the formula: NDVI value of month i; i is the month number (i = 1, 2, 3 ... ... 12), - denotes the NDVI value of the first half month and the second half month, respectively. Using the same MVC method to obtain the maximum monthly NDVI as the annual NDVI value. The formula is

$$Y_{NDVI} = Max(MNDVI_1, MNDVI_2 \cdots, MNDVI_{12}) \quad \text{(Eq.2)}$$

In the formula: Y_{NDVI}--annual NDVI value; $MNDVI_1$, $MNDVI_2$…, $MNDVI_{12}$ --Monthly NDVI values for January–December.

The temperature and precipitation data in the study area are mainly from the website: (http://www.cru.uea.ac.uk/) A gridded time-series dataset. This version, released 18 November 2018, covers the period 1901-2017. Coverage: All land areas (excluding Antarctica) at 0.5° resolution.

DOI: http://dx.doi.org/10.15666/aeer/1702_28652879

Research methods

Linear regression analysis was performed for vegetation, precipitation, and air temperature, along the factor time (Liu et al., 2015). That is, the linear regression coefficient a of vegetation NDVI and climate factor y over time t, as shown in formula (3).

$$y = at + b, \qquad t = 1, 2, \cdots, n(n \le 25) \qquad \text{(Eq.3)}$$

Sen+Mann-Kendall: The trends of changes in the spatial characteristics of vegetation were analyzed using the Sen method and tested using the Mann–Kendall method. These methods can avoid loss of data, outliers' interference, and influence of the data distribution patterns on the analysis results (Liu et al., 2013). The Sen trend was calculated using data pertaining to the NDVI from 1982 to 2013, according to the following formula:

$$\rho = median\frac{(x_j - x_i)}{j - i}, \qquad 1 < \mathrm{i} < \mathrm{j} < \mathrm{n} \qquad \text{(Eq.4)}$$

where x_j, x_i -- time series data. $\rho < 0$ shows a downward trend, whereas the reverse shows an upward trend. The Mann-Kendall method was used to test whether the trend was significant.

The Mann-Kendall test (MK test) is one of the most commonly used time series trend test methods and does not require the sample to follow a certain distribution and is suitable for non-normally distributed data. The method is based in the following formulas:

$$Q = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} sign(x_j - x_i) \qquad \text{(Eq.5)}$$

$$sign(s) = \begin{cases} 1 & (s > 0) \\ 0 & (s = 0) \\ -1 & (s < 0) \end{cases} \qquad \text{(Eq.6)}$$

$$z = \begin{cases} \dfrac{Q-1}{\sqrt{V(Q)}} & (Q > 0) \\ 0 & (Q = 0) \\ \dfrac{Q+1}{\sqrt{V(Q)}} & (Q < 0) \end{cases} \qquad \text{(Eq.7)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28652879

where: Q - test statistic; Z - normalized test statistic; x_j, x_i - time series data; n - sample number; when $n \geq 8$, Q is approximately positive distribution, the mean and variance are calculated as follows:

$$E(Q) = 0 \qquad \text{(Eq.8)}$$

$$V(Q) = \frac{n(n-1)(2n-5)}{18} \qquad \text{(Eq.9)}$$

After standardization, Z is the standard distribution, if $|z| > z_{1-a/2}$, then it is significant trend change. $z_{1-a/2}$ is the corresponding value for the standard positive distribution table at the confidence level a. In this paper, the confidence level is 0.05, and the degree of freedom is 25- 2=23.

Standard Deviation Analysis: The standard deviation indicates the distance of the data variable from the mean, which reflects the discrete degree of a data set. The larger the value is, the farther the NDVI distance is, the greater the vegetation change (Liu et al., 2015). The formula as follow:

$$S_i = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(NDVI - \overline{NDVI}\right)^2} \qquad \text{(Eq.10)}$$

According to the standard deviation value of 5 grades of vegetation change intensity: High ($S_i \leq 2.00$), high ($2.00 \leq S_i < 4.00$), medium ($4.00 \leq S_i < 6.00$), lower ($6.00 \leq S_i < 8.00$), and low ($8.00 \leq S_i < 10.00$). The spatial characteristics of vegetation cover fluctuation in the region for many years.

Hurst index: Time series with long-term dependence in nature are ubiquitous. Hurst index is one of the effective methods to quantitatively describe the long-term dependency of time series information. The calculation principle is as follows:

For any positive integer $\tau \geq 1$, define the mean sequence $\{\xi(t)\}$

$$\langle \xi \rangle_\tau = \frac{1}{\tau}\sum_{t=1}^{\tau}\xi(t) \qquad \tau = 1, 2, \cdots, N \qquad \text{(Eq.11)}$$

Accumulation deviation:

$$X(t,\tau) = \sum_{u}^{t}(\xi(t) - \langle \xi \rangle_\tau), \qquad 1 \leq t \leq \tau \qquad \text{(Eq.12)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28652879

Very poor:

$$R(\tau) = \max_{1 \le t \le \tau} X(t, \tau) - \min_{1 \le t \le \tau} X(t, \tau), \qquad \tau = 1, 2, \cdots, \qquad \text{(Eq.13)}$$

Standard deviation:

$$S(\tau) = \left[\frac{1}{\tau} \sum_{t=1}^{\tau} (\xi(t) - \langle \xi \rangle_{\tau})^2 \right]^{\frac{1}{2}}, \qquad \tau = 1, 2, \cdots N, \qquad \text{(Eq.14)}$$

Consider the ratio R (τ)/S (τ). If there is R / S∝τH, then the time series {ξ (t)} exist Hurst phenomenon, H called Hurst index. In the double logarithmic coordinate system (lnτ, lnR / S) with the least squares fitting.

1) If 0.5 <H <1, it indicates that time series of NDVI as long-term positive correlation.
2) If H = 0.5, the time series of NDVI are independent random sequences.
3) If 0 < H < 0.5, the time series data of NDVI have anti-persistence, and the sequence has abrupt jump characteristics. H value closer to 0, the stronger the anti-persistence; closer to 1, the more positive continuity.

Results

Interannual change of NDVI in the area

Using the values of NDVI corresponding to the period between 1982 and 2013, analysis of regional mean annual variation characteristics, provided the annual NDVI variation characteristics graph below (*Figure 2*):

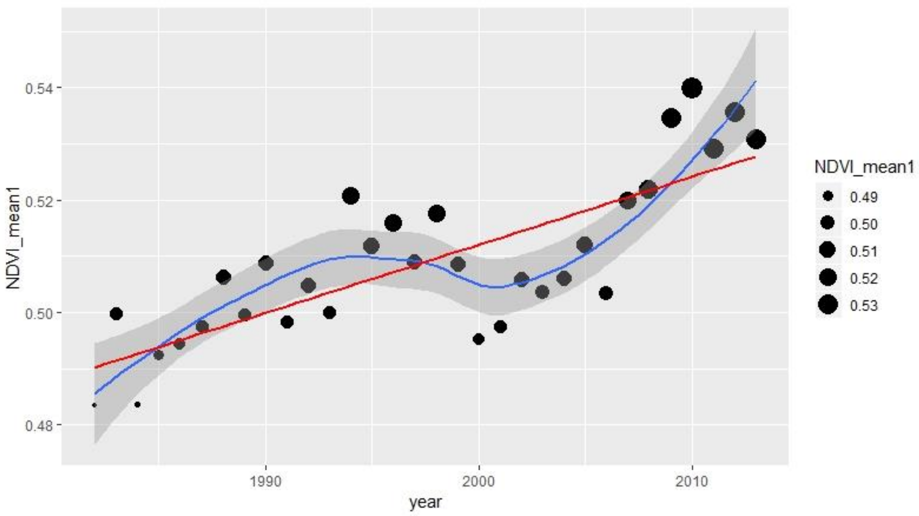

Figure 2. *Annual variation characteristics of NDVI from 1982 to 2013 in South Asia*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28652879

As can be seen from *Figure 2*, Between 1982 and 2013, the interannual variation of the average value of NDVI in South Asia shows an increasing trend. In the late 1990s, there was a small fluctuations, that is a downward trend. High values appeared in 1994 and low values appeared in 2000. After 2000, there was a tendency to resume growth.

From *Figure 3*, the interannual variation of the NDVI regional average in Southeast Asia is the same as that in South Asia. Among them, the growth trend appeared in the 1980s. Also fluctuating in the 1990s, during which low values occurred in 1993 and high values appeared in 1994. After 2000, there is a growing trend.

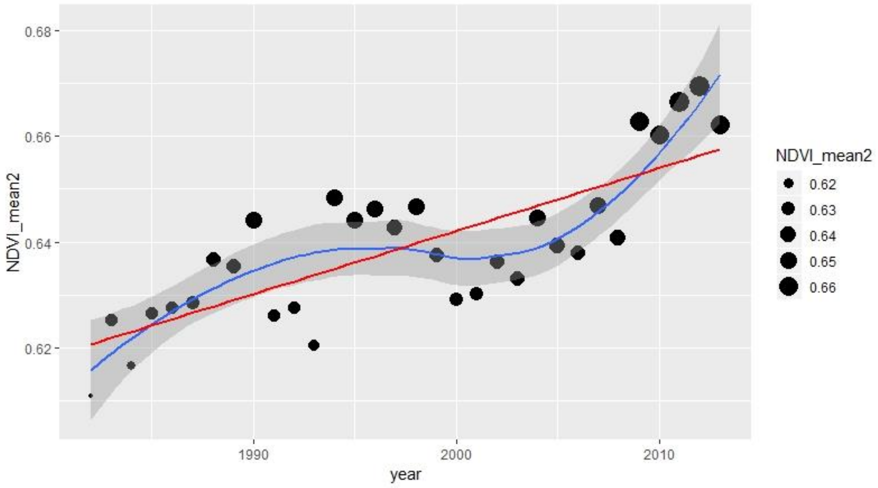

Figure 3. *Annual variation characteristics of NDVI from 1982 to 2013 in Southeast Asia*

From *Figure 4*, between 1982 and 2013, the interannual variability of China's NDVI regional average is the same as that of South Asia and Southeast Asia. It is a growth trend in the 1980s, and it has a downward trend in the 1990s, and then it has become a growth trend. The magnitude of the change is relatively large compared to other regions.

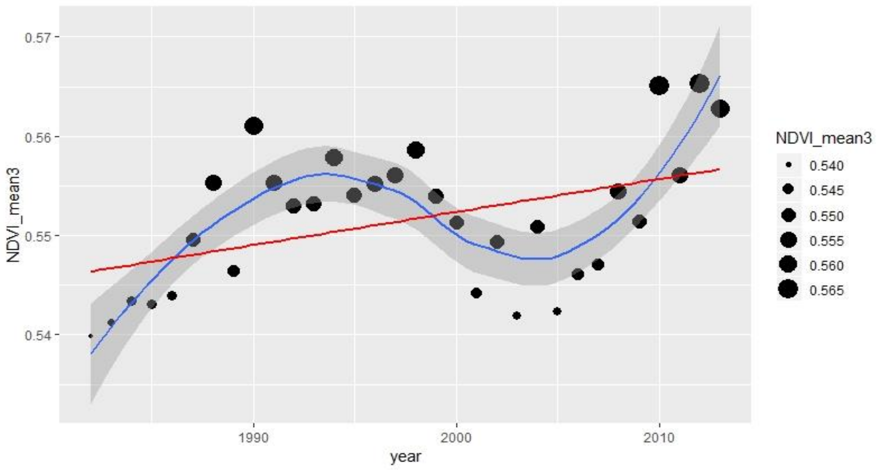

Figure 4. *Interannual variability of NDVI in China from 1982 to 2013*
(Remark: Annual average of the statistical study area)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28652879

Summary, the interannual variability of NDVI in these three regions is similar, showing a growing trend in the 1980s, a downward trend in the 1990s, and a growth trend in the 2000s. In the 1990s, the interannual variation of China's NDVI regional values fluctuated significantly. These are all in sync with regional social development. In the 1990s, all regions were developing, pursuing economic development and neglecting ecological environmental protection. After the 2000s, everyone realized the importance of the ecological environment, so that they pursued economic development while also paying attention to the protection of the ecological environment. Therefore, the regional average NDVI has shown an increasing trend since the 2000s. Due to the rapid development of China, the damage to the environment was so great that there was a large fluctuation in the 1990s.

Spatial distribution of SEN trend in the study area

In the present study, the SEN method was used to analyze the spatial trends of vegetation characteristics and to test them using the Mann-Kendall method, thus determining the trend of NDVI in China, South Asia, and Southeast Asia from 1982 to 2013 (*Figure 5*).

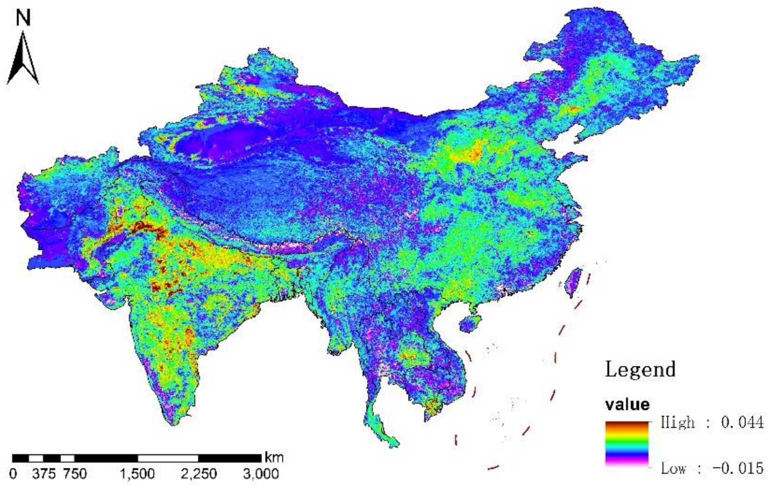

Figure 5. *Spatial distribution of SEN trend in the study area, 1982–2013*

As shown in the above picture, in China, Southeast Asian countries, and South Asian countries, most positive SEN values, indicating a good ecology. The SEN is high in the eastern, central and northeastern China and low in the west and northwest china. Most SEN values are low for Southeast Asia, Vietnam, Cambodia, and Laos and higher in eastern and southern Thailand and central Myanmar. In the South Asian countries of Bangladesh, India, eastern Pakistan, southeast and northeast, northern Afghanistan, eastern Nepal, and southern Bhutan, SEN values are high, with 0.044 being the the highest value observed.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28652879

Spatial distribution characteristics in different periods

The spatial trend of the NDVI in the four periods of 1982-1989, 1990-1997, 1998-2005, and 2006-2013 was analyzed using Hurst exponent and partial correlation analysis (*Figure 6*).

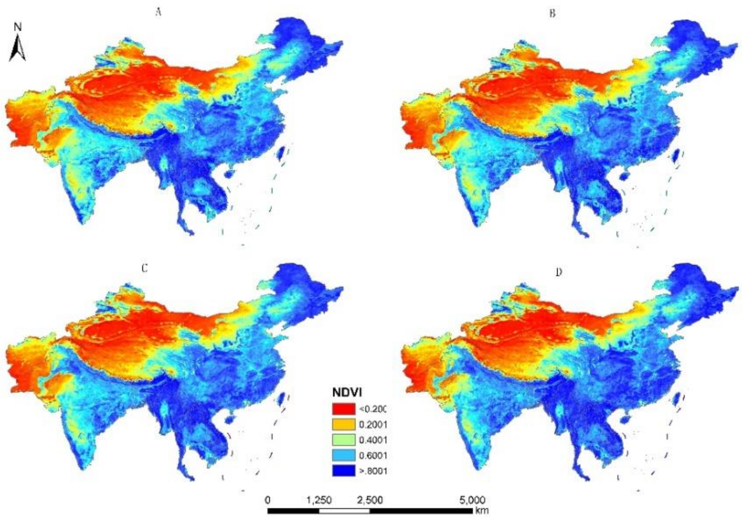

Figure 6. *Multi-year mean spatial distribution of the study area*

The NDVI of the eastern, southeastern and northeastern parts of China was above 0.6, whereas it was lower than 0.2 in the northwestern part of China, and higher than 0.6 in some parts of northern Xinjiang. In the Southeast Asian countries of Vietnam, Cambodia, Laos, Thailand, and Myanmar, as well as in South Asia; Nepal; Bangladesh; Bhutan; and central, eastern, and northern parts of India, the NDVI was higher than 0.6. With in South Afghanistan and Pakistan it was below 0.2, whereas in much of Afghanistan it was below 0.6.

In terms of spatial and temporal distribution, the NDVI decreased from 0.6001 to 0.8, especially in China and India. In Southeast Asia, Bhutan and Bhutan Bengal it remained unchanged. In the four studied time periods, the largest NDVI changes occurred from 2006 to 2013.

Overall, the NDVI values were mainly distributed over Southeast Asia, eastern and northeastern China, with the lowest values concentrated mainly in western South Asia and the Qinghai-Tibet Plateau of China. The spatial distribution of vegetation cover was related to its topographic distribution with a relatively high NDVI near the coast.

Spatial variability of vegetation cover change in the study area

The variation of vegetation coverage in the study area was calculated through the coefficient of variation, whereupon the interannual variability of vegetation coverage increased with an increasing coefficient of variation. For example, in the west and northwest of the study area, the topography is relatively high, as is the coefficient of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28652879

variation. In the Indian Peninsula, Southeast Asia and The coefficient of variation in China's coastal areas is low. The spatial distribution of NDVI is also similar to that of the study area. The interannual variation range of NDVI is low, whereas its overall range is relatively high. Overall, the interannual variability of vegetation cover over the past 32 years was relatively low, which indicated a stable ecological change of vegetation within the study area (*Figure 7*).

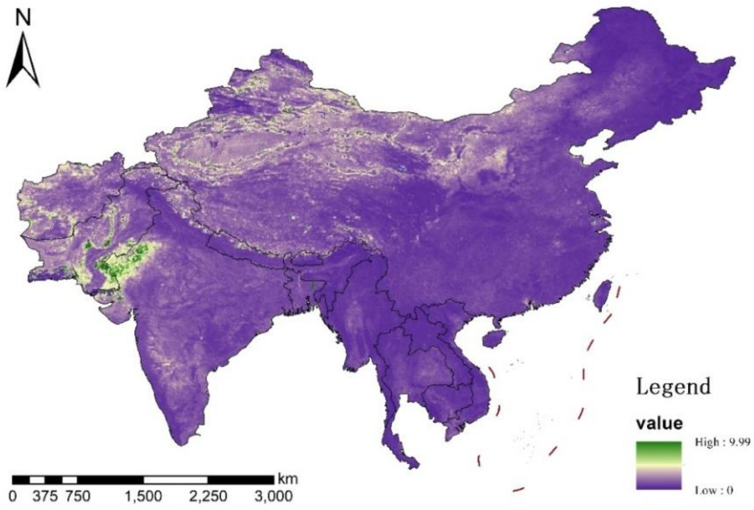

Figure 7. *1982-2013 Spatial distribution of NDVI variation coefficient in the study area*

HURST index space characteristics of sustainable change

The spatial change characteristics of vegetation coverage in the study area from 1982 to 2013 were calculated on the basis of the HURST index (*Figure 8*).

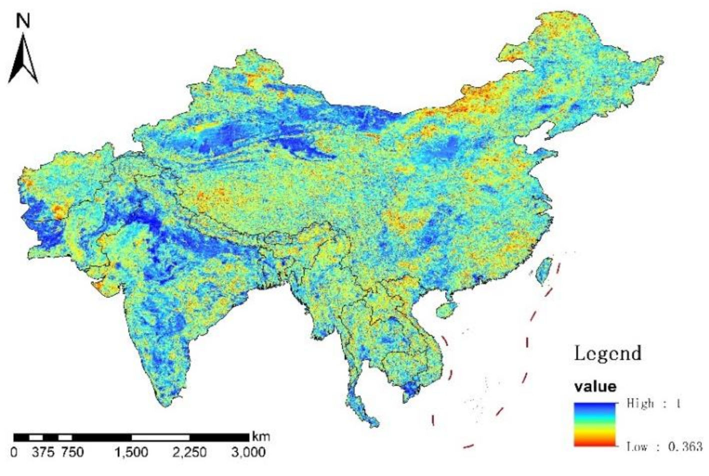

Figure 8. *1982–2013 The HURST spatial distribution in the study area*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28652879

Regarding the spatial distribution of the HURST index, most values within the study area ranged between 0.3 and 1, with most areas exhibiting a value higher than 0.5. Most regions corresponded to northwestern China and parts of the Indian Peninsula in South Asia. Overall, the main trend of vegetation cover change in this region was a normal trend, showing that the ecological vegetation coverage in the study area improved over 32 years, further indicating an improvement of the region's ecological environment.

Spatial distribution characteristics of vegetation cover change and climate response

In the present study, the correlation between vegetation cover and precipitation within the study area was analyzed, and we concluded (*Figure 9*) that in most areas the vegetation cover was obviously correlated with precipitation, especially in South Asia and Inner Mongolia, in northern China. Only a few regions exhibited negative correlations, which were not obvious. It may therefore be concluded that the changes in vegetation cover within the research area and over the past 32 years are strongly influenced by precipitation.

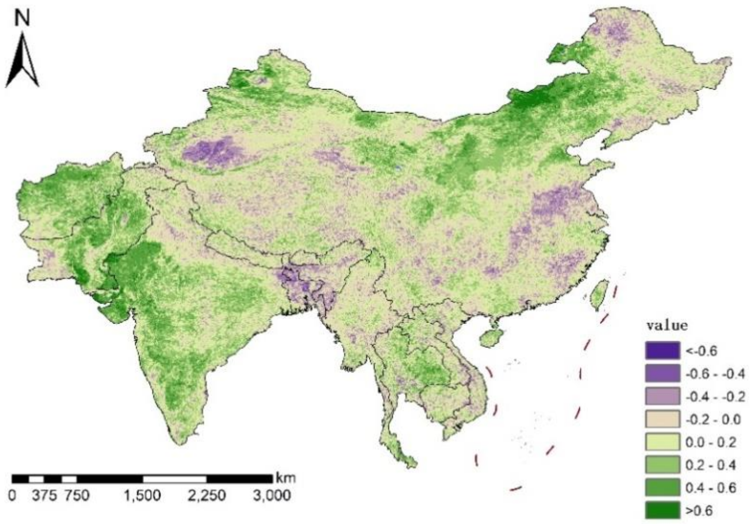

Figure 9. *1982-2013 Partial correlation NDVI and precipitation apace distribution in study area*

Moreover, as can be observed from *Figure 10*, in most areas, the response in vegetation cover changes has a positive correlation with temperature, with only a few areas showing a negative correlation, thus showing vegetation cover changes are affected by temperature.

In summary, the influence of temperature and precipitation is positively correlated with the changes of the vegetation cover, and the area of NDVI and precipitation correlation coefficient in the study area is northeast China, eastern Thailand and Central and northwest of South Asia. The correlation coefficient between NDVI and temperature is in the central, eastern, and southern parts of China; southern Vietnam; eastern Thailand;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28652879

central Burma; and Central Asia. Therefore, it is concluded that vegetation growth is closely related to precipitation and temperature.

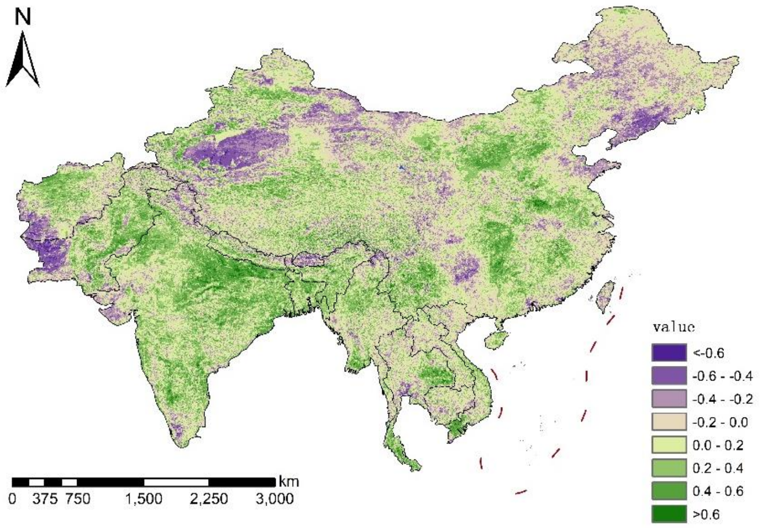

Figure 10. *1982-2013 Partial correlation NDVI and temperature apace distribution in study area*

Discussion

The present study monitored vegetation growth in three regions of China, South Asia, and Southeast Asia by analyzing data pertaining to NDVI time series (Liu et al., 2015a). Additionally, the growth status of agricultural vegetation within the study area was monitored (Zhang et al., 2013b). The results show that large-scale agricultural vegetation monitoring can be carried out by satellite remote sensing. However, due to the constraints of NDVI data resolution and the complexity of vegetation changes, several problems remain to be clarified (Zhang et al., 2013a):

1) The GIMMS-NDVI data resolution is 8 km × 8 km, and the relationship between the agricultural vegetation-climate in China-South Asia and South-East Asia cannot be fully reflected, and the study area should be more refined by using more high-resolution NDVI datasets and data from different sources.
2) Factors affecting agricultural vegetation cover include, in addition to rainfall, temperature and topography, hydrology, and soil and insect infestation, which should be taken into account in subsequent studies.
3) This paper studies changes in climate and agricultural vegetation coverage, without considering the influence of human activities. Human activities include the expansion of urbanization, agricultural modernization management, and ecological environment construction.
4) By studying the NDVI vegetation coverage, this paper studies the agricultural vegetation coverage in the study area, and does not consider the influence of other kinds of vegetation coverage on the study of agricultural vegetation coverage.

Conclusions

On the basis of the analysis of the temporal and spatial NDVI trends in different climatic regions and some countries in China, South Asia, and Southeast Asia from 1982 to 2013, the following conclusions are taken:

1) Between 1982 and 2013, the average annual NDVI trends in China, South Asia, and Southeast Asia increased. Although the increase was relatively small in South Asia, it was higher in Southeast Asia and China. After the 1990s, the NDVI vegetation changes in China, South Asia, and Southeast Asia were fluctuant. After 2008, the NDVI of the three regions all increased significantly, subsequently declining by 2010.
2) The ecological environment of eastern, northeastern, and southern China; eastern Thailand; South Asia; India; Bangladesh; and eastern Pakistan was generally good in 1980 to 2013. The western and northwestern parts of the country, other countries in Southeast Asia, western Pakistan, south, back, eastern Afghanistan, south and southwest of Pakistan are generally poor in terms of ecological environment.
3) From 1998 to 2005, NDVI vegetation indices in China, Southeast Asia, and South Asia decreased, subsequently increasing over 2006 and 2013.
4) During nearly 32 years of study within the area, the interannual vegetation amplitude is small, with a relatively stable vegetation coverage, where only a few areas larger fluctuation.
5) According to the HURST index calculation, most the study area in most of the vegetation coverage were positively state change trend, a handful of areas reverse the trend.

Comprehensive above, study nearly 32 years of vegetation changes gradually in the study area, the ecological environment is improved, a further sign of the government and people pay more and more attention to ecological environment construction, so that the ecological vegetation restoration is more obvious.

Funding. This research was funded by “Management Science and Engineering” construction funding for key disciplines in Guangxi, Karst land use change ecological effect side evaluation ecological security research (GK2015010), and the perspective of rural revitalization of natural resources accounting and ecological security research in Northwest Guangxi (2018QNB13).

(Received 31st Oct 2018; accepted 28th Jan 2019)

Abstract. A total of 30 samples were collected from surface sediments of Xuwei-Liezikou offshore area, northern Jiangsu Province, China, and the concentrations of 7 heavy metals including As, Hg, Cu, Pb, Zn, Cr and Cd and their spatial distributions were determined. Geo-accumulation index (I_{geo}), pollution load index (*PLI*) and potential ecological risk index were applied to evaluate the pollution status. The mean concentrations of Cd, Pb, As, Zn, Cu and Hg were 2.62, 1.96, 1.70, 1.42, 1.32 and 1.30 times of their respective background values, which indicated there were obvious accumulations of these heavy metals in surface sediments. It was observed that the high heavy metal concentrations were in the western and northern regions of the study area except for Cu, mainly located in estuary and port regions. The sediments in the entire study area were moderately polluted, and the main pollution factors were Cd and Pb. The study area suffered from a level between low and moderate ecological risks, and Cd was at the considerable ecological risk level, Hg was a moderate ecological risk, while other metals had low ecological risk level.
Keywords: *heavy metal concentration, spatial distribution, contamination assessment, ecological risk, northern Jiangsu Province*

Introduction

The heavy metal pollution in marine environment has received much attention, becoming a global environmental issue, because of their toxicity, wide sources, persistence, ecological risk, and the non-biodegradable nature of the contamination (Irabien and Velasco, 1999; Burger and Gochfeld, 2003; Hu et al., 2011; Waheed et al., 2013; Bastami et al., 2015; Harikrishnan et al., 2017). As we all know, sediments contain and accumulate a large number of heavy metal elements (Gao et al., 2015; Fang et al., 2016; Zhang et al., 2017). The sediments are not only a 'sink' of heavy metals but also a 'source' (Matthiessen and Law, 2002; Hill et al., 2013; Machado et al., 2016; Chen et al., 2017). On the one hand, heavy metal elements enter the water through various ways, these elements enter the water where they are subsequently adsorbed by suspended substances and settle on the sea floor. On the other hand, when some physical and chemical properties of the water change, the heavy metal elements in sediments would be released and thereafter cause pollution to the water. Therefore, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28812892

analysis of heavy metals in sediments is necessary to our understanding and protection of the marine environment.

Xuwei-Liezikou offshore area is located in the southern part of Lianyungang city in the northern Jiangsu Province of China and is an important part of Lianyungang Port. Because of its superior geographical position, excellent port resources and rich fishery resources, the study area has become a major gathering place for mariculture, port development and coastal industry. The development of ports and a large number of land-based pollutants entering the sea are bound to exert great pressure on the marine environment (Nethaji et al., 2017; Jahan and Strezov, 2018). The evaluations of heavy metal in sediments form Lianyungang offshore area have been investigated (Zhang et al., 2013; Li and Li, 2016; Zhang et al., 2016). However, previous studies mainly focused on the study of heavy metals in columnar sediments form the northern Lianyungang offshore area (e.g. Haizhou bay), and few reports have evaluated heavy metal contents and pollution in surface sediments form the southern Lianyungang offshore area. Therefore, this study evaluates the concentration and pollution level of heavy metals (As, Hg, Cu, Pb, Zn, Cd and Cr) in surface sediments of Xuwei-Liezikou offshore area in northern Jiangsu Province, which is a supplement to the study on heavy metals of Jiangsu Province and provides reference data for controlling heavy metal pollution in the marine environment.

Materials and methods

Study area

Xuwei-Liezikou offshore area is located in the south wing of Lianyungang Port in Jiangsu Province of China, bordered by the Yellow Sea in the east, the Yangtze River Delta Economic Belt in the south, and the Bohai Economic Circle in the north. Its estuaries include the Xishu River estuary on the west side of the Dongxi Island, the Shaoxiang River estuary and Xiaowa Port on the nearshore of the Xuwei Port, and the Liezikou estuary and Guanhe River estuary in the southwest. The coastwise areas of the study sea area belong to a coastal plain. The coast stretching from the Xishu River estuary to Shaoxiang River estuary is a bedrock coast with a coastline of 40.25 km. The coast stretching from the Shaoxiang River estuary to the Liezikou estuary is an erosive muddy coast with a coastline of 32.06 km. The coast stretching from the Liezikou estuary to the Guanhe River estuary is an erosive silty muddy coast with a coastline of 39.08 km.

There are also two sea-discharging projects in the study area, including the Lingang Sewage Treatment Plant treating the sewage from the Harbor Industrial Park in the Guanyun County and the Lianyungang Zhongxin Sewage Treatment Plant treating the sewage from Lianyungang Chemical Industrial Park. The sewage source involves industries about electricity, metallurgy, chemical, shipbuilding, paper making, pesticides, and pharmaceuticals.

Sample collection and processing

In the tide period of October 2014, a survey of the marine environment was carried out in Xuwei-Liezikou offshore area, northern Jiangsu Province, China. A total of 30 surface sediment survey stations were deployed. The coordinates and details of the sampling location points are listed in *Table 1* and shown in *Fig. 1*. Sample 1, Sample 2,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28812892

and Sample 4 are located on the northeast side of Dongxi Island. Sample 3 is on the north side of the west embankment. Sample 8, Sample 11 and Sample 12 are on the northeast side of the Guanhe River estuary, and Sample 13 is on the Guanhe River estuary. Others survey samples are concentrated in the inner areas of the Xuwei Port. The survey investigated items including arsenic (As), mercury (Hg), copper (Cu), lead (Pb), zinc (Zn), chromium (Cr) and cadmium (Cd).

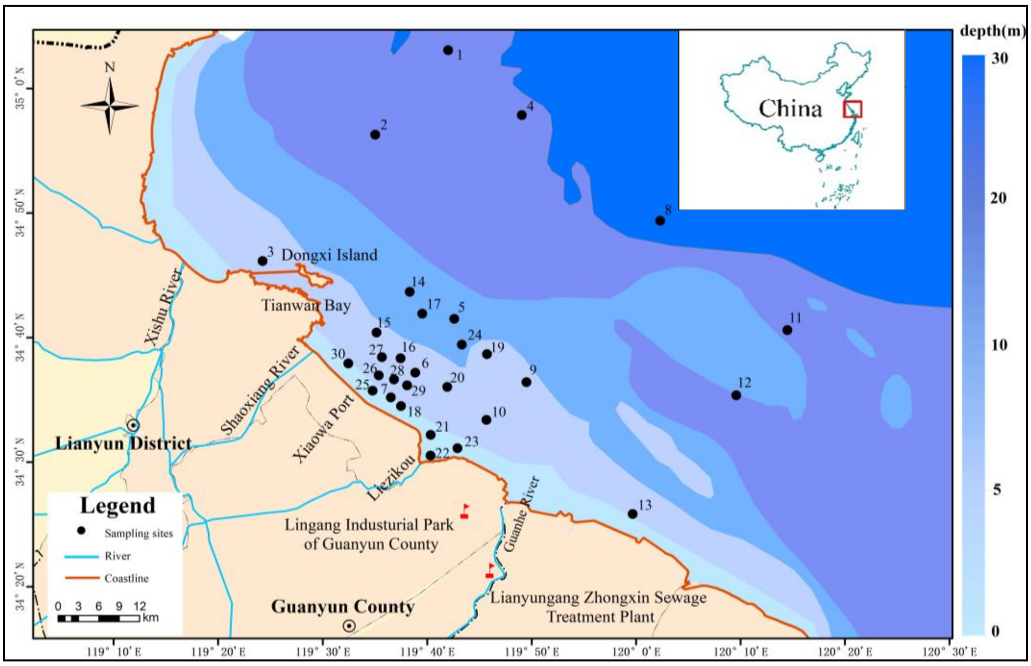

Figure 1. *Locations of surface sediment sampling sites in Xuwei-Liezikou offshore area*

The collection of sediment samples was carried out on October 10th, 2014. The methods used for the sample collection on site, the pretreatment and the preservation were in strict accordance with the *Marine Monitoring Regulations of China* (GB17378.4-2007) (AQSIQ, 2007). Samples that could not be analyzed on site were stored in a dark place after steps concerning subpackage, pre-treatments, freeze or sealing with the added fixing agent, and wrapping with plastic bags. Samples that need to be investigated were transported to the laboratory by the responsible person after the field sampling. Sediment samples were analyzed and tested at Nantong Marine

DOI: http://dx.doi.org/10.15666/aeer/1702_28812892

Environmental Monitoring Center. The concentrations of Cu, Zn, Pb, Cd and Cr were determined by atomic absorption spectrometer (Varian AA240FS), and for As and Hg were measured by atomic fluorescence spectrometry (Beijing Jitian Instrument Co. AFS-930).

Evaluation method

Statistical evaluation

The standard deviation (SD) and coefficient of variation (CV) were calculated for sediment samples in Xuwei-Liezikou offshore area. The inverse distance weight method was used to carry out spatial interpolation of heavy metals, and ArcGIS10.2 spatial analysis module was used to draw the spatial distribution figures of heavy metal contents.

Geo-accumulation index (I_{geo})

Geo-accumulation index (I_{geo}), originally defined by Müller (1969), has been widely used to assess heavy metal pollution in the environment (Wang et al., 2015; Malvandi, 2017; Nethaji et al., 2017; Naifar et al., 2018). The formula used for the calculation of I_{geo} is as follows:

$$I_{geo} = \log_2 \frac{C_n}{1.5B_n} \quad \text{(Eq.1)}$$

where C_n and B_n are the actual measured content of the heavy metal and the natural background value of the heavy metal, respectively. In this study, the background values of heavy metals in coastal soil in Jiangsu Province were used for B_n (Chen et al., 1985). Its degree of pollution of Müller (1981) is shown in *Table 2*.

Pollution load index (PLI)

Pollution load index (*PLI*) is an evaluation method proposed by Tomlinson and others in the study of heavy metal pollution level classification (Tomlinson et al., 1980; Badr et al., 2009), and it is convenient to apply. The index is composed of various heavy metal components in the study area. It can reflect the contribution of various heavy metals to pollution and the changing trend of heavy metals in space. The equation is shown as follows:

$$C_f^i = C_n^i / C_0^i \quad \text{(Eq.2)}$$

$$PLI = \sqrt[n]{C_f^1 \times C_f^2 \times C_f^3 \times \cdots \times C_f^n} \quad \text{(Eq.3)}$$

where C^i_f is the pollution coefficient of the heavy metal i; C_n^i is the measured concentration value of heavy metal i; C_0^i is the background value for heavy metal i. In this study, the natural background values of heavy metals in coastal soil in Jiangsu Province are adopted for C_0^i (Chen et al., 1985); n is the number of heavy metals; PLI is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28812892

the pollution load index at a certain sample site. The pollution load index is generally divided into 4 grades (Zhu et al., 2013; Maanan et al., 2015), as shown in *Table 2*.

Potential ecological risk index

In 1980, Swedish scholar Lars Hakanson proposed a potential ecological risk index method for evaluating heavy metal pollution and ecological risk based on sedimentology principles (Hakanson, 1980). This evaluation method comprehensively considers the toxicity of heavy metals, the difference of background values of heavy metals, the sensitivity of heavy metal pollution under the effect of evaluation areas, and the general rule concerning the migration and transformation of heavy metals in sediments, the calculation equations can be express as follows:

$$C_f^i = C_n^i / C_0^i \quad \text{(Eq.4)}$$

$$C_{RI} = \sum_{i}^{n} C_f^i \quad \text{(Eq.5)}$$

$$E_r^i = T_r^i \times C_f^i \quad \text{(Eq.6)}$$

$$E_{RI} = \sum_{i=1}^{m} E_r^i \quad \text{(Eq.7)}$$

where the meanings of C^i_f, C_n^i and C_0^i are the same as in *Eq.2*; n is the number of heavy metals; C_{RI} is the comprehensive contamination coefficient; E_r^i is the potential ecological risk index for heavy metal i; T_r^i is the heavy metal toxicity response coefficient that reflects the toxicity level of heavy metals and the sensitivity of organisms to heavy metal pollution, the toxicity response coefficient for As, Hg, Cu, Pb, Zn, Cd and Cr are 10, 40, 5, 5, 1, 30 and 2, respectively (Hakanson, 1980); E_{RI} is the comprehensive potential ecological risk index of the heavy metals in the study area. The relationship among the evaluation index of heavy metal pollution, its degree of pollution and the degree of potential ecological risk of Hakanson (1980) are shown in *Table 2*.

Results and discussion

Concentration of heavy metals in Xuwei-Liezikou offshore area

The contents of heavy metals in the surface sediments of Xuwei-Liezikou offshore area are showed in *Table 3*. The concentrations (mg/kg) of As, Hg, Cu, Pb, Zn, Cd and Cr were in the ranges of 4.67~17.90, 0.011~0.062, 10.00~32.30, 14.40~33.50, 40.00~84.70, 0.049~0.211 and 30.10~74.70, with the averages of 12.54, 0.03, 19.84, 22.31, 66.80, 0.11 and 42.67, respectively. The mean concentrations for these metals were ranked as follows: Zn＞Cr＞Pb＞Cu＞As＞Cd＞Hg. All the heavy metals contents were lower than Class I sediment category according to the Chinese Marine Sediment Quality standard criteria (GB 18668-2002) issued by the Administration of Quality Supervision, Inspection and Quarantine (AQSIQ, 2002), indicating that the sediment environment in the study area was generally good.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28812892

Compared to the background values of heavy metals in coastal soil in Jiangsu Province (Chen et al., 1985), the mean concentrations of Cd, Pb, As, Zn, Cu and Hg were higher than the background values in the Jiangsu province except for Cr, which were 2.62, 1.96, 1.70, 1.42, 1.32 and 1.30 times of their respective background values, indicating there were obvious accumulations of these heavy metals in surface sediments. The standard deviation (SD) and coefficient of variation (CV) indicated moderate variability for As, Pb, Zn, Cr (15%＜CV＜36%) and high variability for Hg, Cu, Cd (CV＞36%) according to Phil-Eze (2010). These coefficients of variation of the heavy metals were higher, and the heavy metal concentrations varied over a wide range, which suggested an imbalance in the spatial distribution.

We compared the heavy metal concentrations in the study area with those other representative areas in China are also listed in *Table 3*. The mean concentrations of all heavy metals in study area were lower than those found in sediments of Guangdong coast. The mean Cu and Zn concentrations in study area were higher than those in South Jiangsu Province, Laizhou Bay and Rizhao offshore area. The mean concentrations of Cd and Cr in study area were lower than those in South Jiangsu Province. The mean As, Pb and Cr concentration was higher in study area than in Laizhou Bay, but lower than in Rizhao offshore area. The mean Cd and Hg concentration was higher in study area than in Rizhao offshore area, but lower than in Laizhou Bay.

Spatial distribution of the heavy metal concentrations

The spatial distributions of heavy metals in surface sediments of Xuwei-Liezikou offshore area are presented in *Fig. 2*.

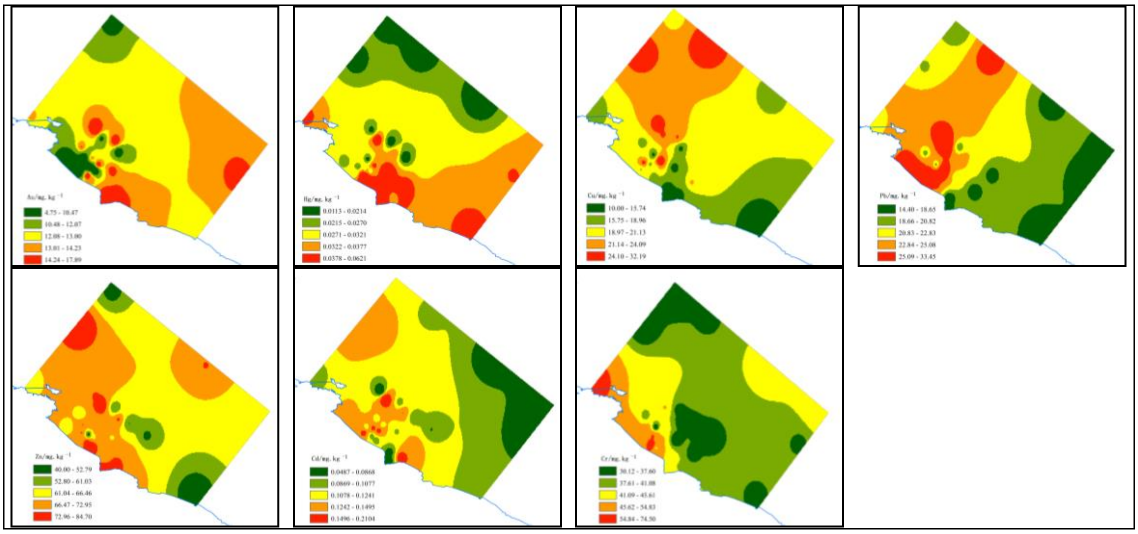

Figure 2. *Spatial distribution of heavy metals in Xuwei-Liezikou offshore Area*

The spatial distributions of Zn, Hg, Cd and As were similar, these elements had high concentration values in the western region of the study area, which was consistent with the major rivers inlets. The high concentration values of Pb were in the northern of the study area mainly located in the Xuwei Port. Cu tended to be higher in the northwest and lower in the southeast. In general, the heavy metal high-values areas, the western and northern region of the study area, were mainly located at the river estuaries and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28812892

Xuwei Port. The result showed that land-based pollutants and ship pollutants had an important influence on heavy metal pollution in the study area.

Assessment of heavy metal contamination

Geo-accumulation indices of the heavy metals

The geo-accumulation indices (I_{geo}) of the heavy metals in Xuwei-Liezikou offshore area are shown in *Table 4*. The I_{geo} values of As, Hg, Cu, Pb, Zn, Cd and Cr were in the ranges of -1.25~0.69, -1.61~0.85, -1.17~0.52, -0.25~0.97, -0.82~0.26, -0.37~1.74 and -1.58~-0.27, with the averages of 0.11, -0.26, -0.23, 0.35, -0.11, 0.76 and -1.12, respectively. The mean I_{geo} values were ranked as follows: Cd>Pb>As>Zn>Cu>Hg>Cr. According to Müller (1981), the mean I_{geo} values in the study area ranged form -2 to 1, showing unpolluted and unpolluted to moderate polluted. The result indicated that the study area has not been obviously polluted as a whole. However, the I_{geo} values of Cd ranged from -0.37 to 1.74, and 10% of the sampling sites were unpolluted, 33% were unpolluted to moderately polluted, 57% were moderately polluted. The sampling sites that were moderately polluted for Cd were mainly distributed in the western region of the study area (*Fig. 3a*), indicating that the land-based pollutants had an important impact on the sediment environment in the study area. Meanwhile, it should be noted that the I_{geo} values form 87% of the sampling sites for Pb ranged form 0 to 1, indicating unpolluted to moderately polluted, the high I_{geo} values were located in the Xuwei port (*Fig. 3b*). Overall, the surface sediments were a low degree of pollution throughout the study area, and Cd and Pb were the main pollution factors.

The pollution load indices (*PLI*) of the heavy metals for surface sediments of Xuwei-Liezikou offshore area are presented in *Table 5*. The *PLI* values in the study area ranged from 1.15 to 1.91, with the averages of 1.44, the Xuwei-Liezikou offshore area was considered to be moderately polluted. 100% of all sample sites showed moderately polluted, indicating that the study area was affected by human activities. The high *PLI* values were in the western and northern region of the study area (*Fig. 4a*). The result was similar to the distribution characteristics of main pollution elements.

Potential ecological risk index in Xuwei-Liezikou offshore area

The contamination factor (C^i_f) values for the heavy metals in Xuwei-Liezikou offshore area are showed in *Table 6*. The mean C^i_f values of As, Hg, Cu, Pb, Zn, Cd and Cr were 1.70, 1.30, 1.32, 1.96, 1.42, 2.62 and 0.71, ranked as follows: Cd>Pb>As>Zn>Cu>Hg>Cr. 67% of the sampling sites for Cd were moderate pollution, while 33% (mainly located in the nearshore region) showed high pollution. 100% of the sampling sites for Pb were moderate pollution, and the high C^i_f values for Pb located in Xuwei Port. The C^i_f values of others elements showed low to moderate pollution. The C_{RI} values of the study area ranged from 8.75 to 15.6, with the mean of 11.21, indicating a moderate pollution. The high C_{RI} value distributed in the western and northern regions of the study area, mainly located in the estuary and port regions (*Fig. 4b*).

The potential ecological risk indices for the heavy metals in Xuwei-Liezikou offshore area are showed in *Table 7* and *Fig. 4c*. The mean E_r^i values for As, Hg, Cu, Pb, Zn, Cd and Cr were 17.03, 55.42, 6.60, 9.78, 1.42, 81.78 and 1.42, ranked as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28812892

follows: Cd > Hg > As > Pb > Cu > Cr=Zn. The mean E_r^i values for Cd showed a considerable ecological risk, Hg was a moderate ecological risk, the others elements were a low ecological risk. The E_{RI} values ranged from 96.97 to 274.62, with an average value of 173.46, which were a low to middle ecological risk (*Table 2*). The high E_{RI} values distributed in the western region of the study area (*Fig. 4c*), mainly located in the estuary regions, which was similar to the Cd distribution characteristics (*Fig. 2*). These results showed that the risks were mainly from Cd.

Table 7. *Potential ecological risk indices of the heavy metals in surface sediments*

	E_r^i							E_{RI}
	As	**Hg**	**Cu**	**Pb**	**Zn**	**Cd**	**Cr**	
Min	6.33	19.65	3.33	6.32	0.85	34.71	1.00	96.97
Max	24.26	108.35	10.75	14.69	1.80	150.71	2.49	274.62
Mean	17.03	55.42	6.60	9.78	1.42	81.78	1.42	173.46

Conclusion

The mean concentrations (mg/kg) of As, Hg, Cu, Pb, Zn, Cd and Cr were 12.54, 0.03, 19.84, 22.31, 66.80, 0.11and 42.67 in surface sediments of Xuwei-Liezikou offshore area, respectively. The averages of Cd, Pb, As, Zn, Cu and Hg were higher than the background values in the Jiangsu province except for Cr, which were 2.62, 1.96, 1.70, 1.42, 1.32 and 1.30 times of their respective background values, indicating there were obvious accumulations of these heavy metals of the study area. The spatial distributions of heavy metals showed that Zn, Hg, Cd and As had high concentration values in the western region of the study area, which was consistent with the rivers inlets, and the high concentration values of Pb were in the northern of the study area mainly located in the Xuwei Port. The results of contamination assessment showed the study area was moderately polluted, and the main pollution areas were in the western and northern region. The pollution mainly came form Cd and Pb. For the main pollution factors, further studies on their sources and impacts can be conducted to provide data for environmental protection. The study area suffered from a level between low and moderate risks, and Cd was an important factor causing ecological risks. The estuary areas where were prone to ecological risk should be paid attention to.

(Received 1st Nov 2018; accepted 20th Dec 2018)

Abstract. The objective of this study was to investigate the effect of dietary *Vachellia karroo* leaf meal inclusion on growth performance, meat quality and histological parameters in bucks**.** A total of thirty yearling Pedi bucks with a mean initial body weight of 16.7 ± 3.3 kg were randomly assigned to five treatments in a completely randomized design. *Vachellia karroo* leaf meal inclusion levels of 20, 25, 30, 40 and 50% were fed to the animals for 60 days. The results showed that dietary treatments had no effect on the final live weights and average daily gains of bucks. Similarly, yields of different carcass components and meat sensory attributes were not affected by the *V. karroo*. Bucks fed 25% *V. karroo* leaf meal had higher meat L* values than those on diets 30 or 40% inclusion levels. The livers of bucks fed 20, 25 or 30% *V. karroo* leaf meal were not adversely affected. However, severe hepatocyte degeneration was noticed in the liver tissues of bucks fed 40 or 50% leaf meal. Dietary *V. karroo* did not cause any serious damage to the kidneys of the bucks. Thus, *V. karroo* leaf meal inclusion levels of 20 to 30% are recommended.
Keywords: *goats, tannin, carcass characteristics, sensory evaluation, acacia*

Introduction

Pedi goats in communal areas of Limpopo province, South Africa depend on *Vachellia karroo* (*Acacia karroo*) leaves, particularly during the dry season (Jamala et al., 2013). *Vachellia karroo* leaves contain high levels of extracted condensed tannins ranging from 55 – 110 g/kg DM and have potent antioxidant properties (Mokoboki et al., 2005; Moon et al., 2014). Antioxidant activity of these plants is attributed to their phenolic compound content (Velasco and Salinas, 2011). Antioxidant activity of plant extracts such as condensed tannins have positive effect on meat quality and oxidative stability (Moyo et al., 2012; Qwele et al., 2013). On the other hand, high condensed tannin contents in the diet negatively affect nutrient availability (Gxasheka et al., 2015). Reports on the effects of tanniferous diets on small ruminant productivity and meat quality are not conclusive. Some authors found that tannin-rich diets positively influence chevon quality (Priolo and Vasta, 2007; Mapiye et al., 2009; Marume, 2010; Bakare and Chimonyo, 2011; Ngambu et al., 2012, 2013), whereas, others found no clear evidence (Mapiye et al., 2010). Additionally, *Vachellia karroo* leaf meal inclusion levels for optimum Pedi bucks meat quality were not found in the literature.

Kidney and liver are vital organs in the animal's body and play vital role in the detoxification process. Dysfunction in liver and kidney may lead to diseases such as ascites and uremia (Karimi et al., 2014). Ruminants browsing on tanniferous forage have adapted rumen micro-organisms that detoxify many, but not all plant secondary

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28932909

metabolites (Cheeke, 1988). A large intake of tannins in the diet may cause kidney irritation and liver damage due to the detoxification process as a consequence of increased enzymatic demand (Van Soest, 1994; Mahgoub et al., 2008). Previous studies have reported a negative effect of condensed tannins on the histopathology of Boer goats (Mbatha et al., 2002). According to the authors, increased dietary tannin levels induced thickening and/or keratinization of epithelial tissue in the reticulum, rumen, omasum and abomasum. Increased tannin levels also resulted in a loss of epithelial cells, erosion of microvilli and shortened villi height in the duodenum (Mbatha et al., 2002). Karimi et al. (2014) reported histological changes in the kidney and liver parenchyma of GhezelxArkhar Merino crossbred lambs fed low tannin sorghum grain. Goats are predominantly browsers and they are able to consume large amounts of tannin-rich forage, which may increase the risk of exposure to sub-clinical systemic toxicity (Gilboa, 1995). Hence, monitoring of these organs in nutritional studies is imperative. There is paucity of information on the effect of tanniferous diets on the liver and kidney of goats. It is hypothesized that increased dietary tannin may result in variable damage of these organs. This study investigated the effects of *Vachellia karroo* leaf meal inclusion on meat quality and histology of livers and kidneys of Pedi bucks.

Materials and methods

Study site

The study was conducted at the University of Limpopo Experimental farm, South Africa (latitude 27.55° S and longitude 24.77° E). The ambient temperatures at the study site range between 20 and 36 °C during summer and between 5 and 25 °C during winter. Mean annual rainfall is 446.8 mm with the dry season occurring between April and October and the rainy season occurring between November and March.

Collection, drying and storage of plant material

Vachellia karroo leaves were harvested during the summer months (November-January). Branches of each shrub were removed manually and placed in a shed. Leaves were allowed to air dry on the branches and then removed by carefully beating the branches with sticks. The leaves were stored in air-tight bags until feeding time. Detailed reviews on the botanical description of *V. karroo* have been described by Barnes et al. (1996). *Setaria verticillata* (L.) P. Beauv. is a perennial grass belonging to the tribe Panacea and is widely grown by commercial farmers in Limpopo Province of South Africa. The grass is well grazed during summer and is suitable for hay making. Botanical authentication of the plant materials was done at the Larry Leach Herbarium, Department of Biodiversity, University of Limpopo.

Animal, management, diet and experimental design

All animal procedures were approved by the Animal Research Ethics Committee of the University of Limpopo, South Africa. A total of thirty yearling Pedi bucks (*Capra hircus*), (a local indigenous breed in Limpopo province of South Africa) with a mean initial body weight of 16.7 ± 3.3 kg were randomly assigned to five treatments in a completely randomized design. Each treatment had three replicates with two goats per replicate. The animals were housed in individual holding pens (1 × 3 m^2) that were installed in a well ventilated shed with one side open to natural light and roofed to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28932909

protect animals against the sun and rain. Yearling Pedi bucks were selected because they are the ones fattened for meat in the province. All animals were drenched with an anthelmintic (Valbazen® broad spectrum dewormer, manufactured by Pfizer Animal NY, USA) and sprayed with Diazintol® (Alfasan International, Holland) before the start of the experiment.. The goats were individually fed ad libitum once a day at 8:00 am, allowing a 15% refusal of each diet (Kaitho et al., 1996) and they had free access to clean water and a salt block. Prior to the trial, the animals were given the dietary treatment for 14 d ad libitum for adaptation, and the feeding trial lasted for 60 d. The grass and *V. karroo* leaves were chopped and thoroughly mixed to avoid diet selection by the animals when fed (*Table 1*). *Vachellia karroo* leaf meal inclusion levels of 20, 25, 30, 40 and 50 were used in the present study. These inclusions include low and high tannin levels as indicated in the literature (Brown et al., 2017). Feed intake was recorded on a daily basis. Intake was calculated by subtracting leftovers from the feed given. Dry matter values of the feeds and feed refusals were determined. The goats were weighed three times, at the start of the experiment, on day 54 and on the 60th day when data collection ended. Goats were weighed before morning feeding to avoid feed effect. Average daily gains were calculated as differences between final and initial body weights divided by number of feeding days.

Table 1. *Feed composition of the experimental diets*

Diets		
Diet code	***Vachellia karroo*** **(%)**	***Setaria verticillata*** **hay (%)**
$V_{20}S_{80}$	20	80
$V_{25}S_{75}$	25	75
$V_{30}S_{70}$	30	70
$V_{40}S_{60}$	40	60
$V_{50}S_{50}$	50	50

Nutrient composition of *V. Karroo* and *S. verticillata* grass was previously reported by Brown and Ng’ambi (2017). The same applies to the nutritive values of dietary mixtures of the browse and grass hay used in the present study (*Tables 2* and *3*).

Table 2. *Nutrient composition of Vachellia karroo leaves and Setaria verticilllata hay*

Slaughter and carcass evaluation

Prior to slaughter and muscle sample collection, the goats were fasted for 16 h with free access to drinking water and their body weight was recorded immediately after fasting. The animals were slaughtered humanely in the abattoir facility at the University Experimental Farm. The weights of the hot carcass and internal organs were recorded. The gastro-intestinal (GI) tract, including alimentary canal, reticulo-rumen and intestines were weighed after the removal of ruminal contents. Carcasses were chilled at 4 °C for 24 h. After this period, cold carcass weight (CCW) was determined.

Meat quality determination

The pH value at 1 h in *Longissimus thoracic et lumborum* muscle was measured after evisceration by using a pH meter equipped with a penetrating electrode (Crison pH25, CRISON instruments S. A., Alella, Spain). Before measurement, pH meter was calibrated with standard pH buffer (pH 4.0, 7.0 and 10.0). At 24 h postmortem, the entire *Longissimus thoracic et lumborum* was removed for pH, meat color and cooking loss. Meat color (L* = lightness, a* = redness and b* = yellowness) was measured using a spectrophotometer with a D-65 illuminant and an aperture size of 50 mm (45/0 BYK-Gardener instrument GmbH, Germany). Before measurement, the spectrophotometer was calibrated with a white tile (model CR-A43). Three readings were taken by rotating the instrument 90° between measurements, in order to obtain a representative average value of the color, and avoiding connective tissues and intramuscular fat. The readings were taken 1 and 24 h post-mortem. The meats were allowed to bloom for 1 h prior to color analysis.

For cooking loss analysis, blocks of *longissimus thoracic et lumborum* muscle, measuring approximately 7 × 4 × 4 cm, were used to determine cooking loss (Babikerm et al., 1990) and shear force values (Chrystall et al., 1994). The muscle was weighed, placed in a water tight PVC plastic bag and cooked in a water bath at 85 °C for 45 min, until an internal temperature of 70 °C was attained. The samples were cooled and re-weighed. Cooking loss (CL) was calculated using the following

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28932909

formula: Cooking loss % = [(weight before cooking – weight after cooking) / weight before cooking] × 100 as described by Ding et al. (2010). After measurement of cooking loss, cooked samples were used to determine meat Warner Bratzler shear force. Three sub-samples (cut parallel to the muscle fibers with a cross-section of 1 × 1 cm and at least 3 cm long) were removed from each cooked muscle. The sub-samples were sheared perpendicular to the fiber direction with an Instron Universal Testing Machine (Model 3344, Instron Industrial Products, GC, USA) equipped with a Warner-Bratzler (WB) shear force apparatus (crosshead speed at 400 mm/min, one shear in the center of each core). The measurements were read in Newton. Dressing percentage was calculated as the ratio of hot carcass weight divided by slaughter body weight and the result multiplied by 100. Water holding capacity (WHC) of the meat was measured as the amount of water expressed from a fresh meat sample (1 g) held under pressure (60 kg) using the filter-paper press method (Trout, 1988).

Meat sensory evaluation

Meat samples used for consumer sensory evaluation were obtained from each carcass and were cut 24 h post-slaughter. The meat samples were cut into cubes (2 × 2 cm), which were placed in watertight PVC plastic bags and cooked in a boiling water bath at a temperature of 85 °C for 45 min (Babikerm et al., 1990). Salt was added to taste. Twenty trained consumer panelists from the University of Limpopo were used for the consumer sensory assessment of meat. Panelists were screened and selected following guidelines from Cross et al. (1978). The panelists were taught how to infer and record scores for each variable. The waiting period between meat sample tastings was 10 min. Distilled water was served to panelists to freshen their mouths between sub-sample assessments to avoid crossover effects. Five-point descriptive scales were used to evaluate the sensory attributes (*Table 4*).

Table 4. *Evaluation scores used by the sensory panel*

	Sensory attribute					
Score	**Tenderness**	**Juiciness**	**Flavor**	**Taste**	**Aroma**	**Overall acceptability**
1	Too tough	Too dry	Very bad flavor	Dislike extremely	Dislike extremely	Dislike extremely
2	Tough	Dry	Poor flavor	Dislike	Dislike	Dislike
3	Neither tough nor tender	Neither dry nor juicy	Neither bad nor good	Neither like nor dislike	Neither like nor dislike	Neither like nor dislike
4	Tender	Juicy	Good flavor	Like	Like	Like
5	Extremely tender	Extremely juicy	Very good flavor	Like extremely	Like extremely	Like extremely

Histological analysis

Liver and kidney samples from each goat were collected and preserved in 10% neutral buffered formalin for 24 h. Subsequently, liver and kidney tissues were dehydrated using standard histological techniques in graded ethanol series and embedded in paraffin wax for histopathology examination (Sanchez-Chardi et al., 2008). From each sample, 60-65 µm sections were cut and mounted on glass slides

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28932909

before staining with haematoxylin and eosin. Slides were examined under light trinocular microscopy at 400X (Leica Microsystems model DM750, Leica, Bannockburn, IL, USA). Each slide was photographed with a DVC digital camera (Digital Video Camera Company, Austin, TX) mounted on a BH-2. The process was as described by Sanchez-Chardi et al. (2009).

Chemical analysis

Dry matter, organic matter and crude protein were determined using the methods described by AOAC (2005). Neutral detergent fibre (NDF) and acid detergent fibre (ADF) were determined by the method of Van Soest (1994). Total phenolics were determined using Folin-Ciocalteau methods and expressed as tannic acid equivalent (% DM) (Water and Mole, 1994). Condensed tannins were determined using the Butanol-HCl method and expressed as leucocyanidin equivalent (%DM) (Porter et al., 1986). For each measurement, duplicate analyses were done.

Statistical analysis

Statistical analysis was performed using the GLM procedure of SAS (SAS, 2010). Initial live weight was fitted as covariate for carcass traits. The data are expressed as the mean ± SEM and analyzed using one-way analysis of variance (ANOVA). Fisher's Protected Least Significant Difference (LSD) test was used for the post hoc analyses. A $P < 0.05$ was considered statistically significant for all data.

Results

Nutrient composition of Vachellia karroo and Seteria verticillata grass hay

Vachellia karroo contained 127 g CP/kg DM and 921 g OM/kg DM. It also contained phenolic compounds. *Seteria verticillata* grass hay contained 79, 779 and 507 g of CP, NDF and ADF/kg DM, respectively. *Setaria verticillata* hay has no traces of phenolic compounds (*Table 2*). The nutritive values of dietary mixtures of *V. karroo* and *S. verticillata* hay are presented in *Table 3*. Diet containing 50% *V. karroo* leaf meal contained 103 g CP/kg DM. The condensed tannin and total phenolic contents were 1.0 and 0.9%, respectively. A diet containing 20% *V. karroo* leaf meal inclusion had 89 g CP/kg DM, 0.4% condensed tannin and 0.3% total phenolic content.

Feed intake and growth performance

Daily dry matter intakes were similar ($P > 0.05$) across the dietary treatments, ranging from 638 to 786 g per goat. Similarly, goats consumed the same ($P > 0.05$) daily amounts of organic matter (OM), crude protein (CP), neutral detergent fibre (NDF) and acid detergent fibre (ADF) contents. *Vachellia karroo* inclusion did not ($P > 0.05$) affect the final body weights and average daily gains of goats (*Table 5*).

Slaughter performance and internal organ weight of bucks

As shown in *Table 6*, dietary *V. karroo* leaf meal inclusion had no effect ($P > 0.05$) on hot and cold carcass weights of bucks. Similarly, the internal organ weights of bucks were not affected ($P > 0.05$) by the dietary treatments.

Meat quality and consumer acceptability

As shown in *Table 7*, there was no observed effect of dietary *V. karroo* leaf meal inclusion on the $pH_{1\ h}$ and $pH_{24\ h}$. Dietary *V. karroo* did not affect (P > 0.05) the meat color 1 h post-mortem, water holding capacity, shear force, cooking loss and dressing percentage. However, there was treatment effect on meat color at 24 h post-mortem. Goats fed 25% *V. karroo* leaf meal had higher (P < 0.05) L* intensity than those on diets 30 or 40% inclusion levels. On average, no differences (P > 0.05) existed among treatments with respect to tenderness, juiciness, flavor, taste, aroma and overall acceptability (*Table 8*).

Effect of dietary Vachellia karroo on histological changes in the liver and kidney tissues of bucks

Histological analysis of the liver tissues of bucks fed 20, 25 or 30% *Vachellia karroo* leaf meal showed moderate hepatocellular hydropic degeneration, dilation of central veins and proliferation of sinusoidal kupfer cells (*Fig. 1a, b* and *c,* respectively). The hepatocytes of bucks fed diets containing 40 or 50% *V. karroo* leaf meal had severe hepatocellular hydropic degeneration with multifocal single cell and clustered cell necrosis (*Fig. 1d* and *e,* respectively). The kidney tissues of bucks fed 20, 25 or 30% *V. karroo* leaf meal had early dilatation of glomerular uriniferous spaces and mild renal tubular nephrosis (*Fig. 2a, b* and *c,* respectively), while those fed 40 or 50% *V. karroo* leaf meal had dilatation of uriniferous spaces and ectasia of some proximal convoluted tubules (*Fig. 2d* and *e*, respectively). Intra-tubular proteinaceous fluids with protein cast formation were also noticed in the kidney of bucks on diets 40 or 50% *V. karroo* leaf meal.

Discussion

In the present study, *V. karroo* inclusion had no effect on diet intake of bucks. Similar results were reported for kids fed tanninferous *Ageritum conyzoides*, *Eupotarium odoratum* and *Crystellina* parasitica (Das et al., 2011). It has also been reported elsewhere that diets high in CT reduce intake of goats (Holechek et al., 1990). On the contrary, Solaiman et al. (2010) reported increased feed intake in Kiko crossbred male kids fed CT forage (*Sericea lespedeza*). Condensed tannins in forage legumes adversely affect feed intake through astringency in the oral cavity (Lamy et al., 2011). However, in the present study, diets with higher levels of CT were well-tolerated by goats. This may be due to the fact that the goats developed mitigatory systems against tannin toxicity such as secretion of proline-rich proteins in their saliva or proliferation of microorganisms resistant to condensed tannins in their digestive tracts (Lamy et al., 2011; Muir, 2011).

Dietary treatment did not improve growth performance of Pedi bucks. This is similar to the findings of Dludla (2010) who reported no differences in body weight gain of goats fed forages with different tannin concentrations. Wright (2015) observed similar results in Kiko-cross goats fed tanninferous *Sericea lespedeza*, pine bark powder and combination of *Sericea lespedeza* and pine bark powder. However, Ngambu et al. (2013) reported improved growth performance when Xhosa lop-eared goats were supplemented with 200 g of fresh *V. karroo* leaves. The lack of significant differences in body weight gain in the present study could be due to the fact that the dietary treatments met the nutrient requirements for a growing goat and hence nutrient supply was adequate for growth (McDonald et al., 2011).

Vachelia karroo leaf meal inclusion had no effect on the carcass weight and yields of Pedi bucks. Wright (2015) reported similar finding in Kiko-cross goats fed *Sericea lespedeza*, pine bark powder and combination of *Sericea lespedeza* and pine bark powder. The result obtained in the present study was expected since the dietary treatments did not influence average daily weight gains of goats.

According to Priolo et al. (2001), meat pH values can be influenced by dietary treatments. In the present study, *V. karroo* leaf meal inclusion had no effect on meat pH values. Previous studies demonstrated that the consumption of tanninferous feeds had no effect on chevon pH (Mapiye et al., 2010). However, Ngambu et al. (2013) observed significant differences in meat pH when goats were supplemented with *V. karroo* leaf meal. The discrepancies in the results could be due to the amount of dietary tannins ingested by the animals in each study. The ultimate pH (pH_u) of a carcass usually varies from 5.3 to 6.8 (Mostert, 2007). Under-nutrition is a primary cause of high pH_u in meats since animals do not have the possibility to accumulate sufficient glycogen reserve in their muscles (Bray et al., 1989). However, the experimental diets in the present study met the nutrient requirements for a growing goat and hence differences in meat pH values were not expected. Additionally, animals stressed prior to death are more likely to have a high pH_u. This is due to depletion of muscle glycogen resulting in lower lactic acid production. The animals in this study were not stressed prior to slaughter.

The present study indicated that goats fed 25% *V. karroo* leaf meal produced meat which was lighter than those on diets 30 or 40% leaf meal. Normally, consumers prefer lighter meat than dark meat. Verna et al. (1989) found similar result when lambs were fed two sorghum varieties with different tannin contents. Effect of tanninferous feed on meat lightness have also been reported by other authors (Priolo et al., 2001). It has been hypothesized that tannins present in forages are responsible for the differences found in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_28932909

meat color (Priolo et al., 2005). The effect of tannins on meat color is attributed to the reduced microbial biosynthesis of vitamin B_{12} (Priolo and Vasta, 2007). An increase in intramuscular and marbling fat is another factor that contributes to meat lightness (Baublits et al., 2004). However, the mechanism of action of forage tannins on meat color is not clear and merits further studies.

Dietary treatments had no effect on water holding capacity, shear force, cooking loss and dressing percentage of buck meat. These findings are similar to the report of Mapiye et al. (2010) who reported that beef from steers supplemented with *V. karroo* leaves had no effect on shear force, WHC, and cooking loss. Further research is needed to deepen the knowledge in this area. Meat sensory attribute values were also similar across the dietary treatments. Ngambu et al. (2012) however reported significant differences in consumer sensory attributes of meat from indigenous Xhosa lop-eared goat breed supplemented with different amounts of *V. karroo* leaves. It is not clear how dietary tannins affect the sensory attributes of goat meat and this may require further studies.

The liver is a primary site of detoxification and is generally the major site of intensive metabolism, hence, it is prone to various disorders as a consequence of exposure to toxins (Ganong, 2005). In the present study, goats fed 20, 25 or 30% *V. karroo* leaf meal inclusion had moderate hepatocyte degeneration, dilation of central veins and proliferation of sinusoidal kupfer cells. This is similar to the findings of Karimi et al. (2014), who reported mild congestion in central veins and sinusoidal abnormality when Merino lambs were fed tanninferous sorghum-based diets. Hervas et al. (2003) reported moderate hydropic degeneration in the hepatocytes of sheep dosed intra-ruminally with 3.0 g quebracho tannin extracts. The results indicate that the livers of the goats fed *V. karroo* leaf meal up to 30% were not adversely affected. However, severe hepatocyte degeneration was noticed in the liver of goats fed diets with 40 or 50% *V. karroo* leaf meal. Lesions associated with natural oak toxicosis characterized by hepatic and renal damage have been reported in cattle (Spier et al., 1987). Histological changes such as shrinkage of hepatocyte, degeneration and necrosis of hepatocytes around the central veins and degeneration of some hepatic sinusoids have been reported in lambs fed high tanninferous sorghum grain diets (Karimi et al., 2014). The present results showed that high *V. karroo* leaf meal inclusion levels of 40 or 50% in the ration may cause damages to the liver of bucks and hence such inclusion levels are not recommended.

The kidney is also an important organ for elimination of waste or toxic materials in the body. Exposure of the kidney to toxins may cause serious damages to this organ (Junqueira and Carneiro, 2003). However, the present study showed that the experimental diets did not cause any serious damage to the kidneys of the goats. This agrees with the findings of Silanikove et al. (1996) who reported no damage to the kidneys of goats fed tannin-containing leaves. On the contrary, Karimi et al. (2014) observed that high levels of sorghum grains in the diets induced histological changes in the kidneys of sheep. Some ruminants on tanninferous forage tend to develop adapted rumen microorganisms that detoxify plant secondary metabolites (Alonso-Diaz et al., 2010). The detoxification process may, however, cause adverse effects in ruminants as a consequence of increased enzymatic demand in the liver, kidney, gut mucosa and other tissues (Van Soest, 1994).

Conclusions

Dietary *V. karroo* leaf meal levels in the present study did not improve feed intake, growth performance, carcass weight and carcass components of bucks. This may be an indication that the diets supplied adequate nutrients for growth of the goats. *Vachelia karroo* leaf meal did not adversely affect meat tenderness, juiciness, flavor, taste, aroma and overall acceptability. This is good for goat meat consumers, and requires further studies to confirm the responses. Meat pH, color, water-holding capacity, shear force, cooking loss and dressing percentage were not influenced by high and low *V. karroo* leaf meal levels. This is an indication that the diets had no adverse effects on these parameters. However, the effect of *V. karroo* on meat lightness was variable, depending on the inclusion level but without any recognizable pattern.

Vachelia karroo leaf meal inclusion levels of 20, 25 or 30% did not have adverse effects on livers and kidneys of bucks. However, severe hepatocyte degeneration was noticed in the liver of bucks fed diets with *V. karroo* leaf meal inclusion levels of 40 or 50%. Thus, *V. karroo* leaf meal inclusion levels of 20 to 30% are suggested. However, more detailed studies are recommended to confirm these results.

(Received 1st Nov 2018; accepted 25th Jan 2019)

Abstract. The use of amino acids (AA) to increase the uptake of nutrients has been increasing dramatically in recent years. This investigation was conducted in the two successive seasons of 2016 and 2017 on soybean in Golestan Province, Iran, to study the effect of time and intensity of defoliation on quantitative and qualitative characteristics of soybean (*Glycine max* L.) under the application of AA. A two-year factorial experiment was conducted based on randomized complete block design with three replications. The first factor included the defoliation intensity at three levels 0, 50 and 100%, the second factor included the defoliation time in five levels V1, V3, V5, V7, and R1 (growth stages), and the third factor was the application and non-application of AA. Results indicated that the effects of the defoliation time and intensity, as well as the foliar application of AA, were significant on morphological traits, yield and yield components, and oil and protein contents. In the quadruple interaction, the highest of grain yield (4040 $kg.ha^{-1}$) was observed in the application of AA under defoliation in V5 with 50% intensity during the first year. The lowest value of this trait was achieved in non-application of AA under 100% defoliation in R1 growth stage during both years of the experiment (1585 and 1525 $kg.ha^{-1}$, respectively). The maximum grain oil and protein yield were observed in 100% defoliation in V7 growth stage under AA application during the first-year experiment (978.5 and 1499 $kg.ha^{-1}$, respectively). Also, the lowest value of the traits was observed in 100% defoliation in the V5 growth stage under non-application of AA during the second year (225.6 and 471.9 $kg.ha^{-1}$, respectively). According to the present study, soybean is regarded generally as a defoliation-tolerant crop. Also, foliar application of AA could be used as an effective amendment for preventing defoliation injury in yield and yield components of soybean.
Keywords: *foliar application, harvest index, oil content, pod, grain yield*

Introduction

Soybean (*Glycine max* L.) is an important industrial legume as human and animal feed in the world with an average of 18-22% oil, 38-56% vegetable protein in its seeds. Soybean is the most widely grown oilseed in the world as a main or second crop (Arslan et al., 2018). Soybean is originated from China. Domestication and cultivation of soybean by humans in China date from about the 11th century BC or a little earlier according to oldest records (Hymowitz and Shurtleff, 2005). The plant is introduced from the ancient world to the new world in the middle of the 17th century and gained its worldwide importance at the beginning of the 20th century (Arslan et al., 2018).

Plants are continuously exposed to biotic and abiotic stresses (Sadak et al., 2015). Plant response to defoliation depends on more than just the total amount of leaf area that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29112929

is lost (Ahmadi et al., 2009). It is also known that defoliation intensity may vary along nutrient availability gradients and that defoliation may alter competition relationship between species (Alhamd and Alrababah, 2008). The ability of soybean to prevent substantial reduction in yield after the loss of leaves caused by defoliators and disease depends on several factors among including intensity of, the phenological stage of development at the time of defoliation, duration of defoliation, the ability of cultivar to tolerate or compensate for defoliation, and environmental conditions, especially rainfall, temperature and solar radiation (Nardino et al., 2016). Regarding the percentage of defoliation, research has established levels for the control of insect pests, when the defoliation is greater than 30% in the vegetative phase, or 15% in the reproductive phase. However, these recommendations are based on work done in the 70-80's decades. In this sense, another key issue for reduction of income is the degree to which defoliation reduces light interception by the canopy (Nardino et al., 2016). Earlier studies addressed the effect of leaf removal on growth and yield. In soybean, during the reproductive period, defoliation levels reduced the rate of the natural trend of losing leaf area. The yield was affected only by 67 and 100% defoliation applied at R6, while main agronomic traits such as date of harvesting maturity, plant loading, and height were not affected by defoliation (An et al., 2003). The defoliation of maize leaf up to 50% at the time of feed shortage did not have adverse in grain and stover yield components of maize (Khaliliaqdam et al., 2012). During the reproductive period, levels of defoliation reduced the rate of the soybean natural trend of losing leaf area (Pickle and Caviness, 2006).

The amino acid (AA) is a well-known biostimulant which has positive effects on plant growth, yield and significantly mitigates the injuries caused by biotic or abiotic stresses (Kowalczyk and Zielony, 2008). Saeed et al. (2005) on soybean found that treatments of AA significantly improved growth parameters of shoots and fresh weight as well as pod yield. Foliar application of nutrients has been recognized by many researchers, as a very efficient method of plant nutrition (Stiegler et al., 2013). Amino acid foliar applications are biostimulants in plants because they enhance the nutrient uptake efficiency because of increases in the leaf cuticle permeability (Moreira and Moraes, 2017), better plant growth, and higher plant biomass and grain yield, and they reduce abiotic stresses (Mendes et al., 2016). Researches are still necessary to verify the effects from amino acid foliar fertilizers under intensity and time of defoliation to improved quality and quantity of soybean plant. The objective of this study was to evaluate the influence of intensity and time of defoliation under amino acid application on yield and yield components and grain oil and protein contents of the soybean plant.

Materials and methods

Experimental design, site, and soil chemical analysis

In order to evaluate the effect of intensity and time of defoliation on quantitative and qualitative traits of soybean (Katol cultivar) under application of amino acid condition, a two-year factorial experiment was used based on randomized complete block design with three replications in, Golestan Province, Iran (Aliabad Katoul city; lat. 34° 54', long. 54° 56' E, altitude 142 m) during two consecutive years 2015-16 and 2016-17. The average annual minimum and maximum temperature and rainfall were 12.5 and 23.6 °C, and 182 mm (*Table 1*). The first factor included the intensity of defoliation soybean leaf in three levels 0, 50 and 100%, the second factor included time of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29112929

defoliation in five levels (V1, V3, V5, V7, and R1; soybean growth stages), and the third factor was the use and non-use of amino acids.

Agronomical operations were carried out in accordance with the tradition of the area. The previous planting on the farm was wheat. In order to determine some physical and chemical properties of the soil, a sample from 0-30 cm depth was prepared and sent to the laboratory and the amount of fertilizer was taken according to the laboratory's recommendations (*Table 2*). After fertilization, cultivation was carried out with a soybean row known as Fatahi's row planter (is a famous brand). The size of each plot was 2 × 3 m (with five rows). The distance between blocks and the distance plot in each block were 2 and 1 m, respectively. The pesticide used in the first stage consisted of Thiodicarb (1 $kg.ha^{-1}$) and secondly, 2 L/ha of Chlorpyrifos and thus, 250 cc Imidacloprid. Hand weeding weeds and 5 irrigations steps were performed.

Table 2. *Physicochemical properties of soil in the experimental farm at depths of 0 to 30 cm*

Soil texture	Sand (%)	Silt (%)	Clay (%)	K (mg/kg)	P (mg/kg)	N total (%)	Organic carbon (%)	Percentage of neutralized matter	pH	EC (dS/m^2)
Clay loam	22	50	28	261	8.8	0.15	1.46	12.5	7.4	2.4

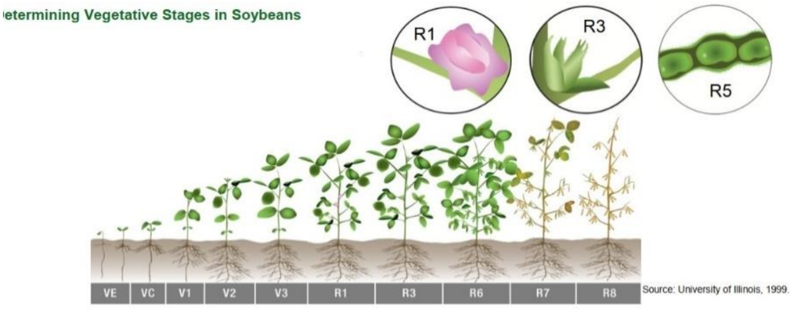
Underuse of AA conditions, spraying with the recommended dose of 1 kg per 1000 liters of water (250 $g.ha^{-1}$) was performed at V3, V5, V7, and R1 growth stages (*Fig. 1*). The AA used by the Nutramin-WSP brand is Biomega, which contains 14-15% nitrogen, 0.3-0.7% calcium, 0.4-1.2% phosphate, 1.1-1.5% potassium, 0.3-0.6% ammonium, and 90% amino acids. The intensity and time of defoliation (by hand) was done also determined by dividing the soybean morphology stages. For this purpose, at 0% level (no defoliation of leaves), 50% (defoliation of 50% the leaves) and 100% (defoliation of 100% the leaves) was performed (*Fig. 2*).

Yield and yield components

To measure morphological and yield characteristics, at the R7 stage, five samplings from each experimental plot were examined for yield components (with marginal effect) and plant height: the height of the first pod from the surface, number of branches, number of pods, number of seeds per pod, and 100-seed weight were measured. In order to determine the grain yield after removing the marginal effects, two rows of middle

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29112929

were harvested for grain yield. In other words, yield components were measured according to plant levels, but grain yield was measured according to surface levels. After calculating the biological yield, the harvest index (from grain yield to biological yield) was also determined (Divsalar et al., 2015).



VE	Cotyledons appear above the soil surface and provide nutrients for 7 to 10 days.
VC	Cotyledons have fully expanded and unifoliate leaves have unfolded. Four dormant growing points are present at the base of the petiole (axil) of unifoliate leaves and cotyledons.
V1	First trifoliate: Second true node, but first node at which a trifoliate leaf is produced. Nodules visible. New V stages develop every 5 days with normal temperatures.
V2	Two fully developed trifoliates unfold. The plant is roughly 8 inches tall. Nodules are actively fixing nitrogen. Cotyledons have fallen off plant. Lateral roots proliferating rapidly in the top 6 inches of soil.
V3-V4	A dramatic increase in the number of nodules visible on roots take place by these stages. This is typically the time that iron chlorosis deficiency syndrome is highly visible in impacted fields.
V5-Vn	Lateral roots extend 15 inches away from the main stem and grow to the centre of 30 inch row. Branches begin developing on the lowest nodes. The total number of nodes that the plant may produce is set at V5.
R1	Beginning bloom: R1 stage is reached when one flower is open at any node on the main stem.
R2	Full bloom: An open flower at one of the two uppermost nodes of the main stem with a fully developed leaf.
R3	Beginning pod: Pods are 3/16 of an inch long at one of the four uppermost nodes on the main stem.
R4	Full pod: Pod is ¾ of an inch long at one of the four uppermost nodes on the main stem. This is the most critical period for seed yield. Any stress from R4-R6 can cause more yield reduction than at any other time in plant development.
R5	Beginning seed: Seed in one of the four uppermost nodes with fully developed leaves is 1/8 of an inch long.
R6	Full seed: Pod containing a green seed filling the pod cavity is present at one of the top four nodes.
R7	Beginning maturity: One normal pod on the main stem has reached its mature pod colour. At this stage, the crop is safe from a killing frost.
R8	Full maturity: Ninety-five percent of the pods on the plant have reached their mature colour. Approximately 5 to 10 days of good drying weather is needed to bring crop to less than 15 percent moisture.

Figure 1. *Determining vegetative stage in soybeans*

Figure 2. *Experimental site and planting farm*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29112929

Grain oil and protein content

To measure the oil content and seed protein, about 50 seeds were randomly selected from each treatment. After powdered, the percentage of oil by Soxhlet method and protein percentage were also measured by Kjeldahl method (Divsalar et al., 2015). To calculate oil yield and protein yield, oil percentage and protein percentage were multiplied in grain yield, respectively.

Statistical analysis

Analysis of variance was performed to test for statistical differences among the treatments, and means were statistically analyzed using least significant difference test (LSD) at P < 0.05 level of significance by using SAS software (Statistical Analysis Software, 9.2).

Results

Plant height

Results indicated that the effect of year (Y), amino acid (AA), defoliation time (DT), and defoliation intensity (DI) were significant on plant height (*Table 3*). The maximum plant height was achieved in first Y (93.02 cm), foliar application of AA (92.16 cm), DT in V1 (94.03 cm), and DI in 0 and 50% (96.0 and 92.8 cm, respectively). Mean comparison results showed the interaction effects of Y × AA and DT × DI were significant on plant height. The highest and lowest plant height were observed DT in V1 and DT in control treatment (98.16 cm) and DT in V5, V7, and R1 under DI in 100% (74.14, 72.33, and 71.66 cm, respectively) (*Fig. 3A*). In interaction Y × AA, the maximum this trait was observed in the first Y under application of AA (99.8 cm), and the lowest value of this trait was achieved in the second Y under non-application of AA (84.4 cm) (*Fig. 3B*).

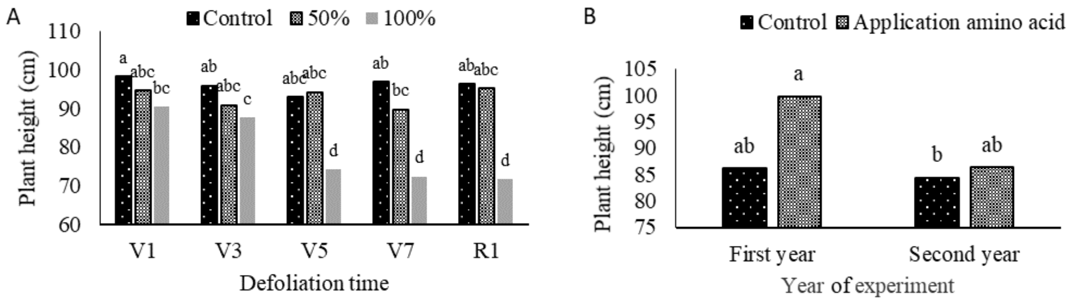


Figure 3. *Effect of intensity (0, 50, and 100%) and time (V1, V3, V5, V7, and R1) of defoliation (A); and defoliation time (V1, V3, V5, V7, and R1) and amino acid (control and application) (B) on plant height of soybean (columns with different letters are significantly different at P = 0.05, using LSD test)*

First pod height from the surface

In the current study, the effects of Y, DT, and interaction DT × DI were significant on the first pod height from the surface. The highest means of this trait was observed in the first Y (21.18 cm) and DT in R1 (22.0 cm) (*Table 3*). Mean comparison of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29112929

interaction DT × DI showed the highest value of the trait was achieved in DT in R1 and DI in 100% (24.75 cm) (*Fig. 4*).

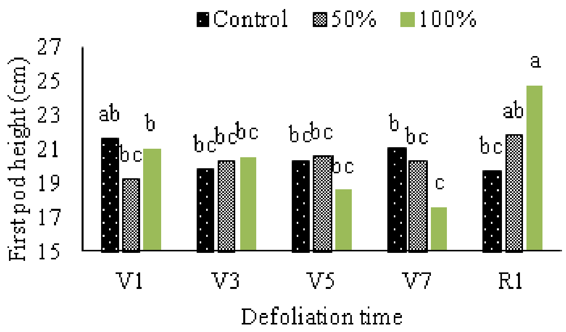

***Figure 4.** Effect of intensity (0, 50, and 100%) and time (V1, V3, V5, V7, and R1) of defoliation on first pods height from the surface (columns with different letters are significantly different at P = 0.05, using LSD test)*

Number of branches

The effects of Y, AA, DT, Y×A, and DT×DI was significant on number of lateral branches. Also, the effects of Y, DT, DI, Y×DI, and AA×DI were significant on number of main branches (*Table 3*). The highest number of lateral branch was observed DT in V3 under DI in 100% (6.93 no.). The lowest value of this trait was achieved in DT in R1 under DI in 100% (3.32 no.) (*Fig. 5A*). In the interaction DT × AA, the highest number of lateral branch was observed first Y under non-application of AA (6.98 no.) and the lowest value of this trait was observed in the second Y under non-application AA (4.15 no.) (*Fig. 5B*).

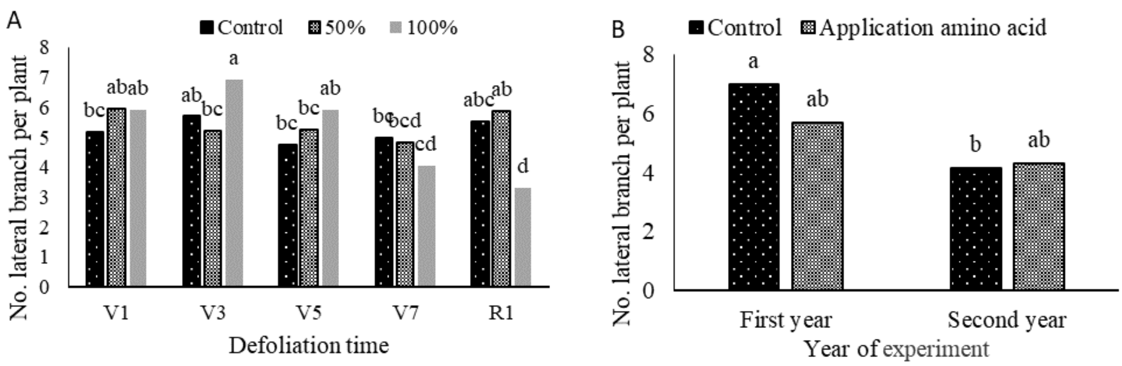

***Figure 5.** Effect of intensity (0, 50, and 100%) and time (V1, V3, V5, V7, and R1) of defoliation (A); and defoliation time (V1, V3, V5, V7, and R1) and amino acid (control and application) (B) on number of lateral branch per plant (columns with different letters are significantly different at P = 0.05, using LSD test)*

Number of the total pods

Results showed that the effect of Y, DT, and DI was significant on number of total pods (*Table 3*). The highest of the number of total pods was observed in the first Y

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29112929

(69.05 no.), DT in V1, V3, and V5 (64.8, 67.0, and 62.3 no., respectively), and DI in 50% (63.4 no.) (*Table 3*).

Number of pod free grain

The effects of Y and Y × AA was significant on number of pod free grain (*Table 4*). The highest number of pod free grain was observed in first Y (5.83 no.). In interaction Y × AA, the highest number of pods free grain was observed in the first Y under non-application and application of amino acid (4.97 and 6.69 no., respectively). The lowest value of the trait was achieved in the second Y under both amino acid treatments (*Fig. 6*).

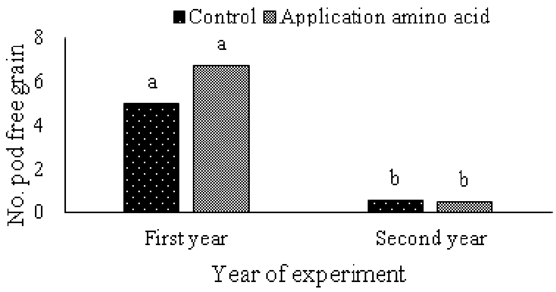

Figure 6. *Effect of the year (first and second) and amino acid (control and application) on number of pod free grain of soybean (columns with different letters are significantly different at P = 0.05, using LSD test)*

Grain number per plant

Results indicated that the effects of Y, DT, DI, and DT × DI was significant on grain number of soybean (*Table 4*). The first Y had superiority in term of grain number in compared to the second Y. Among the DT treatments, defoliation in the V1 growth stage had the highest grain number (152.2 no. per plant). By increasing defoliation intensity observed reduction the grain number per plant, so that the zero and 100% intensity of defoliation has the highest and lowest means of the trait (147.7 and 122.5 no per plant, respectively). In the interaction DT×DI, the highest grain number was achieved in V1 and V5 growth stages under 50% defoliation (164.7 and 163.5 no., respectively). The lowest value of the trait was observed in R1 growth stages under 100% defoliation (74.7 no.) (*Fig. 7*).

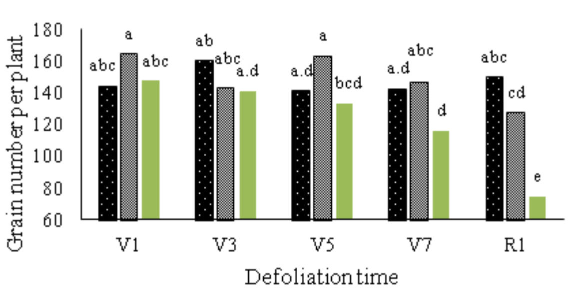

Figure 7. *Effect of intensity (0, 50, and 100%) and time (V1, V3, V5, V7, and R1) of defoliation on grain number of soybean (columns with different letters are significantly different at P = 0.05, using LSD test)*

100-grain weight

The effects of Y, AA, DT, DI, Y×AA, and Y×AA×DT×DI was significant on 100-grain weight (*Table 4*). In the first year (19.98 g), non-application of AA (20.01 g), defoliation in V1 growth stage (20 g), and control treatment of defoliation intensity (20.11 g) showed the highest mean of 100-grain weight (*Table 4*). In the quadruple

DOI: http://dx.doi.org/10.15666/aeer/1702_29112929

interaction, the highest 100-grain weight was observed in control DI in V3 growth stage under non-application of AA during the first year (20.8 g) and lowest was achieved in 100% defoliation of leaf in V5 growth stage under application of AA during the second year (18.58 g) (*Table 5*).

Biological yield

Results indicated that the effects of Y, AA, DT, DI, Y×DT, DT×DI, Y×DT×DI, and Y×AA×DT×DI were significant on biological yield (*Table 4*). The highest mean of biological yield was observed in the first Y (9698.3 $kg.ha^{-1}$), the application of AA (9070.5 $kg.ha^{-1}$). Also, defoliation in V1, V3, and V5 growth stages under intensity 0 and 50% showed the maximum biological yield (*Table 4*). In the quadruple interaction, the highest of biological yield was observed in the application of AA under defoliation in V1 with 50% intensity during the first year (11750 $kg.ha^{-1}$) and also, in the application of AA under defoliation in V5 with 50% intensity during the first year (11733.3 $kg.ha^{-1}$). Results indicated that the lowest mean of the trait was achieved in no-application of AA under 100% defoliation in the R1 growth stage during second Y (5225 $kg.ha^{-1}$) (*Table 5*).

Columns with different letters are significantly different at P = 0.05, using LSD test. The bold number showed the highest and lowest means of trait

Grain yield

The effects of Y, AA, DT, DI, Y×DT, DT×DI, Y×DT×DI, and Y×AA×DT×DI was significant on grain yield (*Table 4*). In the first Y (3233.8 kg.ha^{-1}), AA application (3145.1 kg.ha^{-1}), defoliation in V1 growth stage (3290.4 kg.ha^{-1}), and DI 0 and 50% (3299.9 and 3213.8 kg.ha^{-1}, respectively). In the quadruple interaction, the highest grain yield was observed in the application of AA under defoliation in V5 with 50% intensity during the first year (4040 kg.ha^{-1}). The lowest value of this trait was achieved in non-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1702_29112929

application of AA under 100% defoliation in R1 growth stage during both years of experiments (1585 and 1525 kg.ha^{-1}, respectively) (*Table 5*).

Harvest index

The effects of Y, AA, DT. DI, Y×DI, DT×DI were significant on harvest index (*Table 4*). The highest of harvest index was observed in the second Y (34.56%), AA application (34.73%), defoliation in V1 growth stage (35.4%), 0 and 50% defoliation intensity (34.85 and 34.80%, respectively) (*Table 4*). Interaction effect of DT×DI showed the highest mean of harvest index in defoliation in V1 and R1 growth stages under control intensity treatments (36.2 and 35.7%, respectively). The lowest value of the trait was observed in 100% defoliation during the R1 growth stage (29.7%) (*Fig. 8*).

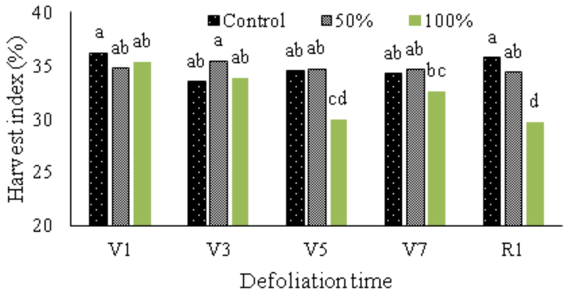

Figure 8. *Effect of intensity (0, 50, and 100%) and time (V1, V3, V5, V7, and R1) of defoliation on harvest index of soybean (columns with different letters are significantly different at P = 0.05, using LSD test)*

Grain oil content

Analysis of variance results showed that the effects of Y and Y×DT×DI were significant on oil percentage. Also, the effects of Y, AA, DT, DI, Y×AA, DT×DI, Y×AA×DT, Y×DT×DI, and Y×AA×DT×DI was significant on oil yield (*Table 6*). The highest grain oil yield was achieved in first Y (726.4 kg.ha^{-1}), AA application (689.7 kg.ha^{-1}), defoliation in the V3 growth stage (699.7 kg.ha^{-1}), and zero percentage of intensity defoliation (700.5 kg.ha^{-1}) (*Table 6*). In the quadruple interaction, the maximum grain oil yield was observed in 100% defoliation in V7 growth stage under AA application during the first-year experiment (978.5 kg.ha^{-1}). Also, the lowest value of the trait was observed in 100% defoliation in the V5 growth stage under non-application of AA during the second year (225.6 kg.ha^{-1}) (*Table 7*).
