In addition, the results of this study can be used as a preliminary study in the planning activities for the future basin planning, urban planning, water resources conservation and uses and the planning of nature conservation.

(Received 23rd Feb 2019; accepted 21st Mar 2019)

Abstract. Transplant density is an important factor which has impacts on rice growth and development in transplanted rice production system. Present study used three transplant densities in paddy field experiment and set as D1 (transplant spacing of 20 cm × 24 cm, about 2.085 hundred thousand hills for each hectare), D2 (transplant spacing of 20 cm × 20 cm, about 2.603 hundred thousand hills for each hectare) and D3 (transplant spacing of 20 cm × 16 cm, about 3.120 hundred thousand hills for each hectare). The results showed that high density (D3) not only reduced the net photosynthetic rate and *LAI* values at heading stage, but also decreased dry matter accumulation and transportation compared to D1 density. The highest yield was recorded in D1 density and the lowest yield was recorded in D3 density. Study also revealed that high density caused yield loss by decreasing the grain number and seed-setting rate. Furthermore, high density also increased chalk rice rate and chalkiness while reducing the amylose content. The activity of sucrose synthase (SS) in D3 was significantly lower than D1 and it might relate to the reduction of grain quality.
Keyword: *rice, density, yield, quality, net photosynthetic rate, dry matter accumulation and transportation*

Introduction

Rice (*Oryza sativa* L.) is a main crop which has been cultivated in China, its production plays an important role in Chinese food security. In recent years, because the area of arable lands is in rapid decline, how to maintain the rice productivity and promote the yield potential had been the main research direction for many experts in last decade (Tao et al., 2019; Tang et al., 2019). There are a lot of factors that could affect grain yield and quality of rice. For example, the transplant density is a key part which affects grain yield and quality significantly in rice production.

Rational close planting is one of the important strategies for high yield and good quality cultivation of rice. A suitable transplanted density not only could give full play to the strong tillering and self-regulation ability of rice population, reduce the competition of inter-row and inter-plant growth in rice population, and avoid the overgrowth of early growth, but also ensure that the rice field can make full use of light energy, carry out photosynthesis, accumulate more organic matter, thereby increasing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60696079

rice yield (Zhou et al., 2018; Huang et al., 2018; Tareq et al., 2018). In 2001, Yuan demonstrated that low plant density enlarged the growth space of above-ground and below-ground parts of rice, enlarges individual strength and panicle size, thus gaining high yield. The study of Hayashi et al. (2006) revealed that over-dense planting strengthens the competition of photosynthetic nutrients among rice individuals and promotes early flowering of rice. Furthermore, Mobasser et al. (2009) indicated that low density treatment could increase the conversion rate and output rate of stem and sheath substances and finally increased rice yield.

High yield and good quality of rice are the major goals in rice production and in transplanted rice production system, suitable transplant density is an important part to gain those two goals. Thus, we explored the process of photosynthesis, dry matter accumulation and transportation in order to study the response of super rice yield and quality under high transplant density in present study.

Materials and Methods

Plant materials and growing condition

A super hybrid rice variety, *Huahang31*, a well-known and widely grown in South China, were in planted during the late season (July-November) in 2010 and the early season (March-July) in 2011 at the College of Agriculture's Experimental Farm, South China Agricultural University (SCAU), Guangzhou, Guangdong Province, China (23°16' N, 113°23' E, elevation 11 m). The air temperature was shown in *Figure 1*.

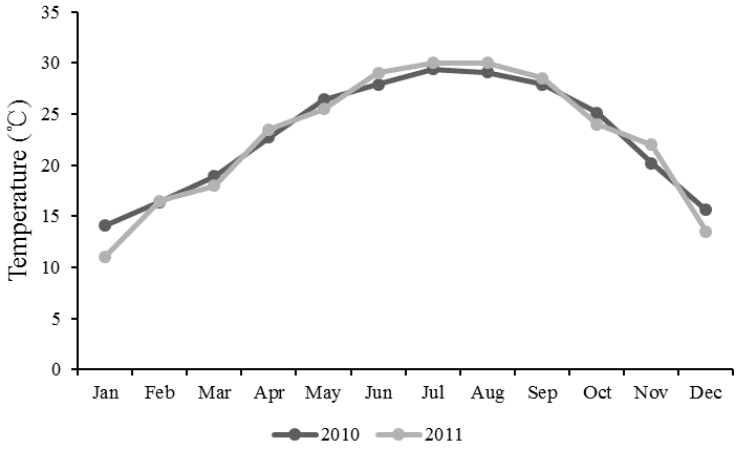

Figure 1. *Mean monthly air temperature in Guangzhou during 2010 and 2011 (Annual average temperature in 2010 was 22.81℃ and in 2011 was 22.63℃*

Before sowing, the seeds were soaked in water for 24 h, germinated in manual climatic box for the next 24 h, shade dried and the germinated seeds were sown in PVC trays for nursery raising. 15-day-old seedlings and 25-day-old seedlings were transplanted to the field in 2010 and 2011, respectively. The experimental soil has been planted rice for many years and it was sandy loam with of 16.80 g kg^{-1} organic matter content, 1.032 g kg^{-1} total N, 0.998 g kg^{-1} total P, 13.598 g kg^{-1} total K, 84.60 mg kg^{-1} available N, 43.58 mg kg^{-1} available P, and 106.10 mg kg^{-1} available K.

Treatments descriptions

Three transplanted densities were applied at the experiment and set as blow.

- D1: Seedlings were transplanted at the rate of 2 seedlings per hill at a spacing of 20cm × 24cm, about 0.2085 million hills per hectare.
- D2: Seedlings were transplanted at the rate of 2 seedlings per hill at a spacing of 20cm × 20cm, about 0.2505 million hills per hectare.
- D3: Seedlings were transplanted at the rate of 2 seedlings per hill at a spacing of 20cm × 16cm, about 0.3120 million hills per hectare.

Commercial compound fertilizer (Total nitrogen contents TN = 15%, K2O contents = 12%, P2O5 contents = 7.2%) was applied at the same amount of 1500 kg ha^{-1}. 80% of fertilizer was applied as basal and 20% was top-dressed at tillering stage.

Plant sampling and determination of biomass accumulation

At tillering stage, heading stage and maturity, the rice plants were harvested from fifteens hills in each plot. The leave, stems and grain were separated from the plants and dried Under the condition of 80ºC respectively in order to get the estimation of dry matter. The output rate of stem matter (OPRS) was calculated as:

$$\text{OPRS} = \frac{(\text{stem weight at heading stage} - \text{stem weight at maturity})}{\text{stem weight at heading stage}} \quad \text{(Eq.1)}$$

The conversion rate of stem matter (CRS) was calculated as:

$$\text{CRS} = \frac{(\text{stem weight at heading stage} - \text{stem weight at maturity})}{\text{grain weight at maturity}} \quad \text{(Eq.2)}$$

The fresh grains were separated and collected from the rice plants 7th day after heading stage, washed with double distilled water and stored Under the condition of -80ºC for the estimation of sucrose synthase (SS), soluble starch synthase (SSS) and Bound starch synthase (GBSS).

Determination of photosynthesis, SPAD and Leaf area index (LAI)

Portable photosynthesis system (LI-6400, LI-COR, USA) was used to determine net photosynthetic rate at 09:00–10:30 a.m. according to the standard method (Pan et al., 2016). SPAD meter 'SPAD-502' (Konica Minolta, Japan) was used for precise, rapid and non-destructive estimation of leaf chlorophyll contents. At tillering stage, heading stage and maturity, the rice plants were harvested from ten hills in each plot. The leaves were separated from main plants and the green leaves area was measured by a leaf area meter (CID-202, Lincoln, NE, USA) to determine the leaf area index (LAI).

Determination of activities of sucrose synthase (SS)

The activity of SS was measured according to the method described by Li et al. (2008). The activity of SS was determinate in both saturating and selective (limiting) conditions. The limiting assay consisted of the same reaction mixture except that 10 mmol L^{-1} Pi was added and the concentrations of uridine diphosphate glucose

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60696079

(UDPG), fructose, and glucose-6-P were reduced to 2, 2 and 10 mmol L^{-1}. The reaction was terminated by using 1 mol L^{-1} NaOH and the mixture was boiled to degrade any unreacted fructose-6-P. After cooling, 0.20 mL of 0.1% (w/v) resorcinol in 95% ethanol and 0.80 mL of 9 mmol L-1 HCl were added and the tubes were incubated at 80ºC for 10 min. Three separate extractions of grain powder were assayed for the activities of enzymes. The activities of SS were shown as specific activities (g^{-1} FW h^{-1}).

Determination of activities of soluble starch synthase (SSS) and granule-bound starch synthase (GBSS)

The activity of SSS and GBSS was determined by Nakamura and Yuki (1992). Twenty shelled grains of the same part were accurately weighed and placed in a pre-cooled mortar. The supernatant was extracted with 4 ml extract (containing 100 mmol L^{-1} Ph7.5 Hepes-NaOH buffer, 8 mmol L^{-1} $MgCl_2$ $6H_2O$, 2 mmol L^{-1} EDTA-Na2, 12.5% (v/v) glycerol, 1% (w/v) PVP-40, 50 mmolL^{-1} mercaptoethanol) by grinding in an ice bath. The supernatant was extracted by centrifugation at 12000 G for 30 min.

SSS activity determination: 1.5 ml centrifuge tube was taken and 20 ml crude enzyme solution was added in turn into 20 ml crude enzyme liquid, 36 μl reaction liquid A (containing 50 mmol L^{-1} pH7.4 Hepes-NaOH, Hepes-NaOH, 1.6 mmol L^{-1} ADPG, 0.7 mg amylose and 15 mmol L^{-1} DTT) was reacted at 30ºC for 20 minutes and then boiling water for 30 s to stopped reaction and ice bath cooled; 20 μl reaction liquid B (containing 50 mmol L^{-1} pH7.4 Hepes-NaOH, 4 mmol L^{-1} mmol L^{-1} $MgCl_2 6H_2O$ and 1.2 unit pyruvate kinase reacted at 30ºC for 20 minutes, then boiling water terminated the reaction for 30 seconds and centrifuged for 10000 g for 10 minutes. The supernatant was extracted at 60 μl and added to 43 μl reaction liquid C (containing 50 mmol L^{-1} pH7.4 Hepes-NaOH, 10 mmol L^{-1} glucose, 20 mmol L^{-1} $MgCl_2 6H_2O$, 2 mmol L^{-1} NADP, 1.4 unit hexokinase and 0.35 unit glucose-6-phosphate dehydrogenase) for 10 minutes. The absorbance at 340 nm was determined after reaction at 30ºC.

GBSS activity determination: The subsoil of SSS crude extract was washed twice with 1 ml extract and centrifuged for 20 minutes at 4ºC for 3000 g. Then the crude enzyme solution of GBSS was obtained by centrifuging the 3 ml extract at 4ºC for 24 hours and 12000 g at 2ºC for 30 minutes. A 1.5 ml centrifugal tube was used, 20 μl GBSS crude enzyme was added in turn, 36 μl reaction liquid A (containing 50 mmol L^{-1} pH7.4 Hepes-NaOH, 1.6 mmol L^{-1} ADPG, 15 mmol L^{-1} DTT), the other two reaction liquids and reaction process were the same as SSS determination.

Estimation of rice yield and related attributes

At maturity stage, the rice grains were harvested from ten unit sampling area (10.00 m^2) in each plot and then threshed by machine. The harvested grains were sundried and weighed in order to determinate the grain yield. Twenty hills of rice from different locations in each plot were sampled for estimating the average effective panicles number per hill. Then, three hills representative plants were taken for estimation of the yield related traits.

Estimation of grain quality

Dry grains were stored at room temperature for two months to determine grain quality attributes. About 1.00 kg rice grains from each treatment was taken from storage and brown rice rate was determined by rice huller (Jiangsu, China) while brown rice and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60696079

head rice rates were calculated by using a Jingmi testing rice grader (Zhejiang, China). Grains with chalkiness and chalkiness degree were determined using an SDE-A light box (Guangzhou, China) while an Infratec-1241 grain analyzer (FOSS-TECATOR) was used to measure the grain amylose and protein contents.

Statistical analysis

Data were analyzed by using statistical software 'Statistix 8.1'(Analytical Software, Tallahassee, FL, USA) while differences amongst means were separated by using least significant difference (LSD) test at 5% probability level. Graphical representation was conducted via Sigma Plot 14.0 (Systat Software Inc., California, USA).

Result

Yield and yield components

As shown in *Table 1*, transplant densities affected rice yield and its components differently. High density could significantly increase panicle number and the highest panicle number was recorded in D3 in both years. However, we observed that the lowest yield was recorded in D3 for 2010 and 2011 and the yield in D3 was significantly lower than D1. The decrement of yield was due to the reduction in both grains number and seed setting rate. Compared to D1, D3 treatment remarkably reduced seed setting rate and grain number. Moreover, there was no significant difference among D1, D2 and D3 in 1000-grain weight.

Table 1. *Effect of transplant densities on rice yield and its components*

Grain quality and its attributes

As shown in *Table 2*, there was no significant difference among D1, D2 and D3 in both brown rice rate and head rice rate. However, compared to D1 treatment, D2 and D3 treatments significant increased chalky rice rate in 2010 and 2011. D3 treatment also

DOI: http://dx.doi.org/10.15666/aeer/1703_60696079

increased chalkiness remarkably for both years. Furthermore, the lower amylose content was recorded in D3 than D1 for 2010 and 2011.

Net photosynthetic rate, LAI and SPAD values

The difference in transplant density could significantly affect rice photosynthesis (*Figure 2*). At tillering stage, heading stage and maturity in 2010, the net photosynthetic rate in D3 was significantly lower than D1 whilst in 2011, only at heading stage the net photosynthetic rate in D3 was remarkably lower than D1. Compared to D1, D3 treatment significantly decreased *LAI* values at heading stage for both years. Furthermore, we observed that the SPAD values in D2 and D3 were remarkably lower than D1 at heading stage and maturity in 2010. However, in 2011, there was no significant difference among D1, D2 and D3 in all growth stages.

Dry matter accumulation and transportation

As shown in *Table 3*, different densities affected dry matter weight differently. At tillering stage, D3 density significantly decreased leaf weight and stem weight compared to D1 in 2010. The leaf weight, stem weight and grain weight at both heading stage and maturity in D3 were remarkably lower than D1 for 2010 and 2011. Furthermore, we observed that high density (D3) had negative impact on transportation of stem matter while the lowest OPRS and CRS were also recorded in D3 treatments for both years while there was no significant difference between D1 and D2.

Enzymes involved sucrose biosynthesis

As shown in *Figure 3*, different densities affected sucrose biosynthesis in grain in terms of SS, SSS and GBSS activities. For SS activity, D3 and D2 had lower acidity than D1 in 2010 while the trend in 2011 was recorded as: D1 > D2 >D3. Compared to D1, D3 treatment also significant decreased the GBSS and SSS activity in 2010 whilst in 2011, there was no significant difference among D1, D2 and D3 in both GBSS and SSS activity.

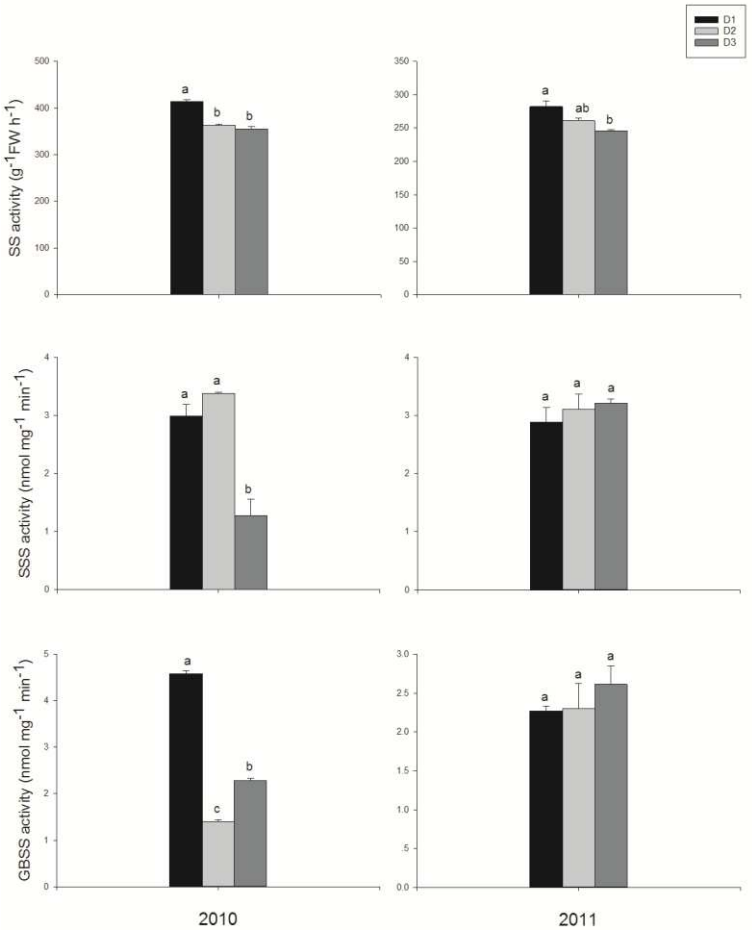

Figure 3. *Effect of transplant densities on SS, SSS and GBSS activity*

Discussion

A suitable plant density is one of the decisive factors for harvesting higher grain yield in rice production (Peng et al., 2018; Lee et al., 2018). Normally, the transplant density determines the competition of nutrients such as photosynthesis and fertilizer uptake among rice individuals in the middle and late growth stages among different rice individuals. In our study, we observed that compared to D1, D2 density significantly decreased rice yield in 2010 but there was no difference between D1 and D2. The D3 density remarkably reduced yield by decreasing the grain number and seed setting rate in both years. Present study showed that high density was able to significantly increase panicle number in paddy field, but it would also have negative impacts on other yield components and then still cause the yield loss without yield increment. Similar result was also reported by Zhao (2011) who demonstrated that the yield of surper rice, *Y-liangyou 302*, was mainly affected by panicles and spikelets per panicle, while the spike length and 1000-grain weight did not showed any significant influence on yield and high nitrogen and low planting density is conducive to increase the yield of rice variety *Y-liangyou 302* in north region of Guangxi. The further reason in reduction of yield might be the increment in competition for photosynthesis among rice individuals under high density. Present study showed that D3 treatment not only decreased the net

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60696079

photosynthetic rate, but also reduced the *LAI* values. Leaf area index (*LAI*) is an important parameter in crop growth status monitoring and yield forecasting (Xue and Wang, 2004). Normally, the values of *LAI* and net photosynthetic rate represent the intensity of population photosynthesis. In our study, the result indicated that the lower population photosynthesis under high density induced the decrement in dry matter accumulation and inadequate supply of dry matter eventually led to a decline in production. Our finding was also consistent with the research of Sultana et al. (2001) who indicated that dry matter accumulation was an important factor in determining rice yield.

Furthermore, worse grain quality was recorded in D3 treatment than D1. Present study revealed that not only D2 and D3 densities would increase both chalky rice rate and chalkiness, but also D3 density would significantly decreased amylose content. The increment in chalkiness and chalky rice rate might be due to the decrement of net photosynthetic rate at heading stage and the matter transportation from stem to grain. The study of Mo et al. (2015) showed that photosynthesis during the filling stage might had a great impact on grain chalkiness of rice. In 2015, the study of Zhou et al. (2015) found that there was a positive correlation among low amylose content, high degree of endosperm chalkiness and percentage of grains with chalkiness in grain and similar conditions were also observed in our study. The lower amylose content in D3 than D1 could be explained by the reduction in SS activity. Moreover, lower OPRS, CRS and net photosynthetic rate in heading stage also could be responsible for amylose content decrement.

Conclusion

Present study showed that high transplanted reduced the rice photosynthesism decreased the dry matter accumulation and transportation and finally caused the loss of grain yield. For revealing the mechanism of rice yield and quality formation by transplant density treatments, much work should be done at molecular and physiological level at the field trials.

Abstract. Microbial proteolytic enzymes are used to hydrolyze proteins in various bio-industrial applications but most of the enzymes are not active in extreme temperature conditions, pH and salt concentrations. This increases the demand to explore enzymes to show activity at such extreme environments. Exciting findings have been described about the extremophilic bacteria isolated first time from coal mines of Orakzai Agency, Pakistan, having protease producing properties. Among various extracted isolates, ~6 isolates were purified based on showing proteolytic activity using 2% skim milk agar media at 37 °C for 24 hrs, to identify various morphological and biochemical characteristics. The isolate, IBC-2 showed maximum zonal activity (21 mm) and was identified as *Pseudomonas aeruginosa* (JCM 5962) using 16S rRNA gene sequencing. The strain IBC-2 exhibited significantly ($P \leq 0.05$) maximum growth and protease production (335 U/ml) at 37 °C and at pH 7 after 24 hrs of incubation. The strain was also significantly ($P \leq 0.05$) more active for protease production at neutral pH (435 U/ml) than at high or low pH, reflected neutral nature of the bacteria. In conclusion, the strain IBC-2 has highest protease producing ability with distinctiveness, which can be used for wide range bio-industrial applications.

Introduction

Microbial proteases are widely used for various physiological and biochemical purposes in a variety of industrial applications worldwide. Proteases having proteolytic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60816093

nature, catalyze the breakdown of peptide bonds between amino acids forming proteins (Rawlings and Barrett, 2013). The overwhelming importance of proteases is due to substrate specificity, active site, catalytic mechanism and stability (Maurer, 2004). Owing to various industrial applications, proteases have marked contribution among global enzyme market (Maurer, 2004).

Commercially, protease has many applications in leather, food and pharmaceutical industries as well as also used for bioremediation purposes (Jellouli et al., 2009; Kirk et al., 2002). Two third of the commercial proteases have been collected from microbial sources (Gupta et al., 2002). Commercial proteases are mostly obtained from bacterial origin and there are copious bacterial strains having protease producing potential, such as *Flavobacterium clostridium, Achromobacter, Actinomyces species, Staphylococcus aureas and Thermoactinomyces including Pseudomonas aurigenosa* (Prakasham et al., 2006). Bacterial proteases are usually preferred source over other sources like plant and animal on the basis of fast-growing nature as well as require minimum space for culturing. Moreover, they can be easily modified genetically for large scale purification compared to plants and animals, in order to get new enzymes with assorted characteristics (Gupta et al., 2002).

Currently, very limited (1-2%) microbes have been explored having commercial importance including extremophiles as well. Extremophiles can significantly tolerate a wide range of environmental conditions like high or low temperature (-2-121 °C), acidic and basic pH, high saline stress, a wide range of radiation as well as unusual conditions such as drought and nutrients limitations (Gomes and Steiner, 2004; Jadhav et al., 2013). In present time, researcher have focused their keen interest to investigate microbes of novel extremophile characteristics having distinctive adaptation and products that further used in stern industrial conditions. Therefore, microbes of such extreme environments need to be targeted and to be screened for novel extremozymes activities.

Coal mines are among those sources that can provides such acid-tolerant and obligate acidophilic extremophiles bacteria (Johnson and McGinness, 1991) and have greater odds to explore novel species in such hostile environments (Roohi et al., 2014). Interestingly, our lab also reported some novel halotolerant bacterial strains from salt mines of Karak (Pakistan) that have significant potential to produce both protease and amylase enzymes (Ali et al., 2016; Shah et al., 2017). Therefore, this further increased our incessant curiosity for exploring cheap microbial source of extremozymes in coal mines.

Materials and methods

Sampling and isolation of bacterial strains

The coal samples (500 g) were collected from the coal mines of Feroz Khel (33.885652°N 71.187346°E); located in Orakzai Agency, Kyber Pakhtunkhwa, Pakistan in sterilized plastic boxes and transported to laboratory (Department of Microbiology, KUST Kohat) for further processing. Before isolation, entire samples of coal were crushed using a clean & sterilized grinder and powdered samples were serially diluted to 10−3, 10−6 and 10−9 working solutions in sterilized autoclaved distilled water. The dilutions were cultured on nutrient agar plates using pour-plate technique. The colonies having contrasting culture features (n = 62) were sub cultured by frequent streaking at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60816093

same conditions to acquire pure colonies or isolates (Jamal et al., 2016; Roohi et al., 2012).

Screening and identification of proteolytic isolates

Pure isolates (n = 6) were observed for proteolytic activities using 2% skim milk (SM) agar media incubated at 37 °C for 24 hrs (Xiong et al., 2007) following Bergey's manual of systematic bacteriology for morphological and biochemical properties (Buchanan and Gibbons, 1974). Despite of producing larger proteolytic inhibitory zone and other differences like shape and color of colony, the zone of the IBC-2 was very clear comparative to IBC-5 (little turbid) which makes IBC-2 a best choice for our onward analysis (*Table 1; Figs. 1* and *S1*). Moreover, 16S rRNA sequence analysis was performed for further recognition of the chosen IBC-2 strain(s). Genomic DNA was extracted from IBC-2 strain(s) using phenol/chloroform method (Ali et al., 2016) and was amplified against 16S rRNA universal primer; 9F (5′-GA GT TT GA TC CT GG CT CA G-3′) and 1510R (5′-GG CT AC CT TG TT AC GA-3′) using DreamTaq™ Green PCR Master Mix (2X) (Thermo Scientific™) as described by Ali et al. (2016). The thermocycler (Veriti™ Applied Biosystems, Foster City, CA, USA) conditions were; a single cycle of initial denaturation (96 °C for 5 min), followed by 25 cycles (95 °C for 45 s, 52 °C for 45 s and 72 °C for 90 s), while the final elongation phase was performed at 72 °C for 10 min. The PCR amplified product of IBC-2 strain(s) was confirmed on 2% agarose gel followed by sequencing from Macrogen Lab, South Korea (http://dna.macrogen.com/eng/index.jsp). The bacterial strain (IBC-2) was BLAST on the server EZ-Biocloud (EZ-Taxon) in order to find out nomenclature (Yoon et al., 2017), whereas the phylogenetic tree was constructed using bioinformatics software MEGA 6.0 (Molecular Evolutionary Genetics Analysis version 6.0) (Tamura et al., 2013).

Partial purification and quantification of protease enzyme

For partial purification of protease enzyme, 1 ml of fresh inoculum was added to 2% SM broth media and was subjected to incubation at 37 °C for 36 hrs using shaking incubator. The cellular enzymes were partially purified by centrifugation of culture for 20 min at 4 °C for 4000g using filter injection (22 µ). Furthermore, ammonium sulphate (70% w/v) precipitation of enzymes was performed from supernatant overnight at 4 °C in a shaking incubator followed by centrifugation (4000g) at 4 °C. The pellets were dissolved in sterile water that were tested for their proteolytic activity (Nadeem et al., 2007).

Moreover, for protease quantification, a modified assay described by Nadeem et al. (2007) was used. Briefly, 1 ml (2% w/v) of the substrate casein (0.05 M glycine-NaOH pH 10) and 1 ml of crude enzyme were incubated at 40 °C for 20 min. The reaction was stopped by adding 3 ml of 10% (w/v) trichloro acetic acid (TCA) at room temperature for 30 min followed by centrifugation (100g) for 10 min at 4 °C. Afterwards, 0.5 ml supernatant was taken and dissolved in 4.5 ml of 0.05 M glycine-NaOH buffer (pH 10) and the absorbance were checked spectrophotometrically (UV-VIS 1800, Shimadzu, Kyoto, Japan) at 280 nm. The calibration curve was plotted using tyrosine (CAS number 60-18-4, Sigma Aldrich, USA) as standard on increasing concentrations of tyrosine such as 1, 2, 3, 4, 5 and 6 µg dissolved in 0.05 M glycine-NaOH buffer. One

Electrophoretic protease separation

Molecular weight of the protease was determined using SDS-PAGE (12%) as depicted by Laemmli (1970). The protease enzyme (partially purified) was assorted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60816093

with loading dye (0.5 M Tris–HCl pH 8.0, SDS 10% (w/v), glycerol 6% (v/v), 2-β-marcaptoethanol and bromophenol blue 0.3% (v/v) after heating at 95 °C for 5 min. The crude protease was resolved with Pre-stained PageRuler™ Protein Ladder 10–180 KDa (Thermo Fisher Scientific™, Rockford, IL, USA) at 120 V for 2-2.5 hrs using Bio-Rad Mini Gel apparatus (Bio-Rad, Hercules, CA, USA). After resolving, SDS-PAGE, gel was stained by Coomassie Brilliant Blue (R-250) and proteins (protease enzyme) bands patterns were observed using white light apparatus.

Growth optimization

The isolate IBC-2 had been further optimized for its growth and protease production at varying physical factors. Pure inoculum (1 ml) of IBC-2 strain(s) was grown in Lauria-Bertani (LB) culture media (50 ml) under different incubation temperatures such as 20, 37, 50 and 60 °C using discrete media pH like 4, 5, 7, 9 and 11. After 24 hrs incubation, optimum growth of bacteria and protease production was calculated at 600 nm and the protease production was measured as per assay procedure (Ali et al., 2016).

Statistical analysis

All tests were carried out in replicates (n = 3) and statistically analyzed using SPSS v.21 (IBM SPSS Inc., Chicago, IL, USA). The results were taken in means and standard error (SE), while Tukey's honest significant difference (HSD) post hoc test were applied using ANOVAs.

Results

Identification and proteolytic potential of IBC-2 bacterial strain

In current study, a total of sixty-two (n = 62) bacterial strains were isolated, first time from coal mines of Orakzai Agency. Among them, thirty-three (n = 33) exhibit proteolytic zones (11-15 mm) but six (n = 6) out of thirty-three (n = 33) had a great potential of producing inhibitory zone with more than 15 mm (*Table 1*) (Sharmin et al., 2005). All the selected six isolates were further analyzed through biochemical and morphological identity (*Tables 1* and *2; Fig. 1*) for tentative identification. Because of largest and clear inhibitory zone, the isolate IBC-2 was with rod shaped, gram negative and showed positive tests for oxidase, catalase and gelatinase that was tentatively acknowledged as *Pseudomonas* (*Tables 1* and *2; Fig. 1*) and was selected to analysed further for their proteolytic optimization and molecular identification of the strain.

Molecular and phylogenetic analysis of isolate IBC-2

The isolate regarding IBC-2, were further evaluated at molecular level (*Fig. 2*). DNA extracted from IBC-2 isolate was amplified with 16S rRNA specific marker from EZ-Taxon server, bearing 99% sequence similarity with Pseudomonas aeruginosa JCM 5962(T) with accession number BAMA01000316. Moreover, phylogenetic tree demonstrated that IBC-2 strain is closely allied with Pseudomonas aeruginosa JCM 5962(T) as illustrated in *Figure 3*. The phylogenetic analysis involved 63 nucleotide sequences that targets 990 positions and data with gaps were removed after alignment by CLUXTAL X.

Table 2. *Tentative identification of the selected isolates (n = 6) on the basis of gram staining and different biochemical tests*

Bacterial isolates	Gram staining/shape	Oxidase	Catalase	Citralase	Sugar fermenter	Gas formation	H_2S formation	Motility test	Indole test	Urease test	Tentative identification (genus)
IBC-1	Gram -ve rod shape	+	+	+	+	+	-	+	-	-	*Pseudomonas spp.*
IBC-2	Gram -ve rod shape	+	+	+	+	+	-	+	-	-	*Pseudomonas spp.*
IBC-5	Gram -ve rod shape	+	+	+	+	+	-	+	-	-	*Pseudomonas spp.*
IBC-6	Gram +ve rod shape	-	+	+	-	+	-	+	-	+	*Bacillus spp.*
IBC-7	Gram -ve rod shape	+	+	+	+	+	-	+	+	+	*Proteobacteria spp.*
IBC-10	Gram +ve cocci	-	+	-	+	+	-	-	-	+	*Staphylococcus spp.*

Enzymatic activity and SDS-PAGE analysis of protease enzyme

The enzymatic activities of partially purified enzymes from all six (n = 6) bacterial isolate were spectrophotometrically performed. Among these, the isolate IBC-2 showed significantly higher proteolytic activity (300 U/ml) compared to other isolates (*Fig. 4*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60816093

Moreover, all isolates were further resolved using polyacrylamide/bis-acrylamide (SDS-PAGE) and confirmed that the isolate IBC-2 belongs from Pseudomonas aeruginosa (30-50 KDa; *Fig. 5*) as per reported literature (Aqel et al., 2009; Dutta and Banerjee, 2006; Raj et al., 2012; Sevinc and Demirkan, 2011; Zambare et al., 2010).

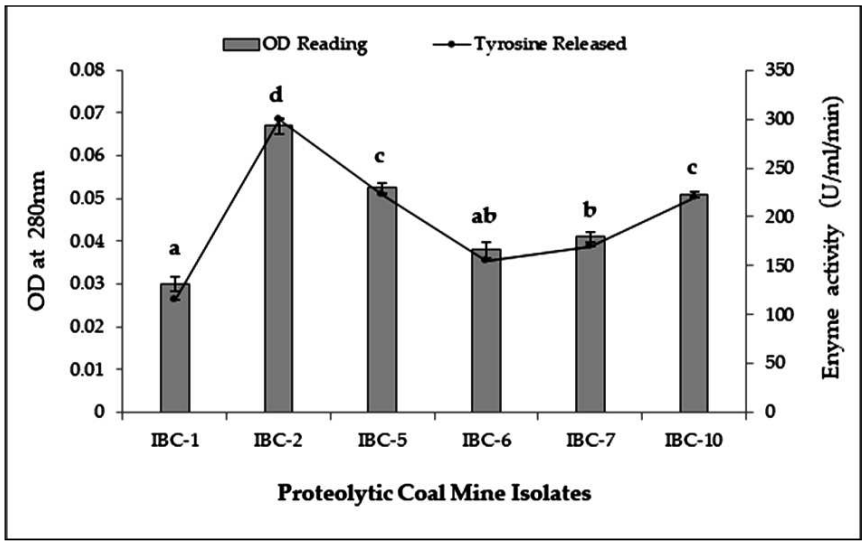

Figure 4. *Enzyme quantification of the six (IBC 1, 2, 5, 6, 7 and 10) proteolytic coal mine isolates. Data shown in bars represents mean OD of replicates (n = 3). Figure 5. *SDS-PAGE gel analysis of partially purified protease enzymes extracted from different isolates of coal bacteria*

Growth optimization and protease production of selected IBC-2 isolates

The optimum growth factors (temperature and pH) were calculated for the selected IBC-2 isolates using varying degree of temperature (20, 37, 50 and 60 °C) and pH (4-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60816093

11) in order to find out optimum bacterial growth and protease production using similar conditions in each case. Among the isolated bacterial stains, IBC-2 showed highest growth concentration at 37 °C at 600 nm after 24 hrs of incubation. Incubation at dissimilar temperatures notably affects the growth as well as protease production of the bacteria and in our study and maximum protease production (335 U/ml) was recorded at 37 °C while at temperatures lower or higher than 37 °C, low growth and lesser protease production was observed (*Fig. 6*).

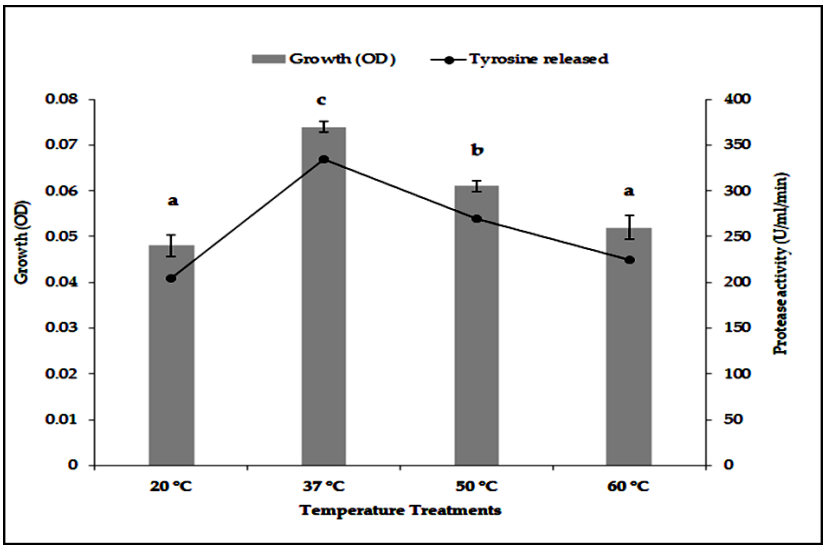

Figure 6. *Pseudomonas aeruginosa strain IBC-2 growth and protease production optimization at different incubation temperatures. Bars and line dots illustrate mean values of replicates ± standard error (n = 3). Different alphabetical letters represent statistically significant differences (based on ANOVA) at different temperature treatments according to Tukey's HSD post-hoc test (P ≤ 0.05)*

Similarly, to find out the pH effects, incubation was performed at 37 °C using different pH conditions (pH4-11). It was observed that the isolate IBC-2 favoured a pH of 7, giving optimum bacterial growth as well as significant protease production (435 U/ml). The protease production was found substantially higher than protease produced at either acidic pH (4 and 5) or alkaline pH (9 and 11) as shown in *Figure 7*. Therefore, it was concluded that IBC-2 gives best growth and maximum protease production at 37 °C while keeping the media pH neutral i.e. pH 7.

Discussion

Proteases have a wide range of commercial applications, including leather industries, food confectionaries and pharmaceuticals as well as also used in bioremediation processes (Jellouli et al., 2009; Kirk et al., 2002). Moreover, microbes, especially bacteria are among the easiest and cheapest source of proteases. On this regard, the coal mines of Orakzai Agency were screened for the isolation of commercially valuable bacteria. In our study, 33 bacterial isolates were found to have protease producing ability among total (n = 62) isolated bacterial strains. Moreover, among these 33 isolates, only 6 isolates had greater potential of casein hydrolyzing using skim milk agar

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60816093

by producing larger zones (above 15 mm) as shown in *Tables 1* and *2*. Usually, various components such as caseins, gelatine and proteins are not utilized by bacteria, because these cannot penetrate into bacterial cell wall. This reveals the importance of extracellular proteases to solubilize the proteins and other components. The formation of zones on media containing proteins has been revealed in several scientific reports, showed that protease is usually excreted from microbial sources (Ali et al., 2016; Rajeeva et al., 2015).

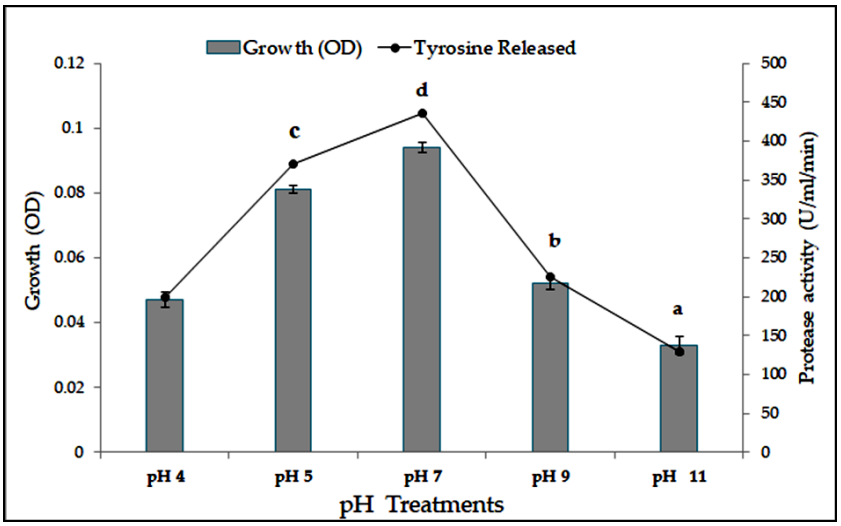

Figure 7. *Pseudomonas aeruginosa strain IBC-2 growth and protease production optimization at different pH culture conditions. Bars and line dots illustrate mean values of replicates ± standard error (n = 3). Different alphabetical letters represent statistically significant differences (based on ANOVA) at different pH treatments according to Tukey's HSD post-hoc test ($P \leq 0.05$)*

The studies for morphological characteristics of selected bacterial isolates (n = 6) showed differences in colony size, shape and color (*Table 2*) reflecting the bacterial diversity in coal mines. Furthermore, these characteristics revealed that the isolated bacteria might belong to *Bacillus, Pseudomonas, Arthrobacter, Brachybacterium* and *Staphylococcus* genus. Previously, these methods found standard for identification of various microbial species such as *Bacillus, Staphylococcus* and *Pseudomonas* spp. on the basis of morphology and different biochemical tests (Jamal et al., 2016; Jasuja et al., 2013; Roohi et al., 2014; Sethy and Behera, 2012). Although morphological and biochemical screening reveals initial microbial identification, but molecular methods such as 16S rRNA, provides precise identification of microbes (Wei Wang, 2009). In our study, the presence of *Pseudomonas aeruginosa* strain IBC-2 was first time reported as coal mine dwelling species and since very little studies have been conducted on coal mines micro flora regarding isolation of *Pseudomonas* species to be used for protease production.

Partial purification of protease from crude extract is possible by ammonium sulphate precipitation and this method is widely used for enzymes purifications (Yossan et al., 2006). As shown in *Figure 1*, all the selected six isolated strains showed clear zones on SM agar media and revealed protease activity. The protease purified from the selected isolated stain(s) were functional and effective after purification and parallel findings

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60816093

were also revealed by Josephine et al. from different *Bacillus* sp., where the samples were collected from soil (Rajeeva et al., 2015). Among the six isolates, IBC-2 apparently revealed high protease productions and protease activity (300 U/ml/24 hrs). Analogous to our findings, maximum protease production (432 U/ml/24 hrs) was reported from *Pseudomonas aeruginosa* (Arioleand and Ilega, 2013), including *Pseudomonas aeruginosa* strain RGSS-09 as well (Rajeeva et al., 2015).

In our analysis, additional confirmation of crude purified enzymes (34-45 KDa) was performed using SDS PAGE for all selected isolates. SDS-PAGE was performed for separation of proteins and protease were found in range of 17 to 60 KDa, which is reported range for proteases (Yossan et al., 2006). Moreover, many *Pseudomonas* species showed specific molecular weights of proteases ranging from 35-50 KDa (Raj et al., 2012). In correlation to our results, a couple of study reported the molecular weight regarding protease enzymes were in the range of 30-52 KDa from various *Bacillus* sp (HS08A, HUTBS71) (Aqel et al., 2009; Dutta and Banerjee, 2006; Sevinc and Demirkan, 2011; Zambare et al., 2010).

Enzymatic activities and growth of microorganisms are significantly ($P \leq 0.05$) correlated with various incubation temperatures and has shown prominent effects on secretion of extracellular proteolytic enzymes using various microbes (Balaji et al., 2012). Similarly, IBC-2 strain significantly ($P \leq 0.05$) revealed that dense bacterial growth occurs at 37 °C when incubated for 24 hrs (*Fig. 6*). This inferred the direct relationship of bacterial growth with protease production. Different researchers worked on proteases and reported the relationship between protease production and bacterial growth under different laboratory conditions such as temperature, media and pH (Ali et al., 2016; Shah et al., 2017; Zambare et al., 2010). The optimum temperature for protease production was reported as 30 °C produced by an extremophilic *Bacillus sp* (MIG) isolated from marine water (Mohapatra et al., 2003). The specific protease producing bacteria (e.g. *Bacillus spp.)* was reported to have different range of optimum temperatures such as 35 °C (Gerze et al., 2005), 40 °C (Josephine et al., 2012), 50 °C (Anwar and Saleemuddin, 2000) and 70 °C (Sookkheo et al., 2000; Morya and Yadav, 2010). An increase in the production of protease was reported when temperature was increased up to 37 °C for *Pseudomonas sp.* from abattoir soil has been reported by Kalaiarsi and Sunitha (2009) and Akujobi et al. (2012), respectively. The decrease in protease production beyond 37 °C reported by these researchers has supported our results and it has been reported that optimum temperature has key role in the production of protease. In similar fashion, time of incubation is also important to have high protease production and it varies for different microorganisms (Mukesh Kumar et al., 2012).

Like temperature, optimum pH also contributes to protease expression and activity. In this study, protease production was observed at pH range 4-11 and bacterial growth is reported in high amount at neutral pH 7 for IBC-2 (*Fig. 7*). In similar approach, Ravishankar et al. (2012) reported high production and enzyme activity of *Bacillus subtilis* AKR3 up to pH 7 and has been found declined beyond the pH from 9-11. Supporting our work, the optimum pH 7 and temperature 37 °C was also previously reported for protease production of *Pseudomonas aeruginosa* (Raj et al., 2012). In case of *Bacillus subtilis* strain reported by Ali et al. (2016), pH 10 was the optimum pH for high protease production. These findings revealed that different bacteria need different conditions as most favourable. The bacteria under study have shown high protease

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60816093

activity at temperature 37 °C and pH 7, which are the most suitable conditions for broad range of bio-industrial applications (Grbavcic et al., 2011; Najafi et al., 2005).

Conclusion

Finally, our finding is the first inveterate report from coal mines of Orakzai Agency that investigated protease producing bacteria. Based on morphological, biochemical and 16S rRNA sequencing, and the bacteria with high protease activity; IBC-2 strain was identified as *Pseudomonas aeruginosa*. The highest protease activity was observed at temperature 37 °C and pH 7 which makes the bacteria as the better producer at conditions favoured/used in most of the bio-industrial applications. Moreover, natural resources need to be further explored in an attempt to find out novel bacterial strain(s), with an exceptional capability of surviving and maintain their hydrolytic activity within harsh condition in order to overcome the bio-industrial problems.

Abstract. Sugarcane is the largest sugar crop in China and the world, and one of the important commercial crops in southern China. However, the influence of sugarcane lodging is more and more serious with increasing cane yield. After lodging, the plant growth and sugar accumulation in stalk was seriously affected, resulting in considerable losses in cane and sugar yield, and difficulty in machine operation in the field. At present, there is no perfect evaluation method for sugarcane lodging, and little has been done on research of related physiological and biochemical indexes, microscopic structures and so on although there have been some reports on the effects of sugarcane lodging. But there has been a lot of research on lodging in rice, corn and wheat, which could be referred for studying the resistance mechanism and evaluation method in sugarcane.
Keywords: *lodging resistance, agronomic character, yield, sugar content, lignin, cellulose*

Introduction

Guangxi Province had been ranking the first in sugarcane planting area, cane and sugar production, and economic benefit in China (Ye et al., 2016; Li, 2010). With tall plant and large biomass above ground, at the late elongation and maturation stages after October, the plant height of sugarcane exceeds 300 cm, the higher the plant is, the greater the risk of lodging meets (Li et al., 2018a). After lodging, the cane yield and sugar content was declined, the photosynthesis, water metabolism, mineral absorption and conversion in plants, and mechanical and hand harvesting were also affected. The relationships between lodging and lignin, cellulose and microscopic structure were closely correlated.

Cause of lodging

Lodging is the phenomenon that crop stem changes from natural upright state to permanent dislocation. Wind and rain were the direct induction factor for lodging. In addition, environmental factors and cultivation measures also played a role in lodging (Merugumala et al., 2019; Ishimaru et al., 2008). According to the occurrence location, lodging was generally divided into two types: root lodging and stem lodging (Tian et al., 2016). Root lodging referred to whole-plant falling down when the load above ground exceeds the misspecified strength of the root system, and stem lodging referred

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60956105

to base stem breaks when the load on the upper part of the stem exceeds the mechanical support power of the base stem (Mizuno et al., 2018; Mulsanti, et al., 2018). For rice, stem lodging occurs frequently because the mechanical strength of the stem was weakened due to the weak base of the stem and the underdeveloped mechanical tissue (Sowadan et al., 2018; Li, 2012).

Effect of lodging on agronomic characters

The lodging of sugarcane was affected by the number of leaves, planting furrow depth, planting density, row spacing and other factors (Singkham et al., 2016). Park et al. (2005) and Cock et al. (1997) found that the relationship between the number of sugarcane leaves and sugarcane yield and lodging was closely related. The results showed that the lodging of sugarcane decreased after removing leaves due to the reduction of wind area, and the lodging of sugarcane decreased with the decline of sugarcane leaves. Meanwhile, each sugarcane plant remaining 4 to 6 leaves could ensure yield and effectively reduce lodging. Berding et al. (2005) conducted a comparative experiment on sugarcane planting with different planting depths and varieties. The results showed that the lodging of sugarcane was less when the row spacing was at 260 mm, the sugarcane was prone to lodging when the row spacing was at 120 mm, and there was less lodging in Q152 than Q187 and Q174. Babu et al. (2010) conducted an experiment to study on the relationship between hardness of sugarcane peel and lodging, and the results showed that sugarcane with high hardness of sugarcane peel was not easy to get lodging. By adding silicon fertilizer, the hardness of sugarcane epidermis could be effectively strengthened, so that the stalk could obtain good supporting force and the lodging rate could be reduced (Brienzo et al., 2014). Loganandhan et al. (2013) conducted a comparative experiment on planting depth and earth-up condition of sugarcane, and the results showed that deep planting could reduce lodging of sugarcane. Sugarcane was not prone to lodging when the number of seedcane buds and millable stems were controlled (Neto et al., 2018). Chiluwal et al. (2018) found that it was useful for improving the lodging resistance when the planting row spacing was more than 1 m.

Effect of lodging on cane yield

Different degrees of lodging had different effects on sugarcane growth. For slightly inclined and semi-inclined sugarcane, their growth have been affected because the plant head was loosened and some sugarcane roots are broken, the sugarcane plants have to grow in bending (Heerden et al., 2014; Singh et al., 2002). For inclined and lodging sugarcane, their stem tips grow upward because sugarcane plants strive for gaining more sunlight, so that the meristematic tissue outside the region of growth on the sugarcane node proliferates rapidly, resulting in tender, fragile, bending and easy-broken outer parts (Paraskevopoulos et al., 2016). The serious lodging causes the sugarcane plant to turn over, break or stop growing. If things go on liked this, the sugarcane stem would become dry. Moreover, rats liked to nest in the sugarcane bushes and steal sugarcane in large quantities. In addition, it was hard to conduct field management after sugarcane lodging, so the early lodging not only caused losses at that time, but also affected the later growth and reduces the cane yield due to the failure to fertilize and control pests such as aphids (Yang et al., 2016). Even worse, the perennial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60956105

root of sugarcane could not be reserved for the next year after lodging due to root breakage, stool turnover, heavy damage in sugarcane stool, excessive nutrient consumption and rotten sugarcane stool with many germs, most sugarcane stools remaining perennial roots for the next year would have no buds to sprout, which resulted in plant deficiency and yield reduction in the ratoon crops (Shanmuganathan, et al., 2017).

Effect of lodging on sucrose content

The growth of sugarcane would be inhibited in root and tip after lodging, and sugarcane plants would be stacked together to give out heat. Together with sufficient water after rain, the root region of sugarcane stem germinated into air roots and lateral buds germinate (Jacobsen et al., 2015). Furthermore, the part above ground was exposed after lodging. When the sun shined directly, soil temperature would increase, resulting in the increase of ineffective tillers in later stage, nutrient consumption, hollow stem, decline of sucrose content, dry sugarcane plant and stem gradually that turned over or broke, rapid conversion of sugar and decline of sugar yield rate (Mcintyre et al., 2015). Therefore, the dry sugarcane stems not only are absorbed sugar content, but also increase the acidity of sugarcane juice while making sugar, which makes it difficult to make sugar and causes certain losses to factories (Singh, 2002).

Sucrose is the main form of carbohydrate transport in sugarcane plants. However, sugarcane plants after lodging have weak photosynthetic capacity, less carbohydrate synthesis and insufficient sunlight, which affect transportation, slow down the sugar accumulation in segmental storage tissues, so that the brix of sugarcane juice was low at harvest time. For instance, sugarcane plants lodged in late September had a full-stem brix 6.13% lower than that of normal plants when harvesting in January next year, and the lower segment was the area where sugar accumulation was seriously affected (Huang, et al., 2014).

Effect of lodging on physiological and biochemical indexes

Sugarcane was a C_4 plant with high photosynthetic intensity and light saturation point (Marchiori et al., 2014). After lodging of sugarcane plants, the leaves could not obtain sufficient light energy due to the deterioration of light conditions in the field, which could not meet the direct needs of photosynthesis for light energy, but also hinder the stomatal opening, increased the diffusion resistance of CO_2 into the leaves and reduce the photosynthetic intensity significantly (Liu et al., 2016a). Moreover, lodging was also not conducive to leaf extension. Zhao et al. (2014) reported that the average leaf area and single stem green leaf area of sugarcane plants after lodging declined by 25.3% and 22.7% respectively compared with normal plants. The reduction of photosynthetic area would inevitably lead to the decrease of synthetic amount of photosynthetic product in the whole sugarcane plant (Mo, 1979).

The water metabolism of sugarcane plants is composed of three closely-related links: water absorption, water transport and water loss, and there are two mechanisms of water absorption in sugarcane plants: active absorption and passive absorption (Jangpromma et al., 2010). After lodging of sugarcane plants, some of the roots are broken by mechanical force and the root system could not get enough carbohydrates from the ground, so the activity of life is weak and the amount of active water absorption

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60956105

decreases (Zhang et al., 2015). Meanwhile, sugarcane plants after lodging are squeezed together with weak light and high relative humidity, as well as weak transpiration, which greatly affect the passive water absorption ability. Since the water absorption and loss (mainly transpiration) of sugarcane plants after lodging are adversely affected, water transport has to proceed gradually, which destroys the normal water metabolism of sugarcane plants and is extremely harmful to their growth and tissue enrichment (Heerden et al., 2015).

After lodging of sugarcane plants, the life activities of root system are adversely affected, and the absorption and transport of mineral nutrients are weakened. According to Chand et al. (2010), the amount of potassium chloride absorbed by the root system of sugarcane plants after lodging and transported by xylem to parts above ground was about half of that of normal plants, and the amount of phosphorus was only 1/4 of that of normal plants. After lodging, the normal physiological condition of phosphorus and potassium absorption and transport from outside during the whole growth process of sugarcane plants was changed obviously, which was an important reason for poor growth, low yield and poor quality (Yanai et al., 2010).

The relationship between lodging and lignin and cellulose

During the period of internode enrichment, a large number of photosynthetic products would flow to the stem, and the cell wall is significantly thicker accompanied by fibrosis and lignification. In the mean time, a large amount of starch accumulated in parenchyma cells significantly increases the dry weight per unit length of stem, which is the key period to determine lodging resistance (Ferreira et al., 2016).

Lignin

As a phenolic polymer synthesized from cinnamon alcohol and other monomers, lignin is the organic component next only to cellulose on the earth, which has a relatively high content in wood plants, generally accounting for 15% to 35% of dry weight (Stewart et al., 2015). With the biological functions of strengthening the mechanical strength of cell wall, improving transport capacity of cells and resisting microbial invasion, lignin exists in the cell walls of tracheids and xylem vessels of various supporting and leading tissues in plants, which is mainly accumulated in the thickened secondary cell wall, cross-linked and arranged with cellulose and hemicellulose (Zhao et al., 2015; Cao et al., 2015). The initial properties of lignin could enhance the hardness of stem and leading tissue so as to maintain the upward growth of plants and the upward transport of water and nutrients through the xylem (Kanran et al., 2018; Tian et al., 2017). Although lignin could improve the mechanical strength and stress tolerance of the stem, its content was closely related to the rigidity of the stem (Hu et al., 2017a), so the varieties with strong lodging resistance had high lignin content. Hasan et al. (1993) reported that there was no significant correlation between lodging resistance and lignin content in different types of rice varieties, but it was generally believed that lignin content significantly affected the mechanical strength of plant stems based on a large number of studies on rice, wheat and maize (Zhang et al., 2017; Kamran et al., 2018a, b).

DOI: http://dx.doi.org/10.15666/aeer/1703_60956105

Cellulose

As the main component of plant skeleton (cell wall), the basic structural unit of cellulose is microfibril, and the content of cellulose affects the degree of thickening of cell wall and further determines the mechanical strength of stem (Hoang et al., 2017; William et al., 2017). For example, Wang et al. (2006) showed that the stem strength of wheat variety was significantly higher than that of its parents, which mainly attributed to higher cellulose content. Subsequently, Wang et al. (2012) and Liu et al. (2016b) drew the similar conclusion in wheat, soybean and rice respectively. Recently, Okuno et al. (2014) considered that, the adverse effect of insufficient lignin content on stem hardness could be compensated by increasing cellulose content so as to improve the lodging resistance of forage rice, which might result from the molecular compensation mechanism in the bio-synthesis pathway of cellulose and lignin. According to Robertson et al. (2017), the contribution of cellulose content under panicle internodes to maize stem reached by 85%, which was in accordance with the study of Ma et al. (2012), indicating that it was an important method to improve the physical strength of maize stem and enhance the lodging resistance of maize by increasing cellulose content. Hernández et al. (2018) showed that the lodging rate of maize was negatively correlated with the crude fiber content of stem.

The relationship between lodging and microscopic structure

At present, there is no report about analysis of microscopic structure with sugarcane lodging, but a lot of research has been done on crops such as maize and rice (Tian et al., 2015; Du et al., 2016). From the perspective of cytology, the mechanical strength of stem mainly came from thick-walled cells, and plant cell walls were divided into primary and secondary walls. Wang et al. (2015) studied the morphological structure in stem, anatomical characteristics and chemical composition of cell wall of 10 maize varieties, and analyzed the correlation between these variables. The results shown that the cortex/radius, thick-walled tissue ratio, mechanical tissue ratio, cellulose content and lignin content of stem were positively correlated with stress tolerance, while the thick-walled tissue ratio, stem length/stem diameter and number of vascular bundles were negatively correlated with stress tolerance. According to Liu et al. (2011), the arrangement of rapeseed longitudinal xylem cells in the main stem of lodging resistant variety was relatively neat, which was distributed in a linear manner parallel to the main stem, the length-width ratio of most horizontal cortical cells was greater than two with compact and ordered arrangement, and the ray of vascular column penetrated the cambium. However, a material with common lodging resistance had irregular longitudinal arrangement of xylem cells, the length-width ratio of most horizontal cortical cells was less than the two with disordered arrangement, and the ray of vascular column had poor coherence with extra-cambium cells.

Evaluation methods of lodging resistance in crops

Crop lodging is the result of plant itself and environmental factors, and there are significant differences in lodging resistance in different crop genotypes, but the phenotypic identification of crop lodging resistance could only be carried out under certain environmental conditions. However, since the environmental conditions could

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60956105

not be accurately predicted, it is necessary to establish a mechanical evaluation system based on the physical and morphological characteristics of the plant itself, which is not depended on climate conditions, so could better evaluate the lodging resistance of crops (Corbin et al., 2014; Tian, 2013).

Tilting angle method

Tilting angle method (Zhang et al., 1999) is to show the lodging resistance of plants by the angle between the stem at the mature stage and the vertical line of the ground. According to tilting angle, degree of lodging could be divided into 3 types: lodging type (60-90 degrees), inclined type (30-60 degrees) and vertical type (0-30 degrees).

Bending moment method

When discussing the lodging resistance of rice with different panicle types, the bending moment method could be adopted (Xu et al., 2004).

Resistance force method

In this method, the dynamometer is placed vertically with the stem and 20 cm away from the ground. Then, the dynamometer is pushed slowly to an angle of 45° between the plant and the ground, so the value showed by the instrument is the bending resistance of the stem. The larger the value is, the stronger the lodging resistance is. Otherwise, the worse the lodging resistance is. The advantage of this method is to evaluate the lodging resistance of rice by measuring the bending resistance of each stem, which was close to the real situation in the field (Li et al., 2018b; Xiao et al., 2015).

Lodging resistance index method

Sun (1987) proposed an acknowledged formula: rice stem lodging resistance index (CLRI), it was calculated with basal stem resistance, stem length and grain weight per panicle. According to this formula, the lodging resistance of rice stem could be divided into four types, that is, none lodging resistant, more lodging resistant, lodging resistant and high lodging resistant. The higher the CLRI was, the greater the lodging resistance was, and vice versa (Li, 2015).

Application of the lodging resistance index

Among the above anti-lodging evaluation methods, the lodging resistance index method is used most frequently, which can effectively reflect severity of corn lodging and yield after harvesting (Chu et al., 2017). Zhao et al. (2017) selected the best combination of silicon application amount by using the anti-lodging index. Zhang et al. (2019) and Hu et al. (2017b) found that lodging resistance coefficient of maize and wheat was closely related to stem folding resistance. Hu et al. (2018) found in the wheat comparative experiment that the four lodging indexes were all significantly positively

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60956105

correlated with the length of the second and third stem segments, and the lodging indexes bending moment and resistance force showed better effects.

Conclusion

After sugarcane lodging, its cane yield and sugar content would reduce seriously. Meanwhile, it reduces the quality of mechanical harvesting, go against to photosynthesis, make destruction of water metabolism, affects mineral absorption and conversion. Lignin and cellulose affect the degree of thickening of cell wall and further determine the mechanical strength of stem. The mechanical strength of stem mainly come from thick-walled cells. There are a lot of evaluation methods of lodging resistance in crops, and lodging resistance index method is used most frequently. It could be used for reference in sugarcane.

Abstract. In order to observe the performance of lodging-related traits, evaluate the lodging-resistant ability of different combinations of sugarcane, a field experiment was conducted in 2018. Thirty sugarcane combinations were used as the materials, and the lodging grade, fracture resistance force, basal stem diameter, middle stem diameter and brix were investigated. With the data of lodging classification, the lodging resistance index was established. It was found that the lodging resistance index was significantly and positively correlated with the ratio of basal and middle stem diameters and brix. A cluster analysis was conducted, for the thirty sugarcane combinations by the lodging resistance index, which showed sixteen were lodging resistant, thirteen half-lodging, and two complete-lodging.
Keywords: *lodging resistance, combination, stem diameter, fracture resistance force, index*

Introduction

Sugarcane (*Saccharum spp. hybrid*) is the largest sugar crop in China and the world, during the 2017/2018 milling season, the planting area was 1.38 million ha and the sugar yield was 10.48 million tones in China. Guangxi is the first in sugarcane planting area, sugar yield, and economic benefit in Chinese sugar industry (Li et al., 2010). Due to the tall plant and large biomass above ground, lodging occurs very common, which seriously affects the yield and sucrose content in cane, in some areas, the cane yield was reduced by 10% to 20% in light, and more than 50% in severe. The surcrose content was reduced by 15% to 35%, and the number of millable canes was reduced by 0.8 stalks/m^2 (Li et al., 2018; Singh et al., 2002). Meanwhile, lodging reduces the quality of mechanical harvesting, results in more harvesting loss, and increases broken rate of stools by 24.8% on average, which seriously hinders the popularization and application of machine harvest in sugarcane (Li, 2010; Mo, 1979) as well as the development of sugarcane industry (Liu and Fan, 2011; Zhang et al., 2010). There have been a lot of research about lodging resistance evaluation of germplasm resources for other crops, such as rice, maize, wheat, etc. (Wang et al., 2014; Kamran et al., 2018; Piñera-Chavez et al., 2016). Up to day, however, there has been no perfect evaluation method for sugarcane lodging at home and abroad, and very few reports about sugarcane lodging research could be referred. Cosidering the changes of climatic and ecological regions and the status of main cultivars, it is necessary to carry out comprehensive and specific

DOI: http://dx.doi.org/10.15666/aeer/1703_61076116

evaluation and research on lodging resistance of different sugarcane genotypes and the mechanisms in sugarcane lodging resistance (Kimbeng et al., 2000; Singh et al., 1999). This study was done by using thirty sugarcane combinations as materials to study the features of sugarcane lodging, establish classification standards for sugarcane lodging, and evaluate the lodging-resistant ability of the combinations, in order to provide a reference for selection of lodging-resistant parent and varieties in sugarcane.

Materials and methods

Plant materials

The tested materials were the seedlings from Sugarcane Research Institute, Guangxi Academy of Agricultural Sciences, Nanning in 2017. Thirty combinations were randomly selected, and the sugarcane variety ROC22 was used as control (*Table 1*). GT and SWS parents were from Sugarcane Research Institute, Guangxi Academy of Agricultural Sciences. YT and ZZ parents were from Guangzhou Sugarncane Industry Research Institute. YZ and DZ parents were from Sugarncane Research Institute of Yunnan Academy of Agricultural Sciences. CP parents were from USDA Canal Point Sugarcane Field Station. FN, LC and ROC parents were from Fujian Agriculture and forestry university, Sugarcane Research Center of Liucheng and Taiwan Sugarcane Research Institute. C1, Co, FR, PR and NongL were imported from Brazil, Franch, Puerto Rico and Japan, respectively.

DOI: http://dx.doi.org/10.15666/aeer/1703_61076116

Experiment design

The seeds of the tested combinations were sowed in late March, 2017, and the seedlings were transplanted to nursery cups in the middle of April when they had two to four leaves. On June 15th, they were planted in the field. Sixty nine individual plants were randomly selected in each combination. Repeated planting was carried out for 3 times in randomized block design. Each plot contained one row of 7 m long, and the space between rows was 1.2 m. Twenty three plants were planted in each plot. Compound fertilizer (N:P:K = 8:6:6) 750 kg/ha was applied as the base fertilizer at the time of planting and urea 75 kg/ha was dressed at tillering stage.

Investigation index and method

From November to December, the resistance grade, lodging resistance index, fracture resistance, basal stem diameter, middle stem diameter, and brix were estimated by measuring 21 seedlings in each plot excluding the first and last seedlings to avoid the marginal effect in each row.

Resistance grade: It was estimated by referring to the partition method of Hao et al. (2008) with modification. The classification was done based on the lodging angle formed by the link between the top and the base of the stem, and the perpendicular line of the ground (*Table 2*).

Lodging resistance index (LRI): It was estimated according to the method of Li et al. (2012) and Xie et al. (2009). The equation is as follows:

$$LRI = \sum(g_i \times n_i)/N \times 100\% \quad \text{(Eq.1)}$$

where n is the number of lodging stalks in a lodging grade, g is the lodging grade, and N is the total number of stalks investigated.

Stem diameter: The middle parts of basal and middle stem internode were measured with vernier caliper at mature stage.

Brix: Cane juice was extracted and measure with ATAGO handheld saccharimeter at mature stage.

Fracture resistance force: Ten upright and uniform plants were selected in each row, not including the plants on the sides. A PROSTRATETESTER DIK-7401 was kept vertically to the middle of the stem and push it hard to the plant to form a 45° included angle. The data showing on the prostrate tester were recorded.

Table 2. *The grading standard of sugarcane lodging resistance in field*

Lodging grade	Lodging angle
Grade 1	＞60°
Grade 2	30-60°
Grade 3	0-30°

Data analysis

The data were processed by Excel 2010 and subjected to ANOVA, and mean values were separated using Duncan's multiple range test. All statistical analyses were performed using the DPS 14.15 statistical package. The correlation between

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61076116

combinations and lodging indexes were evaluated using Person correlation analysis. The lodging resistance index was used for cluster analysis which was carried out with the method of the distance of χ^2 and sum of squares of deviation. The grading standard of sugarcane lodging resistance was made by the observation of the sugarcane lodging and relevant research results (*Table 3*).

Table 3. *The grading standard of sugarcane lodging resistance*

Resistance grade	Lodging resistance index	Lodging level
Grade 1	1.00-1.60	High lodging
Grade 2	1.61-2.30	Middle lodging
Grade 3	2.31-3.00	Erect

Results

Relationship between different agronomic traits and resistance grade

It data in *Table 4* showed that the differences were significant in different lodging types for all the agronomic traits The differences in brix in the erect, half lodging and complete lodging types suggested that the impact of lodging on brix was salient, and lodging would certainly reduce the brix in cane juice. The basal and middle stem diameters also significantly and negatively affected sugarcane lodging. The larger the stem, the higher the lodging resistance was, regardless of middle or basal part. The ratio between basal and middle stem diameter was an important index. Obviously, the stem with consistency from top to base possesses excellent lodging resistance. The stem with thin base and thick middle parts was easy to get lodging.

Table 4. *The relationship of different agronomic traits and lodging*

Type	Brix (°BX)	Basal stem diameter (cm)	Middle stem diameter (cm)	Ratio of middle and basal stem diameter
Erect	19.8±0.9 a	237±21 a	236±20 a	1.00±0.05 a
Half lodging	19.6±1.0 b	225±17 b	231±17 b	0.98±0.05 b
Complete lodging	19.3±1.2 c	206±18 c	219±19 c	0.94±0.05 c

Data in the table are the means of three replicates. Different low case letters in the same column represent the significant difference at 5% in Duncan's multiple range test

The resistance force test was not effective in this experiment. As shown in *Table 5,* the differences in repetitions were very significant, but those in combinations were not significant.

Table 5. *The relationship of resistance force and different combinations in sugarcane*

Item	Df	Sum Sq	Mean Sq	F value	Pr (>F)
Repetition	2	307.5	153.8	14.85	0.000007**
Combination	30	471.9	15.7	1.52	0.0876
Residuals	56	579.7	10.4		

** represent the significance at 1% levels

DOI: http://dx.doi.org/10.15666/aeer/1703_61076116

Analysis on relevance between agricultural traits and lodging resistance index

The lodging index resistance and the diameters of basal and middle stem were highly significantly and positively correlated (r = 0.419** and 0.356**), indicating the thicker the stem was, the more lodging resistant the plant was. The lodging resistance index was significantly and positively correlated with the brix, suggesting that erect stalks had higher sugar content in cane. The lodging resistance index showed significantly positive correlation (r = 0.201* and r = 0.232*) with the ratio of middle and basal stem diameter, indicating that the sugarcane genotypes with uniform stem were more lodging resistant. Though the correlation coefficients were moderate, they were significant in this study. The larger the ratio of middle and basal stem diameter was, the higher lodging resistance the sugarcane genotypes possessed (*Table 6*).

Table 6. *Correlation coefficients between different traits*

Correlation coefficient	Lodging resistance index	Resistance force	The ratio of middle in basal stem diameter	Brix	Basal stem diameter	Middle stem diameter
Lodging resistance index	1					
Resistance force	-0.02	1				
The ratio of middle in basal stem diameter	0.201*	-0.037	1			
Brix	0.232*	0.052	-0.168	1		
Basal stem diameter	0.419**	0.294**	0.432	0.093	1	
Middle stem diameter	0.356**	0.223*	-0.049	0.19	0.87	1

* and ** represent the significance at 5%, and 1% levels, respectively

Cluster analysis

Systematic cluster analysis was done based on the lodging resistance index, and the results were shown in *Figure 1*. The 30 tested combinations were divided into three categories, among them, 16 were in level 3, 13 in level 2, and 2 in level 1 (*Table 7*). GT and YT parents were accounted for 56% and 44% in level 3 respectively, and CP parents were accounted for 30% in level 2. The control variety ROC 22 belonged to the middle lodging type was classified in level 2 in this study, which was in line with its performance in commercial production.

Discussion

Three or more classifications were established according to the angle in other crops (Wang et al., 2015; Stamp and Kiel, 2010; Nakajima et al., 2008). By far, there has been no confirmed classification for lodging in sugarcane. In this study, the lodging of 30 sugarcane was classified into three levels, that is, level 1 (lodging), level 2 (half-lodging) and level 3 (erect) referring to other crops and sugarcane production reality. Meanwhile, the lodging index was brought up, and supported by the test data. The index could be used to judge the capability of lodging resistance of sugarcane rapidly. In the past, many sugarcane breeders had been deducing the lodging resistance trait by visual observation, and deducing whether the sugarcane was lodging resistant or not according to the approximate growth of sugarcane stalks in the field. But it was difficult for breeders to distinguish the status of some sugarcane genotypes which looked either like

DOI: http://dx.doi.org/10.15666/aeer/1703_61076116

lodged or erect, unless they were all erect or lodged. If the plants of a clone tended to lodging, which would be classified as complete lodging. With the lodging resistance index established in this study, we can quickly determine the lodging resistance of a clone and greatly improve the efficiency of sugarcane breeding.

In this study, we identified the relationship between the lodging level and brix and stem diameter in sugarcane. When lodging occurred, the brix was down. Mo (1979) reported that the brix declined after lodging in sugarcane, which is in accordance to the results of this study. In addition, for the first time, this research used the data of the ratio of basal and middle stem diameter. The higher the ratio was, the higher lodging resistance index of sugarcane was. Apparently, they were positively correlated. When the ratio was lower than one, the lodging resistance index decreased and the degree of lodging was significantly higher, caused by the heavy top and light base (Peng, 1988; Feng et al., 2006). In the breeding process of sugarcane or other stalk crops, the breeders preferred to choose the ideal plant type – "tower type" (Liu, 2017). This structure was stable and could minimize losses even in bad weather such as strong wind (Johnson et al., 1998). Especially for the large leafed sugarcane, it is necessary to maintain the stability by selecting the "tower" structure. Therefore, the introduction of the ratio of basal and mid stem diameters would help the breeders to judge sugarcane lodging resistance more comprehensively.

There had been many studies on breeding and selecting resistance traits such as drought resistance, cold resistance and smut resistance by sugarcane germplasm resources (Agboire et al., 2000; Cai et al., 2008; Pan et al., 2006; Zhou et al., 2012). An excellent sugarcane variety was always selected from hundreds of sugarcane combinations (Yang et al., 2011). High yield, high sucrose content, strong ratoon ability and multi-resistance were the breeding targets (Mbuma et al., 2018; Huang et al., 2016; Zhou et al., 2017). However, the most prominent problem encountered in conventional breeding was the narrow genetic basis and insufficient parental innovation, which greatly affects the selection of new breakthrough sugarcane varieties. It is even more difficult to obtain new sugarcane varieties with specific characteristics (Duan et al., 2017; Ramburan et al., 2010). For lodging resistant breeding, it was necessary to have lodging resistant sugarcane germplasm resources (Sengwayo et al., 2018). In this research, based on the lodging resistance index, 30 combinations were classified into three levels, sixteen in level 3, thirteen in level 2, and two in level 1. In the combinations of lodging resistancet, GT and YT parents were accounted for 56% and 44% respectively; In the combination of middle lodging, CP parents were accounted for 30%, indicating that the sugarcane varieties (clones) selected and planted in the local climate zone could better adapt to the cultivation environment. In China, the breeders consider more about the effect of lodging on commercial sugarcane production, so they prefer to select the clones with lodging resistance (Yang et al., 2019; Wu et al., 2019). Because of the complete sugarcane mechanization in the USA, the sugarcane breeders mainly considered yield and sugar, and the lodging resistance of sugarcane might be not the main target (Zhou and Li, 2012). Continuous evaluation of the lodging resistance of germplasm resources, statistical analysis of excellent combinations and excellent parents would be helpful to breed lodging resistant sugarcane varieties.

The instrument for measuring the resistance force, DIK7401, did not produce good results in sugarcane. Considering the limit of measurement range of the instrument, and that sugarcane is relatively high and the stem has strong tenacity, the thrust required should be much higher than that for rice (Xiong et al., 2018) and wheat (He, 2018). In the next step, we will consider to use a broader ranged resistance force tester for the study, and NKK-4005 computer-controlled universal testing machine may be used to measure the mechanical indexes of different lodging forms of sugarcane, such as leaf, skin endurance and stem bending resistance (Yang et al., 2016).

Conclusion

In this study, lodging grades and lodging resistance index were established for sugarcane. According to the lodging degree, sugarcane lodging could be divided into three grades, that is, grade 1 (complete lodging), grade 2 (half lodging) and grade 3 (erect). The established lodging resistance index could be used to evaluate the lodging resistance of sugarcane quickly. The relationship between lodging and brix and stem diameter was confirmed. The brix in cane juice decreased when lodging occurred. The ratio of basal and mid stem diameters was found highly significantly correlated with the lodging resistance in sugarcane. When the ratio was less than one, the lodging resistance index of sugarcane was low and the lodging degree was obviously heavy. With the lodging resistance index, the thirty combinations used in this study were divided into three categories, sixteen in grade 3, thirteen in grade 2, and two in grade 1.

Abstract. Drought is one of the most important abiotic stresses that affects plant growth and development. Polyamines (PAs) can have an active key role in improving plants tolerance to various stresses. Based on global ecological conditions, plants growing in about one third of the potentially viable lands such as Iran are exposed to drought stress during growing season. The objective of the present study was to investigate the enhancing effects of foliar application of Putrescine (PUT) on short-term tolerance against water stress in ornamental sunflowers. This study was conducted in the experimental greenhouse of the Department of Horticultural Sciences and Landscape, Ferdowsi University of Mashhad, Iran. Plant materials used in this study were the F_1 seeds of ornamental sunflower (*Helianthus annus* L. cv. Sunbright kids). The experiment was conducted as a factorial (2 × 3) in complete randomized block design with four replications and 8 plants in each replicate. Plants were irrigated at 40 and 80% field capacity (FC). Foliar spray of PUT (0, 75 and 150 mg l^{-1}) was applied twice during plants growing period. Water stress at 40% FC as compared with 80% FC, significantly affected reproductive and vegetative characteristics of plants. The effects of exogenous application of PUT (75 and 150 mg l^{-1}) in comparison with control, significantly increased leaves number per plant, leaves fresh and dry weight, leaves area, stems fresh and dry weight, stems diameters at soil surface, plants height, roots fresh and dry weight, roots area, number of flowers, flowers longevity, seeds number per head and seeds weight. In this study, there was no significant difference between the effects of PUT levels on most of the reproductive and vegetative characteristics of sunflower plants under water stress conditions. The results confirmed that foliar application of PUT protected plants against drought stress and increased specially flowers retention. Therefore, to improve parameters of the studied plants under drought stress, the commercial application of PUT (75 mg l^{-1}) is recommended for this cultivar.
Keywords: *flower longevity, Helianthus annus, polyamine, reproductive and vegetative parameters, water stress*

Introduction

About one-third of the global potentially viable lands are subject to an inadequate water supply (Zhang and Huang, 2013). Plants are usually exposed to different environmental stress conditions in their life cycles. Drought is one of the most important abiotic stresses that affect plant growth and development. Decrease in water availability to plants due to low soil water potential followed by leaves transpiration will result in an increase in stomatal resistance, low CO_2 influx and a decrease in photosynthesis (Kotakis et al., 2014 and Zgallai et al., 2005).

Polyamines (PAs) have great influence on plant development and stress tolerance (Hussain et al., 2011; Urano et al., 2003). The most important polyamines are diamine

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61176127

putrescine (PUT), triamine spermidine (Spd) and tetramine spermine (Spm) (Marco et al., 2011). There is a direct correlation between drought tolerance and the total plants PUT content which is in agreement with the inherent function of PUT in improving drought resistance regardless of plants Spd and Spm contents (Alcázar et al., 2010).

It is believed that the biosynthesis of PAs especially that of PUT will improve plants abiotic stress-tolerance as compared to non-tolerant ones (Hussain et al., 2011). Since cationic PAs' are inherently capable of binding to cellular polyanions including DNA, RNA and proteins, they can influence the synthesis, structure and function of these macromolecules and also by interacting with other cell components, PAs widely affect plant growth and development and also plants responses to environmental stresses (Kanayama and Kochetov, 2015). PAs are involved in signal transduction leading to a change in other hormones (Bitrian et al., 2012), such as Abscisic acid (ABA) (Hussain et al., 2011) and ethylene (Kaur–Sawhney et al., 2003). PAs maintain cell stability (Legocka and Kluk, 2005), and regulate root growth (Wang et al., 2011). It has been found that PA concentrations are higher in the roots and leaves of stressed plants. This implies that PA metabolism in drought-tolerant plants is an adaptive mechanism to drought stress (Zhang and Huang, 2013). Previous studies have shown that there is a close relation between the PUT levels and the biochemical and morphological responses to dehydration. In addition, it has been observed that by manipulating at the transcriptional level, PUT increases ABA biosynthesis in plants in response to drought stress. It has also been reported that PUT accumulation enhances drought tolerance since the levels of Spm and Spd have not increased during the dehydration period (Espasandin et al., 2014).

Considering the adverse climatic conditions in Iran, and plants in landscapes being exposed to drought stress during growing season, the objective of this study was to investigate whether the direct PUT application on ornamental sunflowers plants can enhance short–term tolerance against water stress in such plants.

Materials and methods

This study was conducted in the experimental greenhouse of the Department of Horticultural Sciences and Landscape, Faculty of Agriculture, Ferdowsi University of Mashhad, Iran, under controlled conditions with relative humidity of 60%, and 25 °C/18 °C (day/night) temperature. The light intensity inside the greenhouse was 500-700 μmol m^{-2} s^{-1}. The environmental conditions of the greenhouse were relatively constant during the whole period of the experiments from germination to vegetative and reproductive growth phases.

Plant materials used in this study were the F_1 seeds of ornamental sunflower (*Helianthus annus* L. cv. Sunbright kids) purchased from Sokata Company, Japan. Seeds were planted in trays containing coco peat, peat moss and perlite (1:1:1, v/v/v). After seedlings were at 6 leaf stage (after one month), they were transplanted into plastic pots containing 4.6 kg of soil, leaf mould, vermicompost and sand (7:1:1:1, v/v/v/v). Before starting the experiments, the physical properties of the soil mixture used were determined (*Table 1*). Forty days after seeds germination, plants were sprayed with Putrescine (PUT) (0, 75 and 150 mg l^{-1}). The amount sprayed was enough to soak the leaves and the solution started to drip and applied 10 times for each plant. Control plants were sprayed with the same amount of distilled water. As the seedlings entered the reproductive phase (60 days after seed germination), soil moisture contents

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61176127

were kept at 40 and 80% field capacity (FC). One month after the first foliar PUT spray (10 days after plants entered the reproductive phase), the second spray was applied, same way as the first one (*Figs. 1* and *2*). At the end of the experiments, the following morphological characters were determined: Flowers number and diameters (Digital calliper), petals length, flowers longevity on the plants, seeds number and seeds weight in each head, leaves number and area (Leaf Area Meter, Model: L1-3100C. LI–COR Biosciences, USA), plants height and stems diameter at soil surface. Roots area and length and mean roots diameter were measured by Root Analyser (Model: DELTA-T DEVICES LTD. CAMBRIDGE. ENGLAND). Plants aerial parts were cut from soil surface and their roots were washed with tap water to remove the soil. After wiping the moisture, roots were separated from each other and put on the surface of Root Analyser for parameters determination. Also, the fresh weight (FW) and dry weight (DW) of flowers, leaves, stems and roots were determined. Dry weights were determined after keeping the samples in an oven at 75 °C for 72 h.

The experiments were conducted as a factorial (2 × 3) in complete randomized block design with four replications and 8 plants in each replicate. Statistical differences between measurements were analyzed following the analysis of variance (ANOVA) using Minitab 16.0 software. Analysis of variance was performed based on Fischer S test. Fischer-LSD test was used to compare means and differences ($P \leq 0.05$).

Results

Effects of water stress on plants reproductive characteristics are shown in *Table 2* and *Figures 3* and *4*. Water stress at 40% FC in comparison with 80% FC significantly reduced flowers number (3.26%), flowers diameter (8.58%), petals length (6.17%), flowers FW (7.5%), flowers longevity (11.11%), seeds number per head (14.38%) and seeds weight (50%).

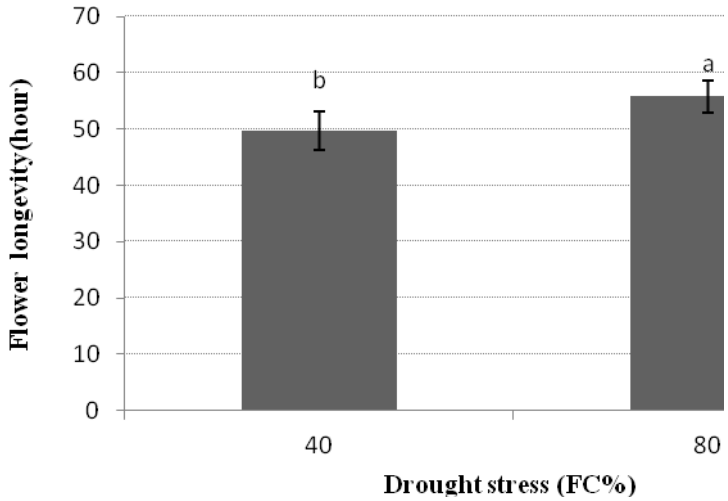

Figure 3. *Effects of drought stress on flower longevity. Histograms with different letters are statistically significant based on LSD test at P ≤ 5% level*

Table 2. *Effects of drought stress on flowers parameters*

Drought stress (FC %)	Parameters					
	Flower diameter (mm)	Petal length (mm)	Flower fresh weight (g)	Flower dry weight (g)	Seed numbers per head	Seeds weight (g)
40	53.3 b*	22.8 b	4.0 a	0.5 a	39.9 b	0.1 b
80	58.3 a	24.3 a	3.7 b	0.5 a	46.6 a	0.2 a

*Means with different letters in a column are statistically significant based on LSD test at $P \leq 5\%$ level

The results of water stress effects on plants vegetative parameters are shown in *Tables 3* and *4* and *Figure 5*. Water stress at 40% FC in comparison with 80% FC significantly reduced leaves number per plant (23.90%), leaves FW (37.5%), leaves DW (32%), leaves area (37.08%), stems FW (35.11%), stems DW (28.20%), stems diameter at soil surface (15.22%), plants height (9.24%), total roots length (32.51%), roots FW (25.30%), roots DW (15.38%) and roots area (27.45%).

The effects of PUT spray on flower parameters are shown in *Table 5* and *Figures 4* and *6*. PUT at 75 and 150 mg l^{-1} in comparison with control, significantly increased flowers number (18.75% and 37.5% respectively), flowers longevity (25.9% and 9.77% respectively), seeds number per head (26.2% and 0.76% respectively) and seeds weight (100% by both PUT concentrations used).

The effects of exogenous application of PUT on plants under water stress are shown in *Tables 6* and *7* and *Figure 7*. PUT (75 and 150 mg l^{-1}) spray in comparison with control (distilled water), significantly increased leaves number per plant (6.15% and 16.22% respectively), leaves FW (23.40% and 29.79% respectively), leaves DW (15.79% and 15.79% respectively) and leaves area (17.58% and 28.49% respectively). Also seedlings stems parameters under water stress conditions were affected by Put spray. PUT (75 and 150 mg l^{-1}) in comparison with control significantly increased stems FW (18.03% and 36.61% respectively), stems DW (14.29% and 39.29% respectively), stems diameter at soil surface (10% and 3.66% respectively), plants height (5.88% and 3.53% respectively), roots FW (23.40% and 28.72% respectively), roots DW (47.37% and 31.58% respectively) and roots area (39.06% and 39.75% respectively).

In this study, there were no significant differences between the effects of the two PUT levels used on most of the vegetative and reproductive parameters under water stress conditions. It was only the seeds number per head which was affected by the two PUT levels.

The interaction effects of water stress levels (40% and 80% FC) and PUT levels (75 and 150 mg l^{-1}) significantly increased plants height, flowers number and seeds number per head (*Table 8* and *Fig. 4*).

Discussion

In the present study, water stress caused a number of changes in ornamental sunflower plants such as leaves number per plant, leaves area, leaves, stems and roots fresh and dry weight, plants height, roots length and roots area. Leaves drop was significantly higher at 40% FC as compared with 80% FC (*Table 3* and *Fig. 5*). Drought induced plant growth inhibition such as plants height and leaves senescence which has also been reported for white clover (Li et al., 2016). The decrease in plants growth and increase in leaves senescence under drought conditions could be due to a decline in plants cytokinin content (Clark et al., 2004; Peleg and Blumwald, 2011). In our study, water stress decreased both plants FW and DW (*Tables 2*, *3* and *4*). The reduction in plants FW under drought stress has also been reported for other plants such as wheat (Rane et al., 2001). The reduction in plants FW under drought stress is mainly due to loss of cell turgor required for cell growth and cell expansion. It has also been reported

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61176127

that PAs play important roles in cell division and elongation (Hummel et al., 2004; Mattoo et al., 2010; Paschalidis and Roubelakis-Angelakis, 2005).

The decrease in plants DW in response to drought stress (*Tables 2*, *3* and *4*), is probably due to decline in plant growth, reduction in photosynthetic activity due to increase in stomatal resistance and leaves senescence (Manivannan et al., 2007; Zgallai et al., 2005).

We found that water stress significantly reduced flowers number, flowers diameter and flowers longevity, but foliar application of PUT significantly increased flowers number and flowers longevity (*Table 2* and *5* and *Figs. 3*, *4* and *6*). Changes in flower parameters under drought stress, might be due to the cytokinin and gibberellin decline and leaves senescence. Application of PUT somehow counteracted the inhibitory effects of drought stress on flowers parameters (*Table 5* and *Figs. 4* and *6*). It has been reported that increase in endogenous PAs leads to the up-regulation of plants cytokinine and gibberellin biosynthesis mechanisms (Li et al., 2016).

In our study, seeds number and seeds weight per head were significantly reduced by water stress (*Table 2*). Our results are in agreement with previous reports which have indicated that drought stress increases the ethylene (ETH) evolution rate of wheat grain leading to the inhibition of wheat grain filling (Liu et al., 2016).

It has been reported that external application of PAs is responsible for the increase in endogenous ABA levels (Steiner et al., 2007). Increase in ABA promotes the transport of carbohydrate from stem to the grain (Liu et al., 2016). It has also been reported that increase in PUT accumulation in plants promotes drought tolerance. However, no increase in plants Spm and Spd contents were observed during dehydration period (Espasandins et al., 2014).

Exogenous application of PUT at both concentrations (75 and 150 mg l^{-1}) significantly increased most sunflowers plants vegetative and reproductive parameters (*Tables 5*, *6* and *7* and *Figs. 4*, *6* and *7*). The protective effects of PUT on cell membrane stability index (MSI) and leaves chlorophylls content as well as on photosynthetic activity (PN) have also been reported by Rahemi et al. (2017).

Application of PUT significantly increased flowers retention in sunflower plants (*Fig. 6*). Similar results have been reported by Baninasab and Rahemi (2008) for flower bud retention in pistachio plants. It has been reported that PAs inhibit the biosynthesis of ETH in plants since S-adenosylmethionine, the precursor of both PA and ETH synthesis will be used mainly for the synthesis of PAs rather than ETH (Liang and Lur, 2002). Exogenous application of PAs has blocked ETH synthesis in rice panicles (Yang et al., 2008).

Conclusion

Our study has indicated that ornamental sunflower Sunbright kids cultivar, is highly sensitive to water stress. PUT treatments before the onset of drought stress, protects plant against drought and inhibits plants water loss, confirming the key role of PUT in its ability to protect plants against water stress. The effect of exogenous application of PUT (75 and 150 mg l^{-1}) in comparison with control, significantly increased leaves number per plant, leaves fresh and dry weight, leaves area, stems fresh and dry weight, stems diameter at soil surface, plants height, roots fresh and dry weight, roots area, number of flowers, flower longevity, seeds number per head and seeds weight. In this study, there was no significant difference between the effects of PUT levels on most of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61176127

the reproductive and vegetative parameters of sunflower plants under water stress conditions. Therefore, to improve the vegetative and reproductive parameters of the studied plants under drought stress, the commercial application of PUT (75 mg l^{-1}) is recommended for this ornamental sunflower cultivar.

The results of our study originally indicate that PUT treatment under drought conditions improves flowers longevity and other plants parameters such as flowers number and leaves number per plant and leaves area which are important in urban landscape.

The determination of the intercellular titer of PUT and other polyamines and analyses of endogenous plant growth substances such as cytokinine, gibberellins and abscisic acid during experiments are suggested. Furthermore, studying some plants physiological parameters under these conditions such as photosynthetic rate (Pn), transpiration rate (Tr), stomatal conductance of CO_2 (gs), stomatal size, plants carbohydrates, proline, chlorophylls and carotenoids contents are recommended.

Abstract. This review discusses phytoextraction and phytostabilisation of acid mine drainage (AMD) alongside with their benefits and limitations with case studies. Furthermore, plants associated with these two approaches of phytoremediation and impact of AMD on aquatic macrophytes used for phytoremediation were also reviewed. Both phytoextraction and phytostabilisation approaches are promising technologies in remediating AMD. However, their limitation of low metal removal and the lack of knowledge of minimum amendments required for their effective remediation call for the proposal, herein made, to combine aquatic macrophytes, as well as include plants from a wide range of families capable of phytoextraction and phytostabilisation in the remediation of AMD.
Keywords: *aquatic macrophytes, conventional treatment, hyperaccumulators, phytoremediation*

Introduction

The activities of the mine cause the production of acidic water that flows down to nearby water bodies causing long term impairment to biodiversity and waterways. The acidic water produced by the mines is termed acid mine drainage (AMD). Acid mine drainage also known as acid rock drainage is a process that occurs as a result of the contact between oxygenated water and mineral pyrite which leads to the oxidation of the pyrite and the production of acids (Evangelou, 1995; Blowes et al., 2003). Because of its environmental impact, acid mine drainage has attracted great attention all over the world, especially in countries where mining activity is very high. Acid mine water is characterized by low pH and a very high concentration of sulphates, iron and heavy metals. Many researchers have pointed out that the metal load of the acid mine drainage is of greater concern than the acidity with respect to the environmental damage (Kleinman, 1990; Fyson et al., 1994; Clarke, 1996; Kuyucak, 2002; Filipek et al., 2003). Furthermore, the source of the AMD may remain active for decades or even centuries after the closure of the mine (Modis et al., 1998). Individually mine have unique conditions and ability to produce AMD and therefore interventions should vary from mine to mine. The impact of AMD is dependent on local conditions and varies widely, depending on the geomorphology, the climate and the extent and distribution of the AMD generating deposits. There are no known standard methods for ranking, measuring and reducing the risk of AMD.

Water, air and soil constitute our environment and the process of removing any contaminants or pollutants from the environment is termed environmental remediation. Various technologies which cut across physical, chemical and biological processes have been employed for adequate remediation of polluted water, air and soil. The application of the various technologies depends on the nature of the pollutants. This is also

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61296149

applicable to environment polluted with acid mine waters. The conventional technologies which involves the neutralization of the acid in AMD using calcium carbonate, lime, hydrated lime, caustic soda and soda ash often cause the production of voluminous sludge. This sludge represents further environmental problems and an increase in the cost of remediation (Fiset et al., 2003). The high cost of this conventional method of AMD remediation has produced economic pressure and caused more research work to be done by many researchers in order to discover cost-effective and environmentally sound ways to treat AMD.

Phytoremediation is a form of bioremediation studied by many researchers for the treatment of AMD that proved to be cost-effective when compared to the conventional method of treatment (Pilon-Smits, 2005). It applies to all chemical and physical processes that involve plants in degrading or immobilizing contaminants in the environment especially in soil and groundwater. Phytoextraction, phytovolatization, phytostabilzation, rhizodegradation, phytohydraulics, and phytodegradation are the six major types of phytoremediation. Howewer, the focus of this review article is phytoextraction and phytostabilization.

Phytoextraction is also known as phytoaccumulation. Hyperaccumulation of contaminants through the roots of plants and the storage of those contaminants in their stem or leaves tissues is the mechanism of contaminants removal in this phytoremediation method. The contaminants are removed from the environment alongside with the plants when harvested. This phytoremediation method is useful particularly for removing metals from soil. It also provides an avenue of recovering the metals through the incineration of the plants, a process called phytomining. Phytovolatilization involves the taking up of volatile compounds by the plants through their roots. The volatile compounds are transpired directly or converted to metabolites that is capable of being transpired by the plants through their leaves. The contaminants are released to atmosphere.

Phytostabilization is also known as phytosequestration. This method involves the absorption of the contaminants by the roots, and adsorption to the surface of roots. It also involves the production of biochemicals by the plant which are then released into the soil or groundwater around the roots. The biochemicals have the ability to sequester, precipitate, or otherwise, immobilize nearby contaminants. Rhizodegradation occurs in the soil or groundwater that surrounds the plant roots. The exudates from the plants stimulate rhizosphere bacteria surrounding the root of plants to initiate biodegradation of contaminants in the soil. Phytohydraulics also involves the sequestration and degradation of contaminants that come in contact with the deep root of trees. In the work done by Hong et al. (2001), poplar trees were used to contain groundwater plume of methyl-tert-butyl-ether. Phytodegradation applies the mechanism of metabolism or biotransformation of the contaminants as they are taken up into the plant tissues. The transformation of the contaminants can occur in root, stem or leaves of plant depending on the type of plants involved in the phytodegradation.

The Indian Mustard, *Brassica juncea* (Brassicaceae), a plant familiar to the ones found in Sri Lanka, is found to be the most promising and well-tested plant for phytoextraction. This weedy mustard is successfully cultivated or naturalised in India, Western Egypt, Central Asia and Europe (Prasad and Freitas, 2003). It produces 18 tons of biomass/hectare/crop and it is able to accumulate and translocate high concentrations of Cr, Cu, Cd, Ni, Zn, and Pb at the same time to the shoot system (Kumar et al., 1995; Blaylock et al., 1997; Begonia et al., 1998; Zhu et al., 1999). Work done by many

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61296149

researchers have shown that this plant has the ability to accumulate heavy metals and the field trial done in the United State of America has shown that this plant can be successfully used in the field remediation of heavy metals and radionuclides (Huang et al., 1998; Lasat et al., 1998; Tucker and Shaw, 2000; Dushenkov, 2003; Qadir et al., 2004). The biomass of Indian Mustard growing in mine soil can be increased by the application of a combination of technosol and biochar and this can improve its effectivity as a bioremediator (Forján et al., 2017). Vetiver grass (*Chrysopogon zizanioides*) has been successfully grown and used in phytoremediation of gold mine tailings in South Africa (Melato et al., 2016). The good qualities of vetiver grass as a bioremediator are well accepted and a compendious account of this is found in Banerjee et al. (2018). This review examines the use of phytoextraction and phytostabilisation approaches for the treatment of mine tailings alongside with their associated benefits and limitations. Phytoextraction and phytostabilisation of mine tailings in temperate and arid environment were considered alongside with the impact of acid mine drainage on aquatic macrophytes used for phytoremediation.

Impact of Acid Mine Drainage (AMD) on Aquatic Macrophytes: A Case Study of *Eichhornia crassipes, Pistia stratiotes and Spirodela polyrhiza*

Activities of the mining industries in the world cause pollution of the surrounding areas. Mining tailings and piles of refuse may contain sulphide minerals such as arsenopyrite. This arsenopyrite is one of the main contamination sources in mining industries. Their exposure to the atmospheric water and oxygen causes their oxidation with the release of potential toxic elements to the environment through AMD system. Sulphur, iron, manganese and arsenic are common elements associated with acid mine drainage and are believe to be highly toxic even at low concentrations (Duker et al., 2005).

Acid mine drainage is believed to influence aquatic systems and alter the biological community structure through the elimination of species in the food chain. In this stance, phytoremediation, an *in situ* remediation technology, is a low cost option for the reclamation of contaminated environments through the use of plants (Pilon-Smits, 2005). Among all the forms of phytoremediation, phytoextraction and phytostabilisation are the commonly used forms of phytoremediation technology. Macrophytes that freely float in water are mostly used plant species for phytoremediation because of their ability to grow fast, accumulate heavy metals and metalloids in large quantities, survive under harsh conditions and tolerate high concentrations of toxic elements (Mishra et al., 2008a; 2008b).

The major setback of phytoremediation studies is that they are limited to some selected plant species and few metals (Hassan et al., 2007; Rahman et al., 2007). As a result, there is an information paucity on the simultaneous absorption of several contaminants especially, in acid mine drainage. *Eichhornia crassipes, Pistia stratiotes* and *Spirodela polyrhiza* species possess the ability to absorb several different elements to some extent and simultaneously accumulate heavy metals and toxic metalloids from acid mine drainage. Preliminary work done by Michelle et al. (2010) showed that *Pistia stratiotes* and *Spirodela polyrhiza* were susceptible to low pH in the aquatic medium which is the main characteristic of acid mine drainage. Furthermore, they observed that *E. crassipes* was more tolerant to acidic environment (*Figure 1*). The decrease in the chlorophyl a content was also observed to be another effect of acid mine

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61296149

drainage on plants as seen in *P. stratiotes* and *S. polyrhiza,* due to the necrosis on the leaves.

Eichhornia crassipes plants were also observed to accumulate part of the soluble arsenic from acid mine drainage in their different tissues with the root accumulating more of the heavy metals. Furthermore, the work done by Mokhtar et al. (2011) indicated that *E. crassipes* showed 97.3% efficiency for copper removal in an aqueous solution containing various concentrations of copper. *Pistia stratiotes* and *S. polyrhiza* die when exposed to acid mine drainage. The work done by Michelle et al. (2010) gave an insight on the ability of some aquatic macrophytes to accumulate heavy metals. However, there exists the need to further evaluate the simultaneous absorption of other heavy metals by aquatic macrophytes and their interactions to enhance the development of a better phytoremediation technology for acid mine drainage while preserving the aquatic macrophytes capable of accumulating the heavy metals.

Limitations of Phytoremediation Using Aquatic Plants

Various research endeavours have shown phytoremediation to be a better environmentally friendly and cost-effective method for the treatment of wastewater and polluted environments with respect to conventional methods (Sood et al., 2012; Sharma et al., 2014; Newete and Byrne, 2016). The production of biomass through its fast

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61296149

growth ability gave more advantages to this method of remediation however, its inability to tolerate high concentrations of metal and the influence of seasons on its effectiveness is disadvantageous (Rai, 2008; Mannino et al., 2008).

Sharma et al. (2014) stated that phytoremediation is used either as a secondary or a tertiary treatment method for industrial or mine wastewater treatment because of high concentration of heavy metals and the toxicity of the metals. As a result of this, Rai (2008) encouraged regular harvest and safe disposal of the biomass for effective phytoremediation treatment in order to avoid the release of the absorbed or adsorbed metals back into their source when the plant dies and decompose.

Plants Associated with Phytoextraction and Phytostabilisation of Heavy Metals: A case study of Sri Lanka and South Africa

The success of phytoextraction and phytostabilisation is dependent on the plant species available. Baker and Whiting (2002) also indicated that those plants that can carry out these two phytoremediation approaches in remedying acid mine drainage are those native to the region of interest and are able to tolerate and accumulate high concentrations of heavy metals. Baker et al. (2000) further pointed out that many hyperaccumulators of heavy metals such as Cu, Co, As, Zn, Pb, Mn, Se, Cd, and Ni are characterised by their ability to survive high concentrations of these heavy metals and always endemic to metal-rich substrates. Over 420 species of heavy metals hyperaccumulators that belong to about 45 plant families have been identified (Cobbett, 2003). In addition, Krämer (2003) reported that new hyperaccumulators are being discovered from field collections with only few number of them tested in the laboratory for their behaviour and mechanisms of hyperaccumulation. Several fascinating patterns have been observed since the events of hyperaccumulators discovery (Ernst, 2000; Baker and Whiting, 2002). First, many families of plants such as Asteraceae, Brassicaceae, Euphorbiaceae, Fabaceae, Flacourtiaceae, and Violaceae were found to contain large numbers of hyperaccumulators. This implied that several genera within the families may be predisposed or preadapted to tolerate high level of heavy metals. The second pattern observed was the high percentage of these hyperaccumulators in tropical regions of the world. About 320 species of Ni hyperaccumulators discovered, two-thirds were found in the tropical regions of the world (Reeves, 2003; Proctor, 2003). The third pattern indicated that more than 80% of the identified hyperaccumulators take up more Ni than the other metals. The reasons behind this observed pattern of hyperaccumulators occurrence could be attributed to the combination of the following factors:

- Availability of time for the evolution of these species of hyperaccumulators in the tropical regions.
- High weathering of naturally occurring ore-bodies in tropical regions which imposes a greater selective pressures on indigenous floras.
- Provision of a selective advantage in dealing with other stresses of tropical regions due to the heavy metal accumulation traits in the hyperaccumulators.
- The availability of Ni over the other metals due to the presence of many tracts of Ni-enriched serpentine outcrops along continental margins.
- The interest of researchers in discovering hyperaccumulators in tropical regions.

Reeves (2003) reported that over 50 species of Ni hyperaccumulators have been found endemic to the metal-rich serpentine outcrops of New Caledonia (an island). These include species from genera such as *Cledion* (Euphorbiaceae), *Argophyllum*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61296149

(Grossulariaceae), *Casearia* (Flacourtiaceae), *Geissois* (Cunoniaceae), *Homalium* (Flacourtiaceae), *Hybanthus* (Violaceae), *Oncotheca* (Oncothecaceae), *Pancheria* (Cunoniaceae), *Phyllanthus* (Euphorbiaceae), and *Xylosma* (Flacourtiaceae) (Jaffré et al., 1979; Reeves, 2003). Jaffré et al. (1976) found that the latex of a small tree called *Seberita acuminata* (Sapotaceae) that is endemic in the island contains more than 20% Ni by dry weight. Proctor (2003) reported that the Asian region have few identified hyperaccumulator and most of them are closely related to the ones found in Sri Lanka. *Myristica* (Myristicaceae), *Planchonella* (Sapotaceae), and *Trichospermum* (Tiliaceae) are the genera of Ni hyperaccumulator found in Indonesia. Another Asian genus called *Rinorea* (Violaceae) has two Ni hyperaccumulating species (Brooks and Wither, 1977a,b; Wither and Brooks, 1977). Wither and Brooks (1977) identified that *Rinorea benghalensis* collected from Sri Lanka's herbarium has 1% Ni hyperaccumulation by dry weight. Rajakaruna and Baker (2004) was in the opinion that this species may have been collected from the serpentinized areas of Katupotha in the south-central part of island. The same species was also found in Sabah (Jopony and Tongkul, 1999) and found to hyperaccumulate Ni. The genera such as *Brackenridgea* (Ochnaceae), *Dichapetalum* (Dichapetalaceae), *Walsura* (Meliaceae) as well as *Phyllanthus* (Euphorbiaceae) and *Shorea* (Dipterocarpaceae) widely represented in the Sri Lankan flora were found to hyperaccumlate Ni in Sabah and Phillipines (Proctor et al., 1989; Baker et al., 1992). Jayasekera and Rossbach (1994, 1996) suggested that there may be several taxa in Sri Lanka with the capacity to accumulate high concentrations of heavy metals.

Sri Lankan endemic plants such as *Crotalaria biflora* (Fabaceae), *Evolvulus alsinoides* (Convolvulaceae), *Hybanthus enneaspermus* (Violaceae) showed high level of whole-plant Ni hyperaccumulation; and *Clerodendrum infortunatum* (Verbenaceae), *Croton bonplandianus* (Euphorbiaceae), *Geniosporum tenuiflorum* (Lamiaceae), *Tephrosia villosa* (Fabaceae), and *Waltheria indica* (Sterculiaceae) showed high level of whole-plant Cu hyperaccumulation (Rajakaruna and Bohm, 2002). It is worth noting that Cu hyperaccumulation is a rare and the taxa shown to accumulate Cu need further review to confirm these preliminary findings. *Cassia kleinii* (Fabaceae), a woody shrub well-suited, found in Ni- and Cr-enriched serpentine outcrop of Ussangoda, has shown Ni hyperaccumulation (Rajakaruna and Bohm, 2002; Iqbal et al., 2006).

Combretum erythrophyllum (River Bush-willow), an indigenous South African tree species that may reach a height of approximately 5 m within 5 years and can further grow to a height of about 15 m after 50 years (Stoffberg et al., 2008), has been used as a phytoextraction and phytostabilisation option on several tailings dams in Johannesburg. This tree can survive in high salinity areas and bears seed. McGaw et al. (2001) reported that the leaves and back of this tree is used in traditional medicine around southern Africa. Based on this, care needs to be taken in the harvest of this tree for traditional medicine when used for phytoremediation.

Eucalyptus camaldulensis (Red River gum) is an invasive plant with Australia as its native country. It is also found in South Africa. This tree is able to strive well in a high salt and acidic conditions and other harsh conditions including drought. It is a hyperaccumulator of Mn and Pb. Singh et al. (2010) found out that *E. camaldulensis* showed high productivity and great reduction in most soil mineral concentrations in an experiment done to assess mineral uptake of *Acacia nilotica* L. (babool), *Dalbergia sissoo* L. (sissoo) and *Eucalyptus camaldulensis* seedlings. From the findings

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61296149

of this work, it was indicated that *E. camaldulensis* was the best option for the rehabilitation of soil because it can tolerate high salt concentration in the soil and water. It is important that sterile plants are planted for phytoextraction to minimise the risk of invasion of the surrounding environment.

Tamarix usneoides (Wild Tamarix) is native to South Africa and can thrive well in highly saline environments. The plant possesses a good root system that can penetrate deep water tables in arid environments and an adaptive salt glands that can secret excess salts. In South Africa, this plant is used for phytoremediation with success around tailings dams. *Sporobolus spicatus* (Salt Grass) is adapted to growing salt pan edges, marsh and river edges as perennial grass. The salt accumulation by the shoots of this grass increases with increasing soil salinity (Ramadan, 2001). This plant is recommended to be used for phytoremediation because of its ability to survive in adverse and wet conditions.

Phytoextraction of Metals in Mine Tailings: A Case Study of Temperate and Arid Environments

Phytoextraction of metals especially from mine tailings entails the application of metal-hyperaccumulating plants that accumulate the metals either in their root, leaves or stem. This accumulation of heavy metals is followed by the harvesting of the plants. The harvested plants could either be destroyed or the accumulated heavy metals are recycled and reused. Plants that concentrate metals into above-ground biomass at a very high concentrations are known as hyperaccumulators. These hyperaccumulators have the tendency to accumulate metals at levels of 0.01–1% of the plant biomass produced. This is dependent on the specific metal being absorbed by these plants (Brooks, 1998; Baker et al., 2000). High biomass production and fast growth rates are the key characteristics of these hyperaccumulators that enhances maximum accumulation of metals. Accumulation factor which is the ratio of metals in the shoot tissue to the metal in the contaminated environment, and translocation factor which is defined as the ratio of the metals in the shoot to the metals in the root of the plants are other measures used to identify and define hyperaccumulators. Based on accumulation factors, translocation factors, high biomass and fast growing rate, over four hundred species of hyperaccumulators that belong to 45 families have been identified as effective hyperaccumulators of metals from contaminated soils with species specifically capable of phytoextraction in mine tailings being identified (Baker et al., 2000; Deng et al., 2007; Turnau et al., 2007). The general method of identifying and defining hyperaccumulators is the metal concentration in the shoot tissues of plants. Furthermore, accumulation factor is also necessary for identifying the feasibility of phytoextraction. This feasibility of phytoextraction means the number of cropping cycles required for the metal removals to the level that is accepted (Zhao et al., 2003).

For the identification of potential plants candidates for phytoextraction in acid mine drainage, several surveys of plants colonizing mine tailings together with hyperaccumulators grown in mine tailings have been done. However, phytoextraction of metals from mine tailings are faced with major challenges. Phytoextraction of metals in mine tailings is known to be generally poor because of low metal bioavailability in tailings amended with compost to enhance the growth of plants (Knight et al., 1997; Meerts and Van Isacker, 1997; Salt et al., 1997; Bennett et al., 2003). Furthermore, Krzaklewski and Pietrzykowski (2002) observed that some plant species have the ability

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61296149

to survive and colonize mine tailings but their metal accumulation was not sufficient for them to be used as hyperaccumulators. In order to enhance hyperaccumulation of metals by hyperacumulators, metal chelators have been tested and used to enhance hyperaccumulation. However, their use posed a problem of phytotoxicity for the plants. Based on this, chelators are applied generally after good plant biomass production is achieved (Berti and Cunningham, 2000). Another challenge faced when chelators are applied is the leaching of metals into the groundwater especially in temperate environments due to increase solubility of metals in the mine tailings (Wu et al., 1999; Schmidt, 2003). This leaching of metals into groundwater leads to their pollution.

Transgenic hyperaccumulator plants have been researched and explored for remediation of mine tailings in many countries of the world. However, the major drawback of these transgenic hyperaccumulators is their adverse impacts on species diversity, soil ecosystems, and the food chain (Wolfenbarger and Phifer, 2000; Wolfe and Bjornstad, 2002). Furthermore, their invasive potentials and ability to colonize disturbed areas in desert environments and establishment of late successional species is also a major concern in the use of transgenic hyperaccumulators (Castellanos et al., 2005). In order to enhance the proper management of this transgenic hyperaccumulators, the use of sterile clones, harvesting of plants before flowering, selection of species that will not outcompete indigenous plants have been encouraged (Pilon-Smits and Pilon, 2002; Snow et al., 2005). Wolfe and Bjornstad (2002) finally observed that poor public acceptance may pose a problem in the implementation of transgenic hyperaccumulators.

Plants growing in temperate environments where there are mine tailings experience low pH, metal toxicity, lack of soil structure, and low nutrient content as challenges that oppose their developments. Those plants that are able to tolerate and overcome the challenges in temperate environments often face the problems of low biomass production. This low biomass production impedes the success of phytoextraction in the temperate environments as the success of metal accumulation by the plants depend on the biomass production. A typical example is found in Europe where the populations of *Thlaspi caerulescens* were found to be thriving in metal contaminated sites and mine tailing sites with the ability to accumulate the metals. In the United Kingdom, *T. caerulescens* were found to thrive in mine tailings and mine spoils. The plant was found to accumulate 50 - 160 mg kg^{-1} Cd and 13,000 - 19,000 mg kg^{-1} Zn with accumulation factors of Zn >1 (Baker et al., 1994). The accumulation factors of the plant was observed to increase up to 73 and 40 for Cd and Zn respectively when the plant was exposed to a lower level of Cd to Zn ratio (Zhao et al., 2003).

Study done in greenhouse using *T. caerulescens* exposed to a mine spoil containing up to 3300 mg kg^{-1} Zn and 58 mg kg^{-1} Cd to evaluate its phytoextraction potential showed that the plant accumulated 250 mg Cd kg plant $biomass^{-1}$ and 8,000 mg Zn kg plant $biomass^{-1}$ (Knight et al., 1997). As a result of low biomass production of the plant in mine tailings, an approximate 100 - 1200 cropping cycles would be needed to remove Cd and 200 - 600 cropping cycles to remove Zn from the studied mine tailings. These cropping cycles translated into decades for complete remediation of the mine tailings. The obtained results showed that *T. caerulescens* may be useful for the remediation of environment contaminated with low Cd and Zn and may not be suitable for more highly contaminated mine spoil that was studied.

In the quest to improve phytoextraction efficiency in mine tailings, two transgenic strains of *Brassica juncea* (L.) Czern were discovered and observed to accumulate up to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61296149

1.5 to 3-fold more metal (Cd, Cr, Cu, Pb, Zn) than the wild type strain in a greenhouse study (Bennett et al., 2003). The enzymes *c*glutamylcysteine synthetase (ECS) and glutathione synthetase (GS) that affect production of the metal-binding thiol peptides, phytochelatin and glutathione, respectively were overproduced by the transgenic strains. Twenty five per cent and five per cent of Cd and Zn respectively were reduced by the strains of this transgenic *B. juncea* from compost-amended tailings however, leaching was later discovered as the primary reason for metal reduction in this study (Ernst, 2005). Bennett et al. (2003) indicated that the addition of compost and lime required for growth of *B. juncea* in the mine tailings decreased plant metal bioavailability and hence the overall phytoextraction efficiency of the transgenic plants.

The growth of plants in arid environment is also faced with the challenges of lack of water and often saline conditions in addition to low pH, metal toxicity, low nutrients and lack of soil structure. Despite the challenges faced by the plants in this environment, a promising list of natural hyperaccumulators that have the ability to colonize mine tailings have been identified however, few of them have been studied in the greenhouse to evaluate their hyperaccumulation potentials (Leita et al., 1989; Bech et al., 2002; Gonzalez and Gonzalez-Chavez, 2006). In Spain, *Cichorium intybus* L. and *Cynodon dactylon* (L.) Pers. which naturally colonize the mine tailings were evaluated for lead (Pb) accumulation. This study was carried out on artificially Pb contaminated potting soils. The shoot Pb accumulation was observed to be 800 - 1500 and 400 – 1200 mg kg^{-1} Pb for *C. intybus* and *C. dactylon*, respectively. Furthermore, it was observed that shoot accumulation of the metal had no inhibition effect on the plant growth and biomass production. However, the limitation of this study was that the authors were not able to show how this phytoextraction ability of these plants would translate to a mine tailings environment (Del Rio-Celestino et al., 2006).

Conesa et al. (2007b) carried out a field and greenhouse study on *Lygeum spartum* L. a grass known to colonize mine tailings site in Mediterranean regions, to evaluate the phytoextraction ability of the grass. It was observed in the field and greenhouse that the metal accumulation was low with the exception of zinc which was extremely high and between 3000 to 6000 mg kg^{-1} when plants were irrigated and fertilized in the greenhouse. Frérot et al. (2006) observed in their work that contrary to the believe that *Armeria arenaria* (Pers.) Schult., *Festuca arvernensis* Auquier, and *Koeleria vallesiana* (Honck.) Gaudin are non-hyperaccumulators, they were found to hyperaccumulate Pb at 1,000 - 2,000 mg kg^{-1} in the field.

Elevated salinity is the most common characteristics of mine tailings in arid environments. The electrical conductivity of the environment is believed to influence by the salinity and this electrical conductivity was observed in arid environments with high salinity (22 dS m^{-1}) to be greater than the tolerant level for plants (Munshower, 1994; Marschner, 1995). *Atriplex* spp accumulate sodium and potassium at a high concentrations in mine tailings and uncontaminated soils and as a result, they are referred to as halophytes (Osmond et al., 1980; Mendez et al., 2007). The work done by Lutts et al. (2004) in a hydroponic greenhouse study using *Atriplex halimus* L. showed that the plant can take up 830 and 440 mg kg plant $tissue^{-1}$ of Cd and Zn respectively in shoot biomass and did not display symptoms of toxicity during growth. This high concentration of the accumulated metals may have been influenced by the low concentrations of cations (Na^+/K^+) in the hydroponic growth medium. However, the occurrence of the same result in the field study is not known.

Limitations of Phytoextraction

The widespread use of phytoextraction as a remediation strategy for mine tailings is faced with major drawbacks. The time taken for a complete phytoextraction might be so long especially with a highly metal polluted mine tailings. Plant metal bioavailability and metal extraction efficiency may decrease as a result of the distribution of different metals in mine tailings alongside with compost amendments required for the plant growth. Ernst (2005) indicated the polymetallic nature of mine tailings as another drawback to the success of the spread of phyotextraction as hyperaccumulators can only accumulate one or two metals and as a result, multiple plant species and ecotypes are required. This drawback is further strengthened in arid regions with high saline content of mine tailings and the preference of Na^+/K^+ by many halophytes (Osmond et al., 1980; Munshower, 1994; Marschner, 1995). Characteristics of plants can also decrease the efficiency of plants to metals from mine tailings. Keller et al. (2003) pointed out that hyperaccumulators generally possess shallow root zone which limit metal removal by plant rooting depth. Metal extraction efficiency may be reduced in tailings with high metal concentrations. Generally, the harsh conditions of mine tailings influences biomass production of plants and consequently, the efficiency of phytoextraction (Ernst, 2005; Audet and Charest, 2007).

Wildlife is in danger of metal exposure as a result of the accumulation of the metals in the shoot system of the hyperaccumulators eatable by wildlife animals. Wood et al. (1995) pointed out that the worst scenario can be seen in arid regions where food sources are limited. All these drawbacks are believed to influence the cost of implementing phytoextraction by making it high and optimisation of this process may also require expensive inputs. Furthermore, the cost of harvesting, disposing and re-seeding of hyperaccumulators which may be required for many cropping cycles add to the total cost of the technology (Cunningham and Berti, 2000). In conclusion, there is the need to consider the safety of wildlife. This do not remove the remediation application of phytoextraction in mine tailings. However, there is the need to balance the costs associated with this strategy and the potential value of the land once it is reclaimed.

Phytostabilization of Mine Tailings: A Case Study of Temperate and Arid Environments

Phytostabilization of mine tailings involves the establishment of plants that have extensive root system which will enable them to create steady vegetative cap that does not accumulate metals into above-ground tissues. The mechanism of action of established plants in the mine tailings include sorption of metals onto the root surfaces, accumulation of metals in the root tissue and stabilization of metals through precipitation (Cunningham et al., 1995; Wong, 2003). Furthermore, established plants in the mine tailings for phytostabilization should have the ability to enhance diverse heterotrophic microbial community interaction that will encourage the growth of plants and promote the transformation of the materials in the mine tailings necessary for the improvement of the soil structure (Mummey et al., 2002a; Glick, 2003; Wong, 2003; Mendez et al., 2007). The established plants also provide the initial plant cover that enhances the growth and establishment of other plants in the environment leaving the environment with diversified and self-sustaining vegetative cap that reduces water erosion, leaching processes and eolian.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61296149

The plants used for phytostabilization varies from region to region and depends on the nature of metal contaminants in the mine tailings. Furthermore, physicochemical factors influences the stability and diversity of naturally established plant communities in the same regions (Conesa et al., 2007a). As a result, physicochemical characteristics of individual mine tailings sites need to be considered before the establishment of plants required for phytostabilization. There is also the need to amend the mine tailings with compost manure or lime required for the growth of the plants so as to remove any toxic effect and decrease metal bioavailability. The plants selected for phytostabilization need not to translocate metals to shoot tissues. This is to safe guard the life of wildlife animals that may depend on them for survival and also to prevent surface contamination. In view of this, the ratio of shoot metal concentrations to root metal concentration or soil metal concentration should be less than one. The plants should also meet the US Domestic Animal Metal Toxicity Limits to prevent exposure to foraging animals (Wood et al., 1995; NRC, 2005).

Grasses are mostly used for phytostabilization in temperate environments because of their rapid growth and extensive rooting systems. In Europe, *Festuca* spp. and *Agrostis* spp. are native grass species that are mostly used for phytostabilization. They are also used in the US and China for phytostabilization (Smith and Bradshaw, 1979; Ye et al., 1999; Pierzynski et al., 2002; Von Willert and Stehouwer, 2003). A greenhouse experiment done in Scotland by Pichtel and Salt (1998) showed that application of NPK fertilizer only enhances the growth of *Festuca ovina* L. and *F. rubra* in a moderately acidic Pb/Zn mine waste sample.

Several field trials done in the UK indicated successful establishment of *F. rubra* and *Agrostis tenuis* Sibthorp in Pb/Zn and Cu mine tailings with a combination of fertilizers and lime (Smith and Bradshaw, 1979). Furthermore, native plants have been explored by many studies in combination of soil cover to achieve phytostabilization. This was seen in the work done in Washington, US by Kramer et al. (2000) using *Alnus viridis* subsp. *sinuate* (Regel) and *Anaphalis margaritacea* (L.) where they observed the two plants demonstrating adequate plant biomass and shoot tissue exclusion of high concentrations of Al and Zn when grown in copper mine tailings amended with biosolids-woodchip mixture before the planting of the plants. Similarly, in China, Shu et al. (2001) carried out a study using 41 native seed species from a soil seed bank obtained from nearby uncontaminated areas. They established the plants in a Pb/Zn mine tailings following application of an 8-cm top-soil layer over the tailings material and observed that 9 of the plants survived with three of them showing both good plant coverage and low metal accumulation.

Drought-, salt- and metal-tolerant plants are required for effective phytostabilization of mine tailings in arid and semiarid climates. Addition of an organic amendment and irrigation enhance the success of re-vegetation in arid environment. In semiarid Western Australia *Atriplex* spp. are known pioneer plants on mine tailings (Osmond et al., 1980; Jefferson, 2004). An irrigated greenhouse study conducted by Mendez et al. (2007), showed that a minimum of 10% compost addition was required for adequate growth of *Atriplex lentiformis* (Torr.) in both moderately acidic and extremely acidic Pb/Zn mine tailings. They also observed that shoot uptake of metals did not exceed US Domestic Animal Metal Toxicity Limits.

Sabey et al. (1990) also conducted a greenhouse study using biosolids which indicated that a sludge application of 60 Mg ha^{-1} was required for growth of *Atriplex canescens* (Pursh) in copper mine tailings. One disadvantage of the high sludge

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61296149

application observed by them was elevated Cu concentrations tissues of the leaves that exceeded recommended US Domestic Animal Metal Toxicity Limits by 5-fold. Rosario et al. (2007) conducted a field experiment to examine the impact of compost on establishment of *A. canescens* in an alkaline mine tailing site in southern Arizona, US. Forty four litres of water over the first eight months of growth was administered to the individual plants. Similar plant growth results were obtained in both composted and uncomposted tailings and 80% of transplants survived. Further observation in this study was that Pb exceeded the US Domestic Animal Metal Toxicity Limits in some plants by up to 3-fold. The information obtained from these studies implied that plant growth requirements and physicochemical factors of the mine tailings determines the amount and type of amendment required by the plants. Therefore, amendment requirements are both site- and plant species-specific.

Re-vegetation through the use of direct-seeding in field studies that have been performed in an arid environment was promising. Study performed in Zimbabwe by Piha et al. (1995) using direct seeding method with no irrigation in a tin mine tailings site where the seeds were subjected initially to seven weeks of drought produced 40% plant cover with a mixture of grasses and legumes after the first growing season using only an initial addition of NPK fertilizer. The study done in South Africa by Van Rensburg and Morgenthal (2004) in a platinum tailings with seeds from a mixture of grasses and amended with fertilizer produced average plant cover of 2%. However, the authors suggested that lack of irrigation and poor timing that did not take advantage of the seasonal rainfall are the cause of these poor results. The seeding study done by Windsor and Clements (2001) in a gold mine tailing site in where the seeds were irrigated showed that seedling density was 3-fold greater in irrigated plots compared to plots without irrigation. This implied that in arid and semi-arid environments, irrigation significantly increases the plant establishment. If irrigation is not feasible, direct seeding studies require precise timing to take advantage of the normal rainfall season.

Limitations of Phytostabilization of Mine Tailings

Phytostabilization being a long-term field studies makes it difficult to evaluate the overall success of this strategy. A 20-year study carried out by Mummey et al. (2002b) showed that both plant and microbial diversity in a re-vegetated mining site was low compared to an adjacent undisturbed site in a semiarid grassland. However, plant cover gave a promising result of the use of this technology because it was higher than the ones found in the undisturbed site. Complete plant coverage is dependent on the environment. Semi-arid and arid shrublands are not likely to produce a complete plant coverage when compared to the temperate environments. This becomes a limitation to the success of the use of phytostabilization to remedy acid mine tailings. The difference in plant coverage in arid and temperate environment is dependent on nitrogen availability, water use efficiency and light. Availability of nitrogen and efficiency of water use influences plant dynamics in semi-arid and arid environment whereas light and nitrogen availability influences plant dynamics in temperate environment (Tilman, 1988; Gebauer and Ehleringer, 2000). Therefore, infrequent rainfall could result to increase mortality of the secondary successional plant communities in semi-arid and arid environment (Watson et al., 1997; Castellanos et al., 2005). To overcome some of the limitations it is recommended that a comprehensive approach which employs various strategies can be embarked upon. Emenike et al. (2018) explores the combined

DOI: http://dx.doi.org/10.15666/aeer/1703_61296149

use of plants and microbes to biotransform contaminated soils and similar mechanisms including the addition of nutrients and nanoremediation as suggested by Das (2018) may prove sustainable. The table below gives a summary of plants and their bioremediation potentials (*Table 1*).

Table 1. *Summary of plant species used in phytoextraction and phytostabilization of metals in acid mine drainage*

Plant species	Family	Remediation Mechanism	Achieved Results	References
Chrysopogon zizanioides	Poaceae	Phytoextraction	Zn, Cu, and Ni removal	Melato et al. (2016)
Brassica juncea	Brassicaceae	Phytoextraction	Cr, Cu, Cd, Ni, Zn, and Pb accumulation and removal	Kumar et al. (1995); Blaylock et al. (1997); Begonia et al. (1998); Zhu et al. (1999)
Eichhornia crassipes	Pontederiaceae	Phytoextraction	97.3% Cu removal efficiency in aqueous solution, arsenic hyperaccumulation	Mokhtar et al. (2011); Michelle et al. (2010)
Waltheria indica	Malvaceae	Phytoextraction	High level of whole-plant Cu removal	Rajakaruna and Bohm (2002)
Cassia kleinii	Fabaceae	Phytoextraction	Ni removal	Iqbal et al. (2006); Rajakaruna and Bohm (2002)
Thlaspi caerulescens	Brassicaceae	Phyotextraction	Accumulation of 50 - 160 mg kg^{-1} Cd and 13,000 - 19,000 mg kg^{-1} Zn	Baker et al. (1994); Zhao et al. (2003)
Seberita acuminata	Sapotaceae	Phytoextraction	Removal of over 20% of Ni	Jaffré et al. (1976)
Rinorea benghalensis	Violaceae	Phytoextraction	1% removal of Ni	Wither and Brooks (1977)
Cichorium intybus L.	Asteraceae	Phytoextraction	Removal of 800 -1500 mg kg^{-1} Pb through shoot accumulation	Del Rio-Celestino et al. (2006)
Cynodon dactylon (L.) Pers.	Poaceae	Phytoextraction	Removal of 400 -1200 mg kg^{-1} Pb through shoot accumulation	Del Rio-Celestino et al. (2006)
Armeria arenaria (Pers.) Schult., *Festuca arvernensis* Auquier, and *Koeleria vallesiana* (Honck.)	Plumbaginaceae, Poaceae, and Poaceae respectively	Phytoextraction	Removal of 1,000 - 2,000 mg kg^{-1} Pb	Frérot et al. (2006)
Crotalaria biflora, *Evolvulus alsinoides*, and *Hybanthus enneaspermus*	Fabaceae, Convolvulaceae, and Violaceae respectively	Phytoextraction	Whole-plant hyperaccumulation of Ni	Rajakaruna and Bohm, (2002)
Clerodendrum infortunatum, Croton bonplandianus, Geniosporum tenuiflorum, Tephrosia villosa, and Waltheria indica	Verbenaceae, Euphorbiaceae, Lamiaceae, Fabaceae, and Sterculiaceae respectively	Phytoextraction	Whole-plant hyperaccumulation of Cu	Rajakaruna and Bohm, (2002)
Atriplex halimus L.	Amaranthaceae	Phytoextraction	Accumulation of 830 and 440 mg kg plant $tissue^{-1}$ of Cd and Zn respectively in shoot biomass	Lutts et al. (2004)
Lygeum spartum L.	Poaceae	Phytoextraction	Removal of 3000 - 6000 mg kg^{-1}Zn	Conesa et al. (2007b)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61296149

Plant species	Family	Remediation Mechanism	Achieved Results	References
Festuca rubra and *Agrostis tenuis* Sibthorp	Both belongs to Poaceae	Phytostabilization	Successful establishment in Pb/Zn and Cu mine tailings with a combination of fertilizers and lime	Smith and Bradshaw (1979)
Alnus viridis subsp. *sinuate* (Regel) and *Anaphalis margaritacea* (L.)	Betulaceae, and Asteraceae respectively	Phytostabilization	Demonstration of adequate plant biomass and shoot tissue exclusion of high concentration of Al and Zn in Cu mine tailings amended with biosolids-woodchip mixture	Kramer et al. (2000)
Atriplex lentiformis	Amaranthaceae	Phytostabilization	Demonstrated adequate growth in moderately acidic and extremely acidic Pb/Zn mine tailings with 10% compost addition	Mendez et al. (2007)
Atriplex canescens	Chenopodiaceae	Phytostabilization	Successfully grown in Cu mine tailings with sludge application of 60 Mg ha^{-1} and displayed high Cu concentrations in the leaves tissues	Sabey et al. (1990)

Conclusion

Remediation of mine tailings through phytoremediation approaches is a promising strategy. Work done on phytoextraction indicated that the approach will be limited to sites where the land values are high, and the time of restoring the site will be long due to high cost and lengthy treatment times. Phytostabilization provides a more suitable generation phytoremediation approach because of its easy nature of implementation and lower cost. However, both approaches need further review and optimization to enhance complete restoration of AMD.

The Indian mustard, *Brassica juncea* (Brassicaceae), *Chrysopogon zizanioides* and an aquatic macrophyte *Eichhornia crassipes* have been identified to be successful in the remediation of AMD. This review suggests further research on their mechanisms of heavy metal remediations, the climatic influence, and the nutrient requirements for the development of enough biomass for phytoremediation. Furthermore, the combination of these three plant species in the remediation of most areas or mine tailings contaminated with heavy metals needs further research.

Abstract. Drought is considered as one of the significant threats to food security worldwide as it inhibits the growth, yield and quality of economically important crops. An increase in crop yield is considered a tremendous achievement as it will be helpful to meet the current growing demand for food in drought-stressed areas. Silicon (Si) is the second most abundant component in the soil. Recent research has revealed that Si can enhance plant tolerance against drought stress. In addition, application of Si can increase seed germination, underground and aboveground biomass, photosynthetic pigments, quality and yield of grains. Therefore, we have summarized the importance of Si in improving the drought tolerance in plants. Furthermore, we have explained the Si-mediated mechanisms which led to modifications in gas exchange properties, homeostasis of the nutrient element, synthesis of compatible solute, osmotic adjustments, antioxidant stimulation and enzymatic action in plants under drought stress. We believe that the current study will help in understanding the importance of Si application in plants under drought stress conditions.

Keywords: *seed germination, antioxidants enzymes, drought tolerance, gene expression, soil*

Introduction

The increasing demand for food day by day is one of the significant challenges for agricultural scientists worldwide (Warner and Jones, 2017). On the other hand, the world's crop productivity is continually decreasing due to extreme climate changes and shrinking resources. In view of that, finding the new options to improve the crop productivity is a challenging task for all nations across the world (George et al., 2018; Lesk et al., 2016; Rizwan et al., 2018). Abiotic stresses (salt, drought, and extreme temperature stress) are the challenging problems for plant development and its productivity in many parts of the world (Khalil et al., 2016, 2018; Suzuki et al., 2014). Among these abiotic stresses, drought is one of the most harmful environmental factors which inhibit growth, yield and quality of economically important crops (Ali et al., 2016; Calvo-Polanco et al., 2016). Therefore, it is estimated to be one of the severe threats for future agricultural crop production (Khalil et al., 2018; Tayyab et al., 2018a). The negative impacts of drought stress on many plants have become the central debate in recent years (Tayyab et al., 2018a). Drought along with other abiotic stresses including heavy metal contamination not only restricts plant production but also poses severe threats to human health (Arshad et al., 2016; Noman and Aqeel, 2017). For example, Liu et al. (2017) revealed that under different growth stages, the translocation and redistribution of cadmium have a different influence for drought in peanut plants. It can affect the processes such as cell dehydration, the inhibition of cell expansion and division, stem elongation, leaf size, root proliferation, disturbed stomatal oscillations, water and nutrient absorption in plants (Kaushal and Wani, 2016; Khalil et al., 2018; Tayyab et al., 2018a). Furthermore, it also reduces photosynthesis (Khan et al., 2017; Zang et al., 2014), soil water potential, water use efficiency (WUE) (Kaushal and Wani, 2016), and induce oxygen deficiency by the production of reactive oxygen species (ROS) (Fukao et al., 2011). Consequently, combating the stress caused by drought is a serious matter to achieve food security in changing climate conditions around the world.

Si is found to be the second most abundant element in soil (Sommer et al., 2006). However, it comprises up to 10% dry weight of many plants. In the past, researchers could not find Si as an essential element for normal development and growth of the plant (Epstein, 1994; Hodson et al., 2005). However, concerning the Si efficiency on the plant's life cycle, Epstein and Bloom (2005) recommended that the proper need of Si element is significant for normal plant growth. Recently, numerous researches have demonstrated that Si mitigates the destructive effects of biotic stresses (pests and diseases) (Dann and Le, 2017; Yang et al., 2017) and abiotic stresses (drought, heavy metal toxicity and salinity) in plants (Biju et al., 2017; Hasanuzzaman et al., 2018; Tayyab et al., 2018b). These benefits are attributed to Si application; thus, Si can play a serious role in order to mitigate drought stress in plants. Moreover, sustainable agriculture has got great importance so it can be used as a high-quality fertilizer because of its non-corrosive and non-polluted nature. Si effect for plant growth and development in unfavorable climatic conditions has been reviewed by many researchers recently around the globe (Guntzer et al., 2012; Tayyab et al., 2018b; Van Bockhaven et al., 2012). Van Bockhaven et al. (2012) reviewed the role of Si for plant disease resistance. However, the mechanisms of Si-mediated mitigation of drought stress in plants are still debatable and need to be reviewed. Si application as a fertilizer for plants also has gained momentum recently. In order to enhance drought tolerance, Si application in term of soil amendment is expected to become a new approach in agricultural farming in the future. Therefore, we have reviewed the current status and progress in understanding the mechanisms of Si-mediated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61516170

drought tolerance in plants. The review unveils the various mechanisms involved in the plant's protection during drought stress as well as suggests guidelines for further research.

History of silicon application

Si is widely distributed as silica or alumino-silicates – better known as rocks and sand. Si is not readily available for plants to use; instead plants can only absorb Si as a monosilicic acid (Marafon and Endres, 2013). Si is beneficial for plants, such as protecting against diseases, insects attacks, reinforcing nutrients and safeguarding under unfavorable conditions like drought, salt or heavy metals toxicity (Debona et al., 2017; Tayyab et al., 2018b). Kutschera and Niklas (2018) highlighted the function of Si in plant biology as "whether silicic acid is an indispensable substance for those plants that contain silica, whether it takes part in the nutritional processes, and what is the relationship that exists between the uptake of silicic acid and the life of the plant?" (Lewin and Reimann, 1969). In the 20th century, several trials were directed on Si to demonstrate its beneficial role in agriculture owing to its safe behavior and presence in nature. For the first time in the world, rice (*Oryza sativa*) soils in Japan were treated with Si in 1955 (Takahashi et al., 1990). Si fertilizers commonly contain neutral or slightly alkaline pH which has the neutralizing effect for acidic soils (Savant et al., 1999). Several kinds of Si fertilizers are applied in the field usually in the form of solids as well as liquids such as calcium silicates, calcium and magnesium silicates wollastonite, potassium silicate and sodium silicate.

Silicon in soils

Si contributes to the second major element existing in soil (Sommer et al., 2006). Si reacts with oxygen and turns into silicates, i.e., feldspars and quartz (*Fig. 1*). Silicate formed by oxygen and pure Si is known as silica (i.e., quartz) whereas other silicates (i.e., feldspars) have some elements (sodium, potassium, aluminum, and calcium) including oxygen and Si. Soils are formed as the results of weathering of rocks made from alumino-silicates and silicates minerals. By biological and physical weathering silicate minerals release Si into soil solution that formulates silicic acid (H_4SiO_4). Then, plant roots absorb silicic acid from soil solution (Epstein, 2009). The plant contains a significant amount of Si owing to its ubiquitous nature and abundance (Epstein, 1999). Si abundance and concentration fluctuates with the soil type. Typically, upper horizons frequently have low Si concentrations in the sandy soils (Marschner, 2011), whereas clay soils have higher phyllo-silicates quantities that release Si. The quartz (SiO_2) mineral is abundantly present in sandy soils which are less prone to decomposition. The complexity of quartz mineral makes sandy soil more responsive to Si application than clayey soil (Demattê et al., 2011). In tropical and subtropical soils, Si commonly is found very low due to desilication because of leaching and some weathering processes (Epstein, 1999). Additionally, it is predicted that 210 to 224 million tons of Si have been removed by intensive arable cultivation throughout the world (Meena et al., 2014).

Silicon uptake and accumulation in plants

Plants differ in their ability to uptaking the Si. Some plants can accumulate more Si in their leaves and those with more than 1.5% of their total dry biomass are known as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61516170

accumulators. Plants containing Si levels less than 0.5% in their leaves are considered as non-accumulators (Marafon and Endres, 2013). Variation of Si concentration in plants is attributed to their Si uptake capability and roots xylem loading (Ma et al., 2001a). The plasma membrane present in plant root cells might provide a path for uncharged monomeric H_4SiO_4 uptake by diffusion. Thus, H_4SiO_4 permeability coefficient of $10^{-10}ms^{-1}$ throughout a plasma membrane (Raven, 2001), does not clarify experimentally measured Si contents in plants (Tamai and Ma, 2003). Passive and active transporters are involved in the Si uptake and transport from growth medium to xylem tissues (Mitani et al., 2005). This hypothesis was confirmed due to Si uptake inhibition as plants were exposed to metabolic inhibitors (i.e., 2,4- dinitrophenol, potassium cyanide) or low temperature (Mitani et al., 2005; Tamai and Ma, 2003). A low-affinity silicic acid transporter involves Si transportation from root medium to cortical cells. Kinetic studies for Si uptake in rice (*O. sativa*), tomato (*Solanum lycopersicum*) and cucumber (*Cucumis sativus*) confirmed that the density of transporters present in the plasma membrane is responsible for Si uptake changes (Mitani et al., 2005). Recently, *Lsi1*, *Lsi2*, and *Lsi6* genes are associated with Si uptake and distribution in rice (*O. sativa*), barley (*Hordeum vulgare*), maize (Z. mays), and cucumber (*C. sativus*) (Ma and Yamaji, 2015). Si-influx transporters (*Lsi1* and *Lsi6*) are associated with Si distribution in the tissues of root and shoot (Mitani et al., 2011). Whereas, putative anion transporter (*Lsi2*) is commonly expressed in roots endodermis (Ma et al., 2007). Ma et al. (2007) reported that *Lsi2* transporter activity is proton-driven and acts as a Si/H^+antiport.

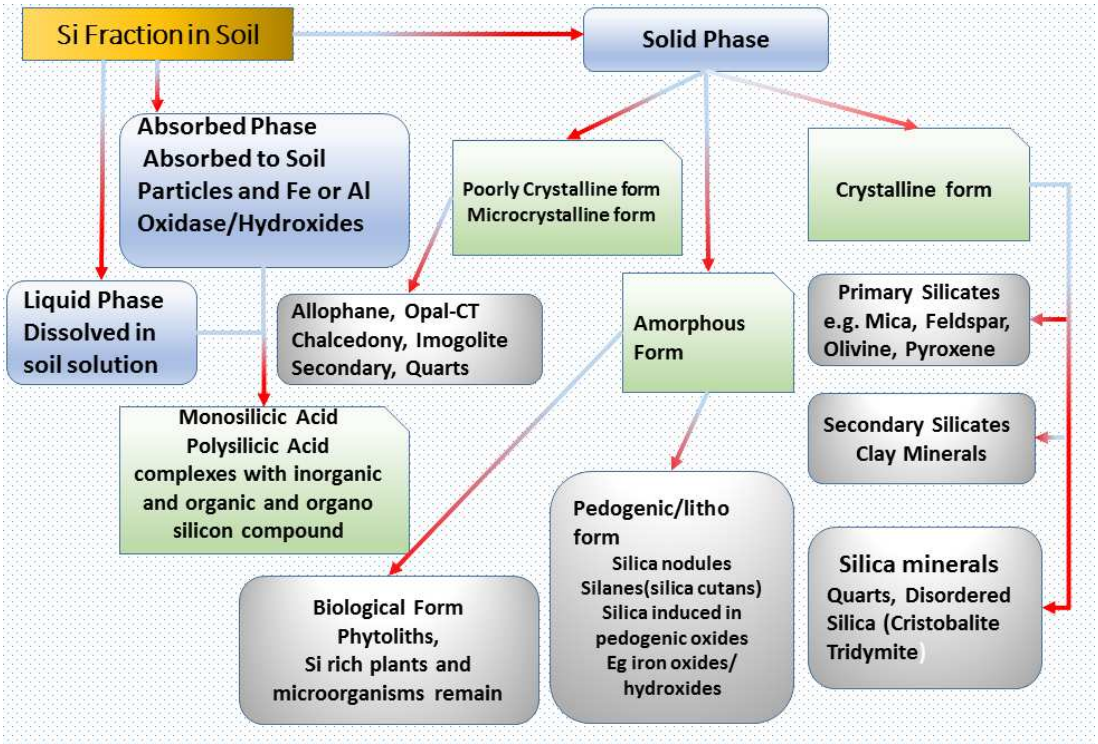

Figure 1. *Various sources of silicon in the soil. (Modified from Zia, 2018)*

Silicon and drought stress

Drought commonly reduces plant growth and its yield in semiarid and arid regions throughout the world (Zandalinas et al., 2018). It adversely affects plant biomass and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61516170

growth of all crops cultivated in main fields as well (Kaushal and Wani, 2016). In contrast, various researchers have demonstrated that Si should consider being a practical approach to overcome these opposing effects stimulated by drought (Guo et al., 2017; Shi et al., 2014). The mechanisms in order to enhance drought tolerance in the plant by Si application at the morphological, physiological and biochemical levels are summarized below (see also *Fig. 2*).

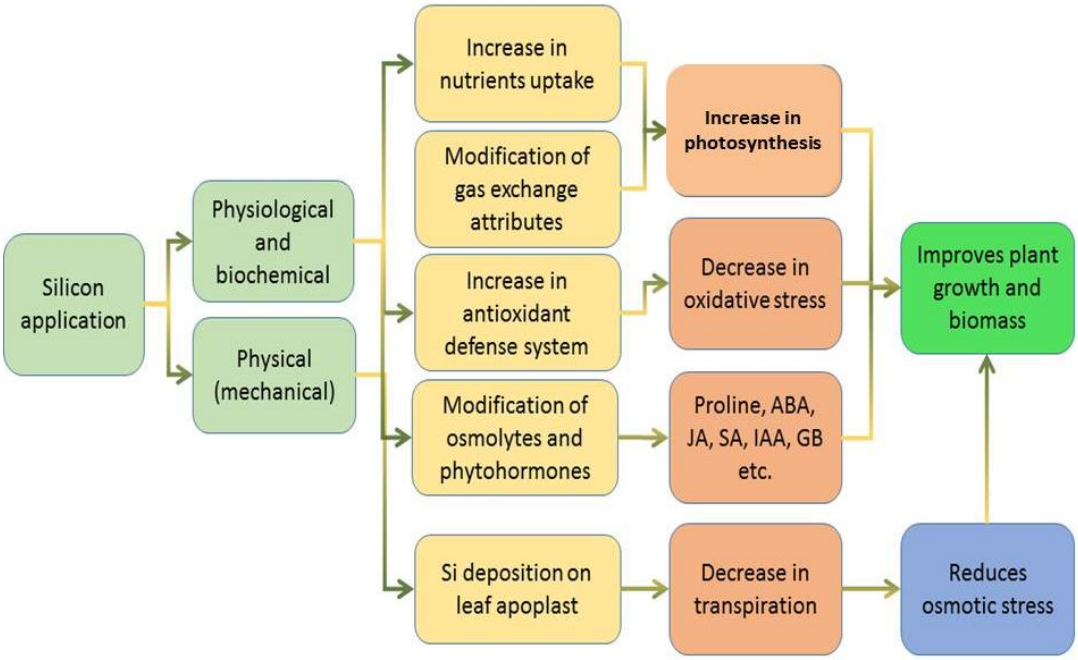

Figure 2. *The mechanism for the Si-mediated alleviation of drought stress tolerance in plants. (Modified from Rizwan et al., 2015; Tayyab et al., 2018b)*

Si-mediated improvement in seed germination under drought condition

Drought stress negatively affects the seed germination leading to considerable reduction in crop yield (Guo et al., 2017; Shi et al., 2014). Until now, a little research was conducted to study the Si effects for seed germination under drought conditions (Ahmed et al., 2016; Hasanuzzaman et al., 2018). On the contrary, Si not only mitigates the adverse effect induced by drought stress on seed germination but also promotes seed development. For instance, seed priming with sodium silicate contributed to recovering wheat (*Triticum aestivum*) seed germination compared to untreated seeds (Hameed et al., 2013). The authors described that soaking of seeds for 8 h in aerated solutions of 20 mM, 40 mM and 60 mM sodium silicate resulted in 97% improvement in seed germination under water-deficit stress induced by 15% polyethylene glycol (PEG)-6000 (Hameed et al., 2013). Similarly, Ahmed et al. (2016) reported seeds priming with Si (silicic acid, sodium silicate, and silica gel) at different concentration (0.5%, 1.0%, and 1.5%) to explore its potential benefits fir couple of wheat (*T. aestivum*) varieties. The authors have shown that silica gel can be used as an active priming practice at 1.5% concentration for better development of a plant under drought conditions. Likewise, calcium silicate employed in the soil in the same conditions enhanced seed germination of maize (*Z. mays*; 15 different cultivars) up to 80.96% under water stress (under rain-fed conditions) (Zargar and Agnihotri, 2013). Shi et al. (2014) reported that the Si

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61516170

application improved the seed germination in four tomatoes (*S. lycopersicum*) cultivars under drought as compared to control (without Si). The authors investigated the effects of exogenous Si (0.5 mM) to tomato (*S. lycopersicum*) bud seedlings under water deficit stress simulated by 10% (w/v) PEG-6000 in four different cultivars ('Jinpengchaoguan', 'Zhongza No.9', 'Houpi L402' and 'Oubao318'), which significantly improved the seed germination by 21.9% - 38.2% (Shi et al., 2014). Similarly, in a recent study, Hasanuzzaman et al. (2018) revealed that application of Si is also an active practice for the alleviation of the destructive effects of drought on seed germination in *Brassica napus*. Furthermore, Si application improved the vigor of seedlings. These reports demonstrate that Si can be effective to mitigate the destructive effects of drought on seed germination of crop plants. However, the general mechanisms must be explored for well understanding of Si functions in seedlings under drought conditions.

Silicon-mediated improvement in plant growth, biomass, and photosynthesis under drought stress

Plant biomass and growth is severely reduced by drought (Amin et al., 2016; Noman et al., 2015), hence the application of Si under drought stress can be considered a practical approach to improve plant biomass and growth. Si should be used in conditions effective for its activity and approach to improve plant growth and biomass under drought stress (Hajiboland et al., 2017; Merwad et al., 2018). Si employed in wheat (*T. aestivum*) grown soil resulted in increased root biomass, shoots, spike weight and dry weight (Ahmad et al., 2007; Gong et al., 2003; Xu et al., 2017). Ratnakumar et al. (2016) reported that foliar application of Si (0, 8, 16, 32 ppm at different plant growth stages such as vegetative, booting and seed development stage) on wheat (*T. aestivum*) in the form of ortho-silicic acid improved the root length, density and growth. In another study shoot and root lengths were improved via seed priming by sodium silicate under PEG-6000-induced drought (Hameed et al., 2013). Similarly, Si supply improved roots and shoot fresh weight of Kentucky bluegrass (*Poa pratensis*) under water stress. The daily amount of water or Si solution was 250 mL per pot. For 14 d, plants were treated with 0, 0.1, and 1.0 mM Si solution for Si treatments and with distilled water for the control (Bae et al., 2017). Application of Si (seed primiprovided the better results of grain yield of wheat (*T. aestivum*) grown under drought in hydroponics in pots and field experiments (Ahmed et al., 2016; Gharineh and Karmollachaab, 2013; Pei et al., 2010). Seed priming combined with other sources of Si improved the grain yield and spike length of the wheat (*T. aestivum*) crop as compared to control without seed priming under drought (Ahmed et al., 2016). The authors used seeds of two wheat varieties, i.e., NARC-2009 and Chakwal-50 which were sown in pots after priming with distilled water and different concentration (0.5%, 1.0%, 1.5%) of Si sources (silicic acid, sodium silicate and silica gel). Maximum Si uptake at three leaves (0.028 µg g−1 dry weight (DW), anthesis (0.072 µg g−1 DW) and maturity (0.103 µg g−1 DW) were recorded for silica gel (15%) (Ahmed et al., 2016). Similarly, the use of Si (potassium silicate) employed on sorghum (*Sorghum bicolor*) resulted in improved roots dry weight by 30% under drought (Ahmed et al., 2011). In a recent study, Si used as fertilizer in sugarcane field enhanced sugarcane (*Saccharum officinarum*) stalk yield, dry biomass and provided the best product under drought (de Camargo et al., 2017). Si applied in soil or through foliar application in the field (five sprays of 1.425 mM Si water solution), resulted in improved potato (*Solanum tuberosum*) yield and dry tuber weight just similar to well-irrigated potato (*S.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61516170

tuberosum) plants (Pilon et al., 2014). Similarly, the application of Si improved the total root length, root surface area, volume and dry weight of rice (*O. sativa*) plants under drought (Ming et al., 2012). However, Nolla et al. (2012) and Moro et al. (2015) demonstrated rice (*O. sativa*) grain yield and plant height improvement by adopting the silicate in soil under drought conditions. Soybean (*Glycine max*) plant shoot length and dry and fresh weight were improved by use of Si under drought (Hamayun et al., 2010). The authors further explained that the adverse effects of PEG-induced drought were alleviated by adding and 200 mg L^{-1} Si to the drought-stressed treatments (Hamayun et al., 2010). Diatomite application in soil provided effective results by improving growth parameter (shoots and roots length) and yield parameters (number of pods, fresh and dry weight of pod) in white lupine (*Lupinus albus L.*) under drought (Abdalla, 2011). Si increased leaf area index in numerous plant species, e.g., wheat (*T. aestivum*) and Fennel (*Foeniculum vulgar Mill*) under drought (Asgharipour and Mosapour, 2016; Gong et al., 2003). The application Si (300 kg of ha^{-1}) increased the quantity of spikelet panicle and grain yield of rice; furthermore, dry matter recovery and yield had a positive linear relationship with shoot Si under drought (Ullah et al., 2017). The application of Si on two maize (*Z. mays*) varieties (hybrid P-33H25 and FH-810) increased the height of plant, stem diameter, number of leaves, cob length, the number of grain/cob, grain yield, and biological yield, which ultimately contributed to better growth and yield (Amin et al., 2016). The application of Si for tobacco (*Nicotiana Rustica L.*) has increased the biomass particularly aboveground parts in drought and control conditions (Hajiboland et al., 2017). Correspondingly, Si application on cowpea increased the yield per plant (Merwad et al., 2018).

Additionally, Si has also progressive influences on straw and grain quality of plants in drought conditions, but unfortunately, the studies are minimal. For example, Si (0.03 mM sodium selenite/1.5 mM potassium silicate) application has a direct relation to levels of phenolic compounds, amylose and flavonoid contents of rice grains. It also increased the lignin, cellulose, pectin, carbohydrates, proteins and fat contents of rice straw under drought conditions in a field experiment (Emam et al., 2014). So, it is necessary to clarify further mechanisms to improve the quality of cereals mediated by Si application under drought, especially at the molecular level. Drought stress is the primary driver which significantly reduces the photosynthesis in plants. On the other hand, various studies have exposed that by absorbing Si, photosynthetic pigments can be increased in various plant species (Hasanuzzaman et al., 2018; Merwad et al., 2018). The application of Si on wheat (*T. aestivum*) plants showed better result by improving the leaves chlorophyll content (Ma et al., 2016), and photosynthesis rate (Sattar et al., 2017). Likewise, Maghsoudi et al. (2016) demonstrated that Si leaf application increased photosynthesis pigments (chlorophyll a, b and total land carotenoids) and chlorophyll stability index (CSI) in different wheat (*T. aestivum*) cultivars under drought conditions. Similarly, Si foliar application on wheat increased leaf chlorophyll content (Ratnakumar et al., 2016). Si usage protected rapeseed (*B. napus*) leaves photosynthetic pigments (Hasanuzzaman et al., 2018), and increased total chlorophyll content of soybean (*G. max*) leaves under drought (Shen et al., 2010). Si was also observed to improve the allocation of light absorbed between PSII and PSI in the chloroplasts of tomato (*S. lycopersicum*) leaves and maintain the chloroplast membrane structure under drought (Cao et al., 2015). Moreover, Si (K_2SiO_3 at the rate of 2.25 mM) increased photosynthesis and chlorophyll content of two cucumber cultivars (*C. sativus*) under drought (Ouzounidou et al., 2016).

DOI: http://dx.doi.org/10.15666/aeer/1703_61516170

In a recent study, Merwad et al. (2018) revealed that Si foliar application on cowpea (*Vigna unguiculata*) leaves improved chlorophyll (a, b, and total carotenoids) contents. Moreover, chlorophyll content and chlorophyll ratio (a:b) in chestnut leaves was improved under drought condition, when Si (Sili-K® solution containing 0.12% Si and 0.15% K) was repeatedly (× 3) sprayed onto leaves of potted chestnut plantlets and irrigation was suspended for 7 weeks (Zhang et al., 2013). Application of Si on two different rice cultivars (Curinga and IAC-202) enhanced the photosynthetic rate which was reduced by the lack of water (Moro et al., 2015). Soil or foliar applied Si enhanced chlorophyll (a and carotenoids) concentration and chlorophyll (a/b ratio) similar to well-irrigated potato (*S. tuberosum*) plants (Pilon et al., 2014). Si foliar application significantly increased the net photosynthesis rate, green leaf color of Blue Kentucky grass (*P. pratensis*) leaves (Saud et al., 2014), whereas enhanced photochemical efficiency and photosynthetic rate of Cacao (*Theobroma cacao*) leave under drought conditions (Zanetti et al., 2016).

Impacts of Si application under drought stress

Si use exhibited positive influences on seed germination, photosynthesis, plant growth and biomass under drought circumstances in the previous segment. These affirmative effects can be owing to various mechanisms such as enhancement of nutrient uptake by plants, by adjusting osmotic potential, by modifying the gaseous exchange attributes, decrease the oxidative stress and by an alteration in expressing of the gene in plants. Details of these mechanisms are given in (*Fig. 2*).

Oxidative stress

Dry conditions damage the photosynthetic pigments and disturb the balance between ROS production and antioxidants thus affect overall crop production (Kim et al., 2017). Through up-regulation of antioxidant activities of catalase (CAT), superoxide dismutase (SOD), and growth regulators (GR), Si treatment of wheat plants resulted in higher drought tolerance (Gong et al., 2005). Si supplements in wheat plants of wheat (*T. aestivum*) shown lesser contents of glutathione, lipid peroxidation and total flavonoid while raised content of ascorbate with Si application (Ma and Takahashi, 2002). Similarly, in tomato plants, Si supplementation upon polyethylene glycol (PEG) induced drought stress resulted in tolerance through increased activities of CAT and SOD along with the enhanced roots ability of water uptake (Shi et al., 2014). Moreover, Si reduced the activities of ascorbate peroxide (APX), under drought conditions in sunflower (*Helianthus annuus*) (Gunes et al., 2008b).

Drought stress produces ROS in plants triggering oxidative stress damage (Fukao et al., 2011; Noman et al., 2015). Various research communities revealed that Si supply increases the antioxidant enzymes activities while decreased oxidative damage stress in plants which can be adequate to the progression of plant drought tolerance (Bae et al., 2017; Hajiboland et al., 2017; Ma et al., 2016). Si application reduced the lipid peroxidation and hydrogen peroxide (H_2O_2) of sunflower (*H. annuus*), chickpea (*Cicer arietinum*) (Gunes et al., 2007, 2008b), and lentil (*Lens culinaris*) plants leave under drought conditions (Biju et al., 2017). Similarly, H_2O_2 and lipid peroxidation were reduced in rapeseed (*B. napus*) leaves (Hasanuzzaman et al., 2018), decreased H_2O_2 contents in tobacco (*Nicotiana tabacum*) (Hajiboland et al., 2017), and wheat (*T. aestivum*) leaves (Gong et al., 2008; Ma et al., 2016). Xu et al. (2017) described that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61516170

usage of Si (potassium silicate 1.0 mM) significantly decreased H_2O_2, malondialdehyde (MDA) contents, and increased superoxide dismutase (SOD) activities in leaves of wheat during drought by Si supplementation (Gharineh and Karmollachaab, 2013). In addition, Pei et al. (2010) stated that the Si (1 mM)-supplying reduced H_2O_2, MDA in wheat (*T. aestivum*) leaves and Chinese liquorice (*Glycyrrhiza uralensis*), under drought conditions induced by 100 mM NaCl with 0, 10 and 20% of PEG-6000 (Zhang et al., 2017). Si supplementation in soil decreased the Lipid peroxidation (LP) in white lupin (*L. albus*) (Abdalla, 2011). Shi et al. (2014) demonstrated that Si addition improved superoxide dismutase (SOD), catalase activities (CAT), and H_2O_2 in bud radicles than non-Si treated tomato (*S. lycopersicum*) seedlings. Similarly, Si supply enhanced antioxidant activity, including SOD, CAT and decreased H_2O_2 & MDA contents in tomato (*S. lycopersicum*) (Cao et al., 2017). Additionally, Si application considerably enhanced peroxidase (POD) and SOD in the Canola (*B. napus*) plants activities (Habibi, 2014). Furthermore, the application of Si improved ascorbate peroxidase activity (APX) and glutathione (GSH) contents in Chinese liquorice (*Glycyrrhiza uralensis*) under drought than non-Si treatments (Zhang et al., 2017). The antioxidant enzyme's activity (e.g., SOD and CAT) was increased by Si application in wheat (*T. aestivum*) (Sattar et al., 2017), Cowpea (*V. unguiculata*) (Merwad et al., 2018) and in potato's plants (*S. tuberosum*) by foliar application of Si under drought (Pilon et al., 2014).

Moro et al. (2015) revealed that the use of Si was effective to increase rice SOD, CAT and APX activities and similarly, CAT, POD, SOD and H_2O_2 were enhanced in soybean (*G. max*) (Shen et al., 2010) and Kentucky bluegrass (*P. pratensis*) during drought stress (Bae et al., 2017). Hasanuzzaman et al. (2018) noted that CAT, APX enhanced in rapeseed (*B. napus*) and similarly SOD activity of mango (*Mangifera indica*) leaves (Helaly et al., 2017). Moreover, SOD, CAT, APX, and POD were enhanced in the wheat (*T. aestivum*) (Tale and Haddad, 2011), chickpea (*C. arietinum*) shoot (Gunes et al., 2007) and tomato (*S. lycopersicum*) as compared to non-Si supplemented plants (Shi et al., 2014). Actions of SOD and POD decreased by the Si use and increased CAT activity of cucumber (*C. sativus*) plants than to Si-deficient plants (Ma et al., 2004). Impact of Si on the antioxidant enzyme of plants not only fluctuates with the changes of plant species but also depends on the plant stages of growth during drought (Gong et al., 2008). However, reports are limited on Si's functions on the antioxidant enzyme actions at various growth periods of the plant. For instance, the activities of APX, SOD and the CAT were not improved at the booting stage however improved the SOD while decreased APX activity at the filling stage of wheat (*T. aestivum*) during drought (Gong et al., 2008). Improvement of non-enzymatic antioxidants contents can provide best results to decrease the plant oxidative stress. Various reports revealed that levels of the nonenzymatic antioxidants of different species of plant could be affected by the Si application (Gong et al., 2005; Pei et al., 2010). For example, the Glutathione reductase (GSH) activity (Gong et al., 2005) and ascorbic acid (AA) concentration were improved through the use of the Si during drought conditions in wheat (*T. aestivum*) (Pei et al., 2010). In deduction, Si application reduced the oxidative stress and increased antioxidant enzymes activities.

Plant nutrients uptake

The plants need sufficient quantity of the essential nutrients for proper development and growth, but nutrients uptake in plants is disturbed under drought conditions (Emam et al., 2014; Merwad et al., 2018; Ratnakumar et al., 2016). However, Si has positive

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61516170

effects on nutrients uptake in plants under drought. For instance, by the application of Si, Potassium (K) and the total Phosphorus (P) level were enhanced straw of wheat (*T. aestivum*) seed (Ratnakumar et al., 2016), and rice (*O. sativa*) straw (Emam et al., 2014) and leaf P in wheat (*T. aestivum*) (Gong and Chen, 2012). Additionally, it was also effective to improve N, P and K of seed and shoot of cowpea (*V. unguiculata*) plants (Merwad et al., 2018). In addition, Calcium (Ca) and K content increase in wheat (*T. aestivum*) leaf and roots was observed (Kaya et al., 2006). Correspondingly, Kentucky Bluegrass (*P. pratensis*) (root, shoot and leaf) C: N ratio improved by the supply of Si under drought (Saud et al., 2014). Gunes et al. (2008a) noted that Si supply in soil enhanced the macronutrients (Ca, K, P, Mg) and the micronutrients (Cu Fe, and Mn) uptake of sunflower (*H. annuus*) cultivar under drought. Exogenous Si supply was effective for wheat (*T. aestivum*) plant growth by modifying the nutrient uptake (Si, Na and Mg) (Xu et al., 2017), and improve (N, P, and K) uptake in different species of grass (Eneji et al., 2008). Contrarily, reports show that the nutrients uptake reduced in a plant with the supply of Si (Chen et al., 2011). For instance, in rice (*O. sativa*) plants Ca, K, Mg, and Fe contents were increased by drought, on the other hand, Si supply reduces these nutrients in plants (Chen et al., 2011).

Regulating osmotic potential

Optimal water level plays a significant role in plants existence under drought. Generally, plants maintain a high water level through osmotic adjustment under dry stress circumstances (Blum, 2017). Although, high drought circumstances trigger a considerable reduction in water content of leaf including water potential in various plants (Abid et al., 2018; Paz-Kagan et al., 2017; Sattar et al., 2017). Various literature highlighted that Si supply extensively enhanced the water potential of plant's leaf and water content under a dry spell (Hasanuzzaman et al., 2018; Ming et al., 2012; Ratnakumar et al., 2016). For instance, supply of Si enhanced water contents in wheat (*T. aestivum*) (Ratnakumar et al., 2016; Sattar et al., 2017; Tale and Haddad, 2011, rapeseed (*B. napus*) (Hasanuzzaman et al., 2018), rice (*O. sativa*) (Ming et al., 2012), chickpea (*C. arietinum*) (Fawaz and Mohammad, 2013), sunflower (*H. annuus*) (Gunes et al., 2008b), cucumber (*C. sativus*) (Ma et al., 2004), and sorghum (*S. bicolor*) (Sonobe et al., 2010) under drought.

Application of Si enhanced the osmotic, relative water contents, turgor and water potential of wheat (*T. aestivum*) flag leaf (Sattar et al., 2017). Such as the water content of wheat (*T. aestivum*) was increased during drought (Ratnakumar et al., 2016). Si use improved the leaf relative water content in cowpea (*V. unguiculata*) (Merwad et al., 2018), rapeseed (*Brassica napus L.*) (Hasanuzzaman et al., 2018), Kentucky bluegrass (*P. pratensis*) (Saud et al., 2014) and maize (*Z. mays*) plants (Amin et al., 2014). On the other hand, under drought Si reduced the osmotic potential of roots in sorghum (*S. bicolor*) without interrupting water contents (Sonobe et al., 2010). Osmotic adjustment is consequence owing to soluble amino acids (alanine and glutamic acid) and sugars. Yin et al. (2014) revealed that Si reduced the proline content and osmotic potential of sorghum (*S. bicolor*) leaf whereas enhanced soluble sugar. Authors proposed that the osmotic adjustment does not contribute to Si mediated rise in drought tolerance in the sorghum (*S. bicolor*). The water content of leaf and the water potential improved by the supply of Si are accredited to a thickness of wheat (*T. aestivum*) leaves (Gong et al., 2003). Furthermore, leaf water potential enhancement might be triggered by Si

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61516170

deposition in the leaves. Additionally, deposition of Si on leaf surface might reduce transpiration through controlling molecules of water (Keller et al., 2015).

Regulation of osmolytes and phytohormones

Osmolytes and phytohormones roles have been already well described for tolerance of plants at different stresses (Kurepin et al., 2017; Zhang et al., 2017). Various studies demonstrated about Si application improving plant tolerance against drought through modifications of osmolytes in different species of plants (Hamayun et al., 2010; Hasanuzzaman et al., 2018; Xu et al., 2017). Si was effective to enhance proline, a non-protein amino acid, but total sugar and soluble protein were decreased in potato (*S. tuberosum*) leaves (Crusciol et al., 2009). On a similar note, use of Si improved proline contents in the wheat (*T. aestivum*) (Gong et al., 2005), pepper (*Capsicum annuum*) (Pereira et al., 2013) and rapeseed (*B. napus*) plant (Hasanuzzaman et al., 2018). Proline is frequently measured as an osmotic protector which may be effective to support plants against drought. However, studies associated with Si supply effects on plants growth hormones are limited under drought condition. Si supply declined Jasmonic acid (JA) level but enhanced salicylic acid (SA) levels in shoots of soybean plant (Hamayun et al., 2010) and pepper (*C. annuum*) plants, nitrate reductase activity (Pereira et al., 2013). The study demonstrated that the Si could be effective to enhance tolerance against drought in the plant through improvement in nitrogen metabolism and signaling of phytohormones. Yin et al. (2014) revealed that the use of Si increased sorghum (*S. bicolor*) drought resistance through regulation of 1-aminocyclopropane-1-carboxylic acid and polyamine synthesis.

Regulation of gene expression

In the first report, Si supply was effective to enhance aquaporin genes expression under drought which prompted water uptake in sorghum (*S. bicolor*) roots (Liu et al., 2014). Also, the Si supply enhanced up-regulation of conjugated polyamines synthesis genes in sorghum (*S. bicolor*) during drought condition (Yin et al., 2014). Khattab et al. (2014) demonstrated that Si supply improved expression of the ring domain carrying protein (OsRDCP1), drought-related protein (OsCMO) and coding choline mono-oxygenase and dehydrin (OsRAB16b) in rice (*O. sativa*) plants of rice. So far, a mechanism of Si-mediated gene expression under alleviation of drought stress is poorly understood; therefore more efforts are required to uncover this aspect.

Regulating gaseous exchange

Leaf gas exchange attributes to deliver beneficial evidence on plant mechanisms in stressed conditions (Chen et al., 2011; Liu et al., 2014). Especially under drought conditions, the stomata regulate the water level of the plant by adjusting the rate of transpiration. Countless studies raveled that supply of the Si regulates plant's gaseous exchange attributes as plant are exposed to the drought (Hajiboland et al., 2017; Ming et al., 2012; Pereira et al., 2013; Saud et al., 2014). For example, the supply of diatomite in the soil provided a reduction in white lupine plants transpiration rate by improving stomatal conductance and the rate of photosynthesis (Abdalla, 2011). Similarly, Hattori et al. (2005) noted a higher transpiration rate and stomatal conductance in plants of sorghum (*S. bicolor*) during drought than without Si supply control plants. The authors concluded that maintenance of higher water level in sorghum (*S. bicolor*) plants was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61516170

because of higher water absorption in the existence of Si. Correspondingly, under drought Si use improved the transpiration and net photosynthesis rate in the rice (*O. sativa*) (Ming et al., 2012), pepper (*C. annuum*) plants (Pereira et al., 2013) and soybean (*G. max*) (Shen et al., 2010).

Furthermore, the use of Si enhanced rate of transpiration and the stomatal conductance in sorghum (*S. bicolor*) seedling (Liu et al., 2014). Gao et al. (2005) noted that Si supply improved WUE in the drought stress maize (*Z. mays*) through a reduction in transpiration rate of the leaf by stomata showed that the Si effects stomatal drive in the plant. Authors suggested that the rate of stomatal transpiration was decreased whereas stomatal density and morphology cannot clarify Si to decrease the rate of stomatal transpiration in maize (*Z. mays*) (Gao et al., 2006). Si use improved the rate of photosynthesis whereas the reduced rate of transpiration under drought condition in Tobacco (*N. Rustica*) (Hajiboland et al., 2017) and in plants of maize (Amin et al., 2014). Furthermore, the increase in WUE by Si supply was noted in chickpea (*C. arietinum*), (Fawaz and Mohammad, 2013), cacao (*Theobroma cacao*) grown in pots (Zanetti et al., 2016), wheat (*T. aestivum*) grown-up in the hydroponics (Ding et al., 2007) and wheat (*T. aestivum*) grown in field condition in drought (Gong and Chen, 2012). Gong et al. (2005) proposed that the use of Si on wheat (*T. aestivum*) was grown in the pots, shown an increased level in net CO_2 incorporation rate of the leaves during drought. The study is limited associated with the diurnal changes of plant gas exchanges characteristics with a supply of Si in drought. Gong and Chen (2012) revealed that Si use was effective for diurnal change in the net photosynthetic rate of leaf, the rate of transpiration and the stomatal conductance of plants of wheat (*T. aestivum*) in the field condition under drought. Likewise, Ma et al. (2004) noted Si mediated diurnal change in the gas exchange characteristic in plants of cucumber (*C. sativus*) in drought.

Conclusion and perspective

Since 1999, many studies have been carried out to enlist benefits of Si for plant growth, but still, there is a lack of application of Si as a fertilizer for agronomic and horticulture benefits. Here is a dire need to create awareness about Si benefits among the masses and estimate its economic prospects. Therefore, the main aim of this review is to explain the mechanisms of the Si mediated mitigation of droughts in the plant. Available literature demonstrated that Si supplementation was sufficient to improve biomass, plant growth, seed germination, and photosynthesis drought stress condition. Si supply increased biomass and plant growth during a drought might be due to various mechanisms. This review can assist in well understanding mechanism of Si-arbitrated development in plants drought tolerance. Moreover, it could be effective to understand how crop production can be increased in drought stresses. We think that in the era of the 21st century where molecular tools are being incorporated at every step in all the field of studies, which genes are expressed under drought stresses in various plant species and which genes are playing their active part in plant growth improvement while Si usage and uptake by plant should be focused. This can take us to modify genetically economically significant crops to generate the drought stress tolerant cultivar which can be very beneficial in the future. Moreover, in all the studies, Si supplementation was in the form of potassium/calcium/sodium silicate. The need is to separate the Si from other anions and it can be applied at indigenous levels so that we may better understand the particular role of Si during plant development.

(Received 27th Oct 2018; accepted 25th Jan 2019)

Abstract. During the present research, the predatory efficiency of nymphs of six coexisting odonate species i.e., *I. elegans*, *T. aurora, P. flavescens*, *L. fulva, S. decoloratum* and *C. servilia* was studied by using the 3rd instar larvae of *Cx. quinquefasciatus* as prey. Among the odonate species, there was observed variation in the daily feeding rate. The highest number of mosquito larvae was ingested by the *P. flavescens* nymph (47.0 ± 5.1 mosquito larvae/day). The predation performance of the odonate nymph was also compared between the day and night times. The feeding rate of nymphs of most odonate species was significantly higher during the daytime as compared to night-time ($P \leq 0.05$). During the present research, feeing rates of odonate nymphs on *Cx. quinquefasciatus* 3rd instar larvae were also studied under varied condition of prey and predator density and water volume. Feeding rate of nymphs of each odonate species was positively correlated with increase in predator and prey density but was negatively correlated with increase in water volume. During the present research, odonate nymphs i.e., *I. elegans*, *T. aurora* and *P. flavescens* were exposed to various concentration of $NH4^+$ and NO_3^- in the laboratory for seven days. Nymph of *P. flavescens* species was found least sensitive to both, NH_4^+ and NO_3^-. From the findings of the present research it was concluded that *P. flavescens* species is more efficient predator of *Cx. quinquefasciatus* 3rd instar larvae and is highly resistant to increasing water level of NH_4^+ and NO_3.
Keywords: *damselfly, dragonfly, predation, feeding rate, ammonium, nitrate*

Introduction

Control of mosquitoes is mostly practiced by using conventional synthetic chemical insecticides such as organochlorine and organophosphate compounds (Ghosh et al., 2012). The frequent application of synthetic chemical insecticides has caused the development of insecticide resistance in insect pests, contamination of the environment, and adverse effects on non-target organisms (Lee et al., 2001). There is the requirement of adopting environment friendly approaches for the control of mosquito population (Ghosh et al., 2012). Biological control is the application of living organisms that can be used as control agents against insect pests. Several living organisms can act as biological control agents against mosquitoes such as bacteria (Phillips, 2001), plants

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61716188

(Ajaegbu et al., 2016), protozoans (Das et al., 2016), larvivorous fish (Walton, 2007) and predatory insects (Mandal et al., 2008).

Predators of mosquito larvae can play important role in regulation of mosquito population (Knight et al., 2004). They not only attack on mosquito larvae but also kill and eat several other co-existing organisms however the presence of alternate preys has no negative influence on the role of predators in regulation of mosquito larval population (Stav et al., 2005). The natural predators that can play role in regulation of mosquito larval population include some larvivorous fish (Chandra et al., 2008), some aquatic bugs (Saha et al., 2007), tadpole shrimps (Su and Mulla, 2002), diving beetles (Lundkvist et al., 2003), Toxorhynchites mosquito larvae (Kumar and Hwang, 2006) and odonate nymphs (Damselfly and dragonfly) (Chatterjee et al., 2007).

Odonate nymphs are important voracious predators and they capture their prey such as mosquito larvae and other smaller aquatic invertebrates and even larvae of fish and amphibians with the help of specialized protractible labium (Boyd, 2005). These nymphs can play important role in the regulation of mosquito population (Din et al., 2013). Due to predatory role against mosquito larvae, they have gained attention for their use in ecofriendly control of mosquitoes (Mitra, 2006). To the best of author knowledge, very few studies have been conducted on the predatory ability of odonate nymphs against mosquito larvae (Mandal et al., 2008; Akram and Ali-Khan, 2016). During the present study, the predatory ability of one species of damselfly (order Odonata, sub order Zygoptera) i.e., *Ischnura elegans* (Vander Linden, 1820) and five species of dragonfly (order Odonata, sub order Anisoptera) i.e., *Trithemis aurora* (Burmeister, 1839), *Pantala flavescens* (Fabricius, 1798), *Libellula fulva* (Muller, 1764), *Sympetrum decoloratum* (Selys, 1884) and *Crocothemis servilia* (Drury, 1770) were studied against *Culex quinquefasciatus* larvae under laboratory conditions during the day and night times. The predatory ability of odonate nymphs under varied conditions of prey and predator density and water volume were also studied.

Odonate nymphs that share the aquatic habitat with mosquito larvae, face increasing environmental pressure due to increasing urbanization and human activities. Ammonium and nitrate are the important nutrient pollutants and their levels in surface water are increasing (Rabalais, 2002; Du et al., 2017). Ammonium, nitrate and other ionic forms of inorganic nitrogen enter the surface water both from natural sources and anthropogenic sources (Wetzel, 2001; Rabalais, 2002; Du et al., 2017). Increased level of different forms of inorganic nitrogen in water is toxic to fresh water invertebrates, fishes and amphibian (Hickey and Vickers, 1994; Camargo et al., 2005). Odonate nymphs are sensitive to environmental pollutants (Clark and Samways, 1996). To the best of author knowledge, a single study has been reported on the effect of ammonium on odonate nymphs such as *Erythromma najas*, *Lestes sponsa* and *Sympetrum flaveolum* (Beketov, 2002). Dida et al. (2015) recently studied the diversity of predators and mosquito larval habitats and the range of their adaptive capacity to water physico-chemical parameters along the Mara River. It was concluded that the invasion of aquatic habitats by the predators of mosquito larvae is driven by the presence of mosquito larvae and the water physico-chemical characteristics. It was suggested that understanding the biotic and abiotic characteristics of aquatic habitats that favor the co-occurrence of mosquito larvae and predators may contribute to the effective control of mosquito borne diseases. During the present study, the sensitivity of nymphs of three odonate species i.e., *Ischnura elegans, Trithemis aurora* and *Pantala flavescens* to ammonium and nitrate was studied.

The present research aimed to explore the comparative predatory efficacy of different odonate nymphs against mosquito larvae and the predatory ability of odonate nymphs under varied conditions of prey and predator density and water volume. The present research also aimed to determine the sensitivity of odonate nymphs to inorganic nutrient pollutants i.e., ammonium and nitrate.

Materials and methods

Laboratory rearing of Cx. quinquefasciatus

Laboratory colonies of *Cx. quinquefasciatus* were maintained during April 2017 (max temperature 29 °C) and September 2017 (max temperature 31 °C). Larvae of *Cx. quinquefasciatus* were collected by using a rectangular plastic dipper (38 cm length, 28 cm width and 6.5 cm height) from a ditch containing stagnant water at the campus of university of Malakand, Chakdara, Dir Lower, Khyber Pakhtunkhwa, Pakistan. The larvae were brought in 700 ml plastic containers with water from the collection site to the laboratory at the University of Malakand and reared for establishing a colony. The larvae were provided with larval food comprising of dog biscuit and dry yeast powder in the ratio of 3:2. The pupae emerged were transferred to a 500 ml plastic jar containing 300 ml non-chlorinated tap water and placed in mosquito cage (45 cm × 45 cm × 45 cm). The adults emerged were fed with carbohydrate food by providing cotton pad soaked in 10% sucrose solution. The female adult mosquitoes laid eggs in the jar containing water inside the cage. The eggs hatched into larvae, thus larvae of each instars were available for experiments. For confirmation of species proper literature was used for identification of both larvae and adults (Harbach, 1988).

Collection and identification of odonate nymphs

Several puddles on the bank of River swat near the campus of University of Malakand, were visited during April and May 2017 and September 2017 for collection of damselfly and dragonfly nymphs. Damselfly and dragonfly nymphs of 8 to 10 instars were collected by using a rectangular plastic dipper (38 cm length, 28 cm width and 6.5 cm height) on the bank of River swat near the campus of University of Malakand, during April 2017, and September 2017. The nymphs were transported in plastic jars containing water of the collection site to the laboratory at University of Malakand within 1 h of capture. In the laboratory damselfly and dragonfly nymphs were separately maintained in small fish aquaria (45 cm length, 40 cm width and 40 cm height) containing water brought from the collection site in large plastic bottles. Aquaria were receiving solar illumination through windows and oxygenated by using air pumps. Few strings of aquatic plants brought from the collection site were also added to the aquaria which provided clinging sites for the nymphs. Before conducting experiments, the nymphs were fed with dried yeast powder and mosquito larvae. The specimens were identified to the species level with the help of literature (Gardner, 1960; Yousuf et al., 1996; Anjum, 1997; Mitra, 2002; Din et al., 2013). During the identification of odonate nymph, help was also taken from the literature and unpublished documents provided by Dr. Ahmad Zia (personal communication), Senior Scientific Officer and Taxonomist in the Insect National Museum at National Agricultural Research Council (NARC), Islamabad, Pakistan. During April 2017 collection of odonate nymphs, one species of damselflies namely *Ischnura elegans* and two species of dragonflies namely *Trithemis*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61716188

aurora and *Pantala flavescens* were identified. During September 2017 collection, dragonfly nymphs of *Libellula fulva*, *Sympetrum decoloratum* and *Crocothemis servilia* were identified and found in sufficient number; therefore, experiments were conducted on nymphs of these genera. All the odonate species identified and studied are shown in *Figure 1*.

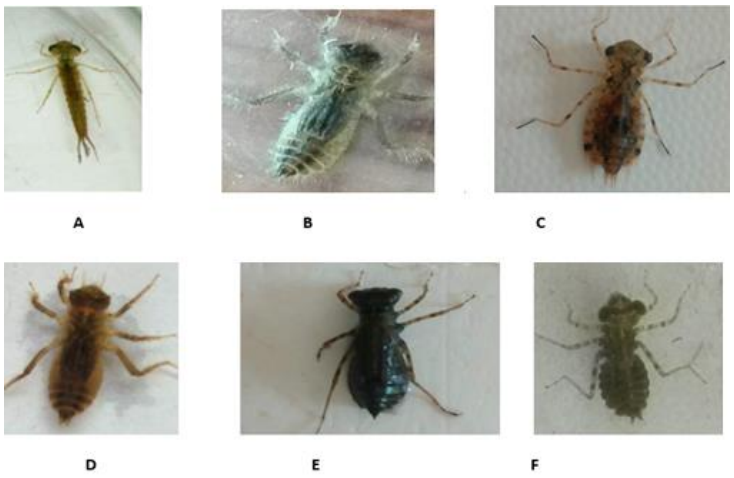

Figure 1. *Pictures of nymphs of different odonate species collected and used during the present research. A - Ischnura elegans, B - Trithemis aurora, C - Pantala flavescens, D - Libellula fulva, E - Sympetrum decoloratum, F - Crocothemis servilia*

24-h feeding rate of donate nymphs during April, 2017

During April 2017, three nymphs of three odonate species (one nymph of each Species) i.e., *Ischnura elegans*, *Trithemis aurora* and *Pantala flavescens*, were placed separately into three labelled 1000 ml plastic jars each jar was containing 700 ml sieved water of collection site. To each container 80 3rd instar larvae were added. Twelve replicates were run for each predator species. The experiments were started at 05:00 h of Pakistan standard time and the results were checked next day at 05:00 h (after 24 h). The number of larvae consumed by each predator species was counted after 24 h.

24-h feeding rate of donate nymphs during September, 2017

During September 2017, the feeding efficiencies of dragonfly nymphs of *L. fulva*, *S. decoloratum* and *C. servilia* on 3rd instar larvae of *Culex quinquefasciatus* were compared. These three dragonfly nymphs were placed separately into three labelled 1000 ml plastic jars each containing 700 ml sieved water of collection site. To each container 50 3rd instar larvae were added. Six replicates were run for each predator species. The experiments were started at 07:00 h of Pakistan standard time and the results were checked next day at 07:00 h (after 24 h). The number of larvae consumed by each predator species was counted after 24 h.

Feeding rate of odonate nymphs during light and dark phases in April, 2017

During April 2017, the feeding rates of *Ischnura elegans*, *Trithemis aurora* and *Pantala flavescens* on 3rd instar larvae of *Cx. quinquefasciatus* were studied during the light (day time) and dark (night time) phases. The durations of light phase (5:00 to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61716188

19:00 h) was 14 h and dark phase (19:00 to 5:00 h) was 10 h. Per hour feeding rate was calculated. One nymph each of *Ischnura elegans*, *Trithemis aurora* and *Pantala flavescens*, were placed separately into three labelled 1000-ml plastic jars each containing 700 ml sieved water of collection site. Eighty 3rd instar larvae of *Cx. quinquefasciatus* were added to each jar at 05:00 h (sunrise time) and the number of larvae consumed by each nymph was noted at 19:00 h (sunset time). The laboratory was receiving sufficient light during the day through windows. To determine the feeding rate of nymphs during the dark phase, 80 3rd instar larvae of *Cx. quinquefasciatus* were added to each jar at 19:00 h (sunset time) and the number of larvae consumed by each nymph was noted at next 05:00 h (sunrise time). The experiment was run in 12 replicates.

Feeding rate of odonate nymphs during light and dark phases in September, 2017

During September 2017 study, three nymphs of three dragonfly species i.e., *Libellula*, *Sympetrum* and *C. servilia* were placed separately into three labelled 700 ml plastic jars (one nymph of one odonate species/jar) each containing 400 ml sieved water of collection site. Fifty 3rd instar larvae of *Cx. quinquefasciatus* were added to each jar at the morning (06:00 h, Pakistan standard time). The duration of light phase (6:00 h to 18:09 h) and dark phase (18:09 to 6:00 h) was 12 h each. Therefore the 12-h feeding rate of dragonfly nymphs was compared between light and dark phases.

Feeding pattern of odonate nymphs after every 3 h interval in day and night

The feeding activities of dragonfly nymphs were also noted after every 3 h for 24 h (6:00–9:00 h, 9:00–12:00 h, 12:00–15:00 h, 15:00–18:00 h, 18:00–21:00 h, 21:00–24:00 h, 24:00–3:00 h, 3:00–6:00 h Pakistan standard time). Sieved water of collection site was utilized for experiment.

Feeding rate under varied condition of predator density, water volume and prey density

The predation of damselfly and dragonfly nymphs on 3rd instar *Cx. quinquefasciatus* larvae with variation in predator density, water volume and prey density were evaluated during April 2017. For each odonate nymph, six 4 L plastic jars were arranged with varied predator density, water volume and prey density. The experiment for each predator species was conducted on three different dates and in triplicate. The six combinations for each odonate species are shown in *Table 1*.

Table 1. *Various combinations of predator density, water volume and prey density*

S. No. of combinations	Combinations
1	1 predator, 1 L and 50 Prey
2	1 predator, 2L and 50 Prey
3	1 predator, 1 Land 100 Prey
4	2 predators, 1 L and 50 Prey
5	2 predators, 2 L and 50 Prey
6	2 predators, 1 Land 100 Prey

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61716188

The number of larvae consumed was noted after 24 h. The predation performance data obtained during September 2017 experiments have been presented separately from the data obtained during April 2017 experiments due to differences in timing and number of replicas.

Sensitivity of odonate nymphs to inorganic nutrient pollutants

During the present research, the sensitivity of nymphs of *I. elegans*, *T. aurora* and *P. flavescens* to various concentrations of inorganic nutrient pollutants i.e., ammonium (NH_4^+) and nitrate (NO_3^-) was investigated. These nymphs were exposed to various concentrations of NH_4^+ and NO_3^- in water.

Sensitivity of odonate nymphs to Ammonium

Stock solution of NH_4^+ was prepared by dissolving ammonium chloride (NH_4Cl) in non-chlorinated tap water. The molecular weight of NH_4Cl is 53.5 g which contains 18 g of NH_4^+. 2.9 g of NH_4Cl was required for preparation of 1000 ml NH_4^+ solution of 1000 ppm. From this stock solution, testing solutions of different concentrations of NH_4^+were prepared by applying the dilution equation C1V1 = C2V2.

According to the WHO (2006) standards for wastewater reuse in the Eastern Mediterranean Region, the maximum permissible concentration of NH4 in effluents for reuse in agricultural irrigation is 5 ppm. Therefore, during the present research, the minimum concentration of NH_4^+ to which odonate nymphs were exposed was 5 ppm. Thus, *I. elegans*, *T. aurora* and *P. flavescens* were initially exposed to testing solutions of 5, 10, 25, 50 and 100 ppm concentrations of NH_4^+ in 400 ml polyethylene containers for finding concentration range to be used for determining the LC50 values. The ecological effects test guidelines of Environmental Protection Agency, USA (US EPA, 1996) were followed with some modifications for determining the concentration range. Volume of testing solution in each polyethylene container was 250 ml. A 400 ml polyethylene control container containing 250 ml non-chlorinated tap water was also kept. Nymphs of each species were exposed individually in containers to avoid cannibalism. Due to individual placement, limited laboratory space and limited availability of nymphs, the method of Hardersen and Wratten (1996) was followed. The detail is as under: six intact 8^{th} to 10^{th} instar nymphs of each species were placed in six plastic containers (five NH_4^+ concentrations and one control). In short, 18 containers were arranged for the nymphs of three odonate species, six for each species. Experiment was run in five replicates. The period of exposure was 7 days. Following standard toxicity protocols, the nymphs were not fed during the 7 days exposure (ASTM, 2008). At day 7^{th} of exposure period, the numbers of dead and live nymphs were noted. The criterion for death was lack of response to prodding. During preliminary experiment, no mortality of nymphs occurred up to 50 ppm. Therefore, further experiments were performed using high concentrations. Therefore, nymphs of each species were exposed to higher concentrations (100, 200, 400 and 600 ppm) of NH_4^+ solution for determining LC50 values. Five intact last instar nymphs of each species were placed individually in their respective five containers (four concentrations and one control). This experiment was run in triplicate. After 7 days of exposure, the number of dead and live nymphs was noted. Several trips were conducted for collection of nymphs and experiments were repeated continuously till the number of nymphs in each replica for each concentration reached 20. In total 20 independent experiments were conducted.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61716188

Sensitivity of odonate nymphs to nitrate

Stock solution of NO_3^- was prepared by dissolving sodium nitrate ($NaNO_3$) in non-chlorinated tap water. The molecular weight of $NaNO_3$ is 85.5 g which contains 62 g of NO_3^-. 1.4 g of $NaNO_3$ was required for preparation of 1000 ml NO_3^- solution of 1000 ppm. From this stock solution, testing solutions of different concentrations of NO_3^- were prepared by applying the dilution equation C1V1 = C2V2.

According to the standards for wastewater reuse in the Eastern Mediterranean Region, the maximum permissible concentration of NO_3^- in effluents for reuse in agricultural irrigation is 45 ppm (WHO, 2006). Therefore, during the present research, the minimum concentration of NO_3^- to which odonate nymphs were exposed was 45ppm. The concentrations of NO_3^- to which nymphs were exposed during range finding bioassay were 45, 100, 150, 200, 400 ppm. The rest of detail of range finding bioassay was the same as described for NH_4^+. During preliminary experiment no mortality of nymphs occurred up to 150 ppm NO_3^-solution. However, at 200 ppm NO_3^- concentration, mortality in nymphs of each Odonate species was observed. Therefore, nymphs of each species were exposed to higher concentrations (200, 400, 550 and 700 ppm) of NO_3^- solution for determining LC50 values. The rest of detail of experiment for determining LC50 values are the same as described for NH_4^+.

Statistical analysis

The 24 h feeding rate of odonate nymphs were compared by applying Tukey test in One Way ANOVA. The difference in feeding rate of each odonate nymph species between light and dark phases was analyzed by Independent Samples t-Test. The effects of variation in predator density, water volume and prey density on daily feeding rate of each odonate nymph was analyzed by multiple linear regression test. During the study on sensitivity of odonate nymphs to inorganic nutrient pollutants, the average of percent mortality data was subjected to log probit analysis (Finney, 1971) for calculating LC_{50}. SPSS 16 software was used for the analysis of the data. The LC_{50} values were compared by 95% confidence limits overlap method.

Results

24-h feeding rate of donate nymphs during April, 2017

During April 2017 experiments, the 24-h feeding rates of *I. elegans*, *T. aurora* and *P. flavescens* on *Cx. quinquefasciatus* 3rd instar larvae were studied in the laboratory (*Table 2*). Significantly higher (P>0.05) number of *Cx. quinquefasciatus* 3rd instar larvae were consumed by *P. flavescens* (47.0 ± 5.1 larvae/24-h) followed by *T. Aurora* (17.8 ± 4.2 larvae/24-h) and *I. elegans* (10.5 ± 3.1 larvae/24-h).

Feeding rate of odonate nymphs during light and dark phases in April, 2017

During April 2017 study, the per hour feeding rates of *I. elegans*, *T. aurora* and *P. flavescens* on 3rd instar larvae of *Cx. quinquefasciatus* were compared between the daytime and night-time (*Table 3*). The nymphs of *I. elegans* species consumed 0.52 $\pm$ 0.19 larvae /hour at the day time and 0.35 $\pm$ 0.16 larvae/hour at the night time. The difference in feeding rate between the day and night time was significant. Similar trend was also observed in *P. flavescens*. However, *T. aurora* showed insignificantly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61716188

($P > 0.05$) higher feeding rate during the night time (1.03 $\pm$ 0.24 larvae /hour) as compared to its feeding rate during the day time (0.91 $\pm$ 0.11 larvae/hour).

24-h feeding rate of donate nymphs during September, 2017

The 24-h feeding rates of *L. fulva*, *S. decoloratum* and *C. servilia* on *Cx. quinquefasciatus* 3rd instar larvae were studied during September 2017 (*Table 4*). Maximum number of mosquito larvae was consumed by *S. decoloratum (*17.2 ± 4.2 larvae/24 h) followed by *L. fulva* (14.2 ± 2.3 larvae/24 h) and *C. servilia* (11.8 ± 2.1 larvae/24 h). The difference in consumption rate between *S. decoloratum* and *C. servilia* was significant ($P < 0.05$) but the difference between the *S. decoloratum* and *L. fulva* or *L. fulva* and *C. servilia* was not significant ($P > 0.05$).

Feeding rate of odonate nymphs during light and dark phases in September, 2017

During September 2017 study, the 12-h feeding rates of *L. fulva, S. decoloratum* and *C. servilia* were compared between the day and night times (*Table 5*). The feeding rate of each of these odonate specie was significantly higher ($P < 0.05$) during the daytime as compared to the night-time.

Feeding pattern of odonate nymphs after every 3 h interval

The feeding pattern of nymphs of *L. fulva*, *S. decoloratum* and *C. servilia* were also noted after every 3 h interval at day and night times for 24 h (*Fig. 2*). Each nymph consumed maximum larvae during the first 3-h interval (6:00 to 9:00 h Pakistan standard time).

Table 2. *24-h feeding rate of odonate nymphs against Cx. quinquefasciatus 3rd instar larvae during April 2017 experiments*

Odonate Sp.	No. of larvae consumed per 24 h (mean + Sd)	95% confidence interval		F value
		Lower bound	Upper bound	
I. elegans	10.5 ± 3.1[c]	8.6	12.4	251.6

Feeding rate under varied condition of predator density, water volume and prey density

The 24-h feeding rate of *I. elegans, T. aurora* and *P. flavescens* on 3rd instar larvae of *Cx. quinquefasciatus* was also studied under varied conditions (combinations) of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61716188

predator density, water volume and prey (mosquito larvae) density (*Table 6*). Nymph of each odonate species consumed significantly higher number ($P < 0.05$) of mosquito larvae in combination no. 6 (condition of increased predator and prey density and decreased water volume) as compared to other combinations. In this combination, *I. elegans, T. aurora* and *P. flavescens* consumed 22.0 ± 2.6, 45.3 ± 4.1 and 63.0 ± 7.5 larvae/day (larvae consumed/24-h), respectively. Strong correlation (R square > 0.70) was observed during determination of correlation of feeding rate of each odonate species with variation in predator density, water volume and prey density. The regression equation for nymphs of each odonate species clearly indicated that the feeding rate is positively correlated with increase in prey and predator density but negatively correlated with increase in water volume.

Sensitivity of predators of mosquito larvae to ammonium (NH_4^+)

During the present research, the sensitivity of *I. elegans, T. aurora* and *P. flavescens* was studied during exposure to various concentrations of NH_4^+ for seven days (*Table 7*). During range finding study, the highest concentration of NH_4^+ that caused no mortality of odonate nymphs was 50 ppm. The lowest concentration of NH_4^+ that caused some mortality among the odonate nymphs was 100 ppm. At this concentration of NH_4^+, lowest mortality (3.3 ± 1.6%) was observed in *P. flaviscans* followed by *T. aurora* (5.0 ± 0%) and *I. elegans* (6.6 ± 1.6%). Similar trend was noted during exposure to highest concentration i.e., 600 ppm. At this concentration, the mean percent mortality of *P. flaviscans*, *T. aurora* and *I. elegans* were 43.3 ± 1.6%, 58.3 ± 7.2% and 71.6 ± 1.6%, respectively. Maximum LC_{50} value was shown by *P. flaviscans* (740.3 ppm) followed by *T. aurora* (516.7 ppm) and *I. elegans* (425.7 ppm).

Table 6. *Feeding rate of odonate nymphs on mosquito larvae under varied conditions of predator density, water volume and prey density*

Species	S. No of combinations	Combination	Larvae consumed/24 h	F value	R^2 value	Y-equation
I. elegans	1	1 predator, 1 L and 50 Prey	10.3 ± 2.1b	59.7	0.78	7.6 + 6.3 (predator) – 7.16 (volume) + 0.07 (prey)

Sensitivity of predators of mosquito larvae to nitrate (NO_3^-)

During the present research, the sensitivity of *I. elegans, T. aurora* and *P. flavescens* was studied during exposure to various concentrations of NO_3^- for seven days (*Table 8*). During range finding study, the highest concentration of NO_3^- that caused no mortality of odonate nymphs was 150 ppm. The lowest concentration of NO_3^- that caused some mortality among the odonate nymphs was 200 ppm. During exposure to this concentration of NO_3^-, minimum mortality (5.0 $\pm$ 0.0%) was observed in *P. flaviscans* followed by *T. aurora* (10.0 $\pm$ 0.0%) and *I. elegans* (11.6 $\pm$ 1.7%). Similar trend was noted during exposure to highest concentration i.e., 700 ppm. At highest concentration of NO_3^-, the mean percent mortality of *P. flaviscans*, *T. aurora* and *I. elegans* were 28.3 $\pm$ 1.6%, 50.0 $\pm$ 5.8% and 65.0 $\pm$ 2.7%, respectively. Maximum LC_{50} value was shown by *P. flaviscans* (LC50 = 1353.1 ppm) followed by *T. aurora* (LC_{50} = 678.4 ppm) and *I. elegans* (LC_{50} = 597.8 ppm).

Discussion

For the control of mosquitoes and other insect pests, alternative approaches that are ecofriendly should be adopted (Ghosh et al., 2012). Biological control strategies are environment friendly, sustainable and targeting a range of different mosquito species which help in reduction of reliance on application of synthetic chemical insecticides (Benelli et al., 2016). Historically, Biological control involves the application of natural predators which is particularly important for the control of mosquito-borne arboviruses, which normally do not have specific antiviral therapies available (Huang et al., 2017). Damselfly and dragonfly nymphs have the predatory ability and share aquatic habitat with the immature stages of mosquitoes therefore they can be considered good biological control agents against mosquitoes (Mitra, 2006; Chatterjee et al., 2007). During the present research, the predatory efficiencies of nymphs of six coexisting

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61716188

odonate species i.e., *I. elegans*, *T. aurora, P. flavescens*, *L. fulva, S. decoloratum* and *C. servilia* were studied by using *Cx. quinquefasciatus* 3rd instar larvae as prey. There was observed variation in the daily (24-h) feeding rate of nymphs of various odonate species (*Tables 2* and *4*). Highest number of mosquito larvae was ingested by the *P. flavescens* nymph (47.0 ± 5.1 mosquito larvae/day). To the best of author knowledge, the predatory ability of *T.* aurora, *P. Flavescens, L. fulva*, *S. decoloratum* and *C. servilia* nymphs have been studied for the first time during the present study. The predation performance of few other odonate nymph species have been reported. For example, Miura and Takahashi (1988) studied the predatory ability of damselfly nymph, *Enallagma civile*, against the *Culex torsalis* larvae. The average 24 h feeding rate of last instar nymph of *E. civile* on 3rd instar larvae of *Cx. tarsalis* was 6.06 larvae. Mandal et al. (2008) studied the predatory efficiency of nymphs of two dragonfly species i.e., *Aeshna flavifrons* and *Sympetrum durum,* and three damselfly species i.e., *Coenagrion kashmirum*, *Ischnura forcipata* and *Rhinocypha ignipennis,* against 4th instar larvae of *Cx. quinquefasciatus*. *I. forcipata* nymph consumed highest number of mosquito larvae (64.3 ± 1.8). Akram and Ali-Khan (2016) studied the predation performance of five odonate nymphs, *Anax parthenope, Bradinopyga geminate, Ischnura forcipata, Rhinocypha quadrimaculata* and *Trithemis aurora* against the 4th instar larvae of *Aedes aegypti* in the laboratory. *Ischnura forcipata* consumed highest number of mosquito larvae (56 larvae/ day). Chandra et al. (2006) studied the predatory efficiency of a dragonfly nymph, *Brachytron pratense*, against the larvae of *Anopheles subpictus* in the laboratory conditions. *Brachytron pretense* consumed up to 66 mosquito larvae through 24 h. The predatory ability of odonate nyphs against non inscet pests have also been studied. For example, Younes et al. (2016) studied the predation performance of odonate nymphs of the species *Hemianax ephippiger* against two species of fresh water snail, *Bulinus truncatus* and *Biomphalaria alexandrina* which act as intermediate hosts of *Schistosoma* species. Odonata nymph consumed both species of the fresh water snail, however the odonate nymphs consumed more *Bulinus truncatus* than *Biomphalaria alexandrina*. Consumption rate also differed according to the snail type, density and size. Odonate nymphs preferred small sized prey.

The predation performance of nymphs of different odonate species was also compared between the day and night times. During the April 2017 study, the per hour feeding rates of *I. elegans*, *T. aurora* and *P. flavescens* on 3rd instar larvae of *Cx. quinquefasciatus* were compared between the day and night times. The nymphs of *I. elegans* and *P. flavescens* species consumed significantly higher ($P \leq 0.05$) number of mosquito larvae during the day time as compared to the night time. The feeding rate of *T. aurora* was also higher during the day time but the difference from the night time was insignificant ($P > 0.05$) (*Table 3*). During the September 2017 study, the 12-h feeding rates of *L. fulva*, *S. decoloratum* and *C. servilia* on 3rd instar larvae of *Cx. quinquefasciatus* were compared between the day and night times. Each nymph consumed maximum larvae during the first 3-h interval (6:00 to 9:00 h Pakistan standard time). Similar trend has also been reported by Venkatesh and Tyagi (2013) during their study on the predatory performance of *Bradinopyga geminata* and *Ceriagrion coromandelianum* larvae on *Aedes aegypti* larvae in the laboratory conditions. During the present study, the duration of the day and night time was 12 h each. Therefore, the feeding rate of nymphs of *L. fulva*, *S. decoloratum* and *C. servilia* was compared between the day and night times (*Table 5*). Nymphs of all these odonate species consumed significantly higher number of mosquito larvae during the day time

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61716188

as compared to the night time ($P < 0.05$). Mandal et al. (2008) reported higher feeding rate of different odonate nymph species at the light phase as compared to the dark phase. A dragonfly nymph, *Brachytron pretense* consumed more *Anopheles subpictus* larvae during the day time compared to the night time (Chandra et al., 2006). Chandra et al. (2008) reported that feeding rate of *A. sulcatus* did not differ between the light and dark phases. Eyes in odonate nymphs are known to be very helpful in capturing prey but mechanoreceptors also play equal role in predation (Mandal et al., 2008). Backswimmers use both mechanoreceptor and vision for detecting their prey (Dieguez and Gilbert, 2003). Mechanoreceptors play role in detecting waves and providing accurate information for discriminating between prey and non-prey vibrations and adjusting their orientation or displaying prey catching behavior (Lang, 1980). In several odonate species, the nymphs come out from perches at night and wander for predation (Corbet, 1980). Dieguez and Gilbert (2003) studied the effect of light and dark on the predation efficiency of Backswimmer, *Buenoa macrotibialis*. It was noted that *Buenoa macrotibialis* can feed on small prey such as *Brachionus calyciflorus* and *Tropocyclops extensus* in presence of light but cannot feed well on these small preys in dark. It was further noted that *Buenoa macrotibialis* can feed equally in light and dark conditions on the largest prey such as *Daphnia pulex*. Their findings show the importance of both visual and mechanical cues in detecting prey of different sizes.

The 24-h feeding rate of *I. elegans, T. aurora* and *P. flavescens* on 3rd instar larvae of *Cx. quinquefasciatus* was also studied under varied conditions of predator density, water volume and prey (mosquito larvae) density (*Table 6*). The feeding rate of nymphs of each odonate species was positively correlated with increase in density of predator and prey but negatively correlated with increase in volume of water. This showed that the independent variables i.e., predator density, water volume and prey density are strong predictors of feeding rate of odonate nymphs on mosquito larvae. The negative impact of increased water volume (search area) on the feeding rate of odonate nymphs on mosquito larvae may be probably due to the evasion tactics of the mosquito larvae (Bhattacharjee et al., 2009). The positive correlation of increase in predator density with increase in predation rate on mosquito larvae may be probably due to intra-specific completion (Chandra et al., 2006). The positive correlation of increase in prey density with increase in predation rate of odonate nymphs on mosquito may be probably due to increase in chances of availability of prey to the odonate nymphs. Similar results have also been reported by other researchers in other odonate nymph species or other predatory insects against mosquito larvae. For example, Chandra et al. (2006) observed a decrease in the feeding rate of a dragonfly nymph (*Brachytron pratense*) on *Anopheles subpictus* larvae with increase in water volume. On the other hand, there occurred an increase in feeding rate of *Brachytron pretense* nymph on *Anopheles subpictus* larvae with increase in predator and prey (mosquito larvae) density. Mandal et al. (2008) studied variation in feeding rate of nymphs of five odonate species on 4th instar larvae of *Culex quinquefasciatus* (as prey) with variation in predator density, water volume (search area) and prey density. The predation rate was negatively correlated with increases in water volume (increase in search area) but linearly related to the increase in the density of predator and density. In the study of Chandra et al. (2008), the feeding rate of *Acilius sulcatus* larvae (predator) on the 4th instar larvae of *Culex quinquefasciatus* (prey) decreased with increase in water volume but increased with increase in the density of prey and predators.

During the present research, *I. elegans, T. aurora* and *P. flavescens* nymphs were exposed to various concentrations of NH_4^+ and NO_3^- for seven days for testing their sensitivity to these pollutants. Nymphs of all the species survived up to 50 ppm concentration of NH_4^+. Nymphs of *P. flavescens* were found less sensitive to NH_4^+. The LC_{50} value of NH_4^+ for *P. flavescens* was significantly higher when compared to the LC_{50} values of NH_4^+ for *T. aurora* and *I. elegans* (*Table 7*). To the author knowledge there are no reports about the toxicity of NH_4^+ or ammonia (NH_3) with *I. elegans*, *T. aurora* and *P. flavescens* nymphs. However, NH_3 toxicity with other odonate nymphs such as *Erythromma najas*, *Lestes sponsa* and *Sympetrum flaveolum* has been reported by Beketov (2002). These nymphs showed high tolerance to NH_3. Toxicity of NH_4^+ is dependent on pH (Körner et al., 2001). Both, un-ionized (NH_3) and ionized (NH_4^+) forms of ammonia may exist in aqueous solution. The ratio of NH_3 to NH_4^+ increases with rise in pH and temperature (Körner et al., 2001). Uncharged ammonia (NH_3) can cross biological membrane more easily than charged NH_4^+, therefore NH_3 is more toxic (Levit, 2010). The toxic effects of NH_3 to aquatic invertebrate is mediated by damaging the respiratory surfaces and changing the pH of hemolymph (Colt and Armstrong, 1981). NH_4^+ become toxic at higher concentration (Monselise and Kost, 1993). During the present study, solutions of NH_4Cl were prepared in non-chlorinated tap water with neutral pH (pH 7.3) and experiment was conducted at room temperature (17 to 23 °C), thus the existence of NH_3 would be less likely. Martinelle and Häggström (1993) presented a model that explains the mechanism of $NH4^+$ toxicity. According to the model, NH_4^+ competes with potassium ions for inward transport over the cell membrane through potassium transport proteins such as Na^+/K^+-ATPase and the Na^+/K^+-$2(Cl^-)$-co-transporter. It was concluded that one important toxic effect of $NH4^+$ is the need for maintaining ion gradients across the membrane that require energy.

During the study of susceptibility of *I. elegans*, *O. sabina* and *P. flavescens* nymphs to different concentrations of NO_3^-, all the nymphs survived up to 150 ppm concentration of NO_3^- (*Table 8*). However, exposure to higher NO_3^- concentrations resulted in mortality. Nymphs of *P. flavescens* were found least susceptible to NO_3^-. For example, maximum LC_{50} value was shown by *P. flaviscans* (1353.1 ppm) followed by *O. sabina* (678.4 ppm) and *I. elegans* (597.8 ppm). During the present research, the LC_{50} values of NO_3^- against odonate nymphs were higher than the LC_{50} values of ammonium against these nymphs. This might be explained by the fact that biological membranes are less permeable to NO_3^- than to NH_4^+, therefore there occurs limited uptake of NO_3^- in aquatic animals, which contribute to relatively low toxicity of NO_3^- (Cheng and Chen, 2002; Alonso and Camargo, 2003). The main toxic action of NO_3^- on aquatic animals is due to the conversion of oxygen-carrying pigments (e.g., hemoglobin, hemocyanin) to forms that are incapable of carrying oxygen (e.g., methemoglobin) (Scott and Crunkilton, 2000; Cheng and Chen, 2002).

To the author knowledge there are no reports about the toxicity of NO_3^- with the odonate nymphs. However, NO_3^- toxicity with other aquatic invertebrates has been reported. For example, Alonso and Camargo (2003) studied short-term toxicity of ammonia, nitrite, and NO_3^- to the aquatic snail, *Potamopyrgus antipodarum* (Hydrobiidae, Mollusca). The 4 days LC_{50} values of NO_3^- for *P. antipodarum* was 1042 ppm. Camargo et al. (2005) studied NO_3^- toxicity to two freshwater Amphipod species, *Eulimnogammarus toletanus* and *Echinogammarus echinosetosus* and a caddisfly (*Hydropsyche exocellata*). The 5 days LC_{50} of NO_3^- for *E. toletanus*, *E. echinosetosus* and *H. exocellata* were 73.1 ppm, 56.2 ppm and 230.2 ppm, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61716188

The LC_{50} values of NO_3^- reported by Camargo et al. (2005) for *E. toletanus*, *E. echinosetosus* and *H. exocellata* are much lower than the LC_{50} values of NO_3^- for Odonate nymphs observed during the present research. The LC_{50} values of NO_3^- reported by Alonso and Camargo (2003) for *P. antipodarum* are comparable to the LC_{50} values of NO_3^- observed during the present research for odonate nymphs. The toxicity of NO_3^- may decrease with increase in body size, water salinity, and environmental adaptation (Camargo et al., 2005). The effects of other environmental pollutants on aquatic insects have also been reported. For example, Lacerda et al. (2014) exposed Chironomus kiiensis lar larvae of Chironomus kiiensis larvae to crude oil. During their study, the 48-h LC_{50} was 26.5 ppm. Maximum mortality for most of the tested concentrations was observed during the first 24 h of the experiment. Similarly, Miles et al. (2017), exposed predatory insects to different concentrations of clothianidin, a neonicotinoid, in a semi-natural mesocosm. They observed high mortality of predatory invertebrates and increasing prey density with increase in clothianidin concentration.

Conclusion

1) From the findings of the study of predatory ability of damselfly and dragonfly nymphs, it was concluded that *I. elegans*, *T. aurora*, *P. flavescens*, *L. fulva*, *S. decoloratum* and *C. servilia* nymphs can play an important role in the eco-friendly control of the *Cx. quinquefasciatus* mosquito, and *P. flavescens* nymph is more efficient predator of *Cx. quinquefasciatus* 3rd instar larvae.

2) From the findings of the study of sensitivity of odonate nymphs to inorganic nutrient pollutants, it was concluded that *I. elegans*, *T. aurora* and *P. flavescens* nymphs can tolerate high concentration of NH_4^+, and NO_3^- under condition of neutral pH and room temperature. *P. flavescens* species is highly resistant to increasing water level of NH_4^+ and NO_3.

Authors contribution and Acknowledgements. This article has been prepared from the first author's (Ikram Ilahi) PhD thesis entitled "Ecofriendly control of *Culex quinquefasciatus* (Say, 1823) and susceptibility of its larvae and predators to different environmental pollutants" at the Department of Zoology, Islamia College, Peshawar, Khyber Pakhtunkhwa, Pakistan. Ali Muhammad Yousafzay acted as the supervisor. The remaining authors participated during collection in fields and/or in statistical analysis of data and preparation of manuscript. The help of Dr. Ahmad Zia, Senior Scientific Officer and Taxonomist in the Insect National Museum at National Agricultural Research Council (NARC), Islamabad, Pakistan, in providing literature and unpublished documents for identification of odonate nymphs is highly acknowledged.

(Received 4th Nov 2018 ; accepted 28th Jan 2019)

Abstract. Designing and implementing a crop pattern is necessary not only to cope with water deficit, but also to control the limiting factors and optimal utilization of available facilities, which have been addressed in many countries of the world. The current study was conducted at five levels of irrigation including I_1, I_2, I_3, I_4 and I_5 (100, 90, 80, 70 and 65% of crop evapotranspiration) and at three different levels of cultivation including S_1, S_2 and S_3 (current cultivated area, 10% increase in cultivated area and 10% decrease in cultivated area compared to current conditions). Optimum crop levels were estimated for each crops of crop pattern. The results show that the model in S_2 allocates a higher level to strategic crops, and in S_3 it allocates a higher level to higher-yielding crops. The S_3I_1 has the highest income among all scenarios. I_2 increased economic productivity at an average level of 7.5% while maintaining income. Therefore, it is possible to allocate a lower amount of area and a lower amount of water, and to earn more income. Also, I_4 and I_5 levels are not recommended due to reduced income and yield. If there is a decrease in available water and I_5 is reached, cropping tomato, beet and alfalfa are not recommended considering economic level.
Keywords: *cropping pattern, drought, linear programming, productivity, water deficit*

Introduction

Regarding world statistic, the greatest water consumption in countries can be found in the agriculture section (Kang et al., 2016; Programme, 2012; Mancosu et al., 2015). Consumed water in agriculture sector guarantees food security of the countries (Daiand Li, 2013). Therefore, optimal usage of water and maintaining the existing water resources are necessary (Garg and Dadhich, 2014). Cultivation pattern has a key role in water management and it can be determined that what level of cultivation and how much water could be allocated to what crops in order to receive more profit, water storage and providing food security (Niu et al., 2016; Zeng et al., 2010).

Amount of cultivation of agricultural products must be determine regarding the existing resources, price of products, cost of production, yield of production, demand of the country and correct policies. Also, in order to supply countries fundamental

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61896200

demands, choosing agronomical and horticultural productions must be based on the existing infrastructures, social-economic issues and level of technologies maintaining basic resources of production.

Jiang et al. (2016) have developed PBREOP model in west north of China. Results of optimization through this model led to 15% increase in profit. In addition, analyzing scenarios including five level of water allocation has shown that allocation of water could be decreased to 23% without declining profit. Mushtaq and Moghaddasi (2011) have investigated the effect of deficit irrigation to respond climate changes and environmental water demands in Murray-Darling basin of Australia. Three scenarios have been compared in this research: Optimization with full irrigation, optimization with deficit irrigation and deficit irrigation without optimization. Results have shown that deficit irrigation is effective to maximize gross yield and increase water consumption efficiency.

About four decades ago, Qazvin plain was one of the five fertile plains of Iran. Agriculture in this plain has supposed to become one of the industrial poles of the country, but it has become the main occupation of people living in the region. Exactly for this reason and while some of the surface waters of the area are transported through the construction of the Taleghan Dam to supply Tehran's drinking water. The utilization of Qazvin plain surface water and groundwater resources has been expanded to the extent. According to the existing reports, it is far beyond the capacity of the water system. The aquifers are progressing towards irreversible degradation. At present, usage of groundwater in the whole consuming sectors is estimated to be 1.8 billion cubic meters, while the authentic limit to use the water resources of Qazvin province is 880 million cubic meters (Shokoohi et al., 2014). In order to resolve the water crisis in Qazvin plain, revise of crop pattern and water management is required especially in the agricultural sector (Shokoohi, 2012; RamezaniEtedali et al., 2015).

Using a single-objective mathematical model, Shirdeli and Dastavar (2014) have dealt with optimization of crop patterns of the lands in the down part of BoiinZahra (Qazvin, Iran) dam. The aim of this study had been to maximize the income of farmers in this area and they developed four 5-year programs for future analysis. The results of their study showed that there is a possibility for a significant increase in farmers' income in this area. Also, farmers' income increases during the second to fourth 5-year program will be 20, 44.7 and 50.3% respectively in compare with the first 5-year period. Upon completion of the last five-year program, water productivity will increase from 50 to 77%.

Yousefdost et al. (2016) turned to optimization for managing the water resources of the Taleghan dam and determining the maximum yield of crop production in Qazvin Plain under different climate conditions. One of the most important results of the research is to determine the new cultivar pattern, so that both objectives which are providing the farmer's profit and allocation of water resources to the other needs by its saving, become available. According to the presented results, 2.81, 2.62, 1.34 and 1.355% profit have obtained for farmers with the new culture pattern in hot and dry, dry, normal, and wet weather situation, respectively.

Parhizkari et al. (2016) have considered three methods of irrigation including full irrigation, 5% deficit irrigation and 10% deficit irrigation for studying the effect of deficit irrigation on crop pattern and farmers profit in Qazvin. The results of using deficit irrigation method have showed that by applying this strategy under different scenarios, it is possible to reduce the area under cultivation of products that are less

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61896200

economic (wheat and water barley) and increase the area under cultivation of those products with more gross profit through the saved volume of water.

The plan of water allocation in irrigation and drainage networks is one of the main issues of optimal management of economic efficiency of water. Therefore, a model that could assess the plan of water allocation in the constraints and ruled conditions in the network, would enjoy of a great importance. Mathematical models and planning methods can help planners and managers in decision making. In previous studies, deficit irrigation has been dealt with, but deficit irrigation and decreasing or increasing the area under cultivation has not been studied at the same time. The purpose of current study is to manage the pattern of cultivation to achieve higher income with less water consumption in Qazvin plain.

Materials and methods

The case study

The area of Qazvin province is 15820 km^2 and is in central sphere of Iran between 48°44' to 50°51' E length and 35°24' to 36° to 36°48' N latitude (QPG, 2016). Qazvin plain is belonging the Central Salt Lake basin. This area has the highest level of cropping of various types of products in the plains of this basin (Shokoohi et al., 2014). Qazvin Plain with an area of 440 thousand ha is in the central plateau of Iran and has semi-arid climates and hot summer and relatively cold winters. The main aim of constructing Taleghan dam is to provide agricultural water in Qazvin Plain, to provide drinking water to Tehran and Karaj, to artificially recharge Qazvin aquifer and to control the seasonal floods of the Taleghan River. *Figure 1* shows the location of the studied area (Yousefdost et al., 2016).

The required statistics were obtained from statistics of the Ministry of Agricultural Jihad or from the Organization of Agricultural Jihad of Qazvin province. *Table 1* shows the current level of cultivation area, income, maximum yield, sensitivity coefficients (K_y), Crop Evapotranspiration (Et_c), water requirement and proportion of areas under cultivation of important products in the studied area in the crop year 2015. The K_y and ET_c in the study area suggested by Tafteh et al. (2014) were used. Monthly weather data for three years (2012–2015), including maximal and minimal temperature and monthly average rainfall were collected from Feizabad (36°8' N, 50°15' E, 1240 m) station in this study area and they are shown in *Figure 2*.

Defining the model and its dependent variables

The method of linear programming modeling which involves the parameters of crop pattern designing including crop water requirement, cultivation frequency and etc., requires designing a model that initially consists of three principles, i.e. objective or objectives, variables, constraints, and limitations, also the relationship between these principles must be defined in a matrix called the planning matrix. In the framework of the program's objective function and by using a linear planning approach, a designer can follow many lateral objectives within the framework of variables and constraints, in addition to what is considered as the ultimate objective.

In current study, the maximum income in thousand USD was considered as the objective function (*Eq. 1*). The objective function was the most economic benefit with considering the decline in yield caused by water shortage, which is presented in the following relation (*Eqs. 1-2)*:

$$Max\ Z : \sum_{i=1}^{n} \alpha_i . A_t (P_i . Y_i - C_i - Q . C_w) \qquad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61896200

$$Y_i = Y_i^{\max}.\left[1 - k_y\left(1 - \frac{W_i}{ET_i}\right)\right] \quad \text{(Eq.2)}$$

where Z: the objective function, α_i: the percentage of the surface area under cultivation for each product, i: the product, A_t: the total area of the lands (Ha), P_i: marketing price of each kg of product (USD), Y_i: the product yield function (Eq. 2), Y_{imax}: Maximum product yield (kg), K_y: Coefficient of the crop yield response to water deficit, W_i: the amount of water entered into the earth (mm), ET_i: the water demand of the product (mm), Q: water used (liter), C_w: Cost of each litre of water (USD), C_i: Cost of production per product (USD). Applying the constraints was done with the following assumptions:

1. Wheat is a strategic product and the least supposed culture is 30%.
2. Products which are below 5% in the current state are determined at least 1% and utmost 15%. The basis for selection 15% is based on the capability to crop yields in the region.
3. Products whose cultivation in the region is less than 20% and are cultivated after strategic crops, their minimum cultivation is as the same as the current cultivation and their maximum area under cultivation is selected 2 times more than the current cultivation.
4. Percent of the present area under cultivation of barely is 21%. Considering the importance of this crop, it is chosen at least 15% and utmost 30%.
5. Total cultivation area was considered as a limitation in different scenarios.
6. The allocated water was considered as water constraint in the five water scenarios.

The crop production function is a function of the relative yield of the product according to the evapotranspiration of the crop. The researchers have presented the Ky of the products in general after analyzing experimental data. In current research, *Equation 3,* which is based on the relative reduction of the product and the relative lack of evapotranspiration, was used to investigate the effect of the reduced water allocated to the crop yield (Doorenbos and Kassam, 1979).

$$1 - \frac{y_i}{y_{i\max}} = k_y\left(1 - \frac{ET_a}{ET_m}\right) \quad \text{(Eq.3)}$$

where Y_i: the product yield function, Y_{imax}: Maximum product yield (kg), $\frac{y_i}{y_{i\max}}$: Actual yield ratio to maximum yield (relative yield), $\frac{ET_a}{ET_m}$: Actual evapotranspiration to the maximum evapotranspiration of the crop (mm), k_y : Coefficient of the crop yield response to water deficit.

The current study was optimized considering five irrigation scenarios including I_1, I_2, I_3, I_4 and I_5 (regarding water allocation of 100, 90, 80, 70 and 65% of crop water requirement, respectively) and three different levels of cultivation including S_1, S_2 and S_3 (respectively equivalent to the existing cultivated area, 10% increase in cultivated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61896200

area and 10% decrease in cultivated area compared to the current situation) and the optimal amount of cropping levels were estimated for each crop pattern of the products. The total cultivation area and water used of fifteen defined scenarios are presented in *Figure 3*.

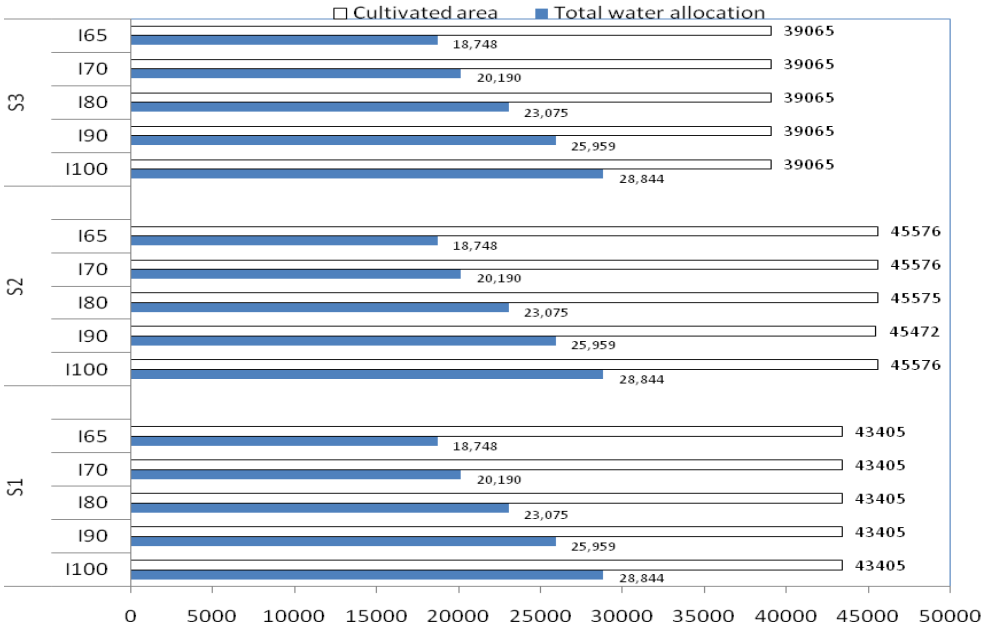

Figure 3. *Cultivated area and total water allocated to each scenario in Qazvin District (the amount of allocated water was calculated based on crop evapotranspiration*

Since farmers generally pay attention to the economic yield of crop cultivation, the economic productivity index ($WP_{\$}$) has also been studied and calculated in this research from different scenarios. The $WP_{\$}$ index was defined and calculated based on thousand USD per cubic meter of crop water requirement as follows (*Eq. 4*):

$$WP_{\$} = \frac{(\$\ kg^{-1})\ (kg\ ha^{-1})}{ET(m^3 ha^{-1})} \qquad \text{(Eq.4)}$$

where \$ has been considered equal to thousand USD.

Results

Relative yield of the products in different water allocations is the most important of water allocation modeling. In the case that the water allocated to the crop is equal to the maximum water requirement of the crop, the relative yield is equal to one. Also, if the water allocated is less than the crop water requirement, its relative yield will be less than one. In *Figure 4,* the relative yield of the products is shown in various water scenarios. The economic level of products yield is 0.7 (Papamichi et al., 2008); therefore, in I_5, the estimated yield for most products is at the level of 0.7, and for the tomato, alfalfa and sugar beet is 0.69, 0.68 and 0.69 respectively, these values are less than those of their economical level. This means that the cultivation of these products in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_61896200

these water conditions is not economic due to high water requirements and decrease in yield. The relative yield of different crops at all cultivation scenarios has been reduced by decreasing the amount of water allocated (*Fig. 5*). The main output of the model, which is related to the objective function of the model, is the income and the area under cultivation ratio for each product. Total income for different irrigation and cultivations scenarios as well as the optimal cultivation ratio is presented in *Table 2*. The income of I_1 at S_1 cultivation level was less than S_3 with income of 91 and 96 thousand USD respectively, while by increasing the level under cultivation (S_2) the amount of income (78 thousand USD) fell down.

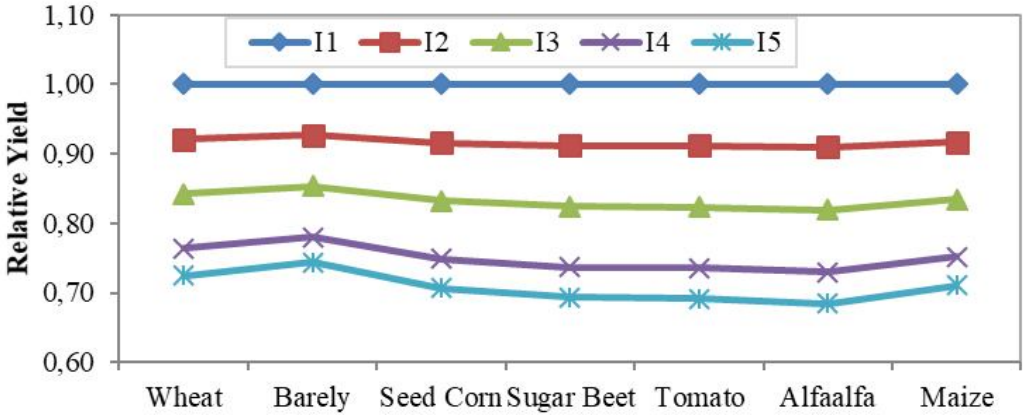

Figure 4. *Relative yield of crops in different water scenarios*

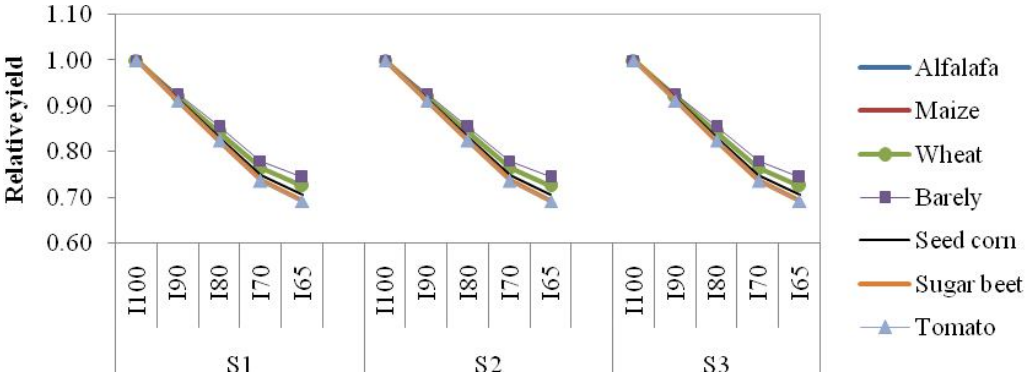

Figure 5. *Relative yield of crops in different water scenarios and cultivations*

The percentage of optimal cultivation area for products with higher incomes in the S_3 is in highest so far as the water allocated is not limited. The highest cultivation areas were for alfalfa, tomato and sugar beet cultivars that are 16.20, 4.70 and 2.40%, respectively in S_3 and the lowest in were 1_2, 1 in S_2. The highest ratio of optimum cultivation area for seed corn was found to be 7% in S_1 and the lowest was observed at S_2, i.e. 1%. However, in S_2, products with high water consumption are at the minimum of the specified constraint domain and strategic products such as wheat and barley are at the maximum specified range in the model. In wheat and barley, the highest culture percentage was observed in S_2, i.e. 47.00% and 30.00%, respectively.

The letters are used to determine the results of scenario adaptation

Figure 6a shows the final income per different levels of area under cultivation for each irrigation scenario and *Figure 6b* shows the final income per different levels of irrigation for each are as under cultivation. In Section A, we can see that the difference between income in I_1 and I_2 is insignificant subtle and income has fallen from I_1 to I_5 totally.

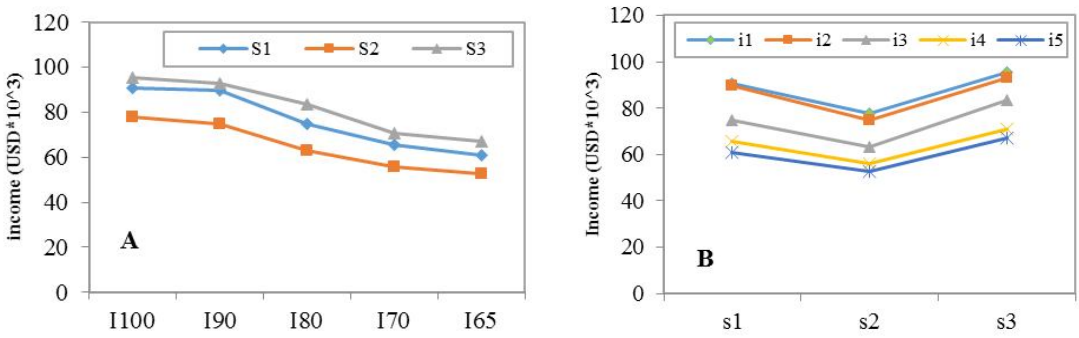

Figure 6. *The final income in (a) cultivar scenarios, (b) irrigation scenarios*

Table 3 shows binary comparison matrix in different products related to the total income. Studies showed that the total income (based on million Rials) has positive correlation with all products except barley (with coefficient equal to -0.072) and they were 0.011, 0.387, 0.449, 0.425, 0.885 and 0.829 for wheat, seed corn, beet, tomato, alfalfa, respectively. Total income has significant correlation with all products except wheat and barley. The highest correlation of total income was with alfalfa, i.e. 0.855.

Figure 7 shows the required water for each crop and total income in a diagram. In I_1S_2 the required water for wheat, barley and alfalfa were increased in compare with I_1S_1 which shows allocating more area under cultivation for these three productions in this scenario. It can be observed that, in this section, income has decreased. This issue reminds two results: first that despite high importance of strategic products, they are not economic necessarily and second that more water consumption and high cultivation area necessarily do not lead to more income. In I_1S_3 water requirement has increased in tomato, beet and Alfalfa which shows allocating more area under cultivation to these three productions in compare with the conditions I_1S_1 and I_2S_2. Income increase has observed in this section.

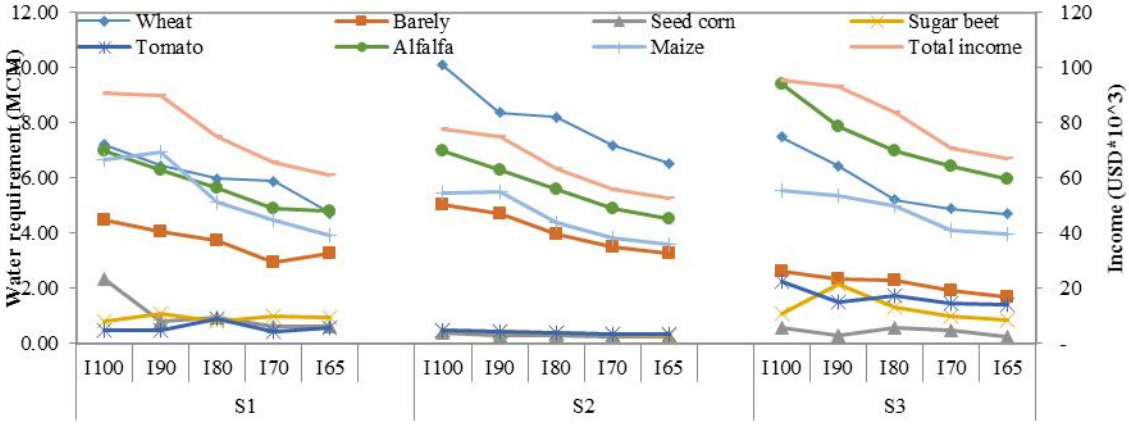

Figure 7. *Water requirement by crops and total income*

In *Figure 8,* economic productivity and total income has been presented in all scenarios. Economic productivity was calculated in different scenarios from 2.7 to 3.6 thousand USD in cubic meter. In addition of maintaining the income, I_2 has averagely increased economic productivity in different levels, i.e. 0.43 thousand USD per cubic meter water. Economic productivity is in the minimum level in S_2. S_3 obtained more income while its water consumption was equal to S_1 and S_2. Economic productivity was more observed in S_3. Generally, water allocation to products with high income in S3 has increased income.

Discussion

Using study results, we can now answer the question which of the strategies 'increasing cultivated area' or 'reducing cultivated area' will result in the highest WP or economic benefit. Reducing the cultivated area will result in higher water productivity. However, it is seen that even a decrease in the area under cultivation and the optimal use of water at a lower level have resulted in an increase of 5.3% of income. Lalezari et al. (2016) reported that the result of applying deficit irrigation plan and increasing economic profit plan at the same time for allocating water and land shows providing more water requirement and decreasing area under cultivation is a more proper strategy for managing water in agriculture in drought condition.

With increasing the cultivation area, since the allocation of water is constant or less than the existing conditions, the model has optimized the high water-consuming products such as tomato and beet at the minimum ratio of the defined area for scenario and developed cultivation area of strategic products such as wheat and barley toward higher bound of cultivation range. The results of this study are not in line with the results of the studies conducted by Jafarzadeh et al. (2016) and Alizadeh et al. (2012) as all concluded that optimization leads to high levels of cultivation for strategic products in the region. It is recommended that greenhouse products and products that can be cultivated in the greenhouse become transferred to the greenhouse and the stored water from removing these products become allocated to strategic products.

I_2, we can save 10% of water consumption with only 1.2% reduction in income. A study in the West of the Palestine Region revealed that optimal cultivation pattern reduces water consumption by as much as 10%, which contributes to the sustainability of water resources (Nazer et al., 2010). In addition, as compared to the previously published results (García-Vila and Fereres, 2012; Zhanget al., 2014), objective function could not only have a feasible computation, but also well consider the benefit coordination between different water conditions and the various cultivated area in the district.

Results showed that it is possible to have more income with lower area and even lower water allocation by managing the cultivation area.

Conclusion

Crop pattern is supposed to be one the most important effective components in management of water resources. This study has determined an optimal Crop pattern in Qazvin plain in order to decrease water allocation and increase or decrease the area under cultivation. I_4 and I_5 are not recommended due to decrease in income and yield. In order of decrease in existing water and reaching to I_5 amount, with regard to economic limit, cultivating of high water consuming products such as tomato, beet and alfalfa is not recommended. According to the results if there were enough cultivation area, Model recommend higher area for strategic products. Also with regard to the higher cultivation area and decrease in water allocation related to the current situation and due to high water demand of crops such as beet, alfalfa and corn, the cultivation area of these products were decreased. Unlike, when the cultivation area is limited constrain, the model would increase area under cultivation of economic products with higher income and allocate water to them. So it has been observed that income in S_2 and S_3 has been decreased and increased in compare with S_1, respectively. In addition of retaining income, I_2 increased economic productivity in different levels, i.e. 0.82 million Rials per cubic meter water averagely. These results could decrease lots of tests and it could be used as a certain criterion for the future research works and management of crop pattern.

Abstract. Anaerobic Fe(II) Oxidation DeNitrifiers (AFODN) have recently been proposed as an option to treat groundwater contaminated by arsenic and nitrates through oxidation of microbiological nitratedependent ferrous oxidation. In previous studies, a pure strain of AFODN bacteria, Clostridium sp. Strain PXL2, was isolated from anoxic activated sludge. In this paper, the growth curve of strain PXL2 is studied under different temperature conditions, along with its Fe(II) oxidation, nitrate reduction, and arsenic removal efficiency. The results showed that at 5°C, the growth of the strain was significantly inhibited. At 15°C, the metabolic rate of growth, denitrification and Fe (II) oxidation rate were optimum and the total arsenic removal rate was high at 51.1%. The strain PXL2 can remove nitrate and arsenic contamination at the same time under normal groundwater temperature conditions. These analyses provide the necessary data to support the application of AFODN in engineering projects.

Introduction

Section title Arsenic contamination in water bodies due to the release of untreated industrial wastewaters has been on the rise due to excessive mining and smelting. The prevalence of arsenic and its compound in water bodies grows more serious every day and currently threatens the lives of more than 140 million people around the world (Karim, 2000; Smedley and Kinniburgh, 2002; Singh et al., 2007; Song et al., 2017). In China alone, it is estimated that more than 3 million people are exposed to elevated levels of As (Sun, 2004). New endemic areas have been progressively identified, such as the Huhot Basins in Inner Mongolia (Guo et al., 2001) and the Datong Basin in Shanxi Province (Wang et al., 2007) since the first case of chronic As poisoning was observed in the Xinjiang autonomous region in 1980 (Wang and Huang, 1994). Populations in affected areas suffer from melanosis, keratosis in their palms and soles, gangrene, and even skin cancer.

Among the numerous reduction processes of the soluble matrix, NO3- reduction plays a key role in the nitrogen cycle and has important implications for agriculture, environmental health, and public health (Shen et al., 2010; Xing et al., 2010). Natural nitrate attenuation is driven by microbial enzyme reduction, although, the abiotic reduction of nitrate also occurs under some extreme conditions (Hansen et al., 1996; Ottley et al., 1997; Zhang et al., 2014). Oxidation of microbiological nitrate-dependent Fe(II) to Fe(III) has been recently described with ferrous iron as the only electron donor

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62016211

and with nitrate as the electron acceptor (Straub et al., 1996; Hafenbradl et al., 1996; Straub et al., 2004; Weber et al., 2006; Chakraborty et al., 2011; Li et al., 2015). These microorganisms are called the Anaerobic Fe(II) Oxidation DeNitrifiers (AFODN) (Wu et al., 2010). Enrichments of AFODN were successfully established with a variety of marine, brackish, or freshwater sediment samples (Kappler, 2005). The metabolism of AFODN is affected by many external factors (Chen et al., 2018). The major environmental factors include temperature, salinity, carbon source, pH, dissolved oxygen, and iron source. The oxidation of ferrous oxide directly affects the removal efficiency of heavy metals. To achieve the highest removal efficiency of nitrate and heavy metals and the best governance effect, it is necessary to provide optimum conditions for the ferrous oxidation and nitrate reduction by AFODN, which will help activate the microorganisms and lay the foundation for its application.

The response of different microorganisms to heavy metals is dependent on their physiologies (Li, 2017). Various treatment technologies to mitigate the severe problem of arsenic tainted groundwater have been extensively studied during last few decades (Hu et al., 2015; Niazi et al., 2018; Cui et al., 2018). Previous studies showed that low concentrations of arsenic promoted the growth of heterotrophic microorganisms. However, the growth of heterotrophic microorganisms was inhibited with the increase of As(III) concentration. While under the same exogenous arsenic concentration, it has a stronger inhibitory effect on autotrophic microorganisms than on heterotrophic microorganisms.

In this study, a novel AFODN species, the Clostridium sp. strain PXL2, was isolated from anaerobic activated sludge (Li et al., 2016), and its growth curve was studied under different temperature conditions. Fe(II) oxidation, nitrate reduction, and arsenic removal efficiency by strain PXL2 were observed under different temperature conditions. The resistance of strain PXL2 to arsenic, as well as its ability to oxidize microbiological nitrate-dependent Fe(II) to Fe(III) in an arsenic contaminated environment made it ideal for application in practical engineering. These analyses can provide the data necessary to support the application of AFODN in engineering projects.

Experimental materials and methods

An anaerobic nitrate-reducing Fe(II) oxidizing bacteria *C. freundii* PXL2 could synchronously remove As(III) and nitrate from water, associated with Fe(II) oxidation. Batch experiments were conducted to study the effect of temperature on ferrous oxidation and denitrification of PXL2 strains. SEM-EDS analyzed the morphologies under different temperature conditions. The removal of arsenic under different temperature conditions was studied at the same time. The selection medium (Li et al., 2014) was used as the culture medium with three repetitions for each sample.

Three tubes of mediums inoculated with AFODN culture were set to determine the efficiency of Fe(II) oxidation and nitrate reduction. The whole experiment was carried out in the G250 anaerobic, insuring microbial metabolism in the absence of oxygen. The amount of inoculation was 4% (vol/vol). All the tubes were sampled every 24 hours to determine the nitrate, nitrite, and Fe(II) concentrations. The effect of temperature on the denitrification of AFODN was performed. The initial concentrations of $FeCl_2 \cdot 4H_2O$ and KNO_3 were 1 mM and 20 mM, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62016211

Arsenic pollution was simulated by $NaAsO_2$ to study the removal of arsenic by strain PXL2 at different temperatures. the initial concentration of As (III) was 60-70 μM (about 5 mg L^{-1}). To improve arsenic removal rate, the experimental analysis was extended to seven days. In addition to the analysis of total arsenic concentrations, the concentrations of As (III) and As (V) were also analyzed separately.

Concentrations of nitrate, nitrite, and Fe(II) were measured by a spectrophotometer (DU 800 UV/Vis Spectrophotometer, Beckman coulter, United States). N-(α-naphthyl)-ethylenediamine spectrophotometry was used to determine the concentrations of nitrite at 540 nm (Geng et al., 1996). Nitrate concentration was measured by UV spectrophotometry at 220 nm and 275 nm (Veena and Narayana, 2009). Phenanthroline spectrophotometry was used to determine Fe(II) concentration at 510 nm (Gendel and Lahav, 2008). For the modified phenanthroline assay, the samples were mixed with 40 mM sulfamic acid (pH approximately 1.8) instead of 25 vol% HCl because the sulfamic acid reacted rapidly with nitrite and prevented Fe(II) oxidation by the nitrite at an acidic pH (Klueglein and Kappler, 2013). All the samples were measured within 2 h after sampling. Total As concentration was measured by an AFS-8X atomic fluorescent spectrophotometer (Jitian Instruments Co., Ltd., Beijing, China). Ten ml of 5% thiourea and 5% vitamin C mixture and 2.5 ml of concentrated HCI were added to 50 ml of sample as As(V) reducing agent and stabilizer, respectively, and 2.0% (W/V) KBH_4 and 0.5% (W/V) KOH were used to transform the ion state As(III) to AsH_3. The flow carrier of samples was 5% (V/V) HCl. The original As(III) concentration in the water samples was measured by the same method without the addition of the 5% thiourea and 5% vitamin C mixture. Microbial morphology was observed by a Scanning Electron Microscope (SEM) (Zeiss Super 55VP, Germany) equipped with and energy dispersive X-ray (EDX) (Bruker XFlash 5010, Germany) spectroscope. Accelerating voltages ranged from 15 to 35 kV.

All the experiments were performed in triplicates. Error bars on graphs show the standard deviation. The data were analyzed by analysis of variance and the means were compared by Tukey's test ($p < 0.05$).

Results and discussion

Growth curve of PXL2 strains at different temperatures

Temperature is a major environmental factor that affects the growth of microorganisms. The temperature at which fastest microbial growth and reproduction occur is called the optimum growth temperature. The reaction rate increases with rising temperature, however, increasing temperature leads to the destruction of intracellular enzymes and nucleic acids and eventually, microbial death. Lower temperatures decrease cellular metabolic activity and lead to slow growth. A temperature that is too low triggers the formation of intracellular ice crystals that would lead to dehydration of the microorganisms and ultimately microbial death.

Based on the variation of groundwater temperature in seasonal alternations, three temperature gradients of 5°C, 15°C and 30°C were selected to study the growth and reproduction ability of PXL2 strains at different temperatures. In the selected medium access, 2% bacterial suspension were placed in 5°C, 15°C, 30°C anaerobic environment static cultures for 72 h and the absorbance of the bacterial liquid was measured at 600 nm. The results are shown in *Figure 1*. As can be seen from the figure, 5°C obviously inhibited the growth of the strain, and the OD value of the 96 h bacterial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62016211

liquid continued to decline, indicating that the strain cannot complete its metabolism at 5°C. At 15°C, some microbes could not adapt to the low-temperature environment and died after about 8 h of inoculation, after which the OD of the bacteria began to increase, indicating that the surviving microbes gradually adapted to the ambient temperature and the growth and metabolism rates were consistent with those at 30°C. The growth, propagation and metabolism rate are the highest, the bacterial stagnation period is short, and the logarithmic phase can be quickly achieved at this temperature.

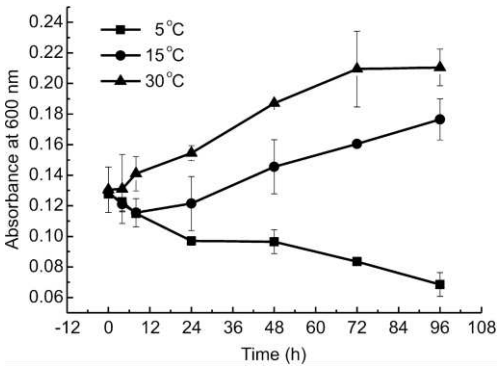

Figure 1. *Growth curves of PXL2 strains at different temperatures*

The optimal temperature for bacterial oxidization under ferrous anaerobic conditions is mainly related to the source of separation. Ehrenreich et al. (1994) isolated two strains of Chromatium strain L7 and Rhodobacter strain SW2 from the sediments of freshwater ditches whose optimal temperature range for growth was 18-20°C, and found that they did not thrive at temperatures above 24°C. Hafenbradl et al. (1996) isolated an extremely thermophilic archaeon named Ferroglobus Placidus gen. Sp. Nov. from a hydrothermal system. The optimal temperature range of this strain was 65°C to 95°C and its doubling time was about 2.8 h. The bacteria could not grow when the environment temperature was under 63°C or exceeded 96°C. AFODN strain HidR2, which was isolated from seabed sediments grew at temperatures of 5 to 40°C while the optimum temperature was 33°C (Benz et al., 1998). For two strains of photosynthetic non-ferrous anaerobic oxidative bacteria, strain N1 and strain N2, which were also separated from seafloor sediments, the optimal temperature ranges were similar to strain HidR2. The optimal growth temperature of strain N1 was 20-25°C, while the optimal growth temperature of strain N2 was 25-28°C (Straub et al., 1999). For AFODN strains BrG1 and BrG2, which were isolated from brackish water lakes and urban ditches, their growth rate at 15°C was greater than that at 28°C (Straub et al., 1996).

The strain PXL2 was isolated from the ditch sediments. It is a normal temperature living environment. So the strain PXL2 can grow at temperatures of 5 to 30°C. And the growth rate increases with temperature within the scope of the study.

Ferrous Oxidation and Nitrate Reduction of PXL2 Strains at Different Temperatures

The effect of temperature on the ferrous oxidation and nitrate reduction of AFODN is primarily due to the metabolic activity of the microorganism (Leahy and Colwell, 1990). The ferrous oxidation of AFODN and nitrate reduction is based on specific metabolic methods of microorganisms, and the catalytic effect of the enzyme is most efficient only within the optimum temperature range.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62016211

Figures 2A, B and C show the changes of Fe (II), NO_3^- and NO_2^- concentrations in the medium inoculated with PXL2 strains with time at different temperatures, respectively.

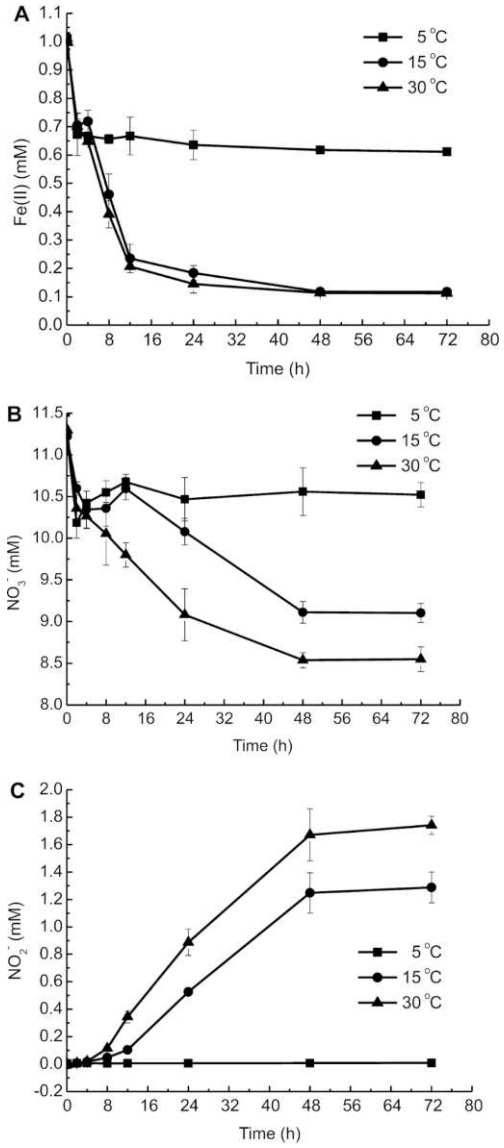

Figure 2. *Time profile of Fe(II), NO_3^- and NO_2^- concentrations in the strain PXL2 culture at different temperatures*

It can be seen from the figure that at the same oxidation rate, the temperature has little or no effect on the oxidation of ferrous ions within 4 h after inoculation. However, with time, the low temperature (5°C) sample significantly inhibits the oxidation of Fe (II). At 5°C, the ferrous oxidation rates were significantly lower than those at 15°C and 30°C. The oxidation rates of ferrous iron at 15°C and 30°C were almost the same as the initial Fe (II) concentration of 1 mM. About 90% of Fe (II) was oxidized after 24 h. Fe(II) oxidation was completed and nitrate degradation was also completed. As shown in *Figure 2B*, the nitrate degradation ability of PXL2 strains did not change significantly within 4 h after the completion of Fe (II) oxidation. However, with the duration of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62016211

inoculation, nitrate degradation ability was quite different. At 5°C, the biomass stagnated after 12 h of inoculation and no longer had the ability to degrade nitrate. The same degradation rate was maintained at 15°C and 30°C, but strain PXL2 completed 19.5% nitrate degradation at 15°C after 72 h of inoculation, While at 30°C, 24.8% nitrate degradation was completed, which is slightly higher than that at 15°C. The trend of accumulation of nitrite coincides with the trend of degradation of nitrate. Higher accumulation of nitrite, 1.7 mM, was observed in 30°C environments. The second highest concentration is the concentration of nitrite at 15°C reached 1.3 mM. No nitrite was accumulated in the environment at 5°C.

The PXL2 strains showed different rates of ferrous oxidation and nitrate degradation at different temperatures, which may affect the reproduction of microorganisms. At the same time, the oxidative degradation ability of AFODN at low temperature was greatly reduced. The low temperature inhibited the growth of microorganism's intracellular enzyme activity, so that it reduced the ability of oxidation and degradation.

SEM-EDS Analysis of Sediments at Low Temperatures

SEM analysis of microbial antioxidant sediments at 5°C, 15°C and 30°C (*Fig. 3*) shows that the morphology of the cells changed significantly at 5°C, the bacillus is coarsened and shortened, and obvious dents generally appear, possibly as a response to the low temperature.

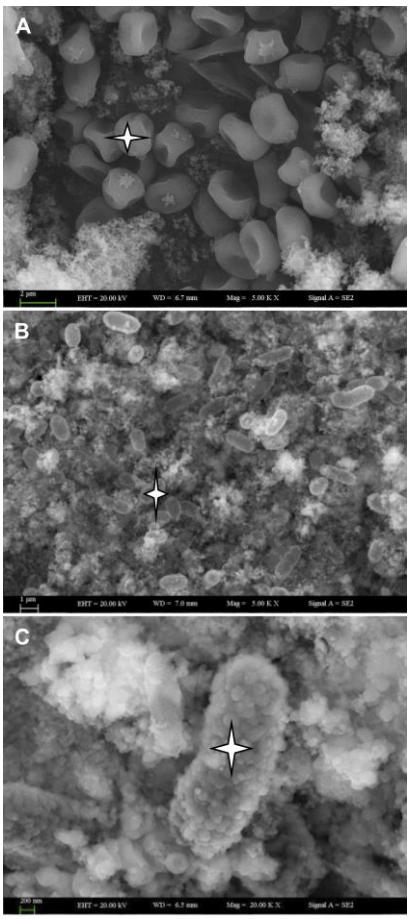

Figure 3. *SEM analysis of microbial ioxidant sediments--strain PXL2 at different temperatures (The star indicated the point of EDS analysis in Figure 4. A: 5ºC; B: 15ºC; C: 30ºC)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62016211

At 30°C, the cells were incrusted in nanosize Fe(III) oxides with only few cells being completely free of surface precipitates (*Fig. 3c*). The average diameter of the Fe(III) oxides was between 100~200 nm.

EDS analysis of ferrous oxide products at 5°C, 15°C and 30°C. *Figure 4* shows that the sediments formed at 5°C mainly consist of C and O, with only a small amount of Fe. The highest C content was 62.41%, the content of O was 33.15% and the content of iron was only 0.35%. The contents of Fe in the sediments formed at 15°C were higher at about 9.64%, which far exceeded the content of Fe in the sediments formed at 5°C. At 30°C, EDS analysis showed that the precipitates were mainly composed of C (22.85%), O (40.68%) and Fe (22.41%). Iron content exceeds at the first two temperatures.

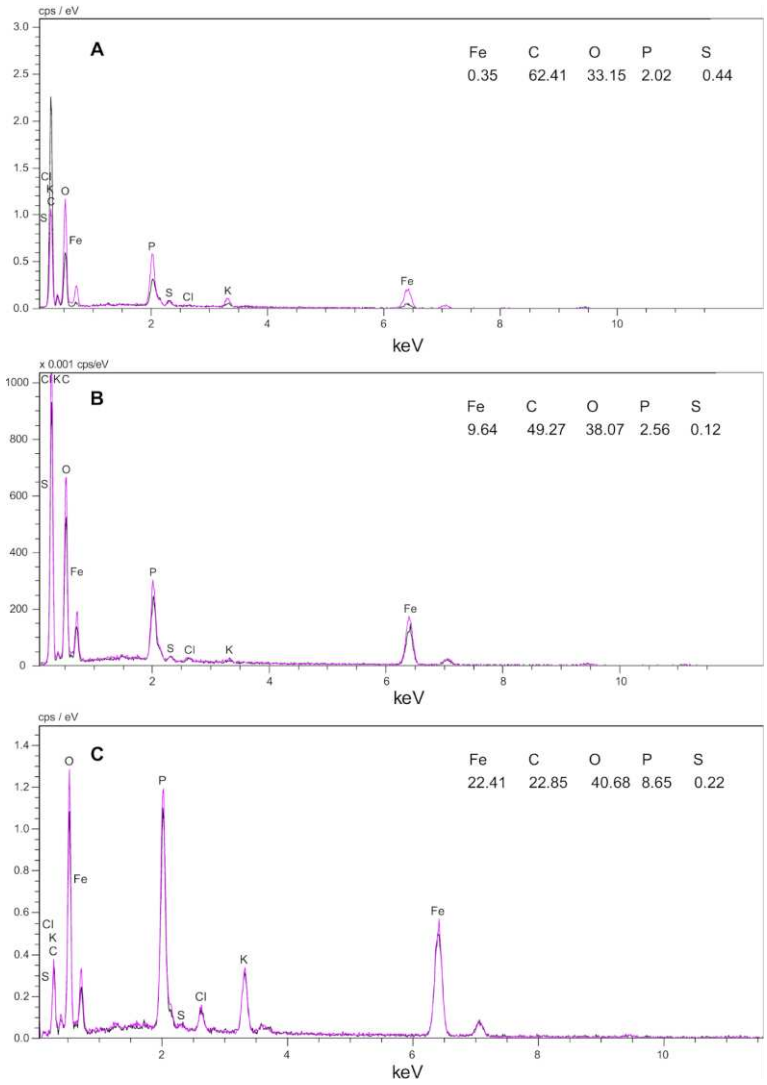

Figure 4. *EDS analysis of strain PXL2 sediments at different temperatures (A corresponding Fig. 3A; B corresponding Fig. 3B; C corresponding Fig. 3C)*

Based on the above analysis, we can see that low temperature environments had inhibitory effects on strain PXL2. At 5°C, the cell morphology changed and the Fe content in sediment was extremely low and mainly existed in pericellular region instead of the cell surface while Temperature of 15°C seemed to have less of an effect on the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62016211

metabolism of microorganisms, and the morphology of the cells remains the same, but the content of Fe was at least 50% lower than the sediment at 30°C. Thus, 30°C is most suitable for the growth and metabolism of strain PXL2. Under this temperature, microbial metabolism is the fastest, and the rate of Fe oxidation and the content of Fe in sediment are the highest.

Removal of arsenic by strain PXL2 at different temperatures

The removal of arsenic at different temperatures is shown in *Figure 5*. The different amounts of arsenic are removed at different temperatures over time. After 7 days of treatment, total arsenic concentrations decreased from 70 μM to 54.9 μM, 34.2 μM and 49.0 μM at 5°C, 15°C and 30°C, the removal rates were 21.6%, 51.1% and 30.0%, respectively. The highest rate was at 15°C.

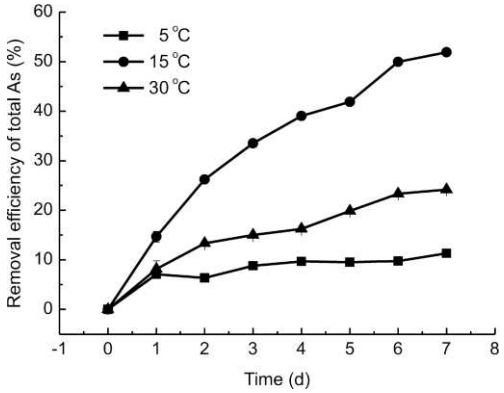

Figure 5. *Total arsenic removal efficiency at different temperatures*

Strain PXL2 has the ability to remove arsenic by arsenic oxidation. As seen in *Figure 6*, as total arsenic is removed, some As (III) is oxidized to As (V). At 5°C and 30°C, with the removal of total arsenic, the concentration of As (III) decreased and the concentration of As (V) increased continuously. The percentage of As (III) in total arsenic dropped from the original 90% to 62.1% and 54.0%, respectively. The corresponding As (V) concentrations increased from 10% to 37.9% and 46.0%, respectively. The conversion of As (III) to As (V) at 15°C is less pronounced with respect to the other conversions at two temperature, but some of the As (V) production can be seen.

From the above analysis we can see that temperatures that are too high or too low are not suitable for strain PXL2 arsenic removal, with 15°C being the most suitable temperature. One of the reasons may be that enzyme catalysis in microbial metabolism is inhibited severely at extreme low and high temperatures. Compared with the medium temperature, microbial metabolism is active in high temperature environments, and therefore results in the fastest ferrous oxide oxidation rate. The rate of ferrous oxidation directly affects the type of oxidation product. Different types of iron oxides have different arsenic adsorption capacities. The environment of oxidative denitrification of AFODN anaerobic ferrous compounds is mainly for the pollution of nitrate and arsenic in groundwater. The perennial groundwater temperature is maintained at 15°C~17°C, which is very conducive to AFODN reproductive metabolism and enzyme catalysis. Therefore, strain PXL2 is suitable for applications to groundwater pollution control.

DOI: http://dx.doi.org/10.15666/aeer/1703_62016211

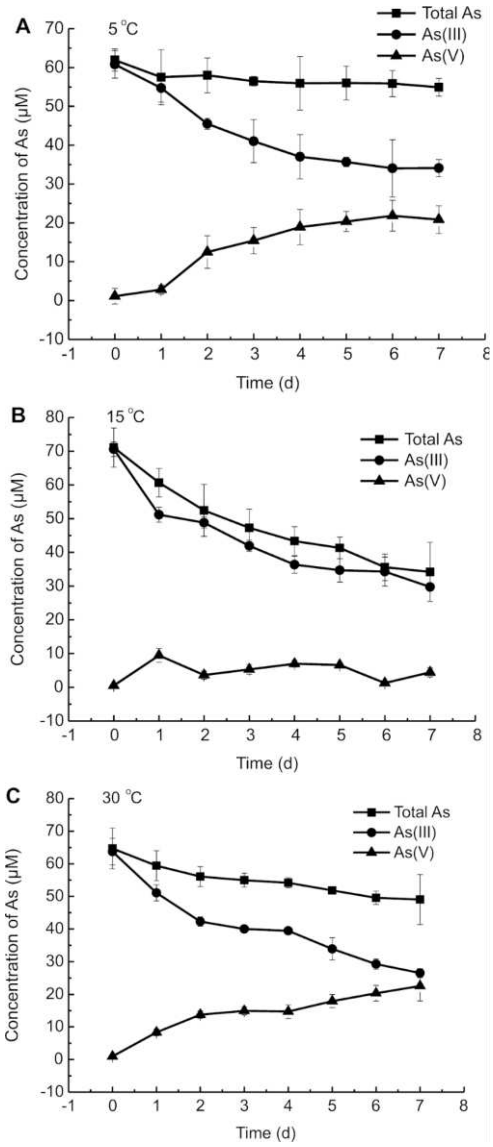

Figure 6. *Time profile of As concentrations in the strain PXL2 culture at different temperatures*

Conclusion

Growth of strain PXL2 was significantly inhibited at 5°C. At this temperature, morphological changes were also seen, where a rod-like shape changed to a spherical one, and dents appeared on the bacterial surface. Under this condition, the denitrification ability and Fe (II) capacity of the strain decreased significantly. The As removal ability was also affected. The total arsenic removal rate was at 21.6%. At 15°C, the metabolic rate of growth, denitrification and Fe (II) oxidation rate were slightly lower than 30°C, but the total arsenic removal rate was the highest at this temperature, at 51.1%. The total arsenic removal rate at 30°C was 30.0%. On the whole, the strain PXL2 metabolized well at 15°C, and was found to be suitable for treating nitrate and arsenic contamination in groundwater. This biological treatment has promising applications in future projects. This research promotes the research of ferrous anaerobic micro-organisms in this new field of research.

(Received 5th Nov 2018; accepted 4th Feb 2019)

Abstract. In order to achieve of the spatial association and optimum collocation, a 1-ha natural spruce-fir mixed forest plot which was established on Changbai Mountains, PR China. Diameter at breast height, height, and the crown width of the standing free trees with ＞1 cm DBH trees were measured, and species were identified. *O*-ring statistics and the nearest neighbor analysis were applied to test the spatial correlations and distribution of number of dominant species at different vertical layers. We found that: (1) according to the importance values, the top four species were *Abies nephrolepis (Trautv.) Maxim.*, *Picea koraiensis Nakai*, *Pinus. koraiensis Sieb. et Zucc.* and *Tilia. amurensis Rupr.*; (2) most of species pairs have positive associations at small scales, while few are no relevance or have negative associations; (3) the number of juveniles and lower layer trees showed positive skewness under the upper layer trees and the maximum number for coniferous species was at a distance 4.5-6.5 m, while it was 6.5-8.5 m for broadleaved species. Our results provide a new insight into the development of reforestation technique in spruce-fir forests in the Changbai Mountains.
Keywords: *inter-specific association, scale, O-ring statistics, nearest neighbor analysis*

Introduction

Studying forest regeneration processes is essential in understanding forest diversity and dynamics, which follows a forest life cycle from germination to death (Darrigo et al., 2016). The information of forest regeneration, moreover, is fundamentally important because it reflects the stability of the structure and composition of overstory, and provides the prerequisites for the developing of ecological, social and economic benefits of forest continuously (Mostacedo et al., 2009; Lydersen et al., 2015). Forest management must change radically to maintain biodiversity and enough juveniles (Liu et al., 2015).

However, natural regeneration of seedlings and species cannot fulfill the requirements for the healthy growth of the forest due to landscape fragmentation, and the limitation of seed dispersal (Levesque et al., 2011; Holeksa et al., 2017). Artificial regeneration, therefore, can supplement the lack of woodland seedling individuals and the number of species (Wagner et al., 2010; Hejel et al., 2016). However, adaptive

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62136225

species must be chosen according to characteristics of alternative tree species (Gonzalez-Rodriguez et al., 2011).

A mount of studies, therefore, have been focused on the species niche and interspecific association of classical ecology with the objective to understand their optimal collocation of species effects on the forest ecosystem (Zhao et al., 2012; Su et al., 2015; Wright et al., 2016). In addition, more studies also have been focused on spatial structure, but only limited to a quantitative description of the forest spatial pattern (Li et al., 2014; Lydersen et al., 2015; Nguyen et al., 2016). Vertical spatial structure, however, is closely related to and affects the different ecological processes which include intra-specific and inter-specific competition, disturbance reaction, and environmental heterogeneity, regeneration mechanisms and understory development (Hao et al., 2007; Zhang et al., 2015). Ecology rules of spatial structure were rarely applied to forest management.

In this study, species spatial associations and distribution were analyzed with the distance at different vertical layers in a 1-ha spruce-fir mixed forest plot, to provide a scientific basis for the best collocation of different forest vertical layers of the mixed forest. We hoped to fulfill three objectives: (1) evaluate mechanisms of species coexistence though calculate species spatial associations between juveniles, lower and upper height class trees; (2) clarify the dependency relationship according to distributions of number of the species with the distance among different height layers; (3) indicate the distance or scale is an important factor among different tree height classes in the forest.

Materials and methods

Study area

Jin Gouling forest farm is our study area, which is located in Changbai Mountain in northeastern PR China (43˚22′ N, 130˚10′ E) (*Fig. 1*). The annual precipitation is 500–600 mm, with most of the rain falling in July. The altitude ranges from 300 to 1200 m and the slopes mostly vary between 5° and 25°. A gray–brown podzolic soil is present on the low and intermediate mountains in the area and is derived from the parent basalt rock.

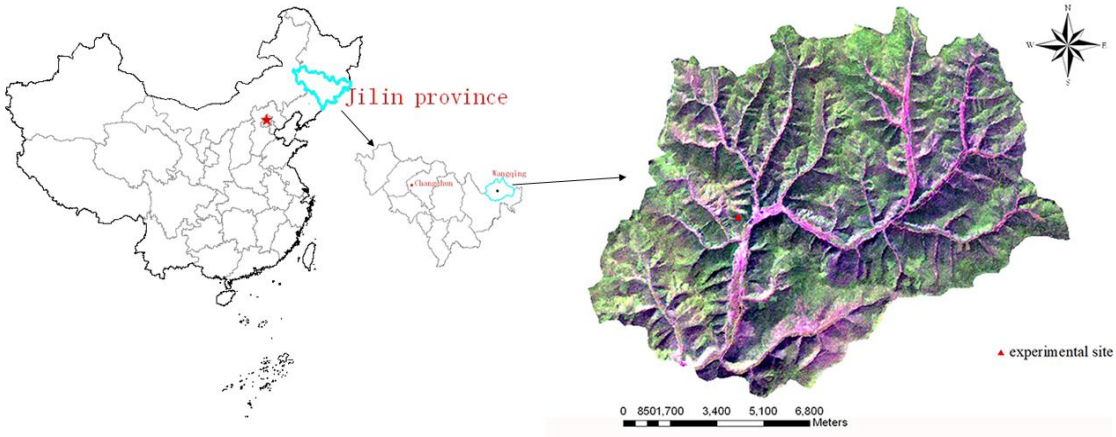

Figure 1. *Location of study site within the Changbai Mountain in northeastern China*

DOI: http://dx.doi.org/10.15666/aeer/1703_62136225

Plot establishment and data collection

A 100m×100m plot was established in natural spruce-fir forest which suffered little distance because of it difficult accessibility. Twenty-five 20 m×20 m subplots were set in above-mentioned plot. All detailed information of stand description factors can be found in (Zhang, 2017).

Data analysis

Forest spatial associations analysis

O-ring statistic model was broadly employed to investigate structural forest processes (Wiegand and Moloney, 2004; Xu et al., 2009). Therefore, *O*-ring statistic model was used to explore the spatial associations of the dominate tree species. The *O*-ring statistics includes both univariate and bivariate statistics (Getzin et al., 2006). The *O*-ring statistic model O_{12}(r) is calculated as:

$$\hat{O}_{12}^{\mathrm{w}}(r) = \frac{\frac{1}{n_1}\sum_{i=1}^{n_i} Po\ \mathrm{int}\, s_2\left[R_1, {}_i^{w}(r)\right]}{\frac{1}{n_1}\sum_{i=1}^{n_i} Area\left[R_1, {}_i^{w}(r)\right]} \quad \text{(Eq.1)}$$

where n_1 is the number of points of pattern 1 (the object 1 of univariate statistic), $R_1, {}_{\mathrm{i}}^{\mathrm{w}}(\mathrm{r})$ means the ring with radius r and ring width w centered on the ith point of pattern 1; Points_2[X] (*Equation 2*) calculate the number of points in regional X of pattern 2 (the object 2 of univariate statistic), Area[X] (*Equation 4*) means the area of the study regional X.

$$Po\ \mathrm{int}\ s_2\left[R_1, {}_i^{w}(r)\right] = \sum_{allx}\sum_{ally} S(x,y)P_2(x,y)I_r(x_i,y_i,x,y) \quad \text{(Eq.2)}$$

$$I_{\mathrm{r}}^{\mathrm{w}}(x_i,y_i,x,y) = \begin{cases} 1 & if \quad r-\frac{w}{2} \le \sqrt{(x-x_i)^2+(y-y_2)^2} \le r+\frac{w}{2} \\ 0 & otherwise \end{cases} \quad \text{(Eq.3)}$$

$$Area\ \left[R_1, {}_i^{w}(r)\right] = z^2 \sum_{allx}\sum_{ally} S(x,y)I_r(x_i,y_i,x,y) \quad \text{(Eq.4)}$$

In these equations, (x_i, y_i) is the coordinate of point i in pattern 1. When the coordinate of point i is inside the study regional X, S(x, y) =1, otherwise, S(x, y) =0. P_2(x, y) means the number of points in pattern 2, I_r (*Equation 3*) is a counter variable to define the circle with radius r that is centered at the ith point of pattern 1, z^2 means the area of one cell. The univariate statistic O_{ii}(r) is calculated by setting the pattern 1 equal to the pattern 2.

Nearest neighbor analysis

Supposing that in a large enough forest stand, which existed plenty of juveniles of species A and adult tree of species B, the number of juveniles of A is N. *Di* is the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62136225

distance from random juveniles of species A to the nearest adult tree of species B, and the average distance between juveniles of species A and nearest adult trees of species B with the following formula:

$$\overline{D} = \frac{1}{N}\sum_{i=1}^{N} Di \quad \text{(Eq.5)}$$

where $\overline{D}$ is the mean distance from juvenile tree to mature individual, which is used to analyze the attachment relationship between juvenile and mature tree, σ^2 is the standard variance of *Di*.

Because of the limited area of the plot and number of individuals (juveniles and mature trees), it is difficult to calculate *Di*. The central limit theorem, therefore, was used here, which assumed that a juvenile and a nearest adult tree constitute a sample unit, when the sample number ≥ 50, the average distance showed an approximately normal distribution (Rice, 2007).

$$\frac{(\overline{d} - \overline{D})}{\sigma / \sqrt{n}} \cdot \underset{n \geq 50}{approximately} \sim N(0,1) \quad \text{(Eq.6)}$$

and the formula can be obtained:

$$p\left\{\left|\overline{d} - \overline{D}\right| \leq U_{\alpha} \cdot \frac{S}{\sqrt{n-1}}\right\} = 1 - \alpha \quad \text{(Eq.7)}$$

where U_{α} is the expected value of the sample distance, S is the variance of the standard sample distance, and the confidence interval is $[\overline{d} - U_{\alpha} \cdot \frac{S}{\sqrt{n-1}}, \overline{d} + U_{\alpha} \cdot \frac{S}{\sqrt{n-1}}]$. In addition, the distribution area was divided into juveniles of species A around the nearest adult tree of species B into several annular zones, and the center point was under the stem of adult tree. The ratio of number of juveniles of species A in each annular zone was counted. The distance, which distributed the maximal number of juveniles, was the optimal distance for replanting juveniles of species A under adult trees of species B (Zhao et al., 2012).

The spatial scale was set 0-20 m, and in this case, 199 randomizations in Monte Carlo simulations were used to provide 95% confidence envelopes. In addition, the nearest neighbor was used to analyzed to test the distribution of number of dominant species with distance and identified the strength of the association among juvenile, lower height class and upper height class.

Results

Stand structure

Table 1 presents the descriptive statistics of species for the entire plot. According to important value, *A. nephrolepis* (Fir) ranked first and had the largest number (1638) and basal area (12.90 m^2 hm^{-1}). *P. jezoensis* (Spruce) followed second with number (415),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62136225

basal area (6.18 m^2 hm^{-1}). Although *P. koraiensis* (Korean pine) had only 278 individuals, it ranked third in terms of important value. *T. amurensis* (Linden) had the largest DBH (64 cm) and its important value ranked fourth. It is basically the same data base that has been used in the study of (Zhang, 2017).

Table 1. *Basic structural characteristics of tree species in a 1-ha uneven-aged natural spruce-fir forest plot in Changbai Mountain*

Species	No. of trees	DBH(cm)		Standard deviation	Basal area (m^2 hm^{-1})	Important value
		Max	Mean			
A. nephrolepis(Trautv.) Maxim. (Fir)	1638	45.2	9.9	9.79	12.90	69.67
P. jezoensis Carr. (Spruce)	415	48.3	16.4	11.90	6.18	45.55
P. koraiensis Sieb. et Zucc. (Korean pine)	278	55.5	13.9	13.22	4.37	40.46
T. amurensis Rupr. (Linden)	342	64.0	6.7	7.88	2.15	39.15
B. platyphylla Suk. (White birch)	33	30.4	17.7	5.73	1.35	10.85
P. amurense Rupr. (Yellow pineapple)	4	11.8	15.2	3.47	0.07	4.20
P. davidiana Dode (Elm)	3	30.4	19	9.95	0.09	4.19

Intra- and interspecies spatial associations of dominant tree species were analyzed among different height classes (*Table 2*). All standing free trees were firstly divided the height into juvenile (h＜5 m), lower (5 m≤h＜10 m), intermediate (10 m≤h＜15 m) and upper (h≥15 m) layer but most species were distributed at the juvenile trees and few individuals were found in the lower, intermediate and upper layer (Zhang, 2017).

Table 2. *Basic quantity characteristics of four dominant tree species at four height classes*

Species	Height (m)			Numbers of different height classes				Total
	Maximum	Minimum	Mean	J	L	M	U	
A. nephrolepis	21.9	0.3	4.58	1185	142	141	170	1638
P. jezoensis	24.4	0.6	5.7	265	101	20	69	415
P. koraiensis	21.0	0.3	5.17	175	50	31	22	278
T. amurensis	19.2	0.4	4.92	224	62	46	10	342

J- juvenile height class (h＜5 m), L-lower height class (5 m≤h＜10 m), M-intermediate height class (10 m≤h＜15 m), U-upper height class (h≥15 m)

Intra- and interspecies spatial association of dominant tree species between juvenile and upper layer trees (juvenile layer vs. upper layer trees)

The spatial associations of the juvenile (J) and upper (U) layer trees varied with the scale that be examined (*Fig. 2*). The most dominant species of juvenile height class were positive correlations at small scales, and with scaling up, no relevance or even negative associations emerged. For instance, *Tilia* (J) was positive associations to *Tilia* (U) and *Pinus* (U) both at scales 0-2 m and 8-9 m scales, *Abies* (U) and *Picea* (U) at 0-7 m and 0-6 m scales, repectively (*Fig. 2a-2d*). Similarly, *Pinus* (J) was positive associations to *Tilia* (U) and *Picea* (U) at 0-10 m and 0-7 m scales (*Fig. 2e, 2h*). *Abies* (J)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62136225

and *Picea* (J), furthermore, were positive correlations to *Tilia* (U) at scales ≤7 m and ≤3 m. *Abies* (J) was also positive associations to *Abies* (U) and *Picea* (U) at scales ≤8 m and ≤10 m (*Fig. 2i, 2k-2m*).

Three different associations were observed as follows: (1) *Pinus* (J) and *Picea* (J) were significant positive associations to *Abies* (U) at the majority of scales, so did *Abies* (J) to *Pinus* (U) and *Picea* (J) to *Pinus* (U) (*Fig. 2g, 2j, 2n and 2o*); (2) *Pinus* (J) exhibited no relevance and negative association to *Pinus* (U) at scales, and with the scales increased, positive association emerged (*Fig. 2f*); (3) *Picea* (J) was negative correlation to *Picea* (U) at 0-3 m and 9-10 m scales (*Fig. 2p*).

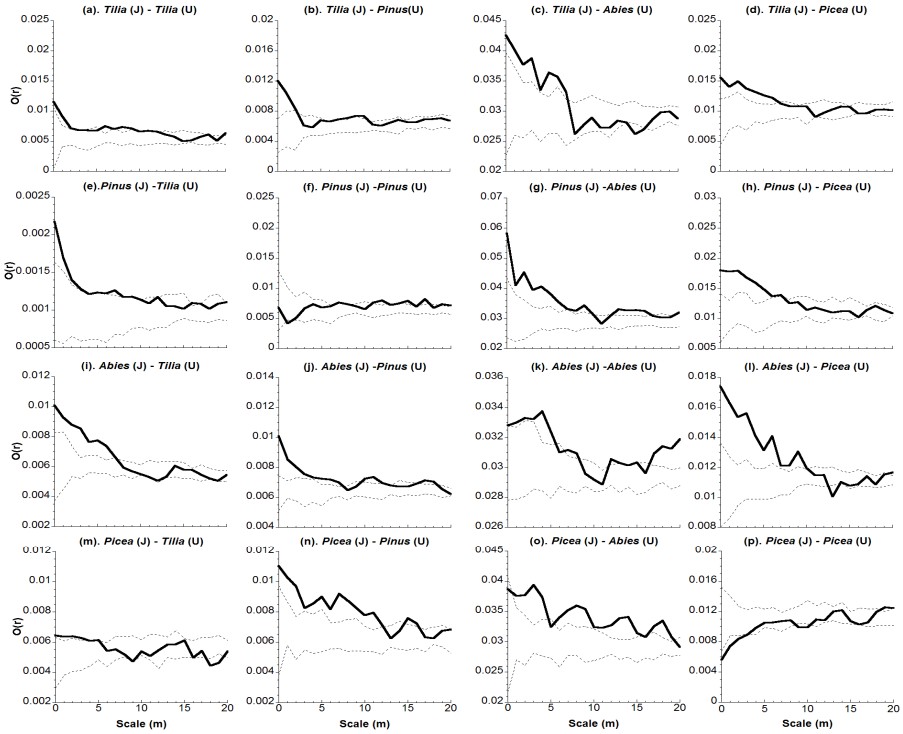

Figure 2. *Spatial associations of juvenile height class to the upper height class. Black lines indicate ring statistics O(r); dashed lines indicate upper and lower of the limit 95% confidence envelopes. Above the dashed lines indicate positive association between species pairs, below the dashed lines indicate positive association, and in the interval of dashed lines indicate independence between species pairs (similarly hereinafter). J: the juvenile height class, U: the upper height class*

Intra- and interspecies spatial association of dominant tree species between lower and upper layer trees (lower vs. upper layer trees)

The spatial associations of the lower (L) height class and upper (U) height class at different vertical layers (*Fig. 3*). *Tilia* (L) tended to show negative association to *Tilia* (U) at 4-6 m and 10-11 m, and was positive correlation to *Abies* (U) at scales ≤1 m, while no relevancies was observed to *Pinus* (U) and *Abies* (U) at the most scales. *Pinus* (L) was positively associated to *Pinus* (U) only at scales ≤3 m and with scaling up, more scales exhibited independence or even inhibition, (*Fig. 3a-3d, 3f*). It was found that *Pinus* (L) was significant positive association was showed at the most scales

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62136225

(≤15 m, ≤15 m and ≤11 m) to *Tilia* (U), *Abies* (U) and *Picea* (U) (*Fig. 3e, 3g, 3h*). Similarly, *Abies* (L) was positive correlation to all four species at scales ≤14 m, ≤3 m and 7-10 m, ≤16 m and ≤8 m (*Fig. 3i-3l*). *Picea* (L) was positive correlation to *Tilia* (U), *Pinus* (U) and *Abies* (U) at scales ≤5 m, ≤4 m, and ≤6 m, while negative association to *Picea* (U) at sacles ≤3 m, respectively (*Fig. 3m-3p*).

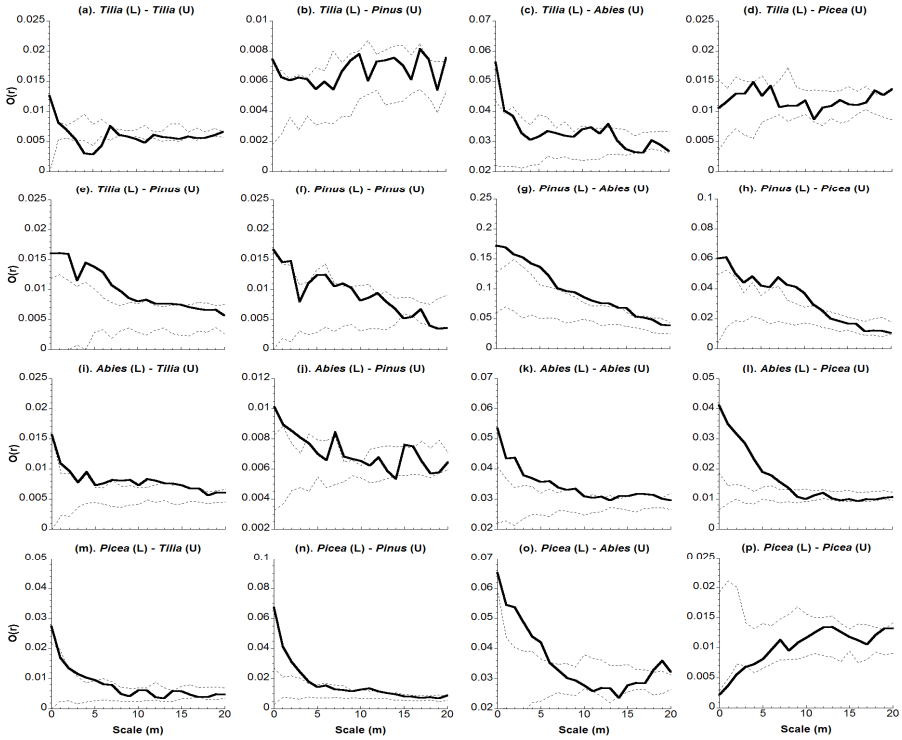

Figure 3. *Spatial associations of lower height class to the upper height class. Black lines indicate ring statistics O(r); dashed lines indicate upper and lower of the limit 95% confidence envelopes. L: the lower height class, U: upper height class*

Distribution of the number of the dominant species with the distance at different height classes

Four dominant species (J) were nearest to *A. nephrolepis* (U), while furthest to *T. amurensis* (U). In addition, the average distances among species (J) and species (U) were observed: (1) *Tilia* (U): *Pinus* (J)＜*Tilia* (J)＜*Picea* (J)＜*Abies* (J); (2) *Pinus* (U): *Picea* (J)＜*Abies* (J)＜*Pinus* (J)＜*Tilia* (J); (3) *Abies* (U): *Picea* (J)＜*Pinus* (J)＜*Abies* (J)＜*Tilia* (J); (4) *Picea* (U): *Tilia* (J)＜*Pinus* (J)＜*Abies* (J)＜*Picea* (J). The average distance between species (L) and species (U) was from 4.729 m to 8.877 m. The average distance to species (U) specific to species (L) were showed: (1) *Tilia* (U): *Tilia* (L)＜*Pinus* (L)＜*Abies* (L)＜*Picea* (L); (2) *Pinus* (U): *Pinus* (L)＜*Abies* (L)＜ *Tilia* (L)＜*Picea* (L); (3) *Abies* (U): *Picea* (L)＜*Abies* (L)＜*Pinus* (L)＜*Tilia* (L); (4) *Picea* (U): *Abies* (L)＜*Pinus* (L)＜*Tilia* (L)＜*Picea* (L).

The results of distribution of the number between juvenile were shown that lower and upper height class trees (*Fig. 4 and Fig. 5*). All skewness values were greater than zero. Positive skewness, therefore, was observed (Tab.3). The number of species (J) and species (L) under the upper layer trees was first gradually increased with the distance,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62136225

and then decreased beyond a certain critical point. It was found that the distributions of the greatest number of species (J) and species (L) from 4.5 m to 10.5 m scales. For instance, four species (J) were mainly distributed in the range of 4.5 to 6.5 m scales under *Picea* (U), 4.5 to 8.5 m under *Pinus* (U) and *Abies* (U), while 6.5 to 10.5 m under *Tilia* (U) (*Fig. 4*). Furthermore, all the species (L) were distributed in the range of 4.5 to 8.5 m under *Tilia* (U), *Abies* (U) and *Picea* (U), while 4.5 to 10.5 m scales under *Pinus* (U) (*Fig. 5*).

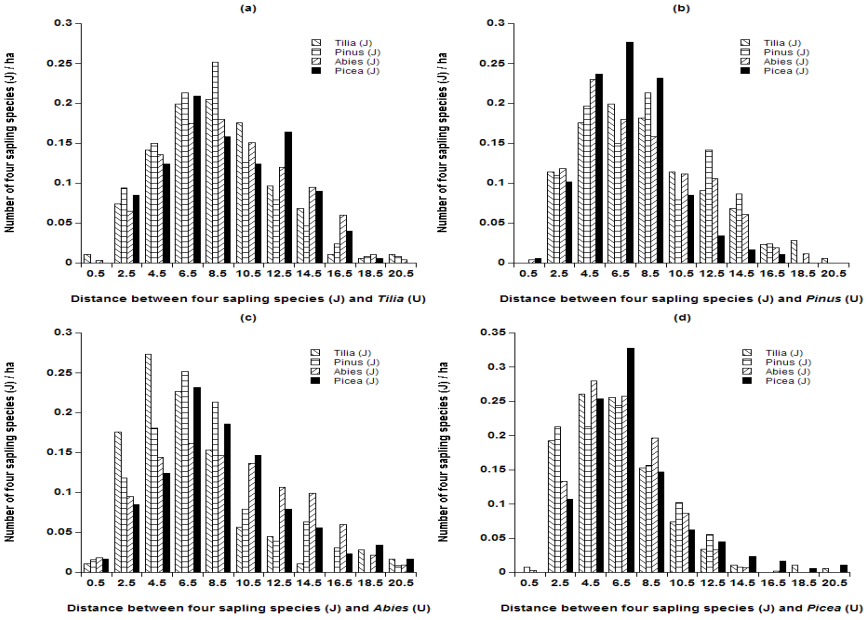

Figure 4. *Distribution between juvenile (J) and upper (U) height classes of four dominant species with the distance*

Discussion

The study site is an uneven-aged spruce-fir mixed forest where has abundant tree species and complicated stand structure. According to importance value index, the dominant species are ranked to *A. nephrolepis*, *P. jezoensis*, *P. koraiensis* and *T. amurensis*. The same result has been reported in previous study (Gong, 2009), which according to analysis of forest dynamic (succession and restoration), the dominant trees were above mentioned species, and they will not change much with the development process.

Forest spatial association is closely related to scales (Navarro-Cerrillo et al., 2013; Zhang et al., 2015). Generally, juvenile and lower height classes tended to be positive association at smaller scales, with scales increased, it was changed by no relevance or even negative association (*Fig. 2 and Fig. 3*). The same results have been reported in some researches (Hao et al., 2007; Zhang et al., 2009). Some researchers thought that habitat heterogeneity and seeds dispersal ability with mother tree which resulted in positive association (Hubbell et al., 1999; Lin et al., 2011; Basnou et al., 2016). In addition, effect of intra specific competition was also important factor (Petritan et al., 2014).

Tilia (J) and *Abies* (J) are positive associations around their mother upper trees at small scales, while with scales increase, no relevance or negative association emerge (*Fig. 2a and 2k*). Limited seed dispersal ability and their shade tolerant characteristics ensure them grow well under the canopy of parent trees in weak light. Although the coexistence may lead to competition and increase mortality, more juveniles can grow well under the canopy of the upper layer trees. Since then, with juveniles grow continually, few nutrients can be supplied for juveniles, more deaths appear. Distance among juveniles increase, therefore, the degree of aggregation decline (Kobe and Vriesendorp, 2011). In addition, positive associations between other three juvenile species and *Tilia* (U) explain coniferous species which can keep exuberant vitality under *Tilia* canopies (*Fig. 2e, 2i and 2m*), which supported the previous researches (Zhang et al., 2007; Chen et al., 2009). Except above-mentioned reasons, positive association of three juvenile and lower layer species to other upper species may suggest two reasons: (1) they have broad niches; (2) complex structure of branches of upper layer trees blocks the seeds dispersal, which leads to wind propagation insignificant. The same results are argued in previous researches (Li et al., 2007; Sebkova et al., 2012).

Strongly positive associations at the most scales were observed between species (J), (L) and species (U) suggest that the canopy of upper layer trees may provide suitable recruitment conditions for the understory. For instance, *Pinus* (J), *Picea* (J) and *Abies* (U), *Abies* (J), *Picea* (J) and *Pinus* (U) (*Fig. 2g, 2j, 2o and 2n*), *Pinus* (L) and Species (U) except *Pinus* (U) (*Fig. 3e, 3g, and 3h*), *Abies* (L) and *Tilia* (U), *Abies* (L) and *Abies* (U) (*Fig. 3i and 3k*), etc. Zhao et al. (2012) argued that these four species were the dominant species in this community, and trees of species pairs needed similar growth environment. Although their niches overlapped with each other, they can coexistence though competition of mutually promotive.

Negative associations for a few species (J) and (L) to their upper layer trees at small scales were observed. Take *Pinus*, *Picea* and *Tilia* for example, the negative association among *Pinus* might be attributable to human interference. Most pinecones were harvested, because of great economic value and this led to the lack of understory trees (Tao et al., 1995; Liu et al., 2004). The reason of exclusion among *Picea* different height class may be unsuited micro environmental conditions for their survival,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62136225

establishment, and growth of juveniles and lower trees. The same result reported in previous research (Gilbert, 2002). Juvenile of *Tilia* has shade tolerant characteristic, with tree height increases, however, the growth of *Tilia* needs more light, which cannot develop under the overstory (Zhang et al., 2007).

The average distance of different tree height layers (Tab.3) are showed that *Pinus* (J) and *Tilia* (J) are most likely to growth under the canopy of *Picea* (U) and *Tilia* (U); similarly, *Picea* (J) establish under the canopy of *Pinus* (U) and *Abies* (U) easily, but difficultly under *Picea* (U). These results are consistent with the spatial association analysis. Nevertheless, the analyses of mean distance are observed that *Tilia* (L), *Pinus*(L) are most favored growth under their parent trees, which is inconsistent with the result of the spatial association. The difference between two analytical of two methods may be led to different results.

The distributions of the number among different tree height class were observed that the number of species (J) and (L) increased with distance until a maximum value reached, and then decreased with distance gradually (*Fig. 3 and Fig. 4*). The distribution of maximum number mainly kept in a range, rather than in their immediate vicinity, the same result was reported in previous research (Schupp and Jordano, 2011). In addition, maximum number of juveniles of four dominant species was distributed from 4.5 m to 10.5 m, and this finding can be illustrated in Janzen-Connell theory in a certain extent, which high mortality is likely to occur near the mature trees (Matthesius et al., 2011; Steinitz et al., 2011). Meanwhile, the distribution of number of juveniles were influenced significantly by the crown widths, because of the canopy inhibited the growth of shrubs and herbs, more understory trees, therefore, can grow well in upper height trees (Pretzsch and Dieler, 2012). The distribution of maximum number for coniferous trees (*Pinus*, *Abies* and *Picea*) was at distance 4.5-6.5 m, while 6.5-8.5 m for broadleaved tree (*Tilia*) (*Fig. 3 and Fig. 4*). (Zhao et al., 2012) considered the length of coniferous tree is longer than broadleaved tree and the larger the crown width, therefore, the longer optimum distance occurred.

Conclusions

Our major aim was to understand the spatial reciprocity among different tree-height classes of dominant species in a mixed forest. The conclusions were shown that: (1) vertical structure plays an important role in population regeneration and community dynamics; (2) relative to the natural regeneration, artificial regeneration by enrichment planting is an expensive method, but has an obvious advantage in terms of the flexibility of either species combinations or spatial arrangements; (3) distance or scale is an important factor for distribution of trees. In different distance or scale, result of distribution of trees may be different. To obtain the optimum result, suitable distance or scale should be chosen according to situation of research in the plot. In addition, environmental factors, natural or human interference factors and the long-term monitoring data should also be considered and examined.

Abstract. The occurrence of ALS-herbicide-resistant *Sinapis arvensis* in wheat crops causes crop yield losses, which makes it necessary to understand the factors that influence the interference of this weed to develop safer management strategies. This study was aimed to evaluate the ecological fitness of wild mustard that is susceptible (S biotypes) and resistant (R biotypes) to Tribenuron Methyl herbicide in competition with wheat in 2014-2017. The experiments were conducted in a greenhouse using a completely randomized design with four replications. The treatments were placed in pots and arranged in replacement series for three experiments: 1) wheat with the R biotype; 2) wheat with the S biotype; and 3) the R biotype with the S biotype) at the following ratios: 100:0, 75:25, 50:50, 25:75, and 0:100. The results showed that S biotype of wild mustard was more competitive than R biotype. There was no significant difference between S biotype and R biotype with accordance of the aggressivity index. The difference between the relative yield of wheat and biotypes of *S. arvensis* was significant, and regarding relative yield total, the S biotype was superior. Relative seed production index as the resultant index of competition at similar densities was not significant.
Keywords: *aggressivity index, herbicide resistance, relative yield total, Sinapis arvensis, Triticum aestivum*

Introduction

Since the advent of agriculture, crops have been at risk of weed invasion and damaged quantitatively and qualitatively. Thus, there have been ongoing efforts to reduce the negative impact of weeds on plant production (Vila-Aiub et al., 2015). Wild mustard is one of the most significant weed reducing the quantity and quality of wheat in Iran (Minbashi Moeini et al., 2006). For more than 40 years, relying too much on the technology of herbicides to reduce the amount of damage caused by weed, resulting in obtaining adaptive traits by weeds that help them survive and reproduce under herbicides application condition (Powles and Yu, 2010). As a consequence, more than 200 species of resistant weeds have been reported in the world (Heap, 2018) and this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62276240

trend of increasing weed resistance is spreading at a high pace (Norsworthy et al., 2012).

The organisms that genetically earn resistance to some environmental stresses may be ecologically inferior under non-stress conditions compared to susceptible plants (Bazzaz et al., 1987). Theoretically, weed resistance to herbicides is along with fitness cost that has been evaluated in several studies (Van Etten et al., 2016). Fitness cost (which is also called resistance cost) can be defined as reduced fitness of the plant in environments without herbicides (Deyle et al., 2013a). When the fitness costs are created by ecological interferences such as competition, it is termed ecological costs (Vila-Aiub et al., 2009). As an example, Gassmann and Futuyama (2005) stated that resistant plants had less fitness than susceptible plants due to less attraction of pollinators or the increase of pest damage. Also, Vila-Aiub et al. (2009) concluded that resistant plants pay more ecological cost due to the reduced competitiveness to capture resources. Based on the theory of resource allocation, plants show a reaction for the increase in ecological success with the approach of adaptability under environmental selection by directing resources to different organs, i.e. stem and root, and cell metabolism (Van Etten et al., 2016). Resistance due to mutation has been reported to reduce the allocation of resources to growth organs (Vencill et al., 2012). This theory helps to understand the phenomenon "resource trade-off" between plant growth, defensive duties, and reproduction (Coley et al., 1985). When a biotype of weed becomes resistant to herbicide, in most cases, its ability to compete for growth resources decreases (Vila-Aiub et al., 2015). The potential mechanism causing resistance cost is determined with the traits such as the plant size and tolerance to the availability of resources that one of these sources is nitrogen (Frenkel et al., 2017).

Competitive interferences in plants consist of two components: the impact of the plant on the availability of resources and plant response to changes in the availability of resources. Effect of a plant on environmental resources to overcome neighboring plants (competitive effects) or to survive regardless of the competitor's presence (competitive response) depends on the ability of a plant (Goldberg, 1995). Fitness is one of the most effective factors in the creation and persistence of resistant and susceptible biotypes of weeds (Gressel and Segel, 1990; Maxwell et al., 1990). Fitness is defined as the ability of an organism to establish, survive and reproduce successfully (Radosevich et al., 1997). Therefore, the difference between the fitness of R biotypes and S biotypes might be due to the difference in survival, fertility (Putwain and Mortimer, 1989), or the ability to compete (Massinga et al., 2005; Marshall et al., 2005).

The reason for estimating the fitness costs about herbicides resistance is that this may reduce the frequency of resistant genotypes in weed communities without herbicide application and it may result in the identification of approaches to managing resistant weeds (Vila-Aiub et al., 2009). The evolution of herbicide resistance in weeds provides an appropriate model to examine the phenomenon "resource trade-off" (development, defense, reproduction) predicted by the theory of resource allocation (Bergelson and Purrington, 1990). Knowing the biological properties of resistant masses and also the mechanisms resulting in resistance may be useful in the management of them (Jordan et al., 1999). Measuring the difference between the fitness of resistant weeds and susceptible weeds, the evolution of resistance to herbicides can be predicted and also, the management strategies can be developed in order to use the traits reducing the ecological traits of resistant masses (Vila-Aiub, et al., 2015). Also, it can be effective in reducing the frequency of resistant plants in the affected population (Gill et al., 1996).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62276240

The difference between the fitness of resistant and susceptible species is an essential factor in predicting the evolution of resistance to the herbicide. In the case of removal of selective pressure of herbicide, if the fitness of resistant plant is less than susceptible plant, the resistant plant is replaced by the susceptible plant (Weiderholt and Stoltenberg, 1996). In this case, after the occurrence of the resistance in weed population, it is hoped that the resistance will be reduced (Zand et al., 2008). However, if this difference is not effective, the frequency of resistant plants will not probably decrease in population, in this case, long-term management of resistant plant needs to adopt the strategies reducing the severity of selection which is desirable for resistant plants and also, needs to combine other management strategies. These strategies are the rational application of herbicides, using the unique biological aspects of resistant weeds and manipulating the farming systems in order to maximize the effectiveness of chemical and non-chemical weed management (Weiderholt and Stoltenberg, 1996). Survival, competitiveness and reproductive success are the criteria of fitness (Massinga et al., 2005). Therefore, this can be performed by performing tests and evaluating the competitive ability and seed production.

As a result, it has been hypothesized that wild mustard has a superior competitive ability than wheat and that there may be differences in the competitiveness among biotypes of wild mustard that are resistant and susceptible to ALS-inhibitor herbicides. Thus, this study aimed to investigate the competitive ability of wheat in coexistence with biotypes of wild mustard that are susceptible and resistant to ALS-inhibitor herbicides and to determine whether there are differences in the competitiveness between the different biotypes.

Materials and methods

This study consisted of two phases: a) collecting the wild mustard seeds of populations which were suspicious to be resistant to Tribenuron Methyl herbicide from the wheat fields of Golestan Province of Iran and gathering the histories of the fields (*Fig. 1*) and then, screening the masses and determining their possible resistance in the greenhouse of Agriculture School of Gonbad-Kavous University, Iran (according to Moss et al., 1999).

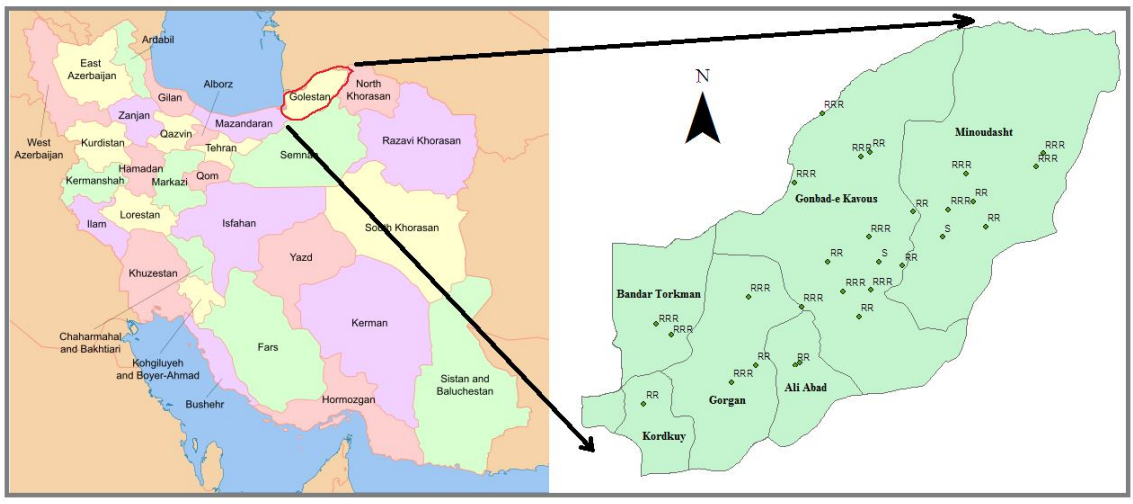

Figure 1. *Geographic location and resistance rates of wild mustard seeds*

DOI: http://dx.doi.org/10.15666/aeer/1703_62276240

b) Selecting a resistant biotype (R biotype) along with susceptible biotype (S biotype) and examining the possible relative fitness of them in competition with wheat after identifying the results of screening at Gonbad-Kavous Agricultural Research Station, Iran (*Table 1*).

*RRR: complete resistant, **R?: suspecting resistant, ***RR: resistant, ****S: susceptible

First phase: in June 2014, the seeds of Wild mustard were collected from the fields in which Tribenuron Methyl herbicide was used for at least 7-years by knowing the history of wheat fields. Totally, from each of 28 fields, 500-gram seeds were collected from the parts which were not controlled by Tribenuron Methyl herbicide. The masses of seeds were planted in the pots with the diameter of 30 cm and depth of 35 cm in fall in the same year to determine the possible resistance to Tribenuron Methyl herbicide. Firstly, in order to break dormancy, the seeds were treated with 2 mg of Gibberellic acid

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62276240

(Abdollahpour et al., 2013). For each biotype, 20 seeds were planted in prepared pots, and they were placed in the open air. After the appearance of true leaves, the density of each pot was reduced to 10 seeds. At 5-7 leaf stage of wild mustard, the common dose of Tribenuron Methyl herbicide (Nezamabadi et al., 2007), 25 g per hectare (commercial form) was used to determine the possible resistance of masses. According to the method provided by Moss et al. (1999) which is used to determine the resistance in a single dose, the possible resistance of masses was determined. In this method, four weeks after spraying, the live plants of each pot were pruned, and after recording the number of plants, their fresh weight was recorded. With comparing the fresh weight of plant of each mass (Wt) treated by herbicide to the control sample not treated (Wo) with herbicide, the possible resistance was estimated by *Equation 1*. In the method provided by Moss et al. (1999), less than 36% reduction, 36-72% reduction, 72-81% reduction and 81-100% reduction in fresh weight are considered as completely resistant (RRR), resistant (R), susceptible to be resistant (R?) and susceptible (S), respectively.

$$W_i = \frac{W_t}{W_o} \times 100 \qquad \text{(Eq.1)}$$

In screening the collected masses by the mentioned method, 57.14%, 25%, 10.71% and 7.14% of samples were resistant (RRR), resistant (R), susceptible to be resistant (R?) and susceptible (S), respectively. Because of collecting the S biotype to Tribenuron Methyl herbicide from the region of Gonbad-Kavous, the most resistant mass of this region was selected as the R biotype so that they have least genetic differences, and these biotypes were used to examine the ecological fitness and possible costs of herbicide resistance. 2nd phase: After selecting the seeds, the steps of dormancy breaking and planting in pots were done under the previous method. The experiment was performed in a randomized complete block design with four replications and nine treatments and the form of replacement series in larger pots with a diameter of 40 cm and a depth of 35 cm. The soil of pots was prepared with a combination of frost soil, manure and washed sand in equal ratios to ensure that there were no seeds of wild mustard. The treatments consisted of R and S biotypes of wild mustard and wheat (Triticum aestivum) in replacement ratios of 0:100, 75:25, 50:50, 25:75 and 100:0 (S and R biotypes of wild mustard and wheat). The total number of pots was 36 (each replication contained nine pots, one pot of wheat, four pots with different densities of S biotype of wild mustard and four pots with different densities of R biotype of wild mustard). Planting dates were 5th January 2014 and 11th November 2015. After examining the wheat and biotypes of wild mustard physiologically, all of them were pruned, and their dry weight and yield components were measured separately. They were weighted by weighing scales with the accuracy of 0.001, and the amount of reproduced seeds of wild mustard was estimated by *Equation 1*. After variance analysis and comparing the means, the indices of competitiveness were used for weeds and crops. With mathematical indices, the features of plant competition, including the intensity of competition and its importance, the effects of competition, reactions, and results of the competition can be examined quantitatively. The indices facilitate the expression and explanation of results, and the results of different studies can be compared by purifying and concentrating the test data (Weigelt and Jolliffe, 2003). Competition indices were divided into three parts of the intensity of competition, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62276240

impact of competition and the results of the competition. SAS software was used to analyze the data.

$$Sn = TSw \times 50 / Sw \quad \text{(Eq.2)}$$

Equation 2 was used to determine the amount of reproduced seeds per wild mustard plant (Vila-Aiub et al., 2009). In this equation, Sn is the number of reproduced seeds per wild mustard plant, TSw is the total weight of reproduced seeds per wild mustard plant, and Sw is the mean weight of 50 reproduced seeds of wild mustard biotypes.

A) In examining the intensity of competition, the indices of aggressivity and competition ratio were used. In examining the intensity of competition, the changes in the competition of the densities of the population are necessary (Sackville and Hamilton, 2001), so, in all equations related to the intensity of competition, the density was not calculated. However, this does not mean that the intensity of competition is independent of density because, in these indices, the variables depend on the density and frequency naturally (Weigelt and Jolliffe, 2003).

Aggressivity was examined by *Equation 3*.

$$A = 1/2\left[(Smix/Wmono) - (Wmix/Smono)\right] \quad \text{(Eq.3)}$$

Smix: wild mustard at different ratios with wheat
Wmix: wheat at different ratios with S and R biotypes
Smono: wild mustard in mono culture
Wmono: wheat in mono culture

Competition ratio was examined by *Equation 4*.

$$CR = \left[Smix/Smono \,/\, Wmix/Wmono \right] \quad \text{(Eq.4)}$$

Smix: wild mustard at different ratios with wheat
Wmix: wheat at different ratios with S and R biotypes
Smono: wild mustard in mono culture
Wmono: wheat in mono culture

B) The competition effects of S and R biotypes were examine with Relative Yield and Relative Yield Total (*Eq. 5*).

$$RY = Amix / Amono \quad \text{(Eq.5)}$$

Amix: Different combinations of wheat and wild mustard biotypes
Amono: wheat and S and R biotypes in pure culture

C) The outcome of competition was examined by Relative seed production index (*Eq. 6*).

$$RRR = Sr / Ss \quad \text{(Eq.6)}$$

Sr: the amount of seeds per resistant wild mustard biotype

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62276240

Ss: the amount of seeds per S biotype

Fitness Cost of R biotype to S biotype was examined by (*Eq. 7*).

$$FC = 1 - (WR / WS) \times 100 \quad \text{(Eq.7)}$$

The analysis of variance, comparison of mean squares and Orthogonal contrasts were performed by SAS software Ver. 9.1 and the figures were designed via Microsoft Excel 2013.

Results

Results showed that with reduction wild mustard ratio, wild mustard dry weight increased significantly for two biotypes, resulting reduction in wheat dry matter. The reduction of wheat dry matter in competition with biotypes of has been almost uniform and in comparing the S and R biotypes was not significant (*Fig. 2(A)* and *Fig. 2(B)*). Comparing these two figures showed that this increase of wild mustard dry matter in S biotype was greater than R biotype. At same wild mustard ratio, the S biotype had greater dry matter than R biotype, and this shows that the increased intraspecific competition in the S biotype compared to R biotype.

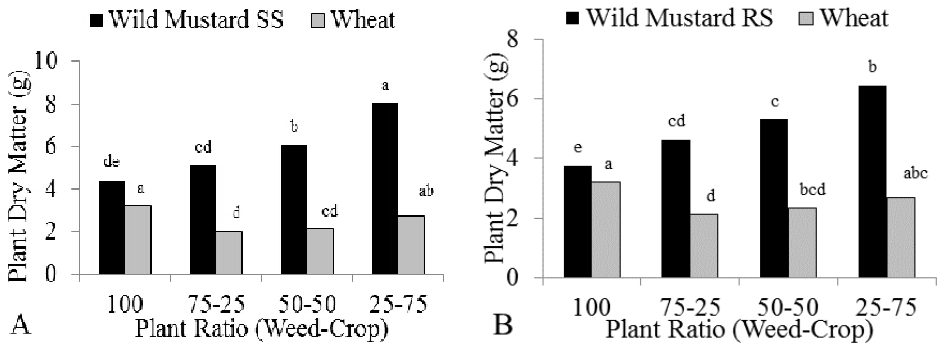

Figure 2. *The impression of wheat and wild mustard (A: S biotype, B: R biotype)*

As shown in *Figure 3,* it was observed that the decrease in the number of the wheat spikelet in competition with S biotype was more than the R biotype, but the difference was significant only at the 50:50 ratios.

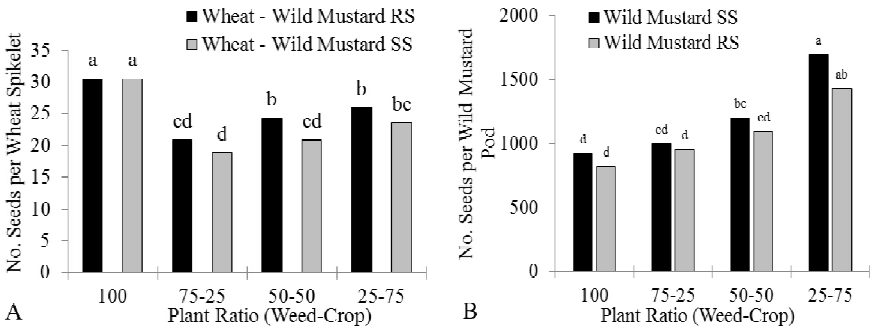

Figure 3. *Number of seeds; A: per wheat spikelet in competition with wild mustard, B: number of seeds per wild mustard pod in competition with wheat*

DOI: http://dx.doi.org/10.15666/aeer/1703_62276240

Figure 4 is related to the number of seeds in the biotypes of wild mustard, the difference between these two types of biotypes was not significant at the density ratio of 50:50, but the amount of reproduced seeds in S biotype was greater than R biotype.

In accordance the variance analysis of the competition indices (*Table 2*), it was observed that the differences between the competition ratios of S and R biotypes of wild mustard were significant at the confidence level of 5% in terms of dry weight, but they were not significant in terms of the number of reproduced seeds. The difference between the indices of aggressivity of S and R biotypes of wild mustard was not statistically significant concerning dry weight (*Table 2*). About wheat, the difference between the relative yields was significant at the confidence level of 5% and about S and R biotypes of wild mustard, it was significant at the confidence level of 1% (*Table 2*). The differences between the indices of RYT of S and R biotypes of wild mustard were not statistically significant (*Table 2*).

Table 3 shows the results of the examination of competition ration based on dry weight. It was observed that the S biotype was superior to the R biotype. In the combination of relative densities of S biotype with wheat, with the decrease in the ratio of combination, the competition index increased and with the increase in it, the index reduced. This shows the increase in the intraspecific competition of S biotype. Nevertheless, in R biotype, in addition to the reduced index, the changes in the ratio in total combination had no significant impact on the competition ratio.

[1]Competition ratio, [2]Aggressivity, [3]Relative yield, [4]Relative yield total. [5]Means within each column followed by the same letter are not significantly different at 0.05 probability level according to LSD

The difference between the aggressivity index of susceptible wild mustard biotype and R biotype was not significant, but this index in S biotype was greater than R biotype. In this index, the degrees of aggressivity of both S and R biotypes increased by the reduction in the ratio in total density. The relative yield of wheat was statistically significant at the confidence level of 5% (*Table 3*). The relative yield of wheat in combination with R biotype was greater. At the highest density of R biotype of wild mustard with wheat (25%:75%), the greatest relative yield was obtained. The relative yield of wheat in combination with S biotype was significantly less than R biotype. It was observed in S biotype that with the increase in the ratio of total density for wild mustard, the relative yield of wheat increased. About this index, it can be said that the S biotype in compared with the R biotype significantly reduced the relative yield of wheat, but with the increase in the density of wild mustard biotypes and also the increase in the intraspecific competition, the relative yield of wheat increased. The difference between the relative yields of wild mustard biotypes was significant at the confidence level of 1%. The differences between the relative yields of S biotype of wild mustard in different combination with wheat were not significant. In orthogonal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62276240

comparisons of *Table 3*, it was observed that the indices of competition significantly changed with the changes in the ratio of wild mustard biotypes and or wheat at different density ratios. This shows the indirect impact of relative density and total density on the estimation of indices.

However, concerning the S biotype, it was observed that the increase in the ratio of this biotype at the different ratios with wheat reduced the relative yield. The highest relative yield of S biotype was obtained at the ratio of 25% of total density.

Figure 5A shows the fitness cost of R biotype in seed reproduction and *Figure 5B* shows it in the biological yield. The fitness cost of R biotype was greater than S biotype in both cases. Cost of resistance for R biotype at different intercropping ratios (resistant wild mustard: Wheat) of 100%: 0%, 25%: 75%, 50%: 50% and 75%: 25% resulted in 14.73, 9.39, 12.21, 19.67 percent decrease in biological yield and 4.60, 10.76, 8.71 and 15.75 percent decrease in seed reproduction, respectively.

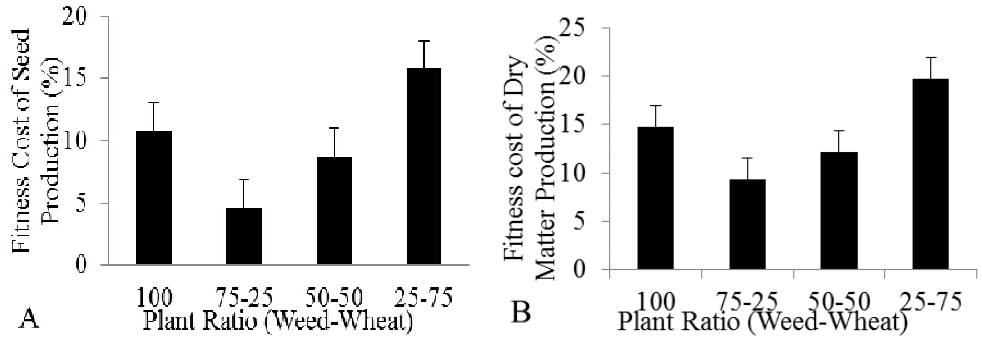

Figure 5. *Percentage of the fitness cost of wild mustard R biotype in seed reproduction (A), and dry mass production (B)*

Discussion

The results of this study showed that the ecological costs are related to the resistance of wild mustard to Tribenuron Methyl herbicide. The R biotype of wild mustard in competition with wheat had fewer damages compared to S biotype (competitive effects). Besides, the capacity of vegetative and reproductive resource allocation in competition with wheat (competitive reaction) in R biotype was significantly less than S biotype. The ecological costs related to the herbicide resistance were in line with the theory of resource allocation that predicts a negative correlation between plant growth and resistance to environmental stresses (Bazzaz et al., 1987; Lerdau and Gershenzon, 1997). Also, the results of this study showed that in conditions of intense competition, the cost of herbicide resistance is higher (*Figs. 1* and *2*). In the higher ratios of wild mustard, the amount of dry matter of R biotypes was less than S biotype. In competition with wheat, S and R biotypes of wild mustard showed different effects. Conard and Radosevich (1979) found dry matter production of S biotypes (*Senecio vulgaris* and *Amaranthus retroflexus*) was higher than that of R biotypes, under both competitive and non-competitive conditions. Costa and Rizzardi (2014) also reported that R and S biotypes of *Raphanus raphanistrum* significantly decreased the wheat shoot dry matter.

Results showed that in the intense competition, R biotype has less fitness than S biotype in attracting resources. This result is consistent with the result of the study by Herms and Mattson (1994) that believed the cost of resistance increases regarding

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62276240

resource constraints. The ability of a plant to reduce the growth of neighboring plants (competitive effect) and to continue to grow despite the presence of neighboring plants (competitive reaction) depends on the capacity of attracting resources (Goldberg, 1995). Such processes, which are related to the difference in the amount of dry matter of the plant height, the potential ability of a plant to attract the light and the continuation of this positive feedback, result in disproportionate resources allocation. Ranking competitive effects based on the ability to reduce the growth of targeted species is associated with ranking the maximum potential of measures between R and S biotypes. So, the larger plants, i.e., S biotypes, overcome the wheat with greater power. In nature, due to this problem, the S biotypes overcome the R biotypes over a long time. This result is consistent with the results of other studies on different competitive effects of plant species in terms of plant size (Goldberg, 1995).

The results showed that intraspecific competition between the S biotypes was more than R biotypes. By accepting that the capacity of attracting the resources is greatly related to the size of a plant, it can be predicted that competitive effects and reaction will have a positive correlation with larger plants and they will have more competitive reactions than smaller plants (Goldberg, 1995). In conditions of competition with wheat, S biotypes clearly showed more competitive reaction than the R biotypes, and this resulted in more reduction in wheat dry matter and yield. Different tolerance to low levels of resources can result in different competitive reactions between S and R biotypes. This potential ability of S biotype to continue the growth regarding resources constraints may appear in the conditions in which there is intense competition for resources. For example, the competitive effects of wheat on R biotype were more compared to S biotype. Its signs can be observed in the effects of vegetative and reproductive organs of R biotype compared to S biotype. The differences in the dry matter of targeted plant showed that the competitive reaction of R biotypes might appear concerning intense competition or significant environmental resource constraints. In the diminished competitive reaction for resources is related to the effect of herbicide resistance, it can reduce the fitness of plant that finally will result in a reduction in R biotype compared to S biotype with natural selection. Therefore, this fitness cost in keeping genetic polymorphism is related to the herbicide resistance (Antonovics and Thrall, 1994). Despite the diminished ability of R biotypes in competition with wheat, herbicide resistant plants showed poor intraspecific competition with the capacity of growth continuation in response to different cultures. This may be related to poor intraspecific competition due to the smaller size. Stoll and Prati (2001) reported that less intraspecific spatial density might be an approach to advance the survival of weaker competitors (R biotype) compared to stronger competitors (S biotype) and also, to prevent the replacement. Vila-Aiub et al. (2009) believed that apart from the concept of evolution of herbicide resistance, the intensity of selective pressure that is caused by humans can change the approaches in the history of plant life during only a few generations. These approaches are different methods of resources allocation in growth, defense, and reproduction models. Now, it is proved that revolutionary changes can earn a place on ecological time scales (Carrol et al., 2007) and this process can be accelerated by human activities (Palumbi, 2001).

Conclusion

The results showed that the R biotype of wild mustard caused significant damage to dry weight and economic yield of wheat, although the damage was less than the S biotype. The trend of variations in the dry weight of resistant and susceptible wild mustard biotypes at different ratios of density showed that the intra-specific competition in the resistant biotype was higher than that of the susceptible biotype. The competitive indices and relative yield of susceptible biotypes of wild mustard were higher than those of resistant biotypes, but the invasive index was not significant. Seed production of the resistant biotype was lower than that of the susceptible biotype of wild mustard, but since the seed production of this weed is very high, this biological characteristic of the R biotype could hardly be used for short-term management of this weed. Due to the fact that the frequency of resistant wild mustard plants in the short term will not be reduced because of reduced fitness cost, the use of integrated methods such as chemical, agronomic and mechanical ones, along with the use of biological and ecological aspects, could be used as a strategy to reduce the population of wild mustard R biotype. It is suggested that the ecological dynamics and fitness cost of wild mustard R and S biotypes should be investigated in infected fields, both practical and long-term.

Abstract. Environmental impacts on plants are becoming more extreme and their response to these effects is a key factor in plant production. Promoting the adaptability of plants is a priority area, one of the opportunities is the symbiotic system of mycorrhizal fungi with plants. Arbuscular mycorrhizal (AM) fungi have beneficial effects on plants' water and nutrient uptake and increasing plant defense mechanisms to alleviate different oxidative stresses. The aim of this study was to investigate how arbuscular mycorrhizal fungi influence the changes in some plant defense enzymes (catalase (CAT), peroxidase (PER), glutathione S-transferase (GST), polyphenol oxidase (PPO)) together with gene expressions under salt, high temperature and drought stresses at an early stage of maize (*Zea mays* L.). The results suggest that AM fungi inoculation may take part in the alleviation processes caused by high temperature, salt and drought stresses. However, these mechanisms are influenced by the age of the plants which is most likely justified by energy considerations.
Keywords: *drought stress, salinity stress, AM fungi inoculation, peroxidase, catalase*

Introduction

Maize (*Zea mays* L.) is one of the most important widely grown crops. According to the latest statistical data on maize growing in Hungary, the total harvested area and output was 0.99 Mha and 6.8 Tg in 2017. Several studies show the dramatically negative impact of climate change on crop production, and similar trend can be found in Hungarian maize production caused by the frequency of extreme agrometeorological phenomenous (Nagy, 2010; Lobell et al., 2012; Pepó and Vári, 2016). However only few works have been done at an early stage, where plants not yet adapted to these conditions. Various biotic and abiotic stresses such as salt, extreme temperature and drought are the most limiting factors on plant growth and decrease crop yield (Molazem and Azimi, 2015). Under stress conditions highly reactive oxygen species (ROS) are generated in plant and ROS-scavenging enzymes (catalase, peroxidase, glutathione S-transferase etc.) together with non-enzymatic way (ascorbic acid, glutathione etc.) are able to detoxify these toxic molecules (Choudhury et al., 2017). Several studies have reported changes in defense enzyme activities and transcriptional alterations of maize under different stress conditions such as drought (Chugh et al., 2011; Song et al., 2017; Zenda et al., 2018), temperature (Zhu et al., 2010; Cetinkaya et al., 2014; Shi et al., 2017), salinity (Estrada et al., 2013; Carrasco-Ríos and Pinto, 2014; AbdElgawad et al., 2016; Forieri et al., 2016). There are some opportunities including the inoculation with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62416253

arbuscular mycorrhizal (AM) fungi for helping the plants to tolerate extreme environmental conditions and alleviate reactive oxygen species. This symbiotic relationship has established more than 400 million years ago and offer some benefits to target plant, including enhanced uptake of water and nutrients - mostly phosphorus - as well as reduction of weeds and protection against pathogens (Feddermann et al., 2010; Ruiz-Sánchez et al., 2010; Smith et al., 2011; Smith and Smith, 2011; Bowles et al., 2016). Several studies suggest that AM fungi induce a plant-wide systemic defense mechanism called mycorrhiza-induced resistance (MIR) (Cameron et al., 2013; Dehghan et al., 2013). The MIR is associated with a more effective activation of JA-dependent system helping plants to alleviate various biotic and abiotic stresses (Chen et al., 2013; Anjum et al., 2016). However, the increased resistance caused by AM fungi is dependent on plant species, arbuscular mycorrhizal fungi and environmental conditions (Pozo and Azcón-Aguilar, 2007; Azcón and Barea, 2010; Vos et al., 2013). Some studies clearly suggest that amelioration of stress resistance by AM fungi symbiosis related to the raising of antioxidant activities in colonized plants (Hajiboland et al., 2010; Baslam and Goicoechea, 2012; Abdel Latef, 2013; Liu et al., 2015; Păun et al., 2015). The mechanisms by which AM fungi alter the production of defense enzymes are still not clarified and only few studies have been carried out at an early stage of plants concerning low level of mycorrhizal colonization.

Therefore, our aim was to investigate how arbuscular mycorrhizal fungi influence the changes in some plant defense enzymes together with gene expressions (catalase (*CAT*), peroxidase (*PER*), glutathione S-transferase (*GST*), polyphenol oxidase (*PPO*)) under salt, high temperature and drought stresses at an early stage of maize (*Zea mays* L.).

Materials and methods

Plant material and growth conditions

The experiment was carried out in Institute of Genetics, Microbiology and Biotechnology, Szent István University (SZIU), Gödöllő, Pest County, Hungary. Seeds of maize ('Golda F1') were sterilized in 1% NaOCl then washed with sterilized water five times and germinated on wet filter paper. Three days after germination the seedlings were transferred to plastic pots containing 0.75 kg sterilized peat and sand 1:2 (v/v) as substrate. Half of the transplanted plants were inoculated with 15 g of a commercial mycorrhizal product, Symbivit® (mixture of *Rhizophagus irregularis, Funneliformis mosseae, Claroideoglomus etunicatum, Claroideoglomus claroideum, G. microaggregatum, Funneliformis geosporum*) produced by Symbiom Ltd. (Lanskroun, Czech Republic; www.symbiom.cz). For non-mycorrhizal treatments sterilized mycorrhizal inoculant were prepared at the same rate (15 g plot^{-1}) and were then used in mycorrhizal treatment. Both treatments were transferred to a climatic chamber EKOCHL 1500 (24/26°C, 60% RH, 16 h light / 8 h dark) for 21 or 42 days. Plants (mycorrhizal and non-mycorrhizal) were exposed to different stress conditions. Plants were irrigated daily with 25 ml of 100 mM NaCl, representing salinity stress. Additional plants were exposed to drought stress (FC 20 ± 5%) compared to control (FC 85 ± 3%). Healthy 20 and 41 days-old seedlings were selected and exposed to 42°C for 24 h as high temperature stress (HT). Altogether eight treatments with two harvest time were designed replicated five times: 21 or 42 days old mycorrhizal inoculated plants (+AM) and non-mycorrhizal plants (-AM) under salt (Salt), high temperature

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62416253

(HT), drought (D) and control (C) conditions, respectively. Plants were harvested after 21 or 42 days of growth, fresh and dry weight of shoots and roots were estimated.

RNA isolation and cDNA synthesis

Total RNA was extracted from maize leaves using Vantage Total RNA Purification Kit (Origene, USA) following the manufacturer's instructions, followed by DNase I (Fermentas) digestion the genomic DNA in the total RNA was eliminated. For qRT-PCR analysis from all treatments first-strand cDNA was synthesized using First-Strand cDNA Synthesis for Quantitative RT-PCR kit (Origene, USA). QRT-PCR was performed on Stratagene Mx3000P QPCR System (Agilent Technologies). Each reaction was performed in a final volume of 25 µl containing 12.5 µl SYBR Green Master Mix reagent (Applied Biosystems), 1 µl of diluted cDNA sample (equal concentration in final volume, 4 ng/µl), 70 nM gene-specific primers and 8 µl nuclease-free water. Gene-specific primers sequences listed in *Table 1*.

Table 1. *Primers for qRT-PCR analysis*

Gene	Primer set (5' to 3')	Product size (bp)
catalase (*CAT*)	forward: ATCAAGTTCCCCGACGTGATCC reverse: AGAAGAAGGTGTGCAGGCTCTC	118
peroxidase (*PER*)	forward: CGCCTCCAAGAACCTCAGTATC reverse: AGTTGTAGAGCCGGTCAACG	128
polyphenol oxidase (*PPO*)	forward: ATCTTCTTCCCGCACCACAC reverse: TCCTCGTCGTAGAACAGGAACG	125
glutathione S-transferase (*GST*)	forward: ACCGACTCGTTGCCTACTTCAC reverse: GATAAACAAGCGGTTTGCACCC	105
actin	forward: CAGTGGTCGAACAACGGGTA reverse: GGTAAGGTCACGACCAGCAA	127

PCR cycle procedure was: 95°C for 15 min, followed by 40 cycles at 95°C for 15 sec, 58°C for 30 sec and 72°C for 16 sec, finally 1 cycle at 95°C 60 sec, 58°C 30 sec and 95°C 30 sec. The real-time PCR experiment was conducted under identical conditions with three replications. As internal reference amplification of *actin* gene was used (*Table 1*). The gene expression of *CAT*, *PER*, *GST*, *PPO* was calculated using the $2^{-\Delta\Delta CT}$ method.

Enzyme assays

In order to determine the enzyme activity of PER and PPO plant extract was prepared using 0.2 g fresh plant leaves in Tris-HCl (3 ml; 50 mM; pH 7.8); polyvinylpyrrolidone-K 25 (7.5% (w/v) and EDTA-Na_2 (1 mM)) buffer. Peroxidase enzyme activities are performed by Rathmell and Sequeira (1974), the change in absorbance is observed at 436 nm wavelength. For the measurement, 1.1 ml of 0.1 M sodium phosphate buffer solution (pH 6.0), 50 µl of 50 mM guaiacol, 50 µl of 12 mM hydrogen peroxide, and 5 µl of plant extract were added to the reaction mixture. The concentration of polyphenol oxidase enzyme - more specifically the degree of the formation of quinone compounds - was carried out by Fehrmann and Dimond (1967).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62416253

The change in absorbance was monitored at 400 nm for 10 minutes. The reaction mixture contained 1.1 ml of buffer solution and 100 µl of plant extract. The buffer solution was prepared by adding 0.1 M sodium phosphate buffer (pH 6.0), 1 mM EDTA and 20 mM catechol. Plant extract for CAT and GST protocol was prepared using 0.2 g fresh leaves in 1.2 ml 0.2 M sodium phosphate buffer (pH 7.8, 0.1 mM EDTA). The catalase enzyme activity was measured by the method of Aebi (1984), based on the dissociation ability of hydrogen peroxide. For measuring 995 µl of 50 mM sodium phosphate buffer (pH 7.0), 500 µl of 10 mM hydrogen peroxide and 5 µl of extract were mixed. The change of absorbance was followed at 240 nm wavelength for 5 minutes. Glutathione S-transferase enzyme activities were measured using Glutathione S-transferase (GST) Assay Kit (Sigma-Aldrich-Merck, Darmstadt, Germany) established on the method of Habig et al. (1974). The concentration of total soluble protein in plant extract solution was determined using Bradford reagent, bovine serum albumin as a standard (Bradford, 1976).

Assessment of mycorrhizal colonization of AM fungi

Root colonization was estimated in five plants both from mycorrhizal and non-mycorrhizal per treatments. Fine roots from each plant were stained with Trypan Blue (Vierheilig et al., 1998). Stereomicroscope at × 100 magnification was used to examine the internal fungal structures (hyphae, arbuscules) and the percentage of root colonization was calculated using grid line intersect method (Giovannetti and Mosse, 1980).

Statistical analysis

Statistical analysis was performed with R Statistical Software 3.3.1 (R Development Core Team, 2011). Values were expressed as means ± SD. Differences between treatments were determined by one-way analysis of variance (ANOVA). A p-value < 0.05 was considered to indicate statistical significance.

Results and discussion

No colonization was recognized when sterilized inoculant were used for inoculation. 21 days after AM fungi inoculation, external hyphae together with germinated spores were only detected, however internal hyphae together with arbuscules were recorded at older age of plants. The highest level of mycorrhizal colonization (52% ± 4) was measured after 6 weeks of growth under drought stress following under high temperature (42% ± 2) and salt stresses (35% ± 3), respectively.

Significant differences in fresh shoots and roots weights were observed in arbuscular mycorrhizal inoculated plants under control conditions and high temperature stresses. Drought and salt stress reduced the biomass of AM fungi inoculated and non-mycorrhizal plants, as well. Generally, lower biomass production of plants caused by drought and salt stress is associated with inhibition of leaf development and consequently reduced light interception (Anjum et al., 2011; Kaya et al., 2013a). The mycorrhizal inoculated salt treated plants did not show statistical difference in the shoot and root biomass compared to the non-mycorrhizal ones. Under drought conditions only the root biomass was affected by mycorrhizal colonisation after 21 days of growth (*Table 2*).

Different lower-case letters within the same column indicate significant differences

Significantly higher fresh and dry shoots and fresh roots biomass were obtained in the inoculated plants (+AM) under control, salt and high temperature stress conditions compared to the non-mycorrhizal ones (-AM) (*Table 3*). Beneficial effects of AM fungi to target plant including enhanced nutrient uptake mostly phosphorus and water uptake, thereby stimulating the growth of the plant are well known (Bowles et al., 2016). Salt stress causes interfere in the homeostasis of the ions wherewith reactive oxygen species release in the plant cell. By the fact that AM fungi reduces the negative effects of salt stress by hyphae network, it promotes the growth of the plant (Wu et al., 2010). However, in this study the mycorrhizal plants under drought condition did not keep higher shoot biomass compared to non-mycorrhizal ones, which can be related to carbon drain effect or dysfunction of maize metabolism (Liu et al., 2004) and correlated with results were reported by Kohler et al. (2008) and Zhu et al. (2012).

Different lower-case letters within the same column indicate significant differences

One of the earliest responses in plants by the colonization of AM fungi is the rapid accumulation of reactive oxygen species (ROS) (Choudhury et al., 2017). ROS is not

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62416253

only harmful to plant cells, but also to mycorrhizal fungi. Under different stress conditions at different rates of enhanced enzyme activities together with gene expressions were found among various treatments. Changing in the activities of antioxidant enzymes as peroxidase, catalase etc. are not exclusive specificity of arbuscular mycorrhizal fungi during colonization process, presumably playing the key role the specific feature of each strain, instead of the colonization.

Catalase is playing a role in the production of monomers, dimers and phenoxy-free radicals and regulates the harmful accumulation of hydrogen peroxide (H_2O_2). In general, higher CAT enzyme activity of non-mycorrhizal plants were measured under different stresses compared to mycorrhizal plants after 21 days of growth. Reverse tendency was observed in CAT enzyme activity under salt and high temperature stresses at older plants (*Fig. 1c,d*).

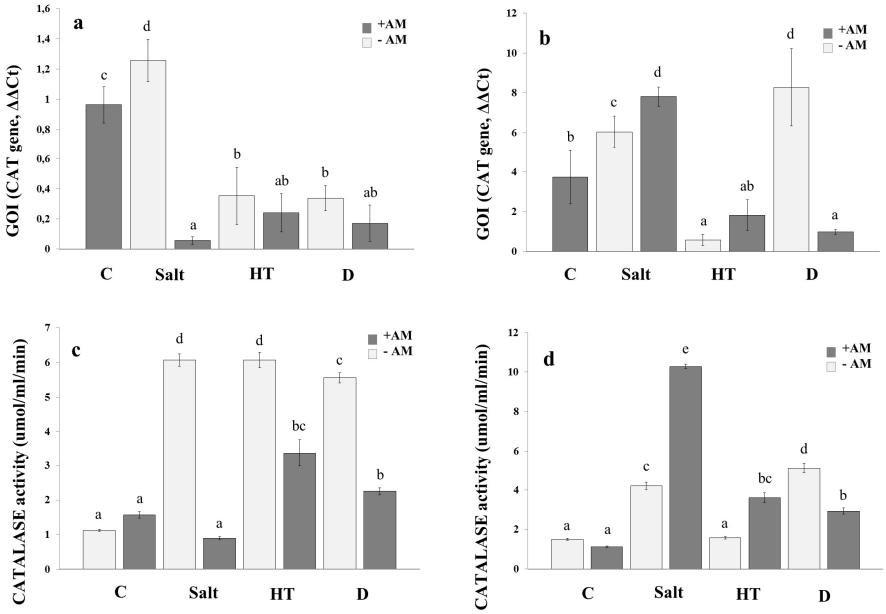

Figure 1. *Catalase gene expression and enzyme activity of mycorrhizal and non-mycorrhizal plants under different stress conditions. a) CAT gene expression in 21-day-old plant b) CAT gene expression in 42-day-old plant c) CAT enzyme activity in 21-day-old plant d) CAT enzyme activity in 42-day-old plant; different letters represent significantly different ($p < 0.05$) values*

At an early stage of plant, mycorrhizal fungi often seems to parasites, which due to the not sufficient production of energy from plant photosynthesis to cover the growth of mycorrhizal fungi together with plant requirement. Without stress the mycorrhizal and non-mycorrhizal control plants showed same enzyme activity. Under stress conditions at early-growth stages of mycorrhizal plants could produce less energy to respond. This could be one of the reasons for the lower enzyme activity of mycorrhizal plants compared to non-mycorrhizal ones after 21 days of growth. In line with the progressing of the incubation time leaf surface increases, plants produce more energy which can be used by both the production of enzymes and by the fungi for growth. As detected during salt and high temperature stress conditions in mycorrhizal plants after 42 days of growth compared to non-mycorrhizal ones. Similar tendency was found measuring 1.3 times higher *CAT* gene expression under salt stress after 42 days of growth. Our results,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62416253

regarding increased catalase enzyme activity under salt stress condition are agreed with the results of AbdElgawad et al (2016) and Chaparzadeh et al. (2004) who treated *Calendula officinalis* with 100 mM NaCl solution. Higher enzyme activity under salt and high temperature stresses in inoculated older plants are often found (Zhu et al., 2010). Under drought stress condition, non-mycorrhizal plants showed higher enzymatic activity at both age of plants. Due to the increased uptake of water resulting from higher AM fungi colonization rate could moderate the drought effect during 42-days term stress. The tendency of gene expression under drought stress was the same as the results of enzyme activity and besides in 21 days old plants no significant difference was observed *(Fig. 1a*). However, significantly higher (7.8 times) gene expression was measured in 42 days old non-mycorhizal plants under drought condition compared to inoculated ones *(Fig. 1b*).

The increased PER activity of plants can occur not only in mycorrhizal plants but also during various abiotic stresses (Borde et al., 2011; Rahmaty and Khara, 2011; Pfeiffer et al., 2013). Interestingly, non-mycorrhizal plants after 42 days of growth had higher peroxidase enzyme activity compared to the inoculated ones under high temperature (*Fig. 2d*).

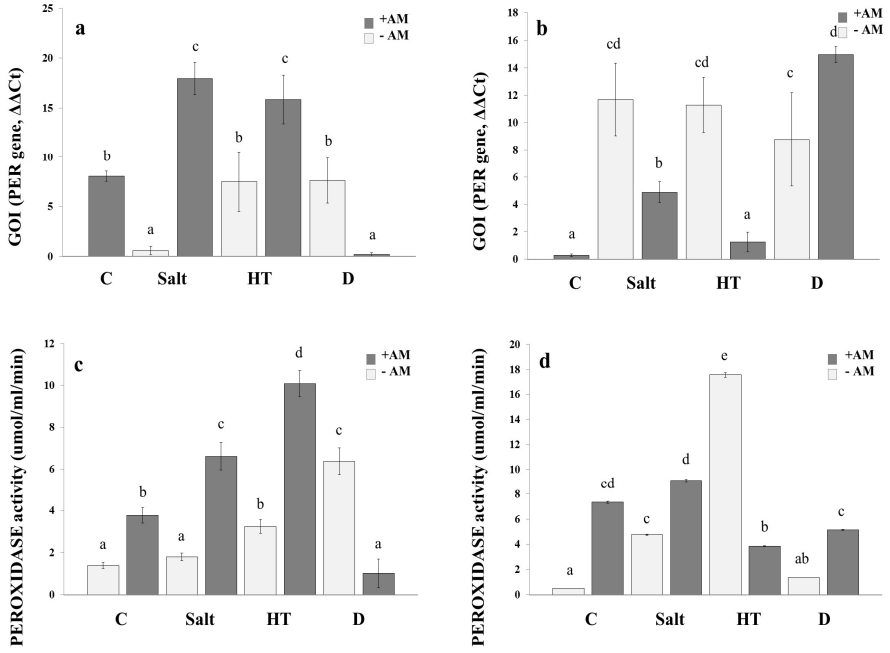

Figure 2. *Peroxidase gene expression and enzyme activity of mycorrhizal and non-mycorrhizal plants under different stress conditions. a) PER gene expression in 21-day-old plant b) PER gene expression in 42-day-old plant c) PER enzyme activity in 21-day-old plant d) PER enzyme activity in 42-day-old plant; different letters represent significantly different ($p < 0.05$) values*

Different results of enzymes activities reported during the colonization of AM fungi indicating that the enzyme activity are somehow connect to the symbiotic processes (Younesi et al., 2013). After 21 days of growth inoculated plants demonstrated higher enzyme activity and gene expression under salt (3 times) and high temperature stresses (2.8 times) compared to non-mycorrhizal ones (*Fig. 2a,c*). At the age of 42-day old mycorrhizal plants showed higher enzyme activity under salt and drought stress

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62416253

compared to non-mycorrhizal treated plants. Under high temperature stress, non-mycorrhizal plants showed higher activity and gene expression than the inoculated ones (*Fig. 2b,d*). Stomatal conductance and transpiration rates of colonized plants are higher than non-colonized ones under high temperature stress, indicating that AM fungi colonization play a role in the gas exchange metabolism improvement with open stoma and increase the rate of transpiration (Zhu et al., 2010). During temperature stress symbiosis improves water retention, preventing the plant of the negative effects of dehydration (Zhu et al., 2012).

Under control condition after 21 and 42 days of incubation, there was no difference in CAT activity regardless of mycorrhization compared to the higher PER activity in mycorrhizal plants. However, under salt stress CAT activity of 21 days old mycorrhizal plants is lower (*Fig. 1a,c*) than PER activity (*Fig. 2a,c*). This strategy of an early stage of plant most likely due to the activity and role function of PER and CAT in the plant defense system. Both are involved in the degradation of H_2O_2, besides Estrada et al. (2013) and Abeer et al. (2015) observed in mycorrhizal plants exhibited much higher activity of PER than CAT enzyme in the elimination of H_2O_2.

Glutathione S-transferases are among the most well-known and most frequently used detoxification enzymes (Nianiou-Obeidat et al., 2017). They play a role in the inactivation of oxidative stress metabolites, which process protects the cell from oxidative damages (Mohsenzadeh et al., 2011). GST in plants neutralize not only toxic substances but also promote a number of defensive mechanisms in the plant. It may facilitate the intracellular storage and transport of hydrophobic non-substrate compounds such as metabolites. Under the various stresses there were no significant differences in GST enzyme activity between mycorrhizal and non-mycorrhizal plants after 21 days of growth (*Fig. 3c*).

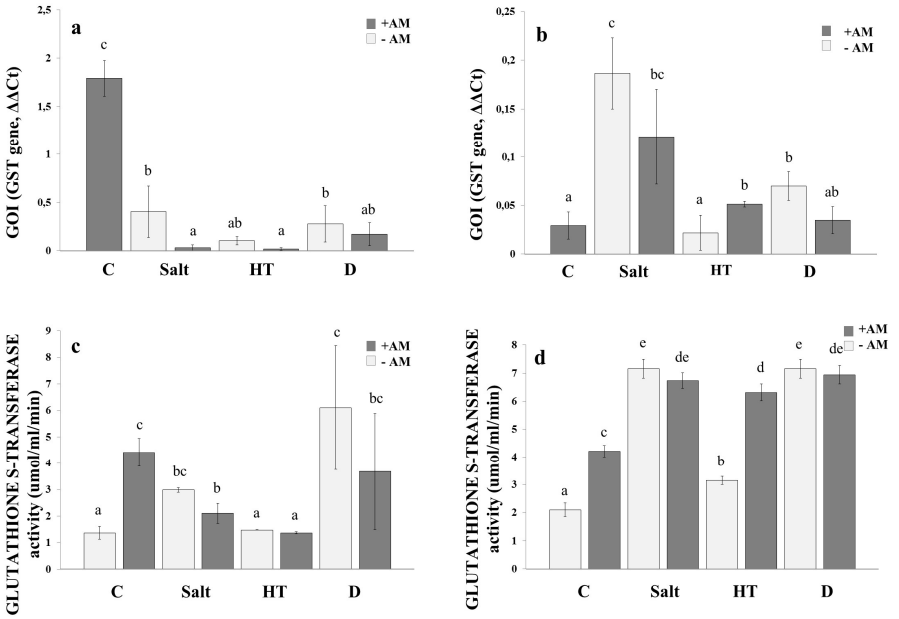

Figure 3. *Glutathione S-transferase gene expression and enzyme activity of mycorrhizal and non-mycorrhizal plants under different stress conditions. a) GST gene expression in 21-day-old plant b) GST gene expression in 42-day-old plant c) GST enzyme activity in 21-day-old plant d) GST enzyme activity in 42-day-old plant; different letters represent significantly different ($p < 0.05$) values*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62416253

By the increase of incubation time all the stress effects induced higher enzyme activity in the plant compared to the control, which trend was previously reported by Haluskova et al. (2009). Depending on the age of the plants Wagner et al. (2002) found also different *GST* gene expression under different stress conditions similar to our results (*Fig. 3a,b*). In the present study, the *GST* gene expression and the GST enzyme activity showed the same tendency under high temperature after 42 days of growth in agreement with the studies of Cetinkaya et al. (2014) and Mayer et al. (2017) (*Fig. 3b,d*).

After three weeks of incubation drought stress induced significantly increased enzyme activity in mycorrhizal plants (*Fig. 4c*). The enzyme activity of PPO is increased in general with the age of the plants. In this study the changes in *PPO* gene expression correlated with the enyzme activity under different stress conditions (*Fig. 4a,c*). Different stresses caused various changes in enzyme activities but only salt stress increased at high rate (8 times) of this enzyme accumulation in mycorrhizal plant after 42 days of growth (*Fig. 4b,d*). The higher polyphenol oxidase activity under salt stress was also observed by Kaya et al. (2013b) and Demir and Kocacaliskan (2001).

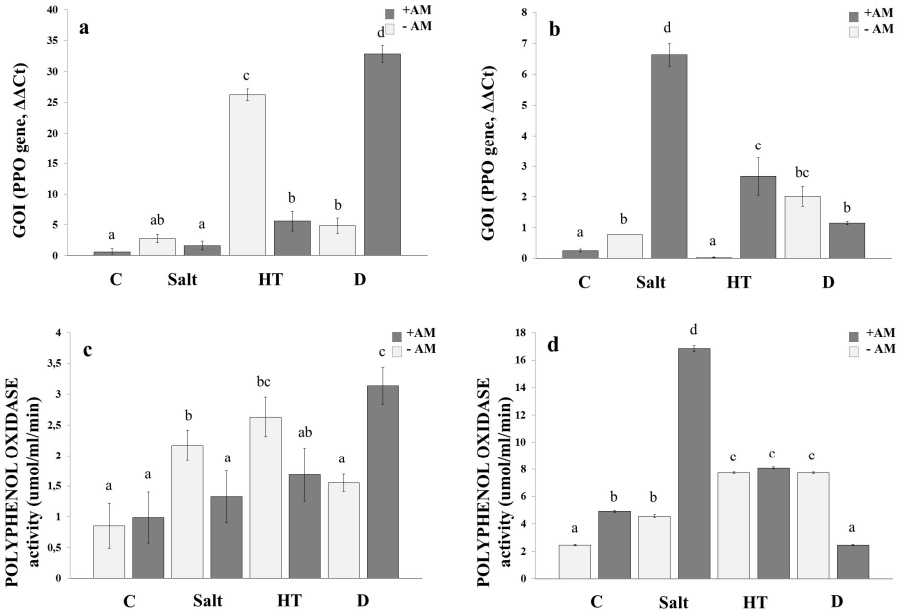

Figure 4. *Polyphenol oxidase gene expression and enzyme activity of mycorrhizal and non-mycorrhizal plants under different stress conditions. a) PPO gene expression in 21-day-old plant b) PPO gene expression in 42-day-old plant c) PPO enzyme activity in 21-day-old plant d) PPO enzyme activity in 42-day-old plant; different letters represent significantly different ($p < 0.05$) values*

Our result suggests that measured defense enzymes are working together in a complex network, influencing to each others. At an early stage of inoculation, when low colonization level but active arbuscule formation could be observed in mycorrhizal plants the highest accumulation of tested enzymes altogether were measured in non-mycorrhizal plants under drought stress. It is almost two times more, than measured in mycorrhizal plants. It shows opposite tendency than expected from mycorrhizae offered balance activity under stresses. Explaination of less damage caused in mycorrhizal plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62416253

than in non-mycorrhizal one under drought condition most likely due to the increased surface offered by external hyphae of mycorrhizal fungi increase the water uptake and water efficiency (Smith and Read, 2010; Zhao et al., 2015). It could be one reason for lower defense enzyme activities measured in mycorrhizal treatment under dry condition. Similar tendency was found applying salt stress, when the mycelium network of AM fungi could also attenuate the strength of this stress using different mechanisms (Mardukhi et al., 2015). Out of the tested stresses, the high temperature caused the biggest change in measured defense enzymes between mycorrhizal and non-mycorrhizal treatments.

Conclusions

Our results suggest that AM inoculation could take part in the alleviation processes caused by high temperature, salt and drought stresses. However, these mechanisms are influenced by the age of the plants which is most likely justified by energy considerations. Besides increased defense enzymes activities of mycorrhizal plants compared to non-mycorrhizal one, the AM fungi could offer some other strategies to increased tolerance of plants against salt and drought stresses. Nevertheless, the activity of CAT, PER, GST and PPO concerning degradation of toxic ROS molecules in plant defense system under various stresses, should be investigated in more detail. Especially the CAT and PER related expression system and not well documented PPO activity supports further studies in plant – AM fungi symbiotic relationship.

Abstract. An increasing demand for assessing the hazard of debris-flow accumulation areas is critical to risk management and policy implication for debris-flow hazard mitigation. In this paper, a framework for hazard assessment in debris flow-prone areas is proposed. Based on the hazard definition, debris-flow hazard is computed by its occurrence probability and disruptive intensity. Debris-flow occurrence probability is defined as a joint probability considering both hydrological and debris supply condition. Debris-flow disruptive intensity is introduced to express the inundated and impact damage of debris flow by the distribution of flow depth and velocity. The distribution is based on an extended geometric model of debris-flow fans, including the maximum length, width, and thickness (or flow depth) of debris-flow fans, and the channel outlet width. A hazard matrix, correlated to debris-flow occurrence probability and disruptive intensity, is used to map the hazard on debris-flow accumulation areas. The proposed procedure is applied to assess the debris-flow hazard on the accumulation area of Shuida gully, located in the Longchi town, Sichuan province of China. Finally, the article considers the effects of hazard maps.
Keywords: hazard recognition, debris-flow fan configuration, occurrence probability, debris-flow disruptive intensity, Shuida gully

Introduction

Debris flows are common phenomena in mountainous regions throughout the world (Coussot and Meunier, 1996). Their accumulation flooding processes always make the foothills of the landform change, and form the alluvial fans which are a preferred location for urban development owing to their good drainage conditions and gently slope. In many densely developed mountainous regions, fans provide the only readily developable land (Jakob and Hungr, 2005). Unfortunately, many fans in active mountains are prone to debris flows, which can constitute a widespread hazard to people and property (Davies and McSaveney, 2008). Therefore, there is an increasing demand for assessing the hazard of debris-flow accumulation areas, which is critical to risk management and policy implication for debris-flow hazard mitigation.

According to the International Union of Geological Sciences definition (IUGS, 1997), a hazard in a given point on an alluvial fan is defined as the probability that a debris flow of a defined intensity will occur. Based on this definition, the hazard assessment mainly includes two parts: one is the debris-flow occurrence probability related to its basin characteristics and hydrological conditions, the other is the debris-flow intensity described by means of variables characterizing its destructive power.

DOI: http://dx.doi.org/10.15666/aeer/1703_62556267

Over the past few decades, the debris-flow hazard assessment has been generally carried out either by using empirical approaches or applying physical and numerical methods. The empirical models (Okunishi and Suwa, 2001; Iverson, 2014; Rickenmann, 2016) are based on few parameters and consequently allow generalized conclusions only. However, they generally offer a readily applicable and verifiable approach. The most common empirical relationships estimate the maximum run-out distance of debris flow. In recent years, data mining has been utilized for assessing debris flow hazards (Lin et al., 2012; Liang et al., 2012). With the development of rheological and physical-mathematical based modeling of debris flows, numerical techniques and geographical information science, quantitative approaches are widely-used to assess the hazard of debris-flow. For example, Wei et al. (2003) simulated the movement process of debris flow out of the outlet, and established the momentum model for debris flow risk zoning. Liu and Huang (2006) introduced the concept of separating the boundary layer and the main flow in fluid mechanics to debris flows, and developed a numerical program for field application on hazard area mapping. Tsai et al. (2011) considered large-scale debris flow simulations in various volumes at the same area by using the DEBRIS-2D numerical program for hazard assessment.

Taking into account the triggering, propagation and stoppage of debris flows, Calvo and Savi (2009) applied a Monte Carlo procedure to quantify debris flow hazard. De Scally et al. (2010) conducted discriminant analysis for identifying controls on fan depositional processes, and implications for the assessment of debris-flow hazard on fans. Hürlimann et al. (2008) reviewed various different run-out and intensity calculation methods and discussed their implication for generating debris-flow hazard maps. In quantitative approaches, Guzzetti et al. (2005) proposed a probabilistic model to determine landslide hazard at the basin scale. Based on debris supply conditions, the basins where debris flows occur can be classified as either supply-limited (or weathering-limited) or supply-unlimited (or transport-limited) (Glade, 2005; Jakob et al., 2005). However, the existing debris-flow occurrence probability calculation methods were generally on the assumption of unlimited sediment availability, neglecting the requirement of a significant recharge period prior to each debris flow event. In addition, the determination of debris-flow magnitude and intensity is also necessary during the hazard assessment (Jakob and Hungr, 2005). Typically, the characteristic parameters such as area inundated, maximum flow velocity, and maximum flow depth are related.

In this study, a framework for hazard assessment of debris-flow accumulation areas was developed. Four key components of this framework were discussed: (i) the debris-flow occurrence probability was estimated by combining the critical hydro-climatic thresholds and debris supply conditions; (ii) the fan configurations were classified as complete, partial and unformed types, and an extended geometric model of debris-flow fans was provided for hazard assessment; (iii) the disruptive intensity was introduced to express the inundated and impact damage of debris flows; (iv) the debris-flow occurrence probability and destructive power were correlated in a hazard matrix which can represent hazard qualitatively by hazard degree classes or quantitatively by a value ranging from zero to unity. Finally, the developed framework was applied to evaluate the debris-flow hazard on the accumulation area of Shuida gully, located in the Longchi town, Sichuan province of China.

Methods and Materials

Methods

The framework for hazard assessment of debris-flow accumulation areas includes the following steps (*Fig. 1*):

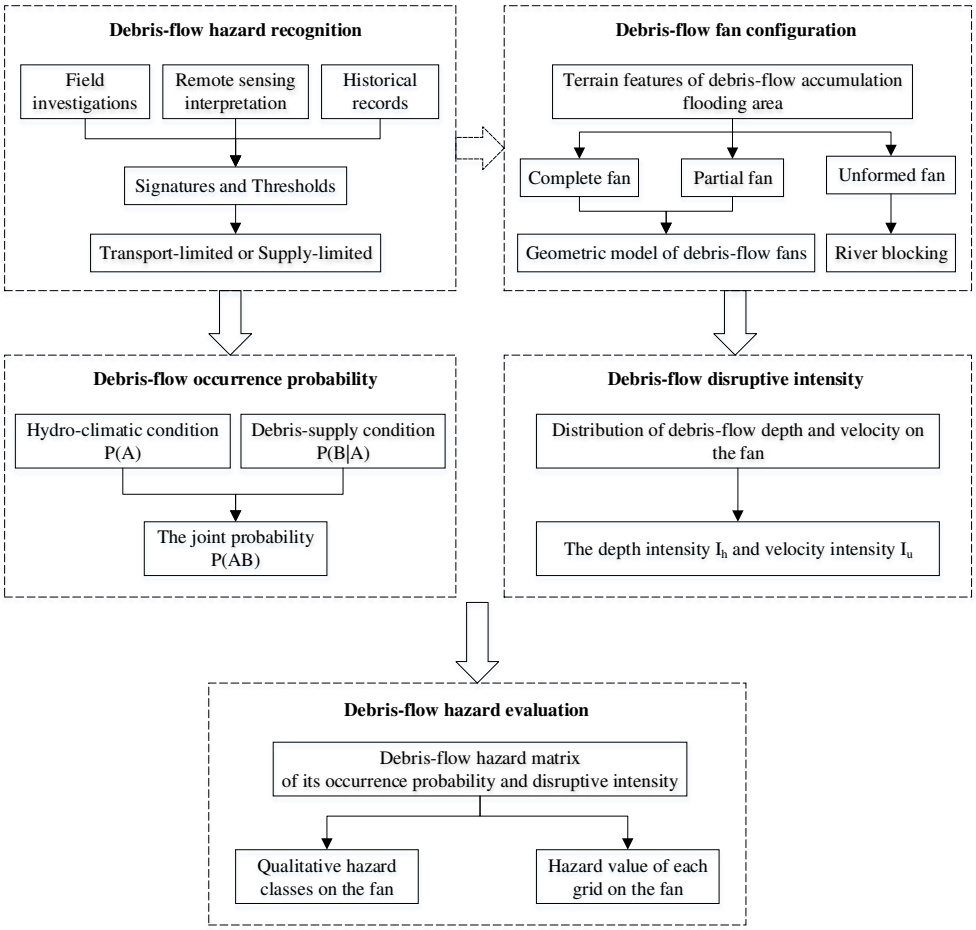

Figure 1. *The framework for hazard assessment of debris-flow accumulation areas*

- Debris-flow hazard recognition is the first, and possibly most important segment. The causes of debris flows, and their behavior once initiated, are known in outline but poorly understood to date (Iverson, 1997; Takahashi, 2009). However, it is clear that a debris flow occurrence requires large volumes of sediment to be available, either on slopes or in a stream channel, and steep slopes to allow rainfall and/or stream-flow of sufficient magnitude to mobilize the sediment (Welsh and Davies, 2011). Thus, we propose a reference method for debris-flow hazard identification based on its occurrence signatures or thresholds (*Table 1*). Additionally, it is necessary for the following probability estimation to divide gullies into transport-limited and supply-limited by field investigation of catchment characteristics.
- Debris-flow occurrence probability is a function of the critical hydro-climatic thresholds and debris supply conditions. Therefore, the authors defined a joint

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62556267

probability to estimate the hazard occurrence probability considering both hydrological and geomorphic characteristics.

- Debris-flow fan configuration is the basis of hazard evaluation. According to the different terrain features of debris-flow accumulation flooding area, the fan configurations may unfold in various spatial patterns. In order to establish a geometric model of debris-flow fans for the following calculations, the fan configurations are classified as complete, partial and unformed types, and an extended geometric model of debris-flow fans is provided.

Table 1. *The reference method for debris-flow hazard recognition*

Criterion	Description	References
Signatures	Steep channel Narrow channel, small width-to-depth ratio Semi-circular to U-shaped channel Accumulation of unconsolidated sediment in the channel Channel scoured to bedrock, or filled with coarse rock-fall debris with high hydraulic conductivity (supply-limited) Scour marks, mud-lines and debris impact scars on the trees well above the flood limit Inverse grading of fan or levee deposits Coarse deposits beyond the channel on the fan Poorly sorted or imbricated deposits on the fan	Meyer et al. (2014); Jakob and Hungr (2005)
Thresholds	Melton ratio $R > 0.5$ Watershed length $WL \leq 2.7\text{km}$ Empirical formula $P = R\,T^{0.2}/G^{0.5} \geq 0.47$, R, T, G is the dimensionless factor related to hydrology, topography, and geology respectively	Wilford et al. (2004); Welsh and Davies (2011); Yu et al. (2014)

- Dividing debris-flow fans into many grids with equal area, we can evaluate hazard of each grid by the disruptive intensity, which is introduced to express the inundated and impact damage of debris flow by the distribution of flow depth and velocity.
- Debris-flow occurrence probability and destructive power are correlated in a hazard matrix which can represent hazard qualitatively by hazard degree classes or quantitatively by a value ranging from zero to unity. For practical use, administrations always use qualitative hazard classes to better correlate with building codes and urbanization plans (Raetzo et al., 2002). However, quantitative methods have their advantages of objectivity.

Debris-flow occurrence probability

Debris flow initiation requires steep slopes, availability of erodible sediments, and a storm of sufficient magnitude. Thus, we apply a joint probability $P(A \cap B)$ to calculate the probability of debris-flow occurrence using *Equation 1*:

$$P_H = P(\mathrm{A} \cap \mathrm{B}) = P(\mathrm{B}|A) \cdot P(A) \qquad \text{(Eq.1)}$$

where P_H is the debris-flow occurrence probability; A represents the local hydro-climatic condition or rainfall exceeding the critical value; B represents the availability of erodible sediments under the given slope channel; $(B|A)$ indicates the occurrence of B under the triggering condition A; $\mathrm{A} \cap \mathrm{B}$ indicates the simultaneous occurrence of A and B; and P is the event occurrence probability.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62556267

As an approximation, rainfalls can be considered as independent random-point events in time (Cowpertwait et al., 1996), the occurrence probability of a rainfall during a period of n years can be estimated using the binomial equation:

$$P(A) = 1 - (1 - 1 / T)^n \quad \text{(Eq.2)}$$

where T is the return period of rainfalls. It can be obtained from a historical catalogue of local rainfalls or from the local hydrological handbook.

To determine the occurrence probability of sediment entrainment under condition A, it is necessary to discuss the debris supply condition and the magnitude (or transport capacity) of A in a given basin. In transport-limited gullies, abundant readily entrainable sediment is present, and whenever a rainfall of sufficient magnitude occurs, a debris flow will result. On the contrary, in supply-limited gullies, the volume of entrainable sediment is limited, and a rainfall of sufficient magnitude may not initiate a debris flow unless enough sediment is available (Brayshaw and Hassan, 2009). In the conceptual model for supply-limited gullies (Glade, 2005), an extrinsic hydro-meteorological threshold is not a sufficient condition, but an intrinsic sediment recharge threshold must be reached for debris flows to occur. Otherwise, there is an inherent danger of overestimating debris-flow occurrence when considering rainfall events only. Generally, rainfall will not necessarily trigger debris flows but floods or hyper-concentrated flows. The sediment recharge threshold is related to channel recharge rate, which can be determined by knowledge of debris storage and the elapsed time since the last debris flow in the basin (Jakob et al., 2005).

Consequently, we set the conditional probability for quantitative hazard assessment as: $P(B|A) = 1$ in transport-limited basins; and $P(B|A)$ values in the interval (0,1) in supply-limited basins. Owing to the difficulty in evaluating sediment recharge rate in gullies, we refer the existing quantitative study on the effect of geological conditions on debris-flow occurrence (Yu et al., 2014), and roughly estimate $P(B|A) = 0.6$ in supply-limited basins where weathering are strong and precipitation are abundant, while $P(B|A) = 0.2$ elsewhere.

Debris-flow fan configuration

Delimiting the spatial extent of potential damage from debris flows relies on understanding of the fan evolution, which is mainly governed by the terrain features of debris-flow accumulation flooding areas, and the physical properties of debris flows, such as rheology, sediment concentration. Since the different depositing conditions for debris flows, fan configurations may unfold in various surficial patterns. We categorize the fan configurations as complete, partial and unformed types. The latter two types always result in river blocking, and the last one may fail to form a fixed shape. Therefore, the authors only proposed a geometric model for the first two types.

Generally, natural debris-flow fans cannot be easily sorted in a precise and uniform shape. In the past, the fan shape has been represented by a semi-circle or semi-ellipse (Tsai, 2006; Takahashi, 2014), which assumes the maximum width of debris-flow fan locates at the outlet of the main channel. In other words, the circumferential angle corresponding to the plane of debris-flow fan is always equal to 90°. To further promote the utilization of the geometric model of debris-flow fans, the authors assumed debris-flow fans as a sector planar, where the effect of hydraulic structures, roads, and buildings on the flowing direction is not considered, and the path of the flow

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62556267

downstream from the mouth is straight. In this study, the maximum length l_m, width b_m, and thickness (or flow depth) h_m of debris-flow fan, and the channel outlet width b_0 are used to derive the geometric model for debris-flow fans, as shown in a rectangular Cartesian coordinate system (*Fig. 2*). For practical use, the channel outlet width can be measured by field investigation, and other parameters can be estimated by empirical formulas (*Table 2*). Additionally, if debris flows occur under the same formation conditions, the four parameters can be valued by the existing field survey record.

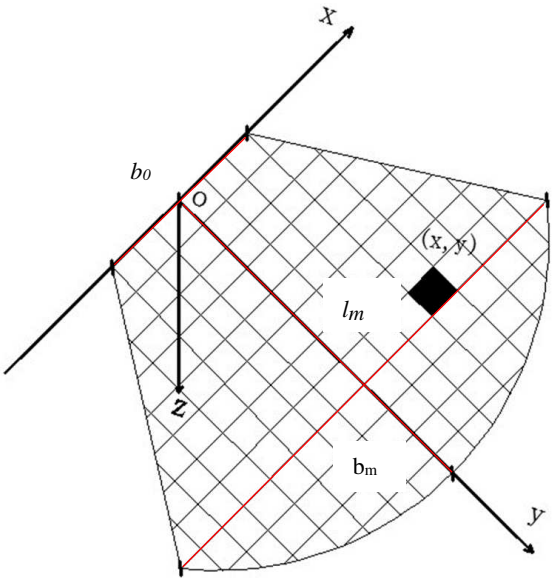

Figure 2. *The coordinate system of the debris-flow fan (The origin is at the outlet center, x is parallel to the transverse section, y points down the fan slope, and z points into the slope, normal to the x-y plane)*

Table 2. *Empirical formulas for estimation of the maximum length, width, and thickness of the debris-flow fan*

Formulations	Scope	References
$l_m = 15V_c^{1/3}$	Worldwide	Rickenmann (1999)
$l_m = -143.3387 + 29.8536\ln V_c$ $b_m = -149.0417 + 25.6293\ln V_c$ $h_m = 0.7067 + 0.0001\ln V_c$	The slope of accumulation area is about 5°; debris flow density is $1.82 g/cm^3$	Liu et al. (1993)
$l_m = 0.36A^{0.06} + 0.03(V_L \cdot H)^{0.54} - 0.18$ $b_m = 0.40A^{0.08} + 0.04(V_L \cdot H)^{0.35} - 0.23$	Wenchuan earthquake area	Tang et al. (2012)

Based on the above coordinate system, the corresponding circumferential angle of the fan plane is firstly derived:

$$\theta = \arcsin\frac{b_m}{\sqrt{4l_m^2 + b_0^2}} - \arctan\frac{b_0}{2l_m} \quad \text{(Eq.3a)}$$

where $0° < \theta < 90°$.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62556267

Then, the fan shape can be described mathematically by the width of each transverse section, the calculation can be expressed as follows:

$$b = \begin{cases} b_0 + 2y\tan\theta & 0 \le y \le \frac{b_m - b_0}{2}\cot\theta \\ \frac{\sqrt{{b_m}^2 - (2y\sin\theta + b_0\cos\theta)^2}}{\sin\theta} & \frac{b_m - b_0}{2}\cot\theta < y \le l_m \end{cases} \quad \text{(Eq.3b)}$$

where y is the longitudinal axis value of each grid center.

When $\theta = 90°$, the fan shape is a semi-circle or semi-ellipse, whose width will be calculated as:

$$b = b_m\sqrt{1 - \left(\frac{y}{l_m}\right)^2} \quad \text{(Eq.3c)}$$

According to the experimental results (Tsai, 2006; Takahashi, 2014), the non-dimensional longitudinal profile of fans can be approximated using a half-Gaussian curve, the calculation can be expressed as:

$$\frac{Z_c}{h_m} = \exp\left[-\frac{1}{2{C_L}^2}\left(\frac{y}{l_m}\right)^2\right] \quad \text{(Eq.3d)}$$

The non-dimensional transverse profile can be approximated by a Gaussian curve:

$$\frac{Z}{Z_c} = \exp\left[-\frac{1}{2{C_T}^2}\left(\frac{x}{b}\right)^2\right] \quad \text{(Eq.3e)}$$

where Z_c denotes the thickness at the center point $(0,y)$ along the longitudinal axis; Z represents the thickness at any grid (x,y); and C_L, C_T are empirical coefficients, given approximately as 0.389 and 0.211.

Thus, if l_m, b_m, h_m, b_0 are given, we can obtain the three-dimensional topography of debris-flow fans using *Equations 3a-3e*.

Debris-flow disruptive intensity

In order to describe the damage degree of debris flow, a relatively disruptive intensity is introduced:

$$I_\xi = \frac{\xi(x,y)}{\xi_m} \quad \text{(Eq.4)}$$

where I_ξ is the debris-flow disruptive intensity represented by variable ξ characterizing the debris-flow destructive power; ξ(x,y) is the variable value of each grid on the fan; and ξ_m is the maximum. For expressing the inundated and impact damage of debris flow, ξ can be considered as flow depth and velocity.

United *Equations 3a-3e*, the inundated damage intensity can be deduced:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62556267

$$I_h = \begin{cases} exp\left[-\frac{y^2}{2{C_L}^2{l_m}^2} - \frac{x^2}{2{C_T}^2(b_0+2y\tan\theta)^2}\right] & 0 \le y \le \frac{b_m-b_0}{2}\cot\theta \\ exp\left[-\frac{y^2}{2{C_L}^2{l_m}^2} - \frac{x^2\sin^2\theta}{2{C_T}^2({b_m}^2-(2y\sin\theta+b_0\cos\theta)^2)}\right] & \frac{b_m-b_0}{2}\cot\theta < y \le l_m \end{cases} \quad \text{(Eq.5a)}$$

When $\theta = 90°$, the intensity can be calculated as:

$$I_h = \exp\left[-\frac{y^2}{2{C_L}^2{l_m}^2} - \frac{x^2{l_m}^2}{2{C_T}^2{b_m}^2({l_m}^2-y^2)}\right] \quad \text{(Eq.5b)}$$

Considering the impact damage intensity, the distribution of velocity on the fan should be known. The authors assumed the debris-flow depositing processes in the mainstream line (along the maximum length) are uniform deceleration motion, and the attenuation processes of flow velocity in the transverse section are linear with the distance from the mainstream line, which will be decelerated to zero at the edge of the fans. Thus, the flow velocity at any grid (x,y) on the fan can be expressed as:

$$\mathrm{u}(x,y) = \frac{b-2|x|}{b} \cdot u_m \cdot \sqrt{1-\frac{y}{l_m}} \quad \text{(Eq.6a)}$$

where u_m is the maximum of flow velocity.

According to *Equation 4*, the impact damage intensity can be expressed as:

$$I_u = \frac{b-2|x|}{b} \cdot \sqrt{1-\frac{y}{l_m}} \quad \text{(Eq.6b)}$$

As a result, debris-flow disruptive intensity can be obtained by l_m, b_m, b_0, including two empirical coefficients C_L, C_T.

Debris-flow hazard evaluation

Based on the above derivation, debris-flow hazard of each unit on the fan can be computed as:

$$P(\xi) = P_H \cdot I_\xi \quad \text{(Eq.7)}$$

where $P(\xi)$ is a probability function of variable ξ characterizing the debris-flow destructive power.

According to the definition of hazard, the necessary parameters at each grid in a hazard map are occurrence probability and disruptive intensity of debris flows (Hürlimann et al., 2008). Thus, these two parameters are correlated in a hazard matrix which can represent hazard qualitatively by hazard degree classes or quantitatively by a value ranging from zero to unity. An example of a debris-flow hazard matrix is given in *Table 3*.

In this hazard matrix, the debris-flow occurrence probability is classified into two groups. When the occurrence probability is smaller, the alluvial fan scale may be larger, and its disruptive intensity is greater. Therefore, we rank hazard degree classes with different intensity intervals in the groups.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62556267

Table 3. *Example of debris-flow hazard matrix*

Class	Occurrence probability, P_H	Disruptive intensity, I_ξ	Occurrence probability, P_H	Disruptive intensity, I_ξ
Very high	[0.01,1)	[0.7,1]	(0,0.01)	[0.5,1]
High		[0.5,0.7)		[0.2,0.5)
Medium		[0.2,0.5)		[0.05,0.2)
Low		[0,0.2)		[0,0.05)

Materials

The proposed framework is applied to evaluate the debris-flow hazard on the accumulation area of Shuida gully, located in the Longchi town, Sichuan province of China (N31°04′30″, E103°33′44″). In the Shuida catchment (*Fig. 3*), which is situated in the Wenchuan earthquake area, a debris flow was triggered by a rainstorm on 13 August 2011.

Figure 3. *(a) Photography showing the whole Shuida catchment and co-seismic landslides developed upslope; (b) The debris-flow scoured channel; (c) The deposited fan*

Field investigations indicated that the gully was transport-limited, where abundant loose materials deposited after the earthquake. According to the local hydrological handbook, the return period of the rainstorm was 50 years. The 0.5 km^2 catchment has 650 m of relief with a mean catchment slope of 0.20. The necessary parameters for hazard assessment of debris flow are reported in *Table 4*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62556267

Table 4. *Parametric values used in the hazard assessment*

$b_0\ (m)$	$b_m\ (m)$	$l_m\ (m)$	$h_m\ (m)$	$u_m\ (m/s)$
35	154	180	7	5

Results

According to the above methods, the annual exceedance probability of Shuida gully debris flow is 0.02. The fan plane can be described by the width of each transverse section, which is deduced from *Equations 3a-3b*, as follows:

$$b = \begin{cases} 35 + 0.71y & 0 \le y \le 166.67 \\ \frac{\sqrt{23716 - (0.67y + 32.96)^2}}{0.34} & 166.67 < y \le 180 \end{cases} \quad \text{(Eq.8)}$$

According to *Fig. 4*, the actual deposited area can be measured at 22832 m^2, and the calculated area is 17118 m^2, while the overlapping area is 17068 m^2. Thus, the accuracy of the proposed geometric model is 75%, and it can be calculated as:

$$A_m = \frac{S_b}{S_a} \cdot \frac{S_b}{S_m} \quad \text{(Eq.9)}$$

where A_m is the accuracy of model; S_a is the actual deposited area; S_b is the overlapping area; and S_m is the area calculated by the above geometric model of debris-flow fan.

Due to the fan partially unfolding, the accuracy of the model may be affected. However, the calculated area basically overlaps the actual accumulation area. In the calculated area, the fan domain is divided into many grids with equal area of 5 m×5 m, and the debris-flow disruptive intensity of each grid was calculated by *Equations 5a* and *6b*. The calculation process was carried out on ArcGIS 10.2. The final hazard maps are shown in *Fig. 4*.

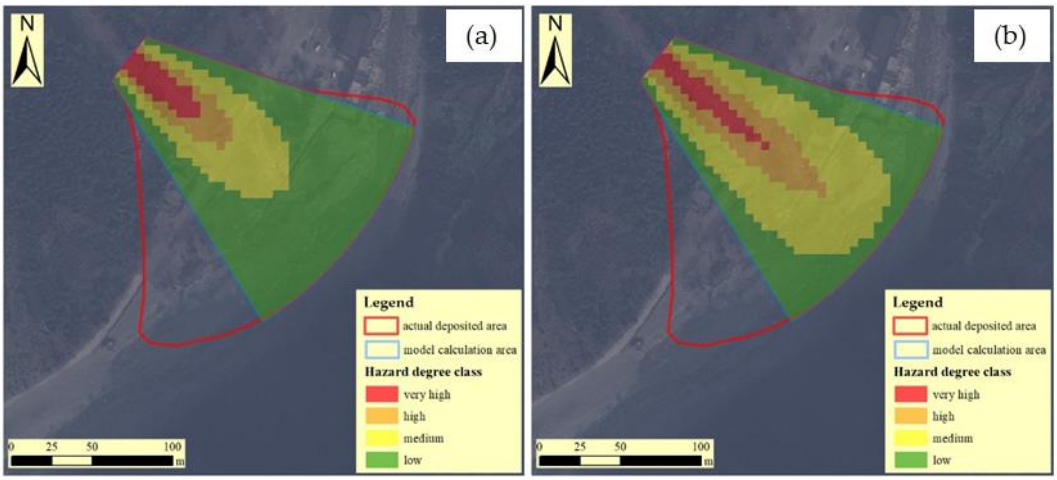

Figure 4. *Hazard map of Shuida gully debris flow according to the proposed methods depending on (a) Flow depth; (b) Flow velocity*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62556267

According to *Fig. 4(a)*, the area proportion of hazard grades from very high to low is 4.9%, 5.8%, 18.2%, and 71.1%, respectively. The proportion of flow depth greater than 1.4 m is 28.9%, which represents the inundated damage of Shuida gully debris flow. *Fig. 4(b)* shows the debris-flow impact damage, and the proportion of flow velocity greater than 1m/s is 54.9%.

Discussion

The developed methods appear useful and efficient for mapping the hazard on debris-flow accumulation area. These methods allow to emphasize and estimate the hazard component of debris flow, including the calculations of debris-flow occurrence probability and disruptive intensity. The hazard matrix, correlated to debris-flow occurrence probability and destructive power, can satisfy different evaluation requirements by hazard degree classes or by a value ranging from zero to unity. Meanwhile, the proposed framework, including five steps in a quantitative way to evaluate hazard of each grid on debris-flow fans, also points out some directions to be further studied:

- During the recognition of debris-flow hazard, it is useful to distinguish the debris supply condition of gullies. In supply-limited gullies, the importance of the recharge rate of sediments that may influence the frequency of occurrence and the magnitude of debris flows should be investigated. Moreover, the appropriate and reliable quantitative methods are expected to put forward for debris-flow hazard recognition.
- The conditional probability $\mathrm{P}(B|A)$ is related to the triggering mechanism of debris flow. So it is important to introduce the initiation law of sediment under different hydro-climatic conditions, and establish the relationship between the conditional probability and the triggering condition of debris flow.
- The fan-forming process is difficult to be described mathematically in a precise shape, owing to the diversity of the terrain features of debris-flow accumulation areas and the complexity of the physical properties of debris flows. Although the developed geometric model of debris-flow fans further promotes the existing model, a more reliable numerical simulation is still regarded as a better method. Thus, the depositing processes of debris flows should be studied by governing equations for more accurate simulation of debris-flow fans.
- The above disruptive intensity is a relative value, which should be measured combined with its maximum. Other variables such as flow discharge, impact force, or momentum may also be available as indicators characterizing debris-flow destructive power.

Conclusion

According to the hazard definition, a framework for hazard assessment of debris-flow accumulation areas was proposed, including the calculations of debris-flow occurrence probability and disruptive intensity. A joint probability was defined to estimate debris-flow occurrence probability considering both hydrological and geomorphic characteristics, which was carried out on dividing basins into transport-limited or supply-limited by debris-flow occurrence signatures or thresholds. A relatively disruptive intensity was introduced to describe the damage degree of debris

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62556267

flows by the distributions of flow depth and velocity. The distributions were obtained by an extended geometric model of debris-flow fans, and a hypothesis of uniform deceleration motions on fans.

The application for mapping the hazard on Shuida alluvial fan indicates that the developed geometric model can reflect the debris-flow accumulation flooding area, and the hazard evaluation by the given hazard map can show the inundated and impact damage of the debris flow in reality. Meanwhile, a numerical simulation, considering accumulation processes of debris flows, will be inspired in the future.

Abstract. The NDVI of GreenSeeker has proven to be an effective tool for Management Zoning. An optimal method on the basis of NDVI was proposed to establish Management Zoning accurately in this study. First, the coefficient of variation of time series distance difference of Greenseeker and UAV NDVI was tested, it was significant to evaluate the accuracy of Greenseeker NDVI for large-areas. On this basis, optimal partition numbers and partitioning algorithm were identified according to the Silhouette Coefficient of data structure, the accuracy of estimation of agronomic parameters and the difference of agronomic parameters in each plot under different partition numbers. Results demonstrate that the difference among the points of the distance sequence is not significant ($F = 0.641 > 0.05$). The NDVI of Greenseeker has high reliability. When the partitioning algorithm and the number of partitions are K-means and four, respectively, the Silhouette Coefficient and the accuracy of estimation of agronomic parameters (plant height, nitrogen content) are higher than in other treatments. At the same time, the agronomic parameters in each plot showed the significant differences. The proposed method provides a good prospect to optimize the establishment of management zones.
Keywords: *nitrogen top dressing, clustering algorithm, the number of cluster, Greenseeker, UAV*

Abbreviations: NDVI: normalized difference vegetation index; GS-NDVI: NDVI was detected by Greenseeker; UAV-NDVI: NDVI was detected by UAV; *Si:* Silhouette Coefficient; NCE: normalized classification entropy; FPI: fuzzy performance index; FCM: fuzzy c-means algorithm; HC: hierarchical clustering; RMSSDT: root mean square standard deviation; RS: R square

Introduction

Nitrogen top dressing is a promising approach to improve yield and quality of maize in the early stages of growth (Sun et al., 2018). Site-specific application of nitrogen top dressing should lead to more efficient use and reduced the load on the environment (Zhou et al., 2018; Jin and Zhou, 2018). Management zones is a common intermediate step of moving from a uniform 'field average' management system to a site-specific crop management system (Ingerstad, 1982; Raun et al., 2002; Aavidai, 2016). The NDVI has a strong correlation with maize nitrogen content. The quest for precision in N management has prompted numerous recent investigations exploring the potential of NDVI by improved prediction of crop N needs (i.e., fertilizer Rate) (Rajkovich et al., 2012; Abbasi et al., 2012; Herbst et al., 2009; Cilia et al., 2014; Allen et al., 1973). Therefore, the NDVI can be regarded as a basis for management zones.

The acquisition methods of NDVI mainly include satellite remote sensing, aerial remote sensing and ground remote sensing. The spectral image sensor of satellite remote sensing and aerial remote sensing uses daylight as a light source to accurately describe the state of plant growth by NDVI and image information. However, due to the influence of cloud, atmosphere and meteorological conditions, it is difficult for them to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62696285

meet the strict requirements of nitrogen top dressing time (Cao et al., 2012). The UAV platform can solve previous problems, and its NDVI has been proved to have high accuracy, but its recharge mileage is limited (McKinion et al., 2009; Cruppe et al., 2017; Ren et al., 2008). The active spectrum sensor of ground remote sensing contains light emitting diodes (LEDs) that emit modulated light onto the canopy (thus, the term active) and detect reflectance of the modulated light from the canopy with photodiodes. Both visible and near-infrared wavelengths are typically included. With their own light sources, these sensors are less sensitive to diurnal variations than sensors that rely on ambient sunlight (Mulla et al., 1992; Fleming et al., 2000). Operationally, these sensors can be mounted on N fertilizer applicators equipped with computer processing and variable rate controllers, so that sensing and fertilization are accomplished in one pass over the crop. Commercial passive spectroscopy sensors mainly include Yara N-Sensor (Yara, Dulmen, Germany), GreenSeeker (Trimble, Sunnyvale, CA., USA), CropCircle (Holland Scientific Inc., Lincoln, NE, USA), and all of the above-mentioned sensors can output NDVI.

At present, there are several approximations for the development of site-specific management zones. For example, the chemical and physical properties (nitrogen content, conductivity) of soil were used to characterize spatial variability (Gerard et al., 1997; John et al., 2007; Wang et al., 2001), including topographic maps (Fu et al., 2010), direct soil sampling (Coque et al., 2006), non invasive soil sampling by electrical conductivity equipment (Colaco et al., 2017). The second approach is based on yield maps, which was established through the difference between the average of yield for many years and the current year's output. The third method is the integration of the two previous approaches and considers soil and/or relief information plus the use of yield maps (Beckie et al., 1997; Jia et al., 2004). More practical approaches have also considered farmers' knowledge in order to delineate management zone s (Yang et al., 2009). All of the above information can be performed using different algorithms, such as K-mean, fuzzy clustering analysis, hierarchical clustering, etc (Orteg and Santibáñez, 2007; Yang et al., 2016; Cai et al., 2006; Chuang et al., 2006). However, the problems, such as high labor intensity and cumbersome operation, make it difficult to obtain the approximations. At the same time, the performance evaluation method of partition method is relatively single.

It is evident that NDVI is strongly associated with plant growth and soil nutrients. In this paper, the clustering method was studied based on the large-area corn canopy NDVI by the ground remote sensing sensor Greenseeker. At the same time, the NDVI of the unified location was obtained by the remote sensing image of the UAV. This study mainly completes the following two research contents.

(1) The accuracy of NDVI of Greenseeker was verified by comparing the different of data between NDVI and UAV.

(2) The optimal of partitioning algorithm and the number of partitions was proposed to establish a reasonable management zones and describe the group differences in corn growth

Materials and methods

Experiment location

The test site was located at Zhao Guang Farm, Hei He City, Heilongjiang Province (E 126°38'-127°38'5", N 47°1'-48°1') in northeastern China. The frost-free period is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62696285

about 120 days. The annual rainfall is 570 mm, the annual average sunshine is more than 2,700 h, and the soil type is mainly black soil. The Institute is located at No. 12-2, Zhao Guang Farm. The corn planting adopts a double ridge with a ridge width of 1.1 m. The area was surrounded by a space to ensure the accuracy of GPS data acceptance. The data collection time was June 12, 2016. The yellow border shows the ground-sensing Greenseeker working area (*Fig. 1*). The corn variety was Demei Ya No. 3, and it is 55 days after emergence. It needs to be ≥10 °C and the accumulated temperature of activity is about 2200 °C. It is a common early maize variety.

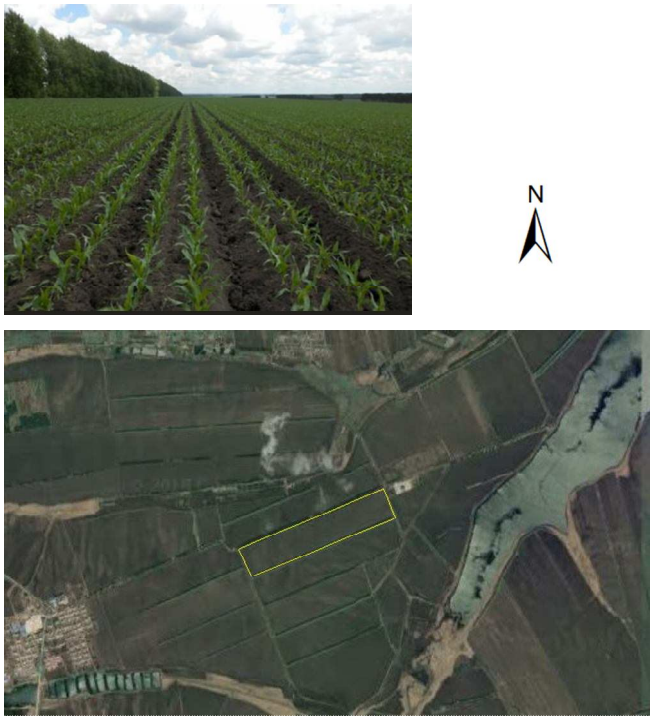

Figure 1. *Sampling area*

Data measurement and acquisition

The data of corn canopy was obtained by the ground remote sensing Greenseeker and the UAV remote sensing platform, respectively (*Fig. 2*). The ground remote sensing platform consists of six Greenseeker (Trimble, USA), Tractor (191, Valmet, Finland), Global positioning system (AG332, Trimble, USA) and VMC 1000 on-board computer (Xin Han, China). The Greenseeker was equipped with a narrow-band LED source with red light 660 nm and near-infrared light of 770 nm, which can obtain NDVI of plant canopy under two bands. It has a measurement area of 61 cm ± 10 cm (width) × 1.5 cm ± 0.5 cm (length). The Greenseeker vertical distance was 70 cm from the canopy and the detection direction was consistent with the ridge (*Fig. 2a*). The measurement accuracy of GPS receiver was centimeter level. The update rate of GS and GPS was 1 Hz. The Valmet 191 tractors with manual throttle mode and speed digital display mode has the ability to work at a constant speed. According to the actual production situation, the test set the working speed to be 9 km/h and the working area is 416000 m^2.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62696285

The UAV has a battery life of 30 minutes, and its gyroscope ensures the stability of the spectral image sensor (*Fig. 2b*). At the same time, the route can be planned to achieve automatic flight. The spectrum image sensor of the UAV was an agricultural-specific multi-spectral camera (SEQUIOA, Mica Sense, USA). It has four wavelengths, Green (540-570) nm, Red (630-670) nm, Red-edge (730-750) nm and NIR (780-820) nm, respectively. The flight height of UAV was 500 m and the measurement area was 39600 m^2.

a b

Figure 2. *Ground remote sensing platform (a); UAV remote sensing platform (b)*

Spectral image processing method for UAV

The spectral images have different degrees of distortion due to the imaging principle, external state and surface condition of the SEQUIOA spectral image sensor. The Agisoft Photoscan software was used to process and splicing spectral images of different channels. The spectral images were processed and spliced by Agisoft Photoscan software to obtain the orthophoto map of the four bands in the detection area, and RED and NIR images synthesized the NDVI images. In order to compare the different of NDVI between UAV and Greenseeker, the spectral image was split into a single zone using meshing methods (*Fig. 3*). The area of the zone was the same as that of the GS detection area. The NDVI of each zone of the spectral image was extracted and use the whiteboard to correct the coordinates of the initial zone and Greenseeker data points. Therefore, the GS-NDVI corresponds to UAV-NDVI one by one, and the difference analysis was carried out. *Figure 3* is the spectral images processing flow chart.

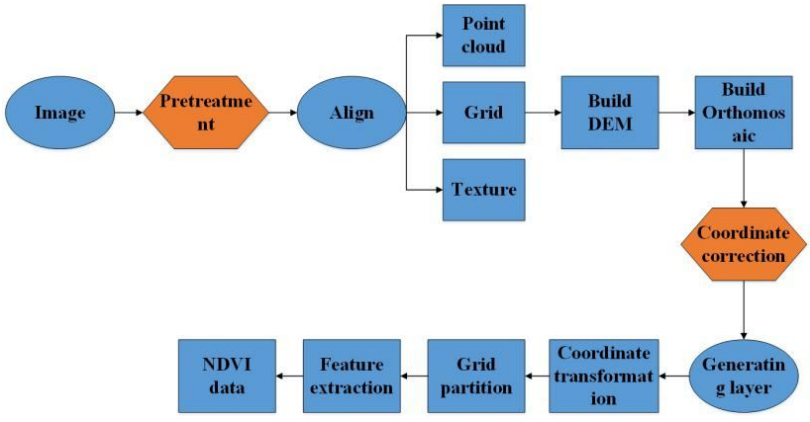

Figure 3. *Spectral images processing flow chart*

DOI: http://dx.doi.org/10.15666/aeer/1703_62696285

Partition method

The unsupervised clustering algorithm was used to divide the MANAGEMENT ZONING of variable fertilization. The purpose of clustering was to have high similarity between objects of the same category, and highly dissimilar with objects in other clusters. This study uses the following three partition clustering algorithms.

Algorithm 1: The K-mean clustering algorithm minimizes the sum of the squares of the Euler distances from the objective function x_j to the cluster center point u_i based on the randomly selected cluster number and the cluster center, and the partition was generated (Zhang et al., 2010). The function was as follows:

$$\text{argmin} \sum_{i=1}^{k} \sum_{x_j \in C_i} \left\| x_j - u_i \right\|^2 \quad \text{(Eq.1)}$$

The number of clusters was determined by *ai* and *bi* (*ai*: Average distance from *i* to other samples in the same cluster; *bi*: Average distance from *i* to samples of different clusters). The smaller the *ai*,, the more accurate classification. The smaller the *bi*, the less accurate classification (Sangalli et al., 2010). The cluster center value will collapse to its cluster data center value after the algorithm runs converged.

Algorithm 2: The fuzzy c-means algorithm obtains the membership degree of each class point to all class centers by finding the iterative minimization of the objective function, and achieves the purpose of clustering (Huang, 1998). The most commonly used objective function is:

$$J(MC) = \sum_{k=1}^{n} \sum_{j=1}^{c} \mu_{ik} d_{ik}^{2} \quad \text{(Eq.2)}$$

C was the clustering category execution matrix $c \times p$. M was the sample fuzzy membership matrix $n \times c$.μ_{ij} is the membership value of the sample attribute of the *i-th* sample to the *j-th* cluster category. φ (fuzziness exponent) is a constant that controls the degree of overlap between clustering results and categories. d^2_{ij} is the square of the distance between the *i-th* sample attribute and the *j-th* category center. The selection of the fuzzy category number C and the fuzzy weighted index φ directly affects the output of the continuous classification. The principle of φ selection is greater than 1, and 1.3 is taken here (Schepers et al., 2004; Ramchandran et al., 2015; Hassan et al., 2018). The clustering number is determined by fuzzy clustering index and normalized classification entropy. The division of the cluster was evident when the value of FPI is close to 0. NCE has similar results. The equation is as follows:

$$FPI = 1 - \frac{c}{(c-1)} \left[1 - \sum_{k=1}^{n} \sum_{i=1}^{c} (u_{ik})^2 / n \right] \quad \text{(Eq.3)}$$

$$NCE = \frac{1}{(c-1)} \left[\sum_{k=1}^{n} \sum_{i=1}^{c} u_{ik} \log_a (u_{ik}) \right] \quad \text{(Eq.4)}$$

Algorithm 3: Hierarchical Clustering divides the nearest two samples into a family, repeating the division until there is only one family left, so there was no need to specify

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62696285

the number of classes (Di Gennaro et al., 2017). The distance between the samples can be calculated by the class average method. The order of hierarchical decomposition is in the bottom-up mode.

In order to define the optimal number of clusters, the following two indices have been used to calculate the cluster validity indicators, which are the root mean square standard deviation and the R square validity index (Condorelli et al., 2018). Since the purpose of clustering is to define homogeneous groups, the lower RMSSTD value in clustering analysis is better. The value ranges from 0-1. The high value of RS indicates that there is a significant difference between the clusters, and the classification effect was better.

$$RMSSTD = \sqrt{\frac{\sum_{i=1}^{n_c}\sum_{j\in C_i}(x_j - \bar{x}_i)^2}{\sum_{i=1}^{n}(r_i - 1)}} \quad \text{(Eq.5)}$$

$$RS = \frac{\left[\sum_{j=1}^{n}(x_j - \bar{x})\right] - \left[\sum_{i=1}^{n_c}\sum_{j\in C_i}(x_j - \bar{x})^2\right]}{\sum_{i=1}^{n}(x_j - \bar{x})^2} \quad \text{(Eq.6)}$$

n_c was the number of clusters; $\bar{x}_i$ was the cluster center.

Evaluation method

Difference between GS-NDVI and UAV-NDVI

The NDVI between Greenseeker and UAV cannot be directly quantified, because the two sensors work differently, the trends were changed. Since the NDVI data is an isochronous sequence, the data only changes on the Y-axis. Therefore, the difference value of the two pairs of data was taken as a single set of random variable sample sequences. If there is no difference in the effect of the two data, the difference between each pair should be an unbiased estimator of the population mean difference. The method was T test.

Performance evaluation method for different clustering algorithms

(1) Clustering performance comprehensive evaluation parameter

The Silhouette Coefficient combines ai and bi and can be used to evaluate the impact of different algorithms or operating modes on clustering results based on the same raw data (Omran et al., 2005). It only considers dataset geometry as shown in *Equation 7*.

$$s(i) = \begin{cases} 1 - \dfrac{a(i)}{b(i)}, a(i) < b(i) \\ 0, a(i) = b(i) \\ \dfrac{b(i)}{a(i)} - 1, a(i) > b(i) \end{cases} \quad \text{(Eq.7)}$$

(2) Rationality verification of clustering method based on agronomic parameters

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62696285

According to the Site-specific fertilizer management method, a reasonable Management Zoning should have the following characteristics. The crops in the same plot have consistent growth status, and the growth status of crops between different plots have significantly different. There was a significant correlation between plant height and biomass of maize and NDVI. There the rationality of Management Zoning of NDVI was verified base on plant height and biomass of maize. The method was as follows, a multi-management partition map with location information was generated by clustering algorithms when the number of partitions is 2-6. In each plot on the map, 100 sets of sample information were collected randomly. (The height of the corn was measured by the distance of the ground to the highest stretch of all the leaves when the blade was naturally stretched. The fresh matter of the aboveground tissue was used as the corn biomass). Regression models of plant height and biomass of Maize in the same plot were established based on the total sample. The consistency of the corn growth status was evaluated by the estimated error RMSE of regression models. Based on the sample mean of plant height and biomass in each plot, comparing the differences in plant height and biomass between the various plots, and evaluating whether the corn growth status between the plots was significantly different. Through the analysis of corn agronomic parameters, the optimal clustering method was proposed to establish a reasonable management partition.

Results

Comparative analysis of differences between UAV-NDVI and GS-NDVI

A significant difference can be clearly seen between soil reflectance (1 in *Fig. 4*) and maize reflectance (2 in *Fig. 4*), and the resolution is relatively high, which shows that the NDVI based on UAV has high accuracy. Red part in *Figure 4a* stands for UAU's working area and the blue part shows the meshing. Based on the whiteboard (3 in *Fig. 4*). UAV mesh and GS mesh are in one-to-one correspondence (4 in *Fig. 4*).

DOI: http://dx.doi.org/10.15666/aeer/1703_62696285

Figure 5a shows the NDVI time series. GS-NDVI was significantly higher than UAV-NDVI, because the detection of GS is closer to the object than the UAV, and the scattering and refraction of light have less effect on GS-NDVI. The Sig > 0.05 of the two sets of data was tested by K-S, indicating that the array belongs to a normal distribution and satisfies the preconditions of the T test (*Fig. 5b* and *c*). Univariate T-tests were performed on the arrays. The results showed that the single factor variation was not significant (Sig > 0.05) (*Table 1*), indicating that GS-NDVI and UAV-NDVI had similar trends throughout the time series.

Performance comparison of clustering algorithms

The GS-NDVI of detection area was described (*Table 2*). The variation was 17.8%, which satisfies the preconditions for the precise agricultural division and implementation of MANAGEMENT ZONING.

The effect of clustering number and clustering method on partitioning results

The initial cluster number was set to 2-6 and the cluster center was randomly selected. When K-mean algorithm was applied, the bi begins to increase, but then again decreased with the increase in a number of clusters, the maximum value was reached when the number of clusters was 4. The change of ai under different cluster numbers was gentle. Therefore, when the number of clusters was 4, the K-mean clustering has a better effect (*Fig. 6a*). PFI and NCE reached a minimum when the number of clusters was 3, so the FCM optimal cluster number was 3 (*Fig. 6b*). In RMSSTD and RS, we searched the map for the critical "knee" to find out that the optimal cluster number was 3 of Hierarchical Clustering (*Fig. 6c*). According to the optimal number of clusters, the *ai* and *bi* of each clustering algorithm was calculated. Then the *Si* was explained by Formula 8. The results were shown in (*Table 3*), the *ai* and *bi* of FCM was the minimum values, it indicates the data in the cell was compact and the cell division was reasonable. However, the difference between each cell in the whole region was small, resulting in lower *Si*. The FCM clustering algorithm could not clearly describe the overall trend of NDVI, and management zone could not be accurately established. Due to the difference in the number of partitions between K-mean and HC, there was a difference between *ai* and *bi*, but *Si* were basically the same and significantly higher than FCM. Both K-mean and HC have excellent ability to create management zone. Although K-mean and HC have similar performance, but the calculation time of HC was significantly longer than that of K-mean.

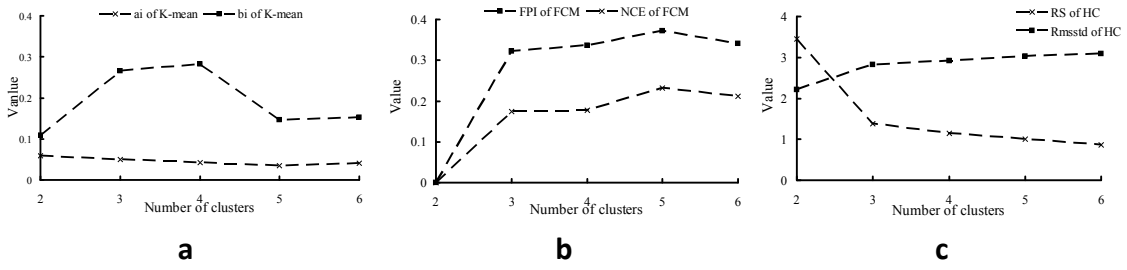

Figure 6. *The ai and bi under different clustering numbers of K-mean (a); the FPI and NCE under different clustering numbers of FCM (b); the RMSSTD and RS under different clustering numbers of HC (c)*

Table 3. *Comparison of different clustering algorithm results*

Cluster	Number of partitions	*ai*	*bi*	*Si*
FCM	3	0.0356	0.169	0.427
K-mean	4	0.0399	0.299	0.817
HC	3	0.0439	0.323	0.811

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62696285

The variation trend of RMSE of plant height under different treatments was shown in *Figure 7a*. With the increase of the number of clusters, the RMSE trend of each clustering algorithm were gentle. The RMSE of K-mean was significantly smaller than that of HC and FCM. Therefore, clustering method was more important than clustering number in estimating maize plant height. K-means performance was stronger. When using biomass data, the RMSE of each algorithm show a trend of decreasing first and then increasing with the increase of clustering number (*Fig. 7b*). The RMSE have the minimum value when the cluster number was 4, which indicates that the number of clusters was more important than the clustering algorithm in the estimation of biomass.

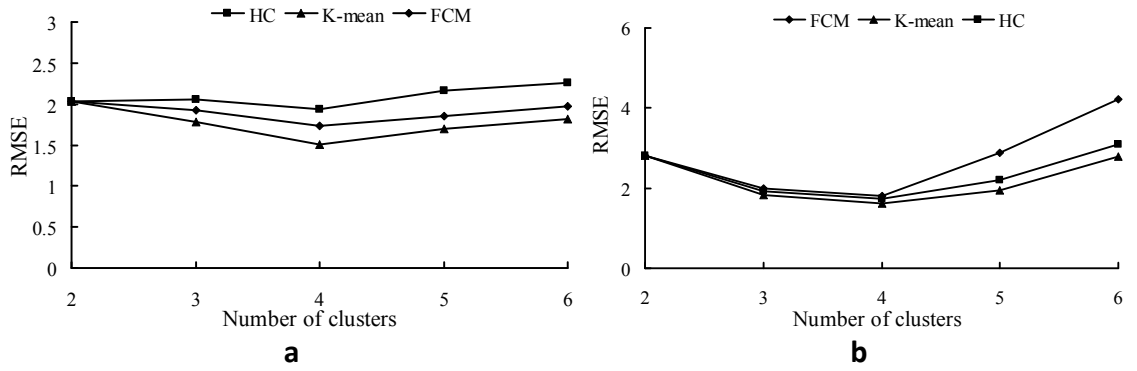

Figure 7. *Plant height and biomass estimation error of different algorithms under different cluster numbers*

The differences of plant height and fresh matter weight in different plots were shown under different clustering methods and cluster numbers (*Fig. 8*). The performance of each algorithm is basically the same when the partition number are 2 and 3, respectively. When using K-mean for partitioning, the results showed that there was a significant difference in plant height and biomass between each plot when the number of clusters was 4. As the number of partitions increases further, several plots with similar growth status of corn appeared (Same Letter), there were no significant differences in the plant height and the weight of fresh matter between them. The optimal result was still 4 partitions (*Fig. 8a*). HC was similar to K-mean results (*Fig. 8b*), but its computational complexity is significantly higher than K-mean. When using Fcm for partitioning, the partition result was similar to K-mean when the number of clusters was 6. But the SD of each plot was higher than K-mean, this indicates that the difference in corn growth in each cell of FCM has a large impact on the accuracy of the partition (*Fig. 8c*). In summary, four partitions can accurately express the population differences of corn growth status when use the K-mean.

Regression analysis of plant height and biomass was conducted by GS-NDVI. The R^2 of fitting curves of plant height and biomass were 0.8655 and 0.9002, respectively (*Fig. 9*). It shows that NDVI prediction is effective. It can be seen from the trend of the curve that the slope of the curve does not change significantly when NDVI is in the range of 0.118-0.246 and 0.658-0.792, respectively. The NDVI value with high or low cannot accurately predict corn plant height and fresh matter weight at this time.

DOI: http://dx.doi.org/10.15666/aeer/1703_62696285

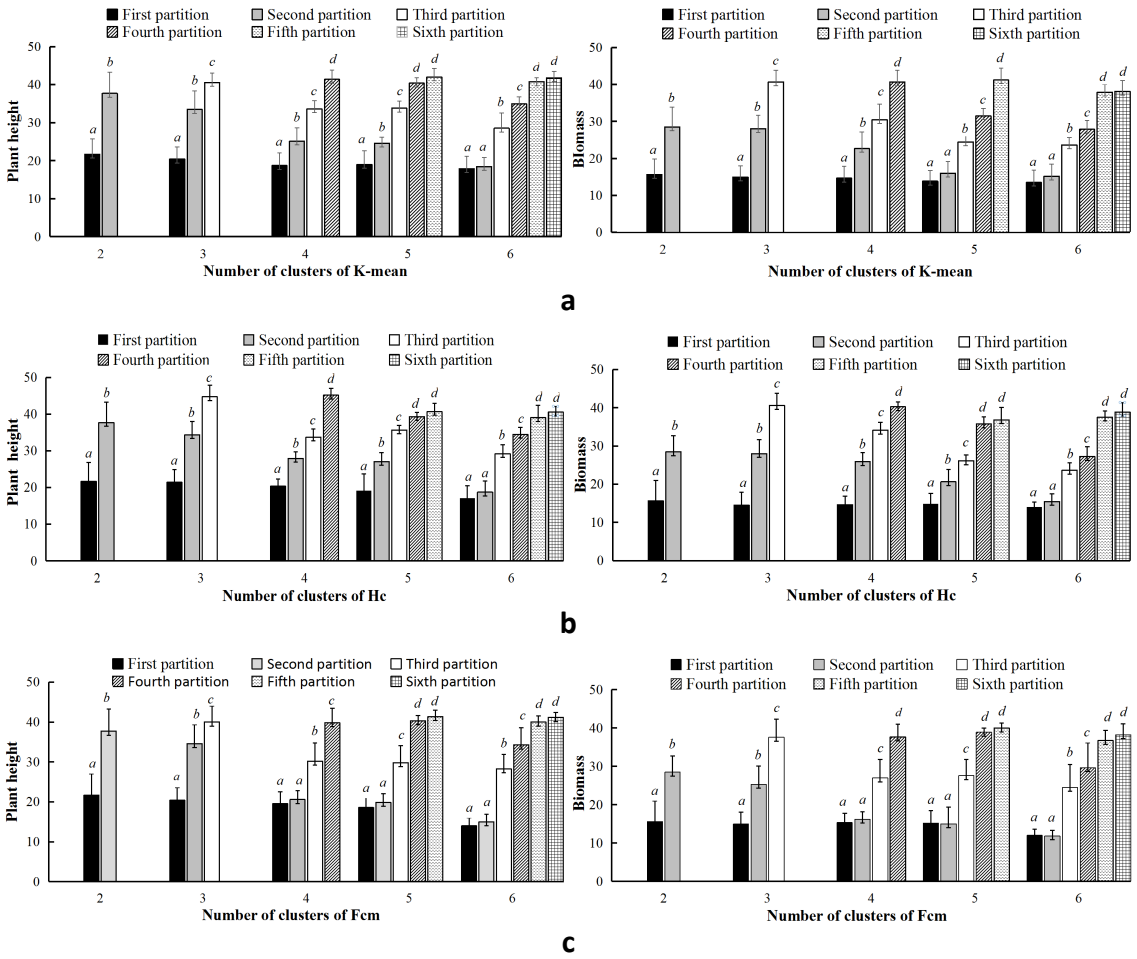

Figure 8. *The difference in plant height and biomass of each plot under different cluster numbers; K-mean (a); Hc (b); Fcm (c). Marking the same letter (such as a and ab) means that the difference is not significant, and different letters (such as a and b) are significant differences. The lower-case letters (a, b, c) indicate a significant level of f = 0.05*

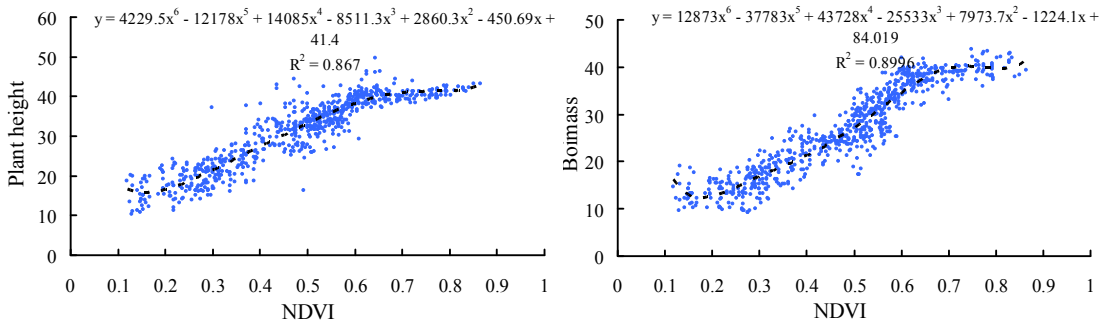

Figure 9. *Prediction models of plant height and biomass by GS-NDVI*

Four partitions can accurately express the group difference of corn growth status when using the K-mean. Although the HC algorithm can achieve better classification results, it has a large amount of computation. Distribution map of maize growth status difference was built by K-mean and 4 cluster numbers based on GS-NDVI (*Fig. 10*).

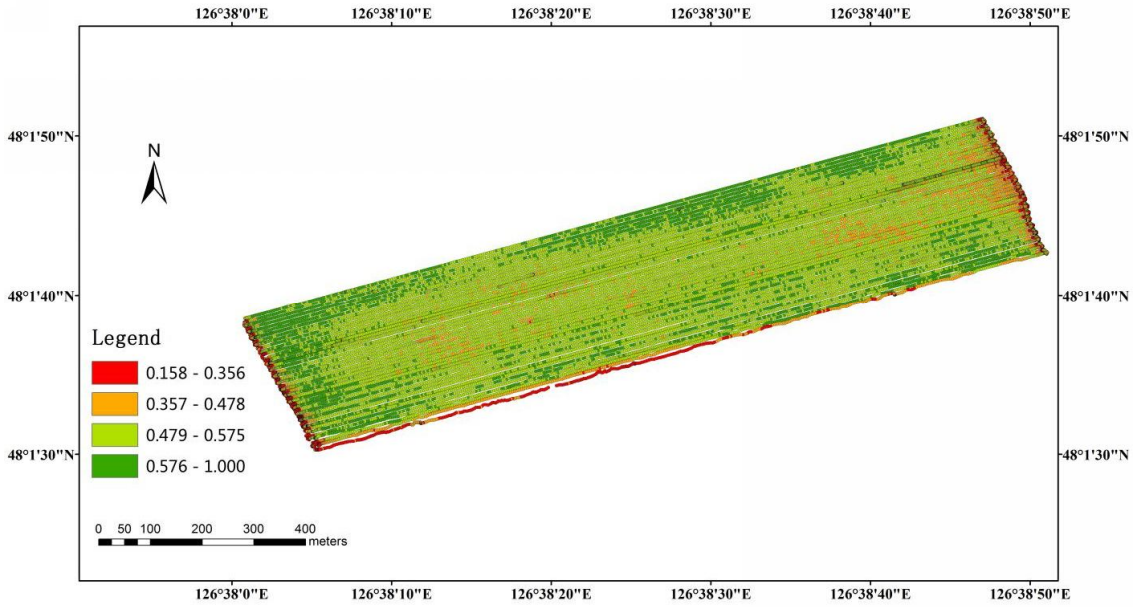

Figure 10. *Maize growth map based on NDVI*

Discussion

The definition of a specific location MANAGEMENT ZONING depends on spatial information that is stable or predictable over time. In this paper, the time series NDVI data were used to reflect the differences of maize growth. The overall variation of NDVI was 12%, and the result is similar to that of previous research (Park and Moon, 2007; Zhang and Qiu, 2012).

Due to the differences in the working methods of the platform and the sensor, there are also differences in the NDVI data obtained in the crop canopy. Previous articles have discussed the differences in large-area plant canopy NDVI data acquired by different sensors. In this investigation, the trend of GS-NDVI and UAV-NDVI time series was compared. We found that there was no significant difference in the change trend of them on the whole plot, the accuracy of large-area GS-NDVI data was proved. Existing methods for comparing NDVI differences between different types of sensors were cumbersome. For example, compare the estimation errors of nitrogen content (Caturegli et al., 2016), the correlation between NDVI and crop yield (Duan et al., 2017). The method of this study directly compares NDVI data without the need to collect large-scale crop samples and test their chemical composition and the results were satisfactory.

K-mean is more effective at expressing corn population differences than Fcm. The results is different from other studies such as NDVI data clustering based on remote sensing images (Yang et al., 2012; Bandyopadhyay et al., 2007; Cammaran et al., 2011; Glass, 2007). The reason for this difference was that the NDVI data of the spectral image is more accurate (such as using image processing, texture features, etc. to remove outliers in the NDVI). In this investigation, we select the m value of Fcm concerning spectral image clustering, but the GS-NDVI collected in real time was greatly disturbed in the field, such as the reflectance of bare soil (Ghobadi et al., 2015). There are many abnormal data, which causes the selected m value of Fcm to be unsuitable for GS-NDVI.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62696285

The effectiveness of the number of partitions can be assessed by several criteria. The measure of variance reduction of the MANAGEMENT ZONING when compared to the within-field variance can be calculated (Sarangi, et al., 2015). Alternatively, the Variable Rate (VR) fertilization nutrients was applied based on a recommendation map derived from data associated with the MANAGEMENT ZONING. Then, a cost-benefit was analyzed based on the nutrients used (input) and yield obtained (output) to evaluate the effectiveness of the number of partitions (Halcro et al., 2013). The evaluation method SC used in this study is based on the same principle as the variance evaluation method. According to the existing research, the agronomic parameters of corn under different growth conditions have significant differences. Therefore, this paper uses agronomic parameters to evaluate the accuracy of the number of partitions and determine the optimal number of partitions. In conclusion, the research methods and evaluation methods used in this paper are feasible, and the result is effective for MANAGEMENT ZONING.

Plant height and biomass are important parameters for expressing corn growth status, and NDVI has a significant relationship with them. However, the GS-NDVI values were not accurate for plant height and biomass evaluation in the lower range (0.118-0.293) and higher range (0.718-0.841). Other scholars have also obtained similar results when studying the correlation between NDVI and corn traits (Hansen et al., 2003; Yang et al., 2010, 2012). The reason for this result was due to excessive soil reflection from the corn canopy NDVI of small leaf area. Conversely, the NDVI high value appears saturated. At this time, NDVI cannot accurately estimate the corn trait.

According to K Lawton research (Lawton, 1946), the air permeability in the edge of the field was conducive to corn growth. The growth status of corn in the edge of lower left corner of experimental field was consistent with his conclusion. However, the growth status of corn in the edge of upper right corner of experimental field has poor growth. This problem may be due to the semi-sloping land, and upper right corner of the area with a low topographical position, the water stress affecting the growth of the corn. The corn in the lower edge of the field near the windbreak was poorly grown. According to the research of Reynolds et al. (2007), tree competition significantly reduced corn photosynthetic radiation (PAR), net assimilation (NA), and individual growth and yield. Relevant scholars have also researched the reasons for the difference in growth in other locations, but there is no unified answer at present.

Conclusions

The comparative method of NDVI time series trend was proposed to Indicate the effectiveness of the large-area NDVI of Greenseeker was worthy of recognition. At the same time, the optimal partition method of NDVI for management zone based on plant height and biomass of maize was discussed. The plant height evaluation accuracy results show that the contribution of cluster algorithm is greater than the number of partitions. The opposite result of biomass performance. When the number of partitions is 4, a reasonable management partition map of NDVI was established based on K-mean.

In this paper, based on the NDVI data of Greenseeker, a reasonable management partition was established by clustering method, but data is processed offline. Therefore, the future research focuses on the development of online clustering methods. Develop a more intelligent and simple management partition real-time creation method.

Abstract. Most of literature on water deficit and water logging tolerance and resistance in faba bean, have not be widely studied. Therefore, it is important to study the different plant responses to these abiotic stresses to understand the mechanisms of tolerance. Towards this goal faba bean plants were cultivated in soil culture at different levels of field capacity, FC (Control), 2FC (flooding), 75% of FC, low water deficit (LWD) and 50% of FC, high water deficit (HWD), for 2 weeks. Fresh and dry weights of plant roots and shoots were significantly decreased under both water stresses (flooding and water deficit). Number of plant nodules was affected as exposed to high and low water deficit levels (75% & 50% FC) by about 47% and 5%, respectively. Alcohol dehydrogenase specific activity of bean roots grown under flooding stress was significantly increased as compared to absolute control while the specific activity of alcohol dehydrogenase activity (ADH) under the two levels of drought (75% & 50% FC) was less affected as compared to reference control. Also, Michael's constant (K_m) and maximum velocity (V_{max}) of ADH in bean roots was decreased under the two levels of drought (75% & 50% FC) and flooding stress (2FC) compared to absolute control. Transfers cross sections stained with safranin examined and photographed at 25 X of 3-weeks old roots of flooded faba been plants showing loosely parenchymal cell of cortex containing many and large intercellular spaces as compared to control and droughted plants. We concluded that flooding cause damage to *Vicia faba* plant more than water deficit through its effects on nodule formation and activity.
Keywords: *water stress, legumes, alcohol dehydrogenase activity (ADH)*

Introduction

Abiotic stress is a major constraint for agricultural production allover the world and drought is the most important limiting factor (Asgher et al., 2017; Hussain et al., 2018). Water deficit and flooding stresses have a negative impact on the living organisms in a specific environment (Armstrong, 1971a, b; El-Enany et al., 2014). The combination of environmental stresses always leads to cellular damage and causes a series of morphological, physiological, biochemical and molecular changes in plant growth, development and productivity (Gao et al., 2007; Mittler et al., 2006). Boyer (1982) and Araus et al. (2002) stated that exposure to water deficit or waterlogging stresses cause metabolism disturbance and damage to biomolecules. Frequent occurrence of climatic extremes water deficit and/or flooding every year in several parts of the world has adversely affected production of may crops (Candian and Tarhan, 2012). As a result, water deficit and waterlogging of the soil have become apparent in crop yields (Parent et al., 2008; Ashraf and Irm, 2005). Plants respond to environmental stresses at morphological, anatomical, cellular and molecular levels, leaf development (Cutler et al., 1980), maintain root development and soil moisture extraction and delayed leaf senescence (Hsiao et al., 1985).

Waterlogging process often prevents plant productivity by inhibiting oxygen diffusion to the roots (Sorrell et al., 2002). The anatomical structure of the roots is important to adapt to anoxic environments for wetland types (Sorrell et al., 2002; Colmer, 2003). Also, some advanced research has shown that the response of plants to waterlogging may be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62876298

due to roots morphology modifications like thickness of root, absence of lateral roots and reduction in root system (Wheeler, 1999; Visser et al., 2000; Romeu et al., 2019). Root propagation is important for plant growth, and the ability of nutrient acquisition depend on root length and structure in heterogeneous environments (Wahl et al., 2001). Vartapetian and Jackson (1997) stated that growth of roots under hypoxia or oxygen deficiency leads to confusion in oxygen-dependent pathways, especially the power generation system, functional relationships between roots and stem and both carbon absorption and photosynthesis. Wetland plants adapt to anaerobic conditions by formation of air roots containing intensive aerenchyma cavities to promote internal oxygen transport (Jackson and Armstrong, 1999; Visser et al., 2000; Colmer, 2003). Lysigenous and schizogenous aerenchyma disturbed in many important crop plant species and tissues (Justin and Armstrong, 1987; Jackson and Armstrong, 1999; Gunawardena et al., 2001). Also, schizogeneous aerenchyma was recorded in some wetland species like *Rumex palustris* and *Ranunculus sceleratus* (Visser et al., 2000). Some species such as *Sagittaria lancifolia* tend to form both schizogenous and lysigenous aerenchyma (Schussler et al., 1997). Our objective was to study the response of growth, nodulation, nodule activity and anatomy of faba bean plant roots under the effect of both water stresses (water deficit or waterlogging). Also, this study aimed to compare the differential response of *Vicia faba* plants to water deficit and waterlogging.

Materials and methods

Surface sterilized seeds of faba bean (*Vicia faba*) plants were conducted at the greenhouse chamber. Ten seeds were sown in culture pots containing 3 kg clay (Three pots for each treatment) and treated as follow. The pots were irrigated with tap water until reach field capacity is referred as control. Two weeks old seedlings were subjected to the following treatment: First group of pots irrigated until reach flooding, 2 FC (WL), second group of pots were irrigated till reach 75% of FC (LWD) and the third group of pots irrigated tell reach 50% of FC (HWD) for two weeks. At the early vegetative stage and after 2-weeks of treatments, plants were separated into roots and shoots. Results of fresh and dry weights of the roots and shoots will be recorded. Another part of fresh roots and shoots were stored in liquid nitrogen and stored at – 80 °C for experimental analysis. Nodule number, nodule fresh and dry weights were recorded. The activity nitrogenase enzyme was measured as described previously by Abd-Alla (1992) using the method recorded by Larue and Kurz (1973). Save each bottle at room temperature with 5% (T/T) acetylene for 1 hour and the emitted ethylene in the reaction bottle was measured by a gas chromatograph (Thermo Scientific TRACE GC Ultra equipped with FID detector). The enzyme activity was calculated as the μmol acetylene/h/g nodule fresh weight. Determination of nodules leghemoglobin was recorded after 45 days of plant growth by the method of Becana et al. (1986). One gram of detached nodules were ground in a mortar and pestle under cooling and macerated with 2 ml KCN, then centrifuged at 10,000 rpm for 30 min in a refrigerated centrifuge. The supernatants were reduced with sodium dithionate and the absorbance was recorded at 540 nm. Oxhemoglobin was used as a standard for calculations.

Alcohol dehydrogenase activity and its kinetics

0.5 g of leaf tissues were mined in 5 ml of 100 mM K-phosphate buffer (pH 7.8) containing 0.1 EDTA and 0.1 g polyvinylpyrrolidone. The mixture was centrifuged at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62876298

15,000 rpm for 15 min and the supernatants were used for measuring the activity of alcohol dehydrogenase enzyme (ADH). The enzyme activity was measured by monitoring NADH oxidation at 340 nm according to Yamanoshita et al. (2005) and modified by Govinda and Shanta (2011). The reaction medium was activated by addition of different volumes (50, 100, 150 and 200 µl of 2.4 mM NADH and extract) and the reaction was initiated with 0.3 M acetaldehyde.

Root anatomy

Five root sections were collected from different plant treatment and immediately fixed in 2% paraformaldehyde, 2% glutaraldehyde, and 100 mM sodium cacodylate buffer, pH 7.35 for sectioning. Fixed prepared tissues were then rinsed with 100 mM sodium cacodylate buffer (pH 7.35) containing 10 mM 2-mercaptoethanol and 130 mM sucrose. These sections were stained using Sato's triple lead solution stain and 5% aqueous uranyl acetate (Sato, 1968). After infiltration with Spurr's resin (Spurr, 1969) and polymerization, ultrathin sections (60–90 nm) were cut with an ultramicrotome, contrasted with uranyl acetate and lead citrate, and examined with a transmission electron microscope (JEOL TEM 100 CXII, Electron Microscope Unit, Assiut University).

Statistical analysis

One-way ANOVA using the SPSS 10.0 software program. Means and standard errors were calculated for three replicate values. Means were compared by the Duncan's multiple range test and statistical significance was determined at 5% level.

Experimental results

Growth criteria

Faba plants grow under **c**ontrolled conditions did not show any symptoms of leaf damage over the longest experimental period. Waterlogging stress induce visible leaf damage was apparent after 20 days of planting, like midrib yellowing, leaf yellow spots and finally wilting, their progression was very rapid. The results of roots and shoots of bean plants grown under water logging and water deficit stresses are presented in *Figure 1*. These results indicate that the stress of water deficit significantly reduced the fresh and dry weights of the roots and shoots of faba bean plants, especially developing at high droughted level (50% FC).

Both stresses flooding and high water deficit reduced significantly the total biomass of faba bean (*Vicia faba)* plants. Water deficit level (50% FC) significantly reduced roots fresh and dry weights more than low water deficit level (75% FC) as compared to control plants. Whereas, roots dry weight of flooded treatment was seems higher and this sometimes occurs at least in part as the result of initiation of several new lateral roots under flooding condition on the sub- merged part of shoot.

Number of nodules

The results of nodule number are presented in *Table 1*, these results showed that the levels of drought (75% & 50% FC) was significantly lowered the number of nodules per plant by about 5% and 47%, respectively. Also, the waterlogging stress significantly decreased the number of nodules by about 52.2%.

Nodule leghemoglobin content

Table 1 showed that the number of nodules significantly reduced at highest level of drought (50% FC) and flooding (2 FC). Also, nodule leghemoglobin content was decreased significantly as a result water stress imposed to the both levels of drought (75% & 50% FC) and flooding. The percentage of reduction in nodule leghemoglobin content of root nodules was 81% and 63% respectively. The results also showed that, nodule leghemoglobin content was decreased significantly under waerlogging.

The results in *Table 1* revealed that the activity of nitrogenase enzyme was significantly decreased especially at the level of 50% FC. The percentage of decrease was reached 85%. Also, the data showed that, a significant decrease in the activity of nitrogenase enzyme in faba bean under flooding treatment.

ADH activity and kinetics

Alcohol dehydrogenase (ADH) activity and specific activity are presented in *Figure 2*. The data expressed as Δ abs. at 340 nm min^{-1} mg^{-1} FW and Δ abs. at 340 nm min^{-1} mg^{-1} protein, respectively. The specific activity of ADH (Δ abs. at 340 nm min^{-1} mg^{-1} FW) of plant roots grown under flooding treatment was increased as compared to control. Whereas, the activity and specific activity of ADH enzyme was significantly decreased under the two level of water deficit (75% and 50%FC) as compared to absolute control.

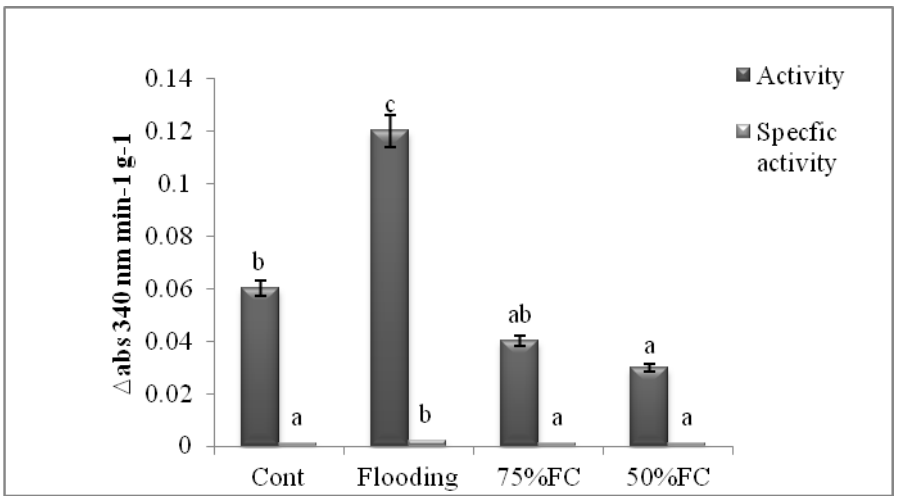

Figure 2. *Alcohol dehydrogenase activity (Δ abs. at 340 nm min^{-1} mg^{-1} FW) and specific activity (Δ abs. at 340 nm min^{-1} mg^{-1} protein) of faba bean plant roots grown under the different level of field capacity. The same letters indicate non-significant differences between treatments at $P < 0.01$*

Lineweaver-Burk plots for Alcohol dehydrogenase (ADH; EC 1.11.1.11) enzyme that was extracted from roots of bean plants grown under flooding and drought are result in the production of lines with different slops and intercepts for ADH activity which presented in *Figure 3*. The intercepts on X-axis (K_m), intercepts of y-axis (V_{max}) and Kcat of the different lines. Michael's constant (K_m) and maximum velocity (V_{max}) of ADH in roots of bean plants grown under both level of drought (75% & 50%FC) of treatments were decreased as compared to absolute control.

Anatomy of root

Transverse sections of plant roots grown under high water deficit and flooding compared to control plant were investigated (*Fig. 4*). The photos showed that aerenchyma was found in the T.S root tested plants under flooding stress as shown in *Figure 4* as compared to plant control. However, under drought we found accumulation of solutes in the parenchyma cells compared to plant control, but didn't recorded in bean plants as shown in the same *Figure 4*. A cross section of control plants section of central tissue cells contains normal parenchymal cells. B-Cortical tissue showing compact parenchymal cells with few intercellular spaces. C- Cortical cells showing loosely parenchymal cell containing many and large intercellular spaces (aerenchyma).

Discussion

The effectiveness of WL and WD on roots and shoots growth of tested faba bean plants are shown in *Figure 1*. The results showed that water stress (WD or WL) significantly reduced the fresh and dry weights of the roots and shoots of faba bean plants, especially when the water shortage reached (50% FC).

Waterlogging and high water deficit stresses significantly decreased the total biomass of faba bean (*Vicia faba)* plants grown under the both stresses. These data are in agreement with many investigators (Sorrell et al., 2000; Chen et al., 2002). Water stress affects the growth of plant organs by alteration of morphological features of the plants (French and Turner, 1991; Cox and Conran, 1996). The mechanisms involved in the adaptation of plants to water deficit is the change in root to shoot dry mass ratio (Turner, 1997; El-Enany et al., 2013). The reduction in water availability results in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62876298

growth inhibition, reduced shoot and root growth of bean plant. Reduction in tissue dry weights during drought stress may be due to decrease in plant growth, photosynthesis, cell expansion and cell division (Sundaravalli, et al., 2005; Rodriguez et al., 2008).

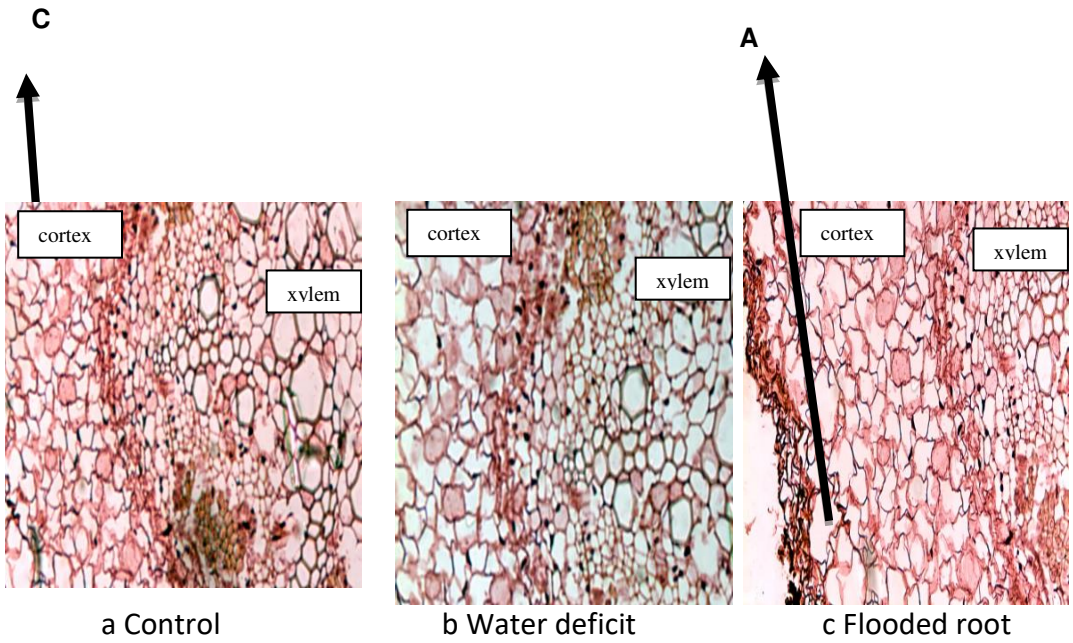

Figure 4. *Transfers cross sections of 3-weeks old of faba been roots stained with safranin examined and photographed at 25 X. A: aerenchyma resulted from lyses of some cortex parenchyma as compared to C: normal cortex in control roots*

Our results indicated that the no. of nodules per plant was significantly decreased under both drought and flooding (*Table 1*). Streeter (2003) and González et al. (2010) concluded that the severely effects on nodulation occur during the establishment of the symbiosis and formation of nodules. Many studies have shown that water deficit negatively affects the stabilization of biological nitrogen fixation by reducing the number of nodules and the activity of nitrogen fixing enzymes (Abd-Alla et al., 2001; Ashraf and Iram, 2005; Christophe et al., 2011; Silvente et al., 2012). In addition, stress may reduce the invasion of leguminous plant roots by living rhizobia in the soil (Latrach et al., 2014; Mouradi et al., 2016). Charlson et al. (2009) reported that the nitrogen fixation in legume plants reduced under drought stress and may due to (i) the accumulation of ureides in both nodules and shoots, (ii) minimize in shoot nitrogen demand, (iii) reduce transpiration rate and thus lower xylem translocation rate and (iv) the decline of metabolic enzyme activity.

Table 2 showed that nitrogenase activity was significantly affected by drought and flooding, This may be due to lowered oxygen diffusion to the bacteroids, thus depressing nodule respiration and consequently nitrogenase activity (Guerin et al., 1990). This process usually involves increased production of oxygen free radicals species such as H_2O_2, O_2, and $OH^{\cdot}$ (Becana et al., 1986). Legume nodules possess a number of enzymatic mechanisms to minimize the toxicity of active oxygen species, including superoxide-dismutase, catalase and peroxidase (Becana et al., 1986). Inhibition of the nitrogen-fixing activities of nodules by waterlogging may by the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62876298

decreased by the bacteroids synthesis of nitrogenase (Bisseling et al., 1980), or by minimizing carbohydrate metabolism of host tissue in the nodule and/or decline in leghemoglobin content (Huang and LaRue, 1985). Higher leghemoglobin content was observed in the nodules of waterlogged plant (*Table 2*) and this may be facilitates the diffusion of oxygen from the nodule surface to the bacteriod and increase biological nitrogen fixation. This was also observed by Huang and LaRue (1985).

Table 2. *Vmax and Km and Kcat and Km/Kcat of alcohol dehydrogenase activity (ADH) of faba bean plant roots grown under water deficit and waterlogging*

Treatments / Parameters	Faba bean plants			
	Cont.	**Flooding**	**75% F.C.**	**50% F.C.**
Vmax	3.13	0.06	0.18	0.21
Km	12.42	0.07	1.55	1.50
Kcat	62.50	1.15	3.67	4.19
Km/Kcat	0.20	0.06	0.42	0.36

The results in *Figure 3* show that waterlogging activate alcohle dehydrogenase activity in roots more than shoots, whereas its activity not affected under different levels of water deficit. These results are consistent with Kato-Noguchi and Morokuma (2007) and Yamanoshita et al. (2005) who observed that waterlogging stimulates sugar fermentation by stimulating the activity of dehydrogenase of roots. Also, (Kang et al., 2009) found that activation of ethanolic fermentation was found in bean and cowpea plant to survive anaerobiosis and considered one of the strategies for growing cucmber seedling under waterlogging. The survival of seedling for many days of waterlogging may due to the oxygen available to roots through aerenchyma (Nada, et al., 2004; Yin et al., 2010). Aerenchyma formation is an important way to increase oxygen penetration from the shoots to the roots, and is essential for maintaining air diffusion, to provide a source of energy for alcoholic fermentation.

The results in *Figure 4* show that formation of aerenchyma in plant roots grown under waterlogging treatment as compared with control plants. Whereas, plan roots sections appear a narrow cortex cells for faba bean plants grown under high water deficit as compared by control plant root. These results are in accordance with many investigators (Ashraf, 2003; Voesenek et al., 2006; Justin and Armstrong, 1987). Jackson and Armstrong (1999) showed that the improvement of the aeration of the rhizosphere in plants grown under flooding induced by formation of aerenchyma. Drew et al. (2000) stated that there are two different processes in plants to form aerenchyma schizogeny or lysigeny, or by their combination. Schizogenous aerenchyma involves cell wall reorganization and cell separation, whereas lysigenous aerenchyma formed by cell death) and cell wall autolysis (Gunawardena et al., 2001; Evans, 2003). Suralta and Yamauchi (2008) and Joshi and Kumer (2012) explained that the formation of aerenchyma tissue may facilitate oxygen aggregation in submerged tissues and reduce hypoxia of waterlogged seedlings. Larger intercellular spaces formed in faba bean plants may improved the plant's capacity for oxygen aggregation and exchange gases within the submerged parts of plants.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62876298

Conclusion

Faba bean plant is significantly affected by water deficit and waterlogging during the vegetative stage. Our data stated that the flooding cause damage to *Vicia faba* plant more than water deficit through its effects on nodule formation and activity. The findings of current study support previous conclusion that ADH enzyme activity and root anatomy can be used as a bioindicator for waterlogging or water deficit stress in legume plants and thereby playing an important role in flooding stress tolerance and signaling in crop plant.

Abstract. In this study, evidence for antagonism of antifungal metabolites produced by *Bacillus amyloliquefaciens* Y1 was described, as they actively inhibit growth of *Fusarium graminearum* under *in vitro* and *in vivo* condition. The culture supernatant and crude butanol extract inhibit the mycelial growth of *F. graminearum*. In addition, an antifungal compound was purified from the metabolites of Y1 and identified as cyclo(L-Pro-D-Tyr) using ^{1}H and ^{13}C NMR spectroscopic analysis. For the first time, cyclo (L-Pro-D-Tyr) displayed potent antifungal activity against *F. graminearum* under *in vitro* condition. The hyphae of this fungal pathogen became deformed with cyclo(L-Pro-D-Tyr). Exposure of *F. graminearum* to various concentrations of cyclo(L-Pro-D-Tyr) on wheat seeds significantly inhibit fungal colonization. Furthermore, during *in vivo* wheat pot experiment, Y1 results in 27% higher total yield and showed a protective effect against *F. graminearum* by reducing low discoloration symptoms on stems. The grain yield per pot was five times higher compared to control pots (water only) infected with *F. graminearum*. To our knowledge, the antifungal activity of the cyclo(L-Pro-D-Tyr) is reported for the first time against the plant pathogenic fungus *F. graminearum.* The present study demonstrated the potential of *B. amyloliquefaciens* Y1 as a biocontrol agent against the wheat crown rot fungal pathogen as well as a plant growth promoter for wheat.
Keywords: *biological control, wheat disease, chemistry, antifungal, pathogen*

Introduction

Two major destructive fungal diseases that posing a serious threat to wheat cultivation and production are head blight and crown rot caused by the mycotoxin-producing fungal pathogen *Fusarium graminearum. Fusarium* crown rot (FCR) is characterized by dry rot of crown, necrosis of root tissue and basal stem, and limited grain yield. *Fusarium* crown rot has never gotten much attention as it is mainly considered to be limited in its geological distribution, but according to latest reports, it occurs in many cereal producing regions (Smiley et al., 2005 a,b). A severe intensive infection can result in more than 50% yield loss, and reduced grain quality. It is known that this fungus is harmful to animals and humans because it produces several mycotoxins in wheat such as zearalenone (ZEA) (Cowger and Arellano, 2013) and deoxynivalenol (DON), that can cause embryotoxic, neurotoxic, immunosuppressive and teratogenic effects (Cowger and Arellano, 2013; Pestka, 2007; Pestka and Smolinski, 2005).

Conventional methods such as crop rotation and inter-row sowing can be used to control diseases caused by *F. graminearum*. Crop rotation is effective, but there are also economic limitations, as *F. graminearum* can reside inside the stubble for several years (Burgess, 2005). The recent reports revealed that there is a remarkable reduction in the *Fusarium* crown rot (FCR) damage due to inter-row sowing (Simpfendorfer et al., 2012). Due to limitations, FCR has recently been reported in cereal-growing regions. Moreover, chemical management is effective but the application of chemicals such as acephate, carbendazin, chlorothalonil, chlopyriphos, Dichlorodiphenyltrichloroethane (DDT), and diazinon causes environmental pollution, affects human health, and enables pathogens to build resistance to these chemicals (Baldwin and Rathmell, 1988). Few studies have been done about the losses caused by *F. graminearum* and more information is needed to manage this pytopathogenic fungus through the application of antagonistic microorganisms (Palazzini et al., 2016).

Several bacteria are available commercially including strains of the genera *Pseudomonas* and *Bacillus*, and have been used successfully as alternative to chemical pesticides in crop production (Choudhary and Johri, 2009). *Bacillus* species are among the most important bacteria that can be most promising for plant protection (Pérez-García et al., 2011). Their most notable characteristics include their ability to survive for extended periods of time, their spore formation, the wide range of biochemically active molecules that can significantly inhibit phytopathogen growth and ease of formulating their commercial products (Broggini et al., 2005). *Bacillus subtilis, Bacillus amyloliquefaciens* and *Paenibacillus polymyxa* mostly found in soil are considered to be safe for use in environment and with mammals (Stabb et al., 1994; Zhao et al., 2015). Two new cyclic lipopeptides (3 and 4) were isolated from the culture filtrate of *Bacillus amyloliquefaciens* strain SD-32, together with two known metabolites, iso-C15 and iso-C16 bacillomycin D (Tanaka et al., 2014). They can provide higher protection to plants (Falcäo et al., 2014; Krebs et al., 1993), because of their antifungal and antibacterial activities against several phytopathogens (Ben Abdallah et al., 2015; Krebs et al., 1998). They produce various types of secondary metabolites (antibiotics) (Asaka and Shoda, 1996; Stabb et al., 1994) and most of them have been identified as low molecular weight dipeptide or cyclic peptides (Dolej and Bochow, 1996; Nakano and Zuber, 1990; Vanittanakom et al., 1986). Among cyclic peptides, diketopiperazines (DKPs) are relatively simple cyclic dipeptides consisting of two α-amino acids produced by bacteria, fungi, mammals, and plants (Ström et al., 2002).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62996314

More attention has paid to study about diversity and biological roles of more than 100 DKPs found in nature (McCleland et al., 2004). Four DKPs from *B. thuringiensis* strain and two from *B. endophyticus* demonstrated their antifungal activities (Sansinenea et al., 2016). Beside their antimicrobial properties, cyclic peptides are involved in root colonization and the systemic stimulation of immune system of the host plant (Ongena and Jacques, 2008). In general, the activities of cyclic peptides from *Bacillus spp*. against fungal phytopathogens have been frequently described. Synthetic DKPs has also been reported to have antibacterial and antifungal activities (Graz, 2002; Pitchen, 2002).

The present study was aimed to evaluate antifungal potential of *B. amyloliquefaciens* Y1 against *F. graminearum* under *in vitro* and *in vivo* condition. In addition, identification of an antifungal compound may have a role in its probable mechanism to control *Fusarium* crown rot in wheat.

Materials and methods

Microorganisms and culture conditions

B. amyloliquefaciens Y1 was isolated previously with accession number KP967704. *Fusarium graminearum* KACC 41040, was obtained from Korea Agriculture Culture Collection (KACC). For *in vitro* and *in vivo* study, a spore suspension was prepared by growing *F. graminearum* in carboxymethyl cellulose (CMC) broth at 25 °C in shaking incubator for 10 days.

Antifungal characterization

Antifungal activity of culture supernatant

Antifungal activities were detected by growing strain Y1 in Luria-Bertani 33 (Palazzini et al., 2016) broth at 40 °C for 7 days at 170 rpm. The culture broth was centrifuged at 7,000 × g for 20 min. The supernatant collected was filtered through Whatman filter paper No. 2 (0.45 μm) and finally with 0.20 μm syringe filter. The resulting supernatant was mixed with sterile PDA to make final concentration of 0, 10, 30, and 50%. A 5 mm diameter mycelial plug of *F. graminearum* from a 7-days-old culture was placed in the centre of the PDA plate and incubated at 28 °C in the dark. Mycelial growth was measured as colony diameter of *F. graminearum* hyphae after 6 days inoculation and growth inhibition percentage were evaluated by using the following formula:

$$\text{Growth inhibition percentage (GI \%)} = [(R - r) / R] \times 100$$

where R is the radius/ diameter of the colony on the control plates and r is the radius of the colony on the treatment plate. Experiment was carried out in triplicate and repeated three times.

Antagonistic activity of bacterial crude extract against the plant pathogens

Strain Y1 was inoculated into the LB broth at 40 °C for 10 days. The pH of Y1 culture broth was adjusted to 3 using concentrated HCl and used to obtain the crude extract by active fractionation (1:1, vol/vol) with an eluotropic series of solvents: ethyl

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62996314

acetate and n-butanol. The partially isolated butanol solvent was concentrated through a rotary evaporator to get crude extract (48 g) (Büchi, Rheinstetten, Germany). A 20% stock solution of crude extract was prepared. From the stock solution, 3, 4 and 5 mg was added on paper disc to check antifungal activity against *F. graminearum*. A 5 mm diameter mycelial plug from 7 days old culture was placed in the centre of the PDA plate. The control consists of an equal volume of methanol added to another paper disc on the same PDA plate. Mycelial growth was measured as colony diameter of *F. graminearum* and growth inhibition was evaluated by using the following formula:

$$(GI\ \%) = [(R - r)/R] \times 100$$

where R is the radius/diameter of the fungal growth towards the paper disc on the control side and r is the radius of the fungal colony growth towards the paper disc on the treatment side. Experiment was carried out in triplicate.

Extraction and purification of the antifungal compound

The butanol crude extract (48 g) was prepared from cell free culture supernatant (36 L) of strain Y1 and was dissolved in methanol and subjected to silica gel column chromatography (Kieselgel 60, 70-230 mesh, Merk, Darmstadt, Germany) with stepwise elution of $CHCl_3$: MeOH (100:0, 90:10, 70:30, 40:60, 50:50, and 0:100; v/v). Total of 3L solvent was used in each step of elution. The vacuum (EYELA rotary vacuum evaporator) was used to concentrate all fractions to a semisolid mass, and each fraction was assayed for antifungal activity. The bioactive fraction $CHCl_3$: MeOH (100:0) was further purified by HPLC (high-performance liquid chromatography) using a system with a PrepHT C18 column (7 × 300 mm, 10 µm). The SPD-10 UV-VIS detector (Shimadzu, Japan) was used to monitor elution with manual injection at 210 and 254 nm using acetonitrile and water as a mobile phase (35:65) at a flow rate of 2 mL/min. All peaks were collected and concentrated using a centrifugal evaporator (Hanil Scientific Inc, South Korea) at 40 °C. The purities of the collected fractions were further analysed using an HPLC analytical C18 column (5 µL, 4.6 × 250 mm). The pure compound with a single peak was used for antifungal activity. The active compound was used for further structural analysis.

Identification of the purified antifungal compound

The ^{1}H and ^{13}C nuclear magnetic resonance (NMR) was used to determine the structure of the purified compound. Briefly, the purified antifungal compound (approx. 12 mg) was dissolved in 0.6 mL methanol-*d*4 (CD_3OD) and used for spectral analysis. NMR spectra were recorded on a DRX 500 NMR instrument (Bruker, Rheinstetten, Germany) operating at 500 MHz for ^{1}H and 125 MHz for ^{13}C at room temperature. Chemical shifts are reported in ppm (δ) using CD_3OD as the solvent (unless otherwise indicated) and tetramethylsilane $(CH_3)_4Si$) as an internal standard.

Determination of antifungal activity of the purified compound and its effect on hyphal deformation

The purified compound was assayed against *F. graminearum* growth. A 4% stock solution of the purified compound was prepared in methanol. A total of 1000 µL (a mixture of 300 µL conidial suspension + 700 µL CMC broth) was added to each well of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62996314

a 24-well microplate except for the first well, which contained 600 µL of the conidial suspension of *F. graminearum* (4×10^6 spores/mL) and 1300 µL CMC. After addition of the conidial suspension, 100 µL of the compound was added to the first well. Further, serial dilution was performed to obtain the desire concentration of 2000, 1000, 500, 250, 125, 62.5, 31.25, 15.625, 7.81, 3.90, and 1.95 ppm in each well. The conidial suspension of *F. graminearum* and methanol were used as a control. The well plate was kept for one h in clean bench to evaporate methanol. The direct effect of the antifungal compound on hyphae was examined using light microscope (Olympus BX41TF, Japan).

Assessment of the purified compound to control F. graminearum on wheat seeds

Wheat seeds (n = 30) per treatment were immersed in 100 mL of DW (distilled water) for 1 h, followed by immersing 1 min in a dilute solution of NaOCl (sodium hypochlorite) for surface sterilization. They were then washed with distilled water and placed in petri dish to dry. Solutions of the purified compound at various concentration were prepared in methanol using serial dilution to obtain serial doses (2000, 1000, 500, 250, 125, 62.5, 31.25 ppm). Then, wheat seeds were soaked for 1 h in various concentration of compound and left in open petri dish to evaporate excess methanol. Seeds soaked in methanol were used as a control. A spore suspension of *F. graminearum* was prepared (4×10^6 spores/ml) and approximately 10 µl of the spore suspension was spread on each wheat seed. The inoculated wheat seeds were incubated at 28 °C on moisten cotton in petri dish, and the inhibition of fungal growth was recorded as white mycelia appeared on all seeds (30 = 100%) in the control treatment. All tests were performed in triplicate.

Glasshouse experiment

The growth promotion and biocontrol effect of strain Y1 in wheat plants were also focused. Two types of pot experiment were performed in a greenhouse at Chonnam national university, South Korea. A glasshouse potting mix was prepared by mixing soil, sand, vermiculite, and compost at a ratio of 2:1:1:0.04 (v/v), respectively. The soil was air-dried and ground to pass through a 2-mm sieve and mixed thoroughly. The potting mixture was transferred to 20 L pots containing 20-25 kg soil. A total 60 seeds per pot were sown in four rows. In one type of pot experiment, at two weeks interval, after 14,28, and 42 days of seeds sowing, each pot was amended by pouring 300 ml of water, or fertilizer media (M) (KH_2PO_4 0.08 g, KCl (0-0-60) 0.02 g, K_2SO_4 0.1 g, $CaCl_2$ 0.1 g, water soluble fertilizer 2.66 ml, blue fertilizer (20-20-20-2, 4g) per litre of water) or Y1 culture grown for 7 days at 40 °C in media known as BB media (chitin 0.5 g, gelatin 0.5 g, Yeast 0.1 g, KH_2PO_4 0.08 g, KCl (0-0-60) 0.02 g, K_2SO_4 0.1 g, $CaCl_2$ 0.1 g, water soluble fertilizer 2.66 ml, blue fertilizer (20-20-20-2, 4 g) and sugar 4 g/L of water) for a total of three times. The treatments were arranged in a randomized complete block design and replicated four times. To assess growth promotion in wheat, plant height, plant weight, root weight and grains per pot was calculated after four months.

To assess the biocontrol of crown rot in wheat by Y1, pots were amended with *F. graminearum* in the soil. One month after seed sowing, one mL of *F. graminearum* suspension containing 4×10^6 spores per mL was drench in each seedling. At 14, 28 and 42 days after seeds sowing, each pot was amended by pouring 300 mL of water (C + Fg), or fertilizer media (M + Fg), or strain Y1 culture grown in BB media

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62996314

(Y1 + Fg) or commercial fungicide (F + Fg). A total of 60 wheat tillers were randomly collected from each replicate after harvesting and assessed for the incidence of crown rot by recording the percentage of tillers with brown discoloration on the lower stems (Liu and Ogbonnaya, 2015). After harvesting the plants, reduction in yield due to crown rot was also measured by measuring plant height, plant weight/pot, root weight, and grains weight/pot.

Statistical analysis

The data were statistically analysed through SAS 9.1 software (SAS Institute, 2003). The least significant difference (LSD) was used to calculate mean values among treatments at a 5% level (p = 0.05) of significance.

Results

Antifungal characterization

The cell-free culture supernatant displayed antifungal activity at various concentrations mixed in PDA as it inhibited the growth of *F. graminearum*. The inhibitory effects increased with concentration increased (*Fig. 1a*). At 10% concentration, the cell-free culture supernatant showed more than 30% growth inhibition of *F. graminearum*. Higher concentration increased the growth inhibition, as 40 and 45% growth inhibition were recorded for the 30 and 50% concentration, respectively.

The paper disc method assessed the antifungal effect of the bacterial *n*-butanol crude extract. The Y1 crude extract at various concentrations had good inhibition effect on the pathogenic fungi (*Fig. 1b*). The crude extract (3 mg) affected the growth of the tested fungi by 13%. An increase in the inhibitory effect was found as the amount of treatment increased. The highest growth inhibition rates of 20% and 17% were obtained when 5 mg and 4 mg of crude extract were added to the paper disc respectively. The antifungal compound-enriched extract revealed interesting antifungal activities.

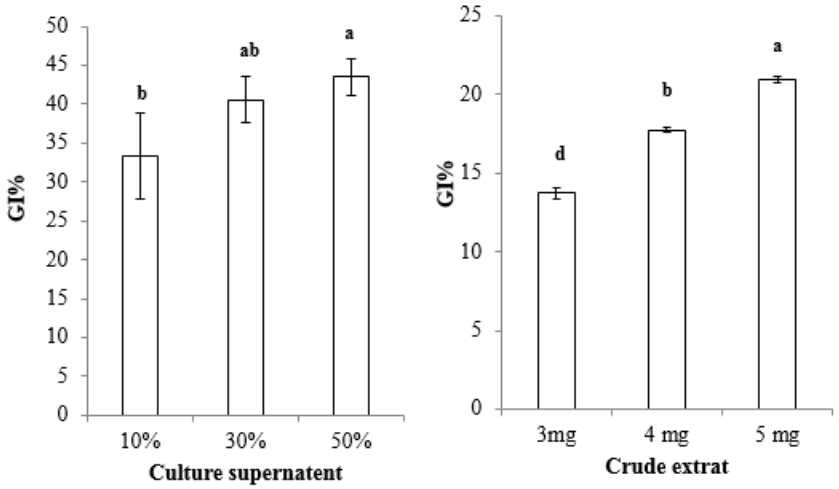

Figure 1. *Effect of Y1 culture filtrate (a) at various concentrations on growth of F. graminearum. Effect of different crude extracts (b) concentration of Y1 on growth of F. graminearum. Calculated mean in chart values are from three replicates. Error bars represent standard deviation of mean*

DOI: http://dx.doi.org/10.15666/aeer/1703_62996314

Extraction and purification of antifungal compound

The Y1 crude extract displayed antifungal activity against *F. graminearum* according to paper disc assay. A bioactive fraction was found because of silica gel column chromatography. The bioactive fraction (2 g) was further subjected to prep HPLC. The purity of the compound was confirmed with a single peak on an analytical HPLC column (*Fig. 2*). The antifungal activity of pure compound was checked and confirmed by testing against *F. graminearum* using paper disc method. The 12 mg of pure active compound obtained from *n*-butanol crude extract of Y1 strain. The bioactive antifungal compound showed a single peak with a 4.93 min retention time.

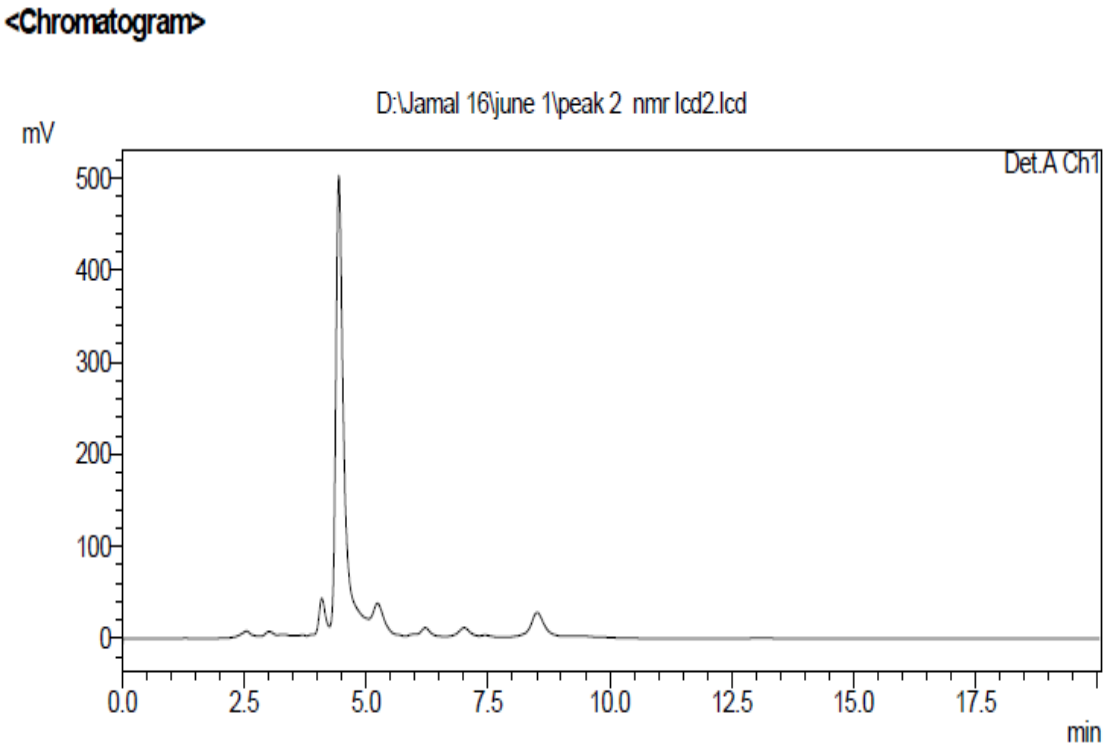

Figure 2. *The high-performance liquid chromatography (HPLC) spectrum of the purified antifungal compound from strain Y1*

Identification of the purified antifungal compound

The structure of the purified antifungal compound was identified according to its ^{1}H- and^{13}C-NMR spectra (*Fig. 3a* and *b*). Peak data were as follows. ^{1}H NMR (500MHz, CD_3OD, δ, *J*/Hz): 4.37 (1H, dt, 5.0, 2.0, H-2), 2.11 (1H, m, H-4a), 1.80 (1H, m, H-4b), 2.09 (1H, m, H-5a), 1.82 (1H, m, H-5b), 3.49-3.61(1H, m, H-6), 7.04 (2H, d, 8.5, H-2',6'), 6.71 (2H, d, 8.5, H-3',5'), 3.06 (1H, ddd, 11.0, 6.5, 1.0, H-7'a), 4.05 (1H, ddd, 11.0, 6.5, 2.0, H-8'), ^{13}C-NMR (125 MHz, CD_3OD): δC (ppm) 170.8 (C-1), 60 (C-2), 46.062 (C-3), 29.4 (C-4), 37.831 (C-5), 45.9 (C-6), 127.6 (C-1'), 132.1 (C-2',6'), 116.2 (C-3',5'), 157.7 (C-4'), 37.7 (C-7), 57.9 (C-8') and 167 (C-9'). From the NMR spectra, the compound was identified as cyclo(L-Pro-D-Tyr) (*Fig. 4*). The NMR spectrum was found to be similar to that reported by Kumar et al. (2013a).

Determination of antifungal activity of the purified compound and its effect on fungal hyphae

Antifungal activity assay showed that various concentration of cyclo(L-Pro-D-Tyr) inhibited growth of *F. graminearum,* as evidenced by decreasing turbidity in wells with increasing treatments concentration. Microscopic examination revealed that the hyphae of *F. graminearum* were altered because of the cyclo(L-Pro-D-Tyr) treatment. The results clearly highlight that 125 ppm affected the mycelia growth of *F. graminearum*,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62996314

and the effects increased with increasing concentration of compound: at 250 ppm and 500 ppm, there was more visible hyphae deformation. Alterations in the shape, including deformation and degradation of hyphae, were observed under light microscopy (*Fig. 5*).

cyclo(L-Pro-D-Tyr)

Figure 4. *The structure of purified compound cyclo(L-Pro-D-Tyr) from strain Y1*

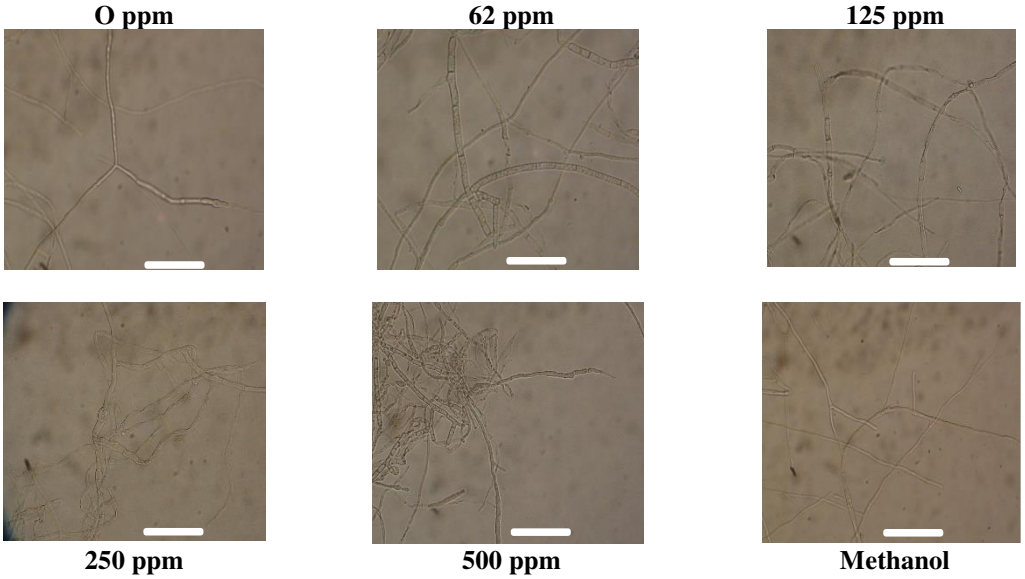

Figure 5. *Microscopically evident of changes in hyphae morphology of F. graminearum when treated with cyclo(L-Pro-D-Tyr). The carboxy methyl cellulase (CMC) containing F. graminearum conidial suspension only as control 0, 62, 125, 250, 500 ppm of Cyclo (L-Pro-D-Tyr) and methanol incubated for 5 days at 30 °C. All bars = 100 µm*

Assessment of the purified compound to control F. graminearum on wheat seeds

The ability of secondary metabolites of strain Y1 to inhibit the growth of *F. graminearum* on wheat seeds would be of major concern to the agricultural economy. Thus, the ability of cyclo(L-Pro-D-Tyr) produced by strain Y1 to protect wheat seeds

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62996314

from diseases caused by *F. graminearum* was investigated. Wheat seeds soaked in various concentration of cyclo(L-Pro-D-Tyr) demonstrated marked delay and inhibited seeds colonization compared to the control (*Fig. 6*). White mycelia were observed in the control wheat seeds 2 days after fungal inoculation, whereas seeds treated with 125 ppm or more of cyclo(L-Pro-D-Tyr) were found with low or no fungal growth.

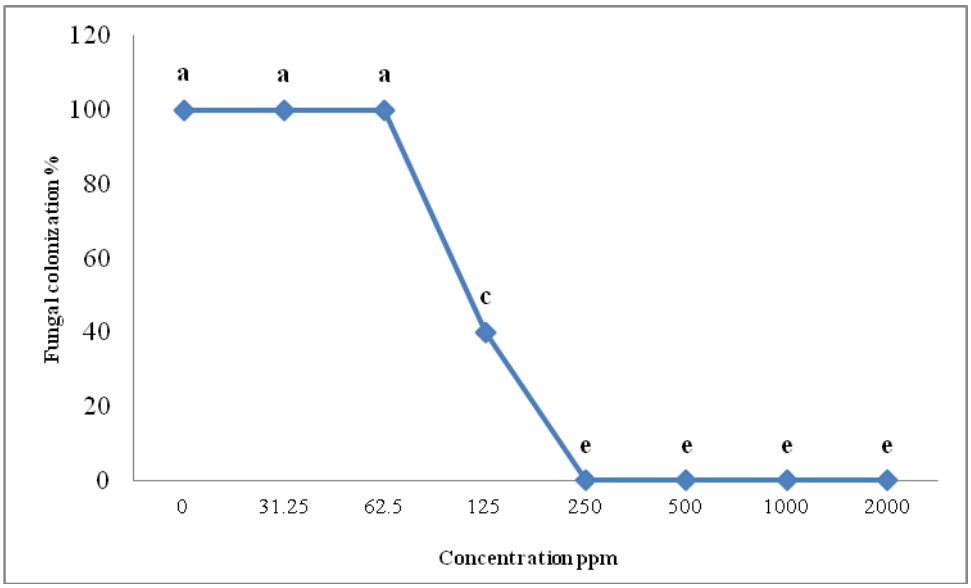

Figure 6. *F. graminearum colonization on wheat seeds with various concentration of cyclo(L-Pro-D-Tyr). Means with the same letter are not significantly different at P = 0.05 when compared by LSD*

Glasshouse experiment

The plant growth-promoting ability of strain Y1 was assessed *in vivo* using pot experiment with fertilizer media and bacterial inoculum. The results obtained from the pot experiment are shown in *Table 1*. The results indicated that at four months after sowing seeds, there were significant differences between the control and strain Y1 treatments. For vegetative growth, total yield significantly improved with the application of strain Y1, as the plant height, weight and root weight were higher with the Y1 treatment. Strain Y1 also caused an increase in the reproductive growth of wheat. The numbers of grains per spike were significantly higher in strain Y1-treated pots compared to all other treatments.

In the biocontrol of FCR, strain Y1 was found to reduce the percentage of disease in plant. The results showed that harvesting plants after four months, the strain Y1 group had the higher plant stand average against crown rot (*Table 1*). Pots treated with strain Y1 displayed high values for plant height, plant weight, root weight, and total grains per pot due to the better response of the plants to the effects of *F. graminearum* in the soil. *F. graminearum* exhibited crown rot symptoms in the control and reduced wheat yield, as the C (without *F. graminearum*) had higher values for plant height, plant weight, root weight, and total grains per pot compared to C + Fg (with *F. graminearum* spores) (*Table 1*). The level of control of crown rot in the pots treated with fertilizer medium was significantly lower (55%) compared to the pots treated with strain Y1 (28%). Total

DOI: http://dx.doi.org/10.15666/aeer/1703_62996314

grain weight per pot increased with the application of medium (40 g) compared to the control only C + Fg (9 g) but was lower compared to the application of strain Y1 (48 g).

Table 1. *Effect of Y1 culture on crown rot severity of wheat in glass house experiment*

Treatment	Disease incidence %	Plant height (cm)	Plant weight/pot (g)	Root weight (g)	Grains weight/pot (g)

Means with the same letter are not significantly different at P≤ 0.05 when compared by LSD
NR = Not Recorded, C = Water control, Y1 = *Bacillus amyloliquefaciens* Y1 culture, M = Fertilizer medium, C + Fg = Water + *F. graminearum*, Y1 + Fg = *B. amyloliquefaciens* Y1 + *F. graminearum*, M + Fg = Fertilizer medium + *F. graminearum*, F + Fg = Fungicide + *F. graminearum*

Discussion

In *in vitro* study, the culture supernatant and crude extract of *B. amyloliquefaciens* Y1 indicated fungicidal activity against *F. graminearum*. The increase in concentration of culture supernatant and crude extract displayed more growth inhibition. Several studies have reported that antagonistic bacteria showed antifungal properties by producing secondary metabolites in their culture broth against pathogens (Blin et al., 2013; Ehteshamul-Haque and Ghaffar, 1993; Liu et al., 2017). Increase in concentration of secondary metabolites produced by *B. amyloliquefaciens* Y1 were likely involve in increases activity (Jamal et al., 2015).

Recently, natural products have been investigated to report biocontrol mechanism of antagonistic microorganisms. In this study, we purified and identified cyclo(L-Pro-D-Tyr) as natural antifungal product from the culture supernatant of Y1 based on ^{1}H and^{13}C-NMR spectra. To our knowledge, this is the first report of cyclo(L-Pro-D-Tyr) from *B. amyloliquefaciens* strain as an antifungal compound. Cyclo(L-Pro-D-Tyr) is a diketopiperazine (DKP) compound (De Rosa et al., 2003) previously purified from body fluids, sponges, microorganisms, and a variety of tissues (Rudi et al., 1994; Ström et al., 2002). Cyclo(L-Pro-D-Tyr) has been isolated from *Callyspongia* sp., a specie of marine sponge in the South China Sea (Huang et al., 2010). Kumar et al. identified cyclo(L-Pro-D-Tyr) in the secondary metabolites of *Bacillus* spp. and reported its antifungal and antibacterial properties (Kumar et al., 2013a).

Both synthetic and natural DKPs displayed biological activities, including antiviral (Sinha et al., 2004), antifungal (Houston et al., 2004), antitumor (Nicholson et al., 2006) and antibacterial (Kwon et al., 2000). The antimicrobial activities of cyclo(L-Pro-D-Tyr) has been less explored; however, here we reported its antifungal activity against *F. graminearum*. The bio-preservative properties of the cyclo(L-Pro-D-Tyr) was also evaluated on growth suppression of *F. graminearum* on wheat seeds. To the best of our knowledge, there is no previous report of DKP cyclo(L-Pro-D-Tyr) to be used as bio-preservative to report antagonistic mechanism to control *F. graminearum* causing foliar disease on wheat seeds. The bio-preservative property of DKP, cyclo(L-Pro-D-Leu) to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_62996314

inhibit growth of *A. flavus* and *A. niger* on soybeans was also reported (Kumar et al., 2013b). Previously, we identified cyclo(D-Pro-L-Val) in Y1 as antifungal metabolites against *F. graminearum* (Jamal et al., 2017). *Bacillus subtilis* L1-21 was also reported to control this pathogen *in vitro* (Munir et al., 2018). These findings showed that Y1 could control wheat foliar disease by producing DKPs and other antifungal metabolites.

The effectiveness of strain Y1 under *in vivo* condition was also evaluated for growth promotion of wheat plants and reduction in wheat crown rot. It has also been reported that many strains of *B. subtilis*, *B. amyloliquefaciens*, and *B. cereus* interact with plants and suppress plant pathogens (Choudhary and Johri, 2009; Jamal et al., 2017). *Pseudomonas fluorescens* LY1–8 was also reported to control the FHB and FCR in greenhouse and field (Wang et al., 2015). Application of *Chlonostachys rosea* ACM941 (10^8 cfu/ml) reduced the disease index in wheat by 30–46% (Xue et al., 2014b). The wheat stalks with several *Fusarium* species was successfully control with *Clonostachys rosea* (Palazzini et al., 2013). Moreover, biocontrol species of *Chlonostachys* suppress the disease on maize debris (Luongo et al., 2005), soybean debris and wheat, (Xue et al., 2014a) and floral crops (Morandi et al., 2008).

Bacteria suppress disease by producing a number of antibiotics (Nelson et al., 2014; Roitman et al., 1990; Xu et al., 2018). Cyclic dipeptides were reported to influence the quorum sensing signalling and has strong inhibitory effect against *Vibrio anguillarum* (Campbell et al., 2009; Fdhila et al., 2003; Yan et al., 2004). Similarly, our *in vitro* study demonstrated that cyclo(L-Pro-D-Tyr) act as an antibiotic to suppress growth of *F. graminearum*. The production of cyclo(L-Pro-D-Tyr) as an antifungal compound by Y1 in its culture broth may partially explain its biocontrol mechanism in wheat pot experiment. The production of cyclic peptides responsible for antimicrobial activity of the *B. licheniformis* N1 strain in the control of tomato gray mold, tomato late blight, and pepper anthracnose were also investigated (Kong et al., 2010). The biocontrol of *Fusarium* dry rot in wounded potato tubers is due to an antibiotic, pyrrolnitrin, produced by *B. cepacia* in its culture broth (Burkhead et al., 1994).

The strain Y1 not only control wheat crown rot but also improve plant growth, as evidenced by increase in plant weight, plant height, and grain yield per pot. The present study agree with the findings of Huang and Wong that *Burkholderia cepacia* (A3R) reduced wheat crown rot significantly in under glasshouse and field condition and increase grain yield (Huang and Wong, 1998). Many plant-growth promoting bacteria improve plant growth by producing antimicrobial compounds (Sophereth et al., 2013; Xu et al., 2018). Briefly, the current and our previous study (Jamal et al., 2017) provides enough evidence to consider Y1 strain as a promising biocontrol agent to control FHB and FCR in wheat by producing antifungal DKPs cyclo(L-Pro-D-Tyr) and cyclo(D-Pro-L-Val) in its culture broth.

Conclusions

In conclusion, isolation of DKP cyclo(L-Pro-D-Tyr) from *B. amyloliquefaciens* Y1, is a new finding in biocontrol literature with its antifungal characterization against *F. graminearum*. Both *in vitro* and *in vivo* study resulted that application of Y1 suppressed growth of *F. graminearum*. Cyclo(L-Pro-D-Tyr) isolated from Y1 can serve as a role model to uncoil the antagonistic mechanism of biocontrol agent. In pot experiment, addition of Y1 significantly inhibited pathogen growth and enhanced wheat plant growth. Thus, our result indicated that Y1 can serve as successful substitute over

DOI: http://dx.doi.org/10.15666/aeer/1703_62996314

synthetic chemicals which are detrimental to control pathogenic fungi causing serious health and environmental concerns. In addition, these biocontrol agents may serve as a potential antagonist to manage other important wheat diseases in the greenhouse and fields.

(Received 27th Dec 2018; accepted 14th Feb 2019)

Abstract. This study was to know the effects of abattoir, chlorinated antimicrobial intervention and brining on microbiology of post 6 months' frozen (-10±2 °C) and thawed mixed chicken portions, as well as determine the optimal brining levels. Broilers (5-6 weeks old, n = 180, 1.12-1.25kg carcass weight) processed at 3 different processing plants (n = 60 per abattoir) into chicken portions of breasts, thighs and wings were packaged in 1 kg bags after applying antimicrobial intervention and brining before quick freezing them. After 6 months quick freezing at -10 °C and thawing, standard plate counts (SPC), spore counts and psychrophilic counts (log cfu/g) were evaluated and subjected to ANOVA in a randomized complete block design (RCBD). No coliforms, molds, staphylococci, and yeasts were not detected due to abattoir, antimicrobial and brining interventions. Also no significant SPC, spore count and psychrophilic bacterial count ($P > 0.05$) effects was recorded due to abattoirs. ASC significantly ($P < 0.05$) lowered all the counts compared to Aq. Cl and ClO_2. The 0% brine had highest ($P < 0.05$) counts (3.33, 3.25 and 3.63 logCFU/g) for SPC, spores and psychrophilic bacteria respectively, while 30 and 35% levels had the least ($P < 0.05$) counts (ranges from 1.06 – 1.87 logCFU/g) per sample tested with no significant interaction effects recorded. There is a significant optimal brining levels of 13.27, 35.87 and 34.10 (%) for SPC, spores and psychrophilic counts based on the quadratic regression model.
Keywords: *psychrophilic bacteria, quadratic function, aqueous chlorine, standard plate count, freezing*

Introduction

Food preservation using low temperatures is the most commonly used method for storing fresh foods as well as its distribution. Fresh meat is among the most perishable foods and chill temperatures are mostly used to delay the spoilage process by spoilage bacteria after slaughter, processing cuts and portions, transportation to distributors and the final storage at various retail sites (Xia et al., 2009). The basic aim of cooling techniques for fresh meat preservation is to slow or limit the spoilage rate as temperature below the optimal range can inhibit the microbial growth (Cassens, 1994). The methods of temperature regulation for storage are chilling, freezing and super-chilling which help to inhibit or completely stop bacterial growth (Zhou et al., 2010). However, the growth of psychrophilic group of bacteria, yeasts and molds is not prevented by all levels of refrigeration (Neumeyer et al., 1997) and both enzymatic and non-enzymatic changes will continue at a much slower rate (Van Berkel et al., 2004). During freezing, about 60% of the viable microbial population dies but the remaining population gradually increases during longer frozen storage periods (Rahman, 1999b). Modi et al. (2006) and Sudheer et al. (2011) reported an increase in psychrophilic bacterial count in prolonged freezing storage of spiced chicken.

Most psychrophilic bacteria belong to the microbial genera of both gram positive, such as lactic acid bacteria, and gram-negative bacteria such as *Pseudomonas* spp. and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63156336

Enterobacteriaceae (Holzapfel, 1998). Particular species involved in the spoilage of meat preserved at chill temperature are of *Pseudomonas* spp. (Ercolini et al., 2007), while the microflora of vacuum packaged frozen-preserved meat is characterized mostly by psychotropic lactic acid bacteria (Nychas et al., 1998). It is assumed that antimicrobial intervention and brining before freezing could significantly reduce such spoilage microbes during long frozen preservation periods, however there is paucity of information on spoilage microbial load of chicken portions thawed after quick frozen at -10 °C for 6 months.

The poultry processing plants make use of antimicrobial interventions (chlorine antimicrobials) such as aqueous chlorine, chlorine dioxide and Acidified Sodium Chlorite to abate the effects of spoilage bacteria as the storage period increases (Alonso-Hernando et al., 2013). Also, the poultry processing industry had introduced the method of brining for processed chicken with an objective of improving the flavour, taste and tenderness of chicken through different liquid additive solutions (Venter, 2015). Although, there is paucity of scientific report on the effect of high levels of brining on the portion's microbial load and its effects on the chicken, it had been speculated that increased brining levels above 60% could result in high levels of salts in the products which could affect the consumer's health (Alvarado and McKee, 2007; Ellinger, 1972). However, there is paucity of information on the effects of antimicrobial intervention and brining on the level of standard plate counts (SPC), spore counts and psychrophilic counts (log cfu/g) in 6 months frozen chicken portions, as well as the optimum levels of inclusion to attain the lowest microbial count in frozen chicken portions.

Therefore, this study is aimed at determining the relative effects of antimicrobial intervention and brining on spoilage microbial load in long term (6 months) frozen chicken portions; determine the best chlorinated antimicrobial to be used among the commonly used ones in the market; as well as determine the optimal brining levels that will lead to the lowest spoilage bacterial levels in frozen chicken portions.

Materials and methods

Sources of experimental materials and laboratory analysis

This research was carried out following the ethical approval given by the College of Agriculture and Environmental Sciences (CAES) research ethics review committee of University of South Africa (Ethics ref no: 2016/CAES/066). 180 freshly slaughtered broiler chickens from 3 different abattoirs (60 per abattoir) was used for this experiment. They were processed into chicken portions comprising of breasts, thighs and wings per chicken. These abattoirs were high through-put commercial poultry abattoirs, referred to as sources A, B and C. The standard plate, spore and psychrophilic bacterial count were carried out in a Biotechnology laboratory.

Chicken sample preparation, chlorinated antimicrobial and brining applications at the abattoir

The freshly slaughtered and processed mixed chicken portions from each abattoir was divided equally into 2 portions for antimicrobial intervention and brining. Three types of chlorinated antimicrobial were purchased from suppliers - Chlorine dioxide, Aqueous Chlorine, and Acidified Sodium Chlorite and applied at the rate of 50 mg/g to the chicken portions with brush (aseptically) after sub-dividing the portions into 3 equal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63156336

parts aseptically. Thereafter, they were bagged into 1 kg cellophane bags and labelled for identification, and a total of 12 bags per abattoir were randomly selected for refrigeration, comprising of 4 bags per treatment. A total of 24 bags per plant was randomly selected, with 12 bags each for antimicrobial intervention and brining respectively, replicated 3 and 2 times per treatment accordingly. Chlorine antimicrobials - Aqueous Chlorine (Aq. Cl), Acidified Sodium Chlorite (ASC) and Chlorine Dioxide (ClO_2) all sprayed before packaging while the other 12 bags were assigned to 6 brining levels (0%, 15%, 20%, 25%, 30%, and 35% of 1 kg chicken portion) per treatment before quick freezing them for 6 months at -10 °C and thawing thereafter for standard plate counts (SPC), spore counts and psychrophilic counts (log cfu/g).

The brine solutions were prepared in the abattoirs at the following brining concentration levels of 0%, 15%, 20%, 25%, 30% and 35% of 1 kg chicken portion as treatments (*Table 1*). The brine solutions were prepared separately for each brining level in stainless steel tanks that were automated and transported through a flexible hose to the brine injection unit. The processed portion per abattoir for brining were subsequently divided into 6 parts after weighing out 1 kg each, before brining and packaging in a cellophane bag and identified with an indelible marker. A total of 12 bags comprising of 2 bags per treatment were randomly selected for refrigeration at -10 °C for 6 months.

Table 1. *Graded levels of brine mixes applied to each replicate of 1 kg chicken portion*

Ingredients	**Brining (%)***					
	0	**15**	**20**	**25**	**30**	**35**
Salt (g)	0	5.5	7.3	9.1	10.9	12.7
Sugar (g)	0	2.6	3.5	4.4	5.3	6.2
Water (L)	0	24.2	34.9	43.7	52.4	61.1

*Chicken to brine ratio = 80:20 in percentage of 1 kg

After 6 months of refrigeration, cold water thawing procedure at 26 °C was applied to thaw the samples. All of the frozen samples were firmly tied and placed in a leak-proof plastic bag, before submerging in a sterile large bowl filled with water and allowed to thaw for 24 h. The samples were then removed aseptically and sampled for standard plate counts (SPC), spore counts and psychrophilic counts (log CFU/g) in the laboratory which were recorded and analyzed for mean effects.

Standard plate counts (SPC), spore counts and psychrophilic counts (log cfu/g)

The procedure of Woteki (1998) was used to determine the microbiological quality by aseptically collected (60 ± 0.1 g) of the sample (either the breast, wing or thigh randomly) from each replicate. The total plate count was conducted using the procedure of (AOAC, 1995). Psychrophilic bacterial count was carried out according to the procedure of (APHA, 2001). The counting was achieved using the same procedure as in Total Plate count; 1 ml of the series dilutions, then the plates were incubated at 5-7 °C for 10 days. The blended samples were then tested for standard plate counts (SPC), bacterial spores, coliform, staphylococci and yeast and molds by pour-plate method as per APHA (2001) procedures (*Fig. 1*).

DOI: http://dx.doi.org/10.15666/aeer/1703_63156336

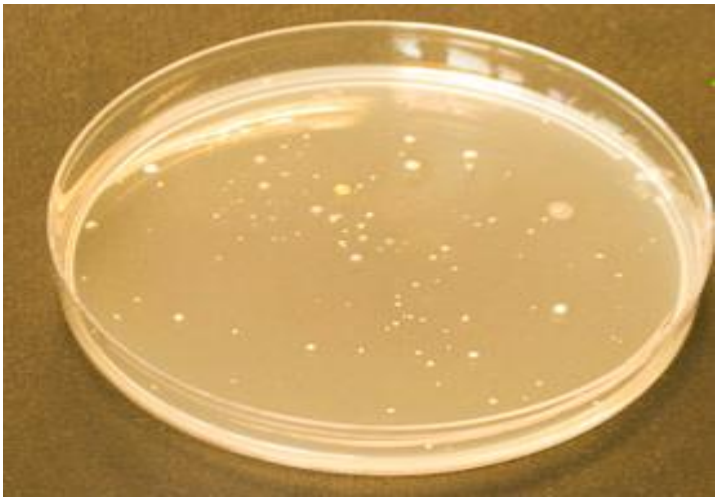

Figure 1. *A petri dish showing a sample colony of psychrophilic bacteria from chicken portions rinsates using the procedure of APHA (2001)*

Statistical analysis

The effects of source, antimicrobial intervention and brining levels on microbiological quality of chicken were analyzed with the general linear model (GLM) procedures of the (SPSS, 2017). The statistical model was:

$$Y_{ijk} = \mu + T_i + B_j + C_k + (TB)_{ij} + (TC)_{ik} + \Sigma_{ijk} \quad \text{(Eq.1)}$$

where Y_{ijk} = the overall observation (Bacterial load); μ = population means; T_i = effect of abattoir source; B_j = effect of antimicrobials; C_k = effect of brining levels; $(TB)_{ij}$ = interaction effect of abattoir source and antimicrobials; $(TC)_{ik}$ = interaction effects of abattoir source and brining and Σ_{ijk} = residual effect.

A breakdown of the experimental design is as shown below:
Treatment 1 = Abattoirs effects only
Treatment 2 = Antimicrobial effects only
Treatment 3 = Brining effects only
Treatment 4 = Abattoirs and antimicrobial agents.
Treatment 5 = Abattoirs and brining levels

Where there was a significant F-test ($P < 0.05$), the Duncan New Multiple Range test method was used to separate the means according to SPSS (2017).

The related responses in Psychrophilic bacterial count to antimicrobial and brining levels were modeled using the quadratic regression model below:

$$Y = a + b_1x + b_2x^2 \quad \text{(Eq.2)}$$

where Y = microbiological load; a = intercepts on Y axis; b = co-efficient of the quadratic equation; x = brining levels in percentages and $b_1/2b_2$ = x value for optimal or minimal responses. The quadratic model was fitted to the experimental data by means of the regression using curve estimation procedure of SPSS (2017). The quadratic model was used because it gave the best fit (Okoro and Mbajiorgu, 2017).

Results

The application of chlorine antimicrobials had a significant effect ($P < 0.05$) on the chicken portions from within abattoirs used in the study (*Table 2*), they however did not differ between different abattoirs within treatments. Although the values of samples treated with acidified sodium chlorite were consistently lower in all the samples from different abattoirs than those treated with aqueous chlorine and chlorine dioxide, no statistical significant differences were recorded between them. However, between the three chlorine antimicrobials, the ASC consistently recorded a significantly lowest SPC, spores and psychrophilic bacterial count while Aq.Cl recorded the highest ($P < 0.05$) But there were no significant difference between values of spore counts generated from abattoir C. This could be due to all three antimicrobials being made from chlorine, resulting in their effectiveness appearing to be the same in terms of reducing standard plate counts (SPC), spore counts and psychrophilic counts.

Table 2. *Effects of chlorine antimicrobials on standard plate count, spores and psychrophilic bacteria count (logCFU/g) of frozen chicken from 3 commercial chicken abattoirs sampled*

Microbial* counts (logCFU/g)	Abattoirs	Chlorine antimicrobials (50 mg/g)				
		ASC	Aq. Cl.	ClO_2	SEM	P-Value
SPC	A	1.33^{c}	2.50^{b}	2.98^{a}	0.189	0.030
	B	1.33^{c}	2.67^{b}	2.92^{a}	0.221	0.029
	C	1.17^{c}	2.92^{b}	3.11^{a}	0.367	0.045
Spores	A	1.36^{c}	2.72^{b}	3.18^{a}	0.379	0.050
	B	1.37^{c}	3.07^{b}	3.22^{a}	0.221	0.052
	C	2.76	3.02	3.21	0.367	0.560
Psychrophiles	A	1.37^{c}	2.60^{b}	2.98^{a}	0.389	0.030
	B	1.51^{c}	2.57^{b}	2.92^{a}	0.321	0.034
	C	1.42^{c}	2.52^{b}	3.09^{a}	0.467	0.025

^{a,b,c}Means in the same row and column not sharing a common superscript are significantly different ($P < 0.05$) SEM = standard error of mean, P- value = probability value, Aq. CI = aqueous chlorine, ASC = acidified sodium chlorite, CIO_2 = chlorine dioxide

The effect of the brining levels on standard plate count, spores and psychrophilic bacterial count was the same across all three major abattoirs (*Table 3*). However, at 0% brine, the microbiological quality was significantly higher ($P < 0.05$) than any other levels in all three abattoirs. Furthermore, the results have indicated no significant difference of SPC, spores and psychrophilic bacterial count between 15, 20 and 25% across all samples from the three abattoirs. The brining levels between 30 and 35% also has no significant differences ($P < 0.05$) among them for the microbial loads.

The levels of brining and chlorine antimicrobials affected the levels of standard plate count, spores and psychrophilic bacterial load in the frozen chicken portions (*Table 4*). The control samples (0% brine) had significantly higher ($P < 0.05$) bacterial load than all samples injected with various brining levels. At 20% and 25% brining levels however, there was no difference ($P > 0.05$) in bacterial count except for SPC where 20% is significantly higher than 25%.

Application of quadratic regression model to identify optimal brining levels to achieve the least SPC, spore and psychrophilic bacterial count resulted in a significant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63156336

($P < 0.05$) optimum levels (*Table 5*). The effect of percentage brining on average SPC, spore and psychrophilic bacteria count had optimum quadratic values of 20.67 + 20.578 brining – 7.986 brining^2, 80.142 – 31.793 brining + 2.178 brining^2 and 31.77 + 5.909 brining - 3.748 brining^2 respectively. The optimal brining levels were 13.27, 35.87 and 34.10 for SPC, spore and psychrophilic counts respectively. These are the optimal brining level to give the lowest microbial count in 6 months frozen (-10 ± 2 °C) chicken portions. The co-efficient of determination (R^2) which is very high, implies that the optimum brining levels have significant influence in reducing microbial load.

The result of the optimization function indicates that brining has a direct effect on the amount of microbial counts that develop during long term refrigeration; hence, the best brining level of inclusion to achieve the fewest number of bacterial loads is determined (*Figs. 2* and *3*).

Discussion

Antimicrobial intervention and brining of chicken portions are important in preservation and storage of meat as Perez-Chabela and Mateo-Oyague (2004) reported that pathogenic microorganisms are commonly isolated from thawed frozen raw meat with larvae of Taenia spp. and Trichinella spiralis killed after 1-3 weeks of refrigeration at -18 °C or after ultra-rapid freezing at -29 °C of raw meat. Also Lowry and Gill (1984) reported that moulds grew at temperatures lower than -10 °C with Knøchel et al. (2007) also reporting the development of spoilage microbes in non-marinated chicken which increases rapidly when refrigerated. Chlorine is a major antimicrobial intervention agent and its widely used in poultry processing industry being effective against a whole range of microorganism in poultry processing (Purnell et al., 2014) and is regarded as the most effective antimicrobial to control bacterial, viral and protozoan pathogens (Duan et al., 2017; Purnell et al., 2014). However, it is reported that the efficacy of the antimicrobials is determined by the level of attachment of bacterial infection on the chicken skin. This factor might have a slight contribution to the results as the samples were sprayed directly on each sample before the portions were packed. It is reported that chlorine dioxide, when used under commercial operations, has the potential to reduce up to 2- 3 logCFU/g in microbial levels in frozen poultry (Tamblyn and Conner, 1997). The present study indicates that all the abattoirs were not affected by the effects of the antimicrobials when they were compared. However, among the antimicrobials, there was a significant difference in terms of the microbial load of the samples tested with acidified sodium chlorite having the least load while chlorine dioxide having the most load. Although all three chosen antimicrobials originated from chlorine as a base, acidified sodium that reduced more bacteria than all other antimicrobials is in acidic format, a form which is very convenient to lactic acid bacteria that is capable of causing great reduction of microbial load in white meat (Oyarzabal, 2008; Vlahova-Vangelova and Dragoev, 2014). This is also in agreement with the findings of Purnell et al. (2014) showing that acidified sodium chloride could be the most effective antimicrobial to be used in the poultry processing industry.

Brining of chicken slows formation of colony for spoilage bacteria and the bacterial development remains below 1.03 logCFU/g (Knøchel et al., 2007; Vlahova-Vangelova and Dragoev, 2014) for a period of 3 months. Different amounts of brine required for use in chicken preservation has been reported by different authors. Alvarado and McKee (2007) reported that salt within brine was meant to reduce rate of deterioration by reducing the growth of microorganisms in the chicken with higher concentration of salt proven to inhibit the microbial spoilage in white meat. This study has shown that higher level of brining consistently reduces the levels of microbial organisms causing spoilage. Although 5% brine is reported for best quality of meat products when assessing the chicken from sensory properties (Venter, 2015); it did not consider levels of spoilage microbes effect on the meat due to longer periods of storage. This study has shown that at lower levels of inclusion of brine (0-10%), the level of spoilage microbes is still within safe limits after 6 months of refrigeration, implying that higher levels might not be necessary. But as the period of refrigeration increases beyond 6 months, the spoilage bacteria level could increase, hence The United States Food and Drug Administration (USFDA) recommended a storage period of 9 months for chicken and turkey parts (FDA, 2017). Meanwhile, Venter (2015) reported the prohibition of abattoirs from exceeding 15% level of brining by the country's regulatory body resulting in a suggested 20% brining levels by the abattoirs as the most accommodative

DOI: http://dx.doi.org/10.15666/aeer/1703_63156336

amount for inclusion when considering longer preservation periods. This study however suggests an inclusion of up to 34.10% brining level to optimally remove psychrophilic microbes, and 13.27 for optimal eradication of standard plate count of microbes. Brining at levels up to 60% may reduce the quality of the chicken through dilution of nutrients such as proteins, fat and energy (Tamblyn and Conner, 1997; Whitman and Marshall, 1971). Farber and Idziak (1984) had reported high moisture content in the 60% brining level treated samples resulting in lower salt which has been diluted by the moisture. However, Farber and Idziak (1984) reported that the highest injection level of 60% was tenderer than lower inclusion levels.

The primary preservation agents of brine are salt and sugar, which do not only prevent spoilage of the chicken but serve to inhibit growth of pathogens and spoilage bacteria when applied correctly (Pichpol, 2009; Purnell et al., 2014). These preservative agents have antimicrobial mechanisms which capacitate them to disrupt microbial enzyme activity and weaken their DNA structure. Sugar's preservative mechanism is to accelerate accumulation of antimicrobial compounds from the growth of spoilage microorganisms. This includes conversion of sugar molecules to organic acids by lactic acid bacteria (Vlahova-Vangelova and Dragoev, 2014). Moreover, Vlahova-Vangelova and Dragoev (2014) had reported that development of spoilage bacteria depend on the presence of lactic acid bacteria solutions not sugars. This may explain why the greatest reduction of spoilage microbes is found between 30-35% of brining level in this study.

Conclusion

Generally, this study has shown that usage of antimicrobial intervention and brining could achieve the same level of microbial reduction, hence either of the two could be used when preserving chicken portions. An antimicrobial intervention of acidified sodium chlorite could be used in the preservation of chicken portions, while brining up to the level of 13.27% for reduced standard plate count and 34.10% for optimum psychrophilic bacterial count reduction could be important. Therefore, ASC could be used interchangeably while brining, as it is easily accessible in the market and relatively cheap, making it a better preservative commercially for chicken preservation than other antimicrobials.

Acknowledgements. The authors wish to acknowledge the active participation of the meat processing plants that allowed the use of their facilities in conducting this experiment.

BIOLOGICAL, SEROLOGICAL AND MOLECULAR DETECTION OF *TOMATO MOSAIC VIRUS* INFECTING PEPPER PLANTS FROM TURKEY

ÇULAL-KILIÇ, H.

Department of Plant Protection, Faculty of Agricultural Sciences and Technologies, Isparta Applied Sciences University, Isparta, Turkey
(e-mail: handankilic@isparta.edu.tr)

(Received 3rd Jan 2019; accepted 27th Feb 2019)

Abstract. This study was carried out to detect the presence *Tomato mosaic virus* (ToMV) by biological, serologic and molecular methods in the pepper production areas in Burdur and Denizli provinces. Symptoms related with virus infections on the pepper plants were observed during the surveys. Mechanical inoculation studies, DAS-ELISA (Double-antibody sandwich enzyme linked immunosorbent assay) tests, IC-RT-PCR (Immunocapture Reverse transcription polimerase chain reaction) studies were carried out during the work carried out to define the virus. The plants collected from the field that were suspicious with regards to being infected with the virus were first tested by the ELISA method. It was determined that 10 of the 209 tested samples were infected with ToMV. The samples that gave positive results during ELISA tests were used in the mechanical inoculation studies. Symptoms were observed in the indicator plants within a period of 7-10 days. 20 plant samples that gave negative ToMV values in the ELISA tests but had absorbance values close to positive along with the 10 samples that were tested as positive in the DAS-ELISA were used in the IC-RT- PCR method. All of the 30 samples produced expected amplification size of band with 318 bp as observed on agarose gel electrophoresis.
Keywords: *vegetables viruses, identification, DAS-ELISA, IC-RT-PCR*

Introduction

Pepper (*Capsicum annum* L.) is a member of the Solanaceae family and is a hot and mild climate plant. The homeland of pepper is stated to be tropical South America and especially Brazil. Pepper was brought England from Spain in the 1500s from where it spread to the rest of Europe. China is the leader in worldwide pepper production as of 2016 with 13.189.303 tons. It is followed by Mexico with 2.335.560 tons whereas Turkey is ranked three with 1.986.700 tons. Turkey is followed by Indonesia and USA (TUIK, 2016; FAO, 2016).

Pepper is rich in vitamins A and C. Peppers can be used as fresh or as canned, in pastes, as pickled, in concentrated tomato soups, ready soups, in making powdered or chili peppers, in paint industry, pharmaceutical industry etc. (Anonymous, 2017).

Burdur and Denizli are important in vegetable production due to their soil and climate properties as well as irrigation options. Especially Kale district of Denizli cultivates good quality peppers.

Significant efficiency losses occur in pepper cultivation due to wrong or insufficient agricultural applications as well as biotic and abiotic disease factors. There are many fungi, bacteria and virus based diseases in the vegetable cultivation areas which limit cultivation. Virus diseases are significant among these factors due to their chemical and physical structures, sizes, types of infection, symptom formation, transport and the lack of an effective struggle against them (Agrios, 1997).

Kenyon et al. (2014) have stated that there are about 68 viruses that cause diseases in peppers. The viruses that are observed in pepper which cause significant losses in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63376347

efficiency are as follows: *Tobacco mosaic virus* (TMV), *Tomato mosaic virus* (ToMV), *Cucumber mosaic virus* (CMV), *Potato Y virus* (PVY), *Tomato spotted wilt virus* (TSWV), *Alfalfa mosaic virus* (AMV), *Pepper mild mottle* (PMMoV), *Pepper veinal mottle virus* (PVMV), *Pepper ringspot virus* (PRSV) (Ryu et al., 2009; Arogundade et al., 2012).

ToMV belongs to the Tobamovirus type. Virus includes linear single helical RNA genome. It has a rod shaped particle structure. The virus has a length of about 300 nm and a width of about 18 nm. Virus particles consist of 5% nucleic acid; 95% protein. The genome is single pieced. ToMV can be spread between plants on workers' hands, tools and clothes with normal activities such as plant tying, harvest. Seed can be infected and pass the virus to the plant. *Tomato mosaic virus* can survive in infected root debris in the soil for up to two years (Silva et al., 2011).

TMV, ToMV, CMV, PMMoV, TSWV, PVY, AMV have been determined during the studies carried out related with the diseases of peppers in our country (Şevik, 2011; Sertkaya, 2012; Özdağ and Sertkaya, 2017; Geyik, 2017).

The existence of virus diseases, their harms and their symptoms vary in accordance with the type of the pepper plant as well as the environmental conditions. That is why, first the detection of the viruses in the culture plant that is cultivated should be made in order to minimize the damages caused by virus disease and to develop control methods. It is not correct to carry out diagnosis based only on observation for virus detection. In recent years, PCR methods have been developed in parallel with molecular techniques which enable sensitive and accurate diagnosis of pepper viruses from plant tissues (Jacobi et al., 1998; Vinayarani et al., 2011; Kumar et al., 2011; Gümüş and Paylan, 2013).

The aim of this study is to determine ToMV in the pepper production areas of Burdur and Denizli provinces by DAS-ELISA, mechanical inoculation and IC-RT-PCR method.

Materials and methods

Plant material

The main material of this study consists of 209 leaf samples (115 samples from Denizli + 84 samples from Burdur) which show virus disease symptoms and which are thought to be infected with virus. The samples were collected from the pepper production areas (8 locations) during June-September in 2012-2013. The samplings were made from plants with leaf deformation, leaf curling, necrosis formation on the leaves, mosaic symptoms and stunting symptoms. There is no difference between sampling sites during surveys. The samples were labeled inside polyethylene bags and brought to the laboratory in ice boxes to be preserved in deep freezer (-20 °C) until the required tests were carried out.

Serological test method (DAS-ELISA)

ToMV-DAS-ELISA (BIOREBA AG, Switzerland) commercial kit was used in the study. The application were performed were performed as described by Clark and Adams (1977).

Accordingly, 200 µl of IgG was added to each of the hole of ELISA plate, which was diluted in the coating buffer at a ratio of 1:1000 which was then kept at +4 °C for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63376347

overnight. Afterwards the ELISA plates were washed with the washing buffer. The washing was repeated 3 times. The plant extracts prepared by diluting at a ratio of 1/10 using extraction buffer was added to each hole as 200 µl and was kept overnight at +4 °C. Washing was repeated the next day. After washing process, conjugated antibody was diluted at a ratio of 1:1000 in the conjugate buffer, 200 µl was added to each hole and was kept at 37 °C for 4 h. After the washing process, each substrate prepared as 1 mg/ml in the substrate solution was added to each hole as 200 µl and was left to wait at room temperature. Finally, p-nitrophenyl phosphate in diethanolamine substrate buffer; (pH: 9.8) was added and 405 nm values were measured at a microplate reader VersaMax microplate reader (Molecular Devices, Sunnyvale, CA) after 60-120 min. Samples with absorbance values greater than twice the mean absorbance reading of healthy controls obtained from (Bioreba, Switzerland) were considered positive for ToMV (Şevik, 2016).

Mechanical inoculation studies

Mechanical inoculation was carried out on test plants during the 3-4 leaf stage using the samples that yielded positive reaction as a result of the ELISA tests of ToMV infection suspicious leaf samples collected during the survey. To this end, plant tissues acquired from ToMV infested plants were prepared at a ratio of 1:1 (W/V) in 0.01 M phosphate buffer solution (pH; 7.2) including 0.01% 'lik 2-Mercaptoethanol and was inoculated to the leaves of the test plants. *Capsicum annuum*, *Chenopodium amaranticolor*, *Nicotiana glutinosa*, *Nicotiana tabacum* L. "Xanthii", *Nicotiana tabacum* "White Burley" were used as test plants (Aghamohammadi et al., 2013). Plant growth cabins at 18- 20 °C temperature were used to observe symptoms in test plants. Mechanical inoculation studies were repeated until symptoms were seen.

Molecular test method (IC-RT-PCR)

Immunocapture-RT-PCR method was used as molecular test method since it is more advantageous due to the direct usage of plant extracts after mixing with water without any need for nucleic acid isolation. Antibodies specific to the virus were used, viral forms in the crushed plant material were captured immunologically and were used in viral RNA amplification. The DAS-ELISA positive samples (10 samples) and the samples with absorbance values close to positive (20 samples) were used in molecular studies for a total of 30 samples. In the Immunocapture-RT-PCR method:

- PCR tubes were coated with the antibody specific to the virus during ELISA studies and were left for incubation at 4° C for the overnight.
- Tubes were washed with PBS-Tween Buffer for 3 times after incubation and they were left to wait in the deep freezer until molecular studies.
- During molecular studies.
- plant tissue extract, as prepared above for ELISA, was loaded into the antibody-coated tubes and incubated. The samples were left for incubation at +4 °C overnight.
- Tubes were washed with PBS-Tween Buffer for 3 times after incubation and were also washed once with sterile pure water.
- RT-PCR mixture was added to these PCR tubes afterwards.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63376347

RT-PCR was performed using a One Step RT-PCR Kit (Bio Basic, Canada Inc). Reverse transcription was performed in a 50 µl reaction mixture containing, 21 µl H_2O, 25 µl 2x1 PrimeScript One Step RT-PCR buffer (containing dNTP mixture, One step Enhancer solution), 2 µl Prime Script 1 step enzyme mix, 1 µl 20 Mm primers. RT-PCR of ToMV replicase gene portion of approximately 318 bp were amplified.

An approximately 318 bp DNA fragment was amplified from ToMV-infected plants by IC-RT-PCR with a ToMV specific primer pairs. Oligonucleotide primer sequences were used to detect ToMV reported by Kumar et al. (2011):

F-5-CGAGAGGGGCAACAAACAT-3

R-5-ACCTGTCTCCATCTCTTTGG-3

Thermocycling (Techne-TC-5000) was programmed as 1 cycle at 50 °C for 30 min, at 94 °C for 2 min and 40 cycles at 94 °C for 30 s, at 54 °C for 30 s, at 72 °C for 30 s and finally at 72 °C for 1 min.

Pepper plant leaves infected with ToMV in DAS-ELISA studies and ToMV-infected *C. amaranticolor* and *Capsicum annuum* plant leaves were used as positive control in molecular studies; whereas healthy pepper plant leaves were used as negative control.

IC-RT-PCR products were separated on a 1% agarose gel by electrophoresis (Bio-Rad) and stained in a 0.5 µg/ml ethidium bromide solution. An image was captured after the exposure of ethidium-bromide-stained gel on a transilluminator with a digital camera (UVP-Doc-It). 100 bp DNA ladder (Thermoscientific, GeneRuler) was used as marker.

Results

Symptoms such as leaf deformation, leaf curling, decoloring of the leaves, necrosis formation on the leaves, mosaic symptoms and stunting symptoms have been observed and these plants have been photographed during the survey (*Fig. 1*).

Firstly, ELISA tests were carried out on the leaf samples collected from 209 plants with virus infection symptoms in order to determine the existence of ToMV. The results showed that 10 out 209 samples were infected with ToMV. Whereas ToMV infection rate for 209 of the collected samples was determined as 4.78%.

Mechanical inoculation studies were carried out using ToMV infected leaves that were detected after ELISA tests. Chlorotic local lesion symptoms were observed in *Chenopodium amaranticolor* of the plants one week after inoculation; whereas local lesion symptoms were observed at *Nicotiana glutinosa* 10 days after inoculation and the symptoms have been photographed (*Figs. 2* and *3*). On the other hand, *Capsicum annuum* directly developed systemic symptoms as mosaic, stunding (Cherian and Muniyappa, 1998; Aghamohammadi et al., 2013; Ullah et al., 2017) (*Fig. 4).* The presence of ToMV was further confirmed through mechanical inoculation and IC-RT-PCR.

IC-RT-PCR method is one of the molecular methods that is widely used in many studies to detect virus diseases in plants and this was used on pepper samples to detected the ToMV. 10 samples yielded positive results as a result of the testing of the 209 leaf samples collected from the pepper cultivation area by DAS-ELISA. At this stage of the study, 20 isolates which yielded negative results in the DAS-ELISA tests but which had absorbance values close to positive along with 10 samples that yielded positive results in DAS-ELISA were used in the IC-RT-PCR studies which is more sensitive in comparison to ELISA. It was determined a result of the RT-PCR works on

plant samples that all of the samples yielded the expected band specific to ToMV (318 bp) and that all of the 30 samples (100%) were infected with ToMV. No fragment was amplified from negative control (*Figs. 5, 6* and *7*).

Discussion

Virus based diseases are quite significant due to the facts that their control is mostly hard and indeed impossible, that there is no effective chemicals and that the viruses spread far and wide via vector insects.

It is essential to first detected the viruses found in the cultivated culture plant in order to minimize the damages due to viruses and to develop control strategies. The symptomatologic studies that will be carried out based on observation for defining the viruses should be supported with serologic and molecular tests that will be carried out. It is possible to take precautions for the control of this virus disease only after carrying out the diagnosis of this factor. Biological, serological, and molecular assays have generally been used for identification of plant viruses. Although ELISA is preferred assay for routine virus detection, RT-PCR has increasingly been used for detection and identification of viruses due to higher level of sensitivity (Almeida et al., 2018). Among the molecular methods, the most widely used is the RT-PCR (Liu et al., 2014). The IC-RT-PCR technique has as an advantage the fact that crushing of the plants for the viral RNA extraction is unnecessary, since only the viral particles that lie on the outside are captured by the specific antiserum (Mulholland, 2009). Another advantage of IC-RT-PCR, compared to RT-PCR, would be the speed of testing. The RNA obtained by IC-RT-PCR is performed in fewer steps when compared with RT-PCR (Chikh-Ali and Karasev, 2015; Çulal-Kılıç et al., 2017).

The mosaic, contraction in the nervures, spotting, leaf and fruit deformations as well as necrosis formation on the leaves observed during the surveys carried out at Burdur and Denizli pepper cultivation areas were in accordance with the symptoms reported in previous studies mosaic symptoms and stunting symptoms (Kumar et al., 2011; Svoboda and Svobodova-Leisova, 2012).

The symptoms that occur in *Capsicum annuum, Chenopodium amaranticolor and Nicotiana glutinosa* as a result of mechanical inoculation put forth the existence of ToMV in leaf samples collected. The acquired symptoms were in accordance with previous study results and supports the view that the virus can be ToMV (Aghamohammadi et al., 2013; Ullah et al., 2017).

However, it is a fact that sometimes symptoms cannot be observed in mechanical inoculation method due to various reasons. That is why, detection studies should be supported with more sensitive methods since the use of this method by itself might lead to errors.

The positive reactions acquired during the serologic test carried out to diagnose the virus signify the existence of ToMV in the plant. The ELISA tests used in the diagnosis work for many plant viruses have widely been used by researchers (Geyik, 2017; Kapoor et al., 2018). The fact that it is fast, sensitive, economical and reliable makes this method a preference (Vinayarani et al., 2011; Almeida et al., 2018).

It has been found in this study as a result of carrying out DAS-ELISA tests on the leaf samples that 10 of the 209 samples were infected with ToMV. ToMV infection has been detected in studies carried out at various parts of our country (Gümüş and Paylan, 2013; Özdağ and Sertkaya, 2017).

Özdağ and Sertkaya and (2017) has carried out survey studies to determine the virus diseases in pepper areas in Hatay province and it has been found as a result that of the 303 plant samples, CMV, PLRV, PVX, PVY, PMMoV, PepMoV, ToMV and TSWV. DAS-ELISA method has been used to detect the viruses.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63376347

20 samples that yield absorbance values close to positive and 10 samples that yield positive results DAS-ELISA have been handled in IC-RT-PCR work. In these studies, base pairs that amplify the 318 bp of ToMV and the replicase gene have been used. As a result, expected band was observed in all of the 30 isolates (%100) which put forth that the samples are infected with ToMV. The results of this study were in accordance with the study by Kumar et al. (2011) carried out using primer pairs designed for ToMV. The same researchers have acquired a 318 bp band in molecular studies. Similarly, Gümüş and Paylan (2013); Almeida et al. (2018) have used IC-RT-PCR method to determine the presence of ToMV in their studies.

10 of the 209 samples used in DAS-ELISA tests were determined to be infected with ToMV, whereas it was determined in IC-RT-PCR studies that all 30 samples (%100) were infected with ToMV putting forth that PCR method is much more sensitive with respect to ELISA especially when virus density is low. IC-RT-PCR showed greater sensitivity in detecting to ToMV.

According to results of symptom inspections on plants, IC-RT-PCR, DAS-ELISA and mechanical inoculation studies, ToMV in Burdur and Denizli provinces was caused by more than one agent. ToMV was not detected in all the symptomatic samples, it is thought those symptoms were also caused by other viruses. Studies on those potential viruses must be carried out to find out the causal viruse of pepper in this region. 179 pepper samples that showed virus-like symptoms did not react with the antiserum of ToMV used in serological test and IC-RT-PCR method indicating that they were possibly infected with other pepper viruses.

Conclusions

In this study, the existence of ToMV in the pepper production areas at Burdur and Denizli provinces have been found out using biological, serological and molecular methods. Previous studies also identified TSWV as common virus infecting pepper (Çulal-Kılıç et al., 2017) in same zone. ToMV in peppers in this region were firstly identified in this study.

(Received 4th Nov 2018; accepted 21st Mar 2019)

Abstract. Limiting factors for riparian ecosystem were previously considered to be riparian habitat structure, water flow variability, sedimentation and erosion. Recent scientific research have started to focus their attention to the feedback between form and function in fluvial ecosystems considering that not only geomorphology controls riparian vegetation dynamics, but also riparian vegetation controls geomorphology. Erosion-sedimentation processes significantly change the channel of the river and its surroundings and the sediment movement indicator is the critical value of the shear stress. This contribution deals with the impact of vegetation on the erosion-sedimentation processes in fluvisols during flood events. Selected vegetation characteristics and their effects on the humus horizons in fluvisols were assessed at the selected area of the River Schwechat followed by modelling of the shear stress during flood events.
Keywords: *riparian ecosystem, floodplain water, biogeomorphic processes, landform dynamics, hydraulic modelling, Schwechat River*

Introduction

Riparian ecosystems are transitional semiterrestrial areas regularly influenced by fresh water, usually extending from the edges of water bodies to the edges of upland communities. Because of their spatial position, they integrate interactions between the aquatic and terrestrial components of the landscape. They are dynamic environments characterized by strong energy regimes, substantial habitat heterogenity, a diversity of ecological processes, and multidimensional gradients (Daigneault et al., 2017). Habitat for riverine and riparian organisms is a constantly changing mosaic biophysically dynamic in space and time. In his context, the biota is uniquely adapted to the dynamics of the system (Dufour et al., 2015). Riparian ecosystems are often locations of concentrated biodiversity at regional to continental scales.

Interactions between riparian vegetation and fluvial hydraulic processes are regulated by the flow regime which is one of the primary drivers shaping morphological patterns and ecological integrity (Wohl et al., 2015; Claude et al., 2018). One of the outcomes of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

these complex interactions are discrete vegetation units that represent snapshots in time characterized by stands of different age and structural features (Egger et al., 2013a, b). Riparian species have developed adaptations and synchronized life history traits with the variable conditions of the river dynamics (Kui et al., 2014; Kui and Stella, 2016). When fluvial characteristics are modified, riparian plant communities and vegetation structure change favouring less bio-diverse environments, worse water quality and more exposed river beds (Stallings et al., 2015), definitely leading to a poor or bad ecological status. In many cases, to achieve a good ecological status of water body can be crucial for the riparian vegetation protection in order to support its hydrological and ecological functions (Garcia-Arias and Francés, 2015; Macura et al., 2012).

As pointed out by Sponseller et al. (2013), running water ecosystems illustrate several principles governing the interaction of landscape form and ecological function. Whereas the control of sediment dynamics by hygromorphic plants has been identified as an important component of intertidal ecosystem function (Passarelli et al., 2014; O'Brian et al., 2018; Kazakova, 2018; Varigin, 2018), the effect of riparian vegetation on sediment erosion and deposition within fluvial systems has been studied mainly from the geomorphic perspective of landform dynamics (Bywater-Reyes et al., 2015).

Fluvial biogeomorphic studies suggested that the geomorphic effects (flow resistance, sediment stabilization and accretion) and biomechanical and life history responses (mechanical resistance, reproduction, dispersion, and growth) of riparian vegetation within and between floods may represent key controls on both the riparian ecosystem and landscape dynamics. Thus, the effects of riparian vegetation on sediment erosion/deposition dynamics may form a biogeomorphic function regulating conjointly succession, biodiversity and landform dynamics within fluvial corridors (van Dijk et al., 2014; Corenblit et al., 2014a). Biogeomorphic approaches are recently investigating back mechanisms between biota, topography and landscape dynamics (Correnblit et al., 2014b; van Oorschot et al., 2017; Dyderski et al., 2015; Gonzales et al., 2014, 2015; Arnold and Toran, 2018).

Riparian ecosystems often represent locations of concentrated biodiversity, and flooding is one of the most important factors accounting for the remarkably high biodiversity associated with the riparian zones (Tagwirey and Sullivan, 2015). Floods recharge the floodplain water table and provide seedlings with access to moist soils, create new sites for plant recruitment, flush organic material such as woody debris, deposit nutrients onto the floodplain and disperse seeds of riparian plants (Warner et al., 2014). The physiological effect of a flood event depends on an individual plant tolerance (Egger et al., 2013a). The most important flood factors affecting plants are flood level and relative water depth, flood duration, flood timing and time since the last flood event.

Because of the sensitivity to the hydrological regime, riparian vegetation composition, structure and vigour respond rapidly to flow regime changes (Boudell et al., 2015; Wohl et al., 2015). Hydrological changes sometimes result in the encroachment of river margins by native riparian species (e.g. Merrit, 2013; Sankey et al., 2015). In other cases, native species may loose their vigour (e.g. Havel et al., 2015; Li, 2013; Gonzalez et al., 2014) and may be replaced by other native or alien species that have different hydrological requirements and tolerances (e.g. Garssen et al., 2014; Capon et al., 2013; Catford et al., 2014).

Morphodynamic processes associated with floods such as sediment deposition/aggradation and fluvial erosion result in the physical disturbances. These

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

disturbances determine species diversity, population recruitment and survival, and the age structure of stands (Solari et al., 2015; Kath et al., 2014; Kondolf and Piégay, 2016). The extent and intensity of flood disturbance can be measured by its destructive impact on the vegetation (Mobaied et al., 2016).

Erosion of sediments during flood events can be estimated by a critical shear stress. When the flow conditions exceed a critical value, sediment particles on the stream bed start to move. The ability of a particle to move is related to hydraulic shear stress, frictional forces, water depth and the specific weight of the particle (Lamb et al., 2017). Riparian vegetation dynamics depends on hydrogeomorphologic parameters (Operman et al., 2017), and, in return, on living and dead riparian plants modulate sediment, diaspore, nutrient and water flows within fluvial corridors (Funk et al., 2018; Habersack et al., 2016). Fluvial corridors are constituted of river channels, their margins and the zone of expansion of frequent floods, occupied by riparian vegetation (Kim and Kupfer, 2016). The ability of some riparian plants to grow on deposited sediment implies that sediment deposition favours plant biomass production. In return, biomass production then increases surface roughness and sediment deposition (Thomas et al., 2015; Corenblit et al., 2014a). Many studies (Camporeale et al., 2013; Clarke et al., 2014; Eichel et al., 2013) suggest that vegetation plays key roles in determining fluvial ecosystem structure, function and channel geometry. During floods many riparian species reproduce both vegetatively and sexually and a lot of sediments are transported with the flow. Vegetation reduces velocity and shear stress on the interface between vegetation patch and flow (Rössler et al., 2018; Hession et al., 2013; Gilyear et al., 2017) that causes increasing sediment deposition within and behind vegetation patches (Surian et al., 2015). The decrease of the shear stress depends on the vegetation density (Rivaes et al., 2014).

The main goal of our research was to find out how important role can riparian vegetation have when it comes to protection of the floodplain soils in the selected area. The research investigates the impact of riparian vegetation on the sediment erosion in floodplain area of River Schwechat in Austria. Another part of our research aimed at the determination of shear stress values exerted in the soil surface during flood events using hydraulic modelling and, also, to assess its impact on erosion-accumulation processes. This impact was surveyed during one big flood, which occurred in spring of 2014 being the biggest flood event in the area of River Schwechat since year 2007.

Materials and methods

The focus of the work consisted of the application of theoretical and methodological approaches in the field of landscape ecology, biogeomorphology, hydrology, geobotany, geographic information systems (GIS) and remote sensing. Furthermore, applied methodology of our research was adopted and modified from the paper of Corenblit et al. (2009, 20014a, b, 2015).

Based on field measurements, a first task was to distinguish different vegetation types and groups followed by series of phytocoenological relevés that were conducted not only in the measured area but in the whole surrounding. That gave us quite clear idea about vegetation types and their characteristics present in the area of interest. Subsequently, humus horizon thickness was calculated and particle size survey was performed.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

Selected vegetation characteristics and their effects on the humus horizons in fluvisols were then statistically assessed followed by modelling of the shear stress during flood events.

The study area

The study site at River Schwechat is located in the Baden district at the south-eastern part of lower Austria about 20 km south of Vienna. Our reference site is located near the Traiskirchen village (starts at N 48°0.065' E 16°17.456' and ends at N 47°59.891', E 16°16.921', see *Fig. 1)*. The area is part of the floodplain forest around the river Schwechat and is protected as a natural monument. Schwechat flows through most of the south-eastern part of lower Austria. The highest point is at Schwechat Schöpfl at 893 m above sea level. With a slight bow, it flows from its origin in the north-east ending at Mannswörth (Schwechat) at 162 m above sea level with its water mouth into the Danube.

A large part of the catchment area is the southern part of the Wienerwald. Within the streams of Agsbach, Lammeraubach and Sattelbach the runoff flows into Schwechat near Baden. The Sattelbach, which joins in the same named village, is the largest tributary stream.

Figure 1. *Study site at the Schwechat River. (Source: Google Maps)*

The Wienerwald region is in the transition zone between the Pannonian climate in the east and the mainly oceanic swayed middle European climate in the west. The study area is located at about 200 m above sea level.

The summers are warm; the winters are very cold, dry, and windy; and it is partly cloudy year round. Over the course of the year the temperature reaches the annual average of about 12 °C. The monthly mean minimum and maximum daily temperature of Baden district is presented in *Figure 2*.

The annual precipitation in this area is around 600 mm (2011) with minimum numbers in winter (February) and the maximum ones in summer (June and July). *Figure 3* shows the average monthly rainy days over the year.

The perceived humidity level in Baden district, as measured by the percentage of time in which the humidity comfort level is *muggy*, *oppressive*, or *miserable*, does not vary significantly over the course of the year, staying within *2%* of *2%* throughout. The mean monthly relative humidity is displayed in *Figure 4*. All presented averages are based on weather reports collected during 2005–2015.

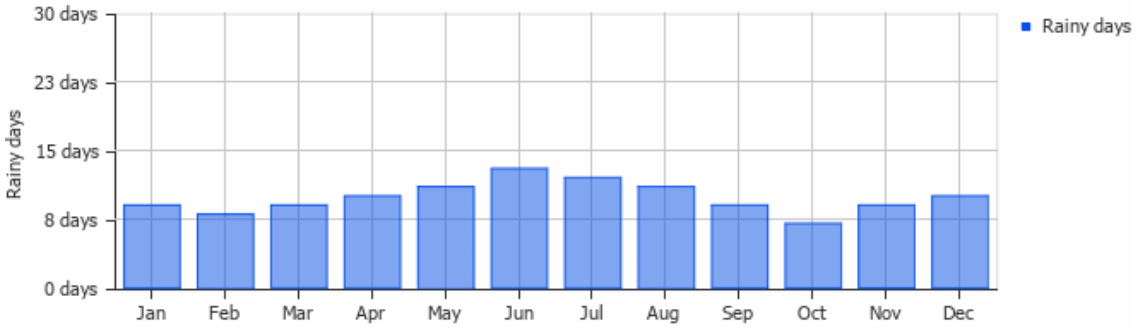

Figure 3. *Average days with precipitation per month in Wiener Neustadt, Baden district. (Source: www.weather-and-climate.com)*

Figure 4. *Average relative humidity in Wiener Neustadt, Baden district. (Source: www.weather-and-climate.com)*

As the considered section for our research is close to the Traiskirchen the deciding discharge site is "Cholerakapelle" which is upstream of Baden. *Table 1* shows recurrence intervals and correspondent discharges at this hydrological station. Run off data before and during the flood are displayed in *Figure 5*.

The flood occurred in May 2014 (peak May 16th, 2014). Maximum discharge that occurred during the flood was 91.7 $m^3 s^{-1}$ (http://ehyd.gv.at) which corresponds to the 4.5 year discharge. Historical maximum discharges are represented in *Table 2*.

Field measurements

Observations were made along one transect (T1) located at River Schwechat; the transect was chosen appropriately to represent characteristics needed in this survey. Eight measuring plots within T1 transect were distinguished.

The research started in June and July 2013 when we determined the position of the transect and the measured plots. The comprehensive survey and field measurements of the floodplain vegetation continued in May and June 2014. Data measured in May 2014 were used to capture the transect state before the flood while data measured in June 2014 were used for defining the changes after the flood.

Plots were determined as areas of 2 m × 2 m, limited by using wooden removable frame *(Fig. 6)* fixed in one corner by an iron stake and three adjustable corners which were levelled using a spirit level. These frames were subdivided into a regular 0.2 m mesh defining 100 sampling subplots. Iron stakes driven into the substrate guided precise relocation of the plots, with starting position of 40 cm above the ground level. Each plot and its surroundings were documented by high-resolution photographs.

Figure 6. *Frame design*

The first step was to estimate total vegetation coverage in each plot followed by precise estimation in each subplot based on photographs. The key for the mapping units is based on the characterization of polygons in the aerial photo. The delimitation of the polygons with similar land cover was done before starting the mapping in the field. The data collection was focused on structural features. The dominant species and their coverage percentages were recorded. Furthermore, maximum plant height, median plant height, vegetation coverage and humus horizon thickness were measured in each subplot. Humus horizon thickness serves as a parameter to estimate amount of eroded/accumulated material, thus to estimate the changes of the humus horizon thickness.

The chosen study site is characterised by both a strong natural meandring and a high occurrence of wood and sediment transport during floods. Trees and debris that were transported during floods were deposited after stage decline and large areas with bare sand. Gravel banks were also observed.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

Phytocoenological survey

One of the most important part of the research was vegetation mapping provided by series of phytocoenological relevés which were conducted not only in the measured transect, but in the whole surrounding. That gave us quite clear idea about vegetation types present in the area of interest. As the riparian areas are considered to be valuable ecosystems because of their biodiversity and functions, part of our research was dedicated to the invasive species which can significantly lower the biodiversity and other important functions of these ecosystems.

Our phytocoenological research followed results of vegetation mapping obtained in Ecoriver project (Egger et al., 2013a). According to this project, 10 vegetation types were distinguished in the whole research area (*Fig. 7).*

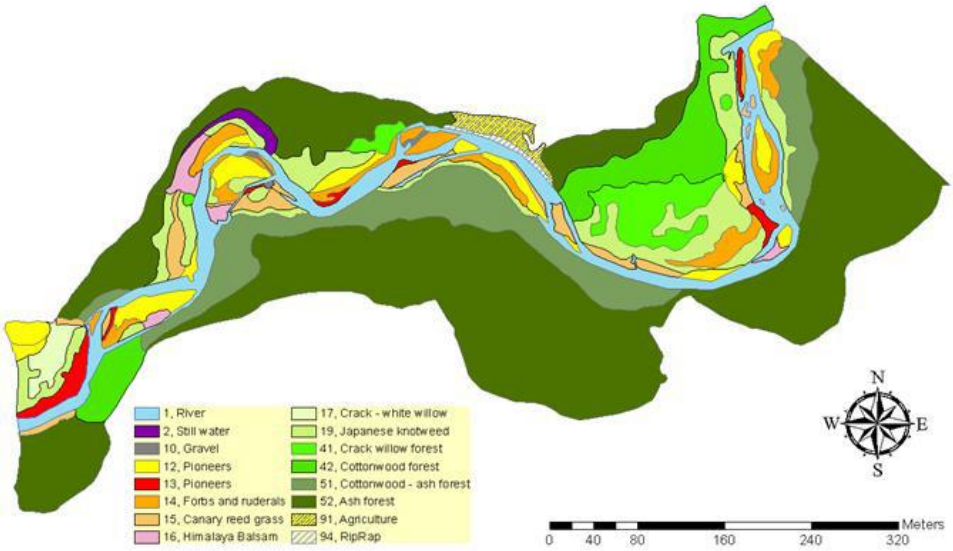

Figure 7. *Mapped vegetation types. (Egger et al., 2013a)*

Vegetation types were investigated by performing a phytocoenological relevés to define a floristic composition of these sites. Abundance of each plant species were classified according to the 7-points Braun-Blanquet classification (Braun-Blanquet, 1964). Nomenclature of plant taxa is presented according to the program TURBOVEG for Windows (Hennekens, 1998-2012). This computer software package was developed in The Netherlands for processing of phytocoenological data. The package comprises of an easy-to-use database management system. The data bank to be managed can be divided into several databases which may consist of up to 100.000 relevés each. The program provides methods for input, import, selection and export of relevés. In 1994, TURBOVEG was accepted as the standard computer package for the European Vegetation Survey. Currently it has been installed in more than 25 countries throughout Europe and overseas (Hennekens, 1998-2012). Relevés were used for defining the floristic composition of the site.

Particle size survey

Samples were taken from individual plots before the flood event (May, 2014). As the first step samples were dried and fine grained components were divided. Subsequently,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

saturated hydraulic conductivity was measured. Then the percentage of the different sized particles in each sample were determined using the Cassagrande densimetric method.

The areometric Cassagrande method is based on the use of special densimeters (areometers) that monitor changes in the density of a soil suspension in water and in various soil particle diameters in terms of the sedimentation time changes. Density changes are caused by the sedimentation process; the density of the hydro-suspension falls with the increasing length of measurement. This method is one of the non-repeated sedimentation methods, which means, that all of the measurements must be performed within one sedimentation process. An appliance for this method consisted of an analytical balance, porcelain dish, laboratory spoon, timer, calibrated cylinder (1000 ml; *Fig. 8*), funnel, manual mixer, densimeter, thermometer, dispersing agent (sodium hexamethaphosphate) and distilled water.

Figure 8. *Calibrated cylinders (1000 ml)*

The charge of fine grained soil differs according to the amount of clay particles in the soil. In the case of clayey soils, the charge ranges from 20 to 30 g (in clays it is 10 g), as far as sandy-clay, loamy and clay-loamy soils are concerned, the charge is approximately 30-50 g and in case of sandy soils it is 100 g. The soil was weighed, placed in a porcelain dish and mixed with distilled water (200 ml). Dispersing agent was then added (10 ml of agent for every 10 g of fine grained soilI) and was boiled for 1 h. The suspension was mulled at the bottom of the dish after cooling while the muddy part was poured directly into a graduated cylinder (1000 ml). The suspension in the graduated cylinder was mixed by a glass rod for one minute before the measurement started. When the glass rod was taken out, an areometer was put in its place and the first density measurement started after 30 s.

The results were analysed with a nomogram in which the size of settling particles is determined depending on the individual sedimentation time. The process is followed by a percentual determination of individual fractions.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

The soil type was identified according to the given values based on the classification system used in Slovak Republic. It is being applied to particles with diameters below 0.01 mm (*Table 3).*

Table 3. *Soil texture classification*

Particle content < 0.01 mm (%)	Soil type nomenclature	Basic soil type
0	Sand	Light soil
0-10	Sandy	
10-20	Loamy sand	
20-30	Sandy loam	Medium heavy soil
30-45	Loamy	
45-60	Clayey loam	
60-75	Clayey	Heavy soil
> 75	Clay	

There were 8 measuring plots placed (T1-1, T1-2, T1-3 up to T1-8) in the evaluated transect. However, due to the huge development of invasive species stands (mostly by *Fallopia japonica)* it was not possible to measure all the parameters in three plots (T1-1, T1-2, T1-3) and they were not assessed.

Statistical evaluation

Similarly, due to the huge development of invasive species of *Fallopia japonica* it was not possible to measure all the parameters in three plots (T1-1, T1-2, T1-3) and they were not statistically evaluated. Therefore, data from 5 plots (T1-4 to T1-8) were evaluated, each plot was divided to 100 subplots (0.2 m × 0.2 m), and in each subplot 4 parameters were measured. That makes 400 datasheets for each plot, altogether 2000 data for 5 evaluated plots. The relationships between parameters (dominant species and their coverage, maximum plant height, median plant height, vegetation coverage and humus horizon thickness) in the transect and also in the individual plots were analysed.

Fallopia japonica was quickly spreading after 2013, especially close to flood areas. That is why differences in the area of distribution were measured before and after flood. Measurements were performed in our area of interest.

Hydraulic modelling

The next step of our research was the modelling of the flood discharge from May 2014 using a MIKE 21 model together with Mud Transport Module (MT). Such module can simulate the processes of erosion, transport, setting and deposition in marine, brackish and fresh water areas. The module takes into account fine non-cohesive materials.

The aim of the hydraulic modelling was to find out the value of the shear stress, which was affecting the plots during the flood event. The model inputs were represented by the digital elevation model, which was created from the topographic data measured at the site, the flood characteristic discharges and the information about sediment character. The output of the model is the point mash with shear stress values. The output was exported to the GIS and used for creating graphic outputs of the modelling.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

The critical shear stress τ crit can be determined from the shields curve (*Fig. 9*). The shields curve presents the relation between non-dimensional critical shear stress and boundary Reynolds number *Re* which is the Reynolds number on the interface between flowing water and surface. For higher Reynolds numbers the critical sheer stress decreases and for Reynolds numbers *Re* >> 500 the shields parameter is constant at 0.057.

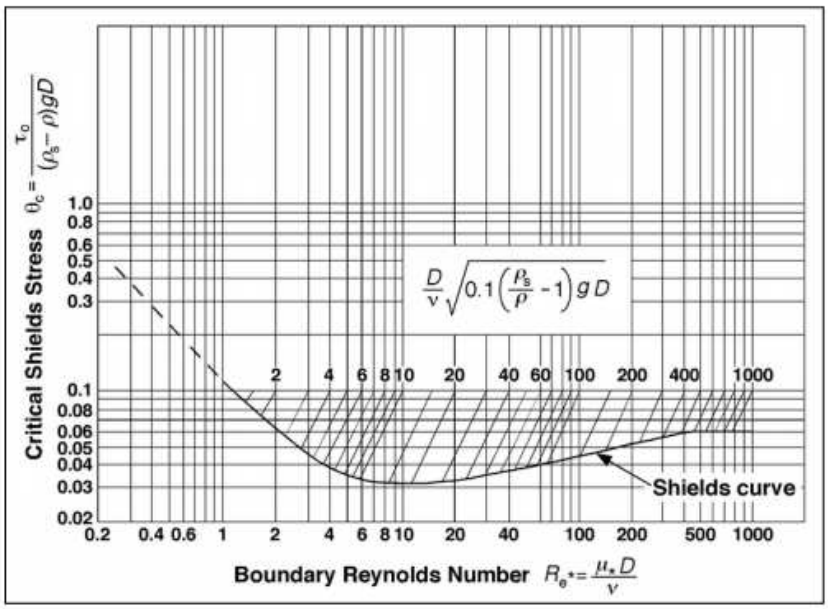

Figure 9. *The shields curve*

Results

Phytocoenological survey of distinct vegetation types

Phytocoenological characterization was performed in order to distinguish all the vegetation types present in the surroundings of T1 transect. Only herb vegetation occurred in the area of transect therefore the effect of herb vegetation on the erosion – sedimentation processes are presented. Hopefully research will continue in the future, when there will be more localities and effect of woody vegetation evaluated, so the research can follow by characterization of the vegetation presented in this study.

Pioneer site at the transect is typically dominated by species of *Saponaria officinalis* usually followed by species of *Chenopodium album*, *Echium vulgare*, *Impatiens glandulifera*, *Melilotus officinalis*, *Papaver rhoeas*, *Persicaria dubia*, *Phalaris arundinacea*, *Poa pratensis*, *Arctium* sp., *Polygonum aviculare* and young tree seedlings of *Populus x canadensis* and *Salix fragilis.* The second type of pioneer site is dominated by species of *Impatiens glandulifera*, subdominated by *Saponaria officinalis* or *Urtica dioica* following with species like *Echium vulgare*, *Galium aparine*, *Phalaris arundinacea*, *Artemisia vulgaris*, *Hedera helix*, *Melilotus album*, *Plantago lanceolata*, *P. major* and *Poa pratensis*.

Closer to the poplar forest edge a pioneer site dominated by seedlings of young *Populus nigra* trees with few individuals with shrub height were found, sometimes subdominated in herb and also in shrub layer by tree species of *Robinia pseudoacacia*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

followed by species *Phalaris arundinacea*, *Saponaria officinalis*, *Urtica dioica* and *Plantago major*, *Hedera helix*, *Chelidonium majus*, *Ulmus laevis*.

There were three types of forbs and ruderals stands in our study site – the first one dominated by *Echium vulgare* and/or *Arrhenatherum elatius (*on the drier stands), the second one dominated by *Impatiens glandulifera* and the third type of forbs and ruderals is dominated by *Phalaris arundinacea*.

Wetter type of forbs and ruderals are stands dominated by *Phalaris arundinacea* often followed by *Urtica dioica*, typical are also young poplar and willow trees in herb or shrub layer, also *Saponaria officinalis* with higher abundance. Among other species found here were for example *Impatiens glandulifera, Rumex obtusifolius, Juglans nigra, Lapsana communis, Lolium perenne, Scrophularia umbrosa, Lythrum salicaria, Stellaria sp., Mentha longifolia, Taraxacum* sect. *Ruderalia, Petasites hybridus, Trifolium hybridum*.

There were just few localities with crack-white willow stands in our study area and they had small coverage. Tree layer is formed by *Salix fragilis*, *S. alba, Robinia pseudoacacia*. Shrub layer is typically covered by *Fallopia japonica* that is present also in herb layer together with *Impatiens glandulifera*. Few patches with the crack willow forest were found at the site with *Salix fragilis* species. *Vitis vinifera* was typical in tree, shrub and also in herb layer. This site has typical shrub layer in crack willow stands, because in most cases it invaded by *Fallopia japonica* that is typical also in herb layer.

Large stands of poplar forest vegetation type were not found so it was possible to put together only one phytocoenological relevé. There was significant dominance of poplar trees in the low tree layer followed with *Fraxinus excelsior, Acer platanoides, Ulmus minor, Acer campestre, Acer negundo, Prunus avium* and *Prunus padus*. Shrub layer was dominated by *Sambucus nigra* and also species of *Cornus sanguinea, Juglans regia, Ulmus minor, Fallopia japonica, Prunus padus* and *Corylus avellana* were found here. Herb layer was dominated by species of *Aegopodium podagraia* with *Urtica dioica, Alium ursinum* and *Galeobdolon luteum*.

Poplar – ash forest occured in both higher and lower tree layers with dominant species of *Fraxinus excelsior*, *Populus nigra*, *Acer campestre*, *Acer platanoides*, *Ulmus minor*, *Ulmus laevis*, *Robinia pseudoacacia* and *Juglans nigra*. Shrub layer was represented by *Cornus sanguinea*, *Acer platanoides*, *Acer campestre*, *Crataegus monogyna*, *Sambucus nigra*, *Ulmus minor*, *Ulmus glabra*, *Cornus mas*, *Juglans regia*, *Ligustrum vulgare* and *Acer negundo*. Herb layer was dominated by *Lonicera xylosteum* and subdominated by *Aegopodium podagraria*. All the above mentioned species from tree and shrub layers can also be found in herb layer together with species of *Salvia glutinosa*, *Knautia arvensis*, *Arum maculatum*, *Rubus caesius.*

Typical maple species in higher tree layer were represented by *Acer campestre, A. platanoides* and *A. negundo*, ash Fraxinus excelsior was dominant in lower tree layer where also *Populus alba, Ulmus laevis Tilia platyphyllos* and less *Ulmus minor, Prunus padus* were found. Shrub layer is also formed by these tree species and seedlings were also found in the herb layer. Typical shrub species in these forests are *Sambucus nigra*, *Ligustrum vulgare*, *Acer campestre*, *Ulmus minor*, *Crataegus monogyna*, *Rosa canina*, *Cornus sanguinea*, *Juglans regia*, *Fraxinus excelsior*. In herb layer a presence of *Lonicera xylosteum*, *Aegopodium podagraria, Hedera helix, Allium ursinum* were noticed as well as species like *Arrhenatherum elatius, Arum maculatum, Calystegia sepium, Chenopodium bonus-henricus, Elymus caninus, Euonymus europaeus, Rubus caesius*, *Ranunculus repens*, *Polygonatum latifolium* and seedlings of tree species.

Phytocoenological relevés were performed in the surroundings of the measured plots (not directly at plots measured) in order to have a better picture of phytocoenological composition of the transect surroundings. Relevés were used for defining the floristic composition of the site. The example of phytocoenological table with relevé is presented in the phytocoenological *Tables 4* and *5*.

Particle size survey

Particle size survey was performed in the laboratory, The Casagrande´s method was used for evaluation (*Table 6*) of 5 samples, each representing one plot (T1-4 to T1-8). Based on our field measurements performed in 2014, 3 plots (T 1-1, T 1-2 and T 1-3) were not assessed due to the presence of *Fallopia japonica.*

From the particle size analysis shown in *Table 6* the soil types in each of our measured plots can be characterized The amount of the sand in the samples is greatest in the last two plots T1 -7 and T1-8.

Statistical evaluation

Analysis of the relationships between individual parameters consisted of the evaluation in the whole transect and within the plots using the linear regression analysis. Data were obtained in May 2014 in two different time periods. The status before and after flood had to be compared as it was necessary to find out the effect of the vegetation on soil during flooding. Flood was culminating on May 16th, 2014 and it was not possible to get to the transect because of the flooded access, *Figures 10 and 11* represent localities upstream and downstream from the research site. Data from 5 plots in T1 transect (T1-4 to T1-8) have been evaluated and, also, analyses of individual

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

parameters dependence on the channel distance and dependence of humus horizon difference on the vegetation parameters (height, coverage) were performed.

Figure 10. *Flood - downstream*

Figure 11. *Flood - upstream*

The graph and the regression line of the dependence between vegetation coverage and the distance from the water body is presented in *Figure 12*. Correlation coefficient is negative and equals to – 0.542, reflecting strong negative relationship between these

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

two parameters. This value means that with the increasing distance from the water, vegetation coverage is getting lower in the area within 12-30 m distance from the water body.

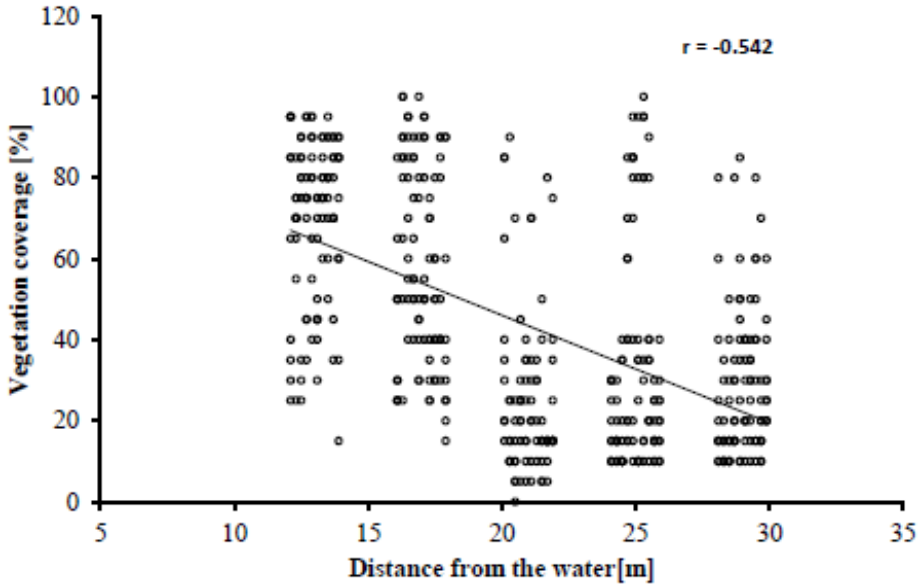

Figure 12. *Dependence of the vegetation coverage on the distance from the water body*

In *Figure 13* the graph of the dependence of the maximum plant height and the distance from the water body is presented. Similar results to the one in the previous case were observed; correlation coefficient is negative and equals -0.454. This value can be interpreted as a strong negative relationship between variables. We can conclude, that in the plots T1-4 to T1-8, the greater is the distance from the river the lower is the maximum plant height.

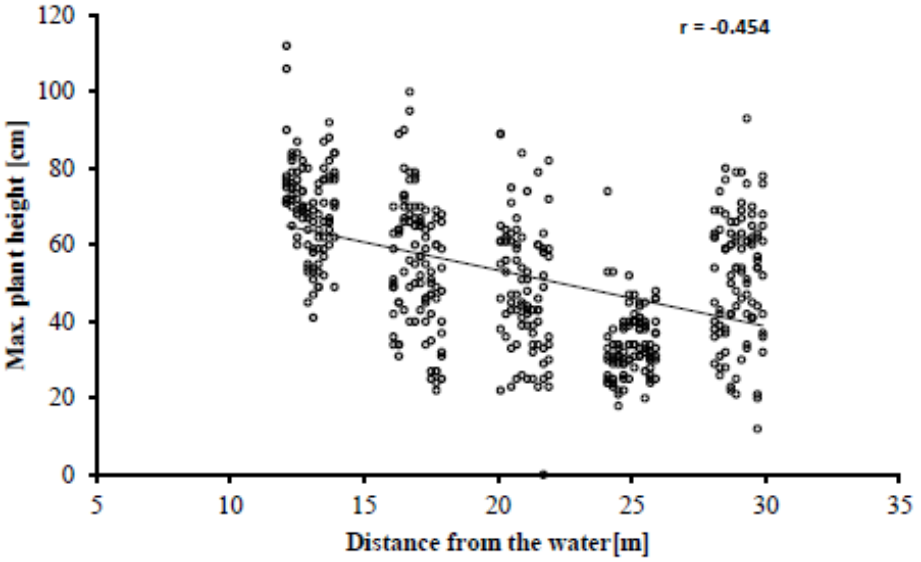

Figure 13. *Dependence of the maximum plant height on the distance from the water body*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

Figure 14 shows dependence of the humus horizon thickness difference (difference before and after flood) and distance from the water body. In this case, the correlation coefficient result was a positive value equal to 0.779. This value reflects positive relationship; with greater distance from the river the humus horizon thickness difference is increasing. Erosion is decreasing and deposition of material is starting to occur with increased distance from the water body. In this case, the effect of the distance from the river on the changes in the humus horizon thickness is more important than other measured vegetation parameters (height, coverage).

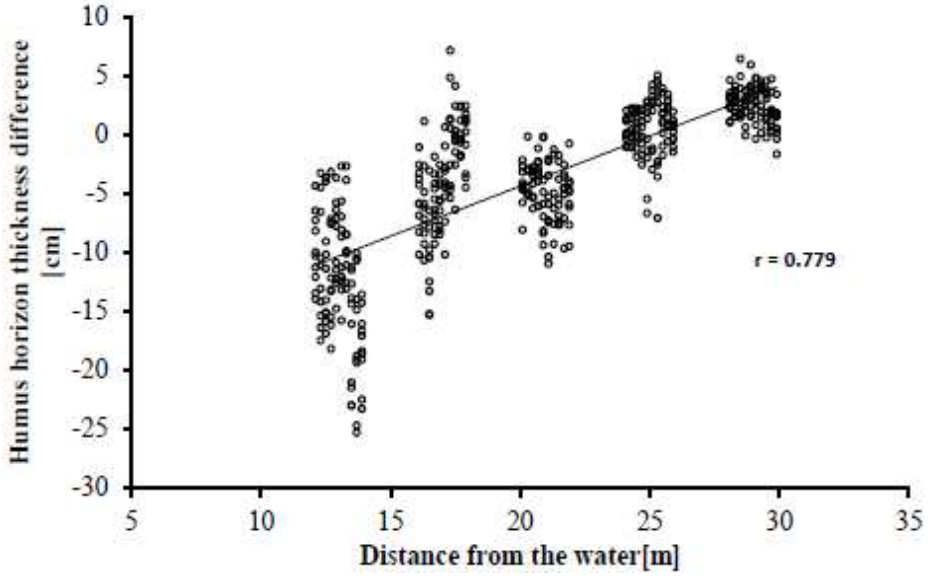

Figure 14. *Dependence of the humus horizon thickness difference on the distance from the water body*

Figure 15 shows dependence between maximum plant height and vegetation coverage. Correlation coefficient value is r = 0.5 and it can be concluded that there is a positive correlation between these two parameters; value of the maximum plant height is increasing with increased vegetation coverage.

In *Figures 16* and *17* relationships between humus horizon thickness differences and vegetation parameters; vegetation coverage and maximum plant height are presented. In both cases the correlation coefficient had negative values (-0.498 a 0.471) reflecting negative relationship between variables. It can be concluded that with higher percentage of vegetation coverage in measured plots the erosion in humus horizons of fluvisols increased and the deposition decreased. Similar conclusion can be confirmed for plant height; erosion is higher with higher maximum plant height.

The above presented results show that distance from the water body was the most important effect on the thickness of the humus horizon in fluvisols at the chosen site. Taking into account the conditions during flood event in spring 2014, the vegetation did not have such important role. It must be noticed that we are dealing with a complex system and complicated process, thus other involved factors (e.g. species composition, size of the root system, roughness of the vegetation cover) were not considered in this study.

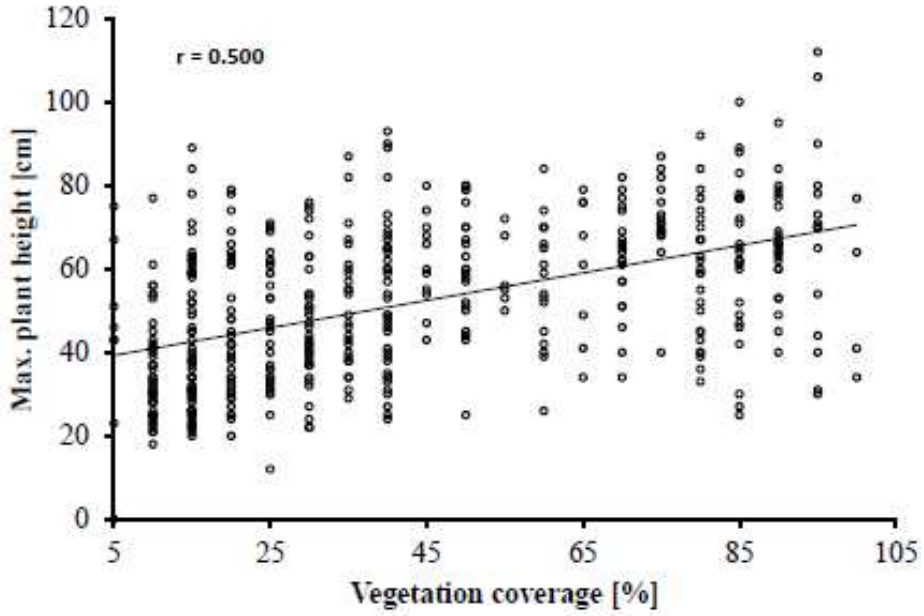

Figure 15. *Dependence of the maximum plant height and the vegetation coverage*

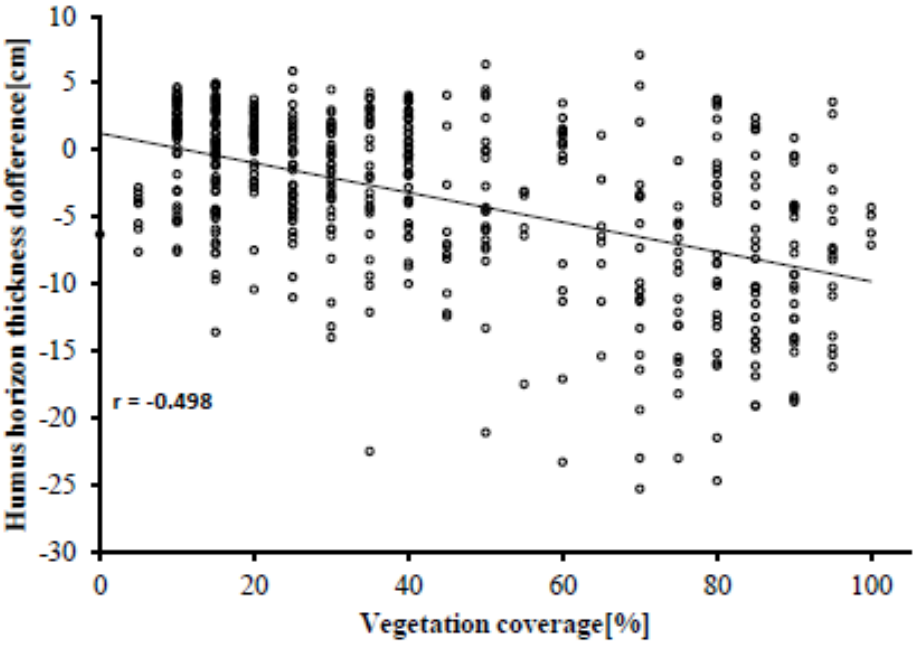

Figure 16. *Dependence of the humus horizon thickness difference and the vegetation coverage*

Our results of the relationship analysis between vegetation characteristics and changes in the humus horizon thickness are in contradictions with the published information. Surprisingly, there are mainly negative correlations between the change in the thickness of humus horizon and vegetation coverage, respectively maximum plant height. The results indicate, that vegetation promote erosion and negatively affect sediment accumulation. Such correlation relationships apparently cannot be a causal relationship but it is only a seeming correlation. Effect of vegetation in the studied

DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

riparian zone is masked by the influence of spatial change of vegetation characteristics. In the matter of fact, very strong negative correlation was recorded for the relationship between the distance from the water body and vegetation coverage, respectively maximum plant height.

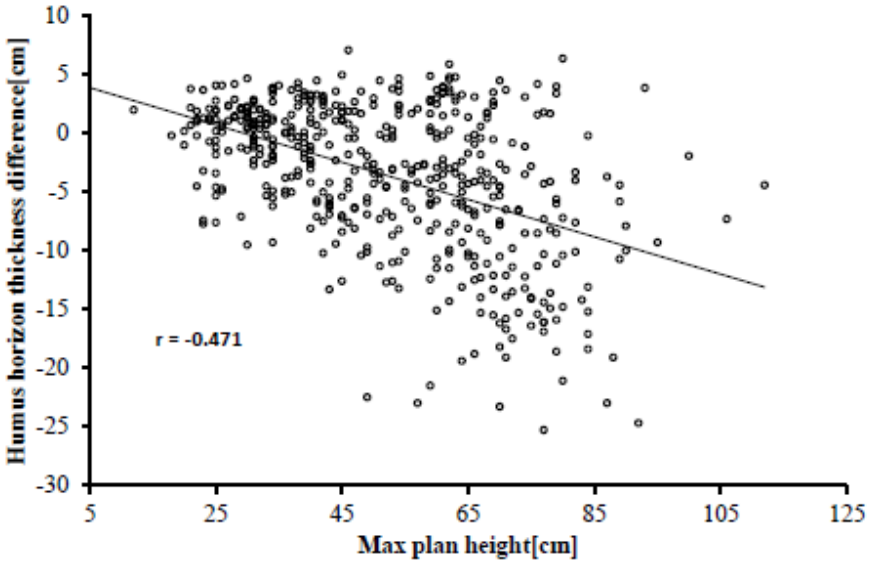

Figure 17. *Dependence of the humus horizon thickness and maximum plant height*

Hydraulic modelling

Shear stress was modelled using MIKE21 processed in the GIS environment; *Figure 18* represents the output from model with shear stress values for whole area while *Figure 19* shows the shear stress values simulated for individual plots. The highest values of shear stress were simulated in the T1-4 and T1-5 plots, in the plot T1-4 shear stress values were equal to 19 $N.m^{-2}$ and in the plot T1-5 there were equal to 17 $N.m^{-2}$. During flooding of such intensity (app. Q4.5), the humus horizon is eroded in the area of these plots. The plot T1-6 appeared to be a "transition zone" between erosion and sedimentation, shear stress values were equal to 16 – 9 $N.m^{-2}$ and humus horizon sinked to minimal values.

Discussion

River channel significantly changes during the flood. The influence of vegetation on the channel transport and dynamics was analysed in few studies (Gurnell, 2014, 2016a, b; Rinaldi et al., 2013, 2015). It can be concluded that vegetation plays significant role in shaping the river channel and morphodynamic river development (Liu and Neph, 2016). Presence of vegetation causes that with lowering the velocity flow the shear stress is lowering and the river bank is stabilizing.

There are few types of erosion occurring around the river during the floods, while thanks to the surface erosion; also plants can be eroded together with soil particles (Rivaes et al., 2014).

Surface erosion can be found on bigger areas closer to the channel, with evenly distributed, high shear stress on the surface.

DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

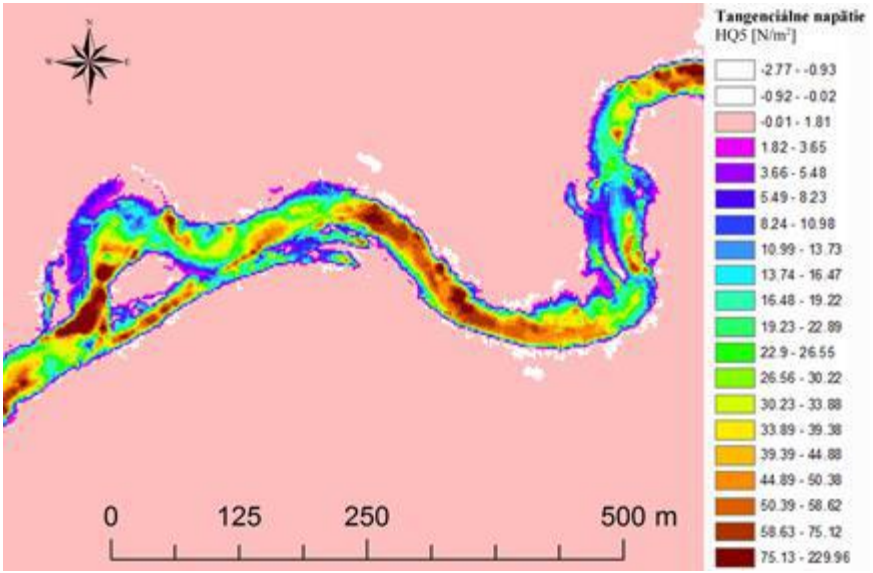

Figure 18. *Modeled shear stress in the evaluated plots of the Schwechat River Q 4,5 (Arc Map)*

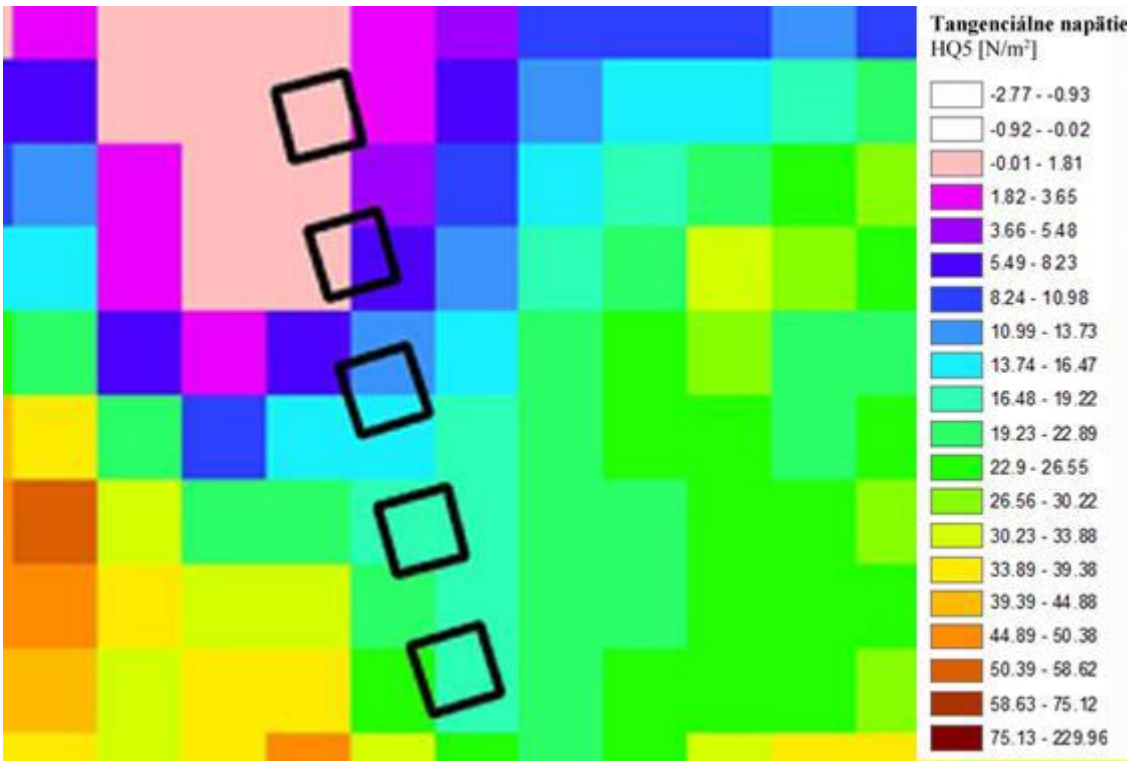

Figure 19. *Modelled shear stress in the evaluated plots of the Schwechat River Q4,5*

Aforementioned studies proved that vegetation, according to its lowering of the flow velocity and the shear stress values, has a significant anti-erosive function. Presence of the vegetation can also support deposition of sediments and cohesive particles brought by water during the floods.

As already mentioned, our results of the relationship analysis between vegetation characteristics and changes in the humus horizon thickness are in contradictions with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

the published information. Surprisingly, there are mainly negative correlations between the change in the thickness of humus horizon and vegetation coverage, respectively maximum plant height. Effect of vegetation in the studied riparian zone is masked by the influence of spatial change of vegetation characteristics. In the matter of fact, very strong negative correlation was recorded for the relationship between the distance from the water body and vegetation coverage, respectively maximum plant height.

As shown by shear stress modelling, changes in the thickness of humus horizons are influenced mainly by a significant decline in the values of shear stress exerted by water during flood events on the soil surface. The sharp decline in shear stress with increasing distances of the water flow has resulted in a gradual shift from erosion processes with a negative change in the thickness of humus horizons, to the accumulation process with a positive change in the thickness of the research areas furthest from the water flow. The impact of changes shear stress on erosion-accumulative processes in the studied area is in addition highlighted by the spatial variation of grain composition of soils. Since with increasing distance from the water flow is the proportion of the lighter particles in the soil lowering, and on the other hand the proportion of heavier sand particles is increasing. The impact of this physical process is so powerful that it completely obscures the effect of vegetation present in the research plots, resulting in the aforementioned correlation relations.

Conclusion

The main aim of this research was to find out how important is the influence of vegetation in floodplain areas on deposition and erosion of the sediment, thus on the thickness of the humus horizon during floods. In the selected site of the river Schwechat in Lower Austria we observed different parameters required for this analysis. Among many data, those that meet the objectives of our study were selected and these were also statistically evaluated.

Statistical evaluation had two stages; the first step was to evaluate the variability across the transverse profile, the second step was to evaluate variability in individual squares - plots. In this case, we can conclude, that the variability within the plots was not as significant; thus, the distance between the pads within a square were not big enough to be able to see any significant difference in the effects of various parameters on the thickness of the humus layer.

From the evaluated data it was obvious that on the T1-4 plot erosion of sediment during the flood originally appeared, but that decreases with a distance from the shore and is changing to sedimentation on the plots T1-7 and T1-8. The role of the statistical evaluation was to determine which factors have the greatest impact on erosion accumulative processes affecting the variations in thickness of humus horizons of fluvisols. The investigated factors on the results of field research were especially distance from the water flow and the plants height and vegetation coverage. There were also modelled values of shear stress exerted by water on the soil surface during flood events.

Trying to characterize a specific process of such a complex system is certainly a difficult task and we have to keep in mind that the thickness of humus horizon of fluvisols in the offshore area is affected by many more factors, which was not taken into account in this work; such as the nature of vegetation, its detailed species composition

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63496374

and distribution, folic coverage, the coverage and the nature of the root system of vegetation.

Unfortunately, it was not possible to evaluate all the selected transect areas as it was not possible to collect data for the amount of sediment during the second measurement thanks to massive distribution of species *Fallopia japonica*. The selected plots with complete data provide characteristics for remote area 16 to 40 meters from a watercourse, with predominantly sandy-loamy to sandy soil and the herb community, with a dominant species *Echium vulgare*, or *Arrhenatherum elatius*. Therefore plots closest to the river, where the positive effect of vegetation is expected is settled by Fallopia japonica which can contrariwise support the erosion of sediments. As we calculated, the rate of spread might be very dangerous and lowering the ecological quality in this protected area.

The flood of May 2014 had an intensity of about 4.5 years water (91.7 m^3 s^{-1}), and during this kind of flood with those growing and soil conditions, the thickness of the humus horizon on the evaluated plots is mostly affected by the distance from the water flow. When evaluating vegetation parameters, it was found that, surprisingly, a higher cover reduces the amount of settled material and increases erosion in the humus horizon.

Similarly surprising, dependence concerns also affect the maximum height of plants. Erosion increases and sedimentation reduces with increasing maximum plant height. These surprising dependences are not the result of vegetation effect but are related to the dominant influence of distance from a watercourse on erosion-accumulative processes. Distance from water has a strong impact on the decrease of the shear stress which during the flood effects on the soil surface. At the same time the negative correlation between the distance from a watercourse and vegetation coverage/maximum plant height was observed. The impact of this factor therefore masks the effect of vegetation characteristics.

From the recorded changes in the humus layer thicknesses during flood events it can be concluded, that the erosion-accumulative processes were dominantly controlled by changes in shear stresses, that were affecting the soil surface during the flood. Influence of shear stress has also enhanced by the spatial variation of grain composition of soils.

As already mentioned, the results indicate that vegetation promote erosion and negatively affect sediment accumulation. Such correlation relationships apparently cannot be a causal relationship but it is only a seeming correlation. Effect of vegetation in the studied riparian zone is masked by the influence of spatial change of vegetation characteristics. In the matter of fact, very strong negative correlation was recorded for the relationship between the distance from the water body and vegetation coverage, respectively maximum plant height.

Phytocoenological characterization can help when performing future research in this area and monitoring of the invasive species spreading is suggested for evaluation during future flood events.

(Received 3rd Jan 2019 ; accepted 21st Mar 2019)

Abstract. There must be unique indicator vegetation at Ecotonal Zone in the border region of Pakistan and Afghanistan. Keeping this hypothesis in mind the forest zone of District Kurram at Durand Line was ecologically surveyed. Stations were established, GPS readings, environmental gradients were recorded and soil samples were collected. Data was statistically analysed using PC-ORD version-5 and CANOCO version-4.5. Indicator Species Analysis (ISA), constancy and fidelity level were used to find indicator species of communities. Preliminary results showed that study area hosts 195 vascular plant species belonging to 145 genera and 60 families. Cluster Analysis classified vegetation into four plant communities; (a) *Elaeagnus angustifolia-Rosa chinensis-Seriphidium kurramense* (b) *Platanus orientalis-Rosa moschata – Epilobium hirsutum* (c) *Quercus baloot – Jasminum auriculatum-Foeniculum vulgare* (d) *Quercus dilatata-Hedera nepalensis-Calamintha umbrosa*. Nitrogen, Sodium and Potassium were the strongest Physico-chemical factors ($P \leq 0.05$) determining plant communities composition. Interestingly, *Vincetoxicum cardiostephanum* was reported as narrow endemic species. Distinguished indicator species had significant environmental preferences. Variables like grazing and fodder chopping were the major vegetation drivers. Altitude was one of the most important determinants, influencing directly species distribution; Current study could be potentially used elsewhere for vegetation management and conservation strategies.
Keywords: *Indicators of Transitional Zone; Kurram Agency at Pak Afghan Border; Edaphic Factors*

Introduction

The "ecotone" term was coined by Clements (1905) for transition zone and considered it as a basic unit of landscape ecology (Hansen et al., 1992; Casalini et al., 2019), having extremely unique vegetation, sensitive ecosystems and sharp communities boundaries (Walker et al., 2003; Gonçalves and Souza, 2014), due to abrupt environmental changes (Arellano et al., 2017). These characteristics enhanced significance to check competing ecological theories (Neilson, 1991) and especially climate change management (Kupfer and Cairns, 1996; Judi et al., 2018). The sensitivity and mechanisms of response are differentially varied among ecosystems and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63756396

communities (Huang et al., 2016). The ecosystem continuations particularly for food security are indispensable, not merely to mountainous highland but for lowlands ecosystem; particularly who are dependent on these mountains resources (Rasul, 2010; Dolezal et al., 2016). Therefore, understanding plant and environmental variables correlations, highlighting leading threats and conservation managements are the fascinating research field for ecologists and environmentalists (Tavili and Jafari, 2009; Khan et al., 2016).

Vegetation structure and composition are persuaded by numerous natural and anthropogenic activities (Shaheen et al., 2012; Lyu et al., 2017). Thus, ecosystem services quantification and evaluating vegetation distribution and mapping are important for conservation (Biondi, 2011). Vegetation classification into possible plant communities is also a mandatory part of ecosystem ecology, natural resource management and habitats degradation and fragmentation studies (Khan et al., 2015). It would visualise heterogeneity insights of particular vegetation's type (Haq et al., 2015b). Plant ecologists often hypothesized vegetation driving mechanism and environmental gradients (Willig et al., 2003; Haq et al., 2015a). In mountainous region topography and elevation had strong effects on species diversity, richness and community structures (Khan et al., 2015; Ullah et al., 2015). Anthopogenic disturbances may trigger species shifting (Johnstone and Chapin, 2003) and/or probably eliminate forest products (Brown and Johnstone, 2012) and alter ecosystem function (D'Amato et al., 2011). Long-term overgrazing could have legacial effects on plant diversity, biomass production and edaphic factors (Sher et al., 2010; Sternberg et al., 2017). The soil micro and macro nutrients level can significantly affect species richness and communities Byrne et al. (2017) examined plant's responses against precipitational change and concluded comparatively high level sensitivity. Chang et al. (2018) and Skagen et al. (2018) emphasized forest sensitivity and responses against precipitation variation in ecotones over a time scale.

The indicator species identification ultimately helps in management and restoration of natural resources (Ahmad and Khan, 2004; Mashwani et al., 2011). Keeping the hypothesis in mind; there must be unique indicator vegetation at Ecotonal Zone. The current study was designed to evaluate the vegetation and communities, indicator species and to determine whether soil characteristics and/or anthropogenic activities influences on community distribution in the ecotonal zone. The aim was designed with three main objectives; to quantify vegetation of the ecotonal region, to classify vegetation in major communities along the geo-climatic and altitudinal environmental gradients and to assess the indicator species under the influence of disturbances for future generation management. Additionally, current study documented suggestions for the mountainous plant biodiversity conservation under the scenario of continuous anthropogenic activities.

Material and methods

Study area description

The Kurram Valley is situated in the far West of the Khyber Pukhtunkhwa (KP), Pakistan, projecting like a neck in Afghanistan and touching Pukthia, Nangarhar and Khost provinces on its West. Previously, study are was called as FATA but on 24 May 2018 in 25th Constitutional amendment, has been merged to KP and give it agency status, It lies between 33° 20' to 34° 10' N-latitudes and 69° 50' to 70° 50' E-longitude,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63756396

with a total length of 115 km and covering 3380 km^2 area (*Fig. 1*). District Orakzai and Khyber are lies on its East, District Hangu is situated at southeast, while District North Waziristan is bordered at south. "Koh-e-Sufaid" the part of Western Himalayas, situated on its North. The highest known peak is Sikaram with an altitude of 4728 m a.s.l. This mountainous range results high annual average precipitation and hence summers remain pleasant. The valley is relatively dry and mostly represents the dry temperate-type of habitat. Heavy snowfall has been experienced in winter with a freezing temperature (*Fig. 6*). The study area, floristically the part of Western Irano-Turanian region of the Western Himalayan province. Moreover, it gains distinctive position to act as botanical buffer zone between the dry temperate and moist temperate vegetation zones of the Himalayan and Hindu Kush mountainous ranges, respectively. Thus, due to this unique transitional locality, the valley hosts typical vegetation and position in the region. Vegetation is predominated by oak, blue pine, cheer pine forests and chilgoza pine in the extreme border with Afghanistan. Despite of high phytogeographic status factor like; geopolitical conflicts, harsh terrain, long history of Afghan war, low literacy rate and feudal tribal laws divert the concentration of the scientific societies to evaluate the region ecologically. Therefore, project was lunched to evaluate quantitatively.

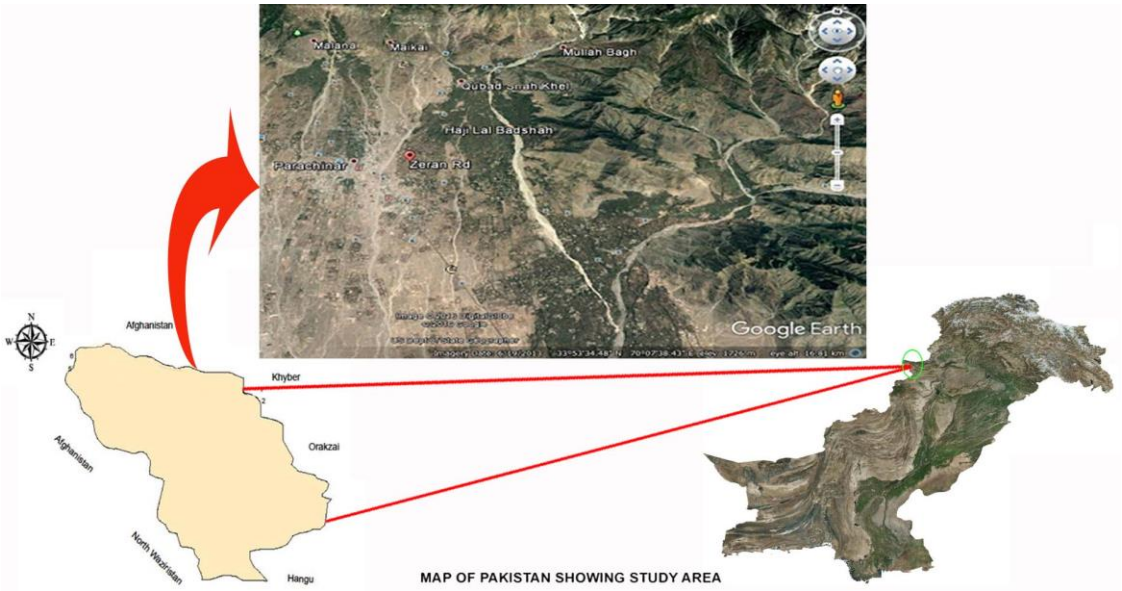

Figure 1. *. Map of the Zeran valley (Border region of Pakistan and Afghanistan).*

Field sampling techniques for vegetation quantification

During the summer season of 2016 to 2017, phytosociological techniques were used for vegetation assessment along edaphic and other related environmental transects (Laurance et al., 2004; Khan et al., 2012). The area was divided into seven different stations on the basis of floristic composition, physiognomy, topography and altitudinal variation (McMahon et al., 2011). Mature and least disturbed vegetation of the study area was focused (Laurance et al., 2004). A mixture of transect and quadrats method was frequently used. Square shape quadrats 1 × 1 m^2, 5 × 5 m^2 and 10 × 10 m^2 for herbs, shrubs and trees respectively were laid in each station. The plant species were collected from respective habit type, vernacular names, family names and other relevant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63756396

information were recorded in the field note books. The collected plant specimens were properly pressed, dried using blotting papers, poisoned and finally mounted on the standard herbarium sheets. All specimens were preserved in the Herbarium of Quaid-I-Azam University, Islamabad, Pakistan for future reference. The specimens were identified with help of the Flora of Pakistan (Ali et al., 1972–2009; Ali and Qaiser, 1986, 1995-2010) and available literatures at Islamabad Herbarium, Quaid-I-Azam University and National Herbarium at National Agriculture Research Centre (NARC), Pakistan. The scientific names of all plant species were confirmed from the plant list website (http://www.theplantlist.org).

The quantitative vegetation attributes i.e., density, cover, frequency and their relative values were recorded. Importance Value Indices of species were also calculated (Curtis and McIntosh, 1950). Various environmental variables like grazing pressure, soil depth and condition, number of stumps, elevation and aspects were recorded with special concentration. Geographical co-ordinates of each site were noted using GPS. The community's names were based on ISA, species constancy and faithfulness.

Soil sampling and analyses

Since the top-soil soil contains greater nutrient concentration ad highest organic matter contents. Mostly roots biomass is accumulated throughout this soil profile (Vallés et al., 2015; Jobbágy and Jackson, 2001). Within each quadrat, soil samples were randomly collected from each microsite, and then mixed accordingly to make a unique pooled. Pebbles and wood pieces were removed. The samples were shad dried, sieved, air dried, grinded and analysed for the selective physico-chemical edaphic factors in a Fauji Fertilizer Company (FFC) limited farm advisory centre, Hasan Abdal, Pakistan. The soil texture was determined by the hydrometer method of particle-size analysis (Day, 1965). The Organic carbon (O.M) contents were analysed via (Nelson and Sommers, 1996) methodology and Nitrogen was measured following the semi-micro Kjeldahl procedure of (Bremner and Mulvaney, 1982). Electric conductivity (E.C) was analysed in saturation extract using (Rhoades, 1982) protocol. Potassium and Phosphorus were analysed according to (Soltanpour, 1985), whilst Sodium was measuerd via (Rhoades and Miyamoto, 1990) methodology.

Data statistical analyses

The data obtained from field work needs to be examined in a statistical framework (Kent and Coker, 2002). It helps ecologists to analyse the effect of environmental factors, vegetation classification and mapping for conservation and management purposes (Anderson et al., 2006). Data of 252 quadrats (84 for each trees, shrubs and herbs species respectively) were alphabetically arranged in MS Excel spread sheet 2010. The utilities of PC-ORD version_5 i.e., Cluster Analysis (CA) and Indicator Species Analysis (ISA) were applied to classify plant communities (Dufrene and Legendre, 1997), analyse distribution pattern and identify indicators species respectively. CA brings stations with similar floristic composition close to each other (Sorensen, 1948; Dalirsefat et al., 2009). The ISA identified indicator plant species with statistical significance ($\leq .05$) of each habitat type, defined by the environmental variable. It also constructed indicator values for each species using Monte Carlo techniques. Each species was evaluated for its ability to categorize among all the treatments of environmental variables and attributed to its suitable habitat type. ISA

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63756396

provided suggestions of how well the presence of a species would indicate a specific station or plant community (Dufrene and Legendre, 1997).

Mantel test as a utility of PCORD was used to estimate the strength of the relationship between species and environmental data matrices. These tests help to test hypothesis, whether variation in factors like aspect and elevation etc would have any impact on the diversity of plant species as well as communities qualitatively as well as quantitatively. The naming of plant communities was based on the indicator plant species, having significant P value ≤ 0.05, identified by ISA, as recommended by Dufrêne and Legendre (1997). Beside this, constancy and fidelity level of the characteristics species of the communities were also checked for further authentication of indicator, to use in naming the communities (Malik and Husain, 2006).

Ordination analyses for identification of ecological responsible gradients

Ordination is a multivariate statistical method that summarizes communities data by constructing a low dimensional space in which similar samples and species come closer together along the specific environmental gradients complex and dissimilar ones goes further apart from each other (Gauch, 2010). Keeping the objectives in mind, we analysed plant species data with measured environmental variables in CANOCO (Ter Braak and Barendregt, 1986). Canonical Correspondence Analyses (CCA) is the most meaningful direct ordination gradient technique (Braak, 1988). It is widely used to examine environmental factors influence (Dufrene and Legendre, 1997). The CANOCRAW, utility of CANOCO was used to construct CCA plots of species-environmental and community-environmental variables.

Results

Species diversity and dominant species

Preliminary findings confirmed total of 195 vascular plant species belongs to 144 genera of 60 Families in the study area (*Table A1* in the *Appendix*). The recorded 195 plant species belong to 144 genera and 60 families (*Table A1*). In which 3 and 5 species belongs pteridophytes and gymnosperms, whilst angiosperms dominating the area with 186 species. Within angiosperms, dicotyledons dominated the region having 160 members whilst 27 species were the representative of monocotyledons (see *Appendix*). The dominant species were evaluated on the basis of the IVI. The lower altitude (1500-2000 m) subtropical evergreen elements like *Olea ferruginea* (7.60%) *and* deciduous Treelets species like *Cotoneaster bacillaris* (3.79) dominated the area. In the middle attitude (2000-2500 m) broad leaved evergreen, *Quercus baloot* (8.63%) found to be dominant whilst at the higher elevational zone (2500-3000 m) moist temperate element and western Himalayan native species *Quercus dilatata* (17.11%) and *Cedrus deodara* (6.37%) forming close gregarious association. The forest thickness was positively correlated whilst species diversity and richness were negatively correlated along the elevational gradient in the study area. The lower xeric elevation was mostly occupied by habitat *Daphne mucronata* (8.58%), *Sophora mollis* (12.17%) and *Berberis lyceum (*7.99%). On the other hand higher elevational zones were dominated by, *Indigofera heterantha, plectranthus rugosus* and Berberis parkeriana by 19.04%, 14.81% and 7.39% of IVI total weightage of 21recorded shrub species. The forest ground flora was dominated by representatives of Poaceae includes; cynodon dactylon (7.73%), *Stipa sibirica* (3.72%), *Setaria pumila* (3.26), *Piptatherum laterale*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63756396

(2.69%), *Apluda mutica* (2.56%), *Agrostis vinealis* (2.11%) with associated species; *Medicago sativa* (6.16%), *Cirsium arvense* (3.91%) Oxalis corniculata (2.71%) and *Viola odorata* (2.44%) in 142 recorded herbs species (*Appendix*). The *V. cardiostephanum* was reported after122 years and confirms their occurance with a rarity in Pakistan. Harsukh, collected for the first time but in non-flowering stage (*Fig. 6C*). Our study re-confirms the occurrence of *V. cardiostephanum* in Pakistan. Its holotype Rechinger 35614 (W) belongs to Afghanistan. Hence, it is a narrow endemic to this ecotonal region of Pak-Afghan border, with a limited distribution; probably less than 100 km^2. According to the IUCN red list categories and criteria it has been declared as Critically Endangered species.

Community's classification

The application of PC-ORD version-5 packages with 1,0 data gave rise to Cluster Analyses (CA); precisely divide the plant species into four major communities (*Fig. 2*). The communities' nomenclatures were based on the species constancy, fidelity level and Indicator Species Analyses (ISA). Each indicator species was studied under the influence of environmental variables. The Monte Carlo test result showed that; Nitrogen (N), Sodium (Na), Soil texture (S.T) and altitude played significant role in communities' composition. The Monte Carlo test result shows the strength of the environment-species relationship. The first community; *Elaeagnus angustifolia-Rosa chinensis-Seriphidium kurramense* was found at the lower altitude. The habitat of this community was mostly xeric. The second community; *Platanus orientalis-Rosa moschata-Epilobium hirsutum* found, where mostly agricultural practices were noticed. The third community; *Quercus baloot-Jasminum auriculatum-Foeniculum vulgare* and fourth communities *Quercus dilatata-Hedera nepalensis-Calamintha umbrosa* were found at the high elevation (*Table 1*).

Table 1. *Detail information of the indicator species of the all communities along with fidelity level, constancy classes and Indicator species analyses*

S No.	Indicator species	Com	Constancy		F. C.	Var	I.V	P*

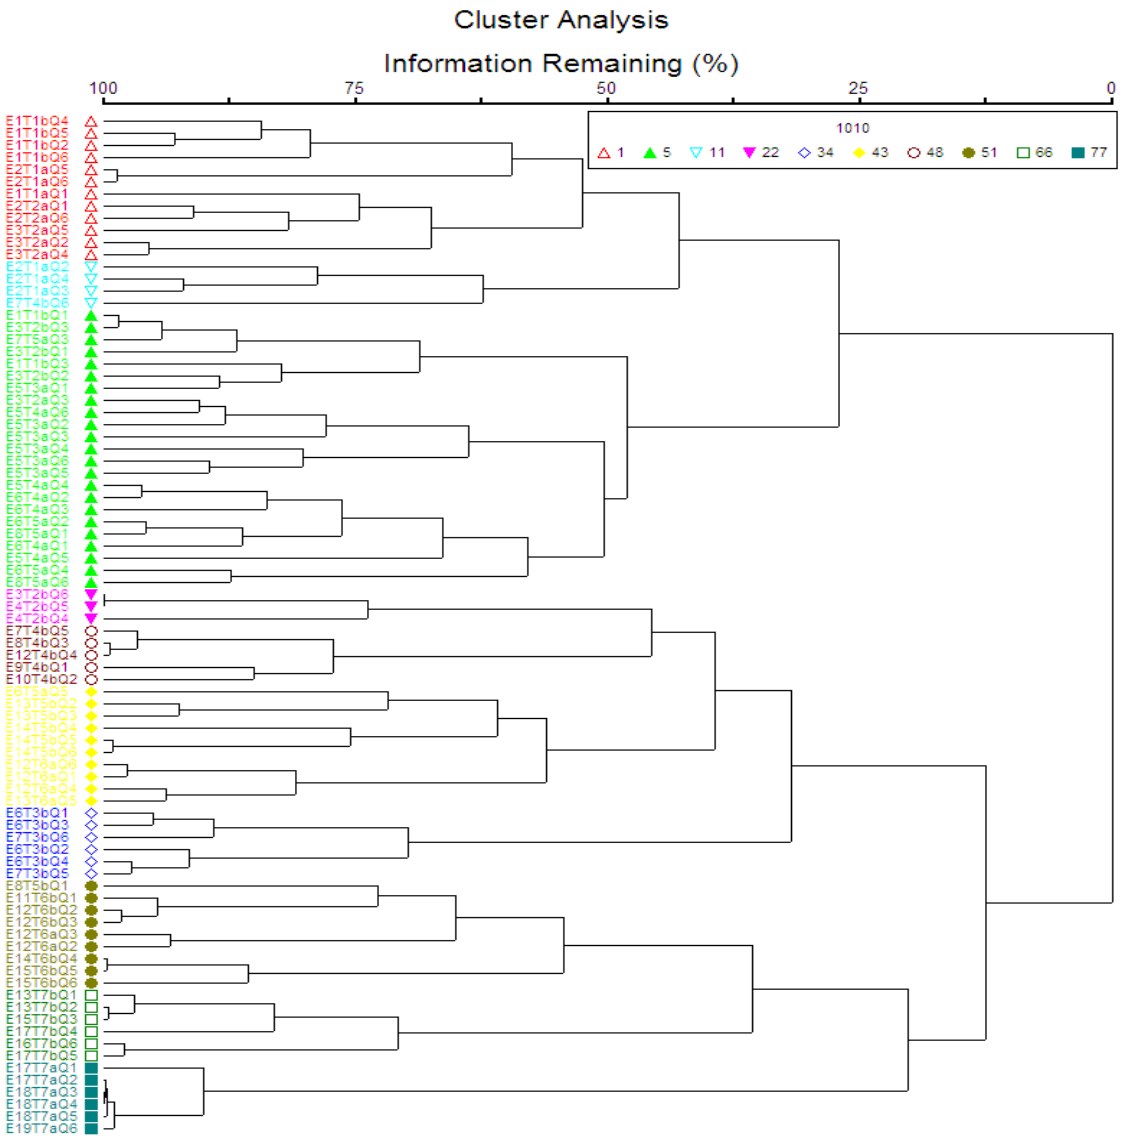

Figure 2. *Cluster Analysis classifying the study sites into four communities.*

1. Elaeagnus angustifolia – Rosa chinensis – Seriphidium kurramense community

The application of CA and TWCA based on Sorenson Similarity Index, a total of 48 releves clustered in this community. It was found at the elevation range of 1550-1900 m above sea level (a.s.l). The name was given based on significant indicator species (P* value ≤ 0.05) i.e., *Elaeagnus angustifolia*, *Rosa chinensis* and *Seriphidium kurramense* respectively (*Table 1*). Impacts of edaphic factors were also analysed and found that higher Nitrogen and Potassium concentration and medium Organic matter were the most prominent driving environmental variables in determination of these indicator species (*Fig. 5*). Moreover, these species have higher constancy fidelity within this community (*Table 1*). The concentration of N and pH in this community is higher as it comprises of the cultivated land, where use of fertilizers like Di-Ammonium Phosphate (Muthuramkumar et al.), Nitro-Phos (NP) and Potassium sulphate are repeatedly used for higher yields. Based on IVI values the dominant tree species includes *Robinia*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63756396

pseudoacacia, *Punica granatum* and *Populus nigra*. Amongst the shrubby layer *Daphne mucronata* and *Berberis lycium* were the dominant whereas in the herbaceous layer *Cynodon dactylon, Sanguisorba minor* and *Dichanthium annulatum* were reported as dominated species of this community.

Being located at lower elevation numbers of anthropogenic activities i.e., deforestation for fuel and fodder purposes, over grazing and agricultural land expansion are the main threats to the vegetation of this community. It was easily accessible to vicinity of human settlement to utilize the local plant resources. The physio-chemical analyses of this community revealed that pH ranges from 6.8 to 7.8, Nitrogen (0.032-0.87%), Sodium (0.5-1.4 mmolc/100 g), Electrical Conductivity (0.17-0.33 dS/m), Phosphorous (1-4 ppm), Potassium (106-420 ppm) and Organic matter (0.51-1.39%).

2. Platanus orientalis – Rosa moschata – Epilobium hirsutum community

This community was found at the middle elevation (1950-2300 m) of the valley. It hosts 84 different quadrats. The characteristic species of tree, shrub and herb layers were *Platanus orientalis*, *Rosa moschata* and *Epilobium hirsutum* respectively. Sodium and EC were the main environmental variables determining the indicator species of this community (*Fig. 5*). We observed that *Rosa moschata* was found in higher while other indicator species observed at a moderate concentration of Sodium and Electrical Conductivity respectively. The indicator species was found with relatively lower constancy level and higher fidelity level within this community (*Table 1*). The other important tree species present were *Populus nigra*, and *Diospyros lotus.* These species were cultivated, therefore gains dominancy in this community as well. Abundant shrub species reported were *Sambucus nigra, Rubus fruticosus* and *Indigofera heterantha.* Dominant herbs species were *Medicago sativa* and *Impatiens edgeworthii* in this community.

Agricultural practices were found as the top disturbing elements in this community. Analysing of soil showed that pH ranges from 7.1 to 7.9, Nitrogen (0.043-0.078%), Sodium (0.6-1.5 mmolc/100 g), Electrical Conductivity (0.15-1.18 dS/m), Phosphorous (2-6 ppm), Potassium (84-900 ppm) and Organic matter (0.69-1.25%).

3. Quercus baloot – Jasminum auriculatum – Foeniculum vulgare community

Based upon Sorenson index of similarity measurement this community was established relatively at the higher elevation, i.e., 2350-2780 m. Vegetation of this community was dominated by woody plants. Diagrammatic presentation of cluster dendogram show total 72 releves clustered together in this community. The principle indicator species of this community were *Quercus baloot*, *Jasminum auriculatum* and *Foeniculum vulgare.* The important environmental variables responsible for the community establishment were slightly higher pH, moderate Sodium and higher concentration of EC (*Fig. 5*). All the characteristic species of this community show higher level of faithfulness (*Table 1*). This community comprises of a thick forest dominated by ever green tree species i.e., *Quercus semicarpifolia*, *Olea ferruginea* and deciduous tree species like *Celtis caucasica*. *Indigofera heterantha*, *Plectranthus rugosus* and *Sophora mollis* were the dominant shrubs. *Piptatherum laterale* and *Thymus linearis* were the dominant herb species.

Fodder, fuel wood, chopping and grazing were observed as main anthropogenic activities disturbing the natural vegetation equilibrium. Soil analyses of this community

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63756396

indicates that pH ranges from 6.8 to 7.8, Nitrogen (0.048-0.079%), Sodium (0.3-2.4 mmolc/100 g), Electrical Conductivity (0.07-1.33 dS/m), Phosphorous (2-10 ppm), Potassium (42-560 ppm) and Organic matter (0.76-1.26%).

4. Quercus dilatata – Hedera nepalensis – Calamintha umbrosa community

This was the community of highest elevation range, that is 2800-3000 m a.s.l. It was represented by 63 quadrats. The analysis inveterate that; *Quercus dilatata, Hedera nepalensis* and *Calamintha umbrosa* were the strongest indicator species with a p values < 0.05, under the influence of high Potassium and moderate Sodium concentration (*Fig. 5*). The characteristic species showed high fidelity and moderate constancy level (*Table 1*). This was tree dominating community comprised of the principle indicator of moist temperate vegetation i.e., *Cedrus deodara*, *Quercus baloot* and *Pinus brutia* as dominant tree species. Dominant shrub species were *Indigofera heterantha*, *Plectranthus rugosus* and *Berberis parkeriana.* This community has slightly lower species richness in comparison to the other communities. *Thymus linearis* and *Apluda mutica* were dominating the herbaceous layer of this community.

Soil depth was shallow, due to rugged topography and steep slopes. Higher grazing pressure make this community very prone for soil erosion. Lower temperature prevails throughout the year. These condition results low plant species diversity. Medicinal plant collectors for commercial purposes were the major anthropogenic activities. Large No of stumps were reported as people collect wood for timber and fuel purposes mainly from this elevation range. Physio-chemical analyses revealed pH ranges from 7.2-8, Nitrogen (0.052-0.072%), Sodium (0.-1.4 mmolc/100 g), Electrical Conductivity (0.08-0.28 dS/m), Phosphorous (2-6 ppm), Potassium (60-8690 ppm) and Organic Matter (0.15-1.12%). Due to thick forest layer soil texture of this community was sandy clay loam.

Direct environmental gradient analyses

The plant and environmental data treatment via CCA identified the core factors; showing high significant p-value < 0.002. The CCA bi-plot showed that both vegetation variations and communities' variations were mainly driven by; stumps, grazing pressure, Phosphorous, Sodium and Nitrogen (*Table 2*). The CCA ordination procedures for species and communities (*Figs. 3, 4* and *5*) indicated that 1st axis strongly correlated with altitude and partially with pH; the 2nd axis was mainly correlated with stumps (due to immense deforestation), high concentration of sodium and strong EC; 3rd quadrat correlated with high Phosphorous and medium organic matter (O.M) whilst the 4th axis was under the immense grazing pressure (*Figs. 3* and *4*). Similarly stations CCA bi-plot (*Fig. 5*) demonstrated clear reflection of altitudinal and latitudinal gradient complexes of the region. The 1st and 2nd community were clustered at the lower altitude. Moreover, it also describes stations of woody and evergreen vegetation was mostly found at the higher elevation. The physiographic and geomorphologic gradient complexes describes that depth soils and sunlight exposures loving vegetation were frequently distributed at lower parts whilst relatively thin soils an shad loving species favoured the high elevated habitats. The sum of all Eigen value Monte Carlo test were 14.312. The 1st axis eigen value was quite high (0.469), which showed the slope in spreading species along with the axis. The 1st axis cumulative percentage of Species-environment relation was 21.6%

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63756396

of total unexplained variance. This value of 4th axis was the highest with 65.1% (*Table 2*).

Discussion

Biological assemblages could evaluate significantly the deteriorative impacts of anthropogenic activities on natural ecosystems (Kusnierz et al., 2015). Ecotones can be differentiated on the bases of the sharpness of their communities (Lloyd et al., 2000). The most appropriate causes are; sharp climatic gradient, elevation, invasion of dominant, steep topography and environmental factor especially human influences (Walker et al., 2003; Casalini, 2017). Results strongly support our hypothesis to have unique indicator vegetation at Ecotonal Zone and edaphological factors affecting

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63756396

community composition. A total of 195 belongs to 60 families of vascular plant species, were reported in varied ecological zones of the valley (*Appendix*). Altitude was one of the most important determinants, influencing directly species distribution; because it governs the micro climate of the habitats (Casalini, 2017; Singh et al., 2009). In the lower altitude (1500-2000 m) subtropical evergreen elements like *Olea ferruginea* (7.60%) in an association with deciduous Treelets species *Cotoneaster bacillaris* (3.79) were recorded as dominated. In the middle attitude (2000-2500 m) broad leaved evergreen species, *Quercus baloot* (8.63%) whilst moist temperate element and western Himalayan native species *Quercus dilatata* (17.11%) and *Cedrus deodara* (6.37%) at the elevation of 2500-3000 m were reported as dominant. *Daphne mucronata* (8.58%), *Sophora mollis* (12.17%) and *Berberis lyceum (*7.99%, sub-tropical indicator) dominated the lower xeric elevation, whilst *Indigofera heterantha* (19.04%,), *plectranthus rugosus* (14.81%) and *Berberis parkeriana* (7.39%) find as dominant shrub species. The herbaceous flora was dominated mostly Poaceae members; cynodon dactylon (7.73%), *Stipa sibirica* (3.72%), *Setaria pumila* (3.26), *Piptatherum laterale* (2.69%), *Apluda mutica* (2.56%), *Agrostis vinealis* (2.11%) along with *Medicago sativa* (6.16%), *Cirsium arvense* (3.91%) Oxalis corniculata (2.71%) and *Viola odorata* (2.44%) in 142 recorded herbs species (*Appendix*). The *V. cardiostephanum* occurrence was reconfirmed after Harsukh (122 years later) and who collected it in non-flowering stage (*Fig. 6C*). We collect it in flowering stage and occupying less than 100 km^2, so applying IUCN category and criteria; declared it as its holotype Rechinger 35614 (W) belongs to Afghanistan. Hence, it is a narrow endemic to this ecotonal region of Pak-Afghan border, with a limited distribution; probably less.

The species richness and Diversity Index were optimum at middle elevations (2000-2400 m a.s.l) as compare to the lower (1500-150 m a.s.l), and higher altitudes due to various pressures and xeric conditions at these areas. Reporting moist indicator climatic species like; *Cedrus deodara, Indigofera heterantha, Bistorta amplexicaulis* and *Trifolium repen* (*Appendix*) in the high elevation is supported by Saima et al. (2009) and Ahmed et al. (2006) studies. The gradual decreasing in species richness along the increasing altitude is considered as a general pattern Shaheen et al. (2011, 2012). Such phenomena of species distribution have also been reported from other mountainous locations using more or less same techniques, i.e., Anderson et al. (2006), Ahmad et al. (2015) and Haq et al. (2017). The micro climatic conditions of the valley vary from sub-tropical to cool temperate zone is in accordance to and Shen et al. (2015) and Zhou et al. (2018). The vegetation of Irano-Toranian and Western Himalayan types for example *Parrotiopsis jacquemontiana* is one of such indicator from the Current location as well. Comparison with previous researches in the adjacent areas indicates similar vegetation zones Khan and Ahmad (2015), Khan et al. (2016) and Haq et al. (2015a).

The multivariate statistical analysis via PCORD V-5 software sorted out the vegetation into 4 plant communities (*Fig. 2*) on the bases of indicator plant species. Approach to the communities naming based on statistical approaches, specifically Indicator Species Analysis in conjunction with fidelity (faithfulness) and constancy measurements of Bergmeier (2002) is one of the technical feature of our finding. The use of indicator species to determine environmental conditions and community types is an emerging technique in vegetation ecology for both theoretical and applied purposes. This use of multispecies environmental or ecological indications instead of single or repetitive indicator has enormously contributed in the bio-indication system and its reliability (Carignan and Villard, 2002; Niemi and McDonald, 2004; Butler et al., 2012;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63756396

Rahman et al., 2019). The characteristic species of each community was confirmed through Indicator Species Analyses, Species fidelity Level and constancy classes. Similar procedure for communities composition were also adopted by Shaheen et al. (2011) Khan et al. (2012), Khan (2012), Ahmad et al. (2016), Bano et al. (2017), Pharswan and Mehta (2010) and Ilyas et al. (2012) in their respective research. Indicator species analyses revealed that Nitrogen, Phosphorous, Sodium, EC and pH were the strongest and significant edaphic factors ($p \leq 0.05$) for the constitutions plant communities and determination of indicator species (*Table 1*). Khan et al. (2016) used the same method with unique results from Thandiani Sub-Forest Division of the Western Himalayas. Soil factors influences over plant distribution in the ecotonal region agreed with the previous studies of El-Keblawy et al. (2015) and Grellier et al. (2014).

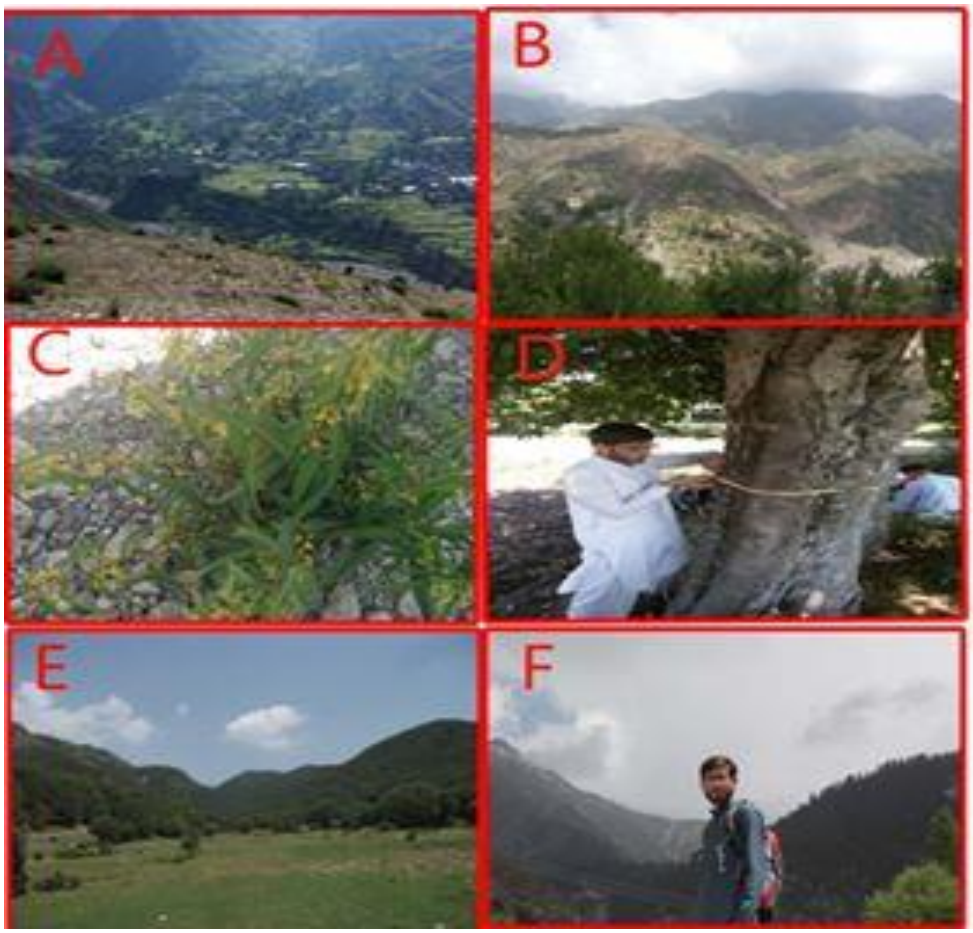

Figure 6. *Pictorial view of the ecotonal region, (A) settlements with agricultural practices, (B) South facing Barren mountains range (C) Vincetoxicum cardiostephanum in flowering stage (D) measuring DBH of Crataegus songarica, (E) Quercus dilatata thick forest and pastures zone, (F) Snow covered high elevated mountains peak*

CANOCO version 4.5 was used to analyse the effect of biotic and abiotic factors on species composition, diversity and community structure (*Figs. 3, 4* and *5*). Use of these Software packages can be seen in the studies of Brown and Bezuidenhout (2005) and Khan et al. (2012b). The elevation, longitude and latitude were responsible for microclimatic variations. Dense vegetation was observed on the north facing slopes as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63756396

compared to south facing slopes in the high elevation of the valley. The environmental gradients like elevation, soil conditions, grazing pressure and soil texture clearly indicates strong impacts on species diversity and composition of the region (*Figs. 4* and *5*; *Table 2*). Soil depth decreases with the high elevation due to steep slopes in areas where soil erodes during rainy seasons. The Organic matter concentration in the lower region (*Figs. 3, 4* and *5*) is quite high, it was the prime factor retaining higher species diversity and thick vegetation cover, is in accordance to the Casalini (2017) and Bao-Liang et al. (2009) because it is reliable to retain greater humidity and moisture concentration in landform (Pei et al., 2010). Ecologists recommended such ecosystems to support higher biodiversity and combat with climatic challenges. CCA bi-plot also revealed that species were highly sensitive to EC, Phosphorous and sodium (*Fig. 3* and *4*). These findings are in agreements with Khan et al. (2013) and Shaukat et al. (2014). Furthermore, increasing herbaceous vegetation along the elevation gradients indicates the positively correlation with eco-physiological stresses along the increasing altitude. The physiographic elements altitudinal range variations and edaphic factors have great effect on vegetation structure and its distribution pattern (*Fig. 5*). Plant species restricted to a particular habitat due to the availability of their requirements and optimum environmental factors. These factors clearly change the community structure and their distribution from point to point. Now a-days such studies have been adopted by numerous of ecologists and environmentalists to correlate the communities with the environmental factors (Chawla et al., 2008 and Khan et al., 2015).

Amongst the anthropogenic stimuli (counting stumps) repeated fuel-wood chopping is considered the major factor having huge impacts on the structure of the vegetation and results declining and almost disappearance of large old trees (*Fig. 3* and *4*). The most preferred species for fuel wood consumptions includes; *Quercus dilatata, Q. baloot, Olea ferruginea, Morus nigra* and *M. alba*. The greater wood extraction level than the carrying capacity causes a proportional changes in structure and community composition. Moreover, harvesting scenarios also increase ecological impacts. Once they become lost, large gap will be created; so forest fragmentation will be enhanced and probably susceptibility to invasion will be promoted (Rüger et al., 2008); and will inhibit the native seedlings regeneration (Cochrane, 2003). The grazing pressure has negatively affected the species diversity and vegetation structure (*Fig. 3* and *4*), this happen because over grazing can alter soil chemistry and also make it prone for the erosion (Rooney and Waller, 1998). The heavy and uncontrolled grazing and trampling by large amount of cattle on daily by local nomads is alarming situation. For best management legislation, the regeneration patterns and the main governing factors should be addressed (Wangda, 2003). Moreover, subsequent soil erosion and harsh climate during winter season also had catastrophic affect. The dense lush green vegetation of the region are now slowly and steadily replaced by stripped steep ridges, with increasing number of houses, roads and terracing fields. Our finding suggests priorities for the biodiversity conservation via indicator species approaches. Border Area of Afghanistan is geopolitically zone of tension that makes it an Ecotonal territory with rich diversity and must be evaluated taxonomically for probable new species. Recently, ecotones have gained greater attention because also species has narrow ecological amplitude (Silva and Souza, 2018; Corenblit et al., 2011) and expected future climatic changes could affect ecotonal vegetation very strongly (Camarero et al., 2017; Gebrekirstos et al., 2014).

DOI: http://dx.doi.org/10.15666/aeer/1703_63756396

Conclusion

The species distribution, communities composition using edaphic and environmental variables contributed valuable information for understanding ecotonal vegetation. We concluded that fragile vegetation of this sensitive region is under tremendous pressure due to diverse anthropogenic activities. It enhanced understanding of phyto-diversity that could potentially lead for conservation, especially in the perspective of anthropogenic impacts. The robustic multivariate statistical tools recognized indicator for micro-climatic and micro-ecological zonation. Results could be improved further if; soil moisture contents studied along the topographical gradient. It will ultimately enhance edaphological and geomorphological role for vegetation management and conservation strategies in landscape ecology. Moreover, presence of endemic species required detail taxonomic and micro-ecological investigation.

Acknowledgments. The authors would like to extend their sincere appreciation to the Deanship of Scientific Research at King Saud University for its funding to this Research group NO (RG-1435-014).

Abstract. The carbon emission prediction model of agroforestry ecosystem based on least squares regression method has no learning process for data samples, it is difficult to accurately describe the non-linear relationship among them, and the prediction accuracy is poor. A carbon emission prediction model of agroforestry ecosystem based on support vector regression was designed. Seven carbon sources, including root decomposition, chemical fertilizer, pesticide, agricultural film, agricultural irrigation, agricultural machinery and farmland tillage, were selected as influencing factors of carbon emissions in agroforestry ecosystem. The SVR model for carbon emissions prediction in agroforestry ecosystem was constructed, and the regression function of sample data was solved by optimizing the training sample data based on the basic principle of support vector regression machine. On this basis, the data of influencing factors of agroforestry ecosystem were normalized and substituted into the model to predict the carbon emission results of agroforestry ecosystem system. Experiments show that the errors of the designed model in predicting the average carbon emissions of agroforestry ecosystems in the two experimental provinces from 2010 to 2017 are $5.9/10^4$ t and $6.4/10^4$ t, respectively, which are lower than those of other models. The average time of predicting the carbon emissions of agroforestry ecosystems in the two experimental provinces from 2006 to 2015 is about 4.15 s, which shows that the model can predict agriculture. The results of forest ecosystem carbon emissions have the advantages of high efficiency, high precision and comprehensiveness.
Keywords: *support vector regression machine, agroforestry ecosystem, carbon emission, prediction, model, regression function*

Introduction

Since the late nineteenth century, the global surface temperature has risen by 0.4-0.8 °C. Global warming, an environmental change problem, has attracted widespread attention in the international community. Greenhouse gas emissions are the main causes of climate warming (Grinblat et al., 2015). The main greenhouse gases produced by human activities are carbon dioxide, methane, nitrous oxide and fluoride, among which carbon dioxide is the most important anthropogenic greenhouse gas (Babaranti, 2019). Fluoride itself does not contain Greenhouse Effect, but a greenhouse gas. The IPCC Fourth Assessment Report pointed out that the increase of global carbon dioxide concentration was mainly attributed to the use of fossil fuels (Onwuka et al., 2019). The increase of nitrogen monoxide concentration was mainly attributed to the use of agriculture and fossil fuels. The increase of nitrogen monoxide concentration was mainly attributed to the agroforestry ecosystem (Zhang et al., 2016). With the progress and extension of agroforestry ecological science and technology, the industrialization trend of agroforestry ecosystem has been strengthened. For example, the United States is a typical modern country of agroforestry ecosystem. Its development of agroforestry ecosystem is essentially based on technology and energy. The degree of mechanization

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63976413

and chemistry of agroforestry ecological production is quite high, and its income and input of agroforestry ecological energy is as high as 1:15, which is the most in the world. Facing the increasingly serious contradiction between land and population, China with a large population is also vigorously promoting the development of modern agroforestry ecology. It can be seen that the agroforestry and ecological production sector has become an important area of fossil energy consumption. In 2014, the share of agricultural greenhouse gas emissions calculated by carbon dioxide equivalent accounted for 13.5% of total greenhouse gas emissions. It can be seen that agroforestry ecosystem has become one of the main sources of greenhouse gas emissions (Ouyang et al., 2019).

Scholars in China and abroad have shown that the broad definition of agroforestry ecosystem refers to the five industrial forms of planting, forestry, animal husbandry, fisheries and sideline (Franzluebbers et al., 2016). Carbon emissions from agroforestry ecosystems mainly come from the following aspects: (1) The use of chemical fertilizers will produce greenhouse gas emissions such as nitrous oxide, methane and so on. At the same time, the production and transportation of chemical fertilizers will produce carbon emissions. (2) The use of pesticides, including their carbon emissions during production and transportation. (3) The use of agricultural film products, including carbon emissions in the production process. (4) Carbon emissions from fossil fuels directly consumed, including the use of agricultural machinery and irrigation equipment. (5) Loss of soil organic carbon during farming. (6) Combustion of crop straw (Khanchoul et al., 2019).

Agroforestry ecosystem is a special ecosystem: it is not only a carbon source manufacturing system, but also a carbon sink absorption system (Vignola et al., 2015). Carbon sources in agroforestry ecosystems mainly come from planting and aquaculture, which are closely related to human beings. Carbon sinks mainly come from forestland and agricultural land (Anderegg et al., 2015). In recent years, the world's agroforestry ecosystem has entered the era of low-carbon economy, while the development of low-carbon agroforestry ecosystem in China is still in its infancy, and low-carbon agroforestry ecosystem is an important issue facing our country at present. In this context, the study of carbon emissions from agroforestry ecosystems in China has a certain practical significance (Oyedotun et al., 2019).

At present, there are many ways to predict carbon emissions in agroforestry ecosystems. Because there are some technical and practical difficulties in observing and counting carbon emissions flux, the existing methods are based on some easy statistical data. Wall et al. (2015) predicted carbon emissions from agroforestry ecosystems through tillage data and meteorological information. Brogniez et al. (2015) predicted carbon emissions from agroforestry ecosystems according to the fertilization on farmland. Maas et al. (2015) predicted carbon emissions from agroforestry ecosystems by testing soil organic carbon content (Roslee, 2019). The least squares regression method and ridge regression method are mostly used in the above-mentioned carbon emission models of agroforestry ecosystems. They have the problems of weak stability and explanability, and are difficult to determine parameters. At the same time, the forecasting model has no learning process for data samples, and it is difficult to accurately describe the non-linear relationship among them, so the forecasting accuracy is poor. Now the mainstream carbon emission prediction method is based on the carbon emissions of fossil energy. The main carbon emissions of agroforestry ecosystem are mainly caused by the use of agricultural, chemical fertilizer, agricultural film and diesel

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63976413

oil, so the carbon emissions are predicted from the perspective of input (Sharma et al., 2019).

Support Vector Machine (SVM) is a new machine learning algorithm based on statistical learning theory. Because of its excellent learning performance, it has been successfully applied in many fields such as face recognition, handwritten numeral recognition and image retrieval, which can be used for classification and regression problems. In order to solve the defects existing in the prior method, an effective carbon emission prediction method is found, and the basis for the implementation of the high-efficiency energy-saving emission reduction decision is provided. In this paper, a prediction model of carbon emissions in agroforestry ecosystem based on SVM is designed, which provides an important basis for making efficient energy-saving and emission reduction decisions (Khanchoul et al., 2019).

Materials and methods

Selection of influencing factors of carbon emission in agroforestry ecosystem

When the carbon source of the ecosystem was predicted, the carbon emissions of the selected two experimental provinces increased at a constant rate. GDP is the final result of the production activities of all permanent units in a country (or region) calculated by market price. and obtaining the GDP data according to the GDP accounting system. There are seven kinds of carbon sources for predicting carbon emissions in agroforestry ecosystems (Sinare and Gordon, 2015): first, the carbon emissions caused by the use of chemical fertilizers; second, the carbon emissions caused by the use of pesticides; third, the carbon emissions caused by the decomposition of residual roots after harvesting crops; fourth, the carbon emissions from indirect consumption of fossil fuels during irrigation; fifth, carbon emissions caused by the use of agricultural film; Sixth, the destruction of soil organic carbon pools by farmland tillage, resulting in the loss of a large amount of organic carbon into the air and carbon emissions; seventh, the direct or indirect consumption of fossil fuels (diesel, electricity, etc.) by agricultural machinery (Michael et al., 2015). These seven carbon sources were selected as independent variables of carbon emission prediction in the studied agroforestry ecosystem.

Figure 1 depicts the proportion of different carbon sources in total carbon emissions in the agroforestry ecosystem of China. It can be concluded that the carbon emissions of agroforestry ecosystem in this province are mainly caused by root decomposition after harvesting (accounting for 59.8712% of the carbon emissions of agroforestry ecosystem). In agroforestry ecosystem, the proportion of carbon emissions of various types in total emissions is in the order of root decomposition (59.8712%), chemical fertilizer (28.0495%), pesticide (4.9972%), agricultural film (3.0612%), agricultural irrigation (2.2927%), agricultural machinery (1.7519%) and farmland tillage (0.0123%). The proportion of root decomposition in agricultural carbon emissions is prominent due to the large agricultural planting area and unscientific farmland management in the province (Carsan et al., 2015).

SVR model for prediction of carbon emissions in agroforestry ecosystem

The SVR model for carbon emission prediction of agroforestry ecosystem was established. The results of carbon emission of agroforestry ecosystem were predicted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63976413

based on the above seven factors: root decomposition, chemical fertilizer, pesticide, agricultural film, agricultural irrigation, agricultural machinery and farmland tillage.

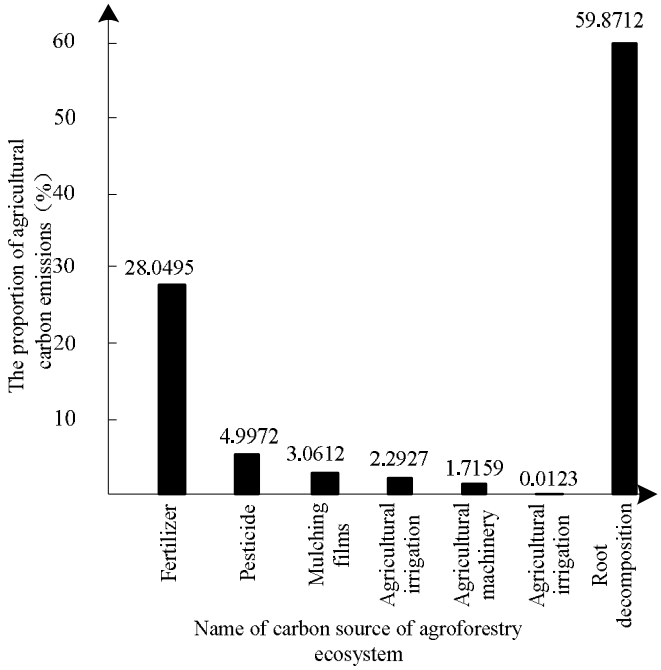

Figure 1. *Emission ratio of agroforestry ecosystem in a province*

Basic principle of support vector regression machine

SVR is a machine learning method based on statistical learning theory (Sloat et al., 2015). Because it is especially suitable for limited samples, it can obtain global optimum theoretically and has a good generalization ability. Moreover, its computational complexity is independent of the dimension of samples. It has been well applied in function approximation and regression estimation (Helen, 2016). Given the training set $T=\{(x_1,y_1),\cdots,(x_n,y_n)\}$, $x_i\in R^m$, $y_i\in R$, $i=1,\cdots,n$, where x_i and y_i represent the input factor and the expected value, respectively, and n is the total number of data points. If we can deduce the y value of any model x by a linear function $y=f(x)=(w\bullet x)+b$ on R^m, it is called linear regression problem. The linear regression problem can be converted to the following optimization problem (Rueda et al., 2015):

$$\begin{cases} \min \dfrac{1}{2}\|w\|^2+C\dfrac{1}{n}\sum\limits_{i=1}^{n}(\xi_i+\xi_i^*), \\ s.t. \\ \quad ((w\bullet x_i)+b)-y_i\le\varepsilon+\xi_i, \\ \quad i=1,2,\cdots,n \\ \quad y_i-((w\bullet x_i)+b)\le\varepsilon+\xi_i^*, \\ \quad i=1,2,\cdots,n \\ \quad \xi_i,\xi_i^*\ge 0, i=1,2,\cdots,n \end{cases} \qquad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63976413

In the formula, C is the penalty parameter, ξ_i and ξ_i^* are the relaxation variables, ε is the threshold of insensitive loss function, which is used for fitting accuracy (He and Rong, 2015). $\|w\|^2$ is the confidence risk; b is the parameter to be identified.

Generally, the dual problem of model (*Eq.1*) is introduced instead of solving model directly.

$$\begin{cases} \min \frac{1}{2}\sum_{i,j=1}^{n}\left(\alpha_i^*-\alpha_i\right)\left(\alpha_j^*-\alpha_j\right)\left(x_i-x_j\right)+ \\ \varepsilon\sum_{i=1}^{n}\left(\alpha_i^*+\alpha_i\right)-\sum_{i=1}^{n}y_i\left(\alpha_i^*-\alpha_i\right), \\ s.t. \quad \sum_{i=1}^{n}\left(\alpha_i-\alpha_i^*\right)=0, \\ \quad 0\le\alpha_i,\alpha_i^*\le\frac{C}{n}, i=1,2,\cdots,n \end{cases} \tag{Eq.2}$$

In the formula, α_i and α_i^* are the support vector parameters.

If $\bar{\alpha}_i \neq 0$ or $\bar{\alpha}_i^* \neq 0$ is the optimal solution, the input x_i in the training set is called support vector. The correlation coefficients of regression function are: $S_1=\left\{i\left|\bar{\alpha}_i\in(0,C/n)\right.\right\}$, $S_2=\left\{i\left|\bar{\alpha}_i^*\in(0,C/n)\right.\right\}$, find $j\in S_1$ or $k\in S_2$, and it can be calculated:

$$\bar{b}=y_i-\sum_{i=1}^{n}\left(\bar{\alpha}_i^*-\bar{\alpha}_i\right)\left(x_i\bullet x_j\right)+\varepsilon \tag{Eq.3}$$

or

$$\bar{b}=y_k-\sum_{i=1}^{n}\left(\bar{\alpha}_i^*-\bar{\alpha}_i\right)\left(x_i\bullet x_k\right)-\varepsilon \tag{Eq.4}$$

Finally, the linear regression function of the training sample is obtained as follows:

$$f(x)=\sum_{i=1}^{n}\left(\bar{\alpha}_i^*-\bar{\alpha}_i\right)\left(x_i\bullet x\right)+\bar{b} \tag{Eq.5}$$

It is not difficult to see that the dual problem (*Eq.2*) and regression function (*Eq.5*) only involve the inner product operation $\left(x_i\bullet x_j\right)$ between sample inputs. Therefore, the inner product kernel function $K\left(x_i,x_j\right)$ can be introduced to transform the linear regression problem into the non-linear regression problem in the high dimensional space (Hilbert space) (Dressler et al., 2015). The support vector regression model ($\varepsilon-$SVR) can be constructed (Marilice et al., 2015).

$$\begin{cases} \min \frac{1}{2}\sum_{i,j=1}^{n}\left(\alpha_i^*-\alpha_i\right)\left(\alpha_j^*-\alpha_j\right)K\left(x_i,x_j\right)+ \\ \varepsilon\sum_{i=1}^{n}\left(\alpha_i^*+\alpha_i\right)-\sum_{i=1}^{n}y_i\left(\alpha_i^*-\alpha_i\right), \\ s.t. \quad \sum_{i=1}^{n}\left(\bar{\alpha}_i-\bar{\alpha}_i^*\right)=0, \\ \quad 0\le\alpha_i,\alpha_i^*\le\frac{C}{n}, i=1,2,\cdots,n \end{cases} \tag{Eq.6}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63976413

When the optimal solution $\bar{\alpha} = \left(\bar{\alpha}_1, \bar{\alpha}_1^*, \cdots, \bar{\alpha}_n, \bar{\alpha}_n^*\right)^T$ is obtained, the corresponding training sample regression function becomes as follows:

$$f(x) = \sum_{i=1}^{n} \left(\bar{\alpha}_i^* - \bar{\alpha}_i\right) K\left(x_i, x\right) + \bar{b} \quad \text{(Eq.7)}$$

Choose $\bar{\alpha}_j$ or $\bar{\alpha}_k^*$ in $\left(0, \frac{C}{n}\right)$, and the corresponding $\bar{b}$ is:

$$\bar{b} = y_j - \sum_{i=1}^{n} \left(\bar{\alpha}_i^* - \bar{\alpha}_i\right) K\left(x_i, x_j\right) + \varepsilon \quad \text{(Eq.8)}$$

or

$$\bar{b} = y_k - \sum_{i=1}^{n} \left(\bar{\alpha}_i^* - \bar{\alpha}_i\right) K\left(x_i, x_k\right) - \varepsilon \quad \text{(Eq.9)}$$

Establishment of SVR carbon emission prediction model

A multi-input and single-output support vector regression model is constructed by constructing the relationship between the input and the output through the SVR model, as shown in *Figure 2* (Benjamin et al., 2018). The specific steps are as follows:

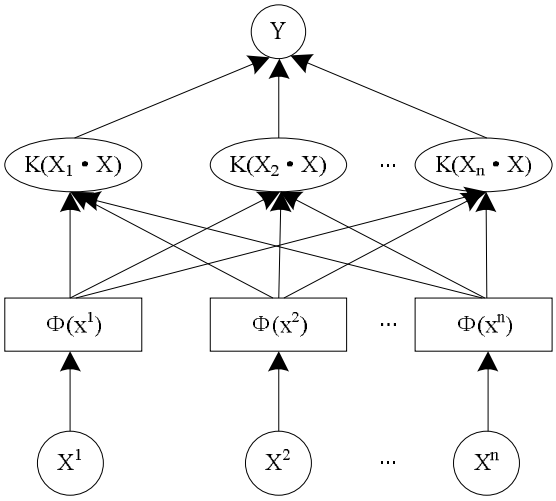

Figure 2. *Support vector regression machine model*

In *Figure 2*, carbon emissions and their influencing factors are input, and carbon emission values are outputted. The first step is to classify the samples (Ping et al., 2015). Taking an agroforestry ecosystem in a province of China as an example, the data of carbon emissions and their influencing factors from 1990 to 2010 and 2011 to 2017 were taken as training samples and testing samples respectively. The influencing factors were root decomposition, chemical fertilizer, pesticide, agricultural film, agricultural irrigation, agricultural machinery and farmland tillage (carbon emissions and their shadows due to space limitation). Sound factor data sheet is not described in detail.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63976413

The second step is to normalize all sample data, that is, to normalize the independent variables and dependent variables in all samples with the following formula, so that all data are in [0, 1] (Terrado et al., 2015).

$$x_{il} = \frac{x_{il}^0 - \min x_{iil}^0}{\max x_{il}^0 - \min x_{iil}^0}, i = 1,2,L,n, l = 1,2,L,7 \quad \text{(Eq.10)}$$

$$y_i = \frac{i_i^0 - \min y_i^0}{\max y_i^0 - \min y_i^0}, i = 1,2,L,n \quad \text{(Eq.11)}$$

The third step is to select the best penalty coefficients C and γ of training samples and test samples. Firstly, the parameters C and γ are selected roughly, and the range of their values are $lbC \in [-10,10]$, $lb\gamma \in [-10,10]$, which are substituted into the model to get the rough map. According to the printed rough map, the range of parameters are $lbC \in [-8,8]$, $lb\gamma \in [-10,10]$, and then substituted into the SVR carbon emission prediction model to get the fine map. The grid width m, cross validation fold k and regression bandwidth ε remain unchanged, which are 1, 5 and 0.05, respectively. The optimum values C^* and γ^* of C and γ are 9.18959 and 0.0358968, respectively.

The fourth step is to construct and test the SVR carbon emission prediction model. The SVR carbon emission prediction model was constructed by using the above optimal parameters C^*, γ^* and all training samples. The regression function was obtained as follows:

$$\begin{aligned} f(x) = {} & 2.5460K(x_2,x) + 1.3375K(x_3,x) - 9.1896K(x_4,x) \\ & + 4.9274K(x_5,x) + 9.1896K(x_6,x) - 9.1896K(x_7,x) \\ & - 7.3493K(x_{10},x) + 5.0624K(x_{12},x) - 9.1896K(x_{13},x) \\ & - 9.1896K(x_{14},x) - 9.1896K(x_{15},x) + 9.1896K(x_{16},x) \\ & + 9.1896K(x_{17},x) - 0.4126K(x_{19},x) + 1.7260K(x_{21},x) \\ & + 9.1896K(x_{22},x) - 1.7442K(x_{24},x) + 0.9176 \end{aligned} \quad \text{(Eq.12)}$$

x is the input sample whose model parameters are not zero, that is, support vector; $f(x)$ is the set of output vectors. After the regression function $f(x)$ is obtained, the correlation coefficients of training samples and test samples are substituted into $f(x)$ to get $S_1 = 0.997601$ and $S_2 = 0.976871$, respectively. At the same time, the training sample and the test sample are substituted into the model to obtain the comparison chart between the original data and the fitting data, as shown in *Figure 3*. Therefore, the regression function $f(x)$ can be used as a carbon emission prediction model of agroforestry ecological coefficient in a province of China.

Results

Accuracy analysis of model prediction results

In order to verify the accuracy of the carbon emission prediction model of agroforestry ecosystem based on vector regression machine, two provinces in China are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63976413

represented by experimental object 1 and experimental object 2. The carbon emissions of agricultural and forestry ecosystems in 2010-2017 in two experimental provinces were predicted by using this model, the carbon emission prediction model of agricultural and fore ecosystems based on tillage data and meteorological information, the carbon emission prediction model of agricultural and forestry ecosystems based on least square regression method and the carbon emission prediction model of agricultural and forestry ecosystems based on ridge regression method, respectively. The results are shown in *Tables 1* and *2*.

In order to reflect the predicted results of different models more clearly, the data in *Tables 1* and *2* are described in the form of polyline graphs, and the results are shown in *Figures 4* and *5*.

Analysis *Table 1* and *Figure 4* show that the average carbon emissions of agroforestry ecosystem in the first province from 2010 to 2017 are about 8747.4/10^4 t. The difference between the average carbon emissions predicted by this model and the average actual carbon emissions is the smallest, about 5.9/10^4 t, while the differences between the other models and the actual emissions are 39.5/10^4 t, 23.9/10^4 t and 167.5/10^4 t, respectively. *Table 2* and *Figure 5* show that the average carbon emissions

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63976413

of agroforestry ecosystems in the two provinces from 2010 to 2017 are about 7675.6/10^4 t. The prediction results of this model are about 7682.0/10^4 t and the error is about 6.4/10^4t. The prediction results of the other three models are 7701.8/10^4 t, 7660.9/10^4 t and 7684.6/10^4 t, respectively. The prediction results of this model are the closest to the actual results. The experimental results show that the prediction accuracy of carbon emissions from agroforestry ecosystems is high.

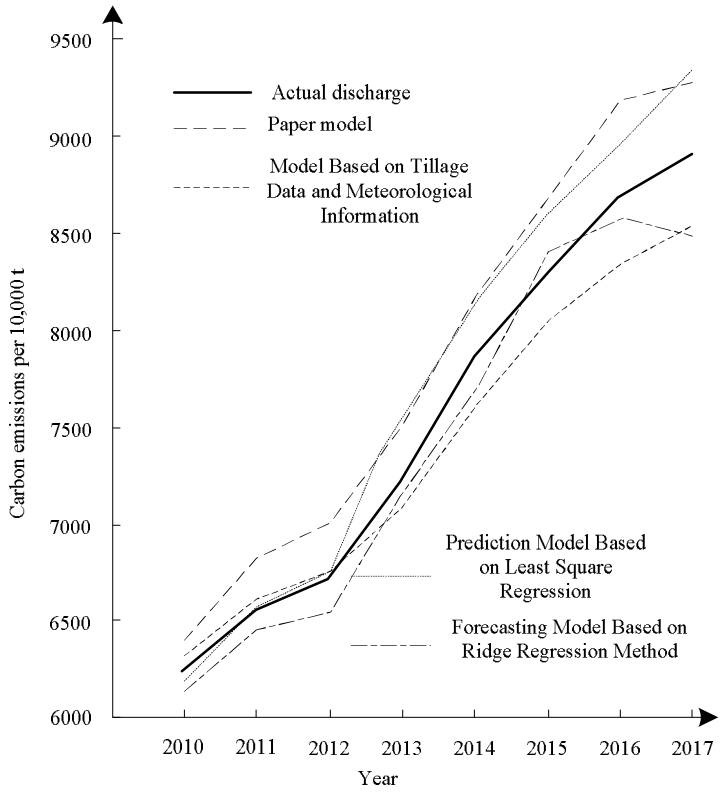

Figure 5. *Prediction of carbon emissions from agroforestry ecosystem in Provinces 2, 2010-2017*

Analysis of correlation between of GDP and carbon emissions

In order to analyze the correlation between GDP and carbon emissions of agroforestry ecosystem, the factors influencing carbon emissions in China in 2010, the factors predicted at different GDP growth rates and different agroforestry ecological consumption rates in 2011-2015 were normalized into the model, and the output results were inversely normalized. The predicted value of carbon emissions in China in 2010 was 1.026 × 10^7 t. The predicted carbon emissions during the 12th Five-Year Plan period at different GDP growth rates and different carbon emission ratios are shown in *Table 3*.

From the above analysis, the projected carbon emissions by 2030 can reach 10.49 billion tons. The model predicts that under the same GDP growth rate, the larger the proportion of agricultural and forestry ecological consumption decreases, the less carbon emissions, and the slower the growth of carbon emissions will be over time. This indicates that the optimization of agricultural and forestry ecological energy structure,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63976413

especially the development and utilization of low-carbon energy, will be conducive to reducing the proportion of carbon dioxide in energy consumption, thereby slowing down the growth trend of carbon emissions. Under the same decline rate of ecological consumption of agriculture and forestry, the greater the growth rate of GDP, the more carbon emissions, and the faster the growth rate of carbon emissions over time, which shows that if we pursue the rapid growth of GDP too much, the carbon emissions in China will increase rapidly. Therefore, in the future, China can appropriately reduce the GDP growth target and continuously promote the optimization of energy structure to ensure the effective realization of carbon emission reduction targets.

Analysis of model practicability

In order to verify the practicability of the model, the model was used to predict soil carbon emissions under different vegetation cover in the agroforestry ecosystem of the experimental object 1. Vegetation coverage refers to the ratio of the vertical projected area of plants to the area of a region, expressed as a percentage. The results are shown in *Table 4*.

Table 4 shows that the prediction errors are less than $9.80/10^4$ t when the model is used to predict the soil carbon emissions under different vegetation cover in the agroforestry ecosystem. The experimental results show that the model can predict the soil carbon emissions in the agroforestry ecosystem comprehensively and has strong practicability.

Analysis of model prediction efficiency

In order to test the prediction efficiency of this model, the carbon emissions of agroforestry ecosystems in two provinces from 2006 to 2015 were predicted by using this model and the other three models respectively. The time required for different

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63976413

models to predict carbon emissions was compared. The results are shown in *Tables 5* and *6*.

Analysis *Tables 5* and *6* show that the time used to predict carbon emissions from agroforestry ecosystems in different years of the experimental object 1 is 3.64-4.53 s, and the average time spent is 4.07 s, while the average time spent by the other three systems is 7.39 s, 9.41 s and 8.20 s respectively. The model predicted the carbon emissions of agroforestry ecosystems in different years of the experimental subjects 2 in 3.85-4.69 s, and the average time spent was 4.23 s. The average time needed for the other three systems to predict carbon emissions was 7.65 s, 9.60 s and 8.55 s, respectively. The experimental results show that it takes less time to predict the carbon emissions of agroforestry ecosystem by using the proposed model. The average time to predict the carbon emissions of different experimental objects is about 4.15 s, which is the highest efficiency.

Discussion

This paper puts forward policy suggestions on carbon emission reduction in agroforestry ecosystem from four aspects: developing agroforestry ecosystem economy, improving agroforestry ecosystem efficiency, adjusting agroforestry ecosystem structure and scientific management. China ranks first among the world's largest carbon emitters, the United States second, and India third, according to data. According to a 2016 report by the American Lung Association, more than half of people in the United States face the risk of breathing air pollution, with carbon dioxide emissions of 54.14 million tons. Although India has signed agreements to reduce emissions and use clean energy, 1.2 million people die every year from respiratory diseases (Deo et al., 2016; Tian and Wang, 2016; Xiao et al., 2018).

Improving the development level of agroforestry ecosystem and vigorously developing low-carbon agroforestry ecosystem

Carbon emissions of agroforestry ecosystems in China are increasing year by year, and the level of economic development of agroforestry ecosystems plays the most important role in promoting the scale of carbon emissions of agroforestry ecosystems expands with the rapid development of agroforestry ecosystems. But the hard measures to restrain economic growth are not advisable. The key is to improve the quality of economic development of agroforestry ecosystem. As long as agroforestry ecosystem takes the road of sustainable development, we can get economic growth and environmental quality improvement at the same time (Brahma et al., 2018; Norhayati Rashid, 2017).

First of all, it needs to be supported by a good policy and legal environment, a perfect training system for new farmers and practical talents, a modern agroforestry ecosystem production and management system, and diversified farmers' cooperative organizations. It exploratively brings the emission reduction of agroforestry ecosystem into the track of legalization, so that the emission reduction of agroforestry ecosystem can be legalized. Secondly, we should increase investment in the development of low-carbon agroforestry

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63976413

ecosystems. It will increase investment in agroforestry ecosystem infrastructure and vigorously develop core technologies in the field of low-carbon agroforestry ecosystem.

Improving the productivity of agroforestry ecosystem and reducing the carbon emission intensity of agroforestry ecosystem

The improvement of production efficiency of agroforestry ecosystem plays a positive role in reducing carbon emission of agroforestry ecosystem. Although the intensity of carbon emission of agroforestry ecosystem in China is decreasing year by year, the production efficiency of agroforestry ecosystem in China is still low. Improving the productivity of agroforestry ecosystem does not only mean scale and mechanization. For example, the scale and mechanization model of the United States brings about high land productivity and commodity efficiency, but also high pollution and high consumption. Therefore, our efficient agroforestry ecosystem should be a technological route with biochemical technology as the main and mechanical technology, promoting the research and development and application of scientific research and innovation, and improving the utilization efficiency of various agricultural funds.

In order to achieve a reasonable combination of nitrogen, phosphorus and potassium fertilizers, it is necessary to apply fertilizers strategically according to different soil nutrient conditions, so as to reduce carbon emissions in the production and transportation of chemical fertilizers, as well as direct carbon emissions in the application process. Promoting the comprehensive utilization of straw resources, strengthening recycling and returning straw to the field will help to improve the soil nutrient status, increase organic matter and improve the soil fertility level (Saleh et al., 2016). Straw can be silage, ammoniation, compaction, microbial fermentation and other ways to produce breeding feed, effectively improve the utilization efficiency of straw resources; biological insecticide-repellent method is used to replace pesticides, using the medicinal properties of various plants in nature and the intergrowth of organisms to achieve the method of resisting pests.

Adjusting the industrial structure of agroforestry ecosystem and reducing the carbon emission of agroforestry ecosystem

The adjustment of industrial structure of agroforestry ecosystem is helpful to reduce carbon emission of agroforestry ecosystem. On the basis of ensuring basic food security, regions should base themselves on resource advantages, face market demand, and develop their own advantages and characteristic departments according to their own resource enjoyment.

First, we should increase the gross domestic product of forestry, fishery and animal husbandry, change the traditional agroforestry ecosystem model and develop diversified agroforestry ecosystems. For example, the emerging agroforestry ecosystem, which combines the traditional agroforestry ecosystem with tourism, meets the requirements of the development of ecological economy, and improves the comprehensive capacity of agroforestry ecosystem production by promoting the comprehensive development of various sectors of agriculture, forestry, animal husbandry and fishery. In the process of structural adjustment of agroforestry ecosystem, each subject should be clearly positioned to give full play to their respective effects. Secondly, we should combine the actual situation, find out the advantages and breakthroughs, scientifically and rationally adjust the structure of planting industry, and combine with aquaculture. Under the condition of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_63976413

guaranteeing the supply of basic grain, efforts should be made to develop the planting industries of peanut, cotton, rape and other cash crops, such as building dry and fresh fruit bases, expanding industrial and vegetable bases, and vigorously planting characteristic horticultural crops.

Implementing scientific farmland management technology

The dynamic change of organic carbon in agroforestry ecosystem is not only affected by natural factors such as temperature, precipitation and vegetation types, but also by agricultural management measures such as fertilization, straw returning, no-tillage and irrigation. Under the current planting mode, the space for increasing the carbon sequestration effect of agroforestry ecosystem through the improvement of existing management measures has been very small, and the potential for further carbon sequestration is limited. In order to further improve the carbon sequestration capacity of agroforestry ecosystem, we must implement scientific agroforestry ecosystem management technology, reduce the carbon dioxide emissions from the residual root decomposition after harvesting, and further improve the carbon sequestration capacity to the residual root decomposition after harvesting, such as scientific irrigation, rational fertilization and so on.

Conclusions

In this paper, a prediction model of carbon emissions in agroforestry ecosystem based on support vector regression machine is designed. Seven different kinds of carbon sources in root system are selected as influencing factors of carbon emissions in agroforestry ecosystem. According to the basic principle of support vector regression machine, a prediction model of carbon emissions in agroforestry ecosystem is established. The prediction model predicts carbon emissions in agroforestry ecosystem based on seven influencing factors data. Experiments show that the difference between the average carbon emission and the actual average carbon emission of agricultural and forestry ecosystems in the two provinces are $5.9/10^4$ t and $6.4/10^4$ t respectively, which is lower than that of other prediction models. The prediction model predicts that under the same GDP growth rate, the optimization of the energy structure of agricultural and forestry ecosystems is conducive to reducing the proportion of carbon dioxide in energy consumption, thus reducing the proportion of carbon dioxide in energy consumption. The average time used to predict the carbon emissions of agricultural and forestry ecosystems in different years was 4.07 s and 4.23 s, respectively, which was lower than the average time of other prediction models. The experimental results showed that the model in this paper can predict carbon emissions of agroforestry ecosystem quickly and completely.

(Received 29th Dec 2018 ; accepted 8th Mar 2019)

Abstract. To evaluate physiological changes of Japanese honeysuckle under lead and cadmium stress, pot-plant experiment was adopted to discover heavy metal Pb or Cd single stress and Pb+Cd combined stress on part of physiological parameters of. Japanese honeysuckle. The results showed that under the same treatment, as time prolonged, the content of soluble sugar and soluble protein was decreased, the activity of SOD declined, the amount of free proline and MDA increased and the activity of CAT elevated. Under Pb stress only, total Chlorophyll content rose first and dropped afterwards and POD activity increased, however, under Cd stress only and Pb+Cd stress, both THCL content and POD activity first rose and then declined. In addition, under Pb or Cd single stress and combined stress, as treatment concentration increased, the contents of soluble sugar, soluble protein, free proline and MDA increased accompanied by POD, CAT and SOD activity increased while TCHL content decreased. All these indicate that under certain range of heavy metal stress, Japanese honeysuckle can reduce metabolic disorder plant damage caused by heavy metal stress through increasing osmotic regulating substances of leaves and inducing scavenging system of active oxygen.
Keywords: *Japanese honeysuckle, heavy metal stress, antioxidative enzyme, chlorophyll, osmosis substances*

Abbreviations: SOD: superoxide dismutase, MDA: malondialdehyde, CAT: catalase, POD: peroxidase, CHL a: chlorophyll a, CHL b: chlorophyll b, TCHL: total chlorophyll, Pb: lead, Cd: cadmium

Introduction

With the acceleration of industrialization and urbanization in China, the issue of environmental pollution has become increasingly prominent, especially air, soil and water pollution caused by man-made factors, which have not only influenced urban ecosystem, but also greatly changed the quality of farmland. Among all the factors, heavy metals in the soil are main sources of pollution and the situation is getting worse (Liu et al., 2016).

Pb and Cd are two main heavy metal pollutants in soil from industrial and agricultural activities such as mining and smelting of metalliferous ores, wastewater irrigation and abuse of chemical fertilizers and pesticides (Wang et al., 2015; Abad-Valle et al., 2016). Both of them, which can stay in the soil for a long time, are easy to accumulate and be absorbed by plants. In plants, they accumulate a lot in various organs not only to cause changes in morphology, physiology and biochemistry, structure, but also to endanger human health through the food chain (Khan et al., 2018). In soil, Cd is easily absorbed by plant roots and transported to other parts of plants, which is harmful to organisms even at very low concentration (Hu et al., 2014; Ran et al., 2016). In many cases, photosynthetic organs are damaged, inducing net photosynthesis rate decreased and leaf senescence accelerated, thus plant growth is inhibited, causing decrease of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64156427

chlorophyll content (Liu et al., 2015; Silva et al., 2017), stomatal closure and affecting water metabolism and nutrient imbalance caused (Schmidt et al., 2015; Anjum et al., 2016) by Cd can also change the activities of several enzymes relating to nitrogen metabolism, carbohydrate metabolism and sulfur metabolism (Mostofa et al., 2015). Pb is another kind of common harmful heavy metal (Okpoli, 2019). Pb entering into plants can alter cell membrane osmosis and cause a certain degree of damage to sub-micro structures like chloroplast, mitochondria and nucleus (Muhammad et al., 2018). Pb can competitively replace metal elements in the active sites of some enzymes and affect the normal activities of enzymes, thereby causing a series of disorders of physiological processes such as photosynthesis, respiration, nitrogen metabolism, nucleic acid metabolism (Hossain, 2019). It indirectly affects plant growth through antagonism leading to element imbalance and nutritious stress.

Japanese honeysuckle (*Lonicera japonica* T.) belongs to Caprifoliaceae Lonicera. Its flower buds, which can be used as medicine with heat-clearing, detoxifying and anti-inflammatory effects (Li et al., 2017; Wang et al., 2017) is a famous Chinese herbal medicine and widely planted in China. Japanese honeysuckle of Fengqiu county, Henan province, which is famous for its long planting history and high quality, has become the largest planting and export base in China. Their products are exported to Japan, Singapore and southeast Asia, etc. In recent years, the phenomenon of heavy metal exceeded in Chinese herbal medicine has caused great concern. It is closely related to Chinese herbal medicine quality and safety (Chen et al., 2017). As the main origin of Japanese honeysuckle, the farmland of Fengqiu is also polluted with the acceleration of industrialization and urbanization in Henan, affecting the production and quality of Japanese honeysuckle (Sarker et al., 2019). For previous studies of Japanese honeysuckle, the focuses were mostly on the efficacy of its medicinal ingredients, extraction and processing and seldom on heavy metal's physiological influence. The purpose of our research is to probe the physiological and biochemical reactions and tolerance of Japanese honeysuckle, which may provide research basis for the further study of the accumulation characteristics of heavy metals in it and to provide evidence for its scientific planting to ensure its quality, production and clinical medication safety (Ogunkunle et al., 2019).

Materials and methods

Materials

The tested yearling seedling of tree-shaped Japanes honeysuckle was provided by the Four Seasons Honeysuckle Seedlings Company in Jia Zhuang, Fengqiu County, Henan province and the tested soil was also collected from the farmland in the Japanese honeysuckle plant base in Jia Zhuang. After naturally dried, the soil was sieved, crushed and put over 5 mm sieve with the physiological and chemical values and the background values of Pb, Cd were determined (see *Table 1*).

Research design

The experiment was conducted in Xinxiang University, Hongqi District, Xinxiang City, Henan Province, China (35.26°N, 113.97°E). It is a warm temperate continental monsoon climate with an average annual temperature of 14.2 °C, an average annual precipitation of 573.4 mm, an average annual sunshine time of 2400 h, an average annual humidity of 68.0%, and a frost-free period of 220 days (Sufiyan et al., 2018).

Test soil was polluted by $Pb(NO_3)_2$ and $CdCl_2$ as sources of Pb and Cd. The four treatments of this research were designed according to the amount of pure heavy metals in each pot of soil, which was measured by its weight in each kilo of dry soil. Treatment one was taken as control with no Pb and Cd added (CK). Treatment two only had Pb stress of different concentrations: L_1 (Pb 400 mg/kg), L_2 (Pb 600 mg/kg), L_3 (Pb 800 mg/kg), L_4 (Pb 1000 mg/kg). Treatment three was under Cd stress of different concentrations: C_1 (Cd 0.5 mg/kg), C_2 (Cd 1.0 mg/kg), C_3 (Cd 5.0 mg/kg), C_4 (Cd 10.0 mg/kg). Treatment four had Pb and Cd combined stress of different concentrations: L_1+C_1(400 mg/kg Pb+0.5 mg/kg Cd), L_2+C_2(600 mg/kg Pb+1.0 mg/kg Cd), L_3+C_3(800 mg/kg Pb+5.0 mg/kg Cd), L_4+C_4 (1000 mg/kg Pb+10.0 mg/kg Cd). There were 12 treatments in total and each one repeated five times. All the reagents were added to the prepared 7 kg soil in pots (25 cm × 14 cm × 18 cm) according to the concentration of each treatment. In order to ensure sufficient nutrients for plant growth, 0.2 g of urea and 0.1 g of potassium dihydrogen phosphate were applied to every kg of soil (Samsudin et al., 2018). The soil was permitted to equilibrate for 30 d after lead and cadmium contamination. 30 d later, one healthy seedling of similar growth status was planted in each pot, which were placed in greenhouse in February, 2017 and given 300-500 ml Deionized water each pot every day during the research. In order to simulate the natural growth conditions of Japanese honeysuckle, the greenhouse uses natural light source and keep ventilation. At the same time, the temperature is consistent with the external temperature (Monteiro Junior et al., 2019).

Determining items and methods

At 45 and 90 days after stress respectively, leaf determination was conducted for each plant. 4-5 pairs of mature leaves under the top buds of new shoots Japanese honeysuckle were quickly packed into plastic bags, sealing tightly for determination. In the whole research, 8 items were determined with different procedures, including acetone extraction method for Chlorophyll content (Arnon, 1949). anthrone method for soluble sugar content (Fairbairn, 1953). Determination of proline by Acidic Ninhydrin (Walter and John, 1955). coomassie blue staining for soluble protein content (Sedmak and Grossberg, 1977). Thiobarbituric acid method for MDA, malanodialdehyde (MDA) content was determined from the difference (A532-A600) in absorbance by using Beerand Lambert's equation and expressed in terms of umol g^{-1} (Jambunathan, 2010). Guaiacol colorimetric method (Bestwick et al., 1998) for POD activity with each OD value changes 0.01 per minute as a enzyme activity unit (U), NBT illumination method for SOD activity with the amount of enzymes for inhibiting 50% of NBT illumination as an enzyme activity unit (U) (Elavarthi and Martin, 2010). Catalase activity was measured according to (Aebi, 1984) where H_2O_2 decomposition is followed spectrophotometrically at 240 nm (Oyedotun, 2019). One enzyme activity unit is equal to 1 mmol H_2O_2 decomposed per minute (Elavarthi and Martin, 2010). Each procedure

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64156427

was repeated three times to get the mean value. Data processing and analysis were conducted by Excel 2007 and SPSS 19.0.

Results and analysis

Chlorophyll content

As the pigment for photosynthesis, the content of chlorophyll is a predominant reflective parameter for photosynthetic capacity of plant leaves (Riccardi et al., 2014). See *Table 2,* at 45 d and 90 d, under single and combined stress, Chl a appears an apparent tendency of declining. When cadmium concentration was 1.0 mg/kg and stress was 90 days, Chl a decreased by 59.11% compared to CK, and Chl b decreased by 77.89% when lead concentration was 1000 mg/kg and stress was 90 days. The content of Chl b decreased more than Chl a. Therefore, Chl b is more sensitive than Chl a under heavy metal stress. Nevertheless, under the same treatment, CHLa, CHL b and TCHL showed downtrend with time increased, manifesting the inhibition effect of heavy metal stress for chlorophyll synthesis.

Data are mean ± SD (n = 5). Different lowercase letters in the same column indicate significant difference at $p < 0.05$ levels between different treatments according to the LSD

Free proline content

As one of the most important osmotic substances in plants, the accumulation of free proline plays an important role for osmotic regulation of cells, stabilization of cell structure and reduction of oxidation (Dawood et al., 2014). Under normal circumstances, the content of free proline keeps at comparatively low level. However, under the adverse conditions such as salinization, drought, heavy metal pollution, etc., free proline will accumulate in cytoplasm to resist stress and carry out osmotic adjustment (Ali et al., 2015). Under Pb, Cd single and combined stress, the contents of free proline were all higher than CK and increased with concentration during 45 d and 90 d treatment processes. Under the same treatment, when the concentration of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64156427

Pb > 800 mg/kg and Cd > 5 mg/kg, the amount of free proline decreased with time, yet under Pb+Cd stress, free proline content increased with time (see *Table 3*).

Table 3. *Effect of Pb, Cd stress on the content of free proline mg/g*

Data are mean ± SD (n = 5). Different lowercase letters in the same column indicate significant difference at $p < 0.05$ levels between different treatments according to the LSD

Soluble sugar content

Soluble sugar, the main osmotica for plants, has a stabilization effect for cell membrane and protoplasmic colloid and a protective effect when the concentration of inorganic ions is high in cells. Under osmotic stress, plants can reduce osmosis by accumulating soluble sugar to adapt to changes of environment (Nawaz et al., 2015) According to data in *Table 4*, soluble sugar content showed a downtrend as treatment time prolonged under the same treatment of Pb, Cd single and combined stress at 45 d and 90 d. For concentration, when it increased, soluble sugar content of each group all showed a gradually rising tendency compared to CK and reached the highest at treatment 4. For Pb stress only, soluble content increased 43.94% and 46.09% respectively in contrast to CK at 45 d and 90 d. For Cd stress, the percentages were 61.36% and 54.69%, whereas 70.45% and 57.81% for Pb+Cd combined stress.

Soluble protein content

Soluble proteins are typical enzymes that specifically bind to the membrane system. Under certain stresses, the higher the content of soluble protein in plants, the stronger the physiological and biochemical reactions and metabolic activities of the plant, which can be used as an indicator of plant's relative resistance. In *Table 5*, Soluble protein

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64156427

content decreased with the increase of time when under the same treatment at 45 d and 90 d separately, The soluble protein content of each treatment was higher than control no matter single or combined stress and increased with concentration.

Table 5. *Effect of Pb, Cd stress on soluble protein mg/g*

MDA content

MDA is the main decomposition product of membrane lipid peroxidase and one of the main parameters reflecting the degree of damage to membrane system (Magwanga et al., 2018). In *Table 6*, the result showed that MDA contents of both single and combined stress were higher than CK at high concentrations. which pointed that high concentrations treatments had damage to plant. Under Pb, Cd single stress, MDA contents of Japanese honeysuckle leaves were higher than CK by 2.62% to 124.8%. While under combined stress, it was higher than CK by 14.24% to 104.31%. At different treatment time, MDA content increased as treatment time increased, which meant that as time prolonged, the damage of membrane lipid peroxidation increased and the ability to clear active oxygen decreased. For single treatment, MDA content increased as treatment concentration increased, indicating that Japanese honeysuckle growth was inhibited to a certain extent. Whereas MDA content had no apparent increase with concentration increase under combined stress, indicating that Japanese honeysuckle was not sensitive to the aggravation of adverse stress under the combined stress.

POD content

POD, a common redox enzyme in plants, is a kind of enzyme with high activity. As a type of enzyme that is very sensitive to environmental factors (Ashraf et al., 2017). It can catalyze the oxidative decomposition of toxic substances. At the 45 d and 90 d, POD activity of Japanese honeysuckle leaves increased as treatment concentration increased under single and combined stress (see *Table 7*). Particularly at 90 d of Pb_4 of single stress, POD activity increased by up to 107.45%, which manifested that under high concentration of Pb treatment, POD acted as protection for heavy metal damage. When under Cd stress, POD activity first increased with treatment concentration. As treatment time prolonged, its activity dropped when Cd concentration ≧ 5.0 mg/kg, but was still higher than CK, indicating that when Cd concentration was beyond the tolerance of plant, POD activity was inhibited. POD activity under combined stress was similar to that under Cd stress. When the concentration of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64156427

Pb+Cd > 1.0 mg/kg + 600 mg/kg, POD activity began to drop, however, it was still higher than CK and Pb, Cd stress, indicating synergistic effect of Pb and Cd. At low concentration, POD activity's increase shows raise in its capacity of scavenging oxygen free radicals and its decrease at high concentration indicates its limitation of defense mechanism.

SOD content

SOD is one of the most important protective enzymes for scavenging active free radicals in plants. It can effectively clear excessive oxygen free radicals in plants and reduce its peroxide degree on membrane lipids (Malar et al., 2014). According to the data in *Table 8*, compared between 45 d and 90 d, the activity of enzyme decreased with the prolong of treatment time. The activity of SOD increased as the treatment concentration increased under single and combined stress, however, it was not so apparent compared to the control, indicating that the influence of Pb, Cd stress was not so obvious on the activity of SOD.

CAT content

As an important redox enzyme in plants as well as a key enzyme for biological defense system, CAT can scavenge superfluous active oxygen, maintain the balance of active oxygen metabolism and protect the integrity of cell membrane (Khan et al., 2018; Anjum et al., 2015). Under single and combined treatment, with the increase of treatment time and concentration, the activity of CAT showed an increasing trend,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64156427

indicating that Japanese honeysuckle leaves can adapt to long time adverse environment by increasing the activity of CAT. The activity of CAT increased more when the concentration of Cd > 1.0 mg/kg, Pb > 600 mg/kg, Pb+Cd > 600 mg/kg + 1.0 mg/kg at 90 d. The increase amplitudes were 50.31%, 45.6% and 70.14% respectively, among which the combined stress had the highest increase (see *Table 9*). The results showed that high concentrations of Pb and Cd stress could promote the increase of CAT activity in leaves of Japanese honeysuckle and the Pb and Cd combined stress had corresponding synergistic effect.

Discussion

Under heavy metal stress, three kinds of osmosis substances, free proline, soluble sugar, soluble protein, accumulated quickly in leaves to reduce osmotic potential in cells, increase osmotic adjustment ability, promote moisture absorption and ensure the norm growth of plants. However, after 45 d of single treatment, the contents of soluble sugar, soluble protein and free proline increased. Both soluble sugar and soluble protein contents decreased after 90 d of single and combined stress. These results are correlated with work of Janmohammadi et al. (2013). This might be caused by physiological mechanism damage of plants after long time single or combined stress, which might inhibit the accumulation of soluble sugar and soluble protein, accelerate their decomposition and reduce their contents. One reason, which might explain the increase of soluble sugar, is that plants can regulate osmotic potential to reduce damage caused

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64156427

by outside environment through increasing soluble sugar content. Since a large number of increased organic small solutes like soluble protein can reduce water potential in cells so as to achieve the purpose of water absorption from the surrounding cells. The other reason might be that under heavy metal stress, the absorption of some essential ions weakened, leading to accelerated decomposition of substances such as starch, protein and nucleic acids, thus plant growth was inhibited. The content of soluble sugar in leaves of Japanese honeysuckle treated with heavy metal stress decreased 90 days compared with 45 days, which may be due to the consumption of plant respiration as time went by. Soluble sugar content in Japanese honeysuckle leaves under Pb, Cd single stress or Pb+Cd combined stress was comparatively high, which might improve the capacity of stress tolerance of plants. Free proline can still maintain a higher concentration. These findings are correlated with work of Jayasri et al. (2017). Their study of Pb stress on Lemna minor demonstrated that the decomposition of soluble protein accelerated under adverse circumstances and separated into various amino acid including free proline, etc., resulting in the rise of proline content. Due to the low osmotic potential of the external environment under heavy metal stress, plants will lose water. In order to avoid infiltration injury, plant cells will take the initiative to absorb and accumulate inorganic salts and soluble substances such as free proline to reduce intracellular osmotic potential and avoid water loss damage. In our study, the higher content of free proline under high concentration of heavy metal stress may be related to this, however, the specific reasons still need further analysis. Stress changes substances metabolism of plants and generates osmotic adjustment substances to accumulate in plants, such as macro molecular substances like starch, protein, which further break down into small molecules such as soluble sugar, soluble protein and free proline. These substances have strong hydrophilic property, stabilizing colloidal property, protecting plant cells from damage or reducing damage in tissue metabolism. The capacity of osmotic adjustment of these substances can directly reflect the strength of stress resistance of plants.

When the reactive oxygen species produced in plant cells under heavy metal stress are beyond scavenging activity of protective enzyme system, free radicals will accumulate in leaf cells, thereby inducing peroxidase damage of plant cells. As one of the antioxidant enzymes, POD plays an important role for plants to resist adversity stress. In our study, Pb, Cd stress have effects for SOD, POD and CAT activities. However, the activity of POD increased more than that of SOD and CAT. 45 d after treatment, under low concentration and high concentration of Pb, Cd single and combined stress, the activities of SOD, POD and CAT all increased to protect Japanese honeysuckle from injury. When the concentration of stress was higher as time prolonged, POD activity further increased whereas SOD and CAT activities began to drop, indicating that POD played a major protective role in stress as the treatment time prolonged. When Cd concentration is in the range of 0.05-0.5 mol/L, the activity of POD and SOD increased with the increase of Cd concentration, but the content of MDA and the permeability of cell membrane also showed an upward trend (Santos et al., 2015). Although Cd increased the activity of POD and SOD to a certain extent, it did not prevent the occurrence of membrane hyperperoxide. Our study indicated that although Pb, Cd stress have influence on SOD, POD and CAT activities, POD activity increased more than that of SOD and CAT. At 45 d of treatment, under low and high concentrations of Pb, Cd stresses or Pb+Cd combined stress, the activities of SOD, POD, CAT all increased to protect Japanese honeysuckle from injury. At 90 d of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64156427

treatment, when Pb, Cd stress or combined stress were of high concentrations, POD activity further increased while SOD and CAT activities began to drop, manifesting that POD act as the main protector under stress with the increase of time. The study showed that Japanese honeysuckle reduce metabolism imbalance damage through increasing osmotic adjustment substances of leaves and inducing the scavenging system of reactive oxygen in a certain range of heavy metal stress.

Conclusions

1. In our study, heavy metal stress hindered CHL synthesis to different extents at 45 d and 90 d. At 90 d, the content of CHL was lower than 45 d, which illustrated that heavy metal stress inhibited CHL synthesis as treatment time prolonged.

2. In our study, all the evidence pointed to the fact that under heavy metal stress, three kinds of osmosis substances, free proline, soluble sugar, soluble protein, accumulated quickly in leaves of Japanese honeysuckle to reduce osmotic potential in cells, increase osmotic adjustment ability, promote moisture absorption and ensure the norm growth of plants. The contents of soluble sugar, soluble protein and free proline increased after 45 d of single treatment. Both soluble sugar and soluble protein contents decreased after 90 d of single and combined stress. This might be caused by physiological mechanism damage of plants after long time single or combined stress, which might inhibit the accumulation of soluble sugar and soluble protein, accelerate their decomposition and reduce their contents. Free proline can still maintain a higher concentration.

3. In our study, Pb, Cd stresses have effects for SOD, POD and CAT activities. However, the activity of POD increased more than that of SOD and CAT. 45 d after treatment, under low concentration and high concentration of Pb, Cd single and combined stress, the activities of SOD, POD and CAT all increased to protect Japanese honeysuckle from injury. When the concentration of stress was higher as time prolonged, POD activity further increased whereas SOD and CAT activities began to drop, indicating that POD played a major protective role in stress as the treatment time prolonged. With the increase of Cd concentration, the content of MDA and the permeability of cell membrane also showed an upward trend. Although Cd increased the activity of POD and SOD to a certain extent, it did not prevent the occurrence of membrane hyperperoxide.

4. The study showed that Japanese honeysuckle can reduce metabolism imbalance damage through increasing osmotic adjustment substances of leaves and inducing the scavenging system of reactive oxygen in a certain range of heavy metal stress.

Abstract. This research aims to find out effective approaches to improve the low carbon economy efficiency of China and to promote its low carbon economy development. This paper utilizes two kinds of data envelopment analysis models to estimate the economic efficiency and low carbon economy efficiency of China. It takes carbon dioxide emissions as an undesirable output and compares them to find out the different performances of economic growth in various regions in China in the context of low carbon economy development, and then explores the potential determinants of low carbon economy efficiency for different regions in different periods. The results show that low carbon economy efficiency is much lower than economy efficiency in most areas in China. Additionally, both low carbon economy efficiency and economy efficiency show a slow downward trend in most provinces in China from 2000 to 2011, which was followed by a slight increase in 2012. Moreover, low carbon economy efficiency and economy efficiency show obvious geographic characters. We propose some policy implications. Several policy implications are also provided for various areas to improve low carbon economy efficiency.
Keywords: *economic efficiency, carbon emissions, data envelopment analysis model, low-carbon economy, China*

Introduction

Since the reform and opening-up policies in 1978, China has become the second-largest economy in the world and seen an average annual economic growth rate of 9.9% from 1979 to 2010, which arouses the interest of many researchers (Xing et al., 2018; Mutlu et al., 2018). Some of these studies have reported a prolonged slowdown in China's total factor productivity. Many studies calculate the economic efficiency with different data envelopment analysis (DEA) models (Deilmann et al., 2016; Xing et al., 2018), super-efficiency DEA window analysis (Huang et al., 2018a), integrated DEA/AHP model etc. In most of these studies, labor, capital, and energy consumption are used as the inputs, while GDP is used as the output to calculate economic efficiency (Ashraf et al., 2018).

However, the rapid economic growth of China brings about increasingly more energy consumption, which results in rapid increase in CO_2 emissions (Dong et al., 2018). China is the largest CO_2 emitter in the world which accounts for 26.7% of global emission in 2012, and consequently, faces significant pressure to reduce carbon emission (Zhang et al., 2014). The carbon intensity goal announced by Chinese government in 2009 shows that the Chinese government pursues the win-win target of GDP growth and carbon emission reduction in the process of economic development.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64296444

However, most previous studies ignored the impact of CO_2 emission constraints on the efficiency of China's economic growth (Haque et al., 2019).

Both GDP and CO_2 emissions are simultaneously produced in the process of production. However, different from GDP which is a desirable output, carbon emission is an undesirable output. As such, traditional DEA models may not be appropriate. The undesired input can be evaluated by both indirect and direct methods (Scheel, 2001). The former one means using the inverse value of undesirable output as desirable output (Golany and Roll, 1989) or seeing the undesirable output as input (Tyteca, 1997) in standard DEA models. However, the direct approach treats the undesirable outputs more appropriately (Wu et al., 2018). Moreover, the slack-based measure (SBM) model with more desirable outputs and less undesirable outputs relative to fewer inputs should be recognized as efficient (Xie et al., 2018).

Therefore, this paper first estimates the Low Carbon Economy Efficiency of China by taking CO_2 emissions as the undesirable output and GDP as the desirable output in the undesirable output DEA model (Kumar et al., 2019). And then, Low Carbon Economy Efficiency with Economy Efficiency is compared to find out the different performances of economic growth in various regions in China in the context of low carbon economy. Moreover, the potential determinants of Low Carbon Economy Efficiency for different regions in different periods are explored to find out the effective ways to improve Low Carbon Economy Efficiency and to promote low carbon economy development (Jeegatheesan et al., 2018).

Plenty of studies contribute to indicate determinants influencing CO_2 emissions and economic growth in China. The following factors are of great importance (Suhaili et al., 2018).

(1) Industry structure. In general, industrial is more energy intensive than tertiary industry. It is estimated that the rapid growth of energy consumption and CO_2 emissions are consistent with the continuing heavy industrialization in China. In this paper, the proportion of industrial added value in GDP is taken as an indicator for measuring industry structure.

(2) Urbanization. The urbanization rate of China expanded from 36.2% in 2000 to 52.6% in 2012 and is estimated to reach 70% in 2030 (World Bank, 2014). The rapid growth of urbanization rate makes carbon emission reductions very difficult (Song et al., 2018a). In this paper, the proportion of urban population residents in the total population is represented as the urbanization rate (Ali et al., 2018).

(3) Research and Development (R&D) support. Extensive studies emphasize the importance of R&D to improve productivity and environmental performance (Song et al., 2018b). Moreover, the literature on climate policy modeling has also indicated the core role that R&D is playing in industrializing countries such as China because R&D exerts opposing influences on energy and emission intensities (Huang et al., 2018b). Therefore, the proportion of R&D expenditure in GDP is taken as a proxy for scientific and technical support (Nordin et al., 2018).

(4) Government support. China is an investment-driven country, as such, the government's attitude towards the environmental problems can be seen from the amount of money invested. In this paper, the proportion of financial expenditure in GDP is considered as a proxy indicator (Majumder et al., 2019).

(5) International trade. The ongoing raising of international trade is a significant driver for GDP growth and carbon dioxide emissions in China (Xu et al., 2017). It is estimated that CO_2 emissions in trade accounted for 19% of its total production-based

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64296444

emissions in 2008 (Zhang, 2014) due to more exports of energy-intensive products. The ratio of the amount of imports and exports to GDP is taken as a proxy indicator in this paper. *Table 1* shows the details of these indicators.

Table 1. *Summary of determinants of low carbon economy efficiency*

Factors	Max	Min	Mean	S.D
The proportion of industrial added value in GDP (IS)	0.530	0.134	0.395	0.080
Urbanization rate (UR)	0.893	0.232	0.468	0.149
Gross domestic expenditure on R&D in GDP (RD)	0.429	0.001	0.024	0.068
The proportion of financial expenditure in GDP (GS)	0.612	0.069	0.177	0.079
The ratio of imports and exports to GDP (IE)	1.632	0.026	0.316	0.367

The objective of this research is to find out effective approaches to improve the low carbon economy efficiency of China and to promote its low carbon economy development. The remainder of this paper is organized as follows. 2 different DEA models are employed to estimate Economy Efficiency and Low Carbon Economy Efficiency, as well as their inputs and outputs, are briefly introduced (Nouaim et al., 2019). Afterwards, the paper presents and discusses in details the results of Economy Efficiency and Low Carbon Economy Efficiency from the viewpoint of different regions in various periods in China. Conclusions and several policy implications can be found in the last section.

Materials and methods

DEA models

As one of the most widely used efficiency evaluation methods, DEA models provide a mechanism for measuring relative efficiency of similar economic production systems. Different DEA models and their applying requirements and advantages have been discussed in details by Wu et al. (2018), Liu and Liu (2016) and Jiang et al. (2016). In this paper, BCC DEA model is employed to estimate Economy Efficiency which aims at constant inputs producing more outputs (GDP). In contrast, undesirable output DEA model is utilized to estimate Low Carbon Economy Efficiency, which implies that constant inputs producing more desirable output (GDP) and fewer undesirable output (CO_2 emissions).

BCC DEA model

BCC DEA model was first proposed by Banker et al. (1984) and largely applied in the situation of "variable returns to scale" (VRS). BCC DEA model can classify the DMUs into efficient and inefficient ones according to the rule that whether the efficiency score equals one.

According to Banker et al. (1984), the envelopment form of BCC DEA model can be expressed as *Equation 1:*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64296444

$$\theta^* = Min(\theta - \varepsilon(e^- S^- + e^+ S^+))$$
$$s.t. \begin{cases} \sum_{j=1}^{n} X_j \lambda_j + S^- = \theta X_0 \\ \sum_{j=1}^{n} Y_j \lambda_j - S^+ = Y_0 \\ \sum_{j=1}^{n} \lambda_j = 1 \\ \lambda, S^+, S^- \geq 0 \end{cases} \quad \text{(Eq.1)}$$

where X_j and Y_j in the model respectively represent inputs and outputs of the j^{th} DMU, λ_j denotes the weights, θ is technological efficiency, $\theta < 1$ means the DMU is inefficient, while $\theta = 1$ shows the DMU is efficient in BCC DEA.

Undesirable output SBM DEA model

Based on Tone (2001) and Zhou et al. (2006), the undesirable output SBM DEA model can be defined as follows.

Given that there are n DMUs in production system P, and each DMU has m inputs, s_1 desirable outputs, and s_2 undesirable outputs.

$$X = [x_1, x_2, \ldots, x_n] \in R^{m \times n}, \quad Y^g = [y_1^g, y_2^g, \ldots, y_n^g] \in R^{s_1 \times n} \text{ and } Y^b = [y_1^b, y_2^b, \ldots, y_n^b] \in R^{s_2 \times n}$$

Matrices represent inputs, desirable outputs and undesirable outputs respectively. Moreover, $X > 0$, $Y^g > 0$, and $Y^b > 0$. The production possibility set (P) is defined as:

$$P = \left\{ \left(x, y^g, y^b \right) \middle| x \geq X\lambda, y^g \leq Y^g \lambda, y^b \geq Y^b \lambda, \sum \lambda = 1 \right\}$$

where $\lambda \in R^n$ is the intensity vector, and $\sum \lambda = 1$ represents the assumption of variable returns to scale (VRS).

We suppose that the DMU$_0$ $\left(x_0, y_0^g, y_0^b \right)$ is efficient if there is no vector $\left(x, y^g, y^b \right) \in P$ that simultaneously satisfies $x_0 \geq x$, $y_0^g \leq y^g$ and $y_0^b \geq y^b$. And the SBM DEA models with undesirable outputs can be written as

$$\rho = Min \frac{1 - \frac{1}{m} \sum_{i=1}^{m} \frac{s_i^{s-}}{x_{i0}}}{1 + \frac{1}{s_1 + s_2} \left(\sum_{r=1}^{s_1} \frac{s_r^g}{y_{r0}^g} + \sum_{r=1}^{s_2} \frac{s_r^b}{y_{r0}^b} \right)}$$
$$s.t. \begin{cases} x_0 - X\lambda - s^- = 0 \\ y_0^g - Y^g \lambda + s^g = 0 \\ y_0^b - Y^b \lambda - s^b = 0 \\ s^- \geq 0, s^g \geq 0, s^b \geq 0, \lambda \geq 0 \end{cases} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64296444

where, s^-, s^g and s^b correspond to slack variables of inputs, desirable outputs, and undesirable outputs respectively. The objective function is strictly decreasing with respect to $s_i^-(\forall i)$, $s_r^g(\forall r)$, $s_r^b(\forall r)$ and the objective value satisfies $0<\rho\leq 1$. Let the optimal solution of the above program be $\left(\lambda^*, s^{-*}, s^{g*}, s^{b*}\right)$, and if and only if $\rho=1$, $s^{-*}=0$, $s^{g*}=0$ and $s^{b*}=0$, the DMU is efficient.

Using the transformation by Charnes and Cooper (1962), the equivalent linear program of *Equation 1* can be obtained to calculate efficiency scores.

Data for inputs and outputs

The empirical study covers 30 provinces in the Chinese mainland, excluding Tibet because of energy consumption data loss. The 30 provinces in China can be aggregated to four areas, the Eastern (E), Northeast (NE), Central (C) and Western (W) areas. The Eastern area is the richest and most developed region in China. The Northeast area is one of the earliest and most important industrial base in the country. The Central area is considered to be a connecting link between the booming Eastern region and the relatively poor Western region by the Chinese government. The Western area is relatively backward but the resource-rich region.

The amount of energy consumption (E), labor force (L), and capital stock (K) are taken as inputs in both DEA models. Moreover, GDP is considered as the only output in BCC DEA model and the desirable output in undesirable DEA model, which presents the performance of economic development. In addition, the amount of CO_2 emissions is taken as the undesirable output in the undesirable DEA model, which reflects the objective to reduce carbon emissions.

CO_2 emissions

The amount of CO_2 emissions of different types of fossil fuel can be calculated. According to the national standard from the National Development and Reform Commission (NDRC) (Guidance for Compiling Provincial Greenhouse Gas Emission Lists (Trial), 2011), eight types of fossil fuel are considered, including coal, coke, crude, gasoline, kerosene, diesel oil, fuel oil, and natural gas. Thus, according to the approach recommended by IPCC (2006), CO_2 emissions from fossil fuel burning can be calculated based on

$$Q_{CO_2}=\sum_{i=1}^{8} Q_i \times NCV_i \times CEF_i \times COF_i \times (44/12) \quad \text{(Eq.3)}$$

where Q_{CO_2} is the quantity of CO_2 emissions from all eight types of fossil fuel consumption; i represents different types of fossil fuel, Q_i is the total consumption of fuel i; NCV_i, CEF_i and COF_i represent the default net calorific value, carbon content factor, and carbon oxidization factor of fuel i; $NCV_i \times CEF_i \times COF_i \times (44/12)$ is CO_2 emission factor of fuel i. All these data can be got from NDRC as shown in *Table 2*.

All the data on fossil fuel are compiled from China Statistical Yearbook. However, the latest China Statistical Yearbook 2013 only provides energy consumption data by fuel by provinces in the year of 2011. As a consequence, we estimated these data in 2012 using the average annual growth rate of 2000-2011. Thus, the amount of CO_2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64296444

emissions for each province can be calculated by *Equation 3* and the descriptive statistics are shown in *Figure 1*.

Table 2. *CO_2 emission factors by fuel*

Fuel	Coal	Coke	Crude	Fuel oil	Gasoline	Kerosene	Diesel	Natural gas
NCV (kJ/kg)	20908	28435	41816	41816	43070	43070	42652	38931
CEF (tonne C/TJ)	26.37	29.5	20.1	21.1	18.9	19.5	20.2	15.3
COF	0.94	0.93	0.98	0.98	0.98	0.98	0.98	0.99
Emission factor k_i	1.9003	2.8604	3.0202	3.1705	2.9251	3.0179	3.0959	2.1622

The unit of k_i is kg-CO_2/kg except natural gas, which is kg-CO_2/m^3

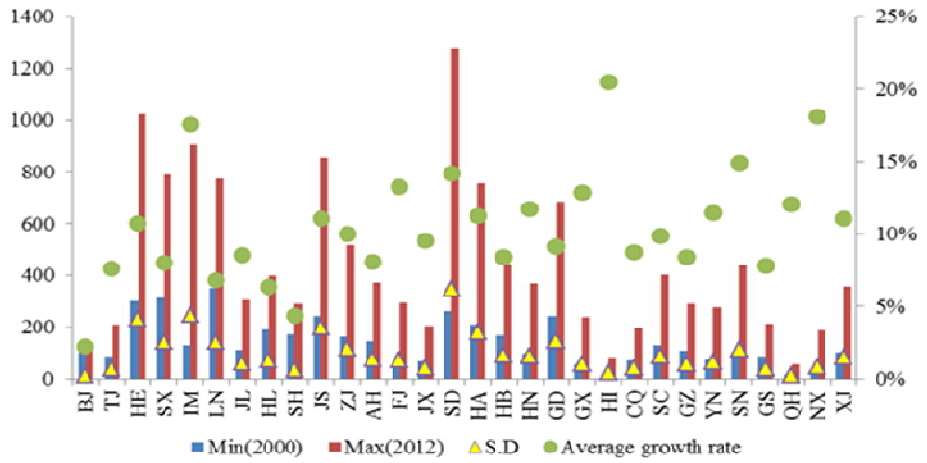

Figure 1. *Total amount of CO_2 emissions for 30 provinces in China (million tons)*

Summary of inputs and outputs

The data on E, L, and GDP are obtained from China Statistical Yearbook. Data for K from 2000 to 2006 are directly acquired from Shan (2008), and the rest of the data from 2007 to 2012 are estimated by perpetual inventory method according to Shan (2008). Considering the fact that Chongqing used to be a part of Sichuan Province before 1997, Shan (2008) estimated their K value on the basis that considering Chongqing still as part of Sichuan. In order to separate the two different regions, K is divided according to gross fixed capital formation in these two provinces. All price values are converted to 2000 prices according to GDP deflator. *Table 3* shows descriptive statistics of the input and output variables by region.

Analysis of impact factors

To further discover the determinants influencing China's economic growth efficiency under carbon emissions constraint, regression analysis method for panel data is applied to measure the relationship between the efficiency and the impact factors mentioned in 2.2.2. Specifically, the econometric model can be defined as:

$$LCEE_{i,t} = C + C_i + \beta_1 * IS_{i,t} + \beta_2 * UR_{i,t} + \beta_3 * RD_{i,t} + \beta_4 * GS_{i,t} + \beta_5 * IE_{i,t} + \varepsilon_{i,t} \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64296444

where, $LCEE_{i,t}$ is carbon efficiency of province i in year t. IS, UR, RD, GS, IE represent the five determinants mentioned before, C is a common intercept, C_i represents the individual effect, $C+C_i$ indicates the varying efficiency among different provinces, $\varepsilon_{i,t}$ is the error term.

The results of Hausman test indicates Fixed Effects estimator should be taken in this study. As such, the estimated coefficients between Low Carbon Economy Efficiency and determinants can be calculated according to *Equation 4* by Eviews software. As a calculation result, the estimated coefficients by region are shown in *Table 4*.

Table 4. *The estimated coefficients in Table 1 by region*

***, **, * indicates 1%, 5%, and 10% significant, respectively

(1) The dependence on the proportion of industrial added value in GDP (IS) has a negative influence on Low Carbon Economy Efficiency in the whole country, which agrees with most research (Hao and Peng, 2017). The high proportion of energy intensive industry in the secondary industry accounts for a large amount of carbon emissions in China (Fan et al., 2018). However, IS has a negative effect on the Eastern and Central areas but a positive effect on the Northeast and Western area. For the Eastern and Central area, the desirable output GDP is huge and presents an upward trend, so the core task of promoting Low Carbon Economy Efficiency improving should be concentrated on carbon abatement. However, in the Northeast and Western area, where the economics are relative backwardness, industrial structure which shifts from industrial to other industries will damage economic growth rather than decrease carbon emissions.

(2) Urbanization rate (UR) is one of the most vital positive factors impact Low Carbon Economy Efficiency of the whole country, as well as the Eastern and Western areas. Low Carbon Economy Efficiency in these areas will respectively go up by 0.677%, 0.763%, 2.074% with the value of UR increase 1%. The fast growing UR in Eastern area can promote the concentration of population lives and improve the efficiency of public infrastructure. Therefore, economies of scale of energy consumption can improve the energy efficiency. For the Western area, where the intensity of population is much smaller than the Eastern, the economies of scale of energy consumption are much more obvious. Therefore, a positive correlation can be seen in UR and Low Carbon Economy Efficiency there. However, UR had a negative and non-significant effect on the Northeast and Central areas. The reason is that with the process of urbanization, residents in urban have a growing demand for higher levels of energy services as living standards rise, which should greatly promote the total energy consumption and ultimately promote CO_2 emissions.

(3) The ratio of R&D expenditure to GDP (RD) contributes to Low Carbon Economy Efficiency in China was negative for every area but the Northeast. Firstly, energy

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64296444

rebound effect can be seen in these areas. Energy rebound effect means that although technological innovations improved the energy efficiency and energy savings, it also promoted rapid economic development and resulted in energy consumption increasing, and the volumes of increased over that of decreased. Secondly, R&D expenditure in China, which covers all aspects of science and technology, should be improved both in volume and structure.

(4) The relationship between the proportion of financial expenditure in GDP (GS) and Low Carbon Economy Efficiency is positive except for the Eastern and Northeast areas. The amount of investment in financial expenditure such as environmental pollution treatment seeing a continuing increase in recent years, which showed the efforts and determination of the government to reduce energy overuse and waste. However, it can be seen from *Table 5* that the government's efforts are negative in the Eastern and Northeast areas. For one thing, the amount of the investment may not be enough, especially for the Eastern area with the largest GDP in China; for another, investing in subsidy of equipment and technologies using have not been effectively used.

***, **, * indicates 1%, 5%, and 10% significant respectively

(5) The ratio of imports and exports to GDP (IE) has a positive impact on Low Carbon Economy Efficiency of China. International trade can impact Low Carbon Economy Efficiency through introducing advanced technology, equipment, and management experience, as well as embodied carbon (Kang et al., 2018). The former factors' effects can be seen from a long horizon while the latter can be seen in the initial stage of IE development. It can be seen that IE showed a positive and significant relationship with Low Carbon Economy Efficiency in the Eastern area where the vast majority of imports and exports in China are produced. The other three areas only account for 13.03% of the total amount of imports and exports in China from 2000 to 2012, and the majority of export-oriented factories in these areas are transferred from the Eastern area because of high energy consumption and environmental pollution. These factories contribute much more carbon emissions rather than GDP. International trade in these three areas was still in the initial stage and saw a negative impact on Low Carbon Economy Efficiency.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64296444

Moreover, this paper divides the period of 2000-2012 into two periods (2000-2007 and 2008-2012) to discover different determinants affecting Low Carbon Economy Efficiency of different areas in different periods. The results are shown in *Table 5*.

(1) IS sees decreased negative affect on Low Carbon Economy Efficiency in all areas except the Northeast, which means that energy and resource saving during the process of industrialization should be taken into account. However, increased positive correlation between IS and Low Carbon Economy Efficiency still can be seen in the Northeast area, for the reason that as an old industry base in China, industrialization is the basis of economic development in the Northeast area. Consequently, they should promote Low Carbon Economy Efficiency improvement during the process of industrialization through means of upgrading the industrial production from high investment, high energy consumption and high emissions to low investment, low energy consumption, and low emissions.

(2) Urbanization shows a further strengthened positive impact on Low Carbon Economy Efficiency improvement in the whole country and the Northeast area, while decreased affection in other three areas. Especially for the Central area, urbanization shows a negative impact on Low Carbon Economy Efficiency in the period of 2008-2012. The average annual growth rate of urbanization in the Central area rose from 1.46% in the period of 2000-2007 to 1.6% in the period of 2008-2012, with an increase of 0.14%, while the Eastern, Northeast and Western areas seeing an increase of 0.5%, 0.16%, 0.3% respectively. The change of average annual growth rate of urbanization in the Central area is the smallest and the rate in the Northeast area is the slowest, where UR has a positive impact on improving economic efficiency under carbon emissions constraints. The results indicate that pursuing the urbanization speed while ignoring its quality should be avoided in the process of urbanization.

(3) RD showed a slightly increased negative impact on Low Carbon Economy Efficiency in the whole country while greatly decreased negative effect on the Eastern and Central areas, and became a negative factor in the period of 2008-2012 in the Northeast and Western areas. Besides the reason of volumes and structure of R&D expenditure mentioned above, the different performances of RD in various areas in China also contribute to these differences. The growth rate of RD in the whole country, Eastern and Central areas increased by 38.11%, 44.39% and 57.52% from the period of 2000-2007 to 2008-2012. However, the Northeast and Western areas only saw 14.83% and 17.87% increase, less than a half comparing with other areas.

(4) Government support plays an increasingly more important role in improving Low Carbon Economy Efficiency in all areas but the Western. These results indicate that local governments paying more attention to the development of Low Carbon Economy Efficiency, and implying the importance of government support in the initial stage of low carbon economy development. However, for a small amount of financial expenditure in the Western area (198.82 billion per year per provinces in 2008-2012, only accounts for 78.27% of that in the whole country), the importance of government support is not obvious.

(5) International trade can be seen a decreased correlation with Low Carbon Economy Efficiency in the whole country, Eastern and Northeast areas in these two periods, especially for the Northeast area where the coefficient turned from positive in 2000-2007 to negative in 2008-2012. However, the correlation between Low Carbon Economy Efficiency and IE went up from 0.144, -0.577 to 0.886 and 0.241 in the Central and Western areas at the same time. The reason is that imports and exports can be seen a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64296444

decreased importance in these two areas. Although the amount of imports and exports increased by 2.3 and 2.6 times per province in the Central and Western areas from the period of 2000-2007 to 2008-2012, the proportion in GDP dropped from 10% to 9.74% in the Central area and slightly increased from 11.12% to 11.49% in the Western area. For the Eastern, Northeast, and the whole country, the amount of imports and exports increased by 1.67, 1.57 and 1.72 times, while the proportion in GDP decreased from 84.3%, 27.89%, 56% to 72.64%, 22.73%, 49.43%.

Results

With the two different DEA models, both Economy Efficiency and Low Carbon Economy Efficiency of different regions from 2000 to 2012 can be calculated. The calculation results show that the majority of provinces in China saw a smaller Low Carbon Economy Efficiency than Economy Efficiency except for Guangdong, Shanghai, Beijing, Tianjin, Hainan, Qinghai, and Ningxia. Jiangsu, Zhejiang, Shandong, Chongqing and Sichuan witnessed an upward trend in both Low Carbon Economy Efficiency and Economy Efficiency. In contrast, both the Low Carbon Economy Efficiency and Economy Efficiency declined in Inner Mongolia, Jilin and Guangxi. Although Low Carbon Economy Efficiency in Hainan and Qinghai pointed at efficiency frontier (the score of Low Carbon Economy Efficiency is one), their Economy Efficiency showed a downward trend, which implied poor economic conditions there. However, most provinces demonstrate gradually increased Low Carbon Economy Efficiency with declined Economy Efficiency after 2007, when the Chinese government proposed the first national plan and policy-based document National Climate Chang Program on climate changes.

As shown in *Table 6,* the majority of provinces in the Eastern area are high-efficiency regions, and most provinces in the Central and Western area of China are low efficiency. These results imply that the Low Carbon Economy Efficiency shows obvious geographic characters. Furthermore, the whole period can be divided into four periods, as shown in *Table 7.*

Table 6. *Average efficiency scores and rank by region (2000-2012)*

Regions	EE		LCEE		Regions	EE		LCEE	
	Score	Ranking	Score	Ranking		Score	Ranking	Score	Ranking
Northeast (NE)	0.808		0.550		Central (C)	0.771		0.780	0.505

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64296444

China's Economy Efficiency had decreased from 0.812 in 2000 to 0.76 in the 12th five-year with a percentage decline of 6.38%. The Western area saw its efficiency rising from 0.642 in the 11th five-year to 0.653 in the 12th five-year, while the other three areas saw downward trends. China's Low Carbon Economy Efficiency had gradually decreased from 0.674 in the period of 9th five-year to 0.623 in the period of 11th five-year, and then slightly increased to 0.627 in the period of 12th five-year. Seeing the same trends as the whole country, Low Carbon Economy Efficiency of the Eastern and Western areas experienced a slight rise in the period of 12th five-year, while the Northeast and Central area had declined from 0.559, 0.537 in 2000 to 0.517, 0.479 in the 12th five-year. Comparing Economy Efficiency with Low Carbon Economy Efficiency, it can be found that Low Carbon Economy Efficiency is smaller than Economy Efficiency in any areas at any time.

Discussion

The analytical methodology of this paper is innovative and can be utilized in similar research. It utilizes two kinds of data envelopment analysis models to estimate the economic efficiency and low carbon economy efficiency of China. It takes carbon dioxide emissions as an undesirable output and compares them to find out the different performances of economic growth in various regions in China in the context of low carbon economy development, and then explores the potential determinants of low carbon economy efficiency for different regions in different periods.

As can be seen in the previous section, it is still a long and tough journey for China to achieve the win-win goal of high GDP growth and low CO_2 emissions, for Low Carbon Economy Efficiency is lower than Economy Efficiency in most provinces in China, which means unbalanced development of high GDP growth and low CO_2 emissions, and implied that most policy makers and implementers prefer increasing desirable output of GDP than decreasing undesirable output of CO_2 emissions. This is because provincial leaders in China pay more emphasis on the quantity of GDP growth over the quality of economic performance because the likelihood of promotion of them increases with GDP growth in their provinces (Chen et al., 2017). Therefore, the quality of economics development, such as carbon emissions, should be considered as the next goal to achieve after getting a high value of GDP. This conclusion has also been supported by the evidence that the richest Eastern area also has the highest Low Carbon Economy Efficiency in China. Consequently, it is necessary to reform the performance evaluation system of policy maker and implementers from the quantity of economic growth to the quality of economic performance. Therefore, the environment protection, energy efficiency, as well as resources and other indicators, should be considered as important as GDP in the performance evaluation system, so as to stimulate policy makers and implementers to take decreasing undesirable outputs equally important as increasing desirable outputs.

Moreover, Low Carbon Economy Efficiency and its determinants vary with regions in China. As a consequence, different provinces should implement different policies and actions based on their actual situation to improve the Low Carbon Economy Efficiency. Provinces in the most developed and richest Eastern area see the highest Low Carbon Economy Efficiency for higher levels of environmental concern than other areas (Lin and Xu, 2018). Also, they have sufficient economic strength to realize the balanced development of GDP growth and CO_2 emissions. Provinces in the Western area have

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64296444

the advantage of the natural ecological environment and benefit from more stringent constraints of promoting GDP growth due to the requirements to protect the natural ecological environment. Therefore, the core task for eastern and western areas to improve Low Carbon Economy Efficiency is expected to maintain a balance between GDP growth and CO_2 emissions. In addition, the reason that the Northeast and Central area saw a continuing decrease Low Carbon Economy Efficiency in recent years is that these two areas emphasis on increasing the desirable output GDP while ignoring the reduction of undesirable output CO_2 emissions. Consequently, the Northeast and Central regions need to treat carbon emissions abatement as important as GDP growth, which can be promoted through the reform of performance evaluation system for policy makers and implementers. In addition, different policies and actions have different effects on Low Carbon Economy Efficiency of various areas. For the Northeast area, the likelihood of promoting efficiency increases with RD, while RD has a negative impact on the Eastern and Western areas. For the Eastern and Western areas, the process of urbanization is more critical to improving Low Carbon Economy Efficiency, they should emphasize the quality of urbanization. Government support, especially financial support, sees more positive and obvious impact for the Central area.

Finally, it is necessary to introduce market-based policy instruments to simultaneously control CO_2 emissions and promote GDP growth. Both the central and local governments play key roles in promoting economic development in China, through the ways of making policy, planning, resources input and allocation and so on (McMillan and Naughton, 1992). However, according to the law of diminishing marginal returns, expanding the volume of production factors input would yield lower per-unit returns at some time, which means relying on factors-driven to promote economic development is unsustainable and possibly increasing CO_2, so as to exacerbate the difficulty of economic efficiency improvement. As a result, market-based policy tools, such as environmental tax and emissions trading, should be introduced to provide incentives for carbon emitters to reduce carbon emissions without damaging economic development. For one thing, the revenue from environmental taxes can be reallocated to investment in energy saving technologies, or expanding the amount of funds invested in environmental pollution control, so as to promote Low Carbon Economy Efficiency improvement. For another, emissions permit trading is also a financial instrument. Several carbon emission trading systems such as EUETS and CCX introduced a series of financial derivative products (Helm, 2014). The purpose of developing emission trading market not only can control carbon emissions but also can be used as a financial instrument to promote the development of the financial market.

Conclusions

Improving the efficiency of economic development is of vital importance of China to achieve sustainable development, and CO_2 emissions impact the development of economics as well. This research compared two kinds of economics development efficiency based on whether considering CO_2 emissions or not (Economy Efficiency or Low Carbon Economy Efficiency). Furthermore, we analyzed in details that the determinants of Low Carbon Economy Efficiency of different areas in China. The following basic conclusions can be obtained:

(1) There is still a long and tough journey for China to achieve the win-win goal of high GDP growth and low CO_2 emissions.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64296444

(2) Low Carbon Economy Efficiency and its determinants vary with regions in China.

(3) It is necessary to introduce market-based policy instruments to simultaneously control CO_2 emissions and promote GDP growth.

Most importantly, the analytical methodology of this paper is innovative and can be utilized in similar research.

Abstract. 18 open-pollinated maize accessions were assessed for variability under randomized complete block design with 3 replications. Each plot comprised of two rows each 5 m in length with a plant to plant distance of 30 cm and a row to row distance of 75 cm. Data on morpho-biochemical traits were collected and subjected to statistical analysis to find out the variability among the maize accessions and association of increasing protein and oil content with the agronomic traits. From the source population 5 varieties with a high percentage of oil and protein, were selected and analyzed for total seed protein profile using Sodium Dodecyl Sulphate Polyacrylamide Gel Electrophoresis. Significant results of variance and covariance were observed for all morpho-biochemical traits, which revealed significant variation among the maize accessions. SDS-PAGE showed considerable variation in protein banding among the maize accessions. Correlation results showed an independent association of morphological traits with oil and protein contents in almost all the source population. This indicated that oil and protein content of maize grain can be increased without negatively affecting the important agronomic traits. Based on the results, the variability could be utilized to develop commercial maize varieties with improved quality of grain utilizing the conventional techniques of selection and hybridization.
Keywords: *biodiversity, correlation, oil content, protein content, SDS-PAGE*

Introduction

Maize is the 3rd most important crop in Pakistan after wheat and rice with an average yield of 4.3 ton ha^{-1} (Farooq, 2013) below the worldwide maize yield of 5.2 ton ha^{-1} (FAOSTAT, 2012). Therefore, it is very important to screen the new indigenous and exotic lines with an improved yield to be used in maize breeding programs (Iqbal et al., 2015). Genetic diversity is a basic tool for crop improvement (Iqbal et al., 2014) which could be managed, maintained and explained by morphological, biochemical and molecular markers (Vojka et al., 2016; Iqbal et al., 2015).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64456456

Pakistan imports 75% of edible oil (Zaidi, 2014) and could save billions by promoting local edible oil. Besides carbohydrates corn grain also has a considerable percentage of oil (3.77 to 11.56%) and protein (5.7 to 11.60%) (Deif et al., 2012; Singh et al., 2005; Mittelmann et al., 2003; Okporie et al., 2002) and annually gives almost 15% of the proteins obtained from food-crops throughout the world (Li and Vassal, 2004). Oil content and protein content of maize grain are positively associated with yield and its components (Sreckov, 2011; Obi and Onysishi, 1994), therefore, could be increased without adversely affecting yield (Okporie et al., 2007). Oil and protein of corn grain can be increased by different breeding techniques, e.g. recurrent selection method, which has been one of the most effective and successful methods used in breeding programs for maize improvement (Berner, et al., 2006; Uguru, 2005; Obi, 1991).

Many studies investigated variability among maize germplasm through morphological (Kariuki et al., 2016; Iqbal et al., 2015; Shrestha, 2014) and biochemical markers (Deif et al., 2012; Mittelmann et al., 2003). These experiments determined variability through morphological and biochemical characterization of maize varieties under RCBD with 3 replications and reported a wide range of variation for different morpho-biochemical characters investigated. Vojka et al. (2016) used morphological and molecular markers to study the variation among 29 inbred lines and reported that morphological and molecular markers are equally effective and accurate practices to determine the pedigree information of tested maize lines.

Other studies (Mittelmann et al., 2003) evaluated oil content, protein content and grain yield in a group of maize test-crosses under RCBD with three replications. Results showed week association and significant variation for oil content, protein content and grain yield. Deif et al. (2012) set an experiment to study the variability of 14 maize inbred lines and 15 crosses for oil and protein content. Results showed significant differences for protein content and oil content ranging from 8.34% to 11.60% and 7.67 to 11.56%, respectively. On the other hand, in crosses protein and oil content ranges from 8.22% to 13.94% and 9.27% to 11.29%, respectively. The highest values for protein content (13.94%), oil content (10.65%) and grain yield per plant (128.73 g) were reported by a cross.

Previous studies suggested that plant height is strongly associated with maize yield (Hegy et al., 2002; Sangoi et al., 1998; Aldrich et al., 1986), while 100-kernel weight and ear length predict yield components, whereas days to 50% silking predicts the maturity time of maize plants (Okporie et al., 2007). Furthermore, maize forage yield is preferred by farmers because it contains sufficient quantities of protein and minerals and possesses high digestibility as compared to other non-legume fodders (Chaudhary et al., 2014). Therefore, Plant height, grain yield, ear length, days to 50% silking and dry forage yield are among the most important agronomic traits to be assessed and should not be adversely affected in the maize breeding programs. Okporie et al. (2007) investigated 8 maize varieties to find out the correlation of increasing oil and protein content with five important agronomic parameters viz., plant height, ear height, 100-kernel weight, kernel density and days to 50% silking, under RCBD with 3 replications. They reported an independent association among the traits investigated and concluded that oil and protein content of maize can be increased without adversely affecting these agronomic traits.

Pakistan is not only facing the problem of having low maize yield ha^{-1} but also the poor quality of corn grain. Therefore, to achieve the goal efforts need to develop high

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64456456

yielding maize varieties with an improved percentage of oil and protein which can be obtained by the determination of variability among the local and exotic germplasm to be used in future breeding programs.

The objectives of this study are: (1) to determine variation among selected maize varieties through morphological, biochemical and molecular markers; (2) to determine the association of oil and protein content with selected agronomic markers.

Materials and methods

The experimental material comprised of 10 open pollinated maize varieties viz., Sadaf, Islamabad Yellow, Agati-2002, SG-2002, Soan-3, Sahiwal-2002, Margala, Rakaposhi, Islamabad white and Kashmir Gold and 8 advance maize lines viz., BS-1, EV-7004 Q, EV-5098, EV-1097, BS-2, EV-6089, EV-6098, and EV-1098. The Seed of 8 open pollinated varieties and 9 advance maize lines were collected from National Agriculture Research Council (NARC) Islamabad and one local variety 'Kashmir Gold' was used as a check. The experiment was carried out using randomized complete block design with three replications at the research area of Faculty of Agriculture, Rawalakot, Department of Plant Breeding and Molecular Genetics. Each plot comprised of two rows each 5 m in length with a plant to plant distance of 20 cm and a row to row distance of 75 cm. All recommended agronomic practices were followed to raise an ideal crop. Data on 5 competitive plants of the selected one-meter square area from each plot was recorded on maturity. Nitrogen and phosphorus fertilizers were applied @ 60 and 90 kg ha^{-1}, respectively. Data was recorded before and after harvesting of the crop for five morphological traits viz., days to 50% silking, plant height, 1000-grain weight, ear length and dry forage yield and two biochemical traits viz., oil content and protein content. Morphological parameters were recorded by using the standard descriptors formulated by IBPGR (1980). The protein content was determined by the Micro-Kjeldahl method as described by Pearson (1976). While the oil content was obtained with the help of Soxhlet's extractor as described by Anon (1978).

From the source population two advance maize lines viz., EV-5098, EV-1097, EV-6089, two commercial varieties viz., Agaiti-2002, Rakaposhi and a Local Check (Kashmir Gold) with a high percentage of oil and protein were selected and analyzed for total seed protein profile using Sodium Dodecyl Sulphate Polyacrylamide Gel Electrophoresis (SDS-PAGE) as described by Laemmli (1970). The gel picture was taken, uploaded to ImageJ software and the distance covered by protein bands was calculated and scored by assigning + or – sign for the presence or absence of bands, respectively.

Data for agronomic and biochemical traits were submitted to analysis of variance using the GLM procedure of the SAS system v9.2 (SAS Institute, 2007) and the treatment means were compared by the Tukey's test at 5% level of significance. Correlation associations of oil content and protein content of maize kernel with plant height, days to silking, ear length, 1000-grain weight, and dry forage yield and correlation coefficients were calculated as given by Okpori (2006).

Results

The mean values for days to silking, plant height, ear length, 1000-grain weight, and dry forage yield are given in *Table 2*. Data for these morphological characters were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64456456

analyzed statistically and genotypic and phenotypic variance and covariance were estimated (*Table 1*). Significant differences were observed among maize accessions for days to silking, plant height, ear length, 1000-grain weight and dry forage weight (*Table 1*). The genotypic and phenotypic variances were significantly different for all the traits (*Table 1*). Genotypic and phenotypic variability values for days to silking (0.22% and 0.23%, respectively), plant height (1.4% and 1.4%, respectively), ear length (0.09% and 0.10%, respectively), 1000-grain weight (7.4% and 7.9%, respectively) and dry forage yield (281.25% and 326%, respectively) showed less environmental influence on these tested characters.

Table 1. *Estimates of parameters of variability for yield and its components*

Characters	Mean	Range	Genotypic variance	Phenotypic variance	GCV	PCV
Days to 50% silking	81.9	71.5-87.8	17.9	18.9	0.2	0.2
Plant height (cm)	199.9	170-241	274	278	1.4	1.4
Ear length (cm)	15.35	12.8-18	1.3	1.6	0.1	0.1
1000 grain weight (g)	232.8	180.83-345	1717	1839	7.4	7.9
Dry matter yield (kg ha^{-1})	12640.3	8564-16295	3555051	4120678	281.3	326.0
Oil content (%)	5.2	2.10 – 8.40	3.72	3.73	36.85	36.88
Protein content (%)	4.80	2.07 – 7.80	3.19	3.20	37.13	37.15

The minimum days to silking were taken by Rakaposhi with an average value of 73, whereas variety EV-1097 took maximum 86.9 days, similarly, Aguiti-2002 attained maximum plant height of 238.0 cm, whereas variety EV-1097 was short stature variety with 172.6 cm plant height. Agaiti-2002 and local check attained the maximum ear length with an average of 17.8 cm and 17.65 cm, respectively, and EV-7004Q attained minimum ear length of 13.10 cm. Maximum grain weight with an average value of 308.8 g was obtained from Agaiti-2002, whereas the minimum weight of 100-grains was presented by Sahiwal-2002 (181.1 g). EV-1098 produced maximum dry matter yield (16190 kg ha^{-1}), whereas the variety EV-7004Q yielded less dry matter ha^{-1} with an average value of 9342.0 kg.

The mean values for oil content and protein content are given in *Table 2*. Data for these biochemical characters were analyzed statistically and significant differences were observed among maize varieties for oil content and protein content and genotypic and phenotypic variance and covariance were estimated (*Table 1*) for oil content (36.85% and 36.88%, respectively) and protein content (37.13% and 37.15%, respectively). Results showed less environmental influence on the traits of oil content and protein content. Maximum values for oil content and protein content were obtained by EV-6089 (8.40%) and Agaiti-2002 (11.80%), respectively. Meanwhile, minimum values were obtained by EV-1098 (2.10%, 6.06%, respectively). The coefficient of variation (CV %) for days to silking (1.15), plant height (1.5), ear length (3.15), 1000-grain weight (4.53), dry forage yield (5.95) oil content (2.83) and protein content (1.78) indicates the excellent experimental precision.

From the photograph of the protein gel (photograph not presented) banding pattern drawn and the distance covered by protein bands measured (*Table 3*). The protein gel expressed nine bands at the marginally variable distance. At the distance of 1 cm (10 kDa) and 1.6 cm (15 kDa), all the varieties showed a common band. EV-6089, Rakaposhi and Local check (Kashmir Gold) recorded one band each at the distance of 2.7 cm (25 kDa). EV-6089 and Local check shared one common band at the distance of 3.1 cm (30 kDa) in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64456456

the protein profile. Agaiti-2002, EV-5098 and EV-1097 gave one band each travelled the distance of 3.4 cm (40 kDa). Rakaposhi had two isolated bands at the distance of 4 cm (70 kDa) and 6.4 cm (130 kDa). Similarly, EV-5098 expressed a solitary band at the distance of 4.8 cm (100 kDa) in the protein profile. EV-5098 and EV-1097 both had one band each at a distance of 7.3 cm (170 kDa).

Discussion

Morphological comparisons were made to know the extent of variation among maize varieties under investigation to estimate the genetic diversity. Statistical analysis of the data reflected a high level of variation for all the morphological traits. This is in agreement with the results reported by Hussain et al. (2011) who have screened the same maize varieties and reported the wide range of variation for all the morphological markers used and reported values ranged from 69 to 84 and 145 to 205 for days to silking and plant height, respectively. Present results for days to silking, plant height and ear length also showed resemblance with the findings of Koirala and Gurung (2002), who reported a significant amount of variability for days to silking, plant height and ear length. Koirala and Gurung (2002) recorded days to silking varied from 72 to 77 days, 198 to 230.0 cm plant height and a similar range of values for ear length. Similar findings were also reported by Borras et al. (2007), Baqa et al. (2014) and Ghimire and Timsina (2015) for days to silking. Present investigation showed that 1000-grain weight results were closer to the findings of Koirala and Gurung (2002) and Sabeena and Dar (2005), who reported a wide range of variability for 1000 grain weight, values ranged from 340 to 325 g. Similarly, significant variations for grain yield were reported by other investigations (Mubeen et al., 2015; Charles et al., 2013; Adebayo and Menkir, 2015). High variability for important agronomic traits, i.e. days to silk, plant height, ear length, 1000-kernel weight and grain yield in our investigation was also supported by the results of previous studies (Sonmez, 2018; Iqbal et al., 2015; Shrestha, 2013; Ranatunga et al., 2009; Miguel et al., 2008; Ihsan et al., 2005; Beyene et al., 2005; Dijak et al., 1999). Results for dry matter yield in this study do not resemble with the findings of Sabeena and Dar (2005), who reported the values ranged from 8150 to 12000 kg ha^{-1} for this trait. These findings also show deviation with the findings of Koirala and Gurung (2002), who observed the maximum dry forage yield of 14000 kg ha^{-1}. Genotypic and phenotypic variances are presented in *Table 1*. For all the traits studied, genotypic and phenotypic variances were significant, which is a piece of evidence that variability within the maize varieties is sufficiently divergent and constitutes potential candidate varieties on which improvement program can be initiated.

The values for oil content and protein content were significantly different and varied between 0.10% - 6.40% and 6.06% - 11.80%, respectively. The results were in clear agreement with the previous findings reported significantly different percentage of oil and protein values ranged from 3.77% to 11.56% and 5.7% to 12.08%, respectively (Sonmez, 2018; Deif et al., 2012; Seiam and Khalifa, 2007; Mittelmann et al., 2003; Singh et al., 2005). Varieties in the present study showed less percentage of oil content as compared to the previous studies. This difference may be due to the environmental factors and plant growth conditions which could modify the percentage of oil percentage (Villalobos et al., 1996).

Use of SDS-PAGE markers for the determination of variability and identification of varieties by extensive study of seed storage protein in many crop species became an efficient tool (Shah et al., 2003; Tawab, 2004; Anjali and Sanjay, 2012; Iqbal et al., 2014). In this study, the variability within selected varieties was confirmed by molecular investigations on the basis of gene product extracted from the seed of six maize accessions using SDS-PAGE markers. At the distance of 1 cm (10 kDa) and 1.6 cm (15 kDa) similar varieties could be an indication of their evolutionary interrelationship. EV-6089, Rakaposhi and Local check (Kashmir Gold) recorded one

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64456456

band each at the distance of 2.7 cm (25 kDa) in the protein gel which indicated their similar genetic makeup. EV-6089 and Local check were different from the others as they shared one common band at the distance of 3.1 cm (30 kDa) in the protein profile. Agaiti-2002, EV-5098 and EV-1097 gave one band each travelled the distance of 3.4 cm (40 kDa) in the protein gel which showed their genetic resemblance as well as evidence that these varieties could have some common heritage. Rakaposhi had two isolated bands at the distance of 4 cm (70 kDa) and 6.4 cm (30 kDa) that showed Rakaposhi is genetically different from all other varieties studied so far. Similarly, EV-5098 expressed a solitary band at a distance of 4.8 cm (100 kDa) in the protein profile and showed that EV-5098 has a different genetic background as compared to other varieties studied so far. EV-5098 and EV-1097 both had one band each at a distance of 7.3 cm (170 kDa) which indicated that these maize accessions have some common genes and genetically they are different from other varieties. Similar results were reported in other investigations which exploited high level of genetic variability among studied germplasm and revealed that some bands are scored by all varieties and some bands shared by one or more than one variety (Khan et al., 2014; Osman et al., 2013; Verma, 2006; Laura, 2006; Haider, 2002; Tubajika, 2001; Gorinstein, 1999). In the present study, 22% of total visible protein bands were monomorphic and 78% were polymorphic. Results are in clear agreement with other findings (Vivodik et al., 2016; Iqbal et al., 2014; Rashed et al., 2010) which reported a wide range of variability among maize germplasm and recorded 31% to 39% monomorphic and 61% to 65% polymorphic protein bands.

The positive or negative and significant results of correlation suggest that an increase in oil content of maize can adversely affect the important agronomic traits. But these results are negligible as not even a single genotype has significant results for all the traits studied and only a few lines showed significant results for few traits. Since no significant relationship existed in the majority of remaining varieties of the source population, it indicates that high oil maize can be bred without adversely affecting the studied agronomic traits. Similar results were reported by Okporie and Oselebe (2007), Okporie and Obi (2002), Obi and Onish (1994) and Rajni et al. (1983). For 1000-grain weight, the present finding was contrary to the work reported by Okporie and Obi (2002) and Obi and Onish (1994), who found oil content to be positively and significantly correlated with 1000-grain weight.

Results of some morphological and biochemical traits deviate from the previous findings. This departure may be due to the environmental factors, variable sample size, and source population. For reliable detection of contrasted varieties usually experiments were performed in two or more consecutive years but the present experiment has not been repeated in consecutive years because Hussain et al. (2011) have previously evaluated the performance of the same varieties which have been screened in the present study and they also recorded significant differences for all the morphological traits studied and reported that these varieties had a wide genetic background, therefore, the results of the present investigation have sufficient and the real scientific interest.

Conclusion

In this study, morphological and biochemical markers confirmed a high level of variability among all the maize varieties investigated. Similarly, molecular markers (SDS-PAGE) also confirmed the wide range of variation among selected maize

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64456456

varieties. The variability can be used in future breeding programs to improve maize varieties. Further, results showed non-significant association between oil and protein content with days to 50% silking, plant height, ear length, 1000-grain weight and dry forage yield, which indicated that oil and protein content that are among the most important and desirable traits of maize grain could be increased by using effective breeding methods without negatively affecting the important agronomic traits studied. Finally, recurrent selection and hybrid breeding might be recommended for developing high yielding maize varieties with the improved percentage of oil content and protein content.

Abstract. Tomato leaf curl virus is a serious threat to an autumn-winter crop of tomato in North India, causing yield losses up to 90-100%. Therefore, nine resistant and one susceptible line (Punjab Chhuhara) of tomato were crossed in half-diallel fashion to develop 45 F_1 hybrids. Parents and their hybrids were evaluated for yield and quality traits under natural epiphytotic field conditions. There were extensive differences in the performance of parental lines carrying similar and different resistance genes (*Ty-X*). Of three parental lines carrying *Ty-2* gene, CLN 17 performed better than 2123D and 2123C in respect of mean and general combining ability (GCA) for total yield and fruit weight. Likewise, out of three parental lines incorporating two resistance genes (*Ty-1* and *Ty-2*), the line CLN 138B had better mean values and GCA for total yield and fruit weight than CLN 138A and CLN 104. However, the parental line CLN 154 with three different resistance genes (*Ty-1*, *Ty-2*, *Ty-3*) showed the best GCA for total yield, and it was followed by genotype CLN 138B comprising of two resistance genes (*Ty-1* and *Ty-2*). However, the parental lines carrying *Ty-2* gene alone produced three useful hybrids expressing 19 to 28% heterosis over top parent for total yield. Four highly significant cross-combinations can be recommended for pedigree selection to develop superior inbred lines. The top parent CLN 154 yielding significantly higher than released varieties along with seven F_1 hybrids manifesting 16 to 31% top parent heterosis for total yield can be recommended after multi-location evaluations. Overall, this study provides useful information on the successful leaf curl virus resistant gene combinations under the north-Indian conditions.
Keywords: *begomovirus, combining ability, diallel cross, heterosis, leaf curl virus resistance, Solanum lycopersicum*

Introduction

Tomato (*Solanum lycopersicum* L.) is one of the most important vegetable crops of India and the world. India contributes 11.1% to world tomato production and is the second largest tomato producer in the world after China (FAOSTAT, 2018). In North Indian plains, the autumn-winter crop of tomato is transplanted during second fortnight of August. The main constraint in this crop is the incidence of tomato leaf curl virus (ToLCV) which may cause yield losses up to 90-100% (Gaikwad et al., 2011a; Kaushik and Dhaliwal, 2018; Moriones et al., 2017). The disease is transmitted by whitefly (*Bemisia tabaci* Gennadius), the population of which is usually high during July to October under Punjab conditions (Kaushik and Dhaliwal, 2018). Management of the whitefly using systemic insecticides has proved futile because of rapid turnover rate of the vector population in the tomato crop (Shankarappa et al., 2008; Singh et al., 2015) and frequent development of resistance against insecticides (Horowitz et al., 2005). Therefore, breeding for disease resistance is the best approach to control this disease

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64576471

(Picó et al., 1996). In this direction, the Punjab Agricultural University has so far developed and released three open-pollinated resistant varieties of tomato viz., Punjab Varkha Bahar 1 (PVB-1), Punjab Varkha Bahar 2 (PVB-2) (Cheema and Dhaliwal, 2010) and Punjab Varkha Bahar 4 (PVB-4). However, it is important to develop F_1 hybrids resistant to ToLCV because tomato hybrids generally outperform open-pollinated varieties and are therefore widely cultivated by farmers in India (Prasanna et al., 2015). Although a few hybrid combinations have been identified by Shankarappa et al. (2008) for cultivation in South India, there is a need to develop and identify resistant hybrids for each geographical region because of the occurrence of a different isolate of the virus in each area. The earlier work on the geographical distribution of tomato leaf curl begomovirus species within India suggested that viruses with bipartite genomes (DNA-A and DNA-B components) were prevalent in North India while those with monopartite genomes (DNA-A) were found in South India (Hong and Harrison, 1995; Kirthi et al., 2002; Muniyappa et al., 2000).

Tomato leaf curl virus is a geminivirus belonging to the *Begomovirus* genus of the family Geminiviridae (Varma and Malathi, 2003). Five different leaf curl viruses predominantly infecting tomato crop have been reported in India. These include tomato leaf curl New Delhi virus (ToLCNDV), tomato leaf curl Palampur virus (ToLCPMV), tomato leaf curl Bangalore virus (ToLCBV), tomato leaf curl Karnataka virus (ToLCKV) and tomato leaf curl Gujarat virus (ToLCGV). A recent survey and molecular characterization of ToLCV revealed that three begomovirus species, viz., ToLCNDV, ToLCPMV and ToLCKV are predominant under Punjab conditions (Gaikwad et al., 2011b; Kaushik et al., 2015).

Six *Ty*-genes (*Ty-1* to *Ty-6*) conferring the variable degree of resistance to ToLCV are available in cultivated tomato (Hanson et al., 2016). Two partially dominant genes *Ty-1* and *Ty-3* are mapped on chromosome 6 (Ji et al., 2007a; Zamir et al., 1994) and are reported to be at the same locus (Verlaan et al., 2013). A dominant gene *Ty-2* was mapped on chromosome 11 (Hanson et al., 2006). The *Ty-4* is a minor QTL on chromosome 3 that accounted for only 16% variation in symptom severity (Ji et al., 2009). Besides, a recessive gene *ty-5* was mapped on chromosome 4 (Hutton et al., 2012). Of late, Hutton and Scott (2014) have identified a *Ty-6* gene on chromosome 10 that confers resistance against the bipartite TYLCV. Of these genes, the dominant *Ty-2* and partially dominant *Ty-3* carrying lines could be potential resources for developing resistant or tolerant hybrids due to the nature of their gene action (Prasanna et al., 2015). The present study was, therefore, undertaken to evaluate ten parental lines along with their 45 F_1 hybrids incorporating *Ty-1*, *Ty-2* and *Ty-3* genes in respect of yield and quality traits under natural field conditions (against local isolate of ToLCV) and to identify superior inbred lines and F_1 hybrids based on their combining ability, heterosis and *per se* performance for yield and other horticultural traits.

Materials and methods

The present investigations were conducted at Vegetable Research Farm, Punjab Agricultural University, Ludhiana, coordinates at 30°55' North latitude, 75°54' East longitude and 247 m altitude. The plant material comprised ten advance generation lines of tomato (*Table 1*). Of these, nine lines, viz., PVB-2, CLN 138A, CLN 138B, CLN 104, CLN 17, 2123D, 2123C, PVB-1 and CLN 154, had a varying degree of resistance to ToLCV. The tenth parental line, viz., Punjab Chhuhara, was susceptible to ToLCV

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64576471

(Gaikwad et al., 2011a; Kaushik and Dhaliwal, 2018). All the ten parental lines were crossed manually during February-March, 2014 in a diallel mating design (Griffing, 1956) without reciprocals to generate 45 F_1 hybrids. The seed of all the 55 entries were sown on 29th July, 2014 after treatment with Thiram @ 2-3 $g \cdot kg^{-1}$ of seed. The seedlings were transplanted on 2nd September, 2014 in a randomized complete block design (RCBD) with three replications. Ten plants of each entry were planted in a single row. Planting was done on one side of the raised beds, and row × plant spacing was maintained at 1.35 m × 0.30 m. The beds were covered with steel gray plastic mulch of 25 µm thickness. The insecticides were not sprayed in the trial so as to enhance the population of whitefly. To increase inoculum pressure, one row of ToLCV susceptible cv. Punjab Chhuhara was planted after every 10 rows in the experimental plots.

The plants were characterized based on the scale shown in *Figure 1*. After that, potential disease incidence (PDI) was determined with the formula as (number of infected plants/total number of plants) × 100 (Kaushik and Dhaliwal, 2018). The observations were recorded for ten traits. Total yield (kg $plant^{-1}$) was calculated by adding the weight of fruits obtained from all pickings and dividing by number of plants per entry per replication. A random sample of five fruits from second picking was taken and fruit weight (g) was estimated by dividing the weight of the sample with the number of fruits in the sample. Five randomly selected fruits from second harvest were used to determine polar diameter of fruit (distance between stem end and blossom end of the fruit), equatorial diameter of fruit (transversal distance of the fruit) and pericarp thickness (after dissecting the equatorial plane of the fruit) with the help of an Absolute Digimatic Vernier Caliper (Mitutoyo Corporation) and average was worked out. The same fruits were used to count the number of locules per fruit and average was worked out. For quality evaluation, five red ripe fruits were taken from second picking and cut longitudinally. Juice was squeezed from the blossom end and filtered through a double

DOI: http://dx.doi.org/10.15666/aeer/1703_64576471

layer of muslin cloth. Total soluble solids (°Brix), titratable acidity (mg/100 ml juice), lycopene (mg/100 g fresh weight) and dry matter (%) were estimated according to the procedure described elsewhere (Garg and Cheema, 2011).

Analysis of variance was performed for each trait, and the differences among mean values of all 55 entries for each trait were tested for significance using standard error of difference. Diallel analysis was carried out according to Griffing (1956) method II, model 1 (fixed effect model) to estimate general combining ability (GCA) and specific combining ability (SCA) effects. Heterosis over mid-parent (MPH), better parent (BPH) and top parent (TPH) was estimated and tested for significance using standard formulas (Garg and Cheema, 2011).

Figure 1. *ToLCV symptoms severity rating in tomato on 0-4 scale, where 0 = Symptomless, 1 = Resistant, 2 = Tolerant, 3 = Susceptible and 4 = Highly susceptible*

Results

Under open field conditions, seven out of ten parents showed a nil PDI (%) (*Fig. 2*). Remaining, one parent PC was susceptible to ToLCV infestation and remaining two parents showed the PDI (%) of 35-45% (*Fig. 2*). Whereas, twenty hybrids out of total forty-five demonstrated nil infection (*Fig. 2*). While for the remaining hybrids the PDI (%) ranged from 25-80% (*Fig. 2*). The analysis of variance for the experimental design revealed that the mean squares for genotypes were significant for all the traits indicating potential genetic differences among genotypes i. e. parents and their F_1 hybrids. The analysis of variance for combining ability revealed that variances for GCA and SCA were significant for all the traits indicating the importance of additive as well as non-additive types of gene effects in the inheritance of the traits studied. The GCA effects represent the additive nature of gene action. A high general combiner parent is characterized by its better breeding value when crossed with several other parents. Besides, mean performance of the parent is also considered in unison with GCA since the former offers reliability to GCA as a guide to the selection of parent (Sharma, 2006; Singh et al., 2014). Four parental lines viz., CLN 154, CLN 138B, PVB-2 and PVB-1 had shown significant positive values of GCA for total yield along with correspondingly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64576471

high mean yield (*Table 2*) reflecting their true breeding value. These lines also showed significant and positive GCA for fruit weight and quality traits. The GCA of parental lines was in consonance with their mean performance. For example, parental lines having high GCA for total yield had high mean yield too. However, there were differences in the combining ability of parental lines carrying the same resistance gene. For example, CLN 17, 2123D and 2123C had the same resistance gene *Ty-2,* but CLN 17 was a better combiner for total yield than the other two parental lines. Likewise, the line CLN 138B was a better combiner than CLN 138A and CLN 104 although all these three lines incorporated same resistant genes, viz., *Ty-1* and *Ty-2*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64576471

The F_1 hybrids had a higher mean and wider range than their parental lines for all the traits. However, the maximum increase was recorded in total yield (47.68%) followed by fruit weight (20.27%), number of locules (15.13%) and titratable acidity (13.73%). For other traits, the average heterosis was less than 10% (*Table 3*). Heterosis of both positive and negative magnitudes was observed for all the traits. For total yield, 38, 19 and 7 hybrids exhibited significant positive values of MPH, BPH and TPH, respectively. Not even a single hybrid manifested significant negative MPH whereas only 3 hybrids recorded significant negative BPH (*Table 4*). The promising hybrids along with their TPH were CLN 138A × CLN 138B (31.20%), CLN 138B × 2123C (28.00%), CLN 138A × CLN 154 (24.00%), CLN 138B × PVB-1 (22.80%), CLN 17 × PVB-1 (20.80%), CLN 138B × 2123D (18.80%) and CLN 104 × CLN 154 (16.00%). All of these seven hybrids had significant positive SCA effects (*Table 4*) reflecting the importance of non-additive gene action in heterosis manifestation for total yield. For fruit weight, 34, 16 and 5 hybrids exhibited significant positive values of MPH, BPH and TPH, respectively. Whereas, there were 3, 15 and 27 hybrids manifesting significant negative values of MPH, BPH and TPH, respectively (*Table 4*). Out of five hybrids exceeding the top parent for fruit weight, three (CLN 138B × PVB-1, CLN 138A × CLN 154 and CLN 138B × 2123C) were the same that recorded significant positive TPH for total yield revealing that increase in total yield was accompanied by an increase in fruit weight. All of these five hybrids manifested significant positive SCA values (*Table 4*) signifying the role of non-additive gene action in the expression of heterosis for fruit weight.

Table 3. *Mean, and range of parental lines and their F_1 hybrids along with average heterosis for yield and quality traits in ten parental lines of tomato evaluated in half-diallel*

Parameter	Total yield (kg plant^{-1})	Fruit weight (g)	Number of locules	Pericarp thickness (mm)	Polar diameter (cm)	Equatorial diameter (cm)	TSS (°Brix)	Titratable acidity (mg/100 ml)	Lycopene (mg/100 g)	Dry matter (%)
Parental mean	1.51	75.67	3.37	5.07	5.22	4.99	4.02	0.51	3.16	4.22
Parental range	0.26-2.50	34.33-102.00	2.30-4.22	3.57-6.57	3.94-6.30	3.62-6.24	2.97-4.80	0.43-0.75	1.96-3.97	3.04-5.01
Hybrid mean	2.23	91.01	3.88	5.32	5.27	5.16	4.30	0.58	3.40	4.32
Hybrid range	0.61-3.28	59.67-129.00	2.23-5.70	3.13-8.17	4.30-6.50	3.40-7.20	2.90-5.67	0.27-0.82	1.03-5.50	2.77-5.80
Average heterosis (%)	47.68	20.27	15.13	4.93	0.96	3.41	6.97	13.73	7.59	2.37

Of 45 hybrids, 15 involved low × low combiner parents for total yield. Although none of these exhibited significant positive TPH, there were 13 and 8 hybrids manifesting 27.94-130.77% and 34.38-102.86% MPH and BPH, respectively. This result raises the importance of low combiner parents in heterosis breeding. On the contrary, there were a few cross-combinations viz., PVB-2 × CLN 138B, PVB-2 × CLN 154, CLN 138B × CLN 154, and PVB-1 × CLN 154, which could not express significant heterosis for commercialization but involved parents having medium × high and high × high combiner parents for total yield. In the present study, three parental lines were incorporating *Ty-2* gene viz., CLN 17, 2123D and 2123C. The yield potential of these three lines was significantly different. The line CLN 17 yielded 1.60 kg plant^{-1} which was substantially higher than 2123D (1.20 kg plant^{-1})

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64576471

and 2123C (0.97 kg plant^{-1}). Likewise, the fruit weight of CLN 17 was 86.33g which was significantly higher than that of 2123D (64.67g) and 2123C (60.33g). The line CLN 17 performed better in hybrid combinations than 2123D and 2123C did, making it a better general combiner for fruit yield and fruit weight. Hence, the line CLN 17 performed better than 2123D and 2123C in respect of yield, fruit weight and GCA for yield & fruit weight. However, there were three promising F_1 hybrids involving these lines viz., CLN 138B × 2123C, CLN 138B × 2123D and CLN 17 × PVB-1 which recorded 28.00, 18.80 and 20.80% increase in total yield over top parent, respectively. Therefore, the parental lines carrying *Ty-2* gene alone should not be considered useless and may yield useful hybrid combinations and hence may be included in tomato breeding programs aimed at developing resistance to ToLCV.

There were three parental lines viz., CLN 138A, CLN 138B and CLN 104 carrying two resistant genes *Ty-1* and *Ty-2*. Of these three lines, the yield and fruit weight of CLN 138B (1.97 kg plant^{-1} and 102.00g) was significantly higher than that of CLN 104 (1.30 kg plant^{-1} and 61.33g) and CLN 138A (1.17 kg plant^{-1} and 67.67g). The line CLN 138B had significant positive GCA for yield and fruit weight whereas the other two lines exhibited negative values of GCA for these two traits. So, the line CLN 138B was better than CLN 138A and CLN 104 concerning yield, fruit weight and GCA for yield & fruit weight. The parental line CLN 154 incorporated three resistant genes *Ty-1*, *Ty-2* and *Ty-3* whereas the lines PVB-1 and PVB-2 had unknown resistance genes. The fruit weight of these three lines was at par with each other. However, CLN 154 yielded 2.50 kg plant^{-1} which was significantly higher than that of PVB-2 (2.13 kg plant^{-1}) and PVB-1 (1.97 kg plant^{-1}). Although all of these three lines had significant positive values of GCA for yield and fruit weight, CLN 154 was better combiner for yield and PVB-1 for fruit weight. The superior performance of CLN 154 as compared to released cultivars (PVB-1 and PVB-2) offers the scope of its commercial release and is, therefore, recommended for multi-location testing across the state.

High yield is one of the most important breeding objectives under disease epiphytotic conditions. Among parents, the line CLN 154 incorporating three resistance genes was the highest yielder (58.65 t ha^{-1}). To cover up the cost of hybrid seeds, it was desirable to identify hybrids yielding significantly higher than the top parent. In this context, seven hybrids exhibiting 16.00-31.20% heterosis over top parent for total yield were identified. These seven hybrids also manifested 16.00-66.95% heterosis over better parent and 52.63-108.92% over mid-parent for total yield. The fruit weight of promising hybrids varied from 82.33 g to 117.33 g which is well within acceptable limits and comparable with that of top parent CLN 154 (89.33 g). The number of locules and pericarp thickness of promising hybrids ranged from 3.33-5.40 and 4.23-7.37 mm, respectively, which were comparable to top parent CLN 154 (4.0, 6.20 mm). The fruit shape of all the promising hybrids was round just like the top parent and round-fruited hybrids are highly acceptable for table purpose. Similarly, the total soluble solids, titratable acidity, lycopene and dry matter of promising hybrids varied from 3.47-5.00°Brix, 0.32-0.59 mg/100 ml, 3.03-5.50 mg/100 g and 3.87-5.30%, respectively, which were comparable with CLN 154 (4.47°Brix, 0.47 mg/100 ml, 3.87 mg/100 g, 4.32%). The desirable horticultural traits of the promising hybrids enhance the feasibility of their commercial acceptability.

Discussion

The cultivated tomato has provided little resistance to the ToLCV (Pico et al., 1998; Ji et al., 2007a). Tolerance was found in Nova (Mayee et al., 1974) and EC 104395 (Varma et al., 1980). Breeding begomovirus-resistant cultivars have involved the introgression of resistance genes from wild tomato species. Among the wild species *L. hirsutum f glabratum and L. peruvianum* were highly resistant (Banerjee and Kalloo, 1987). Resistance in *L. pimpinellifolium* LA1921 was found to be monogenic and incompletely dominant, and two epistatic genes governed resistance in *L. hirsutum f glabratum* (B 6013). Two independent genes for resistance seem to be involved in these two-wild species with that of *L. hirsutum f glabaratum* dominant over the other (Banerjee and Kalloo, 1990). Pilowsky and Cohen (1974) studied crosses between a tomato yellow leaf curl virus (ToYLCV) homozygous resistant line of *L. pimpinellifolium* and the susceptible tomato cv Pearson. Inheritance of ToYLCV was studied by Hassan et al. (1984) in the interspecific crosses between *L. esculentum* Mill. cv UC 82 × *L. cheesmanii* ssp. *minor* (Hook) C H Mill. cv LA 1401, and *L. esculentum* cv. VF 145-B-7879 × *L. hirsutum* Humb. & Bonpl. cv LA 386. They artificially inoculated the genetic population with ToYLCV before transplanting and later evaluated under field conditions. They found that resistance derived from *L. cheesmanii* seems to be recessive, and resistance derived from *L. hirsutum* is dominant and controlled by more than one gene. Dhaliwal and Cheema (2011) have also reported 20.93-58.75% heterosis over better parent for total yield in promising F1 hybrids tested under ToLCV infested conditions. The high yield and disease resistance of F1 hybrids must be accompanied by good horticultural traits like shape, size, flavour etc. for them to become commercially acceptable. Furthermore, these results are in accordance with the result for the other member of Solanaceae, i.e. eggplant (Kaushik et al., 2018; Kaushik 2019)

Banerjee and Kalloo (1987) studied the inheritance of ToLCV resistance in interspecific crosses between ToLCV resistant *L. hirsutum f glabratum* line B6013 and five susceptible cultivars (HS101, HS102, HS110, Pusa Ruby and Punjab Chhuhara) of *L. esculentum*. They reported that resistance derived from *L. hirsutm f glabratum* B6013 based on two epistatic genes one from the wild parent and another from the cultivated one. The inheritance of tolerance of ToYLCV, deriving from the wild tomato *L. peruvianum*, was studied by Pilowsky and Cohen (1990) crossing the cultivated tomato (*L. esculentum* Mill.) line M-60 (ToYLCV-tolerant) with line M-10 (ToYLCV-susceptible line). Genetic data indicated that 5 recessive genes controlled tolerance. Nagaraja et al. (1996) estimated the gene effects for fruit yield, its components and inheritance of leaf curl virus resistance in two interspecific crosses between *L. esculentum* cultivars Arka Saurabh and Arka Vikas and tomato leaf curl virus resistant *L. hirsutum.* They concluded that an additive-dominance model accounted for most of the variation among generations for days to tomato leaf curl virus symptoms expression in both the crosses.

The inheritance of resistance to ToLCV disease was assessed by Nainar and Pappiah (2002) under field conditions in eight crosses involving susceptible tomato cultivars PKM1, CO.2, CO.3 and Pusa Ruby and resistant wild parent's *L. hirsutum* and *L. pimpinellifolium*. They reported that the resistance in *L. hirsutum* was controlled by three recessive genes and a single incomplete dominant gene in *L. pimpinellifolium.*

Shekara et al. (2003) studied the inheritance of resistance to tomato leaf curl virus in tomato using triple test cross analysis. The genotypes consisted of crosses between 148

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64576471

resistant testers and the susceptible cultivar Arka Abha and crosses between the resistant cultivar ATY-1 and the susceptible cultivars Arka Sourabh. The importance of the additive genetic variance for resistance was observed. The magnitude of the additive genetic component was higher than the dominance component and suggested pedigree selection method for the development of cultivars resistant to tomato leaf curl virus.

Resistance to ToYLCV was studied by Castro et al. (2007) in a cross between *S. lycopersicum* × *S. pimpinellifolium* UPV16991. Crosses between four breeding lines susceptible to ToYLCV and L102 were also performed to study the dominance of the resistance in *S. lycopersicum* genetic backgrounds. Response to ToYLCV infection of P_1, P_2, F_1, F_2, BC_1, and BC_2 generations fitted, for this line, a monogenic control with partial recessiveness and incomplete penetrance. Hazra and Nath (2008) conducted an experiment to evaluate 25 tomato genotypes for resistance to tomato leaf curl virus and concluded that percent disease incidence and co-efficient of infection in the genotypes was highest in early autumn (planting in last week of August), followed by spring-summer (planting in first week of February) and autumn-winter (planting in second week of October) seasons. The extent of heterosis for tospovirus resistance, yield and associated characters was studied by Kumar et al. (2009) by using line × tester mating. The lines carrying Ty-2 gene have been reported to be susceptible to bipartite tomato-infecting begomoviruses (Giordano et al., 1998; Prasanna et al., 2015).

Ji and Scott (2006) mapped Ty-3 gene on the long arm of chromosome 6, between cLED-31-P16 and T1079 markers. Recently, Kadirvel et al. (2013) identified new locus (qTy10.1) on chromosome 10 in the line FLA456, named it as *Ty*-6. Similar to our results a series of lines pyramided by Prasanna et al. (2014) using *S. habrochaites* derived resistance (*Ty-2*), and *S. chilense* derived resistance (*Ty-3*). The pyramided lines and *Ty-3* carrying lines exhibited a high level of resistance that could be used as critical genetic stocks for resistance breeding. Also, Shankarappa et al. (2008) developed two hybrids viz., BLRH-3 and BLRH-16 resistant to ToLCV both in the glasshouse and the field conditions. Based on phenotypic survey and virus quantification two highly resistant hybrids SJ12 and RFT112 were identified (Tabein et al., 2017). Recently, Elbaz et al. (2016) found that the entries with Ty-1/Ty-3 + Ty-2 offered the highest levels of resistance to TYLCV. Whereas, Rubio et al. (2016) determined and quantified the effect of Ty-1 gene introgression on yield and quality of tomatoes. Ty-1 introgression negatively affected the yield attributes.

Tomás et al. (2011) screened for ToYLCVD resistance under high disease pressure generated by natural infection in the field. They have concluded two independent loci, one dominant and one recessive, were associated with EELM- 889 resistance. The study showed these loci to be distinct from that of the resistance gene (*Ty-1*) deployed in resistant tomato cultivars. Therefore, both kinds of resistance could be combined to provide improved resistance to ToYLCVD. Dhaliwal and Cheema (2011) have also reported that hybrids were manifesting significant standard heterosis for yield in tomato also expressed significant standard heterosis for fruit weight. Therefore, it is advisable to handle these cross-combinations by pedigree selection to exploit additive gene action to find significant desirable improvement in yield along with resistance to ToLCV (Dhaliwal and Cheema, 2011). In our study, the hybrids identified should not be resorted to selection in segregating generations as their superior performance is attributed to the involvement of non-fixable gene effects.

Conclusions

Extensive and significant difference in the performance of lines carrying different combinations of resistance genes (Ty-X) against ToLCV. The top parent CLN 154 yielding significantly higher than released varieties along with seven F_1 hybrids manifesting 16 to 31% top parent heterosis for total yield can be recommended after multi-location evaluations. Overall, this study provides useful information on the successful leaf curl virus resistant gene combinations under the north-Indian conditions.

Acknowledgements. Authors are thankful to AVRDC – The World Vegetable Centre, Taiwan, for kindly providing the seeds of CLN lines having variable degree of resistance to ToLCV.

Abstract. Higher temperature could induce biological effects in many areas of agriculture. The objective of this study is to investigate the effects of elevated temperature on nutrients and non-point source pollutants in paddy water and soil. Nitrogen and phosphorus were applied based on the recommended application amounts for rice cultivation and there was an unfertilized plot as a control. Paddy soils were flooded with distilled water in an incubator for eight weeks. Temperature treatments included ambient as a control, ambient plus 2ºC, and ambient plus 4ºC. Soil NH_4-N content after elevated temperature treatment was high in sandy loam soil and soil NO_3-N content after elevated temperature treatment was high in clay loam soil. Elevated temperatures induced increments of water total nitrogen (T-N) concentration for no chemical fertilization, standard fertilization, and standard fertilization + 100% in sandy loam soil. T-N concentration dissolved in distilled water in rice straw of ambient + 2ºC temperature increased by 24% more than that of the control temperature treatment, and total phosphorus (T-P) concentration of ambient + 4ºC temperature increased by 16%. Thus, it was considered that water soluble T-N and T-P of rice residue could be released easily by rain from agricultural fields.
Keywords: *higher temperature, nutrient, rice paddy, straw, water soluble nutrient*

Introduction

The Special Report on Global Warming of 1.5ºC (SR15) was approved on October 5, 2018 at the 48th session of the Intergovernmental Panel on Climate Change (IPCC) held in Incheon, Republic of Korea. This IPCC report was prepared by 99 authors and editors from 40 countries from around the world, and it is based on over 6,000 scientific references. The key point of this special report is that human activity has induced about 1ºC (0.8~1.2ºC) global warming at present compared with pre-industrialization times; and, if the current speed of warming continues, the rise will be over 1.5ºC in 2030~2052. Also, global warming is different depending on region and time, and extreme weather changes were detected during global warming of 0.5ºC to the present. In order to reduce global warming within 1.5ºC, carbon dioxide (CO_2) emissions should achieve net zero. Temperature is the most important factor affecting plant growth and yield and every biological process changes depending on temperature (Cross and Zuber, 1972; Yan and Hunt, 1999). Generally, the relationship between air temperature and soil temperature is positive (Groffman et al., 2009), increasing temperature lowers soil moisture (Brzostek et al., 2012), and net nitrogen mineralization was shown to increase depending on higher temperature in an incubation experiment (Pendall et al., 2004), or not (Niklinska et al., 1999). Elevated temperature increases nitrogen mineralization by 45%~52% (Rustad et al., 1998) and net nitrification by 32% (Bai et al., 2013). Higher temperature affects nitrogen leaching by increasing NO_3^- solubility and affects the frequency of soil freezing and thawing (Bai and Houlton, 2009).

Nutrient input materials for crop cultivation are chemical fertilizers, cow manure compost, pig manure compost, and various types of organic compost. Leaching of total nitrogen (T-N) and total phosphorus (T-P) by runoff from cultivated land acts as a non-point pollution source when they move out of the agricultural water system. The amount of non-point pollution sources from rice paddy is estimated at 3 $kg \cdot ha^{-1}$ of nitrogen and 2 $kg \cdot ha^{-1}$ of phosphorus (Shin, 2001; Kim, 2008; Jung, 2013). Soil loss and muddy water from rain are the factors that most affect management of the aqua-ecosystem and water quality control for drinking water sources in an increasingly significant way.

In a higher temperature environment, there could be changes in the decomposition, uptake by crop, volatilization, and runoff of nutrient input materials for crop cultivation. Therefore, this study was conducted to investigate changes in rice cultivation water as a non-point pollutant source under an elevated temperature environment.

Materials and Methods

Fertilization

This study was conducted from June to November 2017 at the National Institute of Agricultural Sciences (NIAST) in Wanju (Lat 35.834, Lon 127.038), Republic of Korea. The soils used were sandy loam and clay loam. Treatment consisted of a control with no added chemical fertilizer, chemical fertilizer, and chemical fertilizer plus 100% increase of the chemical fertilizer. A 50 ml plastic tube was filled with 40 g of soil, which was treated with chemical fertilizer and then distilled water was poured into the tube. The chemical properties of the soils used in this study are shown in *Table 1*.

Table 1. *Chemical properties of soils used in this study*

Soil property	pH (1:5)	EC (dS/m)	OM (g/kg)	Av. P_2O_5 (mg/kg)	Ca	Mg	K	Na
					Ex. cations ($Cmol^+/kg$)			
Sandy loam	6.8	0.74	4	54	1.3	3.7	0.54	1.49
Clay loam	6.5	0.53	22	82	4.3	1.8	0.35	0.13

Temperature treatment

The weather data used for the elevated temperature manipulation was provided by the Buraeing weather station located in Buraeing-myeon, Kimje-si, Jeonbuk province.

In order to calculate the day temperature treatment, the average maximum temperatures from July to September over a ten-year period (2007~2016) were calculated; and to calculate the night temperature treatment, the average minimum temperatures from July to September over a ten-year period (2007~2016) were calculated.

Temperature treatment was conducted from May 23, 2017 for eight months using an incubator. Temperature treatment with the incubator was over ten steps a day for 144 minutes each. Day and night temperatures of the ambient were 25ºC /18ºC, ambient + 2ºC were 27ºC /20ºC, and ambient + 4ºC were 29ºC /22ºC, respectively (*Table 2*).

DOI: http://dx.doi.org/10.15666/aeer/1703_64736481

Table 2. *Elevated temperature treatment in this study at each time by using an incubator*

Time (hour : minute)	Ambient	Ambient + 2℃	Ambient + 4℃
01 : 44	18	20	22
04 : 08	17	19	21
06 : 32	19	21	23
08 : 56	19	21	23
11 : 20	24	26	29
13 : 44	26	28	30
16 : 08	26	28	30
18 : 32	25	27	29
20 : 56	24	26	28
23 : 20	19	21	23

Sampling and analysis

Soil pH and EC were measured by using a pH meter (Model 720A, Orion) and an EC meter (Model 145A, Orion). NH_4-N concentration of soil was measured by the indophenol-blue method, NO_3-N concentration of soil was measured by the chromotropic acid method, and available phosphorus concentration of soil was measured by the Lancaster method (RDA, 2010). For analysis of nutrient content, 80 ml of distilled water was added to 40 g of soil, and the treated water was analysed every two weeks for a total of 4 times on June 6, June 20, July 4, and July 18.

In order to analyse the amount of T-N and T-P concentration of straw leachate in response to elevated temperature, 2 g of straw was soaked with 70 ml of distilled water, and then after 1, 3, 5, and 7 days the water was sampled. T-N concentrations were measured by using a chromotropic acid method kit (C-mac, Korea) at 410 nm, and T-P concentrations were measured by using a molybdovanadate method kit (C-mac, Korea) at 420 nm.

Results and Discussion

Soil Nitrogen

Accumulated NH_4-N concentration was determined every two weeks in soil applied with chemical fertilizer under elevated temperature. The results (*Figure 1*) show that the NH_4-N concentration of no fertilization and standard fertilization treatment with ambient + 2ºC and ambient + 4ºC treatment was higher than that with the control temperature treatment in sandy loam soil. The NH_4-N concentration of no fertilization with ambient + 2ºC and ambient + 4ºC treatment was higher than that with the control temperature treatment in clay loam soil.

The NH_4-N concentration of standard fertilization and standard fertilization + 100 % with ambient + 2ºC and ambient + 4ºC treatment was lower than the control temperature treatment in clay loam soil.

Also, the NH_4-N concentration of no fertilization and standard fertilization was higher in sandy loam than in clay loam soil with an elevated temperature (ambient + 2ºC and ambient + 4ºC treatment).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64736481

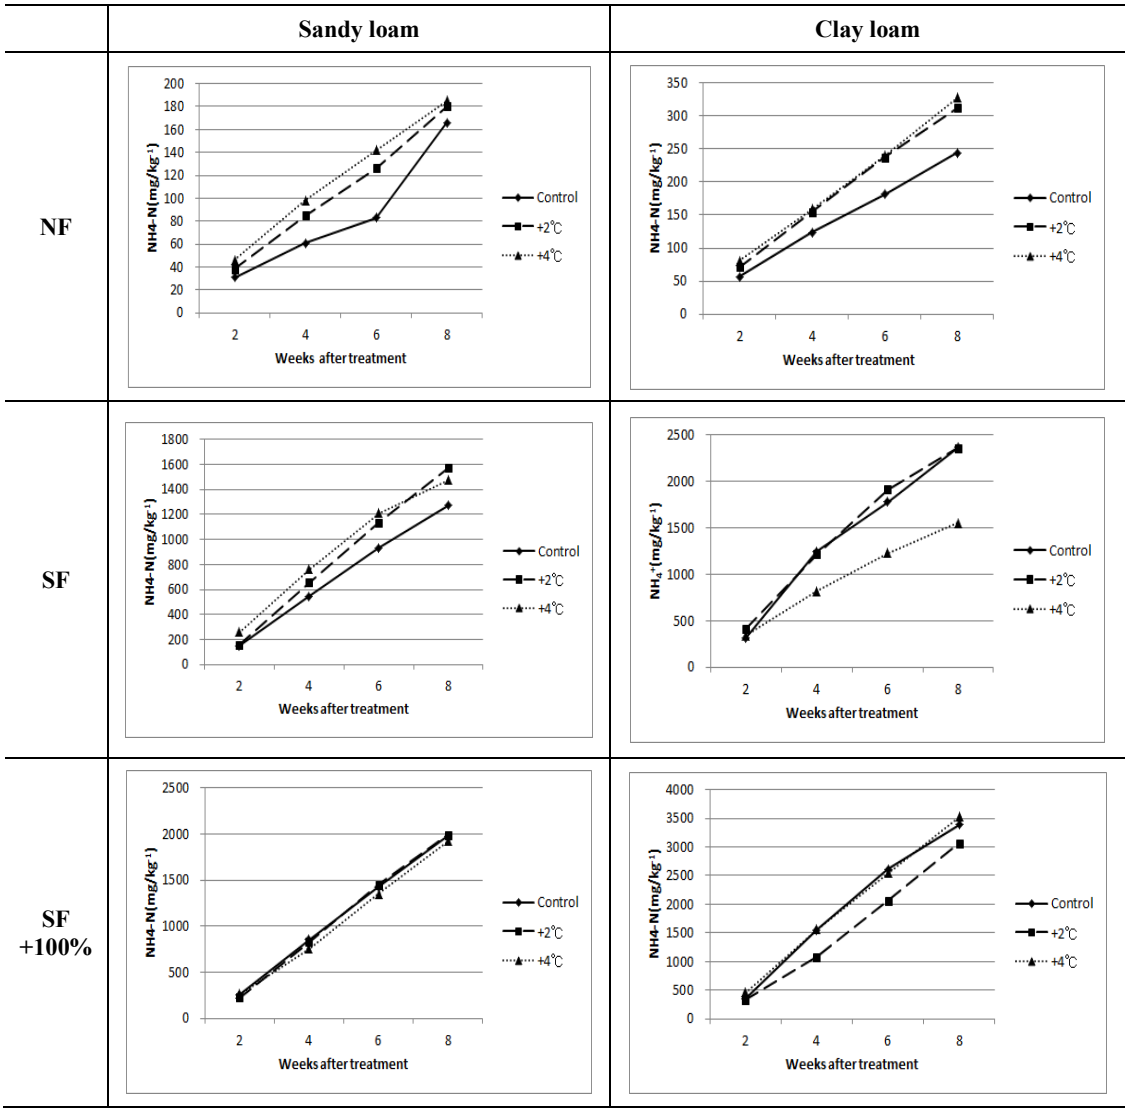

Figure 1. *Concentration of NH4-N of soil treated with elevated temperature for 8 weeks, NF: No fertilization, SF: Standard fertilization, SF + 100 %: Standard fertilization plus 100 percent increase*

Accumulated NO_3-N concentration was determined every two weeks in soil with applied chemical fertilizer under elevated temperature. The results (*Figure 2*) show that the NO_3-N concentration of no fertilization treatment in ambient + 2ºC and ambient + 4 ºC was higher than that with the control temperature treatment in sandy loam soil. The NO_3-N concentration of standard fertilization treatment in ambient + 4ºC was higher than that of the control temperature treatment in sandy loam soil.

The NO_3-N concentration of no fertilization, standard fertilization, standard fertilization + 100% under ambient + 2ºC and ambient + 4ºC was higher than that of the control temperature treatment in clay loam soil.

Rustad et al. (2001) reported that elevated temperature increases soil net mineralization by 45%~52%, and Bai et al. (2013) reported that elevated temperature increases net nitrification by 32%. Rising temperature increase the availability of NO_3-N and affects nitrogen leaching by changing the frequency of soil freezing and thawing (Bai and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64736481

Houlton, 2009). Through various incubation experiments, net nitrogen mineralization increased in relation to increasing temperature (Pendall et al., 2004), or not (Niklinska et al., 1999).

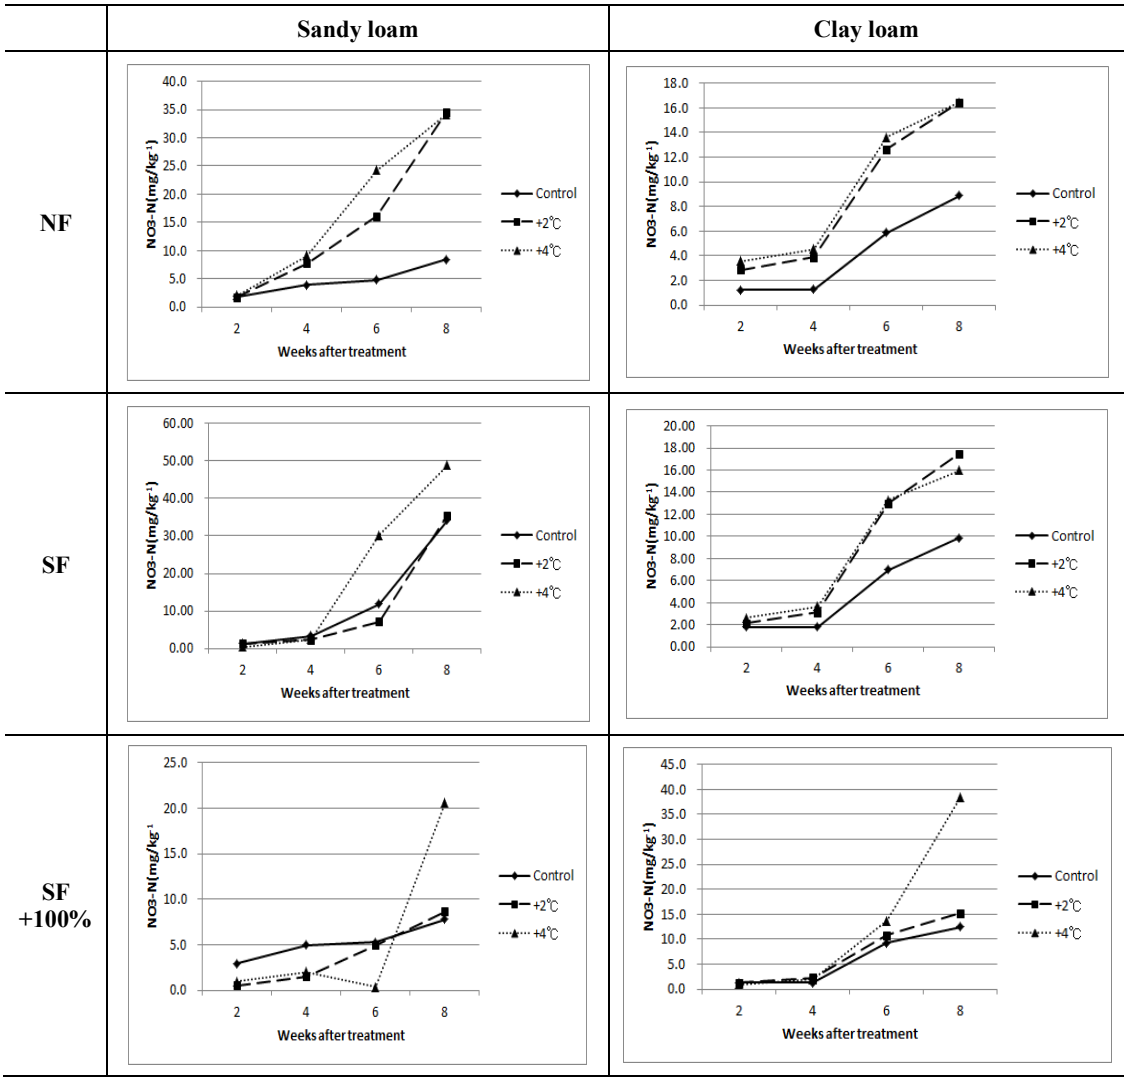

Figure 2. *Concentration of NO3-N of soil treated with elevated temperature for 8 weeks, NF: No fertilization, SF: Standard fertilization, SF + 100 %: Standard fertilization plus 100 percent increase*

Nitrogen, Phosphorus of Water

In an elevated temperature environment, accumulated T-N concentration was determined every two weeks in soil water treated with chemical fertilizer. The results (*Figure 3*) show that elevated temperature induced T-N concentration increases with no chemical fertilizer treatment, standard fertilization, and standard fertilization + 100 % in sandy loam soil. Elevated temperature showed a T-N concentration increase only with standard fertilization in clay loam soil.

These results are similar to results from research showing that nitrification is activated by up-regulated soil temperature treatment (Verburg et al., 1999), nitrogen mineralization

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64736481

and amount of nitrification increase in relation to time at a depth of 15~30 cm, and nitrogen mineralization and amount of nitrification are greater at the surface soil layer than the deep soil layer (Shin and Reddy, 1997). Also, Saad and Conrad (1993) reported that 25~30ºC was the optimal temperature range for nitrification and denitrification in a microbial experiment.

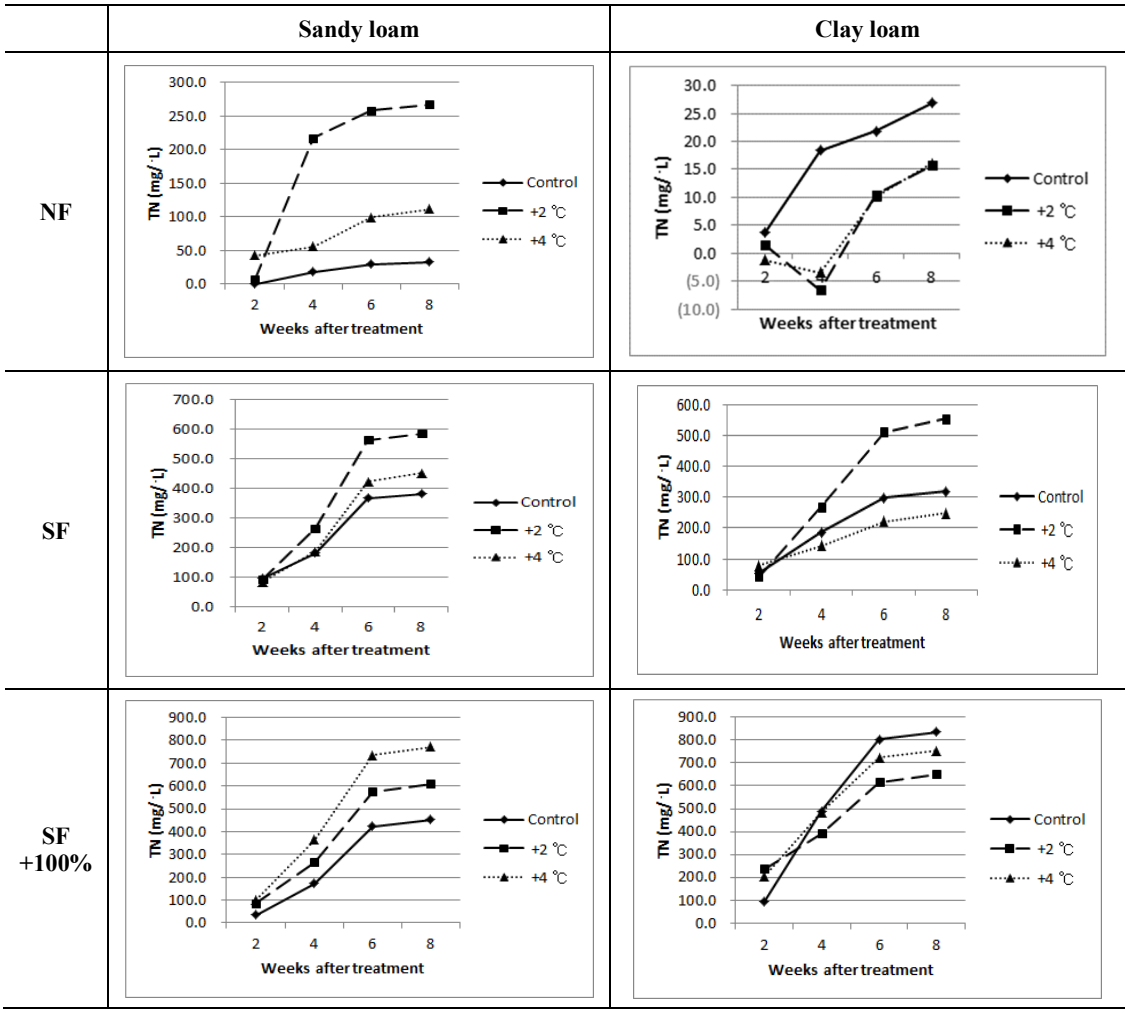

Figure 3. *Concentration of total nitrogen (T-N) of water treated with elevated temperature for 8 weeks. NF: No fertilization, SF: Standard fertilization, SF + 100 %: Standard fertilization plus 100 percent increase*

In an elevated temperature environment, accumulated T-P concentration was determined every two weeks in soil water treated with chemical fertilizer. The results (*Figure 4*) show that elevated temperature treatment of ambient + 2ºC and ambient + 4ºC with no fertilization treatment increased T-P in sandy soil, but no such tendency was shown for T-P content of water in clay loam soil.

Nutrient leaching of straw

The accumulated nutrient concentration of leachate from straw was determined after treatment in an elevated temperature environment for seven days. The results (*Figure 5*)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64736481

show that T-N concentration with the control temperature treatment was 3.2 mg/L^{-1}, while that with the ambient + 2ºC treatment was 4.0 mg/L^{-1}, an increase of 24%.

T-P concentration with the control temperature treatment was 3.4 mg/L^{-1}, while that with the ambient + 4ºC treatment was 4.1 mg/L^{-1}, an increase of 16%.

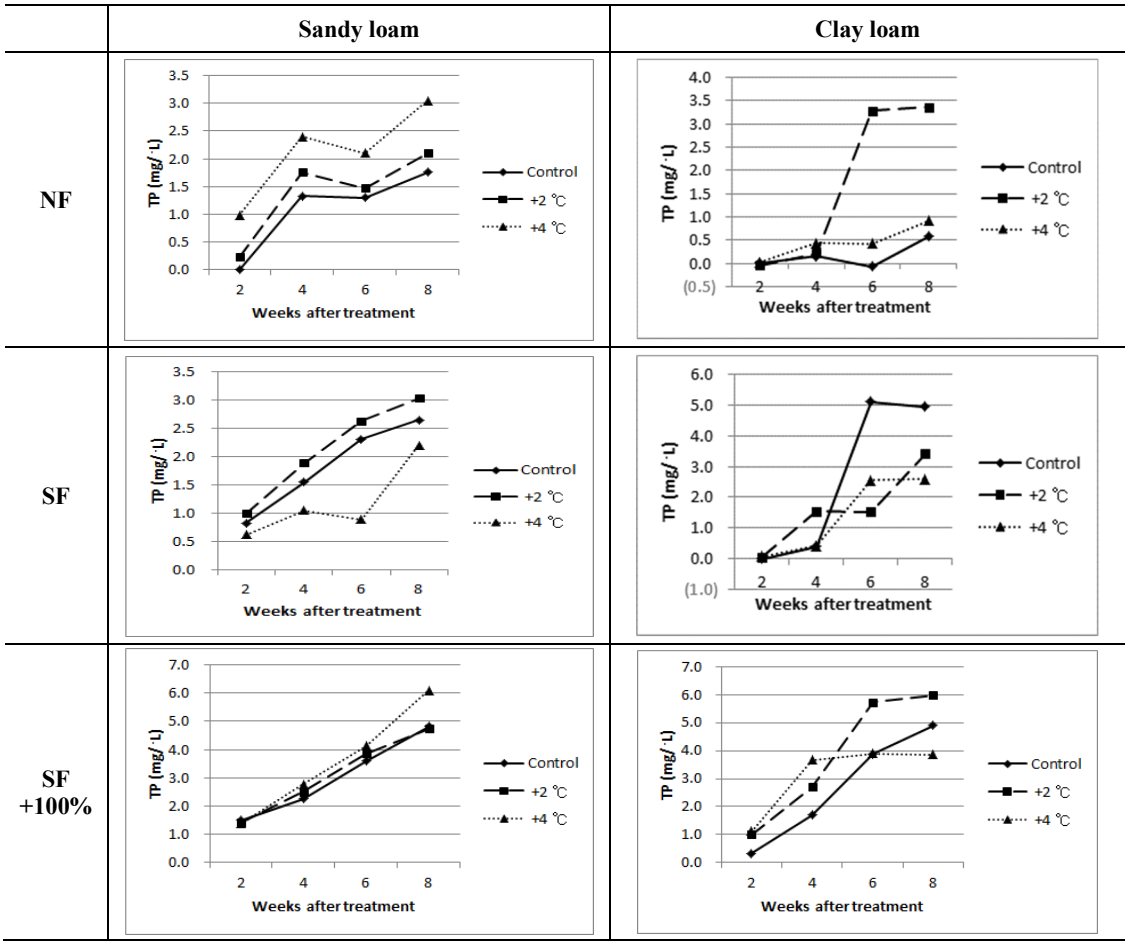

Figure 4. *Concentration of total phosphorus (T-P) of water treated with elevated temperature for 8 weeks. NF: No fertilization, SF: Standard fertilization, SF + 100 %: Standard fertilization plus 100 percent increase*

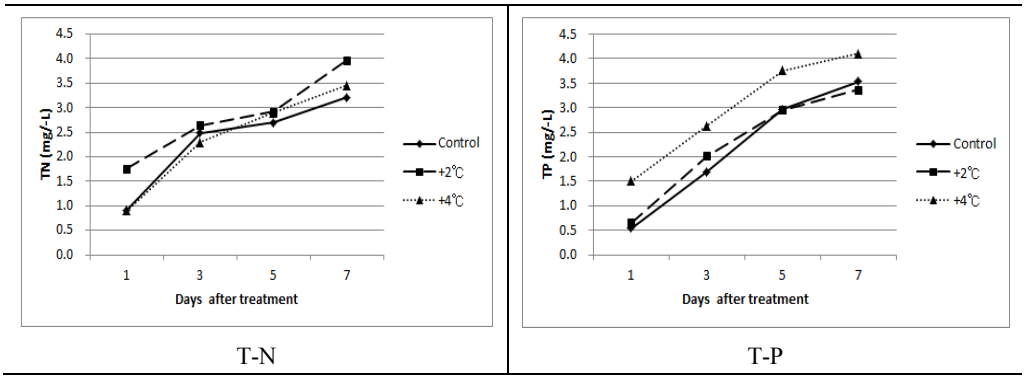

Figure 5. *Concentration of T-N and T-P eluted from straw soaked in distilled water for seven days at three different temperatures*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64736481

Cowen and Lee reported (1973) that 5.4% of total phosphorus of oak tree leaves was soluble and elutable. Schreeg (2013) reported that there is a relationship between solubility and tropical tree leaf amount with $r^2 = 0.79$ for K, $r^2 = 0.51$ for Na, and $r^2 = 0.66$ for P with the weakest relationship of $r^2 = 0.36$ for N. Additionally, when total K content was 100, that of P was 35%, Na 28%, and N 5%. The mineral content of straw was reported to be 0.71% for T-N and 0.16% for P_2O_5 with the T-N and T-P of straw leached well in water; the longer the soaking of the straw, the higher the T-P concentration in the water (Hong, 2016). Hong et al. (2015) also reported that when red pepper furrows were covered with straw, the solubility of phosphorus in rain water led to excess runoff of phosphorus from uplands.

Therefore, under the elevated temperature environment in future in comparison with the current climate, more leaching of soluble nitrogen and phosphorus from crop residues and runoff from crop land can be expected.

Conclusion

Elevated temperatures induced increments of water total nitrogen (T-N) concentration for no chemical fertilization, standard fertilization, and standard fertilization + 100 % in sandy loam soil. Under the elevated temperature environment in future in comparison with the current climate, more leaching of soluble nitrogen and phosphorus from crop residues and runoff from crop land can be expected. These results can be used as the basis for the development of technology in response to climate change that can reduce nutrient runoff and improve water quality at the watershed. There is a need for paddy field scale experiments under a near natural environment for factors such as temperature, precipitation, sunlight, humidity, and wind by using a practically scaled open-top chamber.

Abstract. Dieback of forest trees is considered as serious problem in most parts of the world. Shisham an important multipurpose tree of the Indian subcontinent is suffering from dieback. Changing climate in most parts of the world is considered an important factor of ecosystem disturbance. Impact of environmental variables, tree age and water table on the dieback of shisham was examined in different regions of Punjab, Pakistan. Significant correlation was observed between environmental variables and dieback in minimum, moderate and maximum infected trees among three age classes. Water table and rainfall expressed non- significant correlation. A multiple regression model was developed to determine the relationship between environmental variables and dieback. Coefficient of determination value ($R^2 = 0.89$) depicts that model is statistically good. Model indicated that most of the predictor variables has minor role in disease development except age and time span. With one unit increase in age and time span disease will increase 4.15 and 5.25 units respectively. Values of partial R-square indicated that age class (0.5253), time span (0.2943) and relative humidity (0.0552) are major contributors in disease development. It was concluded form the study that age and time span are significant predictor of dieback.
Keywords: *characterization, disease incidence, correlation, climatic factors, predictive model*

Introduction

Dieback of forest trees is a periodic event caused by premature loss of tree health and forest stand vitality (Clatterbuck, 2006). Forest decline and dieback have been reported from different forest ecosystems and climatic zones of the world (Lowman, 1991; Jump et al., 2006) and in the recent past mortality rate has increased in many forest ecotypes of the world (Hosking, 1989; Jursik, 2004). Natural disturbances, including biotic and abiotic stresses are inherent components of forest ecosystems affecting their functioning and biodiversity (Boydet et al., 2013; Thom and Seidl, 2016). About two to three

DOI: http://dx.doi.org/10.15666/aeer/1703_64836495

decades ago dieback of *Dalbergia sissoo* was reported in different regions of Pakistan (Ciesla, 1994). *D. sissoo* being a nitrogen fixing tree and multiple uses is an important tree of social forestry with good economic returns (Lal and Singh, 2012; Ahmad et al., 2013; Farooq et al., 2018; Rashid et al., 2019). Dieback is a major threat to this multipurpose tree (Ahmad et al., 2016, 2017) and has affected millions of trees in Southern Asia (Vogel et al., 2011). Symptoms of shisham dieback are approximately similar to dieback of mango in southern Punjab of Pakistan (Khan et al., 2014) Climate change, fungal pathogens and nutrient deficiencies have been considered as the major causes of tree decline and dieback (Simpson, 1993; Rajput et al., 2008). In different regions of the world fungal pathogens have been recognized as the responsible causal organisms of tree decline and climate change has also been find associated with forest dieback (Ahmad et al., 2016). Environmental stresses contribute to tree mortality and occurrence of forest diseases due to different pathogens will probably become more common and severe in the near future, as different biotic and abiotic factors are strongly influenced by climatic change (Sturrock et al., 2011; Raza et al., 2015). Dieback in northern hardwood forests was strongly linked with the global climatic change; the coefficient of determination value ($R2 = 0.49$) in the regression analysis showed that climatic changes were responsible for 49% of the dieback occurring in northern hardwood forests (Auclair et al., 2005). An increasing trend in the forest mortality and dieback due to drought was observed. the linear regression model suggested a very strong association between tree mortality and drought conditions due to low rainfall and high temperature (Phillips et al., 2009; Allen et al., 2010). The extent of forest dieback linked with global climate change would be greater than that observed in the past (National Research Council, 2001). High rate of shisham mortality in India was linked with changing climatic conditions, such as increased drought, extremes of winter and summer, with severe foggy conditions which adversely affected the photosynthesis and other physiological processes of the trees (Singh, 1980; Kaushal et al., 2002).

Age is also considered an important factor in development of forest dieback. Nepstad et al. (2008) reported that as trees are perennial woody plants which grow slowly but the mortality rate of trees was very much higher, even within a period of few months as compare to its growth rate which is very interesting. Older trees were more susceptible to dieback compared with younger trees (Auclair et al., 2010). Little scientific information is known about the spread and development of the disease in individual forest trees in different age groups (Timmermann et al., 2017). Sperry et al., 1991 suggested that in older trees, the membranes associated with vessels and tracheids rupture easily under ecological stresses. Acharya and Subedi (2000) recorded mortality of over-mature dieback-affected *D. sissoo* trees in a short period of even few weeks. Along with tree age, certain species of fungi, such as *F. solani* and *G. lucidum*, killed over 20% of older trees of *D. sissoo* under abiotic stresses in Bihar (Chaturvedi et al., 2002).

The effective use of chemical agents against plant diseases requires knowledge of the epidemiology of disease. Understanding disease dynamics, including the pathogen life cycle, provides the basis for forecasting disease outbreaks. Because shisham decline massively reduces both the economic gains and the social uses of this tree, the aim of integrated disease management must be to reduce these losses. Approaches are required which aim to avoid frequent recurrence of shisham decline epidemics. Much research, therefore, remains to be done. Disease severity in relation to different age classes of shisham has not been assessed, and no correlation has been determined between disease

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64836495

occurrence and the water table. The impact of varying environmental conditions in relation to spread of disease has not been studied quantitatively. Therefore the objective of study was to assess the relationship between shisham dieback, environmental variables and tree age.

Materials and methods

D. sissoo dieback disease data collection

A comprehensive survey of different *D. sissoo* (shisham) growing regions of Punjab province of Pakistan was carried out to collect the data regarding incidence of dieback disease (*Fig. 1*). Data were collected for the three consecutive years. Furthermore on the basis of disease severity we categorized the trees into three categories i.e. minimum infected, moderately infected and dead or fully affected trees.

Characterization of environmental factors conducive for shisham dieback in field conditions

Data collected for the incidence of shisham dieback from the different ecological zones of Punjab were subjected to correlation analysis with different climatic variables. The influence of each environmental variable (maximum and minimum air temperature, rainfall, relative humidity wind velocity, age and water table) on the severity of shisham dieback occurrence was determined by correlation.

Regression analysis

Regression analysis was used to determine any link between environmental/climatic factors and disease incidence/development (Chatterjee and Hadi, 2006). There are two types of models i.e. simple and multiple regression models (*Eqs. 1* and *2*). For developing simple linear regression models, the response variable (Y), in this case disease, was a function of the single predictor or explanatory variable (X), here an environmental/climatic variable. The equation for simple linear regression is:

$$Y = \beta 0 + \beta 1X \quad \text{(Eq.1)}$$

where β0 is the intercept and β1 is the slope. In multiple linear regression, however, there are more explanatory or predictor variables when compared with simple linear regression. The relationship is described by:

$$Y = \beta 0 + \beta 1x1 + \beta 2x2 + \cdots + \beta i\, xi + \in \quad \text{(Eq.2)}$$

where x represents the collection of i predictors x1, x2,...xi in the model, and β1, β2,...βi are the corresponding regression coefficients and ∈ is the random error or disturbance.

Development of disease predictive model for the field study

A predictive model for the field data on disease incidence and severity was also developed. Weekly environmental data comprising of maximum and minimum air

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64836495

temperatures, relative humidity, average rainfall and wind speed were collected from the Regional Meteorological Station, Lahore. All the collected environmental data, tree age, underground water table data and dieback disease incidence data in the different districts of Punjab (Faisalabad, Lahore, Sargodha, Sahiwal, Okara, Rawalpindi, Multan, Bahawalpur, Rahim yar khan and Dera Ghazi Khan) from November 2009 to April 2010 and the same months during 2010-11, were subjected to analysis of variance to evaluate the effect of abiotic factors on disease incidence by using the Least Significant Difference Test (LSD at $P < 0.05$).

The influence of these environmental conditions on disease severity was determined by correlation analyses (Steel et al., 1997). R^2, Mallows Cp and mean square error (MSE) were the criteria used to select the best models (Khan and Illayas, 1999).

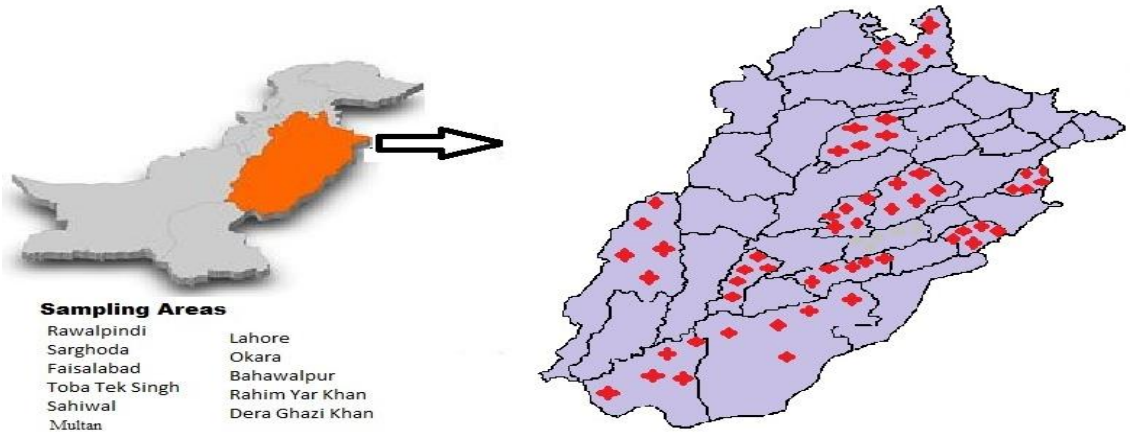

Figure 1. *Study area map showing eleven districts of Punjab province*

Results

Correlation between environmental variables and host (minimum, moderate and maximum infected trees of shisham) in different ecological zones of Punjab

There was a significant correlation between environmental variables (rainfall, relative humidity, minimum temperature, maximum temperature, wind velocity and water table) and host (minimum, moderate and maximum infected with dieback disease) of three age classes in different areas of Punjab ($P < 0.05$). Water table and rainfall expressed non-significant correlation with dieback disease in all categories of host (minimum, moderate and maximum infected with dieback). A weak and negative association was found between maximum temperature and minimum infected ($r = -0.190$), positive in moderately infected ($r = 0.176$) and fully infected trees ($r = 0.175$) followed by wind velocity in minimum infected ($r = -0.166$), moderately affected ($r = 0.184$) and fully infected trees (0.129). Similar results were expressed by maximum temperature (minimum infected, $r = -0.105$; moderately infected, $r = 0.150$; maximum infected, $r = 0.138$) and relative humidity in minimum infected ($r = 0.106$), moderately infected ($r = -0.125$) and maximum infected ($r = -0.076$) trees (*Figs. 2, 3* and *4*).

Regression analyses of environmental variables against dieback disease were carried out independently to observe the effects of each environmental variable separately on the disease development in the major shisham grown areas of the Punjab province. *Table 1* showed the regression equations and R^2 of the correlations of environmental

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64836495

variables with the minimum trees. R^2 value shows that 39.2% of variation in dieback disease was explained by the host categories', followed by time span (20.5%), maximum temperature (3.6%), wind speed (2.7%), minimum temperature (2.4%), relative humidity (1.1%), rainfall (0.3%) and water table (0.2%). For minimum infected trees, category of host was responsible for 29.1% of variation, followed by time (15.7%), wind speed (3.4%), maximum temperature (3.0%), minimum temperature (2.2%), relative humidity (1.5%), water table (0.2%); rainfall did not explain any variation. Similar trend was detected in maximum infected trees, where as 37.6% variation was explained by age class, followed by time span (18.6%), maximum temperature (3.1%), minimum temperature (1.9%), wind speed (1.7%), relative humidity (0.6%), rainfall (0.5%) and 0.2% by water table.

Dalbergia sissoo dieback disease predictive model based on field survey data

Data of dead shisham trees due to dieback disease about different categories of host were collected from different shisham grown areas of Punjab (Pakistan) through a comprehensive survey. The effect of host category, environmental variables (Minimum and maximum temperature, rainfall, relative humidity, wind velocity and water table)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64836495

and years (time) on dieback disease development was determined by correlation and regression analysis. A multiple regression model was developed to determine the inter-relationships between environmental and the development of dieback disease (*Eq. 3*). With R^2 value of 0.89, the model was statistically justified at $P < 0.05$ and, therefore, can be used to predict the likelihood of dieback occurring under a given set of environmental and other variables.

$$Y = 2.51 + 4.15\,x_1 + 5.25\,x_2 + 0.00866\,x_3 - 0.113\,x_4 - 0.0611\,x_5 - 0.0115\,x_6 - 0.0092\,x_7 + .0.514\,x_8 \quad \text{(Eq.3)}$$

R^2 = 0.89, x_1 = host category, x_2 = year (time), x_3 = water table, x_4 = rainfall, x_5 = relative humidity, x_6 = minimum temperature, x_7 = maximum temperature, x_8 = wind velocity.

The model indicated that most predictor variables had a small role in disease development. Age class and time span, however, had an important role. The model equation suggests that with one unit increase in age, dieback incidence will increase by 4.15 units in shisham plantations; with a single unit increase in time span (years), the change in dieback would be 5.25. For rainfall, relative humidity, minimum and maximum temperature, the negative values indicate that an increase in these variables will reduce disease incidence. In the principle component analysis, using the forward selection method, an optimum model was developed. The summary of the forward selection process (*Table 2*) shows that the partial R^2 value after entering the age variable was 0.5253 and for year, relative humidity and wind velocity it was 0.2943, 0.0552 and 0.0154, respectively. Beyond these variables, there was negligible increase in the R^2 value. The R^2 value for both the full model and optimum models was the same (0.89).

Then model was evaluated according to the procedures described by the Chaterjee and Hadi (2006) by a) through comparison of the dependent variable (Dieback disease) and regression coefficients with physical theory b) comparison of observed and predicted data.

Table 2. *Summary of forward selection*

Sr#	Variable entered	Partial R-square	Model R-square	Pr > F
1	Host category (minimum, moderate and maximum infected)	0.5253	0.5253	<0.000
2	Time (year)	0.2943	0.8196	<0.000
3	Relative humidity (%)	0.0552	0.8748	<0.000
4	Wind speed (Km/h)	0.0154	0.8902	<0.000
5	Rainfall (mm)	0.0009	0.8911	<0.000
6	Water table	0.0004	0.8915	<0.023
7	Min Temperature (°C)	0.0003	0.8919	<0.040

Comparison of the dependent variable (dieback disease) and regression coefficients with physical theory

Coefficient of determination (R^2) was an important parameter derived from the present work. Standard error was good with 1.5532 value (*Table 3*) The regression model was significant at $P < 0.05$ (*Tables 4* and *5*). Minimum and maximum

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64836495

temperatures were non- significant in the full predictive model. Role of water table and rainfall were also not much significant and summary of forward selection represents the same (*Table 2*) while all other parameters were significant. In the optimum model age, year, relative humidity and wind velocity were the major contributors in the disease development (*Eq. 4*). The coefficients, standard error, t stat and P values of full and optimum models are given in *Tables 3, 4* and *5*, respectively. It has been concluded from the above results that the model is very good for prediction.

Optimum predictive model for field data:

$$Y = 1.65 + 4.15\ Age + 5.20\ Year - 0.0523\ RH + 0.544\ WS \qquad (Eq.4)$$

$R^2 = 0.89$.

The model was also assessed by comparing the observed and predicted data. *Figure 5* shows that majority of the predictions fell between the 95% confidence intervals and 95% predictive intervals, demonstrating a very good relationship between predicted and observed data. Based on the R^2 (89%), the CI and PI model can be used for forecasting the dieback disease of shisham in various climatic conditions in the future.

Discussion

Dieback is a major threat to *D. sissoo* and has caused huge damage in all areas where this tree is cultivated. In Pakistan dieback of shisham has been recorded in different regions but severity differs with region (Gill and Aziz, 2004; Ahmad et al., 2016). In present study, a detailed survey of *D. sissoo* in four different agro-ecological zones of Punjab, Pakistan was conducted and considerable variation was observed in the incidence of dieback disease in the different zones of Punjab. Similar results were reported by Bajwa et al. (2003) from shisham plantations in all regions of Punjab. In present study incidence of disease was observed in different age classes of host (minimum, moderately and maximum infected trees).

The current work showed that tree age, and climatic factors including relative humidity, minimum and maximum temperature and wind velocity, were significantly correlated ($P < 0.05$) with incidence of dieback disease in the different agro-ecological zones. Tree age showed a prominent and strong association with dieback disease in all the examined districts and zones. Amongst the climatic factors, maximum temperature and wind velocity were more important compared to other variables. Baksha and Basak (2000) and Sharma et al. (2000) correlated mortality of *D. sissoo* with different ages of trees, and found low disease incidence in the early stages of growth, but greater susceptibility in older and larger trees leading to a high mortality rate compared to young plants. These results also support the conclusions of Boland et al. (2004) and Sturrock (2007), Dukes et al. (2009), Tubby and Webber (2010), Timmermann et al. (2017). The disease predictive model developed through regression analysis of the field survey data in this work utilized age class, environmental variables (minimum and maximum temperature, rainfall, relative humidity and wind velocity), time span (years) and underground water table to generate the model. Age class and time span played very important roles in the development of dieback under the field conditions. Hosking and Hutcheson (1992) showed that dieback of *Cordyline australis* was associated with old trees and attack of pathogens. Acharya and Subedi (2000) reported mortality of over mature dieback affected *D. sissoo* trees in a short period of even few weeks. Phillips et al. (2009) and Allen et al. (2010) observed an increasing trend in forest dieback and mortality due to drought on the basis of literature available from 1984 to 2010. In 1984,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64836495

only 1% tree mortality was linked with drought, whereas in 2010 the figure was 4%; the value of $R^2 = 0.61$ in the linear regression model showed a very strong association between tree mortality and drought conditions due to low rainfall and high temperature. These results support the findings reported here, that with the passage of time environmental stresses increased forest mortality. Different researchers (Negi, 2002; Sidhu et al., 2002; Chaudhry, 2006; Thom and Seidl, 2016) observed that the reoccurrence of climatic changes in *D. sissoo* plantations for more than two years may seriously disturb plant growth and reduce resistance of plants to different pathogens which ultimately causes the death of the trees. These findings are confirmed in this present study.

Conclusions

Mortality of *Dalbergia sissoo* due to dieback disease is linked with tree age as disease incidence in different age classes were observed and correlated with various environmental factors. Association was observed between disease and different climatic factors. Varying level of water table in different agro ecological zones of Punjab Province of Pakistan was not considered as a major threat to shisham dieback. Time span in regression equations indicates that with the passage of time disease severity will increase. Farmers and foresters should be careful about the symptoms of disease and harvesting will be a better option for the most affected trees. In future changing climatic conditions of Pakistan can spread disease to least affected areas.

Acknowledgements. We thank Abdul Hannan for guidance with predictive modeling and analysis; Muhammad Kashif, Lecturer Statistics for statistical support; and Amjad Saeed from Punjab Forestry Research Institute, Faisalabad for field assistance. Authors are grateful to the Meteorological Department, Lahore, Punjab for providing climatic data of selected districts.

(Received 21st Jan 2019; accepted 10th Apr 2019)

Abstract. This article aims to introduce a new research topic by investigating the role of banking sector development on Turkey's CO_2 emissions for the time period 1980-2014. Autoregressive Distributed Lag (ARDL), Fully Modified-OLS (FMOLS), and Canonical Co-integrating Regression (CCR) models are applied to test the coefficients between the variables. The newly-developed Bayer-Hanck combined co-integration test is used to support the robustness of the ARDL bounds test. The results show that banking sector development led to an increase in CO_2 emissions. The improvements in the Turkish banking sector development could lead to increased investment and energy consumption, which would subsequently cause raise in CO_2 emissions. Furthermore, the results show that an increase in the RIN would lead to decrease in CO_2 emissions. RIN has fundamental repercussions for the economy by either impacting the cost of capital or influencing the availability of credit, which in turn determines the level of savings as well as that of investment in an economy, which may subsequently affect CO_2 emissions. It is suggested that policy-makers should use the banking sector development and RIN channels to reduce environmental degradation by introducing monetary policy reforms, while also encouraging energy investment and the production of electricity using renewable sources.

Introduction

Since its economy has been liberalized in 1980, Turkey has undergone several key changes in its banking sector. The first major change was introduced in 1985 through the issuance of major banking reform legislation, which was related to the structural problems of the Turkish banking system (Ganioglu, 2008). The second major change in the banking sector was initiated after the economic crisis of 1994. This crisis had a severe impact on the sector due to accumulated risks, including RIN risks, currency risks, liquidity risks and credit risks (Akinci et al., 2013). The third main change in the banking sector occurred in 1999 when the banking sector act was fundamentally reformed in order to support its supervisory authority of the sector and to provide a suitable framework to deal with banks' problems, such as the establishment of the Banking Regulation and Supervision Agency (B.R.S.A.) as an independent agency that aimed to regulate and supervise the sector. The fourth main change happened after the 2001 crisis, whereby the government initiated a comprehensive banking sector restructuring program (Repkova

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64976513

and Stavarek, 2014). According to the Banks Association of Turkey, the banking sector experienced positive developments from 2001 to 2014, the share of non-performing loans to total loans substantially decreased.

Sustainable development, particularly in the banking sector is a critical issue for Turkey, which aims to be among the world's top ten-largest economies (Pata, 2018). It has made efforts to promote economic growth by increasing GDP and investment, and this has caused a rise in greenhouse gas emissions (GHG) and CO_2 emissions. Environmental degradation is an important barrier preventing sustainable development in Turkey (Pata, 2018). The main strategic objective for Turkey is to alleviate the harmful influence of CO_2 emissions. The policy makers play an important role in promoting investments in low emission projects. Moreover, they can enforce different techniques to minimize CO_2 emissions, such as by promoting the use of clean energy technologies like solar and wind (Viebahn et al., 2007). In this respect, this study aims to instigate a new discussion by testing the association among banking sector development, RIN and CO_2 emissions in Turkey through examining the environmental Kuznets curve hypothesis (E.K.C.)

Turkey is an emerging economy; it represents an ideal case to examine the influence of banking sector development, RIN, energy consumption and real income on Turkey's CO2 emissions for several reasons. Firstly, the International Energy Agency (IEA) has shown that Turkey has one of the most energy intensive industries among the organisation for economic co-operation and development (OECD) countries. Uzlu et al. (2014) stated that a fundamental part of primary energy consumption in Turkey is supported by imported oil and gas, thus leading to an increase in the budget deficit. Ates (2015) stated that Turkey had the greatest rate of increase in greenhouse gas emissions (GHG) in the period from 1990 to 2010, primarily consisting of CO_2 emissions. Secondly, Turkey's economy has faced prime economic structural changes over the last decades, mainly in the 1980s. Turkey had liberalized its economy, as a result of which, the economic growth was driven by several factors, particularly the free market economy and the increase in international trade. In this respect, the structure of international trade has changed radically, where trade as a percentage of GDP has risen from 17.08% in 1980 to 51.14% in 2014. Furthermore, the total exports in 1980 were 2.9 billion USD, whereas it reached 157.6 billion USD in 2014 (Guloglu, 2016). In addition, foreign direct investment (FDI) has also increased in Turkey over the last three decades (Isiksal et al., 2017). Net cumulative FDI inflows in Turkey reached 127 billion dollars in the period from 2001 to 2012 (Seker et al., 2015). Thirdly, even though Turkey has faced periods of crisis after the introduction of its liberalization program, the banking sector has experienced positive developments, particularly in the period between 2001 and 2014. Finally, after the 2001 Turkish economic crisis, Turkey changed its exchange rate system from a fixed system to a floating exchange rate regime, which is determined by supply and demand processes in the market (Central bank of Turkey).

This study seeks to examine the dynamic relationship between banking sector development, RIN, income, energy use and Turkey's CO_2 emissions from 1980 to 2014. Banking sector development is measured by credits provided by banks as a percentage to GDP. There are few studies that have used this variable to measure the impact of banking sector development on CO_2 emissions. This study argues that the impact of banking sector development and the RIN on CO_2 emissions can be positive or negative depending on how these variables affect economic growth and energy consumption.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64976513

Positive developments in the banking sector, such as an increase in the credits provided by banks to the private sector, may lead to an increase in total assets, an increase in the shareholders' equity of the sector, improvements in the risk management systems, and a decrease in the share of non-performing loans to total loans, which may affect economic growth and energy consumption and cause a subsequent rise in CO_2 emissions.

On other hand, RIN may affect CO_2 emissions in three channels. Firstly, low interest-rate helps corporations to minimize financing costs and also optimizes asset/liability structure management (Isiksal et al., 2018), which causes an expansion of the operation and production through the purchase of new equipment and increased investments in new projects, which leads to an increase in energy consumption and causes an increase in CO_2 emissions. Secondly, RIN can affect trade and FDI, as the boost in economic growth thus may lead to an increase in energy consumption and an increase in CO_2 emissions (Riti et al., 2017). Finally, when RIN has a significant impact on the real income, it may lead to an increase in consumer loans as well as the consumption of electrical machines, automobiles, etc. which would also increase CO_2 emissions (Beck and Demirguc-Kunt, 2006).

The remainder of this study is organized as follows: Section 2 is a literature review focusing on the relationship between real income, energy consumption, the banking sector, RIN and CO_2 emissions; Section 3 presents the materials and methods; Section 4 is the results and discussion; and Section 5 provides conclusion.

Literature review

Real income, energy consumption and CO_2 emissions

The existing empirical studies show that there is a linkage between energy consumption, real income and CO_2 emissions. Recent empirical studies seem to present varied empirical evidence on linkage between energy consumption, real income and CO_2 emissions. Say and Yucel (2006) found that energy consumption led to an increase in CO_2 emissions and proposed that the E.K.C. hypothesis exists in Turkey. Yavuz (2014) examined the linkage between energy, income and CO_2 emissions in Turkey over the period from 1960 to 2007. Seker et al. (2015) used the ARDL model and found that energy consumption led to an increase in CO2 emissions. Recent studies by Katircioglu and Katircioglu (2018) and Pata (2018) used the ARDL testing model and they found that energy consumption led to an increase in CO_2 emissions in Turkey. They suggested that real income is the primary driver for consumption of energy and it was suggested that the policy makers in Turkey should boost and support energy efficiency in order to promote sustainable growth.

Unlike these studies, some authors argue that the inverted U-shaped linkage between CO_2 emissions and income is not valid. Akbostanci et al. (2009) applied the time series model and Ozturk and Acaravci (2010) used a linear logarithmic model. They also did not find that the E.K.C. hypothesis holds for Turkey and they suggested that energy conservation policies such as rationing energy consumption and controlling CO_2 emissions were not likely to have any evident effect on the economic growth in Turkey.

RIN and CO_2 emissions

RIN is an important factor affecting the economy and the spillover effect of RIN on CO_2 emissions depends on how this variable will affect real income, investment, and how

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64976513

it may lead to an increase (decrease) in energy consumption and then subsequently affect CO_2 emissions. According to many empirical studies, RIN can affect economic performance by macroeconomic channels (Sokolov et al., 2011; Missio et al., 2015; Almahadin and Tuna, 2017; Sehrawat, 2017). The authors showed that the interest rate can have a different impact on economic performance in developing and developed economies; the mixed results can be attributed to different economic structures (Backhaus et al., 2016), different interest rate policies (tight vs expansive) and different inflation levels (Chari et al., 2002). The authors mainly suggested that the stability of the interest rate might lead to better economic performance (Danish et al., 2017; Backhaus and Isiksal, 2016).

Hence, if there is a real impact of RIN on economic activities, it will affect energy consumption and energy prices. Tolis et al. (2010) analyzed the impact of RIN and inflation rates on energy investments and argued that volatility in RIN affected energy investment. That could have a controversial effect on sustainability and could lead to an increase in CO_2 emissions. By using the US interest rate, Ziaei (2018) indicated that a decrease in RIN was accepted as a positive signal in the energy market and the energy consumed by the residential sector.

Banking sector development and CO_2 emissions

Many empirical studies (Beck and Levine, 2004; Wachtel, 2001; Petkovski and Kjosevski, 2014) have stated that development of the financial sector including developed banking performance accelerates the economic growth rate. Beck et al. (2000) stated that more funds are available for distribution as loans, which should stimulate and support consumption, investment, economic growth, and energy demand, and may cause an increase in energy consumption. Aslan et al. (2014) showed a positive relationship between banking development and energy consumption, and stated that deposit money bank assets and domestic credit to the private sector increases energy consumption, which may cause an increase in CO_2 emissions.

Development of the banking sector is a part of financial development; generally, the role of financial development in ecological degradation has received increased attention in the recent literature. Zhang (2011) tested the role of financial development on CO_2 emissions in China for the period 1980 to 2009 and found that China's financial development acts as an important driver for the increase in CO_2 emissions. Similar results were found in India by Shahbaz et al. (2015), who used the Vector Error Correction Model (VECM) approach and supported the assertion that financial development has a positive impact on CO_2 emissions in India over the time period of 1970–2012. Haseeb et al. (2018) used fully modified ordinary least square (FMOLS) panel data and examined the relationship between financial development measured by domestic credit to the private sector (% of GDP) and CO_2 emissions in the BRICS countries from 1995 to 2014 and found that domestic credit to the private sector (% of GDP) led to an increase in CO_2 emissions. Pata (2018) applied the FMOLS and ARDL models and found that financial development had a positive impact on CO_2 emissions in Turkey over the period from 1974 to 2014. These studies confirmed that financial development plays an important role in increasing and improving the economic efficiency of the financial systems and this can affect economic activities and the demand for energy, thus causing an increase in CO_2 emissions.

In contrast, Saidi and Mbarek (2017) used the GMM panel method to analyze 19 emerging countries and found a negative impact of financial development on CO_2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64976513

emissions for the period from 1990 to 2013. Park et al. (2018) used PMG estimates and data from the period 2001 to 2014 for selected European Union (EU) countries, and their findings showed that financial development led to a decrease in CO_2 emissions. In these studies, the authors suggested that financial development may increase energy efficiency and then decrease energy consumption and CO_2 emissions. Ozturk and Acaravci (2013) used the ARDL bounds test and stated that financial development did not affect CO_2 emissions in Turkey over the period from 1960 to 2007.

However, most of the studies focused on financial development measured by domestic credit provided by the financial sector to the private sector and only a minimal number of studies have focused on the banking sector development variable. Tamazian et al. (2009) analysed the role of financial development on CO_2 emissions in the BRIC countries over the period from 1992 to 2004. The authors found that capital market and banking sector development led to a reduction in CO_2 emissions. Sadorsky (2011) used the dynamic panel demand model and examined the nexus between financial development and CO_2 emissions and stated that deposit money bank assets led to an increase in CO_2 emission in nine Central and Eastern European counties. A summary of the EKC hypothesis and other studies is presented in *Table 1*.

Table 1. *Summary of the studies*

Authors	Period	Country	Methodology	Findings
Zhang (2011)	1980-2009	China	Granger causality	FD is significant.

Y is real income, FD is financial development, BD is bank development, EN is energy consumption

Materials and methods

After Grossman and Krueger (1995) proposed the first theoretical linkage between CO_2 emissions and income, many empirical studies (Say and Yucel, 2006; Jalil and Mahmud, 2009; Yavuz, 2014; Katircioglu and Katircioglu, 2018; Pata, 2018) have used the following model:

$$lnCO2_{it} = \beta_0 + \Upsilon_1 lnY_{it} + \Upsilon_2 lnY^2{}_{it} + \varepsilon_{it} \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64976513

where CO_2 is carbon dioxide emissions (measured in metric tons per capita), Y is GDP per capita (constant 2010 US-dollar), Y^2 is the square of GDP, ε_t is the error-term, while *i* and *t* represent the country and years, respectively.

This study is different from the existing literature as it uses other economic factors, namely bank development and RIN. Thus, bank development and RIN are external proxies added to the conventional EKC model. The empirical model of this paper is presented as follows:

$$LnCO2_t = \beta_0 + \Upsilon_1 LnY_t + \Upsilon_2 lnY^2{}_t + \Upsilon_3 LnEG_t + \Upsilon_4 lnBD_t + \Upsilon_5 LnRIN_t + \varepsilon_{it} \quad \text{(Eq.2)}$$

where $lnCO2_t$ represents the logarithm of CO_2, LnY and lnY^2 are the logarithms of $Y(GDP)$ and $Y^2(square\ of\ GDP)$, $LnEG_t$ is the logarithm of energy consumption, $LnBD$ represents the logarithm of banking sector development, and RIN is the real interest rate. The data is annual data covering the years between 1980 and 2014. Descriptive statistics of the variables are represented in *Table 2*. A summary of the descriptions of the variables and sources of the data is represented in *Table 3*.

Table 2. *Descriptive statistics of the variables*

	Mean	Median	Maximum	Minimum	Standard deviation
$CO2_t$	1.093758	1.149764	1.502182	0.54398	0.273282
Y_t	8.963046	8.952993	9.496421	8.51459	0.275895
$Y^2{}_t$	80.41015	80.15609	90.18201	72.49824	4.960866

RIN	-0.00272	0.0458	0.2414	-0.85	0.220229

Table 3. *Summary of the variables' descriptions and sources of the data*

Variables	Description	Source of the data
$CO2_t$	CO_2 emissions (metric-tons-per capita)	World-Bank, $(website)$
Y_t	GDP-per-capita (constant-2010-USD)	World-Bank, $(website)$
$Y^2{}_t$	the square of GDP	World-Bank, $(website)$
EG_t	Energy consumption (kt of oil-equivalent)	World-Bank, $(website)$
BD_t	Credits provided by banks to the private-sector as a % of GDP	World-Bank, $(website)$
RIN	RIN (interest rate of the time-deposit minus inflation-rate)	World-Bank, $(website)$

Unit root tests and co-integration tests

This paper uses the Perron-Vogelsang (1999) with one structural break (SB) and Clemente-Montanes-Reyes (CMR) (Clemente et al., 1998) with two SBs to estimate the order of integration of the variables.

To examine the long-term relationship between CO_2 and the *Y, Y^2, En, BD, RIN* variables, this paper uses the ARDL bounds test within the ARDL methodology introduced by Pesaran et al. (2001). The model is distinguished from other models as it uses different lags to estimate the parameters by employing a single reduced form

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64976513

equation. Considering the sensitivity of this methodology to the number of lags, the Akaike-information-criterion (A.I.C) and Schwarz-Bayesian-criteria (S.B.C) were applied to select the optimal lag length (p). Additionally, in this test, all variables are treated as endogenous, thus excluding the endogeneity problem. Therefore, by employing this test, the paper aims to determine if there is cointegration or not in three options: I(0), I(1) or mixed. In this vein, the *F*-statistics value was compared to the theoretical values introduced by Pesaran et al. (2001). If the *F*-statistics value exceeds the upper bound I(1), the null-hypothesis will be rejected, indicating that there is cointegration among the variables. If the *F*-statistics value is less than the lower bound I(0), the null-hypothesis will be accepted, indicating that there is no cointegration among the variables. Furthermore, if the *F*-statistics value lies between I(0) and I(1), this means that the result is inconclusive. The ARDL approach equation is as follows:

$$\Delta LnCO_{2t} = \beta_0 + \sum_{i=1}^{n} y_1 \Delta lnCO_{2t-j} + \sum_{i=1}^{n} y_2 \Delta lnY_{t-j} + \sum_{i=1}^{n} y_3 \Delta lnY^2{}_{t-j} + \sum_{i=1}^{n} y_4 \Delta lnEG_{t-j} + \sum_{i=1}^{n} y_5 \Delta lnBD_{t-j} + + \sum_{i=1}^{n} y_6 \Delta RIN_{t-j} + \sigma_1 lnCO_{2t-1} + \sigma_2 lnY_{t-1} + \sigma_3 lnY^2{}_{t-1} + \sigma_4 lnEn_{t-1} + \sigma_5 lnBD_{t-1} + \sigma_6 RIN_{t-1} + \varepsilon_{1t} \quad \text{(Eq.3)}$$

In *Equation 4,* Δ represents the operator of the first difference. $LnCO_{2t}$, LnY_t, $lnY^2{}_t$, $LnEG_t$,$LnBD_t$, RIN_t are the dependent and independent variables, *n* is the maximum number of lags, and ε_t represents the error-term. Once the existence of co-integration is validated, in order to capture the speed of adjustment of the dependent variable, the error correction model is estimated using the following equation:

$$\Delta LnCO_{2t} = \beta_0 + \sum_{i=1}^{n} y_1 \Delta lnCO_{2t-j} + \sum_{i=1}^{n} y_2 \Delta lnY_{t-j} + \sum_{i=1}^{n} y_3 \Delta lnY^2{}_{t-j} + \sum_{i=1}^{n} y_4 \Delta lnEG_{t-j} + \sum_{i=1}^{n} y_5 \Delta lnBD_{t-j} + \sum_{i=1}^{n} y_6 \Delta RIN_{t-j} + \omega ECT_{t-1} + \varepsilon_{1t} \quad \text{(Eq.4)}$$

ECT_{t-1} is the one period lagged error correction-term. It is expected that the ECT will be significant with a negative sign (Gujarati, 2003). ECT shows the speed of adjustment among the short-term and long-term levels of the dependent variable.

The Bayer-Hanck (BH) (2013) combined cointegration test is utilized to investigate the robustness of the ARDL model. It is applied to the data with a unique order of integration. It combines four different cointegration tests, namely Engle and Granger (1987) (EG_t), Johansen (1988) (JO_t), Boswijk (1994) (BO_t), and Banerjee et al. (1998) (BA_t). This test combines the outcomes of previous co-integration tests and provides the *Fisher-F* statistics for more reliable and conclusive outcomes. BH provides functional estimates by disregarding the nature of multiple testing proceedings. This test is a combination of the computed *p*-values with the significance level of cointegration tests based on Fisher's formula as follows:

$$EG_t - JOH_t = -2\left[IN\left(P_{EG_t}\right) + \left(P_{JOH_t}\right)\right] \quad \text{(Eq.5)}$$

$$EG_t - JOH_t - BO_t - BDM_t = -2\left[IN\left(P_{EG_t}\right) + \left(P_{JO_t}\right) + \left(P_{BO_t}\right) + \left(P_{BA_t}\right)\right] \quad \text{(Eq.6)}$$

where *p* are the values of individual cointegrations tests (EG_t, JO_t, BO_t, BA_t). The estimated long-run combined cointegration *Fisher F*-statistics will be compared with the critical values (CV), which were presented by Bayer and Hanck (2013). The null hypothesis of the BH test is no long-run combined co-integration. It will be rejected if the computed *Fisher F*-statistics value is higher than the critical values.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64976513

The paper uses other techniques to estimate long-run coefficient, namely fully modified ordinary least square (FMOLS) and canonical co-integrating regression (CCR), which were introduced by Phillips and Hansen (1990) and Park (1992). These tests consider endogeneity and the serial correlation problems, which may appear in the existence of cointegration. These tests can only be utilized when the variables are I(1).

The direction of the causal relationship between CO_2 emissions, *Y, Y^2, EG, BD, and RIN* is tested by using Granger causality within $VECM$. This test identifies if there is co-integration among the time series variables and if so, it is possible to analyze the direction of the causal effect linkage by using the error correction model (ECM) since it includes information about the causality in both the short and long run. This test allows for the addition of an (ECT) to capture the short-term deviations of the time series from their long-term equilibrium path. The (ECM) equation is as follows:

$$\Delta lnCO_{2t} = \beta_0 + \sum_{i=1}^{n} \Upsilon_1 \Delta lnCO_{2t-j} + \sum_{i=1}^{n} \Upsilon_2 \Delta lnY_{t-j} + \sum_{i=1}^{n} \Upsilon_3 \Delta lnY^2{}_{t-j} + \sum_{i=1}^{n} \Upsilon_4 \Delta lnEG_{t-j} + + \sum_{i=1}^{n} \Upsilon_5 \Delta lnBD_{t-j} + \sum_{i=1}^{n} \Upsilon_6 \Delta RIN_{t-j} + ECT_{t-1} + \varepsilon_{1t} \quad \text{(Eq.7)}$$

$$lnY_t = \beta_0 + \sum_{i=1}^{n} \Upsilon_1 \Delta lnY_{t-j} + \sum_{i=1}^{n} \Upsilon_2 \Delta lnCO_{2t-j} + \sum_{i=1}^{n} \Upsilon_3 \Delta lnY^2{}_{t-j} + \sum_{i=1}^{n} \Upsilon_4 \Delta lnEG_{t-j} + \sum_{i=1}^{n} \Upsilon_5 \Delta lnBD_{t-j} + \sum_{i=1}^{n} \Upsilon_6 \Delta RIN_{t-j} + {}_1\, ECT_{t-1} + \varepsilon_{1t} \quad \text{(Eq.8)}$$

$$\Delta lnY^2{}_t = \beta_0 + \sum_{i=1}^{n} \Upsilon_1 \Delta lnY^2{}_{t-j} + \sum_{i=1}^{n} \Upsilon_2 \Delta lnCO_{2t-j} + \sum_{i=1}^{n} \Upsilon_3 \Delta lnY_{t-j} + \sum_{i=1}^{n} \Upsilon_4 \Delta lnEn_{t-j} + \sum_{i=1}^{n} \Upsilon_5 \Delta lnBD_{t-j} + \sum_{i=1}^{n} \Upsilon_6 \Delta RIN_{t-j} + {}_1\, ECT_{t-1} + \varepsilon_{1t} \quad \text{(Eq.9)}$$

$$\Delta lnEn_t = \beta_0 + \sum_{i=1}^{n} \Upsilon_1 \Delta lnEn_{t-j} + \sum_{i=1}^{n} \Upsilon_2 \Delta lnCO_{2t-j} + \sum_{i=1}^{n} \Upsilon_3 \Delta lnY_{t-j} + \sum_{i=1}^{n} \Upsilon_4 \Delta lnY^2{}_{t-j} + \sum_{i=1}^{n} \Upsilon_5 \Delta lnBD_{t-j} + \sum_{i=1}^{n} \Upsilon_6 \Delta RIN_{t-j} + {}_1\, ECT_{t-1} + \varepsilon_{1t} \quad \text{(Eq.10)}$$

$$\Delta lnBD_t = \beta_0 + \sum_{i=1}^{n} \Upsilon_1 \Delta lnBD_{t-j} + \sum_{i=1}^{n} \Upsilon_2 \Delta lnCO_{2t-j} + \sum_{i=1}^{n} \Upsilon_3 \Delta lnY_{t-j} + \sum_{i=1}^{n} \Upsilon_4 \Delta lnY^2{}_{t-j} + \sum_{i=1}^{n} \Upsilon_5 \Delta lnEG_{t-j} + \sum_{i=1}^{n} \Upsilon_6 \Delta RIN_{t-j} + {}_1\, ECT_{t-1} + \varepsilon_{1t} \quad \text{(Eq.11)}$$

$$\Delta RIN_t = \beta_0 + \sum_{i=1}^{n} \Upsilon_1 \Delta RIN_{t-j} + \sum_{i=1}^{n} \Upsilon_2 \Delta lnCO_{2t-j} + \sum_{i=1}^{n} \Upsilon_3 \Delta lnY_{t-j} + \sum_{i=1}^{n} \Upsilon_4 \Delta lnY^2{}_{t-j} + \sum_{i=1}^{n} \Upsilon_5 \Delta lnEG_{t-j} + \sum_{i=1}^{n} \Upsilon_6 \Delta lnBD_{t-j} + ECT_{t-1} + \varepsilon_{1t} \quad \text{(Eq.12)}$$

In *Equations 7-12,* Δ represents the operator of the first difference, $lnCO_2, LnY, lnY^2, lnEG, lnBD,$ and RIN are the dependent and independent variables, ε_t represents the error-term, and ECT_{t-1} is the lagged error correction-term added to the equations. The short-term causality is examined by Wald test's *F*-statistics to define the significance of the related coefficient by applying the first difference of the stationary variables (Masih, 1996). To examine the long-run causality, the test of the related coefficient of the lagged ECT is used.

Results and discussion

Unit root test results

The results of Perron and Vogelsang and CMR with one and two SBs are reported in *Tables 4* and *5*. The results of the Perron and Vogelsang and CMR unit root test with one and two SBs show that all the variables are stationary at first-difference, I(1). *Figure 1* shows the time series plot of the series at the natural logarithm indicating various economic fluctuations and policy changes in Turkey.

The results of the *F* bounds tests are represented in *Table 6.* The results show that the *F*-statistics is higher than 5% (Pesaran et al., 2001). This confirms that there is co-integration among all the variables.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64976513

Table 6 provides powerful evidence on the level relationship for *Equation 2* of this study. The null hypothesis ($\sigma1 = \sigma2 = \sigma3 = \sigma4 = \sigma5 = \sigma6 = 0$) in *Equation 3* can be rejected and this shows that CO_2 emissions in Turkey are in a long-run relationship with the regressed variables (Y, Y^2, En, BD and RIN).

Critical value at 5% sign level	2.39	3.38	

* and ** denote significantly level the 5% and 10%, respectively

The results of the BH combined co-integration test are reported in *Table 7*. The results show that the computed *F*-statistics value is higher than the tabulated *F*-statistics in both $EG_t - JO_t$ and $EG_t - JO_t - BO_t - BA_t$ at 5% and 10% levels of significance. Therefore, the results of the BH (2013) co-integration tests confirm the robustness of the ARDL model. These results imply that there is a long-run association and all the variables are corresponding together in the long term.

Table 7. *BH combined co-integration test results*

	***Fisher-F* statistics**		**Co-integration results**

sig level at (10)%	8.352	16.239	

*, **shows significantly level at 10%, and 5%, respectively

The normality test results confirm that the model is normally distributed. Furthermore, ARCH, LM and the Breusch-Pagan Godfrey, tests results confirm that the model is homoscedastic and there is no autocorrelation. Furthermore, the Ramsey-Reset test results confirm the stability of the results. The results show that the model is correctly formulated. Moreover, *Figures 2* and *3* show the stability tests using CUSUM and CUSUM squares. The figures show that the blue lines are between the two red lines at the 5% significant level, which means that there is stability in the long-run coefficients.

Table 8 shows that the speed of adjustment is negative and statistically reliable; the rate of convergence from the short-run to long-run equilibrium is 85.5%. The results

DOI: http://dx.doi.org/10.15666/aeer/1703_64976513

from ARDL, FMOLS and CCR are presented in *Tables 8* and *9*. The results show that the coefficient of GDP(*Y*) is highly elastic, positive and statistically significant, while the squared GDP(Y^2) is negative and statistically significant in the long-run. This finding strongly confirms that the E.K.C. hypothesis is valid for Turkey.

*, **, ***shows significantly level at 10%, 5% and 1%, respectively

The coefficient of energy consumption in both the short and long run has a positive significant effect on the level of CO_2 emissions. Furthermore, the proxy for banking sector development is positive and significant in both the short and long run. Thus, an increase in credits provided by banks as a percentage of GDP led to an increase in CO_2 emissions. On the other hand, the proxy of RIN is negative and statistically significant in the short and long run. Therefore, an increase in the RIN leads to a decrease in CO_2 emissions.

The coefficient of GDP makes the highest impact on CO2 emissions, which shows that a 1% increase in GDP will lead to a 2.22%-3.01% increase in emissions. The second highest impact is made by energy consumption, which indicates that a 1% increase in energy consumption will lead to 1.09%-1.26% increase in emissions. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64976513

results also show that a 1% increase in bank credits will increase the emissions by 0.01%-0.06%; however, with a 1% increase in RIN, the emissions will decline by 0.0008%-0.02%.

Granger causality test results

Table 10 reports the Granger causality results. The null hypothesis of the causality test is that *x* and *y* are independent, or there is no linkage between *x* and *y*. As shown in *Table 10* there is a long-run unidirectional causality from *Y, EG, BD and RIN to* CO_2 *(Y, EN, BD, RIN→*CO_2*)*. The results strongly confirm that the E.K.C. hypothesis is valid for Turkey. Furthermore, the results show that there is a unidirectional short-run causality running from RIN to the bank credits to the private sector and energy consumption (*RIN→BD, RIN→EG*), which confirms that the RIN may cause banking sector development and energy consumption, which may lead to an increase in CO_2 emissions in Turkey. There is a unidirectional causality from the bank credits to the private sector and energy consumption (*BD→EG*). These results confirm our findings for a strong relationship between banking sector development and CO_2 emissions in Turkey.

Conclusion

This article aims to introduce a new research topic by investigating the role of banking sector development, RIN, real income, and energy consumption on Turkey's CO2 emissions for the time period 1980-2014. This article is different from the existing literature as it introduces a new discussion concerning the role of banking sector development on CO_2 emissions in Turkey. The sophisticated econometric models, Autoregressive Distributed Lag (ARDL), Fully Modified-OLS (FMOLS), and the Canonical Cointegrating Regression (CCR) tests are applied to test the short and long-run coefficients between the variables. The ARDL model was preferred due to its advantages compared to the other models. Firstly, the ARDL model has superior features in small data in particular, and it is not important to test the integration order of the series. This test enables simultaneous analysis of both the short-run and long-run effects of independent variables on the dependent variable. In order to confirm and support the results in the long run, the paper uses the FMOLS, and CCR tests. These tests consider endogeneity and the serial correlation problems, which may appear in the existence of cointegration. The new approach involving the Bayer-Hanck (BH)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_64976513

combined co-integration test is used to enhance and support the robustness of the ARDL bounds test. Moreover, the Granger causality test within the VECM model is applied to examine the causality direction among the variables of this study. The empirical results and policy recommendations are as follows:

Real income and energy consumption

The empirical results from the ARDL, FMOLS and CCR models show strong evidence to confirm that the E.K.C. hypothesis holds for Turkey. The results from the ARDL and causality tests show that the increase in real income and energy consumption led to an increase CO_2 emissions. These results are consistent with Say and Yucel (2006), Yavuz (2014), Katircioglu and Katircioglu (2018), and Pata (2018) who found positive relation between energy consumption and real income CO_2 emissions in Turkey, the policy market should design long-term energy strategies to reduce emissions through efficient energy consumption channels and should also implement some strategies that promote the use of the renewable energy sources.

Banking sector development and RIN

The study can make a significant impact in terms of the policies intended to diminish the carbon dioxide emissions in Turkey. The planning of emission levels by using energy consumption and income association might underestimate the real amount of the pollution produced if the financial development variables like bank development and RIN are not considered. Therefore, while banking sector development has lower long-run elasticity than the long-run coefficients of income and energy consumption, it has a positive and statistically significant impact on carbon dioxide emissions. The empirical findings show that increases in banking sector development increase pollution. These results are consistent with Sadorsky (2011) and Pata (2018). These studies confirmed that financial development plays an important role in increasing the economic efficiency of the financial systems and this can affect economic activities and the demand for energy, thus causing an increase in CO2 emissions. The long-run elasticity of RIN is smaller than the long-run coefficient of credits provided by banks, although it is negative and significant. The larger amount of credits provided by banks as a percentage of GDP shows that there are more funds available as loans for the private sector and this increases consumption, economic growth, energy use, and emissions. However, even a small increase in RIN discourages the consumption of durables like automobiles, mobile phones, etc. and therefore worsens the emissions.

The findings of this article are important for several reasons. Emerging economies like Turkey might experience increases in carbon emissions because of the increase in energy consumption and income levels. Making projections of GHG that do not consider bank credits to the private sector and RIN may underestimate or overestimate the real emissions. It will be difficult to meet greenhouse gas emission targets if the impacts of banking sector development and RIN are not considered.

This study has introduced a new research topic by investigating the role of banking sector development and RIN on Turkey's CO_2 emissions; further research for the developing and developed countries or regions is suggested for comparison purposes. Furthermore, different proxies and other methodologies not only via time series models but also panel data can also be adapted as further researches in order to examine the role of banking sector development and RIN in the environmental concerns of countries.

Abstract. Acid rain as an important environmental problem in China and a stressor may cause gene expression, and tomato is one of model plants and the most important vegetable crops in middle and south China. Tomato seedlings were exposed for 7 days to simulated acid rain (SiAR) of pH 3.0 and control (pH 5.6). The cDNA-amplified fragment length polymorphism (cDNA-AFLP) was carried out to separate differentially expressed gene fragments by using selective base pairs including 8 Mse I primers and 8 EcoR I primers, which allowed the identification and cloning of 45 differential expression transcript-derived fragments (TDFs) corresponding to SiAR, among of which 45 TDFs were successfully cloned and sequenced. 31 of them were found homologies in the NCBI, and 19 displayed homology to genes with known functions, 12 to genes with uncharacterized function. 8 TDFs played significant role in tomato resistance to acid rain-stress. Among of them, TDF5 and TDF8 were stress- inducible transcription factor. TDF4 and TDF20 played important role in resistance to SiAR stress. TDF2 was related to isoprenoid biosynthesis, TDF7 to transcription regulation, TDF11 to metabolism, TDF24 to plant development and defense. Possible roles of the 8 TDFs in the response of tomato to SiAR are also discussed. Moreover, Homologous of amino acid encoded in TDF5 and TDF8 were analyzed.
Keywords: *SiAR stress, Lycopersicum esculentum, cDNA-amplified fragment length polymorphism, transcript-derived fragments*

Abbreviations: SiAR: simulated acid rain, cDNA-AFLP: cDNA-amplified fragment length polymorphism, TDFs: transcript-derived fragments

Introduction

Acid rain emerged as an important environmental problem in China in the late 1970s. The frequency of acid rain has kept increasing since then. It was reported that the loss of forest ecological benefits caused by acid rain exceeded 16 billion Yuan (2.4 billion dollars) per year only in 11 provinces of south China (Feng, 2000). Previous studies have documented acid rain stress causing the leaching of leaf nutrients; changes of physiological and biochemical process; and inhibition of growth and yield of plants (Bellani et al., 1997; Chen et al., 2013; Odiyi et al., 2014; Percy et al., 1990; Qiu et al., 2002, 2005; Ramlall et al., 2015; Wang et al., 2014a, b) Acid rain as an environmental stressor may cause gene differential expression. Gene expression profiles were reported in *Dimocarpus longan* Lour (Zheng et al., 2017), *Synechocystis sp* PCC 6803 (Ohta et al., 2005) and *Arabidopsis thaliana* (L.) Heynh (Liu et al., 2013) in response to acid rain stress. Changes in the total protein profile of *Dimocarpus longan* leaves in response to simulated acid rain (SiAR) stress were documented by Pan et al. (2015).

Tomato (*Lycopersicon esculentum*) is one of model plants and the most important vegetable crops in middle and south China. Previous study has shown that the pigment synthesis, growth and biomass of tomato was inhibited under SiAR stress (Shaukat et al., 2008). One way to study the cellular response to acid rain on a large scale is to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65156533

examine gene expression at the mRNA level using the PCR-based technique of cDNA-amplified fragment length polymorphism (cDNA-AFLP) which has often been described as an extremely efficient method for isolation of differentially expressed genes (Baisakh et al., 2006) and is a less labor-intensive mRNA fingerprinting method for isolation of differentially expressed genes (Bachem et al., 1996). Due to its high sensitivity, it is possible to identify rare transcripts (Fukumura et al., 2003). This technique has been further improved to avoid the possibility of several transcript-derived fragment (TDFs) arising from a single gene/cDNA. Keeping the above in view, the objective of this study was to identify some of the key genes that were differentially expressed in response to SiAR.

Materials and methods

Plant materials and treatments

Tomato seeds (*Lycopersicum esculentum* cv. 'Fudan') were sown in plug trays with peat-based substrate with peat, vermiculite, and perlite medium (3:1:1). 7 days after emergence (DAE), each seedling was transferred to a pot containing a 3:1:1 mixture of peat, vermiculite, and perlite. The plants were kept in a net house with a natural photoperiod at Fujian Agriculture and Forestry University. Simulated acid rain was applied to plants at 42 DAE.

Sulfuric acid and nitric acid were selected for the preparation of SiAR, based on the mole ratio 1:5 of sulfuric acid to nitric acid in the precipitation of southern Fujian, China (Tang et al., 1996). Normal rain has a pH of about 5.6; it is slightly acidic because carbon dioxide (CO_2) dissolves into it forming weak carbonic acid, and the solution with pH value of 5.6 was regarded as the control (Qiu et al., 2005). Solution of SiAR with pH 3.0 was also prepared. Dilution of reagent grade acid was done with distilled water and determined by Orion 828 acidity analyzer (made in America). A sprayer was used to apply the acid solutions. The spray was repeated 7 times during 7 days, at each application, leaves were thoroughly wetted. There were 9 pots in each treatment, and each treatment was repeated triple. Each replicate consisted of 9 plants. After 7 days of application, one leave from each tested plant (symptoms appeared) and control plant (*Fig. 1*) was sampled and immediately frozen in liquid nitrogen and then stored at -80 °C until use.

Figure 1. *Tomato leaves after treated by pH 3.0 and control (pH 5.6) for 1 week*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65156533

RNA preparation and cDNA synthesis

Total RNA was isolated from each sample of frozen tissue (0.1 g). The frozen tissue was homogenized with 0.5 ml of isopropyl alcohol (1:10, v/v) per 1 ml with Trizol extraction method (Invitrogen, Shanghai). The RNA concentration was determined by measuring absorbance at 260 nm. RNA integrity was determined by running 5 μL of total RNA in a 1.0% agarose gel electrophoresis. 4 μg of total RNA was used initially for first strand synthesis, followed by second strand synthesis using SuperScript^{TM} III double stranded cDNA synthesis kit (Invitrogen), according to the manufacturer's protocol.

cDNA-AFLP reaction

The cDNA-AFLP procedure was conducted as described by Bachem et al. (1998) with some modifications. Approximately 100 ng cDNA from from each treatment was digested with EcoRI and MseI restriction enzymes in a three-step reaction at 37 °C for 55 min, 65 °C for 55 min and 80 °C 10 min, respectively. The digested products were ligated to adapters with sequences as follows: EcoRI adapter, 5' CTC GTA GAC TGC GTA CC 3', 3'CAT CTG ACG CAT GGT TAAP5'; MseI adapter, 5'GAC GAT GAG TCC TGA G 3', 3'TAC TCA GGA CTC ATP5'. The ligated products were pre-amplified with the corresponding pre-amplification primers (EcoRI: 5' GAC TGC GTA CCA ATT CA 3', MseI: 5'GAT GAG TCC TGA GTAA C 3'5). Equal amounts of pre-amplified products were amplified with primers having selective nucleotides at the 3' end (EcoRI: 5' GAC TGC GTA CCA ATT CA AC 3'; MseI: 5'GAT GAG TCC TGA GTAA C AA 3' (*Table 1*). Altogether 128 different primer combinations were tested. 4 μL of the AFLP products were heat-denatured and resolved in a 6% denaturing polyacrylamide sequencing gel run with 1 × TBE electrohphoresis buffer. The gels were silver-stained according to the Silver SequenceTM DNA Sequencing System Technical Manual.

Transcript-derived fragment (TDF) isolation and re-amplification

The bands of interest were marked, removed from the gel and soaked in ddH_2O (50 μL) initially at 100 °C for 15 min and then hydrated overnight at 4 °C. 10 μL of the aliquot was used for re-amplification in a total volume of 50 μL, with the same set of corresponding selective primers and the same PCR conditions as for the selective amplification except that an annealing temperature of 56 °C, 35 cycles and a final 4 min extension were used. The PCR products were resolved in a 1.5% 1 × TBE-agarose gel, and each single band corresponding to the selected TDFs was isolated, soaked to elute the DNA according to agarose gel DNA Purification Kit (TAKARA).

Cloning and sequencing of TDFs

The eluted TDFs were cloned into the plasmid pMD_{18}-T vector (TaKaRa Biotechnology (Dalian) Co., Ltd., China) following the manufacturer's protocol. Positive clones were inoculated, and PCR positive cultures from every TDF were sequenced with an ABI automated sequencer.

Analysis of sequences

The sequences of the TDF were analyzed for their homology against the publicly available non-redundant genes/ESTs/Transcripts in GeneBank using the BLASTN and BLASTX algorithms. Multiple sequence alignment was performed with ClustalX2.0

Results

Isolation of the TDFs responsive to SiAR stress

A total of 128 primer combinations were used for the AFLP analysis of cDNAs from simulated acid rain-stressed leaves. cDNAs were obtained from the treatments of pH 5.6 (Control) and pH 3.0 (*Fig. 2*). A total of 45 transcript-derived fragments (TDFs) were isolated from the silver-stained cDNA-AFLP gels based on their presence, and identified as inducibly expressed. Sequence alignment of these 45 cloned TDFs against NCBI databases showed that 31 had a homologous gene in the database. Due to incompleteness of tomato gene annotation and the conservation of gene families between tomato and *Arabidopsis, Vitis vinifera, Populus, Ricinus communis,. Phaeosphaeria nodorum, Glycine max, Ipomoea batatas*, *Sorghum, Zea mays, Artemisia annua*.

We used these matches of the identified inducibly expressed genes as surrogates for function annotation (*Fig. 3*). 14 of 45 TDFs had no annotation in the database. Fourteen of the TDFs had no similar sequences in the NCBI databases. The genes with unknown functions consist of those that have not yet been associated with a response to abiotics stress, and some of these novel genes did not match any sequence from the GenBank

databases. In general, our results indicated that multiple defense strategies lead to an enhanced defense capacity of tomato plants to SiAR.

Sequencing and classification of cDNA

The expression profile was compared between pH 3.0 and control on the basis of their either complete presence or absence (*Fig. 2*). 31 TDFs above 100 bp were eluted from the gel, re-amplified, and sequenced (*Fig. 4* and *Fig. A1* in the *Appendix*).

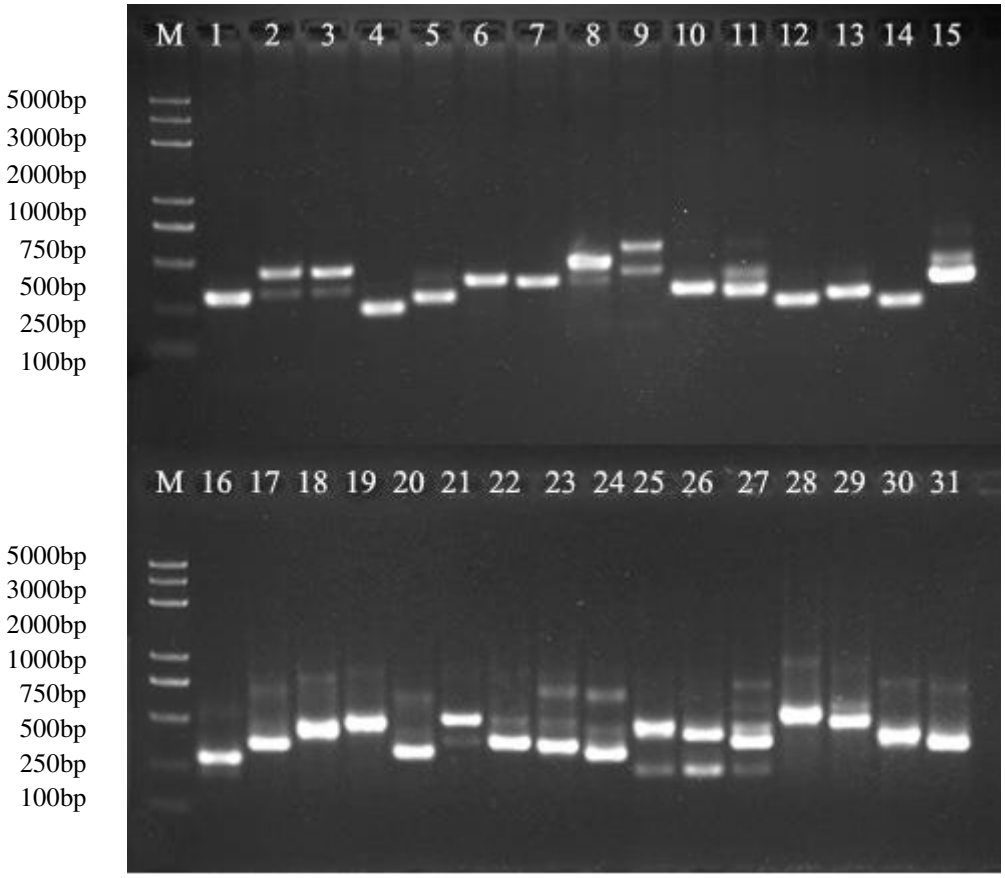

Figure 4. *Agarose gel of re-amplified TDFs from tomato in response to SiAR. M: 2000 bp marker;1-31 showing TDF1-TDF31, respectively*

The TDFs with known or putative function were submitted to the NCBI database and are presented in *Table 2* with GenBank Accession numbers. The up- and down--regulated genes are also categorized into these functional groups (*Table 2*). *Figure 5* shows the percentages of acid rain induced genes assigned to different functional categories. Comparison of the homologies of these sequences and those in the database suggested that most of them (about 68.9%) had homology with genes involved in functions like UBA and UBX domain-containing protein (12.9%, TDF1, TDF6, TDF9, TDF19), Inositol-1, 4, 5 -triphosphate-5-phosphatase (3.2%, TDF15), Inositol polyphosphate 5-phosphatase (3.2%, TDF26), Tobamovirus multiplication protein (3.2%, TDF13), Hypothetical protein (9.7%, TDF11, TDF16, TDF28), RING/U-box superfamily protein (3.2%, TDF7), Stress transcription factor A-6b (6.5%, TDF5, TDF8), Receptor protein (3.2%, TDF27), Plastidic aldolase (3.2%, TDF30), Phenylalanine ammonia-lyase (3.2%, TDF24), Solanesyl diphosphate synthase (3.2%, TDF2), Peroxidase (6.5%, TDF4, TDF20).

Discussion

The biological functions of identified SiAR-responsive genes were categorized according to transcriptional levels. The putative functions of the TDFs that were differentially expressed in SiAR treatments were analyzed. The largest categories with ascribed function are stress-related genes (68.9%) involved in functions like UBA and UBX domain-containing protein (12.99%), peroxidase (6.5%), inositol-1, 4, 5 - triphosphate-5-phosphatase (3.2%), inositol polyphosphate 5-phosphatase (3.2%), tobamovirus multiplication protein (3.2%), hypothetical protein (9.7%), RING/U-box superfamily protein (3.2%), stress transcription factor A-6b (6.5%), receptor protein (3.2%), plastidic aldolase (3.2%), phenylalanine ammonia-lyase (3.2%), solanesyl diphosphate synthase (3.2%). Among of them, the expression of TDFs in tomato leaves under SiAR stress were up-regulated, including TDF2, TDF4, TDF5, TDF7, TDF8, TDF11, TDF20, TDF24, TDF27, TDF30. The results of the differentially regulated TDFs reported to have direct or indirect relation with simulated acid rain stress response are discussed below.

Responses of isoprenoid biosynthetic genes to simulated acid rain

As a part of the plant defense machinery, isoprenoids are employed, among others, to protect plant cells from abiotic stress (Munne-Bosch et al., 2003). TDF2 showed high similarity with the enzymatic proteins in the pathway of isoprenoid biosynthesis, which were down-regulated in the seedlings subjected to simulated acid rain stress. Plastoquinone is regulated by solanesyl diphosphatesynthase (SPPS) (Phatthiya et al., 2007). Simulated acid rain stress affecting phosphorylation of the chloroplast of longan leaves was documented by Qiu et al. (2002). These indicated that simulated acid rain stress influenced photophorylation by the way of inhibiting isopretenoid production. The same result was documented that isoprenoids in Sitka spruce are induced after mechanical wounding due to increased transcription or enzymatic activities of genes and enzymes participating in the biosynthetic pathways of these metabolites (McKay et al., 2006).

Phenylalanin ammonia-lyase

TDF24 showed similarity with phenylalanin ammonia-lyase (PAL-5) gene. Phenylalanine ammonia-lyase catalyzes the conversion of L-phenylalanine intotrans-cinnamate, the initial committed step of the multi-branched phenylpropanoid pathway in higher plants. This is a key biochemical reaction in both plant development and defense. In tomato, at least five different classes of PAL genes were isolated. PAL 5 was distinctly (5-6-fold) more common. TDF24 was up-regulated after simulated acid rain stress. This type of PAL gene sequence also was found to be strongly expressed and differentially regulated in response to changes in light or wounding or to infection by a plant pathogen (Chang et al., 2008).

Glycosyltransferase

Glycosyltransferases, which catalyze the transfer of a sugar residue from an activated donor to an acceptor molecule, are found in all living organisms. Since plants, in contrast to animals, are sessile organisms and cannot move away from adverse environmental conditions they need to adapt themselves to environmental stresses

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65156533

(Wang et al., 2015). TDF11 expressed in tomato which evolved distinct mechanisms by which tolerance against acid rain can be achieved.

Zinc finger protein kinase

About two to three-fold increase in the expression of the cDNA (TDF7) encoding a cys2/his2 zinc finger protein kinase conferred tolerance to simulated acid rain stress in tomato. Over-expression of the members of zinc finger protein kinase family was also documented during salt tolerance in transgenic Arabidopsis and tobacco (Mukhopadhyay et al., 2004; Ragueh et al., 1989; Sakamoto et al., 2004). Stress-responsive zinc finger gene playing a role was reported in drought tolerance in petunia (Sugano et al., 2003).

Peroxisomal acyl-CoA oxidase

The peroxisomal acyl-CoA oxidase family plays an essential role in lipid metabolism by catalyzing the conversion of acyl-CoA into trans-2-enoyl-CoA during fatty acid beta-oxidation (Fabi et al., 2010). The TDFs including TDF4, TDF5, TDF8, TDF20, TDF27 and TDF30 were differentially regulated under simulated acid rain, indicating that these proteins may take part in the mechanism of anti-SiAR and play important role in the resistance to the stress.

Unknown genes

The large group of signal transduction, transcription regulation-related protein, stress- inducible proteins (68.9% of the 31 known or predicted genes) suggested that tomato can rapidly initiate the regulatory system and control the expression of simulated acid rain resistance-related genes. Also, many unknown genes, 31.1% of the total, had not been reported and consist of those that have not yet been associated with a response to abiotics stress, and some of these novel genes did not match any sequence from the GenBank databases, and might play important roles in the response of tomato to SiAR, indicating that multiple defense strategies lead to an enhanced SiAR defense capacity in tomato.

This work helped us to identify the responsive transcripts expressed under SiAR. Most of them are related with their previously studied genes involved in stress responses such as abiotic and biotic factors. The induction of these genes under SiAR suggests their function in possible regulation of acid rain adaptation in tomato. This is suggested by the association of most of the cDNAs with genes involved in biosynthesis of isoprenoid and phenylpropanoid, zinc finger protein kinase family, and lipid metabolism. Knowledge of acid rain tolerance can be enriched by studying the genes involved in the interconnected aspects like preventing or controlling the damage caused by acid rain, establishing the homeostatic environment in the stressful environment and resuming the normal growth at the reduced rate.

TDFs identified in our work revealed the genes related to lipid metabolism and biosynthesis of anti-oxidants of isoprenoid and phenylpropanoid, zinc finger protein kinase conferred tolerance to simulated acid rain stress in tomato which help in establishing homeostatic environment. However, some of the TDFs in the study did not show homology with any other known genes, indicating that further work is necessary to elucidate the mechanism of acid rain and biological roles of these genes in seedlings

DOI: http://dx.doi.org/10.15666/aeer/1703_65156533

of tomato. This progress will bring to the research community a huge wealth of information on novel acid rain-related genes.

Conclusions

Among of which 31 TDFs in leaves of tomato under simulated acid rain stress were cloned and sequenced. TDF5 and TDF8 were stress- inducible proteins. TDF4 and TDF20 played important role in resistance to SiAR stress. TDF2 was related to isoprenoid biosynthesis, TDF7 to transcription regulation, TDF11 to metabolism, TDF24 to plant development and defense. These 8 TDFs may play significant role in tomato resistance to acid rain-stress. Further study is necessary to elucidate the roles of these genes in tomato under SiAR stress.

Abstract. In models of global change, the course of the general circulation of the atmosphere is dependent on the planetary distribution of sources and sinks of energy; during periods of balance, energy is transported by atmospheric air and the water of the oceans. The atmosphere must thus transport the energy of the continents towards the oceans during the summer and that of the oceans towards the continents during the winter. The study of these phenomena on the continents uses data related to studies of actual evapotranspiration on a local level, which is the level presented here. Recent models of actual evapotranspiration dissociate evaporation of the soil from canopy transpiration and interception, and simulate the evolution of the structure of cover, stomatal resistances, and factors which govern vapour water flux resistance and the balance between evaporation and transpiration. In today's models which take a mechanistic approach, the difficulty of choosing income parameters has become significant, especially the problem of their initial state under a given set of environmental conditions. The objective of this paper is to point out the potential use of the Penman-Monteith formula, which has worked well for the actual evapotranspiration phenomenon of close covers and can be adapted to sparse vegetation (herbaceous savannah with areas of bare soil), while treating leaf transpiration and bare-soil evaporation separately. The actual evapotranspiration of the herbaceous savannah is limited by a boundary layer resistance of the same order of magnitude as surface resistance plotted to the stomata and leaf area index, whereas that of woody covers is limited only by surface resistance: the stomata of trees are more sensitive to the drying of the air and soil than those of herbaceous plants.
Keywords: *drylands, Sudano-Sahel, sparse vegetation, Penman-Monteith equation, evapotranspiration, surface resistance*

Introduction

In actual evapotranspiration models of plant cover with mechanistic vocation, the problems are (a) the choice of the most significant input parameters; and (b) their initial calibration in a given set of environmental conditions. The purpose of this paper is to present the advantages of using the Penman-Monteith formula (Monteith and Unsworth, 1990).

The actual evapotranspiration of herbaceous savannahs is limited by boundary layer resistance which is of the same order of magnitude as cover resistance, which in turn is related to stomata resistance and leaf area index, whereas the actual evapotranspiration of plantations is limited only by cover resistance: the stomata of trees are more sensitive to drying of air and soil than those of herbaceous plants.

In this article, for the estimation and modelling of actual evapotranspiration, the time-step resolution is one day; conditions are equivalent to so-called 'conservative flux' in which absorption is equal to transpiration, which is rarely the case in reality for a time-step resolution of less than one day, during which the plant is subject to dehydration and rehydration, but which is realistic for a 24-h time-step resolution.

Historically Penman (1948) and Monteith (1965) laid the physical foundations for calculating the evaporation of a wet surface and subsequently the actual evapotranspiration of closed plant cover.

The aim of the work described in this paper is to highlight the quality and relevance of the Penman-Monteith model. Nevertheless, on the one hand, even for continuous covers, it is necessary to refine the parameters of the canopy resistance. On the other hand, it was relevant to check the Penman Monteith model for sparse covers crops using the field experience (here the savannahs of the Sahel and the Atlantic coast of Congo); this model makes it possible to account for the actual evapotranspiration of closed plant cover (woody plants) and ought be adapted to sparse cover (woody herbaceous savannah with bare soil surfaces) by treating leaf transpiration and evaporation of bare soil separately.

Materials and methods

Theory of evapotranspiration measurements

For uniform and sufficiently large surfaces with very small slope values, sensible heat and latent heat fluxes are considered vertical and are subject to the principle of 'similarity' between the coefficients of sensible heat transfer (k_H) and latent heat (k_E); thus $k_H \approx k_E$. Empirical relationships between flows and vertical gradients of sensible and latent heat can be expressed in the form known as the Penman-Monteith equation (1965):

$$Ea = \frac{ET_0}{\left(1 + \left(\frac{\gamma}{\Delta + \gamma}\right) \cdot \left(\frac{r_{st}}{LAI \cdot r_a}\right)\right)} \quad \text{(Eq.1)}$$

where: Ea is actual evapotranspiration (mm day^{-1}); ET_0 is potential evapotranspiration (mm day^{-1}) (in this paper, we applied an equation associated with the FAO formula used by Allen et al., 1998); γ is the psychrometric constant (mb K^{-1}); Δ is the slope of the saturation vapour pressure vs temperature curve (bar K^{-1}); r_{st} is stomatal resistance (s cm^{-1}); *LAI* is leaf area index; (m^2 m^{-2}); r_a is aerodynamic resistance (s cm^{-1}).

Crop boundary layer diffusion resistance

The Penman-Monteith equation involves the quantification of *aerodynamic resistance* of plant cover (r_a), *crop cover resistance* (cover resistance) (r_c), and climatic variables. Aerodynamic resistance is a physical quantity that accounts for the diffusion of heat or water vapour from leaf surfaces into the atmosphere (*Fig. 1*).

Cover resistance (r_c) is chiefly a biological term that accounts for the diffusion of water vapour from leaves in terms of a leaf's stomatal resistance to such diffusion, r_{st}. The following simplified equations are used for closed plant cover (Saugier, 1996):

$$r_a = \frac{r_b}{LAI} + r_{a(1)} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65356547

$$r_c = \frac{r_b + r_{st}}{LAI} + r_{a(1)} \quad \text{(Eq.3)}$$

where: r_b is leaf boundary layer resistance (s cm^{-1}); *LAI* is leaf area index (m^2 m^{-2}); $r_{a(1)}$ is aerodynamic resistance (s cm^{-1}); r_{st} is stomatal resistance (s cm^{-1}).

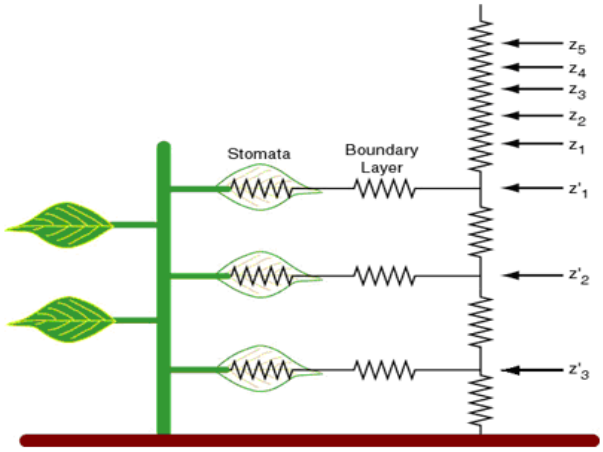

Figure 1. *Model schematically showing the resistance of given vegetation cover (r_c). Resistance levels are represented by serrated segments. In the 'big leaf' model (Monteith, 1965) the resistance of the vegetation cover (r_c) refers to one vegetation layer*

These equations assume that the leaf resistances of the entire canopy are identical at all times, but this is not actually the case: from the top to the bottom of the canopy, r_b increases due to a decrease in wind speed, and r_{st} increases due to a decrease in global radiation (R_g) (see the detailed analysis by Saugier, 1996); in addition, leaf growth conditions depend on the position of leaves in the canopy architecture; the top and bottom leaves do not share the same physiological characteristics (leaves are designated 'shadow' and 'light').

Aerodynamic resistance

Aerodynamic resistance is composed of leaf boundary layer resistance to the diffusion of heat or water vapour and resistance of the air between the middle of the canopy (average height of the canopy) and the height above the canopy where it is technically possible to measure meteorological variables. We calculate r_a or its inverse, $1/r_a = g_a$, and aerodynamic conductance, assuming equality between the transfer coefficients for heat (k_H) and for momentum (k_V):

$$r_a = \left(\frac{1}{\left(k^2 \cdot u_{2m}\right)}\right) \cdot \left[\ln\left(\frac{z-d}{z_0}\right)\right]^2 \quad \text{(Eq.4)}$$

where r_a is aerodynamic resistance (s cm^{-1}); k is the von Kármán constant (0.39); u_{2M} is wind speed (m s^{-1}); *z* is height above ground (m); z_0 is roughness height (m); *d* is zero plane displacement height (m).

For tree-covered areas we calculated g_a from stand height as well:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65356547

$$d = 0.75\ h \quad \text{(Eq.5)}$$

$$z_0 = 0.1\ h \quad \text{(Eq.6)}$$

where h is mean tree height (m).

Cover resistance

Canopy resistance depends on the stomatal resistance of the leaves and the leaf area index of the canopy in question. Canopy transpiration is the sum of transpirations of all leaves; each leaf is characterised by instantaneous stomatal resistance which is dependent on its own physiological characteristics and the microclimate to which it is subjected.

In terms of stomatal resistance: stomatal movements (depending on the turgor of the guard cells) are governed by global radiation, air vapour pressure, soil water content, and leaf water status.

The mechanisms through which stomata respond to the last three factors are still being discussed:

- Humidity of the atmosphere: more and more often, it is said that stomata are dependent on relative air humidity, and may also be dependent on the deficit of saturation of the air associated with the flow of water inside the leaf; however, it is unclear what kind of mechanism is involved;
- Soil water content status: the influence of soil water content on stomatal movements has long been explained by its action on leaf water status, i.e. a decrease in soil water potential leads to a decrease in leaf water potential resulting from a threshold potential stomatal closure. However, today we know that a plant that is adequately supplied with water but subject to high soil water potentials will close its stomata: roots, in contact with dry soil, synthesise abscisic acid which acts directly on the stomata, irrespective of the water status of the plant. Among the species we studied, Balanites aegyptiaca may correspond to this scenario: in the course of soil drying, when higher soil layers contain no more water available for the plant, but deeper layers still contain available water, Balanites aegyptiaca will close its stomata during the days, even from late at night until sunrise, there may be no stomatal opening);
- Plant water status: there is no simple causal relationship between stomatal movements and leaf water potential. Thus, with equal leaf water potential, the stomata are closed at night and open during the day. Depending on the species, soil drying causes stomatal closure, with or without an impact on leaf water potential. The species we worked on correspond to the first case, with the exception of Balanites aegyptiaca. During a period of soil drying, Balanites aegyptiaca employs a leaf area index modification strategy (falling leaves) associated with maintaining a high level of leaf water potential for the remaining leaves (during a period corresponding to a drought). Among the strategies of a plant subject to drought are those relating to the flow of water in the plant and those relating to the distribution of assimilated materials; however, in general, a larger share of carbon goes to the roots, and/or reduction of leaf growth and acceleration of senescence occurs.

Stomatal resistance is usually systematically measured in the field, as we have done here, but currently only empirical models are available to account for variations in this resistance along with environmental factors. The stomatal resistance of a leaf can be calculated, using

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65356547

the empirical models of Jarvis (1976), from the relationships between the minimal stomatal resistance of a leaf, leaf water potential, global radiation, air saturation deficit, and soil water content.

Stomatal resistance depends on *minimal stomatal resistance,* a specific point value corresponding to a situation characterised by the absence of water stress (soil and plant). Minimal stomatal resistance changes over time, from a leaf's appearance to its senescence; it decreases to a minimum value, then rises again (morphological and physiological evolution of the leaf), as we have observed in the species we studied (*Fig. 6a-d*). In deciduous species (oaks, *Acacia*, Rubber tree), where all of the leaves of the canopy evolve grosso modo synchronously, canopy resistance is a function of minimum stomatal resistance and leaf area index.

In evergreen species (*Eucalyptus* spp.), the degree of dependence of canopy resistance on minimum stomatal resistance depends on the renewal rate of the leaves, since leaves of varying ages coexist in the cover (sampling problem).

To estimate historical *crop cover resistance,* we began by assuming that all leaves were similar (i.e. shared the same physiological characteristics, even microclimate).

- Katerji and Perrier (1985) estimated the variability of stomatal resistance throughout the canopy and divided the cover into several layers to which they applied the equation given above (*Eqs. 2* and *3*).
- Saugier and Katerji (1991) proposed a calculation based on the exponential decay of global radiation and the cumulative leaf area index from the top of the canopy, as well as on integration of the variation of stomatal resistance with received global radiation.
- Other authors calculate cover resistance (r_c) from latent heat flux measurements above the canopy using micrometeorologic methods, reversing the Penman-Monteith equation; closed crop cover is considered a 'big leaf' whose aerodynamic resistance must be a known value.

We started by using the Jarvis (1976) model. Then, for the savannah of the Congolese littoral, we used an inverse Penman-Monteith equation, with parallel measures of stomatal resistance and environmental factors; this latter approach enables deterministic analysis of cover resistance. Measurement of leaf area index is decisive in estimating this resistance.

Climate variables

Another variable which is difficult to estimate using the Penman-Monteith equation is the air saturation deficit, which should theoretically and ideally be measured above the vegetation in the layer of the atmosphere constantly modified by evapotranspiration (surface boundary layer) and various meteorological station values (short and well-watered lawns).

Some models exist for the estimation of air saturation deficit from the characteristics of the planetary boundary layer, a global layer subject to the exchange of energy and mass with the surface but not yet subject to the Earth's rotation (20-40 m at night and up to 3,000 m during the day).

Study sites and measurements

Study sites field work was carried out:

1) On a 1-ha plot (*Fig. 2)* situated on a dune's rise (including the dune's crest and hollow with 1.6% slope). The plot was located near Souilène, about 400 km from Dakar and 20 km from Dagana (16°20'30"N, 15°25'40"W). The study area is a Sahelian zone

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65356547

in the northern Ferlo region (North Senegal, West Africa). The climate of the region is dry tropical with mean annual precipitation (1918-1990, Dagana) of 282 mm $year^{-1}$. This Mimosaceae thorn scrub has three main vegetation layers: a herbaceous layer (mainly composed of annual grasses) dominated by shrub and small trees layers. The landscape is typically a gently undulating surface composed of low magnitude non-oriented dunes that end in small hollows. The overstore canopy is mainly 20 year old *Acacia tortilis* (Forsk.) Hayne ssp *raddiana* (Savi) Brenan and 25 year old *Balanites aegyptiaca* (L.) Del; stand density is 151 trees ha^{-1} and the total basal area is 3.87 m^2 ha^{-1}. On the 1 ha plot we seleted agrove with *Acacia tortilis,* a grove with *Balanites aegyptiaca* and a herbaceous zone outside the tree ccrown shade (without trees). Mean height of *Acacia tortilis* and *Balanites aegyptiaca* trees was 6.60 m and 6.40 m, respectively, and mean stem diameter at soil level was 0.56 m and 0.61 m. The age of selected trees, (20 and 25 years, respectively) correspond to the most important populations in the pyramid-shaped diagrams representing the populations of *Acacia tortilis* and *Balanites aegyptiaca* by age-groups. Every grove possessed its characteristic herbaceous layer (annuals). The plot's soils belong to the brown sub-arid sandy soils which are slightly acid (pH 6-6.5) and poor in clay, organic matter, nitrogen and phosphorus. The study zone is a rangeland with average annual primary production of the herbaceous layer (2895 kg DM ha^{-1} $year^{-1}$) being 10% lower than the actual demand of the grazing livestock. The continuous livestock presence destroys the crust at the soil surface and promotes infiltration of rainfall.

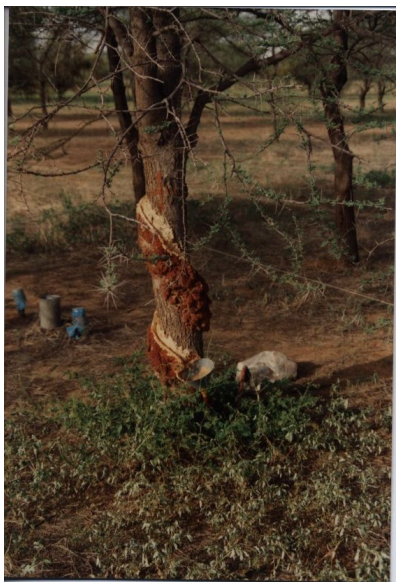

Figure 2. *Experimental site located in the Ferlo region (northern Senegal). Landscape formed by a very open thorny steppe, including a herbaceous layer composed of annual species, dominated by grasses (average dry-matter yield, 2,895 kg ha^{-1} $year^{-1}$) and dotted with trees and shrubs (Acacia tortilis and Balanites aegyptiaca) with an average height of 6.5 m, a density of 151 trees ha^{-1}, and a total basal area of 3.87 m^2 ha^{-1} (Nizinski et al., 1994)*

(2) On two plots located (*Fig. 3a*) near Kondi (latitude 4°34'S, longitude 11°54'E, altitude 80–120 m above sea level), about 40 km north from Pointe Noire (Congo). The Kouilou region (covered 13315 km^2) is situated on the Atlantic Ocean front of the Congo between Cabinda in the South and Gabon in the North; the climate of the region

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65356547

is subequatorial tropical with mean annual rainfall $Pi_{49–98}$ = 1188 mm, potential evapotranspiration $Ep_{92–98}$ = 1390 mm year^{-1} ($Ep_{92–98}$ = 3.8 mm day^{-1}; $Ep_{\text{RAINY SEASON}}$ = 4.2 mm day^{-1}, $Ep_{\text{DRY SEASON}}$ = 3.2 mm day^{-1}), mean air temperature 24.9 °C (t_{max} = 28.2 °C, t_{min} = 21.9 °C), relative air humidity 81.1% (H_{max} = 95.5%, H_{min} = 66.4%) (long-term values estimated over the period of 1949–98, meteorological station, Pointe Noire). The rainy season, which lasts about 180 days, starts in November and ends in April, the dry season from June to September; May and October are the months of transition. The study area is situated on thick detritic formations of continental origin, dating from the pliopleistocene. The soils are ferrallitic and highly desaturated, on sandy to sandy clay material (grayish-ochre colour, more than 90% of sand content and particular structure).

Sampling and measurement techniques: water balance, plant water status and environmental measurements

- Weekly measurements: gross precipitation, throughfall (22 rain gauges "Association"; collecting area 8800 cm^2), stemflow (10 stemflow collars), soil water content (neutron probe "Solo25", Centre d'Etudes Nucléaires, Cadarache, France; 8 permanent access tubes).
- Hourly measurements: leaf water potential (pressure chamber PMS, Inst. Co., Corvallis, Oregon, USA), leaf transpiration, stomatal resistance (porometer AP4, Delta-T-Devices, UK), soil water potential (tensiometers, Soil Moisture Equipment Corporation, Oh, USA).
- Leaf area index (*Fig. 3b*): maximal leaf area index and leaf area distribution will be reported, the total leaf area divided by the area covered by the leaf area, obtained by direct measurements of the number of leaves of the year harvested (litter fresh).
- Stomatal resistance (r_s): measurements were made using an AP4 porometer, Delta-T-Devices® (*Fig. 4*). Porometers measure gaseous exchanges between the leaf and the atmosphere. These fluxes are proportional to the surface of the leaf, to the concentration gradients of the gas between the inside and the outside of the leaf, and to the conductivity (= 1 / resistance) of the leaf. In open systems, a constant flow of air and a known water vapor concentration enters the chamber where the leaf is located, and the concentration of outgoing water vapor is then measured. It is then possible to calculate perspiration and stomatal resistance.

Results and discussion

Impact of leaf area index on actual evapotranspiration: The actual/potential evapotranspiration ratio increases with increasing leaf area index according to the function:

$$E_a/ET_0 = 1\text{-}e^{(-k\ LAI)} \qquad \text{(Eq.7)}$$

where k is the extinction coefficient of light in the cover (Saugier, 1996) and LAI is leaf area index (m^2 m^{-2}).

Depending on the type of vegetation, the differences in this curve (*Eq. 7*) are larger or smaller. The measurement and modelling of leaf area index are therefore essential.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65356547

We will illustrate the influence of leaf area index on actual evapotranspiration with two situations: a temperate oak forest, representing a deciduous forest that we followed several years from bud break until the leaves fell, and the Sahelian steppe, representing heterogeneous vegetation.

a b

Figure 3 a. *Experimental site located in the watershed of Kouilou on the Atlantic coast of Congo (view from the study site).* ***b.*** *LAI measurement of savannah 90% dominated by Loutetia arundinacea (average height, 1.5 m; maximum biomass, 3.5 tonnes ha^{-1}; maximum dead biomass, 4.6 tonnes ha^{-1}; leaf area index, 4.3; root zone, 3 m in depth; field capacity (R_{FC}), 363 mm; permanent wilting point (R_{WP}), 182 mm; available water content (R_{AW}), 181 mm)*

Figure 4. *Stomatal resistance measurements were made using an AP4 porometer, Delta-T-Devices®*

For the savannahs (Sahelian steppe, *Fig. 2;* savannah of the Congolese littoral, *Fig. 3a*), we estimated g_a from the profiles of the wind speeds above these herbaceous covers (from 2.5 to 5.0 cm s^{-1}).

The overall values of aerodynamic resistance reflect the fact that resistance decreases with roughness of the canopy and wind speed. For sparse vegetation, no formula has been developed as yet for the calculation of aerodynamic resistance. For the Sahelian steppe, composed of 80% herbaceous areas (groves of low trees), we assumed the equality of aerodynamic resistance in herbaceous zones and groves, which, given the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65356547

low density of trees within groves, is reasonable: resistance is even higher than density is low; otherwise, regarding estimates of interception (in which only aerodynamic resistance occurs), it can be assumed that there is no overestimation here either, because rains are of great intensity and the water retention capacity of crowns and trunks is low (2.9-3.8 mm for *Balanites aegyptiaca* and *Acacia raddiana*, respectively) (*Fig. 2*).

The maximum values of interception of *Balanites aegyptiaca* and *Acacia raddiana* groves equal 8.4 and 12.4% of incident rainfall (Pi), respectively. These values can reach 40% of Pi for oaks in the temperate zone (forest of Fontainebleau). The maximum values of interception of groves (8.4 and 12.4% of Pi, respectively) are of the same order of magnitude as that of the herbaceous zones of the Sahel savannah (7.5% of Pi) (*Fig. 2*) and the savannah of the Congolese littoral (7% of Pi) (*Fig. 3a*).

In the case of *deciduous species*, it is a question of modelling various phenological stages: the day of bud burst; the period of leaf growth up to maximum leaf area index; the adult phase during which the leaf area index is equivalent to the maximum value ($LAI = LAI_{max}$); the beginning of senescence from the first fall of leaves until the leaf area index equals zero. For *Quercus petraea*, using two simple input variables [mean air temperature and photoperiod] we modelled the day of budburst, the day marking the end of surface growth of the leaves, and the evolution of leaf area index.

In terms of the relationship of minimal stomatal resistance to leaf area index in deciduous species, with the exception of Eucalyptus, the species we studied are deciduous. The leafless period is the cold season in the temperate zone and the dry season in the tropical zone. Thus we were able to analyse the following phenomenon: when setting up the canopy, the minimal stomatal resistance of a leaf decreases with increasing leaf area index and generally continues to decrease to its minimum value as long as the leaf area index is maximal (*Fig. 5*). The leafless period may be longer or shorter depending on the species (LAI_{max} – minimum values $r_{st\text{-}min}$; in *Quercus petraea*, LAI = 100%, $r_{st\text{-}min} = 3.6 \pm 0.9$ s cm^{-1} and LAI = 8%, $r_{st\text{-}min} = 8.7 \pm 3.6$ s cm^{-1}, respectively) (*Fig. 6a-d*); for example, in oaks, it is very short (two to three weeks). Subsequently, $r_{st\text{-}min}$ increases throughout the period of LAI_{max} (two and a half months for the oak) and continues to increase during senescence.

In deciduous forests, actual evapotranspiration follows changes in leaf area index; as there is a gap between the points when $LAI = LAI_{max}$ and when $r_{st\text{-}min}$ reaches its minimum value, actual evapotranspiration reaches its maximum (when not subjected to water stress) when $r_{st\text{-}min}$ is at its minimum value for oaks, i.e. about a month after $LAI = LAI_{max}$ (*Fig. 7*).

Balanites aegyptiaca offers an example of adaptation to drought. To summarise the characteristics that may explain its distribution (this species 'goes up' to the northernmost part of Senegal) and the current increase in its frequency compared to other shrub and tree species of the Sahelian steppe: in the dry season, when water availability becomes limited, we observed that *Balanites aegyptiaca* employed a strategy of maintaining high leaf water potential through increased stomatal resistance ('ABA message' from the roots) and a leaf area index modification strategy (falling leaves). Thus, at the end of the dry season when *Balanites aegyptiaca* no longer has leaves, soil water that was available but not used (increased stomatal resistance, decreased transpiration) remains in the deep layers of the soil (deeper than 2.0 m).

Subsequently, bud break and leaf growth occur prior to the rainy season, during a period when the relative air humidity increases; this leaf growth is possible because there is water available deep in the soil.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65356547

This leads us to make two assumptions:

(1) We posit the existence of a chemical 'message' related to detection of the increase in relative air humidity. This message participates in the chemical equilibrium of induction at bud break. This detection must be performed by an above-ground organ, possibly the photosynthetic stalk (thorns), which remains in place.

(2) We suppose that this message has priority over the 'ABA message' from the roots, since the leaves are being put in place while the soil water content of the upper layers are at the permanent wilting point, in 'soil conditions' identical to those of the end of the dry season. Here, we can question the adaptive advantage of setting up the leaves prior to the arrival of the rainy season.

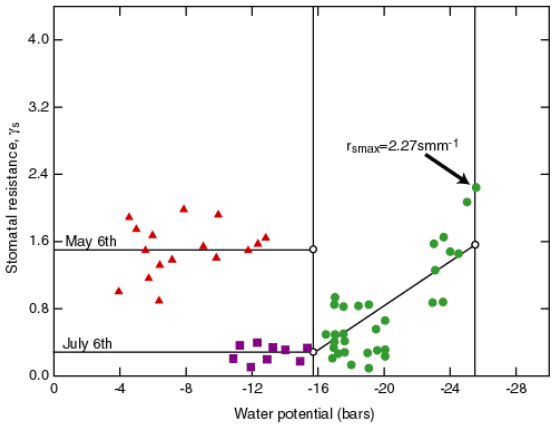

Figure 5. *Evolution of minimal stomatal resistance ($r_{st\text{-}min}$, s cm^{-1}) with leaf water potential (Ψ_m, bars) for oak leaves in the forest of Fontainebleau and in the park of the Orsay University of during the growing seasons of 1983 and 1987, respectively ($r_{st\text{-}min} = 78.501\ SF^{-0.7505}$; $r^2 = 0.905$; N = 12)*

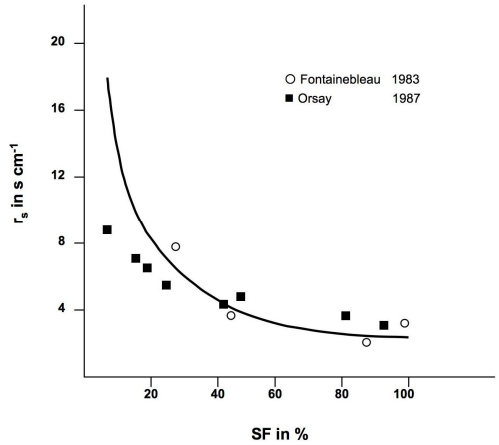

Figure 7. *Evolution of minimal stomatal resistance ($r_{st\text{-}min}$, s cm^{-1}) along with leaf area (SF, %) for oak leaves during the growing season of 1983 in the forest of Fontainebleau*

Conclusion

Humankind has changed and continues to change plant cover; globally, there has been an increase in herbaceous and bare-soil areas to the detriment of areas that had been populated with trees and shrubs since the Neolithic. Changes in vegetation cover have involved changes in local and regional climates as well as in the global climate.

Climate models of the general circulation of the atmosphere require actual evapotranspiration models which incorporate 'vegetation-atmosphere' exchanges as realistically as possible. Our studies of *Acacia raddiana* and *Balanites aegyptiaca* in the steppes of Senegal (Nizinski et al., 1994) and of *Loudetia arundinacea* in the savannah and eucalyptus plantations on the coast of the Congo (Nizinski et al., 2011) offer two examples of the impact of a change in cover on actual evapotranspiration: in Senegal, the groves of the steppe (20% of the surface) may be assimilated into the 'clear forest' of *Acacia senegal* in Northern Senegal before this forest disappears and an 80% herbaceous area represents the new ecosystem.

In Congo, on the coast, there are remnants of pure savannah adjoining the planted eucalyptus forests in the original savannah. The replacement of the forest with a herbaceous ecosystem is increasing drainage and reducing actual evapotranspiration over a complete cycle of vegetation (with seasonal variations which may be marked, since the two ecosystems differ less in periods of water deficit than in wet seasons, when evaporation of intercepted water is greater in the forest due to its high degree of roughness).

For example, the 'boundary layer resistance' of the Congolese savannah is $Z_H \approx 3.0 \times$ stand height of plant cover in the case of sensible heat flux, and $Z_{\lambda E} \approx 3.5 \times$ stand height of plant cover in the case of latent heat flux. Methodologically, any fetch effects should be omitted, so that classical aerodynamic formulas can be applied.

The surface conductance of the two covers differs little; what differs is aerodynamic conductance, in which the two covers differ by a factor of two (from 2.5 to 5.0 cm s^{-1} for 'herbaceous' and from 5.0 to 10.0 cm s^{-1} for 'forest'). The two covers also differ in their albedo (superior in the case of the herbaceous ecosystem) and energy balance (inferior in the case of the herbaceous ecosystem). Actual evapotranspiration of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65356547

herbaceous ecosystem depends mostly on net radiation, actual evapotranspiration of the forest on deficit of air saturation.

Soil plays a major role: the surface state of the soil governs the existence (or absence) of runoff due to the presence (or absence) of a crust on the soil surface in sparse herbaceous ecosystems. The steppe occupied by *Acacia raddiana* in the first year after the experimental plot was set aside was characterised by a crust on the soil surface and non-renewal of the herbaceous layer, because this surface was no longer being trampled by herds of animals; in the second year, weeds replaced trampling. The hydraulic conductivity of the saturated soil also governs the existence (or absence) of runoff; this variable is generally lower in herbaceous ecosystems, which are often subjected to trampling by animals, than in forests.

The depth of soil colonised by tree roots is generally greater than that of soil colonised by grass roots: available water remaining in the soil of the steppe occupied by *Acacia raddiana* could be used if the steppe was forested. Lean and Rowntree (1997) give an example of the replacement of a forest (Amazon rainforest) with a meadow, pointing out that reducing the depth of the exploited soil does not affect the water balance. The Amazon rainforest contains areas where the potentially exploitable soil around the roots is shallow (existence of an impermeable horizon for the roots). In this case the forest has little available soil water content comparable to that of the grassland which succeeds it and whose soil is often characterised by significant underground water circulation. Here we see the importance of soil in regional water balance.

In models of global change, the course of the general circulation of the atmosphere is dependent on the planetary distribution of sources and sinks of energy; during periods of balance, energy is transported by atmospheric air and the water of the oceans. The atmosphere must thus transport the energy of the continents towards the oceans during the summer and that of the oceans towards the continents during the winter.

The study of these phenomena on the continents employs data relating to studies of actual evapotranspiration on a local level, which is the level presented here. Recent models of actual evapotranspiration dissociate evaporation of the soil, canopy transpiration, and interception, and simulate the evolution of the structure of cover, stomatal resistance, and factors which govern the vapour water flux resistances and the balance between evaporation and transpiration. In today's models which take a mechanistic approach, the difficulty of choosing income parameters has become significant, especially the problem of their initial state under a given set of environmental conditions. Currently, from a methodological point of view, for shrubs and tree species, estimation of the transpiration of individual trees using the sap-flow method opens up new perspectives.

The aim of the work described in this paper is to highlight the quality and relevance of the Penman-Monteith model. Nevertheless, on the one hand, even for continuous covers, it is necessary to refine the parameters of the canopy resistance. On the other hand, it was relevant to check the Penman Monteith model for sparse covers crops using the field experience (here the savannahs of the Sahel and the Atlantic coast of Congo); this model makes it possible to account for the actual evapotranspiration of closed plant cover (woody plants) and can be adapted to sparse cover (woody herbaceous savannah with bare soil surfaces) by treating leaf transpiration and evaporation of bare soil separately.

We conclude by stating that the fieldwork parallel to the modelling work is far from complete. We have shown that, for *Quercus petraea*, there is a factor of three between

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65356547

the minimum and maximum values of minimal stomatal resistance or from the range that one may assume very extensive drought adaptation characteristics such as those described for *Balanites aegyptiaca*.

Abstract. Satellite imagery was used to assess the suspended sediment concentration (SSC) of the plume at the Grijalva river mouth, Gulf of Mexico. The SSC was calculated with the algorithm of Topliss. The algorithm was created for Lansdast 5 MSS. For this study it was validated the results for Landsat 7 ETM+ and Landsat 8 OLI. The depth of the ocean floor was measured using the speedtech sounder. The spectral response was registered with a GER-1500 spectroradiometer (with a measurement range of 296.71–1092.08 nm). The spectral responses were used to determine the size of the suspended particles and to perform the atmospheric correction. Spectral responses indicate that silt size particles predominate near the river mouth, whereas clay overtakes further towards the open sea. The trend in the river when water meets seawater, means an increase of suspended sediment towards the surface due to the lower density of fresh water, and the amount of sediment rises in the open sea. The correlation between the measurements in situ and SSC values produced by the algorithm demonstrates that the operation is suitable to estimate suspended sediments.
Keywords: *Grijalva River, spectral response, sediments decrease, particles size, speedtech sounder*

Introduction

Suspended sediments in the plume of a river mouth control the delta morphology and ecology. In water bodies suspended sediments are quantified as a concentration, as the total amount of solids suspended in the mixture water-sediment, generally expressed in mg/l (Carbonneau and Piégay, 2012; Qu, 2016).

The importance of the study of suspended sediment concentration (SSC) in the delta and sediment plume of the Grijalva River, southwestern Gulf of Mexico, lies in the volume of water transported (140 km^3 per year; the river length: 1521 km), and the vulnerability that it represents in physical-geographic terms (Kemp and Piégay, 2016). A serious vulnerability issue in the delta is the coastline retraction; this phenomenon occurs at the State of Tabasco, southern Mexico, from Sanchez Magallanes (3 to 5 m

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65496562

per year) to the mouth of the San Pedro River, with 8–9 m per year (Hernández et al., 2008; Nooren et al., 2017).

The assessment of SSC could be done with sensors capable of detecting the electromagnetic radiations that arrive at Earth's surface from the atmosphere, where its reflectance can be recorded and processed (Sobrino, 2000; Zhou et al., 2017). Remote detection of water body's properties, as suspended and diluted matter, is based in the interaction between the electromagnetic waves and the molecules of water and its components (Bukata et al., 2018; Domínguez et al., 2011). Sediments suspended in water produce an increase in reflection of visible radiation, varying for different particle diameters, mainly in the blue and green bands (Chuvieco, 2008). Hence, remote sensing techniques have been used to measure the SSC, through models and algorithms showing potential at regional, multi-temporal and synoptic levels; costs involved in this procedure are considerably lower than those of in situ sampling and laboratory analysis (Nooren et al., 2017; Ritchie et al., 1987; Topliss et al., 1990; Wang, 2007; Long and Pavelsky, 2013).

Algorithms for SSC quantifying can be used in some cases to predict sediment concentrations under other rivers with similar conditions (Long and Pavelsky, 2013). Some studies had developed universal algorithms to estimate suspended sediments using sensors such as MODIS and MERIS; however, such algorithms require a minimum calibration (Ritchie and Cooper, 1991; Nechad et al., 2015).

Topliss et al. (1990) developed an algorithm to quantify the SSC for concentration ranges of 5–100 and 100–1000 mg/l with the Landsat MSS sensor (bands: green, red and infrared). The data derived from Landsat 7 ETM+ and Landsat 8 OLI TIRS—the sensors employed in this study—are compatible with the data at level 1 (orthorectified) created using Landsat 1 to 5 (Ariza, 2015).

This research has three main objectives. First, to determine the validity of new generation of Landast sensors (ETM+ OLI/TIRS) using the Topliss algorithm, which was designed and calibrated for Landsat 5 MSS sensor (Topliss et al., 1990). Second, to establish the statistical relationship of the algorithm for sensor OLI with the in situ SSC measurements in the Grijalva delta and plume. The third objective was to determine the size of the sedimentary particles suspended in river and sea water in the study area, through reflectance measurements obtained in the field by spectroradiometer, and to compare them with library theoretical signatures. Depending on the reflectance percentage the spectral signature, it is possible to determine of particle size and concentration of sediment.

Review of literature

So far there are only a few works available in the literature regarding suspended sediment concentration calculus. Most of the studies and algorithms developed, using satellite imagery, were carried-out in the 2000-2010 decade. Nevertheless, between current works, we can mention:

He et al. (2013): the authors implemented a monitoring of diurnal dynamics of sediments in the ocean employing meteorological images of GOCI. The variables adjusted in the model were those related with the atmosphere. They found results with differences of less than 5000 mg/l, except during typhoon season.

For the study areas of deltas connecting fresh water to the sea, Long and Pavelsky (2013) used MODIS imagery to determine SSC in the Peace-Athabasca, delta in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65496562

Canada. They applied 31 empiric equations using band 1 (620-670 nm) and band 2 (841-876 nm), obtaining a Sperman's correlation of ρ = 0.95 in 29 years of sampling.

Loisel et al. (2014) studied, over a period of 11 years, the SSC in the west of the Vietnam Sea. They used MERIS (Medium Resolution Imaging Spectrometer) data, with a spatial resolution of 300 m. They applied three algorithms, which allowed to eliminate atmosphere interferences and to differentiate fluvial sediments from those of the sea.

Time series allowed them to recognize the season of the year with the highest SSC (Monzoon season, in September-October). In November SSC starts to decrease, and in March and May is when drier periods appear. Results obtained with MERIS imagery were satisfactory, even with the spatial resolution of 300 meters per pixel. Algorithms employed has been successfully applied in other regions of the world, and with the modifications they made on some variables, they found a correlation coefficient of 0.7 between remote sensing techniques and in situ measurements, which is a good result for a remote sensing methodology (Loisel et al., 2014).

Material and methods

Study area

The delta and plume of the Grijalva river lie to the north of the Centla Municipality, State of Tabasco, southeastern Mexico (*Fig. 1*), between 525221.38 and 535316.162 m N and between 2066918 and 2054176 m W; (UTM North zone 15). The size of the study area is ~60 km^2, and the furthest sampling point was 10 km away from the coastline.

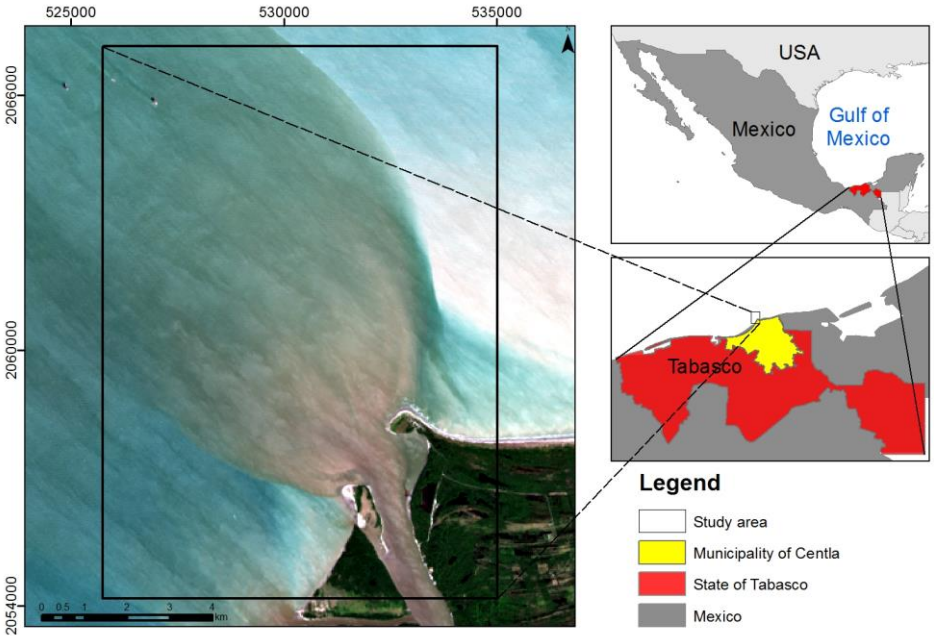

Figure 1. *Plume and delta of Grijalva River, Southeast Mexico. This river flows into the Gulf of Mexico*

The climate is *Am(w)*, that is, warm-humid with abundant rain in the summer, leading to marked periods of precipitation and drought (GET, 2006). Near the river

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65496562

mouth there are coastal cords, roughly parallel to the coastline, formed by sediments supplied by the Grijalva River during the last 5000 years, since the stabilization of the current sea level. Vegetation grows between the cordons formed in the water. The type of vegetation is a riparian forest of white poplar (*Populus alba*) and tule (*Schoenoplectus acutus*) (Bueno and Santiago, 2005; Nooren et al., 2017; Psuty, 1965); there are, in addition, mangrove swamps in zones nearby the river mouth.

Field data gathering and laboratory analysis

Sampling points were selected considering the dynamic distribution of sediments in the plume when entering in contact with seawater (cf. Arche, 2010), to avoid the effect of the soil and vegetation of the riverbank, with at least 1000 m distance between points (*Fig. 2*). Timing of sample collection considered the passing of the Landsat 8 satellite together with the presence of optimal meteorological conditions. Both conditions were encountered on January 25, 2016, when sampling activity was performed.

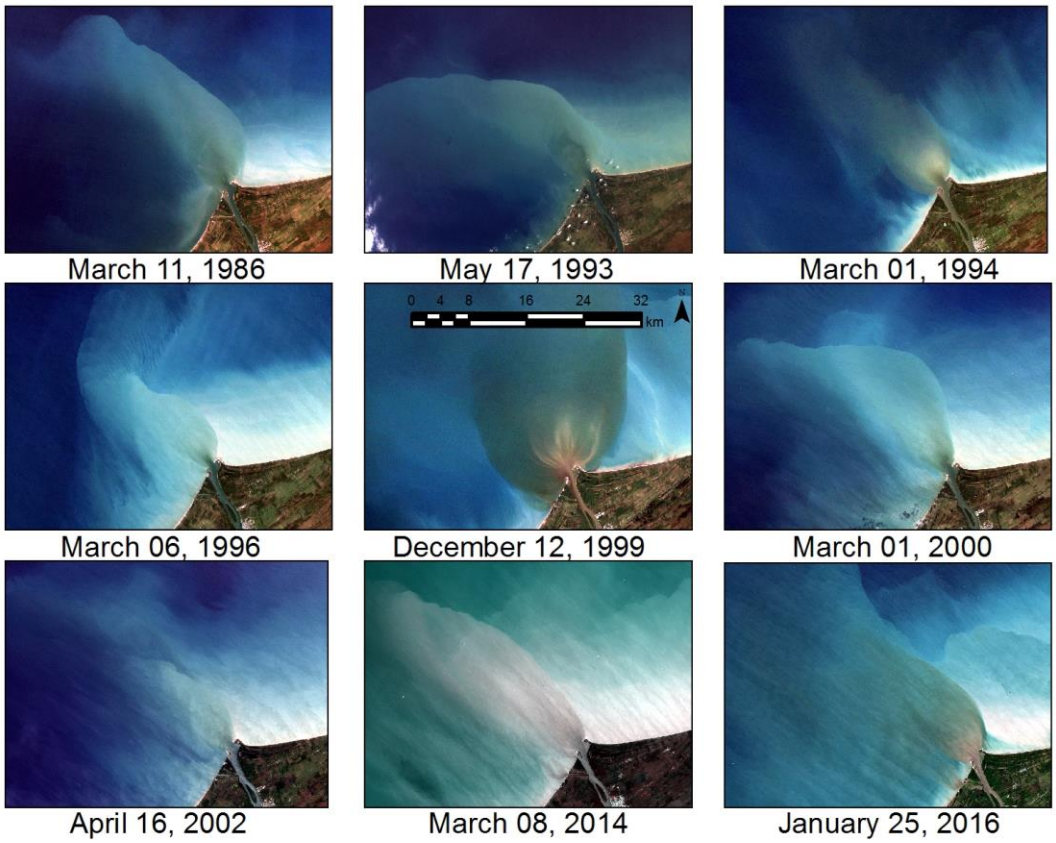

Figure 2. *Historical distribution of the Grijalva river plume. The last map (January 25, 2016) corresponds to the date of sampling*

Samples between 0.6 and 1.0 l of water were collected at a depth of 15 to 30 cm. Depth was measured with a Speedtech instrument and spectral response of the suspended sediments with a GER-1500 spectroradiometer whose measurement range is between 296.71 and 1092.08 nm in intervals of ~1.5 nm (*Fig. 3*).

In the laboratory, sediments were separated by a gravimetric method according to the Mexican norm NMX-AA-034-SCFI-2015. The method allows the quantitative

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65496562

measurement of the solids, dissolved solids, as well as the amount of organic matter contained in natural waters, residual, and treated wastewater.

In concordance with international standards, above mentioned norm coincides with ISO 11923:1997, Water quality – Determination of suspended solid by filtration through glass-fiber filters. However, some differences between them are found in the concepts; international method principle broaden solids determinations, drying device is different, reference suspension used has major concentration, and storage time of the sample is larger in the ISO standard. Mexican Norm maintains calculations for total suspended solids and incorporate them to another species not covered by ISO (Norma Oficial Mexicana, 2016).

Regarding the samples, every crucible with a Whatman 2 µm filter had a constant weight. A vacuum pump in a flask was used to filter 100 ml of each sample. A constant weight of sediment on a Whatman filter (2 µm) in a filtering crucible was dried in a stove at 105 °C for more than 12 h. From the weight of the residue, the concentration of suspended solids (mg/l) was calculated. Correlation and regression analyses compared these data with those obtained by remote sensing.

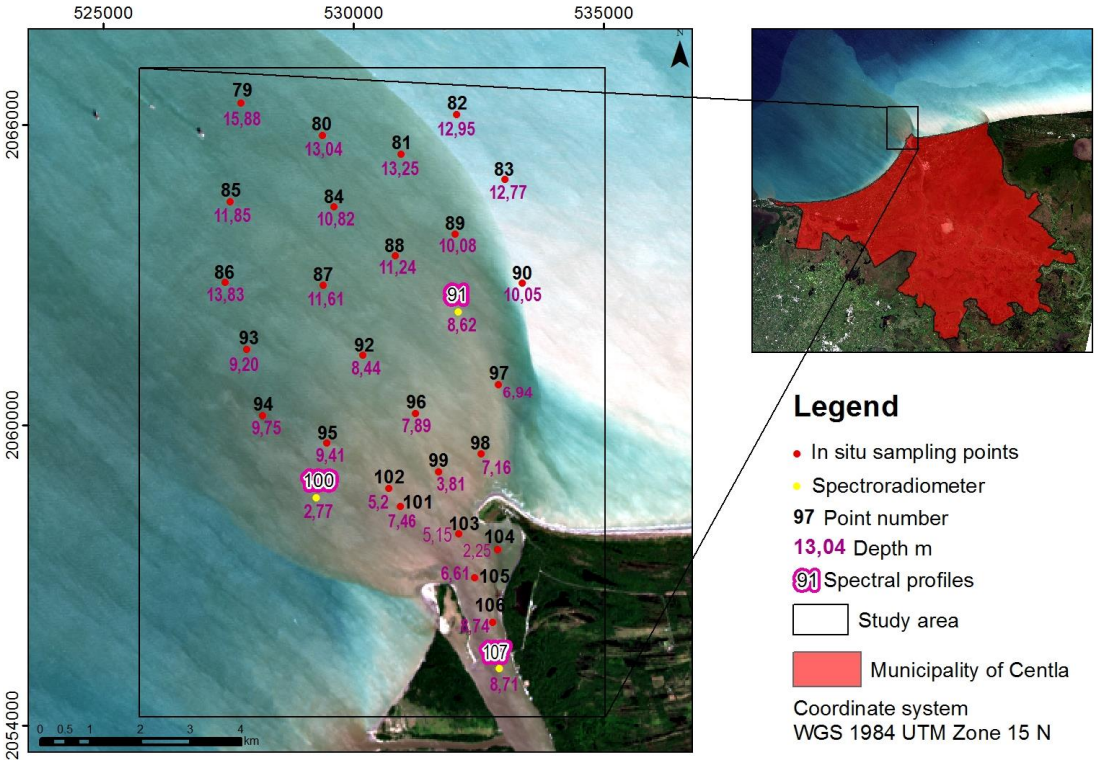

Figure 3. *Distribution of sampling sites in the Grijalva river sediment plume*

Remote sensing data

Satellite imagery of the study area (U.S. Geological Survey, 2016) corresponds to Path 22 and Row 47 for OLI sensor, and Path 21 Row 47 for ETM+. The ETM+ sensor revisit the same place with a difference of eight days. Imagery with adequate meteorological conditions was searched from various dates with no clouds present (0% of clouds). The image that corresponds to the date of sampling was obtained on January 26, 2016 for Landsat 8, with the time in the central scene at 16:35:21 hours and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65496562

February 03, 2016 with a time in the central scene at 16:13, for ETM+. Downloaded images were geometrically corrected with the cartographic projection WGS 1984 UTM zone 15 N.

Atmospheric corrections

The atmospheric conditions affect the radiometric response of the recorded images (Richards, 2013). Radiometric and atmospheric corrections eliminate these effects and convert digital levels in physical and biophysical variables (Padró et al., 2017). In the present study, images were corrected using physical models of radiative transference, usually based on a series of standard atmospheres (Chuvieco, 2008; Sobrino, 2000).

The FLAASH method (*Fast Line-of-sight Atmospheric Analysis of Spectral Hypercubes*) eliminates the effects of the atmosphere, the illumination, and other factors in the reflectance of the surface, and thereby generates more precise values; it combines directly the code of atmospheric radiative transference MODTRAN4, which allows direct selection of atmospheric models such as MODTRAN standard, and the diverse types of aerosols. Furthermore, the method can be applied to correct the adjacency effect and to calculate the visibility in the whole image (Liang and Wang, 2012).

Image processing

After the atmospheric and radiometric corrections, the image was cut according to the study area. The so-called salt and pepper error was corrected applying a media filter with a 3 × 3 kernel.

Land covers not belonging to water were masked with the application of NDVI and NDWI indexes. In the first case the water presents values less than zero and helps in the separability; in the second one higher values correspond to the water. NDWI method is based in the quotient of the reflectance of the near-infrared and the radiation emitted in the green portion of the visible part of the electromagnetic spectrum. This enhancement minimizes the reflectance of the soil and vegetation, highlighting water bodies (Feeters, 2013). NDVI index was developed to separate the reflectance of the green portion of vegetation from any other surface. However, it was proven useful to detect water surfaces (Rokni et al., 2014).

Hence, the two indexes together allow a better separation and identification of water bodies. Finally, the algorithm proposed by Topliss et al. (1990) was applied, this being a transformation of images to generate new variables not available on the original imagery.

Results

Dispersion graphics

The correlation coefficient between the SSC obtained in the laboratory and the SSC captured from satellite imagery using the algorithm (*Fig. 4a*) was 0.47; thus, the relationship between the two measurements is low. The determination coefficient R^2 was 0.228, which suggests that the model explains 23% of the variance. Results from Landsat 7 were very similar, correlation coefficient was 0.52, with a lineal coefficient R^2 of 0.279.

However, if 9 points (80, 81, 83, 84, 87, 90, 91, 92 and 95) were ruled out, because they had depths less < 15 cm. It is possible to have an interference with the basement in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65496562

shallow depth. The correlation coefficient without the discarded samples is 0.65, with $R^2 = 0.42$; this increases the possibility of the estimation of the sediments using the algorithm, since the model here explains 42% of the variance. Results from Landsat 7 without the discarded samples were $R^2 = 0.34$ and the correlation coefficient 0.58 (*Fig. 4b*).

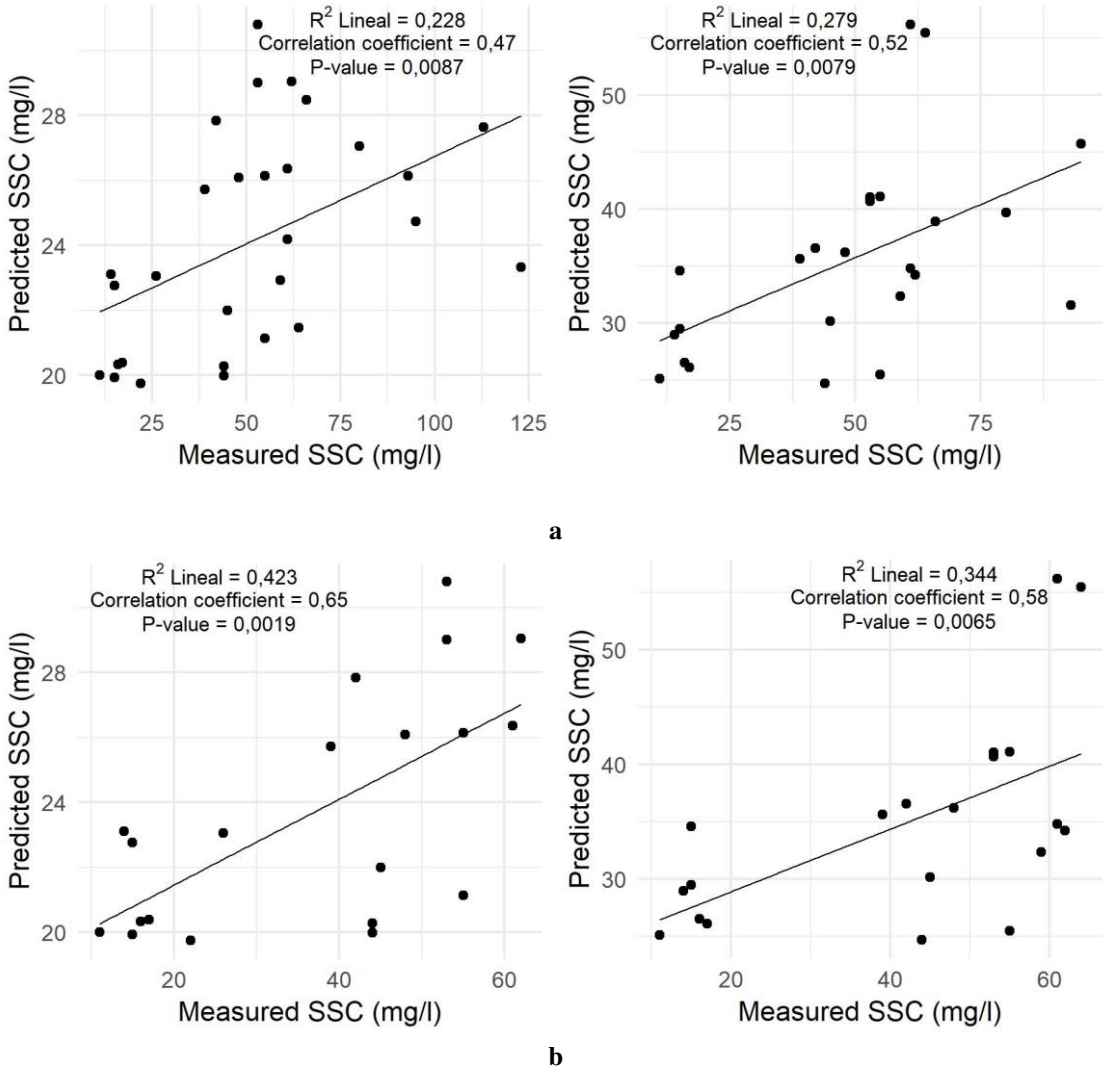

Figure 4. *Dispersion diagrams of SSC measured in situ vs. results obtained by algorithm.* ***a*** *Results with 29 samples. In these plots data obtained from OLI sensor (left) and from ETM+ sensor (right) are shown.* ***b*** *Results with 20 samples are depicted on the left with data obtained from OLI sensor and on the right with data gathered from ETM+ sensor*

The mean squared root (MSR) error between the two methods was 38.71 mg/l, in agreement with the poor correspondence between the algorithm results and the observations, as indicated by the correlation coefficient. When the anomalous points are omitted, the MSR error falls to 17.01 mg/l. The correlation levels indicated by P values suggest that the test statistics are significant and that it is possible to apply the algorithms for Landsat 7 ETM+ and for Landsat 8 OLI.

DOI: http://dx.doi.org/10.15666/aeer/1703_65496562

Mapping SSC

The measurements recorded in situ were geographically represented by kriging interpolation. Maps of the SSC distribution in the delta and the plume of the Grijalva River on 25 January 2016 (*Fig. 5A*) show concentrations to be low at the river mouth and gradually increase as the stream flows out to the open sea. The results of measurements show that SSC at points on the continental shelf are greater than those at the river mouth or in the river channel. This suggests that sediments moving along the river are transported by the water column likely near the bottom, and that when fresh water encounters seawater the difference in their densities causes former to rise, carrying the sediments up towards the surface. These sediments are subsequently distributed to form the plume of the river.

The concentration of suspended sediments measured in the laboratory (*Fig. 5B*) and mapped using kriging interpolation gradually increased in the direction of the open sea. Nevertheless, the result of the interpolation does not show the whole structure of the plume, particularly between 2062000 N and 2066464 N, because this method estimates the data of non-sampled spaces and therefore does not adhere to the shape of the plume.

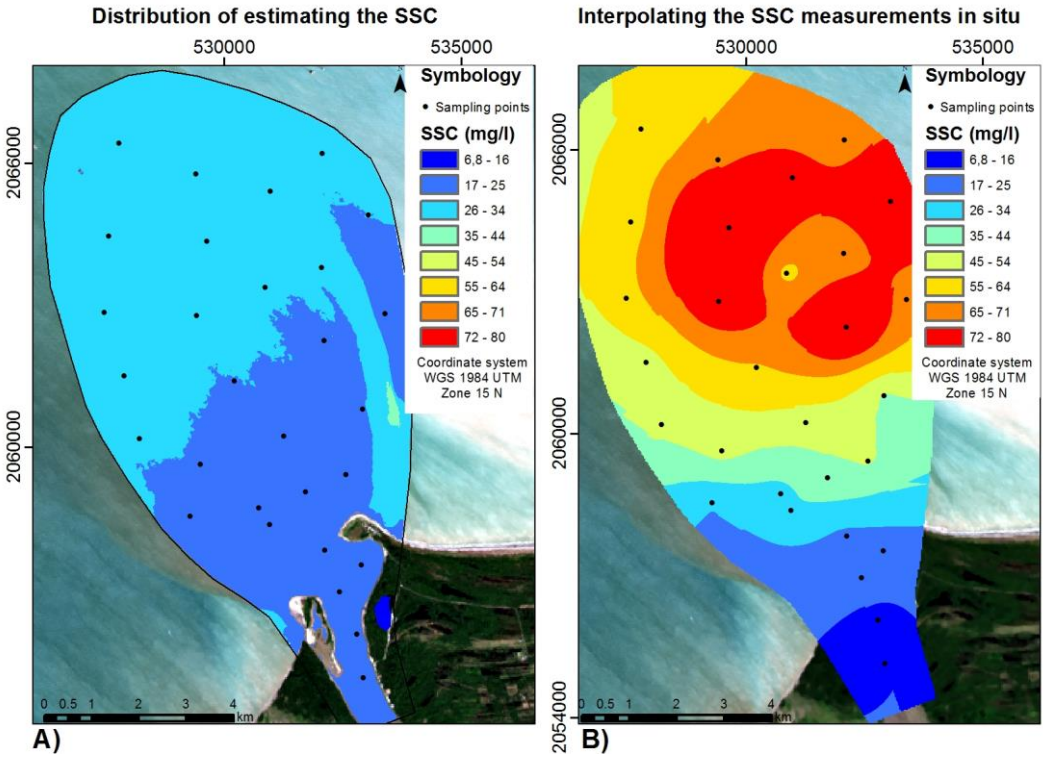

Figure 5. *Cartographic representation of (A) results in laboratory and (B) Kriging interpolation*

Spectral response analysis

In the spectral response analysis of suspended sediments, a comparison of in situ spectral signature against that one extracted from Landsat 8 was carried-out. A covariance between these two variables was found (*Fig. 6*). It is important to mention that the spectral response of Landsat 8 image was obtained using only seven

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65496562

atmospherically corrected bands, meanwhile with the spectroradiometer, 316 bands with intervals of approximately 1.5 nm were used.

Figure 6 shows the spectral responses of the five sampling sites where the spectroradiometer was used; one point with the spectral response obtained from the satellite image is located 35.5 km before of the end of the plume of sediments and another is in the river mouth, where the water is practically free of suspended materials (*Fig. 6*).

At Point 91, the spectroradiometer showed the highest reflectance (16.5%; *Fig. 6a*). This sampling point also coincides with the site of the highest SSC obtained in the laboratory (123 mg/l). However, according to the theoretical signature of SSC, at this point concentration should be 600–1000 mg/l. Measured concentration from the field sample compared against theoretical signature value registered a difference of ±870 mg/l. At point 100 (*Fig. 6b*), reflectance was 8.1% and the concentration was 15 mg/l, whereas the theoretical value is 100–150 mg/l (Jensen, 2007; Rose et al., 2015). In this point, measured difference in the field sample and theoretical oscillated between 85 and 135 mg/l. At point 107 (*Fig. 6c*), reflectance was 12.5% and the concentration was 16 mg/l, whereas the theoretical value is ±500 mg/l. Thus, difference of concentrations between field sample and theoretical value was 484 mg/l. Difference between theoretical and in situ reflectance of the SSC gave a high correlation, $R^2 = 0.71$.

From a comparison of in situ observations of spectral responses (*Fig. 6*) and theoretical signatures, the size of suspended particles can be estimated (Jensen, 2007). The measured reflectance (> 5%) suggests that particle sizes correspond to silt or mud. However, in the response extracted from the image at a point almost at the end of the plume (*Fig. 6d*) reflectance is < 5%, indicating that the dominant particles are clays.

Discussion

Values obtained in the measurement of the suspended sediments in the laboratory are greater than those calculated using the algorithm proposed by Topliss et al. (1990); Chen et al. (1992) found a high correlation ($R^2 = 0.98$ with $n = 29$; $R^2 = 0.83$ with $n = 20$) between the SSC and the reflectance measured in the laboratory, where the environmental effects are scarce. However, correlation between the SSC and the reflectance at the ocean surface was weak ($R^2 = 0.46$), because of the environmental effects (atmosphere, aerosols, tides etc.) (Qu et al., 2016). Data obtained in the delta of the Grijalva river using Landsat 7 and the most recent Landsat 8 satellites, has a correlation of $R^2 = 0.279$ with 29 samples and $R^2 = 0.334$ with 20 samples of Landsat 7 and $R^2 = 0.228$ with 29 samples and $R^2 = 0.423$ with 20 samples of Landsat 8.

Results obtained for Landsat 5 with the algorithm proposed by Topliss et al. (1990), has an average correlation coefficient of $R^2 = 0.70$ (Harrington et al., 1992; Ritchie and Cooper, 1991; Lodhi et al., 1998). The algorithm showed a very good correlation in lakes and the sea, but in 2013 this satellite was no longer acquiring images. Actually, Landsat 7 and Landsat 8 have similar spectral bands, which allowed us to apply the algorithm developed by Topliss et al. (1990) although the results have very low correlations for both satellites.

First calculations of sediments concentrations were based mainly on atmospheric variables due to the fact that they represented major variations in these estimations, however, between 1950 and 1970, rivers in the world with big flows started to show a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65496562

decrement in the sediments they were transporting, this provoked that spectral responses had variations (Qu et al., 2016; Tessler et al., 2015).

In 1983 building of hydroelectric dam Chixoy, caused a decrement in the concentration of the sediments transported by the Grijalva River. Between 1983 and 2009 accumulation of sediments drop from 158 × 10^6 m^3 to 6.1 × 10^6 m^3 yr^{-1} (Nooren et al., 2017). Nowadays, the algorithms and models developed to calculate SSC take into account changes in the spectral response of the sediments, as well as atmospheric variables (Lu et al., 2013; Qu et al., 2016; Zhang et al., 2015).

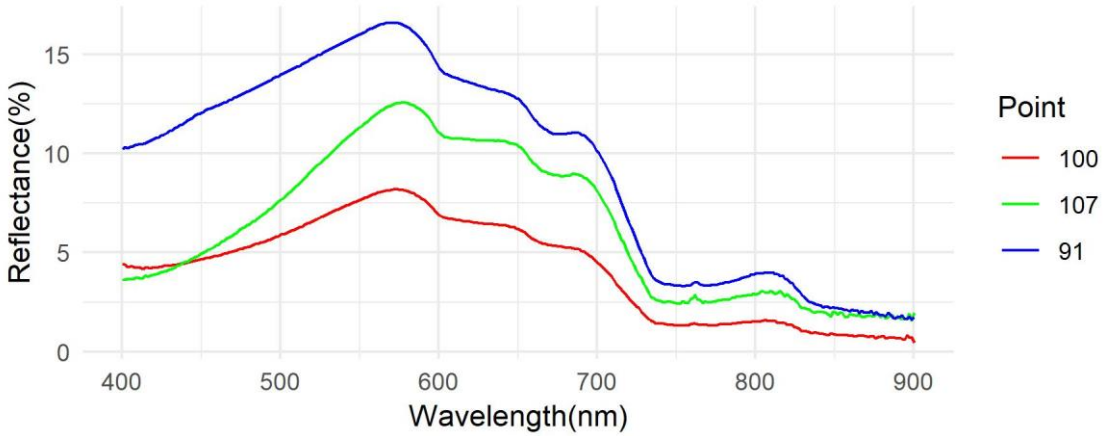

Figure 6. *Three spectral responses in situ and the last spectral response using landsat 8. The blue line is the Fig. 6a; the red line is the sample 100 is the Fig. 6 b and the green line is the Fig. 6c*

In the dispersion diagram the relationship between both variables is low due the high atmospheric interference between the satellite and water surface; additionally, water vapor and aerosols are present, which causes the sensor not to detect the total reflectance of the sediments.

It is possible that the algorithm cannot be applied at latitudes far from the one for which it was proposed (45° North). Furthermore, the climate where the algorithm was originally applied (Dfc, subpolar without dry season; and ET, tundra) differs from the tropical conditions of the present study, where suspended solids dominate. Under tundra climate bottom loading dominates (Arche, 2010). Hence, in the present study area, prediction of suspended sediments by the algorithm is less precise than that obtained in the laboratory.

Distribution analysis of the suspended sediments by kriging showed anisotropy in the river mouth because water transport usually is in one direction (*Fig. 5*). However, the zone with the highest SSC was distinct because the prediction suffered a circular tendency differing from the other points. Nevertheless, water discharged by a river generally has a preferred direction of flow (Arche, 2010).

The SSC can increase along the route to the open sea because a sediment wedge forms in the river mouth (Arche, 2010), where the superficial layer is fresh water brought by the river and this water column also carries suspended sediments that are subsequently exposed. The smaller particles (clays) travel a long distance before sinking to the bottom of the sea.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65496562

The analysis of spectral responses obtained in situ with the spectroradiometer and those obtained with the bands of the image allow calculating the increase in reflectance due to suspended sediments. Likewise, determination of the size of particles in suspension allows the comparison with the signatures allocated in spectral libraries or in the literature that match a reflectance value (%) to the SSC in mg/l (Novo, 1989; Jensen, 2007).

Based on the reflectance, the particle size that dominates in the river mouth corresponds to silt. On the other hand, the signature extracted from the image (*Fig. 6*), with a reflectance value less than 5% at the end of the plume, shows that particle size that dominate are clays (Jensen, 2007). The low percentage of reflectance encountered in clayey sediments is due to the organic matter content.

According to the spectral responses measured in situ at the sampling points, concentrations are lower than those supposed to be present regarding the volume of sediments, which increase the value of the reflectance (Novo, 1989). Because of the above and the low linear relationship between both variables, there are two important points to consider:

a) Since solar radiation interacts with organic and inorganic compounds in the water, the suspended sediments in the water column should be sampled according to the penetrating capacity of the bands in the visible spectrum or at established depths down the column.
b) The relative positions of the Sun and the sensor should be considered because reflection by water surface can be specular. The sensor receives the maximum reflected energy from the surface only if it is situated in the direction of the reflection angle. In the present study the relative positions of the Sun (43° from the horizon) and the satellite precluded measuring all the radiation reflected from the water surface. Consequently, in situ reflectance is 2–4% greater than the reflectivity of the spectral bands of the image. Therefore, the amount estimated by the algorithm is lower than that quantified in the laboratory. Additionally, local variations such as tides can suddenly change the transportation of suspended sediments.

In this study it was shown that the SSC estimation of sediments travelling in the surface can be done using bands 3 and 4. If sampling is performed by water column, the SSC are overestimated and could be calculated using the red and infrared bands for a range of concentrations of 100 to 1000 mg/l.

Conclusions

Although suspended sediments are usually quantified by in situ sampling, this task is time consuming and not economically viable for studies in remote areas. Thus, a good alternative is to use remote sensing techniques for quantification of SSC through spectral images.

This study used a spectroradiometer to obtain spectral responses in situ; real reflectance values at the water surface could be compared with values derived from the atmosphere-corrected image. Additionally, silt and clay particle size were determined in situ. Likewise, in situ reflectance indicated that most of the suspended particles were travelling in the water column rather than on the surface.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65496562

Cartographic representation of the SSC, calculated with satellite imagery and through interpolation with in situ data, indicated a gradual increase in SSC along the route to the open sea, despite the low linear relationship between those two measurements.

For analysis of superficial sediments, according to the statistical significance obtained, the algorithm proposed by Topliss et al. (1990) can be used, with green and red bands. For sediments sampled within the water column, at concentrations exceeding 100 mg/l, red and infrared bands would be used.

Taking into account the recent changes of the sedimentary regime and fluvial dynamics of the Grijalva River, the spectral responses of the sediments are mixed with the water, the shallow oceanic floor, and the predominant minerals. Therefore, it is necessary to carry-out a more extensive sampling in the study area to modify the algorithm of Toppliss et al. (1990) based in spectral mixtures of the SSC.

(Received 24th Jan 2019; accepted 29th Mar 2019)

Abstract. Quantification of soil CO_2 emission under different cropping designs and relating it to the climate parameters can help better understanding the main mechanisms controlling its magnitude and mitigating its release to the atmosphere. Wheat and corn are the most produced crops worldwide contributing highly to total CO_2 emissions from agricultural lands to atmosphere. Long term fluctuations in the soil CO_2 emissions under continuous wheat and corn cropping and bare land were monitored for 509 weeks from 2009 to 2018 in semi arid conditions in the Harran Plain located in southeastern Turkey. The soil CO_2 emissions were modeled for each cropping seasons separately using available meteorological parameters (air temperature (AT), soil temperatures (ST), relative humidity (RH) and rainfall) and field soil moisture (SM) data. The quantity of long term soil CO_2 emission were following order; corn, wheat and bare land and it was around 38% higher (574 vs 792 kg ha^{-1} $week^{-1}$) in soils under field crops than bare soils. Overall there were n increasing trends in seasonal, yearly cumulative and average weekly soil CO_2 emissions over the years. The weekly soil CO_2 emission values were positively correlated with AT and ST but negatively with RH and SM. The linear models were able to explain variations in the long term weekly soil CO_2 emissions obtained during wheat, corn cultivations and bare land up to 77%, 55% and 50%, respectively.
Keywords: *global warming, soil CO_2 emission, wheat, corn, meteorological data, stepwise regression*

Introduction

Global warming increases the soil respiration causing the release of more CO_2 emissions (Lu and Cheng et al., 2009). Among other three greenhouse gases CO_2 has the highest concentration in the atmosphere. Measurements and modeling of the soil CO_2 emissions under different soil types and crop managements are cost effective and crucial for global warming, carbon cycling as well as international agreements that aim to mitigate the amount of carbon released to atmosphere (Allaire et al., 2012). Quantification of the CO_2 emission from soils under different land uses is also important for developing strategies for reducing the CO_2 emissions to atmosphere. A number of researchers have shown atmospheric CO_2 increase very recently. The soil CO_2 respiration consists of basically two parts; roots respiration and microbial respiration as a result of organic matter decomposition (Morell et al., 2012; Zhang et al., 2015). Roots and microbial activities are responsible of 40% and 60% of total the soil respiration, respectively (Kuzyokav and Larionova, 2006).

Methods such as edycovariance or with closed chamber combined with gas chromatography are generally used for measurement of the soil CO_2 emissions. Another most commonly used technique in measuring the soil CO_2 emissions is soda lime (Edwards, 1982). This is advantageous, because it is cheap and easy to perform, enabling the soil CO_2 measurements at higher number of locations simultaneously compare to aforementioned methods which can only be obtained only at limited number of locations.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65636579

In addition, the earlier researchers comparing soda lime method reported that there is no statistically significant different between soda lime method and them (Raich et al.1990).

There are nearly two times more carbon in the soils than atmosphere (Lehmann and Joseph, 2009) and according to Lal (2004) that may be more than that. Depending upon agricultural management, soils can either be source or sink for CO_2 in the atmosphere and the amount of CO_2 released from soils to atmosphere can change based on the soil type, land use type or vegetation type, agricultural management as well as the time of measurement (i.e. seasonal variability) (Iqbal et al., 2009; Panosso et al., 2009, 2011; Mancinelli et al., 2010). Soil CO_2 emissions in the agricultural soils are generally between 0.1 and 6 g CO_2 m^{-2} h^{-1} (Sauerbeck, 2001).

Average soil CO_2 emissions reported by earlier studies were 59 to 527 mg m^2 h^{-1}, 37-498 mg m^2 h^{-1}, 32-397 mg m^2 h^{-1} for forest, grassland and cropland (Wang et al., 2008). The amount of soil CO_2 emissions in peat, sandy and clay soils respectively were obtained as 650 mg m^2 d^{-1}, 300 mg m^2 h^{-1} and 500 mg m^2 h^{-1} (Koizumi et al., 1999). Bauer et al. (2006) for the soils under conservation tillage measured soil CO_2 emissions as 840 mg m^2 h^{-1}. Akbolat et al. (2009) reported as 300-700 mg m^2 h^{-1}. The cropped soils release CO_2 2 to 3 fold higher than bare soils (Rastogi, 2002).

The soil CO_2 emissions are mostly impacted from the factors such as soil temperature and moisture (Bauer et al., 2006; Ngao et al., 2012; Xu et al., 2016; Iqbal et al., 2009; Reth et al., 2005), weather parameters, soil organic matter, C/N ratio, bulk density (Lin et al., 2008; Morell et al., 2012).

Wheat and corn are the most produced grain crops in the world and Turkey is one of the largest producers of both. Yearly around 653 355 000 and 19 674 000 tonnes wheat is produced in 217 312 000 ha and 8 103 000 ha areas in the world and in Turkey, respectively (FAOSTAT, 2010). Worldwide wheat grows on 215 million hectares of land each year (CGIAR, 2017).

Emissions of CO_2 from most of the forest crops, orchards, grasses are well documented (Frank et al., 2006; Almaraz et al., 2009). On the other hand, soil CO_2 emissions from soils under field crops with long terms field studies are limited. The studies available are mostly performed in a short term period which may not be sufficient to construct reliable models. Therefore, information about soil CO_2 emissions of soils under wheat plantation makes it significant.

The goals of this study were to: 1) quantify weekly and seasonal distributions of the long terms (from 2009 to 2018) CO_2 emissions from the soil under wheat and corn plantation 2) compare CO_2 emissions estimations obtained from the soils under field conditions compared with bare soils located nearby field crops, and 3) model the relationships between the soil CO_2 emissions from the soils under different managements (wheat, corn cultivation and uncultivated bare soils) and meteorological parameters and field moisture data at the same locations with soil CO_2 measurements.

Materials and methods

Study site and field management

The study was performed in a field under continuous wheat (2009-2017) and corn (2016-2018) cultivations, in addition to bare land located in the experimental farm of the Harran University, southeastern Turkey (37° 10' N Lat; 38° 59' E Long; *Fig. 1*). The study area has a semi arid climate with an average annual temperature, precipitation, evaporation and altitude values of 17.2 °C, 365.2 mm, 1848 mm and 520 m, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65636579

The soils of the study area are high in percent clay content, pH, percent $CaCO_3$ content and cation exchange capacity (CEC) but low in soil organic matter (<1.5 g kg^{-1}) (Dinç et al., 1998). Detailed information about the soil properties of the area is given in *Table 1*. Soils were clay loam and classified as Vertisol, according to Soil Taxonomy (Dinç et al., 1998).

Table 1. *Soil properties of bare field and the experimental areas under field crops*

Location	Sampling depth (cm)	EC (dS/m)	CaCO3 (%)	pH	P	K	Organic matter	Total N (%)	Sand	Clay	Silt	Texture
Bare area	(0-30)	0.73	17.40	7.70	2.71	112.5	1.36	0.09	22	60	18	Clay
Bare area	(30-60)	0.82	17.40	7.76	0.82	82.0	0.85	0.08	22	60	18	Clay
Field crops	(0-30)	0.83	23.50	7.76	3.04	82.0	1.45	0.09	32	50	18	Clay
Field crops	(30-60)	0.82	25.40	7.84	0.41	36.70	1.01	0.09	26	56	18	Clay

Wheat crops were planted in 2009-2017. Also during the experiment, in 2016-2018, corn crop following wheat was planted. Wheat and corn received regular care which included application of water as flood irrigation, fertilizer and pest control with sowing, 40 kg da^{-1} compose fertilizer as 20+20+Zn has been applied as base fertilizer and as top fertilizer 50 kg da^{-1} urea was applied. The same fertilizer practice was repeated in each year.

Soil laboratory analysis

A composite soil sample was taken as representative of orchard field at the surface (0-30 cm) and subsurface soil (30-60, 60-90 cm). Soil samples were air dried and passed through a 2 mm sieve and analyzed according to the routine soil analyses methods. Particle size distributions were determined by the hydrometer method (Bouyoucos, 1926); organic matter content by the Walkley-Black method (Nelson and Sommers, 1982); $CaCO_3$ content using a calcimeter (Kacar, 1994); soil pH with a 1:2.5 from soil/water suspension using pH meter (McLean, 1982); electrical conductivity (EC) in soil extraction using a conductivity meter (Janzen, 1993), soil N according to Kjeldahl method (Kacar, 1994). Soil available P and K were determined using an ICP-AEAS (Varian-Vista, Palo Alto, CA, USA), after $NaHCO_3$ extraction (pH 8.5) (Olsen and Sommers, 1982) and NH_4OAc extraction (Knudesen et al., 1982), respectively.

Soil CO_2 emissions and meteorological variables

In addition to soil CO_2 emission measurements under wheat and corn plantation, the measurements were also performed in bare soils with no cultivation fields. The soil CO_2 emissions measurements were performed as weekly basis during total of 509 weeks between January, 2009 and October, 2018, using soda lime method (Edwards, 1982).

Soda lime method is advantageous because it is easy to perform and also doe not require expensive equipments. Around 40 g soda lime was oven dried at 105 °C during 24 h, weighted and added in the numbered plastic PVC containers (3 cm tall, and 100 cm^2 area top). The containers that have a known amount of soda lime was placed under a chamber (23 cm width and 33 cm length) inserted 2 cm in soils in order to prevent interaction between soda lime and atmosphere in order to avoid any gas leakage underneath of the chamber as much as possible. A PVC lid (50 cm by 50 cm) was used to provide shadow for the chambers to reduce the temperature difference between inside

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65636579

and outside of the chambers. After one week in the field, the chambers were left and PVC containers with soda lime were weighted in the laboratory to measure changes in weight during one week incubation period. The soil CO_2 emissions were performed with five replications and then averaged to obtain a final emission values.

The amount CO_2 emission was obtained as below:

$$F_{CO2} = \frac{(C_{adsorbed} - C_{initial}) * W}{t_{incubation} * A} \quad \text{(Eq.1)}$$

Here:
F_{CO2} = emitted CO_2 g^{-1} cm^2 h^{-1}
$C_{adsorbed}$: Weight of soda lime after incubation (g)
$C_{initial}$: Weight of soda lime before incubation (g)
W: coefficient of water, taken as 1.69
$t_{incubation}$: Incubation period (week)
A: Area of the chamber, cm^2

Emission of CO_2 calculated as g cm^2 hour was converted into total weekly and monthly amounts.

Meteorological variables used in the study were obtained from Sanlıurfa city meteorological station located around 5 km away from the study site. Daily measurements were converted to weekly basis. The meteorological variables included air temperature (AT), soil temperature (ST) at different depths (5, 10, 20, 50 and 100 cm), relative humidity (RH) and rainfall (mm). Field soil moisture data were obtained gravimetrically from the soils samples taken at the same location where soil CO_2 emissions were measured.

Figure 1. *Photo showing the experimental design set up for soil CO_2 emissions*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65636579

Statistical analyses and modeling

The relationships between CO_2 emissions at different sites (wheat and corn fields, and bare soils) and meteorological parameters and field soil moisture data were examined using correlation analyses and multiple linear regression (MLR) models.

MLR models the relationships between response (soil CO_2 emissions) and predictor variables (meteorological parameters and field soil moisture data) using a linear function between two (*Eq. 2*):

$$y_i = \beta_o + \beta_1 X_{1i} + \cdots\cdots \beta_p X_{pi} + \varepsilon_i \quad \text{(Eq.2)}$$

where y_i refers to response variable which is modeled by a linear function of predictor variables; X_i. β are coefficients; ε is error term.

The models were also validated using independent data set splitting the whole data into two groups; as 70 and 30%; while the former was used for calibration, the latter was used for validation of the model which was constructed using General Linear Model (GLM).

The models were constructed for the data in each sampling sites and each year separately and also for complete years (2009-2018). Correlation analyses and MLR modeling were performed using SPSS program. GLM model used in model validation (testing) was performed using R program.

Results

Soil properties

Averaged soil properties measured at different depths and sites are given in *Table 1*. Soils are high in $CaCO_3$ (>15%) and low in soil organic matter (<2%) contents. These were due to no organic residues given in to soils, conventional tillage and warm climate environment of the study area. Soils have a basic soil pH, a heavy clay texture and do not have any salinity problem which is indicated by low soil EC values (<4 dS m^{-1}). While total nitrogen and plant available P contents in the soils were low, K levels were high. Soil P and organic matter were higher in the soils under field crop rotation but it was opposite for K which was found higher in bare soils compare to the soils under wheat and corn crop rotation. It may be because of plant uptake.

Soil CO_2 emissions

Average, minimum and maximum of the soil CO_2 emissions (kg ha^{-1} $week^{-1}$) measured in the soil during the study periods (2009–2018) are given in *Table 2*. Long term weekly, seasonal and cumulative yearly fluctuations of the soil CO_2 emissions are given in *Figures 2-5*. The results showed that CO_2 emissions were highly variable and the higher emission peaks were obtained in the summer seasons.

The soil CO_2 emissions were highly variable, both seasonally and locally ranging from 54 to 2504 kg ha^{-1} $week^{-1}$. The CO_2 emissions in bare soils ranged from 57 to 1690 kg ha^{-1} $week^{-1}$ with average values of 791 and 523 kg ha^{-1} $week^{-1}$, respectively (*Table 2*). When the fields are under either wheat or corn plantation (excluding the weeks when there is no crop in the field), average soil CO_2 emissions were 534 and 850 kg ha^{-1} $week^{-1}$ for bare soils (CO_2-Bare) and field soils (CO_2-Field), respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65636579

Average weekly CO_2 emissions of the soils under wheat plantations in 2009-2017 were 310, 480, 516, 481, 400, 535, 680 and 696 kg ha^{-1} $week^{-1}$, respectively, which showed a consistent increase over time. Similar to the soils under wheat plantations, average weekly CO_2 emissions of soils under corn plantation were higher compared to the previous years. It was 914 and 1056 kg ha^{-1} $week^{-1}$ in 2016 and 2017, respectively. The average weekly soil CO_2 emissions from bare soils (CO_2-Bare) were always lower than those obtained in the soils under both wheat and corn cultivation (*Table 2*). Average weekly soil CO_2 emissions from the bare soils corresponding to the same weeks when fields under wheat plantation were 310, 480, 516, 481, 400, 535, 680 and 696 kg ha^{-1} $week^{-1}$, respectively in 2009-2017. Average weekly soil CO_2 emissions from bare soils corresponding to the same weeks when the fields under corn plantation in 2016 and 2017 were 687 and 621 kg ha^{-1} $week^{-1}$, respectively.

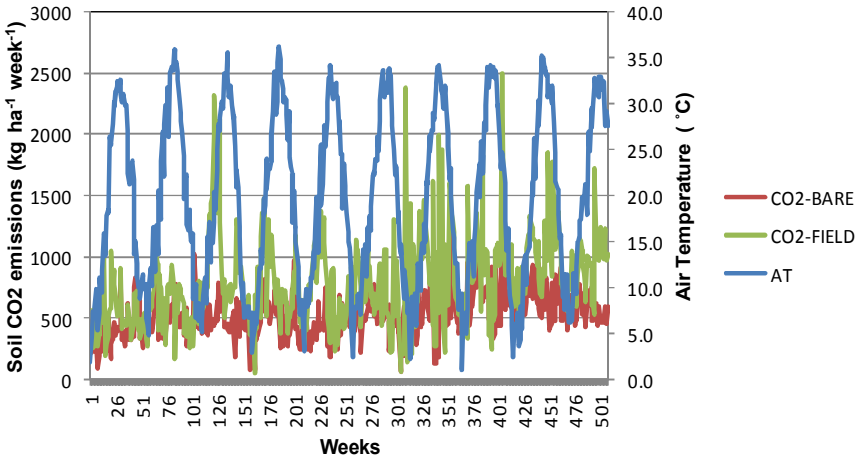

Figure 2. *The weekly fluctuations of field soil CO_2, bare soil CO_2 emissions and air temperature from 2009 to 2018 (509 weeks)*

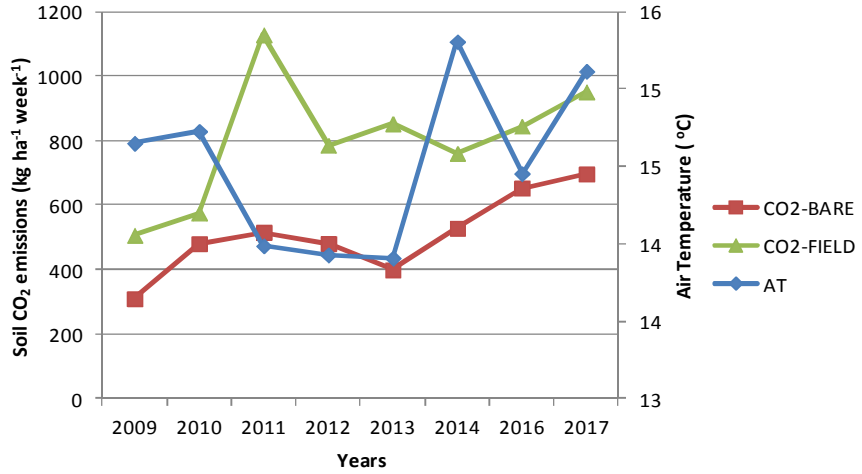

Figure 3. *Changes in yearly mean soil CO_2 emissions from two different sites and air temperature*

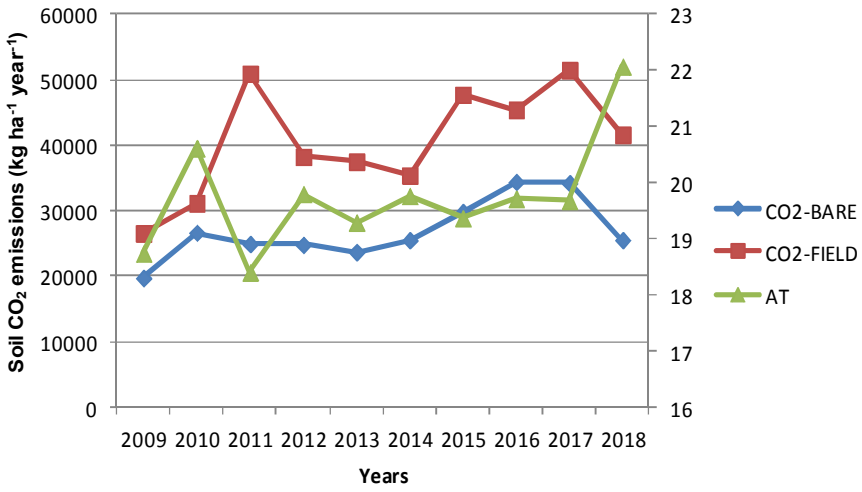

Figure 4. *Variations in cumulative yearly soil CO_2 emissions*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65636579

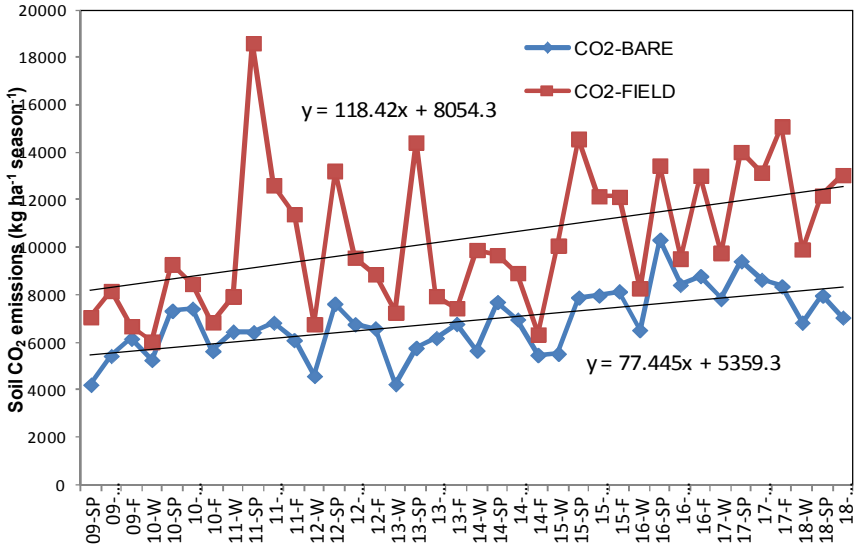

Figure 5. *Seasonal (each points corresponding to seasons starting from spring and followed by summer-fall-winter seasons) variations in soil CO_2 emissions from 2009 to 2018*

Correlations between the soil CO_2 emissions from the bare soils and wheat and corn plantations for each year separately and combined are given in *Table 3*. When all years were considered together, weekly CO_2-field values were significantly correlated ($p < 0.05$) with all meteorological parameters except rainfall, soil temperature at 100 cm and soil moisture data. While weekly CO_2-bare soil values were significantly correlated ($p < 0.05$) with all meteorological and soil moisture parameters (*Table 3*).

In the 2012, 2013, 2016 and 2017 years, weekly soil CO_2 emission values obtained had a statistically significant positive correlations ($p < 0.05$) with air and soil temperatures at different depths while significant negative correlations ($p < 0.05$) with relative humidity. They had statistically significant negative correlation with soil moisture values in 2012 and 2013 and insignificant negative correlations in 2016 and 2017.

In the 2009 and 2011 years, only weekly soil CO_2 emission values obtained from the soils under wheat cultivation had statistically significant negative and positive correlations ($p < 0.05$) with the same variables. The same situation was valid for only weekly soil CO_2 emission values obtained from the bare soils in 2014 (*Table 3*). Rainfall values had statistically ($p < 0.05$) significant negative correlations with weekly soil CO_2 emission values obtained from the soils under wheat cultivation in 2010, 2012 and 2016 years (*Table 3*).

Correlations between the soil CO_2 emissions under corn plantation both in 2016 and 2018 and environmental parameters were mostly insignificant ($p > 0.05$) (*Table 3*). As opposed to bare land and soils under wheat cultivation, the soil CO_2 emissions measured during corn plantation in 2016 had negative correlations with air and soil temperatures but positive correlations with rainfall, relative humidity and soil moisture.

Modeling of soil CO_2 emissions

Multiple Linear Regression models were constructed between the soil CO_2 emissions at different locations (bare land and field crops) and available climate parameters; air

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65636579

temperature, soil temperature, relative humidity, precipitation and field soil moisture data. For different land managements the models were constructed for all weeks in whole years (from 2009 to 2018), for only weeks when the field is planted with wheat or corn (from 2009 and 2018) and for weeks during crop season in each year, separately. Coefficient of Determination (R^2) values showing the per cent variations in soil CO_2 emissions at different time and locations explained by each models and significance of independent variables in terms of contribution to the model are given in *Table 4*. Model R^2 values for complete years considering both planted and also unplanted weeks and considering only planted weeks were 0.16 and 0.22, respectively. They were 0.1 and 0.23 respectively for bare land. For the models constructed separately for each crop season in different years, R^2 values ranged from 0.47 to 0.77 for wheat plantation, between 0.19 and 0.55 for corn plantation and 0.12 to 0.66 for bare land (*Table 4*).

R^2: coefficient of determination; AT: air temperature (°C); ST5, ST10 and ST100 are soil temperature at 5, 10 and 100 cm, respectively; SM: soil moisture; RH: relative humidity

For the models constructed for each crop seasons in different years separately, the significance of independent variables in the models changed based on different crop types and also years. Air temperature were found significant only in the models constructed for soils under wheat plantation in 2010, 2014 and 2016 years and for bare soils in 2010 and 2014 years. Relative humidity values were significant only for models constructed for soils under wheat plantation in 2014 and 2016 and bare soils in 2019. ST at different depths were not found significant in the models constructed for each cropping season year separately for field crops but found significant for bare soils in 2010 (ST10), 2011 (ST100) and 2016 (ST50 and ST100) years. Rainfall was found statistically significant for the models constructed for soils under wheat plantation in 2014 and for bare land in 2016 cropping season (*Table 4*).

Stepwise regression was used to select the most important variables in modeling the soil CO_2 emissions in different cropping seasons and managements. The most significant variables selected by stepwise regressions are shown in *Table 5*. Accordingly, when all weeks (planted and unplanted weeks) considered, the method selected SM and AT as the most important variables explaining the variations in the soil CO_2 emissions under field crops and RH in soil CO_2 emissions from bare land. When considering only planted weeks, the result did not change for soils under field crops but

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65636579

SM, ST5 and ST10 variables in addition to RH were also found as the most significant in modeling the soil CO_2 emissions from bare land.

R^2: coefficient of determination; *p significant at $p < 0.05$ level; **significant $p < 0.01$ level
Variables selected according to stepwise regression; AT: air temperature (°C); ST5, ST10 and ST100 are soil temperatures at 5, 10 and 100 cm, respectively; SM: soil moisture; RH: relative humidity

In other stepwise regression models performed for each crop season separately, the model selected AT as the most significant variable in 2009, 2012, 2013, 2016 and 2017 in explaining the variations in CO_2 emissions from the soils under wheat cultivation, in 2009 and 2014 years from bare land. Rainfall was only found as the most significant parameter in explaining the variations in CO_2 emissions from the soils under wheat cultivation in 2010, when stepwise regression is used. The RH was found the most significant parameter for the variations in soil CO_2 emissions from bare land. Soil temperatures at 5 cm and 100 cm were found the most significant variables for the variations in CO_2 emissions in 2011 from the soils under wheat cultivation and bare land. The ST100 was also found the most significant variable for the variations in soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65636579

CO_2 emissions from the corn field in 2017. Soil moisture was selected as the most significant variable by stepwise regression in explaining variations in the soil CO_2 emissions from wheat plantation in 2011 and 2014 years and from bare land in 2013 (*Table 5*).

Seasonal variations in the soil CO_2 emissions from both field and also bare land were also estimated using GLM model and available meteorological parameters and soil moisture data. For this purpose, the data was first split into two groups. 70% of the data was used for model construction and the rest 30% was estimated using constructed model. R^2 and RMSE values showing the accuracy of the estimations of soil CO_2 emissions of the samples in validation set (test set) were 0.15 and 0.05 and 253 and 178 kg ha^{-1} $week^{-1}$ for field and bare area, respectively. *Figure 6* shows the consistency between actual and model predictions for the CO_2 values in both locations.

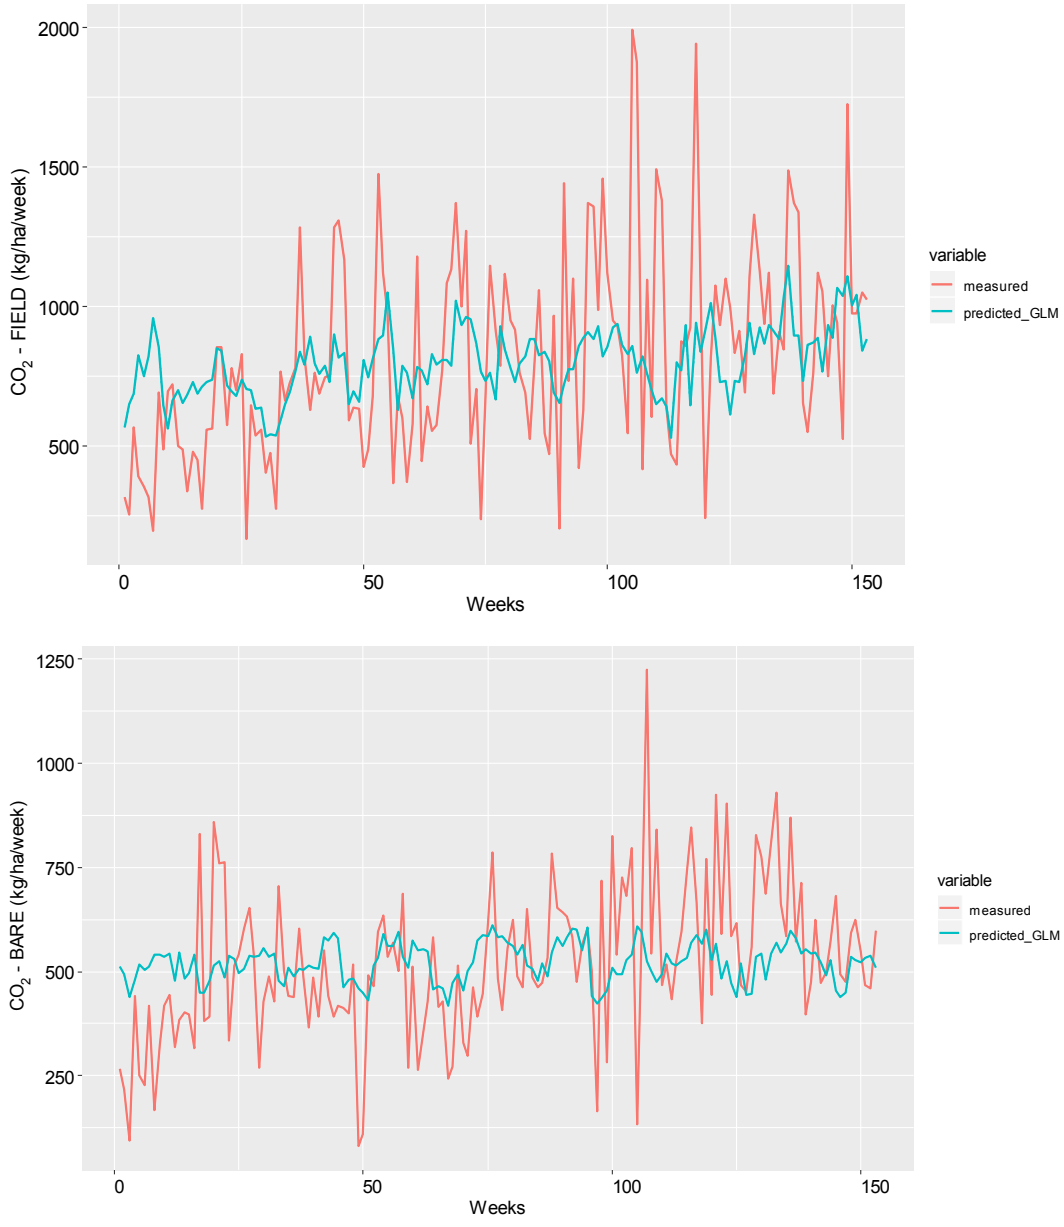

Figure 6. *Actual and GLM model predictions of soil CO_2 emissions in field (CO_2-FIELD; R^2: 0.148; RMSE: 253) and bare areas (CO_2-BARE; R^2: 0.05; RMSE: 178)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Discussion

Around 20% of atmospherically CO_2 is due to agricultural activities (Lal and Bruce, 1999) and grain crops such as wheat and corn are the most produced grain crops worldwide therefore the quantification of soil CO_2 emissions under these types of vegetation are important in terms of accuracy of carbon budgets and modeling.

Long term weekly soil CO_2 emission amounts from field crops and bare land had a distinct trend in seasonal fluctuation. Higher in summer and lower in winter seasons similar to air temperature (*Fig. 2*). Seasonal trends have been often reported for CO_2 emissions from soil under various other crops (Raich et al., 2002).

Soil CO_2 emissions under field crops showed a clearly higher release compare to bare soils. The relation between soil CO_2 emissions over the years and mean air temperature can be observed in *Figure 3*.

The soil CO_2 emissions showed an increase over time, as can be observed in *Figures 4* and *5*. The yearly cumulative soil CO_2 emissions could be explained with increased temperature over years. In addition, the plant residuals increased causes increase in soil organic matter. In some years the rates showed a decrease compared to previous year, however there was a general trend toward the higher cumulative emission.

Soil CO_2 emissions measured varied highly based on time of measurement (seasonal-climate), management (field crop vs. bare land) and cropping season (type of crop). Guo et al. (2013) also showed that the quantity of the soil CO_2 emissions under field cropping (wheat) can change depending on different growing stage of the crop in addition to environmental parameters such as soil temperature and rainfall.

The soil CO_2 emissions obtained from field crop plantation of our study were in a similar range with other ecosystems. Meng-yang et al. (2014) reported soil CO_2 emissions as 829, 629 and 474 g CO_2 m^{-2} from July 1 to September 30 (921, 698 and 526 kg ha^{-1} $week^{-1}$, respectively) for fields under 20- year continuous maize, wheat and soybean cultivation in a similar semi arid area located in northeast China. Gu et al. (2016) reported the soil CO_2 emissions under wheat plantation ranging from 372 to 418 mg m^{-2} h^{-1} (equals to 625-702 kg ha^{-1} $week^{-1}$). Chen et al. (2004) indicated soil CO_2 emissions in wheat field ranging from 10 to 606 mg m^{-2} h^{-1} (equals to 17-1019 kg ha^{-1} $week^{-1}$). The average soil CO_2 emissions from under semi-arid continuous wheat was 2.34 μ mol m^{-2} s^{-1} (equals to 622 kg ha^{-1} $week^{-1}$) by Zhang et al. (2011).

The CO_2 emissions obtained in our study were relatively lower than other ecosystems such as orchards, forests or pastures. In arid region in China for grassland in the Black Chinese soils, Li et al. (2009) measured average weekly soil CO_2 emissions during growing season as 1680 kg ha^{-1} $week^{-1}$. Lessard et al. (1994) measured the soil CO_2 emissions under forest vegetation and found a range between 158 and 1037 kg ha^{-1} $week^{-1}$ and also compared with nearby cultivated fields, which provided soil CO_2 emissions between 18 and 495 ha^{-1} $week^{-1}$. This is three times lower than emissions in the soils under forest. As opposed to these researchers, Iqbal et al. (2009) comparing the soil CO_2 fluxes under different land management, such as vegetables, forest, uplands and orchard stated that the soils under forest and orchard management provided relatively lower CO_2 emissions compare to other agricultural land uses.

According to average weekly emissions, the soils in continuous wheat and corn emitted 38% more CO_2 than the bare soils. The CO_2 emission from soil is the combination of root and soil microbial activities (Kuzyakov and Larionova, 2006). The root contributions to soil emissions are known as 48% (Raich and Tufekcioglu, 2000).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65636579

Soils under plantation can provide 2 to 3 fold higher CO_2 emissions compared to bare soil.

When considering the years for both corn and wheat; the mean soil CO_2 emissions measured during corn production was higher than wheat production in both 2016 and 2017. This may be due to differences in time of growing wheat and corn. Wheat grows in winter and spring seasons, corn is grown in summer season, mostly when the air and soil temperatures are higher. The researcher who compared the soil CO_2 emissions from wheat and corn cultivation in a field experiment specifically designed for comparison purpose reported that emissions were higher in corn than both wheat and also soybean cultivations. The researcher attributed the increase to that of higher residues incorporated into the soil in corn cultivation. Our study was completely under farmer conditions with regular field cares. Relatively higher emissions from the soil under corn crops have been attributed to higher residue incorporation under corn vegetation compare to other crops compared such as wheat and soybean.

We found statistically significant correlations between the soil CO_2 emissions and meteorological variables available and field soil moisture data. Except a few cases, the soil CO_2 emissions had mostly significant positive correlations with AT and ST while significant negative correlations found with RH, rainfall and soil moisture. Significance of variables such as the soil temperature and moisture in modeling the soil CO_2 emissions have been mostly emphasized by earlier researchers. The negative correlations between soil the CO_2 emissions and soil moisture content and rainfall could be due to optimum moisture conditions during the study period which was provided by irrigation. Earlier researchers reported that as long as soil moisture are at optimum level, its impact may be insignificant in the soil CO_2 emissions (Morell et al., 2010; Mancinelli et al., 2010).

Modeling of soil CO_2 emissions

Although the models used to estimate the soil CO_2 emissions at different locations, crop managements and seasons were found statistically significant ($p < 0.05$). The R^2 values showing capability of MLR models for explaining variations in the long terms soil CO_2 emissions were relatively lower, indicating that there are other factors that may involve in overall variations in the emissions. Zhang et al. (2011) emphasized that soil management practices such as tillage had high control over the quantity of soil CO_2 emissions under field conditions in addition to environmental factors such as soil temperature and moisture.

Lower R^2 values have been also found by earlier researchers. Mapanda et al. (2010) obtained R^2 values between the soil CO_2 emissions and various environmental parameters were between 0.12 and 0.48 from the models. Mancinelli et al. (2010) received R^2 values between 0.25 and 0.28 using the soil temperature and moisture as controlling parameter.

According to the MLR and stepwise regression models, the significant and most significant parameters selected in modeling relationships between long terms fluctuations in soil CO_2 emissions from different crop management and climatic parameters along with field soil moisture data were not same for the models constructed for different seasons and cropping managements. All variables included into the models were once selected as the most significant variables in modeling, however in most cases, AT was selected as the most significant variable in modeling the soil CO_2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65636579

emissions, which was followed by soil moisture, soil temperatures at different depth, RH and rainfall data.

Overall the accuracies of the soil CO_2 estimations using GLM models and available meteorological data were low. However the model estimations closely followed the actual observations (*Fig. 6*). Low estimation accuracies were mostly due to the higher emission values within the data sets which were not being able to be captured by the model and were underestimated. In addition to climate variables, agricultural practices such as plowing which are not included in the model may impact magnitude of the distribution of soil CO_2 emissions and cause occurrence of extreme values.

Conclusions

This study evaluated the long term (from 2009 to 2018) seasonal fluctuations in the soil CO_2 emissions under wheat and corn plantation and compared their results with ones obtained from bare soils located nearby. The CO_2 emissions from the soils under field crops were always about 38% higher than bare soils. The soil CO_2 emissions showed an increasing trend over the years which can be explained by increases in air temperature and accumulations of plant residues in the soil. Up to 77% of variations in the soil CO_2 emissions were explained with combined use of MLR model and available meteorological parameters and soil moisture data. Air temperature, soil temperatures at different depth and soil moisture were found the most significant parameters impacting the overall variations in long terms fluctuations in the soil CO_2 emissions under different cropping and bare soils. Overall the results indicated that per cent of variations explained by modeling could be improved by incorporating the soil management factors into models.

Abstract. Aerobic static composting was conducted for 21 days with cattle, pig and chicken manure along with the leavening agent of 10% corn stalk. In the composting process, the changing trend of parameters: temperature, pH and water content and quantities of microorganism including bacteria, fungi and actinomycetes were studied. It showed that the composting treatment of the three types of livestock manure entered the high temperature period of 45 °C on the 6th day and reached the maximum temperature on the 15th day. The number of days with temperature above 55 °C was 6, 6 and 9 d, which all satisfied the maturity standards. At the end of the composting process, the total nutrient content of pig manure was the highest (6.33%), the total nutrient content of cattle manure was the lowest (5.04%). Throughout the composting process, the changes of activities of urease and invertase were the same with a decreasing trend as a whole. However, the activity of catalase increased with the process of composting. At the end of the composting reactions, concentrations of catalase, urease and invertase were the highest with corresponding values of 62.18 ± 0.45/0.002 mol•L^{-1}•g^{-1}, 54.28 ± 8.35 mg•g^{-1}•d^{-1} and 11.28 ± 0.14 mg•g^{-1}•d^{-1}, respectively.

Introduction

Since 1978 onward, the industries related to livestock and poultry breeding have increased exponentially (Awasthi et al., 2018). Their rapid development produced benefit economic benefits, improved human food structure and nutrition comprehensively with enhanced life quality (Wang et al., 2013). However, the unprocessed livestock manure originated from the breeding industries creates huge environmental challenge. In comparison with the traditional dispersed feeding system, extensive feeding decreases the growth cycle of livestock and poultry. Extensive feeding increases the yield and reduces the breeding cost significantly (Yasuda et al., 2017). However, it has been proved that intensive breeding results in the separation of planting and breeding. Thus, the environmental pollution created by animal husbandry is severe. Nowadays, livestock manure has been considered as one of the three non-point sources of environmental pollution.

DOI: http://dx.doi.org/10.15666/aeer/1703_65816593

There are stocks of livestock manure in China with a wide range of environmental effects. However, the utilization level of livestock manure is low (Xi et al., 2011). With the low utilization efficiency, the promotion of resource utilization out of livestock manure has been neglected. To overcome this problem, researches are urgently needed targeting the livestock manure stocks arising. Livestock manure is the main agricultural waste with large quantity and wide distribution. It is urgent to solve the current utilization status of livestock manure as well as to find the optimum utilization pathway in different districts of China (Zhang et al., 2011; Feng et al., 2015). Recent studies on the microbial aerobic conversion processes of compost have been focused on the single livestock manure as raw material. There has been no report on the enzyme activities involved in the composting using raw materials of different livestock manure. The present study aimed to compare the changing pattern of enzyme activities in composting with different livestock manures. The research could provide theoretical evidence and technical support for organic fertilizer production to the local entrepreneurs.

Experiments and methods

Materials

Cattle manure, pig manure and chicken manure used in the composting process with livestock manures were procured at a breeding farm near Shenyang Aerospace University in Shenbei New District, Shenyang, Liaoning. Corn stalks were also provided by the same breeding farm. Corn stalks were cut into pieces of 2-4 cm (length) by the knife mill before use.

The physicochemical properties of composting materials are shown in *Table 1*.

Table 1. *Agrochemical characters of different compost materials*

Raw materials	Water content (%)	pH	Total carbon (%)	Total nitrogen (%)	Total potassium (K_2O%)	Total phosphorus (P_2O_5%)	C/N
Cattle manure	68.9	7.64	38.32	1.78	1.48	1.45	21.53
Pig manure	73.4	7.35	39.41	1.80	1.58	1.78	21.89
Chicken manure	70.8	7.28	41.15	2.99	1.52	2.98	13.76
Corn stalk	21.5	7.19	54.82	1.04	0.98	0.46	52.71

Experimental schemes

An aerobic static composting was conducted using the composting materials of three livestock manures, including cattle manure (R1), pig manure (R2) and chicken manure (R3). The 21 d composting reaction was conducted with six self-designed aerobic composting boxes among which two composing boxes were considered as a group to contain a single type of livestock manure.

The results of every parameter data in the experiments were taken as an average. Additives of 10% corn stalk adjusted the porosity and organic matter content of the livestock manure. In the whole composting process, different parameters like temperature, oxygen concentration, carbon dioxide concentration, density. were monitored. Besides, the gas produced during the composting process was treated using a

DOI: http://dx.doi.org/10.15666/aeer/1703_65816593

bio-filter. The authors compared and analyzed the change in every parameter and the law of enzyme activities in the composting process with different livestock manures.

Experiment apparatus

The self-designed composting box was used in the composting experiment. The experiment apparatus of the composting is shown in *Figure 1*.

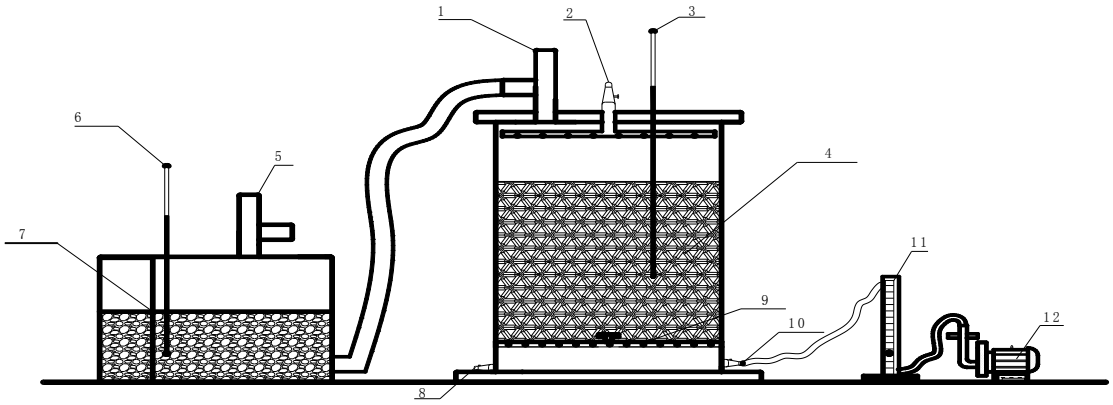

Figure 1. *Experimental apparatus used in the aerobic composting with livestock manures. 1. The vent of the composting box. 2. Back-ejecta nozzle of leachate. 3. Thermometer. 4. Composting box. 5. The gas outlet of bio-filter. 6. Thermometer. 7. Bio-filter. 8. Discharge pipe of leachate. 9. Grid plate. 10. Inlet pipe. 11. The flow meter. 12. Fan*

The livestock manure was mixed evenly and sampled to determine the density, pH value, conductivity, moisture content, organic content and ash content of raw materials. Then in proportion to add additives (straw), full mixing, sampling, determination of mixed materials of the above indicators.

Fill the compost box with the mixed materials, press gently to ensure the material is even, then weigh and measure the height of the material in the box and the diameter of the box. Seal the box with bolts, insert thermometer, add insulation layer, put the box on the reaction rack, connect the air pump and flow meter, and breathe air into the reactor. The first data was recorded from the time the air was pumped in; temperature was recorded every 2 h, O_2 and CO_2 concentrations in the compost bin and biofilter were recorded every 4 h.

Analysis method

Determination of total solid content (TS)

The determination of TS aims to enable the evaporation of material under the condition of 110 °C until the material is completely in the dry state. With the measurement of precise balance, the weight of dry crucible was recorded as m_1. Then the experimental materials were weighed together with precise balance, and the weight was denoted as m_2. Crucible was dried until its mass is no longer changed, and the mass was recorded as m_3.

The equation for the total solid content is as follows (Zhang et al., 2011):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65816593

$$TS = \frac{m_3 - m_1}{m_2 - m_1} \times 100\% \quad \text{(Eq.1)}$$

Determination of volatile solids (VS) content

According to the definition of volatile solid, under the condition of 650 °C, high temperature heat comes out of that part of the solid. When the sample is heated and cooled, the portion of the lost weight is the volatile solid, and the non-volatile residue is called ash (expressed as a percentage or g/L). The drying samples were put in the muffle furnace under the high temperature of 550 °C for 3 h (Feng et al., 2015). Subsequently, the samples were removed for half an hour cooling after being weighted, and the average quality was recorded as m_4. The calculation of volatile solid can be expressed as:

$$VS = \frac{m_3 - m_4}{m_2 - m_1} \times 100\% \quad \text{(Eq.2)}$$

where: VS represents the volatile solid content of the sample, %;

M_1 is the mass of the crucible, g;

M_2 represents the total mass of the sample and crucible before drying, g;

M_3 represents the total mass of the sample and crucible after drying (before putting it into the muffle furnace), g;

M_4 represents the total mass of sample and crucible after putting into a muffle furnace, g.

Determination of pH value

The samples were tested in a special centrifugal tube, and after centrifugation for 30 minutes, the supernatant was removed for pH determination. PH meter was used to measure the supernatant and record the data.

Determination of enzyme activity

The $KMnO_4$ titration method was used to determine the enzyme and catalase activities in soil. The results were demonstrated by the quantity of $KMnO_4$ consumed in ml by unit composting weight with the unit of 0.002 mol•L^{-1}•g^{-1} •20 min^{-1} (Seal et al., 2012).

The determination of urease activity was done via colorimetric method utilizing phenol sodium and sodium hypochlorite. The results were demonstrated by the milligram quantity of NH^{4+}-N per 100 g composting with the unit of mg•g^{-1}•d^{-1} (Gray F, 2015).

The determination of invertase was carried out with the 3,5-dinitrosalicylic acid method and the results were demonstrated by the milligram quantity of glucose produced by 1 g composting in 1 d with the unit of mg•g^{-1}•d^{-1} (Margaritis et al., 2017).

Results and discussion

The change of temperature, pH and water content in the composting process with different livestock manure

Temperature changes

Composting is a biochemical process dominated by microorganisms. In this process, the temperature is an important index that affects both the microbial activity and the microbial

community structure. The duration of the high-temperature stage in the composting process largely determines the composting effect and the quality of the composting product (Chen, 2012; Jieying et al., 2017).

Figure 2 shows the temperature changes during the composting processes of three types of manures. For all three types of manure, the composting process exhibited the high-temperature period (45 °C) at the same time (6 days), and they were subjected at these conditions for 15 days. R1, R2 and R3 reached the highest temperature on the 15th day, with values of 56.1 °C, 58.3 °C and 59.3 °C, respectively. Among them, R3 (chicken manure) treatment stayed at the high-temperature stage for the longest time, while the high-temperature periods for R1 (cattle manure) and R2 (pig manure) treatments were relatively short. After 18 days, all piles entered the cooling stage after lowering for three days, during which the temperature dropped to 45–47 °C at the end of the composting.

During the composting process, the temperature increase of the pile is an accumulative result of the heat generated by the microbial metabolism; therefore it reflects the metabolic intensity of microorganisms and the conversion rate of the composting substances (Jieying et al., 2017). If the temperature is too low or the high-temperature stage is too short, the pest eggs and weed seeds cannot be effectively erased. On the other hand, if the temperature is too high, the production efficiency of the enterprise is compromised, and some medium-temperature microorganisms that mainly decompose cellulose and lignin may not be able to survive, thus affecting the composting process. Research (Wei et al., 2018) suggested that the preferred high-temperature for the solid organic waste composting is 60–65 °C, and that it needs to be maintained for more than 7 days. In this experiment, the composting treatments of the three types of manures showed a rapid heating feature, and the high-temperature (55 °C) duration was 16–18 days.

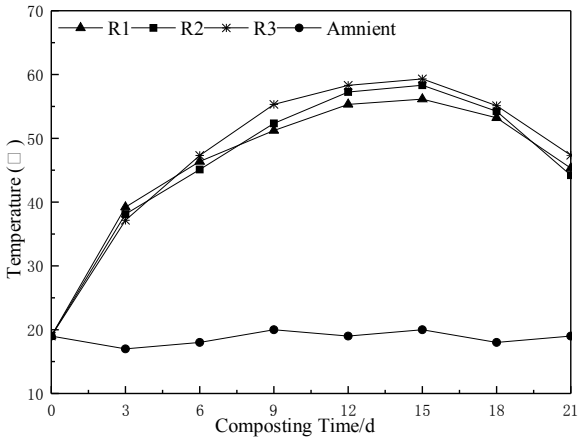

Figure 2. *Temperature changes of the three manures of composting*

Changes in pH during composting of the livestock and poultry manure

Figure 3 shows the changes in pH during the composting of the livestock and poultry manures. For all three types of manures, the pH increased initially and decreased later. At the end of the composting process, the pH showed an increase again. Until day 3, the pH change of R1 was 7.27-7.55. In addition, the corresponding pH change of R2 was 7.29-7.65. Moreover, the pH change of R3 was 7.33-7.87. These changes were mainly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65816593

due to the decomposition of amino acids in the manure, as deamination of the amino acids could cause a slight increase of pH in the whole piles. From day 4, the pH of all the composting reactions started to drop. The lowest pH of R3 (chicken manure) compost was 6.07 during the whole composting process. In addition, the lowest pH of R1 was 6.07 which appeared on day 15. Besides, the lowest pH of R2 was 6.31 which appeared on the day 12. Such low pH was mainly due to the decomposition of the organic matter in the compost material of livestock and poultry that produced organic acids, organic acids led to a decrease of pH. It is worth noting that the organic matter from the chicken manure is more susceptible to hydrolysis and acidification, thus the pH value of R3 decreased to a highest degree.

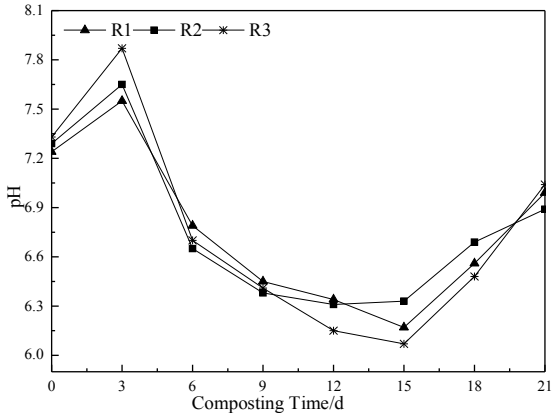

Figure 3. *Changes in pH of three kinds*

On day 15, starting from 6.17 (R1), 6.31 (R2) and 6.07 (R3), the pH values of all the composting reactions began to rise again, during the high-temperature stage, the organic acids in the piles were efficiently decomposed by the thermophilic bacteria to produce CO_2, and the decrease of organic acid content, therefore, led to a rise in pH. At the end of composting, the pH values of the three piles were 6.99 (R1), 6.89 (R2), and 7.04 (R3). These change patterns was due to the oxidative decomposition of the decomposable organic matter in the piles. The produced nitrogen (ammonium) accumulated continuously, causing an increase in the pH of the piles. At the same time, the increase of pH gave rise to the volatilization of ammonium nitrogen; therefore, at the end of composting, the pH values of all the manures were in the range of 6.9–7.1.

Changes in moisture content during composting of manures

Figure 4 shows the changes in moisture content during the composting of the livestock and poultry manure. For all three manure types, the initial moisture percentages were 64-67%. The moisture content reduced, as the composting process started, and the percentage of the moisture content in all piles in the end was 30–32%. R1 (cattle manure) showed a significant moisture loss (about 35%). The period with the largest decrease in the moisture content was the high-temperature stage, probably due to the high metabolic activity of the microorganisms during the heating-stage and high-temperature stage. In particular, during the high-temperature stage, the thermophilic bacteria dominated the microbial community, and at this stage, they rapidly utilized and degraded the organic matter. Consequently, the demand for oxygen significantly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65816593

increased. Because of the cold incoming air and the hot outgoing air, the water saturation of the outgoing air increased significantly, resulting in a faster use of water and more marked evaporation. At the end of the composting experiment, the moisture percentages were 30.11 (R1), 32.22 (R2) and 30.01 (R3). If too much water evaporates during the high-temperature period, the moisture in the late composting period and the rate of decomposing can significantly reduce, thus prolonging the composting cycle. Therefore, appropriate water replenishment needs to be applied when the moisture percentage in the maturity period is less than 20%.

Moisture content and pH are the two important indices of the composting process. Moisture can dissolve the organic matter during composting, participate in microbial metabolism, and regulate the compost temperature. Neither a high moisture content, nor low moisture content is beneficial to the survival of the microorganisms. If the moisture content is too high, it indicates that the ventilation and permeability are poor, and this can lead to partial hypoxia of the pile and produce acid odor. Furthermore, it is not conducive to the export of nutrients, thus resulting in an economic loss. On the other hand, a dry environment restricts the metabolism of the microorganisms. Studies have shown that the optimum moisture percentage in the early stage of composting is 50–65%, and in the later stage of composting, in order to maintain the speed of composting and shorten the composting cycle, the moisture percentage should not be less than 20%. The optimal pH for composting is 5.5–8.5. It is interesting that the initial moisture content and the pH measured in this experiment are in the optimal range.

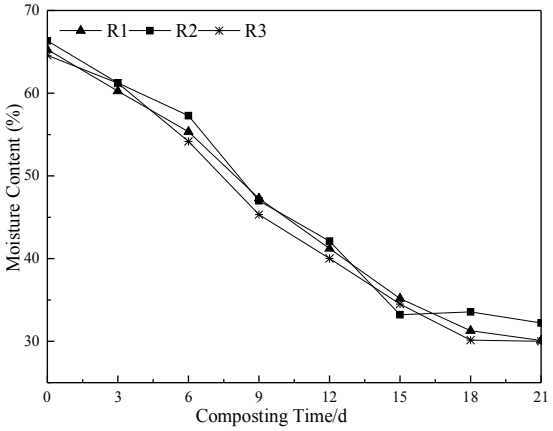

Figure 4. *Change in moisture content of the three manures of three kinds of composting*

The change of C-N-P-K content in the composting process with different livestock manure

The total nutrient of $N+P_2O_5+K_2O$ is an essential index for the quantity of organic fertilizer (Awasthi et al., 2015). There are three pathways of nitrogen transformation in the composting process. The first one is the emission of ammonia gas to the atmosphere, resulting in a loss of nutrients from the composting system. The second one is the transformation of nitrogenous compounds to nitrate or nitrite by nitrifying bacteria or nitrite bacteria, respectively. The third one is the assimilation of nitrogen by microorganisms. The content of total nutrients ($N + P_2O_5 + K_2O$) shows an increasing trend in the composting process due to two reasons. The first reason is the emission of the organic state released and transformed to the inorganic state due to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65816593

decomposition of organic matters in the composting process. The second reason is the quantity of organic carbon decreased due to the functions of microorganisms which caused an increase in the concentration effect. Thus, the total nutrient content increased (Zhuotong et al., 2018; Wang et al., 2017, 2014). According to *Table 2*, the total nutrient content of pig manure was the highest with the value of 6.33% and that of the cattle manure was lowest (5.04%).

According to the *Organic Fertilizer Industry Standards* (NY525-2012) issued in 2012, the mass fraction of organic matters in the qualified products should be larger than 45%. In addition, the mass fraction of the total nutrients ($N + P_2O_5 + K_2O$) should be larger than 5%. Besides, the mass fraction of water content should be smaller than 30%. Besides, values of pH in the qualified products should be in the range of 5.5-8.5. According to *Table 2*, all the four composting products from the present study satisfied the requirements of Organic Fertilizer Industry Standards (NY525-2012) (Jain et al., 2018).

Table 2. *The total nutrients in the composting products with different livestock manure*

The composting products	TN/%	TP/%	TK/%	$(N+P_2O_5+K_2O)$/%
R1 (cattle manure)	1.93±0.18	1.57±0.19	1.54±0.19	5.04
R2 (pig manure)	2.25±0.18	2.41±0.15	1.67±0.12	6.33
R3 (chicken manure)	2.14±0.15	1.83±0.16	1.78±0.19	5.75

The enzyme activity changes in the composting process with different livestock manure

Composting is a biochemical process where decomposition and transformation of organic matters to stable humus take place. The process follows the utilization of the secreted enzymes in the growth and reproduction processes as well as metabolic activities of microorganisms. So, different enzymes are involved in the whole composting process (Hannum et al., 2017). Enzymes are composed of apoenzyme and the cofactor has characteristics of specificity, high efficiency and diversity. In the present study, the relationships between the enzyme activity change of catalase, urease and invertase and the quantity of microorganisms were systematically compared. For the purpose, composting process with four livestock manure was investigated targeting to provide theoretical evidence for the composting mechanism.

The enzyme activity change of catalase in the composting process with different livestock manure

Catalase demonstrates the intensity of the degree of composting oxidation, because catalase can decompose hydrogen peroxide produced in the composting process and thus decrease its poisoning effect to microorganism (Ukalska-Jaruga et al., 2018).

Figure 5 showed the changing trend of the enzyme activity of catalase in the composting process with different livestock manure. It showed that the initial concentration of catalase in the initial composting reaction of R1 (cattle manure) was 48.21 ± 1.11 $mol \bullet L^{-1} \bullet g^{-1}$. Besides, the initial concentration of catalase of R2 (pig manure) was 45.04 ± 0.85 $mol \bullet L^{-1} \bullet g^{-1}$. Moreover, the initial concentration of catalase of R3 (chicken manure) was 44.29 ± 0.65/0.002 $mol \bullet L^{-1} \bullet g^{-1}$.. With the process of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65816593

composting, the concentration of catalase gradually increased. At the end of the reaction, the concentration of catalase were in descending order of R1 (cattle manure) > R2 (pig manure) > R3 (chicken manure) with corresponding values of 62.18 ± 0.45, 55.21 ± 0.58 and 54.28 ± 0.14/0.002 mol•L^{-1}•g^{-1}, respectively. The main reason for the gradual increase of catalase concentration in the composting process with livestock manure was the increase of biochemical metabolism activity. This activity was carried out by the thermophilic bacterium as a replacement for the mesophilic bacterium. The latter bacterium happened to be the active microbial flora with the increase of the pile temperature. Besides, the temperature was also an important factor which influenced enzymatic reactions. Thus, the concentration of catalase increased gradually with the process of reactions.

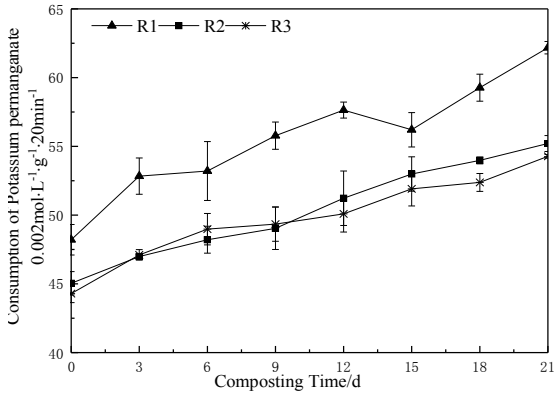

Figure 5. *Activity change in catalase*

The enzyme activity change of urease in the composting process with different livestock manure

Figure 6 shows the changing trend of the enzyme activity of urease in the composting process with different livestock manure. Urease could catalyze the transformation and decomposition of urea to ammonia and CO_2 as well as promote the transformation and decomposition of nitrogenous organic matter. Thus, it was the key index to evaluate the transformation velocity of nitrogen in the composting process. It showed that the initial urease concentrations in the primary reaction period of the composting were 258.47 ± 8.35, 249.78 ± 3.98 and 4261.87 ± 4.28 mg•g^{-1}•d^{-1} for R1 (cattle manure), R2 (pig manure) and R3 (chicken manure), respectively. This illustrates the high activities of microorganisms in the initial composting period which secreted urease rapidly to decompose and transform susceptible nitrogenous organic matters. With the process of the reaction, urease activity became passive with the increase in temperature and demonstrated negative correlation with the change of temperature (Jain et al., 2018; Hannum et al., 2017). The urease content decreased gradually due to the decrease of the mesophilic microorganism quantities. The decrease of urease activities and the slowdown of decomposition and mineralization of nitrogenous organic matters occurred when the process entered into the high temperature period of the composting. At the end of the reaction, the urease concentrations in the pile were in a descending order of R1 (cattle manure) > R3 (chicken manure) > R2 (pig manure) with values of 54.28 ± 8.35, 51.24 ± 1.25 and 50.24 ± 5.36 mg•g^{-1}•d^{-1}, respectively.

DOI: http://dx.doi.org/10.15666/aeer/1703_65816593

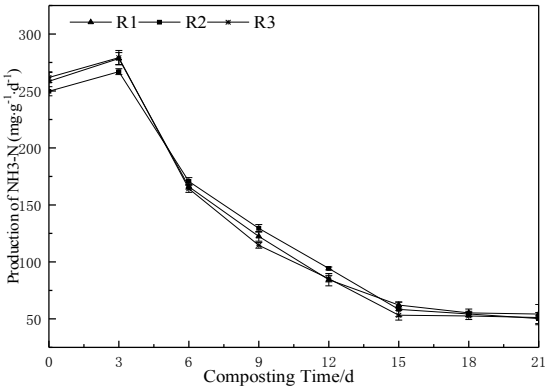

Figure 6. *Activity change of urease in three kinds of livestock dung composting kinds of livestock dung composting*

The change of invertase activity in the composting with different livestock manure

Figure 7 shows the changing trend of invertase activity in the composting with different livestock manures. Results show that the changing trends of invertase and catalase were the same. The initial catalase concentrations of the composting with R1 (cattle manure), R2 (pig manure) and R3 (chicken manure) were 50.28 ± 1.21, 42.27 ± 1.25 and 44.54 ± 1.01mg•g^{-1}•d^{-1}, respectively. Results indicate that the high activity of microorganism in the initial period of composting, which secreted invertase rapidly to decompose and transform susceptible nitrogenous organic matters (Li et al., 2016; Kazemi et al., 2016). With the process of the reaction, the invertase content in the pile decreased gradually, mainly due to the decrease in quantities of mesophilic microorganisms. Therefore, a decrease of invertase activities and the slowdown of the decomposition and mineralization rate of nitrogenous organic matters also occurred when the reaction phases entered into the high-temperature period of the composting. At the end of the reaction, the urease concentrations were in descending order of R2 (pig manure) >R3 (chicken manure) > R1 (cattle manure) with values of 11.28 ± 0.14, 10.94 ± 1.11 and 10.45 ± 0.97mg•g^{-1}•d^{-1}, respectively (Teutscherova et al., 2017; Sharma et al., 2017).

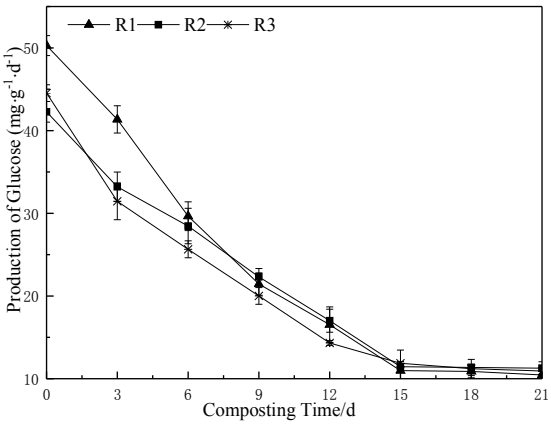

Figure 7. *Activity change of sucrase in three*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Conclusions

The composting treatment of three livestock manure entered the high-temperature period (45 °C) on the 6th day. Besides, their temperatures reached the maximum of 56.1, 58.3 and 59.3 °C, respectively. The number of days with temperature above 55 °C were 6, 6 and 9 d, respectively. Among them, the treatment of R3 (chicken manure) had the most days which belonged to the high temperature period, whereas the treatment of R1 (cattle manure) and R2 (pig manure) had relatively fewer days for belonging high-temperature period. All of them could satisfy the requirement of maturity standards.

pH values of the composting process with three livestock manure demonstrated the trend of initial increase, then decrease and final increase rally. pH of the R3 composting (chicken manure) was the lowest in the whole composting process. The value was 6.07 on the 15th day. Besides, pH values recorded were in the range of 6.9-7.1 at the end of the composting. Furthermore, the change of water content of three composting manures demonstrated the decreasing trend with the decreasing amplitude of 34-36%.

At the end of the composting with livestock manure, the total nutrients of pig manure composting were the highest with the value of 6.33%. The total nutrients of cattle manure composting were the lowest with the value of 5.04%.

Different types of enzymes were involved in different stages in the composting process. In the whole composting system, the activity change of urease and invertase was same with a decreasing trend as a whole. However, the catalase activity increased gradually with the process of composting. At the end of the composting reaction, the concentrations of catalase, urease and invertase were the highest in the piles of R1 (cattle manure), R1 (cattle manure) and R2 (pig manure), respectively, with corresponding values of $62.18 \pm 0.45/0.002 mol \bullet L^{-1} \bullet g^{-1}$, 54.28 ± 8.35 $mg \bullet g^{-1} \bullet d^{-1}$ and 11.28 ± 0.14 $mg \bullet g^{-1} \bullet d^{-1}$.

Recommendation

The paper compared the changing pattern of enzyme activities in composting with different livestock manures added 10% straw as bulking agent and provided theoretical evidence for temperature, pH, moisture content and nutrition parameters. Future studies should focus on the change of microbial population and the correlation between microbial quantity and enzyme activity, so as to further analyze the mechanism of microbial enzymatic reaction and study the biochemical reaction activity of livestock and poultry manure compost.

Abstract. Although *Hypochaeris radicata* L. is a noxious alien species in Korea, there is no effective way to prevent it from spreading. Therefore, this study aims to study the possibility of using *H. radicata* as an effective natural compound source which will contribute to the utilization of the invasive alien species and some extent to prevent invasion. Hot water and ethanol extracts of *H. radicata* showed high efficiency as a natural antioxidant indicating the species may be used as a natural antioxidant material. Extracts of *H. radicata* has shown no toxic effects on cells. Rather, *H. radicata* extract has an function of inhibiting the generation of NO in high concentrations of extracts which means that *H. radicata* extract has a function of anti-inflammatory effect. When the research on the effect of *H. radicata* finds out more, the utilization of this species will be increased and the environmentally friendly public participation management will be possible due to an increase in its collection. Also, it is meaningful that we have attempted to find an ecological engineering approach through utilization methods of alien species that has been spread widely in Korea.
Keywords: *cat's-ear, natural compounds, antioxidant, anti-inflammatory, alien species*

Introduction

Invasive alien plants are species that are dispersed outside their original habitats through intentional or unintentional means, which can harm the environment. This destruction will result in loss of ecosystem function and extinction of native species, eventually reducing biodiversity, ultimately resulting in socioeconomic decline (Samways et al., 1996). However, these exotic species can be used as sources of natural compound (medicine, cosmetic etc.), that such development of these uses may help to manage such exotic species through increase the harvest of this species in the wild (Maema et al., 2016), as a kind of ecological engineering. The free radical and properties containing natural antioxidants that metabolize the endogenous products of several oxidizing species are facilitated by ecological stress (Grassmann et al., 2002) for most plants, and studies of these natural products are useful for confirming the availability of plants. Recently, there has been an increasing interest in natural antioxidants, which can protect humans from damage caused by oxidative stress (Scalbert et al., 2005). This study attempts to approach *Hypochaeris radicata* L., which causes many problems in Jeju Island and some inland regions (Kim et al., 2006), as a new perspective. *H. radicata* is managed because it is designated as a harmful species in the Ministry of Environment. However, in Jeju Island, *H. radicata* is already the most dominant species. Thus, realistic removal and management of this species are difficult

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65956604

and showed no results so far (Ryu et al., 2017). From the discovery of *H. radicata* in Chungcheong and Jeolla, it shows that diffusion and settlement have already occurred inland (Hyun et al., 2018). Therefore, the case of *H. radicata* shows that there is a limitation in the existing management methods for general harmful species. Therefore, we investigated the medicinal efficacy of *H. radicata* through the view as a resource. Through this, the research applying the idea that increasing the use of these alien species is a positive management of alien species (Li et al., 2015). For this purpose, we conducted a study on the efficacy of *H. radicata*.

Materials and methods

Plant sampling

In October 2018, 10 habitats from the northern part of Jeju island, Korea were randomly selected and the *H. radicata* used for the experiment were collected. Every sampling sites were unmanaged areas inside of agricultural fields, mostly close to roads. Sampling sites were relatively flat areas and dominated by *H. radicata*. The geographic coordinates of the center of the sampling sites are 33°27'49"N, 126°29'07"E. Ten plant samples were collected from each site and used as one large sample. Harvested plants were washed and then dried for 24 h. The stems and leaves except roots were cut into the crusher and used as experimental material.

Total antioxidant capacity (TAC) the superoxide dismutase activity (SOD) using raw plant

From plant leaves, crude extracts were prepared by re-suspending the frozen cells in 50 mM phosphate buffer (pH 7.2). The plant samples (0.1 g) were washed and then the cells were quick-frozen in liquid N_2 and milled subsequently. Phosphate buffer (1 ml; Sigma-Aldrich Corp.) was added and the suspension was stirred using Vortex mixer. Waited more than 30 min for protein extraction. After centrifuging at 14,000 rpm at 4 °C for 20 min, 400 µl of the supernatant was collected for the experiments. Absorption was measured using SpectraMax (Molecular Devices, USA). Protein quantities were determined by using Bradford assay (Bradford, 1976) to obtain a standard curve. Total Antioxidant capacity was measured by the antioxidant activity of an organic liquid using bathocuproine (Jaramillo-Flores et al., 2003) with a slight modification of the protocol. Our method comprises the following steps. First, mix a sample of the liquid (15 µl) with bathocuproine (200 µM; 585 µl) and stir using Vortex mixer and Pour a predetermined quantity (200 µl) of each of the samples into the wells of a multi-well plate. Then, Perform spectrophotometric measurements of the samples at 490 nm (S1). Add a predetermined quantity (50 µl) of copper sulfate solution to each well and incubate it at room temperature for 5 min; terminate the reaction using ethylenediaminetetraacetic acid (EDTA). Then again, Perform the second round of spectrophotometric measurements at 490 nm (S2). Total Antioxidant Capacity is calculated as TAC = S2 – S1 (µM/ml). Finally, convert units using the Bradford assay results (µM/mg). The superoxide dismutase activity was measured using the methods established by Peskin and Winterbourn (2000) and protocols of the WST assay by Donindo, Japan.. Using a WST-1 (2-(4-Iodophenyl)- 3-(4-nitrophenyl)-5-(2,4-disulfophenyl)- 2H-tetrazolium, monosodium salt) solution (Dojindo, Japan) and an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65956604

Enzyme Working Solution (Dojindo, Japan), SOD activities were calculated under the Dojindo's protocols.

Extract preparation

The dried aboveground plant parts (i.e., leaves and branches) were coarsely powdered by using an electric blender. 32.6 g of dried plant powder was then, a) extracted with 500 ml of 70% (v/v) ethanol for 24 h (EtOH) or b) extracted with 500 ml of 90 °C distilled water (HW: Hot Water) for 2 h. Then extracted solutions were filtered (Whatman No.1), and then concentrated with a rotary evaporator. Then the solution was freeze-dried to make the final product as powder.

Radical scavenging assay for testing antioxidant effects of extracts

DPPH (1,1-diphenyl-2-picrylhydrazyl) radical scavenging activity of the *H. radicata* were measured by a method suggested by Blois (1958). 180 µL of DPPH solution in 0.4 mM in ethanol was mixed with 20 µL of the extract (DW and ethanol) and incubated in the dark at 25 °C for 10 min. Then, the absorbance of the sample (A sample) and negative control (A control) consisting of only ethanol alone was measured at 517 nm. The DPPH radical scavenging activity of the sample was calculated by using *Equation 1*.

$$\text{Scavenging activity (\%)} = 100 \times \frac{(\text{A control} - \text{A sample})}{\text{A control}} \quad \text{(Eq.1)}$$

ABTS (2,2'-azino-bis-(3-ethylbenzothiazoline-6-sulphonicacid)) radical scavenging activity of the subtropical plant extracts was measured as a method by Zhu et al. (2011). ABTS and potassium persulfate solutions (7 and 2.45 mM, respectively) were mixed and then incubated in the dark at 25 °C for 16 h. The ABTS solution was diluted with ethanol to obtain the working solution with an absorbance at 745 nm. Then, 20-µL aliquots of the plant extract samples were dissolved in ethanol at different concentrations (10–500 µg/mL), mixed with 180 µL of the working solution, incubated in the dark at 25 °C for 10 min, and then the Abs sample and Abs control (ethanol only) were measured. The ABTS radical scavenging activity was calculated by using *Equation 1*.

High performance liquid chromatography (HPLC)

High Performance Liquid Chromatography (HPLC) was analyzed at NICEM (Seoul National University, South Korea) using Ultimate 3000 model, (Thermo Fisher Scientific, Waltham, MA USA). The flow rate was 0.8 mL/min and the gradient was given using Buffer A [0.3% trifluoroacetic acid (TFA)] and Buffer B (Acetonitrile). C-18 column (4.6*250,5 um) was used and wavelength of 280 nm [190-800 nm diode array detection (DAD) scanning] was used for analysis. 12 standards that often used for phenolic compounds were used to detect natural compounds of *H. radicata* (syringic acid, salicylic acid, *p*-coumaric acid 4, ferulic acid, naringin, myricetin, hesperidin, *trans*-cinnamic acid, quercetin, naringenin, confertin, scopoletin).

Cell culture

Murine RAW 264.7 macrophages were obtained from the Korean Cell Line Bank (Seoul, South Korea). Cells were cultured in Dulbecco's modified Eagle's medium, supplemented with 10% fetal bovine serum, penicillin, and streptomycin sulfate (all from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65956604

GIBCO, Grand Island, NY, USA), in an incubator at 37 °C in a humidified atmosphere of 95% air and 5% CO_2. For this study the cells were mechanically passaged by dissociation every other day; they underwent fewer than 25 passages.

Toxicity of plant extract (MTT assay)

A 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay was undertaken as described previously by Yang et al. (2013). Cells were counted with a haemocytometer, and the number of viable cells was assessed by trypan blue dye exclusion method. The RAW 264.7 macrophages were seeded in 24-well plates for 18 h and then stimulated with various treatments (250, 500, 1000, 1500 ug/mL of HW and 50, 100, 200, 500 ug/mL of 70% EtOH) or LPS (lipopolysaccharide) (1 μg/mL) for 1 h. On the day of collection, cells were incubated with MTT solution for 24 h at 37 °C in a humidified atmosphere of 95% air and 5% CO_2. The MTT-containing supernatant was removed and the formazan crystals were solubilized in dimethylsulfoxide. The absorbance of each well at 540 nm was measured using an automatic microplate reader (PowerWave X340, Bio-tech Instruments, Inc., Winooski, VT, USA).

NO (nitric oxide) concentration as indicator of anti-inflammatory effects

The NO concentration in treatments was determined based on the method of Yang et al. (2013). RAW 264.7 cells (5×10^5 cells/well) were cultured on 24-well dishes with 1 μg/mL of LPS and various treatments (250, 500, 1000, 1500 μg/mL of HW and 50, 100, 200, 500 μg/mL of 70% EtOH). After 18 h, culture supernatants were collected and nitrite, a stable oxidized product of NO, was measured by a modified Griess (1879) method. Equal volumes (100 μL) of the Griess (1879). Reagent [1% sulfanilamide and 0.1% *N*-(1-naphthyl)-ethylenediamine dihydrochloride in 5% phosphoric acid] and *D. divaricate, D. prolifera, P. cornea, G. lanceolata*, or *G. filicina* were incubated together at room temperature for 10 min. The absorbance of each well at 540 nm was measured using an automatic microplate reader (PowerWave X340, Bio-tech Instruments).

Statistical analysis

Differences between multiple groups were evaluated using oneway PROC analysis of variance (ANOVA). When a significant treatment effect was detected, post hoc comparisons of the means were performed using Tukey's honest significant difference test (SAS v. 9.1, SAS Institute Inc., USA). Differences were considered significant if $p < 0.05$.

Results and discussion

Total antioxidant capacity (TAC) and superoxide dismutase activity (SOD)

TAC and SOD were measured using fresh plant leaves instead of extracts (*Table 1*). To see the functions of the plant itself as a medicinal herb not the effects of extracts, TAC and SOD were selected. However, most other TAC studies of leaves of plants, results are re-directed to extracts by calculation, so it is difficult to make a direct comparison because the unit is L (liter). Rarely, among the existing studies using the same method as we did, there are results of *Brassica campestris* ssp. *napus* var. *nippo-oleifera* Makina (oilseed rape) and *Lactuca sativa* L. (lettuce), a leap-eating crop (Song

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65956604

et al., 2013). *H. radicata* is expected to have higher efficacy than conventional plants because it shows a high value of three times higher than that of this crop. In addition, the result can have the meaning of the archive showing the antioxidant value of the fresh leaf of *H. radicata*. In the case of SOD, it was possible to make a direct comparison with other papers since it came out as a unit. In the case of overseas studies using the same Dojindo SOD kit for medicinal herbs (Rafat et al., 2010), five herbicides showed an average value of about 60 unit (SOD unit). On the other hand, *H. radicata* has a value of 90 or more. Therefore, the antioxidant effect of *H. radicata* is expected to be high and gave us expectation for noticeable efficacy.

Table 1. *Total antioxidant capacity and superoxide dismutase activity of H. radicata*

Sample	Value
TAC (μM/mg protein)	389.35 ± 41.34
SOD (U/mg protein)	94.03 ± 2.21

Each value represents mean ± S. D. (n = 4)

Radical scavenging assay for testing antioxidant effects of extracts

Free radicals are known to cause various diseases by causing oxidative stress in the body. Therefore, DPPH and ABTS radical scavenging activities were measured to confirm the free radical inhibitory activity of HW extract and 70% EtOH extract on the aboveground part of *H. radicata*. As a result, the DPPH radical scavenging activity of EtOH extract (IC50 = 139.63 ± 5.30 μg/mL) was higher than that of HW extract (IC50 = 167.91 ± 3.94 μg/mL) (*Table 2*). In the ABTS radical scavenging activity, HW extract (IC50 = 58393 ± 13.31 μg/mL) was higher than EtOH extract (IC50 = 155.94 ± 35.27 μg/mL) (*Table 2*). When DDPH radical scavenging activity of *H. radicata* was compared with other popular medicinal plants such as *Trigonella foenum-graecum* and *Elettaria cardamomum* (Khalaf et al., 2008). The IC50 value of *H. radicata* was lower. Therefore, it can be said that *H. radicata* showed higher efficiency as a natural antioxidant than popular medicinal plants (*T. foenum-graecum* and *E. cardamomum*). This suggests that *H. radicata* may be used as a natural antioxidant material. After conducting this experiment, we've found a new reference that has investigated DPPH and ABTS of *H. radicata* extract (Ko et al., 2017). This paper also showed that *H. radicata* extract has strong antioxidant effects, which is consistent with our results. However, our DPPH value of HW extract is low compared to other paper from a research group who have studied this plant steadily (Senguttuvan et al., 2014) while the local paper (Ko et al., 2017) showed similar value (EtOH) to our results. As Korea and India are very distant counties, ecotypes of *H. radicata* in India could be different. Also as climate condition of Korea is different from India (cold winter in Korea), it would affect the chemical composition of plants.

Anti-inflammatory activity and toxicity of HW and EtOH extracts in RAW 264.7 cells

To determine the toxicity and anti-inflammatory effects of extracts, the most common method is to examine the cell viability by RAW 264.7 cells using NO production and MTT assay. In the HW extract, NO production was significantly increased in LPS only treatment (LPS +, Sample 0 μg/mL) compared to control (LPS -, Sample 0 μg/mL), but HW extracts treated with 500, 1000, and 1500 μg/mL showed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65956604

that NO production decreased by concentration compared to LPS only treatment (*Fig. 1*). This shows that the higher the concentration, the stronger resistant the inflammation by NO product inhibition. Cell viability was also reduced in all treatments compared to control (LPS -, Sample 0 μg/mL) and all values are lower than the value of LPS only treatment (LPS +, Sample 0 μg/mL), but with the exception of 1500 μg/mL treatment. As the LPS itself is toxic, it is a normal response. However, when the extract is added, the toxicity is alleviated considering low values in most concentration range. In general, when the cell viability is 80% or more, it is considered that there is no problem, so that the overall extract, even including 1500 μg/mL treatment are safe to be considered as none toxic.

Table 2. *Antioxidant activities of H. radicata extracts*

Sample	DPPH radical scavenging activity	ABTS radical scavenging activity
HW	167.91 ± 3.94	187.04 ± 11.54
EtOH	139.63 ± 5.30	203.6 ± 4.68
Ascrobic acid	6.48 ± 0.25	22.34 ± 0.87

Each value represents mean ± S. D. (n = 4). IC50 (IC50 = μg/mL) values were calculated from regression lines using eight different concentrations in triplicate experiments. HW; hot water extracts. EtOH; 70% ethanol extract

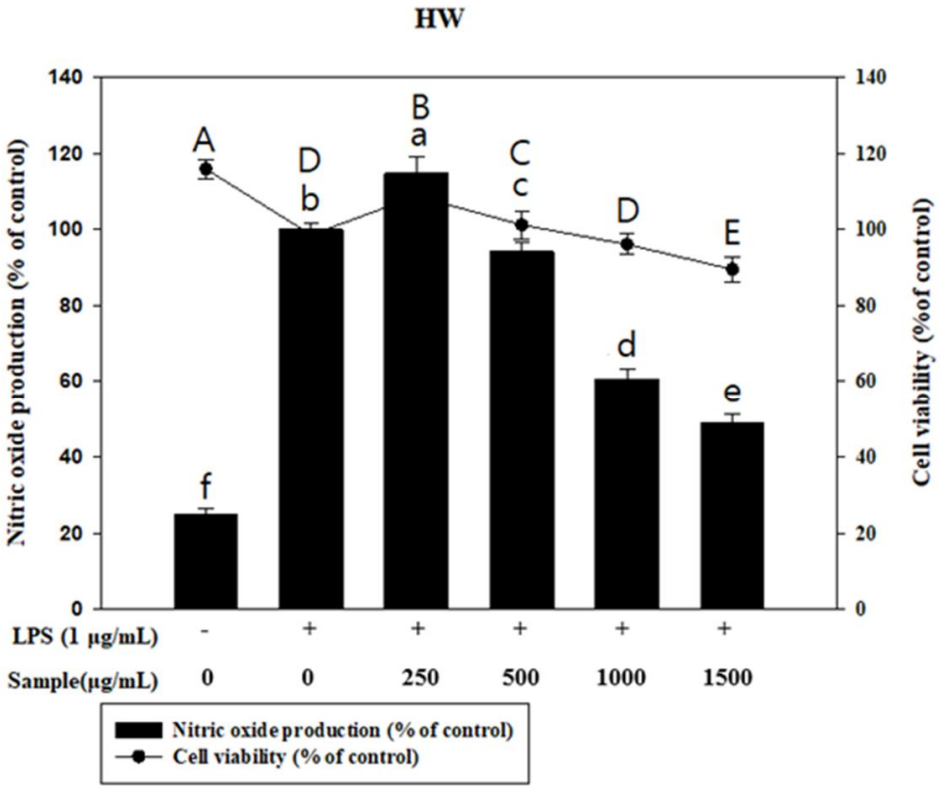

Figure 1. *Effect of HW extract on cell viability and nitric oxide production in LPS-stimulated RAW 264.7 cells. Raw 264.7 cell were incubated with 250, 500, 1000 and 1500 ug/mL of HW extract for 1 h, and then incubated with LPS (1 μg/mL) for 24 h. The data expressed as a mean ± SD (n = 4). Symbols or bars having the same letter are not significantly different at the 0.05 level. Uppercase letters show difference between symbols, while lowercase letters show difference between bars*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65956604

In the 70% EtOH extract, NO production was significantly increased in the LPS only treatment (LPS +, Sample 0 μg/mL) compared to the control (LPS -, Sample 0 μg/mL). However, EtOH extracts treated with 500, 1000, and 1500 μg/mL showed that NO production decreased (*Fig. 2*). Therefore, EtOH extract appears to have anti-inflammatory effect like HW treatment and its effects are considered to be stronger than HW extract. The cell viability was significantly higher in the 50 μg/mL to 200 μg/mL treatment groups, and these results are showing alleviated toxicity at this concentration. And the highest concentration (500 μg/mL) did not show any significant difference with control. Therefore, this suggests that *H. radicata* extract induces cell proliferation by minimizing the effect of cytotoxicity. As a result, the *H. radicata* extract has not been shown to be toxic to the cell. Rather, in some treatments, it can protect cells by reducing the harmful effects on cells. And the *H. radicata* extract can be regarded as a function of inhibiting the generation of NO in high concentrations of extracts. In other words, *H. radicata* extract has a function of anti-inflammatory effect.

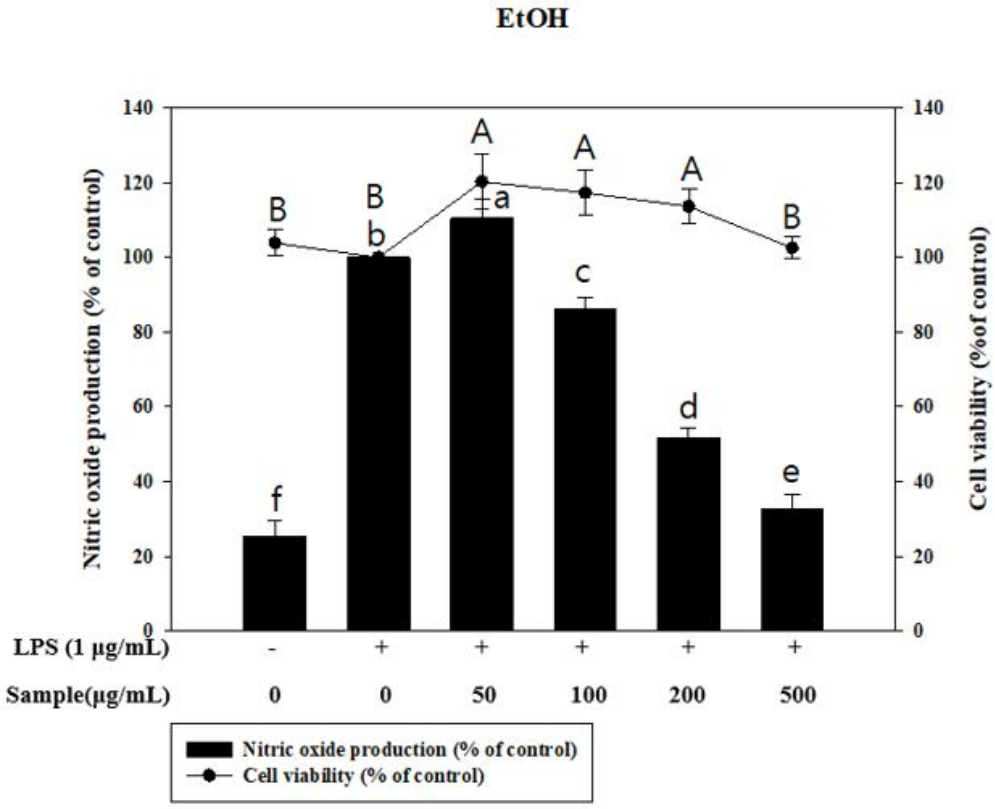

Figure 2. *Effect of EtOH extract on cell viability and nitric oxide production in LPS-stimulated RAW 264.7 cells. Raw 264.7 cell were incubated with 50, 100, 200 and 500 ug/mL of EtOH extract for 1 h, and then incubated with LPS (1 μg/mL) for 24 h. The data expressed as a mean ± SD (n = 4). Symbols or bars having the same letter are not significantly different at the 0.05 level. Uppercase letters show difference between symbols, while lowercase letters show difference between bars*

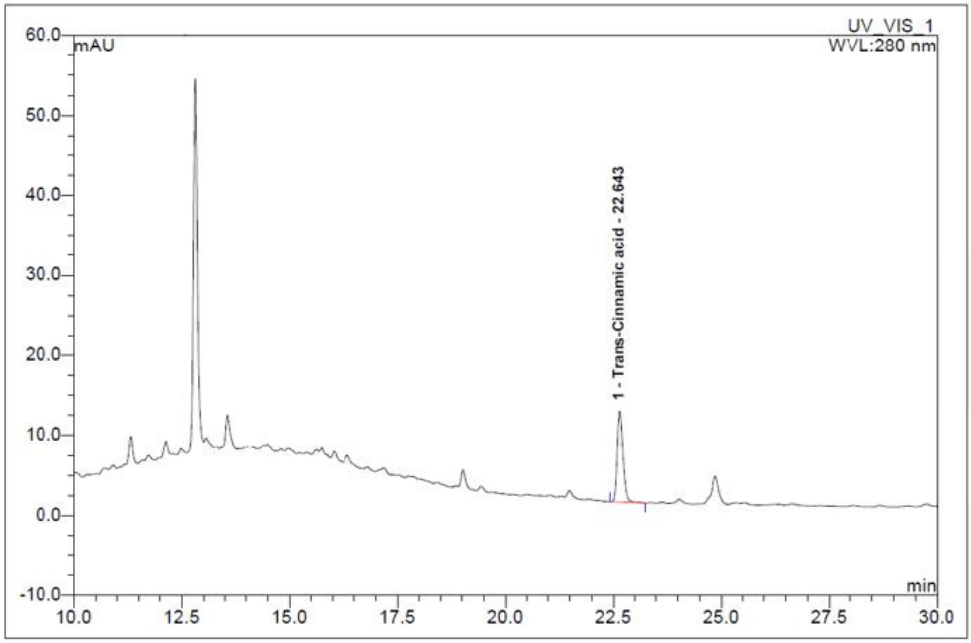
HPLC

Since the extracts of *H. radicata* have shown some effects, HPLC analysis was expected to detect a certain level of natural products. However, only 1-Trans-Cinnamic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65956604

acid was detected in the detection of phenolic compounds using 12 commonly used standards (*Fig. 3*). This suggests that the substances showing the function of the above results are slightly different from those of other plants, and *H. radicata* extracts are likely to contain new natural products rather than general ones. This shows that it is possible to obtain unusual natural products through a detailed analysis of this species in the future.



No.	Ret.Time min	Peak Name	Height mAU	Area mAU*min	Rel.Area %	Amount mg/L	Type
1	22.64	Trans-Cinnamic acid	11.391	1.769	100.00	1.034	BMB
Total:			11.391	1.769	100.00	1.034	

Figure 3. *High performance liquid chromatography (HPLC) result of HW extract*

Conclusion

H. radicata has been reported as an invasive alien species that has been degrading ecosystem functions as a result of environmental damage, resulting in the extinction of native species and ultimately ecosystem diversity. However, despite the fact that it has been designated as a dangerous species, there is no effective way to prevent it from spreading. In Jeju Island, frequent mowing is used for environmental management of *H. radicata*, but still the species are dominating the island. It implies that we need a better engineering solution of management of *H. radicata.* Therefore, this study aims to contribute to the utilization of invasive alien species and resource management, and to some extent to prevent diffusion, by exploring the possibility of using *H. radicata*, an invasive alien species already introduced in Korea. All results show that *H. radicata* can be used for natural antioxidants and anti-inflammatory effects. Further researches could find correlation between environmental factors (soil, climate, species composition etc.) and medicinal effects of *H. radicata* and molecular reactions such as expression of Nuclear factor-kappa B. When the researches on effect of *H. radicata* are discovered more, the utilization of this species will be increased and the environmentally friendly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_65956604

public participation management will be possible due to the increase of the collection. As some medicinal or gardening herbs such as *Panax ginseng* (Park and Park, 2007), *Hanabusaya asiatic*a (Park et al., 2013), *Saccolabium japonicum* (Jung et al., 2012) are endangered because it is being overharvested (Sangwon and Seonyeong, 2005), same effects can help to reduce *H. radicata* by increased usage. As harvesting wild vegetables are the common act in local (Hwang, 1991), this management mechanism is worthy to study. Therefore, we believed that it can be contributed to the prevention of diffusion of *H. radicata* to some degree when functions of *H. radicata* are discovered and be known to the public. In addition, it is meaningful that we have attempted to find an ecological approach (management through utilization) through utilization methods of alien species that has been spread widely in Korea.

Abstract. Hindu Kush Himalayan is facing greater threat from socio-economic and climatic transitions. The current study has assessed livelihood vulnerability due to climatic variability of natural resource dependent mountainous communities. The northern side of Pakistan is expected to bear severe impacts due to its distinct topography, land use and climate change. Based on primary data collected from four villages complemented with secondary climatic data, livelihood vulnerability was evaluated through a composite indicator as livelihood vulnerability index (LVI) and LVI-IPCC. GIS mapping was carried out to assess land use change in the area. The comparative analysis of Tehsil Balakot showed that UC Balakot was more vulnerable with a LVI score of 0.41 than UC Kawai 0.35. The results of in-depth analysis of differential vulnerability showed that households in UC Balakot had the low adaptive capacity and higher exposure to natural disasters. Developmental planners and policy makers should use such indices to assess root causes of vulnerability and specify community needs in policy making.
Keywords: *climate change, natural disaster, differential vulnerability, adaptive capacity, land use change*

Introduction

Rural people living on mountains are "vulnerable" to natural calamities and they need to adapt to climatic changes for their survival and better livelihood opportunities (Macchi, 2011; Gentle and Maraseni, 2012). The fifth assessment report of Intergovernmental Panel on Climate Change (IPCC) states that the climate change is one of the biggest challenges of the 21st century that will bring about unexpected extreme events throughout the world ranging from polar regions to the tropics, islands, developed as well as developing countries (Hijioka et al., 2014). The Himalayas are of prime significance for Pakistan and as known to be the water towers. The ongoing climate change is showing negative impacts on the mountainous life by affecting water volumes, biodiversity, increasing natural hazards, ecosystem structure and function (Basharat et al., 2016; Sarwar et al., 2016). Sustainability of life in the mountainous

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66056624

regions is under extreme pressure due to higher dependence on natural resources and prevailing poverty (de Sherbinin, 2008).

Although, Pakistan has a very little contribution to the global climate change by greenhouse gases emissions but local climate change is becoming visible from the frequency and intensity of natural disasters affecting livelihoods of the rural communities. Pakistan faces a natural disaster almost every year and is now well-thought-out as one of the most vulnerable and highly effected country by changing climate in South Asia (IPCC, 2012; Shah et al., 2017). According to German-watch global climate risk index measured for a period of 1997 to 2016, Pakistan was on number seven among the world's vulnerable countries those faces most economic losses due to climatic changes (Ali and Erenstein, 2016; Abid et al., 2016). Factors that contribute to Pakistan's vulnerability profile are distinct geography, demographic trends, socioeconomic factors, and lack of adaptive capacity along with the perpetuating vicious cycle of poverty (Ainuddin et al., 2013; Elalem et al., 2015). Pakistan is among one of the countries with the least adaptive capacity due to the existence of a high level of poverty and lack of physical as well as financial resources (Chaudhury et al., 2016; Shah et al., 2018). Himalayan part of Pakistan is predominantly facing higher threats from changing climate and specific ecosystems are under significant pressure of loss in its services. In a recent study, people's perception of climate change has reported in terms of reduction in forest ecosystem services. In such marginalized communities, local ecosystems like forest and water provide multiple services, which will either diminished or reduced in quantity or quality (Shahzad et al., 2018). These ecosystems services are lifeline of local communities and in face of changing climate, livelihood and its related opportunities will be threatened (Shahzad et al., 2019).

IPCC defines vulnerability as a term which corresponds more to exposure and sensitivity of a system, place and people, and adaptation based on the wellbeing's resources (IPCC, 2001a, b, 2007). Vulnerability assessment is a study of conditions and process resulting from physical, social, economic and environmental factors that increase the susceptibility of a community to the impacts of hazards (Gerlitz et al., 2016). Different methods and indices have been explained through vulnerability assessment to examine the interactions between social and ecological systems, non-linear feedbacks, spatial and temporal variation, human and their physical, social surroundings. Their application includes the measurement of trends in poverty, human development, food security, vulnerability and bio-diversity (Kotzee and Reyers, 2016). Vulnerability assessments can be conducted according to a range of approaches from descriptive to quantitative (Choe et al., 2017).

Livelihood Vulnerability Index (LVI) is used to analyze the vulnerability of domestic farming to climate change (Hahn et al., 2009). LVI is widely used in different parts of the world by many scientists to understand the specific vulnerability related to water, food, health and others sectors (Alam et al., 2017; Houng et al., 2018; Zhang et al., 2018). LVI is used to assess climate change vulnerability in coastal and inland communities of Mabote and Moma Districts of Mozambique, Africa (Hahn et al., 2009). It is widely used to understand climate based vulnerability of wetland-dependent communities (Shah et al., 2013) and rural riverine households (Alam et al., 2017) of Trinidad and Tobago islands and Bangladesh, respectively. Then LVI was used to indicate vulnerability in flood affected households of Bhagalpur Bihar, India (Madhuri et al., 2014). Gentle et al. (2014) assessed differential impacts of climate change based on distinct well beings of the communities in the Lamjung district of Nepal. The study

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66056624

coupled LVI with participatory well-beings ranking. In agriculture sector, LVI was used to analyze the impact of climate change on agro-livestock smallholders in Gandaki River Basin of Nepal (Panthi et al., 2015) and Northwest Vietnam (Houng et al., 2018) identified livelihood cycle and vulnerability in the rural riverine households of Bangladesh using LVI. However, most recently Zhang et al. (2018) examined the vulnerability of communities to climatic changes using LVI in the Gannan Plateau, which is one of most environmentally sensitive region of China. Such studies identified the root causes of vulnerability in different communities and helped locals in developing adaptations to identified vulnerable sectors. Gerlitz et al. (2016) used the multidimensional livelihood vulnerability index in the Hindu Kush Himalayan (HKH) region to examine livelihood vulnerability due to socio-economic and climatic changes.

However, there are very few reports available about the rural mountainous communities and no such study was undertaken to calculate the livelihood adaptations by using LVI after earthquake, 2005 in Balakot region. The current study has explored the livelihood vulnerability by accounting household adaptations and climate exposure of rural mountainous communities in Tehsil Balakot, Pakistan by using the Livelihood vulnerability index (LVI). The paper investigates potential factors of vulnerability based on community's exposure, sensitivity and adaptive capacity. It also aimed to assess land use changes in the region and its consequences on the livelihood of the rural people.

Materials and methods

Study area

Tehsil Balakot is a sub division of District Mansehra, Khyber Pukhton khawa (KPK) Province of Pakistan with an expected population of 22894 persons distributed in four main villages in almost 2857 households according to Mansehra District Plan Balakot (UNDP, 2007). It is geographically located at 34°33N and 73°20E and encompasses an area of about 740 $km^{2.}$ The mountainous region has an average elevation of 500 to 5000 m asl with dense pine forest and River Kunhar flowing throughout (Somroo et al., 2012). Geologically this area comes under Hazara-Kashmir Syntax (HKS), which is circumscribed by the Main Boundary Thrust (MBT) (Sarwar et al., 2016). On the basis of seismological and structural data of 1904 to 2007, Bagh to Balakot has the most critical fault line of 120 km long (Mona, 2014). This makes the whole region highly susceptible to natural disasters, including earthquakes, landslides and avalanches (Baig, 2006; Kumar et al., 2006). The area was severely affected by the Kashmir Earthquake in 2005 which destroyed about 80 to 90% of the houses and resulted in huge death toll (Halvorson and Hamilton, 2007; Munir and Mirza, 2007). Loss of agricultural land had further enhanced their economic loses (Somroo et al., 2010). Rural people of Balakot are facing livelihood stress due to higher dependence on natural resources of the mountainous region which is already environmentally sensitive (Soomro et al., 2012). The rural community heavily relies on the forest and water resources of the area for subsistence livelihood. As a result, there is a higher threat of ecosystem changes and degradation which will amplify human vulnerabilities (Qasim et al., 2010). Forest cover has reduced due to the requirement of fuelwood and clearing the land to cultivate (UNDP Mansehra District 2007). Most of the people are cultivating seasonal vegetables on steep slopes of mountains. The region is a popular tourist destination of northern Pakistan which has many pros and cons for rural people. This condition has provided a rationale to assess that how the livelihood of the vulnerable rural people of Balakot will

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66056624

be further influenced by the changing climate. The map of study area is shown in *Figure 1*.

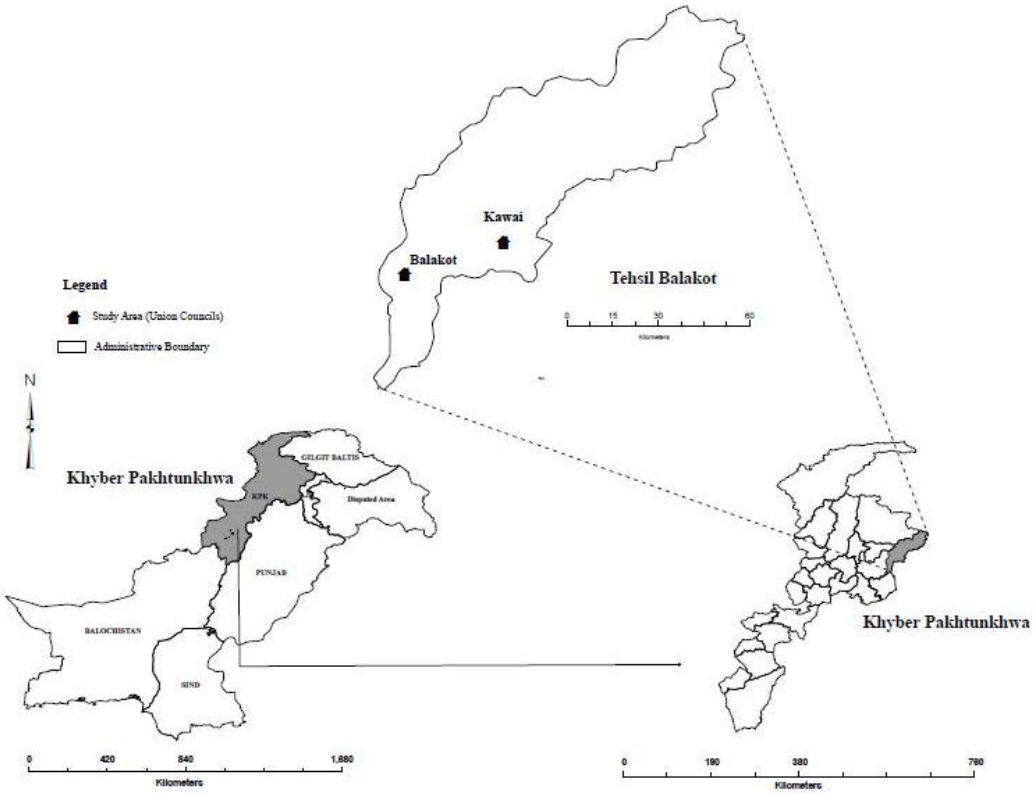

Figure 1. *Map of Tehsil Balakot, District Mansehra, KPK Province-Pakistan indicating surveyed Union Council Balakot and Kawai*

Study population

For the current study, households were the unit of observation to assess vulnerability based on the climatic and socio-ecological changes. The reason to choose such community is their dependence on the respective area's natural resources; so it becomes easy to assess their resilience or status of vulnerability (Shah et al., 2017). On the basis of these facts, two villages were surveyed from each UC to gather desired data. Taking 95% of confidence level, ± 10 interval, a minimum sample size of 96 households was calculated. Keeping this in consideration, a total of 200 households were surveyed, where hundred 100 were chosen from each of two villages in Tehsil Balakot (Shahzad et al., 2018). The first site is Union council Balakot where most of households are close to river Kunhar and on the foothills. This area has sufficient human settlements living in higher vulnerability due to multi-hazards scenario of flood, earthquake and landslides. Second site Union Council Kawai was on the mid hill slopes near cultivated and forested lands, but far from water body. This area has usual landslides resultantly erosion and weathering are common phenomenon (Ullah et al., 2017).

Methods used

A mixed method approach was used to gather data based on interpretivist pragmatism which merges quantitative methods to qualitative methods dealing with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66056624

individuals and their interactions in the society. Two extensive field visits were carried out, first in April 2017 and secondly in October 2017. In primary data collection, qualitative data was gathered through the participant's observations and focus group discussions (FGDs) (N = 10). A field survey to get household level records (n = 200) was also done which provided the quantitative data. Secondary data was taken from the union councils of Balakot and Kawai. Climate data consisting of temperatures and precipitation of Balakot and Kaghan stations was taken for the period of 1988 to 2017, accounting 30 years span. This data was provided by Meteorological Department Pakistan (PMD) and used to measure climatic variability and natural disaster's exposure. Along with LVI, land use maps were generated for the Tehsil to plot the change over the period of 20 years. For mapping land use change, remote sensed data of LANDSAT 5 and LANDSAT 7 were taken with path 150 and row 36. The spatial resolution of images used was 30 m. Images of month of May 1990, 1995, 2010 and 2015 were taken for determining the variability. Images of year 2000 and 2005 were not accessible.

Details of each of method are explained under specific heading:

Participants' observation

In the study, participant's observation as a technique of qualitative research method was used to record the day to day activities and connection within communities (Fine, 2003; Stacy, 2004). This helped the in getting a better picture of community's culture and livelihood setting by observing how the people in the area live their life.

Focus group discussions

After acquiring the brief picture of local community, focus group discussions were carried out with the locals. A total of 10 groups were carried out, 5 in each village which facilitated in mapping the livelihood assets and threats due to changing climatic conditions. Male and female population was requested to be part of the discussions to have a representative approach in the study design.

Household survey

In addition to above methods, 200 households were visited door to door to get livelihood data using a questionnaire.

Livelihood vulnerability index

Two approaches were used to assess livelihood vulnerability: LVI and LVI-IPCC on the gathered data. The livelihood vulnerability index was established on the descriptive information generated by the field survey which was based on set of indicators. These sub components were coupled into eight major components and three factors of vulnerability in both UCs (*Table A1* in the *Appendix*).

Approach I – LVI: The eight major components of vulnerability were inquired using survey questions as livelihood indicators. The eight components calculated at household level were socio-demographic profile (SDP), livelihood strategies (LS), social network (SN), health (H), food (F), water (W), natural disaster (ND) and climatic variability (CV). Each of these major components had different questions; seven indicator questions were placed for LS, six for H, five for F, four for ND, SN, W, SDP and three

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66056624

questions for CV. Therefore, a total of 37 indicator questions were described in column three of *Table A1*. Each major component of LVI was measured through four steps: (1) Compute the questionnaire data of sub-component and transform into percentage, ratio and index. (2) Unit standardization of each sub-component (Sullivan et al., 2002) (3) Calculate the average of each standardized score to get the final value for each main component. (4) Weighed the averages of all major components to obtain the LVI value. This procedure confirms the equal contribution of main components to generate the overall LVI. The scale of LVI calculated from this approach ranges from 0 (minimum) to 0.5 (maximum) as described by Hahn et al. (2009).

The formula is shown as *Equation 1:*

$$Index_s = \frac{S_S - s_{min}}{s_{max} - s_{min}} \quad \text{(Eq.1)}$$

where s_S = original sub-component for each of the site,
s_{min} = minimum value for each sub-component,
s_{max} = maximum value for each sub-component.

After obtaining values of sub-components, average of each sub-component was calculated using *Equation 2:*

$$M_s = \frac{\sum_{i=1}^{n} \text{index } s_{Si}}{n} \quad \text{(Eq.2)}$$

where M_S = one of the eight major components for study site,
$index\ s_{Si}$ = subcomponent, n = number of subcomponents in each major component.

The above values were calculated for each of the eight components and LVI was calculated using the formula mentioned as *Equation 3* and elaborated in *Equation 4:*

$$LVI_S = \sum_{i=1}^{8} W_{M^{iMs}} \Big/ \sum_{i=1}^{8} W_{Mi} \quad \text{(Eq.3)}$$

Equation 3 can also be elaborated as:

$$LVI_S = \frac{W_{SDP}\, SDP_S + W_{LS} + LS_S + W_{SN} SN_S + W_H H_S + W_F F_S + W_W W_S + W_{CV} W_S + W_{ND} W_S}{W_{SDP} + W_{LS} + W_{SN} + W_H + W_F + W_W + W_{CV} + W_{ND}} \quad \text{(Eq.4)}$$

where SDP represents socio-demographic profile for each UC, LS is livelihood strategies, SN is social networking, H is for health, W for water, CV is climatic variability and ND is natural disasters.

Approach II – LVI-IPCC: Livelihood vulnerability based on the IPCC definition was also quantified which is the measurement of exposure, sensitivity and adaptive capacity (represented in *Equation 5*). According to the framework, exposure represented by "e" is ranking of exposure to any natural hazards/disaster which rural community has faced in last 5 years. Whereas "s" is for sensitivity and "a" is for adaptive capacity measured for household. Adaptive capacity is based on the scores of socio-demographic, livelihood strategies and social networks. Exposure is grouped in natural disasters and climatic variability. However Sensitivity is calculated by taking the scores of health, food and water. The LVI-IPCC scale ranges from -1 (minimum) to +1 (maximum).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66056624

$$LVI - IPCC_S = (e_s + a_s) \times s_s \quad \text{(Eq.5)}$$

Land-use change mapping

To obtain information of land use changes in Tehsil Balakot, remote sensing data was interpreted to produce maps of these years; 1990, 1995, 2010 and 2015. Landsat 7 Enhanced thematic Mapper Plus (ETM+) and Landsat 5 Thematic Mapper (TM) were used from United State Geological Survey (USGS). The interpretation was done using Erdas imagine software through supervised maximum likelihood classification, also used Google Earth Engine and ArcGIS for further processing on classified rasters. Final output maps were designed by using ArcGIS 10.5. Six major classes of land use were described and shown in *Table 4*. Changes in time periods were calculated for each land use class between a final year V2 and an initial year, V1 as shown in *Equation 6*.

$$Percentage\ Change = (V_1 - V_2|V_1) \times 100 \quad \text{(Eq.6)}$$

Results

Livelihood vulnerability index in Tehsil Balakot

Household level of vulnerability was calculated at both study sites (*Table A1; Fig. 2*). It was found that both areas were vulnerable to the changing climate, however; LVI values were higher for UC Balakot (0.43) than UC Kawai (0.33). This indicated that riverbank communities were more vulnerable than people living on slopes. The major differences in the sub-component scores were of natural disasters accounting 0.52 for Kawai and 0.78 for Balakot. Balakot community was exposed to higher hazards due to floods and landslides. Climatic variability was similar in both study areas due to having similar meteorological data of Tehsil Balakot. However, health status of the respondents was not much different in both UCs having a major component score of 0.45 (Balakot) and 0.46 (Kawai). Both areas had no household gas supply for cooking, therefore using woods, leaf litter and other biomass fuels to cook and heat the homes. In terms of food availability, households had less storage of seed in Balakot (0.07) which is an adaptation in time of crises. Many households had no crop diversity; they were sowing same crops over time which indicates lower adaptations in changing time. The maximum score of food was shown in Kawai (0.34) relative to Balakot (0.24). Most of the households had higher dependency on natural water sources in Kawai (0.66) rather than Balakot (0.42). In assessing the status of water accessibility in households, Balakot had higher LVI value (0.49) as compared to Kawai (0.45). Socio-demographically Balakot had shown poor statistics with an index value of 0.4 as compared to Kawai (0.28). In UC Balakot, villages are highly vulnerable, due to low income and education having an average score of LVI 0.41.

After calculating and summarizing LVI for both union councils, a spider diagram (*Fig. 2a*) was developed to indicate value of major components and resulting vulnerabilities. In both study areas, exposure to natural disasters had comparatively higher score than other components.

Calculating LVI-IPCC

The three major components of vulnerability were calculated from eight major components. Adaptive capacity index consist of socio demographic profile, livelihood

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66056624

strategies and social networks in a community. Sensitivity index is composed of health, food and water related issues. In exposure index only natural disasters and climate variability is considered. For LVI-IPCC approach, +1 indicates most vulnerable and -1 is for least vulnerable. The contributing factor value for IPCC-LVI approach is 0 for low contributing factor value and 0.6 for high contributing factor value. Results of LVI-IPCC have suggested that the community of Tehsil Balakot has higher exposure level. UC Kawai has comparatively low exposure to natural hazards and climatic variability than UC Balakot. Overall both communities had shown very low adaptive capacity, therefore highly vulnerable to environmental and social changes in the study area. There are three categories to recognize the vulnerability status as shown in *Table 1*.

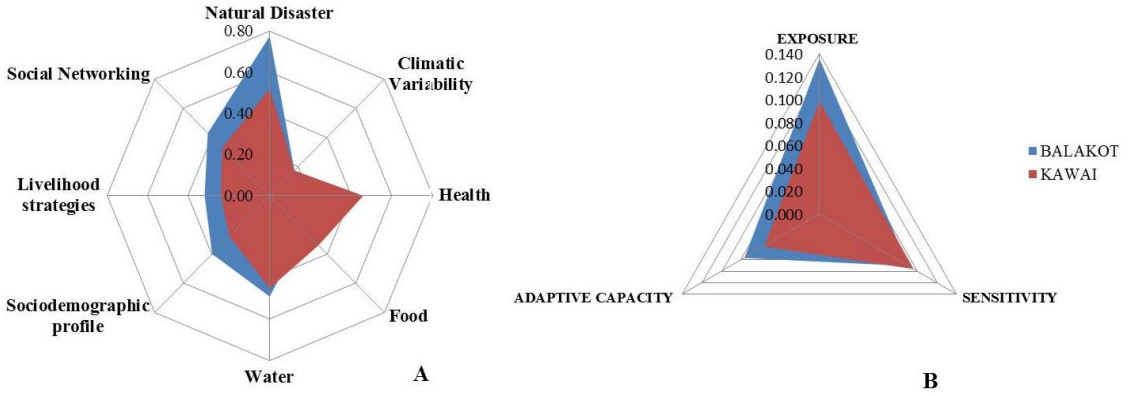

Figure 2. a *Spider diagram indicating major component scores of LVI.* ***b*** *Vulnerability triangular sketch showing scores of LVI-IPCC in Tehsil Balakot*

Table 1. *Status of vulnerability based on IPCC-LVI (a = adaptive capacity; e = exposure and s = sensitivity)*

LVI-IPCC categories	UC Balakot	UC Kawai
Adaptive Capacity > (Exposure + Sensitivity) = *Less Vulnerable*	a < (e + s)	a < (e + s)
Adaptive Capacity = (Exposure + Sensitivity) = *Moderately Vulnerable*	0.077 < (0.091 + 0.136)	0.057 < (0.096 + 0.099)
Adaptive Capacity < (Exposure +Sensitivity) = *Highly Vulnerable*	0.077 < 0.227	0.057 < 0.195

Vulnerability triangular diagram was developed from the scores of LVI-IPCC (*Fig. 2b*). It ranges from 0 to 0.14 which showed that UC Kawai was more sensitive to climatic and livelihood changes with less adaptive capacities however UC Balakot has higher level of exposure. An in-depth analysis showed Balakot has geographically more prone to natural disasters and as a result community has learnt some adaptations due to facing losses. An overall impact analysis indicated (*Table 2*) that low adaptive capacity was due to poor social status coupled with low social support. Sensitivity was influenced by the primary factors of water and health related issues whereas exposure was significantly due to presence of nature hazards already established in study area.

Table 2. *LVI and LVI-IPCC based on contributing factors and vulnerability scores for Tehsil Balakot*

Contributing factors	Major components	No. of sub components	Balakot		Kawai	
			Major components values	Contributing factor values	Major components values	Contributing factor values
Adaptive capacity	Social demographic	4	0.40	0.077	0.28	0.057
	Livelihood strategies	7	0.32		0.24	
	Social networks	4	0.43		0.33	
Sensitivity	Health issues	6	0.45	0.091	0.46	0.096
	Food related	5	0.24		0.34	
	Water issues	4	0.49		0.45	
Exposure	Natural disasters	4	0.78	0.136	0.52	0.099
	Climatic variability	3	0.172		0.172	
LVI (0 minimum to 0.5 maximum)			**0.41**		**0.35**	
LVI-IPCC (-1 minimum to +1 maximum)			**0.0054**		**0.0040**	

Mapping land use change and its effect on livelihood

Tehsil Balakot has been affected by changing in its land use scenarios which was shared by most of the households during in-depth interview. Many were of view that availability of fresh and clean water has reduced along with reduced forest cover. Results revealed (*Table 3; Fig. 3*) that there was significantly increase in the settlements in year 2015 than 1990. A drop in population from 1995 to 2010 was due to a higher death toll in earthquake of 2005. It was documented that 90% households suffered two or more than two deaths in this disaster (Qasim et al., 2010). Forest cover was significantly reduced from 1990s to 1995 and 2010. An increase in forest cover in 2015 was due to a provincial program namely Billion Tree Tsunami Project (BTTP) which was an afforestation effort in line with international Bonn Challenge (WWF, 2017.). Pakistan promised to restore six million hectares of degraded forest land by year 2020 according to this commitment. Another greater change reported by locals in their FGD was conversion of forest land into cultivation. Vegetation in the map and tabular data represents all type of cultivation carried out in the study area. Tehsil Balakot has higher production of maize and wheat, rice production comes in third place with many seasonal vegetables. Agriculture has been a substantial livelihood strategy in this region. It can be seen from the land use mapping that agriculture has got momentous increase which will affect climate and livelihood in positive and negative too. Barren land is the region has increased also which was majorly due to drying of river body. On the hand, ice and snow has reduced too which was supported by aged people during FGD that glacier' melting is amplified in the region coupled with flooding and resulting landslides. Water bodies including rivers, springs and lakes have significantly reduced in its volume affecting agriculture, fishing, livestock rearing and related livelihood activities.

Discussion

The outcome of the study in Tehsil Balakot revealed that all four villages in both UCs were highly vulnerable based on LVI and LVI-IPCC approaches. In the first glance, the study suggests that there was a less difference in the vulnerability scenario of two areas. However a closer look reveals that there were much more differences.

+ indicates increase in certain activity whereas a minus (-) indicates decrease

Livelihood vulnerability status in Tehsil Balakot

The overall analysis has shown that UC Balakot had higher dependence ratio per household with more female headed households than UC Kawai which make their low socio-demographic profile. In addition to this, UC Balakot has low education and less income in most of the households. Most households had shown less or no livelihood diversification that showed their dependence on single source of income which was on-farm activities in most villages. Poverty and vulnerability are thoroughly linked; poor households are characterized as more vulnerable (Isabel and Buchenrieder, 2010). Many studies have reported similar findings (Adu et al., 2018; Sujakhu et al., 2018; Huong et al., 2018) where poverty is leading to vulnerability in most parts of the world. In addition, literature has strongly supported the idea of livelihood diversification leads to community resilience (Rahut et al., 2014; Gautam and Andersen, 2016). Most of the households involved in farming had less or no crop diversification as an adaptation technique. UC Balakot had many households involved in nature-based tourism; ranging from running huts for tourists to selling day to day items. This area is a popular tourist destination which has resulted in unstable construction of motels and huts on the riverbank as well as hill slopes. Social networking is taken as an adaptation strategy in rural livelihood (Sujakhu et al., 2018) as it enhanced community linkages and a support system. The livelihood was under stress due to low adaptive capacity which has indicated the people had low socio-demographic profiles with poor social networking. In addition to this, people had less livelihood adaptations in both areas. Similar finding were reported by an earlier study done by Gerlitz et al. (2016) in Hindu Kush Himalayan (HKH) where the community was identified more vulnerable due to low adaptive capacity and higher exposure to climatic and socio-economic factors. Surveys in this mountainous region has shown that the majority of households observed changes in their environment, precipitation and monthly temperatures; further it was reported that these changes will be adverse in next few years (Colom and Pradhan, 2013; Zaheer and Colom, 2013; Gambhir and Kumar, 2013; Tse-ring et al., 2010). In a similar study

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66056624

conducted by Wang et al. (2016) uneven seasonal precipitation distribution was also reported in this region which wills undesirably effects the agriculture and livestock production. Literature reported less rainfall and extreme weather array in this region of Hindukush Himalayan which has provided environmental and socio-economic shocks to the livelihood of marginalized communities (Akhtar et al., 2008; Gerlitz et al., 2015; Alam, 2017). Reduction in water springs and change in water quality was reported by the people during their focus group discussion. This was severely affecting agriculture productivity as well as food security of rural farmers.

However the regional Himalayan are experiencing similar conditions but different sensitivities also due to different types of income, education household characteristics, and way of livelihood diversification. For instance, in Gannan Plateau, located in the east of the Qinghai-Tibet Plateau, which is highly environmental sensitive region of china showed higher exposure scenarios than sensitivity (Zhang et al., 2018). In another in-depth study, comparative analysis among, India, Nepal and Pakistan; multidimensional vulnerability index showed higher exposure to changing environmental and socio-economic status. Access to basic faculties was highlighted as an additional burden on population of this region (Gerlitz et al., 2016). In riverbank erosion-affected riparian regions of Bnagladesh (Chauhali and Nagarpur), LVI accounted food, water and health issues causing higher vulnerability. Poverty is reasoned as main source of higher exposure to extreme conditions (Alam et al., 2017). However In Ghana Africa, it was reported that livelihood based on climate regulated water resources was highly vulnerable due to low adaptive capacity then exposure and sensitivities. Most municipalities in the Brong-Ahafo region were involved in maize farming and it was indicated that change in water availability was considered as main livelihood threat (Adu et al., 2018). In another study conducted by Jianchu et al. (2007) in context of melting Himalayan showed that mountain people have lived with extreme conditions but more effecting is the pace and magnitude of changing climate. And other contribution in higher community's vulnerability is lack of scientific investigation. Therefore more and more scientific studies coupled with indigenous knowledge are needed to make poor locals of Himalayan more resilient.

Land use changes and livelihood analysis

Field survey with local people and remote sensed data has established the fact that land use change has influenced the socio-economic and livelihood conditions in the region. The data of last five years has seen vivacious effects on forest, agriculture and water resources. In HKH region the environmental changes were reported earlier in 1970s; which included higher deforestation, burgeoning population growth, glacier melting, soil erosion and low lying flooding (Sterling, 1976; World Bank, 1979; Karan and Iijima, 1985; Schickhoff, 1995). Hence with poor evidences and empirical studies, an in-depth livelihood analysis was not possible. The current study therefore provided ground data to support the limited works. The land use change data has long-established fact that agriculture and water bodies were significantly reduced whereas settlements due to growing population had amplified (Khurshid et al., 2016). Higher population will subsequently put higher pressure on natural resources which in turn elevates poverty. This vicious cycle was reported already in Bangladesh, India, Nepal and other neighboring countries (Gentle et al., 2014; Aryal et al., 2016). In the study area, settlements have increased 10-folds since 1990; after 2010 a rapid increase in population was seen which was may be due to higher tourism demand linked to this

DOI: http://dx.doi.org/10.15666/aeer/1703_66056624

area. Better road infrastructure was one of facilitation which has developed access to off-routes. Many people travel to this part of country around the year, which has resulted in environmental degradation. Water resources of HKH are critical for Pakistan as an agricultural economy, the water bodies are reduced and snow and ice are melting; this will have cascading effects. HKH are known as water towers for Pakistan and drying water bodies will threaten country's socioeconomic growth as well. Further, increase in global warming and climate change will likely effect the hydrological cycle.

Agriculture productivity and livelihood of rural mountainous communities heavily depend upon water availability (Sullivan, 2002; Khattak et al., 2011; Yang and Yang, 2014; Aryal et al., 2018). In current scenario, local people are converting more and more forest land into cultivation but in near future with less water available, food insecurity will result. The drying water bodies were extending barren lands in the region (Jainachu et al., 2007; Mahmood et al., 2016). Reduction in forest size and cover was already described by the locals for higher need of fuel wood (Khan, 1970; Gentle and Maraseni, 2012; Aryal et al., 2017). These forests are lifeline to rural community; rapid deforestation will expose local people to more natural hazards and warming also. Many plants and animal species have already moved from these temperate zones as reported by local people during the field surveys. Tehsil Balakot is a famous tourism area in northern Pakistan; which will be severely affected due to loss of forest and water bodies. These land use changes in the HKH region will have long term effects on the livelihood of rural people.

In terms of changes mapped over Himalayan region, many similar studies showed change in land use and related phenomenon. Sharma et al. (2007) carried out land use change mapping in western Himalayan, State of Himachal Pradesh, India indicating two-folded increase in population growth and reduced forest cover. Another change was in form of introduction of profitable crops other than wheat and maize in the region. In a recent study in Garhwal Himalayan region (Batar et al., 2017), vulnerability to life of locals due to higher deforestation and forest fragmentation was reported. The major land-use change was accounted to fuel-wood consumption and other anthropogenic activities. The study has described fast decline in the forest cover which will be higher threat to locals in form of natural hazards. However a study conducted in Himalayan region of Nepal showed transitions in land use change from forest to agriculture and shrubs and agriculture to forested land (Chapagain et al., 2018). It was also reported that beginning of community forest was considered a main driver behind the increase in forest cover in the region, followed by shortage of labor and development of infrastructure. Another study in the landscape of Abaya-Chamo Basin (ACB), southern Ethiopia, the main changes observed were rapid reduction in shrubland and grassland (33.13%), and massive increase in arable land (Yohannes et al., 2018). Rapid population growth was also seen in the region resulting in higher pressure on natural resources.

Overall the higher vulnerability in the different parts of world was due to risk factors related to poverty, poor basic life facilities and low adaptive capacity. Most of the populations had been exposed to climate related threats and thus have vulnerable livelihoods. On the other hand, land use change poses additional burden in all regions of world because of growing population, reduced forest cover and increased arable land (Gentle et al., 2014; Gerlitz et al., 2016; Yohannes et al., 2018; Adu et al., 2018).

Conclusion

People in Tehsil Balakot are vulnerable due to their poor social and environmental conditions. The current study highlighted vulnerability at a household level using acknowledged method. Surveys in this region showed that the majority of households had already observed the change in environment and climatic conditions. Local people had higher exposure to changes but low adaptive capacity to cope it. This condition has made them highly susceptible to bear lose. Land use analysis has also indicated alteration in agriculture and water availability which will negatively affect the rural livelihood. There are few empirical studies using indices to identify root causes of vulnerability across different sectors. The study offers an assessment approach which can be replicated for regional and national level studies to know the causes of susceptibility to natural disasters. Realistic studies are needed to highlight exposure, sensitive and adaptive capacity of rural people to enhance their resilience and adaptations to change. This can help decision makers and planners to address the challenge which is biggest in 21st century.

(Received 1st Feb 2019; accepted 8th Apr 2019)

Abstract. The aim of this study was to measure the quality indices (physico-chemical and microbial assessment) of four popular date palm fruits (*Phoenix dactylifera* L.) varieties (Begamjangi, Haleeni, Dashtri and Peshnah) grown in ecologically same agro climatic condition of Turbat Balochistan, Pakistan. Different date palm characteristics including; harvesting time, color and taste of fruits, diversity in fruit, stone weight, length and diameter, variation in chemical composition, sugar, minerals and amino acids contents were recorded by standard methods. Results indicated that there was slightly to highly significant variations among the investigated parameters in different cultivars. Further that microbial burden (cfu/g) on four fruit sizes classes (large, small, medium and mixed) in three fruit processing techniques (unpressed-unpitted, pressed-pitted and unpressed-pitted date fruits) were examined. The results revealed that the different date varieties showed different load of microbial infections. On the basis of all investigated parameters the fruit performance index (FPI) and valuation classes were calculated. The consequences indicated that the Begamjangi score highest grade point (6) and stood in excellent class, followed by Haleeni with grade point 4.0 and categorized in good class. Other two date cultivars Dashtri and Peshnah score 2.0 & 1.0 grade points and classified into poor and very poor group of date palm fruits, respectively.

Keyworlds: *date cultivars, productivity, sugar and mineral contents, bacterial infection, fruit performance index (FPI), fruit size classes*

Introduction

The date fruit (*Phoenix dactylifera* L.) is an important food product and extensively cultivated all over the world for its edible fruits. It is a monocotyledonous belongs to the family Arecaceae. Mostly cultivated in semi-arid regions of the world (Ashraf and Hamidi-Esfahani, 2011). Fruit is highly nutritious with delicious taste and a basic part of human diet (Vayalil, 2002). Date fruit is constituted high percentage of carbohydrates (glucose and fructose), proteins, vitamins, fats, dietary fibers, minerals and low amount of starch. Their Chemical composition depends on cultivar type, fruit developmental stage and agro-climatic conditions (Al-farsi et al., 2005; Al-farsi and Lee, 2008; Safi et al., 2009; Baliga et al., 2011). Pakistan is well known for its date industry with annual production of 70 thousand tons (Anonymous, 2012), contributing 10.3% of total world's

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

production. Aseel, Dhakki, Begumjungi and Koharba are amongst the most important native date palm varieties. Many other local cultivars are also grown in different agro-ecological zones of Pakistan (Iqbal et al., 2016). The farmers have denominated the cultivars on the basis of shape and color of the fruits or the presence of specific locations (Ahmed et al., 2011). The date palm is selected for cultivation on the basis of better fruit quality and post-harvest life. Based on the botanic interpretation, there are about 244 cultivars in Morocco, 250 in Tunisia, 370 in Iraq, 400 in Iran (Zaid and de Wet, 2002), 400 in Sudan (Osman, 1984), 325 in Pakistan (Botes and Zaid, 2002; Jamil et al., 2010). About 5000 different date palm cultivars are known to present worldwide (Jaradat and Zaid, 2004).

Quality standards of dates must include chemical, physical and sensory attributes. Date varieties significantly vary in terms of their chemical composition. The variation in chemical composition affects the structural, sensory and textural properties of fruits (Rahman and Al-Farsi, 2005). The function of sensory analysis is to provide measurements that are accurate, precise, and valid (Piggott, 1995) and variation in sensory attributes is due to the genetic differences and variable growth conditions. There is a considerable diversity within date palm cultivars. Although, accurate characterization of cultivars need a huge set of morphological as well as biochemical and molecular (isozymes) markers. Moreover, vegetative characteristics, phenotypic diversity and phylogenetic relationship are important to evaluate date palm ecotypes (Haider et al., 2015). This significant plants are endangered through hereditary corrosion, change of agrarian land, irritant and infections. Numerous investigations have emphasized this concern (Zehdi et al., 2005, 2012). Hammadi et al. (2009) and Ahmed et al. (2011) used phenotypic data to classify dissimilar date palm cultivars. Wills et al. (1998) stated that, with respect to consumers, the important quality criteria of a product are appearance (including color, size, and shape, condition and absence of defects), mouth feel or texture, flavor, and nutritional value. So due to the importance of date fruits a number of countries have formulated and applied date standards at the national level both for locally produced and imported dates. So there are many date standards that include both local and international specifications. They contributed to the ease of global trade for dates. However, the standards do not emphasize some important quality parameters of these fruits.

There are no extensive studies on the quality indices and standards for the most abundant and commercially important date palm fruits (Begamjangi, Haleeni, Dashtri and Peshnah) in Turbat Balochistan, Pakistan. Therefore, this study is designed to assess the physico-chemical and microbial estimation of four popular and important date cultivars.

Materials and methods

Plant material and samples collection

Fruit samples were collected from four date palm varieties from same ecological conditions in regional date field of Turbat, Balochistan. These date cultivars were Begamjangi, Haleeni, Dashtri and Peshnah. Study was based on fruit physiochemical characters. Analysis were carried out on 40 randomly selected trees (10 from each cultivar). A total of 20.0 kg of fruit samples from ten randomly selected trees of each cultivar were collected separately at maturity stage (August to September) during 2018. Samples were cleaned, washed and packaged in polyethylene bags inside 20 kg cartons,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

and preserved in a refrigerator at 5˚C until experimental tests were performed. Typical morphological image of the experimental cultivars are shown in *Fig. 1*. Further that on the basis of harvesting time the date palm varieties were classified in to early, mid and late variety (*Table 1*).

Begamjangi Haleeni Dashtri Peshnah

Figure 1. *Picture of investigated dry date palm varieties*

Table 1. *Indication of harvesting time, fruit color, and taste in four date palm varieties*

Date Varity	Parameters			
	Harvesting time	Type	Fruit colour	Taste
Begamjangi	20th August – 20th September	Med verity	Light yellow	Delicious
Haleeni	After 20th September	Late verity	Yellow	Tasteful
Dashtri	20th August – 20th September	Med verity	Dark brown	Slightly tasty
Peshnah	20th July-20th August	Early verity	Light yellow	Poor taste

Physiochemical character study

Fruit and stone weight was assessed by analytical balance and calculated as a mean of randomly designated 30 mature fruits from each cultivar as used by Lemine et al. (2014). Fruit and stones length and breadth were noted by using complete numerical microelectronic Vernier-caliper as the method used by Mughal et al. (2018). Fruit moisture/water contents were measured by dehydrating 5 g date pulp in vacuum oven for 24 hr at 70˚C by using the following formula: % water = [(initial weight- dry weight) × 100]/initial weight] (Leghari et al., 2017). Fruit color was measured by color difference meter and the measurements were performed on 10 individual randomly selected fruits from each cultivar (a total of 120 fruits) with three replicate (Aleid et al., 2014). Entire nitrogen was measured by the Kjeldahl method as described by AOAC (1995) and protein was expressed as the overall factor 6.25 (Laurey, 1997). The entire lipid contents were determined through the methods as described by Folch et al. (1957). Water activity was determined in a water activity meter (Rotronic) and ash level was measured from the differences after warming softened date sample in an oven at 600˚C for 8 h. Electrical conductivity (EC) was noted from dry sieved sample. 20 g dry date sample was stimulated by 50 ml distilled water and left-hand to equilibrate for 40 min and then filter the mixture. The EC of each variety sample was measured by using the electrical conductivity meter (Crison Basic 30+EC-Meter, 08323 Alella-Bacrelona made in EU). Sugars contents from soaked date pulp samples were measured with water at 85˚C and it was computed through the 3,5-dinitrosallicylic acid technique as described by Laurey (1997). Overall sugar (Sucrose, glucose, and fructose) contents were noted by high performance liquid chromatography (HPLC) according to the methods of AOAC (1995). Date samples were spiked by several mixtures of average

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

sugars (1-5 ppm) to display retrieval and the sugar content was intended from highest area of measurement according to the method of Langemeier and Rogers (1995). Minerals (calcium, phosphorus, potassium, sodium and magnesium) contents were determined through atomic absorption spectrophotometer and expressed by mg/100 g dw. Different obtainable amino acids (proline, glycine, histidine, valine, leucine, serine, methionine, isoleucine, tyrosine, phenylalanine, lysine and alanine) were examined through the technique as described by Laurey (1997). Date fruit samples were hydrolysis by vapors HCl and standard for 20 hr at 110°C. After that the date samples were extracted on poly-vinylidene difluoride with 100 µL of 40% aceto-nitrile and 0.5% trifluoroacetic acid for three times. The excerpts were then dehydrated entirely in a Rapidity Vac earlier re-suspension in sample buffer. After that the samples and standards were examined in a Beckman system 6300 (Laurey, 1997). Different amino acids were articulated in to mg/100 g dw. Total acidity was measured by using 10 ml of fruit juice which were titrated against 0.1 M sodium hydroxide solution by the utilization of phenolphthalein as an indicator (AOAC, 1995). Total acidity was calculated according the fallowing formula: Volume NaOH (ml) × 0.1 M × 0.067 and expressed as malic acid content. The pH measurement was done by calibrated digital pH meter (CyberScan 510 USA).

Classification of fruits into fruit size classes

Fruits were classified into four size classes including; large, small, medium and mixed were arranged according to the fruits weight (g). Fuit size classes were calculated by the following formula: large= weight>x gram; medium= x gram>weight>y gram; and small= weight<y gram. For four fruit size classes (large, small, medium and mixed) and three fruit processing methods (unpressed-unpitted, pressed-pitted and unpressed-pitted) a 4 × 3 factorial treatment strategy was acquired. Where the term "pressed" mentions to dates that were compacted into layers through mechanical force and unpressed refers to dates that were packed without powered presser or density. Pressing of entire dates was made with packing in a flexible sealed. The term "pitted" used to date palm fruits whose seeds/stones were removed. In order to remove the pit a sharp knife was used for pitting of whole dates and the date fruits were cut from end to end. As per outcome, there were 12 samples from each date variety and a total number of 36 samples. Microbial burden was measured in the study through Coliform, Moulds and Yeast and total bacterial counts.

Microbial burden study

Pour plate method was used to count the aerobic mesophilic bacteria on plate count agar dishes. These plates were incubated for 3 days at 35°C. From the sample, the counts were expressed as colony forming units per gram (cfu/g). Fruit samples were aseptically destoned by utilizing sterilized pincers and microbial burden was calculated for the skin. Skin samples were weighed 10 g into sterilized stomacher bags and 90 ml of sterilized peptone water. For homogenization of mixture a stomacher was used for 50 seconds and aliquots (1.0 or 0.1 ml) plated out in duplicate as 10-fold dilutions in peptone water. The pour plate/overlay method was used to count the coliforms on Vilet Red Bile Agar (VRBA). The plates were incubated for 48 hours at 35°C. The round, purple-red colonies (0.5-2 mm diameter) surrounded by purple-red haloes on VRBA plates were counted as coliforms. Spread plate method was used to culture the yeasts and moulds on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

potato dextrose agar. Yeasts plates were incubated for 3 days at 35°C and for moulds it was incubated 5-7 days at 25-30°C (Atlas, 2004; Abekhti et al., 2013).

Fruit Quality Assessment

Fully ripened fruits were harvested from four selected varieties and dried until a constant weight was reached (moisture content 12 to 25%). Fruit weight, stone weight, reducing sugar, over all minerals, moisture %/water activity and microbial burden hardy were determined according to the standard methods as described above in this research methodology. Acidity, Taste and flavor of fruit was tested by a panel of six experienced judges (one from food department, two date farmers, two Ph.D. Professor from botany department university of Balochistan Quetta and other one from agriculture department) from and values/scales were given from 1-5/1-10 (Leghari et al., 2019). 10 fruits from each varieties were randomly selected for taste and flavor for each expert/judges.

Fruit performance index (FPI) through fruit quality and valuation Classes

For the date fruit performance index (*FPI*) the methods described by Prajapati and Tripathi (2008) and Leghari et al. (2019) was used. FPI values were calculated by combining the different fruit quality parameters (fruit weight, stone weight, taste of fruit, acidity, reducing sugar, over all minerals, moisture %/water activity and microbial burden hardy) of four date palm varieties based on character grading (+ or -) fixed to the plant.

Statistical analysis

Statistical analysis of data collected during the course of each trial was performed by analysis of variance (ANOVA) to determine the interaction effects among the main factors using SPSS software version 16.0 and for the comparison between the means of treatments duncans multiple-range test (P=0.05) was used (Steel and Torrie, 1980).

Results and discussion

Results shown in *Table 1* indicated that Begumjangi was designated med variety with light yellow fruit color and delicious taste. Haleeni was noted late variety with yellow fruit color and tasteful. Dashtri was found med variety with Dark brown fruit color and slightly tasty. Peshnah was found early variety with light yellow fruit color and poor taste. The variation in harvesting time, fruit color and taste in different date varieties was also noted previously (Abekhti et al., 2013; Aleid et al., 2014). They reported a great differences in date fruits color from different date varieties of Saudi Arabia.

Productivity variation in date varieties

Results in *Table 2* indicated statistically significant variation in average weight, length and breadth of fruits and stone in four date palm varieties grown in agro climatic condition of Turbat. Fruit and stone weight, length and breadth is directly related to productivity of a cultivar. In this study the average weight, length and breadth were noted from the ranged 2.75 - 8.57 g/fruit, 2.7 - 3.1 cm/fruit & 1.3 - 1.9 cm/fruit, respectively. Haleeni showed maximum average fruit weight and Dashtari minimum and the highest length of fruit was noted for Begamjangi and lowest for Dashtari. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

uppermost fruit breadth was presented by Begamjangi and lowermost by Haleeni. The average weight and length of stone were ranged 0.54 - 0.66 g/fruit fw and 1.7 - 1.9 g/fruit fw, respectively, while stone breadth was noted same (0.7 g/fruit fw) in all investigated verities. The extreme average weight and length of stone was found in Dashtari and Peshnah and least in Haleeni and Dashtri, respectively. Variation in these parameters were also observed by Ragab et al. (2011). They reported differences in fruit weight at different stages in diverse variety. Variation in these parameters in diverse varieties led to the variation in total yield.

Table 2. *Diversity in average weight, length and diameter of fruits and stones in four date palm varieties*

Date palm variety	Parameters						P value
	Fruit weight	Stone weight	Fruit length	Stone length	Fruit breadth	Stone breadth	
Begamjangi	6.87^{ab}	0.60^{ab}	3.1^{a}	1.8^{a}	1.9^{a}	0.7^{a}	0.031
Haleeni	8.57^{a}	0.54^{b}	2.9^{a}	1.8^{a}	1.3^{b}	0.7^{a}	0.021
Dashtri	2.75^{b}	0.66^{a}	2.7^{a}	1.7^{a}	1.5^{ab}	0.7^{a}	0.022
Peshnah	4.00^{ab}	0.64^{b}	2.8^{a}	1.9^{a}	1.5^{ab}	0.7^{a}	0.031
P value	0.036	0.002	0.457	0.468	0.034	1.00	

Each value is the mean of 30 replicates, Different letters in the same column and raw indicate statistically significant differences (significance level $P = 0.05$)

Diversity in Chemical composition of date varieties

Consequences displays slightly to highly significant diversity in various chemicals (Moisture, Protein, Lipid, Ash contents and Water activity) composition in four date palm fruits varieties. Results indicated that the moisture contents in four investigated date palm fruits varieties was in ranged between 15.4 - 24.3% and the highest moisture content was found in Peshnah fruits and lowest in Begumjangi. Protein and lipid contents were in between 2.15 - 3.24 g/100g dw, 0.13 - 0.54 g/100g dw, respectively. The uppermost protein and lipid content were showed by Begumjangi fruits and minimum by Dashtari and Peshnah, respectively. The ash contents and water activity in all investigated date varieties were recorded in the range of 1.23 - 3.52 g/100g dw and 0.421 - 0.675 aw, respectively. The highest ash contents were originate by Begumjangi, whereas lowest by Peshnah and Water activity was exhibited highest in Peshnah and lowest in Begumjangi (*Table 3*). The outcomes of this study are analogous to other researchers as they testified before (Elleuch et al., 2008; Assirey, 2015), through approximately variances associated to date cultivar and agro-climatic and environmental circumstances (Myhara et al., 1999; Biglari et al., 2009). It has been also described earlier that the dates are not a decent basis of protein (Al-Hooti et al., 1997).

Sugar contents in date fruits

The sucrose, glucose, fructose, Reducing sugar contents and ratio between glucose and fructose were found from ranged 2.00 - 4.24, 35.5 - 48.5, 27.0 - 35.5, 62.5 - 84.0 and 1.31 - 1.37 g/100g dw, respectively in four different date varieties. The maximum glucose, fructose, reducing sugar and ratio between glucose and fructose was shown by Begumjangi and minimum Peshnah. Highest content of sucrose was noted in Peshnah and lowest in Begumjangi fruits (*Table 4*). Similar observation was also noted by Assirey (2015). Richness in reducing sugars (glucose and fructose) is being significantly decrease its sucrose content (Elleuch et al., 2008; Besbes et al., 2009). Statistical

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

analysis exhibited that sucrose, glucose and reducing sugar were found slightly significant different between the four examine date varieties, while fructose content and ratio between glucose and fructose were non-significant between four date varieties (*Table 4*). Non-significant variation in these parameters were also reported by Assirey (2015) between Ajwa, Shalaby, Suqaey, Sukkari, Burni, Mabroom and Anabarah and between Khodari and Safawy.

Table 3. *Diversity of chemical composition in four different date palm fruits*

Variables	Date Varieties				P value
	Begamjangi	Haleeni	Dashtri	Peshnah	
Fruit moisture (%)	15.4[b]	18.3[b]	23.3[a]	24.3[a]	0.035
Protein (g/100 g dw)	3.24[a]	2.16[b]	2.15[b]	2.54[b]	0.044
Lipid (g/100 g dw)	0.54[a]	0.51[a]	0.34[b]	0.13[c]	0.000
Ash (g/100 g dw)	3.52[a]	2.01[ab]	2.35[ab]	1.23[b]	0.025

Each value is the mean of five replicate, different letters in the same column and raw indicate statistically significant differences (significance level $P = 0.05$)

It is authenticated that dates are vital bases of sugar. In present investigation the overall total sugar was recorded from the ranged of 66.74 - 86 g/100g dw in four date palm varieties. The maximum content was noted in Begumjangi, which followed by Haleeni (79.75 g/100g dw), Dashtari (74.35 g/100g dw) and minimum was found in Peshnah fruit. Statistical analysis indicated that there was significant variation in total sugar contents among four investigated date varieties (*Fig. 2*). The variation in total sugar by different cultivar were also noted by other authors. Elleuch et al. (2008) and Besbes et al. (2009) reported variation in total sugar contents (81.6 - 88.4%, 72.8 - 79.1% and 72.8 - 79.1% and 78.3 - 87.6%), in different date varieties. Contrary to this, Non-significant variation in total sugar was reported by Assirey (2015) between Khodari, Anabarah, Sukkari, Suqaey and Burni and between Ajwa, Shalaby, Safawy and Labanah.

Mineral diversity in date fruits varieties

The mean contents of calcium, phosphorous, potassium, sodium and magnesium were found in ranged from 120 - 180, 12.5 - 25.02, 276 - 450.5, 4.6 - 7.05 and 55.4 - 120.4 mg/100g dw, respectively. The maximum calcium, phosphorus, potassium, sodium and magnesium were recorded in Begumjangi and minimum in Peshnah fruits.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

Statistical analysis indicated that calcium, potassium, sodium and magnesium were found slightly to highly significant different in four investigated date palm varieties, while phosphorus showed non-significant variation (*Table 5*). The mean contents of overall minerals was found in the ranged 156.7 - 93.7 mg/100g. The highest overall minerals contents was recorded in Begumjangi which followed by Haleeni (130.144 mg/100 g) then Dashtri (108.1 mg/100 g) and least in Peshnah (*Fig. 2*). Variation in mineral contents in different date cultivar were also reported by Ragab et al. (2011) and Assirey (2015). They found differences in mineral contents between different date varieties such as; Khodari, Anabarah, Sukkari, Suqaey and Burni and between Ajwa, Shalaby, Safawy and Labanah. The consequences of our study supported by authors of numerous other investigation. They indicated that date fruits had appropriate level of different minerals (calcium, potassium and phosphorus) which are essential for human bodies (Sawaya et al., 1983; Gasim, 1994). The differences in minerals especially; magnesium and sodium contents might be clarified by the influences such as variety, soil types and environmental conditions.

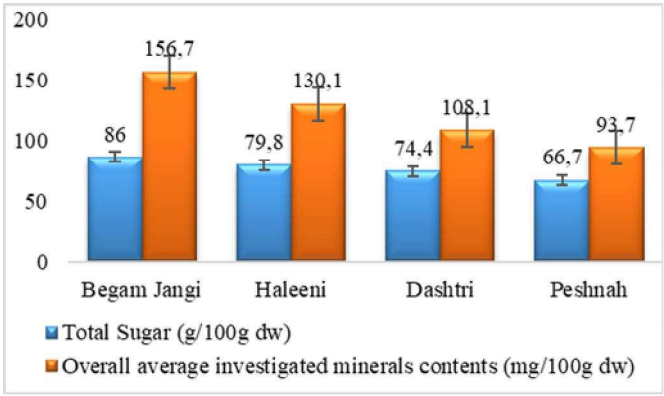

Figure 2. *Total Sugar contents (g/100g dw) and Overall Mineral contents (mg/100g dw) in four different date palm fruits varieties*

Table 5. *Mineral composition in four different date palm fruits varieties*

Minerals variables	Date varieties				*P* value
	Begamjangi	Haleeni	Dashtri	Peshnah	
Calcium (mg/100g dw)	180.4^{b}	150.2^{b}	142.0^{b}	120^{b}	0.002
Phosphorus (mg/100g dw)	25.02^{c}	19.3^{c}	15.8^{c}	12.5^{c}	0.004
Potassium (mg/100g dw)	450.5^{a}	370^{a}	310^{a}	276^{a}	0.037
Sodium (mg/100g dw)	7.05^{d}	6.22^{d}	6.03^{d}	4.6^{d}	0.018
Magnesium (mg/100g dw)	120.4^{b}	105^{b}	66.6^{b}	55.4^{b}	0.000
P value	0.002	0.000	0.000	0.000	

Each value is the mean of five replicate, different letters in the same column and different raws indicates statistically significant differences at significance level $P = 0.05$

Amino Acids Contents

Calculated mean values of proline, glycine, histidine, valine, leucine, serine, methionine, isoleucine, tyrosine, phenylalanine, lysine and alanine in investigated varieties were found ranged between 73 - 114, 89 - 93, 25 - 10, 60 - 77, 51 - 86, 54 - 62, 10 - 25, 35 - 48, 10 - 20, 46 - 55, 44 - 70 and 75 - 86 mg/100 g dw, respectively. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

maximum histidine, leucine, methionine, isoleucine, tyrosine and lysine were shown by Begumjangi and minimum by Peshnah fruits. Glycine and alanine were found highest in Haleeni and lowest in Begumjangi and Peshnah fruits, respectively. However, Peshnah showed uppermost values of serine, phenylalanine, proline and valine and lowermost showed by Haleeni and Begumjangi respectively (*Table 6*). The aspartic acid and overall average amino acid contents were recorded in ranged 105 - 165 and 22.7 - 56.7 mg/100g in four investigated date palm varieties.

Table 6. *Amino Acids Contents (mg/100 g dw) in four different date palm fruits varieties*

Amino acids variables	Date Variety				P value
	Begamjangi	Haleeni	Dashtri	Peshnah	
Proline	73^{b}	82^{b}	94^{ab}	114^{a}	0.027
Glycine	89^{a}	93^{a}	90^{a}	92^{a}	0.056
Histidine	25^{a}	18^{ab}	14^{b}	10^{b}	0.031
Valine	60^{b}	70^{ab}	75^{a}	77^{a}	0.078
Leucine	86^{a}	76^{ab}	60^{ab}	51^{b}	0.013
Serine	58^{a}	54^{b}	60^{a}	62^{a}	0.104
Methionine	25^{a}	23^{a}	16^{b}	10^{b}	0.034
Isoleucine	48^{a}	43^{ab}	40^{b}	35^{b}	0.031
Tyrosine	20^{a}	16^{ab}	12^{b}	10^{b}	0.022
Phenylalanine	50^{ab}	46^{b}	53^{a}	55^{a}	0.033
Lysine	70^{a}	62^{a}	57^{ab}	44^{b}	0.027
Alanine	76^{b}	86^{a}	80^{a}	75^{b}	0.024
P value	0.041	0.041	0.028	0.034	

Each value is the mean of three replicate, different letters in the same column and raw indicate statistically significant differences (significance level $P = 0.05$)

The highest aspartic acid and over average amino acids were found in Begumjangi and lowest in Dashtri (*Fig. 3*). Statistical analysis (p=0.05) showed that proline, leucine, methionine, histidine, isoleucine, tyrosine, lysine, phenylalanine and alanine were noted slightly to highly significant different between the four investigated date palm varieties, but glycine serine, valine, exhibited non-significant variation. Similar observation was reported by Assirey (2015). They found variations in amino acid contents in different date varieties. Further that a normal level of amino acids is essential for human and it cannot be form in human body and it can be provided by diet (Al-Farsi et al., 2005).

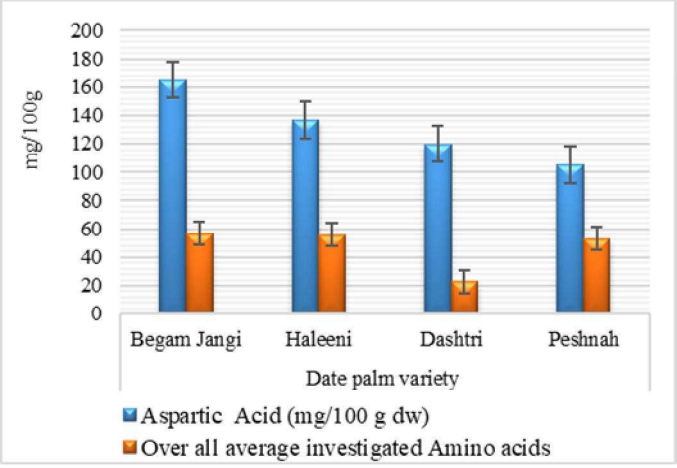

Figure 3. *Aspartic Acid and Overall Ave. investigated Amino acids in date palm fruits*

DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

Fruit extract pH and total acidity

Total acidity and pH in four date palm fruit varieties are shown in *Fig. 4*. The pH and total acidity in four observed date palm varieties were noted in ranged between 4.8 - 5.7 and 2.2 – 4.0 mg/100 g dw, respectively. The maximum pH and total acidity were found in Begumjangi and Peshnah, while minimum in Dashtri and Begumjangi juice respectively. The similar trend was observed by Reynes et al. (1994) in 21 date varieties from Tunisia.

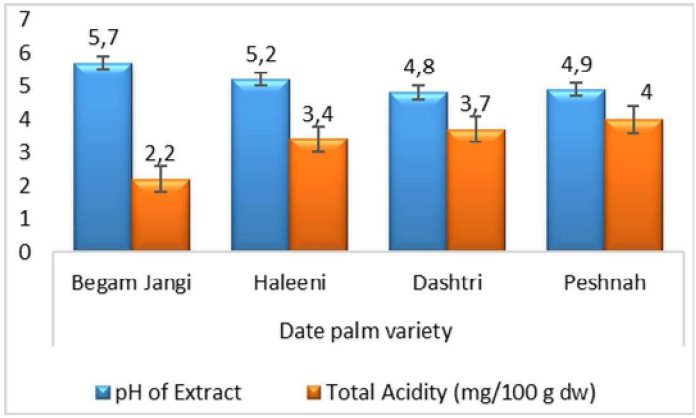

Figure 4. *pH and Total Acidity date palm fruits*

Microbial Burden (cfu/g)

Earlier investigation of microbial burden on examined date palm fruits varieties, the fruits were classified in to four size classes. The consequences of classification revealed that in large, medium, small and mixed size classes the number of fruits were in ranged of 38 - 84, 45 - 125, 69 - 167 and 48 - 127, respectively. In all fruit size classes (large, medium, small and mixed) the maximum number of fruits were noted for Peshnah, followed by Dashtri, and Begamjangi and minimum was noted for Haleeni (*Fig. 5*). Variation in fruit size classes were also absorbed by Aleid (2014).

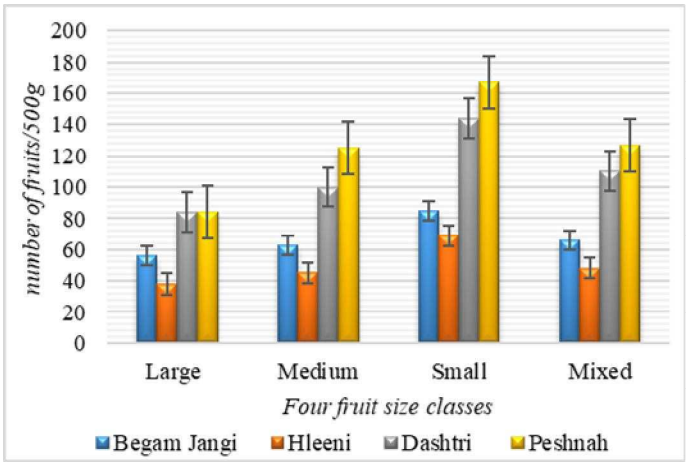

Figure 5. *Classification of date palm fruits in to four size classes according to the number of fruits/500g*

DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

Microbial Burden (cfu/g) in un-pressed un- pitted dates fruits

The results of un-pressed un- pitted dates fruits exhibited that in Begumjangi the microbial load (coliform VRBA, Moulds and yeast and Mesophilic aerobic bacteria) were found in the ranged 0.0 - 0.0, 2.4 - 46.3 and 25.4 - 196.3 cfu/g in four different fruit size classes, respectively. In Begamjangi the maximum microbial load was found by mesophilic aerobic bacteria, followed by moulds and yeast and minimum by Coliform VRBA. *P* value indicated that different microbial organisms put highly significant different burden, similarly different fruit size classes showed highly significant variation in loads of Moulds and yeast and mesophilic aerobic bacteria but non-significant load of Coliform VRBA (*Table 7*). On Haleeni fruit the microbial i.e. Coliform VRBA, Moulds and yeast and Mesophilic aerobic Bacteria, load was recorded in between 0.0 - 3.4, 400.3 - 905.3 and 48.0 - 375.0 cfu/g for four fruit size classes (large, medium, small and mixed), respectively (*Table 7*). Statistical analysis indicated that there was highly significant variation between the fruit size classes as well as among the investigated microbial organisms at p=0.05 significant level (*Table 7*).

Table 7. *Microbial Burden (cfu/g) in un-pressed un- pitted dates of four local verities of date palm*

Date variety	Fruit Size classes	Microbial variable			P value
		Coliform VRBA	Moulds and yeast	Mesophilic aerobic bacteria	
Begumjangi	Large	0.0^{b}	2.4^{b}	25.4^{b}	0.000
	Medium	0.0^{b}	5.3^{b}	75.2^{ab}	0.000
	Small	0.0^{b}	46.3^{a}	196.3^{a}	0.000
	Mixed	0.0^{b}	20.37^{a}	102.66^{ab}	0.007
	***P* value**	**7.078**	**0.000**	**0.007**	
Haleeni	Large	0.0^{b}	400.3^{b}	48.0^{c}	0.000
	Medium	0.0^{b}	662.0^{ab}	106.0^{b}	0.000
	Small	3.4^{a}	905.3^{a}	375.0^{a}	0.000
	Mixed	1.13^{b}	655.87^{ab}	176.33^{b}	0.000
	***P* value**	**0.000**	**0.000**	**0.005**	
Dashtri	Large	0.0^{b}	28.0^{ab}	112^{c}	0.000
	Medium	0.0^{b}	16.4^{b}	345^{b}	0.000
	Small	2.1^{b}	53.2^{a}	712^{a}	0.000

	***P* value**	**0.157**	**0.003**	**0.000**	
Peshnah	Large	0.0^{c}	684.0^{a}	900.0^{b}	0.000
	Medium	5.0^{b}	423.8^{b}	1200.0^{ab}	0.000
	Small	53.7^{a}	100.2^{c}	1607^{a}	0.017
	Mixed	19.57^{b}	402.67^{b}	1235.67^{ab}	0.000
	***P* value**	**0.000**	**0.0234**	**0.000**	

Each value is the mean of four replicate, different letters in the same column and raw indicate statistically significant differences (significance level $P = 0.05$)

In Dashtri fruit the Coliform VRBA, Moulds and yeast and Mesophilic aerobic Bacterial loads were found in the ranged of 0.0 - 2.1, 16.4 - 53.2 and 112 - 712 cfu/g in four fruit size classes, respectively. *P* value indicated that the coliform VRBA was found non-significantly different between the classes and other two microbial organism was recorded with highly significant variation between the fruit size classes (*Table 7*).

Microbial (Coliform VRBA, Moulds and yeast and Mesophilic aerobic Bacteria) burden on Peshnah date palm fruits were from the ranged 0.0 - 53.7, 100.2 - 684.0 and 900.0 - 1600.7 cfu/g, in large, medium, small and mixed fruit size classes respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

The maximum load of Coliform VRBA was noted in small size class and minimum in large size class, but Moulds and yeast burden was noted highest in large and minimum on small size class. Mesophilic aerobic Bacteria was found highest in small size class which fallowed by mixed class and lowest in large size class (*Table 7*). Statistical analysis indicated that there was highly to slightly significant variation in response to microbial load between different date cultivar and fruit size classes at P=0.05 significant level (*Table 7*) in un-pressed un- pitted dates fruits. Among the classes overall investigated microbial load on four cultivar, was recorded highest burden for small fruit size class, followed by mixed and minimum was noted for large fruit size class (*Fig. 6*).

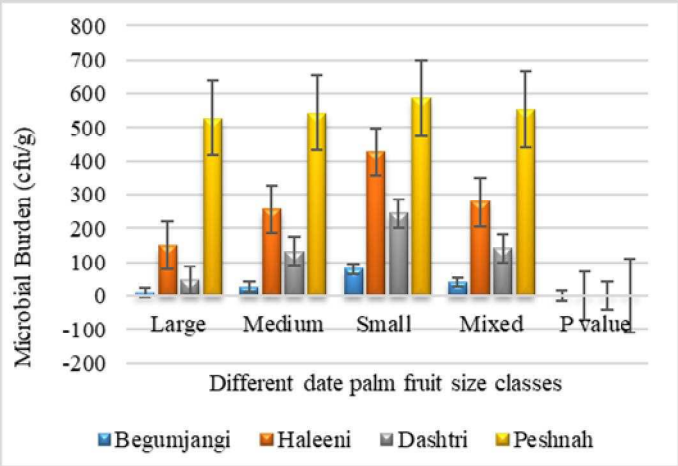

Figure 6. *Overall Microbial Burden (cfu/g) in un-pressed-un pitted date palm varieties*

Microbial burden (cfu/g) in pressed-un pitted dates

Microbial load in pressed-un pitted date fruit of Begumjangi was ranged between 100.0 - 296.0, 1660 - 2800 and 14.0 - 222 cfu/g for the Coliform VRBA, Moulds and yeast and Mesophilic aerobic Bacteria in different fruit size classes, respectively. On Haleeni fruit microbial load was recorded in between 22.0 - 56.7, 542.0 - 5000 and 180 - 500 cfu/g for the Coliform VRBA, Moulds and yeast and Mesophilic aerobic Bacterial in different fruits size classes, respectively and for Dashtri fruit it was found in range between 25.0 - 500.0, 1200.0 - 7807 and 387 - 1000.0 cfu/g for Coliform VRBA, Moulds/yeast and Mesophilic aerobic Bacteria in different fruits size class, respectively. Microbial burden on Peshnah fruit was noted in ranged between 74 - 433, 678 - 7000.0 and 400 - 1300 cfu/g for the Coliform VRBA, Moulds and yeast and Mesophilic aerobic Bacteria in different fruit size classes, respectively. The maximum microbial loads for all four cultivar were found in small size class, which fallowed by mixed and medium class and minimum was in large size class. Similarly Over all investigated microbial burden was noted in small size class which fallowed by mixed then medium and lowest was found for large size class. Statistically analysis indicated that there was highly significant variation among microbial infection in all fruit size classes but individual microbe showed slightly to non-significant variation between the classes (*Table 8 and Fig. 7)*. Aleid (2014) reported that the small-sized fruits of Sukkary cultivar showed significantly ($P \leq 0.05$) higher counts for mesophilic aerobic bacteria and mould and yeasts than the larger or medium-sized fruits. In this investigation among the examined

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

varieties Begamjangi was found hardest to microbial burden and peshnah was noted softed. Similar observation was also reported by Aleid (2014) during study of Microbial loads and physicochemical characteristics of fruits from four Saudi date palm tree cultivars: Conformity with Applicable Date Standards. Nussinovitch et al. (1989) found colony counts of soft dates in the order of 10^4 cfu/g lactic acid bacteria. Aidoo et al. (1996) found bacteria, coliforms and moulds to be pollutants of dates (Tamr) bought from the stores with in greater Glasgow.

Table 8. *Microbial burden (cfu/g) in pressed-un pitted dates of four local date palm varieties*

Date variety	Fruit size classes	Microbial variable			P value

DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

Kader (2007) reported that the microbial spoilage of dates (Tamr) can be caused by yeasts, moulds and bacteria. Abu-Zinada and Ali (1982) reported fungi contamination of different date (Tamr) varieties. Further that the dates contamination with microbial are eaten without further processing may represent a health risk for consumers, and therefore a food safety problem (Brandl, 2006; Hamilton et al., 2006; Tyler and Triplett, 2008). According to the Public Health Laboratory Services (PHLS, 1992, 1996) the Khalas, Sugai and Anbara dates showed unacceptable levels of coliform bacteria.

Fruit Quality Assessment (FQA)

Fruit Quality Assessment (FQA) through fruit performance index (FPI) and valuation classes indicated that the Begamjangi score highest grade point (6) and stand in excellent classes, which fallowed by Haleeni (4 grade point) with good class and other two dates cultivars Dashtri and Peshnah score 2.0 and 1.0 grade points and classified into poor and very poor category, respectively (*Tables 9 and 10*).

Table 9. *Standard of grade point for fruit quality of date palm [references: Prajapati and Tripathi (2008); Govindaraju et al. (2012); Leghari et al. (2019)]*

Valuation classes	Scoring percentage	Grade point
Not recommended	30	0

Conclusion

From the facts cited in this study it could be established that some significant performance characteristics were determined in the investigated dates palm fruits of Turbat, the results provide new information needed to adapt excellent dates standard for cultivation. A proportional examination of microbiological quality and physiochemical

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66256642

properties at the farm level, as well as a complete examination of current guidelines on date quality, are obligatory in order to review the significant quality criteria of date fruit standards. Moreover valuation of the investigated fruit performance or quality index is important for the dates of local area. The present study also concluded that the date variety Begamjangi and Haleeni due to their highest grade point and good financial worth are expected to be a decent performers and might be suggested for the cultivation.

(Received 1st Feb 2019; accepted 8th Mar 2019)

Abstract. Mash bean [*Vigna mungo* (L.) Hepper], is the third largest pulse crop in Pakistan. Nine advanced breeding lines were compared with two commercial varieties, in order to investigate their potential prior to release as cultivated varieties. A field experiment was conducted in three environments in Punjab, Pakistan, during the 2014 kharif (wet) season. Developmental, morphological and yield traits included time to reach 90% maturity, plant height, the number of branches, grain yield (GY) and its components. GY varied between 778 kg ha^{-1} (cv. Mash Arooj) and 1005 kg ha^{-1} (line 11CM-709) in the eleven genotypes, and between 438 and 1667 kg ha^{-1} in the three environments. The lowland environment (Piplan) was the highest yielding, despite significant water deficit. In each genotype average yield across the three environments, plotted against the regression slope of specific yield vs. average yield in each environment, allowed yield potential and stability to be shown. As a result, five breeding lines exhibited a remarkable yield potential in exchange for low stability, i.e. modest suitability for low yielding environments. The remaining lines yielded as the two commercial varieties with a higher stability across environments. These are good premises for mash bean wider diffusion in the surveyed area.
Keywords: *mash bean, black gram, genotypes, plant traits, yield potential, yield stability*

Introduction

Mash bean [*Vigna mungo* (L.) Hepper], black gram, is an important legume crop widely grown in Asia and has great value as food, fodder and green manure. In addition to improving the soil fertility, it is a cheap source of protein for direct human consumption. It has a close relationship with human being due to high and easily digestible protein content (20.8–30.5%) and carbohydrate (56.5–63.7%) on dry weight

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66436654

basis (Sharma et al., 2012). Thus, it has a great potential to improve protein deficiency in human beings by providing a low cost protein. Mash bean not only fixes free atmospheric N_2, but also enriches the soil with nitrogen for the growth of succeeding crops (Sen, 1996). This crop can be successfully grown on marginal lands where other crops perform poorly (Ghafoor et al., 2003).

By establishing the International Year of Pulses in 2016, the FAO has shown renewed interest in these crops as components of the diets in many countries (Sharma, 2014). This is supported by their annual increase rate that, based on the cited source, has resulted slightly higher than that of cereals (1.84% vs. 1.82% over the past two decades).

Despite these premises, worldwide yield of mash bean including Pakistan is very poor. In Pakistan it is the least researched crop among pulses despite its high nutritive and economic value, due to which its area of cultivation and production have both gradually decreased. In Pakistan during 2016-17, mash bean was grown over an area of 17 thousand hectares with a total production of 7 thousand tonnes. However, it is estimated that mash bean is the major food legume grown in Pakistan during the summer season after gram and mung bean: it occupies 1.5% of total pulses area contributing 1.4% to total pulses production (GOP, 2017). Though it is grown all over the country, Punjab is the major mash bean producing province. The productivity of mash bean in the country has remained quite low as compared to other grain legumes (GOP, 2017).

Mash bean is mainly grown as a pulse crop, although sometimes it is used as a green manure to improve soil fertility. Mash bean is a short-duration crop that requires less water as compared to other summer crops and thus qualifies as a suitable candidate for rainfed areas. Successful cultivation in rainfed areas can give significant economic benefits to farmers (Singh et al., 2015). Like other legumes, mash bean also possesses the ability to establish a symbiotic relationship with the nitrogen fixing soil bacteria generally known as "rhizobia", which is a term used for a broad range of microsymbionts from α- and β-*Proteobacteria* that establish symbiosis with leguminous plants for biological nitrogen fixation. Mash bean can fix approximately 37–83 kg ha^{-1} of nitrogen through this symbiotic association (Mohammad et al., 2010).

The performance of any character is a combined result of the genotype, the environment and the interaction between genotype (G) and environment (E). It is necessary to research on yield stability and G × E interactions to improve consistency in performance across diverse environments and years (Blanche et al., 2009). Significant genotype and environment interactions occur when the responses of two genotypes to different levels of environmental stress are variable. An efficient genotype must remain consistent in different years and environmental conditions (Hill, 1975). Better understanding of the G × E interactions and stability in crops is generally used as a decision tool, particularly at the final stage of variety development process, to generate essential information on pattern of adaptation in breeding lines, screen new varieties for release, and determine the recommendation domains for released varieties (Yan and Kang, 2003).

Based on these premises, the main objectives of the present study were to identify more high-yielding, stable and promising lines and areas where mash bean lines would be adapted. The novelty of this research is that promising lines, having desirable plant traits and high yield stability, could be introduced as released varieties.

Material and Methods

Plant materials, environments and experimental conditions

Mash bean germplasm comprising nine advanced breeding lines (11CM-707, 11CM-705, 11CM-709, 11CM-701, 11CM-703, 11CM-706, 11CM-710, 11CM-702, 11CM-704) and two commercial varieties commonly cultivated among farmers (Chakwal Mash and Mash Arooj) was evaluated over three environments in the framework of Barani Agricultural Research Stations: Chakwal (32°55′49″N 72°51′20″E, 525 m asl), Piplan (32°17'12"N 71°21'59E, 198 m asl) and Fateh Jang (33°33'57"N 72°38'57"E, 514 m asl) in Punjab province, Pakistan, during 2014 (*Figure 1*).

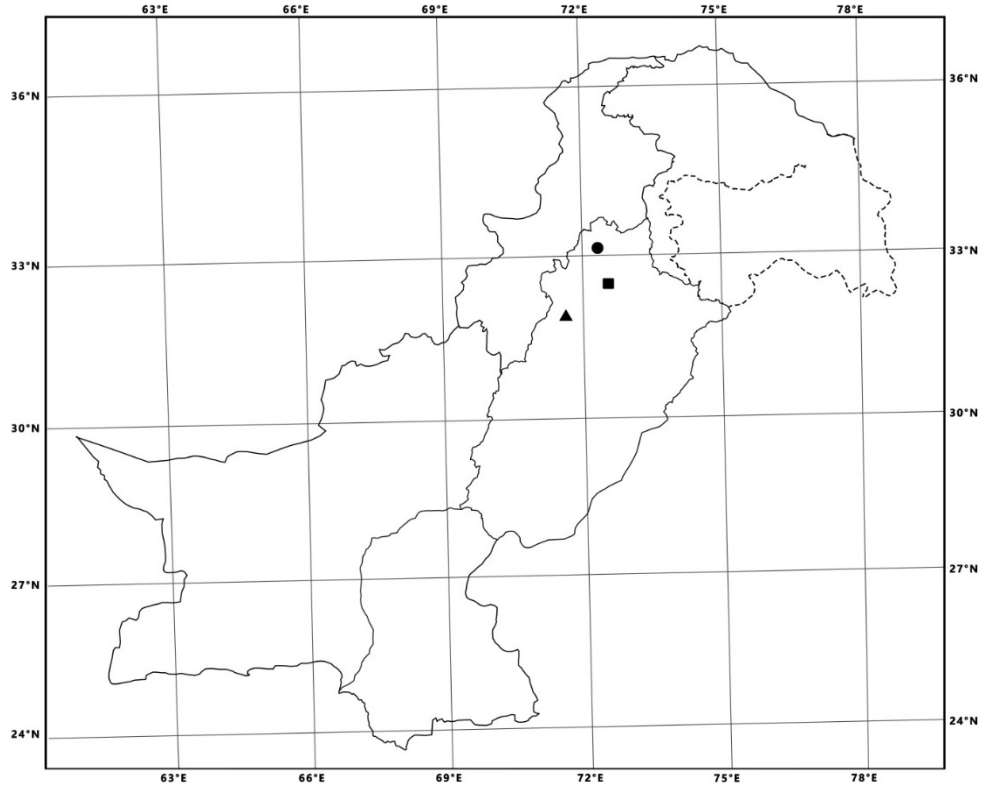

Figure 1. *Mash bean germplasm evaluation at Barani Agricultural Research Stations: Chakwal (▲), Piplan (●) and Fateh Jang (■) in Punjab province, Pakistan*

The experiment was laid out in a Randomized Complete Block Design (RCBD) at three replicates, with a net plot size of 4.8 m^2 (4 × 1.2 m). Preceding crop, in the frame of the National Coordinated Pulses Program, was groundnut at all three environments. The fields were supplied with a recommended dose of Di-Ammonium Phosphate (DAP) fertilizer (50 kg ha^{-1}) before preparation of seed bed. Seeds of mash bean were sown with hand drill and planted at a depth of 3-4 cm. Row width was 30 cm, while plant to plant distance was kept at 10 cm by means of over-seeding and subsequent thinning of seedlings. The crop was sown on July 22 and harvested on October 10, 2014, at all three environments. Hand weeding was carried out, and all recommended cultural practices were followed to maintain a healthy crop stand. Irrigation was not applied.

Weather during the experiment (minimum and maximum temperature, precipitation and relative humidity) was daily monitored at the three environments' meteorological

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66436654

stations. Based on this, reference evapo-traspiration (ET_0) was calculated with the Hargreaves equation (Hargreaves and Samani, 1985). The thermal sum of average daily temperatures above 10°C was also calculated, and expressed as growing degree days (GDD) from sowing to harvest. GDD are a measure of heat accumulation commonly used to predict plant development, and rate genotype behaviour across time and space.

Crop monitoring

The following traits pertaining to plant development and morphology were specifically monitored during the experiment: seedling emergence, days to reach the beginning of the reproductive stage (50% flowering) and final senescence (90% maturity), plant height and the number of primary branches.

At maturity, five plants from each plot were randomly selected and the number of pods per plant and seeds per pod were counted. The grain was then harvested from the whole plot surface (4.8 m²), weighted, and a sample was oven dried (48 hours at 105°C). Based on this, grain yield per hectare adjusted at 12% moisture was determined. Finally, the thousand-seed weight that is the third yield component was determined, based on pods per plant and seeds per pod that are the other two yield components, and grain yield.

Data analysis

Morphological, developmental and yield data were submitted to a combined ANOVA for the sources Genotypes (G), Environments (E), and their interaction (G × E), using R-program 3.2.1 (R Development Core Team 2012). Student Newman-Keuls (SNK) test at $P \leq 0.05$ was used to separate data of significant ANOVA sources.

Pearson's correlation (r) between crop traits was assessed to evaluate the degree of inter-relationship. Additionally, the relative importance of yield components on grain yield was assessed through the Lindeman, Merenda and Gold's (LMG) method (Lindeman et al., 1980).

Lastly, yield data representation according to Eberhart and Russel (1966) was used to highlight each genotype's average yield vs. yield stability among experimental environments.

Results

Meteorological conditions

The experiment was conducted during the kharif (wet) season in 2014. The amount of precipitation greatly differed among the three environments: 390, 169 and 852 mm were received during mash bean cultivation in Chakwal, Piplan and Fateh Jang, respectively. Differences were also shown in average temperature: 27.4, 31.5 and 28.2°C at the three respective environments. Thus, Piplan that has a lower elevation appeared a drier and warmer environment than Chakwal and Fateh Jang. The thermal sum cumulated steadily from sowing to harvest in all environments (*Figure 2*). However, Piplan diverged from the other two environments, achieving a final 1744 GDD vs. an average 1444 GDD of the combined Chakwal and Fateh Jang.

The balance between water supply (precipitation) and demand (ET_0) showed very different patterns (*Figure 2*). Chakwal remained slightly above the break-even line for most of the time. Piplan portrayed increasing water deficit up to -264 mm at harvest.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66436654

Lastly, Fateh Jang featured much more P than ET_0, resulting in a considerable gain (+477 mm).

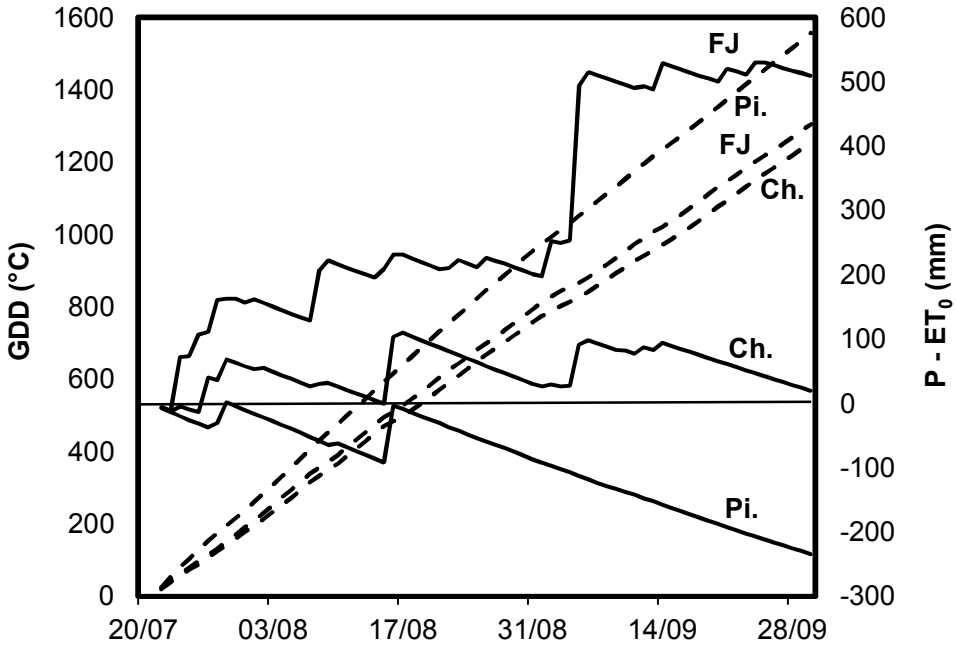

Figure 2. *Cumulated growth degreee days (GDD) (dashed lines) and precipitation minus reference evapo-traspiration (P – ET_0) (solid lines) from seeding to harvesting in the three environments. Ch., Chakwal; Pi., Piplan; FJ, Fateh Jang. The horizontal line indicates the break-even in the balance between precipitation and evapotranspiration*

Plant development and morphology

Seedling emergence was very high (average, 92.6%); no ANOVA source (G, E, G × E) significantly influenced this trait (*Table 1*). The eleven genotypes exhibited a modest difference in earliness at 50% flowering (*Table 1*): only 11CM-703 was significantly earlier that the rest of genotypes by an approximate six days. An average 48 days was needed to achieve 50% flowering in the three environments, corresponding to 969 GDD.

A stronger differentiation was shown at 90% maturity (*Table 1*): 11CM-704 was the earliest genotype at par with 11CM-707, 11CM-703 and 11CM-710. 11CM-706 and 11CM-702 were the latest, and the other five genotypes were statistically undifferentiated between the two groups. Slight differences to achieve 90% maturity were also shown among the three environments. An average 78 days was needed, corresponding to 1515 GDD.

Plant height varied between 37.9 and 44.4 cm among the eleven genotypes (*Table 1*): 11CM-701, 11CM-702 and Mash Arooj were the shortest genotypes; Chakwal Mash was the tallest, while the other seven genotypes were intermediate. Among the three environments, Piplan featured much taller plants (average, +35%) than Chakwal and Fateh Jang.

In contrast to this, the number of primary branches was undifferentiated (*Table 1*). An average 1.88 branches per plant was recorded, with minor differences among genotypes and environments.

ns, * and ** mean non-significant, significant at $P \leq 0.05$ and $P \leq 0.01$, respectively. Different letters indicate statistical differences at $P \leq 0.05$ (SNK test)

Yield and yield components

The number of pods per plant varied in genotypes between 17.1 (Mash Arooj) and 21.8 (average of 11CM-707, 11CM-705, 11CM-709, 11CM-701, 11CM-703, 11CM-706 and Chakwal Mash) (*Table 2*). The remaining three genotypes were intermediate (average, 19.0). The three environments exhibited a much higher variation in this trait: Piplan exhibited a more than double data (32.1) than the combined Chakwal and Fateh Jang (average, 14.9).

Compared to this, the number of seeds per pod did not significantly vary among genotypes, whereas modest but significant differences were shown among environments (*Table 2*): also in this case Piplan displayed a certain advantage over Chakwal and Fateh Jang.

The thousand-seed weight varied among genotypes from a minimum of 17.6 g (11CM-705) to a maximum of 22.5 g (11CM-703), although ANOVA was significant only at $P < 0.10$ (*Table 2*). Stronger differences were evidenced among the three environments: Piplan exhibited a ca. 40% higher data than Fateh Jang, which in turn passed Chakwal by ca. 20%.

Grain yield significantly varied among genotypes (*Table 2*). It ranged from less than 800 kg ha^{-1} (Mash Arooj) to more than 1000 kg ha^{-1} (11CM-709). The remaining genotypes were quite evenly distributed in this range. Much stronger differences were shown among environments: Chakwal and Fateh Jang averaged 485 kg ha^{-1}, whereas Piplan achieved ca. 3.5 times as much.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66436654

The significant G × E interaction (*Table 2*) suggests a different behaviour of the eleven genotypes in the three environments, despite analogous grain yield variation in the single environments (C.V. between 13.9% and 16.4%; not shown).

Table 2. *Grain yield and yield components of eleven genotypes grown at the three environments*

Source	Pods per plant	Seeds per pod	Thousand seed weight (g)	Grain yield (kg ha^{-1})

ns, * and ** mean non-significant, significant at $P \leq 0.05$ and $P \leq 0.01$, respectively. Different letters indicate statistical differences at $P \leq 0.05$ (SNK test)

Data representation according to Eberhart and Russel (1966) allows these differences to be interpreted based on the two factors average yield in the three environments, and regression slope of genotype yield vs. average yield in each environment (*Figure 3*). In practice, almost all genotypes fall in the first and the third quadrant, i.e. all genotypes belong to either high producing under favourable conditions types (first quadrant), or low producing but suited for unfavourable conditions types (third quadrant).

However, in the former group 11CM-703 could be seen a better genotype than 11CM-709 despite lower average yield, thanks to a higher suitability for unfavourable conditions (regression slope closer to 1). In fact, 11CM-703 attained a relative yield > 100.0 in all three environments, whereas 11CM-709 attained a relative yield > 100.0 only in two environments (data not shown).

At the opposite end, 11CM-705 and Mash Arooj appeared to be intrinsically suited for unfavourable conditions (regression slope below 0.9), but did not achieve a relative yield > 100.0 in any of the three environments. Compared to them, 11CM-707 had a similar regression slope, i.e. good suitability for unfavourable conditions, but achieved a relative yield > 100.0 in the two low yielding environments (Chakwal and Fateh Jang) (data not shown).

DOI: http://dx.doi.org/10.15666/aeer/1703_66436654

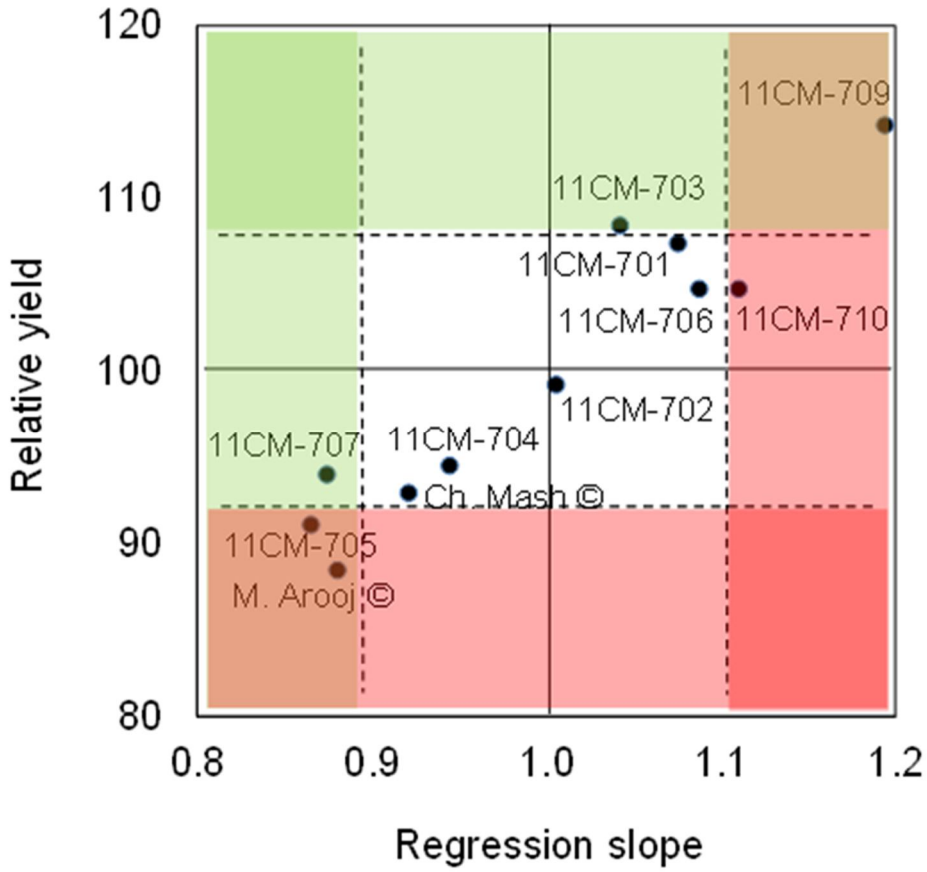

Figure 3. *Slope of the regression between genotype yield and average yield in the three environments (1 = average), and relative yield across the three environments (100 = average). Vertical and horizontal dashed lines indicate ± standard deviation for the two respective traits. Beyond dashed lines, green and red colour indicate favourable and unfavourable conditions, respectively. Based on this, the four quadrants indicate high yield and low stability (top right); low yield and stability (bottom right); low yield and high stability (bottom left); high yield and stability (top left)*

Relationships among developmental, morphological and yield traits

The table of correlations involving all investigated traits displays several inter-relations (*Table 3*). Seedling emergence was not related to any other trait, which is consistent with the low variation observed for this trait (*Table 1*). The time to 50% flowering was not related to any other trait, either, whereas the time to 90% maturity was adversely related to plant height, the number of pods per plant and final yield. Plant height was directly related to the number of primary branches, the three yield components and, especially (r = 0.86**), final yield.

The three yield components were generally inter-related, and unsurprisingly well related to yield. However, the relative importance of yield components through the LMG method (*Figure 4*) indicated pods per plant and thousand-seed weight as prominent components (respective weights, 49% and 39%), compared to seeds per pod weighing a residual 12%. This is consistent with the different influence exerted by the investigated factors on the three yield components (*Table 2*).

Discussion

Increased interest in pulses is stemming research worldwide. New mash bean cultivars are being released to replace old genotypes in the quest for higher and more consistent yields in both traditional (Khaimichho et al., 2014; Sartaj and Anwar, 2015; Mbeyagala et al., 2016) and new cropping areas (Pekşen et al., 2015). The appraisal of yield related attributes and yield stability across environments is of crucial importance in development and introduction of improved varieties.

Several works addressed the genetic control of quantitative traits associated with yield in mash bean genotypes (Khaimichho et al., 2014; Hemavathy et al., 2015; Mbeyagala et al., 2016). Only in one work (Mbeyagala et al., 2016) this process involved a multi-location experiment as in our case. In the cited paper, a two-year test in six locations served to assess genotype yield and stability across environments, as well as each environment's discriminative ability and representativeness. In our case, the significant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66436654

G × E interaction stimulated the assessment of genotype suitability for low vs. high yielding environments through Eberhart and Russel's (1966) approach: the wide range in average yield between Chakwal and Fateh Jang, on one side, and Piplan, on the other side (*Table 2*), facilitated the accomplishment of this task. Additional years are, nevertheless, needed to better state a location's characteristic or rate its value as testing environment, as also Mbeyagala et al. (2016) cautioned.

The procedure described allowed the eleven genotypes to be discriminated based on two equally important attributes as yield potential and stability. Five out of nine advanced breeding lines fell in the first quadrant (*Figure 3*), i.e. they expressed a competitive edge over the two commercial varieties (third quadrant), although at the expenses of stability. Another new line fell very close to the centre of the graph, indicating well balanced yield vs. stability. The remaining three new lines fell in the third quadrant, yet expressed some advantage over the two commercial varieties in either attribute. It results that the nine breeding lines possess in general ameliorated characteristics with respect to the two varieties they are intended to replace. However, no clear advantage in any morphological trait (*Table 1*) or yield component (*Table 2*) can be seen between the nine lines combined, on one side, and the two varieties combined, on the other side. It may be evinced, therefore, that the breeding programme targeted a general better efficiency in plant processes, more than a specific plant type associated with higher yield. It is noticed, incidentally, that the plant traits best related to yield in this experiment (*Table 3*) are almost the same evidenced in other works (Khaimichho et al., 2014; Hemavathy et al., 2015).

Lastly, mash bean is mostly grown in the sub-tropics during the summer, kharif (wet) season, although cultivation under winter, dry (rabi) conditions is also reported (Kumar and Kumar, 2016). Mash bean sensitivity to the drought (Baroowa et al., 2016) and especially heat stress (Kaur et al., 2015; Solai et al., 2015) is generally acknowledged. Flowering and the reproductive stage are indicated as the most critical period, during which time temperatures above 40°C adversely affect yield. In our experiment, this threshold was briefly passed after sowing only in the lowland environment (Piplan). This site also featured a sizeable water deficit (*Figure 2*) cumulating in the most sensitive reproductive stage (Baroowa et al., 2016). However, this circumstance did not hamper growth (*Table 1*) and the achievement of a high yield potential in this specific environment (*Table 2*). These points to factors other than water deficit as main drivers for mash bean yield in the three surveyed environments.

Conclusions

Eleven genotypes of mash bean comprising two commercial varieties and nine advanced breeding lines, tested in three environments in Punjab, Pakistan, have portrayed a remarkable variation in plant development and morphology, as well as grain yield and yield components. This provides enough scope for significant improvement of plant traits through selection.

Five new lines have exhibited higher yield potential under favourable conditions, reaching up to 1000 kg ha^{-1} yield that is a level seldom echoed in the literature. Three other lines have shown a yield potential similar to that of commercial varieties, in exchange for which the new lines have featured a slightly higher yield stability.

DOI: http://dx.doi.org/10.15666/aeer/1703_66436654

The present work demonstrates, in accordance with other literary sources, that there is ample space for improvement of the mash bean crop in view of a wider diffusion in the sub-tropical to temperate areas of the world.

The research on mash bean is committed to further breeding effort aimed at obtaining more genotypes, and multi-location testing in view of releasing new improved varieties.

Compliance with Ethical Standards. There is no potential conflict of interests and authors confirm that the field studies did not involve endangered or protected species.

(Received 1st Feb 2019 ; accepted 29th Mar 2019)

Abstract. The analysis of bacteriological changes in hare internal organs has been performed in the paper. The assessment was made with regards to the individual condition of animals. Anatomical and pathological changes were found in 80% of the hare from the obtained sample. These occurred regardless of the age and gender of animals and were mostly inflammatory infiltrates and necrosis in the testes of males as well as inflammatory infiltrates of the liver and emphysema found in both males and females. There was also an increase in flora of two bacterial strains in hares internal organs. The *Nocardia* strain was found in the testes of two individuals, whereas the *Providencia rustigianii* strain was found, at various severity levels, in the liver, kidneys, lungs and heart of males and females, regardless of their age. Isolated strain of *Providencia rustigianii* proved to be resistant to three antibiotics, while *Nocardia* strain to one of the antibiotics used. The analyses carried out indicate that in addition to population and ecological factors resulting from environmental changes, a number of pathogenic agents, including the presence of bacteria that have not been described in this animal species, are a significant factor limiting the reproductive potential of the population. Therefore, disturbances of physiological processes having a diverse etiological background can lead to numerous anatomical and pathological changes, and thus increase susceptibility to diseases and falls of animals, and at the same time, deepen the ongoing regress of this species population. Not without significance is the fact that the described changes were found regardless of the gender and age of animals.

Introduction

Almost since the end of the 1970s, both in Poland and many European countries, a downward trend of the hare population has been observed (Burel and Baudry, 1990; Flis, 2009, 2016; Frylestam, 1980; Schmidt et al., 2004; Wibbelt and Frölich, 2005; Nasiadka and Dziedzic, 2014). In our country, in many cases, the level of spring density is currently lower compared to the volume of acquisition in the 1960s and 70s of the twentieth century. In the 1970s, the average population density in our country remained at the level of about 50 individuals per 100 ha of the field areas of hunting grounds (Pielowski, 1976, 1979). At the beginning of the 21st century, the average level of hare density in the country varied in individual regions and was within the range of 5-9 individuals/100 ha (Dziedzic et al., 2002; Wasilewski, 2007; Flis, 2009, 2016). However, there are still areas where density of the population is so high that the species

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66556667

is still regularly hunted (Dziedzic et al., 2002; Flis, 2009, 2015, 2016; Nasiadka and Dziedzic, 2014).

Despite the fact that there is no possibility of indicating a clear cause of the persistent population trend, usually the most frequent changes are those in agrocenoses constituting the basic areas of this species. Intensification of agriculture significantly influences the simplification of agrocenosis structures, which in turn leads to a significant decrease in the heterogeneity of these environments. This entails the shrinking of optimal hare habitats (Lewandowski and Nowakowski, 1993; Panek and Kamieniarz, 1999; Schmidt et al., 2004; Kryński et al., 2007; Petrovan, 2011; Kamieniarz et al., 2013; Schai-Braun et al., 2015; Panek, 2018). Another, not less important, element that directly affects the dynamics of the number of hares is predation. The use of oral treatments for immunization of free-living foxes eliminated one of the basic factors limiting the population, which in turn increased the impact of this species on small animals (Demirbas, 2015; Gołdyn, et al., 2003; Goszczyński and Wasilewski, 1992; Panek et al., 2006; Wasilewski, 2007; Flis et al., 2017, 2018). Hušek et al. (2015) a high rate of fox predation targeting hares depending on the habitat and reported that hare males tend to fall as a prey. Therefore, an extremely important element in hare population management as a monomorphic species is knowledge of the individual condition and population structures that have a direct impact on the reproductive potential of the population (Méres et al., 2016; Misiorowska et al., 2014; Pintur et al., 2006). The impact of hare population, and thus local density indices, on the impact of synanthropic predation is also significant (Flis, 2013; Nasiadka and Dziedzic, 2014).

Another elements that directly affect survival, and thus the size of the population are numerous disease entities found in this species. Coccidiosis and other parasitic diseases are the basic mention. Nevertheless, bacterial and viral diseases, such as brucellosis and European Brown Hare Syndrome – EBHS – and many other slightly less common ones also exert quite considerable impact (Gavier-Widén and Mörner, 1991; Duff et al., 1994; Pikula et al., 2004; Wibbelt and Frölich, 2005; Frölich and Lavazza, 2008; Dubinský et al., 2010; Decors et al., 2011; Chroust et al., 2012; Kornaś et al., 2014; Flis et al., 2016).

The aim of the study was the assessment of histopathological changes and bacteriological analysis of internal organs as well as individual condition in the population of European hare originating from the region where hunting acquiring is still taking place.

Materials and methods

Characteristics of the research area

The research was conducted in two hunting districts with a total area of 13,600 ha, the forest cover of which is 25.2%. They are located in the western part of the Lublin region, in the mesoregion of Kotlina Chodelska and the northern part of Wzniesienia Urzędowskie, in Poland (*Fig. 1*). This region is characterized by the presence of fertile soils of the chernozem type on the loess ground (Kondracki, 2000). Despite fairly fertile soils, it is distinguished by significant fragmentation of agricultural crops, and thus large heterogeneity of field environments. Field crops are dominated by plants with high soil requirements, with particular reference to orchards and plantations of perennial soft fruits, mainly raspberries and currants. In the agricultural landscape, there are numerous

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66556667

wastelands as well as small wooded enclaves and forest complexes (Witek, 1991). Heterogeneity evaluation of the natural environment of agrocenoses in the area of research, performed according to the method proposed by Schrödel (1991) showed an average size of individual fields at the level of 0.95 ha, while the average distance between landscape elements ranged from 0.5 to 0.7 km. In turn, the relative length of contour lines in agrocenoses having significant impact on the functioning of small game population, despite the variation in individual regions of the study area, was on average at 0.1−0.2 km/km^2. All described elements determine quite significant mosaicism of field environments, creating almost optimal conditions for living and functioning of the hare population (Pielowski, 1979; Nasiadka and Dziedzic, 2014).

Figure 1. *Location of the research area*

Material for research

As part of the research, hares obtained in collective hunts during the hunting season 2017/18 have been weighed and their gender and age have been determined. The whole material consisted of 20 hares obtained first during two hunts, which is representative of the sample. Due to minimizing the amount of shooting in recent years and the fact that in accordance with the law, holder of the hunting district is the owner of hunting grounds, it was not possible to collect larger number of hare for study. In total, 9 males and 11 females were assessed, of which the share of young and adult hares was half.

Methods and measurements

All shot-off hares were weighed directly in the field. Weighing was carried out to the nearest 0.1 kg. Also in the field, their gender and age were assessed. Gender assessments were made based on the appearance of secondary sexual characteristics.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66556667

The age of hare was also determined directly in the field on the basis of the palpation assessment of the occurrence or disappearance of the Stroh mark (cartilaginous elbow base cap). Such an assessment allows the division of hares into young (up to 1 year old) and adult (over 1 year old) (Stroh, 1931; Pielowski, 1979).

Histopathological and bacteriological material

Lung, liver, kidneys and testes sections in males were taken from all acquired hares for histopathological and bacteriological examinations. Sectional examination performed under the field conditions and material collection for bacteriological examination required the use of a transport set containing rods to collect swabs from pre-isolated organs. Material for histopathological analysis was fixed in 4% formalin, and then dehydrated and embedded in paraffin. The 4 μm thick sections were stained with hematoxylin and eosin (HE). A bacteriological analysis of the collected samples was also carried out.

Laboratory preparations

Different propagating and differentiating media were used to identify individual species of microorganisms. The solid substrate was agar with the addition of 5% sheep blood to breed aerobic microorganisms and possible determination of hemolysis. Sugar broth was used as a liquid substrate to reproduce aerobic bacteria. Other substrates were also used, including Chapman, Mac Conkey and Sabouard medium to identify any organ mycoses that occur. The study also applied a medium with cetrimid to identify microorganisms of the *Pseudomonas* genus and D-coccosel medium to identify fecal bacteria. Further identification of individual bacteria types was carried out with the BioMerieux bio-chemical tests (Analytical Profile Index). The control of substrates fertility was carried out using reference strains. After determining the bacterial strain, the growth rate of bacterial flora was assessed using the criterion of low (+), intensive (++) and very intense (+++) growth. Although it is a simplified method, it allowed preliminary assessment of the health status of the hare, and most of all it revealed the type of bacterial environmental threats. An analysis of the sensitivity of isolated bacterial strains to 8 commonly used antibiotics was also carried out applying the criterion of subdivision into sensitive, medium sensitive and resistant ones. The following antibiotics were used for the analyzes in doses: Enrofloxacin ENR – 5 μg, Amoxicillin/clavulanic acid AMC – 30 μg, Gentamycin CN – 10 μg, Penicillin G P – 10 μg, Oxytetracycline OT – 30 μg, Trimethoprim/sulphamethoxazole SXT – 25 μg (trimetoprim- 1.25 μg+sulfametoksazof 23.75 μg), Marbofloksacin MAR – 5 μg, Tylozyna TY – 30 μg.

Results

Characteristics of the structure and individual quality of the population

The conducted research shows that the average body weight of three young males was 3.9 kg, and 7 young females 3.7 kg (*Table 1*). In adults, the body weight was uniform. The average value of this feature of 6 males and 4 females was at the level of 4.7 kg. The overall value of the gender index was at 1:1.2 in favor of females. The reproductive success rate defined as the ratio of the number of young hares that survived till the hunting season per 1 adult female was high and amounted to 2.5.

20	♀	Young	3.6	x	Small inflammatory infiltrations	x	x	x

Anatomical and pathological analysis

Performed anatomical-pathological analyses of testicles showed that in the examined sample, extensive areas of necrosis were found in three adult males. In the central parts of the necrotic areas, there were numerous foci indicating the progressive process of calcification (*Fig. 2*). In addition, in the testes of two young and one adult males, inflammatory infiltrates of varying intensity were found. Numerous purulent infiltrates

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66556667

contained neutrophil granulocytes, giant cells, fibroblasts and histiocytes. Glandular epithelial atrophy and progressive fibrosis around the glandular tissue were found, which was caused by an ongoing inflammatory process with irreversible effects. Anatomical-pathological changes of liver were found in 6 individuals, which were manifested by a partial lack of individual cells in a radiative manner within some of the hepatic lobes (*Fig. 3*). There were numerous focal inflammatory infiltrates between the hepatic lobes. Small inflammatory infiltrates occurred in 3 young females and one adult. One adult female showed medium inflammatory infiltrates, while in one adult male - intense inflammatory infiltrates. Analysis of kidneys from shot hares showed numerous inflammatory infiltrations within the glomerulus of the vessels with partial or complete closure of the kidney tubules (*Fig. 4*). This indicates the occurrence of glomerulonephritis. This condition was found in one adult male and one young female. Among the analyzed sample, one young and two adult females as well as one young male were diagnosed with emphysema with characteristic foci of congestion and inter-vesicular tissue hyperplasia (*Fig. 5*). Analysis of samples taken from myocardial muscles did not show any anatomical-pathological changes.

Bacteriological analysis

The results of bacteriological analysis of the testes revealed two cases of *Nocardia* bacteria. One young male showed a fairly low (+) growth, and in one adult male a very intense (+++) growth of this bacterium. In turn, in the liver of 1 young female, quite low growth (+) of *Providencia rustigianii* was found. Analysis of kidneys of the acquired individuals showed that 5 of them revealed quite low (+) growth of *Providencia rustigianii*. This condition occurred in one young and three adult males and one adult female. In samples taken from lungs, 2 adult males revealed very intense (++), while in a young male and adult female, quite low growth (+) of *Providencia rustigianii*. In the collected heart tissue samples, two adult males showed a significant very intense growth (++) of *Providencia rustigianii*.

Resistance to antibiotics

As part of the study, the *in vitro* sensitivity assessment of isolated bacterial strains to antibiotics was performed (*Table 2*). The isolated strain of *Providencia rustigianii* turned out to be resistant to three antibiotics used, moderately sensitive to one and sensitive to another four antibiotics. In turn, the isolated *Nocardia* strain was sensitive to seven of the eight antibiotics used and resistant only to one of them.

Table 2. *Sensitivity of isolated bacterial strains to antibiotics*

Antibiotic used	Type of bacterial strain	
	Providencia rustigianii	***Nocardia***
Tylozyna **TY30**	O	W
Amoxicillin/clavulanic acid **AMC 30**	O	W
Gentamycin **CN10**	W	W
Penicillin G **P10**	O	W
Sulphamethoxazol/Trimethoprim **SXT25**	ŚW	O
Marbofloksacin **MAR5**	W	W
Oxytetracycline **OT3**	W	W
Enrofloxacin **ENR5**	W	W

W - sensitive; ŚW - moderately sensitive; O - resistant

Discussion

The analysis of population parameters based on a sample of 20 individuals indicates that the values of body weight, being an expression of the individual condition, in significant way do not differ from those reported by Flis (2015). Obtained body mass values slightly exceed those given by Dziedzic et al. (1998) from Lublin Upland and Podlasie region in the mid-1990s. These results are higher than those from research conducted in areas of the highest population size of this species in our country during the hunting season 2009/2010 (Misiorowska et al., 2014). The presented results are characterized by much higher body weight values than those in Croatia in the 2004/2005 hunting season, reported by Pintura et al. (2006), as well as in Hungary in both age and gender groups (Farkas et al., 2016). In turn, the obtained gender structure is similar to both the research conducted by Flis (2015), and that reported by Misiorowska et al. (2014).

The reservoir of bacteria from the genus *Providencia* are insects, and most of all, houseflies, from which *Providencia alcalifaciens*, *Providencia rettgerii* and *Providencia stuarti* were isolated. The species of *Providencia rettgerii* was isolated from *Helaemyia petrolei* fly larvae found in oil-bearing areas. Bacteria of the genus *Providencia rettgerii* are found as an indispensable element of natural flora of crocodiles, frogs, vipers, as well as snakes, and in particular of python and boa snakes. In addition, the occurrence of *Providencia rettgerii* was found in roundworms, sea lions and seals. Quite rarely, this species is isolated from birds (falcons, bustards). As a rule, they were found in dogs, cats, guinea pigs, as well as in cattle and sheep as part of the natural flora of the gastrointestinal tract and quite often they are referred to as intestinal bacteria. It should be mentioned that the bacteria of *Providencia* genus also cause many diseases. Attention is being paid to *Providencia alcalifaciens* during dog diarrhea and *Providencia rettgeri* causing generalized infections and meningitis, especially in crocodiles up to the age of 3 years. There have also been reports of this type of oral inflammation cases in seals and snakes. These bacteria have never aroused so much interest among the bacteria of the *Encterobacteriaceae* family. This was mainly due to their reduced pathogenicity. Currently, they are beginning to play an increasingly important role as pathogens that cause urinary and digestive tract infections. Up to date, there have been no reports of their presence in hare; however, it is possible that their strong uropathogenic properties confirmed in histopathological studies in mice and monkeys may also have an impact on hare mortality (Janda and Abbot, 2006; O'Hara Mohr et al., 2000).

Nocardia belong to aerobic bacteria. Their natural reservoir is water, soil, vegetation and sewage systems. Infection in animals is quite rare, mainly in tropical countries. These bacteria can be transmitted by castor bean tick. Among animals, they were found in cattle, and the symptoms are dermatitis, pneumonia, mastitis and diarrhea. They were also found in dogs and cats, where lesions were found mainly in lungs and pleural cavity. Infection with these bacteria occurs mainly by inhalation or also by damaged skin. In the skin form, inflammation of regional lymph nodes and nodular lymphangitis are mainly observed. Inhaled form affects the lung and pleura and takes the form of inflammatory granulomas, very similar to those caused by closely related *Actinomyces* bacteria. Due to the fact that so far there have been no reports of their presence on hare, it is difficult to indicate their impact on the health status of this species population. Nevertheless, their numerous occurrences in the testes of two males indicate that they

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66556667

can affect the reproductive processes (Tropiło et al., 1996; Gliński and Chełmiński, 2014; Katkiewicz, 2017; Wiciński et al., 2018).

Conclusions

1. The individual quality expressed as body weight in both young and adult hares is high, and the obtained values of this feature definitely exceed those from other parts of the country, as well as in some European countries. In turn, the balanced gender structure, with a slight majority of females, indicates that this population has developing characteristics, which should favorably affect the dynamics of its size in subsequent years.
2. In the examined sample, only 20% of hares did not reveal any lesions, and this concerned 3 young and one adult. In the rest of the sample, anatomical-pathological changes were found. They occurred regardless of the age and gender of animals. These were inflammatory infiltrates and necrosis in the testes of males as well as inflammatory infiltrates of the liver and emphysema found in both males and females.
3. There was also a growth in bacterial flora of two strains in the hare's internal organs. The *Nocardia* strain was found in the testes of two individuals, whereas the strain of *Providencia rustigianii* was found to vary in severity in the liver, kidneys, lungs and heart of males and females, regardless of their age. These strains have not yet been described in this species. Therefore, it is advisable to carry out further research in this respect, because described bacteria affecting the reproduction processes may be one of the factors contributing to the ongoing regression of this species population.
4. Performed antibiograms indicate that the isolated strain of *Providencia rustigianii* proved to be resistant to three antibiotics, while *Nocardia* strain to one of the antibiotics used.
5. The analyses carried out indicate that in addition to population and ecological factors resulting from environmental changes, numerous pathogenic factors are significant in limiting the reproductive potential of the population. Thus, disturbances of physiological processes having a diverse etiological background can lead to numerous anatomical and pathological changes, and thus increase susceptibility to diseases and falls of animals.
6. Considering the fact that the individual condition and parameters of the population covered by the research are high, it is necessary to conduct further comprehensive research, mainly in the direction of diseases of diverse etiological background. Research should cover larger areas with different densities, and in particular, if possible, concentrate on low-density areas. Such a comprehensive assessment should help to identify environmental hazards for the hare population and to develop directions for actions to reduce the adverse downward trend.

Abstract. Shallow water cage culture is the main marine activity of Xincun Lagoon, Hainan. However, the continuous growth of aquaculture activities not only aggravates the deterioration of the ecological environment of Lagoon, but also affects the healthy development of mariculture. Suitability analysis on net cage mariculture can reduce the pressure of marine ecological environment, increase the yield of aquaculture and alleviate the conflict between different marine activities to a certain extent. However, the interaction of various factors affecting the suitability evaluation of mariculture constitutes a complex system, and the traditional method of weight determination cannot fit the actual situation well. For this reason, this paper attempts to introduce the interaction matrix of rock engineering systems (RES) to evaluate the weight of each index. At the same time, a multi-criteria decision analysis (MCDA) model based on GIS is established. Finally, a continuous graph of the suitability change of shallow sea cage culture in Xincun Lagoon is obtained. The results show that (1) the entrance area of Lagoon is the most suitable area for cage culture in shallow water; (2) the evaluation results are in agreement with the actual situation and previous studies, and the weight determination method is reasonable and feasible.
Keywords: *mariculture, suitability analysis, rock engineering systems, GIS, multivariate analysis, ecosystem approach*

Introduction

Shallow sea cage culture is the main production activity of Xincun Lagoon, Hainan. However, the continuous growth of aquaculture activities not only aggravates the deterioration of Lagoon ecological environment, but also affects the healthy development of mariculture (Yin et al., 2018). In 2016 and 2017, widespread cage-cultured fish deaths occurred continuously in Xincun Lagoon. After field investigations, the main reason was found to be that the fish were hypoxic due to the high density of fish cultures, and the excessive feed also caused eutrophication of the water body. A recent study showed that the amount of TN and TP discharged from cage culture in shallow water accounts for more than 50% of the total discharge of all marine activities (Fang et al., 2018).

With China's attention to eco-environmental protection, the State Oceanic Administration proposed the Blue Bay Remediation Action Plan to restore the ecological environment quality in the Gulf region. Some researches of FAO also show that the ecosystem approach to aquaculture (EAA) and spatial planning are both important tools for sustainable aquaculture (FAO, 2015). Therefore, it is necessary to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66696679

formulate scientific aquaculture planning to reduce the pressure of aquaculture activities on the ecosystem of Xincun Lagoon, to improve the production of mariculture, and to alleviate the conflict between different marine activities. In view of the above objectives, this paper evaluates the suitability of shallow sea cage culture by taking Lagoon as an example, selecting appropriate parameters, using interaction matrix to calculate the weight and combining with Geographic Information System (GIS) to do multi-criteria decision analysis.

Since the end of the 1980s, the academia has begun to study the site selection of aquaculture and guide the actual management of government departments (Parker et al., 1998). For example, when Joaquin (2011) chose the aquaculture area for oysters in the Caribbean Sea, they used multi-factor evaluation method and analytic hierarchy process to calculate the weight of each index and obtain the result of suitability evaluation by combining four kinds of indicators including the internal environment of sea area, the external environment of sea area, the transportation convenience and the social and economic conditions. Dapueto et al. (2015) proposed the spatial multi-criteria evaluation (SMCE) method to determine the area suitable for offshore medium-sized fish farms in Liguria, Italy. The result shows that the SMCE method has good practical significance. Yin et al. (2018) established a high-resolution hydrodynamic model to increase the availability of data, selected environmental and socio-economic indicators and used Multi-Criteria Decision Analysis (MCDA) to determine the suitable aquaculture sites in the coastal areas of Menai Strait.

Considering the complexity of mariculture suitability indicators, this study intends to use interaction matrix to determine the weight of indicators. This method was first proposed by Hudson (1989) to study the problem of rock engineering system (RES). Then it was developed with Mazzoccola to make it more suitable for the application of soft science (Mazzoccola and Hudson, 1996). The basic idea is to treat rock engineering as a complete system. The interaction matrix is constructed by enumerating the variables related to the system, and the interaction between variables is quantitatively evaluated by matrix coding. This method considers not only the influence of each parameter on the system, but also the contribution of the interaction between parameters to the whole system. Compared to other methods, such as Analytic Hierarchy Process, it is more suitable for solving the complex problems of interaction and coupling among various factors (Wu et al., 2011). Subsequently, this method was applied to many disciplines, such as ecosystem assessment (Velasco et al., 2006) and gas spontaneous combustion (Zhou et al., 2017), and so on.

Preparation

Conceptual framework

In this paper, taking Xincun Lagoon as an example and referring to the current research situation in related fields at home and abroad, we select appropriate indicators according to local conditions. Considering the interlaced relationship between indicators, it is difficult for the general method of determining indicators, such as analytic hierarchy process, to reflect the relative importance of indicators perfectly. In this paper, the concept of interaction matrix is introduced and the weight values of indicators are calculated. The spatial distribution of the results of each index is quantified by using the Geographic Information System (GIS) method. Then, the multi-criteria decision

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66696679

analysis method is used to perform linear superposition in ArcGIS software. Finally, the spatial distribution map of the suitability of shallow sea cage culture is obtained.

Study region and area

Xincun Lagoon (N18º22'-18º47', E109º45'-110º08') is located in the southeast part of Xincun Town, Lingshui County, Hainan Province, China, as shown in *Fig. 1*. Its East-West width is 5.1 km, its north-south length is 4.5 km, and its area is 24 km^2. It is a medium-sized sand bar-tidal inlet-lake system, and its ebb-flow tidal delta is relatively developed. According to the analysis of remote sensing images, the area of Lagoon decreased by 1.69 km^2 in the 25 years from 1988 to 2013. There are many marine activities around the Lagoon, including use of the sea areas for tourism, town, land aquaculture pond and shallow sea cage culture, among which the pollutants discharged from shallow sea cage culture account for more than 50%. To this end, the local government has formulated the Beach planning of aquaculture waters in Lingshui Li Autonomous County (2018-2030), which sets a ceiling on the area of cage culture, but does not make recommendations on specific suitable areas for aquaculture.

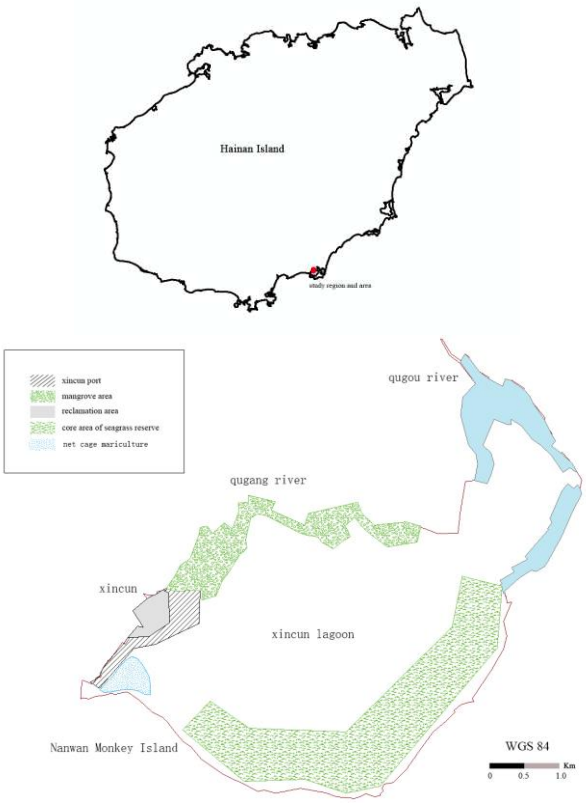

Figure 1. *Map of study region and area*

Methods

Index selection

The rationality of index selection is the basis of determining the rationality of the results of suitability analysis of shallow sea cage culture. In this paper, indicators are chosen according to the following three principles, including (a) reducing the maritime

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66696679

conflicts in other human activities in the region, (b) reducing the pressure on Xincun Lagoon ecosystem caused by aquaculture activities and (c) improving the yield and efficiency of mariculture as much as possible. Specific indicators are explained as follows:

(1) The relations with protected areas. According to the requirements of the Planning of seagrass bed special protection area in New Village port, the Seagrass Bed Reserve is divided into general area and core area. The core area requires prohibition of all human activities, which is a prohibitive index. Other areas of the reserve belong to compatible fisheries and aquaculture, as shown in *Fig. 2*.

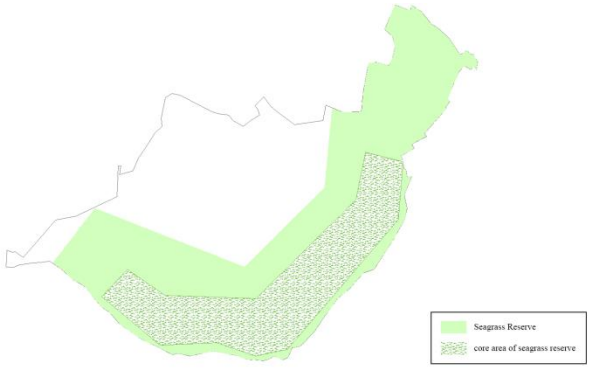

Figure 2. *Scope of Seagrass Bed Reserve*

(2) The water depth condition. The cage culture needs certain water depth conditions. According to the survey, the local cage depth is about 1.5 m. Thus, if the water is too shallow, the cage culture will not work properly.

(3) The hydrodynamic conditions. The self-purification ability of water body is the main factor to ensure that no major environmental problems occur in aquaculture. In this paper, the semi-exchange ability of water body is selected as the hydrodynamic evaluation index. The stronger the semi-exchange ability of water body is, the better the hydrodynamic conditions are, so it is more suitable for aquaculture activities. The semi-exchange ability of water body is shown in *Fig. 3*.

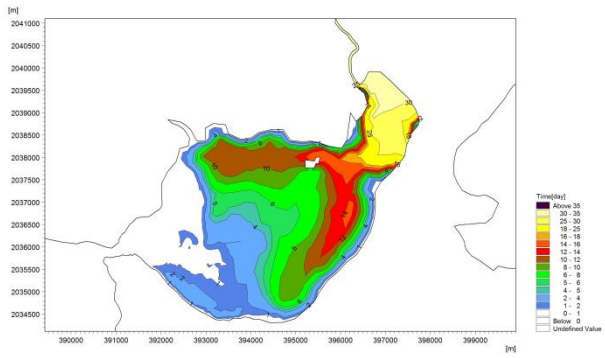

Figure 3. *Semi-exchange time of water body*

(4) Dissolved oxygen content. Considering the phenomenon of fish death caused by hypoxia in the history of Lagoon, dissolved oxygen content was selected as an index to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66696679

determine the suitability of mariculture in this paper. The higher dissolved oxygen content, the more suitable for aquaculture activities.

(5) Water environment quality. The quality of water environment is one of the important factors to decide whether it is suitable for aquaculture. Good water environment can effectively improve the yield of aquaculture. In this paper, eutrophication index is selected to represent the water environment quality. The higher the degree of eutrophication, the worse the water environment quality.

(6) Terrigenous pollution intensity. There are many human activities around the study area, and a large number of pollutants are discharged directly from the land to the sea. Therefore, the direct discharging area should be kept away from as far as possible to avoid the influence of pollutants on aquaculture.

(7) Wind and wave condition. Because of the small size of shallow sea cages and the weak ability to withstand wind and wave, the areas with smaller wind and wave should be selected for aquaculture.

Determination of index weight values

This study used the interaction matrix method to calculate the index weight value. Taking the 3*3 matrix as shown in *Table 1* as an example, all the main factors related to the problem listed on the main diagonal of the square matrix (i. e. A→C), and their state variables possess conceptual attributes. Spaces on the non-diagonal lines of the matrix are assigned a value which can be obtained through the numerical analysis, empirical judgment or experimental research to describe the degree of interaction between the two parameters. The interaction matrix shows asymmetry, such as the effect of A on B can be different from the effect of B on A. Analysis and assignment of influences in a strict clockwise direction after the matrix is established.

Table 1. *Basic principles of rock engineering systems*

A	The effect of A on B	The effect of A on C
The effect of B on A	B	The effect of B on C
The effect of C on A	The effect of C on B	C

When the interaction matrix is built and encoded, the coded values of the matrix rows and columns are added to determine the degree of interaction of each variable in the system, as shown in *Eq.1*. The sum of each row represents the effect of the parameters on the main diagonal of the row on the system, while the sum of each column refers to the effect of the system on the parameters on the main diagonal of the column. The higher the degree of interaction is, the greater the importance of this parameter in the system plays, so the interaction matrix can be used to determine the weight of each relevant parameter in the studied system. The weight of the parameter k_i can be calculated by from *Eq.2* to *Eq.4*:

$$V=\begin{pmatrix} V_{11} & V_{12} & \cdots & V_{1j} & \cdots & V_{1m} \\ V_{21} & V_{22} & \cdots & V_{2j} & \cdots & V_{2m} \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ V_{i1} & V_{i2} & \cdots & V_{ij} & \cdots & V_{im} \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ V_{m1} & V_{m2} & \cdots & V_{mj} & \cdots & V_{mm} \end{pmatrix} \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66696679

$$k_i = \frac{S_R(i)+S_C(i)}{2\sum_{i=1,j=1}^{n} V_{ij}}, (i = 1,2,\cdots,m) \quad \text{(Eq.2)}$$

$$S_R(i) = \sum_{i=1}^{m} V_{ij}, (i = 1,2,\cdots,m) \quad \text{(Eq.3)}$$

$$S_C(i) = \sum_{j=1}^{m} V_{ij}, (i = 1,2,\cdots,m) \quad \text{(Eq.4)}$$

where, in Formula (3) and (4), V_{ij} is the influence degree of parameter i on parameter j; $S_R(i)$ and $S_C(i)$ represent the sum of the elements of each row, and column respectively in the multi-factor interaction matrix. The sum of each row represents the effect of the influence factor in the main diagonal line of the row, and the effect of the factor on the whole system by affecting other influence factors; the sum of each column refers to the effect of the influence factor in the main diagonal line of the column, and the effect of the factor affected by other factors on the entire system.

Weighted stacking

The comprehensive index of suitability evaluation can be calculated by the following weighted model:

$$S = \sum_{i=1}^{n} B_i W_i \quad \text{(Eq.5)}$$

where, S is the comprehensive evaluation index of suitability of net cage mariculture in the shallow sea; B_i refers to the score of the ith evaluation factor (which is dimensionless); W_i denotes the weight of the ith evaluation factor; n refers to the number of factors in the evaluation.

Results

Index space quantization

The spatial distributions of each index on ArcGIS are displayed in *Fig. 4* to *Fig. 10*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66696679

Calculation of indices

According to the previous steps, the interaction matrix of suitability of net cage mariculture in the shallow sea was constructed, as shown in *Table 2*. The degrees of influence between the evaluation indices were divided into 5 levels, represented by the four dimensionless values 0 to 4 respectively: 0 means no effect; 1 indicates weak influence; 2 refers to big influence; 3 represents strong influence; 4 means extremely strong influence.

Table 2. *Values of influence degrees of influence factors and their interactions*

(1)1	0	3	0	3	2	0
3	(2)3	0	0	3	2	0
3	0	(3)2	0	3	3	0
0	2	0	(4)1	1	0	2
2	0	0	0	(5)2	2	0
2	0	0	0	1	(6)3	0
0	3	0	0	2	2	(7)2

The interaction matrix V of the suitability evaluation factors of net cage mariculture in the shallow sea is as follows:

$$V = \begin{pmatrix} 1 & 0 & 3 & 0 & 3 & 2 & 0 \\ 3 & 3 & 0 & 0 & 3 & 2 & 0 \\ 3 & 0 & 2 & 0 & 3 & 3 & 0 \\ 0 & 2 & 0 & 1 & 1 & 0 & 2 \\ 2 & 0 & 0 & 0 & 2 & 2 & 0 \\ 2 & 0 & 0 & 0 & 1 & 3 & 0 \\ 0 & 3 & 0 & 0 & 2 & 2 & 2 \end{pmatrix}$$

Based on *Eq.2* to *Eq.4*, the weights W_i of these seven influence factors can be calculated.

The weight of relationships to the conservation area W_1 was calculated as 0.1724, the hydrodynamic conditions W_2 as 0.1639, the land-based pollution intensity W_3 as 0.1379, the suitability of water depth W_4 as 0.0603, the water environmental quality W_5 as 0.1810, the dissolved oxygen content W_6 as 0.1724, and the status of flows and waves W_7 as 0.1121.

C, the sum of the row values, and E, the sum of the column values, C+E represents the value of interaction strength of each principal factor. The larger the value is, the stronger the importance of the parameter is; C-E indicates the dominance of each principal factor. C-E is greater than 0, indicating that the parameter is dominant, while C-E is less than 0, implying that the parameter is dependent. The detailed relationships are displayed in *Table 3*.

Table 3. *Relationship parameters between C and E*

Relationship of C and E	V_1	V_2	V_3	V_4	V_5	V_6	V_7
C	9	11	11	6	6	6	9
E	11	8	5	1	15	14	4
C+E	20	19	16	7	21	20	13
C-E	-2	3	6	5	-9	-8	5

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66696679

Implementation of weighted stacking on ArcGIS

On the basis of the calculation according to *Eq.5* by using ArcGIS10.0 and the spatial quantitative analysis, the spatial distribution of the suitability of mariculture in the shallow sea on ArcGIS can be obtained (*Fig. 11*). It can be seen that the most suitable area for net cage mariculture in the shallow sea is located at the mouth of the gate, accounting for about 10.00% of the total sea area, while the most unsuitable area for net cage mariculture in the shallow sea stands in the secondary bay, covering approximately 13.04% of the total sea area.

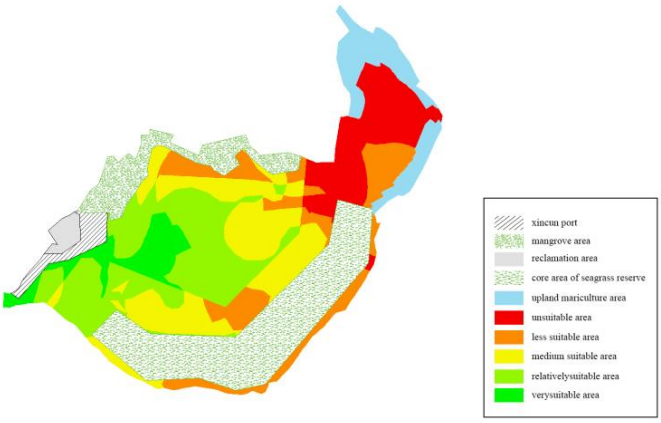

Figure 11. *The spatial distributions of suitability of mariculture in the shallow sea on ArcGIS*

Conclusions

On the above research, it can be determined that the areas suitable for shallow sea net cage mariculture in the Xincun Lagoon are mainly located at Area of 1, 2 and 3 (*Fig. 12*). However, this paper did not take into account factors such as social economy and transportation services in selecting the indicators. Unlike other cage cultures, farmers in the region live in shelters built by cages on the water. Therefore, the site selection should also consider the convenience of transportation to surrounding towns. For the spatial distance, Area 1 demonstrates as the most suitable one, and in fact, it is more conforming with the current farming situation.

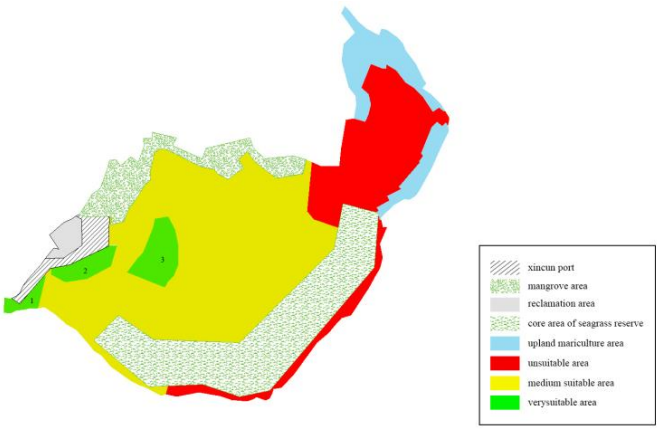

Figure 12. *The simplified distribution of suitable area for mariculture in the shallow sea*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66696679

This paper can clarify the suitable area for net cage mariculture in the shallow sea, but the accumulation of a large number of cages will cause changes in hydrodynamic conditions in the surrounding waters, as well as pollutants. Thus, further research is required to determine the division and layout of the cages to minimize the pressure on the ecosystem in the lagoon.

The interaction matrix can consider the interactions between the factors and calculate the affiliation of the factors. The results show that hydrodynamic conditions, the land-based pollution intensity, the suitability of water depth, and the status of water flows and waves are the dominant parameters, all of which are the driving factors for system changes. Although the conclusions of this study are highly credible, the dynamic changes of the indicators are not taken into account in the calculation process. In the future research work, the changes of the dominating parameters should be focused on and adjusted at any time.

(Received 3rd Feb 2019 ; accepted 29th Mar 2019)

Abstract. Sustainable intensification practice (SIP) facilitates increased and sustained productivity of the limited and existing farmland with less pressure on the environment. Currently, there is a myriad of literature on the effect of SIP on food security. However, unlike previous studies, this study examines the effect of the adoption of multiple sustainable intensification practices on the improvement of food security among smallholder farmers in Ethiopia. Three basic conservation techniques, Agronomic (A), Biological (B) and Physical (P), are analyzed after derivation from 13 implemented soil and water conservation (SWC) practices using principal component analysis (PCA). The result of the multinomial endogenous switching regression (MNESR) shows that SIP adopters have a 55% higher food security, have 51% more access to clean water and sanitation, and consume at least one more dietary food item daily than non SIP adopters. A complete ($A_1B_1P_1$) and combined ($A_0B_1P_1$ and $A_1B_1P_0$) package had the highest food security status as compared to other combination strategies, while single technology users gain the least benefit. Our findings strongly promote the adoption of a complete or combined SIP package in agriculture to leverage the full benefits associated with food security.

Introduction

In African dryland agriculture, food security and livelihood of rural households are highly dependent on crop production and livestock farming, which are sensitive to climate-related impacts leading to deforestation and land degradation (Asfaw and Neka, 2017; Kassie et al., 2013; Nkomoki et al., 2018; Wolka et al., 2018). In Sub-Sahara Africa, those whose livelihood and income depend on the most vulnerable agriculture are adversely affected by climate change (Kim et al., 2018). By 2030, the fraction of population living in poverty is expected to reach 122 million (FAO, 2016). Particularly for Ethiopia, the population is expected to reach 160 million by 2050, which is linked to a sizable increase in agricultural production (Josephson et al., 2014). Increasing productivity will be achieved via extensification (expanding farming area) or by intensification (applying technologies in existing areas) (Anderson and Elisabeth, 2015).

Even though food deficiency and income are linked to farm size, 87% of farming households' in Ethiopia own less than two hectares of cropping land (Anderson and Elisabeth, 2015). Therefore, increasing productivity and securing food demand are prior objectives for adopting new household practice decisions. Rapid population growth and low levels of technology- adopting societies, could contribute to achieving productivity

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

increment at the expense of significant environmental risk through cropland expansion (Kassie et al., 2013). *Figure 1* presents the trade-off between forest share and arable land expansion due to rural population growth.

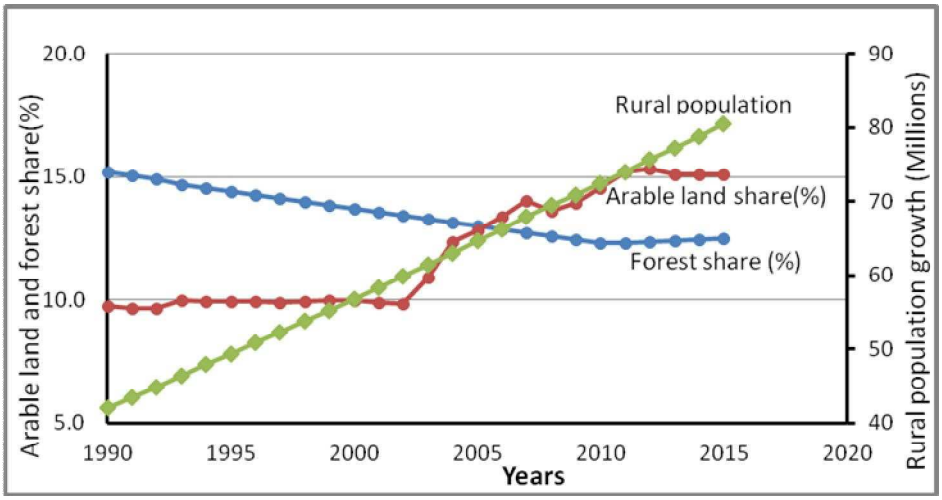

Figure 1. *Rural population growth and land use trend in Ethiopia (1990-2015). (Source: WBdataset, 2018)*

Food security and poverty reduction for subsistence farmer strongly correlate with environmental degradation by exploitation of land, forest, and water resources (Abdul-Rahim et al., 2018; Dejene, 2003). In this context, Ethiopia adopted a Sustainable Intensification Practice (SIP) approach as a new scientific arena for connecting environment and agriculture, which is considered a policy approach for achieving two goals simultaneously (Kassie et al., 2013).

The SIP approach could potentially achieve both economic improvement and environmental protection by maintaining soil fertility and produce higher output in existing cropping areas with less environmental pressure (Kassie et al., 2015a; Kim et al., 2018; Nkomoki et al., 2018). Adopting this strategy improved soil quality and reduced deforestation via climate change mitigation, thereby improving households' nutritional food intake, reducing months of food deficits, as well as food insecurity and poverty (Abdul-Rahim et al., 2018; Kassie et al., 2013, 2015a, b; Nkomoki et al., 2018).

In Ethiopia, farmers adopt different SWC technologies at a given time. Particularly in our chosen study area, more than half of the sampled households (51.04%) used 4-8 practices in a production season. Considering a single technology's effect on food security analysis will lead to a biased estimation. A review of 160 original field studies by Branca et al. (2013) confirms that isolating the impact of a single practice on productivity or food security is intricate. The author explained that a combined SIP package comprised of agronomy, agroforestry, water harvesting, and conservation techniques contributes to increased yield, as well as reduced soil loss and erosion. Similar studies in Ethiopia (e.g., Coulibaly et al., 2017; Asfaw and Neka, 2017; Wolka et al., 2018) showed similar results. More specifically, Amare et al. (2014) found that in northern Ethiopia, farmers increased their yield by 7% and reduced soil loss by 68%, by adopting integrated soil bund and grass strips.

Notwithstanding their benefits, land degradation and soil erosion remain very complex and convoluted problems in Ethiopia. A recent SWC government campaign

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

mainly focused on the participatory community watershed area conservation and to a much lesser extent on individual plot-farm management. Moreover, SIP package combination and structure technical design are not well understood by farmers.

The objectives of this study are twofold: First, to assess factors that influence the SIP choice by smallholder farmers. Second, estimating the effect of SIP adoption and package choice among adopters on households' food security. We found significant food security improvement for households that practiced complete packages.Also, our study showed better performance in nutritional food consumption and food security status in households that adopted combined agro-biological and biophysical packages compared to those that adopted a single package.

Our paper contributes to the existing literature in four aspects. First, most SIP studies focus on the use of a single practice and related adoption constraints (Branca et al., 2013). However, this paper attempts to link the adoption factors and their impact by considering the many SIPs choice strategy, which is important for development agents focusing on SIP adoption strategies. Second, to the best of our knowledge, the related literature in Ethiopia considered the impact of SIP estimation either in the context of general adoption or package choice approach separately. In this study, we analyzed both cases and found a comprehensive and consistent result. Third, we considered three food security measurement indicators at the same instance which helps to address the dimensions of food availability, access, and utilization, resulting in a robust and consistent estimation. Finally, we employed a systematic model combination where Principal Component Analysis (PCA) was used for variable reduction without losing information from data, while the MNESR model was used to avoid endogeneity and self-selection bias.

Materials and methods

Description of the study area

This study was conducted in Benishangul Gumuz National Regional State (BG) in Ethiopia (*Fig. 2*). It is located in the western part of the country and has three administrative provinces and 21 districts. The Blue Nile River divides the region into two main parts, the northern part Metekel province, and southern part Assosa and Kemashi provinces. The region is endowed with water sources such as Beles, Dhidhsa, Dinder and Dabus rivers all of which are a tributary of Abay (Blue Nile) river. From the total estimated area to about 5,069,900 ha of the region, the arable land accounts about 911,877 ha and 24.4% of this land has potential for irrigation (Emana, 2010; Teklemariam et al., 2016); and forest land is estimated to be 3,963,750 ha (WBISPP, 2005).

The three major agro-climatic zones of the region are (i) low land or Kola (about 75% of the region), (ii) Midland or Woynadega (accounts 24%), and (iii) Highland or Dega agro-climatic zone about 1% of the region (Teklemariam et al., 2016). The mean annual rainfall of the region is between 860 and 1275 mm, and the temperature varies with a daily maximum of 20-25 °C in the rainy season and rises to 35-40 °C in the dry season.

According to 2007 CSA (Central Statistics Agency) population census report, the region had a total population of 670,847 with 3% annual growth rate which is higher than the national growth rate of 2.6% per annum. Field crops including maize, sorghum, finger millet, okra, soybean, haricot bean, sesame, and groundnut are majorly produced

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

in seven districts of the study area. The region recently experienced environmental degradation resulting to severe soil erosion, long dry season, erratic rainfall, and loss of soil fertility. Migration and resettlement programmes is the main cause of deforestation and cropland expansion. For example, in Sirba Abay district, between 1987 and 1998, the cultivable land expanded by 100% and between 1998 and 2007, the expansion was tripled (300%). Petteri Vuorinen (2016) in four districts confirmed that 74% of the forest were cleared due to cropland expansion, whereas 11% was done for fuelwood/charcoal as an income source, and 6% attributed for investment purpose. This evidently indicates that agricultural land expansion effect takes a lion-share for environmental degradation that is aimed to increase productivity and smallholders food provision (Petteri Vuorinen, 2016).

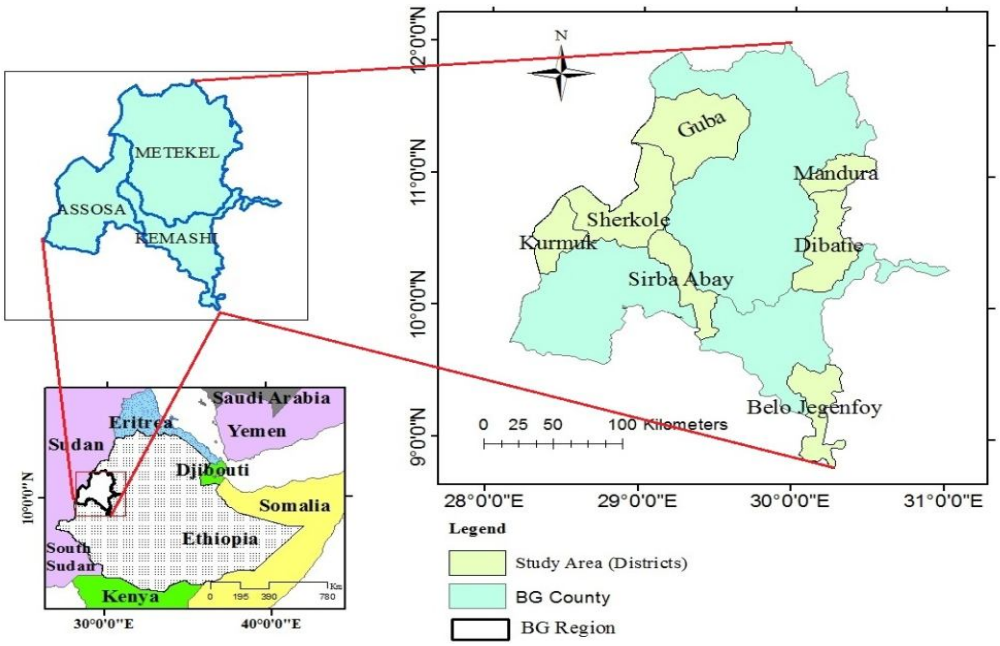

Figure 2. *Study area location*

Data source

We employed a two-stage sampling technique to select respondents, In the first stage, 7 out of 21 districts were purposively selected. The selection was based on regional government, development of stakeholders intervention, and strong SWC campaign. Population size within the seven districts accounted for 27% (179,313) of the total regional population (Emana, 2010). Furthermore, people from neighboring regions also migrated to this area as seasonal and contract farming actors.

In stage two, 30 peasant associations (PAs) from all seven districts were purposively selected. During PA (village) selection, the landscape condition, soil quality, vegetation cover, erosion incidence; SWC practice, farming trends, and experience; and area productivity were taken into consideration. Finally, a simple random sampling technique was employed to select 909 respondents (heads of household) from the PAs (*Table 1*). Trained enumerators interviewed the sampled household heads using a pre-tested and structured questionnaire with supervision of the extension officer.

DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

Prior to conducting the farmer interviews, various key informants and focus group discussions were held on institutional (56 agriculture office experts at a different level), community, and district levels (132 model farmers and community elders). Data on household SIP adoption and food security impact estimation were collected in 2016 using a one-year recall questionnaire. We consider two reference periods of different production seasons: For SIP adoption, the reference period was March 2014 to February 2015, whereas for food security and production, information was gathered from March 2015 to February 2016.

Variable description

Food security measurement

Measuring food (in)security is quite complex, where household behaviors and dimension aspect should be considered. Food security entails multiple aspects, and it is therefore not easy to capture the full range of dimensions relating to food availability, access, and safety of a household or individual from a single measurement (Mabiso et al., 2014). Again, there is no a separate best measurement metric; and using multiple indicators is recommended by Maxwell et al. (2014) and Mabiso et al. (2014).

In this paper, we estimated household food security status using three different indicators as described below. These multiple indicators provide robust estimation for the evaluation's consistency and comparability purposes. *Table 2* presents the definition and summary statistics for all variables.

Dependent variables

1. Household dietary diversity score (HDDS)

Household dietary diversity (HDD) is used to compute a household's access to nutritional food and energy intake within 24-hours consumption recall period (Ecker, 2018; Maxwell et al., 2014; McDonald et al., 2015; Moroda et al., 2018; Pérez-Escamilla et al., 2017). The number of consumable food groups range from 0 to 12 point scale. In this study, they include cereals; and pulse; vegetable with tuber; root and tubers; leafy vegetable; fruits, egg; meat, poultry; fish; milk and milk products; honey and sugar; and oil and condiments. All the food groups have equal value of one, and the total score value is calculated as a whole food list consumed by the family during the last 24 h.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

2. Self-assessed measures of food security (SAFS)

Self-assessment of a household on their food security status examines the change in food availability (shortage or surplus) during the past 12 months (January to December 2016). SAFS used to measure the household's access to enough food. Since SAFS estimation is subjective and constructed from a single question, one might expect this indicator to be less reliable. However, Shiferaw et al. (2014) and Maxwell et al. (2014) from Ethiopia applied it as an indicator to estimate food security. The response was recorded as 1 if the household had no food shortage throughout the year and, zero otherwise.

3. Access to water availability, sanitation, and hygiene (WASH)

The food security outcome is not only determined by food-related constraints of a household, but also by non-food causes that affect its status. WASH is used to estimate the food utilization dimension of food security as an additional parameter. Pinstrup-Andersen (2009) and Moroda et al. (2018) suggested a consideration of the non-food factors like access to clean water and sanitation factors. The households' self-response is recorded as a dummy variable 1 if HH had access to WASH, and 0 otherwise.

Key independent variables

Sustainable intensification practice (SIP) adoption and package choice

To maximize productivity through improving and conserving soil and water resource, farmers are more likely to practice multiple SWC techniques (Kassie et al., 2013). Thirteen SWC practices were reduced and categorized into three main groups Agronomic (A), Biological (B) and Physical (P) conservation practices. We define SIP adoption as a dummy, where 1 denotes a household that practiced at least one of the three categories, and 0 otherwise.

On the other hand, three SIP categories generate six probability combinations *(Table 5)*. The first SIP choice was adopting a complete SIP-$A_1B_1P_1$ (Agronomic-Biological-Physical) package. However, not all farmers practice full SWC techniques, except for innovative and model farmers who may implement many practices at once in a single production season. Adopting a complete package has short-term benefits such as augmented productivity, income, and fodder (Amare et al., 2014; Wolka et al., 2018). The second SIP choice was the $A_1B_1P_0$ (Agronomic-Biological) package that required less technical skill and knowledge. For example, multipurpose trees and grass strips integrated with agronomic practice aided in nutrient recycling for crops, soil fertility improvement, and water-holding capacity enhancement. The third SIP choice considered was the $A_0B_1P_1$ (biophysical) package, which was adopted mainly to support physical structures with grass strips.

Farmers are less likely to practice physical structure alone due to area share from cropping and the higher frequency of repairs. Amare et al. (2014) confirm that the combined bio-physical technique has a substantial effect on runoff reduction and soil loss compared to other treatments.

The fourth SIP choice was the $A_1B_0P_1$ (Agronomic-Physical) combination. Farmers built physical structures when the plot area was gentle or sloppy to minimize the run-off velocity and conserve soil and water. The fifth SIP single package choice was the $A_0B_1P_0$ (Biological) conservation method, which has a dual benefit of conserving and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

recycling soil nutrients and generating income from plants (fodder, fuelwood, and wood product). Our final consideration was the agronomic practice choice $A_1B_0P_0$. Usually, it is assumed that farmers practice at least one measure of the soil fertility improvement techniques as a coping strategy to reduce production risk.

Table 2. *Variable definition and descriptive statistics*

Variables	Description	Mean	Std dev
Outcome variable			
HDD	Household dietary diversity score	5.81	2.25
Food secure (SAFS)	Does HH have enough food in the last year? (yes = 1)	0.53	0.50
Water & sanit access	Household water and sanitation accessibility (yes = 1)	0.47	0.50
Intervention variable			
SIPs adoption (dummy)	Head of HH who adopt sustainable intensification practice (1 = adopter)	0.84	0.37
A0B0P0	Head of HH who do not adopt any SIP practice	0.16	
A0B0P1	Head of HH who adopts physical structure package	0.01	
A0B1P1	Head of HH who adopts a biophysical package	0.12	
A1B1P1	Head of HH who adopts all SIPs package	0.37	
A1B1P0	Head of HH who adopts an agro-biological package	0.15	
A1B0P0	Head of HH who adopts the agronomic practice	0.06	
A0B1P0	Head of HH who adopts the biological practice	0.04	
A1B0P1	Head of HH who adopts the agro-physical practice	0.11	
Explanatory variable			
HH education	Household head have formal education (yes = 1)	0.72	
Gender	Sex of the head of a household (1 = male)	0.85	
Family size (AEU)	Family size in adult equivalent unit (AEU)	6.26	2.63
Cropping area	Household owned Farm size (ha)	1.89	0.91
Livestock asset (TLU)	livestock asset in tropical livestock unit (TLU)	2.16	2.90
Crop income	Annual household crop income in ETB	16069.11	16538.38
Off-farm participate	household participated in off-farm income activity	0.56	
Extension access	Household have access to extension service	0.72	0.45
Market access	Household have access to input & output market	0.65	0.48
Main road access	household who have road access (yes = 1)	0.70	0.46
Access to credit	1 = if a household has access to credit service	0.44	
Group membership	1 = if the household is a member of a rural social network	0.61	0.49
HH trained on SWC	1 = if HH trained on soil and water conservation	0.64	
HH trained on SNRM	1 = if HH trained on sustainable natural resource management	0.60	
Total		909	

Table 4 presents the identified SIP measures and their grouping categories. We consider agronomic package adoption (A_1), if a household head practices at least two techniques from an agronomic; for Biological (B_1) at least one from the biological method; and if HH adopts at least one from four structural measures, we assign as physical practice adopter (P_1). Finally, the causal effect of SIP adoption on food security

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

was estimated in overall (SIP adoption dummy) and unconditional probabilities (six possible combinations) method.

The choice of the explanatory variable was based on related smallholders SIP adoption decision and economic welfare effect study literature and presented in *Table 2* (Amare et al., 2014; Kassie et al., 2013, 2015a, b; Kpadonou et al., 2017; Nkomoki et al., 2018; Wekesa et al., 2018).

Econometrics approach

In many developing countries including Ethiopia, input and output market imperfection and high seasonality are common constraints for smallholder farmers. Also, high fluctuation and volatility nature of food and agricultural input price strongly correlates to the availability of food. Therefore, the adoption intensity and willingness to invest for newly introduced practice is dependent on net benefit gained from the process. The farm household adjusts adoption behavior for readily available technologies by looking for the opportunity. If the utility from a new method is higher than the conventional system, a farmer will decide to adopt. Farmers want to maximize their income by choosing the optimal combination of SIP package.

Unlike experimental studies, the selection of adoption and non-adoption in cross-sectional survey research was not randomized, and observable and unobservable characteristics profoundly influence the decisions. It implies that farmers in the research area were not equally exposed to the new technology. In causal effect analysis, both controlled and treatment groups must have similar behaviors to avoid a biased estimation. As a result, we employed a new two-stage selection-bias correction approach of the multinomial endogenous switching regression (MNLESR) (Bourguignon et al., 2007) to determine the real effects of farmers choice of SIP package and the outcome equation. Use of MNLESR model has a triple advantages. First, it helps to address biasness that arises from the unobservable variable. Second, the model allows getting consistent and efficient estimates of the adoption process with reasonable correction for the outcome equation. Third, it assists in computing the impacts of both separate and combined practice simultaneously (Abdulai and Huffman, 2014; Coulibaly et al., 2017; Kassie et al., 2015b; Wekesa et al., 2018).

Multinomial adoption selection model (MNL)

In the first stage, we used a multinomial logit model (MLM) to examine the factors that affect a farmers SIP packages choice. Farmers have six mutually exclusive (*P*) alternative SIP strategies and will adapt by comparing its effect to maximize their utility. Consider I_{ij}^{*} is a latent variable that represents the jth farmers behavior in practicing SIP combinations $i (i = 1, \ldots 6)$ and expressed as follows (*Eq. 1*):

$$I_{ij}^{*} = X_{ij}\beta_j + \varepsilon_{ij} \quad \text{(Eq.1)}$$

where X_{ij} captures vector observed exogenous variable *(*household characteristics, farm, and asset characteristics, institutional features, and knowledge and extension access variable), while ε_{ij} are the error term from an observed characteristics.

From available mutually exclusive SIP *p* combinations of packages, a farmer will choose ith SIPs combination if:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

$$I = \begin{cases} 1 \text{ if } I_{ij}^{*} > \max_{p \neq 1} \left(I_{pj}^{*}\right) or\ \omega_{1j} < 0 \\ \cdot \\ \cdot \\ \cdot \\ i \text{ if } I_{ij}^{*} > \max_{p \neq i} \left(I_{pj}^{*}\right) or\ \omega_{ij} < 0 \end{cases} \quad \text{for all } p \neq i. \qquad \text{(Eq.2)}$$

According to *Equation 2,* the jth will adopt ith package to maximize utility, if

$$\max_{p \neq i} \left(I_{pj}^{*} - I_{ij}^{*}\right) < 0.$$

Since we are assuming ε_{ij} as the error term from an observed characteristics and to be identically Gumbel distributed and independent, *Equation 2* leads to the multinomial logit model of the probability that farmers will choose combinations (pij) as shown in *Equation 3:*

$$pij = pr\left(\omega_{ij} < 0 X_{ij}\right) = \frac{\exp\left(X_{ij}\,\beta_j\right)}{\sum_{p=1}^{i} \exp\left(X_{ij}\,\beta_p\right)} \qquad \text{(Eq.3)}$$

Multinomial endogenous switching regression estimation

Following similar impact studies of Abdulai and Huffman (2014), Kassie et al. (2015b), Coulibaly et al. (2017) and Wekesa et al. (2018), we applied a multinomial endogenous switching regression model which is developed by Lee (1982) to estimate the SIP adoption causal effect.

An endogenous switching regression model of a selection bias correction framework used to estimate the farmers SIP adoption impact of each strategy on household food security through multiple indicators. The $A_0B_0P_0$ SIPs package was taken as the base category (non-responsive) and denoted as $i = 1$ and the adopter practiced at least one from remaining SIP ($i = 2,3,4,5,6$) combination package. The food security status implication for each regime is described as *Equation 4:*

$$\begin{cases} \text{Regime 1: } \Omega_{i1} = {}_{i}\alpha_1 + \upsilon_{i1} \quad if\ i = 1 \\ \cdot \\ \cdot \\ \cdot \\ \text{Regime } i\text{: } \Omega_{ij} = {}_{i}\alpha_j + \upsilon_{ij} \quad if\ i = j \end{cases} \qquad (1 = 2,3,4,5,6) \qquad \text{(Eq.4)}$$

where Ω_{ij} denoted the jth farmers food security status in regime i combination, ${}_{i}$ is for the set of exogenous variable *(*household characteristics, farm, and asset characteristics, institutional features, and knowledge and extension access variable) and the error term denoted by υ_{ij} that capture the uncertainty and distributed with $E\left(\upsilon_{ij}\right) = 0$ and $var\left(\upsilon_{ij}\right) = \sigma_j^2$. If the error term υ_{ij} and ε_{ij} are not independent a consistent estimation of α_j requires to avoid biased and the inclusion of the selection correction term of alternative choice in *Equation 4*. Then based on Bourguignon et al. (2007) suggestion we can estimate υ_{ij} and ε_{ij} consistently with *Equation 4* by MESR model developed by Lee (1982) and specified as in *Equation 5:*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

$$\begin{cases} \text{Regime 1: } \Omega_{i1} = {}_i\alpha_1 + \sigma_{11} + e_{i1} & if\ i = 1 \\ \vdots \\ \text{Regime } i\text{: } \Omega_{ij} = {}_i\alpha_j + \sigma_{jj} + e_{ij} & if\ i = j, \end{cases} \quad \text{(Eq.5)}$$

where e_{ij} is the error term and σ_j is also the covariance between ε's and v's, while $_j$ is the inverse Mills ratio from the estimated probabilities.

Following (Di Falco et al., 2011), ESR can be used to examine the average treatment effect on the treated (ATT) and by comparing the expected outcome of the food security status of adopters with and without adoption of SIP combination packages in the actual and counterfactual scenario presented and defined in *Equation 6:*

$$ATT = E(\Omega_{ij}|i = j) - E(\Omega_{i1}|i = j) = {}_i(\alpha_j - \alpha_1) + {}_i(\sigma_j - \sigma_1) \quad \text{(Eq.6)}$$

Results and discussion

Descriptive statistics

A household intensity of SIP adoption estimation

Under dry land economy, as in the case of Ethiopia, farmers adopt multiple SWC technologies aimed at increasing productivity and reducing the risk of food deficiency (Kpadonou et al., 2017). *Table 3* presents the households' SIP adoption intensity, which ranges from zero to eleven SWC measures. Households are selective, and have different SIP adoption intensities (Wolka et al., 2018). While some farmers practice up to 11 SWC techniques, 15.62% (142 HHs) do not implement any of the 13 practices. However, from the sampled heads of HHs, 84.38% adopted at least one sustainable intensification technology in their cropping area.

Table 3. *Heads of households adoption intensity on SIP package*

Number of practice	Frequency	Adopters (%)	Cumulative
Heads of HHs who did not practice any SIP (0)	142	15.62	15.62
Heads of HHs who practice 1	29	3.19	18.81
2	48	5.28	24.09
3	128	14.08	38.17
4	119	13.09	51.27
5	125	13.75	65.02
6	91	10.01	75.03

9	51	5.61	94.83
10	32	3.52	98.35
11	15	1.65	100.00
12	0.00	0.00	100.00
13	0.00	0.00	100.00
Total	909	100.00	

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

More than half of the sampled households (51.04%) used 4-8 practices, 22.55% used 1-3 practices and a few (10.78%) used >8 SIP technologies. The adoption intensity descriptive results showed that in the study area, most households experienced at least one practice from each SWC category (Agronomic, Biological and Physical measures), and entirely adopted more than three technologies.

SIP variable reduction and grouping strategy

Table 4 presents the reduced form of linear combination loadings estimation results from multiple on-farm level SIP practices. Following suggestions by Goswami et al. (2012) and Chatterjee et al. (2015), the orthogonal rotation was executed on principal components, and four principal components with eigenvalue > 1 were considered. From the overall data variability, 61.03% is explained by four components. The first component (hereafter called agronomic practice) had a positive effect on loadings and explained 20.11% of the variance from total PC variability.

Principal components 2-4 accounted for 15.6, 14.04, and 11.29% of the loadings, respectively. The second principal component group is hereafter named as biological practice. In this study, the third most determinant component group was associated with a farmers participation in physical structure practices. The fourth principal component included one physical element (employing check dum) and an agronomic element (strip mulching) which was inconsistent with SWC groupings (Abdul-Rahim et al., 2018). We, therefore, excluded component 4 to harmonize SIP groupings. Whether component 4 affects the impact analysis requires further investigation. Therefore, for this study, three component loading variables had more importance in explaining SIP adoption and variance of effect analysis. According to Kaiser (1958), an average communality above 0.60 is the minimum criteria for PCA analysis, which was met in our study 61.03%. This shows that our PCA estimation is a good fit, with good data quality.

Table 4. *Rotated components loading (greater than 0.3)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

A household probability for SIP choice description

After considering varimax rotation from high factor loadings, household choice to different SIP packages (combinations) was estimated. *Table 5* presents the different possible combination of packages chosen by households referring to non-adopters $A_0B_0P_0$ (15.62%) as a base. The study discussed six out of eight SIP probabilities.

Table 5. *Alternative sustainable intensification practices (SIPs) package probabilities*

Choice (ith)	Combination	A = agronomic		B = biological		P = physical		Frequency	Percentage
		A_1	A_0	B_1	B_0	P_1	P_0		
1	$A_0B_0P_0$		✓		✓		✓	142	15.62
2	$A_0B_0P_1$		✓		✓	✓		6	0.70
3	$A_0B_1P_1$		✓	✓		✓		111	12.20
4	$A_1B_1P_1$	✓		✓		✓		336	36.96
5	$A_1B_1P_0$	✓		✓			✓	132	14.52
6	$A_1B_0P_0$	✓			✓		✓	50	5.50
7	$A_0B_1P_0$		✓	✓			✓	32	3.50
8	$A_1B_0P_1$	✓			✓	✓		100	11.00
Total								909	100

A_1 = agronomic users, A_0 = non-users of agronomic and others have a similar interpretation

The farmer had a chance to choose from the set of six mutually exclusive combinations during a production season. Approximately 14.52% of the farmers applied Agro-Biological methods ($A_1B_1P_0$), while 12.2% applied the biophysical conservation package ($A_0B_1P_1$).

Other farmers used packages $A_1B_0P_1$, $A_1B_0P_0$, and $A_0B_1P_0$. Overall the majority of the farmers (37%) applied a complete SIP package ($A_1B_1P_1$). This observation concurs with other studies such as (Kipkoech Anderson et al., 2015; Wekesa et al., 2018).

Empirical result

Determinants of SIP adoption choices

The objective of this study dwelt on the SIP adoption constraints and their impact on households' food security. In the first stage, we used the Multinomial logit (MNL) model to describe SIP packages adoption decision and possible constraints by considering non SIP users ($A_0B_0P_0$) as the base. The result of this estimation is essential for identifying factors that affect SIP package combination adoption and suggesting possible adoption constraints to development partners and policymakers. A unit change in an explanatory variable and its variation on the probability of particular choices was estimated by the MNL marginal effect model and is reported in *Table 6*. The Wald test estimation result of the regression coefficient was jointly equal to zero (Wald ch^2 (91) = 918.10; p = 0.000). Farmers who only adopted the physical structure were not discussed due to the mundane representation of this group. The marginal effect estimation result confirmed that the explanatory variable coefficients varied substantially across the alternative packages.

Among the household characteristics, male household heads positively associated with agronomic ($A_1B_0P_0$) and biological ($A_0B_1P_0$), but negatively associated with labor-intensive Agro-Physical ($A_1B_0P_1$) packages. The results were in agreement with data

DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

from Asfaw and Neka (2017) and Tiwari et al. (2008). However, having the formal education of a household head reduced the probability of adopting agronomic ($A_1B_0P_0$) practice by 4.6%. This could be due to the fact that education is necessary for adopting the knowledge-intensive physical structure compared to the agronomic practice. Kpadonou et al. (2017) also observed a negative correlation between formal education and mulching and sustainable agricultural practices (SAP) adoption.

An increase in a household's plot size by one unit, increased the likelihood of practicing the $A_1B_0P_1$ package by 4%. Large farm owners were closer to perceiving soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

erosion problems and thus highly adopt physical conservation measures (Anim, 1999; Fikru, 2009; Mekuriaw et al., 2018; Moges and Taye, 2017; Nkomoki et al., 2018; Wekesa et al., 2018). Crop income is another important variable (a proxy of household food security status) for SIP adoption. A unit change in the amount of income is associated with a higher likelihood of adopting complete SIP packages ($A_1B_1P_1$) by 43.42%, at 1% significance level. However, it was also negatively associated with other combinations. The change in productivity due to SWC practices, especially from the physical structure, has a long-term effect. Wolka et al. (2018) confirmed that short-term low benefit from conservation practices demotivates farmers' interest in adopting the introduced SWC measures. Household off-farm participation was positively associated with ($A_0B_1P_1$), while negatively associated with the Agronomic-Physical combination ($A_1B_0P_1$). Since building physical structures is a labor-intensive practice, a household that frequently engages in off-farm employment wants to combine physical structures with others like a tree and supportive grass structures.

Information has played a vital role in driving farmers participation in the plot-level sustainable intensification decision process. The more a farmer has contact with agricultural extension workers, the higher the probability of adopting the $A_1B_1P_0$. Moreover, farmers' access to SWC, and SNRM related training showed positive association, and statistically significant with complete package ($A_1B_1P_1$) and Agro-Physical ($A_1B_0P_1$) choices. In essence, building a physical conservation structure demands technical skill and knowledge-intensive with regard to structure depth, width, and length design (Wolka et al., 2018). Similarly, main road access positively influenced SIP usage by farmers, and increased the probability of applying Agro-Physical measures ($A_1B_0P_1$) by 9.6%.

The rural network farmer members were 7 and 14.6% more likely to adopt $A_1B_1P_0$ and $A_1B_1P_1$ practices, respectively. This estimation result was consistent with a report by Kassie et al. (2013). Similarly, HH heads with access to credit were more likely to practice the Agro-Biological measures ($A_1B_1P_0$), but less likely to apply Bio-Physical ($A_0B_1P_1$) and Agronomic ($A_1B_0P_0$) practices. The farmers preferred to expend borrowed money on other short respond business. Nkomoki et al. (2018) and Kpadonou et al. (2017) concurred with the negative influence of credit on SAP adoption.

Impacts of SIPs adoption on smallholder food security

In this section we used a joint analysis framework of SIP adoption average treatment effect on household food security in two ways. First, we compared the overall adoption effect between adopter and non-adopter groups. Second, we estimated a separate analysis of six SIP package choices' effect on the outcome variable to gain a better understanding of package combination.

Overall SIP adoption impact on food security

Table 7 illustrates the causal effect estimation result of SIP adoption on smallholders' food security. We compared changes in food security status among SIP adopters under the actual case and counterfactual (if not adopt) any SIP technology. ATT and ATU in table represent the average treatment effect on the treated and untreated conditions, respectively. ATE Diff column explains the net effect change on the outcome variable. It is calculated by controlling for the effect of several covariates,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

and the selection bias stemming problem, which comes from unobserved and observed conditions.

All food security indicator results showed that SIP adoption had a positive and significant effect, and adopters highly benefited compared to their counterparts in ranges of 1% significance level. SIP adopters were 55% more food secure, had 51% higher access to clean water and sanitation, and consumed at least one more dietary food item daily compared to non SIP adopters. Particularly, for nutritional dietary food access estimation (HDD), adoption would be advantageous and significant for both adopters and non-adopters, although adopter households would benefit the most. The majority of SIP adopters were better-off and exhibited higher dietary food intake compared to non SIP adopters. Likewise, adopting SIP technology ensured the household food availability (SAFS) throughout the year and improve the utilization of pure water and sanitation (WASH) facilities. Weight change was in agreement with results described by Coulibaly et al. (2017) and Kassie et al. (2015b).

In line with our result, other scholars have independently confirmed the positive effect of SIP adoption on the crop productivity and smallholders food security improvement. Kassie et al. (2015b) observed maize productivity increment following SIP adoption in Malawi, and Wekesa et al. (2018) investigated the positive association of Climate Smart Agriculture (CSA) and food security in Kenya. Similarly, Nkomoki et al. (2018) conducted a study on Sustainable Agricultural Practice (SAP) and food security in Zambia; where as Wolka et al. (2018) and Adgo et al. (2013) demonstrated that SAP and SWC adoption positively contributed to crop productivity and food security improvement for smallholders in Ethiopia.

Table 7. *ATET of SIPs intervention on food security: endogenous switching regression estimation*

Specific SIP package choice average treatment effect on food security

Table 8 presents the treatment effect of food security indicators (HDD, SAFS, and WASH) from each combination of SIP choice under actual and counterfactual cases. A household that practices $A_1B_1P_1$ packages benefits from dietary food consumption and has pure water access under the actual and counterfactual condition. Agro-Biological

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

package $A_1B_1P_0$ users would be better off to adopt, because HDD and SAFS measures had a significant ATT value at 1% significance level. Biophysical ($A_0B_1P_1$) strategies integration also had a significant and positive contribution to food security through HDD and WASH improvements. The households that practiced the agro-physical structure combination ($A_1B_0P_1$) were better off in the non-usage (ATU) scenarios suggesting that the household had other better combination available.

The appropriateness of SIP technologies practiced by a farmer was of profound importance in the context of changes in food security status. Overall, average effect estimation confirmed that a household that practiced $A_1B_1P_0$, $A_1B_1P_1$, and $A_0B_1P_1$ packages substantially improved its food security status compared to its counterparts. In contrast, $A_0B_1P_0$, $A_1B_0P_0$ and $A_1B_0P_1$ package usage had less contribution to reducing food insecurity compared to other strategies, while better than a scenario had they not adopted. The above comparison shows that mutually inclusive multiple SIP adoptions had a substantial impact on food security improvement compared to practicing individual agronomic or physical structure packages (Kpadonou et al., 2017)

Planting multi-purpose trees with physical structure would increase crop productivity through recycling soil nutrients as well as benefit farmers through generating diversified income. The benefits include forage for the animal (Amare et al., 2014), fruits, fuelwood, and immediate income (Mbow et al., 2014). Our findings on combined SIP adoption benefit were in accordance with other findings from Ethiopia reported by Sinore et al. (2018) and Wolka et al. (2018) from the south, Mekuriaw et al. (2018) and Amare et al. (2014) and Asfaw and Neka (2017) from the north.

Conclusion and policy implication

Sustainable agricultural discourse comprises food security and SIP, which focus on increasing productivity and improving environmental protection. In Ethiopia, where frequent drought, poverty, and food shortages occur, environmental degradation represents a severe challenge. Therefore, SIP adoption must be considered as a policy approach, due to the fact that farmers in low-income countries are highly dependent on agriculture to increase farm productivity and reduce food deficiency risks.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_66816700

In this study, we investigated the factors that influence the adoption of SIP and their impact on food security using cross-sectional data from 909 farm households in Ethiopia. The study addresses three dimensions of food security- availability, access, and utilization. Principal component analysis (PCA) was employed first for variable reduction. Afterwards, we applied a two-stage multinomial endogenous switching regression model to obtain consistent and efficient estimates. Our study reveals that SIP adoption is positively correlated with households' food security. Adopting at least one SIPs package had a positive effect on food security improvement compared to not adopting a practice. Ultimately, households that adopt all three packages ($A_1B_1P_1$) are the best in all three food security dimensions. Combining of the physical structure with biological measures ($A_0B_1P_1$), and integrating agronomic with biological measures ($A_1B_1P_0$) proved to be the best strategies besides complete SIP adoption.

Furthermore, the findings reveal that a male-headed household is positively associated with the use of Agro-Biological ($A_1B_1P_0$), than labor-intensive Agro-Physical ($A_1B_0P_1$) package. Again, formal education is required for adopting knowledge-intensive physical structures much more so than for agronomic practices, although large farm size owner households are more likely to practice the Agro-Physical (A1B0P1) package. A proxy crop income variable significantly determined complete package adoption, and a unit change income improved the ($A_1B_1P_1$) adoption by 43.42%. A household off-farm participation increases adoption of the Biophysical ($A_0B_1P_1$) package by 6%. Other information and training related variables such as farmers contact to extension worker, training participation on SWC and SNRM, access to roads and farmers' participation in the rural network are positively associated with biophysical and agro-biological adoption compared to the agro-physical and individual package.

Therefore, our findings strongly indicate that SIP adoption has the potential to reduce food insecurities and poverty among smallholder farmers in fixed cropping areas. Regarding SIP adoption campaign and sensitization program for development partners and government, we recommend the adoption of SIP combinations such as Bio-Physical ($A_0B_1P_1$), and Agro-Biological ($A_1B_1P_0$) for integration as a priority policy approach, in addition to the complete package ($A_1B_1P_1$).

Finally, our study is not without limitations, with time being the major limitation in that we used a single round survey of one-year response, which might affect the quality of our impact analysis. Exclusion of plot-level SIP and agro-ecological information is another limitation. However, the sample size, number of outcome variable used, and models applied for consistency and robustness can minimize these limitation effects. Other follow-up studies are needed to support our findings in other settings, with better long-period data and methodologies to validate the analysis.

Abstract. Finding locations suitable for disposal of solid waste is one of the fundamental challenges facing municipal cities and environmental stability. The present study aims to identify the most suitable solid waste disposal site using Geographic Information System (GIS), remote sensing, and the multi criteria decision-making (MCDM) technique. In addition, the study compares the proposed method for suitability with the traditional analytic hierarchy process (AHP) approach. A new validation approach was applied to evaluate the accuracy of the AHP and Fuzzy logic methods based on the selected solid waste locations. Remote sensing data (ASTER GDEM) and field/reference maps were used to derive 12 conditioning factors required to produce a suitable location for solid waste disposal. The result shows that the accuracy of AHP, based on the consistency index (CI), is acceptable (greater than 0.1). However, Fuzzy logic was shown to be more accurate than AHP. The total surface areas of suitable locations based on AHP and Fuzzy models are 4.4 km² and 13.35 km², respectively. This study showed that AHP, Fuzzy logic and GIS can be integrated for waste management decision issues related to site selection to reduce negative effects on the environment and inhabitants.
Keywords: *waste management, landfill site selection, remote sensing, multi-criteria decision analysis*

Introduction

Selection of landfill locations for solid waste (SW) is determined by waste management operations based on multiple factors, including the geographic formation of a region. The decision for this selection is vested in governmental authorities (Hanine et al., 2016). Location selection for solid waste landfills is crucial for every region due to the cost implications, difficulty of reversal, and long-term commitment required (Gorsevski et al., 2012; Liu et al., 2014). Finding suitable location for landfills is also very challenging due to various factors, such as increasing waste quantities, population growth, environmental and public health risk factors, and decreasing land availability for waste disposal (Srivastava and Nema, 2012). Therefore, geographic information should not be the only criteria for site selection, however, flexibility to accommodate future changes should also be considered in regional policies. In determining solid waste disposal landfill sites, environmentally friendly and financially sound

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67016722

selection is a challenge. Selecting a suitable landfill location involves a considerable array of points, criteria, and verification of a given set of limitations to ultimately provide an optimal solution.

The analytic hierarchy process (AHP) method is one of the most commonly used methods for multi-criteria decision-making (MCDM) (Beskese et al., 2015; Moeinaddini et al., 2010). It is capable of solving complex decision-making problems across various fields (Saaty et al., 2000; Uyan, 2013; Tavares et al., 2011). It is also used to determine the consistency of weightings for criteria by constructing a matrix for pairwise comparisons. This combination provides an appropriate language to manage imprecision criteria and integrate qualitative analysis with quantitative factors.

Even though many researches have proposed the use of Fuzzy multi-criteria decision-making methods, very few have applied the combined use of these methods for the selection of suitable landfill location. Torabi-Kaveh et al. (2016) proposed a combination of Geographic Information System (GIS) with a Fuzzy analytical hierarchy process (FAHP) to determine suitable locations for landfill site in Iranshahr, Iran. Chabuk et al. (2017) combined GIS analysis and MCDM for selecting landfill locations in Al-Hashimiyah Qadhaa, Babylon, Iraq. Foroughian and Eslami (2015) presented a study using GIS and AHP indicators for identification of solid waste disposal landfill sites in the city of Susa. Various techniques have been utilized for selecting landfill locations (Gbanie et al., 2013; Khorram et al., 2015; El Baba et al., 2015; Rathore et al., 2016). These authors determined that a combined evaluation using MCDM methods in landfill location selection is imperative. This is due to the fact that relative advantages of several methods depend on the characteristics of the problem domain.

The present study aims to determine a suitable disposal site using Fuzzy logic approach and justify the approach by comparing with traditional AHP approach, which is used for determination of suitable waste disposal sites in Nasiriyah, Iraq. Currently, there is only one available landfill site in Nasiriyah and it does not meet the relevant scientific and environmental standards. The main objective of this paper is to propose the best method for identification of solid waste disposal sites that is suitable for Nasiriyah, Iraq, and fulfills environmental and scientific criteria.

Materials and methods

The map layers were prepared using GIS and cover the most important 12 criteria in the study area. The landfill site selection model is illustrated in *Figure 1*. The raster maps of selected criteria were prepared and the final map of landfill siting was produced in the GIS software. Each raster map for the selected criteria was divided into categories, with each category is given appropriate weight. The final map of landfill siting was determined using GIS single output map algebra. The methodology and framework adopted in this study is presented in *Figure 1*.

Study area

This research was conducted in Nasiriyah, Iraq. The Governorate of Thiqar is located to the south of Iraq at the intersection of longitude 31° 01' E to 31° 08' E and latitude 46° 08' N to 46° 18' N. The city of Nasiriyah is the administrative center of the governorate and is 380 km to the south of Baghdad and 214 km to the north of Basra City. The total area is 12,900 km^2, equivalent to 5,160,000 acres. The desert land area covers 6.7% of the governorate and has a population of about 1.99 million. This population is expected to grow significantly over the next decade as a result of significant economic and security improvements. It is also home

DOI: http://dx.doi.org/10.15666/aeer/1703_67016722

to the largest marshlands of Iraq, with an area of 1,048,600 acres, which is 3.1% of the total area of Iraq. *Figure 2* shows the map of the area.

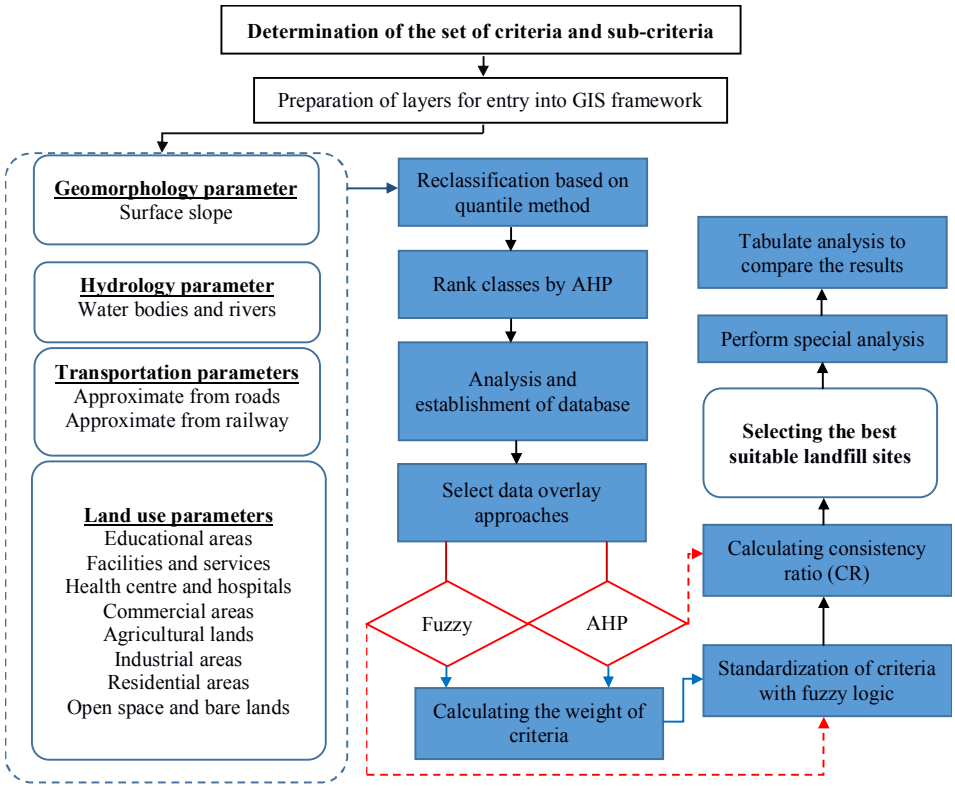

Figure 1. *Conceptual framework of the present study*

Suitability criteria

In this study, 12 criteria were derived from 4 main criteria to determine suitable areas for solid waste disposal sites; these criteria were slope, distance from bodies of water, distance from roads, distance from railways, distance from open space, distance from agricultural lands, distance from health centers and hospitals, distance from residential areas, distance from commercial areas, distance from industrial areas, distance from facilities, and distance from educational areas, as shown in *Table A1* in the *Appendix* and *Figure 3*.

Analytic hierarchy process

Due to its simplicity and robustness in finding weights and combining heterogeneous data, AHP has been applied for MCDM, conflict management, total quality management, suitability analysis, resource allocation, design, and engineering (Jiang and Eastman, 2000; Vaidya and Kumar, 2006; Gorsevski et al., 2006; Şener et al., 2010; Vasiljević et al., 2012). In addition, it has been applied in many practical applications across fields, including site selection (Abdullahi et al., 2014). The various factors considered are not of equal importance in the determination of a potential solid waste site, therefore, the importance of each parameter was identified. In terms of the suitability of a solid waste site, hydrological formation has more importance in weight than distance from railways. Therefore, a weighted linear combination (WLC) was used in this study, in line with Drobne and Lisec (2009) and Kritikos and Davies (2011). It can be considered a hybrid of qualitative and quantitative techniques (Ayalew et al., 2004).

Determination of weights

The MCDM module was used for the weight-selecting criteria (Drobne and Lisec, 2009). A pairwise comparison referred to as the analytic hierarchy process developed by Saaty (1980) was used in this study. This method includes the comparison of each factor against every other factor in pairs (Chang et al., 1996). The weights of criteria in Saaty's technique were computed by applying the main eigenvector of the square reciprocal matrix of the pairwise comparisons between the two factors (Drobne and Lisec, 2009). The pairwise comparison evaluates the two criteria against each other to determine the most important criteria for a given objective.

Estimating consistency of pairwise comparisons

The accuracy of pairwise comparisons was evaluated by calculating the consistency ratio (CR), which is the ratio of the consistency index (CI) and the randomness index (RI). CR was used to estimate the relative weightings of all criteria on a consistency ratio in which values under 10% are considered acceptable. Otherwise, the consistency ratio allows for reevaluation of comparisons. *Table A2* shows the RI developed by Saaty et al. (1977), based on the order of the matrix according to the number of criteria. *Equations 1* and *2* show the consistency ratio and consistency index, respectively.

$$CR = \frac{CI}{RI} \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67016722

CI is calculated using *Equation 2:*

$$CI = \frac{\lambda max - n}{n - 1} \quad \text{(Eq.2)}$$

where: λmax = (Weight1*S1 + Weight2*S2 + Weight3*S3+……) and n = number of criteria.

Application of the fuzzy logic model

In a Fuzzy approach, suitability of land is mapped by pixels of causal factor layers. Pixel values are numeric and range from 0 to 1, from not suitable to very suitable. Pixel values must be within the range of 0 to 1, although there is no practical constraint on the choice of the values. Values can be chosen to reflect the degree of membership of a set based on subjective judgment (Amato et al., 2018) or can be derived by various functions representing reality (Eastman et al., 2003). In this study, linear functions were used to represent the reality function. Fuzzy logic is preferred for land suitability evaluation due to its ability to estimate land use suitability on a continuous scale, which helps to cope with vagueness and uncertainty (Elaalem et al., 2012). Site suitability application using Fuzzy logic comprises three steps, as shown below:

Step 1: Normalization or standardization of land characteristics using fuzzy set models

Fuzzy logic helps the user to determine the likelihood that a site is suitable or unsuitable. This step assigns values from 0 to 1, with 0 being not likely or unsuitable and 1 being most likely or suitable (Elaalem et al., 2012). Thus, the higher Fuzzy value implies the ideal of the site. When assigning Fuzzy values, four types of membership need to be understood to choose the best fits of the analysis criteria. There are four types of membership function in Fuzzy systems: linear, small, large and Gaussian. In this study, the linear membership function was used to normalize the parameters, due to its dependence on input parameters. If the input parameters seem chaotic, similar to a time series, the Gaussian type of membership function would be suggested, otherwise, the linear type is recommended (Qiu et al., 2014). High Fuzzy membership is assigned to large or small values, and Fuzzy membership decreases at a constant rate. A triangular membership function is specified by three parameters {a, b, c} as shown in *Equation 3* (Önüt and Soner, 2008):

$$\text{Triangulation}(x; a, b, c) = \begin{cases} 0, & x \leq a \\ \dfrac{(x-a)}{(b-a)}, & a \leq x \leq b \\ \dfrac{(c-x)}{(c-b)}, & b \leq x \leq c \\ 0, & c \leq x \end{cases} \quad \text{(Eq.3)}$$

Step 2: Generation of the criteria map layers

Fuzzy logic offers an alternative scaling approach, using linguistic variables to represent quantitative and qualitative criteria (Sreedevi et al., 2016). For quantitative criteria, such as return on resources, representation by a linguistic variable requires the definition of term sets, such as “very low,” “low,” “medium,” “high,” and “very high”. In this study, linear membership function was used to normalize the parameters because it depends on input parameters. The linear membership function is suggested if the input parameter is not chaotic (Elaalem et al., 2012). This step assigns values from 0 to 1, with 0 being not likely or unsuitable and 1 being most likely or suitable. The range between 0 and 1 for membership function corresponds to the intensity of importance of each criterion, which is obtained from the literature and experts’ opinions.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67016722

Step 3: Generation of the overall land suitability map layers

Once the appropriate Fuzzy membership value for data criteria is assigned, several reclassified surfaces showing values from 0 to 1 are generated (Klir and Yuan, 1995), and subsequently, the Fuzzy logic model is applied. This step is similar to weighted site selection, which is a site selection method that allows users to rank raster cells and assign a relative importance value to each layer so that different reclassified surfaces can be compared to each other. In order to complete this step, one of several Fuzzy overlay types must be chosen. In this study, the "AND" Fuzzy overlay type was used due to its ability to determine the best values in finding locations that meet all criteria (Qiu et al., 2014).

Results and discussion

Classification of criteria

Each criterion was classified into 10 classes based on the quantile model, except for slope, which was classified into six classes using GIS software. The results showed that variation in each class affects the rank of the class. In some criteria, values were close to the target and thus achieved a higher rank. For some other criteria, values far from the target were considered an advantage and given high weight. For instance, low-distance classes of the open space criteria are more suitable for waste landfill, while far-distance classes in education are more suitable for solid waste landfill allocation. Some criteria prioritize the middle classes; for example, landfill sites should be located neither too close nor too far from residential areas.

Figure 4 illustrates the weight variation in slope, distance from bodies of water, distance from roads, distance from railways, distance from open space, distance from agricultural lands, distance from health centers and hospitals, distance from residential areas, distance from commercial areas, distance from industrial areas, distance from facilities, and distance from educational areas. An indirect linear relationship between the average of each class and its ranking was found for slope indicates that flat areas are weighted higher than steep fields for landfill site selection.

A direct linear relationship was obtained for other criteria. The farther the distance from rivers, the higher the rank for landfill suitability, as shown in *Figure 4*. Greater distance from hospitals or health centers, roads, railways, agricultural lands, public facilities, educational areas, and commercial centers equates to a higher rank and suitability for landfill. For residential areas, the logarithmic relationship shows that distances too close or too far (greater than 3 km) from residential areas receive a lower rank and are thus unsuitable for solid waste disposal. This is because if the distance is too close, the landfill can infect the inhabitants with diseases or odors, while placing dump sites too far away from the source of the waste is uneconomical and time-consuming. *Figure 4* also shows that the class too close or far from industrial areas, mostly out of the city, showed a lower rank for solid waste landfill.

Table A3 shows the classification and rank for 12 criteria based on the quantile method using GIS software. Six classes of slope show that a 0 degree angle of steepness achieved the highest rank using the AHP model, implying that these are the most suitable classes for landfill use. Inversely, the lowest classes are those with a 45 degree angle of steepness; these are ranked as 1. Ten classes of distance from the river indicated that the class at an average of 91 meters away from the river had the lowest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67016722

rank using the AHP model, thus is least suitable for landfill. Inversely, the most suitable class is ranked with 9, which is 3,721 m away from water bodies.

Table A3 also shows that the class at an average of 593 m away from roads achieved the highest rank of suitability for landfills, using the AHP model, while the lowest suitable classes, ranked number 1, recorded the closest and farthest distance classes from the road (0 and 3,684 m). The highest suitable class that attained rank number 10 indicating the greatest distance from the railways (12,393 m) and from railway. For agricultural, commercial and residential areas, the highest suitable class gained ranking number 10 at distance of 7,688 m away from health centers, 2,730 m away from residential areas and 7,839 m away from commercial areas, respectively.

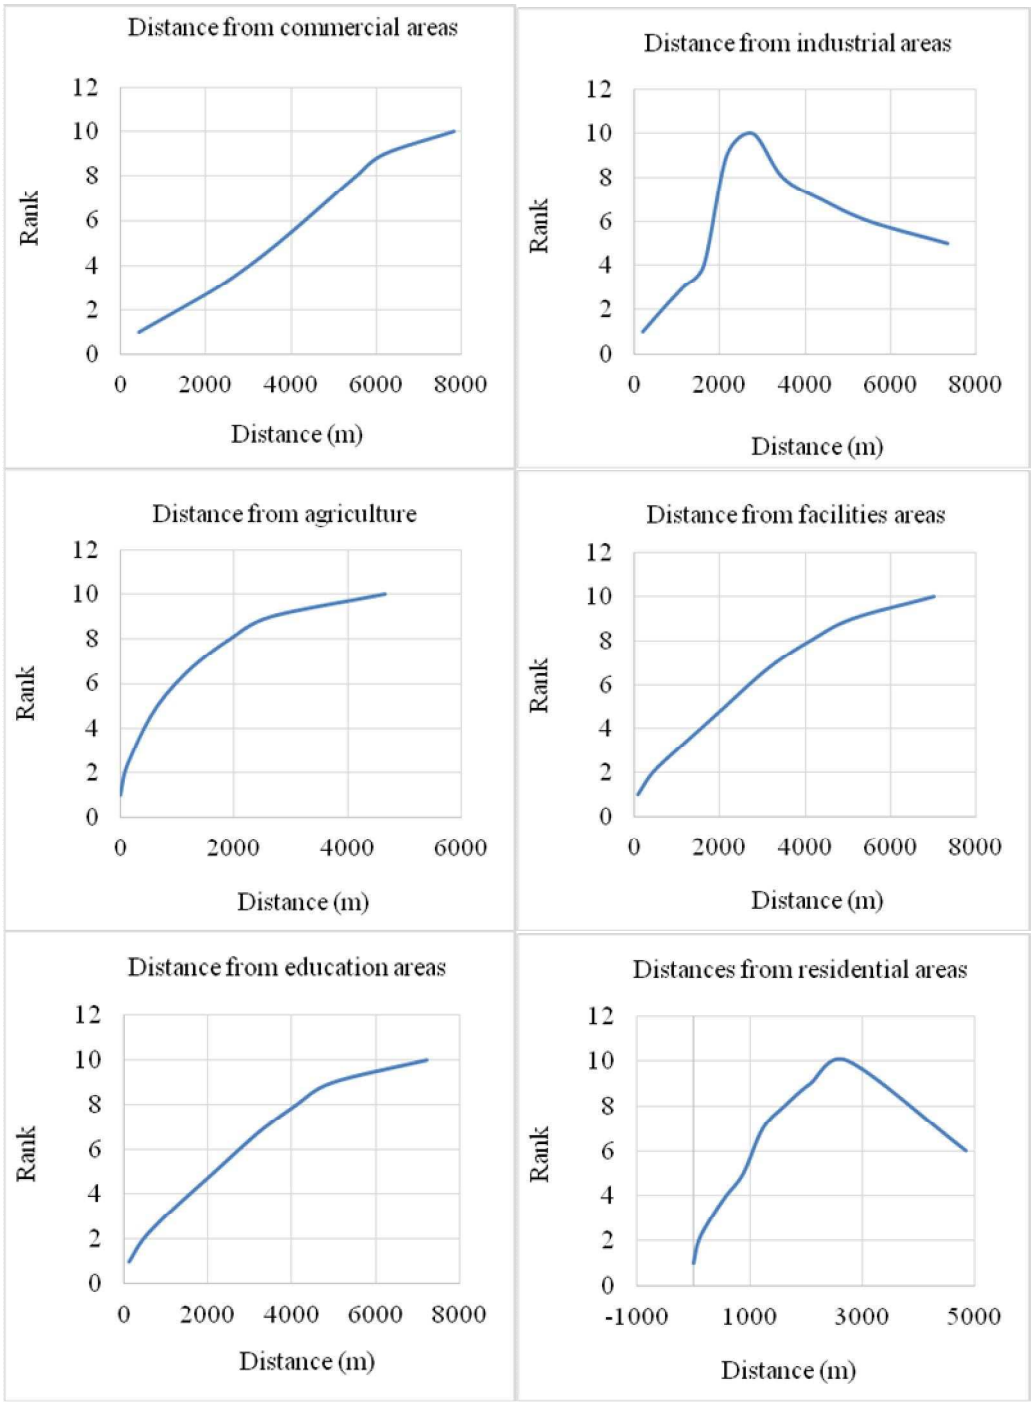

Figure 4. *Weight variation in: slope, distance from river, distance from roads, distance from railways, distance from open space, distance from agricultural lands, distance from health centres and hospitals, distance from residential areas, distance from commercial areas, distance from industrial areas, distance from facilities areas and distance from education areas*

Table A3 also shows that the highest suitable class for industrial areas and facilities ranked number 10, representing an average distance from industrial areas of 2,770 m and from the facilities of 7,007 m, respectively. The highest suitable class for education areas obtained ranking number 10, which is the farthest distance from educational

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67016722

facilities (7,216 m). The soil stratification is not significantly contributed to the site selection as the study area has mostly covered by one soil type. In addition, due to the impervious surface of the study area, pollution might not be possible to deeply penetrate through the soil surface to groundwater. In contrary, there is a high chance to affect the surface water bodies.

Selection of suitable sites for solid waste using the AHP model

Questionnaires were prepared based on expert's response regarding to the most significant factors in the selection of suitable sites for a solid waste landfill in the study area. After the preparation of the conditioning factors using GIS, the weights of each factor were calculated using the geometric mean method to determine the final weight of each factor. Then, the factors were reclassified based on their weights and prepared using a raster calculator to generate a suitability map, which describes the suitable locations for solid waste landfill. The result of the pairwise comparison matrix obtained from questionnaires for the 12 criteria is shown in *Table 1*.

Table 1. *Pairwise comparison matrix extracted from questionnaires for 12 criteria*

Pairwise comparison matrix	**Solid waste landfill selection**											
	Res	**Open**	**Road**	**Ind**	**Agri**	**Edu**	**Health**	**Faci**	**Com**	**Slope**	**Rail**	**WB**
Residential	1	2	4	3	5	8	7	7	9	9	8	6
Open space	1/2	1	3	3	4	6	6	5	8	8	8	4
Road	1/4	1/3	1	1/2	2	5	4	3	6	7	6	2
Industrial	1/3	1/3	2	1	1	4	3	3	5	5	6	2

Educational	1/8	1/6	1/5	1/4	1/3	1	1/3	1/3	2	3	4	1/4
Health	1/7	1/6	1/4	1/3	1/2	3	1	1	4	6	5	1
Facilities	1/7	1/5	1/3	1/3	1/2	3	1	1	3	5	4	1/5
Commercial	1/9	1/8	1/6	1/5	1/5	1/2	1/4	1/3	1	2	2	1/6
Slope	1/9	1/8	1/7	1/5	1/5	1/3	1/6	1/5	1/2	1	1/2	1/7
Railway	1/8	1/8	1/6	1/6	1/5	1/4	1/5	1/4	1/2	2	1	1/9
River	1/6	1/4	1/2	1/2	1	4	1	5	6	7	9	1

*Res = Residential, Open = Open Space, Ind = Industrial, Agri = Agricultural, Edu = Educational, Faci = Facilities, Com = Commercial, Rail = Railway, WB = Water Bodies

The pairwise comparison matrix shown in *Table 1* was assembled from the input of 13 different experts in the field of environmental and waste management. The results were summarized based on the average of the distributed questionnaires. *Table 2* shows the weight of each criteria in percentage and their ranks from the most to the least important criteria. It was deduced that proximity to residential areas was the most important criteria in solid waste selection. The second most important parameter was observed to be proximity to open space followed by distance from roads and industrial facilities. Inversely, the slope and distance from railways were determined to be the least important criteria in terms of landfill selection.

Table 2. *Weightage for criteria in percentage*

Criteria	AHP-Weightage (%)
Residential	26.36
Open Space	19.63
Road	10.35
Industrial	10.13
Agricultural	7.19
Educational	2.97
Health	5.29
Facilities	4.58
commercial	1.97
Slope	1.40
Railway	1.63
River	8.50

The accuracy of AHP is within acceptable limits, as the CI (0.128) is greater than 0.1. In addition, Lambda value of 13.41 and the Randomness Index (RI) with 1.54 were observed to show high accuracy based on the CI. The CI/RI ratio is 0.083 implying that the experts assigned the weight of each criterion logically, and the prioritization of the criteria was consistent. *Figure 5* is a suitability map produced using the AHP model that shows the suitable areas in green and non-suitable areas in gray. It was observed that suitable areas were almost distributed across the entire study area. However, most suitable areas were found outside the city, mostly toward to the west and south of the study area. The overall area of very highly suitable lands for solid waste was found to be about 1.66 km^2. Therefore, field visits are required to identify the final location of the solid waste landfill. The suitability map produced in GIS using AHP model shows that suitable sites are not clustered in one single area, but distributed over different locations within the study area. This indicates that some of the conditioning factors have a huge influence on the selection process for suitable sites and were distributed across the study area.

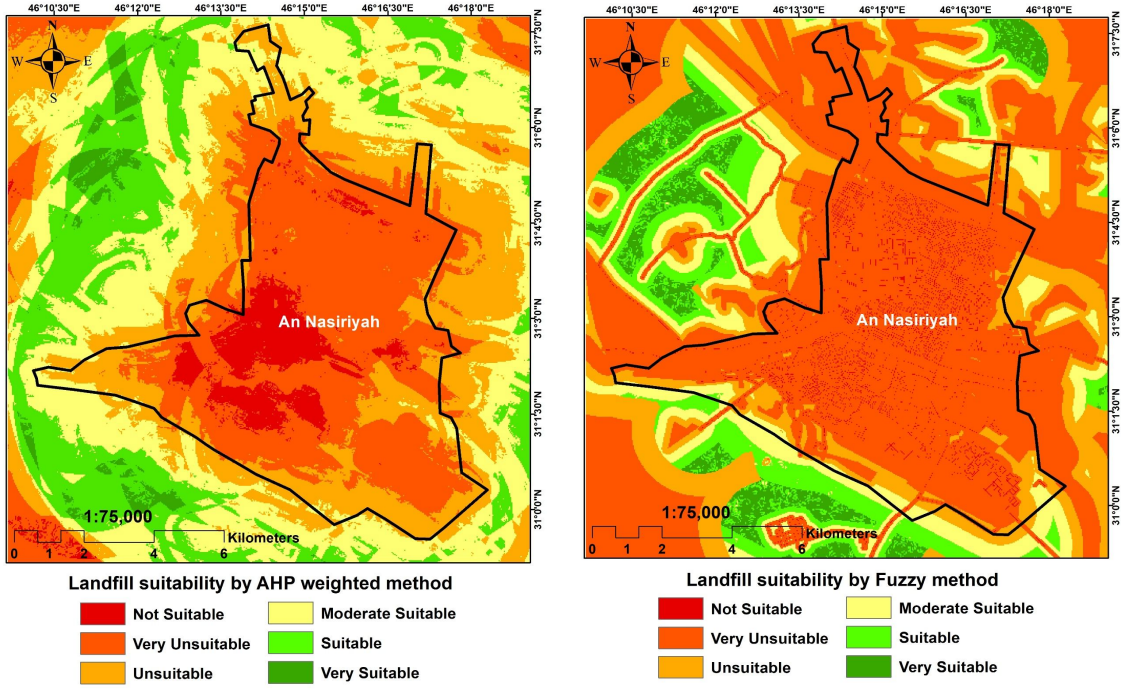
Suitable areas were determined using the AHP model and were mostly found far from urban areas, and no suitable area was observed around the city borders. These sites require further investigation to determine the possibility of constructing a solid waste disposal field.

Selection of suitable sites for solid waste using the fuzzy model

The suitability map produced using the Fuzzy model is presented in *Figure 5*. The map shows suitable and unsuitable locations in the study area, identified based on 12 factors for solid waste disposal. The map shows that most suitable areas are located in the middle and in the north part of the study area. On the other hand, the southern part of the study area was observed to have no identified suitable site for solid waste, thus, should be ignored in the field visit. The overall surface area of suitable land is estimated to be 13.35 km^2. The suitability map produced using the Fuzzy model shows the spatial distribution of the suitable areas and their patterns in the study area. It can be observed that most of the suitable areas are clustered into groups and are not randomly scattered in different directions. This indicates that the suitable areas identified are homogenous

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67016722

and share similar characteristics with each other. This is very important for decision makers, as it makes final selection easier and more accurate. Decision makers can use this method to easily identify suitable areas for constructing solid waste landfill sites in a particular area.



a b

Figure 5. *Map produced using a) AHP model and b) fuzzy model*

It is imperative to compare the results of the AHP and Fuzzy models to identify their similarities and possible differences. The comparison between the maps produced by these models showed that the AHP maps identified the suitable areas as scattered regions, while the Fuzzy model generated a map with clustered suitable areas. It was observed that the AHP map located suitable areas in almost all parts of the study area, while the Fuzzy map identified suitable areas at the middle and northern parts of the study area. In terms of the surface area of suitable lands identified, the AHP model indicated 4.14 km² area as highly suitable, while the Fuzzy model identified 13.35 km² as highly suitable for solid waste landfill. *Figure 6* illustrates the percentage of landfill suitability based on the AHP and Fuzzy Models with 2% and 5% for very suitable areas.

Table 3 shows the results of the AHP model in terms of very suitable landfill areas, 4.14 km^2, and very unsuitable areas, 60.6 km^2. The Fuzzy model obtained 13.35 km^2 for very suitable areas and 131.56 km^2 for very unsuitable areas (*Table* 3). In addition, the Fuzzy model showed more areas considered very suitable compared to the AHP model, which could be due to the mathematical nature of the Fuzzy algorithm. The common areas identified by both methods showed the most suitable lands for waste disposal landfills, far away from residential areas and close to bare lands. Traditional AHP approach is more simplistic and robust while Fuzzy logic approach help in coping with vagueness and uncertainty of determining site suitability. The results further display that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67016722

the AHP maps identified the suitable areas as scattered regions, while the Fuzzy model generated a map with clustered suitable areas.

However, a field visit is required to confirm the final location for the landfill site in order to take into account other factors that were excluded in the model, such as the population and other environmental changes. There may be some changes to the sites that may not be favorable for the intended purposes. Therefore, a field investigation was conducted to further assess the reliability of the proposed methodology. A handheld GPS device (GeoExplorer 6000) was used to determine the location of the sites. *Figure 7* shows the location of the most suitable sites obtained during field investigation. The information acquired from field measurements allow for the assessment of the precision and reliability of the produced suitable areas for waste disposal landfill.

Several studies have been conducted for the site selection and disposal of the solid wastes by applying multi-criteria decision analysis (MCDA) using GIS as shown in *Table 4*. However, in this work shown Fuzzy logic was more accurate than AHP. The most significant physical parameters were derived and then ranked according to their contribution to landfill. This model is a first attempt in our study area. We optimized knowledge driven method by data driven approach in order to minimize the spatial errors.

Conclusion

In this study, 12 criteria were used in an overlaying analysis of potential areas with GIS to identify a suitable landfill site in Nasiriyah, Iraq. A combination of GIS, AHP and Fuzzy logic models were used in this study; layers such as slope, distance from bodies of water, distance from roads, distance from railways, distance from open space, distance from agricultural lands, distance from health centers and hospitals, distance

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67016722

from residential areas, distance from commercial areas, distance from industrial areas, distance from facilities, and distance from educational areas were considered. The criteria weightings were derived from the AHP method by constructing a matrix of pairwise comparisons between criteria.

This study found the areas identified by both methods as most suitable, which were observed to be outside of the city boundary, mostly to the west and south of the study area and met the requirements of environmental, economic and residential factors. The common areas identified in both methods showed the most suitable lands for waste disposal landfill with an appropriate distance from residential areas and open space. Therefore, the result showed that a combination of GIS, AHP and Fuzzy models using multi-scientific and environmental criteria could be used to develop an effective and efficient methodology for selecting suitable landfill sites in Nasiriyah, Iraq. It can be concluded that the methodology applied in the present study is capable in locating the suitable landfill site in Nasiriyah city, thus future study should be carried out as well at other provinces in Iraq. It is recommended that future study should consider other important parameters such as soil type, soil layer stratification, levels and movements of the groundwater, etc. These parameters need to be studied in detail and field work analysis needs to be conducted for providing accurate and comprehensive study.

Abstract. Increasing population and industrialization have caused air pollution and air pollution in some cities has increased to such an extent that it has started to threaten human health and has become one of the most important agenda topics of our day. Many pollutants arise in cities due to exhaust gases, car wheels, vehicles and vehicle wear. Heavy metals are one of the most infamous pollutants, because they can remain in nature for a long time without degradation and the amount of heavy metal concentration in the environment is constantly increasing. Heavy metals also tend to bioaccumulate. Therefore, the determination of heavy metal concentration is of great importance in terms of identifying risk regions and risk levels. Determination of heavy metal concentrations in plants is important both for determining plants' ability to remove heavy metals from the air and thus to improve air quality, as well as for monitoring air quality. Bio-indicators are the most important indicators of the change in the concentration of heavy metal in the atmosphere. This study aims to determine the usability potential of Scotch Pine (*Pinus sylvestris*) in monitoring the traffic related heavy metal concentration. For this purpose, samples of Scotch Pine individuals were collected from one of the busiest highways of Turkey, at the route of Ankara-Istanbul, from refuges, at roadsides and at distances of 3 m, 10 m, 30 m, 50 m and 100 m from the roadside, some of the branch and needle samples were washed and the change of Cu, Pb and Cd concentrations on these samples was determined. As a result of the study, the change of the concentrations of these heavy metals depending on distance to the road, organelle and washing conditions all seem to indicate that the Scotch Pine is a good bio-monitor which could be used especially to monitor the change of Cd concentration.
Keywords: *bioaccumulate, bio-monitor, highway, plant, pollution, Cd concentration*

Introduction

In addition to the rising population of the world, the increasing population density in city centers has brought various problems with it (Cetin and Sevik, 2016a, b; Gülgün et al., 2014; Cetin et al., 2017a, b, 2018a, b, c, d). This process causes destruction of nature, pollution of air, water and soil, and deterioration of the ecological balance (Mutlu, 2016; Mutlu et al., 2016; Kaya et al., 2018). This process brings many problems with it, but one of the biggest problems is the pollution of environment and especially air (Sevik et al., 2018). Air pollution has become such a big problem that approximately 30 million people die every year due to air pollution related reasons (Cetin et al., 2018).

Air pollution can be defined as the existence of one or more contaminants in the air in amounts and durations which could be harmful to humans, animals and plant life and commercial or personal properties and environmental quality (Cetin et al., 2018).

While there are many components responsible for air pollution, heavy metals are one of the more significant among them. Heavy metals do not deteriorate and disappear in nature.

There are various methods that are used to determine the air pollution. Direct measurement of air pollution via these methods requires both expensive measuring instruments and has a higher risk of contamination compared to bioindicators. Plants have many environmental, social and economic contributions to the environment in which we live, one of which is their use as a bio-indicator in the detection and monitoring of air pollution (Gülgün et al., 2015; Cetin et al., 2018b). Using bioindicators is one of the most effective methods of determining air pollution.

This method is inexpensive and easy to provide, as well as its ability to provide more accurate data on the periodic change of heavy metal concentration. Therefore, many studies have been conducted to determine the change of heavy metal concentrations via bioindicators (Sevik et al., 2018; Turkyilmaz et al., 2018b).

However, different heavy metals can accumulate at different levels in the organelles of the plants. Therefore, it is very important to determine the accumulation level of each heavy metal in each organnelle to enable the usage of the right organelle of the right plant as biomonitors in order to get more reliable results from the studies. In this study, it was aimed to determine the change of some heavy metals concentrations depending on the plant organelles and the distance to the road with heavy traffic in Scotch Pines *(Pinus sylvestris)*.

Materials and methods

Materials

The study was conducted on the samples collected from the Scotch Pines from the roadside on the Ankara-İstanbul highway between Kaynaşlı province of Düzce city and Bolu city. The highway that was chosen as the case of this study is one of the busiest highways in Turkey. Samples were especially taken from the closest branches to the road. The Scotch Pine individuals were selected on a specific direction on the highway between Kaynaşlı district of Düzce province and Bolu province from the refuge, roadside and at 3 m, 10 m, 30 m, 50 m and 100 m distances. The half-meter length of branch samples collected from the road side parts of seven Scotch Pines constitute the materials of this study (*Table 1*). The samples used in the study were collected in the last week of September following the end of the vegetation season of 2018.

Determination of heavy metal concentrations

Samples brought to the laboratory were firstly divided into groups and some of the samples were washed. The samples were then separated into organelles and the bark of the wood was peeled; and washed needles, unwashed needles, washed bark, unwashed bark and wood samples were obtained. The samples were labeled and kept for 15 days until they got air dried. Air dried samples were taken into glass containers and dried in drying oven at 50 °C for one week.

The dried samples were pulverized by a steel blender in the laboratory. The pulverized samples were made to weigh 2 g each in 10 ml concentrated HNO_3 at room temperature for 1 day in the fume cupboard, and then boiled at 180 °C for 1 h. 20 ml of distilled water were added to the prepared solutions and the solution was filtered through a 45-µm filter paper. The prepared solutions were numbered in order to prevent any mix-ups and prepared for analysis. In the solutions obtained from the filtrate; heavy metal analysis was performed with the GBC Integra XL ICSDS-270 ICP-OES (Inductively Coupled Plasma Optical Emission Spectrometer) device (Sevik et al., 2018; Turkyilmaz et al., 2018b).

Statistical analysis

The obtained data were evaluated with the help of SPSS package program, variance analysis was applied to the data and homogeneous groups were obtained by applying the Duncan test to the values having at least 95% confidence level differences statistically. The obtained data is simplified and tabulated and interpreted (Sevik et al., 2018; Turkyilmaz et al., 2018b).

Results

The change in Cu concentration due to organelle and distance to the traffic source was determined separately and F value and significance level obtained by variance analysis and homogeneous groups resulting from Duncan test are shown in *Table 2*.

As the result of the variance analysis, it was determined that the change of Cu concentration was significant at a 99.9% confidence level for all factors. When the change of Cu concentration due to distance was examined, no significant change was observed. For example, in the unwashed bark samples, some of the lowest and the

DOI: http://dx.doi.org/10.15666/aeer/1703_67236734

highest values were obtained at the farthest distance from the road. A similar situation is also noticeable in wood samples. The lowest and the highest values of the wood samples were also obtained at the farthest distance to the road.

Table 2. *The change of Cu (ppm) concentration depending on organelle and on distance from the road*

Distance (m)	Needle		Bark		Wood (ppm)	Value (ppm)

*Significant at 0.05 level; **significant at 0.01 level; ***significant at 0.001 level
The letters a, b, c, etc. means according to Duncan test results; show that the group is located. It is statistically different from the values contained in different groups, starting with the letter a, the numerical value grows
Capital letters in rows; lower case letters show groupings in columns. For example, the concentration of Cu in the washed needle is also as the distance of the fifth; C is in the third homogeneous group

When examining the change of Cu concentration depending on the organelles; it is noteworthy that the concentration amounts in wood samples were considerably high. It was observed that the amount of the Cu concentration in wood samples were higher than the values obtained from the other organelles.

The change in Pb concentration due to organelle and distance to the traffic source was determined separately and F value and significance level obtained by variance analysis and homogeneous groups resulting from Duncan test are shown in *Table 3*.

When the results of the analysis of variance in Pb are examined, it is noteworthy that Pb concentration in wood does not differ statistically significant at least at 95% confidence level depending on distance. Apart from this, it can be said that the change of Pb concentration due to distance is statistically meaningless. However, when the change of Pb concentration is examined depending on organelle, it is observed that all values obtained from the wood samples are quite low and all the values obtained from the wood samples are in the first two homogenous groups that were formed as the result of Duncan test. Furthermore, it was observed that the values obtained from needles were lower than the values obtained from the bark samples, while the values of washed samples were also lower than the values of unwashed samples.

The change in Cd concentration due to organelle and distance to the traffic source was determined separately and F value and significance level obtained by variance analysis and homogeneous groups resulting from Duncan test are shown in *Table 4*.

As the result of the variance analysis, it was determined that the change of Cd concentration was significant at a 99.9% confidence level for all factors. When the

DOI: http://dx.doi.org/10.15666/aeer/1703_67236734

change of Cd concentration due to distance was examined, it was seen that Cd concentration decreases generally as the distance increases.

When the change of Cd concentration depending on the organelles was examined, it was determined that the lowest values were obtained from the needle samples, the highest values were obtained from bark samples, and the values obtained from wood samples were higher than the values of needle samples while lower than the values of bark samples. Apart from that, the Cd concentration amount calculated in unwashed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67236734

needle samples were generally higher than the washed needle samples, and the Cd concentration amount calculated in washed bark samples were higher than the unwashed bark samples.

In addition, the Cd concentrations obtained from the unwashed samples in the hands are generally higher than the washed samples and the Cd concentrations in the washed samples are higher than the Cd concentrations obtained in the washed samples.

Discussion

Plants are often used as biomonitors in monitoring the heavy metal concentration. Some of the species that are used as biomonitors of traffic related air pollution are; *Aesculus hippocastanum* (Anicic et al., 2011), *Elaeagnus angustifolia* (Aksoy and Şahin, 1999), *Robinia pseudoacacia* (Celik et al., 2005), *Tilia* sp. (Tomasevic and Anicic, 2010), *Quercus ilex* (Gratani et al., 2008) and some other species (Ozturk and Bozdogan, 2015; Mossi, 2018).

Cu, one of the heavy metals that were evaluated within the scope of this study is quite an important element for plant organisms due to its involvement in enzyme activation, carbohydrate and lipid metabolism (Asri and Sönmez, 2006). It has been determined that copper plays an important role in physiological events such as photosynthesis, respiration, carbohydrate degradation, nitrogen use and storage, cell wall metabolism, and that it regulates xylem permeability, controls the production of DNA and RNA and plays an important role in resistance mechanism against diseases. In case of copper deficiency, it is stated that plant growth stopped (Okcu et al., 2009).

Although plant species need different amounts of it, copper is a highly toxic metal. Some effects of copper poisoning include tissue damage, deterioration of roots and darkening of plant color. Other effects of copper poisoning are, loss of ion as a result of deterioration of membrane permeability in the stem cells and disruption of photosynthesis process as a result of DNA damage (Okcu et al., 2009). Acute copper intoxication may cause abdominal pain, nausea, vomiting and diarrhea in humans (Asri and Sönmez, 2006). While taking low amounts of copper ions may cause liver cirrhosis, Wilson's disease, systemic rheumatic diseases, kidney diseases; taking high amounts of copper ions may cause blood cancer (Mossi, 2018). Therefore, many studies have been conducted to determine Cu concentration in plants and to correlate with traffic density (Turkyilmaz et al., 2018a, b).

Turkyilmaz et al. (2018c) stated that Cu concentration amount in plant organelles differ depending on traffic density and that while they calculated the Cu concentration at 69.615 ppb in areas with none-traffic, it was 71.096 ppb in areas with low dense traffic and it reached up to 110.441 ppb level in areas with heavy traffic. Suzuki et al. (2009) determined that the concentration of Cu could reach up to 22.22 mg kg^{-1} in the leaves of *Rhododendron pulchrum* in Okayama, Japan; while Demirayak et al. (2011) reported that Cu concentration was averagely at 35 ppm level in the leaves of *M. grandiflora* in Samsun city. Li et al. (2007) stated that the amount of Cu concentration in *Sophora japonica* L. leaves were higher in the individual trees on roadside than the ones in the parks.

Sawidis et al. (2011) determined that the Cu concentration in *Pinus nigra* leaves in the control group was calculated at 3.182 µg/g in Salzburg; 3.263 µg/g in Belgrade; and 2.432 µg/g in Thessaloniki; while it increased up to 4.875 µg/g in Salzburg; 25.391 µg/g in Belgrade and 16.486 µg/g in Thessaloniki in contaminated regions.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67236734

Erdem (2018) in his study on different species that the Cu concentration between 0.16 and 24.66 ppm and depending on the intensity of the traffic varies depending on a high level of values, for example, *Ailanthus altissima* in the areas of heavy traffic in the Cu concentration of the determined concentration of Cu in areas where the approximately 80 times. Pınar (2019) in his study of five species on the Cu concentration of 3 ppm to 286.5 ppm ranged between the highest value of the traffic is concentrated in the linden seeds.

Cu concentration in wood samples was higher than in the other organelles. This result is generally consistent with the literature. Cu concentration varies in different species, depending on species and organelles (Mossi, 2018; Turkyilmaz et al., 2018d).

In his study of four different types, Erdem (2018) states that the Cu concentration changes significantly on the basis of the organelle. In some species, the highest values are determined on the leaf and in some species on the branches and seeds. Similar results were obtained by Özel (2019) and Pınar (2019). Pb is one of the other heavy metals that were evaluated within this study. Pb concentration is of great importance among the other heavy metals. Pb, which is a widely used element in industrial and agricultural activities, is a heavy metal that is emitted to the atmosphere as a metal or compound and in each case has toxic properties. Pb is one of the heavy metals that cause the most damage to the ecological system by human activities (Mossi, 2018). Therefore, a large number of studies have been performed on the change of Pb due to traffic density (Lei et al., 2015; Assirey et al., 2015; Galal et al., 2015).

In the study, it was determined that the values obtained in the wood samples were quite low, and the values obtained from the needle samples were lower than the values obtained from the bark samples and the values obtained from the washed samples were lower than the values obtained from the unwashed samples. Mossi (2018) found similar results in different studies; he determined that the lowest values of Pb concentrations were obtained from washed samples while the highest values were calculated in the unwashed samples in areas with heavy traffic.

Pb with more than the normal levels can be found in the foods of animal and vegetable origin that are grown in areas close to the city centers and industrial regions (França et al., 2017; Mossi, 2018). In addition, lead-containing gasoline is an important source (Okcu et al., 2009). Therefore, there are numerous studies documenting the relationship between Pb and traffic density (Qing et al., 2015; Begum et al., 2017).

Erdem (2018) stated that different types of Pb concentrations vary significantly depending on the traffic density, whereas the average Pb concentration in areas where there is no traffic is 346 ppb is 635 ppb in areas with low traffic and 1782 ppb in high traffic areas. Pınar (2019) stated that Pb concentration increased with traffic density and this level was quite high in some organelles.

There are many studies on the change of Pb in organelle and species. In studies, it is stated that Pb changes significantly on organelle basis. For example, Akarsu (2019) stated that the Pb concentration in *Cedrus arizonica* wood was 1619 ppb and this value increased to 5902 ppb in the outer shell. Ozel (2019) indicates that the concentration of Pb in the mulberry shells in the areas where there is no traffic is increased to 2630 ppb in the leaves. The same figures in the areas where traffic is 5352 ppb in the shell, 11582 ppb level in the leaf (Ozel, 2019).

Pb is one of the most studied elements due to the properties of this element. Numerous studies have been conducted on many species to be used as the biomonitor of Pb. Some of the studies that were aimed to determine the change of Pb concentration in

DOI: http://dx.doi.org/10.15666/aeer/1703_67236734

different species depending on traffic density are; Aksoy and Şahin (1999) *Elaeagnus angustifolia*, Tam et al. (1987) *Bauhina varigeata,* Çelik et al. (2005) *Robinia pseudoacacia,* Demirayak et al. (2011) *M. grandiflora* and *A. Cyanophylla,* Tanushree et al. (2011) *Alstonia scholaris, Ficus bengalensis, Morus alba,* and *Polyalthia longifolia,* Sawidis et al. (2011) *Platanus orientalis* (Ozel et al., 2015), *Pinus nigra,* Li et al. (2007) *Sophora japonica*.

Another heavy metal that has been mostly studied is Cd. Cd is a highly toxic metal that comes to the fore with a variety of usage areas and with its role in the environmental pollution. The carcinogen effect of Cd in human body was identified in 1976 and it was classified as Type 1 carcinogen by IARC (International Agency for Cancer Research) in 1993 (Boğa, 2007). Cd is an element that is toxic for both humans and animals as well as plants (Asri and Sönmez, 2006; Boğa, 2007). Not only is it toxic for the human body even at very low doses, but it also has a long biological half-life.

In addition to industrial activities, cadmium is spread through phosphorous fertilizers used in agriculture, sewage wastes in residential areas and atmospheric deposits. It is estimated that 0.2-1.0 mg/m^2 of Cd is added annually in the soils of the roadsides in areas with heavy traffic (Asri and Sönmez, 2006). In our study, it was determined that Cd concentration decreased as the distance to the road increased. In addition, the lowest values were obtained in needles while the highest values were obtained in bark samples.

The results of the study revealed that the amount of Cd changed depending on both traffic density and organelle. In a large number of studies, it was determined that the concentration of Cd varies according to plant species, traffic density and plant organnelle (Mossi, et al., 2018; Turkyilmaz et al., 2018e). Ozel (2019) Cd concentration, depending on the type, organelle and traffic density, Akarsu (2019) *Cedrus arizonica* facing the road in the average Cd concentration of wood at 157 ppb level of this value is 2601 ppb level in the outer shell.

In this study, the possibility of using pine as a biomonitor to determine the heavy metal pollution in the air was investigated. It is stated in the studies that it can be used as biomonitor in determining the heavy metal pollution of traffic origin of pine in different areas (Turkyilmaz et al., 2018b). In order for a species to be used as a biomonitor for monitoring heavy metal pollution, it must first be able to collect heavy metals within that species (Bat et al., 1999). Plants that can collect heavy metals in the air can also remove heavy metals from the air. Therefore, they can clean the air in terms of heavy metal. Therefore, the plants that can collect heavy metals within the body can also contribute to the cleaning of the heavy metal. This situation was also expressed in other studies (Saleh, 2018; Mossi, 2018; Erdem, 2018). In this study, it was determined that pine can collect some heavy metals within its structure. Therefore, in the environment where yellow pine is grown, it will help to remove heavy metals from the air and contribute to the cleaning of air pollution.

Conclusions

Expanding green areas is one of the most effective methods among the solution proposals to tackle air pollution. In many studies, it has been proved that green areas and the plants used in these areas reduce all kinds of air pollution in different ways (Cetin and Sevik, 2016a, b; Cetin et al., 2017).

Although a large number of plant species have been the subject of studies to date, these studies are not yet sufficient. There is no information about the potential of many

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67236734

plant species to accumulate heavy metals. However, it has been reported in numerous studies that there are great differences between the heavy metal deposition potentials of plant species. Therefore, it is necessary to use the species that are not examined yet in similar studies and to identify the plants that will be more effective in monitoring and reducing the heavy metal pollution. Therefore, it is suggested to keep similar studies going by diversifying the studied plant species.

In the selection of the plants used in urban centers, their visual qualities are generally prioritized and their functional uses are made to be of secondary importance. However, in order to use the plants in a proper manner; it is vital to determine the more effective species to perform the desired function and the selection of the species in such areas should be made accordingly. Scotch pine is a tree species that can be used for forestation of the urban areas especially due to being an evergreen species as well as being extremely resistant to cold climates. Also, as it has low needs for maintenance, soil and water tree, it is a valuable landscape plant. It is determined that it is also a good biomonitor especially for the monitoring of Cd pollution.

Within the scope of the study, measurements have only been conducted on needles, branches and wood samples of the tree. However, former studies have proved that the heavy metal concentration in different organelles of the plants such as root, fruit, etc. can be higher. Therefore, the low concentration in the needles, branches and wood samples of a tree may not mean that the plant does not accumulate heavy metals as the plant may have a significant amount of heavy metal concentration in its other organelles. The inclusion of other organelles of the plants in the studies to be carried out in this field may provide important results.

Abstract. Developing countries are often beset by poverty and hunger. While provisioning ecosystem services (Prov.ES) are essential for eradication of these issues, they are being rapidly depleted due to climate change and anthropogenic impacts. However, their depletion has not been accounted for in sustainable use policy. Taking Pakistan as a case study, this research focuses on assessing and evaluating the dynamics of Prov.ES. It evaluates the contribution of Prov.ES to poverty reduction using key indicators over different spatiotemporal scales. Among provisioning services, livestock's contribution was the highest, followed by agricultural products, while fisheries and forests contributed the least. Prov.ES were shown to be important to Pakistan's economy. Product analysis revealed that livestock was the most contributing service (53%), followed by agriculture (44%), while fisheries and forests contributed to a smaller extent (≤2%). Livestock products, major crops, marine fish products, and medicinal plants are the main contributors in those respective fields. Our results showed a net present value of 569 US$/ha/year, which is very close to the median value of the 16 previous studies analyzed. Incorporating natural resource conservation into sustainable development policies, with a focus on the impacts of climate change and the increasing human population, is essential.
Keywords: *conservation, food security, human well-being, poverty reduction, valuation*

Introduction

Poverty, hunger, and food, water and energy security are key issues in the contemporary developing world (Hanjra and Qureshi, 2010). In 2013, 10.7% of the world's population was estimated to live on less than US$1.90 a day (World Bank, 2016). The increasing human population and the resulting degradation of natural resources and climate change are the main causes of drought and poverty (Kraus, 2016). The effects of climate change on ecosystem service processes and flows are apparent (Wood et al., 2018), particularly in the developing world (Lam et al., 2016). The impacts of climate change need to be considered in policymaking for sustainable natural resource use and development (Halsnæs et al., 2014). People in developing countries rely on the provisioning ecosystem services (Prov.ES) for their livelihoods (Khan, 2012), for example, food, water, wood, and NTFPs (non-timber forest products) (MEA, 2005a).

ES functions and drivers are interlinked (Butler, 2006). The sources of Prov.ES, such as crops, livestock, fishery, and forestry, are influenced by other ES and processes (TEEB, 2010a). Food security and hunger have become serious issues in developing countries owing to exponential population growth (Rosegrant et al., 2014), resulting in malnutrition, especially among women and children (MEA, 2005b). The demand for food and food prices will increase as a result of population growth, climate change, and income growth (Rosegrant et al., 2014). Therefore, it is important to protect natural resources and increase production in all sectors linked to human livelihoods. Currently, agroecosystems cover about 40% of the terrestrial landform and provide humans with various Prov.ES, such as food, forage, bioenergy, and pharmaceuticals (Power, 2010). Furthermore, agroecosystems also support other types of regulating, supporting, and cultural ES, such as pest control, soil retention, nutrient cycling, flood control, water quality, carbon storage, climate and disease regulation, beauty, education, recreation, and tourism (Power, 2010). Livestock is widely recognized and valued as a source of food, income, employment, nutrients, and risk insurance. It directly supports 600 million poor smallholders in developing countries, contributing 17% of kilocalorie and 33% of protein consumption globally (Théwis, 2012). Both cropping and livestock husbandry offer many opportunities for sustainability by raising productivity and increasing resource use efficiency (Herrero et al., 2010). Forests provide different ES, including timber, fuelwood, medicines, and other NTFPs (Hlaing et al., 2017), and are home to 1.6 billion people around the globe (IUCN, 2012). Land clearing and deforestation cause floods, local climate change, and contamination of water (Tariq, 2015). The global fisheries sector supports 10–12% of the world population but climate change is predicted to reduce fisheries production by 35% by 2050 (Lam et al., 2016).

Many people in Pakistan depend on agriculture, it contributed 20.9% to GDP in 2014–2015 and 26.0% in 1997–1998 (Chandio et al., 2016). More than 43.5% of the rural population are engaged in this sector (Ahmed and Javed, 2018). Livestock, forestry, and fisheries account for 56.3%, 2.0%, and 2.1% (Chandio et al., 2015) of the agricultural industry, respectively. More than 8.0 million rural families are engaged in raising livestock, which plays an important role in poverty reduction improving socioeconomic conditions (Chandio et al., 2015). Pakistan has 4.8% forest cover area, but 60% of urban and 90% of the rural population depend on fuelwood as their primary source of energy (FAO_UN, 2010). Both inland and marine fish in Pakistan are a source of food (Nazir et al., 2015). Fisheries are important in the economies of developing countries. Pakistan's total coastline covers an area of approximately 300,270 km^2, where the fisheries and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67356759

fishing industry are source of employment, income, and food, as well as a substantial amount of foreign exchange via exports (FAO-UN, 2016a).

The monetary value of ES has recently gained attention (Lienhoop et al., 2015). Market price-based valuation of ES is considered a valid method of estimating the contribution of Prov.ES to human wellbeing, especially in poverty reduction (Daw et al., 2016). In this work, a market price-based approach is used to assess and value the products of Prov.ES. Discounting on the net present value (NPV) of ES is used to explore the future values of ES regarding their sustainable use, policy framework, and intergenerational benefits (Sterner and Kyriakopoulou, 2012). The selection of discount rates depends on the type of ES and future impacts affecting their delivery and flow, such as climate change. Previous studies on ES discount rates reported mean values of 1–12% (Dutton et al., 2015). Most researchers suggest low discount rates since we cannot assume that there will be an abundance of natural resources available in the future (TEEB, 2010b).

Despite their importance, natural resources are being depleted by anthropogenic and climate change impacts; some studies have been undertaken, but still, there is a gap in linking ecosystem services with poverty reduction and informing policymakers for sustainable development through conservation and management. Based on the current level of natural resource degradation in Pakistan, the aims of this research were to: (i) conduct a spatiotemporal assessment and valuation of Prov.ES in Pakistan, (ii) assess the role of the major indicators in poverty reduction and livelihood, (iii) determine the status of the national ES versus other countries; and (iv) assess NPV based on different time horizons and discount rates. The findings of this study will be useful for informing policymaking bodies.

Materials and Methods

Study Area

Pakistan (803,940 km^2) is a predominantly mountainous and desertous country located at 23°37' North and 61°76' east in South Asia at the junction of Central Asia and the Middle East. The highest point is the mountain K2 (8,616.3 m), in the north, and the lowest point is the Arabian Sea (0 m). The 2017 population was 207,774,520, with a growth rate of 2.40%. Pakistan has four provinces (Punjab, Sindh, Khyber Pakhtunkhwa, and Baluchistan) and administers Azad Jammu and Kashmir (AJK) and Gilgit-Baltistan (unofficial province) (*Figure 1*). Pakistan can be divided into five major topographic areas, including mountains, deserts, plateaus, salt ranges, and plains. Pakistan has four seasons, and the temperature varies both seasonally and regionally; the southern part has a hot and dry climate, while the northwest has a temperate climate and the northern part is arctic. Temperatures range from -22°C in winter in the north to 50°C in summer in the south. The precipitation is 1500–2000 mm and 100–200 mm across north and south Pakistan, respectively (Sarfaraz et al., 2014).

Agriculture is the backbone of Pakistan, contributing 21% to the GDP, 43.5% to the livelihood of rural communities, and 43.5% of employment opportunities (GoP, 2013). Livestock is an important sub-sector of agriculture, accounting for 56.3% of this sector and 11.8% of national GDP (Khan et al., 2015). The area covered by natural forests is small (4.2% of the total area), contributing only 2% to the agriculture sector and 0.44% to GDP (FAO_UN, 2010). Fisheries are a potential income generation source in Pakistan, but its growth rate in 2013–2014 was only 0.87% (Altaf et al., 2015). Pakistan has the potential to increase its supply of Prov.ES, which will not only help generate income but

DOI: http://dx.doi.org/10.15666/aeer/1703_67356759

also assist poor people because poverty is linked with the provision of natural resources (Irfan, 2007).

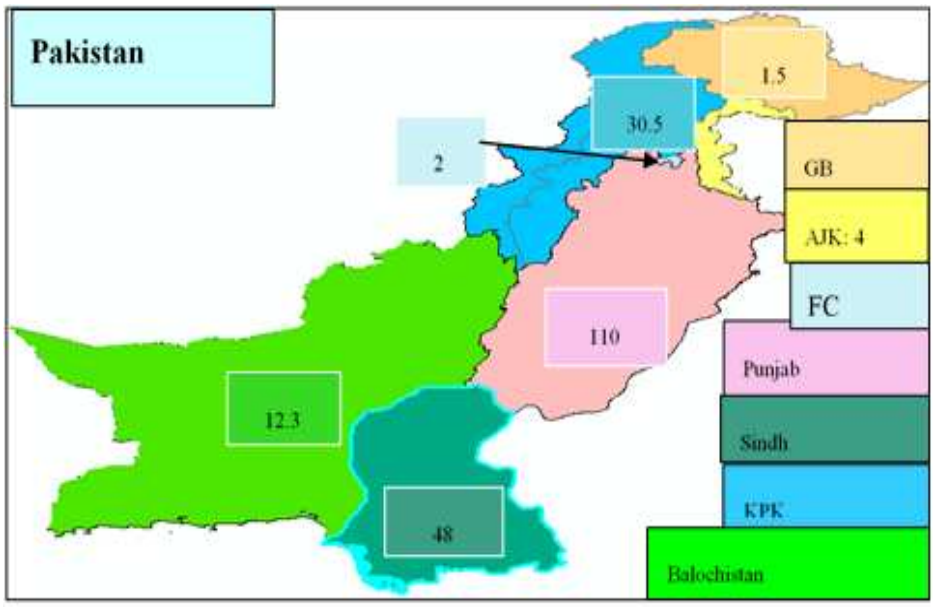

Figure 1. *Map of Pakistan showing the administrative units and population in millions from the 2017 census (Abbreviations: GB (Gilgit-Baltistan), AJK (Azad Jamu & Kashmir, FC (Federal capital), KPK (Khyber Pukhtunkhwa)*

Methods

Data for crops, livestock, and forestry were obtained from the respective government departments and the Pakistan Bureau of Statistics (PBS, 2015); relevant data for agriculture and forestry included area cover, quantity, and market prices. All data was obtained for the five-year period from 2011 to 2015, except for forestry data which was only available for the years 2009 to 2013 and the distribution of livestock by province which was based on 2011 and 2012 (PBS, 2017). The required data was extracted and analyzed for evaluation purpose.

The number of livestock, quantity produced, and market price were considered for livestock, and quantity and market price for fisheries. The market price method was used for direct use values for provisioning products, as in previous studies (Grădinaru, 2013; Siwar et al., 2016). Crops were classified as food crops, cash crops, pulses, and edible oilseeds, and were valued based on major and minor food crops. Major food crops included wheat, maize, rice, sugarcane, cotton, and their byproducts, while minor food crops included vegetables, fruits, condiments, oilseeds, and green fodder. Livestock was divided into major livestock and poultry. Forestry was divided into two main types: major forestry products such as timber and fuelwood and NTFPs; NTFPs is used throughout this research for all products except timber, fuelwood, wildlife, and bushmeat. The estimated value of each Prov.ES product was based on both spatial (by province, marine and inland) and temporal scales for 2011 to 2015 (*Table 1*). ANOVA was also used to describe the significance of variables for the ecosystem assets such as crop, livestock, forestry and fisheries.

Table 1. *Provisioning ecosystem services assessed in this study*

*ESS asset	Sub-type	*Prov.ES type	Value	Method	Time period
Crops	Major and minor crops, fruits, vegetables	Food, trade	Use value	Market price	2011–2015
Livestock	Goats, sheep, cattle, poultry	Food, decoration, trade, manure	Use value	Market price	2011–2015
Forestry	Timber, fuelwood, *NTFPs	Construction, heating, medicine, food, agriculture, tools	Use value	Market price	2011–2015
Fisheries	Marine and freshwater	Food, trade	Use value	Market price	2011–2015

*ESS: ecosystem service, *Prov.ES: provisioning ecosystem service, *NTFPs: non timber forest products

The annual average of the five-year data was calculated to get the gross total value. The NPV, also known as net total value (NTV), for all the environmental assets was calculated using *Equation (1)*.

$$NPV = TGV - IC \quad \text{(Eq.1)}$$

where TGV = total gross value total value and IC = input cost. The ICs vary by environmental asset in agriculture and include seeds, fertilizers, water, electricity, tube wells, mechanization, and labor.

Discount rates of 0.74%, 6%, and 11.26% were applied to the NPV for time horizons of 35 (2050), 85 (2080), and 105 (2120) years to predict future NPV values using *Equation (2)*. A regression model with a 95% confidence interval was used to find the demand curve trend between the quantities and the values.

In Pakistan, the average interest/discount rate for 1992–2017 was 11.26% and the current (2016, 2017) discount rate is 6%. A discount rate of 0.74% was chosen as most scholars recommend a low discount rate to enhance intergenerational benefits. The future NPV was calculated using *Equation (2)* (Griffin, 2006).

$$\text{NPV} = \sum_{t=0}^{T} \frac{\text{NBt}}{(1+r)^t} = Co + \frac{\text{NBt1}}{(1+r)^t} + \frac{\text{NBt2}}{(1+r)^t} + \frac{\text{NBt3}}{(1+r)^t} + \quad \text{(Eq.2)}$$

where t = time period (years); T = planning horizon; NB_t = net benefits in period t; and r = discount rate.

The mean, median, standard error, standard deviation, and other statistical parameters were calculated for the NTV (NPV) and the NPV for 35 (2050), 70 (2080), and 100 (2020) year time horizons.

Our NPV was also compared with those from 16 previous similar studies performed worldwide. The studies were identified by searching for the keywords provisioning ecosystem service, valuation ecosystem service, and valuation of natural resources in the EVRI, Science Direct, and PubMed databases. After screening these articles/reports, based on the keywords, 16 were selected for comparison. Many of the studies did not report the total or unit value, so we calculated the values from these articles and converted all results to USD per hectare, which enabled comparison by mean, median, sum, standard deviation (SD), and maximum and minimum values.

Results

Crops

The total area dedicated to crops in Pakistan is 17,769,000 ha, of which Punjab accounts for the greatest portion and Baluchistan the smallest. Cereals make up the greatest area, followed by fodder, whereas pulses, vegetables, and fruits are grown on merely 13% of the total area. During the period 2011–2015, an annual average of 19,392,000 ha was cultivated, with food crops making up the largest area followed by cash crops, whereas pulses and edible oilseeds covered only a small area. The mean was 16% over the five-year period (*Appendix A*). On average, 92,638,000 tons of agriculture commodities were produced annual over the five-year period (2011-2015), of which fodder production was the highest followed by cereals. The average cultivated crop production was 114,353,000 tons, among which food and cash crops contributed the most. In the study period, the lowest and highest production rates were in 2013 and 2014, respectively. Overall, production was highest in Punjab and lowest in Baluchistan (*Figure 2*). The production of crops at spatial scale were found non-significantly different in the provinces in and ANOVA test with F value 2.7766 and P value 0.0751 (at P >0.05), while the production of crop commodities found a significantly different from each other with F value of 523.710 and P value 3.55E-16.

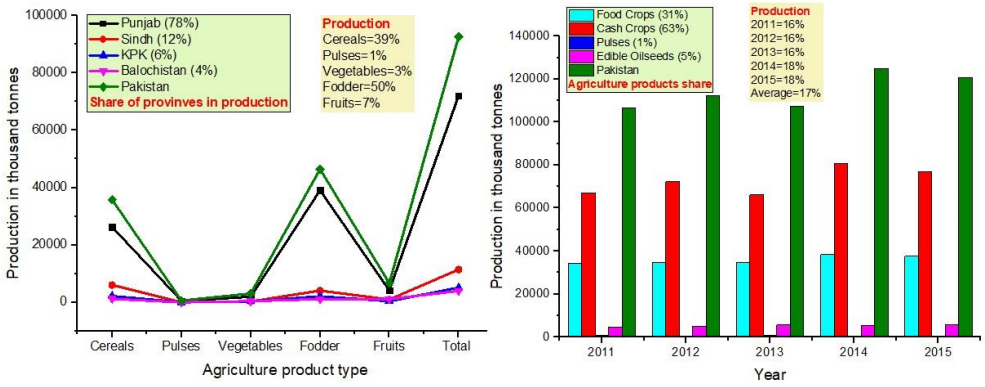

Figure 2. *Agricultural production by province for 2011–2015 (KPK: Khyber Pukhtunkhwa)*

The five-year average TGV, IC, and NPV for major crops and byproducts were 2,454,808, 552,581, and 1,902,227 million PKR, respectively. Wheat had the highest average NPV followed by cotton, while maize was the lowest. Crops had a higher NPV value (86%) than the byproducts (14%). The mean NPVs for the major crops and byproducts for 2011–2015 showed a statistically non-significant difference (p-value = 0.97825). The TGV, IC, and NPV values for minor crops and other agriculture products were found to be 950,199, 121,156 and 829,043 million PKR, respectively, with fruits the highest and pulses the lowest value. The NPV for the given period was found to be highest in 2015 and lowest in 2012, with an overall non-significant difference (p-value = 0.98144) in means (Figure 3). The NPV of the byproducts was 341,295 million PKR in which major crops contributed the more (85%) as compared to the minor crops (15%), over all wheat contributes the highest (55%).

The NPV for crops products consists of the value of the major crops, minor crops and byproducts was estimated to be 2,731,270 million PKR, of which the major crops (62%) and minor crops (28%) contributed more than the byproducts (10%) (*Figure 4*).

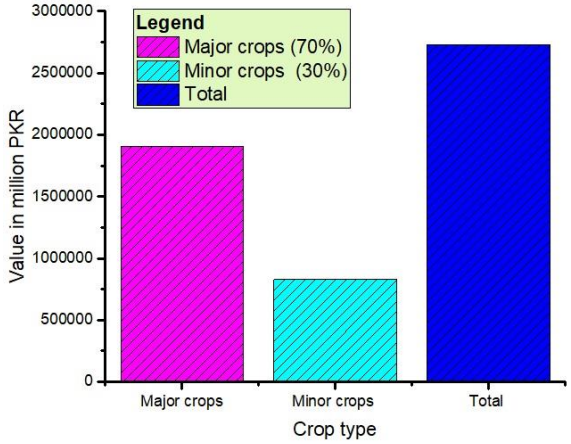

Figure 4. *Total value of agriculture products 2011-2015*

Livestock

The total livestock population was 219,147,000 in 2006, with the highest proportion in Punjab followed by KPK and Sindh. Excluding poultry, goats contributed the most (38%) followed by cattle, buffalo, and sheep. An increasing trend was observed in the number of livestock from 2011 to 2015 (*Figure 5*), but it was not significant with F value 0.0167 and p-value = 0.99904. From the five-year average total milk production, buffalo produced the most followed by cows. The total milk production for the study period tended to increase, although no significant difference (F-value 0.0064, p-value = 0.9991) was found. The five-year average meat production was 3,387,000 tonnes, with beef contributing the most followed by poultry and mutton, and an increasing trend was observed (*Figure 6*) It also showed a non-significantly different value (F-0.0484, p-value 0.9957).

Hide and skin production totaled 65,128,000 with goat the highest, followed by fancy and sheep. Egg, gut, and casings production totaled 80,384,000, of which guts contributed the most and eggs the least (*Appendix B*). Production of skin and hide from different animals showed significantly different values (F-value 1220.864, p-value 4.69E-28). There were 3,228,000 tonnes of other products, with dung, bones, offal, and urine being

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67356759

the main contributions (81%) (*Appendix C*). These products had also significantly different (F-Value 1012.288, p-value 2.84E-44) production for the 5 years' period.

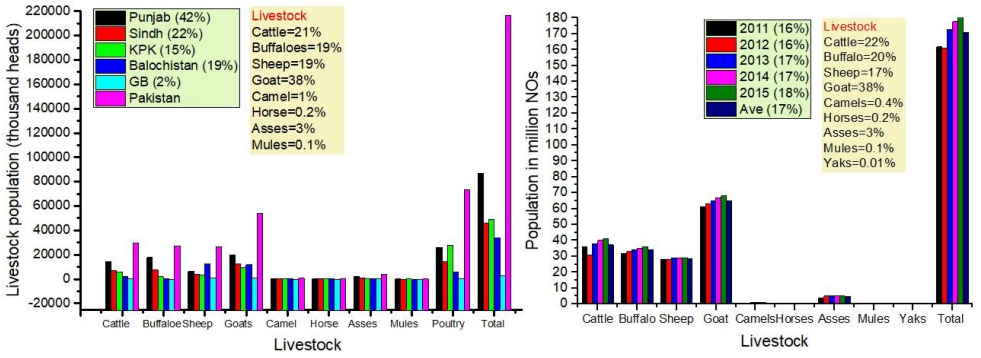

Figure 5. *Livestock type and population*

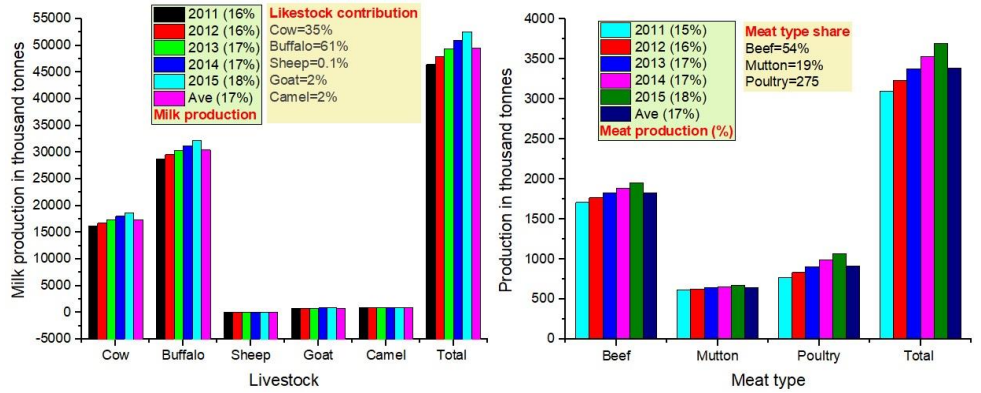

Figure 6. *Milk and meat type and production for 2011–2015*

The five-year average value of livestock was 3,242,691 million PKR, of which livestock products were highest and natural growth and regeneration were lowest. Among the products, the value of milk was the highest while wool and hair contributed the least. The analysis showed an increasing but not significant trend (p-value = 0.99343) (*Figure 7*).

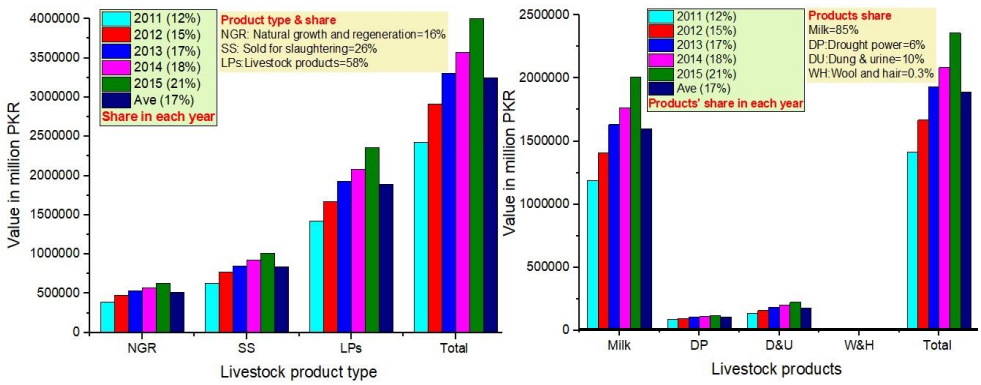

Figure 7. *Livestock product type and value for 2011–2015*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67356759

Similarly, the average value of poultry products was 288,559 million PKR. Farmed chickens contributed the most followed by eggs. The TGV, IC, and NPV were 3,545,051, 634,885 and 2,910,166 million PKR, respectively. Livestock products contributed the most followed by animals sold and slaughtered while poultry products contributed only 8%. Sub-categories showed a generally increasing, but not significant (p-value = 0.945072), trend (*Figure 8*).

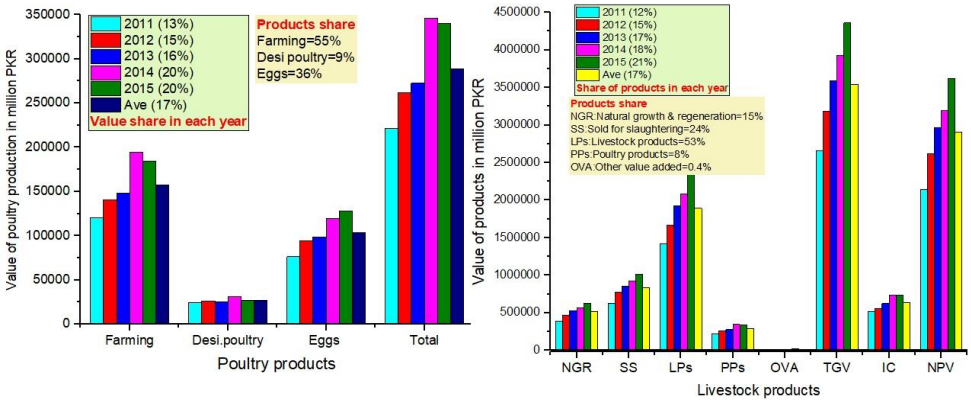

Figure 8. *Value of poultry and overall livestock products for 2011–2015*

Forestry

The total forest cover area in Pakistan is 11,032 thousand hectares, of which 60% and 40% is protected and unprotected, respectively. Punjab and Gilgit-Baltistan have the highest forest coverage (*Appendix D, Fig. 4*). The five-year average major forestry products were estimated to be 462 thousand cubic meters, and there was an increasing trend from 2009 to 2013. Firewood production was higher than timber production. These products had non significantly different values (F-value 2.3566, p-value 0.1632). There were estimated to be 147,478 tonnes of NTFPs, while others were produced in very low quantities. Production levels remained consistent over the study period (*Figure 9*). The five-year mean TGV of the NTFPs was 12,184 million PKR. The NPV was 10,472 million PKR, with medicinal plants contributing the most and vegetables the least. There was an increasing trend in the value of NTFPs from 2011 to 2015 (*Figure 10*).

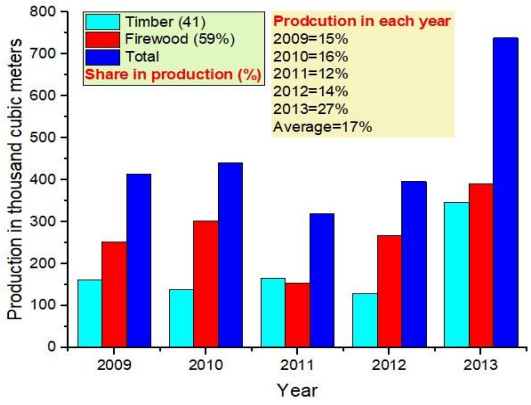

Figure 9. *Major forest products for 2011–2015*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67356759

The five-year mean TGV and NPV of major forest products was estimated to be 1,757 and 1,732 million PKR respectively, in which timber contributed the most as compared to the firewood. An increasing trend in the value of the major forest products was observed from 2011 to 2015; that is, the highest value was in 2015 and the lowest was in 2011 (*Figure 11*). Overall, the NPV of forests was found to be 12,204 million PKR. In which NTFPs products contributed the most, while timber and fuelwood contributed the least. An increasing trend in the value of forestry products was observed from 2011 to 2015 (*Figure 11*).

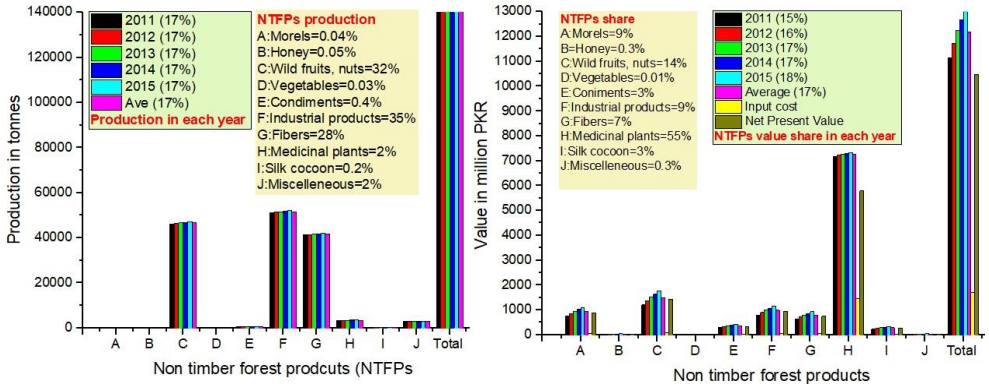

Figure 10. *Minor/Non-timber forest product types and values for 2011–2015*

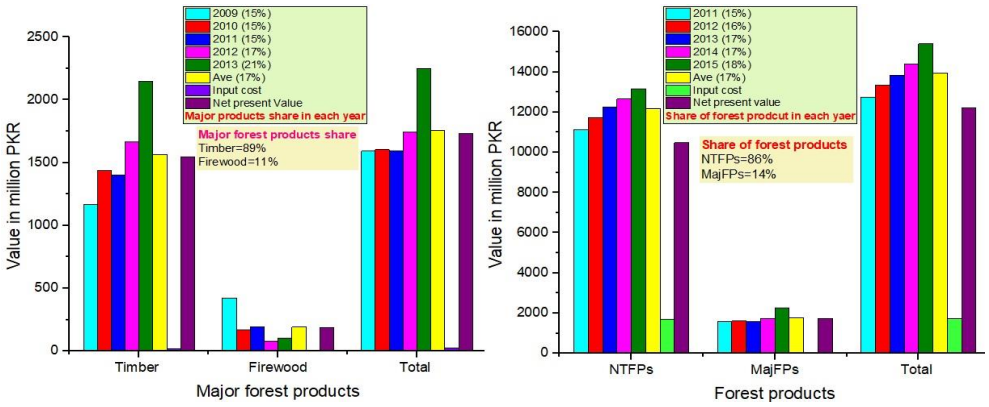

Figure 11. *Value of the major forest products (MajFPs) and net total value of forest products (NTFPs: non timber forest products)*

Fisheries

In Pakistan, the five-year mean total freshwater fish production was 238 thousand tonnes. There was an increasing trend from 2011 to 2015, freshwater fish production was highest in Sindh followed by Punjab, while there was no inland fish production in the Baluchistan province (*Figure 12*). The average annual marine fish production for the five-year period was 492 thousand tonnes, and again an increasing trend for fish production was found from 2011 to 2015. Sindh and Baluchistan were the only marine fish-producing provinces, accounting for 70% and 30% of production, respectively (*Figure 12*). The average total fish production in Pakistan was 730 thousand

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67356759

tonnes per year with an increasing trend from 2011 to 2015. There was an average 67% and 33% of fish production per year from marine and freshwater respectively. Province-wise, fish production was highest in Sindh (66%) followed by Baluchistan (20%), while KPK contributed the least (1%) (*Figure 13*). The spatial distribution of the total fish production was significantly different among the provinces with F-value 17136.97 and P-vale 2.93E-28, while the temporal distribution of the fish production was not different for the period 2010-2015 with F-value 0.000614 and p-value 0.9999.

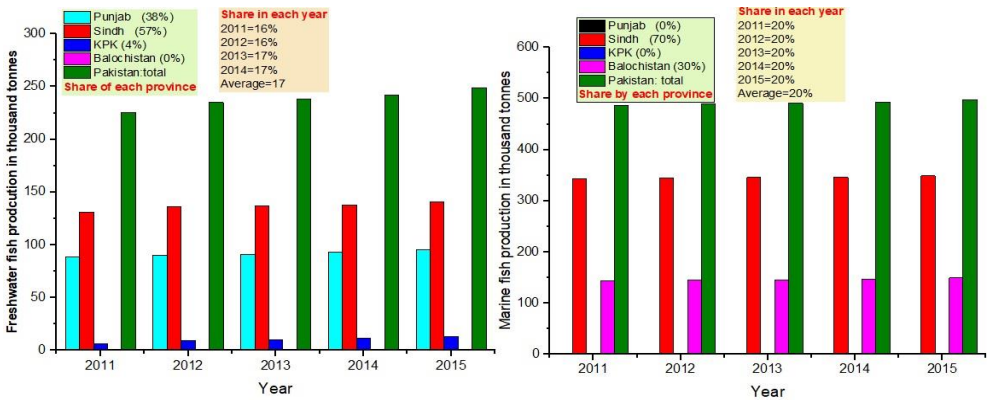

Figure 12. *Freshwater and marine fish production by province for 2011–2015 (KPK: Khyber Pukhtunkhwa)*

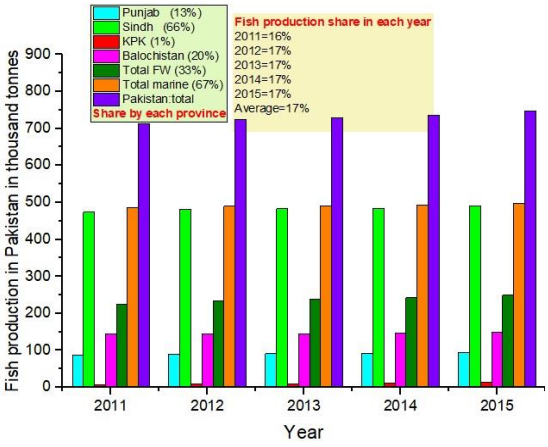

Figure 13. *Total fish production by province for 2011–2015 (KPK: Khyber Pukhtunkhwa, FW: freshwater)*

The five-year average TGV for freshwater fish was 51,755 million PKR, while the NPV was 41,404 million PKR. During the study period, the proportion of the freshwater value ranged from 12% to 21%, with the highest in 2015 and the lowest in 2011. Sindh contributed the most followed by Punjab (*Figure 14*). The average TGV of marine fish for the five-year period was 106,603 million PKR (17%) and the NPV was 85,283 million PKR. The marine fish value was highest in 2015 (20%) and lowest in 2013 (13%). The average NPV for marine fish in Punjab and KPK was zero, while Sindh contributed the most (70%) followed by Baluchistan (30%) (*Figure 14*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67356759

The five-year average TGV of fish production in Pakistan was found to be 158358 million PKR and the NPV was 126686 million PKR. The total market value of fish showed an increasing trend from 2011 to 2015. As a whole, marine fish value contributed higher (67%) than the freshwater fish value (33%). By province, Sindh contributed the most (66%) followed by Punjab (13%), while KPK contributed the least (1%) (*Figure 15*).

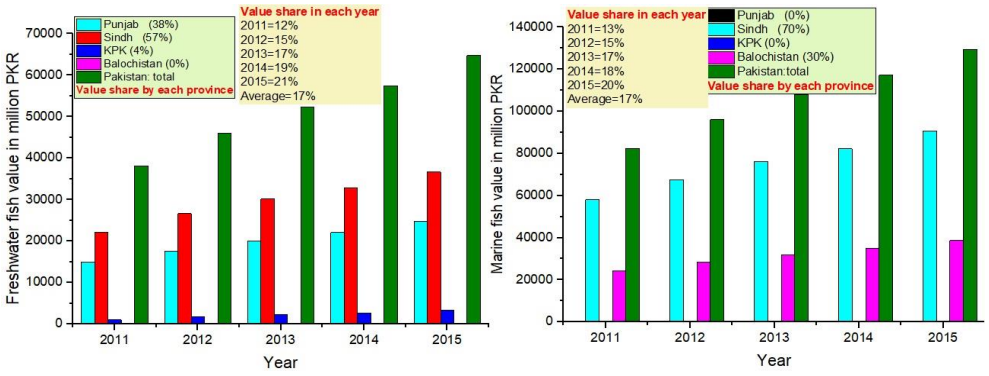

Figure 14. *Value of freshwater and marine fish by province for 2011–2015 (KPK: Khyber Pukhtunkhwa)*

NPV and discounting for Provisioning Ecosystem Services

The mean NPV of provisioning services was estimated to be 5,471,304 million PKR for the period 2011-2015. The NPV for crop, livestock, forest, and fisheries was 2,390,715 (44%), 2,910,166 (53%), 35,105 (1%) and 135,318 (2%), million PKR respectively (*Figure 16*). Discounting rates of 0.74%, 6%, and 11.26% were applied to the NPVs for time horizons of 35, 70 and 105 years. The results clearly show that NPVs decreased with increasing discount rate and increasing time horizon as was expected. Results also shown for mean, SD, minimum and maximum values (*Table 2*).

Comparison with Other Studies

The Prov.ES values obtained in this work were compared with the results from 16 previous studies from around the world. The previous studies showed a sum of 96,985 USD/ha/y, mean 6062, SD 13731, median 666, minimum 7, and maximum 53736 USD/ha/y. While our results showed a value of 569 USD/ha/y, which is very close to the median value of the previous studies (*Figure 17*). Our results were consistent with many of the previous studies (Jenerette et al., 2005; Huxham et al., 2008; Paletto et al., 2008; Häyhä et al., 2015), although some of them presented very high values, ranging from 2,142 to 53,736 USD/ha/y (Chiabai et al., 2008; Wang et al., 2008; Martín-López et al., 2008; Chang et al., 2008; Molnar et al., 2008; Li et al., 2008), while others presented much lower values compared to our results (Fang et al., 2009; Voora and Barg, 2008; Hussain et al., 2008; de Groot et al., 2008; Dupras et al., 2008; Valatin and Starling, 2008).

Discussion

Crops

Agriculture is a dominant land management technique globally, and agricultural ecosystems cover nearly 40% of the terrestrial surface on Earth (FAO, 2015a). In our case study, the products of agricultural ES were evaluated using standard market analysis. Valuing the Prov.ES that are derived from agriculture was relatively straightforward since agricultural commodities are traded in local, regional, or global markets (Power, 2010).

Agriculture is the backbone of Pakistan's economy, contributing 21% to the national GDP, and 43.5% of the labor force is engaged in agriculture (Chandio et al., 2015). Furthermore, it plays a vital role in ensuring food security, generating economic growth, reducing poverty, and the transformation towards industrialization. The major crops cultivated in Pakistan are wheat, rice, cotton, and sugarcane, which attribute for 29% of overall agriculture, while minor crops, e.g. oilseeds, potato and pulses, contribute 6% of GDP (PBS, 2015).

Owing to the demand from the increasing human and livestock populations, fodder is grown in large parts of the country, followed by cereal crops. These provide the basic requirements of humans and livestock. Cereal production requires a lot of resources and labor while fodder crops can be grown with little effort as compared to the food crops. Secondly, the demand for food of livestock is high, which is why in Pakistan fodder crops had the highest production followed by cereals, while the production of fruits, vegetables, and pulses is relatively low. Punjab had the highest production of crops, followed by Sindh, KPK, and Baluchistan, mainly because Punjab covers a larger area than the other provinces. Cash crops showed the highest production, followed by food crops, while edible oil seeds and pulses were produced at low levels because people prefer to grow crops that are more profitable. Statistically a non-significant increasing trend of agriculture production was observed from 2011 to 2015 because people have realized that they need to produce more to meet the demand from the increasing population.

Overall, in the agriculture sector, major crops contributed the most to NPV, followed by minor crops. There was a non-significantly increasing trend for both the major crop and overall NPV of agriculture products. This is because of the higher demand for the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67356759

major crops as compared to the minor crops, and secondly, in most parts of the country, the climatic conditions are more suitable for the major crops than the minor crops.

The agriculture sector showed positive growth of 2.9% in 2015 compared to the previous years (2013 and 2014) (GoP, 2014). This is because of the improvement in the agricultural practices in Pakistan. The production of the agriculture commodities found significantly different from each other. In the agriculture sector, wheat was found to contribute the most served in the income followed by cotton, while other crops such as rice, sugarcane, and maize contributed very little. This is because Pakistan has favorable climatic and soil conditions for wheat growth and secondly the demand for wheat consumption is much higher than that for other crops because wheat foods are popular among the Pakistani people owing to their nutritional value; wheat is served in all three daily meals. It is grown in all the provinces and across a wide range of altitudes. Pakistan ranks fourth and third worldwide among cotton-growing and -consuming countries (PBS, 2015) because the climatic and edaphic conditions in Pakistan are suitable for growing cotton. The other crops include bajra, jowar, gram, barley, rapeseed and mustard, and tobacco. Pulses include masoor, mong, chana, and mash. Besides these, potatoes, onions and chilies are also grown to meet the requirements of the country at the local level.

Agricultural crops are not only important for their value as food for human beings, but also as a source of food for livestock. In many developing countries, some crops, such as maize, wheat, sorghum, and millet, are dual purpose: their grain provides food for humans and their residues are used as feed for livestock. In mixed crop–livestock systems, the value of the crop residues is sometimes as much as that of the grain itself owing to the importance of the residue as a feed for livestock, particularly in the dry season. In mixed agriculture systems, there are always tradeoffs; for example, people obtain milk products from the buffaloes and cows while and at the same time achieving high grain production by manuring their fields using cow or buffalo wastes.

This has increased the demand for dual-purpose crops with relatively high-quality crop residues, and burgeoning fodder markets have developed around cities such as Hyderabad in India (Blummel and Rao, 2006). The cropping–livestock mixed farming system is considered to be more beneficial than a single system. Mixed agro-pastoral systems produce close to 50% of the world's cereals and most of the staples consumed by poor people (Herrero et al., 2010). Depending on their structure and management, agroecosystems also contribute a number of other globally important ecosystem services (MEA, 2005a), such as supporting biodiversity and enhancing carbon sequestration (Power, 2010).

Livestock

Livestock production makes a large contribution to the GDP of developing countries. It is an essential activity that contributes multiple services, such as fertility of land, maintenance of biodiversity, food security, and cultural and rural vitality (Ryschawy et al., 2017). Sustainable farming based on environmental conditions is essential for the livelihood of people in developing counties (Herrero et al., 2009). Livestock contributed 11.8% of the country's GDP and 56.3% of the agriculture sector share of GDP in Pakistan (PBS, 2015). In the livestock sector, the average number of animals was 285 million with a non-significantly increasing trend during the period 2011-2015, of which goat contributed the most followed by cattle, buffalo, and sheep. People prefer to keep goats because they are easily handled and provide manifold benefits compared to other livestock. Goats provide meat, milk, hair, and manure. Most people in Pakistan prefer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67356759

goat meat to fulfil their protein requirements that is also expensive in the market as compared to lamb and beef. People prefer to rear livestock that provide multiple benefits over livestock that provide only one benefit and are expensive to keep, such as asses, poultry, camels, horses, mules, and yaks. Punjab province has the highest population of livestock. Punjab is the most populated province so has more livestock. Milk production from buffaloes was highest followed by cows because these animals are large so produce more milk than smaller animals. In meat production, beef contributed the most followed by poultry and mutton owing to the size and number of animals. The production of livestock product was found non-significantly increasing from 2011-2015, while the production of skin, hide and other products from different animals was found significantly different. The average NPV for livestock was in a non-significantly increasing trend over the five years studied. Livestock-products contributed more to the NPV compared to animals slaughtered or kept live. Overall, milk was the dominant livestock product because people use milk on a daily basis and thus prefer to keep livestock that produce milk. Milk is used for various purposes, such as making tea, yogurt, lassy, and cheese, while meat is used less frequently, which is why milk makes a bigger contribution to NPV compared to the other products.

The economic benefits obtained from livestock are greater than those from the agricultural cropping system. Agro-pastoral and pastoral systems cover 45% of Earth's usable surface (Reid et al., 2008) and supply 24% of global meat production (Steinfeld et al., 2006). Projections show that in the next three decades 30% more grass will be required to meet the global demand for meat and milk and that improved management and use of fertilizers in parts of the world will be necessary to meet this increased demand (Herrero et al., 2009). Mixed agro-pastoral systems generate the bulk of livestock products in the developing world, that is, 75% of the milk and 60% of the meat, and employ many millions of people in farms, formal and informal markets, processing plants, and other parts of long value chains (Herrero et al., 2010).

Forestry

Forests play a significant role in any country's wellbeing and economy (Economics for the Environment, 2011). According to the FAO, the area coverage of the world's forests was 3,999 million ha in 2015, a decrease from 4,128 ha in 1990; forestry cover fell from 31.6% to 30.6% during this period. This change resulted from an increasing deforestation trend, especially in developing countries (FAO-UN, 2016b). Forest components, such as timber, fuelwood, and NTFPs, are important to the livelihood of people in developing counties (TEEB, 2009). In Pakistan, there are more protected forests than unprotected forests. Punjab and Gilgit-Baltistan have the biggest share of the total forest area followed by KPK. A non-significantly increasing trend in the production of major forest products was observed owing to increased plantation sizes in some parts, especially in KPK. Fuelwood production was greater than timber production. More NTFPs, including industrial products, wild fruits and nuts, and fibers, were produced than other NTFPs, such as medicinal plants, condiments, silk cocoons, honey, morels, and vegetables. In the NTV of forest products, NTFPs contribute the biggest share while other products, like timber and fuelwood, contributed very little to the NPV. There was an increasing trend of the NPV over the five-year period, because of the increased production and increasing market value each year. Timber made a higher contribution to the NPV than fuelwood because of its greater market value. Among the NTFPs, the medicinal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67356759

plants' share of the NPV was much higher than for the other products. In addition, forest departments earn a substantial amount of revenue from forests.

Most of the population of Pakistan lives in rural areas, depending on natural resources for their livelihoods. In addition, there are many industries that depend on forest products, such as timber, processed wood and paper, rubber, and fruits. Forests provide essential services for rural agricultural communities, such as fuel, fodder, game, fruits, building materials, medicines, and herbs. A large number of livestock in rural communities, as well as wildlife, also depend on the forest ecosystem for their survival. Forests are blessings that help humans in many ways both in good times and in times of difficulty (Mitchell et al., 2014).

NTFPs play a very important role in the livelihoods of the people in the study area. They are a source of income for poor rural population (Ingram and Bongers, 2009) and provide job opportunities and sources of livelihood to a large number of people (Pandey et al., 2016). In addition, NTFPs are also an important source of foreign exchange; morels, for example, are exported entirely by local grocers (Wahlén, 2017). Honey production from beekeeping is an important source of income as well as being nutritious and having medical applications. In Pakistan, around 15,000 people are involved in beekeeping. Good quality honey production can be increased by modern beekeeping techniques with the introduction of European bees. Other wild NTFPs, including wild fruits, nuts, vegetables, condiments, wild pomegranate seeds, and caraway, are produced in small quantities and consumed locally (FAO, 2015b).

Pakistan has a diverse environment and hosts a large variety of medicinal plants. These medicinal plants are used locally for the treatment of various diseases as well as being sold commercially. Pakistan is gifted with tremendous natural resources and plants have long been used to cure different human and animal diseases (Shedayi et al., 2014, 2016). Thanks to their life-saving properties, medicinal plants are the most expensive among the NTFPs, and they contribute the biggest share of income. Industrial products, such as resin, vegetable tanning, bhabar grass, Sabai grass, babul bark, dwarf palm leaves (Mazri), and silk cocoons, are collected and used in various large and small industries for the synthesis of a range of products (FAO, 1994).

Conservation of forests is important not only because they provide provisioning services to the locals but also for the sociocultural and regulating services they provide to a wide range of people. Developmental activities have both merits and demerits for forest ecosystems; for example, road construction provides easy access to tourists, but it destroys the forests and their natural systems.

Fisheries

According to the Food and Agriculture Organization of the United Nations, feeding more than 9.7 billion people by 2050 the context of climate change impacts, financial uncertainty, and growing competition for food owing to an exponential population growth trend, especially in developing countries, is one of the greatest challenges to face. The annual per capita fish consumption has grown from 5.2 kg in 1961 to 18.8 kg in 2013 in developing countries, while it has increased from 3.5 to 7.6 kg in low-income countries (FAO-UN, 2016a). Pakistan has an arid climate, but it has great potential for small-scale inland fish farming for local consumption as well for earning foreign exchange through exports (Nazir et al., 2016). The long coastline of 1,050 km in Pakistan provides the best opportunity for marine fishing in an area of approximately 300,270 sq. km. Pakistan's fishing grounds are highly rich in marine life with a vast variety of species having

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67356759

commercial value, both for domestic consumption as well as for export. More than one million people depend on the fisheries profession, and they are mainly settled in villages along the coastline (Nazir et al., 2015).

Spatial distribution of fish production was found significantly different among the provinces, while there was a non-significantly increasing trend of fish production at temporal scale. The fisheries and fishing industry are growing in Pakistan, both inland and marine. Marine fish contributes more to the NPV compared to freshwater fish farming. Most fish production is found in the Sindh province, followed by Punjab and Baluchistan. There was an increasing trend over the five-year period of study with an average of 30% in this period because the demand for food increases with increasing population size. The population of Pakistan is increasing with an annual growth rate of 2.6% (Raza and Siddiqui, 2014). There are 760 fish species in total across fresh and marine waters, of which 200 species are economically important; approximately 71% of the fish production in Pakistan is exported (Nazir et al., 2015). Pakistan's contribution to world fish production is 0.30%, which is the lowest in the world market and can be improved by adopting modern techniques (FAO- Fisheries and Aquaculture Department, 2017).

The average annual catch was almost 600,000 tonnes (Nazir et al., 2015) of which most are exported, as noted earlier. Besides exporting fish products, fish is an important source of food for the people of Pakistan, especially those living in Sindh. Seafood is also exported to other provinces, such as from Karachi to Punjab and KPK.

The seafood export rate in Pakistan increased by 49.82 million USD in 2013–2014 as compared to 2012–2013 (Shah et al., 2018) an estimated increase of 12.25% in term of quantity (Nazir et al., 2015). Pakistan exports 60 million seafood products to China and Vietnam. Other markets for Pakistani seafood include Thailand, Saudi Arabia, Malaysia, Bangladesh, Egypt, Hong Kong, Japan, Kuwait, South Korea, and the UAE. (Nazir et al., 2015). Pakistan has a good market for fish products. Inland fish farming is increasing in many provinces to fulfil the demand for protein. The majority of marine fish production is exported to other countries for income generation, and production and export can be increased further by using the latest equipment and techniques.

Climate change and discounting

The world is facing impacts from climate change in the form of global warming, floods, rising sea levels, and drought. Poor people, who depend on natural resources for their livelihood, suffer the most from climate change. Climate change is predicted to have a severe impact on natural resources in the future. This will disturb the processes, functions, and services of ecosystems (Soudzilovskaia et al., 2013). It is important to include climate change impacts in policymaking frameworks (Hermwille et al., 2017). It is thus necessary to estimate the future values for ecosystem services based on current NPVs by employing discount rates on different time horizons. We, therefore, applied three different discount rates (0.74%, 6%, and 11.26%) on three time horizons (2050, 2085, and 2120). With the increasing discount rates and time horizons, the values decreased accordingly. These estimated NPVs for the different time horizons and discount rates will help policymaking bodies, conservation organizations, and researchers assess the impacts of climate change. Discounting is important for the sustainable use of natural resources and development (Gowdy et al., 2010).

Comparison with other studies

Our results were consistent with those of some previous studies, especially with those focused on food (meat and fisheries), wood (timber and fuelwood), and water for irrigation, similar to how we focused on food (agriculture, fisheries, and livestock), wood (timber and fuelwood), and medicinal plants. Those studies that showed high values of provisioning ES, focused on wetland production, freshwater for drinking, and agriculture products. The studies that reported low values of provisioning ES had focused on hydropower, irrigation, and food provision. The variation in the values of providing ecosystem services is attributed to the geographic, ecological, and climatic factors, which vary from country to country. Our results for the provisioning ecosystem services showed reasonable homogeneity with the results of other studies. However, the previous studies did not link Prov.ES to poverty and food, water, and energy security. In addition, policy recommendations were merely discussed and highlighted. We recommend conducting studies linking Prov.ES with poverty reduction, focusing on major drivers of the services.

Conclusions

Provisioning services provide tremendous benefits to people's livelihoods, including food, water, fiber, medicine, energy, and many others. These services are directly taken from nature in various forms, via crops, vegetables, fruits, livestock, forests, and fisheries. More than 60% of the population of Pakistan lives in rural areas, where people depend on natural resources to fulfil their living requirements. Pakistan's natural resources are being depleted by overexploitation, impacts of climate change, and poor management systems. Among the provisioning services, livestock's contribution was the highest followed by agricultural products, while fisheries and forests contributed the least. This situation is alarming for the forestry sector: only 4% of the total land area of Pakistan is covered by forests, which is why its contribution as a provisioning ecosystem services is very low. Poor forest cover leads to other environmental consequences, such as floods and landslides, which cause major destruction and loss to infrastructure, crops, livestock, and human lives, resulting in mass migration to other areas from 2003 to 2014. Livestock is the major contributor in the ecosystem services, but livestock depend on other ecosystems, such as grassland, forests, and agriculture. Forests also provide habitats for many of the rare, threatened, and endangered species in Pakistan. The rapidly accelerating rate of forest depletion is leading to the extinction of some animals from the wild while others have migrated to more suitable areas in neighboring countries. Forests, peatlands, and pastures act as carbon sinks. Land use degradation causes carbon release into the atmosphere, adding to the global atmospheric carbon, which is the main cause of climate change and global warming. All ecosystem services are interlinked with several tradeoffs. Being an agricultural country, Pakistan needs to improve its agricultural system as most of the people in urban and rural areas depend on agricultural products, while a mixed agriculture system is practiced in most parts of the country. Pakistan needs to enhance the quantity and quality of its crop production for both domestic consumption and exporting as a source of income generation. Sustainable agro-forestry and agro-pastoral systems are suitable for Pakistan with the introduction of the latest technology and biological control methods, instead of traditional farming or high doses of synthetic fertilizers. Pakistan has the potential to increase its fish production for domestic and export purposes by improving management systems and reducing freshwater and marine pollution. It is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_67356759

suggested that policies relating to Prov.ES should be reframed for better management, conservation, and utilization purposes. Funds need to be allocated to the research sector, especially universities, to frame policies based on research and on-the-ground realities, keeping the consequences of depleting natural resources in focus in the future.
