Abstract. Aluminum (Al) toxicity is an important cause of forest degradation. Al phytotoxicity is closely related to its chemical forms in soils. In this study, the effects of different mixed planting patterns of Chinese fir (*Cunninghamia lanceolata*) on four chemical forms of Al in soils were examined. One-year-old seedlings of *C. lanceolata, Michelia macclurei* and *Schima superba* were used. The results showed that the content of exchangeable Al and monomer hydroxy Al decreased by 2.3–8.1% and 2.6–14.2% in soil of mixed plantation of *C. lanceolata* with *M. macclurei*, whereas they decreased by 6.6–6.9% and 7.2–7.3% in bulk soil of *C. lanceolata* mixed with *S. superba*. The content of acid-soluble inorganic Al in soil of mixed plantation of *C. lanceolata* also indicated a decreasing tendency, whereas the content of humic acid Al indicated an increasing tendency. Meanwhile, soil pH indicated an increasing tendency and had a negative correlation with all chemical forms of Al in soil. These results indicated that mixed planting patterns of *C. lanceolata* could reduce active Al in soil and would be an alternative alleviation method to control the harmful effects of Al on *C. lanceolata* forest.
Keywords: *Cunninghamia lanceolata*, *exchangeable Al, monomer hydroxy Al, acid-soluble inorganic Al, humic acid Al*

Introduction

Aluminum (Al) in soil is one of the toxic metals to plants, especially for plants growth in acid soil (Kochian et al., 2015). Al can be absorbed by plants, although it is not a nutrient element (Arunakumara et al., 2013). Al in plant cells would be combined with cell pectin, membrane components, proteins, and nucleic acids (Matsumoto, 1988; Jones and Kochian, 1997; Tabuchi et al., 2001; Arunakumara et al., 2013; Shahnawaz et al., 2016), and thus it can influence the growth, cell membrane integrity, photosynthesis, nitrogen metabolism, nutrient uptake, and deoxyribonucleic acid (DNA) fragmentation (Prabagar et al., 2011; Ribeiro et al., 2013; Cruz et al., 2014; Yang et al., 2015; Anjum et al., 2016; Vardar et al., 2016; Awasthi et al., 2017). The potential toxicity of active Al in the terrestrial ecosystem was a major factor leading to the forest degradation overspreading across Central Europe in the 1970s (Ulrich et al., 1980).

However, phytotoxicity of soil Al does not depend on the total content of Al in soil but on its chemical forms (Shahnawaz et al., 2016). In fact, Al is the most abundant metal present in the Earth's crust (Arunakumara et al., 2013). It exists in many different forms in soil such as Al^{3+}, $Al(OH)^{2+}$, $Al(OH)_2^{+}$, $Al(OH)_3$, Al-OH polymer, Al-F complex, Al-SO_4 complex, phosphate, organic species, carbonate species, and oxide species (Wang et al., 2007; Zhou et al., 2011; Shahnawaz et al., 2016). Al toxicity to plants varies according to different chemical forms. Al in insoluble form is nonphytotoxic whereas Al^{3+}, $Al(OH)^{2+}$, and $Al(OH)_2^{+}$ are considered as the most toxic forms in soil and named

DOI: http://dx.doi.org/10.15666/aeer/1703_53415353

active Al (Zhou et al., 2011; Shahnawaz et al., 2016). The distribution of Al forms in the soil can be influenced by many factors including soil pH, soil types, predominant clay mineral, organic matter, organic acid, and plant species (Xu and Zhang, 2017). Therefore, many alleviating methods for Al toxicity are associated with the above-mentioned factors. Controlling soil acidity is one of the most common methods to alleviate Al toxicity, because Al forms are found to be dependent on soil pH. Under acidic conditions, Al can be solubilized into more toxic forms. The addition of alkali materials such as calcium carbonate, magnesium limestone, and calcium silicate could increase soil pH and reduce the stress effects of Al on plants (Cristancho et al., 2011; Elisa et al., 2016). Addition of organic materials and mineral ions are also alternative options (Muhrizal et al., 2003; Yang et al., 2009; Iqbal, 2014; Liu et al., 2014). For forest plants, a mixed species plantation might be an effective ecological method to alleviate Al toxicity. However, only a few cases have been reported until now (Li et al., 2008; Lei et al., 2014).

Chinese fir (*Cunninghamia lanceolata*) is one of the most important timber tree species in Southern China where the soil is acidic and ferrallitic. Increasing soil acidification caused by acid rain and the continuous planting of *C. lanceolata* will inevitably lead to Al toxicity in *C. lanceolata* (Liu et al., 2014), which may be closely related to its chemical forms in soil. A mixed plantation of *C. lanceolata* with other forest species has been confirmed to have promoting effects on phosphorus nutrition, microbial community, chemical properties, and carbon storages in soil (Zou et al., 1995; Liu et al., 2010; Richards et al., 2010; Wang et al., 2010). However, little is known about the changes in Al chemical forms. The aim of this study is to examine the effects of different mixed planting patterns of *C. lanceolata* on the chemical forms of Al in soils including exchangeable Al, monomer hydroxy Al, acid-soluble inorganic Al, and humic acid Al in both the rhizosphere and bulk soils. One-year-old seedlings of *C. lanceolata* were used, and the mixed plantation of *C. lanceolata* with both *Michelia macclurei* and *Schima superba* in high planting density was carried out.

Materials and methods

Study area

The experiment was performed in the Experimental Station of Forest located at a hillside of the campus of Fujian Agriculture and Forestry University, in Fujian Province, China (119°14′ N and 26°05′ E) where has subtropical monsoon climate with an annual average temperature of 15-20°C and an average annual rainfall of 900-2100 mm. The experiment started on May 8, 2014 when it was spring.

Soil for this study was a kind of acid red soil (based on Chinese Soil Taxonomy). The clay mineral composition was characterized by kaolinite with gibbsite and ferric oxide. The soil was taken from the same site of the Experimental Station of Forest. There were no trees except some natural herbs in this chosen area. Only the soil down to a depth of 1-2 m was collected in order to avoid any previous plant residues. Soil properties were examined before the onset of our experiment. The results are presented in *Table 1*.

Table 1. *Properties of the soil used in this experiment*

Mixed plantation

One-year-old seedlings of *C. lanceolata*, *M. Macclurei*, and *S. superba* were used as plant materials. Seedlings were planted in pots (length × width × height = 1 m × 1 m × 0.8 m) (*Fig. 1*). The pots were made of concrete and filled with soils mentioned in the above "Soil" section. Five different planting patterns including pure *C. lanceolata*, pure *M. macclurei*, pure *S. superba*, *C. lanceolata* in mixture with *M. macclurei* (1:1) and *C. lanceolata* in mixture with *S. superba* (1:1) were compared. For each planting patterns, there were four replicates (one pot per replicate). For each replicate, there were 16 seedlings for pure planting patterns and 8:8 seedlings for mixed planting patterns, respectively (*Table 2*). Seedling to seedling distance was 20 cm. All seedlings was watered regularly using tap water to avoid the pot soil too dry. The watering requency differed in different seasons (once per day in spring and autumn, once two days in winter, twice per day in summer). Four seedlings (2:2 for mixed planting patterns) were uprooted together with surrounding soil to the depth of 50 cm by using a plastic tube (15 cm in diameter for 6 months seedlings or 20 cm in diameter for 18 months seedlings) with sharp edge after 6 and 18 months, respectively. The uprooted soils were separated into rhizosphere and bulk soil. The rhizosphere soil was collected by gently shaking the plant roots and carefully removing the soil adhering to them. The rest soil was considered as bulk soil. Both rhizosphere and bulk soils were air-dried, passed through 2-mm sieve after removing visible plant material for further analyses.

Determination of Al chemical forms and pH in soil

Chemical forms of Al in soils were extracted using continuous extraction methods (Huang and Qu, 1996; Zhou et al., 2011). Al in each fraction was determined by an auto discrete analyzer (SmartChem 200, WestCo Scientific Instruments Inc., and Italy).

Exchangeable Al: 1 mol L^{-1} KCl was used to extract exchangeable Al (mainly Al^{3+}).

Monomer hydroxy Al: 1 mol L^{-1} CH_3COONH_4 was used to extract monomer hydroxy Al (mainly $Al(OH)^{2+}$ and $Al(OH)_2^{+}$).

Acid-soluble inorganic Al: 1 mol L^{-1} HCl was used to extract acid-soluble inorganic Al (mainly $Al(OH)_3$).

Humic acid Al: 0.5 mol L^{-1} NaOH was used to extract humic acid Al (mainly humic acid bound Al).

Soil pH was measured in 1 mol L^{-1} KCl (1:2.5, w:v) using an PHS—3C pH meter (Shanghai INESA Scientific Instrument Co., Ltd, China).

Statistical analysis

Initial data were analyzed using Microsoft Excel. Values were represented as the means of four replicates (Mean ± SD) for each treatment. The relationship between soil pH and chemical forms of Al in soil was also analyzed using linear regression in Microsoft Excel. Differences between different treatments were statistically calculated using method of Tukey for analysis of variance (ANOVA) in SPSS 13.0. The data were considered to be significantly different at $P < 0.05$.

Results

Content of exchangeable Al

As presented in *Fig. 2*, the content of exchangeable Al deceased by 2.3–3.0% in rhizosphere soil and 7.3–8.1% ($P < 0.01$ for 6 months and $P < 0.05$ for 18 months) in bulk soil of mixed plantation of *C. lanceolata* with *M. macclurei* when compared to that of pure *C. lanceolata* plantation. The content of exchangeable Al increased by 2.1–5.4% in rhizosphere soil whereas it decreased by 6.6–6.9% ($P < 0.01$ for 6 months) in bulk soil of mixed plantation of *C. lanceolata* with *S. superba*.

As showed in *Table 3*, the content of exchangeable Al increased in rhizosphere soil but decreased in bulk soils of *M. macclurei* after mixed plantation. The soil exchangeable Al reduced in both rhizosphere and buck soils of *S. superba*, and the changes were significant for the 6-month treatment.

Table 3. *Changes in content of exchangeable Al in soils of M. macclurei and S. superba after mixed plantation with C. lanceolata (Mean + SD, n = 4 for all the treatments)*

Planting patterns	Rhizosphere soil (mg/kg)		Bulk soil (mg/kg)

Content of monomer hydroxy Al

Content of monomer hydroxy Al (*Fig. 3*) in rhizosphere soil of mixed plantation of *C. lanceolata* with *M. macclurei* was 13.1–14.2% ($p < 0.01$ for 18 months) less than that of pure *C. lanceolata* plantation whereas the value in bulk soil was 2.6–12.4% ($P < 0.01$ for 18 months). The content of monomer hydroxy Al in bulk soil of mixed plantation of *C. lanceolata* with *S. superba* was 7.2–7.3% ($P < 0.05$ for 18 months) less than that of pure *C. lanceolata* plantation whereas its changing trend in the rhizosphere soil was inconsistent between 6 and 18 months treatments.

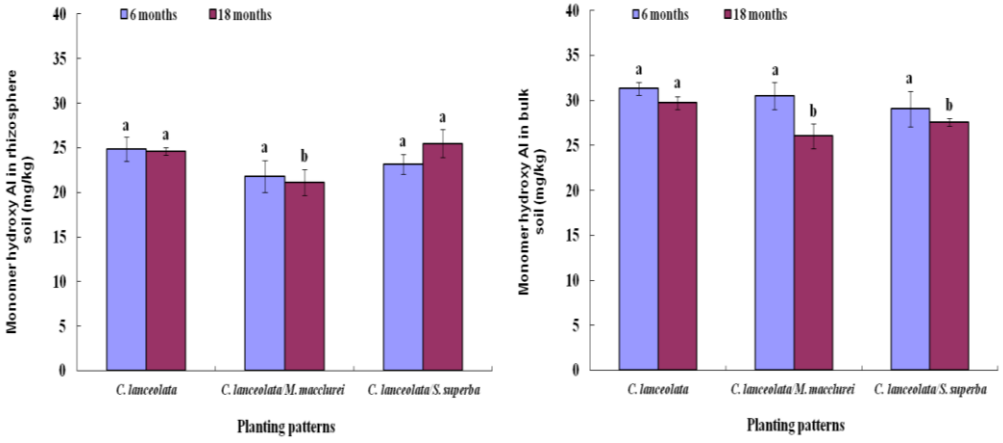

Figure 3. *Effect of the mixed plantation on the content of monomer hydroxy Al in both rhizosphere and bulk soils. Error bars are standard errors of the mean (n = 4 for all the treatments). Significant differences between pure C. lanceolata and its mixed plantation are marked by different letters*

The data of the effects of mixed plantation on *M. macclure*i and *S. superba* soils showed that the content of monomer hydroxy Al in both rhizosphere and bulk soils (*Table 4*) of *M. macclurei* in mixture *with C. lanceolata* and *S. superba* in mixture with

Different letters indicate significant differences at $P < 0.05$ between pure plantation and its mixed plantation as determined by the method of Tukey test

Content of acid-soluble inorganic Al

Content of acid-soluble inorganic Al (*Fig. 4*) in rhizosphere soil of mixed plantation of *C. lanceolata* with *M. macclurei* was 6.5–9.9% less than that of pure *C. lanceolata* plantation whereas it increased slightly in the bulk soil. The content of acid-soluble inorganic Al in rhizosphere soil of mixed plantation of *C. lanceolata* with *S. superba* was 6.2–9.6% less than that of pure *C. lanceolata* plantation whereas the value in bulk soil was 2.5–7.0%. The statistic analysis did not show that all of the above changes in the content of acid-soluble inorganic Al after mixed plantation were significant.

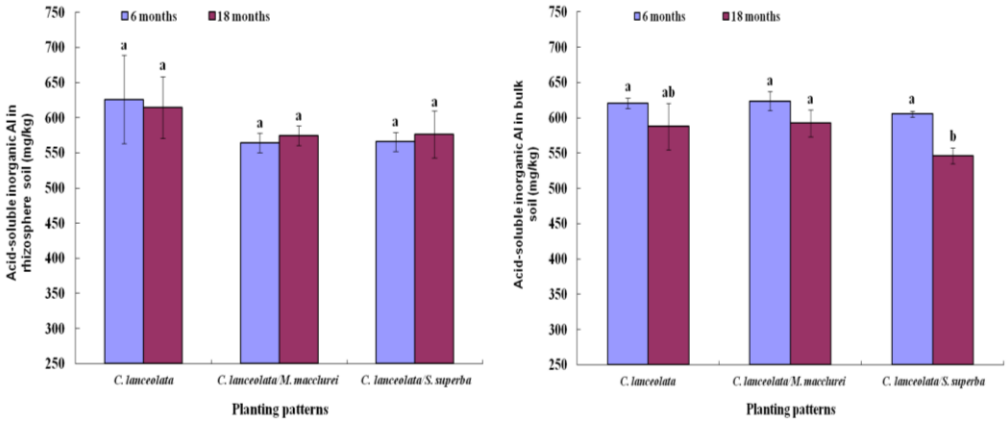

Figure 4. *Effect of the mixed plantation on the content of acid-soluble inorganic Al in both rhizosphere and bulk soils. Error bars were standard errors of the mean (n = 4 for all the treatments). Significant differences between pure C. lanceolata and its mixed plantation are marked by different letters*

Content of acid-soluble inorganic Al in rhizosphere soil of both *M. macclurei* and *S. superba* increased after mixed plantation (*Table 5*). But the changes were not significant. In contrast, the content of acid-soluble inorganic Al in bulk soil was significantly reduced after a 6-month treatment.

Different letters indicate significant differences at $P< 0.05$ between pure plantation and its mixed plantation as determined by the method of Tukey test

Content of humic acid Al

Content of humic acid Al (*Fig. 5*) in rhizosphere and bulk soils of mixed plantation of *C. lanceolata* with *S. superba* increased by 5.4–9.9% and 5.4–6.2% ($P < 0.01$ for bulk soil after 6 months) when compared to that of pure *C. lanceolata* plantation. For mixed plantation of *C. lanceolata* with *M. macclurei*, the content of humic acid Al had an increase of 0.8–3.4% in rhizosphere soil and a decrease of 0.7–3.5% in bulk soil, but the above changes were not significant.

For both *M. macclurei* and *S. superba*, the content of humic acid Al increased after mixed plantation (*Table 6*). The changes were significante in rhizosphere soil except 18 month treatment of *M. macclurei*.

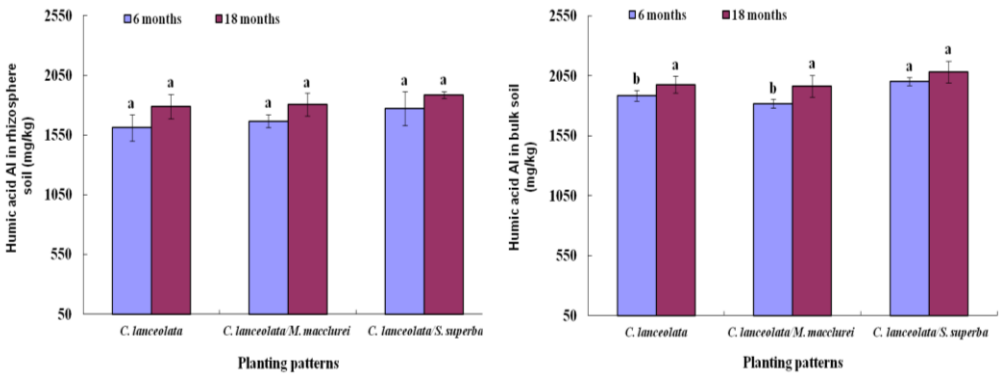

Figure 5. *Effect of the mixed plantation on the content of humic acid Al in both rhizosphere and bulk soils. Error bars are standard errors of the mean (n = 4 for all the treatments). Significant differences between pure C. lanceolata and its mixed plantation are marked by different letters*

Table 6. *Changes in content of humic acid Al in soils of M. macclurei and S. superba after mixed plantation with C. lanceolata (Mean + SD, n = 4 for all the treatments)*

DOI: http://dx.doi.org/10.15666/aeer/1703_53415353

Soil pH

The changed in soil pH was also observed after mixed plantation (*Fig. 6*). There was an increase in pH in both rhizosphere ($P < 0.05$) and bulk soils ($P < 0.05$ after 6 months) of the mixed plantation of *C. lanceolata* with *M. macclurei* when compared to that of pure *C. lanceolata* plantation. For mixed plantation of *C. lanceolata* with *S. superba*, only bulk soil pH showed a significant increase ($P < 0.05$). *Table 7* shows the relationship between soil pH and four chemical forms of Al in soil of *C. lanceolata*. We found that soil pH had a negative correlation with exchangeable Al and monomer hydroxy Al, but the correlation was not significant. There was also a negative correlation between soil pH and both exchangeable Al and humic acid Al in soils of *M. macclurei* and *S. superba* plantation which were used as mixed species with *C. lanceolata* (*Table 8*). The the correlation between soil pH and exchangeable Al in soil was significant at 0.01 level.

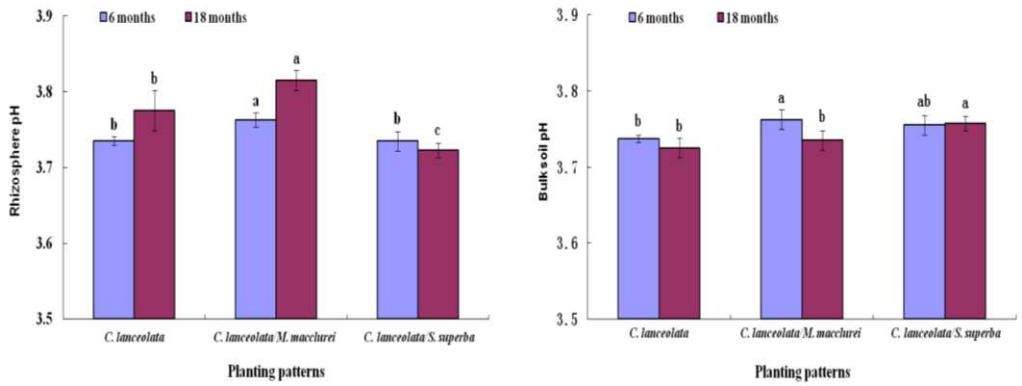

Figure 6. *Effect of different mixed planting patterns of C. lanceolata on soil pH. (a) Rhizosphere soil; (b) Bulk soil. Error bars were standard errors of the mean (n = 4 for all the treatments). Significant differences between pure C. lanceolata and its mixed plantation are marked by different letters*

Discussion

Our results indicated that there were differences in chemical forms of soil Al between mixed and pure plantations of *C. lanceolata*. The mixed plantation of *C. lanceolata* with both *M. macclurei* and *S. superba* could reduce the exchangeable Al and monomer hydroxy Al content in all soils except in the rhizosphere soil of mixed plantation of *C. lanceolata* with *S. superba* (*Figs. 2 and 3*). This decreasing tendency was consistent with the result of Li et al. (2010) on the mixed plantation of *Pinus massoniana* with *Cinnamomum camphora*. Our finding could be explained through some research results related to mixed plantation in the literatures. It has been documented that mixed plantation could increase plant biomass, soil pH, organic carbon, organic matter, phosphorus nutrition, soil N availability, and microbial biomass, as well as an improvement in microbial community diversities and enzyme activities (Li et al., 2010; Richards et al., 2010; Singh et al., 2012; Forrester et al., 2013; Dutta and Hossain, 2017; Tchichelle et al., 2017). Then such changes may be attributed to the changes in Al chemical forms because the distribution of Al chemical forms in soil could be affected by some of the above-mentioned factors such as soil pH, organic carbon, organic matter and phosphorus nutrition (Godsey et al., 2007; Fang et al., 2014; Hagvall et al., 2015). In our experiement, *C. lanceolata* is an important coniferous species whereas *M. macclurei* and *S. superba* are broadleaved tree species. Broadleaf litter generally has higher nutrient concentrations and lower lignin and polyphenol concentrations than needle litter and has faster litter decomposition rate (Prescott et al., 2004). Moreover, coniferous species may create more acid soils (Götmark et al., 2005). Therefore, introducing broadleaved species in C. *lanceolata* plantation would be very useful for the improvement of soil properties. Our results showed that the soil pH in *C. lanceolata* had an increasing tendency after mixed plantation. This results is in accordance with Cremer et al. (2017), who reported that a mixed plantation of Douglas fir (*Pseudotsuga menziesii*) and European beech (*Fagus sylvatica*) had a higher forest floor and mineral soil pH than pure conifer stands. Similar report came from Berger et al. (2004), who documented that soil pHs under mixed species were higher than soil pHs under pure spruce. Statistic analysis further showed that there was a negative correlation between soil pH in *C. lanceolata* and Al chemicla forms in soil, indicating that the change in soil pH may be one of the reasons for the changes in Al chemical forms after mixed plantation. However, further studies on the effects of the mixed plantation of *C. lanceolata* with both species on other soil properties and their relationships with Al chemical forms are needed in the future.

Our results also showed that the content of acid-soluble inorganic Al in soils of *C. lanceolata* decreased after mixed plantation except that in the rhizosphere soil of mixed *C. lanceolata* and *M. macclurei* plantation (*Fig. 4*), whereas content of humic acid Al increased in all soils except in the rhizosphere soil of mixed *C. lanceolata* and *M. macclurei* plantation (*Fig. 5*). Yang had found that there was a significant increase in humic acid in a the mixed forest of *C. lanceolata* when compared to its pure stand (Yang et al., 2002). Therefore, the increase of humic acid Al in soil in our experiment may be because of the increase of humic acid after mixed plantation of *C. lanceolata*. As mentioned in the introduction section, different Al forms in soil differed in their phytotoxicity (Zhou et al., 2011; Shahnawaz et al., 2016). The toxicity potential was ranked in decreasing order as exchangeable Al, monomer hydroxy Al, acid-soluble inorganic Al, and humic acid Al. Therefore, the decrease in exchangeable Al, monomer hydroxy Al, and acid-soluble inorganic Al contents and the increase in humic acid Al

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53415353

content indicated that such a mixed plantation could decrease the toxic Al forms, and consequently, Al phytotoxicity would be reduced.

We observed that chemical forms of Al in soil of *M. macclurei* and *S. superba* plantation also changed to different extent after mixed plantation with *C. lanceolata*. The exchangeable Al and monomer hydroxy Al content showed a decreasing trend as that of *C. lanceolata.* These results suggested that the mixed plantation is not only useful for *C. lanceolata*, but is also good for the two mixed species as for soil aluminum toxicity.

Conclusions

The experimental results indicated that mixed plantation of *C. lanceolata* could change the distribution of Al speciation in the soil. However, the changes varied among different chemical forms. There was a decreasing tendency in exchangeable Al in both mixed planting patterns. Similar results were also observed in the content of monomer hydroxy Al and acid-soluble inorganic Al. These results indicated that there was a general decrease tendency in the content of chemical forms with higher phytotoxicity including two most active chemical forms of Al in soils (i.e., exchangeable Al and monomer hydroxy Al). Therefore, we suggested that mixed planting patterns could be an alternative alleviation method to control the harmful Al effects on *C. lanceolata* forest although further studies are still needed.

Acknowledgements. We thank Rongmei Zhang for her great assistance in the entire soil culture and sampling. We are also grateful to Yu Chen for his professional advice in this study, Guangqiu Cao for his help with getting the plant material, Bifei Hang for her help with the analysis of Al content. We would also like to thank the National Natural Science Foundation of China (grant number 31370609) for providing the funding for this research.

Abstract. Magnetotactic bacteria (MTB) have ability to accumulate biominerals intracellularly as iron nanoparticles in the form of ferric oxide (Magnetite) and ferric sulphide (Greigite), known as magnetosomes. Most of them belong to the α-proteobacteria, β-proteobacteria and γ-proteobacteria class. In Pakistan, the magnetotactic bacterial strains are not yet isolated. In current study, the Magnetotactic bacterial strains are isolated from different environmental samples and a modified specific growth medium was used to culture the isolated MTB strains. The technique used for accumulation of bacteria in water samples was the magnetic enrichment technique. The isolation of magnetotactic bacteria is difficult and identified number of strains of magnetotactic bacteria is less than a hundred. So, there is a need to focus more on the identification and classification of MTB. The selected strains were cultured on scale up production and extraction of magnetosomes were carried out by Boiling method. The extracted magnetosomes were characterized by Scanning electron microscopy (SEM), Fourier Transform Infrared (FTIR) spectroscopy and X-ray powder diffraction (XRD).
Keywords: *magnetosomes, scanning electron microscopy, X-ray powder diffraction, Fourier transform infrared spectroscopy*

Introduction

Many organisms can sense the geomagnetic field and this behaviour of organisms is known as "magneto-reception" (Kirschvink et al., 2001). The well-understood example of magneto-reception is present in prokaryotic organisms that can sense and align themselves along with the geomagnetic field lines (Lefévre et al., 2011b). Those prokaryotes are known as Magnetotactic bacteria (MTB). The evolutionary history of magnetotaxis of MTB might be complex as magnetotaxis in the domain Bacteria is an ancient physiological trait (Lin et al., 2018). Magnetotactic bacteria are a diverse and fascinating group of micro-organisms that shared the ability of orientation towards the geomagnetic fields. The presence of iron oxide and sulphide molecules in bacterial cell makes them little compasses that have ability to direct themselves to the magnetic field lines (Bazylinski and Frankel, 2004). This attribute of MTB is due to the intracellular biomineralization of iron nanoparticles of ferric oxide (magnetite) and ferric sulfide (greigite), known as magnetosomes, which are responsible for magnetotaxis in MTB (Lefèvre and Bazylinski, 2013; Bazylinski et al., 2000). Magnetosomes are individually enclosed by a thin organic covering that confers high and constant dispersion in aqueous solutions as compared with artificial magnetite and this attribute make them ideal for use in biotechnological purpose (Arakaki et al., 2008). These magnetosomes are enclosed within a bilayer membrane that is thought to be an invagination of cytoplasmic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53555367

membrane, known as magnetosome membrane. The bacterial cells use the iron that accumulated in cell by the process of biomineralization. Different types of mechanism are used for assimilation and utilization of iron present in the cell (Tanaka et al., 2010). According to Li et al. (2017), extreme environment could provide the knowledge regarding to the evolution of magnetotaxis and biomineralization in MTB. Although magnetotactic bacteria (MTB) are present in various aquatic environments but the majorities of them are still uncultivable (Flies et al., 2005).

MTB are heterogeneous group of microorganisms, which are numerous in aquatic habitats. MTB are commonly resided in Oxic-Anoxic Interface (OAI) of chemically stratified zone where oxygen is present in low concentrations (Simmons et al., 2004). Magnetite-producing MTB are present in fresh water as well as marine water, while greigite-producing reside marine sediments (Bazylinski and Frankel, 2004). All identified MTB are gram negative as well as positive and microaerophilic in nature. The detection of MTB is easy as they move towards the magnetic field but the cultivation process id difficult (Shivangi and Sinha, 2017). According to Loghin et al. (2017), the magnetic gradient can be used to detect the MTB and can control their movements. MTB include various morphological forms as cocci, bacilli, vibrio, ovoids, spirilla and multicellular aggregates (Schuler et al., 1999).

The current study is about the isolation of magnetotactic bacteria from Pakistan fresh water samples. The magnetotactic bacteria were then optimized and were grew in broth medium. The magnetosomes were extracted and characterized by using analytical techniques, i.e. Scanning Electron Microscopy (SEM), Fourier-transform infrared spectroscopy (FTIR) and X-ray powder diffraction (XRD).

Material and methodology

Collection of water sample and magnetic enrichment technique

The water samples were collected from Tatta Pani (31.2488° N, 77.0895° E, Kashmir) and Attabad Lake (36.19° N, 4.48° E, Hunza) in May, 2017 from Pakistan (*Fig. 1*). The collection of water samples were done in Nalgene sample bottles with magnet inside the bottle. The collection was done about 2-3 feet below the water surface where the oxygen concentration was low and settled down the bottle for 30 min. Then the bottle was carefully closed tightly. The magnetic enrichment technique was used to accumulate the magnetotactic bacteria in water samples by placing bar magnets to the outer wall of sampling jars at room temperature. After 15 days water sample was collected from immediate vicinity of attached magnet so that the chance of isolation of magnetotactic bacteria might be increased (Flies et al., 2005b; Jogler et al., 2010).

Medium composition

The specific growth culturing medium was used for the magnetotactic bacterial growth, named. The composition of the medium was 5 $g.L^{-1}$ of tryptone, 3 $g.L^{-1}$ of beef extract, 5 $g.L^{-1}$ of sodium chloride, 20 $ml.L^{-1}$ of ferric quinate solution (Sharma and Chandrajit, 2011).

Isolation and detection of magnetotactic bacteria

About 0.5 ml of magnetically enriched water sample was spread on specific growth medium. The colonies were then detected on glass slides by movement of magnetotactic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53555367

bacteria as the magnet was placed near the glass slide under compound microscope. The movement of the culture was observed, and the obtained cultures were further confirmed by hanging drop method. Sulphate Indole Medium was used to check the motility of the bacterial strains (Waghmare et al., 2018).

Figure 1. *A map indicating the location of sampling sites: Attabad Lake and Tatta Pani*

Molecular identification through 16S rRNA gene sequencing

The total genomic DNA of selected bacterial strains was extracted by using Phenol/chloroform DNA extraction protocol. DNA was partially sequenced for 16S rRNA gene by Macrogen, Inc., Seoul, South Korea. Sequences were further analysed for the similar strains in NCBI using BLAST software (http://blast.ncbi.nlm.nih.gov/Blast.cgi/). Phylogenetic trees were constructed by using MEGA 6 software, which determined the relationship of our isolates with the closely related strains.

Optimization of physiological properties of magnetotactic bacteria

The isolated strains were optimized on different temperatures (17, 27, 37 °C) and pH (6, 7, 8).

Extraction of magnetotactic bacteria

About 500 ml of specific growth medium was inoculated with the isolated bacterial strains and placed the flask in shaking incubator at 27 °C for 15-20 days. The colour of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53555367

the medium changes from light brown to dark brown that indicate the production of iron in the medium.

Boiling technique was used for the extraction of magnetosomes from magnetotactic bacteria. The growth medium was centrifuged at 8000 rpm for 15 min at 4 °C. The pallet was shifted to test tubes and washed with distilled water two times and then suspended in 5N NaOH solution for 20 min. Then the suspension was boiled by placing the test tubes in water bath for 2 h or until the suspension was turned into dark brown in colour. Then cool down the suspension and again centrifuge the suspension and collected the pallet in Eppendorf tubes (Frankel RB et al., 1983).

Characterization of magnetosomes

Different techniques will be used for the physico-chemical characterization of purified magnetosomes.

Scanning electron microscopy (SEM)

The surface topology of extracted magnetosomes was examined by scanning electron microscopy (JSM5910, JEOL, Japan) to find structure of magnetosomes after extraction. Magnetosomes were thoroughly washed with sterilized distilled water and mounted on copper stubs with gold paint. Gold plating was done in vacuum to increase the conductivity of the samples.

Fourier-transform infrared spectroscopy (FTIR)

In this study, the ATR-FTIR (Parkin Elmer spectrum 65 FTIR) spectrometer is used for the structural analysis of extracted magnetosomes. The sample was placed on the sample holder. The spectrum was recorded using an attenuated reflectance technique involving diamond crystal. The samples were then scanned from 4000-400 cm^{-1} with resolution of 6.0 cm^{-1} and were averaged over 200 scans.

X-ray powder diffraction (XRD)

X-ray powder diffraction (Xpert Pro. PANalytical) used for phase identification of a crystalline material and provide information on unit cell dimensions. The phase and purity of extracted magnetosomes were examined by X-ray diffraction (XRD) with 2Θ range of 5°-65°.

Statistical analysis

Optimization of temperature and pH were performed in duplicate. All the data with repeated measurements were statistically analysed with T-test.

Results

The water samples from Tatta Pani lake and Attabad lake were magnetically enriched by placing magnet and two isolates were selected after doing serial dilutions, Gram staining, inoculation in Sulphate Indole Medium to check the motility assessment and conversion of broth colour from light brown to dark brown by broth activity of inoculum. The colour change in broth showed the production of iron in the broth.

DOI: http://dx.doi.org/10.15666/aeer/1703_53555367

Molecular identification through 16S rRNA gene sequencing

The 16S rRNA sequences of strains were obtained by Macrogen, Inc., Seoul, Korea. The gene sequences were compared with other sequences in the GenBank databases, using the NCBI BLAST software. The bacterial strains CT-K1 and TP6-4 showed 87% and 100% resemblance with *Iron sulfide magnetotactic bacteria* and *Bacillus cereus* species of magnetotactic bacteria respectively (*Fig. 2*). The aligned sequences were then used to construct a phylogenetic tree by neighbour joining method using MEGA6 software. The accession numbers obtained of these strains are MK053797 for CT-K1 and MK053798 for TP6-4.

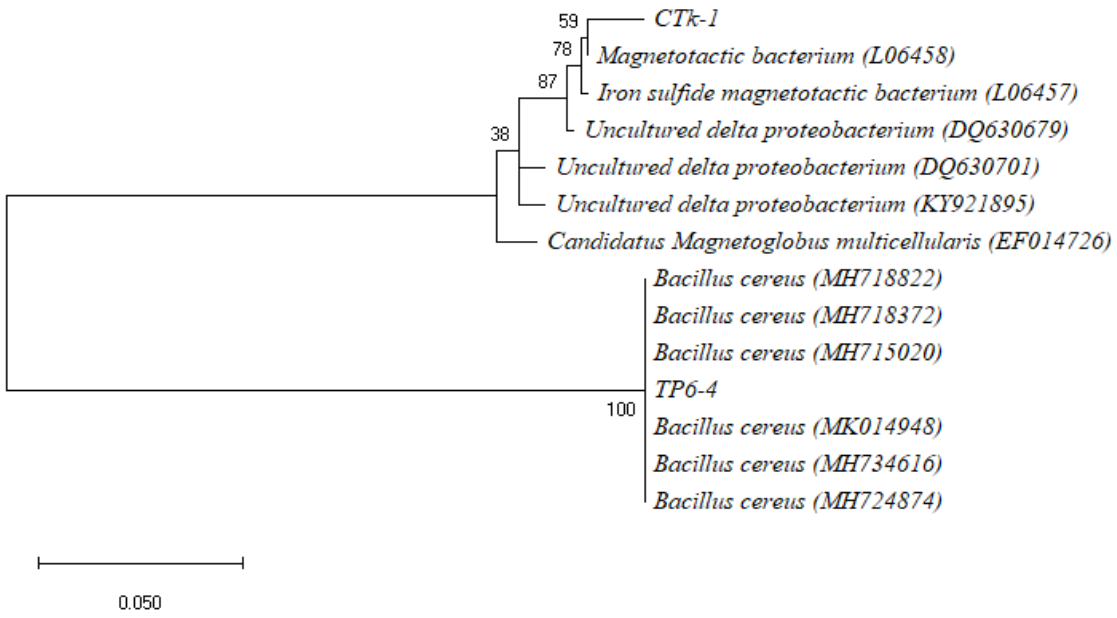

Figure 2. *Phylogenetic trees of magnetotactic bacterial strains CT-K1 and TP6-4*

Effect of temperature and pH on growth of magnetotactic bacteria

Optimization of physical parameters is of vital importance for obtaining a maximum growth of MTB. The bacterial growth was checked at different temperature after every 24 h. The strain TP6-4 showed high growth at 37 °C while the growth is low at 17 and 27 °C. The other bacterial strain CT-K1 also showed the same growth pattern, maximum growth at 27 °C (*Fig. 3*). The growth of Strain TP6-4 was better than the growth of CT-K1 to produce magnetosomes. The bacterial growth was checked at different pH after every 24 h. Both the bacterial strains showed maximum growth at 7 pH (*Fig. 3*). The graphical explanation of optimization of temperature and pH were shown in *Figure 3*.

Magnetosomes extraction

The bacterial strains TP6-4 and CT-K1 were extracted with boiling technique. The extracted product was brown in colour showed the property of iron. The extracted form of magnetosomes was showed in *Figure 4*. The brown coloured pallet were magnetosomes and these extracted magnetosomes were then characterized by different techniques.

Characterization of magnetosomes

Scanning electron microscopy (SEM)

The scanning electron Microscopy showed the structure of magnetosomes that were cleared in the figures (*Fig. 5*). The bacterial strain TP6-4 showed cuboidal shape of magnetosomes and CT-K1 showed hexahedral shape of magnetosomes. The sizes of the magnetosomes extracted by TP6-4 and CT-K1 were 100 nm and 120 nm respectively.

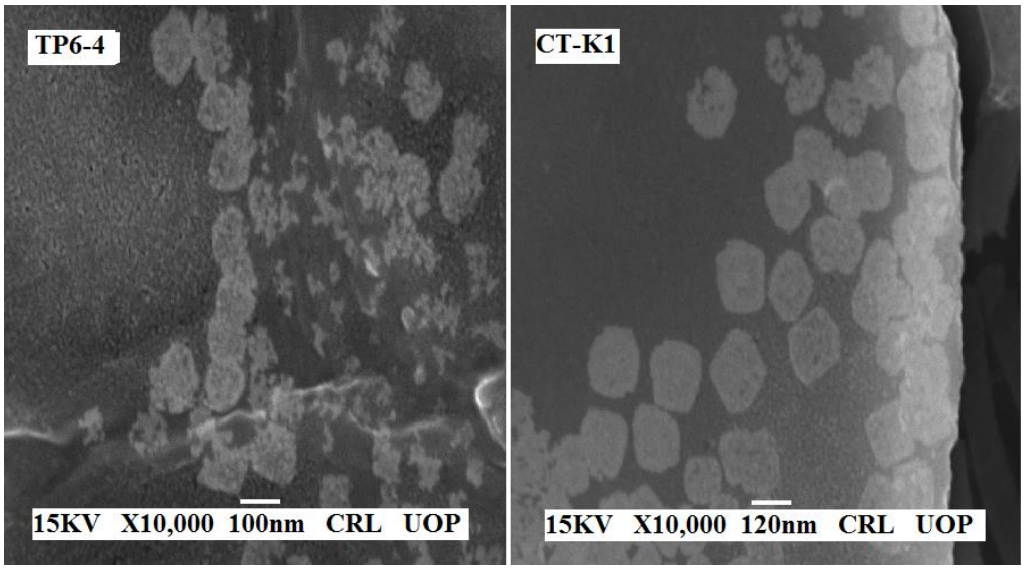

Figure 5. *Scanning electron micrographs of biologically produced magnetosomes from CT-K1 and TP6-4*

Fourier-transform infrared spectroscopy (FTIR)

The magnetosomes extracted from the bacteria were dried out and FTIR analysis done for the samples. The peaks at 631 and 629 cm^{-1} showed the Fe-O presence in the samples. The peaks appeared at 3460, 3422, 2957, 2916, 1725, 1646, 1650, 1469 and 1468 represented the NH bending, CH stretching, C = O and C = C stretching modes (*Fig. 6*).

X-ray powder diffraction (XRD)

The diffraction pattern in *Figure 7* showed all the diffraction index of magnetite, the strong peaks at 101 at 19 and 311 at 25 representing the magnetite (Fe_2O_3) presence in the sample. The presence of intense and broad peaks confirmed the crystalline structure present in the samples.

Discussion

Magnetotactic bacteria are a diverse group of bacteria and are found in a complex environment of oxic-anoxic transition zone of water sediment. Therefore, the isolation of these bacteria is a difficult process and required more attention for their cultivation. These bacteria accumulate the magnetite and greigite depending upon the type of environment they are present. The medium used for the cultivation of these bacteria is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53555367

specific iron containing growth medium. This medium contained tryptone and peptone that is carbon source, ferric quinate solution that is used as an iron source for the bacterial uptake for the production of magnetosomes, NaCl for ion source and beef extract or meat extract for the nitrogen source (Calugay et al., 2004). Bacteria responded to the extreme intricacy of Fe^{3+} by discharging high similarity Fe^{3+} specific legends named as siderophore (Andrews et al., 2003). The molecular biology and microscopy of MTB cells discovered many new species that referred the significant phylogenetic diversity of MTB (Li et al., 2017).

The selected strains of MTB were motile and have flagella for the movement towards magnetic field lines. These bacteria may be monotrichous, peritrichous and amphitrichous according to the type of genus (Bazylinski et al., 1995; Bazylinski and Blakemore, 1983). Both the bacterial strains CT-K1 and TP6-4 are monotrichous in nature. A chemically defined medium known as sulphide indole medium was used to check the motility of the bacterial strains.

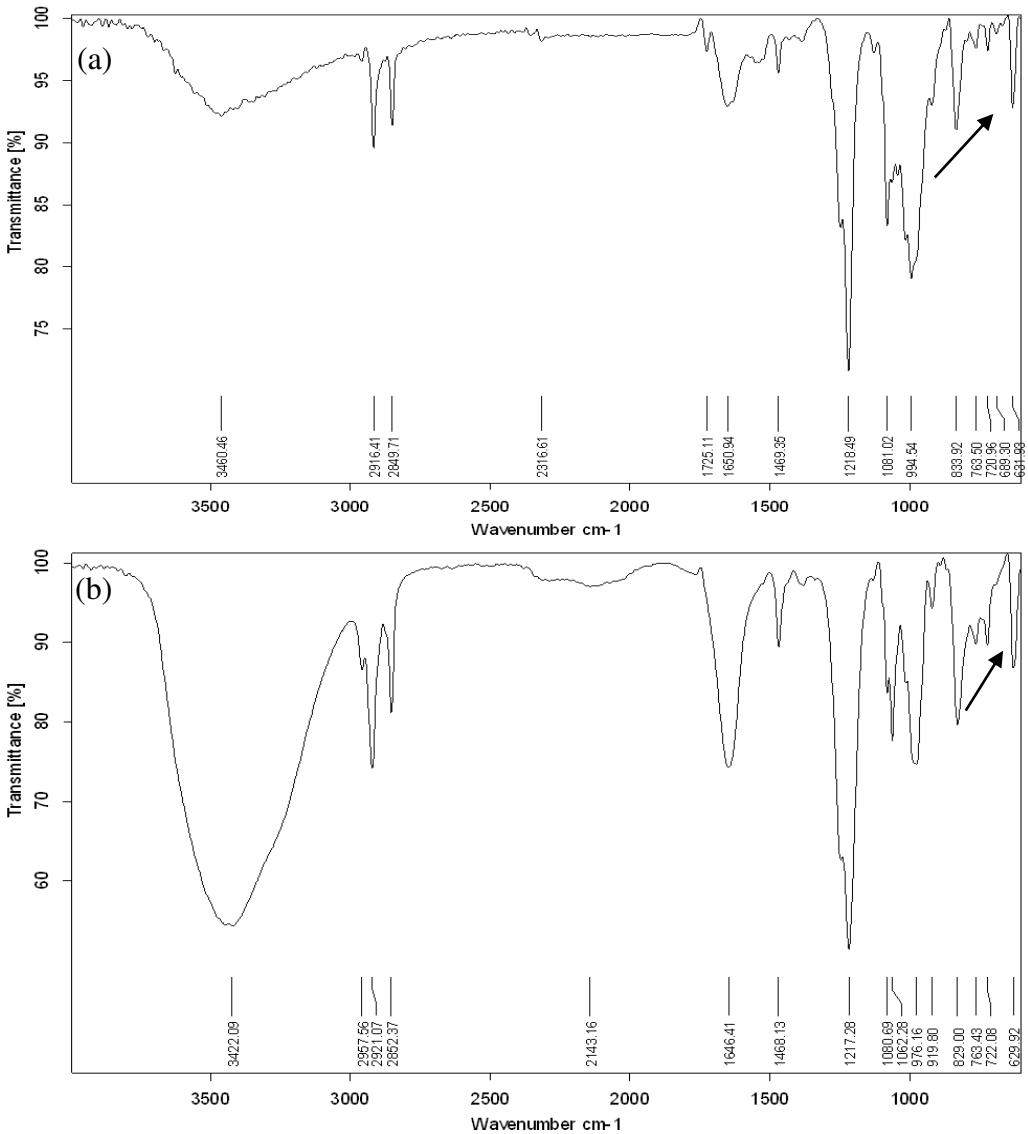

Figure 6. *Fourier transform infrared spectrum of magnetosomes produced in iron specific medium extracted from (a) CT-K1 and (b) TP6-4*

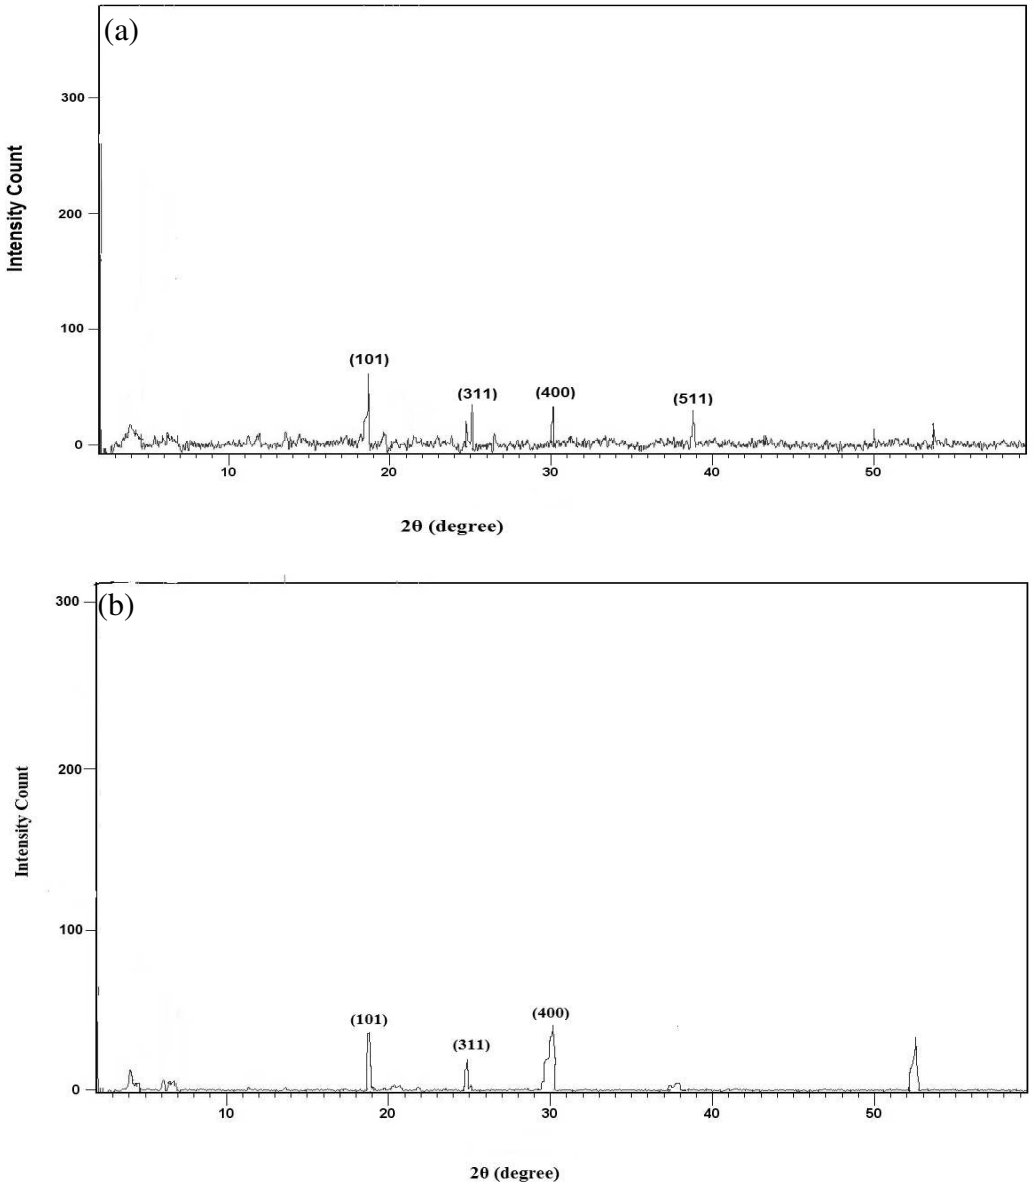

Figure 7. *X-ray powder diffraction patterns of extracted magnetosomes from (a) CT-K1 and (b) TP6-4*

Magnetotactic bacteria that contained chains of magnetosomes may be differentiate or identified from non-magnetotactic bacteria by magnetic assessment technique. In current study different assessment techniques were used for the isolation of bacteria containing magnetosomes. In the first technique the specific growth medium was prepared with 1% nutrient agar and strains were inoculated on medium with a magnet place aside. After 4-5 days the movement of bacteria was clearly observed towards the magnet. This was the indication that these bacterial strains contained iron particles inside their cell. In another method the inoculation of the strains was carried out on semi solid medium. These bacterial strains showed movement towards the magnet. According to Comensoli et al. (2017), the change of colour of the medium was due to the precipitation of iron oxide and iron sulphate in the medium. The change in the colour also occur due to sulphur reduction in the medium. In this study the bacteria that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53555367

showed a clear movement towards the magnet were inoculated in the broth medium. After 10 days the colour of the medium changed to dark brown colour that indicated the bacteria consumed the iron present in the medium and produced magnetosomes. Most cultivated and uncultivated magnetotactic bacteria are related with *alpha, gemma, delta-proteobacteria* classes of *Proteobacteria phylum* and *Nitrospira phylum*. Freshwater MTB biomineralize magnetite (Fe_3O_4) and MTB reside in marine settings, can biomineralize greigite (Fe_3S_4) have found in marine water (Frankel et al., 1979).

The DNA of the strains CT-K1 and TP6-4 were extracted through phenol-chloroform method (McOrist et al., 2002). The DNA was suspended in TE buffer for further process. The bacterial strain CT-K1 showed 87% resemblance with the *Iron sulfide magnetotactic bacteria* and the TP6-4 showed 100% resemblance with *Bacillus cereus.* Both the strains were examined to produce magnetosomes. In MTB, the magnetosome biomineralization process is under genetic and biochemical control. Specific genes are involved in the biomineralization and production of the magnetosome crystals (Werckmann et al., 2017).

The MTB bacterial strains have a wide range of temperatures for their growth. Most of the reported magnetotactic bacteria have an optimum growth temperature range from 25-37 °C (Schuler et al., 1999). The temperature optimization was done on 17, 27 and 37 °C for CT-K1 and TP6-4. The TP6-4 strain grew well at 37 °C while the strain CT-K1 grew well at 27 °C. The bacterial cultures showed a mesophilic nature of habitat growing best at mesophilic temperature. The basic purpose of the optimization study of parameters was to produce and extract the magnetosomes and characterized them by using analytical techniques.

In the current study, the scanning electron microscopy showed magnetosomes produced by TP6-4 were cuboidal in shape while magnetosomes produced by CT-K1 were hexahedral in shape and the size of magnetosomes were 100 nm (CT-K1) and 120 nm (TP6-4). According to the Devouard et al. (1998), the size range of the magnetosomes lied between 30 to 120 nm. According to Keutner et al. (2014), the SEM image of single magnetosomes chain in magnetotactic bacterial cell and also individual magnetosomes. They did the SEM analysis on four magnetotactic bacterial strains of *MS-1* on gold grid. The cryo-SEM and TEM was used to see the individual magnetosomes in bacterial cell and several rosette-like magnetosome bundles in *Candidatus Magnetobacterium bavaricum* from the deep branching Nitrospira phylum (Jogler et al., 2011). According to Revathy et al. (2017), the SEM and HRTEM micrograph clearly showed the cubo-octahedral shape of the magnetosome present in magnetotactic bacterial strain *Magnetospirillum gryphiswaldense (MSR1).*

The Fortier Transform Infrared Spectroscopy is a significant tool for the identification of function groups in a compound. The exclusive assortment of absorption bands to confirm the identity of pure compounds or detection of existence of debris. The FTIR analysis was performed for the identification of presence of iron oxide in the extracted compound. According to the FTIR analysis of iron oxide the wavelength for this is between the range of 400-650 cm^{-1} (Revathy et al., 2017). The wavelength for the detection of iron oxide in the analysis was at 629 and 631 cm^{-1} for CT-K1 and TP6-4 respectively. FTIR spectra of iron oxide was well recognized. It was being observed that the immersion band at high wavelength region was due to the OH enlarging and the minor wavelength because of Fe-O matrix trembling. According to the Revathy et al., the FTIR spectrum showed two peaks, in 418 and 522 cm^{-1} that are due to the stretching vibration mode associated with the metal and oxygen absorption band that is Fe-O

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53555367

bonds in the crystalline lattice of Fe_3O_4. According to Xiang et al. in (2007), the FTIR analysis of purified magnetosomes showed peaks at 3273, 2921, 1735, 1531 and 1645 cm^{-1}. The peaks appeared at 3273 and 2921 cm^{-1} were representing the NH bending and CH stretching modes. These carbon and nitrogen bonding were representing the lipid bilayer and protein in the magnetosomes membrane. C = O and C = C stretching modes peaks were appeared at 1735, 1645 and 1531 cm^{-1}. FTIR analysis can also be used for the purity examination of magnetosomes. In the current study, the peaks appeared at 3460 and 2916 cm^{-1} in the sample of CT-K1 and peaks appeared at 3422 and 2957 cm^{-1} in the sample of TP6-4. The C = O and C = C stretching modes peaks were appeared at 1725 and 1650 cm^{-1} in the sample of CT-K1 and peaks appeared at 1646 and 1468 cm^{-1} in the sample of TP6-4. This study showed significant results for the characterization of magnetosomes.

The X-rays diffraction analysis showed presence of inverse spinel structure of iron oxide. The 2θ corresponded to the scattering angle of the crystal, the more the sharp edge of the sample the clearer will be the peak. The peaks of 101 and 311 showed the presence of iron oxide in sample and the broad spectrum is due to the crystallinity of the iron oxide. According to Bini et al. (2012), the peaks at wavelength 311 showed the iron oxide crystallinity. While according to Revathy et al. (2017) Magnetospirillum gryphiswaldense (MSR-1) produced magnetosomes and the peaks appeared at 27.05, 30.30, 35.71, 43.31, 55, corresponds to the Fe_3O_4. In the current study, the peaks showed resemblance to the 27 (311), 30 (400) and 38.5 (511). These results revealed that the XRD analysis showed the presence of Fe_3O_4 in sample. These results of characterization of magnetosomes produced from *Iron sulfide magnetotactic bacteria* were given good evidences to use then in future studies.

Conclusion

Conclusively, the current study helped in finding the newest class of bacteria from the fresh water samples of Pakistan. This has been the tremendous and improved development in the field of microbiology to isolate the class of magnetite producing bacteria. This current study extensively investigated the new ways to isolate these magnetosomes producing bacteria from fresh water bodies. The diversity and ecology of intracellular bio-mineralizing bacteria and their molecular mechanisms of intracellular biomineralization are needed to be studied. The optimised bacterial strain helped in the maximum production of magnetosomes that would be used in many applications. The extracted magnetosomes shape was characterised by scanning electron microscopy so that significant potential use of magnetosomes in different application and ensuring high yield, increased reliability and stability in optimized conditions.

Abstract. Irises are among the most well-known ornamental flowers in the world. There are probably over 60 species of *Iris* in China, accounting for approximately one-fifth of the world's wild resources; however, there is little information available on the genetic diversity and relationships among these species. We accordingly studied the genetic diversity and relationships among 15 species of *Iris* collected in China using amplified fragment length polymorphism (AFLP) markers in conjunction with a combination of *Eco*RI/*Mse*I restriction enzymes. A total of 378 clear and stable bands with sizes ranging from 50 to 800 bp were obtained using 9 pairs of primers screened from 64 primer combinations; the percentage of polymorphic bands was 99.74%. Some species – *I. setosa, I. uniflora, I. dichotoma, I. typhifolia, I. ventricosa,* and *I. japonica* – were differentiated by just a single specific band, and these band patterns were used for identification. An assessment of genetic diversity parameters using AFLP markers showed that *Iris* has high genetic diversity at the species level. Clustering analysis and principal coordinate analysis showed that the 15 species of *Iris* were genetically similar, and thus related. When the genetic similarity coefficient was 0.55, the 15 species could be divided into five distinct groups. The aforementioned results will verify, replenish, and consummate the classical taxonomy and systematology of *Iris*, and also provide references for the conservation, management, classification, identification, and breeding of *Iris* resources.
Keywords: *Iris, AFLP, genetic diversity, relatedness, conservation*

Introduction

The genus *Iris*, belonging to the family Iridaceae, includes more than 300 species of perennial and herbaceous plants. They are distributed mainly in northern temperate zones such as Asia, Europe, and North America. Among the 300 plus species, there are 60 species, 13 varieties, and 5 variants that are native to China, and these are principally distributed in the northwest, southwest, and northeast of China (Zhao, 1985; Waddick, 1992). The elegant flowers of *Iris* can be found in a breathtaking array of colors, ranging from white, yellow, and orange, through every tone of blue, purple, pink, and brown, to black. *Iris* species also produce beautiful linear foliage (Claire, 1957; Bailly, 2001). These perfect characteristics make irises one of the most favored ornamental plants. Because of their simple cultivation, extensive management, and low maintenance costs, species of *Iris* are widely utilized in landscaping. Additionally, because of their high resistance to cold, drought, disease, and salinity, some species, such as *Iris lactea*, *Iris sanguinea,* and *Iris halophila,* can be applied for improving coast and saline-alkaline land (Bai et al., 2008). In addition, *Iris tectorum*,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53695381

Belamcanda sinensis, *Iris germanica*, and a few other species have medicinal value, containing flavonoids with good detoxification effects (Agarwal et al., 1984; Burcu et al., 2014). Understanding the genetic diversity and relationships among plant species and varieties is very important for breeding and intellectual property rights (IPR) (Tay et al., 2006; Wanjala et al., 2013). *Iris* breeding began very early in Europe. Further, by crossbreeding, many new cultivars with desirable traits have been bred by using the extensive collections of wild species and varieties. Embryo culture, somatic hybridization, and transgenic breeding are a few other successful methods used for *Iris* breeding (Shimizu et al., 1999). Up until 2009, there were more than 30 000 *Iris* cultivars in the world, as catalogued by the American Iris Association (Zhang, 2010). In China, wild *Iris* resources with many good genes are abundant, and these may be used to improve, innovate, and preserve the *Iris* germplasm. However, *Iris* breeding started late and developed relatively slowly in China. Only a small part of the *Iris* resource is utilized directly without any modification, probably due to the lack of systematic research. Further, each year many new cultivars are being introduced, which represents a considerable annual expense. In breeding programs, breeders typically select parents with good performance and a wide hereditary basis, according to their genetic diversity and relatedness to parental germplasm, which are very important criteria for crossbreeding (Hesham et al., 2010; Matus et al., 2002). The classification of the genus *Iris* has been controversial, because of the focus on botany and horticulture. In recent years, the classification system of the American Iris Society, which is based on traditional morphological characteristics, has become popular (Lin et al., 2010). However, morphological classification has certain disadvantages, which often leads to an incorrect evaluation. The morphological characteristics of plants may be expressed differently in different environments, and can only sometimes be appraised correctly in adult plants, which could result in a waste of resources for plant growth and increase the difficulty of evaluation (Poppendieck, 1983; Vieira et al., 2007). Thus, the classification of *Iris* is vague and often invalid in practice. Consequently, it is not surprising to find different cultivars with the same name or to find the same plant referred to by different names (Zhang et al., 2008).

Because of the various species and relatively similar traits, confusion and misuse of *Iris* resources can easily occur. Therefore, it is important that a scientific and reliable identification method be established. With the continuous development of molecular biology techniques, several studies of *Iris* have been conducted at the molecular level. Over the past few decades, DNA-based markers have proven to be very successful in classifying plants (Vos et al., 1995; Qiao, 2007), and in assessing the intraspecific and interspecific genetic diversity of plants (Morales et al., 2013). Although some studies have been conducted on the genetic relationships and population genetic diversity among species or cultivars of *Iris* (Tang et al., 2010; Chung et al., 2014), because of the diversity of natural geographical distribution, only a few species have been studied, and the phylogenetic relationships of many other species in this genus is still currently unclear or disputed and needs to be further clarified.

Amplified fragment length polymorphism studies have been used extensively to examine genetic population structure and provide guidance for conservation efforts. AFLP is a molecular marker technology with high-integrated utility, which combines the advantages of RFLP and RAPD. Due to the characteristics of the required trace levels of DNA, high polymorphism levels, good reproducibility, high stability, ease of standardization, genome-wide marker distribution, and no prior sequence knowledge,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53695381

the AFLP method is considered to be a better tool for evaluating the genetic diversity (Jianab et al., 2009; Garrido et al., 2012) and genetic structure (Breinholt et al., 2009) of plants, and for plant genotyping (Allen et al., 2008) and DNA fingerprinting (Tatikonda et al., 2009) analyses. In addition, AFLP analysis is credibly applied to assessing the genetic diversity of intraspecies and interspecies (Umezuruike et al., 2010; Isaza et al., 2012; Hong et al., 2013).

In this study, using AFLP markers, we objectively evaluated the genetic diversity and genetic relationships of 15 wild *Iris* samples collected in northern China. The objectives of this study were to (1) verify, replenish, and consummate the classical taxonomy and systematology of *Iris*, and (2) provide references for the conservation, management, classification, identification, and breeding of *Iris* resources.

Materials and Methods

Sampling of species

In this study, 15 species of *Iris* were collected and analyzed (*Table 1 and Fig. 1*). The field studies did not involve endangered or protected species, and no specific permissions were required for the locations collected from. All plants were wild species and mainly obtained from northern China. Leaves of each species were taken outdoors, dried with silica gel, and stored in ziplock bags at room temperature for DNA extraction.

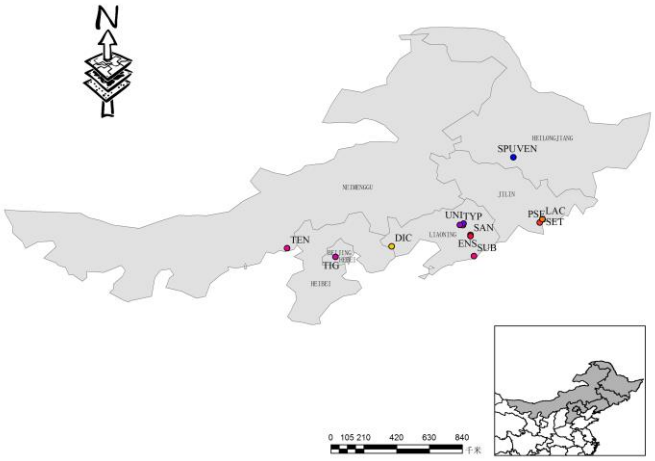

Figure 1. *Locations of sampling sites of 15 species of Iris in North China*

AFLP analysis

Genomic DNA was extracted from dried leaves using the CTAB method described by Wang et al. with some modifications (Wang et al., 2013). PVP was added when DNA extracted because there was more phenolics and flavonoids in leaves of *Iris*, and DNA extraction numbers were increased. The samples were initially ground with a pestle and mortar, and then with magnetic particles, without liquid nitrogen. The concentration and purity of genomic DNA were determined by agarose gel electrophoresis (1%) and UV spectrophotometry. Finally, the genomic DNA was diluted to a concentration of 50 ng/μl and stored at -20°C for AFLP analysis.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53695381

The AFLP reactions and procedures were performed according to the methods of Vos et al. (1995) and Chen et al. (2009) with some modifications. Genomic DNA was digested using an enzyme combination of *Eco*RI (Fermentas) and *Mse*I (Sangon). Three species of *Iris* were selected randomly from the 15 *Iris* accessions for primer screening, namely *I. setosa* (Jilin), *I. lactea* var. *chinensis* (Liaoning), and *I. ventricosa* (Heilongjiang). Nine primer combinations and 64 AFLP primer pairs could amplify clear and reproducible polymorphic bands. AFLP-PCR products were separated by 6% denaturing polyacrylamide gel electrophoresis, with constant power of 55 W for approximately 2 h, and then the DNA bands were visualized by silver staining and imaged using a scanner.

Data analysis

Amplified AFLP bands were scored as present (1) or absent (0) by visual inspection. Data entry in Excel created a 0/1 binary matrix, based on which we could calculate the number and percentage of polymorphic bands (PPB). Clustering analysis and principal component analysis (PCA) were then performed using NTSYS-pc (version 2.10e) software (Rohlf, 2000). The parameters of the differential degree and the genetic diversity among species of *Iris* were calculated using popgene32 (version 1.32) software (Yeh, 1997), including genetic similarity coefficient, genetic distance, the observed number of alleles (Na), the effective number of alleles (Ne), Nei's genetic diversity index (H), and Shannon's information index of diversity (I). All of the aforementioned calculations were performed based on the assumption that these species were in Hardy-Weinberg equilibrium.

Results

Polymorphism of amplified fragments

An AFLP amplification map was obtained using 9 pairs of primers for 15 species of *Iris*. A total of 378 generated bands were clear and stable, ranging in size from 50 to 800 bp, of which 377 bands (99.74%) were polymorphic (*Table 2*). The number of bands amplified per primer combination ranged from 34 to 53, with an average of 42, and the average number of polymorphic bands per primer pair was 41.89. The polymorphic percentage of bands per primer combination was close to 100%, showing that the 15 species of *Iris* have rich genetic diversity.

Furthermore, genetic diversity parameters (*Table 3*) demonstrated that the genus *Iris* has considerable genetic diversity at the species level. Because of the lack of gene flow among species, not only can these species be used as good breeding materials, but they should also be protected as wildlife resources.

Table 2. *Amplified fragment length polymorphism (AFLP) detected using nine primer pairs for 15 species of Iris*

Primer pairs	Total amplified bands	Number of polymorphic bands	Percentage of polymorphic bands (PPB %)

The bold numbers indicate a specific band per species that can be distinguished using only this band. A (B) means that the A band is present (1) or absent (0) in decreasing molecular weight (50–800 bp) of a primer amplification product. B has only two values–0 and 1. E.g., 9(1)[a] under the primer pair E-AAG/M-CTA means that the band of Iris sanguinea appears in E-AAG/M-CTA amplified products at the ninth position by decreasing molecular weight

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53695381

Moreover, different species of *Iris* can be distinguished by these specific bands. Some species–*I. setosa, I. uniflora, I. dichotoma, I. typhifolia, I. ventricosa,* and *I. japonica*–were differentiated by just a single specific band. Nevertheless, some species were differentiated by more than one specific band. In *I. pseudacorus* for instance, the 29th band was absent in the amplification products of primer combination E-AAC/M-CAT, but the 26th band was present among the amplification products of primer combination E-ACT/M-CAC.

Genetic similarity coefficient analysis

In taxonomy, the genetic similarity coefficient or Nei's genetic identity refers to a similarity index between two taxonomic units and is sometimes replaced by genetic distance, which is a complement parameter of the genetic similarity coefficient. The genetic similarity coefficient generally lies between 0 and 1 (Li et al., 2011). For *Iris*, the genetic similarity coefficient ranged from 0.4392 to 0.6296 (*Table 5*), and that between *I. tenuifolia* and *I. uniflora* (approx. 0.4392) was the smallest. The genetic similarity coefficient between *I. setosa* and *I. tenuifolia* (approx. 0.6296) was the largest. The genetic distance reflects the degree of genetic differentiation between species. The genetic distance in *Iris* ranged from 0.4626 to 0.8229, with the genetic distance between *I. setosa* and *I. tenuifolia* (approx. 0.4626) being the smallest, and that between *I. tenuifolia* and *I. uniflora* being the largest (approx. 0.8229). All other genetic distances indicated that the genus *Iris* has substantial genetic differentiation at the species level.

Table 5. *Nei's genetic identity (above diagonal) and genetic distance (below diagonal)*

Clustering analysis and principal component analysis

Based on the genetic similarity coefficient, genetic relationships among the 15 species of *Iris* were examined by clustering analysis using the UPGMA method (*Fig. 2*). When the genetic similarity coefficient was 0.55, the species could be divided into five groups: the first group: *I. dichotoma* and *I. subdichotoma*, belonging to Subgen. *Pardanthopsis*; the second group: *I. pseudacorus* (Subgen. *Limniris* Sect. *Limniris*), *I. ensata* (Subgen. *Limniris* Sect. *Limniris*), *I. spuria* (Subgen. *Xyridion*), *I. tigridia* (Subgen. *Iris* Sect. *Hexapogon*), and *I. japonica* (Subgen. *Crossiris* Sect. *Crossris*); the third group: *I. tenuifolia*, *I. setosa*, *I. lactea* var. *chinensis*, and *I. lacteal*, all belonging to Subgen. *Limniris* Sect. *Limniris*; the fourth group: *I. sanguinea*, *I. ventricosa*, *I. typhifolia*, all belonging to Subgen. *Limniris* Sect. *Limniris*; and the fifth group: *I. uniflora* (Subgen. *Limniris* Sect. *Loniris*).

In addition, a further partition was noted when considering the genetic similarity coefficient of 0.59. The first group had two sub-groups: *I. dichotoma* and *I. subdichotoma*. The second group could be divided into three sub-groups: *I. pseudacorus*; *I. ensata*, *I. spuria*, and *I. tigridia*; and *I. japonica*. The third group had two sub-groups: *I. tenuifolia* and *I. setosa*; and *I. lactea* var. *chinensis* and *I. lacteal*. The fourth group had three sub-groups: *I. sanguinea*, *I. ventricosa*, and *I. typhifolia*.

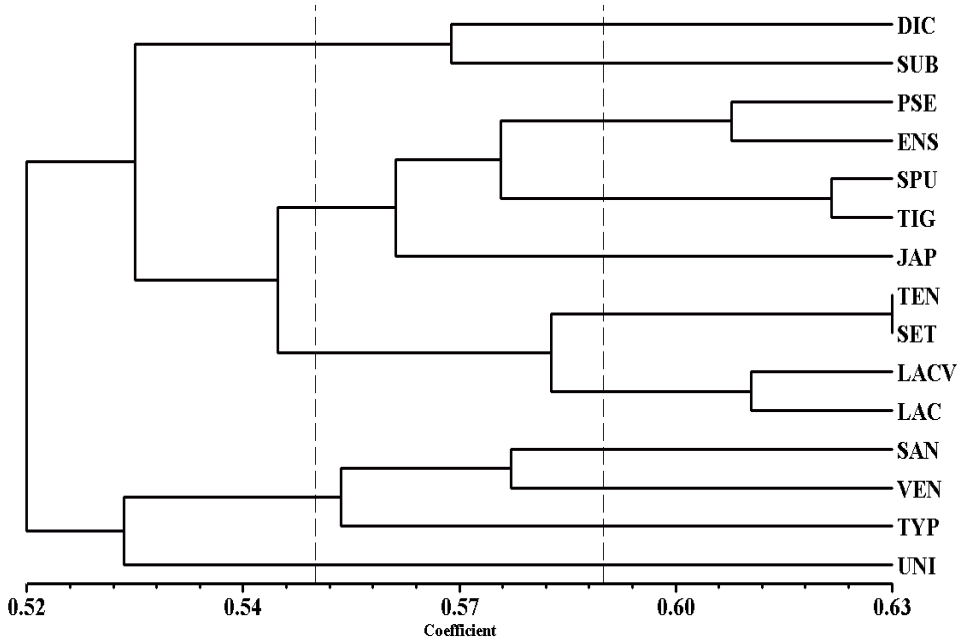

Figure 2. *Phylogenetic analysis of 15 species of Iris based on AFLP markers*

PCA of the 15 species of *Iris* based on the genetic similarity coefficient using NTsys2.10e software (*Fig. 3*) gave an important insight into their genetic relationships. The relationships among species showed a positive correlation with the genetic distance, and species close to each other on the shadow (*Fig. 3a*) were classified together (*Fig. 3b*), showing that the PCA and clustering analysis provided similar results when analyzing relationships. Therefore, PCA could be used to explain and verify the clustering results, which were similar to those reported by Huang et al. (2009).

Discussion

At present, the genetic diversity of many plants has been studied using molecular markers, including AFLP, SRAP, RAPD, ISSR, and SSR (Duffy et al., 2009; Bertoni et al., 2010; Talebi et al., 2011). Here, a total of 378 bands were obtained from 15 species of *Iris* using AFLP markers with 9 pairs of primers. The percentage of polymorphic bands was 99.74%, and the length of amplified fragment was approximately 50–800 bp. A combined analysis of genetic diversity parameters (Na, Ne, H, I) and genetic distance with the polymorphism of amplified fragments showed that the genus *Iris* has a rich genetic diversity and that there is relatively large genetic differentiation at the species level. Thus, it is important to use *Iris* wildlife resources for crossbreeding, as well as for ornamental and medicinal purposes. In addition, our results can assist in making effective decisions for the conservation of the germplasm of this species. The samples used in this study were all wild species, which may be one reason for the high genetic differentiation.

We found that different species of *Iris* had some specific bands, which can be reasonably used for identification. The morphological method and molecular marker method can be used together to accurately identify the species of *Iris*. In addition, the specific alleles will aid the assessment of stability and purity of genotypes in breeding and seed reproduction programs. Further, members of the genus *Iris* lacked mutual bands and there was a high specificity among species.

On the basis of soil and water requirements, *Iris* is divided into three categories (Liu et al., 2009): the first category includes species that prefer weakly alkaline, calcareous, damp, fertile, and well-drained soil, such as *Iris tectorum* Maxim. and *I. germanica*; the second category includes species that thrive in acidic and wet soil, such as *I. japonica* and *I. pseudacorus*; the third category includes species that adapt to any type of soil-poor, dry, or wet-such as *I. lactea* var. *chinensis*. In our study, *I. spuria* and *I. tigridia* in the second group belong to two different subgenera in the morphological classifications Subgen. *Xyridion* and Subgen. *Iris,* respectively. They grow in any soil and have strong adaptability, which contributes to explaining why *I. spuria* and *I. tigridia* clustered together.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53695381

On the basis of morphological systematics, the genus *Iris* is divided into six subgenera as recorded in the "*Flora of China*": *Limniris*, *Xyridion*, *Nepalensis*, *Pardanthopsis*, *Crossiris,* and *Iris* (Zhao, 1985). The results obtained in this study are somewhat inconsistent with the classification mentioned above. For example, *Limniris* species occur in the second, third, fourth, and fifth groups. Therefore, Subgen. *Limniris* is a very unnatural group, and should be divided into several groups or subgenera, which would be more reasonable from the tree diagram analysis and is consistent with the viewpoint of Mou et al. (2011).

The principal components analysis (PCA) revealed some aspects of relationships that were not recognizable by clustering analysis (Marak et al., 2010). We also applied PCA for better presentation of the relationships among the species of *Iris*. *I. dichotoma* was distant from the others, and therefore it seems unreasonable that *I. dichotoma* and *I. subdichotoma* are clustered together. Since *I. uniflora* is clustered close to *I. typhifolia*, it should not be classified into the fifth group by itself.

In the *Iris* relationship analysis based on AFLP, we found that there were inconsistencies between the molecular marker method and the traditional method of classification, and sometimes there was no correspondence between the methods. Perhaps because the polymorphism of AFLP markers reflects differences in complex genomic DNA at the molecular level, whereas morphological traits are the results of certain functional gene expressions mediated by external environmental effects. Differences in DNA content may not be reflected in morphology, since some genes may remain unexpressed. Therefore, the genetic relationship and classification of *Iris* species should be assessed correctly and reasonably using the morphological method combined with the molecular marker method.

An understanding of the levels and patterns of genetic diversity is important for designing better conservation and improved management strategies for threatened and endangered species. Although the *Iris* samples collected in this work have a rich genetic diversity, considerable exploitation of the wild resources together with habitat destruction have led to a loss of *Iris* germplasm genetic diversity. Some wild *Iris* are difficult to collect because they have become rare. In order to actively protect wild plants of the *Iris* genus, wild plant germplasm nurseries have been established in many botany garden, which will provide the necessary genetic basis for breeding new species. The study on genetic diversity among 15 species of *Iris* based on AFLP marker will further identify relationships among species in molecular level. This results combined with morphological systematic, will be useful to breeders in selecting the best parental combinations for *Iris* breeding program in China.

Conclusion

In conclusion, AFLP markers were shown to be a good tool for assessing genetic diversity, genetic relationships, and identifications in *Iris*. The high percentage (99.74%) of polymorphic bands, genetic diversity parameters (Na, Ne, H, I), and genetic distances showed that the genus *Iris* has a rich genetic diversity and relatively large genetic differentiation at the species level. The 15 *Iris* species analyzed in this study can be divided into five groups and separated from each other by a few primer combinations. These results will be useful for the conservation, management, classification, identification, and breeding of *Iris* resources.

Abstract. Intensive agricultural practices coupled with better input services has resulted in exponential growth in crop production in India, particularly in northern region states of the country like Haryana. Though self-sufficiency has been achieved, it was accompanied by negative environmental effects such as serious non-target agricultural pollution. Implementation of eco-friendly smart agricultural practices can effectively overcome such pollution. However, the major constraints in assent and adoption of these practices are not limited only to associate risks and potential benefits, but farmers' attitudes towards knowledge of scientifically validated practices too came into picture. In the presented study, opinions of 180 respondents were explored in personal interviews using a three-point continuum scale for the major constraints (very serious, serious and not so serious) and scores were given as 3, 2 and 1, respectively. Weighted mean score (WMS), rank orders, standard deviation, correlation and regression were computed for the better understanding. Results concluded that major constraints for smart agricultural practices in their assent were non-familiarization with improved practices (WMS = 2.46), procedure of registration for weather forecasting (2.37), conservation agriculture is more labour intensive (2.24), lack of training to access e-information (2.39), Climate change effects the seasonal temperature and rainfall (2.76), Slow result of eco- friendly practices (2.54), high initial cost of protected structure (2.52), and lack of proper training for agro-processing and value addition practices (2.42). The results also indicated that 11 independent variables which were included in the study jointly contributed 37.00% variations in the constraints faced by the farmers in adoption of smart agricultural practices.
Keywords: *agriculture, adoption, climate, constraints, management and production*

Introduction

The major challenge of Indian agriculture is to produce sufficient food grains as it has long been a priority of the country to achieve food security, as it one of the major challenges posed by shrinking landholdings and the over increasing population. About two-third population of Indian population is directly or indirectly depends on related activities for their livelihoods and this sector occupies almost 43% of India's total geographical area (Arjun, 2013). About, 85 percent farmer comes under the category of small and marginal landholding. Demands are continuously increasing on agricultural land for food, fibre, and fuel is predicted to increase exponentially in coming decades with continued population growth (Bommarco et al., 2013). Population growth and dietary changes will drive the global food demand to extraordinary levels in the coming

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53835400

decades. To keep pace, food production will have to increase 60% by 2050 (FAO, 2013). Thus, population growth rate of 1.58%, India is predicted to have more than 1.7 billion people by the end of 2050.

India, with a total of 160 m ha of cultivated land comprises of only 39 million hectare irrigated by ground water and 22 million hectare by canals whereas about two third of cultivation in India is still depending on monsoon (Dhawan, 2017) and now there is a well-established fact and figures that natural resources such as land, water, forests, livestock, fisheries are deteriorating and degrading at a very fast rate which may be attributed to unmindful agricultural intensification, imbalanced use of fertilizers, overuse and inefficient use of irrigation water and deforestation.

While, other constraints like inadequate marketing channels and infrastructure, long intermediation, lack of accurate and timely market information system etc. are major challenges to the agricultural marketing system in the country. To prevent agricultural non-target pollution, ameliorate its effects and protect the environment in India, while maintaining or increasing crop yields, traditional practices are being re-evaluated and new eco-friendly agricultural practices are being intensively researched and developed (Shen and Du, 2009).

Therefore, there is immense need of adoption of smart agricultural practices (SAPs) to enhance the production and productivity to feed the continuous increasing population through sustainable use of natural resources along with to reduce the input cost, increase the net profit, and generate employment. SAPs, further, takes into consideration the diversity of social, economic and environmental contexts including agro-ecological zones/farming systems where it is to be applied. Implementation herein requires identification of integrated package of climate resilient technologies and practices for management of water, energy, land, crops, livestock, aquaculture etc. at the farm level while considering the linkage between agricultural production and ecosystems services at the landscape level. However, the real picture of overall sustainability and adoption of smart agricultural practices seems to be continued to face many challenges. Keeping in view the above concerns, study was conducted with objective to assess the constraints in adoption of smart agricultural practices.

Materials and methods

The study was conducted in Haryana state of India during 2017 (*Fig. 1*). Data were collected from From Hisar and Kaithal because main campus and sub campus of the university is situated in these districts. All respondents were recruited randomly from two districts viz. Hisar from South-West zone and Kaithal from North-East zone and three villages were selected from each district i.e. *Ladwa, Shahrwa* and *Rawalwas Khurd* villages from Hisar, whereas, *Kaul, Rasina* and *Bhana* villages were selected from Kaithal. Thirty farmers from each selected village were selected randomly. A well-structured and pre-tested questionnaire (see *Appendix*) was designed and used to survey opinions of a stratified sample of 180 farmers which were engaged in small-scale production. The data was analysed by Statistical Package for the Social Sciences (SPSS). Weighted mean score, rank orders, standard deviation, correlation and regression were computed for the better understanding. The responses of farmers' were obtained on three-point continuum scale in case of constraints (very serious, serious and not so serious) and scores were given as 3, 2 and 1, respectively. After that frequency was multiplied with the score (3, 2 or 1) and total weighted score was obtained and total

DOI: http://dx.doi.org/10.15666/aeer/1703_53835400

weighted score was divided by total respondents (180) for obtaining weighted mean score (WMS) and according to weighted mean score rank order were given.

$$\text{Weighted Mean Score (WMS)} = \frac{w1 * x1 + w2 * x2 + w3 * x3}{n}$$

where
w = number of respondents
x = value of seriousness i.e. Very Serious (x_1)-3, Serious (x_2)-2 and Not so serious (x_3)-1
n = total number of respondents

Results and discussion

Profile of respondents

Results pertaining to the personal profile of the farmers indicated in *Table 1*. It was found that vast majority of the farmers (78.34%) belonged to productive age group i.e. young to middle. The age-wise distribution of the respondents is quite natural and expected that working farmers usually come from young and middle aged group. More than 85% farmers were found to literate from primary to post graduate. Educational status is important and plays a key role in enhancing the knowledge, encouraging and motivating them towards adopting the innovative technologies and their applications. It is generally presumed that higher the educational status higher will be the adoption level. Majority of the farmers had land holding up to 5 acres, followed by 6-10 acre (36.67%).

Table 1. *Profile of respondents (n = 180)*

Category	Frequency	Percentage
Age		
Young (21-39 Years)	75	41.67
Middle (39-57 Years)	66	36.67
Old (57-76 Years)	39	21.66
Education		
Illiterate	21	11.67
Primary	13	7.22
Middle	19	10.56
Metric	63	35.00
Higher secondary	29	16.11
Graduate	27	15.00
Postgraduate	8	4.44
Land holding		
Less than one acre	15	08.33
Up to 5 acres	83	46.11
6 to 10 acres	66	36.67
11 to 15 acres	9	5.00
16 to 20 acres	1	0.56
More than 20 acres	6	3.33

n = 180 represents the total number of respondents

Constraints in adoption of sustainable farming

The examination of the data presented in *Table 2* indicated the constraints in adoption of sustainable farming viz., 'not familiar with improved practices' as overall major and serious constraint (52.78%) and ranked 1st with highest weighted mean score (WMS) 2.46, followed by 'small and fragmented land holding', 'not aware about training for sustainable farming', 'lack of skill to adopt sustainable farming' and 'lack of finance to adopt improved practices' ranked 2nd, 3rd, 4th and 5th with WMS 2.41, 2.29, 2.24 and 2.21, respectively. The major constraint comes in adoption of smart

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53835400

agricultural practices is that farmers are not familiar with improved practices and it might be possible due to the fact that clearly farmers develop and use cultural practices they are comfortable with and therefore minimize production risk associated with crop failure or yield reductions. Most farmers perceive these practices to be too costly. While Dsouza et al. (1993) concluded that adoption of sustainable agricultural practices is affected most by the environmental characteristic. Ikerd (1990) states that economic considerations and incentives are needed to encourage change to a different system. Secondly lack of awareness, training and skills about these practices are another factor. So, it is important to organize continuous awareness programs and provide the skill oriented training at local level in farming community. These results are in confirmation with those reported by Kumari (2012).

Table 2. *Constraints in adoption of sustainable farming (n = 180)*

S. No.	Sustainable constraints	Constraints			Total weighted score	Weighted mean score	Rank order
		Very serious (%)	Serious (%)	Not so serious (%)			
1	Small and fragmented land holding	95 (52.78)	63 (35.00)	22 (12.22)	433	2.41	II
2	Lack of skill to adopt sustainable farming	57 (31.67)	110 (61.11)	13 (7.22)	404	2.24	IV
3	Lack of finance to adopt improved practices	50 (27.78)	118 (65.56)	12 (6.66)	398	2.21	V
4	Not aware about training for sustainable farming	63 (35.00)	107 (59.44)	10 (5.56)	413	2.29	III
5	Not familiar with improved practices	95 (52.78)	72 (40.00)	13 (7.22)	442	2.46	I

n = 180 represents the total number of respondents

Constraints in adoption of weather forecasting

A perusal of data presented in *Table 3* indicated the weather forecasting viz., 'not aware about the procedure of registration' ranked 1st with highest weighted mean score (WMS) 2.37, followed by 'irregularity in message' ranked 2nd with WMS 2.23. 'Information is useful only for until crop production', 'lack of resources and internet etc.' and 'not proper language of message' ranked 3rd, 4th and 5th with WMS 2.22, 2.19 and 2.12, respectively. Farmers were not aware about the procedure of registration was ranked top and this may be possibly due to the region that extension personnel do not regularly interact with farmers to discuss climate forecasts. These constraints can be trimmed by providing proper guidance from the experts to the farmers with the help of literature, awareness campaign and mass media about weather forecasting advisory services to the farmers. Oyekale (2015) also reported that infrastructure and human capacities that are needed for attaining such efficiency were acutely lacking. This has also been reported by Murthy (2008) with respect to weather forecasts in Andhra Pradesh. Agricultural extension agents, working with farmers and forecasters could help forecasters to focus on the climate variables and spatial resolutions that matter to farmers and provide feedback from farmers to the forecasters about the performance and utility of the forecasts. They could assist farmers to interpret and apply forecasts for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53835400

making decisions such as the time of planting, choice of crops and crop varieties, application of fertilizers, herbicides, pesticides and irrigation water. These constraints can be overcome by frequent visits by extension personnel along with use of different teaching materials and methods, as extension personnel, rarely interact with farmers as well as the use of different teaching materials like display boards, bulletins (Feleke, 2015) and methods like personal contacts, informal discussion (Rajesh et al., 2016) on changing weather conditions were not given the deserved attention. Weather forecasting advisory services to the farmers and Climate Field Schools are discussed in this context by Stigter (2008).

Table 3. *Constraints in adoption of weather forecasting (n = 180)*

S. No.	Weather forecasting constraints	Constraints			Total weighted score	Weighted mean score	Rank order
		Very serious (%)	Serious (%)	Not so serious (%)			
1	Not aware about the procedure of registration	95 (52.78)	56 (31.11	29 (16.11)	426	2.37	I
2	Irregularity in message	57 (31.67)	108 (60.00)	15 (8.33)	402	2.23	II
3	Not proper language of message	49 (27.22)	104 (57.78)	27 (15.00)	382	2.12	V
4	Lack of resources and internet etc.	50 (27.78)	114 (63.33)	16 (8.89)	394	2.19	IV
5	Information is useful only for until crop production	47 (26.11)	126 (70.00)	7 (3.89)	400	2.22	III

n = 180 represents the total number of respondents

Constraints in adoption of conservation agriculture (CA)

Data presented in *Table 4* indicated the conservation agriculture (CA) constraints viz., 'conservation agriculture is more labour intensive' ranked 1st and major constraints with weighted mean score (WMS) 2.24, followed by 'increasing weed infestation', 'poor soil quality' and 'fragmented land holding' ranked 2nd, 3rd and 4th with WMS 2.21, 2.18 and 1.43, respectively. The conservation agriculture (CA) constraints viz., conservation agriculture is more labour intensive as well as prominent among farmers because full implementation of the principles of conservation agriculture involves a drastic change in many farm operations. So, there is immense need of proper training programs and policy about CA promotions (Grabowski, 2011; Kudi et al., 2011). A new knowledge base is needed by farmers to establish crops, manage weeds, manage crop residues, respond to newly emerging diseases and insect pests, and manage diverse crops that make the conservation agriculture more labour intensive (Pieri et al., 2002). Moreover, it cannot be reduced to a simple standard technology and thus pioneers and early adopters' face many hurdles before the benefits of conservation agriculture can be revealed (Derpsch, 2008). Also, it is appeared that conservation agriculture is as yet a relatively unknown concept (Kassam et al., 2009). Indeed, conservation agriculture is not an easily transferable single component technology; the appropriateness of conservation agriculture depends on both biophysical and socioeconomic factors and their interactions.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53835400

Table 4. *Constraints in adoption of conservation agriculture (CA) (n = 180)*

S. No.	Conservation agriculture constraints	Constraints			Total weighted score	Weighted mean score	Rank order
		Very serious (%)	Serious (%)	Not so serious (%)			
1	Fragmented land holding	22 (12.22)	34 (18.89)	124 (68.89)	258	1.43	IV
2	Poor soil quality	47 (26.11)	119 (66.11)	14 (7.78)	393	2.18	III
3	Increasing weed infestation	45 (25.00)	128 (71.11)	7 (3.89)	398	2.21	II
4	Conservation agriculture is more labour intensive	53 (29.44)	118 (65.56)	9 (5.00)	404	2.24	I

n = 180 represents the total number of respondents

Constraints in adoption of information and communication technologies (ICTs)

Table 5 described the constraints in adoption of ICTs viz., 'lack of training to access e-information' ranked 1st with highest weighted mean score (WMS) 2.39, followed by 'low internet access and electricity', 'inadequate infrastructural facilities', 'lack of resources and tools', and 'fear that ICTs provides irrelevant content' ranked 2nd, 3rd, 4th and 5th with WMS 2.30, 2.25, 2.22 and 2.18, respectively. The first rank was ascribed to the statement that there is lack of training to access e-information and this could be possibly due to the reason that regulatory frameworks for ICTs are not necessarily conducive to widespread scale up of ICT in rural areas. Processes take several years and require many regular visits to monitor and encourage progress, without assurance of success. This can be achieved through information and training campaigns, suitable legislations and policy along with regulatory frameworks, research and development, incentive and credit programs (Friedrich and Kassam, 2009). Therefore, training programs should be organized to overcome the constraints along with to provide infrastructure facilities, resources, tools and internet (Albert, 2014). While Rohila et al. (2017) suggested that low cost ICT tools such as mobile phones etc. should be promoted to provide agricultural information.

Table 5. *Constraints in adoption of ICTs (n = 180)*

S. No.	ICTs constraints	Constraints			Total weighted score	Weighted mean score	Rank order
		Very serious (%)	Serious (%)	Not so serious (%)			
1	Inadequate infrastructural facilities	55 (30.56)	115 (63.89)	10 (5.55)	405	2.25	III
2	Lack of resources and tools	51 (28.33)	118 (65.56)	11 (6.11)	400	2.22	IV
3	Low internet access and electricity	64 (35.56)	106 (58.89)	10 (5.55)	414	2.30	II
4	Fear that ICTs provides irrelevant content	52 (28.89)	108 (60.00)	20 (11.11)	392	2.18	V
5	Lack of training to access e-information	79 (43.89)	92 (51.11)	9 (5.00)	430	2.39	I

n = 180 represents the total number of respondents

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53835400

Constraints related to climate change

Table 6 narrated that climate change constraints viz., 'climate change effects the seasonal temperature and rainfall' ranked 1st with highest weighted mean score (WMS) 2.76, followed by 'rapid change in weather conditions' ranked 2nd with WMS 2.49. Whereas, 'deterioration in the quality of crop produce', 'environmental degradation', 'effect on plant population and yield', and 'probability of droughts and floods' ranked 3rd, 4th, 5th and 6th with WMS 2.47, 2.35, 2.28 and 2.22, respectively. The statement climate change effects the seasonal temperature and rainfall was ranked 1st with highest weighted mean score by the respondents and this might be due to the reason that climate change is arguably one of the most important challenge which is faced by farmers, largely due to their geographic exposure, low income, greater reliance on climate-sensitive sectors such as agriculture, and weak capacity to adapt to the changing climate. Farmers are adversely affected by climatic variability and change because of their dependency on rain-fed agriculture, with variability in rainfall and temperature directly affecting crop and livestock yields. Empirical results show that climate variability has significant economic costs as a result of periodic floods and droughts, which lead to major macro-economic costs and reductions in economic growth. This increased complexity requires a degree of experience and knowledge, which has to be acquired and learned. For early adopters this learning process and experiential knowledge has therefore involved a lot of trial and error until sufficient local experience and knowledge is accumulated to make the adoption easier (FAO, 2010; Mahato, 2014).

Table 6. *Constraints related to climate change (n = 180)*

S. No.	Climate change constraints	Constraints			Total weighted score	Weighted mean score	Rank order
		Very serious (%)	Serious (%)	Not so serious (%)			
1	Rapid change in weather conditions	92 (51.11)	85 (47.22)	3 (1.67)	449	2.49	II
2	Environmental degradation	68 (37.78)	107 (59.44)	5 (2.78)	423	2.35	IV
3	Climate change effects the seasonal temperature and rainfall	137 (76.11)	42 (23.33)	1 (0.56)	496	2.76	I
4	Deterioration in the quality of crop produce	93 (51.67)	79 (43.89)	8 (4.44)	445	2.47	III
5	Effect on plant population and yield	54 (30.00)	123 (68.33)	3 (1.67)	411	2.28	V

n = 180 represents the total number of respondents

Constraints in adoption of greenhouse gas mitigation practices

The data in *Table 7* depicted the greenhouse gas mitigation constraints viz., 'slow result of eco-friendly practices' ranked 1st with highest weighted mean score (WMS) 2.54, followed by 'ignorance about the bed effect of chemical hazardous on health' ranked 2nd with WMS 2.45. While, 'no reward for adoption of environmental measures', 'non-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53835400

availability of package of practices' and 'mostly farmers burn crop residue in the fields' ranked 3rd, 4th and 5th with WMS 2.38, 2.22 and 1.88, respectively. The statement slow result of eco-friendly practices ranked 1st may be because of the reason that eco-friendly practices contradicts the knowledge a farmer which he have learned from his experience and been told that the benefits offered by these practices are not obvious in the beginning. However, once the step-wise adoption begins, an eco-friendly practice improves its performance over time (Tebrugge and Bohrnsen, 2000). From the results of the study, it is clear that farmers will more readily adopt sequestration of GHGs if the agricultural extension services, planning and strategies could be improved. These findings are in line with findings of Mukteshawar and Seharawat (2016).

Table 7. *Constraints in adoption of greenhouse gas mitigation practices (n = 180)*

S. No.	Greenhouse gas mitigation constraints	Constraints			Total weighted score	Weighted mean score	Rank order
		Very serious (%)	Serious (%)	Not so serious (%)			
1	Non-availability of package of practices	47 (26.11)	126 (70.00)	7 (3.89	400	2.22	IV
2	No reward for adoption of environmental measures	86 (47.78)	76 (42.22)	18 (10.00)	428	2.38	III
3	Ignorance about the bed effect of chemical hazardous on health	84 (46.67)	93 (51.67)	3 (1.66)	441	2.45	II
4	Slow result of eco- friendly practices	105 (58.33)	68 (37.78)	7 (3.89)	458	2.54	I
5	Mostly farmers burn crop residue in the fields	52 (28.89)	55 (30.56)	73 (40.55)	339	1.88	V

n = 180 represents the total number of respondents

Constraints in adoption of protected cultivation

The data contained in *Table 8* showed the protected cultivation constraints viz., 'high initial cost' ranked 1st as major constraint with highest weighted mean score (WMS) 2.52, followed by 'poor quality of material' ranked 2nd with WMS 2.41. While, 'frequent occurrence of wind storms, hailstorms, rain etc.' and 'problem of nematodes and diseases' ranked 3rd and 4th with WMS 2.23 and 2.04, respectively. The statement high initial cost ranked 1st might be possibly due to the reason that polyhouse cultivation requires quality planting material, inputs, etc. which adds economic burden to the farmers. Singh and Sirohi (2006) also reported that the basic cost of fabrication and the operational cost of the climate-controlled greenhouses are very high, which are not suitable to the growers in India. Therefore, high initial investment, lack of availability of quality planting materials and inputs, poor post-harvest infrastructure and absence of price policy have led to very limited adoption of this technology by few farmers in certain pockets of the country. Above constraints can be countered to enhance farmers' adoption level with the help of manufacturing and financial sector support. It can be increased through capacity building of farmers, research and development coupled with adequate marketing system. Present study got support from the past research study of Ghanghas et al. (2015).

S. No.	Protected cultivation constraints	Constraints			Total weighted score	Weighted mean score	Rank order
		Very serious (%)	Serious (%)	Not so serious (%)			
1	High initial cost	99 (55.00)	76 (42.22)	5 (2.78)	454	2.52	I
2	Poor quality of material	78 (43.33)	97 (53.89)	5 (2.78)	433	2.41	II
3	Frequent occurrence of wind storms, hailstorms, rain etc.	46 (25.56)	129 (71.67)	5 (2.77)	401	2.23	III
4	Problem of nematodes and diseases	25 (13.89)	137 (76.11)	18 (10.00)	367	2.04	IV

n = 180 represents the total number of respondents

Constraints in adoption agro-processing and value addition practices

Table 9 elaborated the agro-processing and value addition constraints viz., 'lack of proper training' ranked 1stas major constraint, followed by 'lack of agro-processing unit' ranked 2nd with WMS 2.38. Whereas, 'lack of procurement policy' and 'lack of proper facilities' ranked 3rd and 4th with WMS 2.25 and 2.23, respectively. However, 'lack of consumption of agro processed food' ranked 5th with lowest WMS 2.13. Lack of proper training among the farmers was encountered as major constraints possibly due to the number of notable factors like socio-economic, contact with extension workers, provision of infrastructure and other institutional factors, which influenced the adoption. Other factors are also reported including society membership, education (Lapar and Pandey, 1999; Weir and Knight, 2000) and household income (Lapar and Simeon, 2004), education levels (Irungu et al., 1998; Lapar and Simeon, 2004) that contribute in adoption of new agricultural technologies. However, these constraints can be adequately addressed through extension agencies by formation of SHGs and by adopting bottom-up approach. While considering these facts, the need-based and skill oriented training awareness campaign including credit support, market-driven and decentralized extension system of the agro-processors to upgrade their knowledge and skills in modern post-harvest technology is strongly recommended. Moreover, provision of credit facilities could change the perceived constraints into enabling factors for adoption of modern post-harvest technology enterprises (Meena et al., 2009; Musebe et al., 2013).

Correlation and regression coefficients of farmers' personality traits with constraints encountered in adoption of smart agricultural practices

Table 10 narrated that correlation coefficient between the farmers' personality traits like education, land holding, cropping system, farming system, mass media exposure, extension contact, risk orientation, economic motivation and innovation proneness had positive and significant correlation. However, remaining traits namely age and irrigation facilities did not show any significant association at 0.05 level of probability. While in case of the partial regression coefficient, the farmers' education and mass media exposure were found significant, whereas, age, land holding, cropping system, farming system, irrigation facilities, extension contact, risk orientation, economic motivation and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53835400

innovation proneness did not show significantly contribution. These finding were found to partially support by the reports of Rajashekar et al. (2017). Further, it is revealed that all the eleven independent variables included in the study jointly contributed 37.00% variation in the constraints of the respondents regarding in adoption of smart agricultural practices when other factors were kept constant. This means that only 37.00% of the variation in the dependent variable was due to these variables and remaining 63.00% variations is due to other variables.

Conclusion

The results of this study showed that many factors can affect the decisions of farmers to accept and adopt the smart agricultural practices (SAPs), but cost is the most

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_53835400

important, followed by risks. Therefore, government should emphasize on the problems faced by farmers in adoption of smart agricultural practices (SAPs). Moreover, the action plans which may be more efficient and effective must be formulated and implemented at ground level by the government.

Abstract. Developing good microbial pesticides depends on isolating and knowing their pathogenicity. For this purpose, entomopathogenic *Metarhizium anisopliae* fungi were isolated from soils in Erzincan province and galleria bait method was used. Molecular identification of the isolates was performed by using ITS rDNA analysis. As a test organism, *Galleria mellonella* and *Tenebrio molitor* larvae were used and suspensions of $2x10^7$ conidia ml^{-1} were prepared adding Tween 80®. Bioassays were performed by dipping technique and mortality was recorded daily for 12 days. Each assay consisted of 3 replicates with 10 insects larvae. Ten fungal isolates were obtained from the bait method. Based on classical and molecular methods, all fungal isolates were identified as *M. anisopliae* and deposited into GenBank database with MH104853 - MH104862 accession numbers. All isolates of *M. anisopliae* were pathogenic to *G. mellonella* and *T. molitor* with a mortality rate of 63.3±3.3% - 83.3±3.3% and 30±5.8% - 66.7±3.3%, respectively 12 days after application. As a result, MaEMR1a and MaEO3 isolates can be applied as good biological control agents for pest insects.
Keywords: *biological control, Metarhizium anisopliae, G. mellonella, T. molitor*

Introduction

Entomopathogenic fungi (EPF) have an increasing prevalence in microbial control (Kılıç, E., 2009-Kılıç, E., 2014). EPF unlike other entomopathogenic microorganism (bacteria and viruses) which have to be ingested to cause diseases, typically infect insects by direct penetration of the cuticle followed by multiplication in the hemocoel (St. Leger et all., 2011). It is reported that EPF causes approximately, 60% of insect diseases (Faria and Wraight, 2007). EPF can be an alternative to chemical pesticides and are considered as non-harmful biological control agents in terms of human and environmental health (Faria and Wraight, 2007). *M. anisopliae* has a global distribution as a member of the soil flora (Zimmermann, 1992). This species has been reported in soils from widely differing climatic zones (Gillespie, 1988; McCoy et al., 1988; Kılıç, 2017). Some researcher pointed out that many isolates of *M. anisopliae* have entomopathogenic activity against a range of arthropod pests (Gillespie, 1988; McCoy et al., 1988). Many scientists reported that *M. anisopliae* has been effective in controlling more than 200 species of insect pests (Pu and Li, 1996; Sabbour, 2002;

Brooks and Wall, 2005; Quesada-Moraga et al., 2008; Shanley et al.; 2009; Dimbi et al., 2009; Dickson et al., 2010; Marius et al., 2011; Niassy et al., 2011).

In this paper, we isolated and characterized pathogenic fungi *M. anisopliae* for possible use as microbial control agent of *G. mellonella* and *T. molitor* and its pathogenicity was determined. Both insect species caused economic losses at storage.

Material And Methods

Insect culture

Galleria mellonella Linnaeus (Lepidoptera: Pyralidae) was collected from different beekepping in 2014 in Erzincan province. At the same time *T. molitor* (Coleoptera: Tenebrionidae) was collected from flour factories in Erzurum and storages in Erzincan provience. *G. mellonella* and *T. molitor* were grown under laboratory conditions [(25ºC±2 and 70%±10 R.H.) (16: 8 h (L:D)] (Zimmermann, 1986).

Isolation and identification of entomopathogenic fungi

Insect-associated fungi were isolated from soil samples by using 'Galleria bait method' (Zimmermann, 1986). The wax moth larvae, *G. mellonella* were reared continuously in constant darkness at 26°C. The third or fourth instar larvae (approximately 30 days after hatching) were used as baits. Ten larvae were placed on the soil samples in each boxes and covered with a lid and incubated at 25±2°C for two weeks. The larvae were examined on days 7 and 14 after inoculation. Surface of dead larvae were sterilized by 3% sodium hypochlorite for 3 min and then rinsed twice with sterile distilled water. After removing free water of the larvae surface, they were placed onto PDA plates. The fungi were identified using morphological characteristics of reproductive structures with the aid of relevant taxonomic literature (de Hoog, 1972; Samson et al., 1988; Tzean et al., 1997; Domsch et al., 1980; Humber, R., 1997; Humber, R., et al., 2012) (*Table 1*).

Table 1. *Fungal material and their geographical origin (2014-2016)*

Fungus Species	Isolate Code	Substrate (Soil)	Geographical Origin of Isolates

The identification of the isolated entomopathogenic fungi were performed using ITS. For this purpose, ITS1 (TCCGTAGGTGAACCTGCGG) and ITS4 (TCCTCCGCTTATTGATATGC) primers were used for the PCR (White et al., 1990). Genomic DNA was isolated from fungal biomass following the protocols of the *EcoSpin.* Genomic DNA isolation kit (EcoTec Biotecnology, Türkey). The PCR cycling conditions were: 2 min at 95 ^{0}C, followed by 30 cycles at 95° C for 45 s, 55° C for 60 s, 72° C for 60 s with a final extension step of 72° C for 10 min. PCR products were analyzed in 1 % (w/v) agarose gels visualized by UV after staining with EtBr. The products were purified by following the protocols of the EcoSpin PCR Purification Kit (EcoTec Biotecnology, Türkey). After purification, ITS rDNA were sequenced in both directions with 4 same primers at OLIGOMER Biotecnology, Turkey. Sequences chromatograms were assembled into one complete sequence using Bioedit Program (Hall, 1999) and the sequences were compared to all known sequences by the use of BLASTN 2.2.26+ program (Zhang et al. 2000) and deposited into GenBank (*Table 2).*

Preparation of conidial suspension

M. anisopliae isolates conidia were harvested by scraping the surface of 3-week-old sporulating cultures grown on potato dextrose agar (PDA) in petri dishes in an incubation at 25ºC±2 for three weeks from sowing. Fungus spores were harvested after three weeks by pouring a suspension that was prepared by adding 0.01% Tween 80 in sterilised and distilled water in a sterilized glass Erlenmeyer flask, into the Petri dish developed by *M. anisopliae.* Liquid mixture with fungi was drained into the sterilised glass Erlenmeyer flasks from cheese cloth. Then it was rinsed on a rinsing device for five minutes. After that, the spores were counted in the suspensions using a haemocytometer to $2x10^7$ spores/ml (Klingen et al., 2002a; Klingen et al., 2002b; Klingen et al., 2002c; Vänninen et al., 1999).

Incubation of fungal spores and its treatment on G. mellonella and T. molitor

Dipping technique was used and the fungus isolate was dipped in the tested spore suspensions for 10 second, then left to dry at room temperature. Every petri dish included 10 larvae for the experiments. For control treatment, the same process was followed but 3ml of sterilized and distilled water with 0.01% of Tween 80 was used instead of fungus isolate for the dipping. After all of the application petri dishes were stored in the incubator (25ºC±2) (Butt et al., 1994; Butt, 2002; Safavi et al., 2010). Mortality was assessed daily for 12 days by direct inspection for any signs of mortality. The experiment was replicated three times.

Statistical analysis

The experimental design was a randomized complete block with three replicates, and each replicate consisted of 10 larvae. The collected data were analyzed by one-way ANOVA test using SPSS 15.0 and means were compered by Duncan test.

Results

All fungal isolates were pathogenic to *G. mellonella* and *T. molitor* with a mortality rate between 63.3±3.3% - 83.3±3.3% and 30±5.8% - 66.7±3.3%, respectively after 12 days from application. Microscopic investigations confirmed mycosis and fungi were reisolated from all dead individuals.

In this study, a total of 10 different isolates belonging to the genera *Metarhizium* were obtained. Based on clasicall and molecular methods, all fungal isolates were identified as *M. anisopliae* and deposited in the GenBank database under the accession numbers MH104853 - MH104862 as seen in *Table 2*.

Table 2. *Fungal material and their geographical origin (2014-2016)*

Species	Isolate Code	GenBank Accession Numbers
Metharzium anisopliae	MaEMR1a	MH104853
	MaEMR2b	MH104854
	MaEK1a	MH104855
	MaEİ3	MH104856
	MaEKLY1a	MH104857
	MaER3	MH104858
	MaEM1	MH104859
	MaET3	MH104860
	MaEÇ3	MH104861
	MaEO3	MH104862

Isolates of MaEMR1a, MaEM1 and MaEO3 caused mortality in more than 80% of *G. mellonella* larvae. There was no significant difference between these isolates ($p<0.05$). However, isolate MaEM1 led to earlier mortality than the others. Mortality was found to increase with time. The mortality percentages of isolates against *G. mellonella* are depicted in *Table 3*.

The most virulent isolates against T. molitor were MaEO3, MaET3, MaEKLY1a and MaEMR1a, which caused 60, 63.3, 66.7 and 63.3% mortality, respectively after 12 days from application. As seen in *Table 4*, M. anisopliae isolate MaEMR1a was consistently more virulent than other isolates because mortality caused by this isolate was found to be significantly different ($p<0.05$) on the 10^{th} day.

It is observed that the death rates have increased as time progressed. As the entomopathogenic fungi feed in the host and complete their development, secondary metabolites secreted to kill the host are exposed and the host is dying more rapidly. At the same time, the fungus develops inside the host and breaks down the integument of the intestine and hyphae appear on the host body surface.

Discussion

Entomopathogenic fungi are used in the control of harmful insects and especially in the Integred pest management system (IPM) and they are used successfully nowadays. It is important to know the virulence of the newly developed mycoinsecticides, the killing rates, the molecular characterization of these fungi and their genetic structure as soon as possible.

According to this study, MaEMR1a, MaEM1 and MaEO3 isolates of *M. anisopliae* have been determined to have potential to suppress *G. mellonella larvae*; MaEO3, MaET3, MaEKLY1a and MaEMR1a isolates have potential to suppress *T. molitor* larvae. Among them these isolates, MaEMR1a and MaEO3 isolates possessed a good potential against both *G. mellonella* and *T. molitor* larvae. Our results overlap with other pataogentite tests on *T. molitor* and *G. mellonella larvae* (Pajar et al., 2013; Mora, E.A.M., 2016). Our results indicated that these two isolates (MaEMR1a and MaEO3) have a broad host range and can be used as biocontrol agents for *G. mellonella* and *T. molitor* and also they can be used as storages of biological control agents.

(Received 29th Nov 2018; accepted 28th Feb 2019)

Abstract. In order to study the impact of humic acid on some morphological, physiological and biochemical traits of Khuzestani savory under salinity stress condition, the present study was conducted in the greenhouse of the agricultural faculty of Lorestan University as a factorial experiment (combination of humic acid and salinity) in the form of randomized complete blocks design (RCBD) in 2017. Factors of the experiment included salinity in five levels (0, 25, 50, 75 and 100 mM of NaCl) and humic acid also in five levels (0, 10, 20, 30 and 40 mg/Kg of soil), which were applied as a pot experiment. Results revealed that in terms of morphological traits including stem length, root length, leaf length, leaf width and leaf area, the highest salinity (S5) and "without humic acid" (H1) (S5H1) produced the lowest values; whereas "without salinity" (S1) and highest humic acid (H5) (S1H5) produced the highest values for these traits. Moreover, S1H5 treatment produced the highest photosynthesis and transpiration rates of 24.04 μmol CO_2 m^{-2} s^{-1} and 2.85 mmol H_2O_2 m^{-2} s^{-1}, respectively; whereas, lowest values for the traits were produced in S5H1 treatment to be 5.67 μmol CO_2 m^{-2} s^{-1} and 0.65 mmol H_2O_2 m^{-2} s^{-1}, respectively. Furthermore, S1H5 treatment produced the highest (0.280mol CO_2 m^{-2} s^{-1}) stomatal conductance rate and lowest substomatal CO_2 (85 ppm); whereas, S5H1 treatment produced the lowest (0.013 mol CO_2 m^{-2} s^{-1}) stomatal conductance rate and highest (406 ppm) substomatal CO_2. The highest organic matter content (89.69% on average) was found in S2H3 treatment, whereas it reached to its lowest value (69.46% overage) in S4H5 treatment. Moreover, S5H2 treatment produced the highest (24.37% on average) and S1H5 treatment the lowest (10.35% on average) ash percentage trait. As for relative water content (RWC) of leaf, the highest (93.01% on average) and lowest (70.94%) values were produced in S1H5 and S5H1 treatments, respectively. S5H1 had the highest (0.334 mg/g of fresh weight) proline content and S5H5 had the highest (2.098 mg/g of dry matter) soluble sugar content; whereas, the lowest proline content (0.155 mg/g of fresh weight) and soluble sugar content (0.808 mg/g of dry matter) were produced in S1H5 and S1H1 (control) treatments, respectively.
Keywords: *salt stress, organic fertilizer, morphology, physiology, biochemistry*

Introduction

Plant growth and its resulting yield are influenced by numerous environmental factors. Worldwide, normal plant growth is challenged by a great number of environmental factors particularly drought, salinity, nutrient imbalance, toxicity and critical temperatures (Ashraf, 1994). Although, secondary plant metabolites are characterized by their importance in plant tolerance against environmental stresses, mechanism of their response to the environmental stresses keeps boggling the minds. Although, there is numerous evidence that the environmental stresses have an increasing effect on the secondary metabolites content of plants; this effect is limited and in some cases even happens in reverse. Furthermore, quality of these substances is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

influenced by the environmental stresses as well. It is known that plant species mainly use the mechanism of growth reduction and change in constituents of the secondary metabolites to survive in the environmental stresses. Environmental stresses, both biotic and abiotic, are serious and unforgiving threats for the crops. Drought, salinity, extreme cold and warm temperatures are the most notable abiotic stresses that reduce yield and increase economical costs at the global level (Nakabayashi and Saito, 2015).

One of the globally most infamous environmental factors is salinity, which is known for its negative impact on growth and yield of plants all over the world (Sevengor et al., 2011; Amirjani et al., 2010; Zhani et al., 2012). More specifically, impacts of salinity stress on the plants include ionic toxicity, osmotic stress, mineral deficiency, physiological and biochemical disorders and a combination of them (Saleh, 2013; Rajaravindran, 2012).

Curiously, salinity inhibits plant growth mainly through decreasing water potential in root zone, salinity-induced accumulation of ions and compromised nourishment balance; which finally lead to physiological, morphological as well as metabolic changes (Parvin et al., 2012). Interestingly, the most important monitoring parameters of effects of environmental stresses, particularly salinity and drought stresses are stem length and root length. This is because roots are in direct contact with the soil and the water and nutrients it absorbs from the soil are transported by the stem to other parts of the plant; thus, changes in the lengths of stem and root can best represent the response of plants to the salinity stress (Jamil, 2005).

Although limited plant growth under salinity stress may not simply be attributed to a change in the specific physiological processes, photosynthesis is known to be the dominant physiological process limiting plant growth (Sudhir and Murthy, 2004). Salinity reduces plant growth and yield by compromising its physiological processes particularly photosynthesis; while intensity of the effect depends on the degree and duration of the salinity stress (Chaves et al., 2009). Reports suggest that lower water potential of leaf causes the stomata to close, compromises CO_2 supply of the plant and finally decreases the rate of photosynthesis. Closing of the stomata is probably the first line of defense against the loss of water and the most important factor affecting the rate of carbon fixation (Da Silva et al., 2008).

Furthermore, salinity stress decreases osmotic potential that leads to decreased water absorption followed by decreased transpiration, which if continued long enough can cause plants to die (Sivritepe et al., 2010). Moreover, proline accumulation is one of the key physiological parameters used to assess plant tolerance and plays an important part in its adaptation to stress. Generally, proline accumulation occurs in plants that are exposed to extreme conditions of drought and salinity. Probably, proline synthesis in a plant is the result of its nonspecific response to low water potential. Moreover, proline may play a part in osmoregulation and maintaining the enzymatic activity of plants. In addition to the part it plays in osmotic modification, this amino acid contributes to fixation of cellular parts, absorption of free radicals, buffering state of cell oxidation potential, and other various processes against stresses (Ashraf and Foolad, 2007).

Under salinity stress, the insoluble sugars (starch) are broken down to soluble ones and this enables the cell to maintain osmotic potential and avoid dehydration. In addition, decreased sugar consumption due to decreased photosynthesis during the salinity stress causes further increase in the intracellular concentration of soluble sugars (Parvaiz and Satyawati, 2008). The salinity induced damages to plants occur through osmotic effect, ion toxicity, and compromised nutrient absorption. Humic acid is a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

constituent of humus and is dark brown in color. As a compound it contains sulfur, nitrogen, phosphorus in various percentages and some of the metals such as calcium, magnesium, copper, zinc etc. Soil salinity can be reduced by using new methods such as application of microorganisms, humic acid and folic acid, algae and herbal extracts to the soil (Bashan et al., 2014; Calvo et al., 2014).

Biochemically, humic acid is the active ingredient of humus (Nasouti Miandoab et al., 2011). Humic acid can have direct and positive impacts on plant growth by stimulating the growth of both shoot and root systems. Its impact on root is more predominant, while it can increase root volume which in turn improves efficiency of the root system. Humic acid can also increase the uptake of nitrogen, potassium, calcium, magnesium and phosphorus by the plant (Soltani, 2002). Possibly, humic acid contributes the growth traits through interaction with mineral ions, conversion to enzymes found in the plant, improving transpiration and photosynthesis and triggering hormonal activities (El-Sherbeny et al., 2012).

Owing to its characteristic composition, humic acid is capable of reducing the salt content of soil and negating its effect. Presence of humic acid in the soil can improve photosynthesis as well as tolerance against the biotic and abiotic stresses including diseases. Moreover, it boosts plant defense system by adding natural antioxidants and phenolic acid. Humic acid delays chlorosis through improving the uptake of magnesium and iron (Nasouti Miandoab et al., 2011).

Based on the above discussion and the increasing interest on medicinal plants, particularly in the technologically advanced communities, the importance of their preservation and propagation by using new cost-effective methods and create jobs and sustainable income can never be overemphasized. Khuzestani savory is one of the important medicinal plants in Iranian as well as global traditional medicine (*Fig. 1*). Khuzestani savory (*Satureja khuzistanica* Jamzad) is an aromatic perennial plant exclusively native to climatically arid southeastern region of Iran where it grows in limy-stony soils (Hadian et al., 2010). Geographical distribution of Khuzestani savory (*Fig. 2*) is in between Andimeshk and Pol Dokhtar towns in Palan village, Lorestan Province; and 72 km far from Andimeshk towards Khorramabad and 5 km after Tang Bridge on the clefts of limestone rocks in Sahara-Sindhi area at 474-520 m elevation (Jamzad, 2009). Savory belongs to Lamiaceae family and is among the species with remarkable antioxidant properties. For a long time, savory is being used as condiment and flavoring ingredient in canned food, soft drinks and manufacturing a variety of meat products and sausages. The essential oil content of above ground parts of savory varies in terms of the climatic condition under which the plant has grown and ranges between 1 and 2%. The most important compounds found in the essential oil of the plant include carvacrol (24.5%), thymol (23.12%), Gamma Terpinene (20.72%) and p-cymene (6.30%) (Kamkar et al., 2013).

More than 800 million hectares of the land area in the world, accounting for six percent of the total, is affected by salinity (Seckin et al., 2010). Salinity is a pervasive problem in Iran and limits sustainable agricultural production. Large parts of the arid and semi-arid regions in the country (especially in the Central Iranian Plateau, the southern coastal plains and the Khuzestan Plain) suffer from salinity (FAO, 1972; Naghizadeh et al., 2014).

Since wild Khuzestani savory (*Satureja khuzestanica*) grows in stony calcareous areas, this research was conducted to determine to what extent it could tolerate salinity and to prepare the ground for planting it on saline soils. Soil salinity plays a deciding

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

role in plant growth and development. Most plants are sensitive to salinity, but a small group of them can somewhat tolerate soil salinity. The quantity of active ingredients in medicinal plants is influenced by soil salinity. Therefore, determination of soil salinity level has an effective role in production of medicinal plants. Naturally, yield of Khuzestani savory also decreases under the harmful influence of salinity.

Figure 1. *Satureja khuzistanica*

Figure 2. *Satureja khuzestanica habitat in Lorestan Province (Mohebbi et al., 2016)*

This plant is wild-growing and found in sunny, stony, and calcareous areas of Lorestan and Khuzestan Provinces of Iran. Its cultivation is not common at present and most studies on it were conducted in greenhouses. Therefore, it is harvested in nature for medicinal purposes, which can be accompanied by the risk of its extinction. Nowadays, *Satureja hortensis* is widely planted. A summary of the method of cultivation this crop is as follows:

Like other annual plants, Khuzestani savory can be planted in rotation with most other crops. The desirable temperature for seed germination is 20-22 °C. Since this plant is sensitive to cold, the most suitable time for planting it is spring (from late April to late May). Seeds are planted in rows in the field in spring. Row spacing differs

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

depending on the planting method. In small-scale planting by hand, the suitable row spacing is 25-30 cm. If seeds are machine-planted, the 45-50 cm row spacing will be more appropriate. The suitable number of seeds is 120-140 per meter of row. Planting depth in different soils varies from 0.5 to 1.5 cm. 4-8 kg of seeds is required per hectare. It is recommended that the land is properly rolled after planting. This operation results in compaction of the surface soil layer and favorably influences uniform seed germination. The field must be irrigated after planting.

If planting density is high, thinning is carried out. The 4-6 leaf stage is suitable for this operation. Weed control is necessary during the growing season. Inter-row weed control by using a cultivator, especially after the first harvest, plays a major role in increasing yield. Plants have their highest essential oil content during the flowering stage. Therefore, harvesting the vegetative part is done at this stage. If plants are suitably looked after with respect to irrigation, soil, and contents of nutrients in soil that are necessary for satisfactory plant growth, it will be possible to harvest the crop 2 or even 3 times per year. The first harvest is carried out at the start of the flowering stage and the second in late September. All aerial organs of the plants are harvested by machine or manually using a scythe. Fruit usually matures 140-160 days after seed germination. Late August, when seeds gradually turn brown, is the suitable time for collecting seeds. Delays in collecting seeds should be avoided as completely mature seeds are scattered by the faintest blows inflicted on the plants.

The present study focused on effect of humic acid on some of the morphological, physiological and biochemical traits of the medicinal plant Khuzestani savory (*Satureja khuzistanica* Jamzad) under salinity stress. Hopefully, results from this study can pave the way for prospective studies in the field and help to promote cultivation of the medicinal plants.

Materials and methods

The present study was conducted as a greenhouse experiment in 2017 at Lorestan University, Iran. The experiment was conducted as factorial based on a randomized complete block design (RCBD) with four replications. The first factor included humic acid in five levels (zero, 10, 20, 30 and 40 mg/Kg soil) that was applied before planting. The second factor was salinity stress in five levels (zero, 25, 50, 75 and 100 mM NaCl) which was applied after sprouting and establishment of the plants during the fourth leaf stage. Levels of the factors being studied are shown in *Table 1*.

The humic acid was applied to the soil in the pots before the plantation of seeds. Pots used in the experiment were plastic pots made of polyethylene, each 280 g in weight 15.5 cm in diameter and 18 cm in height. Volume of each pot was 4 Kg and they were filled with soil-gravel-sheep manure in 2:1:0.5 ratio. Prior to plantation, savory seeds (*Satureja Khuzistanica* Jamzad) were disinfected by sodium hypochlorite 10% solution for 3 min and as many as 15 seeds were planted in each pot at a depth of 1-2 cm. After sprouting and during the fourth leaf stage the planting density was thinned to 8 plants. Cultivation included weeding, irrigation and application of salinity after fourth leaf stage to the treatments.

In order to study the morphological parameters, 5 plants were selected randomly from each experimental unit and average values were calculated in mm for traits such as stem length, root length, leaf length and leaf width by using a ruler.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

Finally, analysis of variance of data was done using SAS9.4 software. Also, for post-hoc analysis, the comparing the means of combination of treatment was done using Duncan's multiple range test at 5% probability level.

Table 1. *Different levels of salinity and humic acid applied in the experiment*

Humic acid (mg/kg soil)		**Salinity (NaCl mM)**	
Level of treatment	**Abbreviation**	**Level of treatment**	**Abbreviation**
0	H1	0	S1
10	H2	25	S2
20	H3	50	S3
30	H4	75	S4
40	H5	100	S5

Leaf relative water content (RWC)

In order to measure the RWC of leaf, samples were taken from the reference leaf (last developed leaf) in the experimental units and immediately put into ice; then their wet weight was measured (in 0.0001 accuracy) in the lab. The samples were put into distilled water and kept in Cold Room under 4 °C for 24 h. Then, saturated weight of the leafs was measured before putting them in an oven under 70 °C for another 24 h and measuring their dry weight. The obtained values and the following equation were used to calculate the RWC (Ritchie et al., 1990):

$$RWC = (Fw - Dw / Sw - Dw) \times 100$$

where Fw is the wet weight of leaf immediately after sampling, Dw is the dry weight of leaf after taken out of oven, Sw is the saturated weight of leaf after removed from distilled water.

Measurement of leaf area

Leaf area were obtained using the leaf area measuring instrument (LI-3000A, USA) by putting leafs on the instrument.

Measurement of soluble sugars

Firstly, the sample leafs were dried out by putting into the oven under 110 °C for 48 h and digital scale was used to take 0.1 g of each sample. Then, as much as 10 mL 70% alcohol was added to each sample in polyethylene containers and kept in refrigerator for one week. During this process, the soluble sugars were solved in ethanol and accumulated at the top layer, from which 1 mL was taken and added to a mixture containing 1 mL 5% phenol and 5 mL concentrated sulfuric acid. The obtained solution was initially yellow in color, which changed over time. The solution was kept in the ambient temperature of laboratory to cool down for half an hour to obtain its final color. Finally, optical absorbance of the solution in 485 nm was obtained by using spectrophotometer. In order to calculate the density of soluble sugars for the samples (C), solutions with glucose 0, 10, 20, 50, 100, 200 and 300 mg/L were prepared as control sugar by using the standard curve and all the procedures were repeated on 2 mL

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

of each solution. Sugar value was obtained for the plant samples in mg/g (Kochert, 1978).

Extraction and measurement of proline

In the present study proline content was measured by using method of Bates et al. (1973). The measurement process involved pulverizing 0.5 g of wet plant material inside a porcelain mortar while gradually adding 10 mL 3% sulfosalicylic acid. Then, the obtained solution was centrifuged inside a test tube at 3000 round/min for 15 min to become homogenous. The solution was filtered and 2 mL of it was taken and after adding 2 mL ninhydrin as reagent and 2 mL pure acetic acid was put in bain-marie under 100 °C for 1 hour before being put into ice bath. After adding 4 mL toluene in each tube, two phases were formed. The upper phase containing colored complex, was used to measure the proline content. Absorbance of the upper phase was read at 520 nm wavelength by using spectrophotometer, while proline content was obtained by using the standard diagram.

Measurement of ash and organic matter

As much as 1 g of dried shoot and leaf of the savory was pulverized using a mortar and weighed in porcelain containers. Then, the samples were burned on the heater for 2 h and put into an oven under 550 °C for 6 h. The residual grey colored matter in the container was ash. The porcelain containers were reweighed in order to obtain the ash percentage. Following equation was used to determine the ash percentage (AOAC, 1990).

$$\text{Ash\%} = (M3 - M2 / M1) \times 100$$

where M_3 was weight of porcelain container containing ash; M_2 was weight of porcelain container; and M_1 was weight of sample.

Furthermore, organic matter was measured using the following equation:

$$\text{Organic matter percentage} = 100 - \text{ash percentage}$$

Measurement of photosynthesis, transpiration, stomatal conductance and substomatal CO_2 concentration

Traits associated with gas exchanges were measured based on method developed by Sudhakar et al. (2016). Gas exchange analyzer (LCA4, ADC, England) was used to measure stomatal conductance ($molCO_2.m^{-2}.s^{-1}$), transpiration rate ($mmol\ H_2O.m^{-2}.s^{-1}$), photosynthesis rate ($\mu molCO_2.m^{-2}.s^{-1}$) and substomatal CO_2 concentration (ppm). All the measurements and note-takings concerning gas exchange values were carried out during morning hours (almost 8-10 PM).

Results

Length of stem and root

ANOVA results on the stem and root length traits (*Table 2*) and results obtained from comparing the means of interactive effects (*Table 3*) indicated that the S1H5

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

treatment composition produced the longest stems (28.4 cm) although there were no significant differences between them and those of the treatment composition S2H5. The shortest stems (14.5 cm) belonged to the treatment composition S5H1, but there were no significant differences between them and those of the treatment composition S5H2.

Means with at least one common alphabet have not significant differences based on Duncan's multiple range test at 5% probability level

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

The S1H5 treatment composition also had the longest roots (18.5 cm), but they were not significantly different from those of the S2H4, S1H3, S1H4, and S2H5 treatment compositions. The shortest roots (13.1 cm) were also observed in the S5H1 treatment composition, but they were not significantly different from those in the S4H2, S5H2, S4H1, and S3H1 treatment compositions.

Leaf length, leaf width and leaf area

ANOVA results on leaf length, leaf width and leaf area index, are presented in *Table 2*. Results obtained from comparing the means of the interactive effects (*Table 3*) revealed that the S1H5 treatment composition had the largest leaf area index (81.5 mm^2), which was not significantly different from those of the S2H5 and S1H4 treatments. The smallest leaf area index (59 mm^2) belonged to the S5H1 treatment composition, which was not significantly different from those of the S5H2 and S4H1 treatment compositions.

The largest leaf width (4.64 mm) was found in the S1H5 treatment composition, but it was not significantly different from those of the S1H4 and S1H3 treatment compositions. The smallest leaf width (2.15 mm) was observed in the S5H1 treatment compositions, but it was not significantly different from those of the S3H1, S4H1, S4H2, S5H2, S5H3 treatment compositions.

The treatment composition S1H5 enjoyed the longest leaves (4.17 cm), which was not significantly different from those in the S2H5, S1H4, and S3H5 treatment compositions. The shortest leaves (2.22 cm) were that of the S5H1 treatment composition, but they were not significantly different from those of the S4H1, S4H2, S5H2, and S3H1 treatment compositions.

Photosynthesis and transpiration

Significant interaction was observed in terms of the traits being studied, at 1% probability level (*Table 4*). Based on the results the highest rate of photosynthesis (24.04 $\mu molCO_2\, m^{-2}\, s^{-1}$) and of transpiration (2.85 mmol $H_2O_2\, m^{-2}\, s^{-1}$) were produced in S1H5 treatment; whereas the lowest values produced in S5H1 treatments and were as low as 5.67 $\mu molCO_2\, m^{-2}\, s^{-1}$ and 0.65 mmol $H_2O_2\, m^{-2}\, s^{-1}$, respectively (*Figs. 3* and *4*).

Stomatal conductance and substomatal cavity CO_2 concentration

Results from analysis of variance on these traits are shown in *Table 4*. There was a significant interaction between the salinity and humic acid factors in terms of the traits. Among the treatment levels, S1H5 produced the highest (0.280 $molCO_2\ m^{-2}\ s^{-1}$) stomatal conductance and lowest (85 ppm) substomatal cavity CO_2 concentration. In contrast, S5H1 produced the lowest (0.013 $molCO_2\ m^{-2}\ s^{-1}$) stomatal conductance and highest (406 ppm) substomatal cavity CO_2 concentration (*Figs. 5* and *6*).

Organic matter percentage

There was a significant interaction between the factors in terms of the organic matter percentage, at 1% probability level (*Table 5*). The highest (89.69% on average) and lowest (69.46% on average) organic matter percentage were produced in S2H3 and S4H5 treatments, respectively (*Fig. 7*).

Proline and soluble sugar

Significant interaction was found between the salinity and humic acid factors in terms of proline and soluble sugar traits, at 1% probability level (*Table 6*). Results showed that S5H1 and S5H5 treatments produced the highest proline content (0.334 mg/g in fresh weight) and highest soluble sugar content (2.098 mg/g in dry matter), respectively. Whereas, S1H5 and S1H1 (control) treatments produced the lowest (0.155 mg/g in fresh weight) and lowest soluble sugar content (0.808 mg/g in dry matter), respectively (*Figs. 10* and *11*).

Discussion

Length of stem and root

Plant growth and height invariably depends on the environmental conditions in which it grows. One of these conditions is the availability of sufficient water to the plant. Otherwise, decreased height can be resulted by decreased turgor pressure of the cells that leads to decreased length of each individual cell. The osmotic stress resulted from salinity stress during the early stages leads to decreased water content of the cells caused by compromised water uptake. If salt accumulation continued to the next stages and its concentration in plant tissues reached to a toxic level, premature aging of leaves and decreased photosynthesizing area of leafs may ensue, which in turn leads to decreased growth and lengthening of the cells (Munnz et al., 2006).

Amiraa and Abdul (2011) stated that although increased salinity stress led to a severe decrease in root and stem lengths, it increased the protein content of the samples . application of humic acid leads to increased height in plant by enabling it to uptake

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

micronutrients more efficiently. Acid humic can be used as a growth regulator, because it has an increasing effect on auxins, gibberellins and cytokinins, higher amounts of which cause lengthening of stems and improve plant growth. Results from the present study are consistent with those of study by Jariene et al. (2007) on pumpkin and of study by Ebrahimi and Miri Karbasak (2016) on Spaghetti.

Moreover, humic acid is characterized by its chelating effect on various nutrients such as sodium, potassium, magnesium, zinc, calcium, iron, copper, among others, that ensures sufficient nutrient supply to the plant and cause increased length and weight of primary root and formation of new lateral roots (Abedi and Pakniat, 2010). Humic acid application to pepper seedlings (Capsicum annum cv Derme) grown in pots and under salinity stress showed that in 1000 and 2000 mg/Kg dosages it increased traits such as stem and root lengths and wet and dry weights (Gulser et al., 2010).

Study on effects of irrigation regimes and humic acid spraying on some of the morphological and physiological traits of savory revealed that plants sprayed with 300 mg/L dosage of humic acid had the highest growth indices. More specifically, the highest values for plant height, dry and wet weights, leaf length and carbohydrate content were obtained in "100% irrigation + 300 mg/L humic acid" treatment (Sabouri et al., 2017). Humic acid increases plant growth and height through hormonal effects, boosting cellular metabolisms of plants, and improving uptake of nutrients by acting as a chelating agent (Salimon et al., 2012). Jumat et al. (2012) in their research into the impact of humic and folic acids on wheat reported that effect of humic acid fertilizer on the plant height was significant ($P < 0.01$).

Leaf length, leaf width and leaf area

Decreased leaf area may be due to the direct effect of salt on the cell division rate or to the shortened cell formation period. Seemingly, in glycophytes salt transport rate from root to shoot is higher than salt capacity of leafs; this slows down leaf growth and finally causes it to die (Parihar et al., 2015). There are three possible reasons for the decreased leaf area including decreased number of single-leafs, decreased production in young leafs and falling off of old leafs (Fahad et al., 2015).

Study on impacts of salinity from sodium chloride on savory has revealed that increased salinity stress has a decreasing effect on the growth parameters of the plant including leaf area; leaf water content; dry weight of root, stem and leaf; and chlorophyll and carotenoid contents. In contrast, it had an increasing effect on the proline and soluble sugar contents of the samples (Najafi et al., 2010). Root is the first plant organ affected by salinity stress and most of the times plays an important part in preventing salinity to reach the leafs. Leaf size depends on the number and size of its individual cells. Early leaf development stages are not sensitive to drought and salinity stresses; however leaf expansion is heavily influenced by salinity. Under salinity conditions leaf cellular swelling is decreased heavily, through which the stress can negatively affect leaf expansion (Razavizadeh and Rostami, 2003).

Based on the results from a study on myrtle plant (*Myrthus communis*) there was a significant difference between the salinity treatments in terms of most of the traits including plant height, leaf length and leaf width ($P < 0.01$). More specifically, the highest (1.69 cm) mean value of leaf length belonged to control treatment; whereas the lowest (1.28 cm) value for the trait was produced at the highest stress level of 6 dS/m). Furthermore, leaf width decreased as the salinity stress level and its application period increased (Vafadar et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

In a research, savory sprayed with 300 mg/L of humic acid produced the highest growth indices. More specifically, the highest values for traits such as plant height, wet and dry weights, leaf length and carbohydrate content were produced in "100% irrigation level + 300 mg/L humic acid spraying" treatment (Sabouri et al., 2017). High salinity can decrease leaf area through decreased water uptake. In addition to decreasing leaf area, salinity stress decreases dry weight of the plant, which is responsible for decreased photosynthetic area and hormonal imbalance of the plant. Salinity stress increases CO_2 concentration of substomatal cavity through decreased stomatal conductance and diminishes dry weight of plant by preventing biochemical activities and sucrose synthesis (Salimi et al., 2014).

Based on the results from a study on Moldavian dragonhead plant, leaf length increased significantly with the increasing salinity stress, while the highest (5.66 cm) value for the trait was produced in "without salinity stress + 200 mM humic acid" treatment. Application of 200 mM humic acid and 100 mM ascorbic acid improved this trait at 50 and 100 mM salinity levels, respectively (Narimani et al., 2018).

Photosynthesis and transpiration

The reason for decreased photosynthetic activity under salinity stress is twofold: dehydration of cell membrane that reduces its CO_2 permeability and the reduced CO_2 absorption of leaf that causes stomata to close. Furthermore, salt toxicity increases the salinity-induced sensitivity; consequently, activity of the induced enzymes changes due to the structural changes in cytoplasm. At the end, the negative feedback of reduced SINK activity and reduced water potential have also been reported as the photosynthesis-decreasing factors (Negrao et al., 2017).

Reduced photosynthetic activity depends on two other aspects of salinity including the final salt concentration and availability of the other ions. High salinity concentration of soil and water leads to increased osmotic potential, consequently Na^+ ions permeate into cytosol and inactivate electron transport in photosynthesis and transpiration. Moreover, there has been report that under high salinity condition the high concentration of sodium and reduced concentration of potassium lead to inhibition of photosystem II and reduced Rabiesco carboxylation, dilation of thylakoid membranes, reduced number and depth of grana and finally reduced number of mesophyll cells (Parihar et al., 2015).

A great number of physiological studies suggest that salinity impedes plant growth through decreasing photosynthesis. It is known that decreased photosynthesis due to salinity stress involves numerous intervening factors such as cell dehydration and subsequently its reduced permeability to CO_2, toxicity caused by accumulation of sodium and chloride elements, decreased CO_2 concentration due to stomatal closure, accelerated aging process due to salt accumulation (leaf fall), changed activity of the enzymes due to structural changes in cytoplasm, and plant failure to utilize assimilates due to reduced growth (Negrao et al., 2017).

However, owing to the numerous parts it can play in improvement of plant growth, humic acid could diminish the effect of salinity stress on the photosynthetic activity of savory. It has been reported that humic acid increased photosynthetic activity of plant through the increased activity of RuBisCO enzyme. Moreover, humic acid improves longevity of the photosynthetic tissues and increases grain yield. Humic acid increases nutrient content of crops through improved synthesis of carbohydrate, protein and vitamin in the plant and its positive effect on the photosynthetic aspects (Sharif, 2002). There are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

also numerous reports concerning the impacts of humic acid on decreasing transpiration rate under the stressed condition.

Under salinity stress condition, excessive diffusion of Na^+ ions into the cell inactivates photosynthetic electron transport systems; this in turn leads to decreased photosynthetic activity of the plant (Allahverdiev et al., 1998). In addition, under the salinity stress Na^+ ion competes with other ions, particularly potassium, which leads to decreased absorption of potassium by the plant as well as decreased cellular potassium/sodium ratio; this will negatively influence photosynthesis and development of the plant (Parida and Das, 2005). Salinity stress leads to nutrient imbalance, destruction of cellular organelles and compromised photosynthesis and transpiration in the plants (Aroca et al., 2013).

In a study conducted by Khalvandi et al. (2018), salinity stress led to a significant decrease in transpiration rate of peppermint. More specifically, an increase from 0 to 9 dS/m in salinity level decreased the transpiration rate by 56.49%. This means that in response to salinity stress, in order to minimize its impacts and maintain water balance of its leaves, the plant closed its stomata and prevented water loss through transpiration (Khalvandi et al., 2018).

Humic compounds influence plant growth and development both directly and indirectly. As for their indirect impacts, humic compounds improve soil fertility through by increasing beneficial microorganisms of soil, improving soil structure, increasing cationic exchange capacity and soil buffering capacity; whereas, their direct impacts are through increased photosynthesis, transpiration, and synthesis of proteins etc. (Saruhan et al., 2011). Molecules of humic acid prevent evaporation by binding to water molecules. Furthermore, molecules of folic acid (sub molecular part of humic acid) contribute to maintaining tissue hydration of plants as they penetrate into plant tissues and decrease transpiration by binding to water molecules (Bronick and Lay, 2005). Researchers demonstrated that humic substances contribute to uptake of nutrients, particularly nitrogen, which in high amount can increase chlorophyll content and photosynthesis of plants and accelerate their growth (Khayyat et al., 2007). In sour tea, humic acid spraying caused improved mobility and efficiency of nutrients, increased zinc and iron content of leaf and consequently increased photosynthesis and synthesis of carbohydrate and protein (Minai and Heidari, 2013). Humic acid contributes to photosynthetic activity through increasing the activity of RuBisCO (Chamani et al., 2012).

Stomatal conductance and substomatal cavity CO_2 concentration

It appears stomatal blockage under intensive stressed conditions contribute to reduction in stomatal conductance. Moreover, results have shown that decreased matter synthesis is mainly caused by reduced stomatal conductance; however, impacts of high salt concentrations on carboxylation efficiency should not be ignored (Ashraf and Harris, 2013). Reduced stomatal conductance under stressed conditions can be associated with low number and concentration of stomata. Researchers have argued that mesophyll cells in the plants subjected to salinity stress were smaller and more compact than those in control and even attributed the decreased CO_2 distribution to this physiological and anatomical change. Reduced stomatal conductance is the main pathway of leaf dehydration under stressed condition and is accompanied by reduced CO_2 absorption into the leaves and subsequently reduced photosynthesis. Another factor that can limit CO_2 distribution to its fixation site (chloroplasts) is mesophyll conductance, which is reduced under the stressed conditions particularly in response to salinity stress; and when CO_2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

fails to make it to the sites of carbon fixation sites, reduced photosynthesis and stomatal conductance can ensue (Negrao et al., 2017).

Results from the present study concerning the substomatal CO_2 revealed that increased NaCl concentration led to decreased stomatal conductance. However, substomatal CO_2 rates exhibited an increasing trend, while there was a negatively significant correlation between them. Thus, it is expectable that in addition to reduced stomatal conductance, some other non-stomatal restrictions such as a potential damage to optical systems are influencing salinity-induced photosynthesis reduction.

Based on the results from a study on Moldavian dragonhead plant, stomatal conductance differed significantly at different levels of salinity stress in the absence of the stress relievers. Whereas, presence of humic acid and ascorbic acid led to a significant increase in this trait at all stressed levels, as compared to the control (absence of stress reliever) (Narimani et al., 2018).

Decreased water uptake induced by high salinity can result in decreased leaf area. In addition, salinity stress can cause a decrease in dry weight of plant; this in turn can cause decreased photosynthetic area as well as compromised hormonal balance inside the plant. Salinity stress leads to increased intrastomatal CO_2 concentration through decreased stomatal conductance, and to diminished dry weight of plant by preventing biochemical activities and sucrose synthesis (Salimi et al., 2014).

Organic matter percentage

Researches in the field have shown that soil salinity leads to decreased growth and subsequently decreased plant biomass through primary and secondary impacts; curiously, plant organs such as root, stem and offshoot respond differently to salinity stress as they differ in terms of sensitivity to it (Setia et al., 2013). Under the stressed conditions, application of compounds such as humic acid can influence plant growth through changing physiology of the plant and improving the physical, chemical and biological properties of the soil. Furthermore, humic acid can directly influence plant growth by stimulating growth of both shoot and root systems of plant. Impact of humic acid is more prominent on root system, as it can improve its efficiency through increasing its volume. Lastly yet importantly, humic acid can increase uptake of nitrogen, potassium, calcium, magnesium and phosphorus by the plant (Balakunbahan and Rajamani, 2010).

Ash percentage

Ash percentage is indicative of minerals content of plant tissues; while uptake of minerals by root is increased under salinity stress conditions. Humic acid improves root growth and increases uptake of nutrients and their transport into the organs, while has a decreasing effect on charging of the ionic salts (Shaaban et al., 2009).

Product of burning the organic plants is nonorganic ash (minerals) and the lesser is the residual ash the higher is the plant's quality. Some medicinal plants vary relatively highly in terms of ash percentage, which is very helpful in plant quality assessment (Omidbaigi, 2004). Thus, it can be seen that application of humic acid led to decreased ash percentage, which represents high quality of the treatments.

Relative water content (RWC) of leaf

Environmental stresses, particularly salinity stress, lead to reduction of available interstitial moisture through creating physiological drought so that plant water relations

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

are compromised and water imbalance ensues. However, positive effect of humic acid fertilizers on enlargement of plant root and subsequently on its ability to uptake water and nutrients, make them a desirable tool to improve plant water status. This is consistent with the result of the present study, as humic acid led to the increase of RWC of leaf. Sinclair and Ludlow (1985) reported the normal range of RWC to be 85-95%; in which, they believe water uptake by root and water loss through transpiration are in balance, so that the plant can maintain its natural functioning. Results from a study on peppermint revealed that increased salinity led to a significant decrease in RWC of all the treatments. This decrease is mainly associated with the decrease in stomatal conductance rate that leads to stomatal closing and decreased transpiration, and finally to decreased water uptake by the roots (Khalvandi et al., 2018).

Based on results of study by Beheshti and Tadayyon (2017) humic acid had a significant effect on RWC of leaf. More specifically, the highest RWC (83.6%) was obtained in 6 L/ha application of humic acid. Based on results from another study on Moldavian dragonhead plant the highest RWC (81%) was produced at both 100 mg/L and 200 mg/L humic acid levels under without stress condition. Furthermore, as the stress level increased the value of trait decreased and reached to its lowest value (56%) at 150 mmolar salinity stress in the absence of humic and ascorbic acids. However, in the same salinity stress level, application of 100 and 200 mg/L of humic acid and 200 mg/L of ascorbic acid is capable of improving the trait (Narimani et al., 2017).

Proline and soluble sugar

Proline is one of the active amino acids involved in osmoregulation. Accumulation of proline triggered by increased salinity and increased intracellular osmotic pressure is one of the mechanisms of salinity tolerance in plants. Since in plants proline is accumulated in response to salt and drought stresses, proline synthesis in plants may be the result of non-specific response to low water potential. Moreover, appropriation of more carbons to synthesize organic substances effective on osmoregulation such as proline, also can reduce plant growth (Ashraf and Foolad, 2007). Thus, increased synthesis of proline by the savory triggered by increased salinity may be one of the growth-reducing factors under the same condition. It has been reported that humic acid is capable of reducing the synthesis and accumulation of compounds compatible with cytoplasm such as proline.

Soluble sugars act as the osmoregulators, stabilizer of cell membrane and maintainer of cell turgidity. Actually, plants capable of accumulating higher amount of sugars under the stressed condition exhibit higher tolerance against the stress (Slama et al., 2007). Plants use various physiological mechanisms to deal with salinity stress such as storing sodium in vacuoles in order to reduce its toxic effects and producing osmolytes including glycine betaine, proline, soluble sugars, phenolic compounds etc. (Jouyban, 2012).

When under stress conditions, plants use proline as the source of energy, carbon and nitrogen to regenerate the damaged tissue (Najafi et al., 2010). As salinity level increases so does the amount of osmoregulators such as probline, which enable the plant to tolerate the environmental stresses. Proline is synthesized from glutamate and ornithine. Increased synthesis of proline is a type of osmoregulation strategy that may lead to reduced plant growth (Mirza Masoumzadeh et al., 2012). Reduced consumption of proline for protein synthesis under stressed condition may be another reason for proline accumulation (Mudgal et al., 2009).

Study on effects of salinity stress of sodium chloride on savory revealed that increased salinity stress caused a severe decrease in growth parameters including leaf area; leaf water content; dry weights of root, stem and leaf; and in chlorophyll and carotenoid content of leaf. Whereas, increased salinity caused increase in proline and soluble sugar content of the samples (Najafi et al., 2010). In their study on savory grown under salinity stress Vojodi Mehrabani et al. (2017) concluded that savory is capable of tolerating salinity up the level as high as 50 mmolar without suffering a considerable decrease in its dry weight. Furthermore, as salinity stress increases so does the proline content of the samples. More specifically, in their study the highest proline contents of the samples were found at 100 mmolar and 150 mmolar concentrations of NaCl; whereas control treatment produced the lowest proline content; which is consistent with the results of study by Akbari et al. (2013) concerning the proline content of savory samples under salinity stress. Furthermore, the highest soluble sugar content was produced at 100 and 150 mmolar NaCl concentrations.

Moreover, study by Najafi et al. (2010) on savory revealed that increased salt concentration led to increased soluble sugar content of the plant. Curiously, soluble sugars contribute to osmoregulation, and maintain membrane integrity and stability of the intracellular proteins.

Nouri et al. (2013) demonstrated that increased salinity led to increased proline content of stem in Shirazi chamomile, while the highest proline content was produced in 9.5 dS/m salinity treatment and the lowest value in control. Kafi et al. (2012) reported that increased content of soluble sugars under salinity stress condition may reveal that transport from above ground organs to the root of soluble carbohydrates has been compromised.

Conclusion

Salinity is one of the main environmental stresses in most parts of the globe that affect plant traits negatively. Based on the results from the present study, humic acid can alleviate the negative effects of salinity stress, while increasing concentrations of humic acid under salinity stress led to a significant increase in growth traits as compared with control. In conclusion, as water is becoming increasingly scarce and agricultural lands in arid and law rainfall areas are becoming increasingly saline, the importance of humic acid fertilizer as a tool to alleviate the harmful impacts of these agricultural and environmental challenges can never be overemphasized.

Suggestions

- Since Khuzestani savory is a wild species and its overexploitation may be accompanied by the danger of its extinction, it is necessary to conduct more experiments on expanding its cultivation. This will reduce its illegal harvest in nature and prevent its extinction.
- It is suggested that similar studies be carried out at higher salinity levels.
- The present research was conducted in a greenhouse. Therefore, it is suggested that studies be carried out at field level.
- It seems that long-term experiments are needed for more accurate studies on effects humic acid and salinity have on Khuzestani savory.

DOI: http://dx.doi.org/10.15666/aeer/1703_54095433

- It is suggested that effects of other organic fertilizers and environmental stresses, and also their interactive effects, on this plant be determined, and also effects of organic and chemical fertilizers on it be compared.
- Since this is a native plant of Lorestan and Khuzestan Provinces, it is suggested similar studies should be conducted in other regions and climates to determine its adaptability to different conditions.

(Received 6th Dec 2018; accepted 4th Feb 2019)

Abstract. Indoor experiments were conducted to fully understand soil metal contamination around coal mines in Pingdingshan, Henan province, China. Forty-three paired soil and wheat product samples were collected from three main mining areas in Pingdingshan. Soil Cd, Zn and Pb were assessed using the diffusive gradients in thin films (DGT) and pentetic acid or diethylene triamine penlaacetic acid (DTPA). The pollution levels were evaluated. The Nemero comprehensive pollution index shows the soil heavy metal pollution is slight; the single coefficient of potential ecological hazard indicates the soil pollution degree of heavy metals ranks as Cd > Pb > Zn, which is the most serious pollution. Cd is close to medium ecological hazard, and other heavy metals are minor ecological hazards.
Keywords: *coal mines, wheat, DGT, DTPA, potential ecological risk*

Introduction

Mineral resources are the basic source of human production and life, and an important material basis for socioeconomic development. As the demand for energy has increased since the industrial revolution, the human society has increasingly exploited fossil energy such as coal. The development of mineral resources plays an important role in promoting the national economy growth, but has also brought some environmental pollution problems. During the mining process, heavy metals in coal and coal gangue can enter and the soil around mining areas through leaching, infiltration, migration and other ways. Heavy metal pollution in the soil affects the soil microbial activity and thus the structure and function of the soil ecosystem. Heavy metals in the soil enter the food chain through food and vegetables, causing health risks to humans.

Various heavy metal environmental pollutants have received much attention in recent years because of their persistent bioaccumulation and high toxicity.

Some heavy metals such as Zn and Cu above the safe concentration can be toxic, while other heavy metals can be harmful even at low concentrations. As reported, the farmland soil around a coal mine in north Bangladesh was severely contaminated by heavy metals such as Mn, Zn, As, Pb and Ti (Bhuiyan et al., 2010). Behaddya et al. used GIS to characterize the spatial distribution of heavy metal pollution in the surface soil of a coal mine area in Algeria (Behaddya and Hadjel, 2014). However, the effective assessment of health risks to residents is of very insufficient. In this research, The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54355447

objective of this study is used diffusive gradients in thin-films (DGT) to assess the heavy metal contents around the mining areas in Pingdingshan and to evaluate the heavy metal pollution levels and environmental risks.

Materials and methods

Sampling and sample pretreatment

Pingdingshan (33°08′-34°20′ N, 112°14′-113°45′ E) in Henan Province is known as the coal bunker of middle China. It is also an important base of the energy and raw material industry. In this study, 42 paired samples of soil and wheat were collected from mining areas of Pingdingshan in June 2017. The sampling sites were chosen near three local mines (Hugou-RA, Zaoyuan-RB, Bishan mines-RC). The sample number and GPS coordinates of Pingdingshan area are shown in *Table 1*. The soil samples were air-dried and then passed through < 2 mm, < 0.25 mm and < 0.15 mm sieves. The wheat samples were washed with deionized water, separated into roots and straws, and dried at 75 °C until constant weight.

Table 1. *Sample number and GPS coordinates in Pingdingshan area*

Soil physicochemical analyses

Soil pH was measured by a pH detector in a 1:2.5 soil/water suspension (w/v). SOM (soil organic matter) was determined using the potassium dichromate volumetric method. Particle size was analyzed using a Mastersizer 3000 device (Cai et al., 2015).

DOI: http://dx.doi.org/10.15666/aeer/1703_54355447

Soil available Cd

Since it is available Cd rather than total Cd that matters in Cd toxicity, here available Cd was focused. Cd extracted by passive sampling methods such as diethylene triamine penlaacetic acid (DTPA) and DGT can be considered as available Cd in this work.

DGT deployment

DGT developed in 1994 by British scientists Davison and Zhang Hao is a contaminant in-situ research technique based on Fick's first law of diffusion. With DGT, the bioavailability of heavy metals can be studied by simulating the heavy metal absorption by plants or other organisms, and the results reflect both static processes (soil particles and soil solutions) and dynamic processes (Luo et al., 2011).

Compared with other traditional morphological analysis techniques, DGT can more efficiently measure the biological effective states of heavy metals in the nature and better reflect the heavy metals absorbed by organisms.

The DGT device consists of an innermost adsorption layer, a diffusion layer covered with specific thickness, and protective filter membranes (Wei et al., 2018).

As the adsorbent in the adsorption film has strong binding capacity with specific phosphorus and metals (metalloid), the target substance (analyte) in the solution can be rapidly and irreversibly fixed on the binding phase and consumed through the diffusion membrane.

Based on Fick's first law (Zhou et al., 2011), the diffusion flux F of the analyte is:

$$F = D\partial C / \partial x \quad \text{(Eq.1)}$$

where D is the diffusion coefficient of the tested substance in the diffusion membrane; C is the concentration of the test substance in the solution.

The time-averaged concentration of the target substance measured by DGT can be calculated as follows:

$$C_{DGT} = M\Delta g / DAt \quad \text{(Eq.2)}$$

where M is the amount of the target substance in the adsorbent, Δg is the thickness of the diffusive layer, A is the area of the DGT device window, and t is the adsorption time.

Soil and heavy metal determination

Air-dried soil samples over a 2-mm nylon sieve were weighed (20 g) and placed into 250-mL plastic containers (Fan et al., 2010).

Then deionized water with the maximum field water holding capacity of 70% was added under full stirring. The plastic wrap was covered to prevent moisture and evaporation, followed by equilibration at 25 °C constantly for 48 h.

After that, a small amount of the treated soil (about 3 g) was placed with a clean plastic spoon into the round hole of the DGT device and gently shaken parallel on the table surface, making the soil fully contact with the filter surface. Soil was further added until the inner cavity was filled.

The loaded DGT device was transferred to a ziplock bag added with a small amount of deionized water in advance, and the bag mouth was semi-closed (Xu et al., 2004).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54355447

After placement at a constant temperature for 24 h, the soil was removed and the DGT device was rinsed with deionized water. Then the fixed membrane was removed into the ziplock bag, and minor deionized water was dripped to wet it. After sealing, it was stored at 4 °C for analysis.

Single and comprehensive pollution indices

The soil pollution degree of each metal was measured using the single pollution index (P_i), which is the ratio of the heavy metal concentration in the contaminated soil to that in the reference soil. P_i was calculated as follows (Cai et al., 2015; Yang et al., 2012):

$$P_i = \frac{C_i}{C_o} \quad \text{(Eq.3)}$$

where C_i and C_o are the heavy metal concentrations in the contaminated soil and the reference soil, respectively. The soil comprehensive pollution status for all the heavy metals was calculated as the Nemero comprehensive pollution index P_c. The result not only considers the average pollution level of various heavy metals, but also indicates the most serious pollution in the soil contributed by single heavy metals. P_c was calculated as follows (Zhou et al., 2011; Chen et al., 2014; Gil-Sotres et al., 2004):

$$P_c = \sqrt{\frac{(\overline{P_i})^2 + \max(P_i)^2}{2}} \quad \text{(Eq.4)}$$

Potential ecological hazard index

The potential ecological hazard index is based on the characteristics, environmental migration and sedimentation of heavy metals and evaluates heavy metals in soil or sediments from the perspective of sedimentology. This index considers the soil contents of heavy metals and combines ecology, environmental science and biotoxicology (Fan et al., 2003; Li et al., 2014). It comprehensively analyzes the heavy metal migration and transformation in soils and sediments and evaluates the sensitivity of geographical regions to heavy metals and the differences in background values of geographical regions. The degree of potential ecological hazard eliminates the influence of geographical differences (Xiong et al., 2017; Wang et al., 2017), reflects the relative contribution of biological effectiveness and spatial differences, and uncovers the potential impact of heavy metals on the ecoenvironment. It is suitable for largescale comparison of sediments and soils (Xu et al., 2004). Relevant formulas are:

$$\mathrm{RI} = \sum_{i=1}^{n} E_r^i \quad \text{(Eq.5)}$$

$$E_r^i = T_r^i \times C_f^i \quad \text{(Eq.6)}$$

$$C_f^i = \frac{C_s^i}{C_n^i} \quad \text{(Eq.7)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54355447

where E_r^i is a potential ecological hazard individual coefficient; T_r^i is the toxicity response coefficient of a certain metal based on Hakanson's standardized heavy metal toxicity coefficient (Cd = 30, Pb = 5, Zn = 1); C_r^i is the single pollution coefficient; C_s^i is the measured heavy metal content in surface soil; C_n^i is the reference value (from National Secondary Standard for Soil Environmental Quality).

Results and discussion

Soil properties and contents of metals

The general characteristics of the soils are shown in *Table 2*. Soil pH ranges from 5.2 to 8.3. In RA, the soils are weakly alkaline, with pH between 7.5 and 8.3. In RB, the majority of the soils are acidic, with pH between 5.2 and 6.6. As for RC, the pH is mainly in the neutral range, with the mean of 7.3. The soil organic carbon (OC) in the research areas ranges between 1.9% and 9.2%, which indicates the difference in soil fertilization degree. The Cd content ranges between 0.13 and 0.4 mg·kg^{-1}, with only one sample from RB exceeding farmland soil pollution risk screening value (GB 15618-2008). The Zn content ranges between 50.7 and 125.1 mg·kg^{-1}, while the Pb content ranges between 15.5 and 38.2 mg·kg^{-1}.

Table 2. *General characteristics of soils collected from the study area*

Sites		pH	OC (%)	Total concentration (mg·kg^{-1})		
				Cd	Zn	Pb
RA	Mean	7.8	5.1	0.16	69.8	34.8
	Range	7.5 - 8.3	2.6 - 9.2	0.15 - 0.19	61.9 - 79.8	30.8 - 38.2
RB	Mean	5.8	4.1	0.18	67.9	22.6
	Range	5.2 - 6.6	1.9 - 6.6	0.13 - 0.4	50.7 - 125.1	15.5 - 35.5
RC	Mean	7.3	5.4	0.15	66.9	26.6
	Range	6.7 - 8.3	2.9 - 7.3	0.1 - 0.3	57.4 - 94.9	17.7 - 35.7
Standard limit	Soil background value of Henan Province[1]			0.064	62.5	21.8
	Environmental quality standard for soils[2]			0.25 [a]	150 [a]	80 [a]
				0.30 [b]	200 [b]	80 [b]
				0.45 [c]	250 [c]	80 [c]
				0.80 [d]	300 [d]	80 [d]

[1]The soil background value of Henan province is derived from literature (Shao et al., 1998)
[2]The standard value of soil environmental quality originates from the secondary standard of soil environmental quality standard (GB15618-2008), a is soil pH < 5.50, b is pH between 5.50 and 6.50, c is soil pH between 6.50 and 7.50, and d is the corresponding quality standard when soil pH > 7.50

Table 3 shows the metal contents measured by DTPA and DGT. The ranges of Cd, Zn and Pb are 2.5-11.1, 85.3-520.2 and 0.65-4.88 μg·kg^{-1} respectively (DTPA), and 2.3-5.5, 57.1-491.3 and 1.1-9.4 μg·kg^{-1} respectively (DGT). DTPA has higher extraction capacity than DGT, which may be related to the different chemical properties of the extractants. DTPA is an efficient chelating agent with strong extraction ability and can extract water-soluble, exchange, mineral-bound and organic complex heavy metals in soil.

Tables 4 and *5* show the bioavailable concentrations of Zn, Cd, Pb in the DGT resin eluent and the concentrations of heavy metals measured by DTPA. DTPA extractable heavy metals fraction, as a form of heavy metals with high biological effectiveness, can be used as an effective index of heavy metal pollution in similar soil by its rapid and convenient leaching (Yang et al., 2012; Lu and Zhao, 2017). DTPA can extract water-soluble, exchangeable, adsorptive, organic stationary and partially-oxidized heavy metals from soil, which is considered to be a highly bioactive form related to its total amount. The available heavy metals measured by DGT include the free state of soil solution and the unstable organic and inorganic complex state released from the surface of soil particles (Chen et al., 2012; Bernalte et al., 2013). The average extraction rates (i.e. the percentage of extracted heavy metal content in the total amount of this heavy metal) of Zn, Cd and Pb are 3.18%, 30.46% and 13.03%, respectively in DTPA, and 0.21%, 2.01% and 0.02%, respectively in DGT.

Table 6 presents the soil particle concentration (P_c) in each sampling point, the Rdiff calculated using the 2D DIFS model, and the effective concentration (CE) calculated as the ratio between C_{DGT} and Rdiff. In general, soil P_c in the same area is approximately the same, with the lowest SA. The CE ranks as Zn > Pb > Cd, while the heavy metal content extracted by DTPA ranks as Pb > Zn > Cd.

The relationships between Cd, Zn, Pb in the roots, straws and that extracted by DGT and DTPA are shown in *Figure 1* and *Table 7*. Although the C_{DGT} of Cd, Zn and Pb in the soil is one to two orders-of-magnitude lower than those extracted by DTPA, C_{DGT} extraction is closer to wheat availability than DTPA extraction, and DTPA extraction may overestimate the concentration of available states, and some of the extracted metals may not be absorbed by wheat. More studies also show DGT better reflects plant uptake than chemical extraction. For example, PUEYO M used DGT to assess the influence factors on cadmium accumulation in rice grains from paddy soils of three parent materials and found that cadmium bioavailability could well be assessed by DGT (Pueyo et al., 2008). Bernd Nowack et al. used DGT to test undisturbed field soils and suggested that DGT can be successfully used under undisturbed field conditions to study the kinetics of metal resupply.

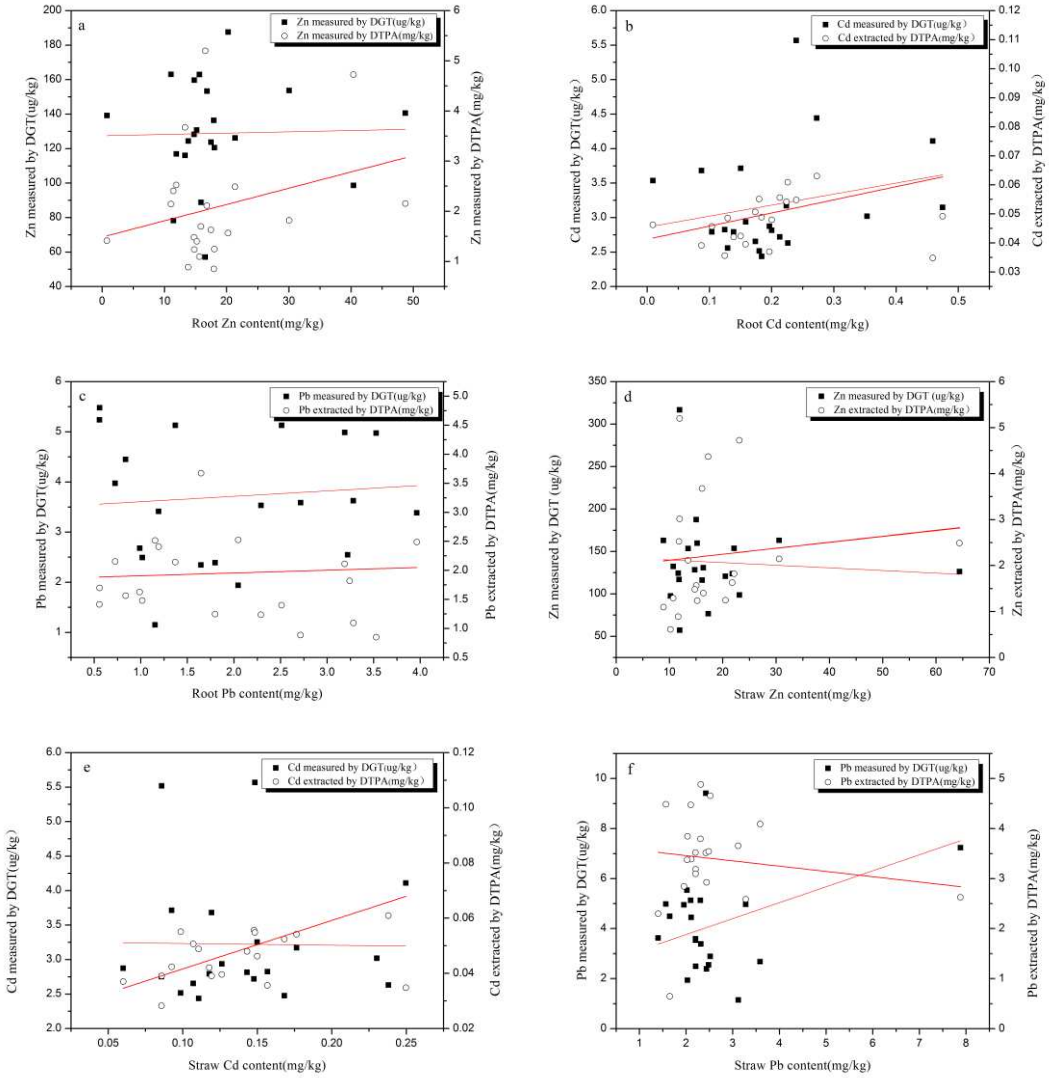

Figure 1. *Relationship between heavy metals extracted by DGT and DTPA: relationship between the contents of (a) Zn, (b) Cd, (c) Pb in roots and from DGT and DTPA; relationship between the contents of (d) Zn, (e) Cd and (f) Pb in straw and from DGT and DTPA*

Environment evaluation

Single and comprehensive pollution indices

The results of heavy metal pollution index are shown in *Table 8.* In terms of Zn, more than half of the samples are at light pollution, while others are still at clean level. In terms of Cd, most of the samples are in mild pollution (Liu et al., 2017; Shi et al., 2013), and only 9.76% of them are in moderate pollution. Noticeably, 3 samples are in severe pollution, which indicates high risks. As for Pb, 53.69 of the samples are in moderate pollution and others are in mild pollution. The Nemero comprehensive pollution index of 43 samples ranges from 1.22 to 3.36 with a mean of 1.7 < 2, indicating the soil is at slight pollution, and Cd is under the severest pollution.

The E^i_r and RI were calculated by *Equations 3, 4* and *5* (*Table 9*). The single coefficient of potential ecological hazard and other elements belong to minor ecological hazards. Chu Chunjie et al. pointed out that Cu, Zn, Ni and Pb induced chronic non-

carcinogenic health risks (Chen et al., 2017; Bhuiyan et al., 2010), while Cr had a clear risk of cancer in the soil of hilly slopes around mining areas in Pingdingshan. The results indicate Zn and Pb in the soil around the mining areas of Pingdingshan exceed the standard, which is a non-carcinogenic health risk (Yenilmez et al., 2011).

General situation of heavy metal pollution in soil

The results showed that the average pH values of wheat fields in the study area were 7.8, 5.8 and 7.3, respectively, in which RA and RC were at the alkaline level and RB was at the acidic level. According to the statistical results in *Table 2,* the average content of heavy metal elements in the wheat fields in the three mining areas all

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54355447

exceeded the background value of soil elements in Henan province. The average values of Cd, Zn and Pb in the wheat fields in RA mining area were 2.50, 2.81 and 2.34 times of the background value, respectively. The average values of Cd, Zn and Pb in the wheat field in the RB mining area were 1.12, 1.09 and 1.07 times of the background values, respectively. The average values of Cd, Zn and Pb in wheat field in RC mining area were 1.60, 1.04 and 1.22 times of the background values, respectively. According to the grade ii standard of soil environmental quality standard (GB15618-2008), the average values of Cd, Zn and Pb in wheat fields in RA mining area were 0.20, 0.23 and 0.44 times of the standard values, respectively. The average values of Cd, Zn and Pb in the wheat field in the RB mining area were 0.60, 0.34 and 0.28 times of the standard values, respectively. RC mining area of wheat to Cd, Zn and Pb respectively, the average standard value of 0.33, 0.27, and 0.33 times. The soil heavy metal pollution degree of RB > RC > RA, and by a single heavy metal pollution degree, Cd > Pb > Zn, along with the exploitation of coal mine, the content of soil heavy metal levels in gradually rise, which is consistent with the research results of Chen et al. (2017).

Conclusions

In this paper, three typical coal mines in Pingdingshan were investigated to study the heavy metal pollution in the surrounding soil and wheat using the diffusive gradients in thin films (DGT) and pentetic acid or diethylene triamine penlaacetic acid (DTPA), and to explore its potential ecological risks. The results show that the soil heavy metal pollution around the main mining areas of Pingdingshan is under different levels. The average soil contents of Zn, Cd and Pb are 68.64, 0.68 and 26.96 $mg \cdot L^{-1}$, respectively. According to the extraction effect of different extractants. DTPA has higher extraction capacity than DGT, which may be related to the different chemical properties of the extractants. From the average extraction efficiency of different extraction methods for the same heavy metal. The average extraction rates (i.e. the percentage of extracted heavy metal content in the total amount of this heavy metal) of Zn, Cd and Pb are 3.18%, 30.46% and 13.03%, respectively in DTPA, and 0.21%, 2.01% and 0.02%, respectively in DGT. The Nemero comprehensive pollution index shows the soil pollution of heavy metals is slight. The single ecological coefficient of potential ecological hazard indicates the soil pollution degrees of various heavy metals rank as Cd > Pb > Zn, and the most serious pollution is Cd, which is close to medium ecohazards, while other heavy metals are under minor ecological hazards.

(Received 7th Dec 2018; accepted 28th Feb 2019)

Abstract. Land Cover Maps (LCMs) represent the integrated information about general status of a specific region, which are widely used as a baseline for many related purposes. This study aims to extract the land covers of Sanandaj County, Kurdistan, Iran, along with to highlight the occurred changes compared with an old map prepared by the Iranian Institute of Water and Soil in 2010. The combination model of Sentinel-1 and Landsat-8 satellite imageries was used for the dates 10/05/2017 and 11/05/2017, respectively. It is noted that based on the location of the study area we acquired Sentinel-1 data (S1A, IW,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54495463

and GRD) and a pair of Landsat-8 images. Using Sentinel Application Platform (SNAP) and Environment for Visualizing Image (ENVI) softwares all images were corrected, co-registered and stacked. The combination of RADAR, NDVI and thermal bands was utilized as the best combination for the visual interpretation, with which all land covers can be easily differentiated. However, with help of the Google Earth images the land covers (polygon by polygon) were checked and digitized. Results indicate that the visual interpretation of the combination model with the assist of Google Earth is a robust way to extract land covers, provided that the researchers have enough knowledge on the land covers of the study area. This study can be applicable for decision makers of Sanandaj City.

Introduction

Land Cover (LC) is one of the most important factors that reflects the impacts of human on the environment (Belal and Moghanm, 2011; Lausch and Herzog, 2002), which it is constantly changing due to human activities (Chen et al., 2003). The importance of identifying, quantifying and supervising LCMs and their changes have widely been considered by the global and the regional studies (Jin et al., 2013; Kumar et al., 2016; Xian et al., 2009; Zhu and Woodcock, 2014). LC is a key factor, which affects the function and the condition of an ecosystem (El-Kawy et al., 2011; Hansen and Loveland, 2012; Lunetta et al., 2006). As a matter of fact, satellite based remote data have been widely employed as a robust and fast way to provide LC coverage in a large geographic scope (Grecchi et al., 2014; Li et al., 2017; Liu and Yang, 2015; Lunetta, et al., 2006; Myint et al., 2011). LCM studies and their monitoring using the combination of a few satellite imageries is greatly associated with the appropriate satellite images to evaluate the LC map (Liu and Yang, 2015; Lunetta, et al., 2006).

Understanding and identifying the human activities and LC changes' patterns are essential for the proper land management and sustainable development (Rawat et al., 2013; Rawat and Kumar, 2015). Regarding its impact on a natural ecosystem, the LCM is one of the main concerns of the conservationists, the environmentalists and the land cover planners (Halmy et al., 2015). Development of an appropriate analytical procedure and the techniques to map all the land covers in an area, is one of the main problems in LCMs (Hansen and Loveland, 2012; Xian, et al., 2009). Extracting land covers by using a combination of satellite images is normally faced a number of challenges, including acquisition of two or more satellite imageries at the regional or the national scales.

LCM provides the valuable information for a better understanding of the changes' mechanism on the environment (Boori et al., 2015; Xian and Crane, 2005; Xian, et al., 2009). Continuous, precise and up-to-date LC information is essential for the natural resources and the environmental management (Homer et al., 2004; Loveland et al., 2002; Rawat and Kumar, 2015; Xian, et al., 2009). Another significance of this study is the availability of both satellite imageries of RADAR (Sentinel-1) and multispectral (Landsat-8).

Many researches have been conducted with the LCM studies using a variety of techniques and imageries, including Markov-chain analysis (López et al., 2001), multiple regression analysis (Theobald and Hobbs, 1998), logistic regression (Wu and Yeh, 1997), artificial neural networks (ANNs) (Li and Yeh, 2002), cellular automata (CA) (Batty and Xie, 1994, 1997; Clarke and Gaydos, 1998; White and Engelen, 1997; Yeh and Li, 2001), multi-agent systems (Brown et al., 2005; Sanders et al., 1997), updating LC automatically based on change detection using satellite images (Chen et al., 2012; Huang et al., 2017; Jin, et al., 2013; Xian, et al., 2009), multi-temporal remote

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54495463

sensed imagery (Butt et al., 2015; Fichera et al., 2012; Islam et al., 2018; Nutini et al., 2013), and multispectral airborne laser scanner data (Matikainen et al., 2017). On the other hand, a combination model of RADAR imagery of Sentinel-1 and multispectral imagery of Landsat-8 Operational Land Imager (OLI) has not been performed by other researchers for extracting land covers.

The main objective of this study was to update land cover map using the Google Earth images and the visual interpretation of a combined imagery of RADAR (Sentinel-1) and multispectral (Landsat-8) in Sanandaj County, Kurdistan Province, Iran.

Materials and methods

Description of the study area

Sanandaj County was selected as the study area for this research. The city of Sanandaj, with a population of 432,330, is the most important and the biggest city in Kurdistan Province, Iran. Besides, this scope is located in the Longitudes 46° 24' 00" E to 47° 19' 00" E and Latitudes 35° 3' 00" N to 35° 39' 00" N (*Fig. 1*).

Moreover, it lies on the border area of Marivan, Divandarreh, Bijar, Dehgolan and Kamyaran Counties. Sanandaj County has a total area of about 3024 km^2. Furthermore, the elevation of the scope ranges from 1450 to 1538 m above the sea level. According to the meteorological department of Iran, the county has the cold and semi-arid climate, but the moderate weather during spring and summer seasons. On the other hand, the maximum and the minimum temperature are about 44 °C and -13.5 °C, in order. While, the average temperature in the spring, summer, autumn and winter are 15.20 °C, 25.20 °C, 10.40 °C and 1.60 °C, respectively (*Table 1*) (Hosseini et al., 2015; Izady, 2015).

Image enhancement and visual interpretation

Visual interpretation is highly associated with the knowledge of an applicant about the land covers of an area. Its advantage compared to the automated classification methods is recognizing the dynamic changes more precisely (Kibret et al., 2016; Zhang et al., 2014). The automated classification methods, usually concentrate on the technological approaches, while the visual interpretation is applied for the practical usage (Zhang, et al., 2014).

One of the most important techniques to enhance image's spatial resolution and information is the co-registration and the combination with higher spatial resolution satellite imagery, which improve the visual interpretability of the imagery. However, the enhanced images are normally used for the visual analyses, while the original images are utilized for the automated one (Eastman, 1999; Lillesand et al., 2014).

In the most of remote sensing studies, pre-processing of satellite imageries is undeniable (Belward and Skøien, 2015; Ma et al., 2017). Data pre-processing was applied to provide a radiometrically, atmospherically, spectrally and geometrically corrected imageries. However, based on the study area we acquired 2 Landsat-8 imagery of two different rows of 35 and 36, but the same path of 167, which they were mosaicked and clipped as extend of the study area. Moreover, Sentinel-1 data was acquired for the combination with Landsat-8.

Improvement of the Landsat-8 spatial resolution from 15 m (after pan-sharpening with the 15 m panchromatic band) to 10 m as well as using for the combination model, are among positive points of Sentinel-1 satellite imagery in this study. Using ENVI software, multispectral bands of Landsat-8 imageries of the two rows were pre-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54495463

processed and mosaicked. Besides, the thermal band of Landsat-8 and created Normalized Difference Vegetation Index (NDVI) were stacked with the multispectral bands. Furthermore, using SNAP software, Sentinel-1 imagery was pre-processed and clipped as the study area. Moreover, using ENVI software the stacked imagery of multispectral, NDVI and thermal bands (as the slave imagery) was co-registered and stacked with the Sentinel-1 imagery (as the master image). However, the combination of NDVI, RADAR and thermal bands was used for the visual interpretation. At the same time, after extracting the land covers using the Google Earth images with the help of the visual interpretation, the topological errors was fixed in ArcGIS (*Fig. 2*).

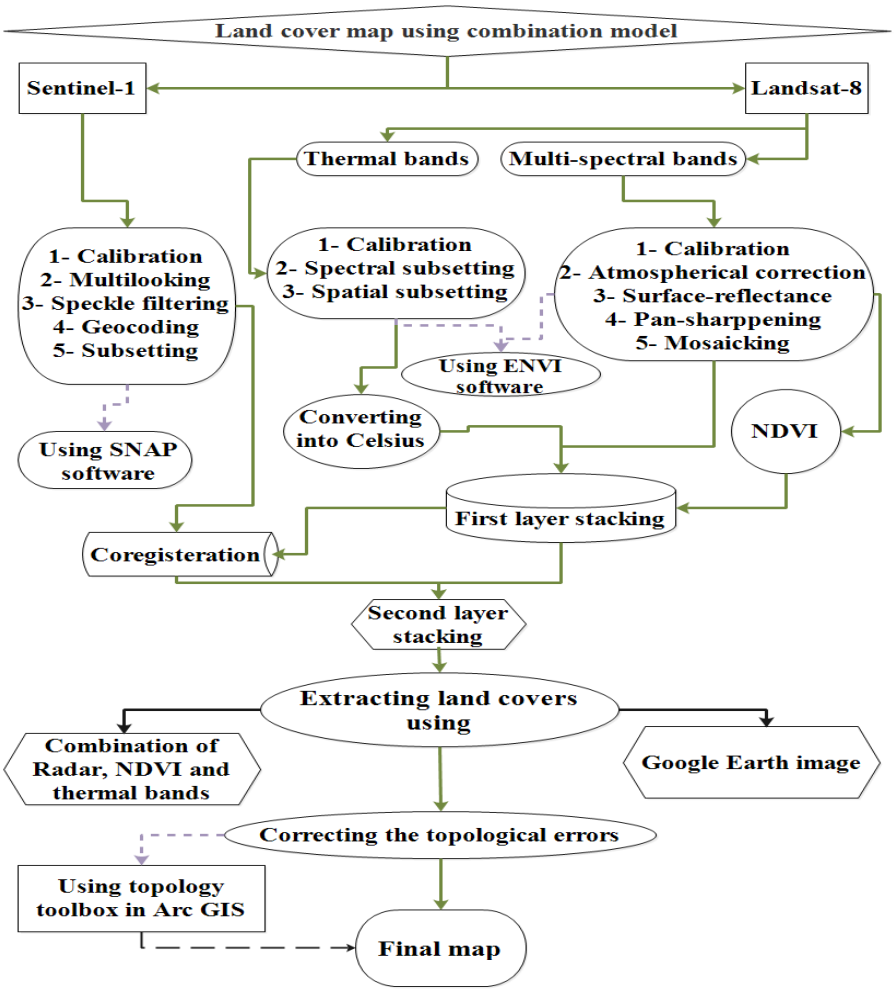

Figure 2. *Methodology of the study*

RADAR, NDVI and thermal bands as a clear combination were interpreted visually, by which the land covers can be differentiated easily. The contrast and brightness level panels were used to adjust the image view to an appropriate level. *Figure 3* illustrates the differences among the land covers by the combined imagery.

Because of the distinguishing in the shape and color, the delineation of the land covers was clear from the combined image's visual interpretation. LCM of the study area was produced from the visual interpretation and digitization using the Google Earth image of the same date in Geographic Information System (GIS).

Dataset

A pair of Landsat-8 satellite imageries of a same path but two different rows (167-35 and 167-36) were acquired for the study area through https://libra.developementseed.org website. However, these datasets through ENVI software, were corrected and finalized to be co-registered with Sentinel-1 (*Fig. 4*).

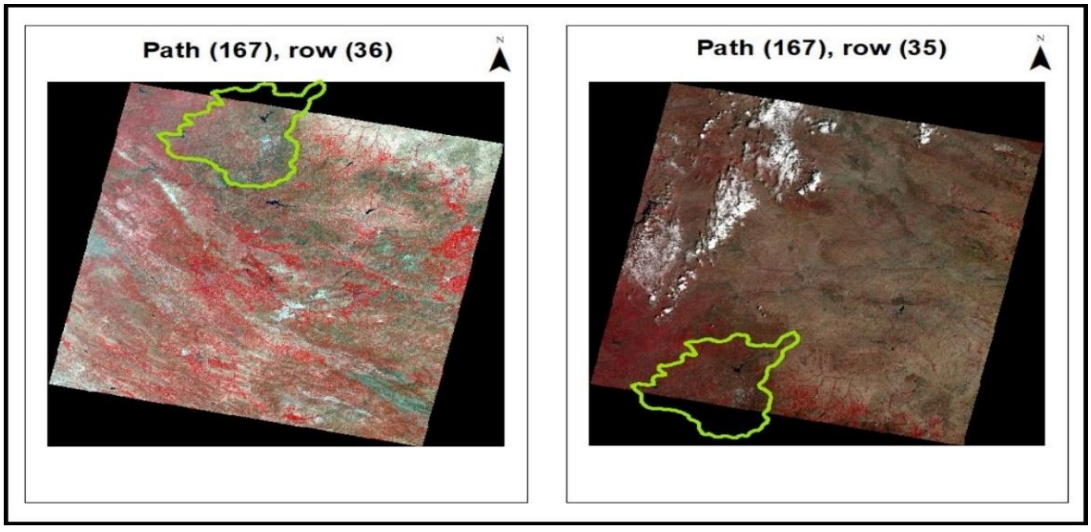

Figure 4. *Landsat-8 images of scope of the study*

Accuracy assessment

In general, accuracy assessment illustrates the quality of information extracted from remotely sensed data (Alqurashi and Kumar, 2014; Congalton and Green, 2008). The used method for the accuracy assessment in this study was through applying the Google Earth images of the same date. However, it must be considered that using this method only applicable when the researchers have a complete knowledge about the land covers of the study area. For this reason, first the land covers through the visual interpretation of the combined imagery were identified, then all the land covers (polygon by polygon) were digitized and validated through the Google Earth images of the same date.

Results and discussion

The selection of a suitable combination among different bands of satellite imagery is an essential process for the visual interpretation. In order to make a better image visual interpretation, the enhancement technique was fulfilled. In this study, the band

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54495463

combination of RADAR, NDVI and thermal, was selected as the best combination. An old map was prepared by the Iranian Institute of Water and Soil in 11/05/2010 using Landsat 7 images, ETM$^+$ sensor with resolution 30 m (multispectral), with row 35 and path 167, which they were mosaicked and clipped as extend of the study area. The extracted images unbalanced machine support model and supervised classification (*Fig. 6*). Because of the big area of Sanandaj County and difficulties in preparation of a new map, this map has been the only available source for citation since 2010.

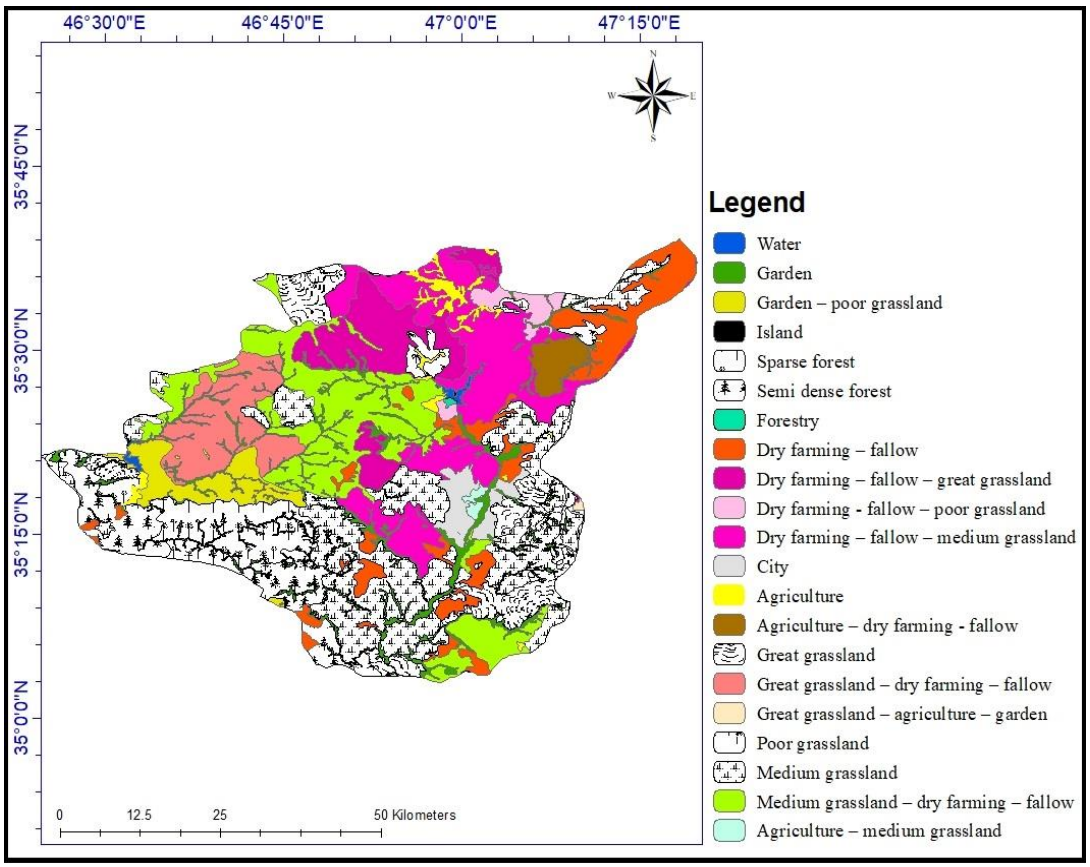

Figure 6. *The land cover map of the study area in the year 2010*

In this study a total number of 19 different land covers ranging from the small to big scales were extracted. However, medium grassland and medium grassland–dry farming–fallow have the biggest area of 497.5818 km^2 and 409.6083 km^2, respectively. Dry farming fallow is the third biggest area with 360.1108 km^2. Moreover, Dry farming–fallow–medium grassland with 259.4949 km^2 is one of the biggest land covers in Sanandaj County. Dry farming–fallow–great grassland, garden and great grassland–dry farming–fallow with 226.3668 km^2, 200.3053 km^2 and 187.1039 km^2, respectively are amongst the substantial land covers of the region. The minimum area of land cover belongs to the island with only 0.119052 km^2. Furthermore, great grassland–agriculture–garden with 1.370851 km^2 is the second smallest area in the study area. The land covers are highlighted in *Figure 7* from the biggest to the smallest.

The final LCM was topologically corrected through the topology toolbox in ArcGIS. However, regardless the applicant patience in digitizing, new digitized layers will be faced with the small topologically errors, which can only be recognized and fixed using

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54495463

the topology toolbox. Furthermore, in this study, after digitizing a total number of 146 small overlaps and 56 small gaps were identified and corrected one by one through the abovementioned toolbox. *Figure 8* and *Table 3* show the extracted land covers of the study area in the year 2017 and the occurred changes compared with the year of 2010, respectively.

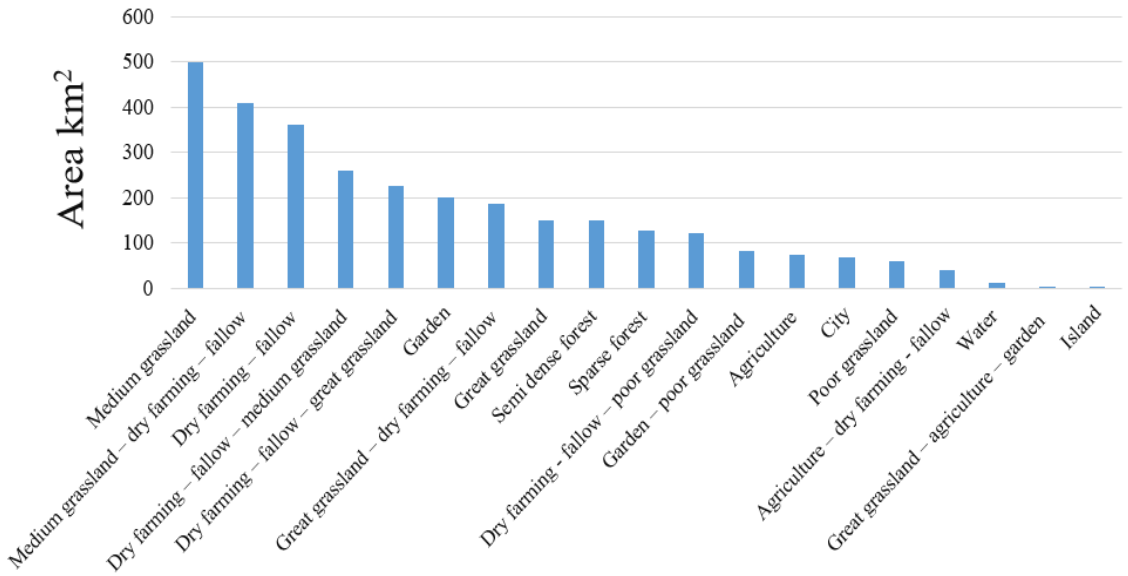

Figure 7. *The land covers and area (km^2) for the study area*

DOI: http://dx.doi.org/10.15666/aeer/1703_54495463

Table 3. *The land cover types and area of each category for the years 2010 and 2017*

No.	Land covers	Area ($km^{2)}$ 2010	Area ($km^{2)}$ 2017
1	Garden	196.561	200.3053
2	water	10.0364	11.61852
3	Garden–poor grassland	101.792	80.78231
4	island	0.238093	0.119052
5	Sparse forest	171.598	128.0167
6	Semi dense forest	171.892	149.8309
7	Forestry	1.4632	Replaced by the dry farming–fallow–poor grassland
8	Dry farming–fallow	230.546	360.1108
9	Dry farming–fallow–great grassland	210.06	226.3668
10	Dry farming–fallow–poor grassland	39.0384	122.2905
11	Dry farming–fallow–medium grassland	378.942	259.4949
12	City	58.6013	67.36704
13	Agriculture	40.9321	73.53178
14	Agriculture–dry farming–fallow	44.0775	39.24857
15	Agriculture–medium grassland	7.68398	Replaced by the city area
16	Great grassland	190.396	150.6862
17	Great grassland–dry farming–fallow	184.367	187.1039
18	Great grassland–agriculture–garden	1.58959	1.370851
19	Poor grassland	41.978	58.51491
20	Medium grassland	543.059	497.5818
21	Medium grassland–dry farming–fallow	399.51	409.6083

Comparing the results of the current study with the results of the research conducted with the Iranian soil and water organization (2010) showed that all the land covers have been faced changes of the small to the large scales. In the year 2017, dry farming–fallow has seen the most considerable changes, where 129.5648 km^2 has been added to its area in comparison with the year 2010. Dry farming–fallow–medium grassland has lost about 119.4471 km^2 of its area by the year 2017. However, because of rising in the water level, the island area decreased to 0.119052 km^2 by 2017 from 0.238093 km^2 in 2010. It is worth indicating that the forestry by the dry farming–fallow–poor grassland and the agriculture-medium grassland by the city area have been replaced.

Extracting land covers using the visual interpretation and the Google Earth is highly associated with the basic knowledge about the study area. However, this technique is very time consuming, but precise and reliable. For example, the water body was recognized from the visual interpretation and digitized through the Google earth image in full zoom, then using ArcGIS converted to the layer format and digitized through the editor toolbox. The obtained results of current study is similar with several previous published studies that investigate land use changes using satellite data in which some will be referred to in this part of the work. Sunar (1998) used five techniques, including: adding, subtracting, dividing, principle component (PCI), and post classification analysis to detect land cover changes in Aykitali, Turkey. He found out that the technique of adding and subtracting images was the most simple among these

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54495463

techniques, while PCI and post classification analyses showed better results in change detection. Xian et al. (2009) applied Landsat imagery change detection methods for updating the 2001 National Land Cover Database land cover classification to 2006 in several metropolitan areas including Seattle, Washington; San Diego, California; Sioux Falls, South Dakota; Jackson, Mississippi; and Manchester. Results from the five study areas showed that the vast majority of land cover change was captured and updated with overall land cover classification accuracies of 78.32%, 87.5%, 88.57%, 78.36%, and 83.33% for these areas. Shahabi et al. (2012) investigated that green space destruction in urban area using three remote sensing techniques including NDVI, PCA, and post classification methods. To carry out these techniques, Thematic Mapper (TM) and Enhanced Thematic Mapper Plus (ETM+) LANDSAT data within the year 1989 to 2009 were used to recognize land use changes, especially the physical development of the area and its devastating effects on the green space. The result showed that green space has been reduced from 530 ha in 1989 to 198.3 ha in 2009. Butt et al. (2015) applied supervised classification-maximum likelihood algorithm in ERDAS imagine to detection of land cover/land use changes observed in Simly watershed, Pakistan using multispectral satellite data obtained from Landsat 5 and SPOT 5 for the years 1992 and 2012 respectively. The accrued results showed that land cover/land use practices in the study area have altered significantly in 20 years. The land cover/land use shift in the watershed area was evident by the decline in the area of vegetation and water class (38.2% and 74.3% respectively) and augmentation of area covered by classes of settlements (80.1%), Agriculture (163.7%) and barren land (63.3%). Islam et al. (2018) evaluated land use changes of Chunati wildlife sanctuary, Bangladesh from 2005 to 2015 using Landsat TM and Landsat 8 OLI/TIRS images. In the present study Maximum likelihood classification algorithm was used in order to derive supervised land use classification. The obtained results showed that about 256 ha of degraded forest area had been increased within 10 years (2005–2015) and the annual rate of change was 25.56%. Another 159 ha of naturally forested land had been changed to other land uses having an (-) annual rate of change of 15.88%.

Conclusion

In this study, in order to extract the land covers, the satellite imageries of RADAR with multispectral data were combined. The study area lies on an area about 3024 km^2. For this goal, we acquired satellite imageries of Sentinel-1 and Landsat-8 (OLI) for the dates 10/05/2017 and 11/05/2017, respectively (when vegetation coverage is in its best situation). Because of the scope of the study, two Landsat-8 imageries of two different rows (35 and 36) but the same path (167) were downloaded. Moreover, after correcting either Landsat imageries through ENVI Software they were mosaicked as a single image. Sentinel-1 data was corrected using SNAP Software, then as the master image co-registered and stacked with Landsat-8 as the slave image. Besides, RADAR, NDVI and thermal bands were used for the visual interpretation.

Through visual interpretation of the combined imagery with assist of the Google Earth image of the same date, all the land covers were extracted and the topological errors through the topology toolbox in ArcGIS were recognized and corrected. For accuracy assessment the Google Earth image was used, which is a robust way to validate land cover map provided that the researchers have a complete knowledge on the study area. Results illustrate that a total number of 19 different land covers were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54495463

recognized and mapped. However, medium grassland, medium grassland–dry farming–fallow and dry farming fallow have the biggest area of 497.5818 km^2, 409.6083 km^2 and 360.1108 km^2, respectively. The smallest area belongs to the island with only 0.119052 km^2, followed by the great grassland–agriculture–garden with 1.370851 km^2. The forestry by the dry farming–fallow–poor grassland and the agriculture-medium grassland by the city area have been replaced.

In this study RADAR imagery of Sentinel-1 (10-m pixel size) was combined with the multispectral data of Landsat-8 (15-m pixel size after pan-sharpening with its panchromatic band), to map the land covers of the study area; however, the combination of the Radar imagery of Sentinel-1 with the multispectral imagery of Sentinel-2 (10-m and 20-m pixel sizes) is highly recommended for such studies in the future.

(Received 9th Dec 2018; accepted 28th Feb 2019)

Abstract. Cotton with Bt gene is only resistant against bollworms. Sucking insect pests also cause huge losses to cotton crop. It is reported that okra leaf cotton genotypes are resistant to sucking insect pests. The objective of this research was to explore the potential of okra leaf Bt cotton for resistance against bollworms and sucking insect pests. Okra leaf Bt cotton recombinant lines were developed by hybridization and selection process for use in this study. Comparative insect pest buildup/infestation was studied on non Bt normal leaf, normal leaf Bt, non Bt okra leaf and okra leaf Bt genotypes/cultivars/recombinant lines under field conditions using randomized complete block design with three replications. The genotypes/cultivars/recombinant lines were separated by nets to confined the insect population buildup within the genotype. Significantly lower buildup of sucking insect pests was found on okra leaf cotton compared to normal leaf cotton and significantly lower buildup/infestation of sucking insects as well bollworms was found on okra leaf recombinant lines with Bt gene. Development of Bt cultivars with okra leaf is recommended which would be resistant against bollworms as well as sucking insect pests attacks.
Keywords: *sucking insects, bollworms, okra leaf, normal leaf, Bt cotton*

Introduction

Pakistan is the 4th largest producer of cotton in the world. Cotton crop is severely damaged by many sucking insects (Jassid, whitefly, aphid, thrips) and bollworms (American bollworm, Spotted bollworm and Pink bollworm). Genetically modified Bt cotton is only resistant to bollworms but is not resistant to sucking insect pests (Din et al., 2016). Huge quantity of insecticide is applied to protect Bt cotton from sucking insect pests which increases production cost of cotton crop and pollute the environment. So, Bt cotton cultivars which may be resistant to sucking insect pests as well may be developed.

It has been reported that population buildup of sucking insect pests on cotton with okra leaf trait is comparatively low due to its open canopy (Chu et al., 2000; Soomro et al., 2000; Ahmad et al., 2005; Din et al., 2016). The objective of present research was to explore the potential of Bt cotton with okra leaf trait for resistance against sucking insect pests and bollworms.

Assessment of cotton against insect pests by scoring insect pest population buildup on genotype under field conditions is tedious work as the experimental plots of the genotypes have to be separated by nets to confine the insect population within the genotype. Thus, only a small number of such studies are found in the literature. The present study was conducted to assess the comparative insect pest buildup/infestation on okra leaf (non Bt and Bt) and normal leaf (non Bt and Bt) cotton under field condition.

Material and methods

The study was conducted in the field area of the University of Agriculture Faisalabad (Latitude = 31° 26' N, Longitude = 73° 06' E, Altitude = 184.4 m), Pakistan, during the year 2014 to 2016. Faisalabad possess the arid climate. It can touch both extremes, with a summer with maximum temperature 50 °C and winter temperature of -2 °C.

Development of okra leaf Bt cotton recombinant lines

In year 2014 crosses were made and F_1 generation was developed ((MNH-886 × Gumbo Okra), (CRS-456×Gumbo Okra) and (PB-38×Gumbo Okra)), in season 2015 F_1 were sown and F_2 was raised into the field. Recombinant okra leaf Bt cotton lines were selected from the F_2 populations of the cross of Gumbo okra (okra leaf) with normal leaf genotypes/cultivars. Recombinant plants from F_2 were selected on the basis of okra leaves with high yielding traits and Bt proteins test by using ELISA (Quali-Plate™ Kit for Cry1Ab/Cry1Ac by Enviro-Logics). The Enviro-Logix QualiPlate Kit is a "sandwich Enzyme-Linked Immuno Sorbent Assay" (ELISA). List of cotton genotypes/cultivars/recombinant lines used in the study is given in *Table 1*.

To assess the comparative insect pest buildup/infestation, Eight *G. hirsutum* genotypes/cultivars/recombinant lines were sown at the 27th of March (2016) under normal soil and irrigation conditions in randomized complete block design with three replications. Standard agronomic practices of growing cotton crop were used in the experiment. There were 24 rows, each 300 cm in length (10 plant in each row) in each replication (three rows for each genotype/cultivar/ recombinant line) by keeping the plant to plant distance of 30 cm and row to row distance of 75 cm.

Table 1. *List of cotton genotypes/cultivars/recombinant lines evaluated for resistance against different insect pests under field condition*

Sr. No.	Genotype/cultivar	Description
1.	PB-38	Cultivar with Normal leaf trait
2.	MNH-886	Cultivar with Normal leaf trait + Cry1Ac
3.	FH-142	Cultivar with Normal leaf trait + Cry1Ac
4.	FH-lalazar	Cultivar with Normal leaf trait + Cry1Ac
5.	Gumbo Okra	Genotype with Okra leaf trait
6.	RP_1 (MNH-886 × Gumbo Okra)	Recombinant population with Okra leaf + Cry1Ac
7.	RP_2 (CRS-456 × Gumbo Okra)	Recombinant population with Okra leaf + Cry1Ac
8.	RP_3 (PB-38 × Gumbo Okra)	Recombinant population with Okra leaf trait

The data were taken at ten-day intervals beginning from 15th of May 2016 to 15th of November 2016 from ten healthy plants randomly selected from each genotype/cultivar/recombinant line. For sucking insects (thrips, jassid, aphid, whitefly and mites), from each plant three leaves were selected (one each from top, middle and bottom) and examined for both adult and nymph, using magnifying glass. The population of bollworms (Pink bollworm, Spotted bollworm, and American bollworm) were assessed by counting infested bolls, squares and flowers on per plant basis. Analysis of variance of insect pest's data was conducted and means were separated by LSD test as in Steel et al. (1997).

Results

The population means of insect pest buildup/infestation (Pink bollworm, American bollworm, thrips, jassid, whitefly, mites, aphid) on different genotypes/cultivars/recombinant lines are given in *Table 2*. The analysis of variance showed significant variation for insect pest population built up on different genotypes/cultivars/recombinant lines. Comparison of means of insect pests buildup/infestation of (Pink bollworm, American bollworm, thrips, jassid, whitefly, mites, aphid) on different genotypes/cultivars/ recombinant lines by using LSD test is also given in *Table 2*. The results showed that *Gossypium hirsutum* genotypes/cultivars with normal leaf trait had significantly higher thrips population buildup comparatively to the okra leaf genotypes/recombinant lines. Maximum infestation was found on FH-lalazar which is a normal leaf variety while minimum infestation was found on okra leaf line RP_2. Maximum number of Jassid population was found on FH-lalazar followed by other normal leaf cultivars while minimum number of infestations was found on okra leaf line RP_2. Results showed that comparative population built up of whitefly was significantly higher on normal leaf genotypes/cultivars as compared to okra leaf genotype/cultivar/ line.

Genotypes/cultivars/recombinant lines not sharing the same letter are significantly different

Maximum number of whiteflies was found on normal leaf cultivar FH-142 followed by other normal leaf genotype/cultivar PB-38 and MNH-886. Minimum number of whiteflies were found on okra leaf line RP_1. Results showed that comparative population built up of whitefly was significantly higher on normal leaf genotypes/cultivars as compared to okra leaf genotype/cultivar/ recombinant line. Maximum number of whiteflies was found on normal leaf cultivar FH-142 followed by other normal leaf genotype/cultivar PB-38 and MNH-886. Minimum number of whiteflies was found on okra leaf line RP_1. Comparatively high infestation of mites was found on normal leaf genotypes/cultivars as compared to okra leaf genotypes/cultivars/ recombinant lines. Maximum number of mites population was found on MNH-886 and FH-142 while minimum number of infestation was found at Gumbo okra followed by other okra leaf genotype/ recombinant lines. Overall results showed that normal leaf cotton (PB-38, MNH-886, FH-142 and FH-lalazar) had high buildup of sucking insect

DOI: http://dx.doi.org/10.15666/aeer/1703_54655469

pests compared to okra leaf cotton (Gumbo Okra, RP_1, RP_2 and RP_3). Significantly higher infestation of bollworms was found on non Bt cotton (PB-38, Gumbo Okra, and RP_3) compared to Bt cotton (MNH-886, FH-142, FH-lalazar RP_1 and RP_2). Non Bt okra leaf Cotton (Gumbo Okra, and RP_3) had lower infestation compared to normal leaf non Bt cotton (PB-38).

Discussion

Okra leaf trait is characterized by narrowly lobbed and deeply cleft leaves with less per leaf surface area compared to normal leaf cotton. It has been reported that okra leaf cotton is resistant to sucking insect pests and also relatively resistant to bollworms compared to normal leaf cotton. In the present study and in earlier reports lower buildup of sucking insect on okra leaf cotton compared to normal leaf cotton was due to its reduced leaf surface area and open canopy (Kular and Butter, 1999; Arif et al., 2006; Din et al., 2016). In a study of eight cotton cultivars from USA and six from Australia, Chu et al. (1999) observed that okra leaf cotton cultivars had lower attack of whitefly compared to normal leaf cotton cultivars. It was suggested that okra leaf trait had great potential for breeding upland cotton resistant to whitefly. Kanher et al. (2016) reported positive correlation of leaf area and aphid population on cotton. So, development of okra leaf cultivars has been suggested to control sucking insect pests (Wilson, 1994; Soomro et al., 2000; Chu et al., 2002; Ahmad et al., 2005; Din et al., 2016; Kanher et al., 2016). Wilson (1889) observed that okra leaf cotton required 33% less insecticide and had less damage by insect pests but yield was as much as normal leaf cultivars. Smith (2001) also compared okra leaf cotton with normal leaf cotton and found that okra leaf cotton was equal in fiber length, fiber strength and fiber fineness as well as yield. Wilson and George (1982) found that okra leaf cultivars were resistant to bollworms compared to the normal leaf cultivars. They concluded that okra leaf cultivars had smaller leaf area and open plant canopy leading to better light penetration and more air circulation which made these cultivars resistant to bollworms. Din et al. (2016) also found in a field study that okra leaf cotton was resistant to bollworms.

Okra leaf trait in cotton is controlled by single gene. Its locus has been reported on chromosome 15 on D genome (Andres et al., 2016). Okra leaf trait is monogenic in inheritance so, breeding cultivars with okra leaf trait may not be difficult. Results of present study and earlier findings suggest that okra leaf cotton Bt cultivars should be tailored to control sucking insect pests and bollworms.

Conclusion

Findings of this study revealed significantly lower buildup/infestation of bollworms (pink bollworm, American bollworm, spotted bollworm) and sucking insects (Aphid, Jassid, Whitefly, thrips and whitefly) on okra leaf Bt cotton compared to normal leaf Bt cotton. So, Bt cotton cultivars with okra leaf trait should be engineered which would be resistant to bollworms as well as sucking insect pests.

Abstract. Mutualism is a fundamental relationship that can shape species communities through co-evolutionary adaptations and also has great ability to change ecosystem functions. Aphids and ants are common insect groups which are distributed widely across the world. The mutualistic relationships between them have gained much attention in history. However, very few studies have been carried out on the diversity of associated aphid and ant species pairs. In this study, we tried to gather available published data about the diversity of species pairs of aphids and ants to find out potential ecological and geographical patterns. The results showed that 284 species of aphids belonging to 83 genera and 9 subfamilies were mutualistically associated with 193 species of ants belonging to 38 genera and 4 subfamilies. In this report we elucidated a total of 972 aphid-ant interactions and 915 ant-aphid interactions (one aphid species may associate with many ant species and vice versa). Among these relationships, a highest number of ant species were associated with the aphid genus *Aphis*, while a highest number of aphids were associated with the ant genus *Formica*. Besides, an obvious geographical pattern was indicated that the subtropical region may have a higher diversity of aphid-ant associations. This global analysis of current knowledge about diversity and patterns of aphid-ant mutualistic relationships also indicates that more taxonomic and ecological studies are needed to enrich our understanding of these associations.
Keywords: *multispecies interaction, symbiosis, myrmecophiles, Hymenoptera, Formicidae*

Introduction

Reciprocally beneficial associations (e.g. mutualism) support and promote biodiversity (Herre et al., 1999; Bascompte and Jordano, 2007; Ito and Gobin, 2009). These interactions are common and conspicuous in terrestrial communities from tropical to temperate regions (Buckley, 1987; Hölldobler and Wilson, 1990; Delabie, 2001; Styrsky and Eubanks, 2007). These associations trigger the dynamics of ecological communities by influencing the environmental variables, species evolution and survival rate (Bronstein, 2009; Hosseini et al., 2017). One classic example of mutualistic relationship are the interactions between aphids and ants (Darwin, 1859; Stadler and Dixon, 2005).

The aphids (Hemiptera: Aphididae) are a group with 24 subfamilies and more than 5000 species all over the world (Favret, 2018). The diversity of aphid species is far higher in the northern hemisphere temperate regions than anywhere else (Dixon et al., 1987; Heie, 1994; Huang et al., 2012). Some aphid species are destructive pests and voracious feeder of various crops, and also vectors of various plants diseases (Mittler, 1958;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54715524

Blackman and Eastop, 1984; Buruchara et al., 2010). The ants (Hymenoptera: Formicidae) are one of the most common insect group on the Earth, which is divided into 21 subfamilies with 497 genera and more than 26700 species (Ward, 2013). Ants usually are very diverse and economically important social insects mostly dominant in the tropical regions (Hölldobler and Wilson, 1990; Philpott and Armbrecht, 2006). Ants fulfill their dietary requirements by performing various roles like decomposers, pollinators, scavengers, predators, and herbivores (Blackman and Eastop, 1984). Ants also feed on honeydew secretions of hemipterans such as aphids, and have a symbiotic association among them (Jahn and Beardsley, 1996; Styrsky and Eubanks, 2007).

Mutualism is a fundamental element in aphid-ant communities and behavior through co-evolutionary adaptation (Herre et al., 1999; Carabalí-Banguero et al., 2013). These relationships can abundantly be found within various aphid-ant groups (Styrsky and Eubanks, 2007) and can shape the species richness, abundance, and distribution. There are two main groups of aphids; myrmecophilous (tended by ants) and non-myrmecophilous (untended by ants) (Novgorodova, 2002, 2005). Myrmecophilous aphids and ants share their habitats and build a strong bond by providing food and security. Ants collect honeydew produced by aphids, and in return they protect them from their predators, parasitoids, and adverse climatic conditions (Hölldobler and Wilson, 1990; Stadler and Dixon, 2005; Novgorodova and Ryabinin, 2017). Moreover, ants provide aphids protection from the sooty mold infestation by sanitation, which propagates in the presences of honeydew accumulation (Way, 1963; Hölldobler and Wilson, 1990; Stadler and Dixon, 2005; Novgorodova and Ryabinin, 2017). For example, the population of associated aphids increased due to these relationships, and they can damage host plants and reduce yield. Honeydew-producing hemipterans tended by ants have a wide range of host plants, including trees, shrubs, vines (Floate and Whitham, 1994; Rico-Gray and Castro, 1996; Styrsky and Eubanks, 2007), fobs and grasses (Moya-Ragoza and Nault, 2000). Besides, the degree of such protection was observed to differ among aphids attending by ants (Addicott, 1978; Katayama and Suzuki, 2003; Novsgorodova and Gavrilyuk, 2012) and also depend on the aggressiveness of ants and honeydew collection approaches, in particular degree of specialty among foragers (Novgorodova and Gavrilyuk, 2012; Novgorodova, 2015). Due to the close aphid-ant interactions, complex networks of mutualistic interactions are formed between these insect groups of multispecies communities. The reason for their successful interaction is that they exist in a wide range of natural habitats (Buckley, 1987; Way and Khoo, 1992). However, ethological and ecological mechanisms of mutualism are still poorly understood.

The majority of previous studies have mainly focused on one or few pairs of aphid-ant species, while the general information of trophobiotic interactions among aphids and ants in most of regions are still limited. Besides, many review papers demonstrated the mutualistic ecology, cost and constraints, positive or negative mutualistic interactions of aphids and ants (Boucher et al., 1982; Buckley, 1987; Bronstein, 1994; Stadler and Dixon, 1998; Hoeksema and Bruna, 2000; Bronstein and Barbosa, 2002; Stadler and Dixon, 2005). However, there is a lack of the knowledge of diversity of aphid-ant species pairs which can provide complete information about their relationships in different ecological zones and can elaborate the patterns of these associations. A reason for this gap may be due to the lack of integration and meta-analysis of dispersed information on aphid-ant interactions in previous literature.

This study will generate an interest in quantifying the importance of aphid-ant interactions for global diversity patterns, distribution of species pairs and will also help

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54715524

the examination of the interactions of aphid-ant species across different ecological zones. Furthermore, data on species pairs along with geographical information can be used to study aphid-ant interactions at regional and global scale. Therefore, there is a need to investigate the current state of knowledge about the diversity of aphid-ant species associations. Based on data from published literature, this paper aimed to depict the current state of the taxonomic diversity of aphid-ant species pairs as well as the spatial patterns of their interactions (Tylianakis et al., 2008; Gilman et al., 2010).

Materials and methods

Data collection of aphid-ant species pairs

We collected species and distribution data from the available previously published researches (1906 to 2016) on species pairs of mutualistic aphids and ants (*Table A1* in the *Appendix*). Literature searching was done by using tools including Web of Science, Google Scholar and Goolge. The data such as names of subfamilies, tribes, genera, and species as well as locations of aphids and associated ants were extracted from published researches. Many articles contained only species names and location, so for getting more details about their higher taxa the databases of Aphid Species File (http://aphid.speciesfile.org) and AntWeb (https://www.antweb.org) were used. These databases provide the complete taxonomic hierarchy of aphids and ants. The validation of species names was also rechecked based on these taxonomic databases. The Aphid Species File contained comprehensive information about aphids from all over the world and provided the taxonomic keys, taxa hierarchy, bibliographic data of aphids from all parts of the world. The AntWeb provides taxonomic keys, taxa hierarchy, specimen records, and natural history information and distribution maps on ants. Up till now, all types of biodiversity data of almost all species has been updated on these databases. The data in these two databases are freely accessible. Other information was fetched from the available published researches in different journals. Distribution localities for available species pairs along with geographical coordinates were compiled and arranged into a database (Microsoft Excel). Species localities were identified from the descriptions of previous literature. The accurate locality data points were collected according to the literature description, google earth and by using the website (www.findlatitudeandlongitude.com).

Geographical patterns of species associations

Latitudes and longitudes of species pairs were plotted on the outline of the World map with the help of Arc Map 10.2 (Geographical Information System, GIS) software. The ecological zones were selected by using the coordinates of temperate (35-66.5°), subtropical (23.5-35°) and tropical (0-23.5°) zones. The coordinates of temperate, subtropical and tropical regions were separated from primary data set. Separated data was plotted according to the coordinates of temperate, tropical and subtropical regions to find out the diversity of aphid-ant interactions in different regions.

Data analysis

Data analysis was conducted by using correlation test. For percentage of ant-associated aphids, non-parametric Spearman's test (two-tail) was used while for percentage of aphid-associated ants parametric Pearson test (two-tail) was used. To calculate the percentages

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54715524

of genera and their species, the genera and species of each subfamily was divided by the total genera and species in all subfamilies. The fundamental statistical analysis has been applied to find out the diversity of species pairs in different regions of the world. The bar graphs were developed in Microsoft Excel by using extracted data.

Results

Taxonomic diversity

Aphid-associated ants

The percentage of all species numbers failed the normality test, so the non-parametric Spearman's test was used (two-tailed $P < 0.01$) for aphid associated ants. The results showed a positive correlation between the number of aphid species in relation with ant species ($t = 0.983$, $df = 8$, $P < 0.001$). Their patterns can be seen in (*Table 1*). Subfamily Aphidinae with about 59.85% of total aphid species was found associated with four subfamilies of ants (*Table 1*). Out of total 83 genera, the genus *Aphis* of subfamily Aphidinae was chiefly associated with 70.5% of ant species (*Table 1*).

Out of nine genera of subfamily Calaphidinae, genus *Symydobius* were associated with maximum number of ant species from four genera. Among the four genera of subfamily Chaitophorinae, about 81.25% species of the genus *Chaitophorus* were associated with 16 genera of ants. Out of 10 genera of the subfamily Eriosomatinae, the genus *Pemphigus* (only one species) was found supremely associated with 11 genera of ants. Among the eight genera of subfamily Lachninae, about 74.57% species of ants were interacting with the genus *Cinara*. In subfamily Drepanosiphinae the genus *Drepanaphis* having more interactions with ants. Genus *Thelaxes* received more ants than other genera under the subfamily Thelaxinae. For subfamilies Anoeciinae and Saltusaphidinae, only one genus from each was associated with ants (*Table 1*). Except subfamilies Thelaxinae and Saltusaphidinae, all genera from the other 7 subfamilies were mainly associated with species of ant genus *Formica*.

Table 1. *The diversity of ant-associated aphids, with the numbers and percentages of aphid genera and species in each subfamily. The information of associated ants for each aphid group are also provided*

Ant-associated aphids

The data was found normal through the normality test, so the parametric Pearman's test was applied (two-tailed $P < 0.01$) for ant-associated aphids. The results showed a positive correlation between the numbers of aphid species and that of ant species ($t = 0.983$, $df = 3$, $P = 0.009$). The data presented graphically in *Table 2*. Out of four ant subfamilies, the Formicinae had maximum associations (66.84% of all) with all nine aphid subfamilies. The genus *Formica* was found highly associated with a maximum number of aphid species. Subfamily Myrmicinae contributes 29.53% of all associations with aphids, and out of the 16 genera associated with aphids, genus *Myrmica* tended maximum aphid species. Genus *Tapinoma* of subfamily Dolichoderinae found higher associations with aphids out of 6 other genera. Only genus *Tetraponera* of subfamily Pseudomyrmecinae interacted with only one species of ant (*Table 2*). Genus *Aphis* was found highly associated with almost all genera of all ant subfamilies.

Geographical diversity

Geographical diversity of species pairs varies in different geographical zones. *Figure 1* showed that the maximum aphid-ant species pairs were in the subtropical region. The ratios of species numbers of aphid to ant in these geographical zones were measured as 1.9:1 in the temperate, 1:2.8 in tropical while nearly equal associations with the ratio 1.1:1 in the subtropical region. In the temperate zone, eight subfamilies of aphids and three subfamilies of ants were associated. Only two aphid subfamilies and three ant subfamilies were associated in the tropical area. Higher associations were found in the subtropical region with eight aphid subfamilies and four ant subfamilies (*Table 3*). All collected information was extracted from 21 countries and the aphid-ant species pairs in each country were measured. In the current database, the USA contained a maximum number of species pairs in both temperate and subtropical zones. The second highest number of species pairs was recored in Turkey (*Fig. 2*). However, equally associated species pairs were documented from subtropical areas of the world. Overall the patterns of aphid-ant interactions in different ecological zones can be seen in the *Figure 3*.

Discussion

Our data showed that among the 24 subfamilies of Aphididae (Favret, 2018), only nine are myrmecophilous (*Table 1*). The aphid subfamily Aphidinae has maximum number of associations with ant species, which corresponds well to the total species diversity of this aphid subfamily. Their maximum associations might be due to some ecological traits and population dynamics (Stadler and Dixon, 2005). A large variety of biological components have been projected to account for population-level variance in aphid-ant interactions including local species abundance and composition of aphids (Horvitz and Schemske, 1984). There are total 23 subfamilies of ants, but only six of them are associated with hemipteran insects (Styrsky and Eubanks, 2007). According to previous statistics, only the subfamilies Dolichoderinae, Formicinae and Myrmicinae harvest honeydew from aphids (Nixon, 1951; Stadler and Dixon, 2005). According to this study, four ant subfamilies, Dolichoderinae, Formicinae, Myrmicinae, and Pseudomyrmecinae (*Table 2*), are involved in aphid-ant interactions. Styrsky and Eubank (2007) indicated that 89% of ants from Formicinae and Myrmicinae involved in ant-hemipteran relationships. In the data we complied, it is observed that about 92% species of ants from Formicinae and Myrmicinae are associated with aphids. According to the Novgorodova and Gavrilyuk (2012) these subfamilies also have maximum trophobiotic interactions with aphids that have a significant effect on aphido-fauna. However, according to the results of this study few species of subfamilies Dolichoderinae and Pseudomyrmecinae were associated in trophobiotic relationships with aphid. The diversity of the mutualistic interaction of subfamily Formicinae might be due to their abundance and ecological dominance. Some subfamilies were less associated with aphids that might be due to less attention paid on these genera of ants.

Diversity and richness of aphid species was higher than ants in the temperate zone (Dixon et al., 1987; Clua et al., 2004), an aphid-ant species ratio of 1.2:1 indicated their abundance in this region (*Figure 1*). In the temperate region, one aphid species tended by many ant species such as the Novgorodova and Ryabinin (2017) documented that the aphid species *Symydobius oblongus*, *Chaitophorus populeti*, *Glyphina betulae*, *Aphis fabae*, *A. farinosa*, *A. urticata*, *Rhopalosiphum padi* were associated with 7 to 18 species of ants from temperate areas of Russia. In contrast, ants are exclusively abundant in the tropical zone (Hölldobler and Wilson, 1990; Sarnat et al., 2015). According to current study the aphid-ant species ratios in tropical areas were 1:2.8,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_54715524

which indicated that the ants are more than half of the aphid species in these regions. For example, a tropical aphid *Cerataphis fransseni* attended by various species of ants (Stadler and Dixon, 2005) indicated the dominance of ants in the tropical region. On the other hand, the aphid-ant species ratio was 1.1:1 in subtropical region, which shows that the diversity of species pairs relativity higher in subtropical than the temperate and tropical regions (*Figure 1*). Most likely the aphids and ants might interact more in subtropical regions which have more favorable conditions for both groups.

The subtropical region consists of a typical warm humid climate with diverse vegetations (e.g. semi-evergreen or semi-deciduous forests, savannah, hardwood forests, pastures, warm temperate moist forests, semi-desert and nemoral deciduous forests) (Prentice et al., 1992; Webb, 2015), which supports the insect and plant biodiversity**.** Considering aphids are abundant in the temperate zone while ants are most diverse in the tropical, it is suggested that there should be more diverse aphid-ant associations because both groups can interact more in the subtropical zone located between temperate and tropical zones. Geographical species distribution patterns found linear on the borders of temperate and subtropics (*Figure 3*). There might be two possibilities, 1) the diversity of species pairs higher than other regions, and 2) the studies recorded aphid-ant interactions vastly carried out in these regions. However, the current data may also indicate the research on diversity of aphid-ant interactions is still inadequate, which causes an imbalance of information. Therefore, we suggest more future studies should be undertaken to record more associated species of aphids and ants and then we can understand more about their mutualistic relationships.

Conclusion

Based on a meta-analysis of currently available records of aphid-ant interactions, this study reports that 284 species belonging to the 83 genera of eight aphid subfamilies have mutualistic association with 193 species belonging to 38 genera of four subfamilies of ants. These species support a total of 972 aphid-ant interactions and 915 ant-aphid interactions (one aphid species may associate with many ant species and vice versa). The aphid genus *Aphis* has a highest number of associations with ant species while highest number of aphids are associated with the ant genus *Formica*. Geographically, maximum aphid-ant species pairs were found in subtropical areas of the world. Our results provide a base for identifying general patterns of aphid-ant species pairs in different ecological zones. Besides, more taxonomic and ecological studies are needed to enrich our understanding of the aphid-ant associations.

Acknowledgements. We would like to thank help from Dr. Jun Deng, Taimoor Hassan Farooq, Waqar Ahmed during this work. This work was supported by National Key R&D Program of China (2016YFE0203100) and Open Fund of Fujian Provincial Key Laboratory of Insect Ecology, Fujian Agriculture and Forestry University.

Author contribution. J.A.S., X. H. conceived and designed the study. J.A.S. performed all the formal analysis. J.L. performed the distribution mapping. J.A.S. and X.Z. collected and compiled the data. X.H. and I.B. reviewed and edited the manuscript.

Conflict of interests. Authors declared that there is no conflict of interests.

(Received 11th Dec 2018; accepted 26th Feb 2019)

Abstract. Body color plays important roles in various behaviors of fish. *Leptobotia taeniops* exhibits two body color phenotypes at the same habitat. However, the mechanism is unclear. Tyrosinase plays a significant role in regulating synthesis of melanin. Therefore, we inferred that expression differences of tyrosinase gene was the primary reason for the different body colors of *L. taeniops*. To verify our inference, we firstly cloned and sequenced the whole-length cDNA sequence of *L. taeniops* tyrosinase gene through the rapid-amplification of cDNA ends cloning technology, and compared the expressions of the tyrosinase gene at different tissues between light and dark phenotypes using real-time quantitative reverse transcription PCR. The results showed the cDNA sequence was very similar to those from Cyprinidae fish. The expressions of tyrosinase gene in eyeball, dorsal fin, skin, muscle, liver and gill of the light phenotype were significantly lower than these in the dark phenotype. These results implied the expression of tyrosinase gene played an important role in regulating the body color of *L. taeniops*. The results provided important reference information to further elaborate the molecular mechanism of *L. taeniops* to adapt to their surrounding environment through changing color, protect wild *L. taeniops* resource, and cultivate new ornamental fish varieties.
Keywords: *Leptobotia taeniops, tyrosinase, melanin, tissue differential expression, rapid-amplification of cDNA ends*

Introduction

Body color plays important roles in various behaviors of fish, such as competition, courtship, avoiding predators and warning (Moretz and Morris, 2003; Hubbard et al., 2010; Culumber, 2013). Changes of body color is considered an adaptive response to environment changes. The way that the mechanism of body color changing works is a fundamental question in conservation ecology.

Leptobotia taeniops (Cyprinformes: Cobitidae) is an indigenous species in China, which mainly distributes in the Yangtze River and its tributary (Chen, 1980). There are two body color phenotypes of *L. taeniops* at the same freshwater habitat. The light phenotype of *L. taeniops* is near golden color. There are small black stripes and splashes on their body. The dark phenotype of *L. taeniops* is yellowish-brown. There are massive black stripes and splashes on their body. No obvious genetic differentiation is detected

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55255537

between the light and the dark phenotypes (Meng, 2011). So far, the mechanism that regulated the body color phenotypes is still unclear.

Body color of fish is controlled by types, proportion and distribution of pigment cells in epidermis. The pigment cells mainly include melanocytes, xanthophore, erythrophore, iridophore and leucophore (Schartl et al., 2016). Melanocytes contain melanin and are widely distributed in skin, hair, retina and bone of vertebrates. Melanin plays important roles in preventing damage to DNA and proteins from ultraviolet rays (Slominski et al., 2015), enhancing antioxidant capacity (Tu et al., 2009), maintaining intracellular calcium homeostasis (Parekh, 2016), and regulating immunization of organisms through NF-κB signaling pathway (Zhou et al., 2013). It is synthetized through tyrosine-tyrosinase reaction system and tyrosinase (TYR, EC 1.14.18.1) catalyzes tyrosine to the L-dihydroxyphenylalanine through hydroxylation and then converts to the dopaquinone. Therefore, tyrosinase is an iconic enzyme to melanin synthesis (Sánchez-Ferrer et al., 1995; Chen et al., 2015).

Therefore, we inferred that synthetic amount of melanin controlled the body colors of *L. taeniops* that living in the same freshwater habitat. To verify the inference, we firstly cloned and sequenced the whole-length cDNA sequence of tyrosinase gene through the rapid-amplification of cDNA ends (RACE) cloning technology. Then we compared the expression differences of the tyrosinase gene at different tissues between light and dark sub-populations of *L. taeniops* using real-time quantitative reverse transcription PCR (qRT-PCR). The results provided important reference information to further elaborate the molecular mechanism of *L. taeniops* to adapt to their surrounding environment through body color, protect wild *L. taeniops* resource, as well as cultivate new ornamental fish variety.

Materials and Methods

Sample collection

Total of 40 *L. taeniops* specimens (20 light phenotypic specimens and 20 dark phenotypic specimens) were collected from the Yueyang section of the Yangtze River during July to September, 2017. The specimens were transported to the Aquaculture Laboratory of Hunan Agricultural University, and temporary cultured 7 days in a culture system with circulating water at 25 ± 1°C before anaesthetized. The specimens were starved during the temporary cultured period. To eliminate the effect of healthy status on gene expression, each 6 specimens of light and dark phenotypes were chosen to further analyze according to their healthy status and exercise ability. The specimens were anaesthetized using MS-222, taken pictures, and measured their body lengths and body weights before dissected. After dissected, their sex was identified through sex gland. Their eyeball, skin at dorsal fin base, muscle, dorsal fin, gill, brain, liver and fish blubber were collected into freezing tubes and stored at -80°C for further analysis.

RNA extraction and sequencing cDNA of tyrosinase gene

The RNA used to synthetize cDNA of *L. taeniops* tyrosinase gene were extracted from 50-80 mg of skin using E.Z.N.A. Total RNA I kit (OMEGA, China) according to the manufacturer's introduction. The concentration and purity of RNA were measured using a nucleic acid and protein detector (Eppendorf, Germany). The degradation was assessed by 1.5% agarose gel electrophoresis with 120 V. The first strand of cDNA was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55255537

synthetized using a RevertAid™ First Strand cDNA Synthesis kit (Fermentas, USA) according to the manufacturer's introduction.

The intermediate primers, TYR-F and TYR-R, were designed according to the sequences of Cyprinidae tyrosinase genes in GenBank database using primer 6.0 software. Then the intermediate sequence was amplified using the primers and the first strand of cDNA as a template. The PCR product was purified using a Gel Extraction kit (Omega, China) and bound to pTOPO-T vectors (Aidlab, China) and cloned as a previous report (Ni et al., 2017). Five positive clones were screened and bidirectional sequenced to obtain the intermediate sequence of *L. taeniops* tyrosinase gene using ABI 3730 system at Wuhan Aokedingsheng Bio-Science, Ltd., China.

According to the sequences of Cyprinidae tyrosinase genes and the intermediate sequence of *L. taeniops* tyrosinase gene, the 5′ and 3′ bilateral primers TYR5′-outer and TYR3′-outer and 5′ and 3′ medial primers TYR5′-inner and TYR3′-inner for RACE amplifying were designed using Oligo 7.0 software (*Table 1*). The 5' RACE cDNA and 3' RACE cDNA were synthetized using the primers and approximately 2 μg RNA as the template according to the user manual of the SMARTer RACE 5'/3' kit (Clontech, USA). Subsequently, the 3′ RACE and 5′ RACE of *L. taeniops* tyrosinase gene were amplified using the 3' RACE cDNA and 5' RACE cDNA as the template. The PCR product was purified and sequenced as described above.

Table 1. *The primer sequences used in the present study. RACE, rapid-amplification of cDNA ends; TYR, tyrosinase*

* F: forward primer; R: reverse primer

The sequences were merged to whole-length cDNA sequence of *L. taeniops* tyrosinase using SeqMan 5.01 module of DNAStar software. The amino acid sequence of *L. taeniops* tyrosinase was predicted based on the cDNA sequence using DNAMAN 7.0 software. The similar amino acid sequences of *L. taeniops* tyrosinase were retrieved from GenBank database using BLAST (http://www.ncbi.nlm.nih.gov/blast). The amino acid sequences of tyrosinase from koi carp (*Cyprinus carpio*, ANN11899.1), zebrafish

(*Danio rerio*, NP_571088.3), goldfish (*Carassius auratus*, ABI93943.1), Atlantic salmon (*Salmo salar*, ABD73809.1), finless eel (*Monopterus albus*, XP_020475631.1), midas cichlid (*Amphilophus citrinellus*, ANE23829.1), snakehead (*Channa argus*, AMQ24769.1), rainbow trout (*Oncorhynchus mykiss*, NP_001117694.1), medaka (*Oryzias latipes*, BAA31348.1), fugu rubripes (*Takifugu rubripes*, AAK13523.1), swordtail fish (*Xiphophorus maculatus*, XP_023207866.1), red crucian carp (*Carassius auratus auratus*, BAH03534.1), channel catfish (*Ictalurus punctatus*, AAF20161.1), sea pineapple (Ha*locynthia roretzi*, BAC76424.1), lancelet (*Branchiostoma japonicum*, AFS33098.1), black-spotted pond frog (*Pelophylax nigromaculatus*, BAA02077.1), soft-shell turtle (*Pelodiscus sinensis japonicas*, BAB79632.1), egret (*Egretta garzetta*, KFP18390.1), chicken (*Gallus gallus*, AAB36375.1), horse (*Equus caballus*, XP_001492610.4), sheep (*Ovis aries*, NP_001123499.1), mouse (*Mus nusculus*, NP_035791.1), and human being (*Homo sapiens*, NP_000363.1) were chose as reference sequences to construct phylogenetic tree. The sequences as well as that from *L. taeniaps* were aligned using Clustal X2.1 and neighbor-joining phylogenetic tree with 1000 times of bootstrap was constructed using MEGA 6.0. Expasy (http://www.expasy.org/) and SMART (http://smart.embl-heidelberg.de) were used to analyze the amino acid sequences of *L. taeniops* tyrosinase and predict functional domains of the protein.

The whole-length cDNA sequence has been submitted to the GenBank database with accession number MG870259.

Expression analysis of tyrosinase gene in different tissues of L. taeniops

Total RNA in eyeball, skin, muscle, dorsal fin, eyeball, gill, brain, liver and fish blubber of light and dark *L. taeniops* phenotypes were extracted using an E.Z.N.A. Total RNA I kit (OMEGA, China). The first strand of cDNA was synthetized using a RevertAid™ First Strand cDNA Synthesis kit (Fermentas, USA) with Oligo(dT)$_{18}$ primer. Primers qRT-TYR-F and qRT-TYR-R were designed according to the coding sequence (CDS) of the tyrosinase gene for real-time qRT-PCR (*Table 1*). Primers β-Actin-F and β-Actin-R (*Table 1*) were designed according to the sequence of *β*-Actin gene for endogenous reference to detect the amplification efficiencies (*E%*) and the correlation coefficients (R^2).

Real-time qRT-PCR was conducted on a CFX96 TouchTM real-time PCR detection system (Bio-Rad, USA) as a previous report (Ni et al., 2018) with minor modification. Briefly, each 25 μl reaction mixture consisted of 1 × SYBR Green Ⅱ PCR master mix (TaKaRa, China) containing 200 nM each primer and 20 ng of cDNA. The reactions were performed by incubation for 10 min at 95°C, following by 10 s at 95°C, 10 s at 60°C and 15 s at 72°C for 35 cycles. The program of melt curve was increased 0.5°C each 5 s from 65°C to 95°C. The relative expressions of tyrosinase gene in different tissues were calculated by the comparative Ct ($2^{-\triangle\triangle Ct}$) method (Li et al., 2012; Spivak et al., 2012).

Statistical analysis

One-way analysis of variance (ANOVA) for comparing the expressions of tyrosinase gene among different issues and Duncan's multiple range test for post-hoc test was conducted using R version 3.5.1. Independent *t*-test was conducted using R version 3.5.1 for comparing the body weights, the body lengths, and the expressions of

tyrosinase gene in specific issue between the light and the dark phenotypes. Binomial test for comparing the sex ratio between the light and the dark phenotypes was also conducted using R version 3.5.1. Results for each parameter are presented as means ± standard deviation (SD) for each group. P-values < 0.05 were considered statistically significant.

Results

Physical characteristics of L. taeniops

The background color of *L. taeniops* was yellowish-brown. A lot of sparse black spots were on back of the light phenotype. Only very small gray spots were on their body sides (*Fig. 1A*). However, there were massive black stripes and splashes on the back and body sides of the dark phenotype (*Fig. 1B*). Body lengths of the light phenotype were 10.30 ± 0.60 cm, and these of the dark phenotype were 10.27 ± 0.95 cm (*Fig. 1*). Body weights of the light phenotype were 14.85 ± 2.30 g, and these of the dark phenotype were 15.33 ± 4.32 g. Neither the body length nor the body weight was detected significant difference between the light and dark phenotypes in the body length (independent *t*-test, $t = -0.073$, $p = 0.94$) and the body weight (independent *t*-test, $t = 0.24$, $p = 0.82$). Sex ratio between the light and dark phenotypes was also no significant difference (♀ : ♂ was 1 : 5 for the light phenotype; ♀ : ♂ was 2 : 4 for the dark phenotype; Binomial test, $p = 0.263$).

Figure 1. *Light (A) and dark (B) phenotypes of Leptobotia taeniops*

cDNA and amino acid sequences of tyrosinase of L. taeniops

The whole-length cDNA sequence of *L. taeniops* tyrosinase was 2643 bp, which was comprised by a 1617 bp of open reading frame, a 22 bp of untranslated region (UTR) at upstream of 5' end, and a 1004 bp of UTR at downstream of 3' end. The cDNA sequence contained the typically polyadenylation signal (AATAAA) and Poly(A)-tail of vertebrates (*Appendix 1*). The complete CDS of *L. taeniops* tyrosinase gene was approximately 90% of similarity to those of Cyprinidae fishes, such as *Cryprinus carpiod*, *C. auratis* and *D. rerio.* Putative amino acid sequence was 538 amino-acid residues and was constituted by 4 conserved domains, i.e. signal peptide, epithelial growth factor-like domain (EGF-like domain), tyrosinase domain, and transmembrane region. Tyrosinase domain included two copper binding sites (CuA and CuB; *Appendix 2*). The structure of the CuA was (H-x(4,5)-F-[LIVMFTP]-x-[FW]-H-R-x(2)-[LVMT]-x(3)-E), which corresponding amino acid sequence was HESAAFLPWHRVYLLFWE. The structure of the CuB was (D-P-x-F-[LIVMFYW]-x(2-)-x(3)-D), which corresponding amino acid sequence was DPIFLLHHAFID. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55255537

structures of the CuA and CuB were highly conserved among vertebrate species. The structures of CuA and CuB of *L. taeniops* were completely identical with Cyprinidae *Cryprinus carpiod*, *C. auratis* and *D. rerio* (*Appendix 3*). The molecular weight of *L. taeniops* tyrosinase was 60.81 kD. Theoretical isoelectric point of *L. taeniops* tyrosinase was 6.13. The predictive chemical structure formula was $C_{2718}H_{4105}N_{749}O_{788}S_{29}$. The instability coefficient was 56.16, which indicated that the protein was unstable. The prediction atlas of hydrophobicity showed that the tyrosinase of *L. taeniops* contained more hydrophilic regions than hydrophobic regions. Therefore, the tyrosinase was hydrophilic protein (*Appendix 4*). There were 13 cysteines in the tyrosinase of *L. taeniops*. Nine of 13 cysteines were at N-terminal, and other 4 cysteines were in the middle between CuA and CuB (*Appendix 1*).

Neighbor-Joining tree showed that all amino acid sequences of fish tyrosinase were clustered together, and those of amphibians, reptiles, birds and mammals were clustered to another cluster. *H. roretzi* of Urochordata and *B. japonicum* of Cephalochorda was clustered to two separate branches. *L. taeniops* was clustered together to Cyprinidae fishes (*Fig. 2*).

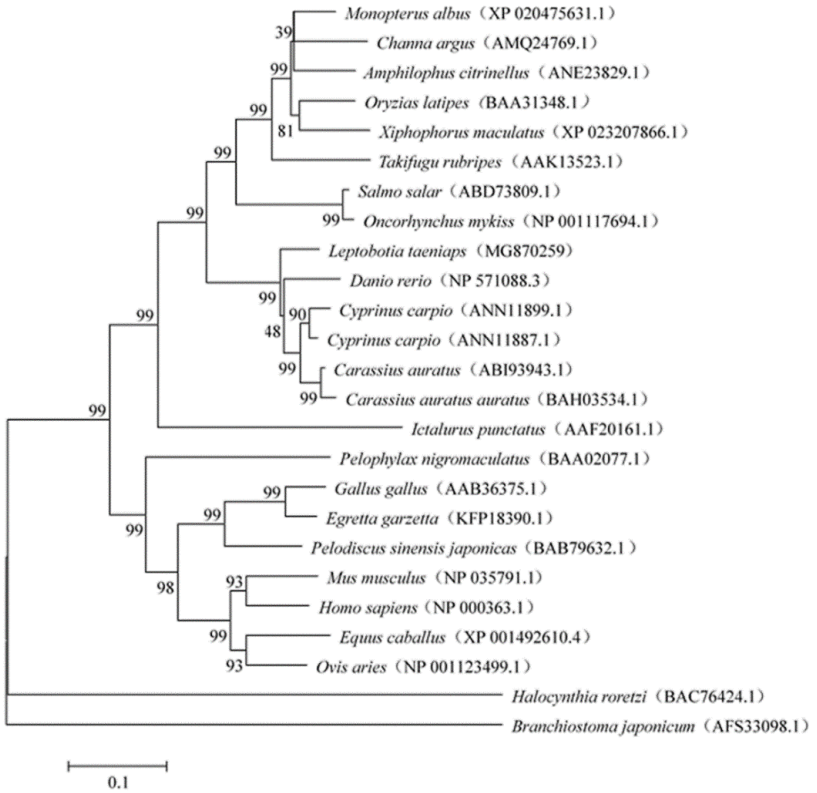

Figure 2. *Phylogenetic relationships of Leptobotia taeniaps and other representative vertebrates constructed based on amino acid sequences of tyrosinase*

Expression of tyrosinase gene in different tissues and organs of L. taeniaps

The amplification efficiencies ($E\%$) and the correlation coefficients (R^2) showed that the primer pairs qRT-TYR-F/R ($E\%$ = 104.8%, R^2=0.991) and β-Actin-F/R ($E\%$ = 104.7%, R^2 = 0.998) were in sufficient to the requirements of real-time qRT-PCR

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55255537

(90% < *E*% < 105%, and R^2 > 0.98). The expressional trend of tyrosinase gene in skin, muscle, dorsal fin, eyeball, gill, brain, liver, and fish blubber was concordant between the light and dark phenotypes of *L. taeniops*. It was highest expressed in eyeball, and significantly different to other tissues (One-way ANOVA, $p < 0.01$), followed by dorsal fin, skin, muscle and brain. The expressions of tyrosinase gene in gill, liver and fish blubber of *L. taeniops* were very low, and no significant difference was detected among the three issues (One-way ANOVA, $p > 0.05$; *Fig. 3*). The expressions of tyrosinase gene in eyeball (independent *t*-test, $t = 34.88$, $p < 0.01$), dorsal fin (independent *t*-test, $t = 19.85$, $p < 0.01$), skin (independent *t*-test, $t = 25.60$, $p < 0.01$), muscle (independent *t*-test, $t = 15.53$, $p < 0.01$), liver (independent *t*-test, $t = 5.77$, $p < 0.01$) and gill (independent *t*-test, $t = 7.35$, $p < 0.01$) of the light phenotype were significantly lower than these in the dark phenotype. No significant difference of the expressions in brain (independent *t*-test, $t = 1.07$, $p = 0.31$) and fish blubber (independent *t*-test, $t = 0$, $p = 1.00$) was found between the light and the dark phenotypes of *L. taeniops* (*Fig. 3*).

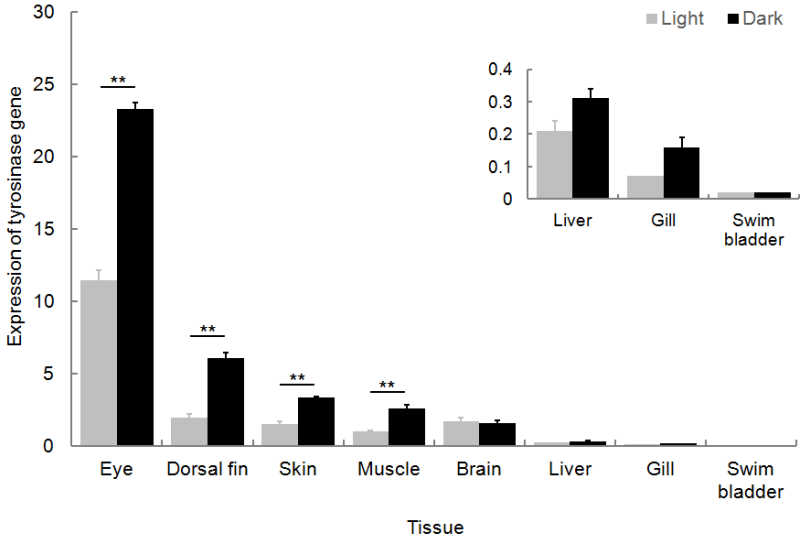

Figure 3. *Expressions of tyrosinase gene in eight tissues of Leptobotia taeniaps. The asterisks indicating differences between light and dark phenotypes. Independent t-test was used to compare the expressions of tyrosinase gene between the light and dark phenotypes of L. taeniaps.* **,* $p < 0.05$*;* ***,* $p < 0.01$

Discussion

Tyrosinase is a key enzyme to synthesize melanin. The expression of tyrosinase gene controls the speed and production of melanin. The higher expression of tyrosinase gene promotes the intracellular synthetization of melanin (Gutiérrez-Gil et al., 2007). The expressions of tyrosinase gene in the peoples with dark skin are higher than those in the peoples with pale skin (Huang et al., 2008). The expressions of tyrosinase gene in skin are differences among different varieties of *Cryprinus carpiod*, and the expression is the highest in dark *C. carpiod* (Wang et al., 2012). The expressions of tyrosinase gene in scale, skin and tail fin of dark *A. citrinellus* are significantly higher than those of bright yellow ones (Jiang, 2016). Our results showed that the expressions of tyrosinase gene in eyeball (independent *t*-test, $t = 34.88$, $p < 0.01$), dorsal fin (independent *t*-test, $t = 19.85$, $p < 0.01$), skin (independent *t*-test, $t = 25.60$, $p < 0.01$), muscle (independent *t*-test,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55255537

$t = 15.53$, $p < 0.01$), liver (independent t-test, $t = 5.77$, $p < 0.01$) and gill (independent t-test, $t = 7.35$, $p < 0.01$) of the light phenotype were significantly lower than these in the dark phenotype. The result implied that the expressional differences of tyrosinase gene was the major reason that caused the differentiation of *L. taeniops* body color.

Expressional patterns of tyrosinase gene are different among fishes. The gene was expressed in eyeballs and skins of *D. rerio* (Chiu, 2003) and *O. latipes* (Zou et al., 2006), while it is not expressed in their livers. Our results showed that the expression of tyrosinase gene in eyeball of *L. taeniops* was the highest, followed by dorsal fin, skin, muscle and brain. The expressions of tyrosinase gene in gill, liver and fish blubber of *L. taeniops* were the lowest, coincident with the results in *C. auratus* (Chiu, 2003) and *C. carpiod* (Wang et al., 2012).

Melanin participates in many physiological processes of organisms. And tyrosinase is the essential enzyme to synthetize melanin. Therefore, the tyrosinase gene is expressed in various issues of *L. taeniops*. There are lots of melanocytes in retinal pigment epithelium (RPE). As an antioxidant, the melanin protects RPE and nerve cells from oxidative damage (Zhang et al., 2011). Therefore, tyrosinase gene was highly expressed in eyeball. Nerve cells produce melanin during their development, and brain is the tissue in which nerve cells are concentrated. Therefore, tyrosinase gene was also expressed in brain (Sulzer et al., 2000). In addition, the expressions of tyrosinase gene in heart, fish blubber and liver implied that the tyrosinase probably did not only participate in the synthetizing melanin, but also regulating other physiological activities (Wang et al., 2012).

Although melanin plays important roles in preventing damage to DNA and proteins from ultraviolet rays (Slominski et al., 2015), enhancing antioxidant capacity (Tu et al., 2009), maintaining intracellular calcium homeostasis (Parekh, 2016), and regulating immunization of organisms through NF-κB signaling pathway (Zhou et al., 2013), the reason caused the differentiation of *L. taeniops* body color are still needed to further study. Sex and development phase are two major factors that influence body color of fish (Bjerkeng et al., 2000; Suqimoto, 2002; Li et al., 2014). However, no significant difference in sex and development phase (it was indicated by the body length and the body weight) were detected between the light and the dark phenotypes in our study. Therefore, externally special stimulation was probably the reason that caused the expressional differences of tyrosinase gene between the light and dark phenotypes of *L. taeniops* and the differentiation of their body colors. It should be further studied which environmental factors regulate the expression of *L. taeniops* tyrosinase gene.

Our results showed the structure of *L. taeniops* tyrosinase was accordance with other vertebrates (Jagirdar et al., 2014; Ming et al., 2016; Yu et al., 2017). A signal peptide comprised 20 amino-acid residues (MRPSSISPLLFFIQYLGLSL) was in tyrosinase gene of *L. taeniops*, which was the requisite structure to lead the newly synthesized protein to enter the endoplasmic reticulum to complete its modification (Wang et al., 2005). It can influence expression of the protein (Güler-Gane et al., 2016), and control location of the protein (Wei et al., 2006). Compared with amphibians, reptiles, birds and mammals, the tyrosinase gene sequence of *L. taeniops* was highly similar to the tyrosinase gene sequences from other fishes, especially Cyprinidae fishes. There were 13 cysteines in the tyrosinase of *L. taeniops*. Nine of 13 cysteines were at N-terminal, and other 4 cysteines were in the middle between CuA and CuB, in accordance with *C. carpiod* (Wang et al., 2012). This result verified that the amino acid sequence of tyrosinase was highly conservative in fishes, as showed by the phylogenetic tree

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55255537

(*Figure 2*). The cysteine in protein promotes the active sites of tyrosinase to bind copper ion during its process (Bijelic et al., 2015; Lai et al., 2018). The EGF-like domain (CQCAGNYMGFDC) was rich in cysteines, which coded protein activating EGF signal pathway and was connected with the multienzyme complex that induces expression of the tyrosinase-related proteins (Jackson et al., 1990, 1992; Dunning et al., 2015). Tyrosinase was type III copper oxidase. Its tyrosinase domain included two domains of histidine residues (HESAAFLPWHRVYLLFWE and DPIFLLHHAFID) that bind to copper ion (Pretzler and Rompel, 2018). Binding by metal ion commonly changes the stability and function of protein. Copper ion endows the redox properties to tyrosinase (Solano, 2018), and plays important role in synthetizing melanin.

In conclustion, we firstly cloned and sequenced the whole-length cDNA sequence of *L. taeniops* tyrosinase gene, and compared the expressions of tyrosinase gene in different issues between the light and dark phenotypes of *L. taeniops*. Tyrosinase gene was mainly expressed in eyeball, skin, dorsal fin, muscle and brain of both the light and dark phenotypes of *L. taeniops*. The expressions of tyrosinase gene in eyeball, dorsal fin, skin and muscle of the light phenotype were significantly lower than these in the dark phenotype ($p < 0.01$). These results implied that the expression of tyrosinase gene played important role in regulating the synthesis of melanin and the body color of *L. taeniops*. Our results provided important reference information to further elaborate the molecular mechanism of *L. taeniops* to adapt to their surrounding environment through body color, protect wild *L. taeniops* resource, as well as cultivate new ornamental fish variety. However, how external and intrinsic factors influence the expression of tyrosinase gene and which genes participate in regulation of the expression of tyrosinase gene should be further studied in the future.

Abstract. The 12 main crops in the Yellow River Basin were selected as the research objects. Based on crop water consumption and effective precipitation, the regional crop water consumption and agricultural water footprint of the Yellow River Basin are studied. The results showed that the distribution of crop water consumption in the Yellow River Basin was similar to that of the annual average precipitation. Irrigation affected the data distribution in some areas. The areas with high crop water consumption value were mainly concentrated in the irrigation areas along the Yellow River. Rain-fed agriculture was dominant in other areas, and crop water consumption was relatively small. The total crop water consumption in the Yellow River Basin was 84.25 billion m^3 in 2017, 66% of which is in Henan and Shandong provinces and 60% is for wheat and maize. The proportion of green water to crop water consumption in the Yellow River Basin was 78.7%. The spatial distribution of green water consumption in crops was basically the same as that of crop water consumption. The agricultural water footprint of the Yellow River Basin is 49.45 billion m^3, accounting for 58.7% of the crop water consumption. The proportion of green water consumption to total water consumption of most crops is more than 80%, and the lowest is 58% for wheat. 56% of blue water in the river basin is used for wheat. Crop water consumption coefficient reflects the level of water use in production. The average crop water consumption coefficient in the Yellow River Basin is about 0.622 m^3/kg.
Keywords: *water consumption coefficient distribution, annual average precipitation, reference evapotranspiration, green water, blue water*

Introduction

Humanity's direct need of fresh water is mainly due to food production, among which green water has a function that cannot be ignored on food production (Veettil and Mishra, 2016). The green water is a water resource that comes from precipitation, is stored in soil and consumed by evaporation of vegetation (Zuo et al., 2015). Green water has made outstanding contributions to crop production (Hoff et al., 2010). Thus the need to consider this resource in water availability and water scarcity studies (Fader et al., 2011). Water for agricultural irrigation in the Yellow River Basin, China is mainly originated from precipitation, and the role of green water is more prominent (Zhang et al., 2014). Defining the characteristics of human need for agricultural water helps to find a way of increasing agricultural production and reducing agricultural water consumption (Feng et al., 2012). In the Yellow River Basin, water is less efficiently consumed for agricultural irrigation. Less than half of irrigation water resource

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

consumed by agriculture is consumed by humans. In the Yellow River Basin in which the situation of agricultural water is grim, water is wasted in large quantities (Xiang et al., 2017). Coupled with imperfect water conservancy facilities, unreasonable water-saving irrigation system and unreasonable planting structure, the water consumption efficiency is very low in the basin (Gonçalves et al., 2007; Bai et al., 2017). Therefore, improving efficiency of irrigating water and giving full play to green water in the Yellow River Basin is an important way to improve efficiency of agricultural water, develop water-saving high-efficiency agriculture and alleviate the lack of water resource in the basin (Zhuo et al., 2014). A systematic analysis of the agricultural water footprint and crop water consumption in the basin provides the necessary scientific support for regional water resources safety and eco-economic system.

Crop water consumption, as a key indicator of analyzing the agricultural water footprint, is generally represented by the (evapotranspiration, ET) and subject to the calculation method of ET at the regional scale (González-Dugo et al., 2013; Yin et al., 2017; Wang et al., 2018). The difference is that when the ET at the regional scale is estimated, ET values of only a plant are selected at several moments (Serrano-Coronel et al., 2018). However, as there are multiple agricultural crops planted, calculation of agricultural water consumption should be subject to the amount of water consumed by all crops in their growth duration (Zhang et al., 2010). In addition, when the spatial distribution of water consumption of crops in growth duration is calculated, the existing research generally measures the amount of water that the crop takes up from the soil according to the water balance of the crops in the grid at the beginning and end of the growth duration to reduce the computational work. However, there are many factors affecting soil water content during the growth duration, beside crop water consumption (Mo et al., 2009; Li et al., 2016). Thus, subdividing the growth duration can approximate to the real facts. In order to improve the computational accuracy, inclusion of major crops in the study area, subdivision of the growth duration and use of high spatial resolution data is also a development direction (Barbagallo et al., 2004; Wei et al., 2016). In addition, advancement of remote sensing technique also provides the necessary conditions for monitoring crop water consumption in a real-time manner (Calera et al., 2017).

The 12 major crops in eight provinces of the Yellow River Basin are selected to analyze the spatial distribution of agricultural water consumption and green water consumption. Additionally, water consumption and primary industry water footprint are used as a basis to further study the agricultural water footprint. In order to provide support for formulating appropriate agricultural water-saving measures and ensuring the efficient and rational utilization of regional agricultural water resources.

Materials

The study area

The Yellow River originates from the Qinghai-Tibet Plateau and flows into the Bohai Sea. It flows through nine provinces (regions) including Qinghai, Sichuan, Gansu, Ningxia, Inner Mongolia, Shanxi, Shaanxi, Henan and Shandong, with 795,000 km^2 drainage area and 546 4 km total length of the main river channel (*Fig. 1*). Of the Yellow River Basin, the terrain is rugged violently, descending in three steps from west to east. During 1956 to 2017, the average temperature of the basin is 8.6 °C; the average annual precipitation is 466 mm, decreasing from the southeast to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

northwest (*Fig. 2*); the annual sunshine hours fall between 1400 and 3300 h. The climate difference is distinct. The west is arid and the east is humid; The basin is divided by water condition into semi-humid region, semi-arid region and arid region from west to east, and by temperature condition into warm temperate zone, the middle temperate zone and the plateau climate zone.

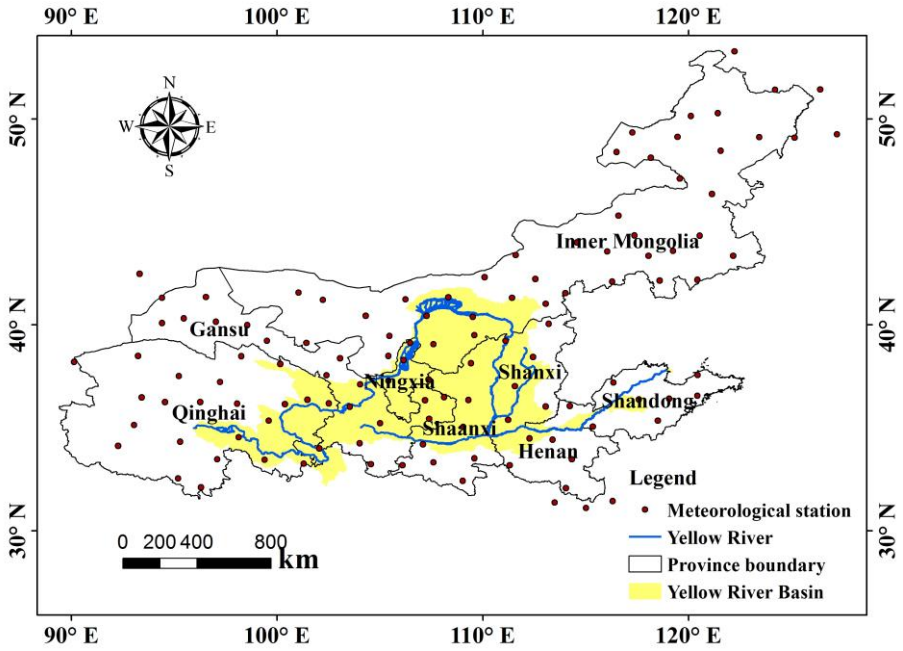

Figure 1. *The map of the Yellow River Basin and the related nine provinces*

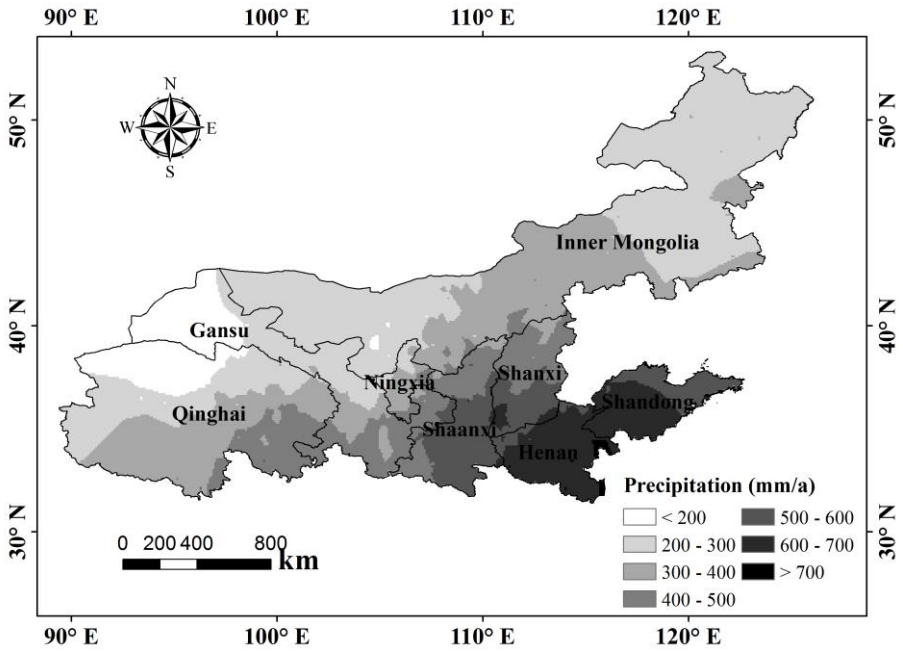

Figure 2. *Spatial distribution of annual average precipitation in the Yellow River Basin (1956-2017)*

Data

The planting area and yield data of the crop are obtained from the global major crop distribution map and yield distribution map formulated by You et al. (2014). The former gives a percentage of the harvest area of each crop in grid area, while the latter lists the average yield（t/ha）of each crop in the grid. In this study, 12 crops are selected, basically covering the varieties in the Yellow River Basin. Among them, wheat and corn have a large planting area, accounting for 4.3% and 2.9% of the total area of eight provinces, respectively. The meteorological data are collected from the 121 meteorological stations of Chinese National Meteorological Bureau (*Fig. 1*). They are mainly used as input terms of CROPWAT software, including maximum and minimum temperature, wind speed, daylight hours, relative humidity and precipitation. The above kinds of data are based on the statistical information of 2017.

The irrigation area distribution map (*Fig. 3*) is obtained from the websit of FAO (*http://www.fao.org/nr/water/aquastat/irrigationmap/index.stm*). Irrigation facilities are concentrated in Shandong and Henan, between which irrigation facilities appear in more than 80% of Shandong (except central and southern region), and in more than 60% of Henan (except western region). The irrigated farmlands appear in a decentralized manner in Ningxia, Shanxi, Shaanxi and Gansu, and there are irrigated farmlands in the Yellow River irrigation area and Tongliao district in Inner Mongolia. Irrigated farmlands are scattered across the north side of the Yellow River Valley in eastern Qinghai. Regions with an irrigation ratio exceeding 70% include Ningmeng irrigation area, Central Shaanxi Plain, Jinzhong, lower reach of Yellow River (Henan section) and areas in Shandong along Yellow River, which are commonly characterized by border on Yellow River, convenience for water intaking, superior agricultural natural conditions and development of irrigated agriculture. The ArcGIS 10.3 was employed to realize data calculation and visualization.

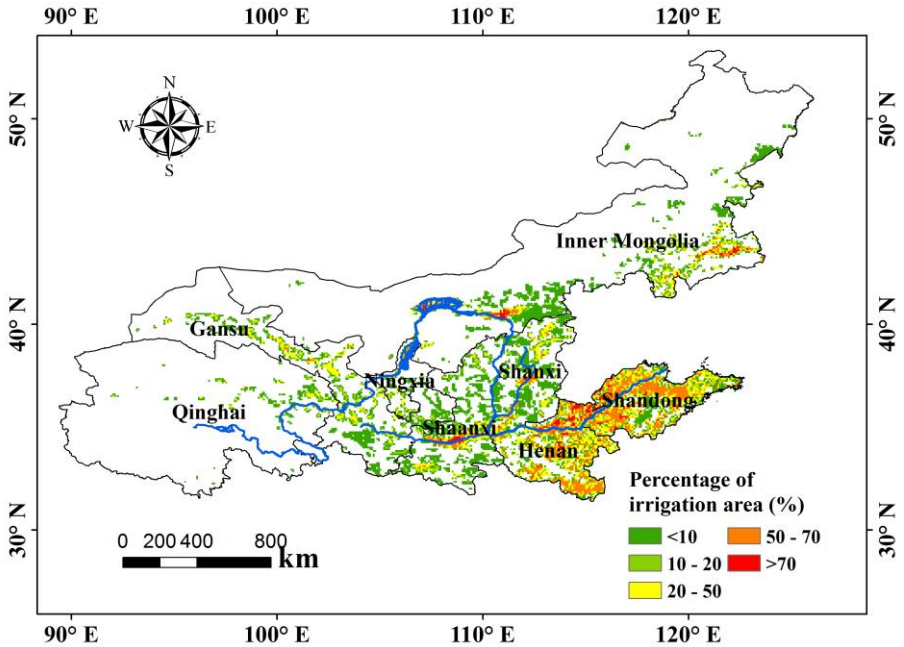

Figure 3. *The percentage of irrigation area of the total agricultural land in 2017*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

Methodology

Crop water consumption

The calculation steps of regional crop water consumption are as *Equations 1–5:*

$$CWU = \sum_{c=1}^{12} CWU(c) \quad \text{(Eq.1)}$$

where c is the crop type, $CWU(c)$ is the regional water consumption of the c-th crop, with the unit of m^3.

$$CWU(c) = ET(c) \quad \text{(Eq.2)}$$

The actual regional ET of the c-th crop $ET(c)$ is calculated by *Equation 3*.

$$ET(c) = ET_g(c) + ET_b(c) \quad \text{(Eq.3)}$$

where $ET(c)_g$ *and* $ET(c)_b$ are respectively represent the green and blue water consumption of the c-th crop in the region. The blue water is the water resources of surface runoff and underground runoff. Then, the contribution rate of green water to the c-th crop's water consumption is:

$$GW(c) = \frac{ET_g(c)}{CWU(c)} \quad \text{(Eq.4)}$$

Contribution rate of green water in the region is calculated as:

$$GW = \frac{\sum_{c=1}^{12} ET_g(c)}{\sum_{c=1}^{12} CWU(c)} \quad \text{(Eq.5)}$$

Green water consumption

Crop evapotranspiration depends on crop water demand and soil water supply which comes from effective precipitation and irrigation. Here, a 5-arc minute resolution distribution map of irrigated farmland is selected. For Rain-fed Agricultural areas, effective precipitation is the only source of water available in soil, and evapotranspiration of crops is completely composed of green water. For irrigated areas, due to the lack of irrigation system data, it is assumed that irrigation water can meet crop water demand. Therefore, the transpiration of crops is the water demand of crops, in which the green water is supplied by effective precipitation and the blue water is supplied by irrigation water.

Crop water demand

When the blue and green water consumption of each crop in an area is analyzed, the crop water demand is first calculated at the observatory; then, Kriging interpolation is adopted to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

determine the crop water demand in each grid of this area; Later, according to the agricultural crop sown area distribution map and the irrigated area distribution map, the blue and green water consumption in each grid is obtained and then separately accumulated to finally get the blue and green water consumption of the crop in this area.

The crop water demand for a certain growth period t is represented by $ET_c(c, t)$ which is calculated by *Equation 6:*

$$ET_c(c,t) = K_c(c,t) \times ET_0(c,t) \quad \text{(Eq.6)}$$

where $K_c(c, t)$ and $ET_0(c, t)$ are respectively represent the crop coefficient and the reference ET.

CROPWAT 8.0 is used to calculated crop water demand, effective precipitation and irrigation water demand. In CROPWAT, the ET_0 was calculated by Penman-Monteith formula (Allen et al., 1998). K_c varies with crop growth stages, the K_c values refer to *http://www.fao.org/docrep/X0490E/x0490e0b.htm*.

Effective precipitation

Effective precipitation is defined depending on different professional fields. Without a clear definition in agricultural production field, effective precipitation usually refers to part of precipitation that can meet the need for crop evapotranspiration, excluding surface runoff and deep seepage (Sikorska et al., 2018). In the CROPWAT software, there are four methods to calculate effective precipitation, namely the fixed ratio method, precipitation-based method, empirical formula method and USDA SCS method. Among them, the SCS method is the most widely used for agricultural water resources management. The SCS method is an empirical formula as *Equation 7*, which is deduced by analyzing precipitation data at 22 test stations for 50 years, and has been simplified to calculate the effective precipitation (Mishra and Singh, 2007).

$$P_e = \begin{cases} P_t \times \dfrac{125 - 0.2P_t}{125}, & P_t < 250\text{mm} \\ 125 + 0.1 \times P_t, & P_t \geq 250\text{mm} \end{cases} \quad \text{(Eq.7)}$$

where P_e is effective precipitation, mm; P_t is monthly precipitation, mm.

Green water consumption in grids

Taking 10 days as the calculation period, the green water consumption $ET_g(c, i, t)$ of the c-th crop in the No. i grid is determined by the crop water requirement $ET_c(c, i, t)$ and effective precipitation $P_\varepsilon(c, i, t)$ in the period t, through *Equation 8:*

$$ET_g(c,i,t) = \min[ET_c(c,i,t), P_e(c,i,t)] \quad \text{(Eq.8)}$$

Irrigation water requirement $IRR(c, i, t)$ during period t is calculated by *Equation 9:*

$$IRR(c,i,t) = ET_c(c,i,t), -ET_g(c,i,t) \quad \text{(Eq.9)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

That is the amount of blue water is by (*Eq. 10*):

$$ET_b(c,i,t) = IRR(c,i,t) \quad \text{(Eq.10)}$$

During the whole growth period, the amount of green water focr the c-th crop on the i-th grid is:

$$ET_g(c,i) = \sum_t ET_g(c,i,t) \quad \text{(Eq.11)}$$

During the whole growth period, the amount of blue water for the c-th crop on the i-th grid is:

$$ET_{b_g}(c,i) = \sum_t ET_b(c,i,t) \quad \text{(Eq.12)}$$

Regional green water consumption

The regional green water consumption of the c-th crop $ET_g(c)$ is calculated by *Equation 13*:

$$ET_g(c) = \sum_i [ET_g(c,i) \times A(c,i)] \quad \text{(Eq.13)}$$

where the $A(c, i)$ is the planting area percentage of the c-th crop on the i-th grid.

The regional blue water consumption of the c-th crop $ET_b(c)$ is obtained through *Equation 14*:

$$ET_b(c) = \sum_i [ET_b(c,i) \times A(c,i) \times I(c,i)] \quad \text{(Eq.14)}$$

where the $I(c, i)$ is the irrigation area percentage of the c-th crop on the i-th grid.

Agricultural water footprint

The agricultural water footprint includes blue water and green water. The primary industry water footprint refers only to blue water. Some water consumed by crops flows out of the area, and some is used by local residents. The rest is the agricultural water footprint. Thus, calculation of agricultural water footprint is based on the primary industry water footprint and crop water consumption, and the total water consumed by the primary industry is composed of the water footprint of the primary industry and the primary industry net output virtual water. Considering that the Yellow River Basin is an important agricultural base, it is assumed that the net output virtual water of agriculture does not flow in but flow out. Then, the crop water consumption is equal to the amount of the agricultural water footprint and the net output. Thus, the proportion of the agricultural water footprint to the crop water consumption is equal to the proportion of the primary industry water footprint to the primary industry water. The agricultural water footprint can be calculated as shown in *Equation 15*:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

$$WFP_{agr} = CWU \times \frac{WFP_{fir}}{WFP_{fir} - EWFP_{fir}} \quad \text{(Eq.15)}$$

where WFP_{agr} is agricultural water footprint, m^3; WFP_{fir} is water footprint of primary industry, m^3; $EWFP_{fir}$ is external water footprint of primary industry, m^3. WFP_{fir} and $EWFP_{fir}$ are calculated by input-output method according to the reference (Yin et al., 2016).

Crop water consumption coefficient

The crop water consumption coefficient refers to the water consumed per unit of yield, which is the ratio of crop water consumption to the yield. It is an important indicator to measure the water consumption efficiency in crop production. Here, the crop water consumption of each grid is obtained with the above method, and the yield data adopts a crop yield distribution map with 50-arc resolution. The water consumption coefficient calculation processes are *Equations 16-18:*

$$WCC(c,i) = ET(c,i) / Y(c,i) \quad \text{(Eq.16)}$$

where $WCC(c, i)$ is the water consumption coefficient of the c-th crop on the i-th grid, and $Y(c, i)$ is the yield of the c-th crop on the i-th grid.

$$WCC(c) = \sum_i [ET(c,i)] / \sum_i [Y(c,i)] \quad \text{(Eq.17)}$$

where $WCC(c)$ is the water consumption coefficient of the c-th crop cin the area.

$$WCC = \frac{\sum_{c=1}^{12} \sum_i ET(c,i)}{\sum_{c=1}^{12} \sum_i Y(c,i)} \quad \text{(Eq.18)}$$

where WCC is the agricultural water consumption coefficient in the area.

Results

Distribution of crop water consumption

We can see from *Figure 4* that similar to the precipitation contour, crop water consumption in the Yellow River Basin roughly tends to descend to zero from southeast to northwest, and local areas are affected by irrigation. Areas with high water consumption are closely related to irrigation facilities. The irrigation areas account for a large proportion in total irrigation districts along Yellow River, and the crop water consumption per unit area is also large. Crop water consumption has the maximum value in the areas with an irrigation area exceeding 70%, in which the crop water demand can be fully met and the multiple index and the planting density of crops are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

high. Especially in Shandong and central and eastern Henan, the water consumption in the grid basically exceeds more than 10 million m^3 per year.

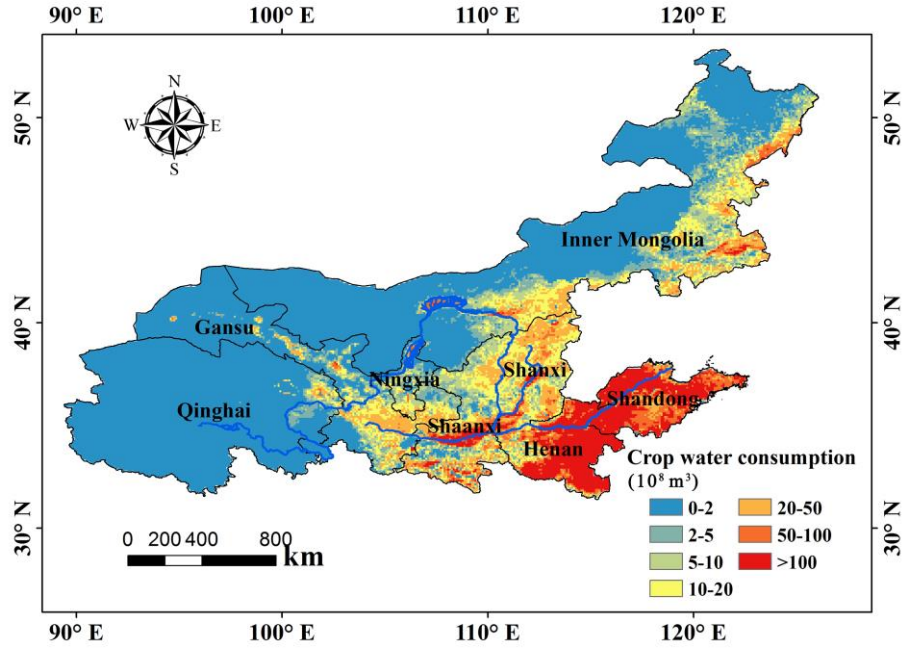

Figure 4. *Spatial distribution of crop water consumption in 5 arc-minutes grid (10^5 m^3/a)*

The entire range of Ningxia, Shanxi and Shaanxi, most part of Gansu and southeastern Inner Mongolia are basically covered by crop water consumption, as the proportion of irrigation areas in those regions are low and the agriculture is mostly rainfed. Except for the irrigated regions along Yellow River, the water consumption per unit area keeps basically less than 5 million m^3 per year in those regions, followed by regions along the northwest of which the water consumption per unit area is less than 1 million m^3 (roughly 150 m^3/ha). The eastern valley in Qinghai Province is the area with small water consumption per unit area.

As far as crop water consumption is concerned (*Fig. 5*), corn and wheat are major crops that consume 31% and 29% of total crop water consumption, followed by cotton and soybeans, which both consume 9% of total water.

It can be seen from *Table 1*, the crop water consumption in the Yellow River Basin in 2017 was 84.25 billion m^3. Henan and Shandong are at the top (36.1% and 30.0% respectively). Consistent with the above, the crop planting area is large in both provinces, and the water consumed per unit area is large. Inner Mongolia and Shaanxi are the next (respectively 11.1% and 10.1%), followed by Qinghai and Ningxia (0.5% and 1.1% respectively).

Agricultural water footprint

The agricultural water footprint of the Yellow River Basin amounts to 49.45 billion m^3 (*Table 2*), which is mainly caused by food production and is greatly related to the population. Henan tops the water footprint of the Yellow River Basin by 29.93 billion m^3 and Qinghai is at the bottom at 480 million m^3. The proportion of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

agricultural water footprint to crop water consumption explains the proportion of local food water consumption to the local water consumption, compared to 0.587 in the basin. Henan and Gansu are among the largest to 0.985 and 0.980 respectively. The food produced in these two provinces is basically self-consumed.

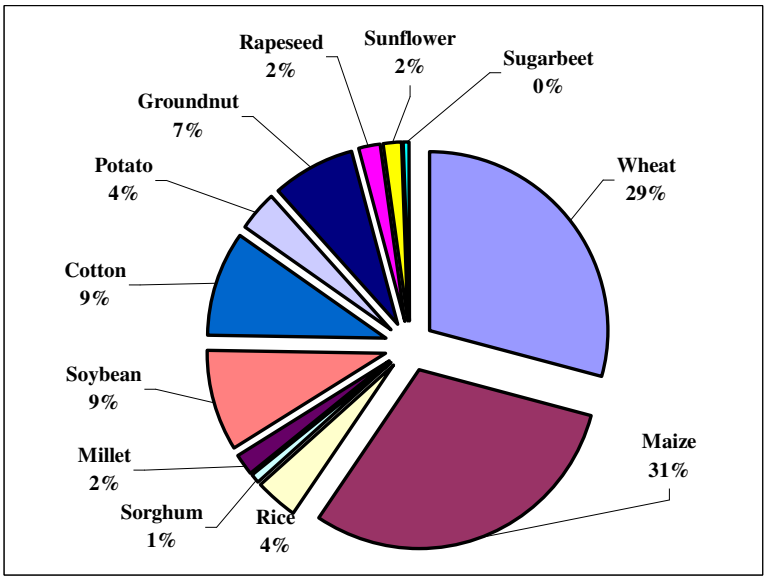

Figure 5. *Percentage of crop water consumption per crop*

Table 1. *Crop water consumption and composition of provinces and autonomous regions in the Yellow River Basin*

Province	Crop water consumption (10^8 m^3)			Percentage of green water (%)	Percentage of crop water consumption in each province (%)
	Green water	Blue water	Total		
Qinghai	4.1	0.4	4.5	90.3	0.5
Gansu	26.7	5.3	32.0	83.5	3.8
Ningxia	5.0	4.2	9.2	54.5	1.1
Inner Mongolia	77.7	15.1	92.8	83.7	11.0
Shaanxi	69.8	14.9	84.7	82.4	10.1
Shanxi	52.0	10.8	62.8	82.7	7.5
Henan	240.6	63.4	303.9	79.1	36.1
Shandong	186.9	65.6	252.5	74.0	30.0
Total	662.7	179.7	842.5	78.7	100.0

The primary industry water footprint is all blue water. Difference with the agricultural blue water footprint lies that: firstly, the blue water footprint is the crop water consumption, while the primary industry water footprint contains irrigation losses; secondly, the blue water footprint is direct water consumption, but the primary industry water footprint contains indirect water consumption; thirdly, agriculture, forestry, animal husbandry and fishery industries are involved in the primary industry water footprint.

Henan	0.985	299.3	236.9	62.4	98.9
Shandong	0.697	176.1	130.3	45.8	72.4
Total	0.587	494.5	389.0	105.5	398.4

Green water consumption

As shown in *Table 1*, the green water consumption accounted for 78.7% of the crop water consumption in the Yellow River Basin, falling within the world average 75%～81% caused by different research methods. Among 8 provinces, Qinghai consumes the most water with a percentage of 90.3%, followed by Inner Mongolia, Gansu, Shanxi and Shaanxi, of which the green water consumption percentage is close and measured between 82 and 84%. The third are Henan and Shandong with a percentage of 79.1% and 74.0%, respectively. The bottom one is Ningxia with a percentage of 54.5%. Obviously, in areas with more developed irrigated agriculture and high blue water utilization volume, the utilization rate of green water consumption is relatively low. Ningxia especially falls behind the other provinces in green water utilization rate, probably because of backward irrigation practice and the low water consumption efficiency. In addition, when the green water can meet the growth demand, unnecessary irrigation results in unnecessary wastage of water resources, and a decrease in the proportion of green water consumption.

Consistent with the distribution of water consumption (as shown in *Fig. 6*), the spatial distribution green water consumption in the Yellow River Basin tends to descent from southeast to northwest, partially affected by irrigation. In other words, the utilization volume of green water is related to the agricultural development intensity. In areas with developed agriculture, planting more corps lead to higher green water consumption. Relatively speaking, as the southeast is a natural and suitable area for agriculture owing to abundant precipitation, the agricultural is relatively highly developed. In the Ningmeng Irrigation Region in the northwest, Central Shaanxi Plain and Jinzhong, it is easy to draw the Yellow River water for agricultural irrigation purpose, although there is no abundant precipitation. The green water consumption in the above areas is correspondingly large.

The proportion of green water to crop water consumption reflects the extent to which natural water resources are used in agriculture. As shown in *Figure 7,* the percentage of green water consumption is mostly greater than 95% in the Yellow River Basin, dominated by rainfed agriculture. Except for several regions, the proportion of Ningmeng Irrigation Region, Central Shaanxi Plain, Jinzhong and East Inner Mongolia

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

Irrigation Region and the western Gansu are among the lowest in green water consumption to below 50%, followed by the northwest of Shanxi and the north of Henan at 50% to 70%. Among these areas, except for the western Gansu, the irrigation density is high in other areas; the proportion of green water consumption in western Gansu is smaller because of scarce precipitation and strong evaporation, and less effective precipitation available to crops.

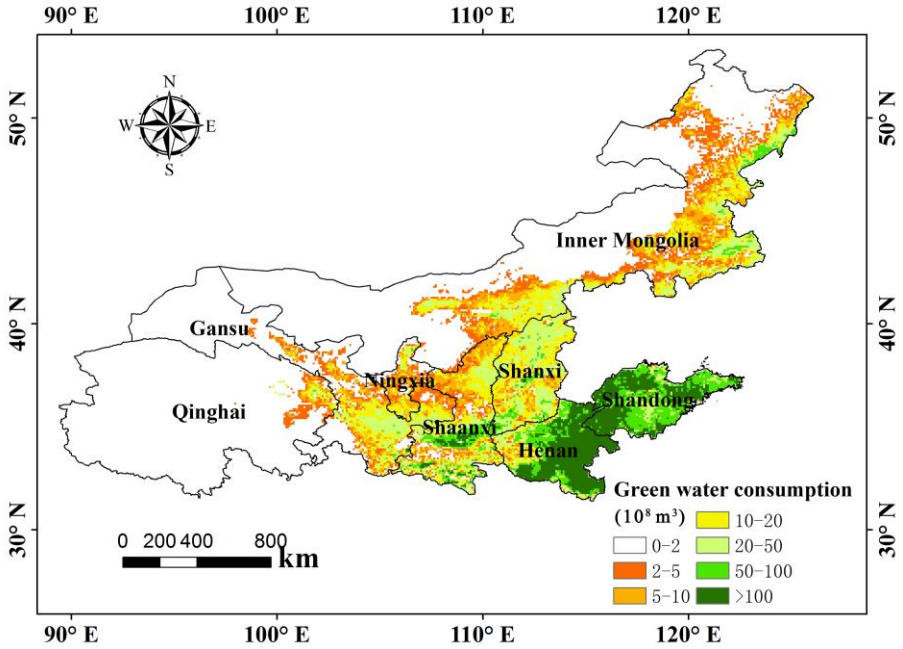

Figure 6. *Spatial distribution of crop green water consumption in arc-minutes grid (10^5 m^3)*

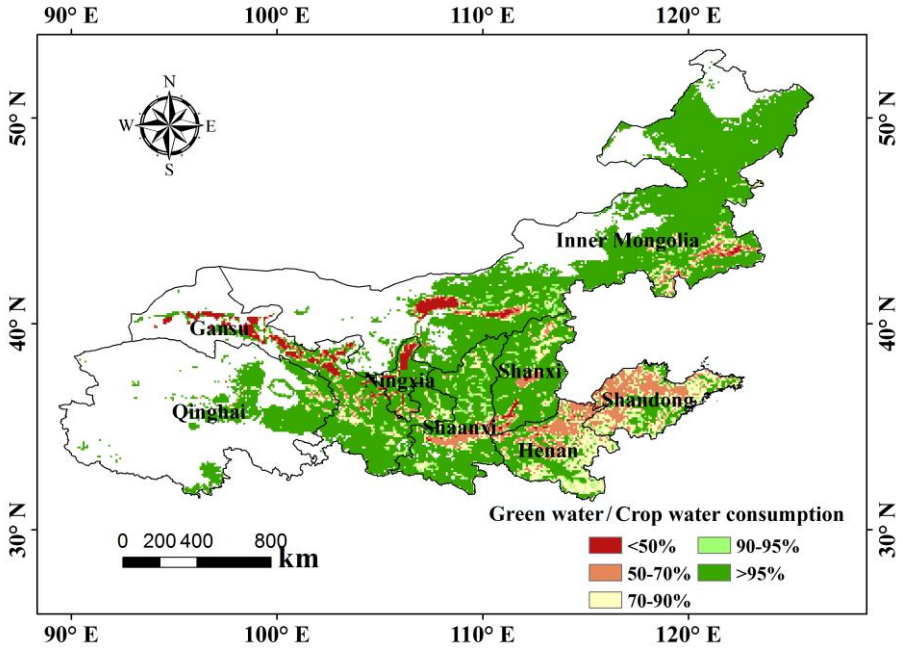

Figure 7. *The percentage of green water consumption to crop water consumption*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

As shown in *Figure 8,* among the 12 crops, the rapeseed consume the most water with a percentage of 98%, and wheat and sugar beet consume the least water with a percentage of 58% and 66% respectively. The other crops account for 80 to 95% of water consumption. Wheat and corn are two crops with the largest planting area and water consumption in the Yellow River Basin, between which corn generally grows in rainy and hot season and its demand for water can be basically met by natural precipitation. On the contrary, in the critical growth period of wheat, the irrigation practice is required due to less precipitation. The wheat accounts for 29% of the total water consumption in the basin. According to the 74.1% percentage of green water consumption to crop water consumption in the basin, it can be concluded that the wheat accounts for 56% of the blue water consumption of the basin.

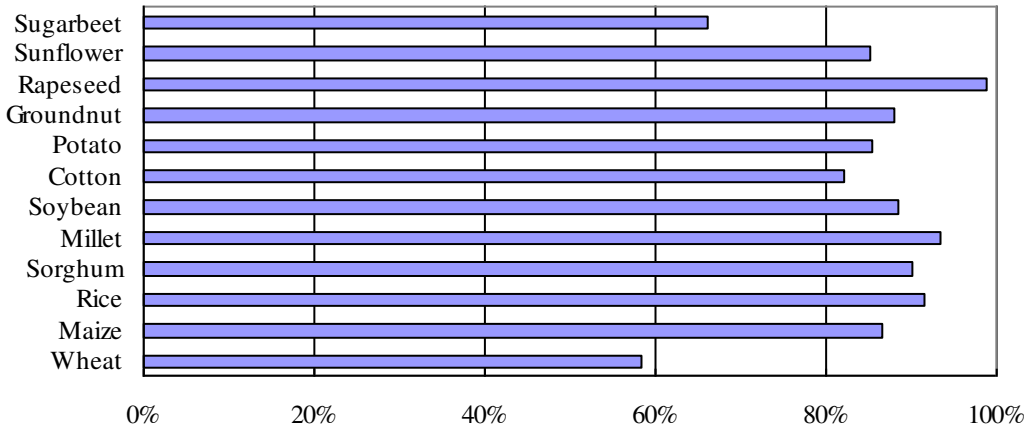

Figure 8. *The percentage of green water in crop water*

Crop water consumption coefficient

The crop water consumption coefficient refers to the water consumption per specific yield. Similar to the total water input coefficient defined in the water footprint (water consumption per specific yield), this coefficient can denote the crop water efficiency. The difference is that the total water input coefficient targets at withdrawals of blue water, including blue water consumption and recovery amount; however, the crop water consumption coefficient includes the portion of blue water that is consumed by the crops and the green water. As shown in *Figure 9,* the water consumption coefficient lies between 0.4-1.0 m^3/kg for most areas. The water consumption coefficient is high in the southern part of the basin, and is low in western Gansu, northern Ningxia (excluding the Yellow River irrigation area), and central and southern Shandong. The low coefficient of western Gansu is caused by the low water consumption. This region has sufficient sunshine, which is conducive to crop growth, and keeps up certain production even if the water demand cannot be met. The central part of Shandong is a mountainous area with relatively underdeveloped irrigation facilities. Irrigation is to achieve output at the cost of water resources, and cannot significantly increase the crop water consumption coefficient.

The crop water consumption coefficient of the basin is 0.622 m^3/kg, as shown in *Figure 10.* Those eight provinces can be divided by the crop water consumption coefficient into three levels: Ningxia, Gansu and Qinghai are at the bottom (less than 0.5 m^3/kg) at 0.400 m3/kg, 0.427 m^3/kg and 0.430 m^3/kg, respectively, followed by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

Inner Mongolia, Shandong and Shanxi (basically 0.5 - 0.6 m^3/kg) measured 0.536 m^3/kg and 0.562 m^3/kg respectively. Shaanxi and Henan are at the top at 0.754 m^3/kg and 0.748 m^3/kg, respectively. For the entire basin, the level of agricultural production is highest in Henan and Shandong and lowest in Qinghai. Therefore, the current crop water consumption coefficient of the Yellow River Basin has no obvious relationship with the agricultural production level.

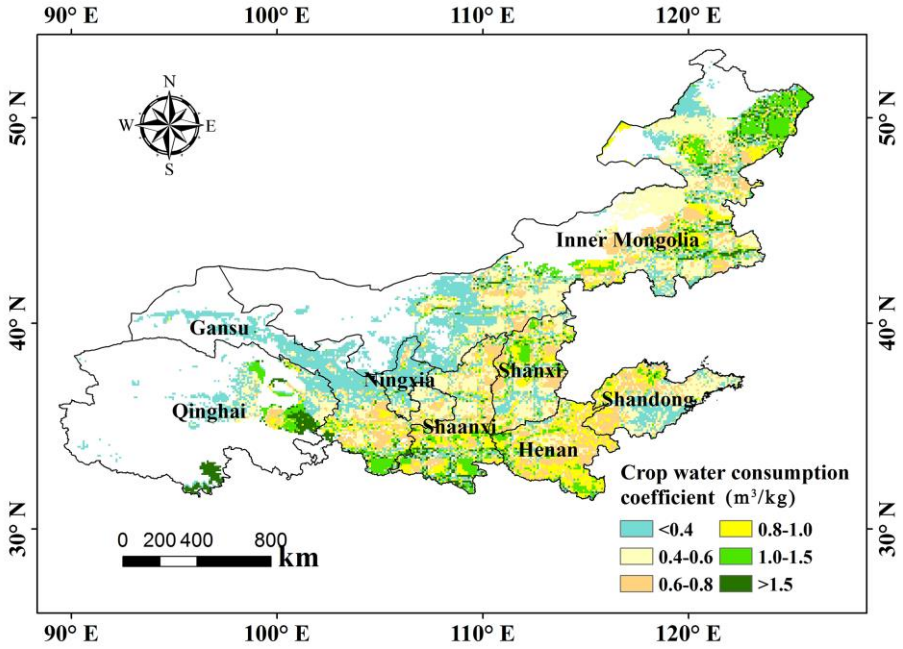

Figure 9. *The spatial distribution of crop water consumption coefficient*

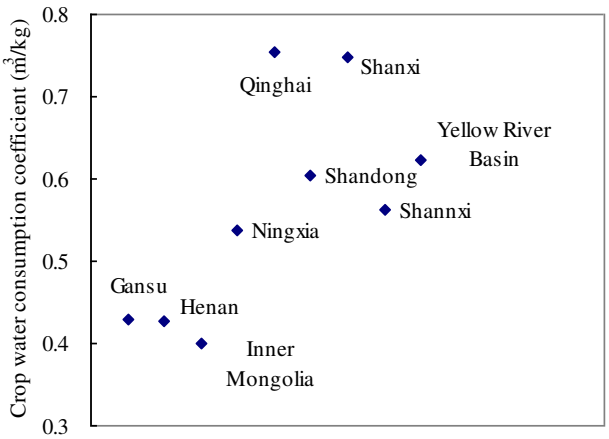

Figure 10. *Crop water consumption coefficient in each province*

For different crops, the water consumption coefficient is mainly related to crop characteristics. In the basin, sugar beet and potato consume the least water with a coefficient measured 0.118 m^3/kg and 0.150 m^3/kg, respectively. Cotton consumes the most water with a coefficient of 1.846 m^3/kg (as shown in *Fig. 11*). Sugar beet and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

potato have a high density of harvested products because tubers are harvested, while the cotton is low-density in the harvested product because fiber is harvested. The water consumption coefficient is almost the same among cereals, wheat, corn, sorghum and rice, close to oil crops. The water consumption coefficient of broomcorn millet is large mainly because of low yield of these two crops.

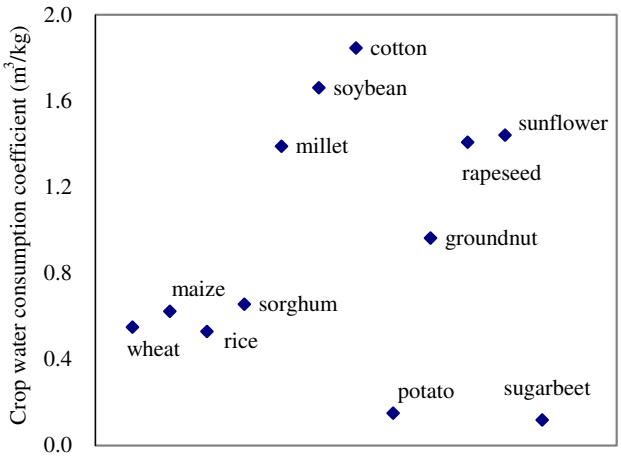

Figure 11. *Crop water consumption coefficient for different crop types*

Distribution of wheat's water consumption

Wheat is the crop in the Yellow River Basin (*Table 3*) with the largest planting area. As described earlier, the blue water consumed accounts for 56% of the total water consumption in the basin, mainly for wheat production. Understanding the water consumption characteristics of wheat, especially distribution of blue water, helps to propose measures of improving the wheat's water consumption efficiency and will have a significant effect on reducing agricultural water consumption throughout the basin.

Firstly, by analyzing wheat's overall water consumption and yield in all provinces/regions of the basin, we can see that the characteristic is obvious that wheat's water consumption is mainly confined to Henan and Shandong, as shown in *Table 3*. Henan is at the top, with 10.13 billion m^3 of wheat's water consumption, followed by Shandong with 7.70 billion m^3. Both provinces take up 72.8% of the total water consumed in the basin. Henan and Shandong also consume most of blue water, respectively 4.06 billion m^3 and 3.86 billion m^3, accounting for 39.8% and 37.9% of the total blue water consumption in the basin. Both provinces are equal in wheat yield and are the largest contributors in the basin for wheat, both accounting for 36.4% of the total wheat yield in the basin.

For the wheat's water consumption coefficient, Qinghai is at the lowest point to 0.350 m^3/kg, mainly because there are few irrigation facilities in the province featured with basically rainfed agriculture and the small water consumption. It is similar with Gansu to this point. For other provinces, the water consumption coefficient depends mainly on the agricultural water productivity. Shaanxi is at the top to 0.704 m^3/kg, and the agricultural water productivity is low. The water consumption coefficient of Henan is above the average, and its agricultural water productivity is also low. The water consumption coefficient of Shandong is under the average.

DOI: http://dx.doi.org/10.15666/aeer1703_55395559

Table 3. *Water consumption of wheat in provinces of the Yellow River Basin*

Province	Water consumption (10^8 m^3)			Yield (10^9 kg)	Water consumption coefficient (m^3/kg)	Green water/total (%)	Blue water consumption proportion (%)
	Green water	Blue water	Total value				
Qinghai	1.6	0.3	1.9	0.5	0.350	84.2	0.3
Gansu	9.8	2.7	12.5	2.7	0.462	78.4	2.6
Ningxia	1.3	1.5	2.8	0.6	0.466	46.4	1.4
Inner Mongolia	11.0	4.2	15.2	2.7	0.557	72.4	4.1
Shaanxi	13.2	9.2	22.4	3.2	0.704	58.9	9.0
Shanxi	6.8	4.8	11.6	2.4	0.488	58.6	4.8
Henan	60.7	40.6	101.3	16.2	0.625	59.9	39.8
Shandong	38.4	38.6	77.0	16.2	0.476	49.9	37.9
Total	142.8	101.9	244.7	44.55	0.549	58.4	100.0

By comparing the proportion of green and blue water consumption in wheat's water consumption (*Fig. 12*), the spatial distribution of wheat's water consumption in each province of the basin is analyzed.

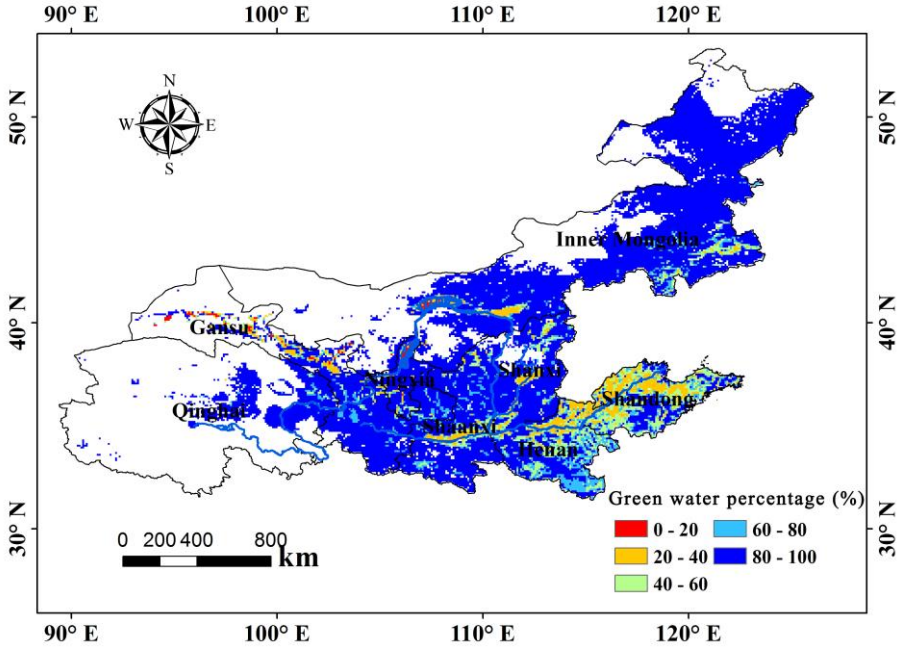

Figure 12. *The percentage of green water to total water consumption in wheat*

Wheat is widely cultivated in the basin, and the distribution of blue water consumption is consistent with that of irrigation facilities. As the largest blue water consumption per unit area is primarily centered on most areas of Henan and Shandong, and Central Shaanxi Plain, the wheat's irrigating water consumption in these three provinces is relatively large. Correspondingly, a bigger green water consumption corresponds to a smaller green water consumption. The spatial distribution of proportion of wheat's

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

green water consumption in wheat water consumption is similar to population distribution of all crops in the basin (*Fig. 13*). The proportion is bigger than 80% for most of planting areas, compared to 20-% of Ningmeng irrigation region which is at the bottom one. From this point, it can also be proved that wheat is the main water-consuming crop in the basin, and its distribution has a greater impact on the population distribution of water consumption in the basin. Correspondingly, in Shandong, Henan, Central Shaanxi Plain, Ningmeng irrigation region, etc., according to the law of crop water demand, making full use of green water can effectively reduce the amount of irrigating water consumed, when guaranteeing the yield.

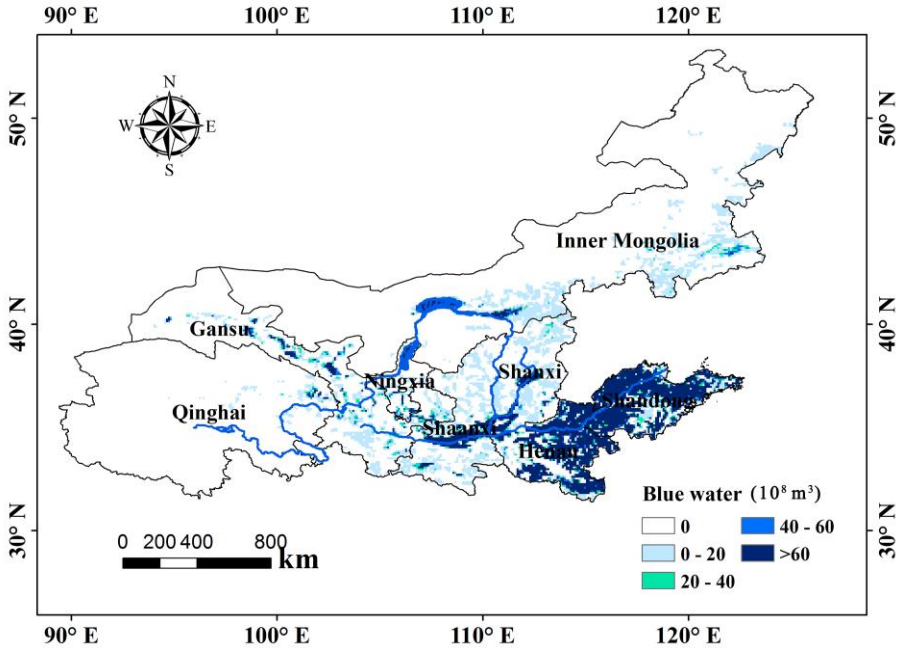

Figure 13. *The spatial distribution of wheat blue water consumption in the 5 arc-minutes grid (10^5 m^3)*

Conclusions and discussion

In this study, rainfed and irrigated farmlands are divided according to the irrigation area distribution map, and 12 major crops in the basin are selected as objects. According to crop water demand and effective precipitation, the method of calculating regional crop water consumption and agricultural water footprint is proposed to study the situation of the Yellow River Basin. The main conclusions are as follows:

(1) Similar to precipitation contour, distribution of crop water consumption in the Yellow River Basin tends to descend from southeast to northwest. Local areas are affected by irrigation. High value areas are mainly irrigation regions along the Yellow River and the others have small water consumption due to rainfed agriculture. In the Yellow River Basin, the agricultural water consumption in 2017 was 84.25 billion m^3. Henan and Shandong take up 66% of the total water consumption, and the wheat and corn take up 60% of the total water consumption.

(2) The proportion of green water consumed in the Yellow River Basin is 78.7%, which is around the global average. The spatial distribution of crop green water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

consumption generally conforms to the water consumption distribution. In areas with high water consumption, the amount of green water consumed increases because the agriculture is developed and there are more crops planted. As for most of rainfed agriculture -based areas in Yellow River Basin, green water consumption accounts for 95+% of crop water consumption. The lower values are in areas with well-developed irrigated agriculture, and in western Gansu due to less precipitation, strong evaporation, and less available effective precipitation for crops. In the irrigation areas, unnecessary irrigation can reduce the green water consumption.

(3) The agricultural water footprint is 52 billion m^3 in the Yellow River Basin, in which Henan is at the top at 29.93 billion m^3 and Qinghai is at the bottom at 480 million m^3. The largest in Henan is m^3, and the minimum in s 480 million m^3. Agricultural water footprint accounts for 0.587 of crop water consumption. Henan and Gansu are at the top respectively at 0.985 and 0.980, indicating that the grain produced by these two provinces is basically used for themselves.

(4) The proportion of green water consumption is mostly higher than 80%. Wheat is required for water irrigation because the rain season does not move in line with high-temperature season during its growth duration. Its green water consumption accounts for 58% of the total water consumed during the growth period. In addition, wheat consumes 56% of the total blue water consumed by crops in the basin.

(5) The crop water consumption coefficient reflects the water utilization level. The average water consumption coefficient is 0.622 m^3/kg for the Yellow River Basin, in which most of areas fall between 0.4-1.0 m^3/kg. Ningxia, Gansu and Qinghai have the low water consumption coefficient, among which western Gansu, northern Ningxia (excluding the irrigation areas along Yellow River) and central and southern Shandong are among the lowest. The crop water consumption coefficient of the Yellow River Basin has no obvious relationship with the agricultural production level, and the irrigation cannot enhance the coefficient. For different crops, the water consumption coefficient is mainly related to the crop characteristics, and the water consumption coefficient of the tuberiferous crops is the largest.

In Rain-fed Agricultural areas, green water absorptivity is closely related to crop yield. Raising the utilization rate of green water in irrigated agricultural areas can reduce irrigation water use. The reason lies not in the low precipitation, but in the uneven distribution of precipitation, which is not consistent with the period of crop water demand. The total amount of water for crops is sufficient, but not at the right time.

Making full use of green water can start from two aspects. One is to increase the storage of green water through various measures, including deep tillage, mulching and other field management means to promote precipitation infiltration, reduce soil evaporation; and terraces in mountainous areas, rainwater collection and other facilities. Secondly, in view of irrigated agriculture, we should understand the distribution law of precipitation, the dynamics of soil moisture and the law of crop water demand, and supplement irrigation under the premise of insufficient green water.

Proportion of green water consumption to water consumption depends mainly on the volume of irrigating water. The green water consumption is negatively related to the irrigation amount. Ningxia is at the bottom, followed by Shandong. Both provinces rely too much on irrigating water and do not make full use of green water.

Irrigated area is one of the main factors of water footprint growth, so it is imperative to restrict the development of irrigation area. This refers to the traditional irrigated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer1703_55395559

farmland. Irrigation is an important guarantee for grain production in the basin. The effect of water saving irrigation on increasing income has been widely recognized and still needs to be vigorously implemented. In addition, improving the effective utilization rate of irrigation water are mainly aimed at the existing problems. Firstly, the irrigation facilities should be renovated to reduce the waste of water resources; secondly, the traditional surface irrigation methods should be changed and furrow irrigation should be adopted to improve the utilization rate of irrigation water; thirdly, a reasonable irrigation system should be established to improve the water use efficiency of crops by determining irrigation time and irrigation quota according to the critical period of crop water demand; thirdly, the crop planting structure should be adjusted according to the rainy season. Reasonable arrangement of crop distribution, such as crop water demand characteristics, can make full use of precipitation and alleviate the contradiction between irrigation and water use.

In the study, a comprehensive calculation method for the total water consumption of various crops was established, and the main crop such as wheat was selected for detailed analysis. The crop growth period was divided into smaller periods to improve the calculation accuracy. According to the export-oriented characteristics of agriculture in the Yellow River Basin, the calculation method of agricultural water footprint in the Yellow River Basin is put forward. Zhuo et al. (2016) studied the changes of water footprint and blue-green water of some crops in the Yellow River basin from 1961 to 2009. The spatial distribution of the results is relatively stable. The spatial distribution of agricultural water footprint and blue and green water in this study have the similar spatial correlation with the results of Zhuo et al.'s study.

The calculation of water consumption is mainly based on the empirical formula of reference crop ET and crop coefficient provided by FAO. The adaptability of this method to the study area needs further study. At present, there are many actual ET products available, such as (MODIS Global Evapotranspiration Project, MOD16), which can provide 8-day ET data. It is worth studying to compare the results based on the MOD16 or other ET products with the results of this study. At the same time, the spatial resolution of 5 arc-minutes is adopted, which may not be applicable to some smaller irrigation areas. Therefore, it is very important to study crop distribution on higher spatial resolution scale, which involves near-surface remote sensing, field mapping, high-resolution image data, and the collection of corresponding agricultural sector data. The above research will be launched in the near future to achieve in-depth study of regional agricultural water footprint and green water.

(Received 18th Dec 2018; accepted 28th Feb 2019)

Abstract. Wild gladiolus (*Gladiolus segetum*) is a problematic weed in dry land winter wheat fields of northwest and west provinces in Iran, and accounts for about 23% of yield losses in winter wheat. Greenhouse studies were conducted from 2014 to 2015 to evaluate different herbicide treatments to control of the noxious weed, *Gladiolus segetum,* commonly found in northwest of Iran. The objective was to evaluate potential control possibilities with commercial herbicides containing sulfosulfuron (Apirus®), mesosulfuron+ idosulfuron (Atlantis®), mesosulfuron-methyl + Iodosulfuron-methyl-sodium + Diflufenican (Othello®), metsulfuron-methyl + sulfosulfuron(Total®), clodinafop-propargyl (Topik®), and glyphosate. Herbicides were applied to fully developed stems (10 cm), at the 2-3 leaf stage of the weed which coincides with the tillering stage in wheat. Similar to sulfosulfuron and mesosulfuron + idosulfuron, higher rates of glyphosate resulted in higherbiomass reduction of *G. segetum*in both years. But the application rates of glyphosate were remarkably higher compared to sulfosulfuron and mesosulfuron + idosulfuron. The ED_{50} values of glyphosate were 1751.99 and 1919.93 g ai ha^{-1}, and the ED_{90} values were 6349.96 and 7031.84 g ai ha^{-1}, in 2014 and 2015, respectively.
Keywords: *dose response, dry weight, effective dose, noxious weed, weed management*

Introduction

Gladiolus spp. from the Iridaceae family (subfamily of Crocoideaehas) is distributed in Africa, the Mediterranean basin, and Western Asia. It is a large genus that includes approximately 300 species (Goldblatt et al., 2001). *Gladiolus segetum* Ker Gawl and *G. italicus* Mill. are important weeds in dry land winter wheat fields of the Ardabil province in Iran (Ebadi et al., 2004-2007). The species can be identified by a set of characteristics such as narrow leaves, parallel venation, lowest leaf reduced to a subterranean sheathing cataphyll, and tubular or funnel-shaped perianth with synsepalous sepals (Davis, 1984; Dahlgren, 1985). Wild gladiolus (*Gladiolus segetum*) is a native weed in Greece, Turkey, Iraq, and Iran. They invade disturbed fields in the northern and western parts of Iran, particularly wheat, legume and other dryland fields (Rashed Mohassel et al., 2001; Majd et al., 2017). It is a major

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55615570

constraint to wheat production in Iran, accounting for about 23% of yield losses (Khalaghani, 2008); and weed control in winter wheat relies almost exclusively on herbicides (Deihim-Fard and Zand, 2006).

Since wild gladiolus has high vigor and emerges simultaneously with winter wheat, it can become dominant and has the potential to cause heavy yield losses in infested wheat fields. It is thus necessary to identify strategies to effectively manage this problematic weed as like as others which can be nonchemical including fertilizer management had beneficial effect against Velvetleaf (Aghaie et al., 2013), physical (Majd et al., 2017) or chemical by applying new herbicides or using alternative herbicide to delay resistance (Alebrahim et al., 2017; Tahmasebi et al., 2018). Additionally, since wheat fields in different regions of Iran have variable climatic conditions, there is a need to tailor weed control strategies specific to each region. Finding an effective weed control strategy will greatly depend on the use of herbicides at effective doses; therefore, selecting an appropriate herbicide and dose is most important. Ebadi et al. (2015) reported that biomass of wild gladiolus was reduced by incorporating cultural strategies with herbicide mixtures such as clodinafop-propargyl, difenzoquat + 2,4-D, Topik + 2,4-D, clodinafop-propargyl + tribenuron-methyl, and glyphosate + fallow. The above mentioned mixtures had no differences in their effect on wild gladiolus. The highest and lowest percentage of biomass reduction was obtained by hand weeding and spraying with 2,4-D, respectively. In addition, their results revealed that clodinafop-propargyl controlled wild gladiolus and other weeds results in an increase in crop yield.

Herbicide dose response curves help determine the selectivity and efficacy of herbicides and in some situations help unravel the dose-range for effective weed control and minimal crop damage. Relationships of dose response depends on the weed species, range of doses used, herbicide type, and various environmental conditions, such as temperature, humidity, wind velocity, CO_2 and O_2 levels, and geographical altittude (Streibig et al., 1993). In our current study we selected several herbicides that belong to three mode-of-action groups: acetolactate synthase (ALS) inhibitors (including mesosulfuron-methyl + iodosulfuron-methyl-sodium + diflufenican, mesosulfuron + idosulfuron, metsulfuron-methyl + sulfosulfuron, and sulfosulfuron), inhibitors of aromatic amino acid biosynthesis (including glyphosate), and acetyl-CoA carboxylase inhibitors (including clodinafop-propargyl). Herbicides such as the pyrimidinyl salicylates (Shimizu et al., 1994), triazolopyrimidine sulfonamide (Subramanian and Gerwick, 1989), imidazolinone (Shaner et al., 1984), and sulfonylurea (LaRossa and Schloss, 1984; Ray, 1984) herbicides has ALS as their primary target site of action. The ALS enzyme catalyzes the biosynthetic pathway for the production of three branched-chain amino acids such as valine, leucine and isoleucine. Exposure of plants to ALS-inhibitors therefore inhibits production of the three branched-chain amino acids.

Glyphosate [N-(phosphonomethyl)glycine], is a nonselective, broad spectrum herbicide discovered in 1971 (Baird et al., 1971), and was introduced in 1974 (Franz et al., 1997). Glyphosate was one of the first commercially important herbicide whose site of action was characterized as a single target enzyme in plants, and is the only herbicide known to inhibit 5-enolpyruvylshikimate 3-phosphate synthase (EPSPS). EPSPS catalyzes the penultimate reaction of the shikimate (Shk) pathway (Gruys and Sikorski, 1999) in certain bacteria and plants.

The cyclohexanediones (CHD) and aryloxyphenoxypropanoates (AOPP) inhibits the plastidic enzyme acetyl-CoA carboxylase (ACCase). CHD and AOPP herbicides are used to control a wide selection of grass weeds in both monocot and dicot crops. The basis of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55615570

selectivity differs between dicot and grasses: in dicots, tolerance is based on the inherent insensitivity of the ACCase to these herbicides, whereas in certain cereal crops, selectivity is based on higher rates of herbicide detoxification in the crop species (Devine and Shimabukuro, 1994).

The goal of our study was to compare the efficacy of different herbicides treatments, sulfosulfuron (Apirus®), mesosulfuron + idosulfuron (Atlantis®), mesosulfuron methyl + iodosulfuron-methyl-sodium + diflufenican (Othello®), metsulfuron-methyl + sulfosulfuron (Total®), clodinafop-propargyl (Topik®), and glyphosate (Roundup®), on the dry weight of wild gladiolus populations. These herbicides were selected because they are primarily used for weed control in wheat in Iran.

Materials and Methods

Study sites

Experiments were carried out from May 20, 2014 to August 22, 2014 and from May 20, 2015 to August 22, 2015 in the research greenhouse located in the College of Agriculture and Natural Resources, University of Mohaghegh Ardabili (longitude 48°17.600' 20.72" E, latitude 38°12.607' 29.51" N, and 1,386 m altitude), Ardabil, Iran.

Experimental design and treatments

The experiment was a completely randomized design (CRD) with 4 replications, and were independently repeated in time. Six herbicides with a range of doses were applied and the dry weight of gladiolus measured (*Table 1*). In April 2014, mature corms of wild gladiolus were collected from several fields of north-western part of Iran, from Germi city; located near Ardabil at longitude 48° 9' 24.46" E, latitude 39° 6' 36.20" N, and 1,350 m altitude. The rate per hectare was calculated based on the surface area of the pot (942 cm^2). Herbicides were applied using a CO_2-pressurized backpack sprayer fitted with 8002 VS flat fan nozzles, MATABI model, calibrated to a deliver 250 L ha^{-1} at 276 KPa, while maintaining the constant speed of 4.8 KPH. Herbicides were applied to fully developed stems (10 cm), at the two-to-three leaf stage of the weed and coincided with the tillering stage of wheat. Irrigation was performed every week from the begging to end of experiments. Temperature was 19-25ºC. Fertigation by using NPK (20:20:20) was done during experimets.

Table 1. *List of herbicides used in the study*

Herbicide	Rate (g ai ha^{-1})	Recommended Rate for Wheat in Iran (g ai ha^{-1}) (Zand et al., 2017)
Sulfosulfuron (Apirus®)	0, 3.75, 7.5, 15, 22.5, 30	20
Mesosulfuron + Idosulfuron (Atlantis®)	0, 6, 18, 24, 30, 36	24
Mesosulfuron-methyl + Iodosulfuron-methyl-sodium + Diflufenican (Othello®)	0, 33, 66, 82.5, 99, 132	96
Metsulfuron-methyl + sulfosulfuron (Total®)	0, 22.5, 27, 31.5, 36, 40.5, 45	33
Clodinafop-propargyl (Topik®)	0, 0.032, 0.064, 0.080, 0.096, 0.128	60
Glyphosate®	0, 1025, 1230, 1435, 1640, 1845	1600

DOI: http://dx.doi.org/10.15666/aeer/1703_55615570

Sampling procedure

Shoots of weeds were collected from the soil surface in each pot, four weeks after herbicide treatment application. After drying in an oven at 70ºC (for 72 h) dry weights were measured.

Statistical analysis

The dry weight per pot, y, was estimated using a log-logistic dose-response model with dose x in ai/haby R software:

$$y = \frac{d}{1+exp(b\cdot[\log(x)-\log(ED_{50})])} \quad \text{(Eq.1)}$$

where, b denotes the relative slope around ED_{50} (Effective Dose), which is the dose required to produce one-half of the dry-weight relative to the upper limit, d. The dose-response curve takes a snapshot of the dry matter production at the time of harvesting the biomass (Ritz et al., 2006).

Results

The analysis of residuals and test for lack of fit (p<0.05) confirmed the assumption that the data had constant variance, were normally distributed, and the dose-response curves described the variation in data. The efficacy of the herbicides were compared based on the ED_{50} and ED_{90} levels (*Tables 2, 3, 4 and 5*). As noted in *Figs. 1 and 2*, the doses were concentrated around the middle of the dose-response curve in order to obtain a precise ED_{50}.

Table 2. *The nonlinear log-logistic regression fit of dry weight in the first year. Standard errors in parenthesis, and with upper 95% confidence interval of* ED_{50} (g ai ha^{-1})

Herbicide	Upper limit	Slope	ED_{50}
Sulfosulfuron	0.36(0.01)	0.87(0.10)	20.6(2.72)
Mesosulfuron + Idosulfuron	0.33(0.02)	3.80(2.80)	44.03(4.48)
Glyphosate	1.24(0.03)	1.70(0.18)	1751(74.77)
Mesosulfuron-methyl + Iodosulfuron-methyl-sodium + Diflufenican	0.43(0.01)	0.64(0.13)	102.7(18.48)
Clodinafop-propargyl	0.35(0.01)	1.33(0.31)	193.8(27.55)
Metsulfuron-methyl + sulfosulfuron	0.33(0.01)	1.84(0.31)	61.24(4.55)

Table 3. *The nonlinear log-logistic regression fit of dry weight in the second year. Standard errors in parenthesis, and with upper 95% confidence interval of* ED_{50} (g ai ha^{-1})

Herbicide	Upper limit	Slope	ED_{50}
Sulfosulfuron	0.42 (0.01)	0.67(0.08)	20.8(3.43)
Mesosulfuron + Idosulfuron	0.42(0.02)	3.02(0.92)	38.29(2.12)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55615570

Sulfosulfuron

The application rates of sulfosulfuron required to reduce wild gladiolus dry matter by 50% in 2014 and 2015, was 20.6 and 20.8 g ai ha^{-1}, respectively (*Tables 2 and 3*). Moreover, the application rates of sulfosulfuron required to achieve 90% wild gladiolus control in 2014 and 2015, were 255 and 541 g ai ha^{-1}, respectively (*Tables 4 and 5*). In both instances, the ED_{90} was significantly different from zero even though there were not many observations at the lower part the curve, which is reflected in the precision of ED_{90}. The recommended rate for this herbicide in wheat is around 20 g ai ha^{-1} (*Table 1*). Some studies have shown that the height of weed species and weed biomass at the time of post herbicide applications is an important factor in determining the level of control achieved (Craigmyle et al., 2013; Chahal et al., 2014).

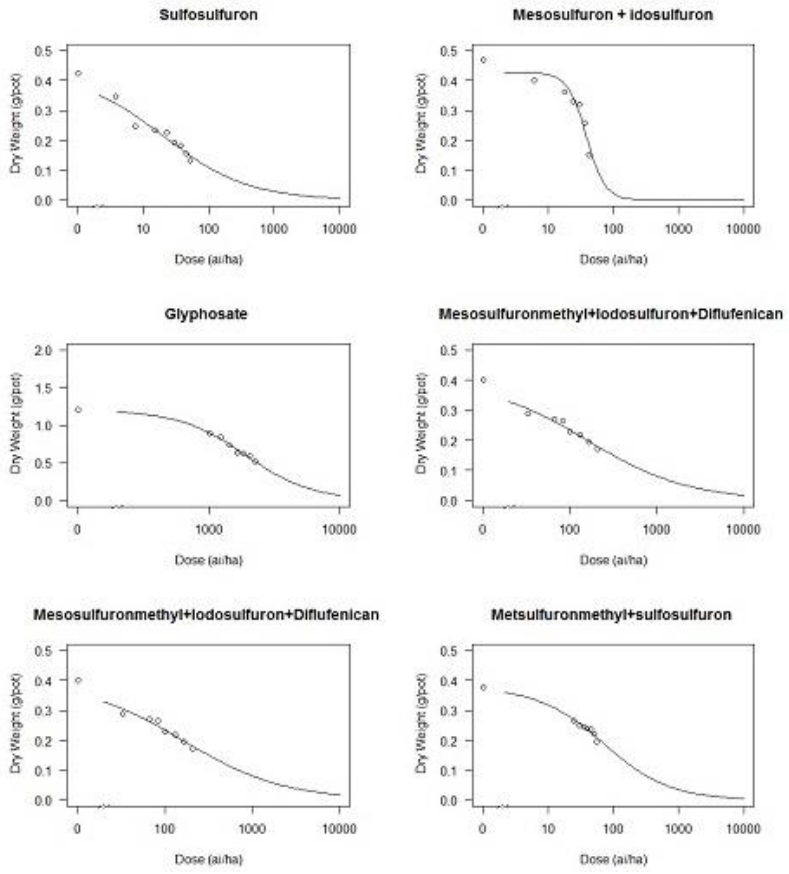

Figure 2. *Estimated dose response curves of wild gladiolus to six herbicide treatments. Data shown as dry weight in the second year*

Mesosulfuron+idosulfuron

In the case of mesosulfuron + idosulfuron application,the ED_{50} increased almost 50% compared to the Sulfosulfuron (*Figs. 1 and 2*; and *Tables 2 and 3*). However, the mixtures had a much steeper dose-response curve than the sulfosulfuron, and thus, the ED_{90} was much smaller forsulfosulfuron in 2014 and 2015, and were 78 and 79g ai ha^{-1}, respectively (*Tables 4 and 5*).The recommended rate for this herbicide in wheat is around 24 g ai ha^{-1} (*Table 1*). Kaiser and Gerhards (2015) reported different levels of ED_{50} for several

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55615570

multiple-resistant blackgrass (*Alopecurus myosuroides*). There was sufficient control of population ALOMY-S with an ED_{50} of 2.42 g ai ha^{-1}. ED_{50} values of 21.36 and 9.19 g ai ha^{-1}, were obtained for ALOMY-R1 and ALOMY-R2, respectively. Why you provide explanation on why you think so?

Glyphosate

Although the ED_{50} was rather similar for both sulfosulfuron and mesosulfuron + idosulfuron, it is obvious that glyphosate will require much larger rates to attain ED_{50} in both years (*Figs. 1 and 2*; *Tables 2 and 3*). The relative slopes of the glyphosate response curves were around 1 and were therefore comparatively flat in nature (*Figs. 1 and 2*). The ED_{50} of glyphosate was 1751 and 1919 g ai ha^{-1}, in 2014 and 2015, respectively (*Tables 2 and 3*). In 2014 and 2015, the ED_{90} values of glyphosate were 6349 and 7031 g ai ha^{-1}, respectively (*Tables 4 and 5*). It shows that although effective control of wild gladioluscan be achieved using glyphosate, a rather high dose is required; the recommended rate for this herbicide in wheat is around 1600 g ai ha^{-1} (*Table 1*). Chahal et al. (2015) showed that the shoot biomass curve indicated a 50 and 90% reduction at 227 and 3704 g ai ha^{-1}, respectively, in 10-cm tall kochia; whereas, the ED_{50} and ED_{90} were 612 and 5885 gai ha^{-1}, respectively for a 20-cm tall kochia.

Mesosulfuron-methyl + Iodosulfuron-methyl-sodium + Diflufenican

Results show that the ED_{50} for this mixture of compounds had higher efficacy of weed control than glyphosate alone (*Figs. 1 and 2*; *Tables 2 and 3*). An up to 50% biomass reduction of wild gladiolus was observed at 102.75 and 161.20 g ai ha^{-1}, in the first and second year of experiment, respectively. The application rates of Mesosulfuron-methyl + Iodosulfuron-methyl-sodium + Diflufenican required for 90% reduction in wild gladiolus biomass in 2014 and 2015 were 3077 and 3053 g ai ha^{-1}, respectively. In this case, ED_{90} values in two experimental years were similar, but was not significantly different from zero (*Tables 4 and 5*); the recommended rate for this herbicide in wheat is around 96 g ai ha^{-1} (*Table 1*).

Clodinafop-propargyl

The ED_{50} values of clodinafop-propargyl were 193.84 and 92.57 g ai ha^{-1} in 2014 and 2015, respectively, with the ED_{50} in 2014 being two times higher than in 2015. However, the ED_{50} variation between the two years cancelled out, because the rates were not significantly different from zero (*Tables 2 and 3*). The ED_{90} values in 2014 and 2015, were 1005 and 651 g ai ha^{-1}, respectively, and the difference is not dramatic considering the precision of the 95% confidence intervals. The relative slope of the dose-response curves in *Figs. 1 and 2* suggest that the herbicide had a similarslope as glyphosate; the recommended rate for this herbicide in wheat is around 60 g ai ha^{-1} (*Table 1*). Stagnari et al. (2006) conducted a two years experiment to determine the ED_{90} of clodinafop-propargyl for several weed species. The amount of ED_{90} for *Lolium multiflorum, Avena ludoviciana*, and *Phalaris minor* were 60, 32 and 33.6 g ai ha^{-1} in the first year, respectively. In the second year of experiment, the amount of ED_{90} for *Avena ludoviciana* and *Phalaris minor* were 64.5 and 99.8 g ai ha^{-1}, respectively. It indicated that wild gladiolus can tolerate clodinafop-propargyl better than the grasses.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55615570

Metsulfuron-methyl + sulfosulfuron

Based on the results in *Figs. 1 and 2*, and *Tables 2 and 3*, the differences in ED_{50} was not that dramatic between the first and second experimental years; ED_{50} was 61.24 and 71.05 g ai ha^{-1}, respectively. ED_{90} was 201.35 and 918.36 g ai ha^{-1} in 2014 and 2015, respectively. There was vast difference in ED_{90} between the two years, however, the ED_{90} values were not different from zero (*Tables 4 and 5*). This poor precision of the ED_{90} could be due to lack of observations to support the lower part of the curve and the much lower relative slope of 0.85 (*Table 3*). The recommended rate for this herbicide in wheat is 33 g ai ha^{-1} (*Table 1*). Izadi-Darbandi and Aliverdi (2015) reported that the amount of ED_{50} and ED_{90} of sulfosulfuron+metsulfuron-methyl to control wild barley in wheat field were 26.64 and 41.95 g ai ha^{-1}, respectively.

Discussion

In our study, results revealed that the highest weed dry weight was associated with glyphosate treatment (*Tables 2 and 3*). This suggests that even after exposure to glyphosate, the weed is able to grow before the herbicide is distributed throughout whole plant and begin exerting its action. Atlantis, a mixture of mesosulfuron+idosulfuron, resulted in the next highest weed dry weight, while sulfosulfuron produced the lowest weed dry weight, thus indicating high efficacy of sulfosulfuron on the weed compared to other herbicides (*Tables 2 and 3*). The relative steepness of the dose-response curves for ED_{50} were different; for example, a sharp decrease in wild gladiolus dry weight was observed after application of sulfosulfuron. Mesosulfuron+idosulfuron curve declined after a steady phase while other herbicide curves dropped slowly (*Tables 2 and 3*; *Figs. 1 and 2*). We observed that better control of wild gladiolus was obtained in the second year at the highest dose for all herbicides (*Fig. 2*). It is important to note that optimum efficacy is influenced by weed size, so that when the size of the weed is bigger, the control will be lower (Everitt and Keeling, 2007; Robinson et al., 2012).

Generally, among all herbicides tested, sulfosulfuron had the lowest ED_{50} in both years, 2014 (20.6 g ai ha^{-1}) and 2015 (20.8 g ai ha^{-1}) (*Tables 2 and 3*); while glyphosate had the highest ED_{50} in 2014 (1751.99 g ai ha^{-1}) and 2015 (1919.93 g ai ha^{-1}) (*Tables 2 and 3*). This suggests that sulfosulfuron and glyphosate were the highest and lowest performing herbicides with respect to wild gladiolus control. In the case of ED_{90}, mesosulfuron+idosulfuron and glyphosate had the highest and lowest influence on the control of wild gladiolus. The ED_{90} values of mesosulfuron+idosulfuron were 78 and 79 g ai ha^{-1} in 2014 and 2015, respectively (*Tables 4 and 5*). Also, the ED_{90} values of glyphosate were 6349 and 7031g ai ha^{-1} in 2014 and 2015, respectively (*Tables 4 and 5*).

Conclusion

The greenhouse experiment with six different herbicide treatments identified sulfosulfuron to be the most effective in controlling wild gladiolus. Although a few herbicides were identified to be most effective, it is crucial that we use incorporate the use of different herbicides with various modes of action to prevent or manage herbicide resistance in wild gladiolus. This will encourage herbicide rotation and tank mixing herbicides with different modes of action for effective and sustainable weed control. Further research on studying the effects of natural environmental conditions on the

(Received 20th Dec 2018; accepted 19th Feb 2019)

Abstract. Determining nutritional quality of indigenous forage species constitutes prerequisite to improve the productivity of ruminants. This research was carried out at the research field of the Agricultural Research and Application Center of Igdır University, Turkey in consecutive two years (2015 & 2016) to evaluate the herbage yield and nutritive value of eight forage species having diverse genetic make-up. Eight forage species such as Kentucky bluegrass (*Poa pratensis* var. Geromino), Perennial rye-grass (*Lolium perenne* var. Ovation), Red rescue (*Festuca rubra* rubra var. Corail), Slender creeping red fescue (*Festuca rubra* tricphylla var. Pinafore), Sheep fescue (*Festuca ovina* var. Ridu), Tall fescue (*Festuca arundinaceae* var. Jaguar 4G), Chewings fescue (*Festuca comutata* var. Longfellow II) and Colonial bentgras (*Agrostis tenuis* var. Aristata) were used as plant materials and the experiment was arranged in a randomized complete design with three replications. Data on biomass yield, crude ash, crude protein, crude oil, crude cellulose, net digestible fiber (NDF), acid detergent fiber (ADF), dry matter intake (DMI), digestible dry matter (DDM) and relative feed value (RFV) were recorded during the investigation. Results of the present study indicated that species 'Tall fescue' (*Festuca arundinaceae* var. Jaguar 4G) yielded the highest herbage yield, followed by cultivar 'Perennial rye-grass' (*Lolium perenne* var. Ovation). While, 'Kentucky bluegrass' (*Poa pratensis* var. Geromino) was found to be inferior to all other forage species in the studied years. When nutritional quality was observed, the species 'Colonial bentgrass' (*Agrostis tenuis* var. Aristata) had the maximum crude protein and RFV, while cultivar 'Perennial rye-grass' had significantly higher RFV, DMI, DMD and the minimum fiber content, which indicated its superior quality for milch animals.

Keywords: *forage species, Iğdır-Turkey environmental, nutritional quality, yield.*

Abbreviations: ADF: acid detergent fiber; DDM: digestible dry matter; DMI: dry matter intake; NDF: net digestible fiber; RFV: relative feed value

Introduction

To meet the food demand of increasing population, crop intensification and a sustainability should be continued globally (Jiang and Huang, 2001, Iqbal et al., 2019). The efficient use of farm resources, such as organic manure and home-grown forage, is the key to a sustainable and successful farm operation for the grassland farmers, while to improve the quality of home-grown forage from meadows and pastures, different strategies have been developed (Iqbal et al., 2018). For example, establishment and renovation of grassland by over seeding with high-quality seed mixtures are the most importance task to meet the fodder demand (Poetsch et al., 2016).

Turkey is bestowed with a great number of animals; however, animals' productivity in terms of milk and meat production is very low as compared to their potential. One of the main reasons for this under-performance of animals is owing to deficiency of good quality forages. The most important feed sources are pastures for grazing and those are composed of forage crops such as alfalfa, vetch and sainfoin grown as field crops (Iqbal et al., 2017). Cultivation of forage crops as field crops is rather low in Turkey and areas under forage crop are continuously declining due to increasing demand for food crops. Therefore, it is necessary to expand the forage crops growing area, along with investigating intercropping and crop rotation, as well as developing improved high yielding forage crop species. Although there are some species of vetch and alfalfa, but most of these forage species are perennial grasses; as a result, the number of improved varieties is far beyond the demand (Özpınar et al., 2014).

Among the forage species, 'Kentucky bluegrass' is a common turf species used on golf courses, sports fields, municipal parks, sod farms, road banks, as well as residential and school yards. 'Turfgrass' productivity is largely influenced by fertilization, particularly nitrogen. However, a greater N use efficiency is observed in the soils with low N levels (Below, 1995; Muir et al., 2001; Wims et al., 2013). 'Turfgrass' plants need sufficient soil moisture to maintain normal growth and development. The ornamental value and quality of 'Turfgrass' is severely affected by drought (Kanapeckas et al., 2008). However, the most cool-season 'Turfgrass' species are particularly susceptible to salinity stress during seed germination, with the possible exception of 'perennial ryegrass' (*Lolium perenne* L.). 'Ryegrass' is one of the most important and valuable forage plants in grasslands and constitutes an indispensable component of seed mixtures for meadows, pastures, ley farming, and re-seeding measures (Poetsch et al., 2016). Grazed perennial ryegrass is one of the most important forages for dairy cows in temperate regions due to its high forage yield and nutritive value (van Wijk et al., 1993; Lemus et al., 2008; Kering et al., 2012; Kumar et al., 2016), and hence, provides a cheaper feed than silage or concentrates. Traditionally, perennial ryegrass species were mainly bred for high forage production. Many studies indicated that environmental stresses affected physiological changes, especially antioxidant responses, in many cool-season 'Turfgrass' species (Xu et al., 2006; Senthil-Kumar et al., 2007). The ability for avoiding oxidative stress is a very important factor in determining the environmental stress tolerance of turf-grasses (Wang et al., 2012). Creeping bent-grass (*Agrostis stolonifera* L.) establishment and management practices are well understood for this turf-grass, hence its popularity is widespread (Beard, 2002).

'Red fescue' (*Festuca rubra*), 'Sheep fescue' (*F. ovina*), and 'meadow fescue' (*F. pratensis*) are the subjects of intensive research. All are valued for both forage production and special purposes, ranging from the preparation of sport grounds, parks,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55715581

and house gardens, to preventing the erosion of soil from embankments and railroads (Stanisavljević et al., 2012). 'Tall fescue' has been considered one of the best-adapted cool-season grasses for hot and dry conditions (Turgeon, 1980; Smit et al., 2005a, b).

It is well-established that forage grasses require less intensive management and inputs that impart them superiority over conventional turf blends by reducing the need for fertilization, pest control, irrigation and mowing. The quality of a low maintenance turf is usually not so high, since minimal inputs cannot be expected to produce high quality forage (Prendes and Palencia, 2015). Up-till now, there are a very few studies which provide concrete and conclusive results pertaining to the variability of yield and seed quality including viability of these forage species. It is hypothesized that some of the forage species may outperform others in terms of herbage yield and nutritional quality under Mediterranean environment. Thus, considering the burning issue, the aim of this study was to assess the herbage yield and nutritive value for some forage crop species grown in Mediterranean conditions to meet the quality feed demand for increasing number of cattle.

Materials and methods

Locations and soil properties

This research was carried out at the research field of the Agricultural Research and Application Center, Igdır University, Turkey during consecutive two years (2015 & 2016). Soil of the research site was characterized as clay-loamy texture, highly alkaline (pH: 8.6), lightly salted (EC: 1.37 dS/m), low organic matter content (1.20%) and rich in lime ($CaCO_3$: 22.27%). Beside these, available phosphorus (P) and potassium (K) contents in the soil were found to be 51.7 ppm and 852.4 ppm (Erdogan, 2013).

Treatments and experimental design and using materials

Selected eight forage species such as Kentucky bluegrass (*Poa pratensis* var. Geromino), Perennial rye-grass (*Lolium perenne* var. Ovation), Red rescue (*Festuca rubra* rubra var. Corail), Slender creeping red fescue (*Festuca rubra* tricphylla var. Pinafore), Sheep fescue (*Festuca ovina* var. Ridu), Tall fescue (*Festuca arundinaceae* var. Jaguar 4G), Chewings fescue (*Festuca comutata* var. Longfellow II) and Colonial bentgras (*Agrostis tenuis* var. Aristata) were arranged in a randomized complete design with three replications. Each experimental plot had the net area of 12 m^2 (3 × 4 m). The list of the forage crops under investigation are described in *Table 1*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55715581

Experimental procedure

In the first year, 5 kg nitrogen (N) and 8 kg phosphorus da^{-1} were applied in all plots during the final land preparation. In the second year, 15 kg da^{-1} nitrogen was applied to all plots. while half of the nitrogen was applied during April and May each year. During first year, seeds of all forage species were sown on 15 March 2014 and no yield could be recorded in this year. Therefore, the data obtained in the first year of the establishing were not taken into consideration and only the second and third year data were evaluated. Irrigation was applied as per field capacity. Cutting time was June 15, 2015 in the second year and June 20, 2016 the third year. After leaving 0.5 m from the sides of each plots l, the rest of the plots (6 m^2) were cut with a machine called 'Figaro' and were weighed immediately using spring balance. Since the first year is the establishing year, the second and third year data are taken into consideration and subsequently analyzed statistically.

Chemical analyses

Chemical analyses regarding crude protein (CP) and ash concentration were performed as per procedures outlined by AOAC (2000). Neutral detergent fiber (NDF), acid detergent fiber (ADF), cellulose and lignin were determined by following Van Soest et al. (1991) using Fiber Tech analyzer (FibraPlus FES 6, Pelican, Chennai, India). Heat-labile α-amylase and sodium sulphite were used in NDF solution. Lignin (sa) was determined by dissolving cellulose with sulfuric acid in the ADF residue (Van Soest et al., 1991). Cellulose was estimated as the difference between ADF and lignin (sa) in the sequential analysis and hemicellulose was calculated as difference between NDF and ADF concentrations. Dry matter intake (DMI), digestible of dry matter (DDM), relative feed value (RFV) for different animal functions was determined as described by Undersander et al. (1993).

Statistical analysis

The obtained data were statistically analyzed, separately and combined, using "SAS" statistical package program. Variable means were compared at the significance level of $P < 0.05$. Correlation coefficients between different yield attributes were done by using the same statistical software (Snedecor and Cochran, 1994).

Results and discussion

Dry hay yield of different forage species

It was revealed that 'tall fescue' performed the best over other forage species under study in terms of dry matter yield, this result is in agreement with the finding of Campbell and Xia (2002). Forage cultivars 'Perennial rye-grass' and 'slender creeping red fescue' followed 'tall fescue' in terms of herbage yield in both years. 'Kentucky bluegrass' and 'colonial bentgras' yielded the minimum hay (*Fig. 1; Table 2*). The significantly higher herbage yield contributed by 'tall fescue' might be attributed to significantly higher plant height and fast regrowth rate after cutting. In addition to this, early and strong spring growth could have positive effect on it (Özpınar et al., 2014, Campbell and Xia, 2002). To achieve appropriate yield and quality herbage and change

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55715581

greatly depending on cultural practice, the species, variety and environment (Barutcular et al., 2017; Akdeniz et al., 2018a).

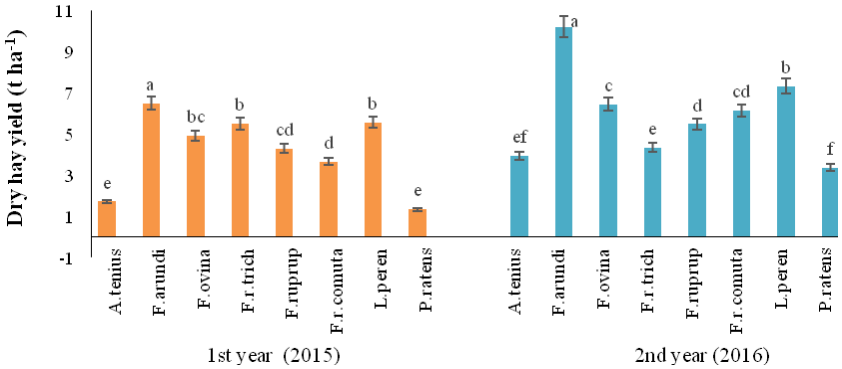

Figure 1. *Dry hay yield (t ha^{-1}) of different forage species grown under the Mediterranean environment of Turkey during 2015 and 2016. Bar with same letter indicates that does not differ significantly, while with dissimilar letters indicates that differ significantly. Mean (±SE) was calculated from three replicates for each forage cultivars. Error bars represent significant difference at p ≤ 0.01 (LSD test)*

NDF: neutral detergent fiber; ADF: acid detergent fiber; DMI: intake, digestibility to calculate DM intake; DDM: digestible dry matter; RFV: relative feed value

Crude protein, crude ash, oil content, NDF, ADF and cellulose

Ash, oil content, NDF, ADF and cellulose were found to be varying among the species under investigation (*Figs. 2* and *3; Table 2*). However, 'Colonial bentgras'

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55715581

proved to be superior to all in terms of crude protein content and it was followed by 'perennial rye-grass'. The minimum crude protein content was recorded by 'sheep fescue' followed by 'chewings fescue'. On the other hand, 'tall fescue' had the maximum ash and was closely followed by 'perennial rye-grass', 'slender creeping red fescue', 'red rescue. Chewings fescue' recorded the lowest crude oil content while 'perennial rye-grass' had quite high oil concentration. 'Perennial rye-grass' remained outstanding by recording the lowest cellulose and NDF as well as ADF contents (*Fig. 3; Table 2*).

Cereal stover and straws are usually low in crude protein and rich in fiber concentrations, and thus unable to meet the minimum crude protein requirements (7%) for maintenance of animals and rumen microbes (Minson, 1990). There is a dire need to supplement this stover with protein rich leguminous forage or non-protein nitrogen or protein sources in order to obtain sustainable supplies of milk from dairy animals. It was observed significant differences among the crops and their interaction with environment regarding yield and quality properties However, variations have been also observed in different agronomic and quality were also noted by Barutcular et al. (2016a, b, c; Akdeniz et al., 2018b; Yıldırım et al.,2018). The variability in NDF, ADF, cellulose and lignin concentrations of sorghum stover in different species has been reported earlier (Hamed et al., 2015) and it is reported that forage with high NDF levels had higher concentrations of the CB2 fraction, which is more slowly degraded in the rumen, impacting microbial synthesis and animal performance (Ribeiro et al., 2001). Carvalho et al. (2007) reported that NDF concentration influences carbohydrate fraction CB2 and forages high in NDF concentration usually have higher values of CB2.

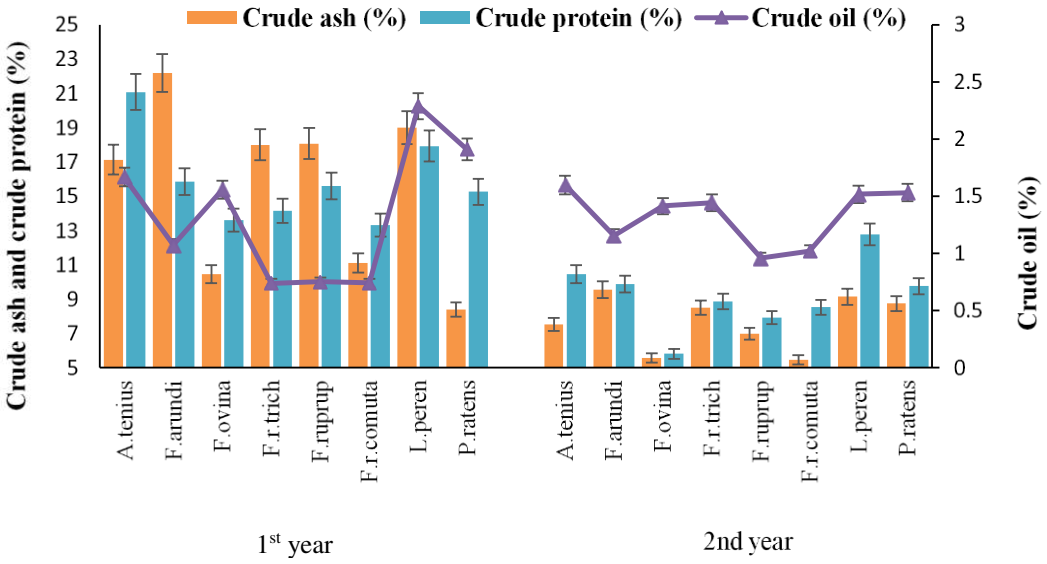

Figure 2. *Crude ash, crude protein and crude oil of hay/forage as influenced by different forage species grown under Mediterranean environment*

Intake, digestibility and relative feed value

The calculated values of DMI, DDM and RFV for different forage crops varied significantly during both years of study (*Fig. 4*). 'Perennial rye-grass' proved its superiority to other forage species by recording the highest DMI, DMD and RFV, while

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55715581

it was followed by 'colonial bentgras'. It was also revealed that 'kentucky bluegrass' was better than 'slender creeping red fescue', 'red rescue' and 'chewings fescue', but remained inferior to 'perennial rye-grass' and 'Colonial bentgras'. Dietary fiber concentration, its digestibility and rate of degradation in the rumen are the most important forage characteristics that determine DMI (Roche et al., 2008). We attributed the lower RFV of stover in the present study to its lower quality relative to the whole plants examined at the younger age which is agreement with Bean et al. (2011), who noted that higher NDF and ADF concentrations influence the intake and digestibility of a fodder.

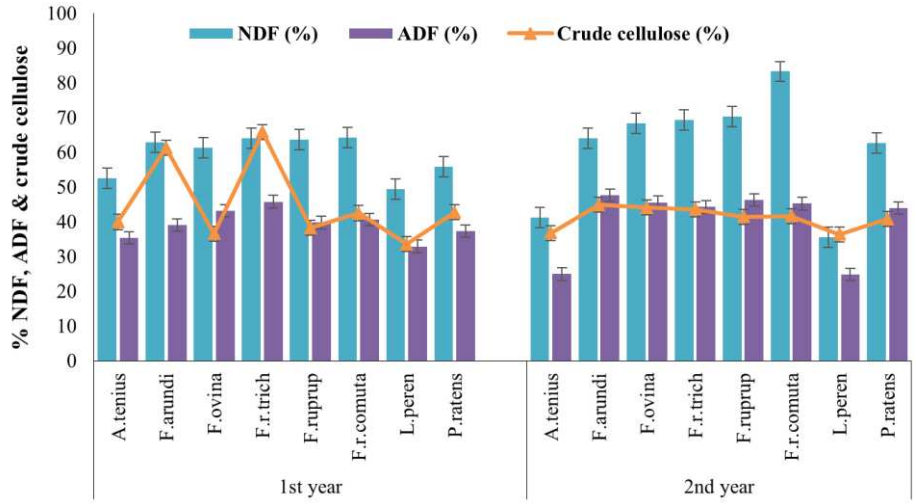

Figure 3. *Acid detergent fiber (ADF), neutral detergent fiber (NDF) and crude cellulose of hay/forage as influenced by different forage species grown under Mediterranean environment*

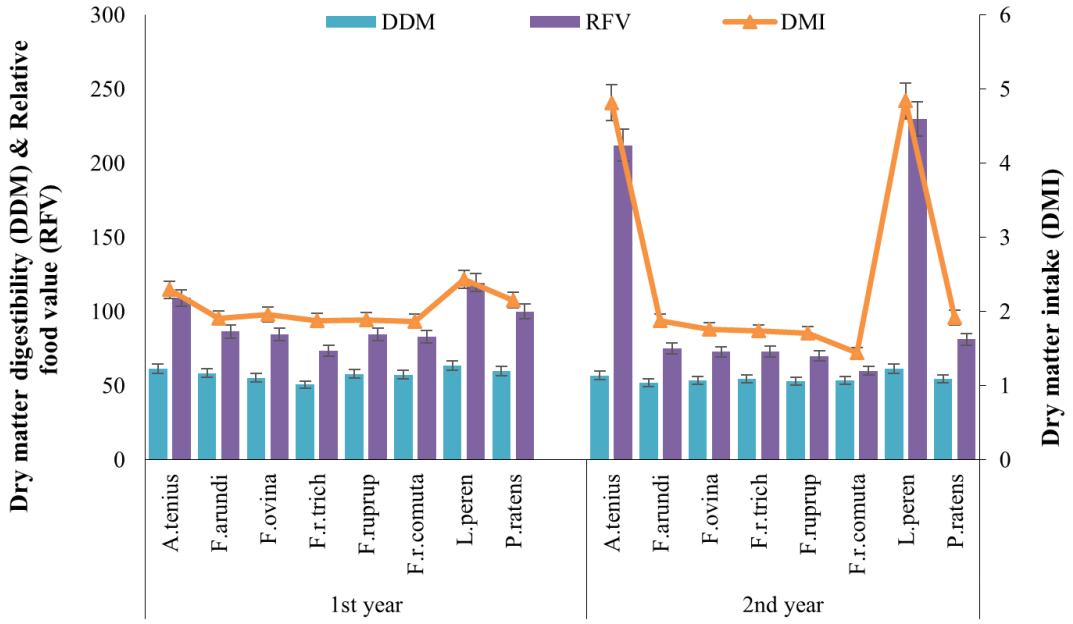

Figure 4. *Intake, digestibility and relative value of dry hay/forage as influenced by different forage species grown under Mediterranean environment*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55715581

Correlation coefficients among the different variables

Correlation coefficients among the variables under study were found to be significant (*Table 3*). In the present study, dry yield was positively correlated with ADF and NDF, while ADF remained positively correlated with NDF. The findings are in confirmation with those of Badrzadeh (2008), who reported ADF direct relationship with NDF. On the other hand, the NDF was negatively correlated with the DDM and RFV. The ADF was negative correlated with DMI, DDM and RFV. Genotypic differences in terms of all quality parameters were found significant, while ADF ratio was non-significant, our results are in accordance with the findings of (Yılmaz and Erol, 2015). Bani et al. (2007) recorded an inverse relationship between forage fiber fractions and DM digestibility.

Conclusion

The results from this study revealed that significant variability exists among forage species under study in terms of their potential for herbage yield and nutritive value under Mediterranean environment. This indicates that there is a considerable potential for selecting appropriate forage species, which have the adequate nutritional quality to improve forage supply for as well as to meeting ruminant dietary requirements. It is clear that the potentiality of *Festuca* species as forage and pasture plants under prevalent agro-climatic conditions is very high due to specific nutritional characteristics. *F. arundinacea* can also be promoted as forage and pasture specie due to higher potential to yield dry matter while using *F. rubra* as a pasture plants to improve natural grassland seems to be more suitable.

Abstract. Rapid urbanization that caused urban sprawl is a major worldwide concern. In this study an assessment of urban sprawl was carried out based on Land Use Land Cover (LULC), Normalized Difference Vegetation Index (NDVI) and Normalized Difference Built-up Index (NDBI) variation in Sepang, Malaysia. The land cover classification consisted of Built-up Area (BUA), Vegetation Area (VA), Open Space Area (OSA), and Water Bodies (WB) from 1990 to 2018. Supervised classification based on maximum likelihood techniques were used to identify the land use classes. Based on the analysis of LULC, the majority of VA (i.e. forest field) was transformed into OSA and gradually the land was converted into BUA. Observation within 25 years, supported by NDVI and NDBI has discovered a consistent increase of BUA while contrastingly a decline of VA, while WB and OSA are suspected to have inconsistently varying highs and lows. This study has demonstrated that urban sprawl caused by rapid urbanization has not favour the population. Without proper planning and growth control, urban sprawl in Sepang would have undesirable consequences to the quality of life and the environment. Therefore, comprehensive land use and progressive environmental change can serve as prognostic measures to mitigate urban sprawl, and to achieve sustainable urbanization and to carry out effective planning and decision making.
Keywords: *urban sprawl, land use land cover, normalized difference vegetation index, normalized difference built-up index*

Introduction

Urban sprawl occurs on a micro basis in almost every major cities in the world in response to increased wealth and growing dependence on private transportation (Burchell et al., 2002). Population, resources and productive activity are highly and increasingly concentrated in cities, thus require comprehensive understanding especially in the context of demographic, geographic and economic. In regard to urban sprawl, it is a global phenomenon but it is always viewed in different ways on how and why it was resulted (Barnes et al., 2002). In Eastern Europe, urban sprawl was considered as an outcome of post-socialist of autocratic transformation into liberalization of economic and social well-being (Bussauw, 2012; Nuissl and Rink, 2005). In the USA, early spatial form of sprawl occurred after World War II because of the perception that the new suburbs are safer, more desirable and cheaper than urban alternatives (Peiser, 2001). In Asia, most recently China and India are experiencing the largest and most rapid urban sprawl because of their enormous economic transformation which affecting agricultural productivities (Yue, 2011). Generally, majority scholars admit that urban sprawl had indirectly provide negative impacts especially towards the social segregation and environmental degradation (Squires, 2002; Burchell et al., 2002). Strong supported by Hua and Ping (2018), Hua (2018, 2017a), Noor and Rosni (2013) as well as Abdullahs (2012) view that the problems caused by urban sprawl are exceeded the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55835602

expected of benefits due to increasing of population growth that live based on their own desires. Nevertheless, many academicians are invited to provide the ideas on urban sprawl for effectively containment, especially focuses about the sustainability development (Hua and Ping, 2018).

Since urbanization process taking place worldwide and are considered a universal phenomenon, therefore population growth, economy and infrastructure could be responsible to the increasing of this bewildering phenomenon. Specifically, any development of an urban area with no ability to visualize the growth through planning, policies and decision making process could resulted the sprawl. Therefore, urban sprawl is likely to be considered as the development of a city due to unplanned, uncontrolled, and uncoordinated growth, it could impact the wildlife habitat, encroachment of natural resources and farmland, increased environmental degradation, as well as social and economy deprivation (Hua, 2018, 2017b; Tehrany et al., 2013). Malaysia already going towards an over urbanized nation with 75% of the population is expected to live in urban areas in 2020 (Abdullah, 2012). His study also indicated, urban sprawl in Malaysia will continuously become part of the landscape of metropolitan and other major cities with the expansion of regional economic corridors. Greater Kuala Lumpur, an area surrounded by 10 municipalities surrounding Kuala Lumpur are considered far reaching the socio-economic and cultural conditions. These cities are having desire to compete among each other, and this had caused the economic activities to concentrated in the urban area and leaving the rural areas far behind in term of development. Since Greater Kuala Lumpur had a greater growth in the area and this trend had cause greater number of populations to reside in suburban areas rather than city.

Sepang is considered very significant in term of suburban living and sprawl. The study area was mainly selected based on the rapid urbanization and sudden increase in population especially in 1997-2007. This is probably due to government's decision on the relocation of the administrative of Putrajaya in 1995. Putrajaya is the biggest integrated development with a total land area of 4581.1 ha, conveniently located within the district of Sepang but with separated autonomy. Another integrated development located within Sepang is Cyberjaya, the IT-themed city aspired as Malaysia's Silicon Valley. Cyberjaya is part of Multimedia Super Corridor, a special economic corridor and high technology business district, Federal Government's knowledge based initiative. Sepang also houses KLIA and F1 Sepang circuit, both generated many chain of businesses and employment. This study examined the conceptualization and measurement of sprawl whereby its equates with non-urban e.g. farmland, cropland and open space that change into urban land e.g. building, infrastructures. Therefore, urban sprawl must be considered as the rate of increase relative to physical urban growth or land use change in a space-time context. Consequently the main objective of this study is to assess the land use change from 1990 to 2018 through detection techniques using Land Use Land Cover (LULC) and Normalized Differences Vegetation Index (NDVI). Both methods are considered accurate, common, and effective in change detection for mapping of urban sprawl (Lu et al., 2004).

The review on theoretical for measured urban sprawl

Another definition by pattern of growth is brought by Ewing and Hamidi (2008), refers urban sprawl as undesirable land use patterns whether scattered, leapfrog, ribbon or continuous low density development and at the same time has poor accessibility and lack of functional open spaces. The growth patterns are usually determined by the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55835602

availability of adjacent land and variations of terrain. Accessibility has direct correlation with the extent of scattered-ness of the pattern. The more scattered the pattern, the lower their accessibility. Ewing also included any urban growth pattern that have poor accessibility and lack of functional open space.

Combination rather than individually separated on the application techniques of remote sensing and GIS in the study for urban sprawl are better especially in monitoring nor simulation for the physical, social and economic data (Mohd Noor et al., 2012). Majority researchers are tends to use remote sensing and GIS to monitor and measure the urban sprawl (Hua, 2018; Noor and Rosni, 2013; Mohd Noor et al., 2012). Nevertheless, having strong definition on sprawl term with focus towards the problematic and undesirable development characteristic which majority stakeholders are debate on. Therefore, the advantageous of using remote sensing is the capability of producing consistent spatial dataset with coverage of larger areas assisted with its high spatial and temporal resolution. In other words, remote sensing can be considered as "unique view" on the spatial temporal change of the urban growth process and land use change (Herold et al., 2003). Another advantageous of using satellite remote sensing are land cover monitoring and detection at various scales to provide useful results (Wilson et al., 2003; Stefanov et al., 2001).

The present technology enable the integration of remote sensing and Geographical Information System (GIS) with Global Positioning System (GPS) allowing land use change detection and assessment become more effective (Muller and Zeller, 2002; Weng, 2002). The technique of mapping urban areas as source of data for modelling and urban growth analysis as well as dynamic change detection in land use land cover was proven as very beneficial (Wilson et al., 2003; Herold et al., 2003; Stefanov et al., 2001).

Materials and methods

Study area

The study area is Sepang, Selangor, Malaysia located at 2°45'38"N and 101°44'15"E with a total coverage of 56150 km^2 and the main land use are: built-up areas, vegetation and open spaces (*Fig. 1a* and *b*. The population within 20 years from 1995 is approximately 90,000 and the number is rising up to 190,000 in 2015 (Statistical Department of Malaysia, 2015). Geographically it is in the southern part of Selangor, neighboring to the district of Hulu Langat in the northeast, district of Kuala Langat in the west, and Petaling in the north and also neighboring to District of Nilai, Negeri Sembilan and surrounding the federal territory and administrative capital of Putrajaya. The municipal administration office originally located in pekan Sepang, a very small town consists of not more than 3 shop houses at that time. When the Kuala Lumpur International Airport (KLIA) was officially inaugurated in 1998, the office was moved to Salak Tinggi. For a second time, after Putrajaya was established and become the new administrative capital of Malaysia, the municipal was moved to Cyberjaya in 2008.

Primary data sources of Landsat thematic mapper (TM) and operational land imager (OLI) and thermal infrared sensor (TIRS)

Remotely sensed data was acquired from the United State Geological Survey (USGS) Earth Explorer for Landsat data of Thematic Mapper (TM) as well as

DOI: http://dx.doi.org/10.15666/aeer/1703_55835602

Operational Land Imager (OLI) and Thermal Infrared Sensor (TIRS). Supported by Landsat data, the boundary of Sepang district, Malaysia is based on the Department of Survey and Mapping Malaysia (JUPEM), which is important for abstracting process on the raw map using Area of Interest (AOI) technique in mapping procedures. The details on primary satellite data can be shown in *Table 1*.

Table 1. *Primary satellite data of Landsat TM and OLI/TIRS*

Data preprocessing and land use/land cover classification

It is essential for a newly obtained time series of remotely sensed data to be preprocessed before any analytical process are made. First, using ArcGIS Ver. 10.1, the images have to go through pre-processing for geo-referencing, mosaicking, and sub

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55835602

setting where only then, the specific area can be selected through Area of Interest (AOI) technique (Behera et al., 2012).

The main purposes to conduct preprocessing are to correct the sensor- and platform-specific radiometric and geometric distortions of data. This correction technique on the radiometric is required because of the variation in scene illumination and viewing geometry, atmospheric conditions, and sensor noise and responses. Fortunately, all satellite images obtained is cloud free or <10% cloud coverage (Tan et al., 2010). To avoid error and imprecise interpretation, the images for Landsat TM and OLI/TIRS were in original resolution of 30 m (*Table 1*).

Next, further processing for band combination of 3-2-1 in Landsat TM and 4-3-2 in Landsat OLI/TIRS are carried out in ArcGIS 10. Then classification of land use is conducted in ENVI Version 4.0. Classification was performed using Maximum Likelihood supervised using selected regions and Regions of Interest (ROI), which based on delineated classes of built-up area, vegetation area, water bodies, and open space area (*Table 2*). The built-up areas classes consists of residential, industrial, commercial, administration, cemetery and transportation, and sewage treatment plant. The vegetation classes consists of all forest and agricultural land, as well as open space whereby it include barren land. The final class is the water bodies which consists of rivers, lakes, stream, canals and reservoirs.

Table 2. *Land use classification based on maximum likelihood supervised techniques*

Land use class	Definition
Built up area	Includes all residential, industrial, commercial, administration, cemetery and transportation, and sewage treatment plant
Vegetation area	Includes all forest field and agricultural lands
Water bodies	Includes all water bodies (river, lakes, gravels, stream, canals, and reservoirs)
Open space area	Includes all land area that are in soil and barren area due to the human activities

Accuracy assessment

It is compulsory to conduct accuracy assessment of classified images from 1990 to 2018 (i.e. 15 images) to ensure accuracy, integrity and quality. Kappa tests are used to measure the accuracy of classification which have capability to test all confusion matrix of elements based on minimum requirement (Halmy et al., 2015). The Kappa tests can be measured based on the producer and user rating of assignment, which can be interpreted in formula as *Equation 1:*

$$K = \frac{P(A)-P(E)}{1-P(E)} \quad \text{(Eq.1)}$$

where, *P(A)* is the total of *k* raters agree, and *P(E)* is the total of *k* raters which expected to agree by chance (El-Kawy et al., 2011; Pontius and Millones, 2011). The accuracy of user can be explained as probability defined the pixel on image to represent a class on ground, while accuracy of producer is the probability pixel is correctly classified and usually it determine how good for particular area can be classified (Pontius and Millones, 2011). Therefore, four (4) classes had been set up earlier, whereby the delineated should be 50 points and above for each category to enhance the accuracy

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55835602

assessment percentage (El-Kawy et al., 2011; Pontius and Malanson, 2005). So, the accuracy assessment for 1990, 1992, 1994, 1996, 1998, 2000, 2002, 2004, 2006, 2008, 2010, 2012, 2014, 2016, and 2018 are having the kappa value of 0.87, 0.84, 0.82, 0.83, 0.86, 0.88, 0.91, 0.80, 0.82, 0.82, 0.90, 0.86, 0.85, 0.84, and 0.91, respectively (*Table 3a-o*). Identified categories of LULC in accuracy assessment are considered achieved the required minimum, which is need to be at least 80% (Weng, 2010). Hence, the data can be exported into ENVI 4.0 for further analysis.

Analysis of change detection in land use land cover

In LULC change detection, post-classification detection technique is proposed in this study using ENVI 4.0, where two classified images were compared to provide the information of changes on the pixel basis. In other words, these two images were interpreted to produce the changes "from- to" information. A 30 × 30 m to ground resolution of Landsat TM and Landsat OLI/TIRS were resampled and geo-rectified based on WGS84 UTM with RMSE less than 0.5 pixels were projected. Then, classified images based on two comparisons of data sets using cross-tabulation to determine the qualitative and quantitative changes for the periods from 1990 to 2018. The frequency and percentage of changes can be calculated according to simple formula as *Equations 2* and *3:*

$$K = F - I \quad \text{(Eq.2)}$$

$$A = \frac{(F-I)}{I} x\ 100 \quad \text{(Eq.3)}$$

where, K is the magnitude of changes, A is the percentage of changes, F is the first data, and I is the references data (Mahmud and Achide, 2012). This research study uses LULC methods to map the urban sprawl by determine the differences of land use changes and to explain the percentages changes within the period of time.

Normalized difference vegetation index (NDVI)

Normalized difference vegetation index (NDVI) is measuring the vegetation through quantifies between near-infrared of differences (which refer to the stronger reflected light by vegetation) and red light (which refer to the light that absorbs by vegetation). The NDVI value is ranges from -1 to 1, but it is no exact boundary line between each type of land cover. For instance, when the value is negatives, which showing the pixel are in water coverage; meanwhile the value that close to +1, then the result are having high possibility of green leaves surrounding the area. Nevertheless, when the value of NDVI is close to zero, then the land use indicates no green leaves and probably showing an urbanized area. The NDVI can be interpreted into formula as *Equation 4:*

$$NDVI = \frac{(NIR-RED)}{(NIR+RED)} \quad \text{(Eq.4)}$$

where, NIR - RED and NIR + RED indicate the surface reflectance averaged over ranges of wavelengths in the visible of red (λ~0.6 μm) and near infrared, IR (λ~0.8 μm),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_55835602

respectively. In other words, NDVI is a standardized way to measure the healthy vegetation. When the NDVI value is higher, then the healthier is the vegetation at the study area.

Normalized difference built-up index (NDBI)

Having similar with NDVI, the normalized difference built-up index (NDBI) is used to measured the build-up area through quantifies between differences of short-wave infrared (SWIR) and near-infrared (NIR). The NDBI value is ranges from -1 to 1, whereby the negative value showing the pixel are non-built-up coverage area; meanwhile the positive value are having high possibility of built-up area surrounding the environment. The NDBI can be expressed into formula as *Equation 5:*

$$NDBI = \frac{(SWIR - NIR)}{(SWIR + NIR)} \quad \text{(Eq.5)}$$

where, SWIR – NIR and SWIR + NIR can be defined as surface reflectance averaged over ranges of wavelengths in the short infrared (λ~0.7 μm) and near infrared (λ~0.8 μm). When the NDBI value is higher, this circumstances indicate the study area is clustered with highly built-up activities within surrounding area.

Results and discussion

According to *Table 4,* the result indicated the density of LULC changes from 1990 to 2018 with four classes: built-up area, vegetation area, water bodies, and open space area (*Fig. 2*). Except in year 1992, the built-up area (BUA) class is observed to have continuously increase for 25 years. The percentage of increment is about 25.4% from 1990 to 2018. The study concluded that BUA classes are considered having the most increment due to rapid urbanization and population growth. It is followed by OSA class from 1990 to 2004 with an increment of 4.75% in average but beginning to decrease by 18.5% in the next 13 years. In other words, majority OSA class has gain benefit from the vegetation area (VA), and the most open space is suspected to change into BUA and/or other classes. Vegetation Area (VA) class consistently decreasing from 1990 to 2018 (*Fig. 3*) by 64.33%. This amount to 36123.07 ha of land. Except for waterbodies which has not seen any significant change, this uppermost land use changes is due to high demand in BOA to cater with population need and demand for residential-industrial-commercial activities as well as transportation facilities.

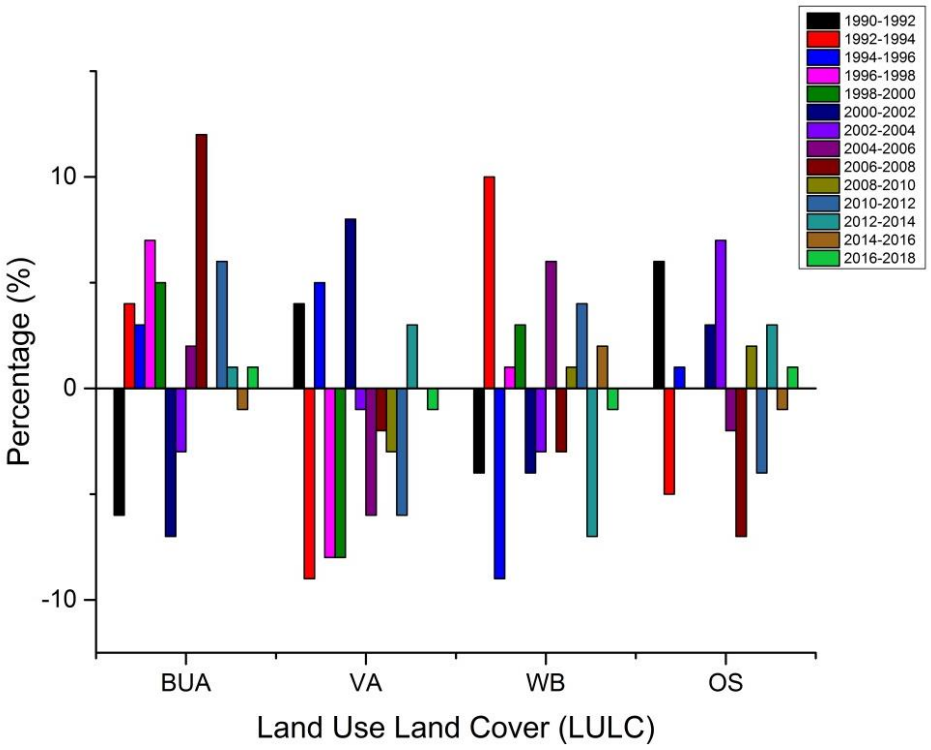

Figure 3. *The comparison of areas and rate of changes in LULC classes between each two years from 1990 to 2018*

Combining LULC change with Normalized Difference Vegetation Index (NDVI) and Normalized Difference Built-up Index (NDBI) techniques is considered recent and novelty. An NDVI is an equation that takes into account the amount of infrared reflected by plants. In classification process, supervised classification method based maximum likelihood algorithm was employed for NDVI, which is based on a set of user-defined classes and training areas through creating appropriate spectral signatures from Landsat TM and OLI/ TIRS. The result of changes of NDVI density classes for 25 years indicated that the vegetation index gradually reduced about 27.91% from year 1990 to year 2010, but the value sustained about 28.75% for the next 8 years from 2010 onwards (see *Table 5*).

Table 5. *Change of the NDVI density classes from 1990 to 2018*

In other words, the higher the value of index, indicated the healthier the vegetation would be. Therefore, the value constantly changing due to the majority of vegetation classes are subjected to transform to open space and built-up classes. The pattern of vegetation classes derived from NDVI density (see *Fig. 4*) were predominantly the main land use class in year 1990 to 1994. Beginning 1996 onwards, patches of other classes spread across Sepang starting to gradually increase year by year. This was interpreted as an encroachment and an environmental degradation of forest, farm and cropland and further reducing agricultural productive land. The encroachment of these land uses, the environmental degradation and reduced in agricultural productivities are among the characteristic of urban sprawl defined earlier in this study.

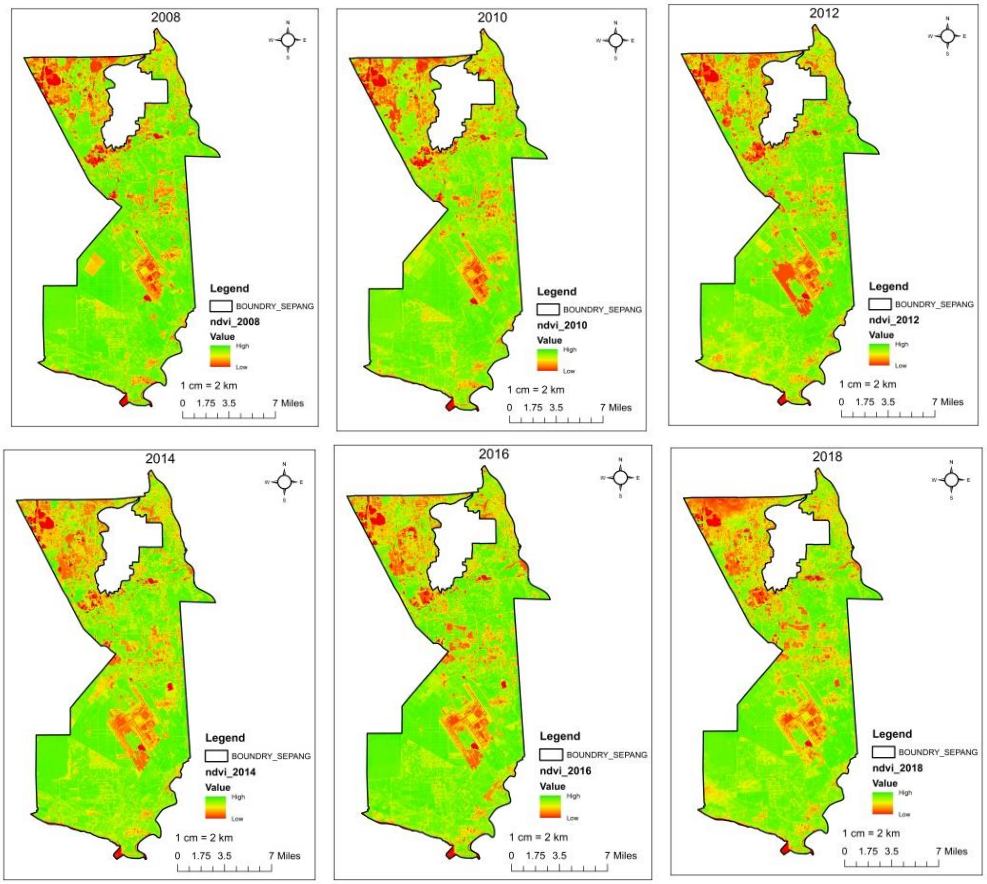

Figure 4. *The NDVI density from 1990 to 2018 in Sepang district*

A Normalized Difference Built-up Index (NDBI) is an arithmetic manipulation of NDVI except it is used for mapping built-up areas. The result of changes of index of very-high and high of NDBI density classes for 25 years indicated inconsistent of ups and downs of built-up classes. In contrarily, the result of changes of index of medium-and-low of NDBI indicated a consistent decreased throughput the longitudinal study. This is due to the fact that the highly demand for development on land use purposes will eventually cause an increasing in building index and reducing in vegetation index (Ewing and Hamidi, 2014). The pattern of built-up classes derived from NDBI density (see *Fig. 5*) was not the primary land use in early years. However, as early as the beginning of the longitudinal study, the built-up classes were already shown a sign of leapfrog, low density and scattered with polycentric development. Increased in built-up classes are necessary result in increase of impervious surface which effect water quality and increased of runoff water. By interpretation, Sepang has no specific urban growth boundary. Sepang was also part of Greater Kuala Lumpur with greater number of populations to reside in suburban areas. To add to the scenario, Putrajaya was rapidly growing at beginning of mid-1990s and continuously to do so, while Cyberjaya which also located within Sepang was the special economic corridor. Thus, Sepang was critically sprawled; backed with all the sprawl pattern – leapfrog, low density and scattered development; without any urban growth boundary; formed an urban environmental degradation, become the overpopulated suburban living for Putrajaya and Cyberjaya; and houses mass population for Greater Kuala Lumpur.

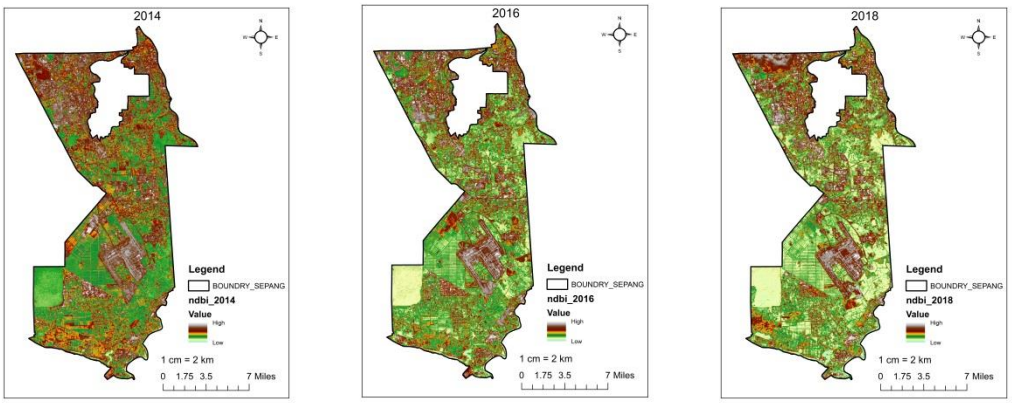

Figure 5. *The NDBI density from 1990 to 2018 in Sepang district*

Conclusion

Urbanization and rapid population growth are a major cause of land use changes and land conversions. It is essential in change detection to determine what type of land classes has change and the rate of change. Analyzing the spatial change with temporal aspects of urban growth can contribute to an effective planning and mitigate urban sprawl. Through this study, the urban expansion of Sepang over different period using time-series LULC and NDVI variation was achieved. The classification was able to clearly distinguished built-up area, vegetation area, water bodies, and open space. Land use land cover change detection showed an increased percentage of built-up area and open space, while reduce vegetation area. Only waterbodies had not shown any significant change. An NDVI quantified a steady declined of vegetation classes. The pattern of vegetation derived from NDVI density showed an encroachment and an environmental degradation of forest, farm and cropland and further reducing agricultural productive land. This is urban sprawl by definition. On the contrary, NDBI indicated inconsistent of ups and downs of built-up classes. However, the pattern of vegetation derived from NDBI density indicated urban sprawl patterns, urban sprawl characteristics and are associated with urban sprawl causes. Thus, the study proved urbanization and rapid population growth has caused urban sprawl to Sepang.

Abstract. Agriculture can use the sewage sludge resulting from wastewater treatment. In order to use sewage sludge, it is necessary to eliminate the content of toxic pollutants, including heavy metals through phytoremediation. The purpose of this research work was to assess the capacity of *Phragmites australis* to remove As, Cu and Fe in wastewater sludge of the municipal treatment plant in Cd. Victoria, Tamaulipas. We established four treatments: T1 = sewage sludge + soil + *Phragmites australis*; T2 = sewage sludge + soil; T3 = Sludge + *Phragmites australis*; T4 = Check test. Each treatment had six replicates. The phytoremediation process lasted eight months. We took monthly samples from the substrate and samples of *P. australis* every four months to determine the contents of As, Fe and Cu. The sludge + soil + P. australis treatment was able to remove higher percentages of Fe (96.63%) and Cu (47.67%); while sludge + P. australis was able to remove higher percentage of arsenic (81.18%), with a bio-concentration factor of 7.76. The amount of metals removed from the substrates from highest to lowest were: Fe > Cu > As. Furthermore, the final concentration of Fe, Cu and Arsenic in the sludge was below the allowable limit established by NOM-004- SEMARNAT-2002 Standard.
Keywords: *bio-concentration factor, heavy metals, Phytoremediation, translocation factor*

Introduction

Wastewater treatment is a worldwide strategy to recover water contaminated by residential and industrial use. The process does not only produce treated water, but also suspended solids known as sewage sludge or bio-sludge (Jing et al., 2017). Sewage sludge is treated and biologically stabilized to avoid harming living creatures and the environment. Once stabilized, sewage sludge turns into bio-solids used in fertilization, crop enhancement, forest remediation, composting and power generation (Castañeda et al., 2011; CRA, 2000).

Like other countries, Mexico has implemented wastewater treatment programs since 2008, including PROTAR (Wastewater Treatment Program), aiming to increase the volume of treated water and improve existing treatment processes. Thanks to these projects, the number of operating wastewater treatment plants in the country increased to 2447 by December 2015, representing an installed capacity of 177973.58 L s^{-1}. Nevertheless, those plants treat only 120902.20 L s^{-1} of wastewater, leaving behind 2911234 t $year^{-1}$ of bio-solids (CONAGUA 2015). CONAGUA (2011) reported that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56035617

37% of the treated wastewater streams produce 640,000 to 10 million t year^{-1} of bio-solids. This difference is because sometimes the quantity is reported in terms of dry weight and in other cases the moisture content is not even mentioned; so in fact, there is no official data regarding sewage sludge and bio-solids production, and therefore, the percentage of treated bio-sludge is very low.

Sewage sludge obtained from wastewater treatment does not only have a high level of nutrients, but also several pollutants, such as heavy metals. The presence of trace elements transforms sewage sludge in a source of environmental pollution. The gases released when the sludge breaks down produce a fetid odor coming from a large number of fecal coliforms, including some pathogens like *Salmonella spp.,* and elements that are toxic in high concentrations. It is therefore important to treat sewage sludge and eliminate, reduce or form compounds that will not harm living organisms and the environment (Rojas and Mendoza 2012).

Stabilizing sewage sludge from wastewater plants implies very high operating costs. Phytoremediation is a solution to this problem, offering an effective, low-cost *in situ* solution. Wetlands retain trace elements in a natural way, in particular *Typha latifolia* L. and *P. australis* Cav. Trin. (Salema et al., 2014).

The cost of conventional stabilization and reuse of sewage sludge is unaffordable at Cd. Victoria, Tamaulipas' wastewater treatment plant. Therefore, untreated sludge is disposed inside the plant facilities, becoming a source of environmental pollution. This research work is aiming to determine *Phragmites australis'* capacity to remove arsenic, copper and iron from sewage sludge produced by Ciudad Victoria, Tamaulipas' wastewater treatment plant.

Materials and methods

The experiment was conducted from May 2015 to January 2016 at the hydroponic module of Ciudad Victoria's Technology Institute (ITCV).

500 kg of untreated sewage sludge were collected at Cd. Victoria, Tamaulipas' wastewater treatment plant and taken to ITVC facilities to fill 19 kg-pots which were used as individual experimental units, using a 5-cm gravel bed for planting and propagating *P. australis.* We established four treatments, each one with six replicates; 24 experimental units in total (*Table 1*).

We collected *P. australis* spikes from San Marcos River banks, Cd. Victoria, Tamaulipas. We selected the thicker spikes with the largest number of nodes for propagation. We made diagonal cuts every three nodes, in order to propagate the cuttings in every experimental unit. We organized the experimental units at random and we planted three cuttings in each experimental unit, watering them with drinking water. The experiment lasted eight months under uncontrolled conditions at an average temperature of 26 °C. We took monthly samples of the substrate (30 g) close to the roots and we selectted one plant per treatment every four months, to determine the concentration of As, Cu and Fe on the substrate and on *P. australis*. (The first sampling was in September).

Substrate characteristics

Table 1 shows the soil and sludge initial characteristics. The initial pH of soil and the sewage sludge was slightly acidic and had a small increase after mixing both substrates. As and Cu concentrations were lower than the maximum allowable limits of 41-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56035617

75 mg kg^{-1} and 1500-4300 mg kg^{-1} respectively in dry weight, according to NOM-004-SEMARNAT-2002 standard.

Table 1. *Initial characteristics of the waste sludge, soil and the mixture of both substrates*

Parameter	Sludge	Soil	Sludge + soil
As (mg kg^{-1})	1.61	0.283	1.893*
Cu (mg kg^{-1})	12.411	1.29	13.701*
Fe (mg kg^{-1})	656.365	5.839	662.204*
pH	6.780	6.750	6.990
CE (dS m^{-1})	4.360	1.855	1.030
PR (mV)	-50.2	-45.9	-39.7
MO (%)	5.414	1.083	1.963
Nt (%)	1.072	0.142	0.389
P (mg kg^{-1})	33.161	1.005	15.576
K ($cmol_{(+)}$ kg^{-1})	0.189	0.492	0.082

CE = Electrical conductivity, Nt = total nitrogen, ORP = redox potential
*For the case of the mixture, the concentrations of As, Cu and Fe were not determined, so the value presented here is an approximation, based on the initial concentration of the metals in the waste sludge and the soil

Heavy metals' determination: We analyzed the substrate and *P. australis* samples to determine the content of metals using inductively coupled plasma atomic emission spectroscopy (ICP-OES Varian model 725-ES, Agilent, Mulgrave, Australia).

Data analysis

The bio-concentration factor (BFC) (Chandra, 2013), was calculated using *Equation 1:*

$$BFC = \frac{C_p}{C_i} \quad \text{(Eq.1)}$$

where: C_i = initial metal concentration in the substrate, and C_p= metal concentration in the plant.

The translocation factor (TF) (Chandra, 2013) was determined by *Equation 2:*

$$TF = \frac{C_a}{C_r} \quad \text{(Eq.2)}$$

where: C_a = metal concentration in aerial plant parts and C_r = metal concentration in plant roots.

pH and reduction-oxidation potential (PR) results were analyzed by linear regression, to determine their dependency. Metal concentrations in the substrates were submitted to repeated measures analysis of variance and Fisher's LSD test ($p < 0.05$). We analyzed metal concentrations, BCF and TF of the plants by discrimination functions, in order to determine the difference among these variables. Finally, we applied a canonical correlation to find the relation between metal concentrations in the plant and the

DOI: http://dx.doi.org/10.15666/aeer/1703_56035617

substrates. We conducted the statistical analysis of the variables with PROC REG, MIXED, DISCRIM and CANCORR procedures, using SAS software (2002) and Statistica, version 7.

Results

The high temperatures in Cd. Victoria 18.5–31 °C dehydrated the substrates, reducing their initial volume. We had to add 12 kg more of sewage sludge to the experimental units in June and September in order to maintain the ratios that were originally proposed for each treatment (we determined the concentration of As, Cu and Fe in the sludge before the addition). The sewage sludge added during those months had lower concentrations of the three metals, than the initial concentrations of As, Cu and Fe found in the original substrates used for the experimental units (*Table 2*).

Table 2. *Concentration of As, Cu and Fe in waste sludge and irrigation water*

Sample	As (mg kg^{-1})	Cu (mg kg^{-1})	Fe (mg kg^{-1})
Sludge initial	1.61	12.411	656.365
Sludge july	0.000001	1.01	318.032
Sludge september	0.000001	1.143	270.181
Water sample irrigation	0.034	0.088	0.021

Only two, out of three plants that we planted in the experimental units survived. During the eight months that the experiment lasted, the plants showed phenotypic differences. Plants with sludge + *P. australis* had more foliage in the aerial parts; while plants growing on the sludge and soil + *P. australis* mix were taller.

We measured the pH and the reduction-oxidation potential (PR) in the samples of each substrate, four months after planting. The pH increased from 6.7 to 8.3, and significant differences were found in the correlation of pH with time ($R^2 = 0.307$ and $p < 0.05$) and PR ($R^2 = 0.312$ and $p < 0.05$). This parameter changed from -39.7 to 101.4 (*Fig. 1*).

Figure 1. *Plants of P. australis three months after sowing in the pots. T1 = sewage + soil + P. australis, T2 = sewage + soil, T3 = sewage + P. australis*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

We found significant differences in Arsenic concentration in the substrates throughout the eight months (F = 2.43 and $p < 0.05$). The higher concentration was in May, with 1.61 mg kg^{-1} and the lowest concentration was in November (0.08 ± 0.06 mg kg^{-1}). There were significant time differences among treatments (F = 2.74 and $p < 0.05$). In the second month (June) the sludge and soil + *P. australis* treatment had the highest concentration (0.86 ± 0.51 mg kg^{-1}), while the lowest concentration was found in October (0.10 ± 0.24 mg kg^{-1}). The sludge + soil treatment had the highest concentration in July (0.44 ± 0.38 mg kg^{-1}) and the lowest in November (0.11 ± 0.06 mg kg^{-1}). The sludge + *P. australis* treatment had the highest concentration in September (0.56 ± 0.46 mg kg^{-1}) and the lowest in November (0.11 ± 0.10 mg kg^{-1}). The check test (Sludge) had the highest concentration in August (1.04 ± 0.72 mg kg^{-1}) and the lowest in November (0.08 ± 0.05 mg kg^{-1}) (*Fig. 2a*). The sludge and soil + *P. australis* treatments, as well as the check test showed significant differences (t = 0.74 and $p = 0.0449$).

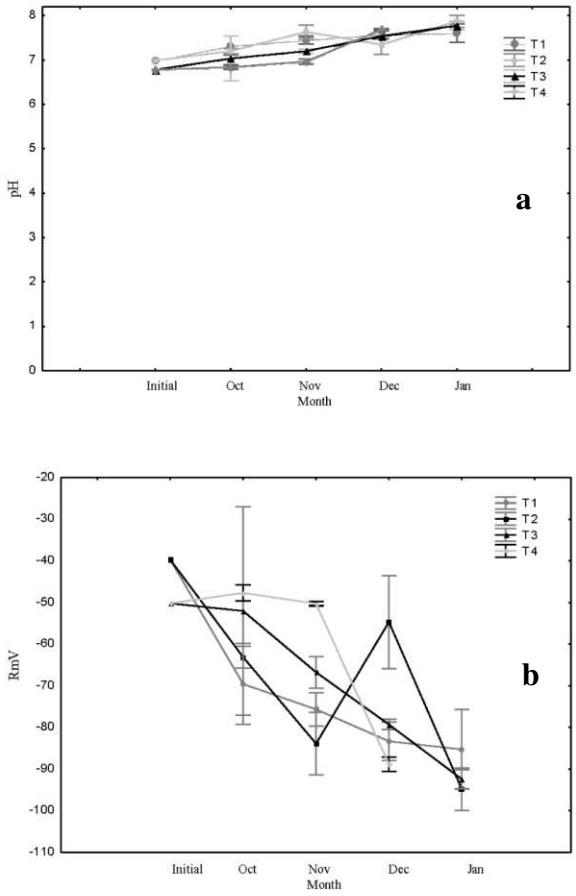

Figure 2. *Average values of a) pH and b) PR with SD bars, during the last four months of the phytoremediation process, for the treatments, T1 = sewage + soil + P. australis, T2 = sewage + soil, T3 = sewage + P. australis and T4 = sewage, (n = 6) with confidence interval of ± 0.95*

Cu concentration in all treatments had significant differences throughout the months (F = 7.09 and $p < 0.05$). The highest concentration was in May 12.41 mg kg^{-1} and the lowest was in December (3.42 ± 2.34 mg kg^{-1}). The treatments had significant time differences (F = 3.06 and $p < 0.05$), (*Fig. 2b*). LSD analysis showed that there are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56035617

significant differences in the sludge and soil + *P. australis* mix, and the check test (t = 2.92 and $p < 0.05$); as well as between the sludge + soil and the mix sludge and soil + *P. australis* (t = 4.06 and $p < 0.05$).

The mg kg^{-1} of Fe showed significant differences throughout the months (F = 44.98 and $p < 0.05$), with lower concentrations switching from one month to another, until reaching a final concentration (14.19 mg kg^{-1}) lower than the initial concentration (656.36 mg kg^{-1}). There were also differences among treatments and among the months (F = 13.25 and $p < 0.05$), (*Fig. 2c*). LSD analysis proved that there were significant differences among the four treatments with $p < 0.05$.

The percentage of Arsenic removal from the substrates did not show significant differences among the months and the treatments (F = 0.89 and F = 0.61 respectively; $p \geq 0.05$). We defined a range of 73-83% in the eight months and in the four treatments. We found significant differences among the months for Cu removal percentage; however, there were no differences among the treatments (F = 2.72, $p < 0.05$; F = 2.07, $p \geq 0.05$). The treatments did not show significant differences on Fe removal percentage (F = 3.38, $p < 0.05$; F = 2.98, $p \geq 0.05$). We determined the overall removal percentage during the eight months in the four treatments, showing a higher value for Arsenic in the sludge + *P. australis* treatment, as well as for Cu and Fe in the mix of sludge and soil + *P. australis* (*Table 3*).

Table 3. *Summary of the analysis of discriminant functions*

% Removal	Treatment							
	SSP		SS		SP		S	
As	80.18	±3.74	80.78	±3.09	83.67	±9.08	73.67	±6.75
Cu	47.67	±10.41	31.08	±6.47	42.30	±11.75	23.11	±11.09

Accumulation of As, Cu and Fe in P. australis

Metal concentration in *P. australis* organs was the following: As: 0.07- 1.96, Cu: 0.92-28.7 and Fe: 121.13-10224.01 mg kg^{-1} in dry weight. The discrimination analysis found significant differences among the plant parts, regarding the accumulation of heavy metals [F = 6.2994, Wilks' Lambda = 0.00019, $p < 0.05$)] (*Table 4*). We found differences in Arsenic concentration in the stem, and Cu concentration differences in the leaves (*Fig. 3*). There was a significant difference of $p = 0.1129$ at different times, in the sludge and soil + *P. australis* and sludge + *P. australis* mix treatments.

Estimated BCF values for Cu and Fe in the sludge and soil + *P. australis* and the sludge + *P. australis* mix treatments on September and January were greater than 1; while for As, the values were greater than 1 in September, and they were lower than 1 in January. TF for As was greater than 1 in the two samplings, on the sludge and soil + *P. australis* and sludge + *P. australis* mix treatments; while TF was below 1 for Cu and Fe (*Table 5*). BCF value was higher in Fe accumulation and lower in As with *P. australis.* The opposite happened with TF value, which was higher in Arsenic and lower in Fe (*Fig. 4*). Results of the discrimination function analysis showed that there were no significant differences among the months and the treatments regarding the BCF values for Cu and Fe (F = 1.4780, Wilks' Lambda = 0.15692, p = 0.1697). The only significant difference for BCF was Arsenic ($p < 0.001$) (*Fig. 5*).

Discussion

General characteristics of plants during the phytoremediation process using P. australis

The optimal temperature range for *P. australis* plants is between 12–33 °C, according to Cooper (1996). However, in this essay, the plants were exposed to ambient temperature of 03–42 °C; exceeding by 8 °C the maximum value of said temperature. The temperature had an impact on the oldest leaves, which turned yellowish before wilting, a potential sign of heat stress (Yepes and Buckeridge, 2011). Although plants received consistent watering, the high temperatures affected the structure of substrates, leading to dehydration, compaction and low water availability (Paradelo, 2013).

Substrate characterization

pH was slightly acidic in every treatment, allowing the mobility and retention of As, Cu and Fe, since most metals have better availability at acidic pH (As, Ni, Cu, Fe, Pb) (Wilson et al., 2010; Bolan et al., 2014). Ansari et al. (2014) indicate that Cu solubility increases at pH = 5.5. In this case, the initial and final pH of substrates led to low solubility of Cu and Fe. Plants therefore showed a lower uptake of these metals (Pha et al., 2014); while As mobility increased at alkaline pH, as shown by the pH increase in the substrates, from 6.75 to 8.36 (Bolan et al., 2011). pH increases in this essay did not show significant differences among treatments. This pH increase was due to organic matter (MO) breakdown, the content of N in the sewage sludge, and the rainfall events where water leached some cations, afterwards replaced by acidic elements, such as iron (Valentín-Vargas et al., 2014).

PR is another property affecting metal bioavailability by changing the state of ions. PR value in this essay was low, allowing As, Fe and Cu to be available in the soil, at more soluble forms (Wilson et al., 2010; Bolan et al., 2014).

Heavy metal concentrations in initial substrates (As = 1.61, Cu = 12.411 and Fe = 656.365 mg kg^{-1}) did not exceed the values established by NOM-004-SEMARNAT-2002 (As = 41 and Cu = 1500 mg kg^{-1}). Nevertheless, it is important to minimize the metal content in sewage sludge, since metals have high capacity of bioaccumulation and biomagnification that increase their toxicity in trophic chains (Sabir et al., 2015; David et al., 2012).

Initial concentration of Arsenic in sewage sludge decreased from 1.61 to 0.345 mg kg^{-1}, which is equal to 79.57% removal. Sludge + *P. australis* treatment had the highest removal percentage (83.67%). Among the treatments of sludge and soil + *P. australis;* sludge and soil and sludge + *P. australis* there were no significant differences, indicating that *P. australis*, is not the only factor leading to Arsenic reduction in these treatments. These results were confirmed by the correlation analysis among plants and substrates, where we found a low correlation between the concentration of Arsenic in the substrate and Arsenic concentration in the plant (R = 0.37). However, we found significant differences between the treatment of sludge and soil + *P. australis* mix, and the Sludge treatment. Therefore, the type of substrate and the presence/absence of *P. australis* allowed us to determine that Arsenic removal was impacted by the reduction-oxidation potential; leaching during rainfall events and the mobility of Arsenic at the bottom of pots. The release of Arsenic particles depends on the formation of strong bonds between As particles and soil particles due to PR. In our case, soil aeration produced at low PR, led to a depletion of electron acceptors and the development of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56035617

anoxic conditions forming iron oxides and oxygen hydroxides requiring reduction and dissolution, minimizing the uptake of arsenic from the sludge solution where it can be leached (Elekes, 2014; Punshon et al., 2017).

Initial Cu concentration in sewage sludge decreased from 12.411 to 9.437 mg kg^{-1}, corresponding to an average removal percentage of 79.57%. The treatment of sludge and soil + *P. australis* mix showed a higher removal percentage of 47.67%. We observed significant differences among treatments, due to the type of substrate and the presence of *P. australis.* This is because alkaline pH affects trace elements like Cu, in terms of solubility and bioavailability of the element, besides transportation at soil level (Avci and Deveci, 2013). These results coincide with the reports of Torres et al. (2010), who used similar treatments to remove Cr with vetiver, finding that the most effective treatment was the plant + sewage sludge + organic manure. Canonical correlation was R = 0.482 when comparing Cu present in the substrates versus Cu present in the plants. This result explains the low removal percentage of Cu.

Likewise, in case of Fe, initial concentration of the sewage sludge decreased from 656.36 to 91.90 mg kg^{-1}, corresponding to an average removal percentage of 86.35. Sludge and soil + *P. australis* mix treatment achieved the largest percentage of Fe removal (96.63%). We found significant differences among the four treatments, showing that in the case of Fe, the variables of plant and type of substrate (only sewage sludge or sludge and soil mix) had an impact on Fe removal. Canonical correlation indicated a low negative relation, when Fe decreased in the substrate, Fe increased in the plant (R = -0.408). However, the percentage of removal in substrates was high, maybe due to the leaching of Arsenic and the affinity to form iron sulfide under reduction conditions, such as the conditions found at test substrates. Other reasons might be a pH close to 7 and MO content, leading to low Fe solubility in the soil (Willscher et al., 2017).

Accumulation of As, Cu, Fe in P. australis

The test results showed significant differences among treatments (sludge and soil + *P. australis* mix and Sludge + *P. australis*) regarding Arsenic concentration in the stems and Cu concentration in the leaves. These results may imply that the type of substrate, pH, MO and PR can have an impact on the affinity of these elements towards specific plant organs (Willscher et al. 2017). We found significant differences in metal concentrations along the time, for the sludge and soil + *P. australis* mix (As = 1.96 to 0. 65 mg kg^{-1}, Cu = 25.56 to 14.47 mg kg^{-1} and Fe = 5142.22 to 722.23). The decrease in metal accumulation by the plants from September to January was due to the metals availability, depending on the different physical/chemical properties of substrates (Willscher et al., 2017; Avci and Deveci, 2013), and the variability of such properties, (pH, PR, MO) as a consequence of the sludge addition before the first sampling in September. This addition modified As, Cu and Fe concentrations, as well as the substrate characteristics (like it happened when mixing sewage sludge and soil), enabling better uptake of the three metals. The treatment sludge + *P. australis*, did not have any significant differences along the sampling months. We attributed this to the reports by Torres et al. (2010), indicating that the addition of the same substrate, in this case sewage sludge, does not imply a higher rate of metal uptake by the plants.

Plant tolerance to heavy metals like As, Cu and Fe is due to the fact that these metals are transition metals with oxidizing capacity, as well as with an the capacity to reduce different biomolecules (Choppala et al., 2014). Therefore, these effects in the reduction-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56035617

oxidation state of the cells enhanced due to the bonding reaction of these metals with biomolecules. This capacity can explain that the average concentration of As, Cu and Fe in the organs of *P. australis* in dry weight. These elements, (As: 0.61, Cu: 11.56 and Fe: 1420.99 mg kg^{-1}) were found within the typical ranges in plants reported by Larcher (2003) = Cu: 4 – 20 but not typical for Fe: 2 – 700 mg kg^{-1}. Although Cu is within the typical value range, it exceeds the value required by plants, just like Fe (1 – 5 mg kg^{-1} Cu and 100 mg kg^{-1} Fe).

As, Cu and Fe accumulation was found in certain plant organs. We found accumulated arsenic in the leaves (0.497 mg kg^{-1}). These results do not coincide with literature reports. *P. australis* belongs to the Poaceae family, characterized for having a great deal of roots promoting the accumulation of trace elements like As (Desjardins et al., 2018). According to Zhang et al. (2009) reports, there was an increase of As the roots of *Phragmites communis* (Trin., 1763).

Metals accumulated in the following order: root > stem > leaf. Higher concentration in the roots is due to the uptake of elements from the substrate, whereas the low concentration found in the stems may be due to their function as carriers of nutrients and minerals from the soil to aerial parts (Avci and Deveci, 2013).

BCF was determined in order to assess the accumulation efficiency of As, Cu and Fe by *P. australis.* For Fe and Cu the values were greater than one, in sludge and soil + *P. australis* and Sludge + *P. australis* treatments, during the two sampling months. These data indicates that *P. australis* is a hyper-accumulating species of these two metals, following the criterion established by Baker and Brooks (1989). The discrimination analysis showed that there were no significant differences in the BCF of Cu among the sampling months. However, the Sludge + *P. australis* treatment had a slightly higher value, indicating that Cu uptake efficiency is better in soilless substrates. The reason is the changes in the substrate characteristics, such as the pH increase and the bonding affinity of metal particles to the substrate (Avci and Deveci, 2013). In the case of arsenic, BFC value changed along the time and the treatments. We observed significant differences in this metal among different months and treatments, which can be attributed to leaching, and may be also to the chemical similarity between P and As contents in the substrate, as mentioned by Yan et al. (2017); Escutia-Lara and Lindig-Cisneros (2012). The roots were not able to uptake arsenic and the presence of other metals reduced the accumulation capacity of arsenic, coinciding with the reports of Desjardins et al. (2016).

BCF value for Cu (2.03) in *P. australis* was higher, compared to the reports from other species, including *Malva parviflora* (0.85), *Datura stramonium* L. (0.79), *Citrullus colocynthis* L. (0.84), *Lycium shawii* (Roem and Schult., 1990) (0.94) (Ibrahim et al., 2013). BCF value in Fe (7.38) was higher in *Elodea canadensis* (Michx.) (3.93), but it was lower, compared to *Polytrychum commune* (Hedw.) (0.9) and *Spirogyra* sp. (Link.) (10.25) (Busuioc et al., 2012). In both cases, Cu vales depended on the species, type of substrate, pH, PR and metal bioavailability (Desjardins et al., 2018; Ezeudo, 2014).

The translocation factor determining the capacity of metals to move from the roots to aerial parts was higher for arsenic (5.76 > 1), showing that Arsenic has great capacity to move into the leaves. This capacity can be the result of physiological factors of the species. *P. australis* has an extensive root system that can favor Arsenic permeability. Furthermore, this plant has the capacity to accumulate and transfer Arsenic from the roots to aerial parts (Yan et al., 2017). With regards to Cu (0.23) and Fe (0.17) TF

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56035617

values were smaller than one, indicating that these metals are not easily taken to *P. australis* aerial parts. According to Padmavathiamma and Li (2009), immobilization may be due to metal scavenging by the vacuoles or by the cell wall in the roots, inhibiting the interaction with high molecular weight compounds of the cytoplasm.

Conclusions and recommendations

-The order of heavy metals removal by *P. australis* was the following: Fe > Cu > As
-pH, PR and MO affected the mobility and availability of As, Cu and Fe.
-*P. australis* is a tolerant species capable of accumulating large concentrations of Fe and Cu in its organs, according to the following order: root > stem > leaf.
-The values of high BCF and low TF indicate that *P. australis* is a plant species that can be used to phytostabilize substrates polluted with Fe and Cu.

In the process of phytoremediation metal removal was observed not attributed to the plants so it may be appropriate to carry out leaching tests such as the Tessier scheme, in the waste sludge, soil and mixture in order to identify if it is because of these processes that decrease the concentration of metals in the waste sludge.

Abstract. As climate change is forcing plant species to migrate northward and upward, it is important to know how species' vegetative traits and reproductive success vary along different climatic conditions. We aimed to examine the impact of elevation on the morphological and reproductive characteristics of *Cephalanthera rubra* in four different altitudes in Hungary: in a lowland oak forest (103 m), and in the beech forests of the Bükk-mountains (361 m, 533 m, 657 m). We counted the number of leaves, flowers, and fruits, and measured the height of each plant with the length and width of all leaves. Linear, negative binomial, and quasipoisson regressions were used to compare the populations. Our study has shown that the lowland and mountain populations of *C. rubra* are sharply different regarding their life history strategy and reproductive success, and altitudinal effects can be found only in the mountain populations. The number of flowers depends strongly on the vegetative production (height and leaf area) of the plants, but at the same time, the area that facilitates greater vegetative production - possibly because it also facilitates species with better competitiveness, and it is less favorable to its mimicked partners - were less beneficial in terms of fruit production.
Keywords: *Orchidaceae, elevation, Hungary, height, leaf size, floral display, pollination success*

Introduction

Extreme weather phenomena are becoming more and more frequent all over the world (WMO, 2011; Rahmstorf and Coumou, 2011; Coumou and Rahmstorf, 2012), which suggests that climate change is not just a future threat but is also an accelerating process in the present. The impacts of climate change can be detectable at different levels (e.g., community (Woodward et al., 1998) in species (Johnston and Schmitz, 1997), in population (Cochrane et al., 2014)) and they have already been examined on various aspects (mainly distribution (Parmesan and Yohe, 2003; Thuiller et al., 2005; Molnár V. et al., 2011) but also in survival, phenology (Fitter and Fitter, 2002; Morellato et al., 2016) or reproductive success (Ackermann, 1989; Aizen et al., 2002))

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

of many different species or communities (Parmesan and Handley, 2015; Molnár, 2015). Understanding the species' answer to this changing environment is extremely important in the case of plants, as their primary productive role is one of the essential components of almost all ecosystems on the Earth. In the context of this, the phenological or reproductive changes in the vegetation or populations may be the primary mediators for these effects on fauna and humankind (Parmesan and Hanley, 2015).

Orchidaceae is the largest family of flowering plants, incorporating almost 10% of all flowering plants, approximately 880 genera (Chase et al., 2015) and 20-30.000 species (Chase et al., 2003; Pillon and Chase, 2007). Simultaneously, it is one of the most vulnerable plant groups (Pridgeon, 1996; Scotland and Wortley, 2003; Clemente, 2009).

In general, global warming compels plants to migrate to higher latitudes and altitudes, searching for new, suitable habitats (Lenoir et al., 2008; Engler et al., 2011; Chen et al., 2011), which makes boreal and alpine vegetation and populations extremely vulnerable (Thuiller et al., 2005). Orchid populations showed a similar behaviour: in the planar region, they moved upward or poleward during the warming period (Jackson et al., 1987), while species in the mountain area with mild slopes, migrated upward along the elevation gradient (Thompson, 1990).

Availability of light and moisture is also affected by the changing climate. Orchids are known to be very sensitive to the change in the environmental factors (Fitter and Fitter, 2002; Seaton et al., 2010), and although they can tolerate slight variations in temperature and light, climate change of the last decade have forced them to migrate to more suitable places (Barman and Devadas, 2013).

During the last ca. 30 years, an increasing number of European terrestrial orchid species have experienced habitat loss (Barman and Devadas, 2013), population reduction and increased risk of extinction, thus they cannot keep pace with the climate change (Root et al., 2003; Thomas et al., 2004).

On the other hand, extreme rainfall can accelerate erosion (Selby, 1976), and an increased degree and frequency of erosion may negatively affect also the populations of orchids which live on hills (Barman and Devadas, 2013).

However, considering the life strategy components (individual survival and reproductive success) and their responses and vulnerability to biotic and abiotic environmental conditions, maintaining the highest fertilization rate is the most crucial factor for the species' survival, which highly depends on the pollinators (Tremblay et al., 2005). The flowering of orchid species and the temporal harmonization with their pollinators are the result of fine coevolution processes, leading to a high variety of flower structure and adaptation to pollination in this family, which are often in the focus of researchers (Darwin, 1984; Tremblay et al., 2005). This harmonization, as well, as directly the survival or flower/fruit production of the plants can be harmed due to climate change (Hegland et al., 2009), based on the fluctuation and change in temperature (Barman and Devadas, 2013) which is one of the main drivers of insect and plant phenology (Forest and Thompson, 2011), but we do not have enough information yet to predict the magnitude and direction of this.

To examine the potential response of morphological and phenological traits of orchids to climate change, in our study we focused on the morphological variability of a *Cephalantera* (Orchidaceae) species between four Hungarian populations living on different altitudes. One characteristic of this group is that various breeding and reproductive strategies are present in it (Scacchi et al., 1991). In the genus, there are 15

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56195639

food deceptive species, most of them are generalized food deceptive (Jersáková et al., 2006; Renner, 2006), but there are some species (e.g., *C. rubra* and *C. longifolia*, which also live in Hungary), which specifically imitate a special nectar producing group with Batesian mimicry. *C. longifolia* imitates *Cistus spp.* (Dafni and Ivri, 1981a,b) and *C. rubra* imitates *Campanula spp.* (Nilsson, 1983a). Deceptive species are strongly pollinator-limited, so that their fruit set is usually lower, than in the case of the nectar producing species (Tremblay et al., 2005). To increase the odds of the pollination, the flowering period of the generalized food deceptive species starts earlier, so that they could lure the naive pollinators (Pellissier et al., 2010a). According to Sonkoly et al. (2016), however the fruit number is low, they contain more seeds in general, as a compensation, and the gene flow is also found to be stronger within the populations than in the case of their nectar-producing relatives (Cozzolino and Widmer, 2005).

In Hungary, three species of the genus can be found: *C. damasonium* (Mill.) Druce, *C. longifolia* (L.) Fritsch, and *C. rubra* (L.) Rich (Tutin et al., 1980; Molnár, 2011). Although they frequently share the same habitat (beech forest), they show different morphological characters, as well as some differences in the flowering period (*C. rubra* flowers approximately 20-30 days later than the other two) (Scacchi et al., 1991). All of them are rhizomatous, perennial plants, but while *C. longifolia* is a typically outbreeding species, and *C. damasonium* is generally considered as an inbreeder (Summerhayes, 1985). *C. rubra* is an outbreeder which frequently reproduces vegetatively. In this latter case, a reduced ratio of plants germinated from seeds has been observed, while the number of plants originated from adventitious buds on the primary roots can be considerable (Ziegenspeck, 1936).

Considering this interesting variability in breeding systems and success, we chose *Cephalanthera rubra* to examine the impact of elevation (indirectly the temperature and precipitation) on the population's morphological characteristics, fecundity and reproduction strategy to predict the effects of the increasing temperature on this rare, endangered species.

C. rubra is a rhizomatous, perennial plant. The 4-10 pink flowers appear on a flexible flowering stalk, between June and at the beginning of July. *Chelostoma campanularum* and *Ch. fuliginosum* (Megachilidae) were reported as the main pollinators of the species (Nilsson, 1983b; Szlachetko and Skakuj, 1996; Newman et al., 2007).

The above-mentioned, relatively unrefined mechanism and the method of attracting pollinators by deception can explain, why most *Cephalanthera* species produce few ripe capsules and it gives the hypothesis that the populations are probably maintained and propagated mostly vegetatively (Delforge, 2006).

However, in the case of *C. rubra*, studies focusing on the reproduction strategy are ambivalent: on the one hand, the reproduction from seeds is considered to be dominant and vegetative propagation is sporadic (Kaźmierczakowa and Zarzycki, 2001), but in Italy a study showed that plants germinated from seeds were rare (Scacchi et al., 1991). According to Scacchi et al. (1991), *C. rubra* is an outbreeder, but at the same time, some results are showing that this species can frequently reproduce vegetatively.

As for the habitat, *Cephalanthera rubra* lives in 0-2000 m altitude, typically in scrubby grasslands, woodland margins, warmer calcareous beech forests, and oak forests. It prefers to grow in calcareous or slightly acidic soils in shaded or semi-shaded light conditions (Delforge, 1995; Vakhrameeva et al., 2008).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56195639

The distribution area of *Cephalanthera rubra* extends from Northern Europe to Iran and North-Africa (*Fig. 1a*). The northernmost localities were found in southern Finland, where according to Tuulik (1998), the plant is infrequent and flowers very rarely. In Poland, the middle of the European distribution area of this species is known from approximately 300 localities, but only half of them have been confirmed (Kaźmierczakowa and Zarzycki, 2001). In the European Region, the populations are found throughout the temperate regions and in parts of the Mediterranean, extending from the Atlantic to the Caspian Sea. It lives in every altitude in Hungary, from planar to mountain regions. Most of the populations are found in the Transdanubian Mountains, Mecsek, North Hungarian Mountains and in the Danube-Tisza interfluvial region (Molnár, 2011) (*Fig. 1b*).

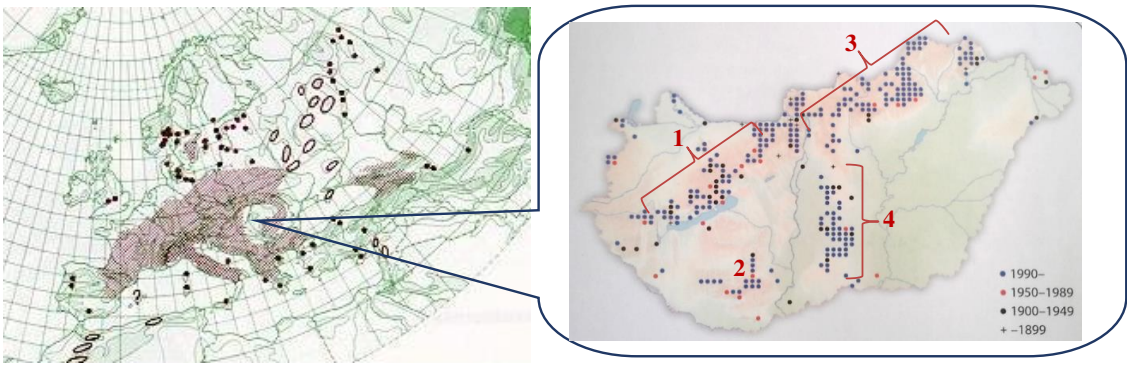

***Figure 1. a** Distribution of C. Rubra (http1) and **b** in Hungary (Molnár, 2011). 1: Transdanubian Mountains; 2: Mecsek; 3 North Hungarian Mountains; 4: Danube-Tisza interfluvial region*

Although the species is widespread and often abundant, its distribution appears in small, isolated and severely fragmented populations and becomes rare in the margins of its distribution. The populations usually comprise 1-20, very occasionally more than 100 plants (Brzosko and Wróblewska, 2003). The size of the population is suspected to be declining, and many sites have already been lost (Delforge, 1995; Lang, 2004; Newman et al., 2007; Vakhrameeva et al., 2008; Harrap and Harrap, 2009).

The IUCN degree of threat of this species on the Red List of the Vascular Flora of Hungary is Least Concern (Király, 2007). Many populations have been lost and declined due to inappropriate site management, lack of pollination, forest fires, deforestation for building and construction work purposes as well as plant collection. In addition, populations may be genetically depauperate as this species can form clonal populations (Micheneau et al., 2010). However, the species occurs in numerous European countries with less threat in some; therefore, the risk of extinction at the European level is low, and *Cephalanthera rubra* is assessed as Least Concern (Rankou, 2011).

Jakubska et al. (2014) have investigated the extinction of the *Cephalantera* species in Poland during the last 120 years, and conclude that their decline cannot be attributed to global change (climate warming or nitrogen deposition) as the shift took place in the first half of the 20th century. They suggest that the species decline should rather be explained by changes in land use, including alteration of deciduous forests into coniferous monocultures, as well as by intensification of agriculture.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56195639

In Hungary, the declining degree of the species is 22% (Molnár, 2011.) Some of the main reasons behind the disappearance of the species are those processes which are leading to increased shading of the forest floor (Brzosko and Wróblewska, 2003).

Regarding the predicted future changes, the Pannonian region is highly vulnerable: according to Thuiller et al. (2005), the expected species turnover in this area is about 66% which means a substantial species loss (migration to north) but also a huge species gain from the eastern Mediterranean region. Based on this, it is essential to examine the opportunities and behaviour of the Hungarian populations.

Materials and methods

Study sites

In this study, we examined four Hungarian populations in different altitudes (*Fig. 2*): One in the planar region (Jászfényszaru (J), 103 m), and three from different elevations of the Bükk-mountains: Kis-Oltár (KO, 361 m), Bikk-bérc (BB, 533 m), and Pongorlyuk peak (PP, 657 m).

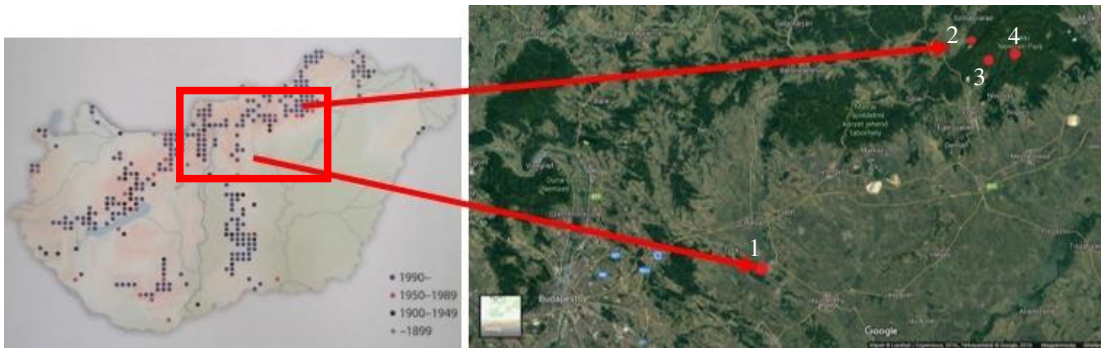

Figure 2. *Habitats of the examined populations in Hungary (Molnár, 2011; GoogleEarth, 2018). 1: Jászfényszaru; 2: Kis-Oltár; 3: Bikk-bérc; 4: Pongorlyuk peak*

Populations on the Bükk-mountain

The Bükk-mountain is located in the North Hungarian Mountains. We examined three populations living here, at different elevations. The soil of the study sites are brown forest soil on limestone bedrock. The annual average temperature is about 2 °C below the national average, only 7-8 °C, while on the highest part of the Bükk plateau it is even lower, only 6 °C.

Because of the continental effect, winter is cold (average temperature in January is -4 °C), the number of snowy days are the highest in the country. Summer is warm, frequently rainy at the beginning of July and the end of August. The distribution of annual precipitation is also affected by continentality. There are two precipitation maximums, one in the early summer and one in the autumn. The annual rainfall is 600-700 mm, and 800 mm on the Beech plateau. Based on data of MetNet (http2), the Walter-Lieth climate diagram (*Fig. 3*) represents the average climate of the study areas in the Bükk-mountain in 2018.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56195639

It is noticeable that there were three wet periods: at the end of the winter, at the end of February and at beginning of March, when the snow melts; also in June and in September.

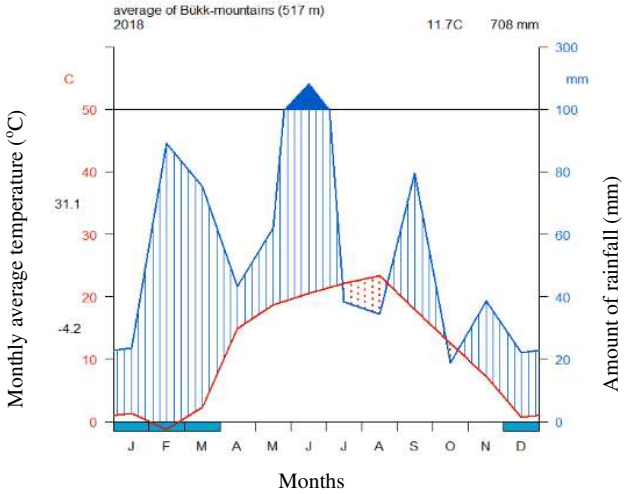

Figure 3. *Walter-Lieth climate diagram of the Bükk mountain in average for 2018*

Our three examined populations situated in Medio-European limestone beech forests of the *Cephalantero-Fagion* (Natura 2000 habitat category is 9150). All their habitats can be found in light-spotted, mostly flat, bit rocky places. The shrub layer (because of the forestry activity) and the herbaceous layer are not dense, so that the amount of light, which reaches the surface is quite a lot.

The habitat of the Jászfényszaru population

The town of Jászfényszaru is located in the Great Plain, on the sub-region called Hatvani Plane. Its climate is moderately warm and dry, the dominant soil type is pise and chernozem brown forest soil on calcareus sand at the study site.

The annual average temperature is about 11 °C. The number of sunny hours is high.

Due to the characteristics of the continental climate, distribution of precipitation shows extremities within, and also between years (MNDI, 2010). The Walter-Lieth climate diagram (*Fig. 4*) represents the climate of the study area in Jászfényszaru in 2018. It was made from the online data through MetNet and were drawn in RStudio program by us. As it can be seen, there were two humid periods: in February and in the middle of June.

The examined population is situated in Euro-Siberian steppic woods with *Quercus robur* (Natura 2000 habitat category is 91I0). It is found in the pedunculate oak forests, with high density of herbaceous- and shrub layers. The terrain is flat, as it is typical in the Great Plain.

Data collection

In our study, we examined the four populations two times in 2018. First, in the flowering period, in May-June we counted and marked all (J: 100, KO: 22, BB: 85, PP: 27) individuals by recording their GPS coordinates and we counted the number of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56195639

flowers, the number of the leaves, and measured the height of each plant and the length and width of all leaves. On the second occasion, in July-August, we counted the fruits of the same plants in the cases of three populations, but in the PP population (on the highest altitude), we did not have fruit data from 10/27 plants, partly because they had not started the fruiting period yet or the fruiting stems were consumed by animals.

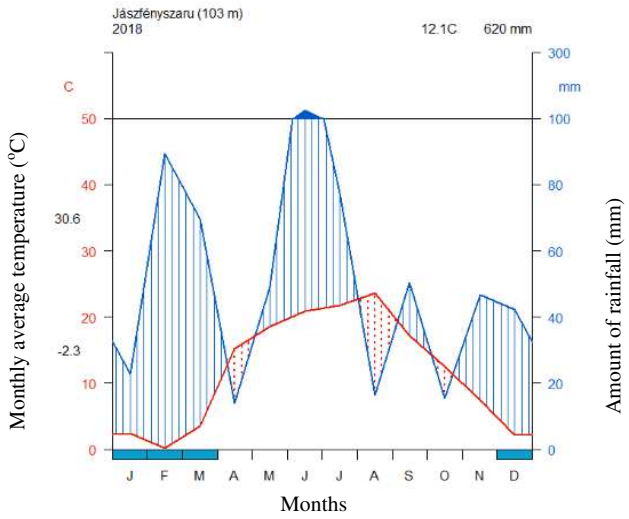

Figure 4. *Walter-Lieth climate diagram of Jászfényszaru for 2018*

Data analysis

Statistical analysis was made in R statistical software (R Core Team, 2017). The boxplots, scatterplots, and histograms which were used to visualize our data were made with the ggpubr package (Kassambara, 2017).

One-way analysis of variance (ANOVA, on the log-transformed height and leaf size data, lm function (R Core Team, 2017)), negative binomial regression (on the number of flowers and fruits, glm.nb function of the MASS package (Venables and Ripley, 2002)), and quasipoisson regression (on the number of leaves, glm function (R Core Team, 2017)) were used to compare the populations. Differences between the populations were tested with post-hoc analyses based on Tukey all-pair multiple comparisons, using the glht function of the multcomp package (Hothorn et al., 2008).

Results

Growth-related traits

Height

The average height of the plants was 29.44 centimeters, the highest individual (71 cm) was found in the lowest altitude (J), while the shortest individual (5.8 cm) was found at the highest altitude (PP) (*Fig. 5*). The average heights showed the same pattern: while the mountain populations looked similar, the average height of the plants in the Jászfényszaru population was (almost two times) greater (*Fig. 5b*).

This difference was found to be significant ($p < 2.2e\text{-}16$; *Table A1* and *Fig. A1* in the *Appendix*): according to the pair-wise comparisons, at the lowest altitude (J), the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56195639

expected average height of the plants is 2.125 (95% CI: [1.8; 2.5]) times higher than in the BB population, and even 1.79 (95% CI: [1.4; 2.3]) and 1.86 (95% CI: [1.5; 2.3]) times higher than in the KO and PP populations. The three mountain populations did not differ from each other (*Table A1*).

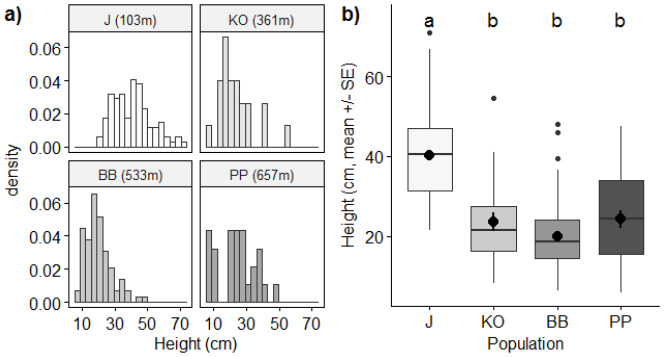

Figure 5. *Histogram (a) and bloxpot (b) based on the height in the examined populations. Significant differences are indicated by different letters*

Leaves

The average number of the leaves was 4.7, the most leaves (10 pcs) were found on an individual in J population, while the less (2 pcs) were found in the BB population. The number of leaves per individual showed a similar pattern (*Fig. 6*) as the heights of the plants (*Fig. 5*): individuals living at the lowest (J) altitudes had more leaves (*Fig. 6b*), however, in this case, only the J-BB, J-KO and PP-BB population pairs differed significantly ($p < 0.001$; *Table A2*) from each other.

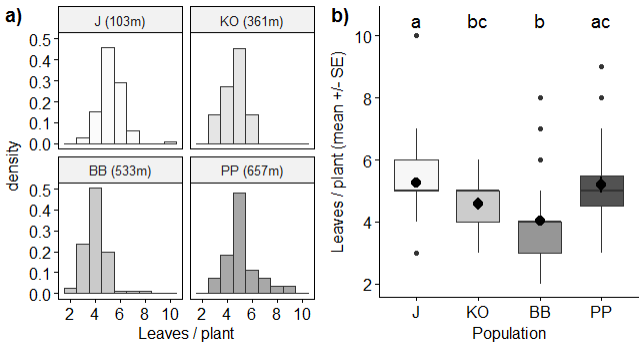

Figure 6. *Histogram (a) and bloxpot (b) based on the leaves/plants in the examined populations. Significant differences are indicated by different letters*

Regarding the estimated leaf size index (sum of the all leaf's lengths × leaf widths per individual), our populations looked more similar (*Figs. 7* and *A1*). Again, only the J population showed a significantly higher average value than the others ($p < 0.001$; *Table A3*), which were not different from each other.

Summarizing the results regarding the growth-related traits of our populations, we can state that at a lower altitude (J population) the plants showed significantly longer stems, bigger- (*Fig. 5*) and a higher number (*Fig. 6*) of leaves. The three mountain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56195639

populations looked more similar, but because in some cases the BB population showed less production, the KO-PP population pair is considered to be the most similar regarding the growth-related traits.

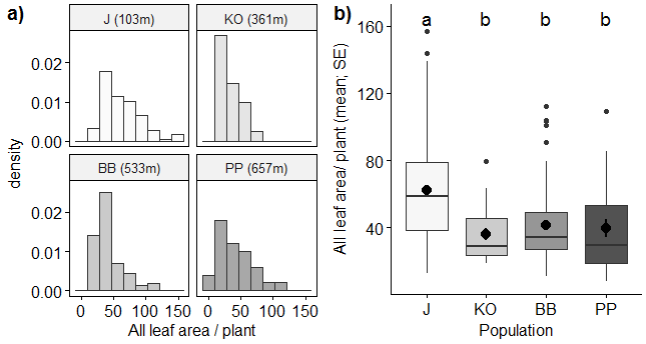

Figure 7*. Histogram (a) and bloxpot (b) based on the all leaf area/plants in the examined populations. Significant differences are indicated by different letters*

Reproduction-related traits

Flowers

The average number of the flowers was 4.5, most of the flowers (20 pcs) were found on an individual in J population, while the fewest (0 pcs) were found in the PP and BB populations. According to the average number of flowers per individual, we did not find huge differences between the four habitats (*Figs. 8* and *A1*), but the pattern is similar to that regarding the number of leaves (*Fig. 6*). The negative binomial regression showed significantly fewer flowers at the BB populations than in the J and the PP populations ($p < 0.001$; *Table A4*): The expected average flower number/individual is 1.84 times (95% CI: [1-38; 2.44]) and 2 times (95% CI: [1.35; 3,01]) times higher in the J and the PP populations than in the BB population.

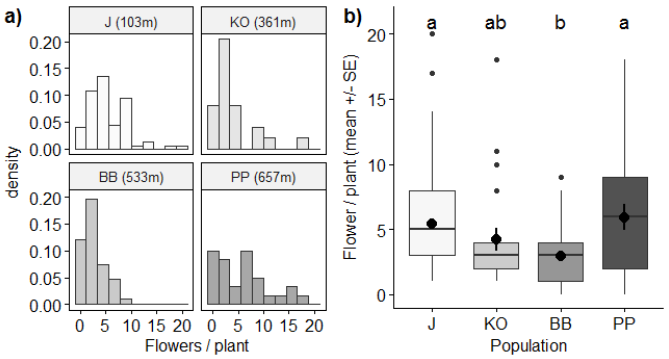

Figure 8. *Histogram (a) and bloxpot (b) based on the flowers/plants in the examined populations. Significant differences are indicated by different letters*

Fruits

The average number of the fruits was 1.15, the most fruits (18 pcs) were found on an individual in KO population, while individuals with no fruits were found in all of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56195639

four examined populations. Although we found a little bit more flowers per individual in the J and PP populations (*Fig. 8*), these two populations showed the least amount of fruits (in average) because there were plenty of plants in these habitats which had no fruit at all (*Fig. 9*). On the other hand, in the KO population, there was a plant which had an extremely high amount (18) of fruits compared to the others. Due to this outlier, the fine differences between the populations cannot be visible on the figures (*Fig. A2*), thus for the better visibility, we eliminated the outlier from *Figure 9* (but not from the model).

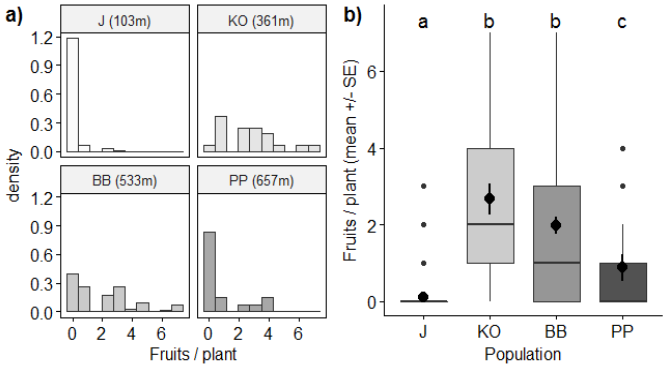

Figure 9. *Histogram (a) and bloxpot (b) based on the fruits/plants in the examined populations. Significant differences are indicated by different letters*

According to the model and the pair-wise comparisons, except the KO-BB population pair ($p = 0.177$; *Table A5*), all population-pairs were different considering the average number of fruits/individuals ($p < 0.002$; *Table A5*). It is visible from these results and the figure (*Fig. 9*) that the population in Pongorlyuk-peak also had a significantly higher average fruit/individuals number than the Jászfényszaru population.

Based on the reproduction-related traits, the J-PP population pair seems to be the most similar, but the KO-BB population pair also behaves similarly (*Fig. 10*).

Correlations

From the results mentioned above, it is easy to see that the growth-related traits (height, leaf size, and leaf number) should be highly correlated with the number of flowers: the populations with higher plants (*Fig. 5*) and bigger leaf surface (*Fig. 7*) had a little bit more flowers (*Fig. 8*), but this does not increase the expected number of fruits (*Fig. 9*).

On the other hand, we checked the relationship between the growth-related traits and the number of flowers within the populations, too. In this case, both the heights (*Fig. 11a*) and the size of the leaves (*Fig. 11b*) showed a good correlation with the number of flowers, but there are some differences between the populations: the height of the plant shows a stronger relationship with the number of flowers in the cases of the KO and BB populations.

Considering the impact of the flower number on the number of fruits, *Fig. 11c* shows that in the cases of the mountain populations, the size of the inflorescence does not have impact on the number of the fruits. Although, in the J population, only individuals with

DOI: http://dx.doi.org/10.15666/aeer/1703_56195639

more than 10 flowers succeeded to produce any fruits and above this threshold, the number of fruits is highly dependent from the number of flowers.

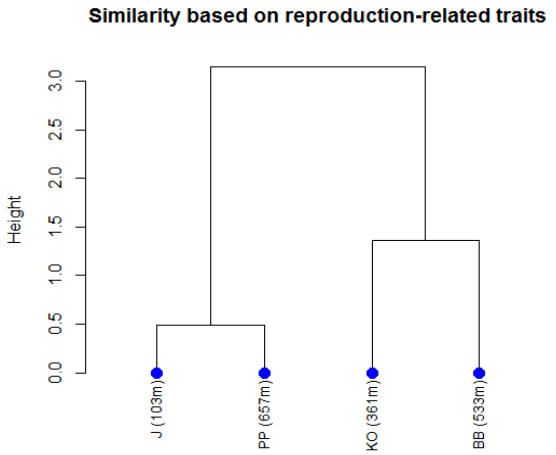

Figure10. *Similarity based on reproduction-related traits*

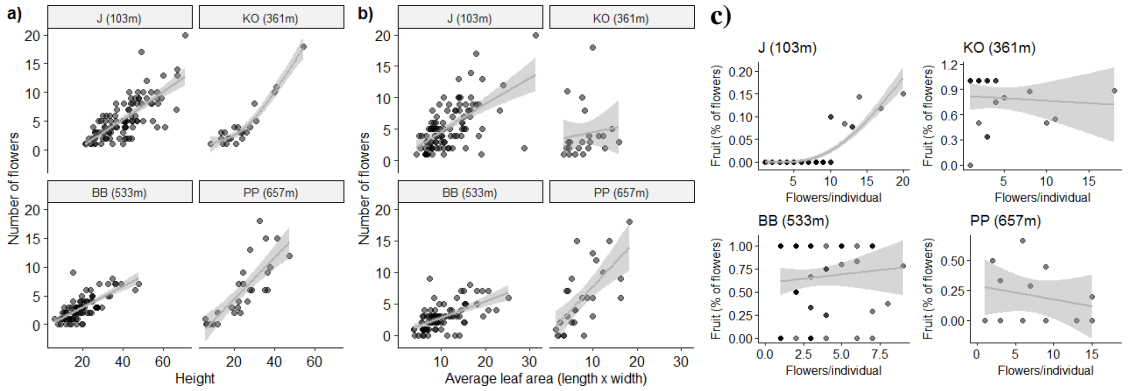

Figure 11. *Relationship between the growth-related traits and the number of flowers (a-b) and the impact of flower number on the fruit/flower ratio (c) within the different populations*

Discussion

Latitudinal and altitudinal range shifts have been already reported for many plant species, as the borders of the vegetation zones are moving to the north and increasing in the mountain regions due to climate change (e.g., Chen et al., 2011) or other factors like land use change (e.g., Bodin et al., 2013; Jakubska-Busse et al., 2014). Recently, it is a central challenge to predict future changes in the environment, the communities and the way how different species will adapt or not to the new environmental conditions of the future.

Examining populations of the same, widespread species or a given community in different latitude or altitude can give us valuable data about the species' requirements and adaptation capability; thus future tendencies can be predicted better. E.g., recent studies have shown, that individuals of a species usually become shorter with increasing altitude due to the decrease in temperature (Bjorkman et al., 2018), vegetative reproduction can become more important on higher altitudes (Young et al., 2002) and,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56195639

however, most montane plant species will profit from the increasing temperature (e.g., general food-deceptive orchids (Pellissier et al., 2010b)), high-elevation, cold-adapted plants are more vulnerable (Rumpf et al., 2018).

In our study, we chose Cephalanthera rubra, a widespread terrestrial orchid to see how its vegetative and reproductive traits change with altitude. The species inhabits semi-shade forests up to 2.000 m (Delforge, 2006), and although we do not have too much information about its altitudinal shift, Jakubska-Busse et al. (2014) found that in Poland the plant's populations moved upwards in the first half of the previous century, most probably due to land-use change. A bigger problem is that the number and size of the populations are usually small and continuously decreasing (Brzosko and Wróblewska, 2013, 2003; Scacchi et al., 1991), and the reproduction success is low (Brzosko and Wróblewska, 2013; Vakhrameeva et al., 2008), as it is in the case of every food-deceptive terrestrial orchid (Tremblay et al., 2005), which leads to low genetic diversity (Brzosko and Wróblewska, 2013; Scacchi et al., 1991), so a higher vulnerability of the populations.

In this study, we examined four populations at different altitudes. As the temperature is decreasing with increasing altitude, we expected a decrease also in height, flowering and fruit production on higher altitudes.

Although a continuous decrease in height could not be visible in our data, at the lowland (Jászfényszaru) habitat, the plants had significantly higher stems and bigger leaves than the individuals living in the Bükk-mountains, which were similar in height. On the other hand, the ratio of the flowering individuals decreased with the altitude: at the lowland habitat and the lowest mountain habitat, 100% of the examined specimens had flowers, while the flowering decreased to 90% and then to 81.5% at the highest altitudes. The decreasing temperature with increasing altitude can partially explain the flowering pattern, but light conditions can also have an impact on it. While at the lowland habitat, the canopy coverage was about 75-90%, at the mountain habitats it was above 90%, except a fifth of the lowest mountain habitat, where due to some tree-cutting, the light conditions were temporarily better than at the other two.

It is known that the species' populations and reproduction show high sensitivity to increased shading (Vakhrameeva et al., 2008; Fay and Taylor, 2015), however, the plants can get about 26% (SD = 11%) of their carbon needs from their mycorrhizal partner (Bidartondo et al., 2004), which make them moderately tolerate to shady conditions. In contrast, open habitats provide more light, - thus energy – to grow and flower, but also an increased competition which is also suspected to be disadvantageous to the plant (Fay and Taylor, 2015). It also must be noted that although the height and leaf area are considered to be a good proxy for condition and flowering capability, in the case of rhizomatous or tuberous orchids, these vegetative traits can affect more the flowering of the next year than the given year (Jersáková and Kindlman, 2002). E.g., Janečková et al. (2006) found that in the case of another nectarless orchid, *Dactylorhiza majalis*, the leaf area of the previous year was the best predictor of the flowering of the plants in the current year. Furthermore, although the leaf area in the given year was correlated with the height of the plant, it was affected mainly by the leaf area of the previous year (via carbohydrates stored in the tubers), while the stalk's heights could be explained more by the temperature and precipitation.

Based on these literature data, it seems that at the two lowest examined populations, the temperature and light were enough previously to all plants to produce flowers, while the more shady habitat of the highest mountain populations probably could not provide

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56195639

enough energy to make all plants flower. However, it must be noted that these decreased flowerings are still extremely high compared to the literature data which implies that the plants of these populations were in good condition in this year.

Considering the number of flowers, although there was a similar - but not significant - decreasing pattern at the three lowest habitats with the altitude, the population of the highest altitude showed more flower per individual than the expected. The ratio of fruiting individuals also showed a decrease with the altitude in the case of the mountain habitats, but was much less at the lowland habitat, and the fruit number showed a reverse pattern compared to the flower number: the lowest and highest populations – which had the most flowers on average - had the least fruits per individual in general.

Deceptive orchids are strongly pollinator- and pollen-limited and their reproductive success is generally low (Tremblay et al., 2005). *C. rubra* is a mimicking food-deceptive orchid which mimics the flowers of the *Campanula* spp. (Nilsson, 1983b; Szlachetko and Skakuj, 1996; Newman et al., 2007), and although the species is completely self-compatible, spontaneous autogamy has not been observed yet (Tałałaj et al., 2017), thus reproductive success highly depends on the presence and abundance of its pollinator and mimicked species too. The observed pollinators (*Chelostoma fuliginosum* (Claessens et al., 2015; Newman et al., 2007), *Ch. campanularum* (Nilsson, 1983b, but see Newman et al., 2007), and *Miarus campanulae* (Claessens et al., 2015)) are highly related to *Campanula* spp. Furthermore, *Chelostoma* species also need standing dead trunks as a nesting place.

The habitat of our lowland population has a more open canopy, which could lead to a higher irradiance but also a higher herb competition which can decrease the visibility, thus the probability of the pollination. In a habitat like this, being taller and having more flowers can be a good strategy, especially because the abundance of the mimicking species is low at the neighborhood; thus pollinator abundance should also be low. Competition for the small number of pollinators can explain, why only the striking, high, and multi-flowered individuals showed remarkable pollination success (Kindlmann and Jersáková, 2006; Suetsugu et al., 2015) and it can lead to a more frequent vegetative reproduction as well. A higher frequency of vegetative reproduction may also be suggested by the fact, that this population contained much more individuals than the other examined populations.

The mountain populations had a higher abundance of *Campanula persicifolia* and *Campanula trachelium* nearby. The *Cephalanthera rubra* specimens showed shorter stems than in the lowland population, and also a decrease in flowering and fruiting individuals with the altitude. The reproduction success of the two lowest mountain populations was extremely high (83-85% of the flowers turned into fruits), while the Pongorlyuk-peak population, on the highest altitude, had a little bit more flowers but significantly fewer fruits (about 40% of the flowers turned into fruits). These results suggest that these areas are more suitable for the species, except at the highest altitude, where possibly the temperature or the irradiance is not enough to mature the fruits. On the other hand, it is worth mentioning, that the low number of fruits here does not necessarily mean low pollination success. It is also possible that the low number of fruits/individuals is attributable to the stronger herbivory pressure or some infections, as it is suggested by the fact that we have found several damaged shoots in the area.

Conclusions

Our study has shown that the lowland and mountain population of *C. rubra* are sharply different regarding their life history strategy and reproductive success, and altitudinal effects can be found only in the mountain populations.

The number of flowers of *C. rubra* depends strongly on the vegetative production (height and leaf area) of the plants, but at the same time the area that facilitated greater vegetative reproduction - possibly because they also facilitate species with better competitiveness and less favorable to its mimicked partners - were less beneficial in terms of fruit production.

To predict the expected population dynamics, trait distributions and vulnerability of the species it is important to continue the monitoring of the examined populations and combine the results with genetic examinations.

Abstract. Stevia is a perennial plant and is well-known for its high content of steviol glycoside in dryleaf matter that is responsible for providing the non-caloric value sweet taste. Stevia rebaudiana leaves contain diterpen glycosides, which are about 250 to 300 times more sweetened than sucrose, and their sweeteners are widely used today in the food and pharmaceutical industries. In order to study the effect of mycorrhiza fungi on some growth characteristics of the stevia herb in inoculum conditions with mycorrhizal fungus, a factorial experiment based on randomized complete block design with four replications was conducted in greenhouse of Mohaghegh Ardabili University in 2016. The first factor was Imma & Angel and Novella nutrient solutions, the second factor was planting bed including leaf composts, vermicompost and biolan (peat & perlite) and third factor Inoculation with mycorrhiza and control fungi showed that the highest fresh and dry weight of leaves and number of number of leaves to the Imma & Angel nutrient solution in vermicompost planting bed under inoculation with mycorrhiza. The highest plant height was related to the Imma & Angel nutrient solution in leaf composts planting bed was observed under inoculum with mycorrhiza and the highest chlorophyll content was observed for Novella nutrient solution in vermicompost planting bed under inoculation conditions with mycorrhiza.
Keywords: *Stevia, biofertilizers, hydroponic, mycorrhiza*

Introduction

Stevia rebaudiana Bertoni (Asteracea family) is a herbaceous, perennial and indigenous herbaceous plant in Paraguay and Brazil and its leaf is used as a calorie-free natural sweetener for diabetic patients and for the prevention of obesity (Garana et al., 2010). Stevia has high nutrient requirements, especially N, P and K, and the lack of these elements has a major constraint on the quantity and quality of biomass of this plant (Pramanik and Singh, 2003). A proposal to prevent the effects of chemical fertilizers on the plant, which may overwhelm the good properties of the plant, is to examine the impact of bio-fertilizers that are present in mycorrhizal fungi or bacteria on the growth of this plant. Growth stimulating microorganisms include mycorrhizal fungi and a group of bacteria, and the most important glomus mycorrhizal fungi can be mentioned (Cocking, 2003). In hydroponic system, all essential elements should be given as soluble salts to the plant. A proper nutritional solution is a solution that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

contains all the nutrients in certain concentrations, and the experts, based on the research components and the conditions of cultivation and plant species studied, have changed from standard solutions or different concentrations of it (Tabatabaei et al., 2006). Proper media, in addition to the desired physical, chemical and biological properties, should be accessible, sustainable and economically feasible (Davidson et al., 1998). The planting bed used in this qualification were listed (*Table 1*).

Table 1. *Concentration of nutrient solution elements (mg / l)*

Elements	Imma & Angel (2006)	Novella et al. (2008)

Fe-EDDHA	13.25	4

Vermicompost has substances such as plant growth hormones and enzymes that increase the microbial population of the soil and preserve the nutrients for longer periods without negative effects on the environment (Padmavathiamma et al., 2008). Perlite has a slight weight, is chemically neutral and has a high porosity and water holding capacity. Vermiculite also has a high cation exchange capacity and is chemically active (Malakouti et al., 2005). Perlites are often used alone or in combination with vermiculite 1: 1 volumes alone (Malakouti et al., 2008). This material provides suitable conditions for plant growth, such as ventilation, drainage and access to nutrients, especially in combination with other substrates (Martinez and Abad, 1992). Peat Moss is a degraded particle that is produced in humid and cold areas. The type of composition and its constituent varies in different types (Rafiei and Akbarzadeh, 2007).

Peat Moss is a plant material that breaks down slightly in mossy soils, as well as anaerobic conditions such as swamps and marshes, and has acidic pH. The cation exchange capacity of this substance is very high and the EC has a low (about ds.m 0.5) (Samiei et al., 2004). Mycorrhizal fungi in direct ways such as improving plant nutrition by increasing the absorption of water and nutrients, in particular, low-mobility elements such as phosphorus (Smith and Read, 1997), as well as the production of hormones such as auxin, cytokinin and abscisic acid in stimulating plant growth (Awotoye et al., 2009) and indirectly, such as reduction of biological stresses of plant diseases (Calvet et al., 1995) and non-toxic (salinity, drought, heavy metals, etc.) increase growth and yield Plants are hosted (Raiesi and Ghollarata, 2006). Research has shown that bio-fertilizers significantly provide plant nutrients such as nitrogen, phosphorus and potassium, and The other side protects the plant against various environmental stresses and increases plant resistance under stress conditions (Smith and Read, 1997).

The purpose of this study was to investigate the effect of nutrient solutions and planting bed (Peat moss and Perlite, leaf compost and vermicompost) simultaneously on Glomus mosseae mycorrhiza inoculum on some growth characteristics of stevia herb.

Methods and materials

In order to investigate the effect of Nutrient solutions and different planting bed on some growth characteristics of Stevia rebaudiana under inoculation with mycorrhizal fungus, a factorial design based on randomized complete block design with 4 replications in greenhouse of Mohaghegh Ardebili University in 2016 was conducted. The first factor was two levels: two different Nutrient solution solutions including Imma & Angel and Novella et al. (*Table 1*), the second factor was planting bed including Peat Moss and Perlite (Biolan), Vermicompost and Leaf composts in three levels and the third factor were inoculated with mycorrhizal fungus from Glomus mosseae and control treatment at two levels. After planting seedlings in pots, they were fed continuously with drops in nutrient solutions. Height of plant with ruler, number of leaves with counting, vegetation rate with cost meter (chlorophyll meter) Konica Minolta 502 according to SPAD index, fresh and dry weight of leaf was measured by digital scale. The analysis of data variance was done using SAS 9.2 software and the mean values were compared at the probability level of 1% and 5% using LSD Test.

Results and discussion

Leaf fresh weight

The results of analysis of variance of trait weight of leaf in stevia were significantly affected by the treatments at 1% level (*Table 2*). The results of analysis of variance of interaction between Nutrient solution solutions, different planting bed and inoculation with mycorrhizal fungus showed a significant difference. Mean comparison showed that the Imma & Angel solution in the planting bed of vermicompost under the conditions of mycorrhizal fungus (666.8 g) had the highest leaf fresh weight (*Table 3*).

Similar letters to the averages in each column indicate no significant difference at the 5% level (LSD test)

Leaf dry weight

The results of this experiment showed that this trait was affected by different nutrient solutions, different planting bed and inoculation with mycorrhizal fungus at a one percent significance level (*Table 2*). The results of analysis of variance of interaction between Nutrient solution solutions, different planting bed and inoculation with mycorrhizal fungus showed a significant difference. Mean comparison showed that the Imma & Angel nutrient solution in the planting bed of vermicompost had the highest leaf dry weight under inoculation with mycorrhizal fungus (128.1 g) (*Table 3*).

Research by Silveira et al. (2006) showed that the symbiosis of plants with mycorrhizal fungi improves plant growth characteristics, including the development of vegetative parts and the increase of fresh and dry weight of plant tissues. (Hawkesford et al., 2012) stated that phosphorus deficiency impairs plant growth and affects its various aspects of metabolism. Deficiency of phosphorus disrupts the transfer of water through the root, and because of the lack of adequate water for expansion of the cells, the leaves remain small and the growth of the air organs is prevented, thus, in the present experiment, Mycorrhiza fungus, with the availability of more phosphorus for the plant, increased the growth of the plant's airways. Also, vermicompost planting bed caused more vegetative growth because of the presence of more amounts of precipitated elements.

The trait of leaf number in Stevia plant was affected by the treatments at 1% level (*Table 2*). The results of analysis of variance of interaction between Nutrient solution solutions, different planting bed and inoculation with mycorrhizal fungus showed a significant difference. The mean comparison showed that the Imma & Angel diet in the planting bed of vermicompost had the highest number of leaves in inoculation with mycorrhizal fungus (4653) (*Table 3*). The growth of Imma & Angel, due to providing more suitable conditions for vegetative growth, resulted in more leaves. Vermicompost

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56415648

has a positive effect on the amount of photosynthesis and production of biomass of stevia, by increasing the water absorption capacity and the optimum access to high-consumption and low nutrient elements, resulting in more plant growth and increased leaf number. Also, according to Yousefi Shayade et al. (2015), the planting bed containing vermicompost increased the number of leaves in the stevia. (Bachman and Metzger, 2008) reported that adding vermicompost to soil increases leaf number, leaf area. The amount of photosynthesis in the French spring rose. Today it is known that direct mycorrhizal fungi increase plant growth by direct methods such as improving plant nutrition through absorption of nutrients, as well as increasing plant and inbound water absorption, such as decreasing biological stresses (Tahat and Sijam, 2012). The increase in the number of leaves in plants was reported by inoculation with mycorrhizal fungus in comparison with non-inoculated plants in tomato (Khalied and Elkhider, 1993) and Citrus tangering seedlings (Wu and Xia, 2006). An increase in the number and level of leaf associated with mycorrhizal fungi has also been reported by Copetta et al. (2006) in Basil, which is consistent with the results of this experiment.

Plant height

The height of plant was affected by different nutrient solutions at 5% level, and the highest number of leaves belonged to Imma & Angel (91.313 cm). Inoculation with mycorrhizal fungus (105.063 cm) also showed a significant difference in the level of one percent (*Table 2*). The results of analysis of variance of interaction between different substrates of culture and inoculation with mycorrhizal fungi showed a significant difference at 1% level. The highest plant height was related to the culture of leaf soil culture under inoculation with mycorrhizal fungus with 111.375 (cm). The comparison of the mean showed that the Imma & Angel nutrient solution in the soil planting bed under inoculum conditions with mycorrhizae (123 cm) had the highest plant height (*Table 3*). Utumi et al. (1999) conducted a stevia test The effect of nitrogen nutrient deficiency on the absorption of high-energy elements by the plant was that they said that the deficiency of this nutrient component would reduce the absorption of high-energy nutrients in this plant and decrease the plant's height. Studies by Sheelavanta (1993) showed that with increasing nitrogen fertilization, the length of safflower stem increased. Principally, the cause of increasing altitude due to the use of urea can be attributed to the effect of nitrogen escalation on vegetative growth and cell division in the plant, especially the stem, and more photosynthetic extraction is expected to be produced by the plant, which is a good condition Provides for elongation of the stem (Nourmohammadi et al., 2001). Saberhamishiegi et al. (2012) reported a study on the effects of nitrogen and potassium on the Stevia plant. The highest stem length (altitude) was observed in 60 kg / ha treatment and the least nitrogen application was obtained. Due to the fact that the percentage of nitrogen in the Imma & Angel sugars is higher, it can be attributed to the effect of nitrogen on the height of plants treated with this solution. According to the results, arbuscular mycorrhizal fungi had a positive effect on growth traits (plant height and branch number), which was consistent with the results of Piedra et al. (2005) and Soriano et al. (2009).

Chlorophyll

The results of analysis of variance of interaction between Nutrient solution solutions, different planting bed and inoculation with mycorrhizal fungus showed significant differences. Comparison of the mean showed that Novella nutrient solution in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56415648

vermicompost was in inoculated with mycorrhizal fungus at 45.513 (*Table 3*). With the presence of nitrogen in the chlorophyll components, it can be expected that with increasing nitrogen levels, it will have a significant effect on the chlorophyll content of leaves. The presence of chlorophyll as a source of light absorption and the synthesis of essential elements for the growth of plants associated with this element is critical (Saberhamishi et al., 2014). Sedeghi Moghadam and Mirzaie (2008) reported that adding vermicompost to soil causes nitrogen absorption by the roots, increasing vegetative growth and producing more leaves, which in turn increases the level of absorption of light, the level of photosynthesis, the creation and b, a hydrocarbon substances in leaves and total chlorophyll content increase.

Increasing chlorophyll content of leaves due to mycorrhizal coexistence can be due to increased phosphorus absorption from the soil by these fungi. Demir (2004) showed that mycorrhizal coexistence increases the concentration of chlorophyll in pepper plant leaves. According to the results of Hoseini et al. (2015), mycorrhizal inoculated plants contain more vegetation than control. Also, Tang et al. (2009) observed in their study of maize that insemination with the G.mossea mushroom improved the chlorophyll synthesis in the plant and increased the photosynthesis of the plant. They attributed this to increasing nitrogen absorption by mycorrhizal plants.

Abstract. Root system plays an important role in plant's nutrient acquisition and ecosystem carbon cycle. Nitrogen (N) and phosphorus (P) work significantly in promoting root system growth. To reveal the influence of N and P application on landscaping plants' root morphology characteristics, Ingrowth soil core fertilization method was applied in the coastal reclaimed soil (196.25 cm^3) where *Ligustrum lucidum ait* grew from June to August in 2018. We set 11 processing gradients, including 0, 1, 3, 5, 7, 9, 11, 13, 15, 17, 20 g, and explored the influence of different N and P addition types on *Ligustrum lucidum ait* root morphology, biomass and other indicators. The results showed that compared with the control group, 3 g N application increased length of root by 62.39%, surface area by 120.87%, volume by 169.97%, biomass by 102.75%, root length density by 59.19% and root surface area density by 106.99%. 3 g P application increased those indexes by 77.37%, 111.15%, 147.50%, 98.05%, 73.87%, and 97.88%. The study indicated that compared with the control group, the application of 3 g N and P into 196.25 cm^3 soil made significant differences on total length, diameter, surface area, volume, biomass, root length density, and root surface area density ($P < 0.05$).
Keywords: *root system, plant's nutrient acquisition, biomass, root morphology, Ligustrum lucidum ait*

Introduction

Most of the new coastal reclamation areas are the new land which forms through the sediment's being dredging from the seabed into the coastal tidal flat. After many years of natural desalination, salt washing and land abandonment for soil salinity reducing, they have gradually got suitable for the growth of green vegetation. However, this type of soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56495662

is extremely deficient in nutrients, such as nitrogen and phosphorus, which is the key factor that restricts the growth of plants. The lack of nitrogen and phosphorus in soil will slow the growth of vegetation, which will affect the artificial afforestation and ecological restoration in the reclamation area. The problem of artificial afforestation and ecological restoration in the new coastal reclamation area is urgent to be solved.

The survival of artificial afforestation is determined by plant roots. Root system is the interface between plants and soil, and is an important organ that absorbs nutrients and water. Nutrient content in soil directly affects plant growth. The addition of nitrogen and phosphorus to soil can change the influence of soil environment, and then affect the characteristics of plant root system. Roots often adapt to the environmental changes by adjusting the characteristics of root system, such as morphology, surface area, volume and biomass, showing high plasticity (Pregitzer et al., 1993; Eissenstat and Yanai, 1997; Eissenstat et al., 2000; Robinson, 2010; Wurzburger and Wright, 2016). Studies have shown that, under the condition of poor soil nutrients, the application of nutrient elements can help the root system grow rapidly enough to adapt to the changes in the environment (Schiefelbein and Benfey, 1991; Pregitzer et al., 1993; Bates and Lynch, 1996; Pregitzer et al., 1997, 2002; Wells et al., 2010; Robinson, 2010). For example, increased availability of soil nitrogen can lead to an increased fine root length, higher biomass and coarser diameters (Lynch, 1995; Messier, 2002; Pregitzer et al., 2002). It has also been found that N application increases root surface area and total length (King et al., 1997). It can also significantly affect the diameter, root length and specific root length of lower root order (Fitter and Stickland, 1991). Root plasticity has the same response to phosphorus (Fitter et al., 2010). For example, with the increase of soil phosphorus availability, *Larix gmelinii* increased root length to enhance the absorption of P, leading to the significant differences in root volume and lateral root tillers of *Pinus massoniana* in different species (Lynch, 1995).

However, most previous studies focused on the good soil environment and indoor experiments. The researches on phosphorus content in the wild arid field are very few. Then, the soil's nitrogen and phosphorus adding referred to be the surface spraying method, which was easily affected by weather (rain, snow), thus causing errors in the experiment results. Meanwhile, the way of adding nitrogen and phosphorus to soil was to apply fertilizer to the existing roots. The sampled roots included both old roots and new roots which grew right after the nutrient adding, so it's impossible to determine its specific influence on the characteristics of old roots or new roots. Ingrowth soil core avoids the above problems and can help master the growth characteristics of new root under different treatment conditions. And it can also contribute to clarifying the relationship between new root characteristics and soil nutrients (Peterjohn et al., 1999; Mcgrath et al., 2001).

Therefore, this study chose *Ligustrum lucidum ait* which grew on Shanghai coastal reclaimed soil with poor nitrogen and phosphorus content as the research object, applied ingrowth soil core to carry out short-term experiment of nitrogen and phosphorus adding to investigate the response of *Ligustrum lucidum ait* root morphology, biomass and other characteristics to soil's short-term nitrogen and phosphorus addition, so as to provide basic reference materials for the study on the relationship between root morphology and soil resource effectiveness as well as the construction and ecological restoration of artificial forests.

Materials and methods

Study area

The field site (30 ° 52 '54" N, 121 ° 54 '24 "E) was located in Lingang new Urban area in Shanghai (*Fig. 1*). It was damp, windy, warm, humid with abundant rainfall as well as with abundant sunshine in the region with four distinct seasons. And the annual average temperature in 2018 was 15℃ to 15.8℃, with the lowest temperature (3.3℃) in January, the highest temperature in August (38℃). The annual total sunshine was 2000-2200 h, the annual precipitation was 900-1050 mm and the monthly average evaporation is 91.9 mm, which was a typical subtropical maritime climate. Soil was that of saline and alkaline sandy soil. Soil with a pH value greater than 8.5 took up 97.5%, and the organic matter content was less than 20 g/kg. The groundwater level was between 0.5 and 2.5 m. In order to solve the problem of barren soil vegetation, different vegetation planting experiments were carried out. Vegetation planting began in February 2010 and was completed in April 2010. The test site was 1200 m long, 20 m wide and 24000 m^2 for total area. All the plants in the site were native species. Representative plant *Ligustrum lucidum ait* was selected as the experimental sample.

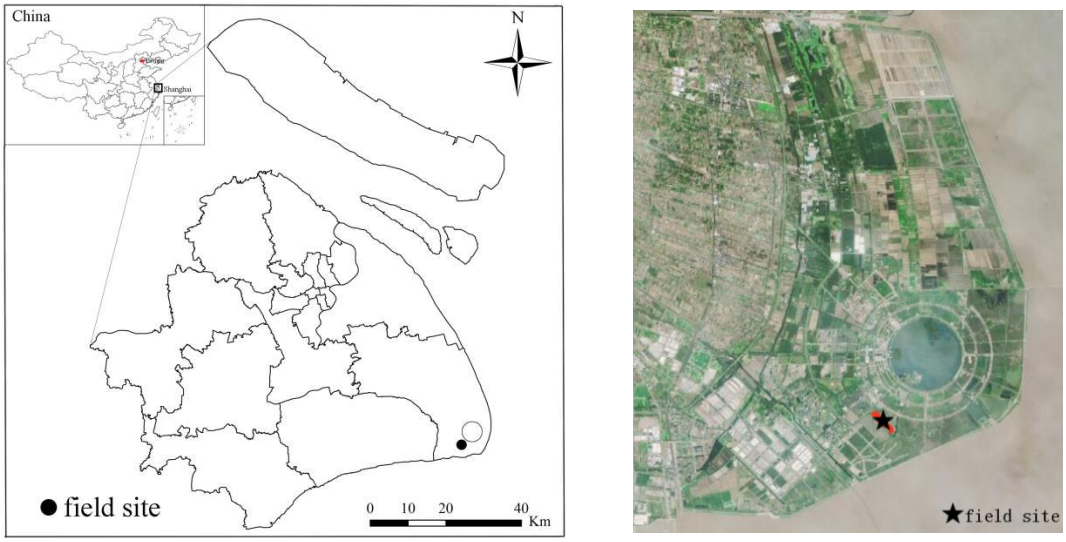

Figure 1. *Map of the study area*

Plot design

In the privet plantation (8 years old), a fixed standard plots of 20×30 m were set, and the privet with the same chest diameter, crown width and tree height were selected as samples in the sample plot (*Table 1*). The field within 1 m from the tree trunk was fertilized. A total of three groups were designed. I for nitrogen treatment, ten fertilizing gradients were set as: 1, 3, 5, 7, 9, 11, 13, 15, 17, 20 g; II for phosphorus processing, the gradients were set the same as those of nitrogen; III no treatment was done as a control.

Plant root sampler (l=10 cm, φ=5 cm, h=10 cm) was used. Most root system evenly distributed in surface area (Wang, 2004; Jiang, 2016), and the sampling depth was 10 cm. Then with the trunk as the center, 1 m from the center of trunk as the radius for sampling, 9 soil column samples were taken at the same distance around each tree, and 3 privet samples were taken as a treatment (*Fig. 2*). There was a total of 63 samples of *Ligustrum*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56495662

lucidum ait, and a total of 567 sample points were set. All roots were removed from soil cores with a sieve with a diameter of 3 mm. The soil was kept without roots, and then N, P was added to the soil. 270 soil cores of 30 privet samples were dealt with N of the 10 gradients, while another 270 soil cores of 30 privet samples were dealt with P of the 10 gradients, and 27 sampling points of three privet samples were not done with any fertilizer processing thus as a control.

Table 1. *Tree and Soil characteristics properties*

Tree characteristics		Soil characteristics	
Tree height (m)	4.37±0.31	pH	8.79±0.09
DBH (cm)	10.01±0.27	EC (ms/cm)	0.42±0.06
Crown width (m)	2.31±0.25	Organic matter (g/kg)	3.60±0.63
Plant distance (m)	3×3	Total salt content（g/kg）	0.78±0.03
Planting age (years)	8	Bulk density (g/cm^3)	1.37±0.02
		Soil Moisture (%)	29.23±2.92
		Total N (g·kg^{-1})	0.82 ± 0.04
		Total P (g·kg^{-1})	0.27 ± 0.02
		Total K (g·kg^{-1})	11.85 ± 0.73
		Texture	Sand loam

Data are provided in the form of mean ± standard deviation (SD). *DBH* diameter at breast height or basal

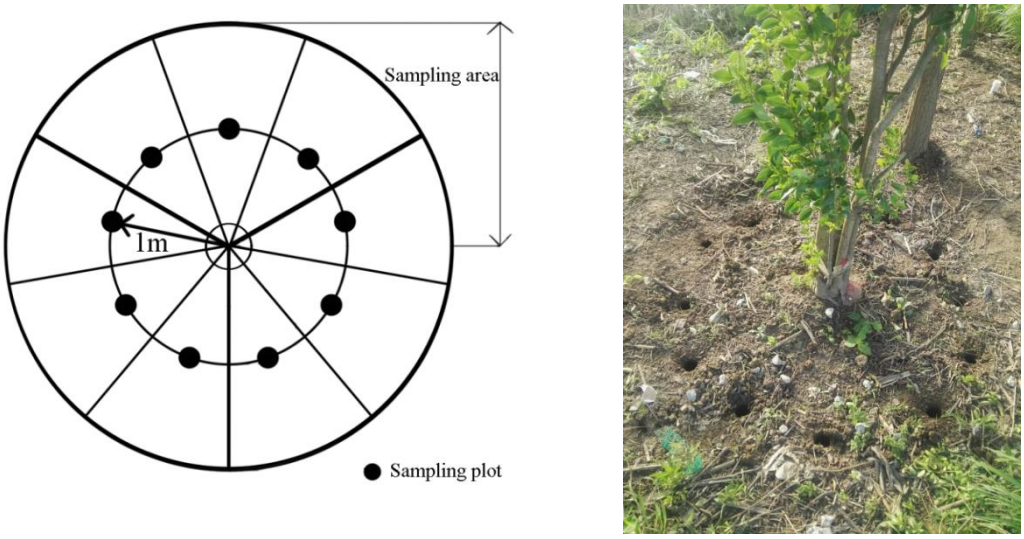

Figure 2. *Sample points for soil N and P addition*

Urea (CON_2H_4, 43% nitrogen content) was chosen as N fertilizer and calcium superphosphate (P_2O_5,13% phosphorus content) as P fertilizer. Then the treated soil was put into nylon mesh bags with a pore size of 2 mm (l=10 cm, w=6cm), then the nylon mesh bags were placed in the cavities made through the core drilling. Then the soil inside the cores was gently patted, making its bulk density to a certain extent consistent with the surrounding soil bulk density. Then PVC tubes were put in the core positions (φ=5 cm, h=1 cm). The PVC pipes were covered with thin soil, in case that soil erosion caused by rainfall should affect the experiment results. The soil cores were set from June 16th, 2018 to June 18th, 2018 when it's the peak growth season for privet root system as well as the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56495662

most demanding season of privet for nitrogen and phosphorus fertilizer to blossom. During the study period in 2018, the average temperature was 18~28℃. The average precipitation was 134 mm. The average soil moisture content was 19.09%, and the average soil temperature was 21.34℃. The average temperature in July was 21~30℃, the average precipitation was 156 mm, the average moisture content of soil was 27.58, and the average temperature of soil was 28.41℃. In August, the average temperature was 20 ~ 30℃, the average precipitation was 140 mm, the average moisture content of the soil was 23.79 and the average temperature of the soil was 26.51℃.

Root sampling

The fine roots of *Ligustrum lucidum ait* grew slowly after August, so the soil cores was removed again (Wang, 2004; Jiang, 2016) after 60 days of root removal (in mid-August). The roots between nylon mesh and soil were cut off with a sharp soil knife. The soil cores were cut with a soil knife at the bottom and the excavated cores were taken out. Then, they were put into plastic bags and brought back to the laboratory in time.

Root determination

After the soil core being fully rinsed in water, the roots in nylon bags were sifted out with a soil sieve with a 2 mm diameter and the root surface were dried with absorbent paper. The prepared root samples were placed in a transparent scanner tray for the roots' full stretching. The root samples were scanned with a digital scanner Epson scanner. The root scan & analysis system of Win-RHIZO 2005C (Regent Instruments Inc., Quebec, Canada) was used to scan the root image and the length, diameter, surface area and other data of the root system were obtained then. Afterwards, root samples were placed in 80℃ oven for drying for 48 h to a constant weight, and then the dry weight was weighed (accuracy: 0.0001 g). According to the root length and dry weight of each sample point, we calculated the biomass and specific root length, and then calculated root length density, specific surface area and surface area density according to the root length, surface area and the volume of soil cores. Finally, we calculated the average value of the samples in 27 soil cores in each treated soil layer and converted the average values into root biomass, root length density, specific root length, specific surface area, and root surface area density per unit volume. Root biomass, root length density, specific root length, specific surface area, and root surface area density were calculated as follows:

$$\text{Root biomass } (g/m^2) = g \times A \quad \text{(Eq.1)}$$

$$\text{Root length density } (m/m^3) = L/V \quad \text{(Eq.2)}$$

$$\text{Specific root length } (m/g) = m/g \quad \text{(Eq.3)}$$

$$\text{Specific surface area } (cm^2/g) = a/g \quad \text{(Eq.4)}$$

$$\text{Root surface area density } (m^2/\ m^3) = a/V \quad \text{(Eq.5)}$$

where, a is Root surface area; A is the area of soil; g is fine root dry weight; L is total length of fine root; m is the length of dry fine root in each Sample point; V is the volume of soil.

Statistical analysis

The average value of each processed sample was calculated and was ready for statistical analysis. Univariate anova and LSD multiple comparisons ($\alpha = 0.05$) were used to test the significant differences in the effects of different nitrogen and phosphorus addition treatments on the total length, average diameter, surface area, volume, biomass, specific root length, root length density, specific surface area, and root surface area density of the great privet root system. All statistical analyses were performed with SPSS 20.0 (IBM SPSS, Chicago, USA) software. Excel 2010 software was used to draw pictures.

Results

Effects of N and P addition on root morphology

As is seen in *Fig. 3a*, the total length of the root-system of *Ligustrum lucidum ait* appeared to increase first and decrease later under different N treatments. When 1 and 3 g were added, compared with the control group, the total length of root significantly increased by 57.62% and 62.39% ($P < 0.05$), when 5-11 g nitrogen were respectively applied, the total length of root system decreased gradually. No root growth was observed when 13 g N was applied. Under different P treatments, when 1 and 3 g were added, the root total length increased by 9.50% and 77.37% ($P < 0.05$). With 5-20 g applied, the total length of the root system gradually decreased, but no non-root-growth was found (*Fig. 3a*).

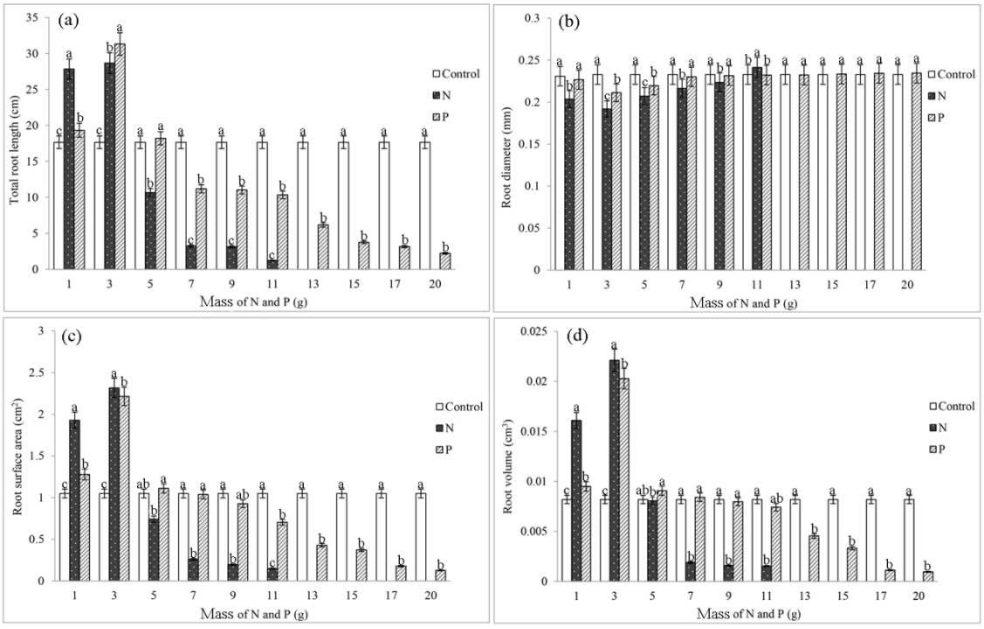

Figure 3. *Effects of fertilization on the morphology of the root system of Ligustrum lucidum ait.(a) total root length, (b) root diameter, (c) root surface area, (d) root volume*

The average diameter of root showed a tendency of thinning first and thickening then under different nitrogen and phosphorus treatments (*Fig. 3b*). Compared with the control group, the average diameter of the privet roots was thinned and significant difference was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56495662

found when 1 and 3 g N were applied ($P < 0.05$). When 3 g N was applied, the average diameter of root system reduced to the minimum, 0.19 mm. The average diameter of root system gradually increased when 5-11 g nitrogen were applied, and the maximum diameter 0.24 mm appeared at 11 g. When 1-20 g P were applied, the average diameter of roots showed a trend of thickening after thinning. When 3 g P was applied, the average diameter of the root system reduced to the minimum and the significant difference was achieved ($P < 0.05$). When 20 g P was applied, the maximum diameter was 0.23 mm.

When 1, 3 g N and P were applied, the average surface area and volume of root system gradually increased and the significant difference occurred, compared with the control group ($P < 0.05$) (*Fig. 3c,d*). The root surface area increased by 45.61% and 120.87%, and root volume increased by 96.34% and 169.97% when 1 and 3 g nitrogen were applied. With 5-11 g N, root surface area and volume gradually decreased. When 1 and 3 g P were applied, the root surface area increased by 21.79%, 111.15%, and the volume 15.96%, 147.50%. And the difference was significant ($P < 0.05$). When 11-20 g P were applied, compared with the control, no significant difference was found about the root diameter ($P > 0.05$) (*Fig. 3b*).

Effects of N and P addition on root biomass, root length density and specific root length

As is seen in *Fig. 4a*, with the increase of nitrogen and phosphate application, root biomass showed a trend of increasing first and decreasing then. Compared with the control group, the biomass and root length density of privet root increased and significant differences were found when 3 g N and P were applied ($P < 0.05$).

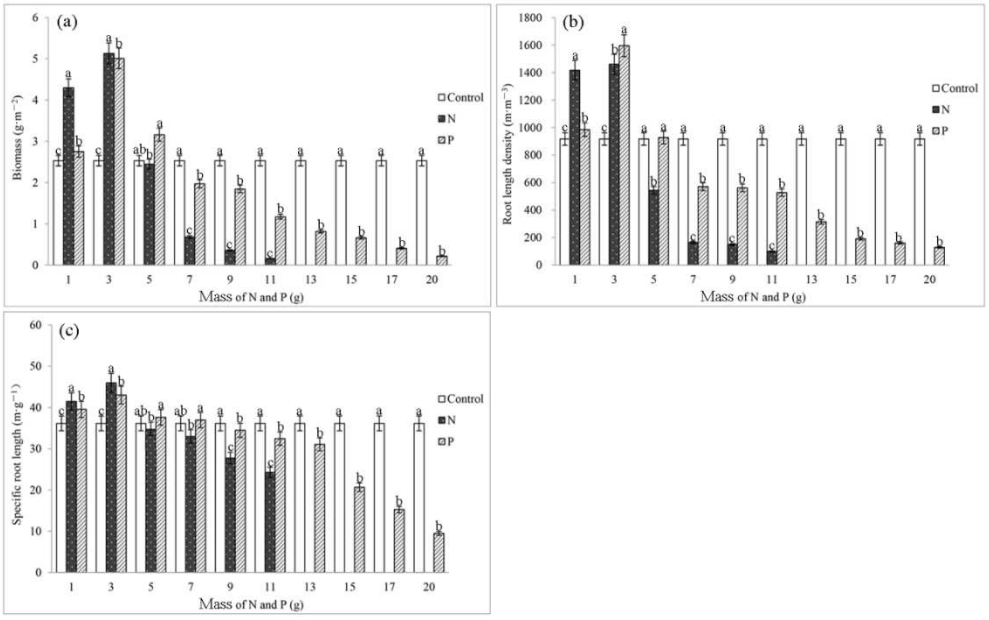

Figure 4. *Effects of fertilization on root biomass (a), root length density(b), and specific root length(c) of Ligustrum lucidum ait*

The application of 1 and 3 g N increased the biomass by 69.85% and 102.75%, respectively 4.30 $g \cdot m^{-2}$ and 5.13 $g \cdot m^{-2}$, and it also increased the root length density by 54.51% and 59.19%, respectively 1417.99 $m \cdot m^{-3}$ and 1460.90 $m \cdot m^{-3}$. The application of 3 g P increased the biomass by 98.05% and the root length density by 73.87%, respectively 5.01 $g \cdot m^{-3}$ and 1595.62 $g \cdot m^{-2}$ (*Fig. 4a,b*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56495662

With the increase of N application, specific root length increased first and decreased then. When 1 and 3 g N and P were applied, the specific root length significantly increased compared with the control ($P < 0.05$) (*Fig. 4c*). The maximum specific root length reached 45.96 $m \cdot g^{-1}$ and 43.01 $m \cdot g^{-1}$ when nitrogen and phosphorus were applied to the roots respectively. The effect of nitrogen on specific root length was more significant compared with phosphate. When 5-11 g nitrogen were applied, the specific root length gradually reduced. The root stopped growing at 13 g. When 5-20 g phosphate fertilizer were applied, the specific root length gradually reduced.

Effects of N and P on specific surface area and surface area density

As is seen in *Fig. 5a*, with the increase of N and P application, the specific surface area of root showed a trend of increasing first and decreasing then. Compared with the control group, the root specific surface area reached the maximum and significant difference was found ($P < 0.05$) when 7 g N and P were applied (350.20 $cm^2 \cdot g^{-1}$ and 279.02 $cm^2 \cdot g^{-1}$). With the increase of N and P application, the surface area density increased first and decreased then (*Fig. 5b*). Compared with the control group, the root surface area density had a significant difference ($P < 0.05$) when 1 and 3 g N and P were applied. The root surface area density was also the largest, increasing by 106.99% and 97.88%, respectively, which were 1.18 $m^2 \cdot m^{-3}$ and 1.13 $m^2 \cdot m^{-3}$ when 3 g N and 3 g P were added (*Fig. 5b*).

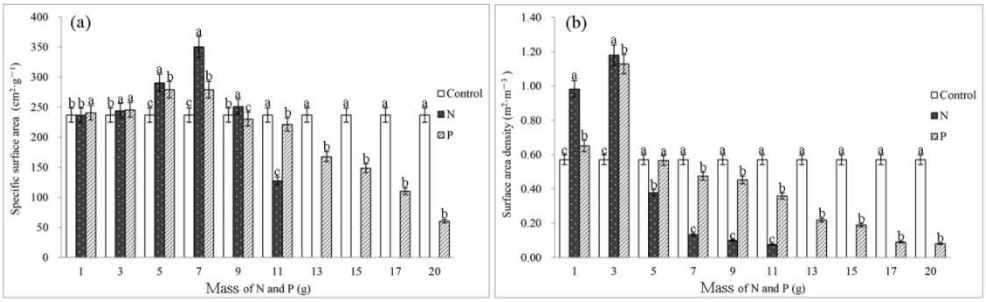

Figure 5. *Effects of fertilization on specific surface area (a) and surface area density (b) of the root system of Ligustrum lucidum ait*

Discussion

Effects of N and P addition on root morphology

Studies have shown that plant roots are highly plastic and can respond to the availability of different soil N and P contents. That is to say, when nutrients are limited, the ability to obtain nutrients can be improved by increasing the total length, surface area and volume of roots (Cuevas et al., 1991; Schmid and Kazda, 2002; Yang et al., 2003).

Increasing root length is an effective strategy for plants' nutrient and water obtaining. Under the treatments of 3 g N and 3 g P, the total length of root system increased by 62.39% and 77.37%, Wang et al. (2005) got this result too. Different nitrogen and phosphorus treatments had different effects on the total length of the root system of privet (*Fig. 3a,b*). Among those, 1 g, 3 g N and P significantly increased the total length of root system. 5-11 g N applications significantly decreased the total length of root system. No root growth was observed when 13-20 g N were applied. The total length of root system

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56495662

significantly decreased when 5-20 g P were applied and no root growth was found. The reason was that the application of 1 g, 3 g N and P can change the ways of root system to obtain nutrient resources, promote the growth of the root system, and reflect the effects of N and P on the promotion (positive feedback) of the root system. Secondly, the lignification degree of the newly formed root system was low, which was easily affected by the soil environment and was very sensitive to the changes of soil resources. To obtain more nutrients, the root system grew rapidly. The applications of 5-20 g N and P inhibited the root growth to some extent, especially the death of plant roots was found after 13g addition of N.

Root diameter is an important parameter reflecting root structure and function (Robinson, 2010). Under different nitrogen and phosphorus treatments, the average diameter of root showed the phenomenon of first thinning and then thickening (*Fig. 3b*). N application of 1 g, 3 g and 5 g had a significant impact on the average diameter of root system, under which the average diameter became thinner. The average diameter under P application of 5-20 g gradually increased. The reason why the diameter first decreased and then increased under different fertilization treatments was that under the condition of low addition of N and P, the extension of root cells made the root diameter decrease for the root system to obtain more nutrient resources. With the high addition of N and P, N relatively inhibited the growth of the root system. To survive, the root system changed its survival strategies, appearing to be the increase of the root diameter and the prolonging of the root life to obtain nutrients and maintain its survival. For example, Wells et al. (2002) proved the relationship between root life and diameter of *Amygdalus persica l.* And it testified to a significant positive correlation between root life and diameter (Wells et al., 2002). Kern (2004)'s research showed that fertilization could significantly increase the root diameter of a poplar and shorten the root turnover time (Kern et al., 2004). According to the characteristics of root plasticity and the "cost-benefit" theory, the growth strategy of the root system always tends to choose the method with the minimum cost and the maximum benefit for survival (Eissenstat and Yanai, 1997; Bardgett et al., 2014).

Different N and P treatments can significantly affect root surface area and volume (*Fig. 3c,d*). Compared with the control group, application of 1 g, 3 g N and P increased root surface area by 45.61%, 120.87%, root volume by 96.34% and 169.97%. The increase of root surface area and volume is a way for the root system to have greater absorption surface area and maximally obtain soil nutrient resources.

Effects of N and P addition on root biomass, root length density, specific root length and surface area density

Addition of N and P significantly affected root biomass and root length density (*Fig. 4a,b*). At present, the effects of increased soil nitrogen availability on root biomass and production appear to be reduction and increase (Cotrufo and Gorissen, 1997; Kou et al., 2015). For example, the application of N can increase the fine root biomass of *Populus deltoides* by 21% (Kern et al., 2004) and the fine root biomass of *Picea abies* by 92% (Majdi, 2001). For example, the application of N can reduce the fine root biomass of *Larix kaempferi* by 15% and that of *Pseudotsuga menziesii* by 40% (Son and Wang, 2010). The response of root biomass to N addition may be related to the climate and soil nutrient conditions in the study area. And the effect of N addition on root biomass is also related to the genetic characteristics, phenological characteristics, N addition amount and treatment time of different roots.

DOI: http://dx.doi.org/10.15666/aeer/1703_56495662

In this study, compared with the control group, the biomass of root significantly increased after 1 and 3 g N application (69.85% and 102.75%, respectively) (*Fig. 4a*). Root biomass significantly decreased after 5-11 g N applications ($P < 0.05$). When 13 g N application was applied, no root growth was observed, and high nitrogen directly caused little root growth, reflecting the negative feedback effect of N on root. The increase of root biomass may be attributed to the increase in the effectiveness of soil N following the fertilization, which met the demand for N of the root system. Plant roots adopted the strategy of "rapid investment - income" to increase the carbon distribution to the root system and promote the growth of the root system. High nitrogen inhibits the growth or non-growth of the root system, leading to the reduction of root biomass. With respect to phosphorus addition, the biomass of root significantly increased after the 3 g phosphate fertilizer application (an increase of 98.05%). The reason may be that the phosphorus elements were involved in the composition of nucleic acids, nucleotides, and phospholipids, which was also the main component of cytoplasm and nuclei, so under a reasonable phosphorus add, the elongation of root cells can be increased. The total root length and root length density increased, leading to the increase of biomass. Under the treatment of high phosphorus, the root cell elongation decreased, root length decreased, and the biomass showed a trend of gradual decreasing. Root biomass gradually reduced when 5-20 g phosphate fertilizers were applied.

Specific root length refers to the total root length of unit mass root system, and it is an important indicator of root morphology and physiological function (Eissenstat, 1992; Pregitzer et al., 2002). Studies have shown that the value of specific root length is associated with the effectiveness of soil resources (Burton et al., 2000; Gordon and Jackson, 2000). It is generally believed that a root with a larger length has relatively higher nutrient and water absorption efficiency, and the value of specific root length can indicate the physiological activity of the root (Pregitzer et al., 2002).

The effects on specific root length are manifested in: under low N/P addition, compared with the control, the specific root length significantly increased ($P < 0.05$), and the high addition of N/P (5-20 g) significantly inhibited the increase of root length (*Fig. 4c*). The main reason was that the newly formed long roots had low lignification degree and high plasticity, and were easily affected by the soil environment, leading to the root system's length adjustment to satisfy its absorption of nutrients from soil (Guo et al., 2004). Different N and P addition's influence on root length density and surface area density was consistent with that of root biomass (*Fig. 4b,5b*). Among those, under the application of 5 g nitrogen and phosphorus, the root length density under phosphorus treatment was 9.22% higher than that under nitrogen treatment. The reason may be that under reasonable fertilization, phosphate fertilizer can increase the number of root tillers and stem tillers, leading to the increase of underground biomass and root length density.

In general, in the case of 1 g, 3 g N and P, N had a significant effect on total length, surface area, volume, biomass, and root length density of the root system, whose reason may be related to the mobility of N and P elements in soil. Phosphate roots in soil are usually affected by the obligate adsorption of iron oxide and aluminum oxide in soil. In the soil, N has a stronger mobility than P, mainly because nitrate nitrogen mobility is very strong. Under the condition of good ventilation, ammonia nitrogen can be converted into nitrate nitrogen through the action of nitrifying bacteria. The nitrate nitrogen which has a good mobility can easily spread to the root surface, realizing the rapid absorption of N elements and promoting the changes of root morphology and the biomass increase (Wang, 2004).

Scientific fertilization of artificial forests in new reclamation areas

N and P are the most demanding limiting nutrients for plant root growth. According to the cost-benefit theory, root growth depends on a large amount of nitrogen and phosphorus input (Eissenstat and Yanai, 1997; Nadelhoffer, 2000; Norby and Jackson, 2000). For example, Jackson et al. (1997) found that for every unit of nitrogen absorbed by the root system, 41 units of carbon were consumed (Jackson et al., 1997). Statistics also showed that when the first fruit of tomato grew to 4 cm in length, the amount of phosphorus absorbed from soil accounted for about 90% of that in the whole growth period. Therefore, the effectiveness of soil N and P significantly affected root growth. Hendrick and Pregitzer (1996) believed that root biomass may be positively correlated with soil nutrient availability or negatively correlated, depending on the plant species and the spatial heterogeneity of available nutrients distributed in soil (Hendrick and Pregitzer, 1996). In this study, it was found that the total length, surface area, volume, biomass, root length density and surface area density of the roots significantly increased when 1 g, 3 g N and P were applied, among which the effect of 3 g N and P was the best, showing that N and P promoted (positive feedback) the root system. When 5-20 g N and P were applied, the total length, surface area, volume, biomass, root length density and surface area density of the root significantly reduced, reflecting the inhibition (negative feedback) of N and P on the root system. Among those, no root growth was found in the soil core when 11 g N was applied, seriously hindering the growth of the root system. Although the soil's N and P content in coastal salt land is very low for the growth of vegetation, it is not better to apply more N and P but better to master the threshold of N and P required by plants. In this way a scientific and reasonable fertilization can be achieved.

Plant root growth, death and turnover is a dynamic process. The time of experiment design makes a great difference to the results of the experiment. In different months, root growth, death and turnover laws are constantly changing (Pregitzer et al., 1993). The effect of fertilization on the annual and monthly dynamics of root system needs to be further studied in the future. In this experiment, root systems were not classified. In different N and P treatment cases, the differences between all levels of N and P content within the root sequences and the different treatments are not clear. From the research of root physiological processes of carbon - nitrogen - phosphorus, it's more helpful for knowing the root better, and more helpful for knowing soil's N and P availability and reaction mechanism of spatial heterogeneity better, all of which needs to be discussed further.

Conclusions

The results showed that reasonable addition of N and P could significantly change the morphology and biomass of root system. Reasonable N and P add (3 g) can make the root total length, surface area, volume , biomass, root length density and root surface area density increase significantly, reflecting the promotion of root system (positive feedback) of N and P. More of that than the threshold will reduce these indexes gradually, reflecting the nitrogen and phosphorus's inhibition to the root system (negative feedback). With the treatments of different N and P gradients, the root diameter showed a tendency of first thinning and then coarsening, and the specific root length and specific surface area showed a trend of first increasing and then decreasing. The main reason for the occurrence was that the mobility of the two elements in soil was related to the absorption strategy of the root system. The study showed that the application of 3 g N and P into the soil filled

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56495662

with 196.25 cm^3 significantly promoted the growth of the root system, and more of that than the threshold will lead in the inhibition of N and P on the root. Short-term N and P addition had significant effects on total length, diameter, surface area, volume, biomass, root length density, specific root length, specific surface area and root surface area density of the privet root system ($P < 0.05$).

(Received 9th Jan 2019; accepted 6th Mar 2019)

Abstract. Evaluation of mineral nitrogen content (N_{min}) was performed for the 60-90 cm layer of grassland soils relative to other selected agricultural fodder crops. Soil samples were collected two times per year, in spring and autumn, over the period 2010-2012 from fixed locations scattered across whole Poland territory. Additionally, particle-size distribution was assessed in the tested soil samples, which allowed to assign soil agronomic categories to them and assess the relationship between N_{min} content and assigned categories. Regardless of sampling date and land use, agronomic category had a significant effect on N_{min} content. Generally the relationships between the percentage of particles with dimensions below 0.02 mm and N_{min} content were characterized by a negative correlations, but in maize crops they were found to be positively correlated. Based on the obtained correlations, linear regression equations were developed. Calculated relations were less pronounced in spring, before fertilization, than in the autumn, after harvest. These equations can be very important from the practical point of view, as they may be used by farmer to plan a rational and sustainable fertilization based on forecasting of losses of mineral nitrogen content in the soil depending on the percentage of fine particles (agronomic category) of cultivated soil.
Keywords: *mineral soils, organic soils, maize, mixed cereals, regression equations*

Introduction

Nitrogen is one of the most important macronutrients, playing crucial role in crop growth process. The management of mineral nitrogen to ensure optimal level for plants is strongly dependent on physico-chemical properties of cultivated soil, such as particle-size distribution, bulk density, porosity or pH, crop management practices, as well as climatic conditions, which not only are a subject of constant changes, but also experienced a sudden shift related to climate change resulting in temperature increase (Swanson and Tsonis, 2009) and variation in precipitation structure. Increasing global food demand and gradually diminishing arable land area put new challenges for crop

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56635675

production, which can be fulfilled by precision agriculture and sustainable soil management. For example, in Poland arable land as a share of land area fell gradually from 45.6 % in 2000 to 35.6 % in 2015 (The World Bank, 2015), but yields per hectare are increasing, which is related to the intensification of plant production. Usually it involves the use of higher doses of fertilizers, what results in the stronger impact of agriculture on the environment, as about 40 to 70% of nitrogen applied as normal fertilizer is either chemically bound in the soil and becomes unavailable to plants or is lost to the environment due to leaching (Jarosiewicz and Tomaszewska, 2003). In terms of sustainable agriculture, intensification should be strongly connected with optimization of efficiency of fertilizers use by modifications leading to graduation of their release time and biochemical activity. Also, the application of fertilizers for specific location should take into account soil bio-physico-chemical status, expressed through particle size distribution, mineralogical composition, soil pH, water retention properties and hydraulic conductivity, organic matter content or soil microbial community composition, activity of which can depend not only on N fertilization (Gleń-Karolczyk et al., 2018; Walkiewicz et al., 2018), but also on contamination (Walkiewicz et al., 2016; Wnuk et al., 2017). Poland is a region characterized by a significant diversification of soils and thus, the agricultural production conditions. Therefore, regular monitoring of soil properties and analysis of their relations with macro and micronutrients status (Tkaczyk et al., 2017; 2018a; 2018b) that is taking into account the diversity of soils is necessary for appropriate distribution and application of NPK fertilizers and their sustainable management (Tunbare et al., 2005; Watros et al., 2018). This can be done by precise prediction of soil properties variations in space and time using physical-mathematical modelling (Lamorski et al., 2013), which consider spatio-temporal variations of soil and climate conditions. To consider crop production in the conditions of a changing climate, various approaches can be applied. They capture projections of future climate from climatic models, which take into account various climate change scenarios, by either modification of amplitudes of partial density functions of measured time series to be in accordance with predicted climate change (Pirttioja et al., 2015; Fronzek et al., 2018) and consider adaptation measures (Ruiz-Ramos et al., 2018; Rodríguez et al., 2019), or take into account various statistical models (Murat et al., 2018) to forecast hourly or daily courses of future time series. It was shown that modifications of the weather time series structure (either by changing amplitudes or by an spatio-temporal aggregation) interfere with their inherent properties, such as long distance power-law correlations (Baranowski et al., 2015; Hoffmann et al., 2017; Krzyszczak et al., 2017a; 2017b; Krzyszczak et al., 2018) and therefore should be done with appropriate caution, as it may highly influence the results of modelling.

The most general form of presenting soil properties and analyzing their impact on crop production is the use of agronomic category. The studies on impact of agronomic category on mineral nitrogen in soil makes it possible for farmers to easily evaluate fertilization needs for a specific soil type. Up to this moment there are not many studies regarding the relation agronomic category on soil mineral nitrogen performed in large scale covering whole country area, which consider sampling date and land use. For example, it was already shown that, in general, soil mineral nitrogen content is affected by soil agronomic category (Paz and Ramos, 2004). Differences in soil mineral nitrogen content in spring and autumn sampling dates, as well as the assessment of percentage of nitrate and ammonium nitrogen in mineral nitrogen content were assessed by Fotyma

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56635675

and Pietruch (2000) and Pietrzak (2014). Fotyma and Pietruch (2000) showed that in the 0-60 cm layer, the greatest variations in this respect were found in very light and light soils, whereas in the 60-90 cm layer heavy soils exhibited the largest differences. In medium and heavy soils, the percentage of ammonium nitrogen is about 30% of the total amount of mineral nitrogen, while in light soils this percentage is substantially higher, standing at 50%. It can be explained by greater denitrification intensity in heavy soils (Mosier et al., 2002). Pietrzak (2014) stated that in the topsoil (0-30cm) the highest content of mineral nitrogen are found in meadow soils with high permeability, i.e. light and very light soils, and that the amount of mineral nitrogen in meadow soils generally increases during growing season and decreases in the off-season.

Mineral nitrogen located in the 0-30 cm layer can migrate to deeper layers of the soil profile due to leaching (Powlson, 1988; Coyne and Frye, 2005). In the Soon et al. (2001) opinion, nitrogen losses in agriculture caused by nitrogen leaching are of significant importance for economic, production and environmental reasons. A direct consequence of mineral nitrogen leaching is pollution of ground and surface waters (Fotyma et al., 2010). In Poland monitoring of soil mineral nitrogen has been conducted for many years (Fotyma and Pietruch, 2000; Regulation, 2002; Jadczyszyn et al., 2010; Pietrzak, 2014). Based on this monitoring, the impact of soil N_{min} content on water quality can be predicted. This study attempted to identify factors determining nitrogen content in the 60-90 cm soil layer from which nitrogen can migrate to waters. As soil mineral nitrogen content is expected to be highly varied in time (Yu et al., 2003), with higher content during the spring and lower at the turn of August and September, which is a result of changes in the intensity of nitrification and enhanced nitrogen uptake by plants (Łoginow et al., 1987), therefore the analysis was carried out for two sampling dates – spring and autumn.

The study hypothesis is that, depending on selected soil properties, land use and sampling dates, significant differences exist in the content of mineral nitrogen in the soil layer beneath 60 cm, which is beyond the reach of the main root mass of crop plants in grassland soils (Mezhunts et al., 2005; Bonin et al., 2013) and in arable soils (Fan et al., 2016). The aim of this study was to evaluate mineral nitrogen content in grassland soils relative to other selected agricultural fodder crops in 60-90 cm layer depending on soil agronomic category.

Material and methods

Sampling sites

The results of environmental investigations conducted by the Regional Chemical and Agricultural Stations in agricultural farms across Poland over the period 2010-2012 were used to evaluate soil mineral nitrogen content for Polish soils under different land uses. The number of analyzed soil samples with the specified land use is presented in *Table 1*. Soil sampling sites, scattered over whole Poland territory, were identified by their geographical coordinates using GPS Pathfinder ProXT by Trimble (Westminster, CO 80021, USA, www.trimble.com) and were fixed for the entire study period. Locations of soil sampling points are presented in *Fig. 1*.

Soil samples were collected twice a year, in spring and autumn dates, from fields with a total area of not more than 4 ha. Soil sampling in spring were conducted in the period from February to April (before applying fertilizers), whereas in autumn in the period from September to October (after harvesting). Sampling done for 3 consecutive

DOI: http://dx.doi.org/10.15666/aeer/1703_56635675

years diverse in terms of meteorological conditions (*Tab. 2),* with 2010 being cold and wet, 2011 – very warn and dry and 2012 – varm and moderate (Statistical yearbook, 2011; 2012; 2013), two times per year, allow to average out the influence of year-by-year variations of these conditions and reveal more the influence of agronomic categories on N content. Each sample, weighing about 200 g, consisted of 15-20 primary soil samples collected from 60-90 cm layer using Egner stick from an area no larger than 100 m^2.

For each site selected, if the same crop was grown in successive years of the study, the average value for the respective period was calculated. In the case of sites located in grasslands, the same land use was continued over the entire study period and the average N_{min} content for the period 2010-2012 was considered.

Table 1. *Number of analyzed soil samples taken from the 60-90 cm soil layer in grasslands on mineral soils, maize and mixed cereal (mostly oat and barley) crops*

Crop type/land use		Number of samples
Grasslands (on mineral soils)	Total	859
	Meadows	521
	Pastures	160
	Hay and pasture	84
	Alternate	98
Maize		826
Mixed cereal (mostly oat and barley)		951

Soil samples analysis

Collected samples were delivered to the respective laboratory in tightly sealed containers and kept at a temperature of -18°C until an analysis of mineral nitrogen was performed. The soil samples with natural moisture content (after defrosting) were subjected to extraction with a 1% potassium sulfate solution at a ratio of 1:10. In the extracts obtained, nitrate and ammonium nitrogen content was determined spectrophotometrically using a Skalar San Plus System auto-analyzer (in accordance with the PN-R-04028:1997 norm, which is slightly modified, but equivalent to International Standard ISO 14256). Mineral nitrogen content (a sum of nitrate and ammonium nitrogen) was expressed in $mg \cdot kg^{-1}$ of dry matter of the soil sample (DM). Determination of dry matter was made using the gravimetric method after drying at 105°C (according to PN-ISO 11465:1999). In the air-dried samples, particle size distribution was determined using the laser diffraction method. As the extraction of nitrate and ammonium is carried out in a sample with natural moisture content, therefore obtained results were recalculated to the dry matter content using the empirical coefficient suitable for the soil of specific granulometric composition. Based on the content of particles with a diameter of <0.02 mm, one of four soil agronomic categories has been assigned to each soil sample (IUNG, 1990): very light soils (< 10% of fine particles), light soils (11-20%), medium soils (21-35%), and heavy soils (> 35% of fine particles).

Statistical analysis

To assess the relationship between soil agronomic category and content of mineral nitrogen in layer beyond the reach of roots of crop plants, N_{min} content in the 60-90 cm soil layer beneath ground surface in grasslands, as well as in soils under maize and mixed cereals was calculated as an annual average. Separately, averages were calculated for the spring and autumn sampling dates, depending on the assigned agronomic category and land use. Beside average values, standard deviations (SD) of mineral nitrogen content were calculated and presented on the figures. The relationships between N_{min} content and agronomic category were characterized by Pearson's correlation coefficients and assessed statistically using the one-way non-orthogonal analysis of variance classification with Tukey confidence intervals ($p = 0.05$). Additionally, simple regression analysis performed in SAS v. 9.1 software was carried out to obtain linear equations describing the relationship between the soil agronomic category and the N_{min} content in the 60-90 cm soil layer for varying land use. The goodness of fit of linear regression was evaluated using determination coefficients (R^2).

Results and discussion

The analyses show that indeed mineral nitrogen content in in the 60-90 cm soil layer depends on agronomic category (*Fig. 2*). The highest mineral nitrogen content was observed in light soils, whereas a slightly lower one in very light soils. This trend persisted both in spring and in autumn, except for very light soils for which a higher content of this form of nitrogen was noted in spring than in autumn (*Fig. 3*). The effect of seasonality on nitrogen mineralization in soils of peatland ecosystems is discussed by Pawluczuk and Gotkiewicz (2003). They showed much higher amounts of soil N_{min} in spring than in summer and autumn. In their opinion, the reason for this is that in muck

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56635675

and peat soils enhanced mineralization occurs also in winter and the quantities of nitrogen unused by plants (because of the non-growing period) are lost. Also, Arbačiauskas et al. (2014) obtained similar tendencies for the 60-90 cm soil layer of Lithuanian agricultural lands, irrespective of soil texture or nitrogen fertilisation rate.

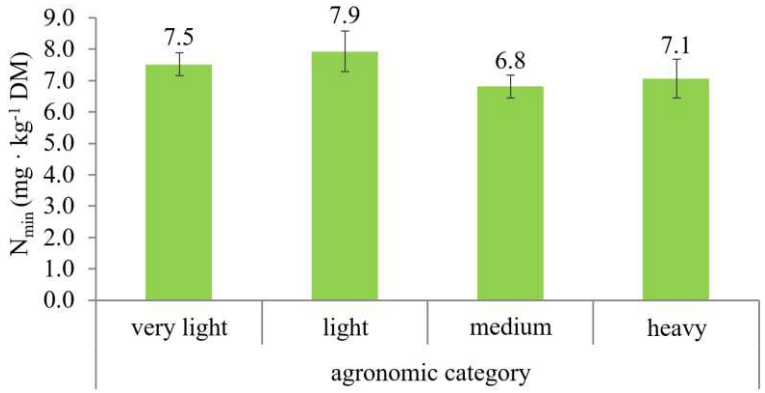

Figure 2. *Average mineral nitrogen N_{min} content in the 60-90 cm soil layer with its standard deviation depending on soil agronomic category. DM stands for dry matter of the soil sample*

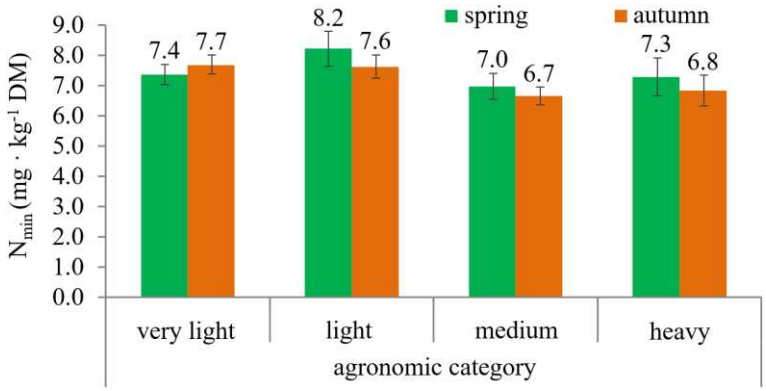

Figure 3. *Average mineral nitrogen N_{min} content in the 60-90 cm layer of mineral soil with its standard deviation depending on agronomic category and soil sampling date. DM stands for dry matter of the soil sample*

Higher mineral nitrogen contents in the 60-90 cm layer of very light and light soils relative to medium or heavy soils were also found in soil material taken from grassland soils and soils under mixed cereals. On the other hand, this relationship was opposite in the investigated layer in soils under maize because the highest N_{min} content was found in heavy soils (*Fig. 4*). A much higher N_{min} content in heavy soils relative to light soils was also found by Fotyma and Pietruch (2000). It was also shown that grassland soils accumulate less mineral nitrogen in the 60-90 cm layer than soils under mixed cereals or, which was even more evident, maize. Strong dependence of runoff and dissolved mineral nitrogen losses, and therefore differentiation of N_{min} content in the deeper soil layers, on vegetation cover was noticed by García-Díaz et al. (2017) for vineyards. Also De Notaris et al. (2017) showed that N leaching is influenced by vegetation cover, with spring wheat and potatoes being the two crops with highest N leaching.

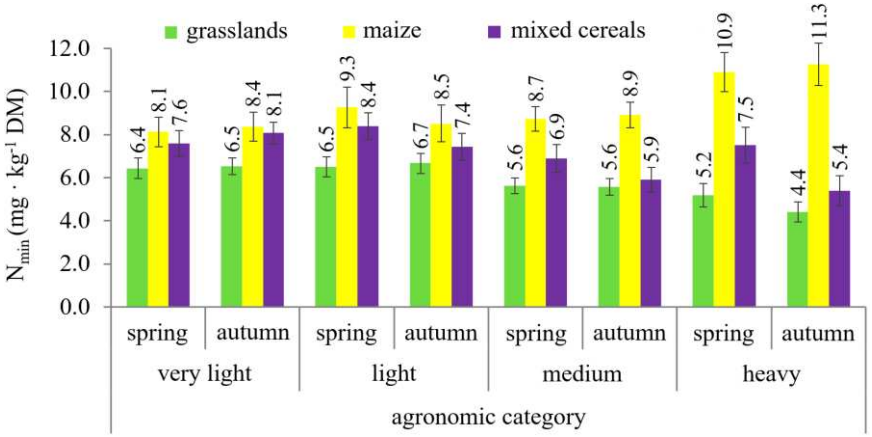

Figure 4. *Average mineral nitrogen N_{min} content in the 60-90 cm layer of grassland soils and soils under maize and mixed cereals with its standard deviation depending on agronomic category and sampling date. DM stands for dry matter of the soil sample*

Considering in turn mineral nitrogen content under different agronomic categories of grassland soils depending on land use, it was found that in most cases the highest content of this form of nitrogen at a depth of 60-90 cm was found in meadows (*Fig. 5*). The N_{min} contents in pasture grasslands as well as in hay and pastures grasslands were at a similar level, whereas the lowest amount of nitrogen was detected in alternate grasslands, which was particularly visible in heavy soils. Under the specific soil agronomic categories, greater differences in mineral nitrogen content between particular grassland uses were noted in autumn than in spring. Pawluczuk and Szymczyk (2008) obtained similar results. They found a lower mineral nitrogen content in muck and peat soils in extensively used meadows compared to this content in muck and peat soils in pastures. In the case of extensive grassland use, they found a higher nitrate content in groundwater under meadows than under pastures. These authors substantiate this fact by greater phytosorption of nitrogen by pasture vegetation and a low groundwater level. Above factors adversely affect the movement of the nitrate form of nitrogen deeper into the soil profile.

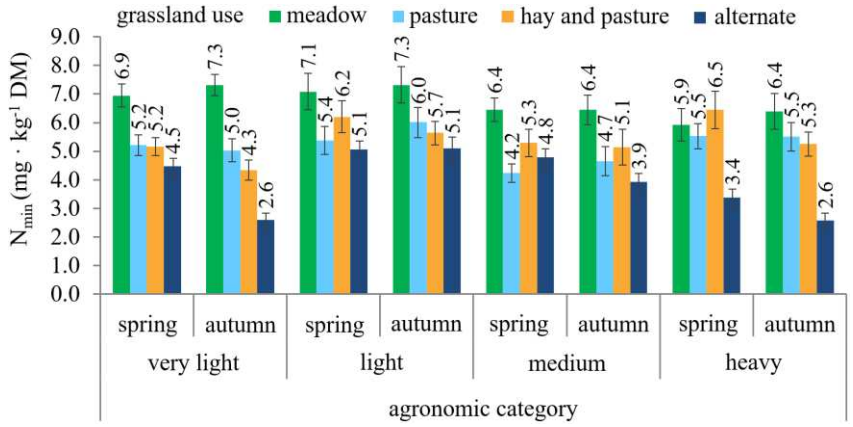

Figure 5. *Average mineral nitrogen N_{min} content in the 60-90 cm layer of grassland soils with its standard deviation depending on grassland land use, sampling date and agronomic category. DM stands for dry matter of the soil sample*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56635675

Observed relationships between soil agronomic category and mineral nitrogen content in the 60-90 cm soil layer (below the main root mass of the crops under investigation) were statistically confirmed (*Table 3*). Regardless of sampling date and land use, soil agronomic category had a significant effect on N_{min} content (R = -0.68), but this relationship was weaker in spring (R = -0.42) and stronger in autumn (R = -0.86). It means that the N_{min} losses decreased with the increase of percentage of fine particles with dimensions below 0.02 mm in soil, which is probably connected with lower permeability of heavier soils and therefore – reduced leaching. The dependence of N content on clay fraction (and, therefore, on agronomic category) was observed for USA, Australian rainforest, Denmark and the Netherlands, but those relations are not universal, however (Homann et al., 2007). According to Sapek and Kalińska (2004) the release of mineral forms during and after the growing season is increased due to the more intensive mineralization of nitrogen in the early summer months (May to July), which results in increased leaching in autumn and more pronouced relationships. The highest negative correlation was obtained for the relationship between the percentage of fine particles with dimensions below 0.02 mm and N_{min} content for meadows (R = -0.94). In turn, a positive relationship was demonstrated for hay and pasture use. A negative correlation was also obtained for alternate grasslands, but for autumn sampling date this correlation was statistically insignificant. As far as the field crop plants in question are concerned, a positive relationship between N_{min} content in the 60-90 cm layer and soil agronomic category was confirmed for maize crops. Opposite relationships were revealed for mixed cereal crops for both sampling dates and though for spring sampling these relationships are insignificant from the statistical point of view, a high and statistically significant correlation coefficient in the case of the autumn sampling date was obtained.

Table 3. *Correlation coefficients between soil agronomic categories and mineral nitrogen N_{min} content in the 60-90 cm soil layer with a breakdown into both land use and sampling date*

Land use	Sampling date	
	spring	autumn
Grasslands (on mineral soils)	-0.96*	-0.95*
Meadows (on mineral soils)	-0.94*	-0.92*
Pastures (on mineral soils)	-0.02	-0.02
Hay and pasture grasslands (on mineral soils)	0.57*	0.45*
Alternate grasslands (on mineral soils)	-0.69*	-0.22
Maize	0.84*	0.89*
Mixed cereals	-0.40	-0.98*
Total soils	-0.42*	-0.86*
Total soils (on an annual basis)	-0.68*	

* correlation significant at significance level p = 0.05

After confirming that the relationship between soil agronomic category and content of mineral nitrogen in 60-90 cm soil layer exists, equations describing those relations were elaborated (*Figs 6-8*). The determined linear regression equations can be of great importance from the practical point of view, as they may be used to forecast changes in mineral nitrogen content depending on the percentage of fine particles in mineral soil. Therefore they may help the farmer to identify the optimal dose of mineral nitrogen in soils with different agronomic category and suppress nitrogen losses and thus adverse

DOI: http://dx.doi.org/10.15666/aeer/1703_56635675

impact on the environment. Significance of relationships described by obtained equations was confirmed by the high coefficients of determination.

Conclusions

The results of this study confirm that significant differences in the content of mineral nitrogen can be observed in the soil layer beneath 60 cm, which is beyond the reach of the main root mass of crop plants in grassland soils and in arable soils, depending on agronomic categories and sampling date. It speaks for the fact that the leeching into deeper layers of soil occurs, which can have significant environmental consequences. Therefore, fertilization doses should take into account agronomic soil categories and type of land use. Regardless of observation period and the percentage of fine particles in mineral soils, the lowest content of N_{min} was shown in grassland soils, whereas greater accumulation of this nutrient in the soil profile at a depth of 60-90 cm was observed in the soils under both maize and mixed cereals. This was especially evident for soils under maize. It was revealed that agronomic category and the content of N_{min} in the 60-90 cm soil layer, regardless of the land use or sampling date, are strongly correlated. Elaborated equations describing those relationships for different land uses and sampling dates are characterized by very high coefficients of determination R^2, which suggest that they may be successfully used in precision agriculture and contribute to sustainable management of fertilizers usage leading to reduction of nitrogen leaching from topsoil to groundwater, thus decreasing the negative impact of agricultural land use on environment.

(Received 11th Jan 2019; accepted 8th Mar 2019)

Abstract. The traditional ecological footprint model is found poorly applicable in the ecological sustainability assessment of regional land utilization. This paper designs a "consumption-output" ecological footprint model and establishes the standard for judging the ecological sustainability of regional land utilization with the sustainable ecological deficit of land as the assessment indicator. On this basis, this paper accounts and judges the ecological sustainability of land utilization in Linxiang City during the 2005-2013 period. The results showed: 1) The sustainable ecological deficit of the land in Linxiang City tended to grow amid fluctuation and remained at an ecological sustainability status; 2) The city has fully tapped the potential of available ecological capacity of cultivated land, pasture land and waters but has not made full use of that of construction lands and forest lands; 3) The ecological sustainability of regional land use is high in the north, low in the south and the weakest in the center. A comparison to the accounting results output from the traditional model shows that the improved model is more comprehensive and consistent with the reality in the assessment of ecological sustainability of regional land utilization. Finally, this paper provides corresponding suggestions for the city to realize ecological sustainability.

Keywords: *sustainable ecological deficit, ecological capacity, consumption-output, regional ecological sustainability, the assessment criterion*

Introduction

The indicator systems used for quantitative sustainability measurement have mushroomed, such as "drive-status-response" indicator system, sustainable economic welfare indicator, true development indicator and sustainability barometer, since the United Nations Conference on Environment and Development that took place in Rio de Janeiro, Brazil in 1992 (Xu and Zhang, 2000; Cha et al., 2013). Regional ecological sustainability means the long-term maintenance and development of the natural regional ecosystem as to the integrity of its structure and function (including supply of natural resources and ecosystem service) under the interference from nature and mankind (Peng et al., 2011, 2012). The natural ecosystem supports and regulates the life system of the earth and cannot be replaced by any artificial capital in this sense. Therefore, the concept of sustainability, which is derived from the concern over the depletion of natural resources and degradation of the ecological environment, can be realized only with regional ecological sustainability as an important condition precedent and basic way

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56775692

(Franke, 1996; Parris, 2003), and the essence of regional ecological sustainability is to coordinate mankind's demand and the ecological capacity. William Rees, a Canadian ecological economist, invented the ecological footprint approach in 1992, and his doctoral student Mathis Wackernagel has gradually refined the approach (Rees, 1992; Wackernagel and Rees, 1996; Wackernagel et al., 1999). The new approach reflects the utilization status of the ecosystem and assesses the ecological sustainability of regional land utilization through quantitative measurement of the gap between the mankind demand for the natural ecological service and the supply of the ecological service provided by nature (Xu et al., 2006). The approach has quickly become a hot research topic in the area of sustainability assessment and promoted many scholars to perform extensive empirical studies, due to its advantages, including novelty of theory, visualization of concept, enrichment of connotation, operability, easy acceptance and global comparability (Lenzen and Murray, 2001; Monfreda, 2004; Chen et al., 2008a, b; Zhao et al., 2012, 2014a, b; Xiong et al., 2003; Tian et al., 2015; Wei and Wu, 2011; He et al., 2011; Lu, 2011; Zhang et al., 2009; Dai and He, 2013; Liu et al., 2015; Lai and Huang, 2005).

However, according to most of the studies, when the traditional model is used to assess regional ecological sustainability, it is often found that if a region has a lower consumption level and less developed economy, it will be more sustainable, which, however, is obviously contrary to the sustainability theory. Some scholars have studied on how to improve the model:

(1) In 2003, Xiong Deguo proposed to classify the ecological footprint into the ecological footprint of consumption and that of production and measure the stress of human activities on the local ecosystem with the ecological footprint of output for the purpose of judging the sustainability of the regional ecosystem and reflect the fairness of regional development with the ecological footprint of consumption (Xiong et al., 2003). Tian Long has calculated and assessed the ecological sustainability of land utilization in the Northwest Region of China in 2012 by replacing the ecological footprint with that of production and using the adjusted balancing factor and the output factor (Tian et al., 2015). Though the concept of ecological footprint of output has been put forward, no scholars have explored the internal relation between the ecological footprint of consumption and that of production. Moreover, most of the researchers have used the monotonous resource account to perform the ecological footprint accounting in related researches, but the decision on what resource account is used is rather discretionary and less justifiable.

(2) Wei Yuan, He Feng and other researchers have introduced the ecological footprint index, ecological footprint intensity, ecological moderate population, ecosystem utilization efficiency and other indicators on the basis of the ecological footprint model to make the model more suitable for the assessment of ecological sustainability of land utilization (Wei and Wu, 2011; He et al., 2011). Chen Chunfeng, Zhao Guishen and Lu Xiaoli suggested combining the theory of energy value and ecosystem service value with the ecological footprint model (Chen et al., 2008a; Zhao et al., 2014a; Lu, 2011). The improved model combined with other indicators and approaches can measure to what extent does mankind consume natural resources in a more comprehensive and accurate manner, but it cannot accurately reflect the ecological sustainability of land utilization in a specific region, as it does not take into account the true resource consumption of the region.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56775692

(3) Zhao Xingguo, Zhang Hengyi and Dai Yanan have adjusted and corrected the balancing factor and output factor based on the concept of "national hectare", "provincial hectare" and "regional hectare" respectively (Zhao et al., 2014b; Zhang et al., 2009). Compared to the traditional model, the improved model based on the balancing factor and output factor can reflect the actual condition of the research region with the calculation of ecological footprint and ecological capacity. However, it always measures the sustainability status of a region with the ecological footprint of consumption as a scale and ignores the biological output the research region can obtain from the ecosystem.

The concept of ecological footprint in the traditional model is actually the ecological footprint of consumption, namely, the area of the land with an ecological production required to satisfy the resource demand of the population in the region. What corresponds to the ecological footprint of consumption is the ecological footprint of output, that is, the area of the land with an ecological production needed to produce resources of the regional ecosystem. The traditional ecological footprint theory is based on the global perspective. The global ecosystem can be seen as a closed system with self-sufficiency, and the resource consumption of mankind is equal to the resource output of the ecosystem. Therefore, the ecological footprint of consumption can be used to measure the pressure of mankind activities on the global ecosystem and further asses the sustainability of the ecosystem. However, a region always imports and exports resources, so the pressure generated from the ecological footprint of consumption does not all come from inside the region and the pressure derived from the ecological footprint of output will not be fully borne by the region. Therefore, during the assessment of ecological sustainability of regional land utilization, either the ecological footprint of consumption or that of production cannot alone reflect the pressure of human activities on the regional ecosystem, and thus cannot accurately reflect the sustainability of the regional ecosystem. In recent years, Liu Yanzhong has designed the sustainable ecological deficit of land on the basis of the classified accounting for ecological footprints of consumption and output to reflect the extent of sustainable utilization of the regional ecosystem (Liu et al., 2015). However, they have not thoroughly analyzed the relation between the ecological footprints of "consumption-production" and the ecological capacity, which makes it unable to accurately reflect the sustainability statuses under different situations.

To sum up, the researches on the improvement and application of the ecological footprint model only make some technical upgrades to the model in part and can realize more precise accounting of ecological footprints. However, there are no reasonable, scientific and uniform standards for judging the ecological sustainability of regional land utilization, which will usually deliver a serious impact on accurate judgment of regional ecological sustainability and cause the assessment result to deviate from the actual condition. Therefore, it is particularly important to establish the standard for judging the ecological sustainability of regional land utilization.

Based on the analysis above, this paper will further explore the connotations of the ecological footprint of consumption, ecological footprint of output and ecological capacity as well as internal relations among them. Moreover, this paper will, based on the improved "consumption-production" ecological footprint model, establish the standard for judging the ecological sustainability of regional land utilization with the sustainable ecological deficit of land as the assessment indicator. On this basis, the paper accounts and judges the ecological sustainability of land utilization in Linxiang City.

Materials and methods

Introduction of traditional ecological footprint model

The traditional ecological footprint model classifies various biological resources and energy consumption items required for human activities into the areas of six types of ecological production land (cultivated land, pasture land, forest land (including garden land), waters, fossil energy land and construction land), namely ecological footprint (*EF*). Then, the model calculates the area of the land with an ecological production that can be provided by one region, namely, ecological capacity (*EC*), and compares the difference between the *EC* and the *EF*, namely, ecological surplus (*ER*) or ecological deficit (*ED*) to judge whether the region is sustainable.

Improved "consumption-production" ecological footprint model

Analysis of connotations of related concepts

The improved ecological footprint model classifies ecological footprints into ecological footprint of consumption (*EFc*) and ecological footprint of output (*EFo*). The *EFc* assesses the extent to which the population in the region demand the area of the land with an ecological production from the perspective of resource consumption. As one region may import resources when the supply of resources cannot satisfy the consumption demand in the region, the *EFc* can reflect the extent to which the region demands the ecological production land inside and outside the region, and this can be expressed in terms of the difference between the *EC* and the *EF*, namely *ERc* or *EDc*. The *EFo* accounts the ecological footprint from the perspective of corresponding output in the consumption resource account. One region may export resources to other regions after satisfying the internal consumption demand, so the *EFo* reflects the extent to which the region and other regions demand the area of the land with an ecological production in the region, which represent the *EFc* in broad sense. The difference between the *EFo* and the usable *EC* is the *ERo* or *EDo*, and the *EDo* represents the boundary of the ecological deficit borne by the regional ecosystem in the year. Specifically:

$$EFc = Nr_j \sum(c_i/p_i) \quad \text{(Eq.1)}$$

$$EFo = Nr_j \sum(o_i/p_i) \quad \text{(Eq.2)}$$

$$EC = N \sum(a_j\, r_j\, y_j) \quad \text{(Eq.3)}$$

$$ERc(EDc) = EC - EFc \quad \text{(Eq.4)}$$

$$ERo(EDo) = EFo - EC \quad \text{(Eq.5)}$$

In the formulas: N is the population size, j is the ecological production land type ($j = 1, 2, 3\ldots6$), i is the "consumption-output" item type ($i = 1, 2, 3\ldots n$), r_j is the balancing factor, c_i is the per capita consumption of item i, o_i is the per capita output of item i, p_i is the global average capacity for item i, a_j is the per capita area of land type j, y_j is the output factor. When the ecological capacity is calculated, a 12% biodiversity production area shall be deducted to protect the biodiversity.

DOI: http://dx.doi.org/10.15666/aeer/1703_56775692

Classification of ecological production land types

In China, the land planning classifies lands into three tier-1 types, including (cultivated land, garden land, forest land and pasture land), construction land and other lands (including waters and nature reserves) in terms of purpose. Based on the characteristics of the land planning, this paper divides ecological production lands in the research region into seven types, namely, cultivated land, pasture land, forest land (including garden land), waters, fossil energy land, construction land and nature reserves (including unused grassland, alkaline land, marshland, sandy land, bare land and other unused lands). Nature reserves have important ecological values, and should be included in the ecological capacity calculation. However, these reserves do not directly provide human consumption products, so they can be excluded from the accounting of *EFc* and *EFo*.

Establishment of assessment indicators for ecological sustainability of land utilization

Based on the relation between the consumption surplus/deficit and output surplus/deficit, this paper has designed the sustainable ecological deficit (*EL*) of land as the indicator that is used to assess the regional ecological sustainability and perform quantitative measurement of ecological sustainability. The *EL* represents the deficit in the area of the land with an ecological production the region can still withstand from the time point of research (Liu et al., 2015). For concrete formula, please see Section 1.4 "Standard for judging ecological sustainability of land utilization" in this paper.

Establishment of standard for judging ecological sustainability of land utilization

This paper has established the standard for judging the ecological sustainability under eight scenarios in two statuses, based on the analysis of the internal relations among the *EFc*, *EFo* and *EC* (see *Table 1*).

Status 1: If *EFo* is less than *EC*, the region will not make full use of the *EC* in the year, and the potential of the sustainable ecological deficit of the land will be the difference between the *EC* and the *EFo* in the region. Below is the calculation formula of *EL*:

$$EL = EC - EFc \quad \text{(Eq.6)}$$

If: $EFc<EFo$, then: the region can export the ecological production land and display an ecological surplus. If: $EL > 0$, then: the region will remain at an ecological sustainability status;

If: $EFc = EFo$, then: the region will have no ecological production land available for export and display an ecological balance. If: $EL > 0$, then: the region will remain at an ecological sustainability status;

If: $EFo < EFc < EC$, then: the region will need to import the ecological production land and display an ecological deficit. If: $EL > 0$, then: the region will remain at an ecological sustainability status;

If: $EFo < EFc = EC$, then: the region will need to import the ecological production land and display an ecological deficit. If: $EL = 0$, then: the region will come at the critical point of ecological sustainability;

If: $EFo < EC < EFc$, then: the region will need to import the ecological production land and display an ecological deficit. If: $EL < 0$, then: the region will remain at an ecological non-sustainability status.

Table 1. *Standard for judging ecological sustainability of regional land utilization based on "consumption-output" ecological footprint model*

Status		Condition	Import & export capacity	Ecological balance status	EL formula	EL value	Annual judgment of sustainability
Status 1: *EFo < EC*	The region will not make full use of the EC in the year, and the potential of the sustainable ecological deficit of the land will be the difference between the EC and the EFo in the region	(1) *EFc<EFo*	It can export ecological production land	Ecological surplus	*EC – EFc*	*EL* > 0	Sustainable
		(2) *EFc =EFo*	It cannot export ecological production land	Ecological balance		*EL* > 0	Sustainable
		(3) *EFo<EFc<EC*	It must import ecological production land	Ecological deficit		*EL* > 0	Sustainable
		(4) *EFo<EFc<EC*	It must import ecological production land	Ecological deficit		*EL* = 0	Critical point of sustainability
		(5) *EFo<EC<EFc*	It must import ecological production land	Ecological deficit		*EL* <0	Unsustainable
Status 2: *EFo > EC*	EF will be the maximum footprint the region can bear in the year, the potential of available ecological capacity will be fully utilized, and the corresponding ecological deficit of output will be the maximum deficit the region can tolerate in the year	(1) *EFc<EFo*	It can export ecological production land	Ecological surplus	*ERo* + (*EC – EFc*)	*EL* > 0	Sustainable

Status 2: If: $EFo > EC$, then: the *EF* will be the maximum footprint the region can bear in the year, the potential of available ecological capacity will be fully utilized, and the corresponding ecological deficit of output will be the maximum deficit the region can tolerate in the year.

If: $EFc < EFo$, then: the region can export the ecological production land and display an ecological surplus. If: $EL > 0$, then: the region will remain at an ecological sustainability status. Below is the calculation formula of EL:

$$EL = ERo + (EC - EFc \quad \text{(Eq.7)}$$

If: $EFc = EFo$, then: the region will have no ecological production land available for export and display an ecological balance If: $EL = 0$, then: the region will come at the critical point of ecological sustainability. Below is the calculation formula of *EL*:

$$EL = ERo + EDc \quad \text{(Eq.8)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56775692

If: $EFc > EFo$, then: the region will need to import the ecological production land and display an ecological deficit. If: $EL < 0$, then: the region will remain at an ecological non-sustainability status. The *EL* calculation formula is the same as formula (*Eq. 8*).

Overview of research region

As a county-level city under Yueyang City, Hunan Province, Linxiang lies along the border between Hunan Province and Hubei Province, covers a total land area of 1,743.68 square kilometers and supervises 19 towns. The terrain is high in the south and low in the north with diversified land utilization types, including serial mountains in the northeast part, continuous hills in the central part and vast low-altitude lakes in the northwest part. The city has abundant resources, including nonferrous metals, and products, including bamboo products, and was identified as a resource city by the State Council in December 2013. Resource cities constitute important strategic bases assuring China's energy and resource security and represent an important support for sustainable development of the national economy. A research on the assessment of ecological sustainability of land utilization in these cities is necessary to promote sustainable development of these cities, accelerate the transformation of the economic development pattern and construct a comprehensive well-off society. This paper will perform the empirical study based on Linxiang City, so the results will be representative, suitable and promising for application to some extent.

Notes on calculation data

The *EFc* and *EFo* of Linxiang City during 2005-2013 are calculated in accordance with the statistical yearbooks (2005-2013), overall land planning data (2006-2020) and land change data (2005-2013) of Linxiang City. This paper converts various "consumption-output" items of Linxiang City into the areas of 7 types of ecological production lands, where the "consumption-output" items of cultivated land include grains, beans, yams, oil seeds, cotton, hemps, sugar canes, vegetables and fruits, those of forest land include tea, camellia seeds, palm sheets, dry bamboo shoots and woods, those of pasture land include meats and poultry eggs, those of waters include aquatic products, those of construction land are mainly electric power, and those of fossil energy lands include coal, liquefied petroleum gas and gasoline.

The balancing factor and output factor used in the ecological footprint accounting are mainly the values of the traditional accounting model designed by Wackernagel (Rees, 1992; Wackernagel and Rees, 1996; Wackernagel et al., 1999). In detail, the output factor of cultivated land is defined as the ratio of the average productivity of the cultivated land in Linxiang City to that in the world, or 1.73. As to nature reserves, the balancing factor is defined as 0.12 (Lai and Huang, 2005), which is calculated with the balancing factor formula proposed by Lai Li for the unused land, and the output factor is set to 1.

Results

Analysis of ecological sustainability of land utilization in Linxiang City

Analysis of time series trend for ecological sustainability of land utilization

The research has found (as shown in *Table 2*) that in Linxiang City, the aggregate ecological footprint of output always exceeded the aggregate available ecological capacity

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56775692

and kept growing at a faster speed than that of the aggregate available ecological capacity. During the 8-year period, the aggregate ecological footprint of output grew at an average speed of 5.47%, which was higher than the annual average growth rate of 0.19% of the aggregate available ecological capacity and the aggregate ecological footprint of output at 2.42%. As a result, the aggregate ecological balance of consumption changed from an ecological surplus in the beginning to an ecological deficit in 2012. However, the aggregate ecological footprint of consumption was still less than the aggregate ecological footprint of output, and the sustainable ecological deficit of the land in Linxiang City tended to grow amid fluctuation and always remained at an ecological sustainability status.

Characteristics of spatial arrangement for ecological sustainability of land utilization

As illustrated in *Figure 1a,* the towns with strong sustainability included Huanggai Town, Chengfeng Town, Yuantan Town, Dinghu Town, Tandu Town, Wulipai Town, Yanglousi Town and Taolin Town, most of which lie in the central and northern parts of Linxiang City, in 2005. As illustrated in *Figure 1b,* the towns with strong sustainability included Huanggai Town, Jiangnan Town, Ruxi Town, Yuantan Town, Dinghu Town, Tandu Town, Nieshi Town and Taolin Town, most of which lie in the northern part of Linxiang City, in 2010. As illustrated in *Figure 1c,* the towns with strong sustainability included Huanggai Town, Jiangnan Town, Chengfeng Town, Ruxi Town, Yuantan Town, Dinghu Town, Tandu Town, Nieshi Town and Taolin Town, most of which lie in the northern part of Linxiang City, in 2013. Wulipai Town in the central part is a major town engaged in specialty agriculture and agricultural product processing as the pillar industry in the central economic zone of the city, Yanglousi Town is an important town

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56775692

along the border engaged in bamboo product and tea processing as the pillar industry, and the river plain area in the northern part is home to major towns specializing in agricultural production and aquatic breeding. High output is the major reason why these towns maintained strong ecological sustainability. In 2005-2013, the ecological footprint of consumption of Chang'an Sub-district was always far higher than its ecological footprint of output and available ecological capacity, and the sustainable ecological capacity of the region was always negative. This made the region always at an ecological non-sustainability status and indicated the region mainly mitigated its pressure by importing the ecological production land from the outside. This is mainly because Chang'an Sub-district, the downtown of Linxiang City, specializes in tourism and comprehensive light industries as the pillar industry and has an industrial structure with inadequate resources. Tourism and industrial production drive rapid growth of the ecological footprint of consumption, while the low resource output renders the ecological footprint of output and available ecological capacity unable to support the rapid growth of the ecological footprint of consumption.

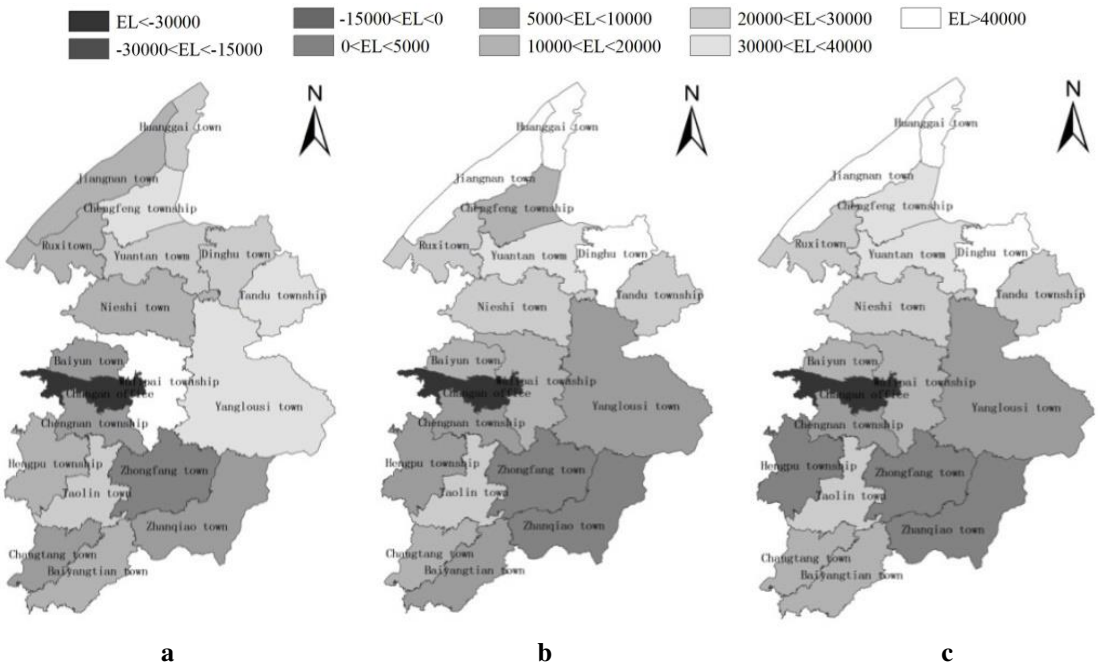

Figure 1. *Spatial distribution of sustainable ecological deficit of Linxiang in* ***a*** *2005,* ***b*** *2010 and* ***c*** *2013 (Ghm^2)*

Analysis of ecological sustainability by land type

It can be inferred from *Table 3* that the ecological footprints of output of cultivated land, pasture land and waters all exceeded their available ecological capacities and ecological footprints of consumption over the years, indicating these three types of ecological production lands maintained an ecological surplus and could moderately export the output to mitigate the ecological sustainability pressure outside the region. These lands feature full use of their ecological capacity in the year, high utilization rate and high output ratio and kept ecologically sustainable with their sustainable ecological deficit above zero.

DOI: http://dx.doi.org/10.15666/aeer/1703_56775692

Table 3. *Composition of "consumption-output" ecological footprint lands. (Unit: Ghm^2)*

Classification of ecological production lands		Cultivated land	Pasture land	Forest land	Waters	Construction land	Fossil energy land	Nature reserve
2005	Available ecological capacity	162536.11	5.1	85017.54	2190.78	63609.66	0	157.63
	Ecological footprint of consumption	101855.36	60328.35	270.26	32478.07	1471.18	35613.68	0
	Ecological footprint of output	210034.63	207716.31	25911.75	166689.66	2758.09	0	0
2010	Available ecological capacity	162361.08	5.03	84635.6	2185.17	66737.28	0	152.37
	Ecological footprint of consumption	108430.82	72967.13	1538.78	35430.32	3562.81	89014.73	0
	Ecological footprint of output	233407.77	231122.88	23199.91	187068.97	2785.71	0	0
2013	Available ecological capacity	162997.5	5.03	84414.94	2183.95	68467.77	0	149.18
	Ecological footprint of consumption	159653.76	79003.71	992.3	38214.13	4546.25	51111.73	0
	Ecological footprint of output	230487.79	240106.27	21418.29	237434.48	2464.56	0	0

During the period, the ecological footprint of consumption of the construction land kept growing and gradually overtook the ecological footprint of output to suffer an ecological deficit. However, the ecological footprint of consumption was always lower than the available ecological capacity, and the sustainable ecological deficit of the land was always above zero, indicating the ecological sustainability of the land. However, the available ecological potential of the construction land was not fully tapped, and Linxiang City can increase the utilization rate of the construction land to offset the ecological deficit and promote ecological sustainability. During the period, the ecological footprint of output of the forest land was smaller than the ecological capacity and bigger than the ecological footprint of consumption, and the sustainable ecological deficit of the land was above zero, indicating the land was ecologically sustainable. Therefore, Linxiang City can export the ecological surplus of the forest land to mitigate the ecological sustainability pressure of the external regions and promote its economic development.

Linxiang City has no fossil energy land but sees growing demand for consumption of fossil energy. Therefore, the growing demand for the ecological production land of fossil energy should be satisfied by exporting ecological resources of the ecological production land. This has delivered a huge pressure on the ecological sustainability of the region. Nature reserves do not supply direct products for mankind consumption, so this paper will only consider their ecological capacity. During regional development, Linxiang City can moderately adjust land utilization types to improve the contribution of nature reserves to the ecological capacity.

Comparison of assessment results output from the "consumption-output" ecological footprint model and traditional ecological footprint model

This paper has analyzed the assessment indicators with the "consumption-output" ecological footprint model as shown in *Table 2*, and discovered the time series trend in the ecological sustainability of land utilization. The result show that the sustainable ecological deficit of Linxiang City arrived at the peak value in 2011, then started falling

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56775692

in the two years to follow but always remained above zero. This shows that Linxiang City has always maintained an ecological sustainable status, but the extent of ecological sustainability has tended to decline. Linxiang is a city with abundant mineral resources but only a few small mines are still under production after the Taolin Lead-Zinc Mine went bankruptcy. The Ruxi Tiger Mountain Large Tungsten Mine has not started formal mining and the resource exploration cannot continue. This which will definitely affect the economic and social development of the city and further affect the ecological sustainability of land utilization in the region. According to the assessment standard of the traditional ecological footprint model, Linxiang City started incurring an ecological deficit in 2012 and the deficit kept rising. This shows that the region is ecologically unsustainable, which is still changing for the worse. In 2013, Linxiang City was defined as a mature resource city by the State Council. The Sustainable Development Planning for National Resource Cities (2013-2020) defines a mature resource city as follows: "A mature resource city stays at the stable stage of resource exploitation, has strong capacity to assure resource security and high level of economic and social development and represents the core area that assures China's energy and resource security at the current stage". Yet, the traditional ecological footprint model assesses Linxiang City as ecologically unsustainable, which is inconsistent with the positioning as a mature resource city.

When analyzing the spatial distribution of ecological sustainability of land utilization, this paper compares the results output from the two models for the year 2013. As illustrated in *Figure 1c,* the "consumption-out" ecological footprint model has output the following results: The ecological sustainability of regional land use is high in the north, low in the south and the weakest in the central, the towns in the northern part are strong in ecological sustainability, those in the southern part are general, the central part is weak and the downtown Chang'an Sub-district is even unsustainable. It can be inferred from *Figure 2* that the analysis results from the traditional model are bipolarized. The towns in the northern part are strong in ecological sustainability, those in the central and southern parts are not ecologically sustainable, and only a few towns maintain weak ecological sustainability. *Figure 2* shows that Chang'an Sub-district, Zhongfang Town, Taolin Town, Zhanqiao Town and Changtang Town are all ecologically unsustainable, indicating that these towns must import ecological production lands to satisfy their excessive ecological footprint of consumption. In contrast, Zhongfang Town, Taolin Town, Zhanqiao Town and Changtang Town are major forces in the economic development engaged in mineral resource exploitation and processing, mining, construction material and personalized agricultural products as pillar industries. They all export ecological production resources, meaning that their ecological production lands can both satisfy their own development needs and help mitigate the external ecological pressure. The results from the "consumption-output" ecological footprint model show that the ecological footprints of output of Zhongfang Town, Taolin Town, Zhanqiao Town and Changtang Town are bigger than their ecological footprints of consumption, so these towns maintain an ecological surplus and can export ecological production lands. At the same time, the sustainable ecological deficits of these four towns are all above zero, indicating they are all ecologically sustainable. These results are more consistent with the actual conditions.

As far as the ecological sustainability of different land types is concerned, it can be inferred from the "consumption-output" ecological footprint model has output the results below (see *Table 4*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56775692

Table 4. *Comparison of assessment results from the "consumption-output" ecological footprint model and traditional ecological footprint model. (Unit: Ghm^2)*

Classification of ecological production lands		Cultivated land	Pasture land	Forest land	Waters	Construction land	Fossil energy land	Nature reserve
2005	"Consumption-Output" model	108179.27	147387.96	84747.28	134211.59	62138.48	-35613.68	157.63
	Traditional model	60680.75	-60323.25	84747.28	-30287.29	62138.48	-35613.68	157.63
2010	"Consumption-Output" model	124976.95	158155.75	83096.82	151638.65	63174.47	-89014.73	152.37
	Traditional model	53930.26	-72962.1	83096.82	-33245.15	63174.47	-89014.73	152.37
2013	"Consumption-Output" model	70834.03	161102.56	83422.64	199220.35	63921.52	-51111.73	149.18
	Traditional model	3343.74	-78998.68	83422.64	-36030.18	63921.52	-51111.73	149.18

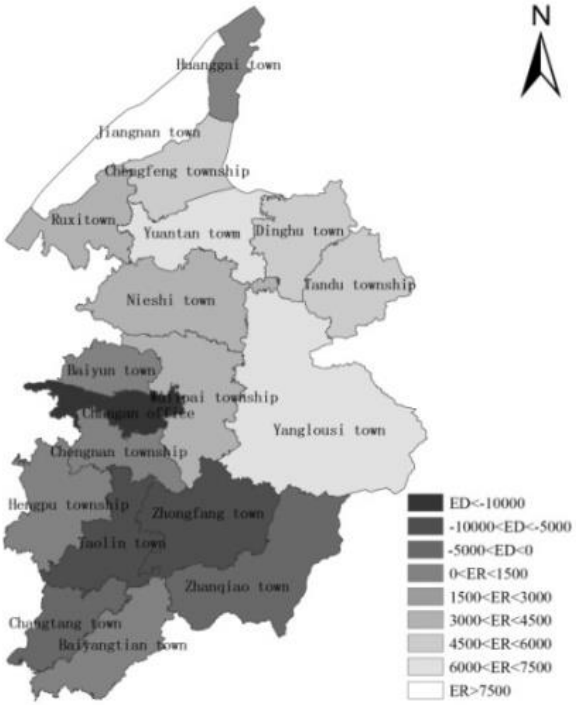

Figure 2. *Spatial distribution of ecological surplus/deficit of Linxiang City in 2013 (Ghm^2)*

All the land types are ecologically sustainable, except that the sustainable ecological deficit of the fossil energy land is less than zero, indicating the land is ecologically unsustainable. According to the results from the traditional model, cultivated land, forest land, construction land and nature reserve all maintain an ecological surplus and are ecologically sustainable, while pasture land, waters and fossil energy land all record an ecological deficit and are ecologically unsustainable. Linxiang City has no fossil energy land but sees growing demand for consumption of fossil energy, so the fossil land is truly ecologically unsustainable. The ecological footprints of output of pasture land and waters are more than 3 times and about 6 times their ecological footprints of consumption in the years. This reveals that the biological resource outputs of pasture land and waters can fully satisfy the consumption demand in the region and reflects the status of ecological sustainability. This is because the traditional model measures the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56775692

ecological capacity of the ecological production land based on the true area of the land and compares the capacity to the ecological footprint of consumption to judge the ecological sustainability of the land. However, this approach ignores the fact that the output of biological resources changes with the advance of production technologies and the change in the input level. In contrast, the "consumption-output" model measures the relations among the ecological footprint of consumption, ecological footprint of output and ecological capacity and assesses the ecological sustainability of land utilization with the sustainable ecological deficit as the indicator to make the result more consistent with the reality.

Discussion

Based on the improved "consumption-production" ecological footprint model, this paper has established the standard for judging the ecological sustainability of regional land utilization with the sustainable ecological deficit of land as the assessment indicator. On this basis, this paper has performed an empirical study based on Linxiang City and drawn the following basic conclusions through the analysis above:

(1) In Linxiang City, the ecological footprints of consumption mainly come from people's demand for cultivated land, pasture land, fossil energy land and waters, while cultivated land, pasture land and waters are principal contributors of ecological footprints of output. At present, cultivated land, pasture land and waters are all ecologically sustainable. However, as the ecological footprint of consumption keeps rising, the ecological surplus of the cultivated land will continuously decline and the ecological deficits of pasture land and waters will keep rising. The ecological footprints of output will grow annually, but the area of the lands with an ecological production will have a limited space for further expansion. Therefore, if mankind increases the output to satisfy the consumption without control, this will lead to the reduction of ecological capacity, ecological imbalance and other problems. To assure long-term sustainability of land utilization, Linxiang City should moderately implement intermittent suspension of farming, pasturing and fishing activities to recover the capacity of ecological production lands.

The construction land is ecologically sustainable in utilization, but its ecological footprint of output is far smaller than the ecological capacity. This reveals extensive utilization and low efficiency of the construction land. Therefore, Linxiang City should gradually lift the intensive utilization level of the construction land, and protect the areas of cultivated land and other lands with the function of ecological production to promote ecological sustainability of different types of lands.

The growing demand for fossil energy consumption has delivered a huge pressure on regional ecological sustainability. Linxiang City should consider reducing the use of fossil energies, develop green energies, encourage the production and use of energy-saving products. At the same time, it should improve the utilization rate and cleanness rate of fossil energies.

(2) Due to different spatial distribution and functional positioning, the towns in the northern river plain area are high in ecological sustainability. Yet, restricted by the industrial structure and consumption mode, the ecological footprints of consumption of the towns in the central urban area have quickly grown and overtaken their ecological capacity. Therefore, these towns are low in ecological sustainability and even unsustainable. Linxiang City should pay attention to adjusting the industrial structure,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56775692

optimizing the industrial arrangement and coordinating urban development and rural development, advocate sustainable consumption, and encourage the production and use of energy-saving products. It should save resources, develop the circular economy and protect the ecological environment. It should change the extensive economic development pattern, establish the production and consumption modes, intensive, economical and ecological, and promote the economic development to harmonize with resources and environment.

Conclusion

The "consumption-output" ecological footprint model is improved a lot as opposed to the traditional model as to suitability, integrity and reliability of the approach used to assess the ecological sustainability of regional land utilization. The analysis results based on the assessment indicators and judgment standards are more consistent with the reality and more reasonable than those from the traditional model.

This paper can to some extent solve the problem when the traditional ecological footprint model is employed to measure the ecological sustainability of regional land utilization. However, it is hard to collect related data used to calculate the balancing factor and output factor of ecological production lands. For this reason, these factors used in the research are both based on the "global hectare", which restricts the precision of the research to some extent. Related indicators fluctuate over a broad band, which also restricts easy understanding of the rule to some extent. In future, we will still need to strengthen the research on the values of these factors. However, these points are not the major topics of this paper. When the indicator *EL* for ecological sustainability assessment of regional land utilization is applied to the horizontal comparison of ecological sustainability in different regions, the scientificity of comparative analysis will be affected by the difference of ecological footprint and ecological capacity. In other words, sustainable ecological deficit (*EL*) can only preliminarily judge the absolute ecological sustainability of land, but can not quantitatively evaluate the extent of sustainable utilization of the regional land, which is valuable for follow-up research. And we will discuss these more in-depth during future studies.

Abstract. In the present investigation, soil nutrient characteristics of three stands were studied. The soil organic matter content showed a hierarchy of *Pinus massoniana* forest > slope farmland > *Eucommia ulmoides* plantation> maple-*Cinnamomum camphora* mixed plantation in horizontal direction. However, with an increasing depth of soil layer, the soil organic matter content showed a decreasing pattern. The soil total nitrogen phosphorus and potassium contents of different vegetation types followed a pattern of *Eucommia ulmoides* plantation > maple-*Cinnamomum camphora* mixed plantation > *Pinus massoniana* forest > slope farmland. In this, the soil total nitrogen and phosphorus content decreased significantly with the increase in soil depths. The soil available nitrogen, potassium and phosphorus content of different vegetation types exhibited a pattern which follows slope farmland > *Eucommia ulmoides* plantation > maple-*Cinnamomum camphora* mixed plantation > *Pinus massoniana* forest. The soil available nitrogen, potassium and phosphorus content decreased with the soil depth increase. The pattern followed for soil trace elements of different vegetation types were *Eucommia ulmoides* plantation > slope farmland > *Pinus massoniana* forest > maple-*Cinnamomum camphora* mixed plantation. The average contents of trace elements in 0-10 and 10-20 cm of soil layer followed a gradation of Fe > Mn > Zn > Pb > Ni > Cu > Cd. 'Grain to Green Program' increased the soil nutrient content of different vegetation types, and soil nutrient content decreased with the soil depth increase. In this study, significant correlations were observed among soil nutrient elements in different vegetation types.
Keywords: *organic matter and total nutrients contents, available nutrients contents, contents of soil microelements, correlation, three typical vegetation types*

Introduction

The types of forest stands affect the accumulation, distribution and circulation of nutrients in soil. Thus, different vegetation types stimulate different soil nutrient contents (Xiang et al., 2014) and affect the formation and development of soil (Huang, 2000; David et al., 2018). Soil, as an essential component for supporting vegetation and is one of the important environmental factors affecting the survival, structure and function of plant communities (He et al., 2017). In forest ecosystem, soil nutrients serve as major factor affecting vegetation growth (Jiang et al., 2011). Since 1970s, with the rapid development of precision agriculture and introduction of geostatistics, the study on soil nutrients has drawn much attention. Chen et al. (2017) studied the soil nutrient content of different vegetation types which provides clues to understand the relationship between forest growth and soil nutrient formation. The study of soil nutrient change is significant to understand the soil fertility and nutrient cycling mechanisms of different vegetation types (Finzi et al., 1998; Augusto et al., 2002). Many authors have evaluated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56935706

the performances of different small-watershed forest stands in respect to water conservation and sediment yield reduction, the rules of sediment yield and runoff yield, and the regulation of vegetation restoration patterns for a long time (Lopes and Canfield, 2004; Yuan et al., 2006). The characteristics of soil nutrients and their influencing factors were also studied, but these works focused on the effects of variation of individual nutrient elements (Liu and Tong, 2005; Wei and Shao, 2007), spatial heterogeneity (Wang et al., 2002; Wang et al., 2007), soil types (Wen et al., 2005), land utilization patterns (Wang et al., 2001) and site conditions (McGrath et a1., 2001; Latty et al., 2004) on the characteristics of soil nutrients. Some authors studied the soil nutrients, soil nutrient output mechanisms, microbial diversity and enzymatic activity of different forest stands (Peng et al., 2018; Hu et al., 2018; Zhang et al., 2018). However, the quantitative analysis of the availability of various soil nutrients to different forest stands was rarely studied (Yan et al., 2007). In China forest soil nutrients have been studied in a widespread manner extending from north to south (Gong et al., 2005; Huang et al., 2018). But the soil nutrient contents of different vegetation types after returning from farmland to forests and vertical heterogeneity of the soil nutrients were scarcely investigated (Cao et al., 2016). Especially, the hilly regions subjected to erosion in the south China with different water and soil erosion characteristics were rarely reported. Therefore, for the present study the Wuling Mountain small watershed was found as a typical example of hilly erosion regions of South China. A systematic study on the total and available nutrients and trace elements of soil covered by *Pinus massoniana* forest, *Eucommia ulmoides* plantation, maple-*Cinnamomum camphora* mixed plantation and slope farmland with different vegetation types was targeted. All these study sites were previously farmlands but returned to forests (the so called 'Grain to Green') later. Moreover, it was anticipated that the results of the present investigation could be beneficial for the soil conservation after returning farmland to forests as well as for vegetation optimization pattern selection and manual regulation in the hilly erosion regions of South China.

Field test region

The study area was located in the Nverzhai small watershed (111°12′42.836″E and 29°25′27.582″N) of Wuling mountain region in West Hunan Province of China. This watershed was well closed, containing a second-class small tributary of the Lishui River, and generally extended from north to south. It was a low mountain range with a total area of 3.15 km^2. The lowest elevation (outlet of the main ditch) was 210 m and the highest elevation was 917.4 m above MSL. The main ditch was about 1.2 km in length and the longitudinal slope of the main ditch was about 28.4‰. The forest coverage rate in this region was over 80%. The vegetation types were mainly characteristic to dense secondary forests after returning from farmland habitats. The soil-forming rock of the area was mainly sandy shale with yellow-red acidic soil. The light, heat and rainfall were abundant. The annual average sunshine time reached 1440 h, and the annual average temperature was 16ºC. The annual average precipitation was about 1400 mm, and the annual frost-free period was 216–269 days. A prototype monsoon humid climate of the middle subtropical mountains prevailed in the area. The main vegetation types included *Eucommia ulmoides* plantation, *Pinus massoniana* forest, *Citrus reticulata* plantation and slope farmland.

Methods

Test fields and measurements

In August 2015, three typical vegetation types of *P. massoniana* forest, E. *ulmoides* plantation and maple-*cinnamomum camphora* mixed plantation under similar growing environmental conditions (such as slope, slope aspect and altitude) and after returning from farmland were selected. With reference to a slope farmland, three blocks of test fields (20 ×20 m) were selected for each vegetation type. The distance between two study sites was above 200 m. The height, diameter at breast height (DBH) and growing conditions of all trees with DBH values ≥ 5 cm were measured and recorded. Three shrub blocks (2 × 2 m) were randomly arranged in each test field, and the shrub species, number of plants and average height were recorded. Five herbaceous blocks (1 × 1 m) were also arranged in each test field, and the species, number, coverage and average height of the herbaceous plants were recorded. This work is guided on "Observation Methodology for Long-term Forest Ecosystem Research" of National Standards of the People's Republic of China (GB/T 33027-2016).The test field characteristics of each forest stand are shown in *Table 1*.

Soil sampling and processing

Three blocks (5 × 5 m) were selected in each forest stand. After removing dry branches and fallen leaves, the soil sampling was done following the "S"-shaped 5-point method. Soil layers at depths of 0-10 and 10-20 cm were separately sampled. The samplings were made in triplicates. After an air-drying process, the stones and roots in the soil samples were removed and the samples were crushed and screened with a screen (1 mm mesh size) for the measurements of relevant indicators.

Determination of soil chemical indicators

In October 2015, the soil nutrient indices were measured following Soil Agrochemical Analysis (Qi et al., 2008). The total nitrogen content was determined

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56935706

with the semi-micro Kjeldahl method and NaOH-melting-molybdenum-antimony colorimetry was used to determine the total phosphorus content. For measuring total potassium content, NaOH-melting-flame-photometry was used. The alkali-hydrolyzed nitrogen content was determined with the alkali-hydrolyzed diffusion method. Available P was measured with the sodium-bicarbonate, extraction-molybdenum-antimony-colorimetry method while for the available potassium content, the NH_4OAc-leaching-flame-photometry was used. The organic matter content was determined with the potassium-dichromate-volumetry-heating-method. The iron, zinc and manganese contents were determined with the diethylene tri-amine penta acetic-acid-leaching-ICP (DTPA-ICP) method. For the determination of copper, cadmium, nickel and lead contents the ICP-MS method was used. The ICP-MS is displayed in *Figure 1*.

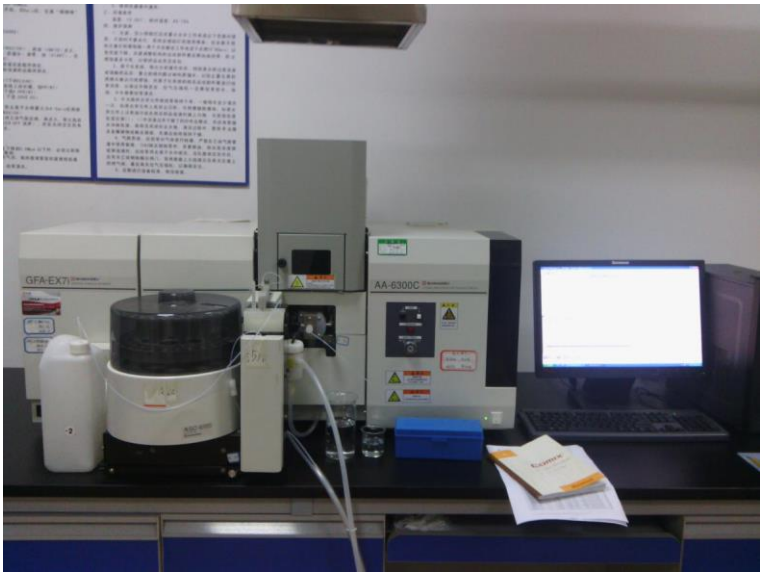

Figure 1. *The equipment of ICP-MS used in this study*

Data processing

The software SPSS 17.0 and R3.3.4 were used for data processing and analysis. One-way ANOVA and least significant difference (LSD) methods were applied for the comparison of the differences between the data groups. The software R3.3.4 was used to study the correlations between different soil nutrients.

Results and analysis

Organic matter and total nutrient contents in the soil of different forest stands

The differences in the contents of soil organic matter and total nutrients among different stands were significant (*Figure 2*). From 0–10 cm soil layers, the organic matter contents were ranked: *Pinus massoniana* forest > *Eucommia ulmoides* plantation > maple-Cinnamomum camphora mixed plantation > slope farmland. The organic matter content in the soil of *Eucommia ulmoides* plantation in the 10–20 cm soil layer reached a maximum, 1.80 times the lowest value (slope farmland). Its concentration in the soil of different stands through 0–20 cm soil layers were ranked as follows: The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56935706

Pinus massoniana forest (27.44 ± 9.37 g·kg^{-1}) > *Eucommia ulmoides* plantation (23.88 ± 3.15 g·kg^{-1}) > maple-*Cinnamomum camphora* mixed plantation (16.98 ± 1.98 g·kg^{-1}) > slope farmland (13.38 ± 1.86 g·kg^{-1}). With the increase of soil depth, the contents of soil organic matter in the soil of all stands decreased. For instance, the content of soil organic matter in the soil of the secondary *Pinus massoniana* forest decreased from 36.81 ± 0.002 to 18.07 ± 0.22 g·kg^{-1}.

The average contents of total nitrogen, total phosphorus and total potassium in the 0-20 cm soil layers of different forest stands followed the order of *Eucommia ulmoides* plantation > maple-*Cinnamomum camphora* mixed plantation > Masson Pine secondary forest > slope farmland. Besides, the contents of total nitrogen and total phosphorus in the soil of all stands decreased with the increase of soil depth, similar to the trend of the contents of organic matter against soil depth. For instance, the contents of total nitrogen and total phosphorus in the 0–10 cm soil layer of *Eucommia ulmoides* plantation were 1.64 ± 0.10 and 1.14 ± 0.01 g·kg^{-1}, respectively. While those in the 10–20 cm soil layer were lower (1.46 ± 0.15 and 1.07 ± 0.03 g·kg^{-1}, respectively). The contents of total nitrogen and phosphorus in the 10–20 cm soil layer of slope farmland was also lower than those in the 0–10-cm soil layer.

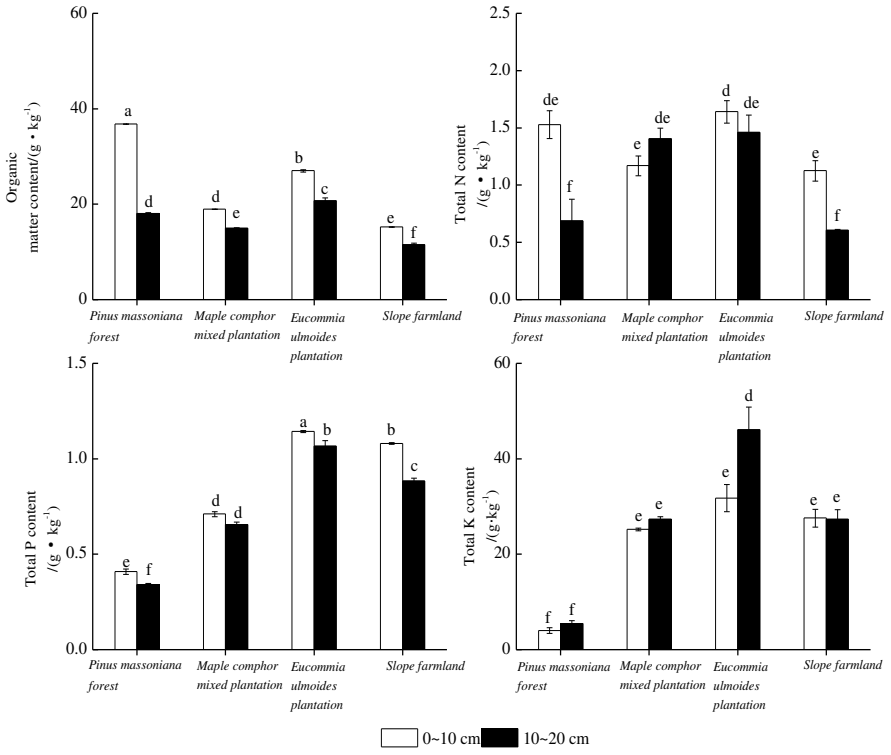

Figure 2. *Soil organic matter and total nutrient content of different stand types (different lowercase letters represent the significance of difference between different vegetation types in the same soil layer, P < 0.05)*

The contents of total potassium in the 0–10 cm soil layers of different vegetation types were ranked as follows: *Eucommia ulmoides* plantation (31.79 ± 2.85 g·kg^{-1}) > slope farmland (27.61 ± 1.87 g·kg^{-1}) > maple-*Cinnamomum camphora* mixed plantation (25.22 ± 0.30 g·kg^{-1}) > *Pinus massoniana* forest (4.02 ± 0.60 g·kg^{-1}). The contents in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56935706

the 10–20-cm soil layers were ranked as follows: *Eucommia ulmoides* plantation > maple-*Cinnamomum camphora* mixed plantation > slope farmland > *Pinus massoniana* forest. The contents of total potassium in soil of different stands increased with the increase of soil depth except for slope farmland. It can be conjectured that the accumulation of potassium in the *Pinus massoniana* forest was lower, while that in the *Eucommia ulmoides* plantation was higher; most of the potassium for uptake was concentrated on the upper soil.

Available nutrient contents in soil of different forest stands

Table 2 shows the total contents of available nitrogen, phosphorus and potassium in the 0-10and 10-20cm soil layers of different stands. These are ranked as follows: Slope farmland > *Eucommia ulmoides* plantation > maple-*Cinnamomum camphora* mixed plantation > *Pinus massoniana* forest. Soil available nitrogen from the study sites have been ranked as follows: *Pinus massoniana* forest > *Eucommia ulmoides* plantation > maple-*Cinnamomum camphora* mixed plantation > slope farmland. The state of available phosphorus was ranked as follows: Slope farmland > *Eucommia ulmoides* plantation > *Pinus massoniana* forest > maple-*Cinnamomum camphora* mixed plantation. The available potassium was ranked as follows: Slope farmland > *Eucommia ulmoides* plantation > maple-*Cinnamomum camphora* mixed plantation > *Pinus massoniana* forest. Both the contents of available phosphorus and available potassium in the soil of slope farmland were significantly higher than those in the soil of other vegetation types ($P < 0.05$), which may be related to the fertilization management. The available nitrogen content in the soil of maple-*Cinnamomum camphora* mixed plantation was higher, probably because its vegetation coverage was the highest. Liu et al. (2006) suggested that the vegetation coverage was positively affected by height, biomass, community species diversity and soil nutrient contents. In this study, the maple-*Cinnamomum camphora* mixed plantation had the highest vegetation coverage, so the available nutrient contents in the soil of this forest were higher.

Table 2. *Soil available nutrient content of different stand types*

Stand type	Soil layer/cm	Available Nitrogen /(mg·kg^{-1})	Available Phosphorus/(mg·kg^{-1})	Available Potassium/(mg·kg^{-1})
Pinus massoniana forest	0-10	108.36±2.11a	0.87±0.68bc	50.45±1.24c
	10-20	59.36±1.48b	0.58±0.04a	4.30±0.01a
Maple-*Cinnamomum camphora* mixed plantation	0-10	87.36±0.01cd	0.72±0.04ab	86.66±0.01d
	10-20	78.40±2.96de	0.50±0.14a	39.23±1.25b
Eucommia ulmoides plantation	0-10	96.60±0.84ab	1.42±0.01d	131.53±0.01g
	10-20	70.56±4.22c	1.08±0.02c	49.21±2.1c
Slope farmland	0-10	71.12±2.44ab	3.60±0.05f	116.56±0.01f
	10-20	62.70±2.01bc	1.97±0.02e	109.08±0.01f

The different lowercase letters indicate the significance of difference between different vegetation types in the same soil layer ($P < 0.05$)

As shown in *Table 2*, the average available nitrogen contents in the 0-20 cm soil layers were higher in *Eucommia ulmoides* plantation and *Pinus massoniana* forest i.e., 83.58 and 83.86 mg·kg^{-1}, respectively. The average nitrogen content in the slope farmland was the lowest (66.91 mg·kg^{-1}). In the 0–10-cm soil layer, the difference between the available nitrogen contents in the soil of the maple-*Cinnamomum*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56935706

camphora mixed plantation and *Eucommia ulmoides* plantation was significant ($P < 0.05$), but the difference between them in the 10–20-cm soil layer was not significant ($P < 0.05$). The content of available phosphorus in the soil of slope farmland was the highest (2.79 mg·kg^{-1}, $P < 0.05$), 4.5 times that in the soil of the maple-*Cinnamomum camphora* mixed plantation (the lowest, 0.61 mg·kg^{-1}). On the other hand, the average available potassium content in the soil of slope farmland was also the highest (112.82 mg·kg^{-1}), followed by that of the *Eucommia ulmoides* plantation (90.37 mg·kg^{-1}).

The available nutrients of all stands decreased with the increase of soil depth. Especially, the soil available nitrogen content of *Pinus massoniana* forest and *Eucommia ulmoides* plantation decreased from 108.36 and 96.60 mg·kg^{-1} in the depth of 0–10 cm to 59.36 and 70.56 mg·kg^{-1} in the depth of 10–20 cm, respectively, indicating that the available phosphorus and potassium contents changed significantly with the soil depth among different forest stands.

Soil microelements among different forest stands

All the data on trace elements presented in *Table 3* represents the average content from different forests stands within 0-10 and 10-20 cm soil depth profiles. The range of the trace elements followed a pattern like Fe > Mn > Zn > Pb > Ni > Cu > Cd. On the other hand, Fe, Mn, Zn, Pb, Ni, Cu and Cd content through 0-10 cm soil layers were ranked as *Eucommia ulmoides* plantation > slope farmland > *Pinus massoniana* forest > maple-*Cinnamomum camphora* mixed plantation.

Table 3. *Showing the content of soil trace elements in different forest stand types*

Stand type	Soil layer(cm)	Cu (mg·kg^{-1})	Fe (mg·kg^{-1})	Zn (mg·kg^{-1})	Mn (mg·kg^{-1})	Cd (mg·kg^{-1})	Ni (mg·kg^{-1})	Pb (mg·kg^{-1})
Pinus massoniana forest	0-10	4.30	4582.05	32.13	83.24	0.53	9.24	32.58
	10-20	4.60	4483.64	28.31	60.97	0.14	8.01	29.97
Maple-Cinnamomum camphora mixed plantation	0-10	7.84	4941.38	48.49	478.68	0.53	16.63	37.81
	10-20	7.55	637.97	53.48	551.08	0.53	16.63	37.81
Eucommia ulmoides plantation	0-10	10.79	5001.27	54.40	718.17	0.27	25.87	29.97
	10-20	11.68	4997.00	53.71	729.31	0.40	24.64	29.97
Slope farmland	0-10	8.73	4958.49	51.04	695.89	0.40	21.56	29.97
	10-20	9.61	4937.11	50.93	662.47	0.40	24.03	24.74

In detail, Fe contents in 0–10 and 10-20cm soil layers showed a range of 637.98–5001.27 mg·kg^{-1}. However, the average Fe content in the soil of *Eucommia ulmoides* plantation was the highest but the concentration of it in the soil of maple-*Cinnamomum camphora* mixed plantation was the lowest. On the other hand, Cu contents ranged from 4.30–11.68 mg·kg^{-1}. It was highest in the soil of *Eucommia ulmoides* plantation but lowest in the *Pinus massoniana* forest. The Zn content varied from 28.31–54.40 mg·kg^{-1}. In *Eucommia ulmoides* plantation, this parameter was the highest while in the *Pinus massoniana* forest it was lowest. Mn contents showed a range of 60.97–729.31 mg·kg^{-1} representing the highest value in the soil of *Eucommia ulmoides* plantation. Its concentration fell to a lower value in the soil of *Pinus massoniana* secondary forest. The recorded range of Cd content was 0.15–0.53 mg·kg^{-1}. The soil of maple-*Cinnamomum camphora* mixed plantation showed the highest concentration of Cd. Another trace element Ni ranged from 8.01–25.87 mg·kg^{-1} showing its highest presence in the soil of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56935706

Eucommia ulmoides plantation. In the soil of *Pinus massoniana* forest low Ni concentration was seen. Pb varied from 24.74–37.81 $mg \cdot kg^{-1}$ showing its highest concentration in the soil of maple-*Cinnamomum camphora* mixed plantation. The average Fe content in the soil of *Eucommia ulmoides* plantation decreased from 5001.27 $mg \cdot kg^{-1}$ in the depth of 0–10 cm to 4995.55 $mg \cdot kg^{-1}$ in the depth of 10–20 cm. While its concentration greatly decreased in the soil of maple-*Cinnamomum camphora* mixed plantation. The decreasing pattern was 4941.38 $mg \cdot kg^{-1}$ in the depth of 0–10 cm to 637.97 $mg \cdot kg^{-1}$ in the depth of 10–20 cm. In addition, the contents of trace elements in the soil of *Pinus massoniana* forest and slope farmland also showed the similar trend with the increase of soil depth. To sum up, it could be mentioned here that the contents of trace elements in the soil of different forest stands decreased with the increase of soil depth. It indicates that the contents of trace elements in the upper soil layer were much higher than those in the lower soil layer.

Correlation between soil nutrient contents

The results of correlation analysis between different soil nutrients for different stands are shown in *Table 4*.

Table 4. *Showing the values of correlation coefficient (r) among different soil nutrient parameters*

The symbol * is added if *P* was< 0.05; the symbol ** is added if *P* was< 0.01

Total phosphorus showed a positive correlation with total potassium ($r = 0.94$, $P < 0.05$). This parameter also showed significant positive correlation with the contents of Cu, Mn and Ni ($r = 0.98$, $P < 0.05$); $r = 0.96$, $P < 0.05$) and $r = 1$, $P < 0.01$), respectively). In the analysis, total potassium correlated significantly and positively ($P < 0.05$) with the contents of Cu, Zn, Mn and Ni, (the values of *r* were 0.98, 0.96, 0.96 and 0.95, respectively). Among these trace elements, Cu had significantly positive relationships with the contents of Mn and Ni ($P < 0.05$), and the correlation coefficients were 0.96 and 0.99, respectively. Zn correlated significantly and positively with Mn ($r =$

0.97, P < 0.05). Mn showed significant positive correlation with Ni (r = 0.98, P < 0.05). Significant negative correlation was observed between Fe and Pb (r = -0.96, P < 0.05).

Discussion

Effects of returning farmland to forest on the different soil nutrient contents

The interactions between soil and vegetation promote the change of spatial heterogeneity of soil and vegetation, and soil quality is the result of interactions between human and natural factors (Wang et al., 2010a). In the present work, the results showed that after returning farmland to forest, the organic matter contents in the soil of different forest stands were ranked as follows: *Pinus massoniana* forest > slope farmland > *Eucommia ulmoides* plantation > maple-*Cinnamomum camphora* mixed plantation. The reasons can be summarized as follows: The root system of *Pinus massoniana* secondary forest was more developed, and the canopy width was greater with more litter. Because of long-term fertilization, the organic matter content of slope farmland was high. Hence, the carbon source input of *Pinus massoniana* forest and slope farmland was high. The *Eucommia ulmoides* plantation accumulated abundant organic matter under the conditions of manual disturbance and cultivation management. The maple-*Cinnamomum camphora* mixed plantation was a secondary forest, of which the accumulation of organic matter was less affected by external factors. Therefore, its organic matter content was lower. The soil organic matter, as a cementing material between soil particles, can form water-resistant aggregates and large aggregates with moderate ratios and stable structures (Albiach et al., 2001). Hence, it has the ability to enhance soil and water conservation and to improve soil structure, thereby enhancing the ability of decomposing litter and leaves and improving the nutrients exchange rate between plants and soil. As a result, a benign circulation system will be formed.

The contents of total nitrogen, total phosphorus and total potassium in the soil of different forest stands after returning farmland to forest were relatively high, indicating that the soil in this area was not barren. Compared with the slope farmland, the total nitrogen content in the soil of *Eucommia ulmoides* plantation was the highest, principally because the soil nitrogen content mainly depended on the decomposition extent of organic matter and the accumulation of biomass. The *Eucommia ulmoides* plantation had high species diversity, and the biomass accumulation of shrubs and herbs was high also. Thereby, the return, decomposition and enrichment of nutrients were intense. Qi et al. (2007) also reported that the soil nitrogen content mainly depended on the decomposition extent of organic matter and accumulation of biomass. Except the slope farmland, the *Pinus massoniana* forest, *Eucommia ulmoides* plantation and the maple-*Cinnamomum camphora* mixed plantation were rich in understory vegetation, litter and biomass, which favored the accumulation of organic matter and nitrogen. The higher contents of organic matter also benefited the contents of nitrogen and phosphorus. The high contents of total potassium should be ascribed to the soil parent material in this area. The potassium in the soil mainly existed in the form of minerals. Thus, the supply level of potassium in the soil mainly depended on the amount of potassium minerals in the soil, so the potassium content in this area was enough. The results of our study showed that the soil organic matter in the woodlands, after returning farmland to forest, had been improved, indicating that the returning was beneficial to the accumulation of soil organic matter. This result is consistent with the results of Han et al. (2012) and Gong et al. (2005). Gong et al. (2005) also reported that the differences

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56935706

between soil organic matter contents in different soil layers of various forest stands were significant.

It is assumed that the content of available nutrients serves as an indicator for the supply of soil nutrients (Wang et al., 2014). The results in this work showed that the average content of soil available nitrogen in 0-10 and 10-20 cm layers was higher than 78 $g \cdot kg^{-1}$. The average content of available phosphorus was lower than 1.35 $g \cdot kg^{-1}$ and the average content of available potassium was lower than 75 $g \cdot kg^{-1}$. The variation trend of the available nitrogen content in this region was in agreement with that of the total nitrogen content. According to the dynamic variation laws of nutrients in forest soil, the content of organic matter should be positively correlated with the content of soil available nitrogen to a certain extent (Yang and Zhang, 1986). Namely, the higher the organic matter content, the higher the available nitrogen content is. In the 0–10 cm soil layer, the contents of available nitrogen, available phosphorus and available potassium in the soil of *Eucommia ulmoides* plantation were relatively high. Because the litter fall from a relatively wide canopy of *Eucommia ulmoides* plantation was intense. This results a high content of organic carbon in the upper soil layer (Wang et al., 2010b), which was favorable to the accumulation of nitrogen and phosphorus.

After returning from farmland to forest, the contents of soil organic matter, total phosphorus and nitrogen and available potassium, phosphorus and nitrogen decreased with the increase of soil depth among various forest stands. This is because the soil nutrients generated mainly from soil minerals and soil organic matter and the latter compound is mainly generated from the litter of aboveground parts, underground roots, precipitation, slope infiltration, groundwater, fertilization and irrigation during cultivation. Therefore, most of the sources of soil nutrients were above ground, and these sources first contacted with the upper soil layer for enriched storage. Then, the nutrients were transported to the lower layer through leaching or uptake with roots. Consequently, the contents of organic matter, total phosphorus and nitrogen and available potassium phosphorus and nitrogen in the soil of different forest stands declined with the increase of soil depth.

Relationship between soil nutrients after returning farmland to forest

The contents of trace elements in the soil of different forest stands followed the order: Fe > Mn > Zn > Pb > Ni > Cu > Cd. The soluble Fe species could be involved in the growth of plants (Qi et al., 2008), so the content of Fe was high. All the organics and biological residues in the soil contained Zn and the acidic substances produced from organic matter during decomposition could increase the solubility of Zn compounds. The order of total contents of soil trace elements in the soil of different stands was ranked as follows: *Eucommia ulmoides* plantation > slope farmland > *Pinus massoniana* forest > maple-*Cinnamomum camphora* mixed plantation. In addition, generally the total contents of trace elements in the 0–10 cm soil layers were higher than those in the 10–20 cm soil layers. This is mainly due to the compensation effect of litter decomposition, nutrients release and return on the contents of trace elements in soil. This distribution phenomenon also reflects the weak leaching and deposition effects in the lower soil layers.

Based on the correlation analyses among soil nutrients of different forest stands after returning farmland to forest, the positive correlations between the content of soil organic matter and the contents of total and available nitrogen were found. This indicated that nitrogen and carbon elements were closely related in the accumulation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56935706

and storage process. This result is in accordance with the conclusion of Li et al. (2014) that the content of organic matter in soil had significantly positive correlations with the contents of total nitrogen, available nitrogen, total phosphorus and available phosphorus in the soil. On the other hand, Li et al. (2014) also found that the content of organic matter in soil correlated positively but weakly with the contents of soil total potassium and available potassium. This result was also consistent with the present study. Additionally, in the present work, we found that the content of phosphorus in soil was significantly positively correlated with the contents of trace elements Cu, Mn and Ni. This result agrees with the conclusions drawn by Huang et al. (2016), who reported that the contents of Cu, B, and N were significantly positively correlated with various minerals in the soil for the cultivation of wild tara vine. In this study, the content of total potassium was significantly positively correlated with contents of Cu, Zn, Mn and Ni, but Huang et al. (2016) suggested that the content of total potassium was significantly and negatively correlated with contents of Cu, Zn, Ni and other elements. This difference should be attributed to the reason that the soil used in Huang's study was acidic black loam located at the foot of the Changbai Mountain in Antu County, Yanbian Prefecture, Jilin Province, China, and the black loam, containing a small amount of soluble salts, had a great texture without salinization. As for the soil in our present work, the red and yellow soil had a parent material of shale and slate, and the soil texture was poor, compared to the black loam. These results show that the distribution of soil nutrients depends on the structural factors such as climate, topography, parent material and soil type which can lead to the spatial relationships between soil nutrients.

In this study, the content of Cu was correlated significantly and positively with Mn and Ni. On the other hand, Zn correlated significantly and positively with Mn. Mn however, correlated significantly and positively with Ni. In this study significant negative correlation was observed between Fe and Pb. These results indicate that the trace elements in various types of soil interacted with each other showing a pattern that, when the content of an element increased, the contents of relative trace elements changed.

Conclusion

After returning farmland to forest (i.e., Grain to Green), the accumulation of soil organic matter in the soil of the three vegetation types and slope farmland was increased, but the accumulation was different depending upon the vegetation types. The accumulation in the soil of *Pinus massoniana* forest was the highest, and that of the maple-*Cinnamomum camphora* mixed plantation was the lowest. In the vertical direction, the contents of organic matter in the soil of all forest stands were decreased. After returning farmland to forest, the contents of total nitrogen, phosphorusand potassium and organic matter in the soil of woodlands were the highest and those in the soil of the slope farmland were the lowest. This had indicated that the accumulation of nutrients in the soil of slope farmland was slower. Nevertheless, the accumulation of available nutrients in the soil of slope farmland was the fastest. The contents of available nitrogen and available phosphorus decreased with the increase of soil depth, but the content of available potassium increased with the increase of soil depth. After returning farmland to forest, the trace elements accumulated to a small extent but their differences based on different stands were negligible. The nutrient elements in the soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_56935706

of different vegetation types had significant correlations with each other and the soil trace elements interacted with each other following a pattern that when the content of an element increased, the contents of relative trace elements changed.

In addition, only the correlation between soil nutrients were studied in this research, and many other future studies such as dynamic changes of nutrient, change mechanism and so on would also play an important role in nutrient cycling research. And this needs to be studied further in the future. The result of this research can provide data support and theoretical basis for soil conservation, vegetation optimization model selection and artificial control in the erosion area of southern mountainous range of China.

Abstract. We investigated the ecological restoration problems of dehydration river reaches, which are downstream of diversion-type hydropower station in medium and small watersheds. Based on this information, we calculated the ecological flow using the following five methods: the minimum monthly ecological flow method, the dynamic calculation method of ecological water demand, the Northern Great Plains Resource Program method (NGPRP), and the monthly frequency method. Then, we combined Matter Element Analysis (ME) and Tennant method to construct a ME-Tennant model. Furthermore, the ecological flow process of a river was evaluated with ME-Tennant model. The case study was performed at the Liujiaping Hydropower Station in Hunan Province, China. In this study, ME-Tennant evaluation model was applied to determine the ecological flow process, and the results were used to verify the validity and the applicability of the model. The study provides a basis for the ecological restoration of dehydration river reaches, which are downstream of the diversion-type hydropower stations. The proposed evaluation model does provide a new way to reasonably determine the ecological flow process of a river.
Keywords: *river reaches, minimum ecological flow, matter element analysis method, ME-Tennant method, Liujiaping hydropower station*

Introduction

Diversion-type hydropower stations are generally built in mountain reaches using a pipeline or artificial channels that lead water to the downstream. Diversion-type hydropower stations, which have small flow but large slope, utilizes the large water head to generate electricity. To construct the diversion-type hydroelectric power station, the runoff of the river is divided and dehydration river reaches are formed between the dumpsite and tail water stream. However, a diversion-type hydroelectric power station has adversely affected the quality of river water, causing harm to the ecological environment; moreover, it has negatively impacted the hydrology and the number of water resources in a given area. By maintaining the ecological runoff and its variation characteristics in a river, we can protect the ecosystem of a river and ensure its normal ecological functions. To offer protection to a river ecosystem and to restore its normal functioning, we need to essentially study the ecological runoff process of a river. Both Chinese and international scholars have proposed the idea of ecological runoff calculation. To fulfill this objective, they have used a variety of methods to calculate the ecological runoff of a river. After comparison and analysis of various methods, they have selected the calculation methods and results that reflect the actual situation of rivers. Zhang used five methods to study hydrology and ecological flow of the Pearl River basin. Thus, the ecological runoff of the Pearl River basin was calculated by five methods. By comparing the results with those of Tennant method, he preferred to use the minimum monthly ecological flow method and the monthly frequency method to calculate the minimum ecological runoff and the suitable ecological runoff, respectively

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57075722

(Zhang, 2010); Shi used four hydrological methods to calculate the ecological flow, which was produced by the main rivers in Xiangyang City; the methods complied with the requirements of the river ecological water, and they were used to determine the basic ecological flow (Shi and Zuo, 2017). Yu used six methods to calculate the ecological base flow in Guanzhong section of Weihe River. Then, they analyzed the annual runoff distribution characteristics of Weihe River. The results indicated that the Tennant method produced the most accurate results, so it was the best method for calculating the ecological base flow of Weihe River (Palau and Alcázar, 2012). Palau used several methods to determine the minimum ecological flow, and they used BFM method to calculate it (Zhang, 2008).

Different methods may be used to calculate the ecological runoff of different rivers. A single method may produce unreasonable results for different rivers, so a variety of methods should be used to calculate and analyze the ecological runoff of different rivers. However, in this process, the evaluation is not accurate and intuitive enough as it subject to different factors, causing some difficulties in the final determination of ecological runoff. To tackle this situation, we combined Matter Element (ME) analysis and Tennant method to come up with an ME-Tennant model. This model was used to evaluate the ecological flow process of a river. Our main aim was to restore the ecology of dehydrated river reaches, which were located downstream of the diversion-type hydropower stations. Moreover, the ME-Tennant model was projected as a new way of reasonably determining the ecological flow process of a river.

Materials and Methods

Materials

The Liujiaping hydropower station is selected as the study area. Its coordinate is 11036'E-1100 42'E and 270 26'N-270 38'N. Liujiaping River is the primary tributary of Erdu River, which originates from Liangfengjie Mountain, Longhui County, Hunan Province, China. The river is zigzagged and it flows from the southeast to the northwest regions of China. In total, the area and length of the river basin area are 72 km^2 and 30 km, respectively. A large slope is a characteristic feature of the Erdu River basin. The conditions of the natural river are not conducive for fish farming, and there is no valuable and rare aquatic organism in the river. The basin belongs to the monsoon regions of Southeast Asia. Liujiaping reservoir is located in Longzhuangwan Village, Xupu County. In the reservoir, the rainwater harvesting area is 53.63 km^2, while the length of the mainstream above the dam site is 21.0 km. The average slope of the river is 91%, and the total reservoir capacity is 33.652×10^6 m^3.

Liujiaping powerhouse is located approximately 3 km away in the downstream of the dam. It is a diversion-type hydroelectric power station, which should be regulated for multiple times in a year. There are dehydration river reaches between the dam site and the tail water stream, and a little pond is observed in the foundation pit; the riverbed sand is exposed and there is no habitat for the fish to survive and thrive. A definite ecological flow should be discharged to meet the requirements of ecological environment and water demands of the dehydration river reaches, which are downstream.

An ecological runoff refers to a flow of a certain quality, which is required to maintain the ecological function of a specific river ecosystem; it is affected by the river's ecohydrology and the changes inflicted with temporal and spatial variation. The ecological flow corresponds with the time axis. Therefore, we drew a response curve of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57075722

flow and time, which is known as ecological runoff process (Li, 2015). An ecological runoff process emphasizes the changing characteristics of an ecological flow, which is determined with respect to space and time scales and dynamic demands. It reflects the different requirements of ecological flow in different time-scales.

In order to protect the ecological conditions of dehydration river reaches, a certain ecological flow should be discharged (Wang, 2014); moreover, the ecological runoff process should be performed according to ecological flow requirements of each month. The ecological flow process of dehydration river reaches has many goals, and their implementation sequences are as follows: (1) ensure continuous flow; (2) provide a minimum living space for aquatic organisms; (3) provide suitable habitat conditions for aquatic organisms.

Calculation methods of ecological flow process

Presently, more than 200 kinds of calculation methods are used to determine the ecological flow of a river (Thame, 2003); these methods are mainly classified into four types: i) the hydrologic method is based on the historical hydrological flow data, such as the Tennant method; ii) the hydraulic method is based on hydraulic foundation and cross-section parameters used for calculation, such as the R2-Cross method and the wetted perimeter method; iii) the habitat simulation method is based on biological factors, which are combined with the results of hydraulic analysis and habitat evaluation. For example, the instream flow incremental method (IFIM method) and physical habitat model simulation method (PHABSIM method); and iv) the holistic analysis method is based on the theory of river system integrity, which is combined with the flow data and information. The overall evaluation method and the BBM method (Building Block Methodology) are the most commonly used methods of this type.

Due to a lack of ecological data, it is difficult to apply the following methods in China: the habitat simulation method, the hydraulic method, and the holistic analyze method. However, hydrology method only needs historical flow data to ascertain the ecological flow of a river, and most of China's regional historical flow data is sufficient; therefore, hydrology method is quite appropriate for use in China. Moreover, the method can be suitably used to analyze the research data of small and medium-sized rivers' ecological flow. In this study, we analyzed several common hydrological methods.

The minimum monthly ecological flow method

In the monthly minimum ecological flow method, the ecological flow of each month is calculated from the minimum monthly average flow observed in the historical runoff series of several years. With this method, we calculated the minimum ecological flow process (Yu, 2004). The formula is as follows:

$$q_i = \min(q_{ij}) \text{ , } j=1,2,\ldots n \quad \text{(Eq.1)}$$

where, q_i is the minimum ecological flow of the month i, and it is expressed in m^3/s; q_{ij} is the average monthly flow of the month i in the year j, and it is expressed in m^3/s; n is the statistical year.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57075722

The dynamic calculation method of ecological water demand

The dynamic calculation method was based on the historical flow data, and it introduced the mean value ratio of the same period (Pan and Ruan, 2015; Pan, 2013); moreover, it was also used to determine the relationship between the monthly ecological flow and the annual average flow of each month. Thus, we determined the minimum ecological flow process. The concrete calculation process is as follows:

(1) Calculate the annual average and the minimum annual flow using a long series of natural flow data.

$$\bar{Q} = \frac{1}{12}\sum_{i=1}^{12} \bar{q}_i \quad \text{(Eq.2)}$$

$$\bar{Q}_{\min} = \frac{1}{12}\sum_{i=1}^{12} q_{\min(i)} \quad \text{(Eq.3)}$$

$$q_{\min(i)} = \min(q_{ij}) \, , j=1,2,\ldots n \quad \text{(Eq.4)}$$

where, $\bar{Q}$ is the annual average flow, and it is expressed in m^3/s; $\bar{q}_i$ is the annual average monthly flow of each month i, and it is expressed in m^3/s; $\bar{Q}_{\min}$ is the minimum annual average flow, and it is expressed in m^3/s; $q_{\min(i)}$ is the minimum monthly average flow of the month i in several years, and it is expressed in m^3/s; q_{ij} is the monthly average flow of month i in year j, and it is expressed in m^3/s; n is the statistical number.

(2) Calculate the mean value ratio of the same period according to the annual average flow and the minimum annual average flow:

$$\eta = \bar{Q}_{\min} / \bar{Q} \quad \text{(Eq.5)}$$

(3) Calculate the monthly ecological flow according to the annual average monthly flow:

$$Q_i = \bar{q}_i \times \eta \quad \text{(Eq.6)}$$

where, Q_i is the ecological flow of month i, and it is expressed in m^3/s.

NGPRP method

In the Northern Great Plains Resource Program method (NGPRP), the hydrological year group was classified into three types: low flow year group, normal flow year group, and flood year group. This method confirms that each month flow can be included in the normal flow year group, with a guaranteed rate of 90%. The minimum ecological flow is calculated by this approach (Wang, 2015). The anomaly percentage method was used to divide the group.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57075722

$$P_i = (Q_i - Q_a) / Q_a \quad \text{(Eq.7)}$$

where, P_i is the anomaly percentage of annual average flow, and it is expressed in %. When $-10\% \leq Pi \leq 10\%$, it belongs to the normal flow year group; Q_i is the annual average flow of year i, and it is expressed in m^3/s; Q_a is the annual average flow of several years, and it is expressed in m^3/s.

Monthly frequency method

In the monthly frequency method, the year is divided into different periods by referring to the historical monthly flow data. Then, different guarantee rates are selected to calculate the flow of each period, and this information is an estimate of the ecological flow process. To select different guarantee rates for each period, we referred to the main research studies of prominent scholars: Yu first proposed the monthly frequency method to calculate the ecological flow of Luohe River and Yihe River, and he assumed that the guaranteed rate of monthly flow was 80% in winter, 75% in spring and autumn, 50% in summer; these guaranteed rates of monthly flow were considered as the river's ecological flow in different seasons. Li proposed that the guaranteed rate of month flow was always greater than 50% in each month (Li, 2007). Guo assumed the guaranteed rate of monthly flow as 80% in the low water period and 50% in the normal flow period. For the flood period, he directly took the annual average flow as the ecological flow (Guo, 2008). In this study, the small river flow was divided into three phases: the low flow period, the normal flow period, and the flood period; the different selections of guaranteed rate are as follows: i) 90% in the low flow period, 80% in the normal flow period, and 50% in the flood period; ii) 50% guaranteed rate for each month; and iii) 80% in the low flow period,50% in the normal flow period, and the annual average flow in the flood period.

Tennant method

The ecological flow was calculated using the Tennant method: a percentage of the annual average flow of the river channel was considered as the recommended flow (Xu, 2003), and different percentages were considered in different months. Moreover, the year was divided into the spawning period (April-September) and the general period (October-March) of water use. *Table 1* elucidates the relation between the channel flow and the river's ecological health in each period.

Table 1. *The relation between the channel flow and the river ecological health*

River ecological health	The percentage of channel flow accounts for annual average flow	
	General using water period (Oct-Mar.)	Spawning period (Apr-Sept.)
Maximum	200	200
Optimum range	60~100	60~100
very good	40	60
good	30	50
preferably	20	40
average or inferior	10	30
Poor or minimum	10	10
Severe degradation	＜10	＜10

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57075722

In practical application, many Chinese scholars have modified the Tennant method to suit the specific conditions of the study area. Zhang Mei calculated ecological flow by dividing the year into non-flood period (November-May) and flood period (June-October) (Zhang, 2005). He considered the specific characteristics of the water diversion area in the west route of South-to-North Water Transfer Project. Zheng Zhihong emphasized the obvious seasons variations of North China River; the river's ecological water demand period was further classified into three different periods by considering a seasonal variation. For each period, the percentage of recommended base flow was reselected according to the expert suggestion (Zhen, 2010). Chen proved that the ecological flow of Yellow River was different in the following two periods: the non-flood period (November-July) and flood period (July-October). After analyzing the characteristics of Yellow River in each period, they further derived a new percentage coefficient by multiplying the bed gradient: this parameter was more suitable for the sandy river (Chen, 2011).

To perform the minimum monthly ecological flow method, we require hydrological data of more than 20 years; however, the calculation process is simple, and the minimum ecological flow can meet the minimum living conditions of aquatic organisms. Nevertheless, it is not conducive for the healthy development of the aquatic ecosystem in the long-term. To determine ecological water demand by the dynamic calculation method, we have to calculate the mean value ratio of the same period; this method rectifies the subjectivity and experience of the traditional hydrological method, and it reflects the change characteristics of river flow in times of abundance and drought; however, the method does not apply to strong seasonal rivers. Furthermore, NGPRP method takes into account climatic conditions, acceptable frequency factors, and the difference between the normal flows of different years, but the method lacks a biological basis. The monthly frequency method considers the different requirements of the ecological system in different periods; different assurance rates are chosen to ensure that the ecological flow process adapts with the natural flow process, but it is difficult to select the most reasonable assurance rate. The Tennant method is simple and convenient, but it does not analyze the flow characteristics from the river basin's characteristics; moreover, there are no formation rules. It is usually used to analyze a river of low priority or to inspect the results of other methods.

Both advantages and disadvantages are encountered when we use different methods to calculate ecological flow. The basin's geographical location, climate, underlying surface, and the influencing human activities are considered when we use a variety of calculation methods. Thus, an unreasonable result of ecological flow can be definitely avoided. However, the suitable methods used for calculating the ecological flow of different river types are different; therefore, the calculation results will be different when we use a variety of methods to calculate the ecological flow of a river. Furthermore, we also encountered some difficulties in the final determination of the ecological runoff process. Therefore, it is important to objectively evaluate the ecological flow process, which was calculated by different methods. The evaluation results can serve as the basis for the determination of ecological flow process. In this study, we proposed an evaluation model based on ME-Tennant method. This model was specifically developed to calculate the ecological flow process of a river.

Ecological flow process evaluation model based on ME-Tennant method

The matter element analysis method is based on the following principle: everything can be described by three elements-"things N, the characteristics of things C, the corresponding value of the characteristics X" which are basic elements of an ordered triple. These are known as matter elements. Using the ordered triple $R = (N, C, X)$, we describe things as basic elements (Feng and Hong, 2014).

(1) Construct the matter element matrix

The ecological flow conditions of 12 months were used as evaluation indexes of the ecological flow process, and we recorded them as 12 characteristics. The matter element matrix was established as follows:

$$R = \begin{pmatrix} P_0 & C_1 & X_1 \\ & C_2 & X_2 \\ & \vdots & \vdots \\ & C_n & X_n \end{pmatrix} \quad \text{(Eq.8)}$$

where, R is the n-dimension matter element; P_0 is the unevaluated unit of the ecological flow process; $C_i \left(i = 1, 2 \ldots n\right)$ is the i-th evaluation index, which is the ecological flow condition of month i; $X_i \left(i = 1, 2 \ldots n\right)$ is the corresponding value of the evaluation index C_i, and the percentage of the ecological flow of month i accounts for the annual average flow.

(2) Construct the classical domain and the joint domain matter-element

The classical domain and the joint domain matter-element were constructed according to the evaluation criterion of the ecological flow process.

The classical domain matter-element R_j can be expressed as follows:

$$R_j(N_j, C, X_j) = \begin{pmatrix} N_j & C_1 & X_{j1} \\ & C_2 & X_{j2} \\ & \vdots & \vdots \\ & C_n & X_{jn} \end{pmatrix} = \begin{pmatrix} N_j & C_1 & [a_{j1}, b_{j1}] \\ & C_2 & [a_{j2}, b_{j2}] \\ & \vdots & \vdots \\ & C_n & [a_{jn}, b_{jn}] \end{pmatrix} \quad \text{(Eq.9)}$$

where, $N_j \left(j = 1,2 \ldots m\right)$ is the j-th grade of the ecological flow process; $X_{ji} = [a_{ji}, b_{ji}]$ is the classical domain, representing the percentage range of the ecological flow that accounts for the annual average flow corresponding with the j-th grade.

The joint domain matter-element can be expressed as follows:

$$R_p(N_p, C, X_p) = \begin{pmatrix} N_p & C_1 & X_{p1} \\ & C_2 & X_{p2} \\ & \vdots & \vdots \\ & C_n & X_{pn} \end{pmatrix} = \begin{pmatrix} N_p & C_1 & [a_{p1}, b_{p1}] \\ & C_2 & [a_{p2}, b_{p2}] \\ & \vdots & \vdots \\ & C_n & [a_{pn}, b_{pn}] \end{pmatrix} \quad \text{(Eq.10)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57075722

where, N_p is the set of evaluation grade; $X_{pi} = [a_{pi}, b_{pi}]$ is the joint domain, which represents the sum of the numerical range of the classical domain of each index.

(3) Determine the correlation function and the correlation degree.

The correlation function indicates that when the value of the matter element is taken as a point on the real axis, the conformity degree of the matter element lies within the required range of values. If $|X_o| = |b-a|$ is used to represent the length of the bounded interval $X_0 = [a, b]$, the distance from x_i to $X_{ji} = [a_{ji}, b_{ji}]$ and x_i to $X_{pi} = [a_{pi}, b_{pi}]$, respectively:

$$\rho\left(x_i, X_{ji}\right) = \left|x_i - \frac{1}{2}\left(a_{ji} + b_{ji}\right)\right| - \frac{1}{2}\left(b_{ji} - a_{ji}\right) = \begin{cases} a_{ji} - x_i, & x_i \le \dfrac{a_{ji} + b_{ji}}{2} \\ x_i - b_{ji}, & x_i > \dfrac{a_{ji} + b_{ji}}{2} \end{cases} \quad \text{(Eq.11)}$$

$$\rho\left(x_i, X_{pi}\right) = \left|x_i - \frac{1}{2}\left(a_{pi} + b_{pi}\right)\right| - \frac{1}{2}\left(b_{pi} - a_{pi}\right) = \begin{cases} a_{pi} - x_i, & x_i \le \dfrac{a_{pi} + b_{pi}}{2} \\ x_i - b_{pi}, & x_i > \dfrac{a_{pi} + b_{pi}}{2} \end{cases} \quad \text{(Eq.12)}$$

The calculation formula of the correlation function $K_j\left(x_i\right)$ is as follows:

$$K_j\left(x_i\right) = \begin{cases} \dfrac{-\rho\left(x_i, X_{ji}\right)}{\left|X_{ji}\right|} & x_i \in X_{ji} \\ \dfrac{\rho\left(x_i, X_{ji}\right)}{\rho\left(x_i, X_{pi}\right) - \rho\left(x_i, X_{ji}\right)} & x_i \notin X_{ji} \end{cases} \quad \text{(Eq.13)}$$

where, $|X_{ji}| = |a_{ji} - b_{ji}|$.

(4) Determine the weight of each evaluation index

Weight refers to the importance of an index in the whole index system. Greater the value of the weight, more important it is in the system. To determine the weight of the index, we divided the method into two categories: the subjective weight method and the objective weight method. In this study, an analytic hierarchy process was used to determine the importance of each month's ecological flow (Fan and Jiang, 2001; Fan, 2001). The main steps are as follows:

a) Determine the evaluation target and the evaluation index set

b) Establish a fuzzy consistent judgment matrix

The fuzzy consistent judgment matrix reflects the relative importance degree of each two elements in a_1, a_2, a_3, …, a_n, and it is expressed as follows:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57075722

$$R=\begin{pmatrix} r_{11} & \cdots & r_{1n} \\ \vdots & \ddots & \vdots \\ r_{n1} & \cdots & r_{nn} \end{pmatrix} \quad \text{(Eq.14)}$$

where, r_{ij} is the membership degree that indicates how much more important a_i is than a_j; greater the value of r_{ij}, more important is a_i than a_j. We used the 0.1–0.9 scale method (*Table 2*) to determine it.

Table 2. *Scale of 0.1~0.9 measure*

Scale	0.5	0.6	0.7	0.8	0.9
Definition	equal important	slightly more important	obviously more important	much more important	extremely more important

The properties of fuzzy judgment consistency matrix R are as follows:

1) $r_{ii}=0.5$, i=1,2,3,…,n;

2) $r_{ij}+r_{ji}=1$, i, j=1,2,3,…,n;

3) $r_{ij}=r_{ik}-r_{jk}+0.5$, $i,j,k=1,2,3,\cdots,n$.

For R to be a fuzzy consistent judgment matrix, the necessary and the sufficient condition is as follows: there exist an n-order non-negative normalized vector $W=(\omega_1,\omega_2,\cdots,\omega_n)$ and a positive number a make $\forall i,j$ that satisfy the following condition:

$$r_{ij}=a(\omega_i-\omega_j)+0.5 \quad \text{(Eq.15)}$$

where, parameter a$\geq$(n-1)/2 (in this paper, set a = (n–1)/2); the value of a reflects the decision makers' personal preference. Smaller the value of a, more attention would experts pay to the difference between the weight of elements (Lv, 2002).

a) Calculate index weight

Fix the i in formula (15) and obtain the following equation:

$$\omega_i=\frac{1}{a}(r_{ik}-\frac{1}{2})+\omega_k, \quad k=1,2,3,\cdots,n \quad \text{(Eq.16)}$$

Calculate the sum of k and obtain the following equation:

$$n\omega_i=\frac{1}{a}\sum_{k=1}^{n}r_{ik}-\frac{n}{2a}+\sum_{k=1}^{n}\omega_k \quad \text{(Eq.17)}$$

From the weight vector normalization condition, we obtained the following equation:

$$\omega_i=\frac{1}{n}-\frac{1}{2a}+\frac{1}{na}\sum_{k=1}^{n}r_{ik}, \quad i=1,2,3,\cdots,n \quad \text{(Eq.18)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57075722

In the formula, $0 \le \omega_i \le 1$.

(5) Calculate the comprehensive correlation degree

$$K_j\left(P_0\right) = \sum_{i=1}^{n} \omega_i K_j\left(x_i\right) \quad \text{(Eq.19)}$$

where, $K_j\left(P_0\right)$ is the comprehensive correlation degree of the j-th evaluation grade.

(6) Grade evaluation

If $K_j = \max\left\{K_j\left(P_0\right)\right\}\left(j = 1, 2, \cdots, m\right)$, the ecological flow process is in grade j. When $0 < K_j(P_0) < 1$, it indicates that the unevaluated unit meets the requirements of the standard object. When $-1 < K_j\left(P_0\right) < 0$, the evaluation unit can't meet the requirements of the evaluation grade; however, it has the capacity to transform into a form that conforms with the standard. When $K_j\left(P_0\right) < -1$, the evaluation unit neither meet the requirements nor can it transform. When $K_j\left(P_0\right) > 1$, the evaluation unit exceeds the upper limit of the standard grade.

(7) Determine the ecological flow process

The ecological flow process was determined reasonably using the evaluation grade of the ecological flow process, which was calculated by different calculation methods and combined with the ecological water requirement of the basin.

Results and discussion

Calculate the ecological flow process

In this paper, we selected measured monthly flow data of Liujiaping dam site from 1987 to 2015, which is period of 29 years in total. The annual average flow was 1.51 m^3/s. In theory, we must calculate the ecological flow process using natural flow data; however, since 1987, the river was more or less affected by human activities, so the ecological status might not have been restored to the original status. The altered ecosystem was further adapted to the present flow process. In fact, the so-called "natural state" was only considered as the state that was less affected by human activity. After analyzing the period 1987-2015, we found that the average flow of each year was slightly different from the average annual flow; moreover, there was no obvious mutation, indicating that the average annual flow was least affected by human activities. Therefore, the ecological flow process was calculated using the directly measured data instead of the natural flow data. After determining the multi-year average flow process at the dam site, we divided the whole year is divided into three periods: low water period (November-February), normal water period (March-April, September-October), and flood period (May-August). The hydrological frequency analysis was carried out using PIII curve. The minimum monthly ecological flow method, the dynamic calculation method of ecological water demand, the NGPRP method, and the monthly frequency method were used to calculate the ecological flow process of Liujiaping

Evaluation of the ecological flow process based on ME-Tennant method

According to the present ecological situation of Liujiaping hydropower station downstream, the goals of discharging the ecological flow and their implementation sequences are as follows: (i) ensure a continuous flow; (ii) provide a minimum living space for aquatic organisms; and (iii) provide suitable habitat conditions for aquatic organisms. Because dry flow often occurs in the natural river reach of Liujiaping River during the dry season, we had to offer ecological protection and restoration; therefore, the order of ecological flow conditions and the importance degree of each period is as follows: low flow period > normal flow period > flood period. Drier the month, higher is its importance. Based on this finding, we constructed a fuzzy consistent judgment matrix to elucidate the relative importance of the ecological flow conditions observed in two consecutive months. Moreover, the weight of each month was determined by fuzzy analytic hierarchy process (AHP). The index value Xi is the percentage of ecological flow of month i, and it accounts for the annual average flow. The classical domain Xji and the joint domain Xp were determined using the evaluation criteria laid down for the river's ecological flow process. As shown in *Table 4*, the values of indexes, the classical domain, and the joint domain were calculated by the six methods.

We calculated the correlation degree of each evaluation index with respect to each evaluation. By considering the weight of the index, we calculated the comprehensive correlation degree of each evaluation grade. As shown in *Table 5*, the comprehensive correlation degree and the evaluation results of an ecological flow process were calculated by six different methods.

Analysis of the evaluation result

Based on the evaluation results, we present the following observations: the minimum ecological flow process was calculated by different methods; the evaluation grade was "Average" when it was calculated by minimum monthly ecological flow method, but it was "Preferable" when calculated by dynamic calculation method and NGPRP method. In order to ensure a continuous flow and to provide the minimum living space for aquatic organisms, we selected and coupled only those ecological flow processes that had evaluation grades of "Preferable;" we considered the outer envelope curve as the minimum ecological flow process, which was no less than the 10% of the average annual flow. *Table 6* presents the ecological flow of each month in the minimum ecological flow process.

Table 6. *The ecological runoff process*

Month	1	2	3	4	5	6	7	8	9	10	11	12
Minimum flow	0.40	0.56	0.55	0.83	1.08	1.63	1.35	0.83	0.54	0.45	0.38	0.43
Suitable flow	0.48-0.75	0.54-0.83	1.04	1.34	1.51-1.88	1.51-2.35	1.51-2.54	1.51-1.84	1.24	0.94	0.49-0.79	0.49-0.75

The minimum ecological flow process is just used to meet the short-term hydrological condition, and it is used as the lower limit to satisfy the river ecosystem's stability and health conditions. Although it can ensure a continuous flow and provide the minimum living space for aquatic organisms, it seems to be harmful for the sustainable development of a river's ecosystem in the long-term. In order to maintain the stability of the basin ecosystem and its function, a suitable ecological flow process should be determined.

To evaluate a suitable ecological flow process, the conditions are as follows: i) the evaluation grade should be "Preferable" for the one calculated by monthly frequency method Ⅰ; ii) the evaluation grade should be "Good" for the one calculated by the monthly frequency method Ⅲ; and iii) the evaluation grade should be "Very good" for the one calculated by the monthly frequency method Ⅱ. It is important to note that rare aquatic organisms and dense vegetation exist on both the sides of the Liujiaping River Basin, so it is relatively easy to conserve both soil and water in this region; moreover, natural precipitation occurs frequently and groundwater levels are sufficient to supply water. Therefore, when the monthly frequency method Ⅱ and Ⅲ have an evaluation grade of "Very good" and "Good," respectively, the ecological water requirements of the river are satisfied by both methods. Thus, we ensure a healthy development of the river's ecosystem. After coupling the two ecological flow processes, we considered the inner envelope curve and the outer envelope curve as the threshold of a suitable ecological flow process. *Table 6* presents the ecological flow of each month in the suitable ecological flow process.

At the Liujiaping hydropower station, scientists perform the most important task of power generation. By determining a suitable ecological flow process, we can ensure that the discharge of ecological flow is more flexible in nature. After combining the actual situation of the hydrological conditions and the demand of water and electricity, the generation benefit was considered as the basis of satisfying the ecological water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57075722

requirement. In this way, we improved the efficiency of water usage and the comprehensive benefits of electricity generation.

The minimum ecological flow process and the suitable ecological flow process were determined by taking into account following parameters: the evaluation results, the river's ecological status, and the demand for utilizing water resources in the dehydration river reaches. The minimum ecological flow process can maintain a certain amount of water in the river channel, and it can prevent the ecological condition of the river from deterioration or barrenness. A suitable ecological flow process can ensure that the ecosystem in its best condition, and it can sustain the development of a river's life and health. The two ecological flow processes can reflect the variation of an annual flow; they have a certain reference significance for the ecological protection and restoration of the lower reaches of hydropower stations.

Conclusion

In this study, we constructed the ME-Tennant model by combining Matter Element Analysis and Tennant method. This model was used to evaluate the ecological flow process of a river. The model was used to evaluate the ecological flow process of dehydration river reaches, which are downstream of Liujiaping Hydropower Station in Hunan Province, China. Furthermore, the minimum ecological flow process and the suitable ecological flow process were determined after analyzing the evaluation results of ecological flow process, which were obtained by six different calculation methods. To restore the ecology of the dehydration river reaches, we can use these evaluation results as a reference.

In the case study, we used the ME-Tennant model to evaluate the ecological flow of the dehydration river reaches. We found that the evaluation grade of a suitable ecological flow process method was greater than that of the minimum ecological flow process calculation method. Moreover, the evaluation results were in good agreement with the actual trends. This indicates that the evaluation results have certain credibility. A percentage of an ecological flow accounted for the annual average flow, which was calculated by the minimum monthly ecological flow method and the dynamic calculation method, were the same but the allocation of annual ecological flow was different. The evaluation model took into account the difference between the important ecological flow conditions of different months, so the evaluation grades were different. The evaluation results were more reasonable. To determine ecological flow process, we developed an evaluation model based on ME-Tennant method. This model was both reasonable and applicable; the evaluation process was simplified and the evaluation result was intuitive. Thus, the ecological flow process can be determined rationally with this innovative model.

Different rivers have different geographical locations, and hydrological conditions; moreover, the impact of human activity is different in different river basins. Furthermore, the ecological flow process method that is most suitable would be different for different rivers. In the evaluation model, the weight of each month, period division, and evaluation criteria should be adjusted according to the watershed situation. Moreover, the ecological data of most small and medium-sized watershed areas are scarce; therefore, the methods involved in this paper are largely based on the historical flow data and the hydrological data, so the hydrological sequence should be checked to ensure the reliability of the data.

DOI: http://dx.doi.org/10.15666/aeer/1703_57075722

The calculation method of ecological runoff process has high dependence on historical runoff data and requirements. The hydrological sequence should be tested to ensure the reliability of the data. In the process of evaluating and determining the ecological runoff process by applying the ME-Tennant method, due to the different geographical location, hydrological situation and the focus of the river ecological restoration target, the monthly weight, period division and evaluation criteria should be targeted to the basin. Information is adjusted.

Abstract. Natural disasters occur frequently in China and cause inordinate social and economic losses every year. Great attention has been paid to assessing the impact disasters has brought in order to take appropriate prevention as well as follow-up steps. The existing assessment indexes are not comprehensive and systematic enough to evaluate the disasters' social, economic and environmental impact. Besides, the assessment method and standard are not objective. A more comprehensive natural disaster evaluation index system is proposed and the weight determination and severity rating methods based on cloud model is presented in this paper to provide a reference to appropriately select the assessment method for different kinds of disasters. The index system and severity rating method are applied to 6 typical rainstorms and flood events. Five indicators on social and economic aspects are implemented to demonstrate the adaptability of the proposed method. The results of analysis and evaluation show that the weight set based on cloud model can gather all information from experts objectively, and the assessment method can achieve a reasonable standard of disaster grades reasonably and determine the grade level objectively.
Keywords: *evaluation of natural disaster situation, evaluation index system, weight determination method, disaster identification degree, rainstorm flooding*

Introduction

Natural disasters have an adverse impact on personal safety, agriculture, industry, society, economic and ecological environment. For example, in China, 190 million natural disaster victims were recorded in 2016, 1706 dead or missing, 9.1 million people needed emergency resettlement, 521,000 houses collapsed, 3.34 million houses were damaged, the affected area of crops reached 26220.7 thousand hectares, and the proportion of crop failure or death was 2902.2 thousand hectares. Direct economic losses amounted to 503.29 billion yuan (Liu et al., 2017). In recent years, vulnerability of China's natural environment has been increasing, ecological and environmental issues have become prominent, and natural disasters have been frequent and high-intensity. With the continuous growth of urbanization level and the development of social productive forces, population density continues to rise, economic aggregates and density increase rapidly, inter-regional economic linkages and cooperation increase, disaster prevention and rescue measures continue to improve, and economic losses and society caused by disasters The impact is constantly increasing. The characteristics of disaster losses are also changing: the number of deaths due to disasters has dropped, the number of people affected has risen, and direct and indirect economic losses have risen sharply. According to statistics, the average annual disaster loss in China since the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57235735

1990s is 40% higher than in the 1980s (Tang and Yu, 2016). In order to objectively and comprehensively reflect the damage severity and loss characteristics of natural disasters, and provide the basis for defensive measures optimization and disaster mitigation strategies, it is of absolute necessity to conduct disaster evaluation study.

At present, there have been numerous studies on disaster damage assessment such as floods, typhoons, storm surges and geological disasters. For example, Yang et al. (2010) selected indicators such as the number of death, the number of people affected, the number of collapsed houses, the area affected by crops, and the direct economic loss. The entropy method was used to calculate the weight, and the flood damage in 22 regions of China was evaluated in 1999. Gong et al. (2015) took 25 factors in disaster factors, disaster-bearing bodies and disaster prevention and mitigation capabilities with the number of deaths, the number of collapsed houses, the area affected by crops, the direct economic loss and the disaster index to conduct correlation analysis and studied the index selection of typhoon disaster damage assessment. Yin et al. (2012) established an index system from the aspects of casualties, fisheries and agriculture, and direct economic losses of living facilities, and applied the analytic hierarchy process and entropy method to determine the weights and assess the economic losses of 7 storm surge disasters in Guangdong Province. Cheng et al. (2011) selected the average earthquake intensity, the number of deaths missing, the death and disappearance rate of 10,000 people, the number of collapsed houses, the rate of collapsed houses, the risk of geological disasters, and the resettlement rate of 10,000 people to conduct county-wise grade evaluation of disasters in the earthquake-stricken areas; Shi et al. (2017) constructed the economic loss indicators and risk indicators for disaster relief based on the affected area of the disaster, the area planted with crops, the total production value and the frequency of disaster relief by the county of Xinjiang Statistics from 1984 to 2014, to assess the hail disaster in Xinjiang. In addition, the Ministry of Water Resources approved the Flood Disaster Assessment Standard (Standard) in 2012, mainly selecting the number of deaths, the number of people affected, the area affected by crops, the number of collapsed houses, the direct economic loss, and the economic loss of water conservancy facilities as a direct economic loss. Such indicators are employed to the assessment of the number of events and regional annual floods.

There are some shortcomings in the above research. The indicators selected for the disaster damage assessment are not comprehensive enough: only the agricultural impact is considered, the influence of industry and the tertiary industry is neglected; the socio-economic impact is considered, and the natural environmental impact is not considered; The indicators are scattered, without a comprehensive and systematic evaluation index system; At present, China's official disaster information reporting indicators also need to be fully expanded. On the other hand, the evaluation methods used mainly include fuzzy comprehensive evaluation method, entropy weight method, gray clustering method, gray correlation degree method, and matter element analysis method. However, weighting and rating criteria of most methods are often determined by experience and subjective. Although the entropy weight method can determine the objective weight, it depends on a large number of representative data information, and the effect is poor when the data representation is not strong. Secondly, the general method determines the case level by comparing the case evaluation value with the level threshold value, and the difference of the disastrous situation in different cases within the same disaster level is difficult to accurately express. Yu and Shen (1997) studied the ranking method of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57235735

different cases in the same level based on the grey clustering disaster classification model, but it is not intuitive enough..

The purpose of this paper is mainly as follows: it summarizes a comprehensive set of disaster damage assessment index system that considers the impact of various aspects, provides reference for the selection of indicators for damage assessment of different disasters, and reports indicators and contents for disaster information. The cloud model-based evaluation method is applied to the weight determination and model construction of the disaster damage assessment, thereby objectively transforming the expert weight evaluation information into quantitative data, and based on the basis of the level evaluation criteria and the intuitive and effective determination of the level.

Disaster damage assessment index system

The disaster damage assessment is to carry out hierarchical and comprehensive management according to the losses and impacts caused by various aspects. Based on the existing research, a systematic and comprehensive disaster damage assessment index system is constructed from the aspects of disaster attribute, social impact, economic impact and natural environment impact (*Table 1*).

Table1. *Index system of disaster damages assessment*

Target layer	Benchmark layer	Indicator layer	Key indicators
Assessment index system of natural disaster loss	Disaster properties	Time	Disaster duration Emergency resettlement time Disaster area repair time
		Space	Disaster coverage
	Social impact	Population	Death toll Missing Number of people affected Number of people to be resettled The age structure of the affected population The unemployment rate of the affected population The damage rate of the affected population
		Building facilities	Collapsed housing Damage housing Lifeline project Infrastructure
		Agricultural losses	Area affected Disaster area Failures area Agricultural production output
		Industrial and third industrial losses	Accumulated stagnation time Due to disaster number Due to disastrous bankruptcy
	Economic influence	Direct loss and its relative GDP ratio Indirect loss and its relative GDP ratio	
		Rescue and reconstruction	Disaster relief put into disaster area restoration and reconstruction
	Natural environment influence	All kinds of resources loss or pollution Topographic geological landform influence or repair input Ecosystem influence or repair input	

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57235735

Disaster attribute is a description of the scope, duration, emergency rescue and resettlement of disaster impacts. The societal impact mainly includes the damage to human health and life caused by disasters, the destruction of houses, lifeline projects and public infrastructure, and the direct and indirect effects of industrial activities such as agriculture, industry and service industries. Economic impacts are divided into direct losses, indirect losses, and emergency rescue and reconstruction efforts. The direct loss mainly refers to the direct loss or repair cost measured by the available monetary currency caused by the disaster. The indirect loss is mainly caused by the direct loss and destruction, which will not support and circulate the future sustainable development of the disaster area and the surrounding areas. The losses caused by emergency rescue and reconstruction in the disaster area refer to the investment in the rescue and resettlement of the affected people during the disaster, as well as the various inputs of the disaster-stricken areas to restore normal social order and restore production to the pre-disaster level. Ecological environmental impacts are mainly loss or pollution of water and soil resources, mineral resources, forest vegetation resources, landscape resources, biological resources, etc., changes in topographic geological features, and balanced destruction of local ecosystems. The natural ecological impact of a disaster can be understood as a loss of natural resources and a higher investment in environmental protection and ecological reconstruction.

Cloud model based disaster rating evaluation model

The weight determination method of expert evaluation information based on cloud model is proposed, and the cloud model correlation method is applicable to evaluation model construction and case level determination. This method can objectively synthesize the weight information given by all experts based on experience and reflect the fuzziness and randomness contained in subjective information.

Cloud model theory

The cloud model is an uncertainty transformation model between qualitative concept expressed by linguistic value and its quantitative numerical representation, which constitutes the uncertainty mapping between qualitative and quantitative, which is convenient for portraying the randomness and fuzziness in natural language description (Li et al., 2004; Gao et al., 2017; Li et al., 2010). Using the numerical characteristics of the cloud to reflect the overall characteristics of the concept plays an extremely important role in understanding the connotation and extension of the qualitative concept (Li et al., 2014). The cloud requires a three-dimensional feature of expected, entropy and super entropy to represent a concept in its entirety. The cloud model is the specific implementation of the cloud.

(1) According to the qualitative concept and the quantitative transformation direction, it is divided into a forward cloud model and a reverse cloud model.

(2) According to the symmetry, it is divided into a symmetric cloud model, a semi-cloud model, and a combined cloud model.

(3) Dimensions can be extended from one-dimensional cloud models to two-dimensional or even arbitrary dimensional cloud models.

The universal distribution of normal distribution and normal membership functions lays the theoretical foundation for the universality of the normal cloud model (Li and Liu, 2004). The normal cloud model is widely used in research.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57235735

Cloud model accuracy test and parameter correction

According to the reverse cloud model, it is possible that the cloud droplet dispersion is large, so it is necessary to make an accurate check and parameter correction.

The cloud drip that describe the qualitative concept are from the normal distribution $N(E_x, E_n^2 + H_e^2)$. It is well known from the central limit theorem that when any cloud drop $x \in [E_x - Z_{\alpha/2}\sqrt{E_n^2 + H_e^2}, E_x + Z_{\alpha/2}\sqrt{E_n^2 + H_e^2}]$ is used. The degree of certainty of the qualitative concept can be expressed by the confidence degree $1-\alpha$, where $Z_{\alpha/2}$ is the two-sided percentile of the standard normal distribution.

The accuracy test steps are as follows: (1) Use the forward cloud model to generate several cloud drops, such as the number of clouds with $n_1 = 1000$. (2) Select the qualitative concept to determine the degree and find the value $Z_{\alpha/2}$, if the degree of determination is 95%, $Z_{\alpha/2} = 1.96$. (3) Calculate $\left(x < E_x - Z_{\alpha/2}\sqrt{E_n^2 + H_e^2}\right)$ is the mean of the cloud drop points X_{L} and $\left(x > E_x + Z_{\alpha/2}\sqrt{E_n^2 + H_e^2}\right)$ the mean value of the cloud drop points X_{H}. When *Equation 1* is met, the cloud model has higher precision, otherwise the cloud parameters need to be corrected (Xu et al., 2013; Ma et al., 2010).

$$\begin{aligned} &\left|\left(d - d_0\right)/d\right| \times 100\% \le 20\% \\ &d = X_{\mathrm{H}} - X_{\mathrm{L}},\ \ d_0 = 2Z_{\alpha/2}\sqrt{E_n^2 + H_e^2} \end{aligned} \tag{Eq.1}$$

The cloud parameter correction steps are as follows: (1) Generates n_1 cloud droplet that belongs to the confidence interval $[E_x - Z_{\alpha/2}\sqrt{E_n^2 + H_e^2}, E_x + Z_{\alpha/2}\sqrt{E_n^2 + H_e^2}]$. (2) Calculates the sample mean $\overline{X}$ and the variance of cloud droplets S^2. (3) According to the Bayesian theory-based correction method to calculate (Liu et al., 2008):

$$\begin{cases} E_x^{(1)} = \left[\dfrac{\overline{X}}{\left(E_n^{\,2} + H_e^{\,2}\right)/n_1} + \dfrac{E_x}{E_n^{\,2}}\right] \Bigg/ \left[\dfrac{1}{\left(E_n^{\,2} + H_e^{\,2}\right)/n_1} + \dfrac{1}{E_n^{\,2}}\right] \\ E_n^{(1)} = \sqrt{\dfrac{\pi}{2}} \times \sum_{i=1}^{n_1} \left|x_i - E_x^{(1)}\right| \Big/ n_1 \\ H_e^{(1)} = \sqrt{S^2 - \left(E_n^{(1)}\right)^2} \end{cases} \tag{Eq.2}$$

In *Equation 2:* $E_x^{(1)}$, $E_n^{(1)}$ and $H_e^{(1)}$ are the revised expectation, entropy and hyper-entropy, respectively, x_i for the i cloud drops. After the correction, the new cloud model parameters are tested and modified to meet the accuracy requirement.

Cloud model based weight determination method

The weight determination steps of the expert evaluation information based on the cloud model are as follows:

(1) Invite n experts (to ensure the weight calculation results are convincing, need to invite more than 10 experts to evaluate) give the weight distribution results of *m* indicators, constitute the evaluation matrix $V=(V_{ij})(i=1,2,\cdots,m;\ j=1,2,\cdots,n)$.

(2) Using the inverse cloud algorithm without certainty, calculate the *n* weight evaluation values of the index *i* to obtain the weight cloud model parameters $\left(E_x^{\ i},E_n^{\ i},H_e^{\ i}\right)$.

(3) Perform accurate test and parameter correction on the weight cloud model of indicator.

(4) For the weighted cloud model of the modified indicator *i*, a forward cloud algorithm is used to randomly generate *t* (such as $t=1000$) cloud drops, and the weights calculated x_i as the index *i* corresponding to the maximum degree of cloud drop point determination $\mu_i\left(x_i\right)$.

(5) Normalize the weight calculation values of the *m* indicators to obtain the weight vector $\boldsymbol{\Omega}=\left(\omega_1,\omega_2,\mathrm{L}\ ,\omega_m\right)^{\mathrm{T}}$.

Based on the weight calculation method of the cloud model, based on the existing expert evaluation values, the expert evaluation expectation (E_x) and the uncertainty eigenvalues (E_n and H_e) can be extracted to generate any number of evaluation values that meet the characteristics of the expert evaluation (Cloud drop). Finally calculate the weight vector, increase in the number of samples calculated by weight, and improve the credibility. As *t* increases, the weight calculated on the basis of the cloud model will tend to the expected value of the weight cloud model, which tends to the arithmetic mean of the expert weighting of the indicator. The weight vector calculated based on the cloud model considers the randomness and ambiguity of expert evaluation, and is of great importance for the study of the uncertainty method of qualitative evaluation weight calculation.

Cloud-based disaster damage assessment process

Different from the previous research, the disaster damage assessment level is directly determined in accordance with the expert experience. This model mainly determines the disaster level scale cloud with randomness and ambiguity based on the overall situation of the case evaluation, and determines the disaster level of each case. Proceed as follows:

(1) Indicator data are normalized. In order to measure the degree of disaster loss for a single indicator, the reference ceiling for each indicator has to be selected. The historical maximum value of each indicator in the existing historical data of the evaluation object can be invoked as the index reference for the upper limit. The ratio of the raw data to the reference upper limit of the corresponding indicator is the indicator value. Set the indicator data matrix $Y=Y_{ik}$ of *p* cases $(i=1,2,\cdots,m;k=1,2,\cdots,p)$.

(2) Evaluation vector calculation. Calculate the disaster damage assessment value of each case to form a disaster damage assessment vector $\boldsymbol{Z}=\left(z_1,z_2,\mathrm{L}\ ,z_p\right)^{\mathrm{T}}$, where the element z_k of the vector can be expressed as *Equation 3*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57235735

$$z_k = \sum_{i=1}^{m} \left(Y_{ik} \omega_i \right) \quad \text{(Eq.3)}$$

(3) Cloud model generation. The overall disaster cloud model for *Z* using inverse cloud algorithm without a degree of certainty, and the accuracy test and correction are performed.

(4) High-level disaster clouds and low-level disaster cloud computing. Taking the E_x value of the overall disaster cloud as the dividing line, the case is split into high-level and low-level cases: the case where the disaster evaluation value is greater than E_x is a high-level case, and vice versa is a low-level case. Repeat step 3 for the disaster damage assessment values of all high-level cases to obtain a high-level disaster cloud model, and a low-level disaster cloud model.

(5) Disaster level scale clouds construction. First, based on the overall disaster situation cloud, high-level disaster situation cloud and low-level disaster situation cloud, combined with the case disaster situation, etc., the evaluation value interval of the evaluation level is established. Let the evaluation value interval of the *s* grade be $[a_s, b_s]$ $\left(s = 1,2,\mathrm{L}\ ,S'\right)$, and the cloud parameter $\left(E_{xs}, E_{ns}\right)$is calculated according to the *Equation 4* (Xu et al., 2011), H_{es} is specified according to the uncertainty of the evaluation language, and is generally regarded as 0.005.

$$\begin{cases} E_{xs} = \left(a_s + b_s\right)/2 \\ E_{ns} = \left(b_s - a_s\right)/6 \end{cases} \quad \text{(Eq.4)}$$

Secondly, the accuracy test is made on each level of the cloud. Each level of cloud constitutes a disaster level scale and generates a scale cloud map.

(6) Each case level is determined. Calculate the case disaster evaluation value and the degree of the determination of the cloud, the *k* case Disaster damage assessment value and the second grade cloud model of the determination of $\eta_{k,s} = \exp\left(-\left(x_k - E_{xs}\right)^2 / 2E_{ns}^{'2}\right)$, where $E_{ns}^{'}$ is expected E_{ns}, H_{es} is the variance of the normal random number. The level of the most certain degree is the case level, and the second-largest level is the level deviation of the case, reflecting the difference in the disastrous situation of different cases in the same level. For example, the case of "middle disasters and partial disasters" is more serious than the case of "middle disasters and partial disasters".

Example application

The cloud model-based disaster rating assessment model was applied to six typical storms and flood disaster damage assessments. Cases 1-3 are examples of three storms and floods that occurred in 2015 (China Meteorological Disaster Yearbook, 2016), and cases 4-6 were examples of evaluations in the standards.

According to the type of disaster and the actual situation of disaster loss, the indicators of population, building facilities, agricultural losses in social impact, and direct economic loss indicators in economic impact are selected for analysis. Due to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57235735

the lack of comprehensive statistical data, the disaster attribute and natural environmental impact indicators have not been selected yet. Based on available disaster loss data statistics, the population indicators have the number of people affected and the number of death, which are recorded as u_1 and u_2 respectively; the building facilities index selects the number of collapsed houses, which is recorded as u_3; the agricultural loss index selects the area affected by crops, recorded at u_4; and the direct economic loss is recorded as u_5. Statistics of 6 typical storm flood disaster losses are shown in *Table 2*.

Weight determination

Ten experts were invited to evaluate the index weight, and the weights were calculated by the weighting method of the expert evaluation information based on the cloud model. The weight of the experts and the weight calculated based on the cloud model is shown in *Table 3*.

Table 2. *Statistic data of 6 rainstorm and flood disaster loss*

Case	Disaster details	Number of people affected (million)	Death toll (person)	House collapse (million rooms)	Area affected by crops (thousand hectares)	Direct economic losses (billion yuan)
1	May 18, 2015-22nd Fujian Rainstorm	29.9	11	0.28	34	30.6
2	July 20, 2015-25th Fujian Rainstorm	41.8	16	0.27	21	40

Case evaluation value and disaster situation cloud model calculation

The disaster damage assessment values of the six cases calculated in accordance with *Equation 3* were 0.1006, 0.1335, 0.1064, 0.6365, 0.3879, and 0.5304, respectively. For disaster damage assessment values of the six cases, inverse cloud algorithm (Ep.1~2) was used. After the accuracy test and parameter correction, the parameters of the overall disaster cloud model (E_x, E_n, H_e) were (0.3092, 0.2228, 0.0122). With the overall

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57235735

disaster cloud E_x=0.3092 as the demarcation point, six cases were divided into low-level cases (Cases 1-3) and high-level cases (Cases 4-6). In the same way, the high-level disaster cloud parameters and the low-level disaster cloud parameters after the accuracy test and parameter correction are: (0.5236, 0.0899, 0.0258), (0.1135, 0.0167, 0.0054). Generate 1000 cloud drops for each of the three disaster clouds, and generate a cloud map in the [0,1] interval as showed in *Figure 1*.

Disaster level scale cloud computing

It can be seen from *Figure 1* that the disaster damage assessment values of the low-level cases are concentrated in [0.06, 0.16], and the closer the evaluation value is to the "low-level case disaster cloud" corresponding to 0.1135, the closer the determination is to 1. At the same time, the analysis of the disastrous situation in 1-3 cases found that the impact of the disaster situation was small, so the initial definition of the low-level case as a whole was a general disaster. The disaster damage assessment of high-level cases is concentrated in [0.25, 0.80], and the closer the evaluation value is to the "high-level case disaster cloud" corresponding to 0.5236, the closer the determination is to 1. The analysis of the disastrous situation in the 4-6 case found that the disaster situation had a great impact. The preliminary definition of the high-level case was a major disaster. The disaster damage assessment value of the overall disaster cloud is mainly concentrated in [0, 0.8], and the closer the evaluation value is to 0.3092, the closer determination of the "total disaster cloud" is to 1. The overall disaster situation cloud integrates the general disaster situation and major disaster situation, reflecting the average level of disaster losses. It is initially considered that the case where the evaluation value is around 0.3092 is a major disaster.

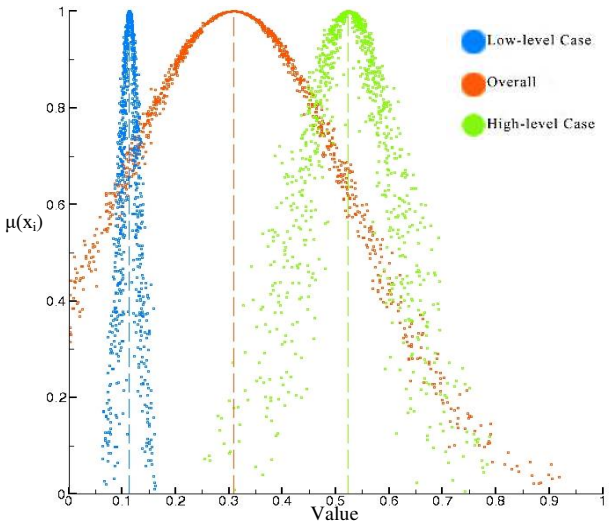

Figure 1. *Each disaster cloud*

According to the above analysis, considering the possibility of occurrence of disasters that are more serious than major disasters (i.e., "special major disasters"), and the construction of equidistant disaster scales, the assessment intervals for the classification of disasters are shown in *Table 4*. Among them, the straight line intervals [0, 0.115] and [0.805, 1] respectively indicate that the degree of certainty for "general

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57235735

disaster" and "special major disaster" is 1 when the evaluation value belongs to the interval.

Table 4. *Disaster damage assessment level*

Interval type	Interval type	Evaluation interval
General disasters	Linear interval	[0, 0.115]
	Semi-descending cloud	[0.115, 0.345]
Large disasters	Symmetric cloud	[0.115, 0.575]
Major disasters	Symmetric cloud	[0.345, 0.805]
Special major disasters	Half-liter cloud	[0.575, 0.805]
	Straight zone	[0.805, 1]

According to the *Equation 4* cloud parameters are calculated for each cloud model interval, and the Cloud model parameters (E_x, E_n,H_e) of different disaster classes are obtained as follows: General disasters (0.115,0.077,0.005); Large disasters (0.345,0.077,0.005), Major Disasters (0.575,0.077,0.005), particularly major Disasters (0.805,0.077,0.005). Ching model accuracy test is in line with the requirements. Generate the ruler clouds as showed in *Figure 2*.

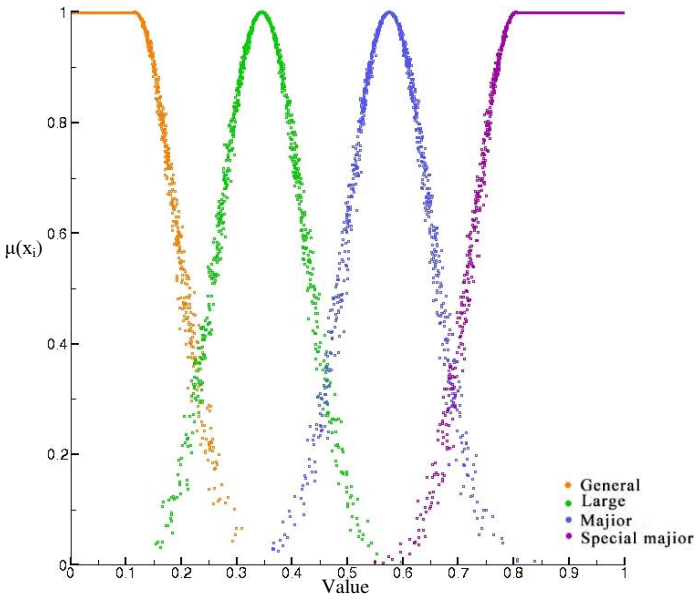

Figure 2. *Disaster rating assessment ruler cloud*

Case rating

Calculate the disaster damage assessment value of each case and the certain degree of cloud of each level in the scale cloud, and determine the case level according to the principle of maximum certainty. The results are presented in *Table 5* and *Figure 3*.

It can be seen from *Table 5* and *Figure 3* that the most certain grades in Case 4 and Case 6 are "major disasters", and the second most important grades are "Special Major Disasters" and "Greater Disasters". In addition to simply recognizing that both are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57235735

"significant disasters", it can be said that the disaster level of Case 4 is "significant disasters and biased towards special major disasters", and the disaster level of Case 6 is "significant disasters and biased towards larger disasters". This is in line with the actual situation: in the Case 4 indicator data, except for the "number of death" is smaller than Case 6. The other indicators are 2.2-9.4 times of Case 6. Therefore, on the whole, the disastrous situation of Case 4 is more influential than Case 6. This shows that the cloud model method can express the disaster level deviation of different cases in the same level, and intuitively reflect the difference of the disastrous situation of the same level of disaster.

Table 5. *The determination of each case level and grade evaluation results*

Case	Determination				Cloud model evaluation results	Cloud model evaluation results
	General disasters	General disasters	Major disasters	Special major disaster		
1	1	0.0055	0	0	General disasters	General disasters
2	0.9743	0.0202	0	0	General disasters	General disasters
3	1	0.0173	0	0	General disasters	General disasters
4	0	0.0009	0.7173	0.1706	Major disasters	Major disasters
5	0.0005	0.8585	0.0553	0.0000	General disasters	General disasters
6	0	0.0906	0.8202	0.0019	Major disasters	Special major disaster

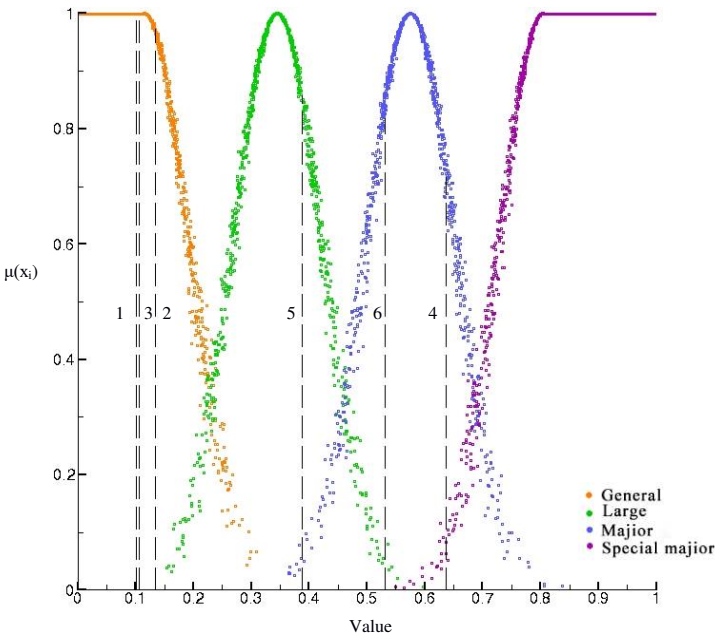

Figure 3. *Case level determination chart. (The number in the figure indicates the case number, and the intersection of the dashed line with each level cloud model determines the degree of the value of the case evaluation for each level cloud)*

It can be seen from *Table 5* that the evaluation results of the application cloud model method are compared with the results confirmed according to the "standard": the results of Case 1-5 are the same, and the results of Case 6 are different. The consistency of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57235735

results of Cases 1-5 indicates that the model is applied to the applicability and rationality of storm flood and flood disaster damage assessment. Case 6 is applicable to both the identification method of the indicator system and the direct identification method ("when the death population reaches 100 people or the direct economic loss reaches 20 billion yuan, it is recognized as a special major disaster; the death population reaches 50". When there are less than 100 people or the direct economic loss reaches 10 billion yuan and less than 20 billion yuan, it is considered a "major disaster". The former conclusion is the same as the result of this paper, which is "major disaster"; the latter conclusion is different from the result of this paper, and it is "special major disaster". According to the principle of high, the conclusion that the evaluation of the Standard is adopted is "special major disaster". The model of this paper is the same as the results obtained by the identification system of the Standards, which verifies the rationality and applicability of the model. When using the direct identification method to evaluate the disaster situation, the model may not be consistent with its evaluation results (for example, Case 6 in the example in this paper), and this situation will be further analyzed in subsequent studies.

Conclusion

This paper summarizes the disaster damage assessment index system of the aspects of disaster attribute, social impact, economic impact and natural environmental influence to form a comprehensive disaster damage assessment index system that considers the impact of various aspects. It can provide reference for the selection of disaster damage assessment indicators for different disasters. The shortcoming is that the topographic geological and geomorphological impacts and ecological environmental impacts in the natural environmental impact need to be further refined according to the characteristics of disaster losses, and more specific evaluation indicators are proposed.

Based on the weight determination method of cloud model, the correlation between randomness and fuzziness was revealed, and the expert evaluation was conducted with quantification, realizes the evaluation weight of multiple experts to the uncertainty conversion of comprehensive weight data, and can fully and comprehensively consider expert opinions and common weight determination methods. More objective than comparison.

A cloud model-based disaster rating model is proposed. The model evaluation results are basically consistent with the "standard" evaluation results, which verify the rationality and applicability of the model. The model can fully consider the overall situation of the disasters studied, and reduce the subjective dependence on expert experience. The case degree is determined by the principle of maximum certainty, and the degree of disaster level of different cases of the same level is reflected by the second largest degree of certainty level. Disaster identification degree of different cases of the same level is improved based on the effective classification of the disaster level, and the general evaluation method more objective and scientific. The case level determination process reflects the ambiguity and randomness of the cloud model when the quantitative evaluation data are converted into a graded comment. However, it is found that there may be a different evaluation result between the result obtained by the direct identification method and the cloud model is used for disaster assessment in the case study, and the specific reason for the difference is still unclear, which needs further analysis and discussion in the following research.

Abstract. This research investigates the effect of pH and sludge retention time (SRT) on denitrifying phosphorus removal. A series of experiments were conducted using two 20L sequencing batch units with the following configuration: anaerobic/anoxic and aerobic sequencing batch reactors (SBRs). It was found that variation in pH form 6.5 to 8 resulted in obvious increase in phosphorus release and uptake, organic matter degradation [measured by the chemical oxygen demand (COD) and the percentage volatile suspended solid (VSS)] and polyhydroxybutyrate (PHB) accumulation also showed a rising trend in the anaerobic period, but sludge acclimatized under pH 8.5 condition exhibited a slightly lower denitrifying phosphorus removal capability. In addition, the rates of phosphorus release and uptake were 20.95 and 23.29 mg/g VSS / h in condition of pH 8 value. Activated sludge with the SRT of 16 days possessed better nitrite nitrogen utilization, organic matter degradation and phosphorus removal than sludge with the SRT of 6, 10 and 22 days, and polyphosphate concentration in anaerobic activated sludge per VSS decreased to 23.1 mg/g VSS, PHB concentration in anoxic activated sludge per VSS reduced to16.3 mg/g VSS, thus, a dramatic denitrifying dephosphatation has occurred.
Keywords: *phosphorus removal, organic matter degradation, sludge, pH, SRT*

Introduction

In recent years, eutrophication caused by nitrogen and phosphorus pollution has attracted wide and intensive attention. Biological nutrient removal processes have been widely used in many municipal sewage treatment plants for several years (Wong et al., 2015). Conventional nitrogen and phosphorus removal were separately achieved by denitrifying bacteria and polyphosphate accumulating organisms (PAOs). Traditional biological nutrient removal processes have some problems between polyphosphate accumulating organism and denitrifying bacteria, such as external carbon source and sludge age. Kuba et al. (1993) reported that denitrifying polyphosphate accumulating organisms (DNPAOs) could achieve simultaneous nitrogen and phosphorus removal by using nitrate and/or nitrite as an electron donor. Denitrification and dephosphatation occur in sequencing batch reactor (SBR), which is different from continuous-flow-activated sludge system. DNPAOs have the similar metabolic characteristics to PAOs, degrade polyphosphate to orthophosphate and absorb organic compounds, are stored as polyhydroxyalkanoates (PHAs) in the cell under anaerobic condition. Under anoxic condition bacteria takes orthophosphate from liquid to synthesis polyphosphate with PHAs as electron donor and nitrate/nitrite as electron acceptor, meanwhile, achieves cell growth and maintance. Compared with traditional anaerobic/aerobic phosphorus removal,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57375751

denitrifying phosphorus removal not only saves 50% organic carbon source and 30% energy consumption but also reduces 50% surplus sludge.

Nitrate as electron acceptor for denitrifying phosphorus removal has been recognized by scholars (Tayà et al., 2013; Wang et al., 2015a,b; Basset et al., 2016). However, in the early studies of biological nutrient removal processes, it was supposed that nitrite has been recognized as one of inhibitors in microbial metabolism (Zhou et al., 2011; Ge et al., 2016; Jabari et al., 2016). The nitrification reaction bath effluent may be not suitable for denitrifying phosphorus removal, it did not specially inoculate microorganisms with nitrite as electron acceptor under anoxic condition. Once up a time some people already realized that nitrite could also become electron acceptor of DNPAOs. Meinhold et al. (1999) showed that nitrite at low concentration levels (4-5 mg-NO_2^--N) was not detrimental to anoxic phosphorus uptake and could serve as electron acceptor for anoxic phosphorus uptake. Introduce an phosphorus uptake ability of denitrifying polyphosphate accumulating bacteria, phosphorus uptake amount was over 30 mg/L by dosing 20 mg/L NO_2^--N in the SBR (Liu et al., 2014). According to the above literatures, different scholars gave the controversial conclusions of the nitrite influence on the biological anoxic phosphorus removal. It is necessary to evaluate adequately weather denitrifying phosphorus removal is efficiency and stability with nitrite as electron acceptor.

Although the A^2N process has the capacity of denitrifying dephosphatation, they differ in operational mode. The former operates in a single sludge system with nitrifiers and DPB mixed. In the A^2N processes, only DPB will be present. In this process, the minimum SRT for nitrifiers no longer dominates the minimum SRT for DPB (Bortone et al., 1994; Kuba et al., 1996a).

Denitrifying phosphorus removal using nitrite as electron acceptor has been considered difficult due to the lack of available control parameters. It is reported that pH and sludge retention time (SRT) are critical factors, which affect the performance of denitrification and dephosphatation of DNPAOs-nitrite.

The pH value of biological nutrient removal systems respond to cell membrane permeability and electric charge of microorganisms. Microbe growth and multiplication are closely related to the pH in the environment. Obviously, the suitable pH is crucial to ensure the dominant position of functional bacteria in the wastewater treatment processes. Many scholars studied the relationship between pH and biological phosphorus removal characteristics, it was found that the efficiency of anoxic phosphate uptake enhanced with the increase of pH for DNPAOs sludge. (Smolders et al., 1994; Sun et al., 2015; Liu et al., 2015). However, there is no publication investigated the mechanism of denitrifying polyphosphate accumulating organisms with nitrite as electron acceptor under different pH values till now.

Phosphorus in wastewater is removed by surplus sludge discharge, the effect of anoxic phosphorus removal could decrease if SRT is too high or too low. SRT not only reflects the growth environment and the generation period of microorganisms, what's more, it also influences the efficiency of nutrient removal, effluent quality and sludge yield in the biological nutrient removal processes. Impact of SRT on the biological phosphorus removal process has always been studying with PAOs in recent years (Ge et al., 2013, 2015). Liu et al. (2008) discovered that the optimal SRT was 15 d for polyphosphate accumulating organism with nitrate as electron acceptor in modified A^2N process. In accordance with a review of these literatures, it is found that few investigations have been conducted on the SRT influence on metabolic behavior of DNPAO with respect to anoxic phosphorus uptake using nitrites as electron acceptor.

DOI: http://dx.doi.org/10.15666/aeer/1703_57375751

The purpose of this study is to study the correlation between pH and nutrient removal efficiency, seek a reliable sludge retention time (SRT) for achieving a high-level denitrifying phosphorus removal by using nitrite as electron acceptor, investigate the effect of pH and SRT on metabolic mechanism of DNPAO-nitrite, and also establish the control strategies for denitrifying phosphorus removal processes.

Materials and methods

A^2N-SBR system

The tow-sludge A^2NSBR process consisted of A^2SBR reactor and NSBR reactor which were made from transparent plexiglass, were fed with synthetic wastewater and operated under anaerobic/anoxic/shortcut nitrifying condition separately. Anoxic denitrifying phosphorus uptake occurred in A^2SBR reactor by using nitrite as electron acceptor from NSBR reactor effluent. NSBR reactor with a working volume of 3 L, ran with two 4h-cycles per day to realize shortcut nitrification by micro oxygen aeration, each cycle consisted of instantaneous feeding, 180 min aerobic reaction, 45 min settling and 15 min decanting. The sludge retention time (SRT) was 14 days, COD/N and COD/P ratios were 0.2:1 and 23:1.

A^2SBR reactor with a working volume of 10 L was inoculated with activated sludge from the secondary sedimentation tank of northern sewage treatment plant (Shenyang, China) and a laboratory-scale anaerobic-anoxic (A/A) reactor in which denitrifying polyphosphate accumulating organisms with nitrite electron acceptor were enriched. The denitrifying phosphorus removal reactor was conducted on 5.5h-cycle per day, operated with instantaneous feeding, 120 min anaerobic reaction, 150 min anoxic reaction, 45 min settling and 15 min drainage. All experiments were completed in the key laboratory of Liaoning university, China.

The operational critical factors of operation system were concluded as follow:

1) Effluent time of NSBR was consistent with anoxic phosphorus removal time of A^2SBR, NO_2^--N provided by shortcut nitrification could be completely utilized by denitrifying phosphorus removal as electron acceptor, realized coupling link of shortcut nitrification reactor and denitrifying phosphorus removal reactor.
2) Effluent NO_2^--N concentration of NSBR met the need of anoxic phosphorus uptake and no interfering substance in the effluent flow was added to A^2SBR.

Batch experiments

Activated sludge taken from the anaerobic-anoxic SBR was subjected to effect of pH on denitrifying dephosphatation, the batch experiments were conducted after the SBR with circulating steadily and good performance. The performance of SBRs operation was that nitrite and nitrate concentration and nitrite accumulation rate in NSBR effluent were 92.6 mg/L, 5 mg/L, and 94%, the denitrifying phosphorus removal rate in A^2SBR was 95%. Amount of sewage was taken at the end of anoxic phase, and put in four 1-liter sealed glass bottles separately, domestic sewage was added to the glass as substrate. At different pH (6.5, 7.5, 8 and 8.5), some batch tests were operated to understand the effect of pH on metabolism of denitrifying polyphosphate accumulating organisms very well. The operation mode of batch experiments was agreement with A^2SBR. The slurry mixture was stirred by magnetic stirring and mixed liquor suspended solid (MLSS) was 3300 mg/L. In initial anaerobic reaction, nitrogen was injected into

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57375751

glass bottles to guarantee the anaerobic environment. In the anoxic phase nitrite and nitrate solution was continuously added into glass bottles as electron acceptor, and the concentrations of nitrite and nitrate could refer to A^2SBR, which were 21.7 mg/L 1.4 mg/L.

The pH was controlled by using pH detection probe, acid pump and alkali pump. The other reaction conditions, such as temperature, DO and stirring speed were the same as SBR reactor.

The nutrient removal efficiency was stable, and the average denitrifying dephosphatation was above 90%, effluent TN and P from the process can satisfy the GB effluent standards (P 0.5mg/L and TN 3mg/L), when the A^2N-SBR ran to 80^{th} day. A^2SBR sludge was designed to study the denitrifying phosphorus removal performance without sludge discharge and effect of SBR (6d, 10d, 16d and 22d) on nutrients removal. Surplus Sludge discharged was 0.5L, 0.5L, 0.5L, and 0.5L, respectively. COD, TP, NO_2^--N, NO_3^--N, PHB, poly-P, MLSS, MLVSS were detected.

Synthetic wastewater

Synthetic wastewater was used in the experiment, the feed contained sodium acetate as carbon sources, KH_2PO_4 was used as phosphorus source, NH_4Cl was added to provide nitrogen source, additionally, the other components also included $MgSO_47H_2O$, $CaCl_2$, $NaHCO_3$, and trace elements. Characteristics of synthetic domestic sewage were NSBR influent: CODcr 20.2～27.5 mg/L, NH_4^+-N 92.5～103 mg/L, TN 93～105.1 mg/L, TP 0.8～1.2 mg/L, pH 7～7.5; A^2SBR influent: CODcr 141～158.7 mg/L, NH_4^+-N 1.0～3.0 mg/L, TN 1.6～4.0 mg/L, TP 7.8～13 mg/L, pH 7.5～8.

Analytical methods

COD, TP, NO_2^--N, MLSS and MLVSS were analyzed in accordance with standard methods, and were measured according to the Chinese State Environmental Protection Agency Standard Methods (Chinese SEPA, 2002). The pH value and dissolved oxygen (DO) were measured online using pH and meters (DO530 and PH160, sinomeasure company, China), respectively. Glycogen was calculated according to Zhang et al. (2015). Biomass PHB content was detected by capillary-gas chromatography according to Cavaillé et al. (2013). GC working condition: A gas Perkin-Elmer gas chromatograph, equipped with a DB-5 column (30 m × 0.25 mm × 0.25 μm), and fitted with a flame ionization detector,1:20 split, high purity nitrogen gas as carrier, 1:20 injection mode, sample volume 3 μl, furnace temperature 100°C. Biomass sample preparation: Added 2 to 3 drops of formaldehyde to sewage samples to inhibit the biochemical reaction, centrifuged and removed the supernatant, then washed with phosphate buffer solution, after centrifugation, the sewage samples were moved into ampere tube and then dried with a freeze dryer and stored in frozen tube seal at 4°C temperature. Esterification: The 50 mg dried sewage was placed in 10 mL glass tube, mixed with equal volumes of 1-propanol / HCl and dichloroethane, added 1mg benzoic acid as internal standard substance. Benzoic acid as internal standard substance was added to mixture, heated in 100°C for 2 hours. After esterification, the samples were left to be cooled at room temperature and distilled water was added to 5 ml, shocked and solution for 10 minutes for effective extraction of potential residual-free organic acid, mixed with Na_2SO_4 to remove water and stored with gas chromatography automatic sampling bottle at 4°C temperature.

Results and discussion

Effect of pH

Effect of pH on phosphorus concentration

pH is an important parameter for denitrifying phosphorus removal process, could affect the enzymes activity of denitrifying polyphosphate accumulating organisms, because it is related to the change of cell membrane charge (Nittami et al., 2011). The competition between glycogen accumulating organism and polyphosphate accumulating organism could lead to a decrease of phosphorus removal rate in inappropriate pH environment.

The effect of various pH values on anaerobic and anoxic transformations of TP concentration and efficiency was investigated (*Figure 1*). The phosphorus specific release rate and uptake rate, expressed as net amount of phosphorus release and uptake per unit amount of VSS per hour in reactor (mg phosphorus/g VSS/ hour). It can be seen from *Figure 1* that the anaerobic phosphate release increased from 27.52 mg/L to 42.69 mg/L when pH increased from 6.5 to 8.

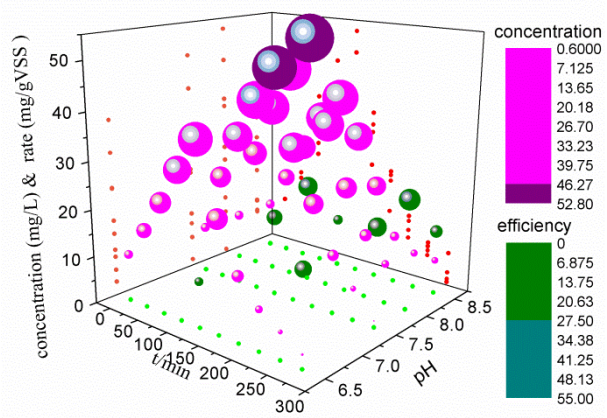

Figure 1. *Effect of pH on phosphorus concentration and release and uptake rate*

The scatter graph of phosphorus maximum specific anaerobic release rate showed upward trend with pH up to 8, but a plateau appeared to be reached 20.95 mg/g VSS/h at this value. The result was coincided well with previous investigation, in which it was assumed that acetic acid absorption need proton motive force, which need adenosine triphosphate (ATP) formed by polyphosphate degradation. Higher pH value could reduce proton motive force and more phosphate release (Zhao et al., 2016; Reza et al., 2016; Lu et al., 2016). However, when pH value increased to 8.5, anaerobic phosphorus release decreased to 28.69 mg/L. The phosphorus maximum specific anaerobic release rate began to decrease and reached 10.59 mg/g VSS/h in pH 8.5. The main possible reason was the formation of chemical precipitation phosphate compounds. Some phosphorus precipitations were absorbed on the surface of bacteria, it hindered the absorption and release of phosphate by denitrifying polyphosphate accumulating organisms (Sun et al., 2015). Experimental results showed that anaerobic phosphorus release was the maximum under pH 8. The pH also influences anoxic phosphorus uptake when using NO_2^--N as electron acceptor, the concentration of effluent

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57375751

phosphorus reduced, and the rate of anoxic phosphorus uptake increased with pH increase during anoxic denitrifying phosphorus uptake. The amount of phosphorus uptake was 34.63 mg/L, when pH was 6.5. There was a remarkable downtrend, phosphorus concentration reached nearly 0 mg/L sharply, and anoxic phosphorus uptake reached 52.02 mg/L when pH was kept at 8. When pHs were 6.5, 7.5 and 8, the corresponding phosphorus specific uptake rates were 18.92, 20.55, and 23.29 mg/g VSS/h. The influence of pH on the specific uptake velocity was rather moderate (as in the case of net phosphorus production), except at the highest pH 8.5, at which the specific uptake rate was reduced almost half of that calculated at pH 8. Similar phenomena took place in anaerobic phosphorus release reaction, but the effect of pH value on phosphorus specific uptake rate was not greater than specific release rate. The reason was that a large number of polyhydroxybutyrate (PHB) were synthesized under higher pH condition, which provided electron donor for anoxic phosphorus uptake. The batch tests indicated pH was an important influencing factor of denitrifying phosphorus removal, the amount of phosphorus uptake was directly proportional to pH (between 6.5 and 8).

Effect of pH on metabolic mechanism

The anaerobic acetic acid absorption, PHB production, and polyphosphate degradation of active sludge from batch tests in different pH condition were illustrated in *Figure 2*. Clearly, the columnar diagrams of anaerobic acetic acid absorption, PHB synthesis and polyphosphate decomposition per unit amount of VSS in reactor showed rising trend by pH condition in the range of 6.5~8. The rate of acetic acid absorption and PHB accumulation were 33.57 mg/g VSS/h and 20.73 mg/g VSS/h, poly-P degradation percentage was 62.32% at pH 6.5, and the rate of acetic acid absorption and PHB accumulation increased to 42.13mg/g VSS/h and 31.43 mg/g VSS/h, poly-P degradation percentage was 68.82% at pH 8.

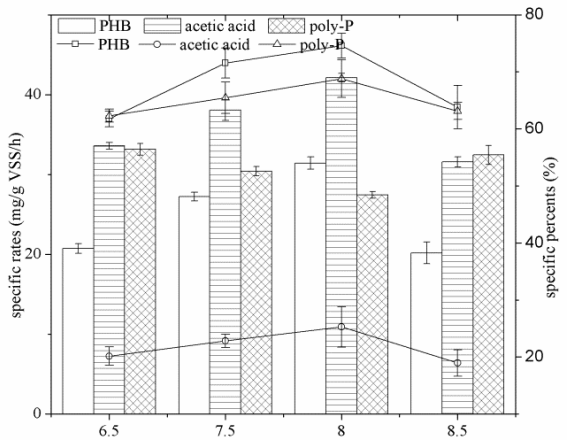

Figure 2. *Specific rates and percents of PHB accumulation, acetic acid absorption and poly-P degradation*

The trend curves of organic matter degradation, polyphosphate degradation rate and PHB conversion ratio along with pH value were the same as columnar diagrams. The main possible reason for different pH causing different PHB synthesis was related to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57375751

potential difference caused by pH gradient. The greater potential difference was, the more phosphate was released and the more PHB was transformed (Wang et al., 2015). The pH was adjusted to 8 by addition HCL or NaOH, it would be found that PHB conversion rate increased obviously, naturally acetic acid conversion rate and polyphosphate degradation ratio were also the largest. Thus increasing the anaerobic pH value would benefit to the microbial metabolism and phosphate removal. When pH was increased up to 8.5, because of chemical phosphorus precipitation, the rate of acetic acid absorption, PHB synthesis and poly-P degradation apparently decreased to 31.6 mg/g VSS/h, 20.17 mg/g VSS/h and 32.44 mg/g VSS/h. From the above considerations, it seems that pH should be strictly controlled below 8, it is the most favorable for biological denitrifying phosphorus removal.

The variation of COD, phosphorus, NO_2-$^-$N, PHB and polyphosphate concentration in stable anaerobic-anoxic SBR reactor at about pH 8 was highlighted in *Figure 3*. In 2 hours anaerobic P-release phase, sludge polyphosphate content showed downward trend in 2 hours anaerobic P-release sludge, the poly-phosphorus decomposition was 33.52 mg/g VSS, PHB production was 62.87 mg/g VSS. It has been demonstrated that propionic acid enhances the accumulation of polyhydroxyalkanoates (PHB) in sludge, which could apply electron donor for the simultaneous denitritation and phosphorus removal in the presence of nitrite (Oehmen et al., 2005a,b, 2006; Kishida et al., 2006; Katsou et al., 2015).

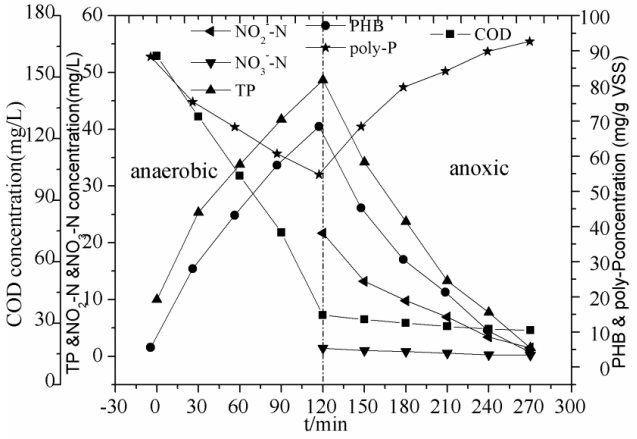

Figure 3. *Variations of COD, TP, NO2--N, PHB and poly-P in typical cycle*

Meanwhile COD concentration gradually decreased, and phosphate concentration increased to 48.98 mg/L. The possible reason was that the higher energy demand for active uptake of acetic acid, which caused more polyphosphate degradation for producing more adenosine triphosphate (ATP) and resulted in more phosphorus release. In 2.5 hours anoxic P-uptake phase, sludge polyphosphate gradually accumulated to 92.67 mg/g VSS at the end of reaction, meanwhile, there were steadily decrease in the curves of PHB, NO_2^--N, NO_3^--N, and phosphorus, the concentrations of phosphate, NO_2^--N and NO_3^--N reached 1.47 mg/L, 1.5 mg/L and 0.21 mg/L in effluent. One explanation for this observation was that soluble orthophosphate (SOP) was absorbed and stored intracellular polyphosphate, which used PHB as electron acceptor and nitrite nitrogen as electron donor (Mielcarek et al., 2015). And additionally, the curve of COD concentration declined drastically in the anaerobic period, the curve of COD

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57375751

concentration declined more sharply in P-release than P- uptake, COD concentration was 33.93 mg/L in anaerobic effluent, and anaerobic COD removal rate sped up to 78.84%. COD was removed mainly in anaerobic stage, which avoided the competition of traditional denitrification bacteria in anoxic stage. This experimental phenomenon was similar to the one of Liu et al. (2015). 22 mg/L NO_2^--N and 1.5 mg/L NO_3^--N as electron acceptors were removed by denitrifying phosphorus removal organisms, meanwhile 47.21 mg/L phosphorus was removed. The injections concentration of NO_2^--N and NO_3^--N were consistent with the A^2SBR. It was shown that the majority of nitrite and nitrate were consumed by denitrifying phosphorus accumulating bacteria, but not by conventional denitrifying bacteria.

It is verified through batch experiment that 22 mg/L nitrite as the main electron acceptor has a good performance, these nitrite levels did not inhibit the DBPRN. It is completely suitable for applying to denitrifying phosphorus remove, and the results is quite similar to the A^2N-SBR operation. Previous findings suggest that the nitrite levels at the end of the aerobic phase did not exceed 35 mg L and were usually in the range of 10~25 mg/L. Plotting $sPUR_{anoxic}$ versus the initial nitrite concentration at the end of the aerobic phase for a specific experimental period (i.e. period V) did not show any activity inhibition (Katsou et al., 2015).

Effect of SRT

Denitrifying phosphorus removal without sludge discharge

The effects of denitrifying phosphorus removal were investigated under condition of 18 days operation without sludge discharge that could make sure the optimum sludge age range. With reactor running continuously without sludge discharge, the effect of phosphorus removal was not stable. Results depicted in *Figure 4* indicated that phosphorus removal percentage fluctuated between 48% and 86.75%.

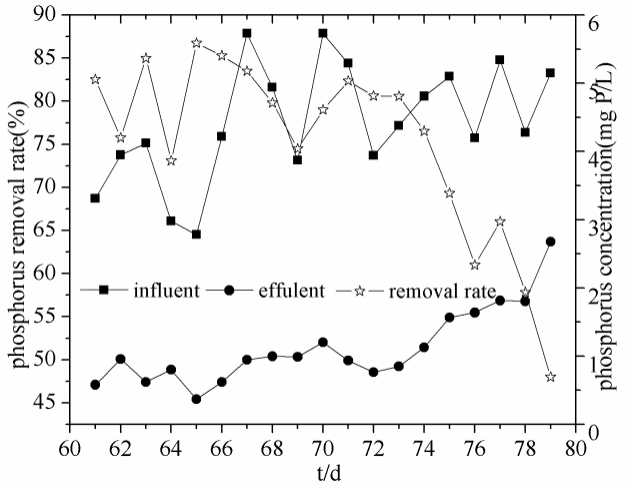

Figure 4. *Performance of phosphorus removal of the system without sludge discharge*

It was noted that the phosphorus concentration of the effluent was less than 3 mg/L, the average percentage of phosphorus removal reached 80.67% at the 16th day, over a period of 16 days, yield of phosphorus removal decreased gradually. It can be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57375751

concluded that there was a phenomenon of denitrifying phosphorus removal in condition of no sludge discharge. However, the phosphorus removal efficiency began to decline after the reactor was operated for more than 16 days without surplus sludge discharge. This result was not consistent with traditional theory of phosphorus removal, which argued that the shorter sludge age, the higher phosphorus removal efficiency. While Hatamoto et al. (2015) obtained the same conclusions, they believed that denitrifying poly-phosphorus accumulating microorganisms (DPAO) grew slowly and resulted in a longer sludge age.

The anaerobic/anoxic SBR ran continuously over 18 days and without sludge discharge, and the effect of SRT on NO_2^--N and COD removal was shown in *Figure 5*. Unlike phosphorus, COD and NO_2^--N removal ratios were 84.02%~92.71% and 75.83%~88.75% respectively, COD and NO_2^--N average discharge concentration were 22.91 mg/L and 2.01 mg/L, implying that no excess sludge discharge would not instinct degradation of organic compounds, even if phosphorus bacteria decreased above 16 days' sludge age. The main reason is that organic compounds have been used as nutrients not only by denitrifying polyphosphate accumulating microorganisms but also other heterotrophic bacteria (Kuba et al., 1996b; Ge et al., 2015). Most of Nitrite nitrogen was absorbed as electron acceptor mainly by DPAO. Additionally, a small amount was removed by denitrification.

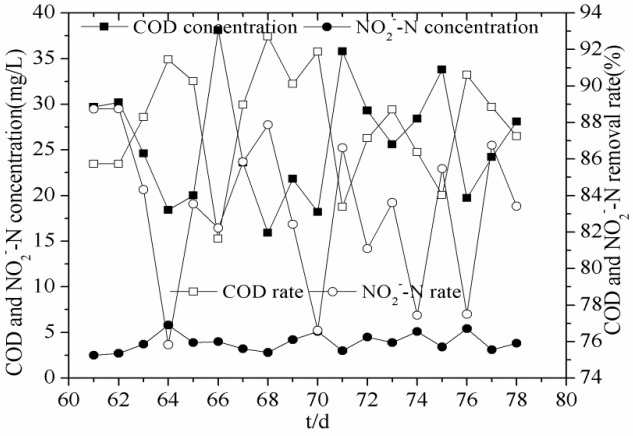

Figure 5. *Performance of COD and NO2--N removal in the system without sludge discharge*

Effect of SRT on phosphorus removal

Figure 6 showed the removal rate and content variation of phosphorus achieved by sludge at different sludge age (6d, 10d, 16d and 22d). It was indicated that the average phosphorus removal ratio was 61.32% and average phosphorus concentration in effluent was 7.78 mg/L in average, when the sludge age was 6 days. Since SRT is shorter than generation period of bacteria, lots of DPB sludge was discharged and SRT was too short to metabolize actively for denitrifying polyphosphate accumulating organisms, this made DPB become non dominant strains. In addition, short SRT led to high sludge organic loading and residual carbon source, which inhibited microbial physiological activity of denitrifying polyphosphate accumulating organisms and traditional denitrifying bacteria grew rapidly. When the SRT was increased from 6d to 16d, the average denitrifying phosphorus removal ratio increased gradually and finally stabilized

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57375751

at about 93.12%, with a decreased phosphorus effluent concentration of 0.69 mg/L. This is not consistent with the traditional view that at the smaller SRT, the better effect of phosphorus removal. However, when SRT reached 22d, sewage treatment performance of SBR got worse and phosphorus removal ratio decreased to 60.27%. The main reason is that the excessive sludge retention time resulted in reduction of organic load and ineffective phosphorus release (Luo et al., 2014). The literature suggests that denitrifying phosphorus removal sludge in strict anaerobic/anoxic systems showed the richest denitrifying phosphorus removal bacteria diversity when SRT were approximately 15-20d (Lv et al., 2013). A^2N processes can accommodate denitrifying dephosphatation, in the range of SRT (15~20d), effluent N and P from the two processes can satisfy the EC effluent standards ($P < 1$ g/m^3 and $N < 10$ g/m^3) (Hao et al., 2001). Other works have also shown that a sludge retention time of 15~16 days was favorable for denitrifying phosphorus removal (Zeng et al., 2002; Peng et al., 2004).

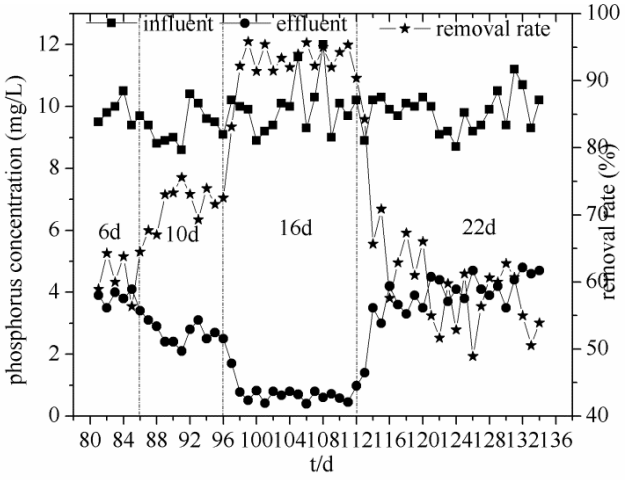

Figure 6. *Effect of SRT on the performance of phosphorus removal*

The anaerobic acetic acid degradation [measured by chemical oxygen demand (COD)] and PHB production were shown in *Figure 7*. It was found that activated sludge with an SRT of 16 days possessed better anaerobic acetic acid degradation and PHB production than other sludge time. The result was the same as the phosphorus variation. The average concentrations of COD and PHB in anaerobic effluent were 31.31 mg/L and 95.1 mg/L with an SRT of 16 days. The one possible reason is that SRT theoretically determines the microbial lifetime and microbial community. From our result, the shorter SRT may select microbial population with smaller COD consumption and PHB production ability compared with the longer SRT, this conclusion was in accord with literatures (Chen et al., 2016). Some a simulation SRT has been successful applied in A^2N process, and total effluent COD is always below 45 g/m^3, which satisfies the EC effluent standards (Hao et al., 2001). In addition, SRT could affect the PHB accumulation capability by sludge organic loading to biomass. In general, the SRT is proportional to biomass. But in this study, the concentration of COD and PHB in effluent with SRT of 22 days was similar to SRT of 16 days. This is probably because that the activated sludge with too long SRT contains aging microorganisms which might contribute to lower microbial activity. The growth of denitrifying polyphosphate accumulating organisms is inhibited with the too short or too long sludge retention time.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57375751

Microorganisms absorbed carbon source and stored by polyhydroxybutyrate are related to SRT and organic loading. In this study, 16 days is the most suitable sludge retention time for denitrifying polyphosphate accumulating organisms.

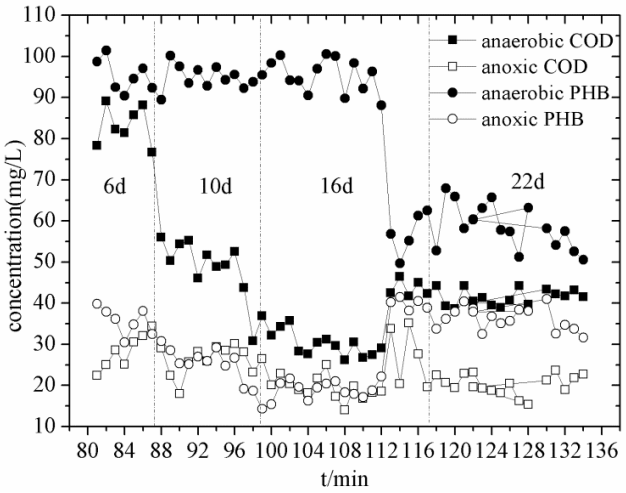

Figure 7. *Effect of SRT on carbon removal*

Effect of SRT on sludge concentration and metabolism mechanism

Activated sludge was the medium for microbial growth, results of SRT influence on mixed liquor suspended solid (MLSS), mixed liquor volatile suspended solid (MLVSS) and intracellular polymer content depicted in *Table 1* indicated that SRT was positively correlated to MLSS and MLVSS (6, 10, 16, 22 days). In this study, the MLSS in the anaerobic condition with an SRT of 6 days was around 1860 mg/L, and the value with a SRT of 22 days was around 4512 mg/L, the poly-P content amount per unit of MLVSS decreased from 40.7 to 24.2 mg/g VSS. The higher MLVSS promoted a complete phosphorus release and a lower content of phosphorus in the anaerobic sludge, but variation of phosphorus content per unit amount of MLVSS was less than the MLVSS. The main reason is that organic loading reduce with MLVSS increase, and phosphorus release per unit amount of MLVSS decrease. Accordingly, anaerobic phosphorus release per unit amount of MLVSS was proportional to SRT in condition of SRT≤ 16d (MLVSS≤ 2301 mg/L), otherwise anaerobic phosphorus release per unit amount of MLVSS increased slightly with SRT enhancing in condition of SRT ＞ 16d (MLVSS ＞ 2301 mg/L). Acetic acid are taken up into the cell and stored as PHB, energy (ATP) is required for this process, which is generated by degradation of the internal storage products polyphosphate and glycogen. In this case, anaerobic poly-P release would partly affect PHB synthesis, otherwise, intracellular glycogen of denitrifying phosphorus accumulating organisms could decompose PHB. The anaerobic PHB synthesis per unit amount of MLVSS was the most 63.8 mg/g VSS with an SRT of 16 days, the SRT had a little effect on anaerobic PHB synthesis. In theory, the content of PHB improves with SRT increasing, but there was no obvious influence on anaerobic PHB synthesis per unit amount of MLVSS because of organic load increase.

In the anoxic period, the MLVSS increased from 1342 mg/L to 3203 mg/L while SRT was from 6 to 22 days. The poly-P content increased gradually during anoxic denitrifying phosphorus uptake with the SRT increasing from 6 to 16 days, however,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57375751

these was a significant low at the point of SRT 22 days .Whereas SRT had less effect on anaerobic PHB production per unit amount of MLVSS in the reactor, it was because that MLVSS also increased with prolonged SRT, there was no significant difference in the amount of PHB synthesis of unit mass sludge. In the following electron acceptor phase, polyhydroxyalcanoates were degraded as electron for cell growth, polyphosphate synthesis. The system was slightly more effective in denitrifying phosphorus uptake at SRTs of 16 days than of 8, 10, 22 days, the PHB decomposition and polyphosphate accumulation were 16.3 mg/g VSS and 89.4 mg/g VSS at SRT of 16 days. PHB consumed more, phosphorus uptake more completely.

Table 1. *Effect of SRT on MLSS, MLVSS, PHB and poly-P*

Conclusions

In conclution, our investigation showed that pH and SRT as the main operational conditions to improve anaerobic organic matter degradation, PHB accumulation and anoxic nitrite nitrogen utilization, polyphosphate synthesis in anaerobic/anoxic activated sludge process. The optimal pH for denitrifying poly-phosphorus accumulating bacteria was 8, the rate of anaerobic phosphorus release and anoxic phosphorus uptake was 20.95 and 23.29 mg/g VSS/h. Activated sludge with the SRT of 16 days possessed better nitrite nitrogen utilization, organic matter degradation and phosphorus removal than sludge with the SRT of 6, 10 and 22 days. Although the pH and SRT could affect denitrifying phosphorus removal, the exct mechanism of action is still unknown. Therefore, futher research is needed to elucidate the exact mode of action of key factors on the activity of microorganisms in system.

Abstract. Water is a kind of important component in natural environment, while the ecological construction can influence the hydrological regime. A successful ecology construction is based on effective recognition of the relationship between the regional vegetation and surface water resources. This work used several datasets, including meteorological data, remote sensing data and hydrologic data. The objective of this work is to identify the effects of the precipitation and the ecological succession of vegetation on the surface runoff. The results indicated that: (1) the precipitation and surface runoff reduced by 4.8-7.3% and 20.6-43.2% during 1961-1985 and 1986-2011, respectively. The reduction of the surface runoff was higher than that of the precipitation; (2) the natural surface runoff of the Taihang Mountain is positively correlated with the precipitation and negatively correlated with NDVI. The natural surface runoff would increase by 16.6-66.7% with the hypothesis that vegetation during 1986-2011 was the same with that during 1961-1985; (3) considering the regional climate conditions, drought-tolerant native species should be chosen in landscape engineering of the Taihang Mountain. This effort can avoid exhaustion of water resource caused by the excessive construction of ecological project.
Keywords: *precipitation, NDVI, surface runoff, attribution assessment*

Introduction

Forest cover plays an important role in regulating land hydrological cycle, especially in precipitation redistribution, the impact of soil moisture movement and changing of runoff generation and confluence condition. Meanwhile, forest cover can reduce flood peak, increase runoff during dry season, control soil erosion and improve water quality. However, the relationship between forest and runoff has not reached a coincident conclusion. The main divergence is whether the forest cover will increase the soil moisture and decrease the runoff of the basin. There are two different views about this issue: the forest cover will increase the annual runoff for the retaining water capacity of forest, and the forest cover will increase precipitation and decrease ground surface evaporation. Hao, et al. (2004) did research in basin above Lushi hydrological station of the Luohe River, tributary of lower reaches of the Yellow River and the results indicated that the forest had increased the runoff. The annual runoff decreased obviously when most of the forest and grassland in the upper reaches of Mayinghe River Basin was turned into farmland (Wang et al., 2005). Because of the forest cover will increase evaporation and retain precipitation, enhance the use and exchange of deep

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57535764

phreatic water, accelerate the partial hydrological cycle and reduce surface runoff, many researches also demonstrated that the forest cover can reduce annual runoff. Similarly, the river runoff and flood peak can also be reduced. Zhou, et al. (2001) found that evapotranspiration will be the main factor of losing water when the basin is small. Therefore, the runoff will decrease if the forest cover increases.

Based on the data from more than 600 observation stations in the southern hemisphere, the runoff within ten years will decrease to a large degree after planting trees for carbon sequestration (Jackson et al., 2005). This phenomenon would lead to betrunking of the stream (Wang et al., 2006; Chen et al., 2009; Cao et al., 2009). After analyzing 94 basins around the world, Bosch, et al. (1982) found that the decrease of forest will result in the increase of runoff, while forestation in open field will cause the decrease of total runoff. Based on different methods, many other researches in different basins have reached the similar conclusion that the decrease of forest cover will lead to the increase of runoff (Siriwardena et al., 2006; Zhang and Schilling, 2006; Wang et al., 2008; Mao and Keith, 2009).

In addition, the annual runoff of the basin could be influenced by the forest vegetation change and the type of climatic region. For instance, the decrease of the forest cover rate would make the runoff coefficient markedly increase in the Loess Plateau. In arid and semi-arid areas, the evaporation capacity of forest is greater than the precipitation. The evaporation is the mainly moisture outlay of the ecosystem. Therefore, the forest coverage increase will result in the decrease of water yield of the drainage basin. Moreover, the variation of forest coverage exerts little effect on the annual runoff generation of the basin in the tropical and subtropical region. In the tropical and subtropical basin with abundant rainfall, the moisture evapotranspiration is depended on the climatic factor, and the vegetation coverage is not a key factor affecting the moisture evapotranspiration of the basin. The forest coverage variation had no significant influence on the runoff volume (Wang and Zhang, 2001). Currently, regional difference still exsits in the relationship between vegetation coverage and runoff. Therefore, taking into account the response of streamflow after vegetation change and precipitation becomes necessary.

In this study, we (1) investigated the relationship between precipitation and runoff depth, and the variation characteristics of NDVI in typical basin for analyzing vegetation effects on surface runoff; (2) compared the runoff generation and runoff coefficient variation as estimated using different calibration periods; and (3) examined the restoring computation of natural runoff based on the approach to estimate the characteristic of the precipitation and runoff and explored a general framework to incorporate the effects of precipitation and vegetation variation on runoff in typical basin.

Materials and methods

Study area

The Taihang Mountain is situated in a topographical transforming region. The North China Plain is in its eastward, and the Loess Plateau is in the west. This mountain is roughly parallel with the coast line of eastern China. In the summer time, the warm, moist air from the Pacific Ocean will be raised up to cause rainfall in the area where the elevation is higher than 800 m. This is the reason why in the area where the elevation is higher than 800 m has a humid climate compared with places lower than 800 m in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57535764

Taihang Mountain. When the elevation is lower than 800 m, the annual average temperature is around 12.3℃, precipitation is around 500 mm, and the annual potential evaporation is about 1700 mm. Based on the special environmental characteristics, the ecology system are more fragile in this region. The eastern Taihang Mountain, situated between 112°7′E and 115°30′E and between 37°17′N and 41°15′N, is the area investigated in this study, including the Yanghe River Basin, Yongdinghe Upriver Basin and Ziyahe Upriver Basin.

The daily precipitation data from 1961 to 2011 were gathered from the meteorological stations located in East Taihang Mountain Area (the stations close to the boundary were also included). Runoff data used in this research are collected from 3 typical hydrological stations of East Taihang Mountain. The representative hydrological stations are Xiangshuibao, Shixiali and Huangbizhuang reservoir, respectively (*Table 1*). Meanwhile, the actual measured streamflow data and natural streamflow data are available for the period of 1961-2011. The spatial distribution of 81 meteorological stations was screened in *Figure 1*.

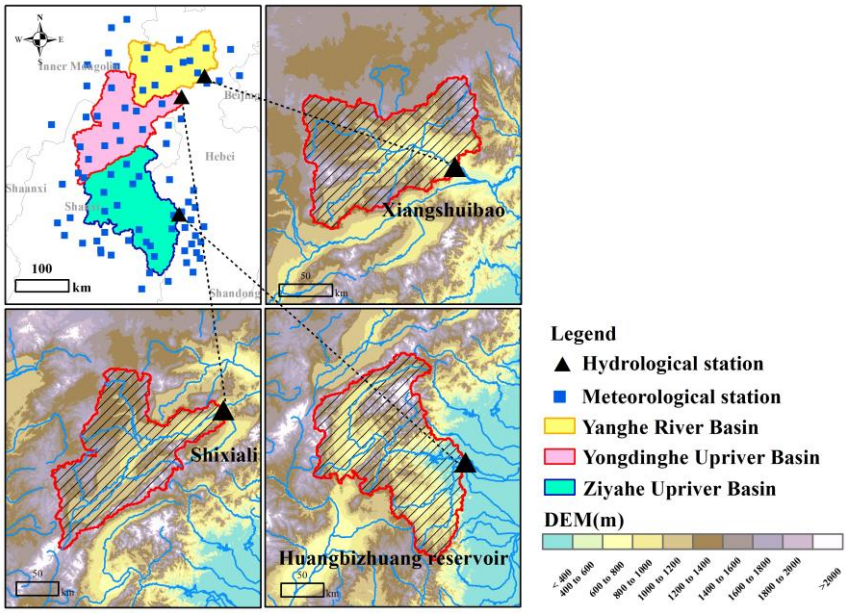

Figure 1. *Locations of the paired catchments in Eastern Taihang Mountain*

Table 1. *Basic information of the 12 hydrological stations*

Hydrological station	Longitude	Latitude	Control area (km^2)	River basin
Xiangshuibao	115°11′	40°31′	14507	Yanghe River Basin
Shixiali	114°33′	40°15′	23944	Yongdinghe Upriver Basin
Huangbizhuang reservoir	114°18′	38°15′	23272	Ziyahe Upriver Basin

In this study, GIMMS NDVI data and MODIS NDVI data are selected. These two data sets are provided by the Godard Space Flight Center in the National Aeronautics and Space Administration (NASA). The GIMMS data is 15 day compound product with 8 km resolution in global scale. MODIS NDVI data is calculated from MODIS

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57535764

reflectance data based on the generalized algorithm. The preprocessing procedures include: quality assessment, region of interesting extraction, mosaicking and geometric rectification.

Time trend analysis of NDVI

According to the monthly NDVI data of the two datasets from 2000 to 2006, the monthly NDVI sequence (1982–2013) was derived through the per-pixel unary linear regression model. The per-pixel unary linear regression model can acquire the most appropriate regression equation for each pixel. The elementary structure form of the model for different data is calculated as *Equations 1* and *2* (Ma, 2009).

$$G_i = a + bV_i + \varepsilon_i \quad \text{(Eq.1)}$$

where, parameter a and b are estimated by the least square method, and ε_i is random error.

$$b = \frac{\sum_{i=1}^{n}\left(G_i - \overline{V}\right)\times\left(G_i - \overline{G}\right)}{\sum_{i=1}^{n}\left(V_i - \overline{V}\right)} \qquad a = \overline{G} - b \times \overline{V} \quad \text{(Eq.2)}$$

where, G_i represents GIMMS NDVI in ith month, and V_i is MODIS NDVI (8 km × 8 km) in ith month. $\overline{\ }$,G is the mean of all monthly GIMMS data from 2000 to 2009 at corresponding pixel. $\bar{\ }$,V is the mean of all monthly MODIS NDVI data (8 km × 8 km) from 2000 to 2009 at corresponding pixel.

Zonal statistics for precipitation and NDVI

Since the meteorological stations are dense enough to capture the extent of East Taihang Mountain Area surface variation, the IDW (Inversed Distance Weighted) method is chosen to convert daily precipitation to grid surface data (Garcia et al., 2008). The spatial resolution of the interpolated areal daily precipitation is 5 × 5 km². Data processing was carried out in the ArcInfo Workstation 10.0. The relative calculation is conducted by ARC Macro Language (AML). The key codes of IDW are listed as follows:

IDW = idw (point_cover, spot_item, #, 2, sample, 12, #, %cellsize%, %xmin%, %ymin%, %xmax%, %ymax%)

where, the point_cover indicates the source of the data containing points with z values to be converted to a grid surface; spot_item is the item in the point coverage to be used as the z value for the interpolation; cellsize is the width or height of a cell, in map units. cellsize is set as 5000 in this study, which means the spatial resolution of the grid file is 10 × 10 km². {xmin, ymin, xmax, ymax} represents the interpolation within the data processing, and xmin, ymin, xmax, ymax are 560000, 4000000, 915000, 4510000, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57535764

According to the values of the enclosed grid cells, the mean value of annual precipitation and NDVI was calculated for each catchment. The code used in ZONALSTATS is shown as follows:

outtable = zonalstats(zonegrid, valuegrid, mean)

where, the zonegrid represents the integer grid that identifies the zone for each cell, valuegrid is the floating grid that defines the annual precipitation and NDVI values of the cells, and mean is a keyword for zonal mean calculations. The computation process was conducted in the ArcInfo Workstation 10.0 platform.

Determination of the streamflow decrease

The statistic model of precipitation (X_1), NDVI (X_2) and runoff (Y) was developed by the regression analysis method (*Table 2*). Then the responding relationship of precipitation, NDVI and runoff was analyzed through this statistic model.

Table 2. *The responding relationship of precipitation, NDVI and annual runoff depth*

Item	Factor	Variable
Dependent variable	Annual runoff depth	Y
Independent variable	Annual precipitation	X_1
	NDVI	X_2

According to the starting time of the landscape engineering in Taihang Mountain, the time sequence of this work is divided into two periods: natural period (1961-1985) and impacted period (1986-2011). The vegetation coverage remained natural during the natural period. However, the vegetation has gained relative recovery in the impacted period, and the relationship between the precipitation and streamflow was changed in a certain extent. After the break point, R_{nature} is indicated the average natural runoff (*Fig. 2*). Meanwhile, during the impacted period, the simulated natural runoff volume R_{retrieve} could be obtained under the assumption that the relationship between precipitation and streamflow was the same as that in the natural period. Thus, decrement runoff volume caused by the vegetation recovery after 1985 can be derived from the function as *Equation 3*.

$$\Delta R = R_{retrieve} - R_{nature} \quad \text{(Eq.3)}$$

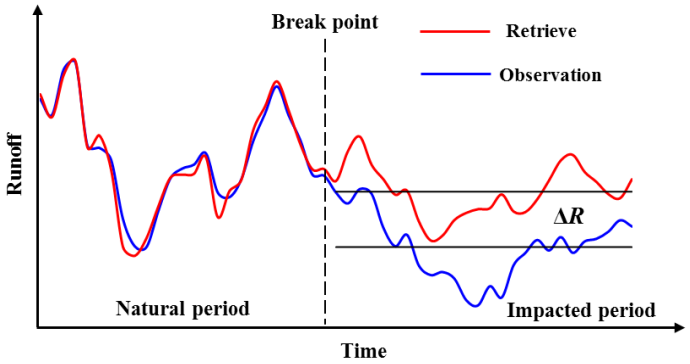

Figure 2. *The framework for quantitative assessment of streamflow decrease*

Results

The relationship between precipitation and runoff depth

During 1961-2011, the annual precipitation within the Yanghe River Basin, Yongdinghe Upriver Basin and Ziyahe Upriver Basin showed a decreasing tendency, and the changing rate of annual precipitation were -8.6 mm/10a, -8.0 mm/10a and -15.3 mm/10a, respectively. Compared with the period 1961-1985, the average annual precipitation of three catchments reduced by 5.1%, 4.8% and 7.3% during 1986-2011. The runoff and precipitation variation showed a similarity in the decreasing tendency. The variation rate of natural runoff of Yanghe River Basin, Yongdinghe Upriver Basin and Ziyahe Upriver Basin were -5.9 mm/10a, -3.9/10a and -9.9 mm/10a, respectively. The results demonstrated that the actual measured runoff depth decreased obviously within the study periods. The changing rates of actual measured runoff depth in the three typical basins were -7.2 mm/10a, -6.5 mm/10a and -16.1 mm/10a, respectively. After 1985, the natural runoff depth reduced by 43.2%, 30.7% and 20.6% compared with the average runoff depth during 1961-1985. Similarly, the actual measured runoff depths were 66.8%, 76.1% and 54.3% lesser than the average value before 1985. The difference between natural runoff and actual measured runoff is obvious under the pressure of anthropologic influence and it would be more obviously in the future (*Fig. 3*).

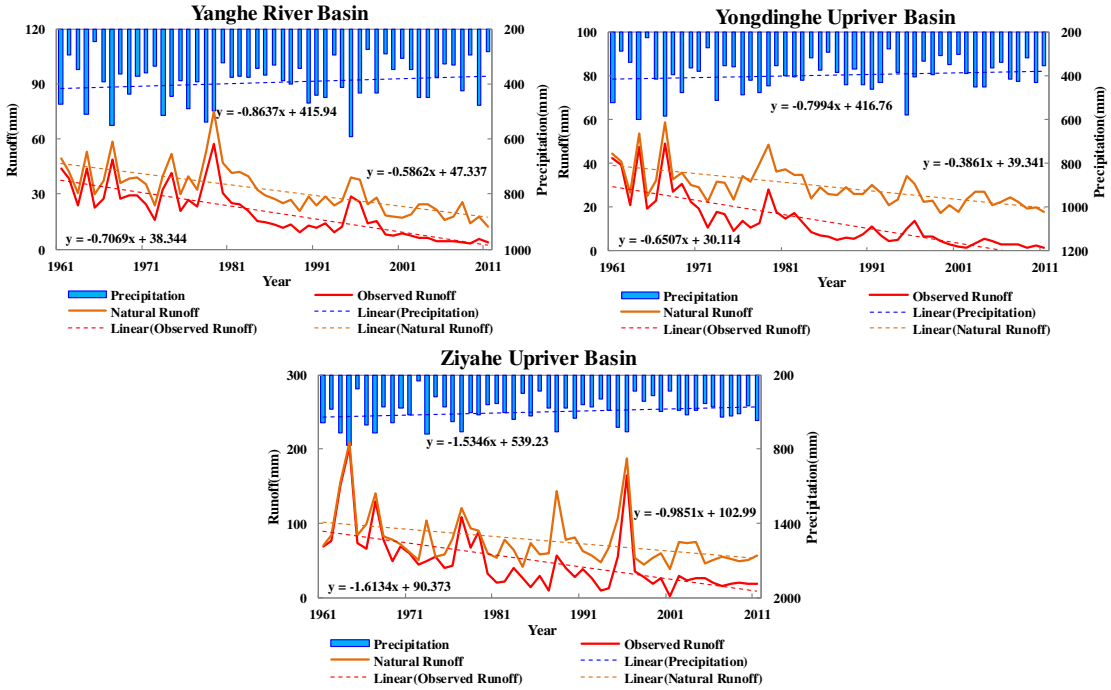

Figure 3. *The annual precipitation and runoff depth variation in 1961-2011*

The ratio of annual average intensive precipitation (S > 25 mm/d) was gradually increasing from north area to south area. The probability of intensive precipitation in Yanghe River Basin, Yongdinghe Upriver Basin and Ziyahe Upriver Basin were 13.4%, 15.0% and 23.0%, respectively. The intensive precipitation ratio in the Yanghe River Basin and Yongdinghe Upriver Basin presented decreasing tendency during the 1961-

DOI: http://dx.doi.org/10.15666/aeer/1703_57535764

2011 (*Fig. 4*). However, this ratio in Ziyahe Upriver Basin had an increasing tendency during the study period. Specially, the variation of intensive precipitation was obviously in the Yongdinghe Upriver Basin and Ziyahe Upriver Basin. With respect to the average intensive precipitation before 1985, the intensive precipitation ratio has reduced by 9.9% in the Yongdinghe Upriver Basin. Moreover, the intensive precipitation ratio has increased by 3.6% in the Ziyahe Upriver Basin.

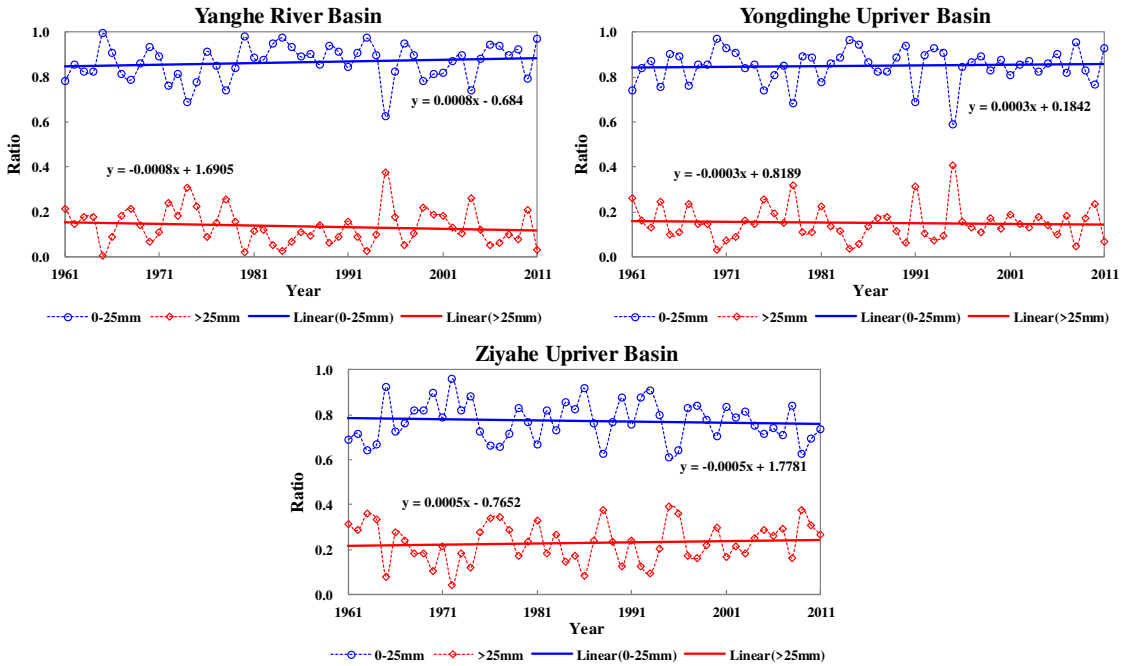

Figure 4. *The probability of different intensive precipitation during 1961-2011*

Characteristics of NDVI variation in typical basin

The NDVI of the Yanghe River Basin, Yongdinghe Upriver Basin and Ziyahe Upriver Basin presented an increasing tendency during 1983-2013 (*Fig. 5*), and their variation tendency rates were 0.017/10a, 0.015/10a and 0.009/10a, respectively. The results demonstrated that the increased range of NDVI value in the north region was obviously higher than that in the south region (*Fig. 6*). The variation tendency ratio of NDVI in the north area was generally above 0.010/10a. The large-scale vegetation recovery was mainly benefited by the landscape engineering in Taihang Mountain. The vegetation recovery project built 1.36 million hectares of forest from 1986 to 2000. As in the second stage (2001-2010), the recovery project built 1.78 million hectares of forest. During the third stage (2011-2050), the project aims to build 0.42 million hectares of forest. The forest cover rate will be enhanced from 15% to 35% after this project completed.

Evidence for runoff generation and runoff coefficient variation

The runoff generation coefficient and runoff coefficient decreased obviously from 1961 to 2011. During the period, the runoff generation coefficients of Yanghe River Basin, Yongdinghe Upriver Basin and Ziyahe Upriver Basin reduced by -0.014/10a,-0.009/10a and -0.015/10a, and the runoff coefficient in the typical basins were -0.017/10a, -0.016/10a and -0.029/10a, respectively. The results indicated that the runoff

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57535764

coefficient has more significant decreasing tendency since 1985 (*Fig. 7*). The average runoff generation coefficients in the Yanghe River Basin, Yongdinghe Upriver Basin and Ziyahe Upriver Basin were 0.10, 0.09 and 0.17 from 1961 to 1985. And the runoff coefficients in the typical basins were 0.07, 0.05 and 0.13, respectively. However, during 1986-2011, the average runoff generation coefficients/runoff coefficients were 0.06/0.03, 0.06/0.01 and 0.14/0.06, respectively. Meanwhile, the average runoff generation coefficients/runoff coefficients of the three typical basins have reduced by 40.1%/64.0%, 27.2%/74.9% and 14.3%/50.7% compared to the average value during 1961-1985 (*Fig. 8*). The runoff generation coefficient and runoff coefficient decreased obviously in the northern region.

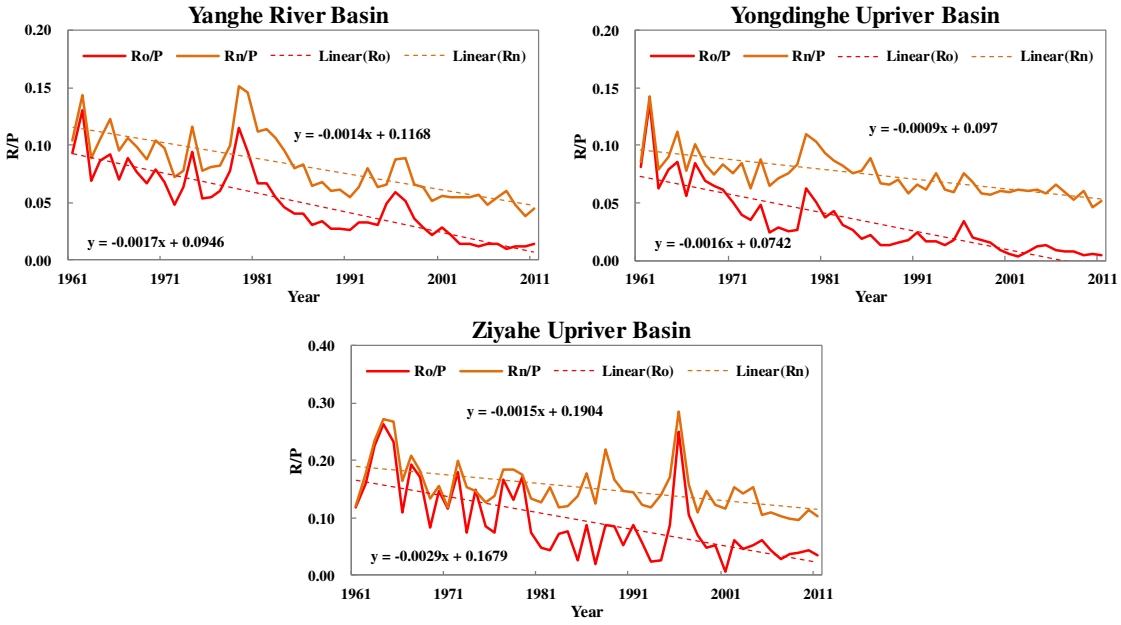

Figure 7. *The interannual variation of runoff generation coefficient and runoff coefficient*

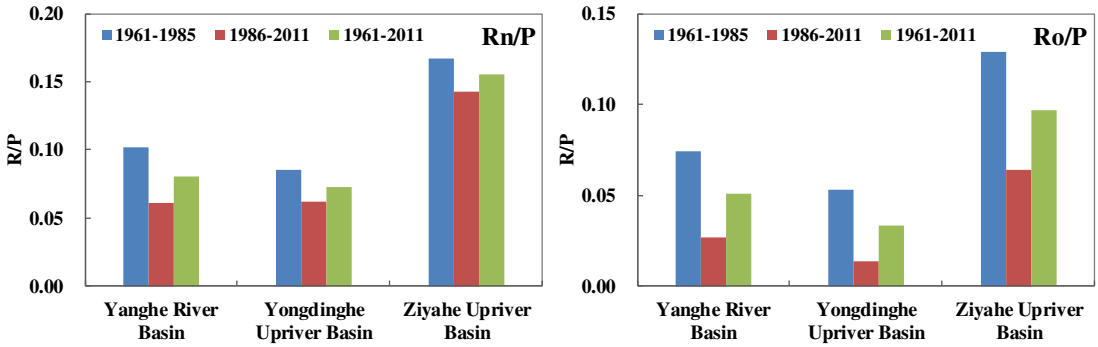

Figure 8. *Different periods of runoff generation coefficient and runoff coefficient in typical basins*

The least square method was carried out to conduct the regression analysis of precipitation (X_1), NDVI (X_2) and natural runoff depth (Y). The regression analysis results demonstrated that the volume of runoff has positive relationship with the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57535764

precipitation, and the NDVI has negative relationship with to the volume of runoff (*Table 3*). In conclusion, the vegetation in the eastern Taihang Mountain had greatly recovered due to the implement of landscape engineering. However, the forest covered area has unreasonable increased due to the excessive construction of vegetation. Thus, the volume of runoff in the typical basins was decreased to a certain degree for the influence of evapotranspiration increase.

Table 3. *Regression analysis of precipitation, NDVI and natural runoff*

River basin	Regression equation	R2
Yanghe River Basin	$Y = 0.07\ X_1\text{-}198.59X_2 + 47.93$	0.55
Yongdinghe Upriver Basin	$Y = 0.06\ X_1\text{-}148.50\ X_2 + 37.77$	0.68
Ziyahe Upriver Basin	$Y = 0.27\ X_1\text{-}308.13\ X_2 + 40.47$	0.55

Restoring computation of natural runoff

Compared with the period of 1961-1985, the precipitation in the typical basins had reduced by 4.8-7.3% during 1986-2011. Nevertheless, the volume of natural runoff has reduced by 27.2-40.1% (*Table 4*). The decreased runoff volume was greater than the amount of precipitation in the typical basins. Specifically, the reduction amplitude of runoff generation coefficient was 14.3-40.1%. Moreover, the reduction amplitude was increasing from south to north region, especially in the Yanghe River Basin. The relationship of precipitation and natural runoff in the typical basins are assumed to be similar with that during1961-1985, and the precipitation still remained the level during1986-2011. On this condition, the annual natural runoff depths of the Yanghe River Basin, Yongdinghe Upriver Basin and Ziyahe Upriver Basin were 39.0 mm, 33.1 mm and 80.1 mm. At the same time, the results demonstrated that the annual natural runoff depths within the typical basins has increased by 66.7%, 37.3% and 16.6% compared with that in the practical condition.

Table 4. *Changes of annual mean precipitation and streamflow during the two periods in Yanghe River Basin, Yongdinghe Upriver Basin and Ziyahe Upriver Basin*

River basin	Period	R/P	P_{mean}/mm	R_{mean}/mm	$R_{retrieve}$/mm
Yanghe River Basin	1961-1985	0.10	404.1	41.2	**39.0**
	1986-2011	0.06	383.3	**23.4**	
	Change	-40.1%	-5.1%	-43.2%

	Change	-14.3%	-7.3%	-20.6%	

Conclusion

In the recent 50 years, the annual precipitation in the eastern Taihang Mountain presented the decreasing tendency. In the Yanghe River Basin, Yongdinghe Upriver

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57535764

Basin and Ziyahe Upriver, the annual precipitation of the typical basins has reduced by 5.1%, 4.8% and 7.3%, respectively. The volume of the natural surface runoff has larger decrease compared with that of precipitation. On the basis of the Taihang Mountains afforestation project, the vegetation coverage was greatly recovered. The variation tendency rate of the regional averaged NDVI was 0.009~0.017/10a. The increase of the forest coverage can enhance the evapotranspiration of the surface, which is one of the major reasons for the runoff decrease. Similarly, the relationship of precipitation and natural runoff in the typical basins are assumed to be similar with those during1961-1985, and the vegetation coverage remained the level before 1985. On this condition, the annual natural runoff depths of the Yanghe River Basin, Yongdinghe Upriver Basin and Ziyahe Upriver Basin were 39.0 mm, 33.1 mm and 80.1 mm. At the same time, the results demonstrated that the annual natural runoff depths within the typical basins increased by 66.7%, 37.3% and 16.6% compared with that during the practical condition. Thus, the vegetation's restoration causes the regional runoff's decrease by 16.6~66.7%.

The precipitation may continue decreasing in the future due to climate change and global warming. However, the surface evapotranspiration will be greatly enhanced for the continuous increasing temperature in this region. For this reason, the Taihang Mountain region may face the water shortage crisis in the future. Because of the water shortage tends to exist in long-term, how to balance water usage and vegetation restoration under the water shortage condition is becoming a challenge. In the future work, the selected vegetation species for afforestation project should consume less water and have a higher tolerance for water shortage condition. Furthermore, because of the water restrictions, the planted vegetation should keep lower densities to reduce water consume.

This research has adopted statistical methods to identify the impact of precipitation and vegetation variation on surface runoff. The formation of surface runoff is not only affected by precipitation and vegetation, but also by many other factors such as soil and temperature. Further research may use physically-based watershed eco-hydrological model to do more refined simulation of the eco-hydrological process, thus identifying the spatial difference of the impact of precipitation and vegetation variation on surface runoff. In the meantime, multi-set of vegetation restoration and repair scheme can be set. Optimal scheme which is the most suitable for the eastern Taihang Mountain can be selected.

Abstract. Recognizing intra- and inter-daily dynamics of chlorophyll a (Chl-a) and its related environmental variables on consecutive days is essential to assessing and managing water quality and eutrophication. In this study, the Chl-a concentration, nutrients, water temperature and meteorological factors in Guanting Reservoir in Beijing were collected at six sampling times during summer. The Chl-a concentration generally decreased from May to September. At both test times, thermal stratification and mixing in the water column controlled temporal and vertical variations in the maximum Chl-a concentration layer. The position of the maximum Chl-a concentration layer between days generally followed that of the thermocline. Daily stratifications were temporary and downwelling variations in the maximum Chl-a concentration layer were wind driven; therefore, the vertical distribution of Chl-a was homogenized at night. Surface Chl-a concentrations increased at night and decreased during the day, except on rainy days. Principal component analysis and Pearson's correlations indicated that daily average and raw surface Chl-a concentrations generally changed as a negative function of air temperature, solar radiation, wind speed and water temperature. However, when a 5-hour time lag was considered, the relationship between surface Chl-a concentration, all meteorological factors and water temperature became significantly positive.
Keywords: *eutrophication, reservoir stratification, phytoplankton occurrence, meteorological factors, short-term distribution*

Introduction

Chlorophyll a (Chl-a) is an important indicator of phytoplankton biomass that is of significance to analysis of the magnitude and extent of trophic state in lakes and reservoirs (Felip and Catalan, 2000; Bresciani et al., 2013; Wu et al., 2014). To adequately recognize the response of Chl-a to ecological changes in phytoplankton and its life cycle, spatial and temporal phytoplankton distributions have been analyzed and documented by many researchers (Pérez-Ruzafa et al., 2005; Wu and Kong, 2009; Zhou et al., 2016; Li et al., 2017). It is generally known that the dynamics of phytoplankton growth and algal blooms are controlled by combined environmental factors such as hydrodynamic conditions (wind speed and direction, bottom topography, stratification pattern, water velocity and discharge) (Cao et al., 2006; Cardoso and Motta-Marques, 2009; Li et al., 2017), nutrients (total nitrogen, total phosphorus, and TN:TP ratio) (Wang et al., 2008; Wu et al., 2014), physical variables (air temperature, light, water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57655780

temperature and turbidity) (Serra et al., 2007), characteristics of phytoplankton (species, size and buoyancy) (Lopes et al., 2005) and hydraulic management (León et al., 2016). Of these factors, nutrient supply and light are generally considered the primary variables limiting phytoplankton growth (Phlips et al., 1995; Becker et al., 2010; Zhou et al., 2016). However, the most influential or primary environmental factor controlling phytoplankton growth differs according to spatial and temporal scale and trophic state of the studied systems. León et al. (2016) demonstrated that stratification pattern and residence time are of great importance to reservoir trophic state and vertical distribution of Chl-a between seasons. Moreover, water temperature has been shown to be a more important factor in mesotrophic lakes than oligotrophic and eutrophic lakes (Rigosi et al., 2016). In shallow lakes, the negative effects of increasing wind on phytoplankton growth can be crucial because it leads to increased resuspension (Cardoso and Motta-Marques, 2009).

Investigating the phytoplankton dynamics in the short term is of great importance to recognizing the mechanism of phytoplankton growth for long term variations (Bresciani et al., 2013). It is well known that phytoplankton is characterized by obvious circadian variations (Neveux et al., 2003), which depend directly on their response to diurnal available solar radiation during the day (Wu and Kong, 2009). Serra et al. (2007) demonstrated that most processes involved in phytoplankton growth occur for less than 1 week. When investigating phytoplankton at short time intervals, previous studies have mainly focused on phytoplankton species and community structure (Lopes et al., 2005), the effects of stratification and wind on vertical mixing and advection movement of phytoplankton (Antenucci and Imerito, 2000; Marcé et al., 2006; León et al., 2016) and the relationship between Chl-a and environmental variables (Felip and Catalan, 2000; Cyr, 2017), as well as the time lag of Chl-a (Pérez-Ruzafa et al., 2005; Bresciani et al., 2013). For instance, León et al. (2016) reported that stratification changes the vertical profile of residence time, which is negatively correlated with phytoplankton biomass. Wind driven phytoplankton vertical downwelling (Cardoso and Motta-Marques, 2009) and night-time convective cooling would homogenize the vertical distribution of phytoplankton (Serra et al., 2007). Moreover, the interannual data ln (Chl-a) illustrated a positive correlation with average air temperature (Zhou et al., 2016); however, when the short-term data set was evaluated, Chl-a concentration was negatively correlated with average air temperature (Bresciani et al., 2013). These discrepancies in the association of Chl-a concentration and other environmental variables may be caused by differences in the time scales of the investigated datasets.

Before 1997, Guanting Reservoir was a source of drinking, industrial, and agricultural water in Beijing, China (Dai et al., 2008). However, the reservoir is now in a eutrophic state (He et al., 2008), and the concentration of phosphorus in the reservoir is much higher than the normal criterion for drinking water (Cui et al., 2005). Additionally, the trophic state index is higher than 50, which is based on total nitrogen (TN) and total phosphorus (TP) (He et al., 2011). Previous studies conducted in Guanting Reservoir have investigated the trophic state of its water body based on monitoring of sediment P-decomposing bacteria (Cui et al., 2005), water quality (He et al., 2008), cyanobacteria and their toxins (Dai et al., 2008), and microcystis water blooms (Chen et al., 2011), as well as water quality modeling (He et al., 2011). However, knowledge regarding short-term variations in phytoplankton distribution in the reservoir is relatively scarce and the relationship between Chl-a and other environmental variables in unclear. Therefore, continuous and multiple measurements

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57655780

taken in the short term are needed to acquire a better understanding of the variability in Chl-a concentrations. Fluorescence method may not measure all phytoplankton activity (Bresciani et al., 2013). Distinct phytoplankton groups can be measured by fluorometric probes and the phytoplankton groups are summarized in Beutler et al. (2002). However, it has been used as a reliable alternative to the in situ and in vivo study of phytoplankton distribution and activity (Serra et al., 2007; Wu and Kong, 2009). According to a previous study, algal blooms in Guanting Reservoir began in late May and disappeared in early October (He et al., 2011). In the present study, samples were collected over six periods ranging from 2 to 3 days from late May to early September to detect vertical and surface variations in Chl-a concentration.

The specific objectives of this study were (1) to investigate vertical and surface distributions and diurnal variations in Chl-a, (2) to relate this variability of Chl-a to stratification patterns, nutrients and wind during the study period and (3) to correlate Chl-a data with water temperature and meteorological data during the study period.

Materials and methods

Reservoir and site description

This study was conducted in Guanting Reservoir, which is located in northwest Beijing (*Fig. 1*). The watershed area and storage capacity of the reservoir are approximately 4.34×10^4 km^2 and 2.19×10^{10} m^3, respectively. In the past 30 years, Guanting Reservoir has played an important role in local development through electricity generation, fishing, tourism, and other uses. More importantly, it has been a source of drinking, industrial, and agricultural water in Beijing. However, the rapid development of upriver and surrounding areas has led to serious pollution. As a result, Guanting Reservoir has not been used as a drinking water source since 1997 (Dai et al., 2008). The government made great efforts to restore the reservoir in 2006 and its water quality recovered to Level III according to the Environmental Quality Standards for Surface Water (He et al., 2008). Thus, Guanting Reservoir has the potential to once again be a drinking water source for Beijing.

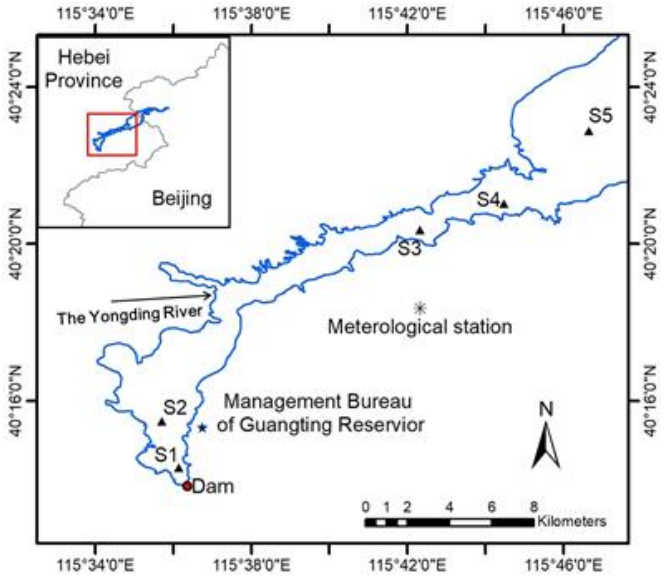

Figure 1. *Map of sampling locations in Guanting Reservoir*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57655780

Measurements of spatial and seasonal variations of Chl-a has been carried out in Guanting Reservoir in 2014 (Sun et al., 2015), which shows the algal blooms appeared in the area near the dam during summer in Guanting Reservoir (*Figs. 1* and *2*). Consequently, this present study extends the work of Sun et al. (2015) by investigating short-term variability of Chl-a concentrations in the area near the dam during summer. The average hydraulic residence time of Guanting reservoir is 467 days. A field sample site located in a relatively closed and calm area with maximum Chl-a concentration of 2014 that was suitable for in-situ testing was selected to investigate short-term vertical variations in Chl-a concentration (S1 in *Fig. 2*). The topography contour map of Guanting reservoir can be seen in He et al. (2011). The outlet discharge varies by time of week and draws off water at a depth of 8 m. The site was located near the dam in the deepest portion of the entire reservoir. The average water depth for each test time was about 11 m, which was ideal for investigation of the vertical dynamics of Chl-a concentration.

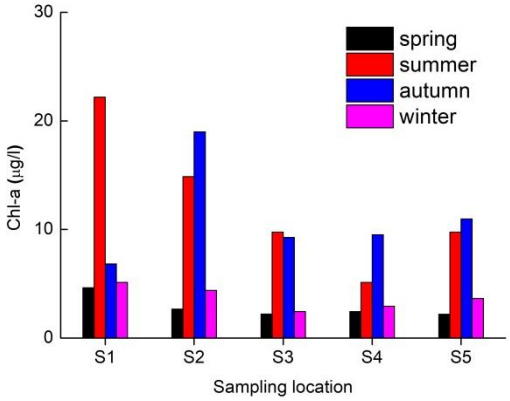

Figure 2. *Spatial and seasonal variability of Chl-a in Guanting Reservoir. (Adapted from Sun et al., 2015)*

Sampling and analysis

A total of six investigations including four rounds of vertical sampling and two rounds of surface sampling were conducted from 29 May to 9 Sep, 2015 (*Figs. 3* and *4*). On the vertical sampling days, the Chl-a concentration was obtained based on the fluorescent attributes of Chl-a concentration using an INFINITY water quality sensor (Onset, USA). The water temperature at each water depth was measured using a HOBO U20 recorder (Onset, USA), which had a measurement accuracy of ±0.21 °C. A self-made lifting device was employed to move the aforementioned devices throughout each day (*Fig. 5*), six times during daytime (8:00 h, 10:00 h, 12:00 h, 14:00 h, 16:00 h and 18:00 h) and four times during night (21:00 h, 0:00 h, 3:00 h and 6:00 h). Chl-a concentration and water temperature data were vertically collected for each lifting time at 1-min intervals. Throughout all sampling times, a global positioning system (GPS, HOLUXGM-101, China) was used to precisely ensure the sampling location. It should be noted that few vertical samples were obtained from the water column during the last test period (*Fig. 3d*). This occurred because of a lack of power for the self-made lifting device from 6:00 h on 8/September, which caused it to stop lifting; therefore, only surface samples were collected from this point to the end of the study period. Water quality parameters including DO, pH and turbidity were determined in situ using a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57655780

Hydrolab Multi-parameter water quality sensor (Hach, USA). Based on He et al. (2011), the thermocline appeared at a depth of 4 m of Guanting reservoir during summer. Representative water samples (1500 ml) were collected from a depth of 2 m at noon during each test period and transported to the laboratory, where they were analyzed for total nitrogen (TN), ammonium (NH_4), total phosphorus (TP) and chemical oxygen demand (COD_{Mn}) according to the American Public Health Association (APHA, 1998). Furthermore, the daily discharge at the dam was obtained from Beijing Guanting Reservoir Management Bureau. A small meteorological sensor (JLC-QTF, China) was installed on shore (*Fig. 1*) and meteorological factors including air temperature, solar radiation, wind speed, wind direction and precipitation were recorded at 5-min intervals.

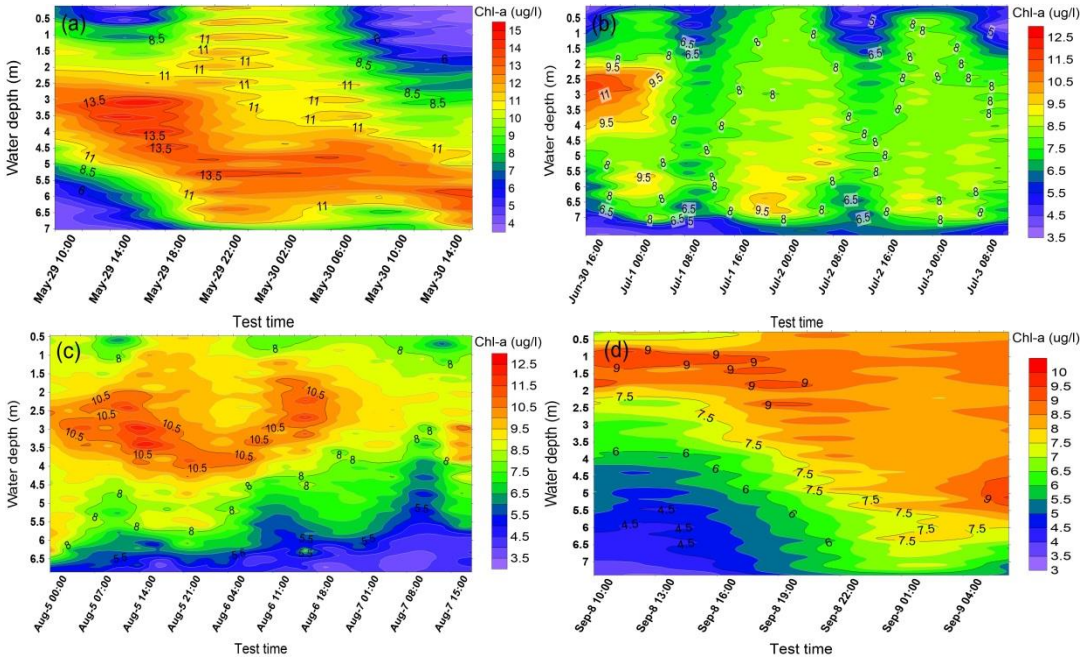

Figure 3. *Interpolated contour maps of vertical Chl-a distributions for each test time*

Data analysis

To detect short-term variations in Chl-a concentration and water temperature during each test time, isocline interpolation maps were prepared using the Surfer 8.0 package of Windows (Lopes et al., 2005). Additionally, SPSS 19.0 for Windows was used to conduct Pearson's correlations between Chl-a concentration and environmental variables (Wu et al., 2014), while principal component analysis (PCA) was performed using the CANOCO 4.5 software (Bresciani et al., 2013). It should be noted that PCA could not be applied to the water quality data because there were too few samples; therefore, the average daily Chl-a was set as an environment variable, and average daily values for each variable were used to test its relationship with water temperature, turbidity, discharge and meteorological data.

Results

Meteorological data during each test time is shown in *Figure 6*. The range of air temperature and wind speed (*Table 1*) of this study year is generally consistent with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57655780

meteorological factors reported in previous study (Xie and Xu, 2014). Generally, lower levels of solar radiation were recorded in May and July and the wind speed was mostly below 0.5 m/s at night (*Fig. 6a* and *b*). Because of the effects of cloudiness, solar radiation was largely half sinusoidal (*Fig. 6c* and *f*). However, the wind speed was clearly greater in May and July than August and September (*Fig. 6d* and *e*). Moreover, relatively high wind speeds (>5 m/s) were observed on 30/May and 1/July. Specifically, there was no obviously predominant wind direction in August and September, while the predominant wind direction and frequency were northwest and north (27% and 30%) on 30/May and 1/July, respectively (*Table 1*). The study period was rain free except for an event on 1/Jul from 18:00 h to 23:00 h and on 9/September from 8:00 to 22:00, during which time the daily precipitation was 16.5 mm and 5.4 mm, respectively.

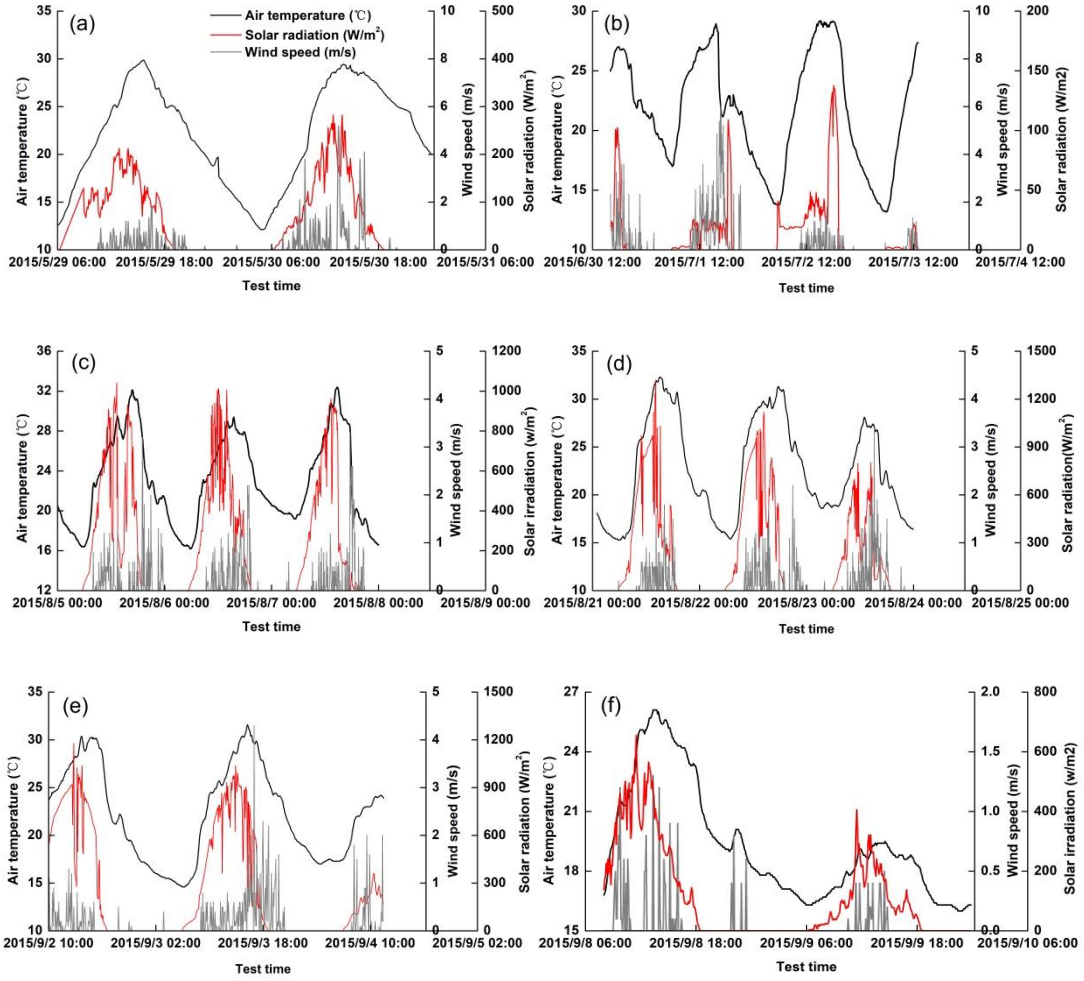

Figure 6. *Meteorological data sequences for each test time including four times for vertical sampling (a, b, c and f) and two times (d and e) for surface water sampling*

During investigation of vertical Chl-a, air temperature and average water temperature varied by only 0.6 °C in May, while they varied by up to 3.7 °C in August (*Table 1*). On the contrary, the difference in water temperature between the epilimnion and hypolimnion was much higher in May than August and September (*Fig. 4a*). These findings indicate that the reservoir was in the primary stages of thermal stratification in May and well stratified in August. However, because of the rain and higher discharge at the dam (*Table 1*), the stratifications broke down from 1/July (*Fig. 4b*). The reservoir outlet discharge at both test times (*Table 1*) is within the range of reservoir withdrawals (0.26-20.7 m^3/s) during 2008. Besides, stratifications were temporary in the daytime, while the water column underwent mixing at night time (*Fig. 4c* and *d*). The depth of the mixing zone during night was smaller in August than in other surveys, indicating great water column stability in August. Taken together, these findings indicate that solar radiation increased water temperature, which drove thermal stratification and shoals the mixed layer.

Based on the criteria defined by Nürnberg (1996), Guanting Reservoir is a mesotrophic system. As shown in *Figure 7,* relatively low TP concentrations (<0.1

DOI: http://dx.doi.org/10.15666/aeer/1703_57655780

mg/l) were observed throughout the study period, and there were no significant differences in the TP and TN concentrations among water samples. All TN: TP ratios were greater than 16, which is regarded as the optimum ratio for phytoplankton growth (OECD, 2006).

*Brackets are corresponding to the range of measurements and displayed values are averages

In general, temporal variations in Chl-a concentrations varied slightly from May to September (*Table 1*); however, a general decrease in monthly Chl-a concentration was observed (*Fig. 8a*). Furthermore, the variations in Chl-a concentrations corresponded to differences in water temperature between the epilimnion and hypolimnion (*Fig. 8b*). Our results indicate that thermal stratification and mixing may limit phytoplankton growth vertically. Furthermore, a lower coefficient of variation (CV) of Chl-a vertical distribution was shown in August and September, when the reservoir was well stratified (*Table 1*).

In the four Chl-a vertical distribution investigations, the vertical profile of Chl-a concentration varied significantly between daytime and nighttime (*Fig. 3*). In May, the vertical profile of the Chl-a concentration primarily peaked around 3 m during daytime, with a maximum Chl-a concentration layer for thickness of 1.5 m (*Fig. 3a*). The maximum Chl-a concentration in the water column was about 1.5 times that in the surface water, whereas the depth of this layer changed with time and decreased to 7 m at night (*Fig. 3a*). At the same time, the surface Chl-a concentration increased at night. The surface Chl-a distribution recovered until sunset on the second day. However, this was not the case for the July survey. Specifically, the water column mixed from 1/Jul, at which time the Chl-a concentration was homogenous during the day and night (*Fig. 3b*). The reservoir was well stratified in August, when there was a shallow-surface mixing layer at the top of the water column (*Fig. 3c*) and there was a similar vertical profile of Chl-a concentration in the daytime as in May. However, the maximum Chl-a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57655780

concentration layer decreased slightly to 4 m at night (*Fig. 3c*). Therefore, the vertical profile of Chl-a was more stable through August. The Chl-a concentration showed a maximum concentration at around 1.5 m in the daytime on 8/September. Because of water mixing at night, the maximum Chl-a concentration layer decreased and its thickness increased to 5.5 m (*Fig. 3d*). The linear regression between the maximum Chl-a concentration and the thermocline for all test times is significant ($R^2 = 0.871$, $P < 0.001$). Specifically, although the position of the maximum Chl-a concentration layer varied temporally over the entire water column, it generally followed the same dynamics as the thermocline (*Figs. 3* and *4*).

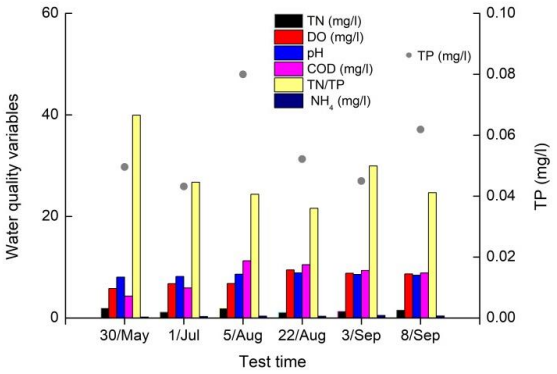

Figure 7. *Water quality variables collected from a depth of 2 m at noon at S1 on each sampling day*

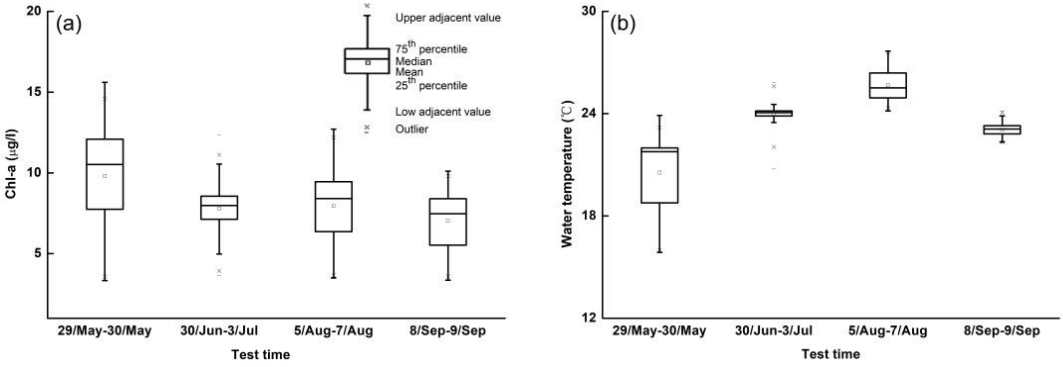

Figure 8. *Box plots of vertical Chl-a concentration (a) and water temperature (b) at S1 for each test time*

With the exception of July, the surface Chl-a concentration was inversely proportional to water temperature (*Fig. 9b*). Surface water temperature decreased during the rainfall events on 9/Sep and 1/July (*Fig. 9b* and *f*). With the exception of the rainy days, surface Chl-a showed a clearly diurnal variation in which concentration increased at night and decreased during the day (*Fig. 9a* and *c*). It is clear that the surface water temperature was correlated with Chl-a after an approximately 5-hour time lag, particularly in the August and September surveys (*Fig. 9d* and *e*). These findings suggest that phytoplankton took several hours to respond to the water temperature in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57655780

surface water column. Pearson's correlation analysis was calculated directly from the raw surface Chl-a data and environmental variables (*Table 2*), which indicated that Chl-a was significantly negatively correlated with meteorological variables and water temperature for each test time and all data (all P values <0.01), except for wind speed and Chl-a on 8/Sep and 9/Sep (P > 0.05). However, when the 5-hour time lag was considered, the Chl-a values generally became significantly positively correlated with meteorological variables and water temperature (all P values <0.01), except for results of May and 8/Sep (*Table 2*).

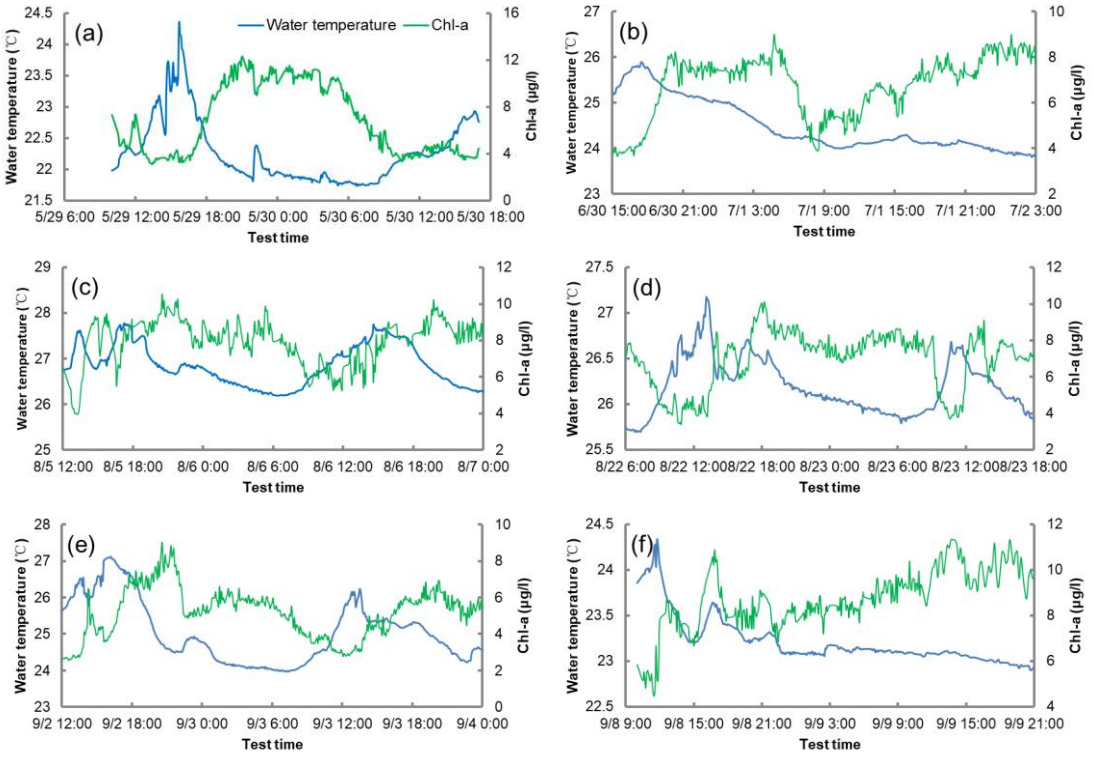

Figure 9. *Variations in surface Chl-a concentration and surface water temperature during each test time*

To identify the relationship between surface Chl-a and other environment variables, PCA was applied to daily Chl-a and water temperature, turbidity, discharge and meteorological data. *Figure 10* shows the biplot ordination of samples and environment variables. The biplot ordination explains 78.3% of this variation and exhibits well-defined spatial patterns. The first ordination (42.5%) was determined by most of the variables, particularly water temperature. Moreover, solar radiation and air temperature were on the positive side of the chart, while discharge and turbidity were on the negative side. The second ordination (35.8%) was positively related to wind speed, whereas it was inversely correlated with Chl-a. The relationship on the Y-axis likely illustrates the negative effects of wind speed, solar radiation and air temperature on daily average Chl-a concentration. Additionally, discharge and turbidity contributed slightly to Chl-a concentration. Hence, the results of PCA are generally in accordance with the correlation results of raw data describing surface Chl-a and meteorological variables.

Discussion

The Chl-a concentrations observed from May to September showed a slight degree of variability from 2.6 to 15.6 μg/l (*Table 1*), which was within the range of Chl-a values (about 2.5–20 μg/l) reported in an earlier study conducted in Guanting Reservoir from June to December (He et al., 2011). It is well known that the lower CV values of vertical distributions are calculated when relatively higher wind speeds occur (Wu and Kong, 2009). However, our results showed a lower CV of the Chl-a value appeared in August, when the reservoir was well stratified and there was great water column

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57655780

stability. Several previous studies have reported that reservoir trophic state is controlled by metrological factors and stratification pattern (Wu et al., 2014; Bresciani et al., 2013; León et al., 2016). Generally, a decrease in monthly Chl-a concentration was shown for the four vertical Chl-a measurements in summer. Smaller variations in Chl-a concentration were in accordance with the smaller difference in water temperature between the epilimnion and hypolimnion. When lower water temperature difference existed in the water column, the phytoplankton tended to be homogenous, and therefore leaded to less variation of Chl-a concentration (Lopes et al., 2005; Serra et al., 2007).

It is well known that phytoplankton in lakes and reservoirs are recognized as limited by TP if the TN: TP ratio is relatively large, while they are limited by TN if the ratio is relatively small (Wang et al., 2008). These findings suggest that phytoplankton at both test times in Guanting Reservoir were probably limited by TP. Because of the limited water quality samples, the relationship between water quality parameters was not examined. The TP concentrations varied slightly at both test times (*Fig. 7*). It is likely the main reason to induce less difference of mean Chl-a concentration for each test time. In general, Chl-a concentration was significantly correlated with TP concentration (Zhou et al., 2016). Hence, the smaller Chl-a concentration observed in September was likely because of the lower TP (*Fig. 7*). According to Deng et al. (2012), a temperature range of 21–29 °C is suitable for phytoplankton growth. The TP concentration peak in August was likely the result of stronger activity of P-decomposing bacteria at higher temperature (Cui et al., 2005). However, the Chl-a in August was lower than that in May (*Fig. 8a*). Wu et al. (2014) reported that the effects of nutrients on Chl-a were not obvious. Therefore, seasonal variations in Chl-a during summer were not caused by the TP concentration and water temperature. In fact, highest light were observed in August (*Fig. 6c*), similar results were reported by Edwards et al. (2016), who confirmed that very strong light could restrain phytoplankton growth. Light might be a limiting factor when the euphotic zone is much smaller than the mixing zone (Kalff, 2002; Becker et al., 2010). The lowest solar radiation was recorded in July, indicating that it controlled phytoplankton growth (*Fig. 6b*). In addition, flow condition was inversely proportional to algal level in the short term (Kim et al., 2014), and the high discharge of the dam suggests that Chl-a may have been diluted during rainy days (*Table 1*).

Our investigations provide a broader understanding of short-term Chl-a vertical distribution within consecutive days. In both surveys, the lowest Chl-a appeared at the bottom of the water column, which is consistent with the findings of a previous study (Wu and Kong, 2009). Water temperature was the environmental variable that best explained vertical distributions of the phytoplankton community (Lopes et al., 2005). Variations in the position of the maximum Chl-a concentration layer between days generally followed the same dynamics as thermoclines, which is in accordance with the results reported by Serra et al. (2007). The Chl-a vertical distribution showed different behavior at each test time. Because of continuous mixing during the day and night in early July, Chl-a was likely directly influenced by rain and higher discharge. When the reservoir was primarily stratified in May (*Fig. 4a*), the developing thermocline was shallow and the epilimnion was easily mixed by winds and night-time convection, which tended to homogenize the vertical distribution of phytoplankton (Cyr, 2017). In contrast, stratification may decouple vertical circulation and mixing at night (Marcé et al., 2006). Guanting Reservoir was well stratified in August; therefore, the maximum Chl-a concentration layer was relatively stable at around 3 m during both the day and night. In September, the maximum concentration was located at the epilimnion during

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57655780

the day, similar to the vertical distribution of phytoplankton suggested by Serra et al. (2007), who investigated phytoplankton that accumulated close to the surface during calm periods in September.

In the present study, stratifications were temporary and the maximum Chl-a concentration layer varied with downwelling at night. Wind speed (Cao et al., 2006), wind direction (Serra et al., 2007) and wind time (Cyr, 2017) play important roles in regulation of daily phytoplankton vertical downwelling (Cardoso and Motta-Marques, 2009) and horizontal movement (He et al., 2011). Minor stratifications can be easily broken down by wind (Li et al., 2007), and relatively strong winds of above 5 m/s directly induce vertical mixing and disturbance in the water column (Antenucci and Imerito, 2000). A few periods in which there were strong winds were recorded in our results. In particular, the test site is located near the south boundary of the entire reservoir, while on windy days (30/May and 1/July) the predominant wind direction was from the northwest and north, respectively. These results are similar to those reported by Cyr (2017), who suggested that when the wind was small but continuous, wind stress pushes the surface water downwind, creating downward flow at the downwind end of the basin.

Additionally, the surface Chl-a concentration exhibited diurnal periodic variation. It is well known that night-time vertical circulation and mixing as well as sinking of phytoplankton was induced by wind (Wu and Kong, 2009; Bresciani et al., 2013), consequently, this would homogenize the phytoplankton and enhance surface Chl-a concentrations at night. When considering seasonal and interannual data during long-term surveys, the relationship between Chl-a and light (Phlips et al., 1995), ln (Chl-a) and average air temperature (Zhou et al., 2016) was positively correlated. Moreover, interannual decreasing wind speed led to longer cyanobacterial bloom durations (Zhang et al., 2012). However, in the present short-term investigation, the results of PCA suggested that the daily average Chl-a was negatively correlated with daily average meteorological factors and water temperature. Our results agree with those of previous studies that showed Chl-a was negatively correlated with water temperature and light (Felip and Catalan, 2000) and wind speed (Serra et al., 2007). Our results demonstrate raw surface Chl-a values generally change as a negative function of meteorological factors and water temperature. However, when surface Chl-a was considered based on a 5-hour lag time, the relationship generally became significantly positive. Pérez-Ruzafa et al. (2005) found a 1-week time lag between Chl-a and nutrients and Bresciani et al. (2013) demonstrated that the time lags between Chl-a and solar radiation, water temperature and wind speed were 3 hours, 8–9 hours and 5 days, respectively. Therefore, time lag is a known phenomenon in short-term investigations, and the five-hour time lag in our study suggests a very rapid response of Chl-a to meteorological factors and water temperature in Guanting Reservoir.

Conclusions

This study describes the monthly and diurnal variation in vertical and surface distribution of Chl-a, as well as elucidates the quantitative relationships between Chl-a, water temperature, nutrients, meteorological factors and other physical variables in Guanting Reservoir during summer. In general, monthly Chl-a concentration exhibited a decreasing trend. Moreover, thermal stratification and mixing were found to be of great importance in controlling variation in the maximum Chl-a concentration layer in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57655780

water column and variations in the position of the maximum Chl-a concentration layer between days generally followed the same dynamics as the thermocline. Furthermore, stratifications were temporary, with the maximum Chl-a concentration layer varying with downwelling and becoming homogenized at night because of wind driven mixing. The surface Chl-a concentration was also found to increase at night and decrease during the day, except on rainy days. The results of PCA and Pearson's correlation analysis indicated that the surface Chl-a concentration was significantly negatively correlated with air temperature, solar radiation, wind speed and water temperature. However, when a 5-hour time lag was considered, the relationships among surface Chl-a concentration, meteorological factors and water temperature became significantly positive.

Spatial and temporal variations in phytoplankton are always dynamic and highly variable, and more work is needed to assess the combined effects of environment variables on Chl-a concentration. Based on the species, size and buoyancy characteristics, further research will be devoted to hydrodynamics variables that drive phytoplankton communities spatially and temporally on a large scale.

Abstract. Inflow rivers have crucial impact on lake eutrophication. Ammonia nitrogen (NH_4^+–N) in inflow rivers have tightly coupled relationships with water quality in Lake Taihu, China. Based on the monthly concentrations from 2009 to 2015, this study focused on the spatiotemporal dynamics of NH_4^+–N in northwest Taihu Lake and utilised random forest (RF) model to simulate its response to inflow rivers. Results indicated that (1) in northwest Lake Taihu, the spatiotemporal distribution patterns of NH_4^+–N concentrations are distinct, and river inputs were the major source of NH_4^+–N loadings. (2) Scenario simulation results in RF models indicated that the inflow loads should be controlled under 6427.38, 3248.01, 2206.92 and 1107.58 ta^{-1} for the protective targets. (3) In 2015, NH_4^+–N concentrations in four lake regions and NH_4^+–N loads from inflow rivers were consistent with the simulation results in RF models. The NH_4^+–N concentrations decreased approximately 6%, 34%, 44.44% and 6.67% in North Zone and Zhushan, Meiliang and Gonghu Bays, respectively, despite reduction in external NH_4^+–N loads by 8.99%, 11.41%, 51.38% and 62.87%. This study provides further understand on quantifying the reduction of nutrient loading from inflow rivers and governing Lake Taihu or other typical eutrophic lakes.
Keywords: eutrophication, inflow river, load reduction, NH_4^+–N, Taihu Lake, water quality

Introduction

With urbanisation development and population expansion, a large number of ecologically important freshwater bodies have experienced harmful water quality degradation and algal blooms, which have been a national concern in the recent decades (Schindler and Hecky, 2009; Qin et al., 2015; Wu et al., 2016). Previous research suggests that lake eutrophication is driven by physical, chemical and biological parameters and land use influences, including sediment dredging, aquatic organisms and hydrodynamic conditions (Wang et al., 2011; Bian et al., 2016). A great amount of nutrients and other contaminants enter lakes from river inputs, which are the main pollution route among all the influencing factors and considerably affecting the aquatic environment and ecosystem heath of lakes (Rao and Schwab, 2007; Chen et al., 2011; Juma et al., 2014). Studies have found that the pollutant input from inflow rivers has a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57815796

meaningful effect on the nutrient concentration with certain relationships (Zhang et al., 2016).

As one of the five largest fresh lake and a long-term eutrophic water body in China, many efforts have been undertaken by researchers and government entities to restore the Lake Taihu since 1990, including sediment dredging, wetland construction, water transfer projects, the use of macrophytes and so on (Hu et al., 2010; Li et al., 2011a, 2013). Researchers have shown that increasing the amount of pollutant discharge into the lakes is crucial, and efforts to control the nutrient input from the catchment of Lake Taihu are essential (Chen et al., 2003; Qin et al., 2007; Wang et al., 2011). In addition to light, temperature and salinity, nitrogen (N) and phosphorus (P) are the most common factors of limiting algal growth and relevant control has been widely implemented to address eutrophication in many freshwater system (Nixon, 1995; Schindler and Vallentyne, 2008; Conley et al., 2009; Suttle and Harrison, 2010; Xu et al., 2010, 2015). With the tendency of being co-limited by N and P in Lake Taihu, evidence suggests that the lake has been in a nutrient-imbalance condition owing to focusing more on P reduction rather than together these two elements (Paerl, 2009; Lewis et al., 2011; Tang et al., 2016). In general, the pollution level of nitrogen and phosphorus is indicated by total nitrogen (TN) and total phosphorous (TP), and some studies have estimated the TN reduction in Lake Taihu and its inflow rivers (Du et al., 2017). Meanwhile, ammonia nitrogen (NH_4^+–N) is one of the three main forms of TN in natural water, and studies have indicated that NH_4^+–N has tightly coupled relationships with TN and water quality in Lake Taihu Basin (Liang et al., 2008; Ferard and Blaise, 2013). Therefore, this study focuses on the spatiotemporal dynamics of NH_4^+–N and its response to inflow river. In the interactional study of eutrophication, hydrodynamics and ecosystem in various freshwater bodies, lots of mathematical modelling approaches have been extensively applied to simulate the flow, water quality, spatiotemporal pattern of hydrodynamics and so on (Rasmussen et al., 2009; Min and Wise, 2010; Zhang et al., 2017). For instance, Mike21, a two-dimensional mathematic model, has been usually used to calculated aquatic environment capacity and total emission reduction according to aquatic environmental functions and targets (DHI, 2007; Zhu et al., 2013; Zhang, 2017). Several empirical models, such as the Wisconsin Department of Natural Resources' (WDNR) Wisconsin Lakes Modelling Suite, Seepage Lake Model and BATHTUB, have been previously developed and tested for predicting eutrophication-related water quality conditions in complex lakes and reservoirs (USEPA, 2000, 2010; WDNR, 2004; MPCA, 2006). However, these methods usually have certain data requirements or index restrictions (Wang et al., 2005). Random forest (RF) is a new machine learning algorithm and is combined with a predictor of multiple decision trees. It was proposed as a new soft computing method (Breiman et al., 1984). The RF has been developed to optimise predictive performance because of its several advantages, including a limited number of user defined parameters and the capability to model nonlinear relationships; reduce overfitting; remain robust despite of missing data and outliers; manage qualitative and quantitative variables; and evaluate, summarise and interpret final models (Breiman, 2001; Friedman, 2001; Friedman and Meulman, 2010). Over the past years, RF has been successfully applied to simulate soil organic carbon stocks, suspended sediment concentration, NO_2 concentration and nutrient concentrations (such as chemical oxygen demand); during these simulations, RFs have high tendency (Francke et al., 2008; Were et al., 2015; Rodriguez-Galiano et al., 2015; Ye et al., 2018; Muthukrishnan et al., 2018; Marttila et al., 2018; Kaminska, 2019).

DOI: http://dx.doi.org/10.15666/aeer/1703_57815796

The present work took the northwest Lake Taihu as an example for the analysis. Generally, this study aims to (1) analyse the temporal and spatial variations in NH_4^+–N in the lake and its inflow rivers; (2) develop RF model to simulate the correspondence between the NH_4^+–N concentrations in the lake and its inflow rivers; and (3) address the water quality in the northwest Lake Taihu response to the river inflow.

Materials and Methods

Study area

As the third largest freshwater lake in China, Lake Taihu is situated in Southeast Jiangsu Province and the lower reach of the Yangtze River Basin with a surface area of 2338 km^2 and drainage area of 36500 km^2 (Lake Taihu Basin Authority, 2012). Lake Taihu is the main drinking water source for its neighbouring residents despite being heavily polluted and inferior to Grade V in GB3838-2002 (Bai et al., 2009). With the deterioration of environment and water quality, it has caused serious pollution in the lake ecosystems and algal blooms have long been frequency and concerning phenomenon, especially northwest part of the lake, and rivers flowing into Lake Taihu are the crucial factor (Qin et al., 2008; Tao et al., 2018). Excessive nutrients from inflow rivers are the major source of pollutant loadings to the lake and subsequently lead to spatial heterogeneity (Li et al., 2013; Liu et al., 2017). Lake Taihu has a tanglesome river and channel network, and more than 200 rivers at different scales are connected to it (Zhang et al., 2014). As shown in *Fig. 1*, the inflow rivers are primarily located in the northwest regions, covering North Zone, Zhushan Bay, Meiliang Bay and Gonghu Bay, and the outflows in the eastern and southern part of the lake (Du et al., 2017; Li et al., 2019). Inflow rivers in northwest Lake Taihu contribute the most water discharge and nearly 80% of COD, N and P to the lake (Zhang and Chen, 2011). Eutrophication studies in Lake Taihu have often focused on P because it is the most universal limiting nutrient and is thus typically targeted for loading reduction (Morton et al., 2003; Niu et al., 2004; Schindler, 2006; Lewis and Wurtsbaugh, 2008). Nevertheless, it is fundamentally important and cannot be ignored to control N inputs. Therefore, the present work focuses on the NH_4^+–N concentrations in northwest Lake Taihu and its inflow rivers based on the monthly monitoring data covering the period of 2009–2015.

Data analysis

Monthly NH_4^+–N concentrations of inflow rivers and of northwest Lake Taihu during the period of 2009–2015 were provided by Jiangsu Province Hydrology and Water Resources Investigation Bureau. The locations of the monitoring sites distributed across northwest Lake Taihu and its inflow rivers are shown in *Fig. 1*. These monitoring stations were located by GPS, and water samples were collected monthly from 2009 to 2015, from approximately 1 m below the water. The samples were then delivered to a laboratory by cryopreservation, and their correlation processing, such as the sampling, preservation, transportation and analysis, were performed within 24 h. All the samples were measured three times, and results were expressed in average. All chemical analyses followed the standards established by the State Environmental Protection Bureau of China.

For the convenience of describing the influences of the inflow rivers, Lake Taihu was divided into seven sub-areas (*Fig. 1*), namely, North Zone, Zhushan Bay, Meiliang Bay,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57815796

Gonghu Bay, Southwest Zone, Central Zone, East Epigeal Zone and Dongtaihu Bay (Hu et al., 2008; Li et al., 2011b). This study focuses on the NH_4^+-N concentration in northwest Lake Taihu and thus included only the sub-lakes of North Zone, Zhushan Bay, Meiliang Bay, Gonghu Bay and their inflow rivers. In view of data availability and the links between the sub-lakes and their inflow rivers, corresponding sites were selected, as shown in *Fig. 2*.

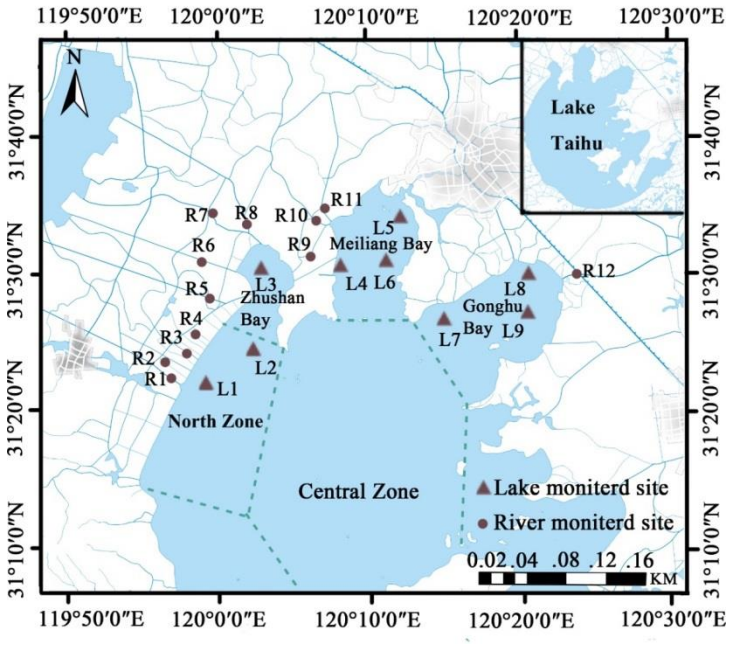

Figure 1. *Study area and its monitoring sites*

Model description

A RF model is made up of a number of simple (binary) decision trees, which were predetermined by a subset of predictors with the random selection strategy and grown on a bootstrap sample of the training set (Breiman, 2001). An RF makes no any additional assumptions about either the dependent or independent variables and could describe nonlinear and linear relationships (Cutler et al., 2007). The final model predictions are the average of the forest predictions and this method has been successfully used in analysis of many fileds (Maraqa et al., 2007; Paliwal and Patra, 2011). Despite the optimise predictive performance and wide potential, the complex relationship between pollutant concentrations and ambient conditions couldn't be provided and satisfactory descripted in this model (Khan et al., 2017; Kaminska, 2019).

Three important parameters, the number of trees to grow in the forests (ntree), the number of randomly selected predictor variables at each node (mtry) and the minimal number of observations at the terminal nodes of the trees (nodesize), must be specified in the RF model. Ntree is the most important one since its determination of the strength of each individual tree and correlation among trees (Peters et al., 2008). The random in an RF is performed by randomizing the observed subsets and mtry candidate variables both, which influence the tree and the split creation in the tree respectively. Mulitdimensional step function is produced by each individual tree, which results in that the average of the individual tree is a multidimensional step function, namely the whole

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57815796

prediction of the forest. The multidimensional step function can predict smooth function as it has large number of sample values (Gromping and Ulrike, 2009).

In order to determine the fitting quality of each model, several possible error functions were computed and considered in the present work. As one of the basic measures to estimate a model's goodness of fit, the coefficient of determination R^2 is fundamental and the value ranges between <0, 1>. The closer it is to 1, the smaller are the differences between the empirical values and the estimated values.

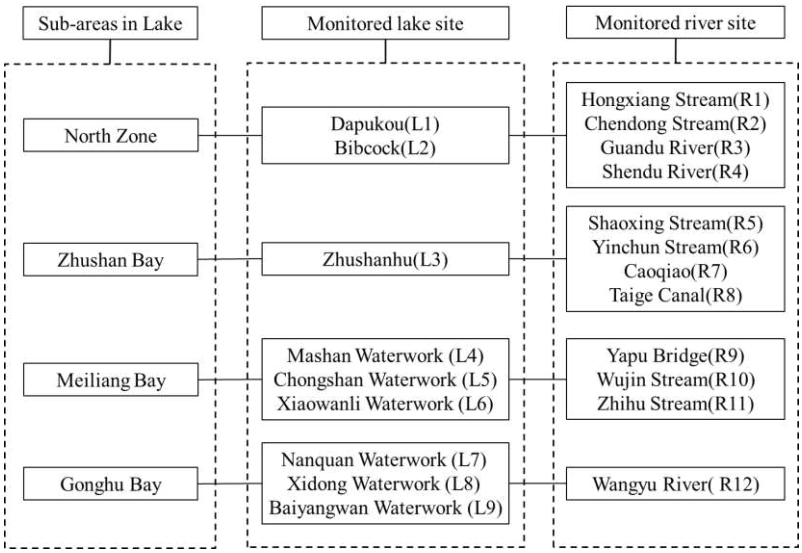

Figure 2. *Sampling stations in Lake Taihu and its inflow rivers*

Model scenarios

Developing effective and feasible nutrient reduction targets is necessary to improve trophic status and reduce bloom potentials. According to the Environmental Quality Standards for Surface Water in China (GB3838-2002) (*Table 1*), two nutrient reduction modeling scenarios were con-ducted to assess water quality response to nutrient load reductions in this study (*Table 2*).

Table 1. *The standard of NH_4^+–N in the Environmental Quality Standards for Surface Water in China (GB3838-2002) (mg/L)*

	Class I	**Class II**	**Class III**	**Class IV**	**Class V**
NH_4^+–N (≤)	0.15	0.5	1.0	1.5	2.0

Table 2. *Nutrient reduction scenarios and Water quality targets*

	North Zone	**Zhushan Bay**	**Meiliang Bay**	**Gonghu Bay**
Scenario 1	Class III	Class III	Class II	Class II
Scenario 2	Class II	Class II	Class I	Class I

There is a possibility that water circumstances could be altered by climate change in the future which is not easy to control. Although the answers are clearer now that nutrients, light, temperature and hydrodynamic force have all have been shown to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57815796

influence formation of cyanobacterial blooms, the mechanism of a specific cyanobacterial bloom remains unknown (Qin et al., 2013). For example, temperature, precipitation and the distribution the runoff water have significant effect on the ammonium concentration and they are so complex and hard to predictable (Qin et al., 2010; Paerl et al., 2014). However, anthropogenic nutrient reduction to control water quality in lake is a direct and potentially achievable step that can be taken (Paerl et al., 2011; Xu et al., 2015). The two scenarios were made according to the water quality targets for the northwest Taihu Lake in the Master Plan of Integrated Regulation of Water Environment and the Water Function Zoning of the Lake Taihu Basin.

Results and Discussion

Spatiotemporal distribution of NH_4^+–N in northwest Lake Taihu

The northwest Lake Taihu area is the most contaminated and has yet to be studied in detail. Thus, it was selected for the analysis of the spatial and temporal changes that occurred in 2009–2015. The spatiotemporal distribution of NH_4^+–N in North Zone, Zhushan Bay, Meiliang Bay and Gonghu Bay are detailed as follows.

In the northwest Lake Taihu, the spatiotemporal distribution patterns of nutrient concentrations are distinct. In general, ammonia concentration tends to decrease gradually from 2009 to 2015 (*Fig. 3*).

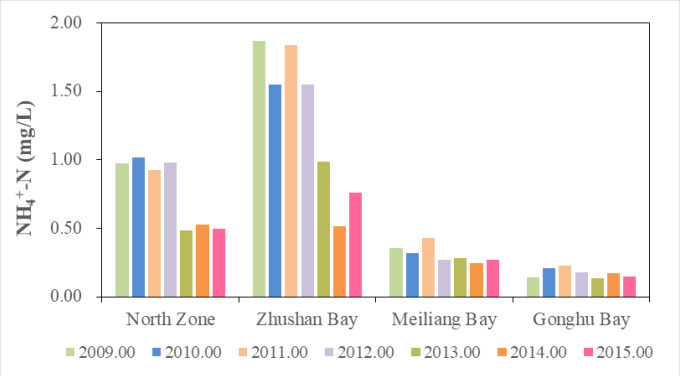

Figure 3. *Yearly mean values of NH_4^+–N concentration in northwest Lake Taihu*

The North Zone and Zhushan Bay were the two heavily polluted areas, whereas Gonghu Bay was in the best and cleanest condition. The range of NH_4^+–N concentration in the North Zone and Zhushan Bay was 0.5–2.5 mg/L, whereas those in Meiliang Bay and Gonghu Bay were approximately 0.5 mg/L (*Fig. 4*). The Environmental Quality Standards for Surface Water in China (GB3838-2002) has indicated that the NH_4^+–N concentration in the North Zone and Zhushan Bay is classified as Class III–V, and that in the other two lake regions is classified as Class I or II; this classification indicates that the further consideration of the limiting nutrient in the North Zone and Zhushan Bay is important prior to other lake regions. The NH_4^+–N content in the four seasons (that is, Winter: December, January and February; Spring: March, April and May; Summer: June, July and August; and Autumn: September, October and November) in northwest Lake Taihu were calculated (*Table 3*). The standard deviations of monthly mean values of NH_4^+–N concentration in northwest Lake Taihu in *Fig. 4* are 0.52, 0.8,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57815796

0.1 and 0.09, separately. The results showed that season had a considerable effect on the NH_4^+–N concentration of northwest Lake Taihu, which was remarkably higher in winter and spring than those in other seasons. In the studied area, the NH_4^+–N concentration was the highest in winter. Therewith, the concentration started gradually decreasing in spring. Finally, it dropped to the minimum value in the summer or autumn. The seasonal tendency in the four regions was similar and especially evident in the North Zone and Zhushan Bay. The variations of concentrations in different seasons were in accordance with the change trend of air temperature. The solubility of ammonia nitrogen in water decreases with temperature increasing. What's more, these winter maxima possibly arise from (1) around lake, surface and subsurface catchment inputs are high in the non-growing season; (2) nutrients are concentrated in lower water levels; and (3) microbial activity is low due to low temperatures (Wang et al., 2017). It also may due to the relationships between ammonium loadings and rainfall, that's precipitation had a summer maximum and a fall minimum and followed an inverse seasonal cycle compared to NH_4^+–N concentrations (Nõges et al., 2007).

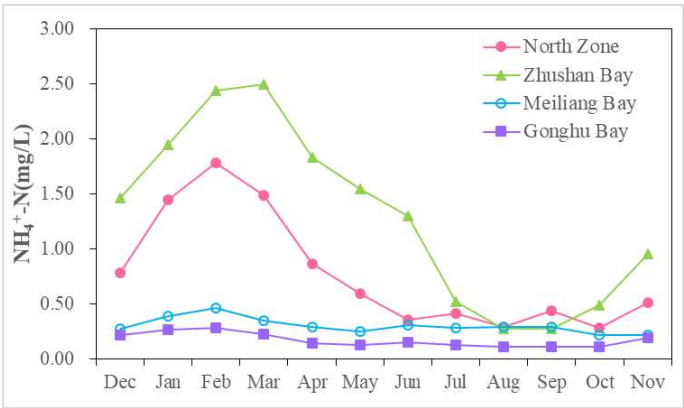

Figure 4. *Monthly mean values of NH_4^+–N concentration in northwest Lake Taihu*

Table 3. *Monthly mean values of NH_4^+–N concentration in northwest Lake Taihu (mg/L)*

	North Zone	Zhushan Bay	Meiliang Bay	Gonghu Bay
Winter	1.34	1.96	0.38	0.26
Spring	0.98	1.95	0.30	0.17

Autumn	0.41	0.57	0.24	0.14

NH_4^+–N input from inflow rivers in northwest Lake Taihu

The annual NH_4^+–N loads to the northwest Lake Taihu from its tributaries mean a large amount of nutrients and pollutant. Besides Gonghu Bay, NH_4^+–N concentrations of inflow rivers in the regions were classified as Class IV–V or worse. By contrast, the water quality of inflow rivers in Gonghu Bay was relatively good. The NH_4^+–N concentrations in the main inflow rivers in northwest Lake Taihu directly affected the northwest lake regions from 2009 to 2015, as shown in *Fig. 5*. The R^2 values of these scatter diagrams are all approximately 0.70 (that is, 0.763, 0.775, 0.641 and 0.758), and $p<0.01$ (*Fig. 5*). In conclusion, river inputs are the major source of NH_4^+–N loadings to the northwest Lake Taihu, and water quality in the lake is closely related to that in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57815796

inflow rivers. Declining water quality in inflow rivers have a considerable influence on lake restoration, and NH_4^+–N concentrations evidently decrease with the reduction of inflow load.

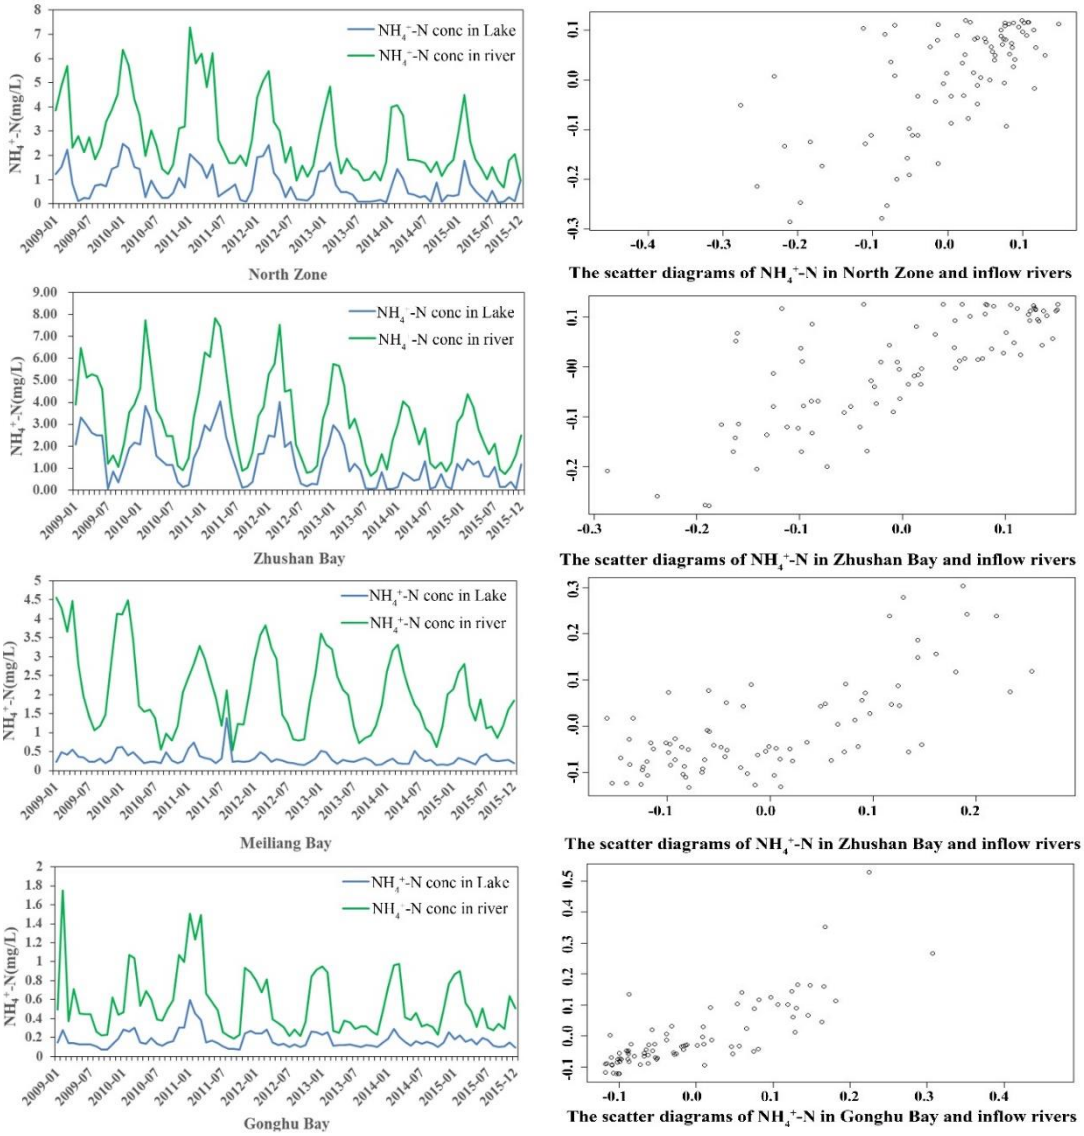

Figure 5. *Monthly mean values of NH_4^+–N concentration in northwest Lake Taihu and its inflow rivers from 2009 to 2015 and the scatter diagrams in corresponding regions*

System response to nutrient reduction

Simulated results in RF model

By using the acquired monitoring data, the RF model set up the forecast model between the water quality of monitoring sites in the lake (NH_4^+–N concentrations) and its inflow rivers (NH_4^+–N loads). Given the relatively small dataset, every one of the seventh data were extracted as the testing stage, whereas the others are randomly assigned as the training stage after sorting the monthly monitoring data during 2009-2014, thereby ensuring that the RF model was fully calibrated. Then the data of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57815796

2015 in the inflow rivers were the independent validation set and used to test the model. The simulation results showed that the values of R^2 in the training stage of NH_4^+-N were 0.87, 0.95, 0.73 and 0.97 in the RF model for the four pairs of lake and river stations. Meanwhile, the values of R^2 in the testing stage of NH_4^+–N were 0.53, 0.52, 0.57 and 0.58 in the RF model. Moreover, the data of 2015 in the inflow rivers were used to the established model to stimulate the water quality in the lake. As shown in *Fig. 6*, the relationships between the measured NH_4^+–N concentration and those predicted by the RF are proved to have good curve fitting characteristics. Consequently, the established RF model had a relatively high precision, and the forecast model could be used in the next step of stimulating the scene of water quality in the northwest Taihu Lake.

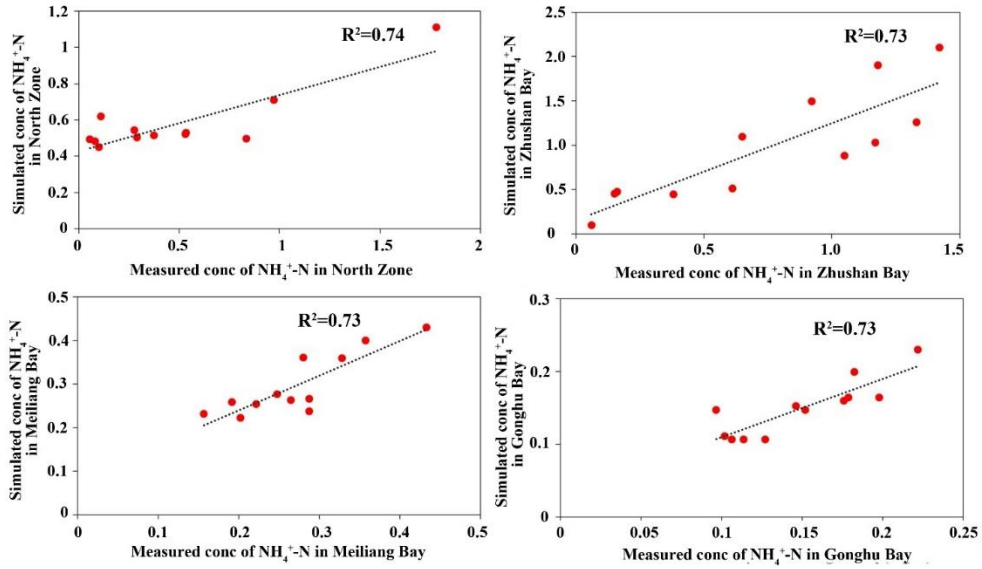

Figure 6. *Measured and simulated NH_4^+–N concentration in 2015 in the RF model (mg/L)*

The Master Plan of Integrated Regulation of Water Environment of Taihu Basin, which was ratified by the State Council in 2008 and revised in 2013, had proposed the control targets of water quality indices in the lake (TN–Class V) for agricultural irrigation purpose. In addition, the Chinese State Council ratified the Master Plan of Integrated Regulation of Water Environment and the Water Function Zoning of the Lake Taihu Basin, thereby initiating the comprehensive treatment of the water environment in the basin. On the basis of the master plan, the NH_4^+–N protective goals of the North Zone and Zhushan Bay belong to Class Ⅲ, and those of Meiliang Bay and Gonghu Bay belong to Class Ⅱ. As mentioned in Section 3.1, research has shown that NH_4^+–N concentrations in the North Zone and Zhushan Bay were classified as Class III–V, whereas those in other two lake regions were classified as Class I or II. The setting of the NH_4^+–N concentration in the lake as the target value should continuously debug the NH_4^+–N concentration in the inflow rivers and allow the target value to be predicted in the debugged RF models (*Table 4*). Consequently, for the protective targets in the Master Plan of Integrated Regulation of Water Environment and the Water Function Zoning of the Lake Taihu Basin [Scenario 1: North Zone and Zhushan Bay (Class Ⅲ), Meiliang Bay and Gonghu Bay (Class Ⅱ)], the inflow loads should be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57815796

controlled under 6427.38, 3248.01, 2206.92 and 1107.58 $t\,a^{-1}$, respectively. The total NH_4^+–N loads in the northwest Lake Taihu should be maintained under 12989.89 $t\,a^{-1}$. To achieve better water quality goal in Scenario 2 [North Zone and Zhushan Bay (Class Ⅱ), and Meiliang and Gonghu Bays (Class I)], the inflow loads in the North Zone , Zhushan Bay, Meiliang Bay and Gonghu Bay should be maintained under 3304.64, 2466.53, 615.26 and 281.93 $t\,a^{-1}$, respectively. The total NH_4^+–N loads from the northwest Lake Taihu should be maintained under 6668.37 $t\,a^{-1}$.

Table 4. *Water quality goals in the lake and statistics of water quality values in different scenarios*

Sub-lake	Water functional zone	Scenario 1		Scenario 2	
		Goal in lake (mg/L)	Inflow loads (ta^{-1})	Goal in lake (mg/L)	Inflow loads (ta^{-1})
North Zone	Conservation areas of Lake Taihu	1.0 (III)	6427.38	0.5 (II)	3304.64
Zhushan Bay	Conservation areas of Zhushan Lake	1.0 (III)	3248.01	0.5 (II)	2466.53
Meiliang Bay	Conservation areas of water scenery	0.5 (II)	2206.92	0.15 (I)	615.26
Gonghu Bay	Conservation areas of drinking water source	0.5 (II)	1107.58	0.15 (I)	281.93

Influences of loads on NH_4^+–N

The overall results indicated that the NH_4^+–N concentrations evidently decreased with the inflow loads in the lake regions. In 2015, the NH_4^+–N loads from inflow rivers were less than the standards in Scenario 1, and the NH_4^+–N concentrations in the four lake regions agreed with the simulation results in RF models in *Table 5*, that's the NH_4^+–N concentration in the North Zone and Zhushan Bay were classified as Class Ⅲ and Meiliang Bay and Gonghu Bay were classified as Class Ⅱ, which once again proved the practicability of the simulated results of the RF models. The NH_4^+–N concentrations in the four lake regions achieved the basic goals in the Master Plan of Integrated Regulation of Water Environment and the Water Function Zoning of the Lake Taihu Basin. Under 8.99% reduction of inflow loads in the North Zone, the water quality in this region could be suitable to Class Ⅱ. Similarly, the NH_4^+–N loads from the inflow rivers of the North Zone, Zhushan Bay, Meiliang Bay and Gonghu Bay should be reduced by nearly 8.99%, 11.41%, 51.38% and 62.87%, respectively, for better water quality in the lake regions (the NH_4^+–N concentrations decreased by approximately 6%, 34%, 44.44% and 6.67%, respectively). The total NH_4^+–N loads from the inflow rivers of northwest Lake Taihu should be maintained under 6668.37 $t\,a^{-1}$, which is 20.96% lower than that in 2015.

Table 5. *Mass budgets for NH_4^+–N in inflow rivers in northwest Lake Taihu and load reductions in two scenarios in contrast to the situation in 2015*

	NH_4^+–N loads from inflow rivers	NH_4^+–N concentrations in the lake regions	In comparison to Scenario 1	In comparison to Scenario 2
North Zone	3627.83	0.53 (III)	−77.17%	+8.91%
Zhushan Bay	2784.15	0.76 (III)	−16.66%	+11.41%
Meiliang Bay	1265.52	0.27(II)	−74.39%	+51.38%
Gonghu Bay	759.31	0.16(II)	−45.87%	+62.87%

Conclusions

In the present study, monthly NH_4^+–N water quality data in inflow rivers and corresponding sub-lake were used to analyse the NH_4^+–N distributions in northwest Lake Taihu. RF models were constructed to simulate the correspondence between the NH_4^+–N concentrations in the lake and its inflow rivers in different scenarios.

In the northwest Lake Taihu, the spatiotemporal distribution patterns of nutrient concentrations are distinct, and river inputs were the major source of NH_4^+–N loadings to the northwest Lake Taihu. The North Zone and Zhushan Bay were the most seriously polluted among the lake areas, whereas Gonghu Bay was the cleanest region. In winter and spring, NH_4^+–N concentrations were significantly higher than in summer and autumn, and seasons had a significant effect on the NH_4^+–N concentrations of northwest Lake Taihu. In the RF models, the R^2 and relationships between measured NH_4^+–N concentrations and those predicted by the RF proved that the established RF models had a relatively high precision and that the forecast model could be used in the further stimulation of the scene of water quality in northwest Taihu Lake. In 2015, the NH_4^+–N loads from inflow rivers were less than the standards in Scenario 1, and the NH_4^+–N concentrations in the four lake regions agreed with the simulation results in RF models. For the protective targets [Scenario 1: North Zone and Zhushan Bay (Class Ⅲ), Meiliang Bay and Gonghu Bay (Class Ⅱ)], the inflow loads should be controlled under 6427.38, 3248.01, 2206.92 and 1107.58 $t\,a^{-1}$, respectively. To achieve better water quality goal for North Zone and Zhushan Bay (Class Ⅱ), Meiliang Bay and Gonghu Bay (Class I), the inflow loads should be maintained under 3304.64, 2466.53, 615.26 and 281.93 $t\,a^{-1}$, respectively. The nutrient reduction scenarios showed that NH_4^+–N concentrations decreased by approximately 6%, 34%, 44.44% and 6.67% in the North Zone, Zhushan Bay, Meiliang Bay and Gonghu Bay, despite the reduction of external NH_4^+–N loads by 8.99%, 11.41%, 51.38% and 62.87%, respectively.

Eutrophication and algal blooms are worldwide environmental issues in lakes and the eutrophication process and forming mechanisms of algal blooms are particularly complicated in shallow lakes due to the strong lake–land, air–water and water–sediment interactions (Qin et al., 2007). This study provides further understand on the water quality distribution pattern in Lake Taihu, quantifying the reduction of nutrient loading from inflow rivers and governing Lake Taihu or other typical eutrophic lakes. However, only the northwest Lake Taihu Basin was studied instead of the entire lake, and only monthly NH_4^+–N monitoring data during 2009–2015 were utilised as modelling variables instead of using other indices. Additional water quality indices and theoretical explorations are still needed in future works. Thus, stricter external nutrient managements and other ecological restoration tools must still be considered and investigated for the water environment recovery and protection in the Taihu basin. Under the control of exogenous nutrients, the variation characteristics and distribution of nutrient concentration in eutrophicated shallow lakes are closely related to the hydrodynamic process of shallow lakes and the action of underlying lake flow (Jing et al., 2000). At the same time, submerged plants can contain the dynamic suspension process of sediments, absorb nutrients in water and sediments, reduce the load of nutrients, and purify the water quality of lakes (Jöbgen et al., 2004; Wang et al., 2019). Therefore, it also shows that it is not enough to govern Taihu lake only by controlling external pollution, and the treatment of internal pollution of Taihu lake also needs to be strengthened.

Abstract. Global climate change and intensifying human activities have dramatically changed the runoff of Dongting Lake. This study investigated the runoff variations and associated impacts of climate change and human activity for the four inflow sub-basins of Dongting Lake. Multiple linear regression method and double-mass curve method were used to quantify the effects of climate change and human activities on water discharge. Results showed that the streamflow of the Xiangjiang, Zishui and Yuanjiang rivers exhibited an abrupt change in 2003, 2003 and 2005, respectively, whereas no significant turning year was detected for Lishui River. The impacts of climate factors and human activities were consistent using the two methods. The contribution rate of climate change to runoff reduction in Xiangjiang River was about 85–92% and the impact of human activities ranged from 8 to 15%. For the runoff changes in the Zishui and Yuanjiang River basins, results showed that the impact of climate factors ranged from 63 to 88% and from 62 to 82%, respectively. In comparison, the anthropogenic impact ranged from 12 to 37% and from 18 to 38%, respectively. This study will provide important insights into water resource management and planning for Dongting Lake basins.
Keywords: *streamflow, precipitation, evapotranspiration, human activities, Dongting Lake*

Introduction

River runoff changes are mainly affected by climate factors, such as precipitation and evapotranspiration. However, as an indirect influencing factor, increasing human activities (e.g. land utilisation change, water diversion for agricultural irrigation, hydropower engineering, water and soil conservation, etc.) have caused a change in water circulation (Allen and Ingram, 2002; Millán, 2014; Amin et al., 2016). Various studies have revealed a contradiction between water resources supply and demand due to the runoff changes in many river basins worldwide (Fu et al., 2004; Xu et al., 2010, 2013a, b). An analysis of the trends and characteristics of runoff changes and a quantitative evaluation on the effects of climate variability and human activities are important for the assessment and management of regional water resources.

Quantifying the impacts of climate change and anthropogenic activities on hydrological processes has become a hot topic in climatic and hydrologic studies (Zhang et al., 2015; Ahn and Merwade, 2014; Buendia et al., 2016; Griffioen, 2016). Extensive research has been conducted on several typical watersheds, such as the Nile River basin (Hasan et al., 2018), Columbia River basin, Colorado River basin, Mississippi River basin (Naik and Jay, 2011; Timilsena and Piechota, 2008), Mekong basin (Raghavan et al., 2012), Brahmani River basin (Islam et al., 2012), and in China,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57975812

the Yangtze River basin (Zhao et al., 2015), Yellow River basin (Wang et al., 2014; Kong, 2017), Wei River basin (Huang et al., 2016; Zhang et al., 2015) and Hei River basin (Luo et al., 2016). Two methods are commonly used for evaluating the contribution rates of the main influencing factors on runoff changes, including hydrological modelling (Huang et al., 2016; Liu et al., 2016) and quantitative evaluation method [e.g. climatic elastic coefficient method (Ahn and Merwade, 2014; Ye et al., 2013), multivariate regressive (Jiang et al., 2011), sensitivity analysis (Zuo et al., 2016) and double-mass curve (DMC) method (Li and Xu et al., 2016)]. Although these studies quantitatively evaluated the comprehensive effects of climate change and human activities on runoff change, some shortcomings and deficiencies were observed. For example, although the hydrological model has a good physical foundation, its structure and parameter sensitivity possess several uncertainties. Furthermore, while the quantitative evaluation method requires less data, a longer data series is needed to reach the effect of quantitative assessment, and noise in the long-time data series interferes with the evaluation results (Sankarasubramanian et al., 2001). Improvement of the accuracy to identify the change points of runoff variation and comprehensive application of various methods to quantify the contribution of climate change and human activities are necessary to obtain reasonable results.

Dongting Lake, the second largest freshwater lake in China, plays an important role in regulating the amount of water in Yangtze River, China's longest river. In recent decades, especially after the Three Gorges project operation, lake runoffs were changed greatly and the surrounding basins suffered from frequent droughts (Mao, 1998), which seriously disrupted water supply for agricultural production, human consumption and ecological water requirement. Several studies have discussed the variation trend of runoff and sediment discharge in Dongting Lake basin. Li and Gu et al. (2016) revealed that the annual discharge of the Dongting outlet lake has shown a decreasing trend since 1983, with the most obvious decrease from 2003 to 2014. The results also indicated that runoff and rainfall synchronised within a certain range of fluctuations. Qin et al. (2012) analysed the long-term changes of runoff and sediment discharge of the Four Rivers in Dongting Lake basin and pointed out that the annual runoff change is mainly affected by the abundance and deficiency of precipitation. Zhang and Liu (2018) investigated the runoff and sediment discharge change trend in Xiangjiang River basin and its relationship with rainfall, drought regime, dam engineering construction and vegetation change. These studies indicated that the variations of streamflow are considerably related to regional climate, especially precipitation. However, to our knowledge, the present studies have paid little attention to quantifying the contribution rate of the driving factors of runoff changes in Dongting Lake basin. Furthermore, quantifying the impacts of climate variability and human activities with a single method is challenging because of the complex processes involved. Thus, further studies are needed to provide a conclusive interpretation of the changes observed. The present study is essential not only for an improved understanding on the mechanism of hydrological response in the basin but also for local water resources management as well as flood and drought protection and disaster mitigation.

In this study, Sen's slope method, moving t-test, Pettitt test, multiple linear regression and DMC method were used to explore the streamflow variations of the Dongting Lake sub-basin and quantify the relative impacts of climate variability on human activity. The specific objectives of this study were as follows: (1) analyse the variability of long-term historical records of hydrological and climate data of the main

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57975812

tributaries in Dongting Lake basin, (2) investigate the abrupt change points of runoff variations and (3) estimate quantitatively the contribution rate of climate factors and human activities to runoff changes.

Dataset and methodology

Study area

Dongting Lake, the second largest freshwater lake in China, is located at 28°30'N–30°20'N and 111°40'E–113°10'E (*Fig. 1*). With a drainage area of 2.63 × 10^5 km^2, it occupies a large part of Hunan Province and a small part of Hubei, Chongqing, Guizhou, the Guangxi Zhuang Autonomous Region and Jiangxi provinces. Dongting Lake is connected to Yangtze River. The lake receives water flows mainly from Yangtze River and four tributaries from upstream (Xiangjiang, Zishui, Yuanjiang and Lishui) and discharges into Yangtze River through an outlet in the north. Runoffs from four rivers account for 54.6% of the total runoff (Qin et al., 2012), and changes in the runoffs directly impact the water quantity of Dongting Lake, The basin has well-developed river systems and includes four sub-basins: Xiangjiang, Zishui, Yuanjiang and Lishui River basins. Dongting Lake basin belongs to the subtropical monsoon climate zone. Its annual mean precipitation ranges from 1200 to 1400 mm depending on the position in the basin (Cui et al., 2012) and average annual runoff is 2608 × 10^8 km^2.

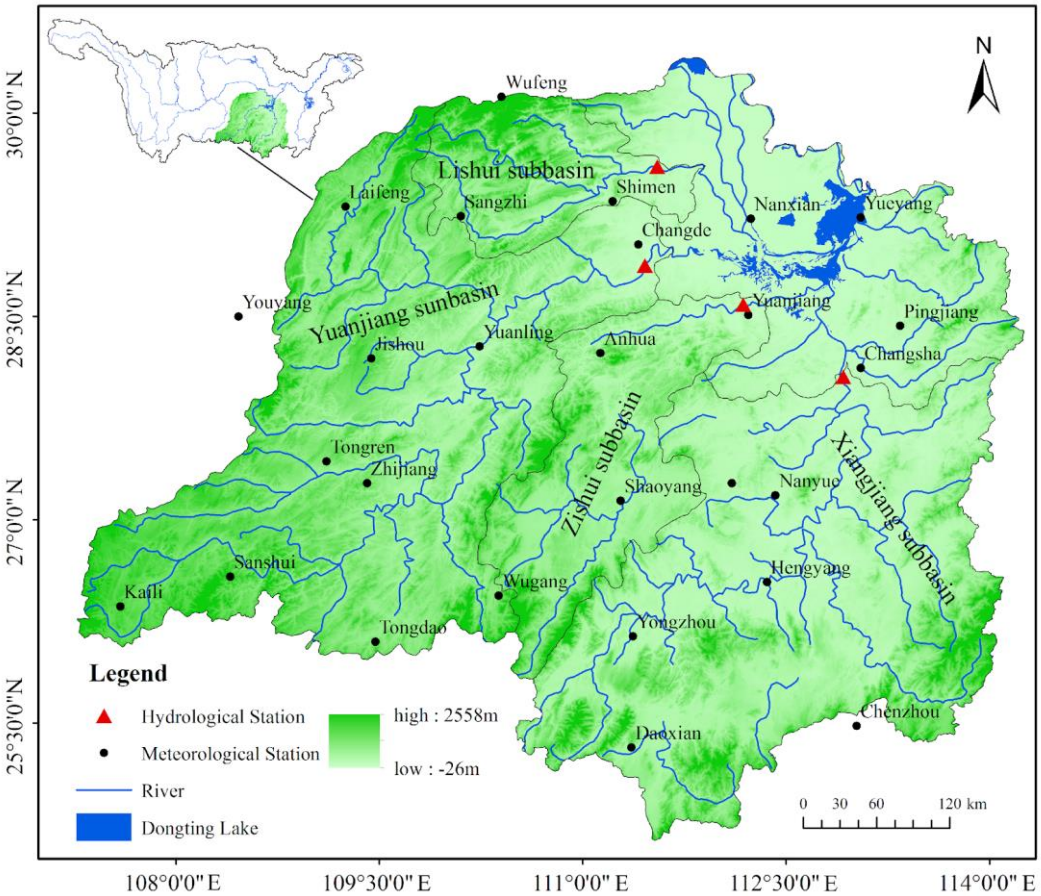

Figure 1. *Location of the study area and the distribution of meteorological stations and hydrological stations*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57975812

Dataset

Daily runoff observations (1980–2014) from four gauging stations, including Xiangtan, Taojiang, Taoyuan and Shimen stations, were derived from the *Yangtze River Hydrological Data*. The meteorological data from 25 weather stations inside the catchment (*Fig. 1*) were obtained from the National Meteorological Information Center (http://data.cma.cn). The stations provide daily observations on precipitation, temperature, maximum temperature, minimum temperature, actual vapour pressure, relative humidity, sunshine duration and wind speed. Potential evaporation is calculated using the Penman–Monteith formula (Penman, 1948). Considering the uneven distribution of meteorological stations, the precipitation and potential evaporation in each basin are calculated using the Thiessen polygon method on the ArcGIS platform.

Methodology

Trend test

Sen's slope, a non-parametric estimation method, can reflect the magnitude of the monotonic (Sen, 1968) trend and is given as *Equation 1:*

$$\beta = Median(\frac{X_i - X_j}{i - j}) 1 < j < i < n \quad \text{(Eq.1)}$$

where β is the median over all combinations of record pairs for the whole data set and is, therefore, not affected by extreme values in the observations (Hirsch et al., 1982). A positive value of β indicates the variables increase with time, whereas a negative value represents a decreasing trend.

Change-point analysis

Various methods can be used to detect abrupt climate change, such as Mann–Kendall method (Mann, 1945), moving t-test (Buishand, 1982), Pettitt test (Pettitt, 1979) and cumulative anomaly method (Weber and Stewart, 2010). According to the characteristics and virtues of these methods, moving t-test and Pettitt test methods are used to analyse the change points of runoff.

Moving t-test is used to test the significant difference of two random samples' mean. The method is simple, reliable and capable of avoiding artificial interference on the subsequence selection (Chen and Gupta, 2000). The method assumes the distribution functions before and after the change point as $F_1(x)$ and $F_2(x)$ and extracts two samples with the capacity of n_1 and n_2 from them, respectively. A T statistic is then constructed as follows:

$$T = \frac{\overline{x_1} - \overline{x_2}}{\sqrt{\frac{(n_1 - 1)S_1^2 + (n_2 - 1)S_2^2}{n_1 + n_2 - 2}(\frac{1}{n_1} + \frac{1}{n_2})^{1/2}}} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57975812

In the above equation, $\overline{x_i}$ and S_i are the means and variances of the samples, respectively. At a given confidence level α, if $|T| > T_{\alpha/2}$, then the sequence has a significant difference. Among all the points satisfying $|T| > T_{\alpha/2}$, the point where T reaches the maximum is the most possible change point.

Pettitt test, put forward by A. N. Pettitt (1979), is used to determine the occurrence of a change point. This approach considers a time series as two samples represented by $X_1, \cdots X_t$ and $X_{t+1}, \cdots X_N$. The Pettitt index $U_{t,N}$ is based on Mann–Whitney's statistical function and can be calculated using *Equation 3:*

$$U_{t,N} = U_{t-1,N} + \sum_{j=1}^{N} \operatorname{sgn}(x_t - x_j) \quad (t = 2, \cdots, N) \tag{Eq.3}$$

where if $x_t - x_j > 0$, then $\operatorname{sgn}(x_t - x_j) = 1$; if $x_t - x_j = 0$, then $\operatorname{sgn}(x_t - x_j) = 0$; and if $x_t - x_j < 0$, then $\operatorname{sgn}(x_t - x_j) = -1$.

The test statistic counts the number of times a member of the first sample exceeds that of the second. Moreover, the null hypothesis does not change in the distribution of a sequence of random variables. The most significant change point is selected where the value of $U_{t,N}$ is the largest (*Eq. 4*), and a change point occurs at time t when the statistic $k(t)$ is significantly different from zero at a given level. For $P \leq 0.5$, the approximate significant level is given by *Equation 5* (Pettitt, 1979).

$$k(t) = Max_{1 \leq t \leq N} |U_{t,N}| \tag{Eq.4}$$

$$P \cong 2 \exp\{-6(K_N)^2 / (N^3 + N^2)\} \tag{Eq.5}$$

Contribution rate analysis

Multi-regression method

Runoff changes involve the superposition of the effects of climate change and human activities, while climate factors influence the runoff mainly by precipitation and evaporation. Jiang et al. (2011) suggested a linear regression approach to estimate the monthly runoff using a function of precipitation and potential evapotranspiration (PET). On a monthly time scale, groundwater storage may play a role in runoff generation. Therefore, the original equation is modified by adding the precipitation from the previous month. Liu et al. (2016) showed that a three-variable linear regression model that considers precipitation, PET and precipitation from the previous month fitted well. The equation is given as

$$Q_i = aP_i + bP_{i-1} + cPET_i + d \tag{Eq.6}$$

where Q, P and PET represent the runoff, precipitation and potential evapotranspiration during the natural period, respectively, for month i; and a, b, c and d are constants estimated by least square estimation. Then, simulated runoff is estimated for the impact period using *Equation 6*. The difference between the observed runoff and the calculated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57975812

runoff will represent the contribution from human activities in the impact period. The runoff change caused by climate factors and human activities can be quantified respectively according to *Equations 7* and *8*.

$$\Delta Q_h = \left| \overline{O_m} - \overline{Q_m} \right| \quad \text{(Eq.7)}$$

$$\Delta Q_c = \left| \overline{O_n} - \overline{Q_m} \right| \quad \text{(Eq.8)}$$

$$\Delta Q_t = \Delta Q_c + \Delta Q_h \quad \text{(Eq.9)}$$

where ΔQ_h and ΔQ_c represent the change in mean annual runoff due to human activities and climate factors, respectively; $\overline{O_m}$ and $\overline{O_n}$ are the average observed monthly runoff during the impact period and the natural period, respectively; and $\overline{Q_m}$ represents the calculated average monthly runoff during the impact period.

Nash–Sutcliffe Coefficient (NSC) was used to evaluate the model performance as follows:

$$NSC = 1 - \frac{\sum_{t-1}^{T} (O_t - Q_t)^2}{\sum_{t-1}^{T} (O_t - \overline{O_t})^2} \quad \text{(Eq.10)}$$

where O and Q are the observed and simulated monthly runoffs, respectively. NSC changes between -∞ and 1, and the closer this value is to 1, the higher the reliability of the model. Moriasi et al. (2007) suggested that the accuracy of simulations is satisfactory if the value of NCS is greater than 0.5.

Double mass curve analysis

DMC was first proposed by C. F. Merriam (1937) for the consistence analysis of a rainfall series in the Susquehanna Valley of the United States. Recently, DMC has been widely used in identifying the hydrological regime changes caused by anthropogenic disturbances (Huo et al., 2010; Gao et al., 2015). DMC is a plot of the accumulated values of one variable against the accumulated values of another related variable for the same period. Theoretically, it is a straight line when affected by climate change only. A break in the slope of the DMC indicates that human activities began to significantly influence runoff. In this study, precipitation and PET were the reference variable, and runoff was the tested variable. For a detailed description of this method, see Li et al. (2016).

Results

Variations of precipitation and potential evaporation

The results of Sen's slope of annual precipitation and annual potential evaporation in Dongting Lake basin from 1980 to 2014 are shown in *Fig. 2a* and *b*, respectively. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57975812

annual precipitation did not show the same upward or downward trending in the whole basin. Overall, the trend of precipitation change in the Xiangjiang River basin was more significant, and the precipitation of some weather stations in the Yuanjiang River basin had an upward tendency. The trend of precipitation change of weather stations failed to achieve a significant level, except for Wufeng Station (*Table 1*). As shown in *Fig. 2b*, potential evaporation in the whole basin showed an upward trend. From the spatial distribution, the trend of potential evaporation change decreased progressively from the eastern to the western region. Similarly, compared with the Lishui and Yuanjiang River basins, the increasing trend of PET in the Xiangjiang and Zishui River basins was more significant (*Table 1*).

Positive values mean an increase, negative values mean a decrease. The bold font indicates the trend of change is significant at the 95% confidence interval

Figure 3a and *b* shows the respective long-term trends and mean annual value of annual precipitation and potential evaporation in Dongting Lake basin. The annual average precipitation in the basin was 1391.65 mm from 1980 to 2014 and great inter-annual variations could be observed, with the largest ratio at 1.89. Furthermore, the precipitation indicated a decreasing trend with a Sen of -1.57 mm/a (P = 0.39) (*Fig. 3a*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57975812

Compared with other periods, rainfall was relatively abundant in the 1990s. However, the PET of Dongting Lake basin showed a significant increasing trend ($P < 0.05$) at a rate of 2.33 mm/a. The average PET was 1013.01 mm in 1980–2014, during which PET fluctuated greatly especially after 2000.

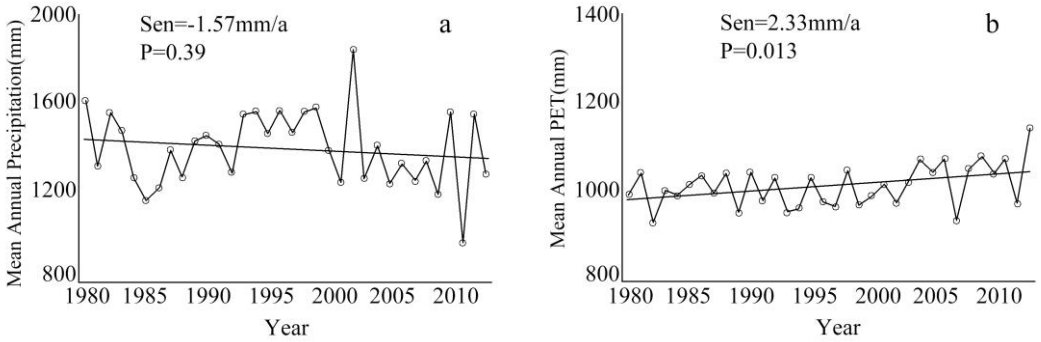

Figure 3. *Variations of mean annual precipitation (a) and potential evaporation (b) from 1980 to 2014*

Trend and change-point analysis of runoff

The variations of mean annual runoff for the four sub-basins in Dongting Lake basin are illustrated in *Figure 4a1, b1, c1* and *d1*, respectively. Xiangjiang River basin had the highest annual runoff (667×10^8 m^3, about 40% of the total), followed by Yuanjiang (629×10^8 m^3) and Zishui (227×10^8 m^3) and the lowest was Lishui River basin at only 145×10^8 m^3. Except for Lishui River basin, the runoff of the other three basins had similar inter-annual fluctuation patterns, firstly decreasing, then increasing and again decreasing. Similar to the precipitation changes, the annual runoff in the 1990s was significantly higher than that in the 1980s and the 2000s. The runoffs of four sub-basins were all lower than the previous record for the period after 2003. The annual runoff in Lishui had no clear increasing or decreasing trend.

DOI: http://dx.doi.org/10.15666/aeer/1703_57975812

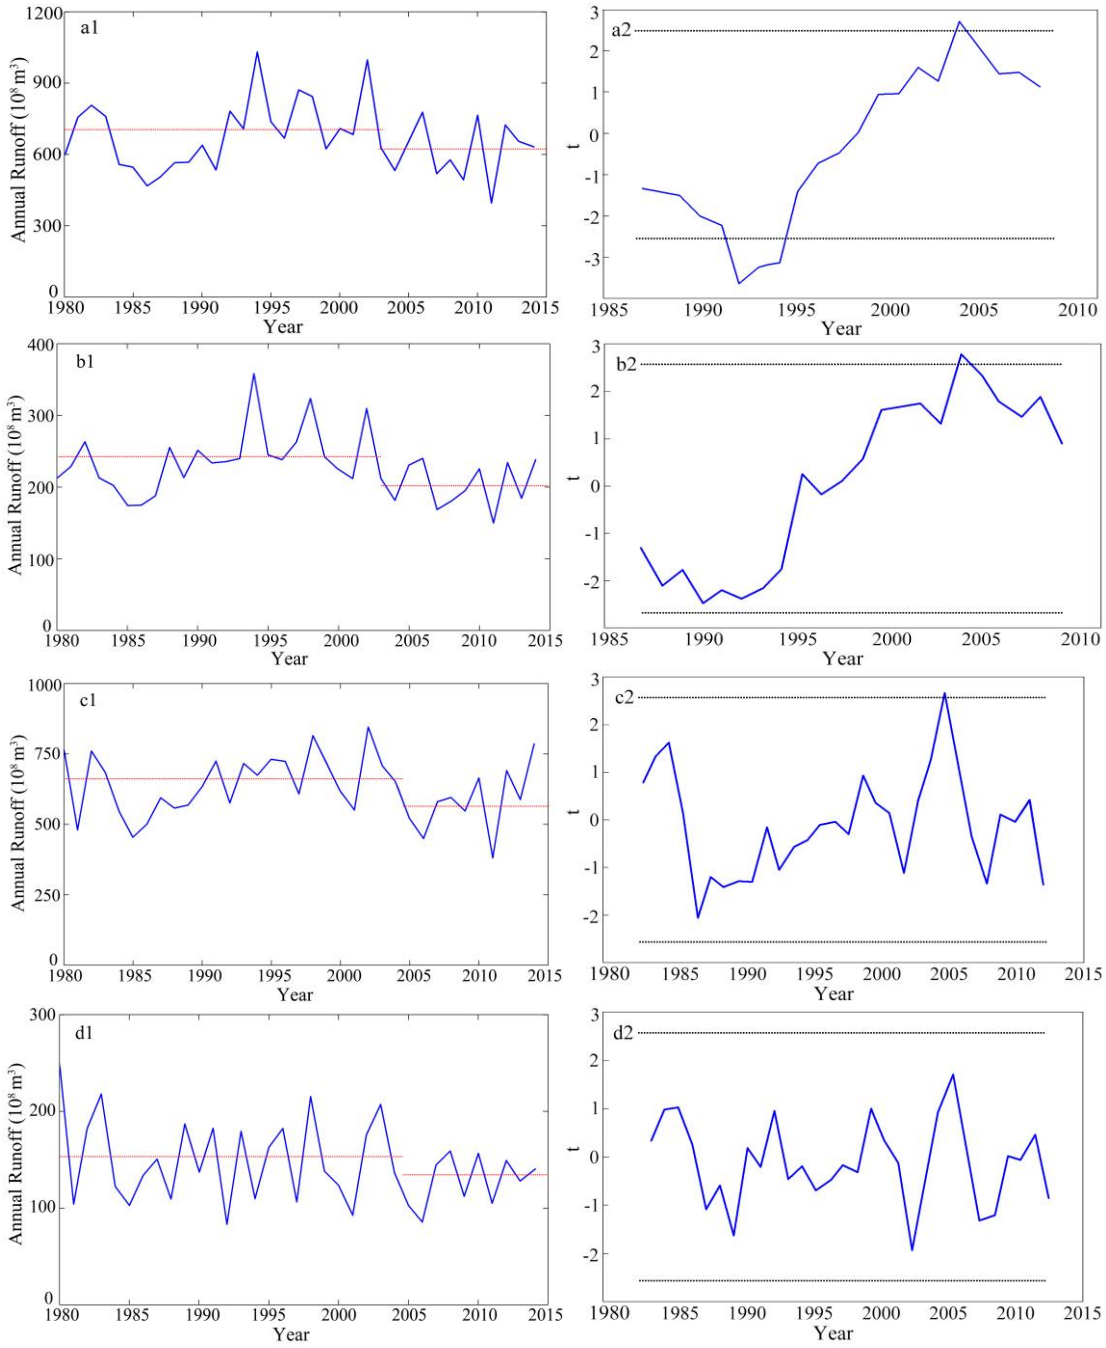

Figure 4. *Variations and moving t-test on runoff in Dongting Lake basin (a: Xiangjiang River basin, b: Zishui River basin, c: Yuanjiang River basin and d: Lishui River basin). The red dotted line stands for mean annual runoff before and after the turning years on the left. The dotted line means the significance level of 0.05 on the right*

The moving t-test and non-parametric Pettitt test were applied to detect the change point of the annual runoff series of the sub-basins. Similar results were obtained (*Table 2*). As shown in *Figure 4a2, b2, c2, d2* and *Table 2*, the turning years in the runoff changes were 2003 for Xiangjiang River basin, 2003 for Zishui and 2005 for Yuanjiang River basin. No significant change point was found for Lishui River basin. On the basis of this finding, this study will analyse the runoff trend of the other three

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57975812

sub-basins. Through trend and change-point analysis, the runoff series will be divided into a natural period series and an impact period series. The comparison and analysis of the mean runoff before and after the abrupt change indicated that the annual runoff of every sub-basin had a remarkable decline after the abrupt change. The drops were 11.46%, 14.87% and 8.77% in Xiangjiang, Zishui and Yuanjiang River basins, respectively.

Quantification of climatic and anthropogenic influences

Multi-regression method

The natural period was taken as a baseline, and the effects of climate change and human activities on runoff of each sub-basin were estimated for the impact period using two methods.

Multi-regression equations of the three sub-basins were developed based on the monthly average precipitation and potential evaporation of the natural period (*Table 3*). The coefficients of determination (R^2) were all greater than 0.75 (significance level of 0.001), and the NSCs were all greater than 0.65. These results indicate that the multi-regression models can accurately simulate runoff. The simulated runoff series was obtained with the use of precipitation and PET of the impact period as input. The contribution of climate factors and human activities to runoff were calculated according to *Equations 7* and *8,* respectively. The quantitative results are shown in *Table 4*.

Double mass curve analysis

The DMCs of precipitation–runoff and PET–runoff, along with the linear regression lines, are shown in *Figures 5* and *6,* respectively. Clearly, the DMCs showed the turning points for runoff, which indicated that the runoff changes were influenced by both climate factors and human activities in the three sub-basins of Dongting Lake. This result further verifies the correctness of the test for abrupt change.

The contribution rates of climate factors and human activities in runoff changes in these sub-basins were calculated and shown in *Table 5*. For Xiangjiang River basin, the annual average observed runoffs in the natural period and the impact period were 694.02×10^8 m^3 and 611.40×10^8 m^3, respectively. Based on the DMCs, the influence quantities of precipitation and evaporation on runoff reduction were 48.39×10^8 m^3 and 27.56×10^8 m^3, respectively. Accordingly, the contribution rates of precipitation and PET accounted for 58.58% and 33.35% of the runoff change, respectively. The reduction ratio due to human activities was only 8.07%. Similarly, the contribution rates

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57975812

of climate factors and human activities to the runoff reduction in Zishui and Yuanjiang River basins were 62.56% and 37.44% and 61.68% and 38.32%, respectively.

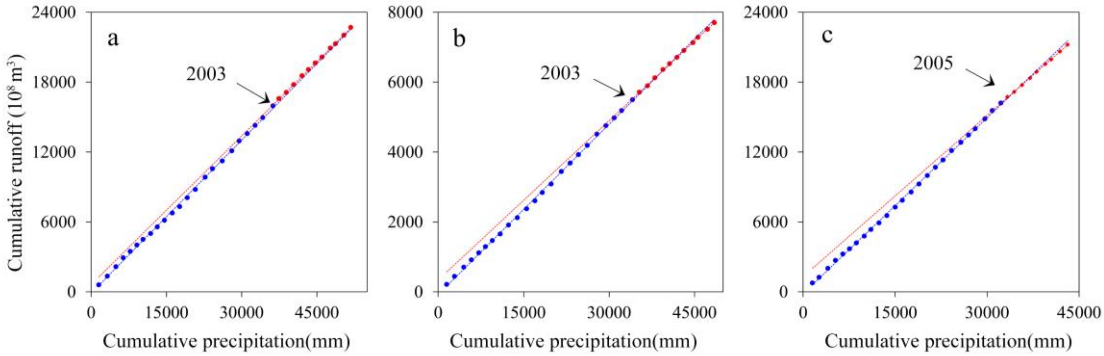

Figure 5. *DMCs of annual runoff and precipitation at different sub-basins. The blue and red lines are the regression lines for the cumulative data before and after the change-point years, respectively (a: Xiangjiang River basin, b: Zishui River basin and c: Yuanjiang River basin)*

Discussion

The results above showed that the annual runoff decreased significantly in Xiangjiang, Zishui and Yuanjiang River basins. Decreasing precipitation and increasing PET play critical roles in affecting the reduced runoff changes. Some studies showed that temperature and precipitation were the predominant factors that caused the shortage of water resources and drought and flood. Guo et al. (2001) indicated that the runoffs of semi-humid regions in the north of China are more sensitive to climate change than those of humid regions such as Yangtze River basin. In the present study, the climate variation features are consistent with those of the runoff series, providing further evidence that climate change are the dominant factor decreasing runoff. From the whole basin, the climate change trend in Xiangjiang and Zishui River basin are more significant, which corresponds to the conclusion that the contribution rate of climate change in decreasing runoff was larger in the two basins. No significant change point was detected in the runoff variation of Lishui River basin, consistent with the results of Liu et al. (2014) and Zheng and Sun (2014). Their studies showed that the annual runoff of Lishui River basin has not changed significantly since the 1980s. On the one hand, the annual rainfall of the study period has not changed significantly; on the other hand, although the underlying surface conditions of the middle and upper reaches of Lishui River have been changing, human activities have not affected the annual runoff. This outcome may be related to the well-developed river system and abundant runoff. While human activities are gradually intensifying, they have not caused significant changes to the hydrological characteristics of Lishui River. The relevant physical mechanisms need to be further verified and determined as well.

Through multi-regression method and DMC analysis, the contribution rates of climate change and human activities to runoff changes in the four sub-basins were obtained. The conclusions from the two methods are consistent: runoff reduction was mainly caused by climate change in the whole basin and human activities played an assisting role in such a change, a finding that is consistent with the conclusion of Xiao (2014). Zhang and Liu (2018) also indicated that regional climate change (precipitation and PET) are the main factors influencing the runoff of Xiangjiang River basin. The two kinds of methods confirm each other and improve the reliability of the evaluated results. With the results of the two methods combined, the impact of human activities on the runoff change was revealed to be negative. In addition, owing to the discrepancy in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_57975812

regional climate and the intensive human activities in these sub-basins, the contribution of individual impacts varied under different regions. According to *Tables 4* and *5*, the contribution rate of human activities in decreasing runoff in Yuanjiang River basin was the largest at 18–38%. However, a percentage of the impact of climate change in Xiangjiang River basin was bigger than those in other sub-basins, and the impact of human activities accounted for 8–15% of decreasing runoff.

Human activities affect the basin hydrological process mainly through two aspects: changing the conditions of the underlying surface and developing hydropower engineering (Ye et al., 2009). The former involves the variation of land utilisation and land cover, urbanisation, water and soil conservation and vegetation restoration. Relevant documents show that the total population of Dongting Lake basin has increased by 12.07 million since 1980, and the areas for construction land have also increased (Xiao, 2014). In recent decades, according to statistics from the Hunan Water Conservancy Bureau (http://www.hnwr.gov.cn), the proportion of agricultural water use has dropped and industrial and domestic water use in urban and rural areas has increased. In addition, the forest coverage rate of the whole province increased from 36.7 to 57% during 1989–2010 (Xiao, 2014). Studies have shown that the implementation of soil and water conservation measures was conducive to increasing water storage capacity and reducing runoff (Ye et al., 2009). Water conservancy projects have a tremendous impact on runoff, in addition to changing channel characteristics. They likewise influence regional precipitation and evaporation by increasing the water area, especially through large reservoirs. According to the first water resources census of Hunan Province (http://hnrb.voc.com.cn), by the end of 2011, there were 14,121 reservoirs of various types with a total reservoir capacity of 53.07 billion m^3, of which the large reservoirs accounted for 68.2%. According to the statistical data of existing large reservoirs (Xiao, 2014), the ratio of control areas of reservoirs in Xiangjiang River basin was the smallest among all sub-basins. This fact is one of the possible causes for the results on the contribution rate of human activities in Xiangjiang River basin being the least. Overall, the effect of human activities on runoff is very complex, and the degree of influence of human activities on runoff change and the correlation between them need to be further verified.

Conclusions

On the basis of analysing the trend of runoff variation, this study used moving t-test and Pettitt method to detect turning points. Then, taking the natural period as the baseline, the impact of climatic factors and human activities on runoff variation was evaluated by multi-regression and DMC methods. The conclusions are as follows:

(1) During 1980–2014, the trend of runoff reduction in Dongting Lake basin was obvious. Besides Lishui River basin, the runoff of Xiangjiang, Zishui and Yuanjiang River basins showed abrupt changes in 2003, 2003 and 2005, respectively.

(2) Climate change was the dominant factor of runoff reduction in Dongting Lake basin, while human activities play a subsidiary role. The contribution rate of climate change to runoff reduction in Xiangjiang River Basin was approximately 85–92%, and the impact of human activities was 8–15%. In Zishui, the contribution of climate change accounted for 63–88% of the changes in runoff, while human activities were responsible for 12–37% of the change. Similarly, the impacts of climate change and human activities in Yuanjiang River basin were 62–82% and 18–38%, respectively.

The method adopted in this study can be easily used to quantify the impact of changing environments on runoff in areas that lack historical data. Some uncertainties exist because of the correlation of climate variability and anthropogenic activities. More attention should be directed to these uncertainties in future research on the quantitative estimation of influence of climate change and human activities on runoff in Dongting Lake basin. Furthermore, although the runoff reduction of Dongting Lake basin was caused by climate change, human disturbance will bring challenges to the utilisation of water resources. To maintain the ecosystem services of the river basin and ensure a certain degree of ecological water requirement, the dispatch and management of basin water resources should be strengthened.

Abstract. It is greatly significant to implement water-saving irrigation and establish a water-saving system for forage grass, on basis of non-full irrigation principles, in order to meet the demands for forage grass from the rapidly-developing Chinese dairy industry distributing in rural-urban fringes, and improve the utilization efficiency of limited water resources in the central dairy production area of Inner Mongolia. The paper targets four different planting patterns of maize/alfalfa, and discusses water demand rules of herbage groups, variation of evapotranspiration, influence of water shortage at different stages on evapotranspiration, and moisture sensitive period of the forage grass under multi-storey cropping conditions, based on the experimental data of forage multi-storey cropping field under different water stress conditions in the outskirts of Hohhot. According to the results, the change in water demand of maize/alfalfa belt type multi-storey cropping field presents a wavy rule during the whole growth period; compared to evapotranspiration of monocropping maize/alfalfa, the evapotranspiration of maize/alfalfa multi-storey cropping herbage group was not significantly variable. The moisture sensitive period of monoculture maize and alfalfa were respectively heading-milk ripe stage and branching-squaring stage, and the moisture sensitive period of 4//8-type multi-storey cropping pattern is branching-jointing stage.
Keywords: *water-saving irrigation, moisture sensitive period, designed moisting layer, water utilization efficiency, evapotranspiration, moisture sensitive period, water balance equation, modal coefficient*

Introduction

The development level of the dairy industry is deemed as a significant indicator of the quality of modern agriculture in a country, especially animal husbandry. Dairy industry is recognized as a food-saving, economic and efficient industry, among the animal by-products with the highest forage conversion intensity. The World Health Organization regards the average dairy consumption of the population as one of the key indicators to measure the standard of living of the people in a country, and many

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58135822

countries worldwide, including China. In order to meet the demands for forage grass from the rapidly-developing Chinese dairy industry, it is very significant to research water-saving technologies on basis of non-full irrigation principles, implement water-saving irrigation on dairy forage grass, and improve utilization efficiency of limited water resources in production. Meanwhile, dairy industry mainly distributes in rural-urban fringes, the evapotranspiration for forage production and irrigation has been exhausting urban water resources, the proper distribution of limited water resources will become a critical issue in water management (Zhou et al., 2015; Wang et al., 2003; Chen et al., 1997; Li et al., 2003; Guo et al., 2005; Zhang et al., 2002; Zhao et al., 2008; Liu and Yin, 2013; Liu et al., 2016).

In Hohhot, well-known as "Chinese Dairy City", the high-quality forage cultivated area reached 173,000 hm^2 in 2006, accounting for 33% of the city's total arable land area. The paper analyzes the experimental data of forage multi-storey cropping field under different water stress conditions in the outskirts of Hohhot from 2011 to 2015, discusses water demand rules of herbage groups, variation of evapotranspiration, influence of water shortage at different stages of evapotranspiration, and determines the moisture sensitive period of the forage grass under multi-storey cropping conditions, based on analyzing the forage crops yield under different moisture treatment conditions. The research results provide the basis for the implementation of scientific water management on dairy forage production in Hohhot and even central Inner Mongolia.

Materials and methods

Experimental region

The experiment was conducted in Agricultural Technology Demonstration Park, Xigoumen Town, with coordinates of E111 59'38.97", N40 37'56.48". The experimental region is located in semi-arid temperate continental monsoon climate zone, the soil is sandy loam, the mass ratio of organic matter, total nitrogen and total phosphorus is respectively 1.0%, 0.7% and 0.1%, the dry bulk density is 1.4 g/cm^3 and the field capacity is 22.2%.

Experimental design

The experimental materials adopt feed & storage dual-purpose type Jinshan No. 1 maize and mow-resistant high-protein content algonquin alfalfa, control index of soil moisture shown in *Table 1*. By adopting field comparison experimental method, total four kinds of crop combinations is planted, including monoculture maize, monoculture alfalfa, 2 rows of maize intercropped with 12 rows of alfalfa (2//12 type), 4 rows of maize intercropped with 8 rows of alfalfa (4//8 type). The total 17 treatment means are implemented, each treatment is made three times, each unit area is 32 m^2 as shown in *Table 2*. As for 2//12 type, the alfalfa/maize belt width is 2.4 m and 0.8 m, as for the 4//8 type, the alfalfa/maize belt width is 1.6 m, as for monoculture alfalfa/maize field, the belt width is 3.2 m. The climate condition is divided into non-drought and moderate drought, the soil moisture is regarded as the control index. Experimental photograph was shown in *Figure 1*.

Experimental data acquisition

The meteorological data is obtained and purchased from local meteorological bureau. It is available to sample soil by manual earth boring auger, and determine soil water content by drying and weighing method. The quadrates is adopted to measure the yield before harvest. The tube irrigation method is adopted to record time, the meter is adopted to record irrigation water yield.

Results and analysis

Characteristic of water demand of forage groups under different planting patterns

In accordance with the principle of water balance, in any period of the whole growth term (t), the changes in moisture storage capacity in soil designed moisting layer (h) is expressed by the following water balance equation:

$$W_t - W_0 = W_r + P_0 + K + M + ET_a \quad \text{(Eq.1)}$$

In *Equation 1,* W_0, W_t represents moisture storage capacity in soil designed moisting layer at the beginning of time interval and at any time *t*; *Wr* represents increased moisture storage capacity due to increase of soil designed moisting layer, if the soil designed moisting layer does not change, the option can be ignored; P_0 is rainfall; *K* is groundwater recharge within the period *t*, if in the experimental region, the groundwater level is below 10 m within a long period, *K* should be equal to 0; *M* is the irrigation water volume within the period t; ET_a is the actual evapotranspiration.

Table 3 show the actual evapotranspiration and rules of water demand of maize/ alfalfa forage group of different cropping patterns under full irrigation conditions according to *Equation 1*.

Table 3. *Forage group evapotranspiration of different planting pattern*

Trt.	Items		Main technical parameters								
			Crop 1				Crop 2			Crop 3	Whole growth period
	Alfalfa	Growth period	Seeding-sprouting	Sprouting-branching	Branching-squaring	Squaring-flowering (clipping)	Seedling establishment-branching	Branching-squaring	Heading-flowering (clipping)	Seedling establishment-branching

The percentage of soil moisture in the total soil dry weight, %

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58135822

Under full-irrigation conditions, the evapotranspiration of monoculture alfalfa is 726.7 mm as the maximum value, and the evapotranspiration of monoculture maize is 600.6 mm as the minimum value, the maize/alfalfa multi-storey cropping evapotranspiration is between the above data, the growing season of monoculture alfalfa within a year is longer than the monoculture maize, the evapotranspiration of monoculture alfalfa is also higher than the monoculture maize during the whole growth period; because mowing is implemented several times a year, evapotranspiration intensity is peaked with alfalfa mowing frequency, each peak occurs in alfalfa squaring-flowering stage, the maximum peak occurs between the first mowing and the Secord mowing, during the branching-squaring stage, the evapotranspiration of alfalfa is maximum, accounting for 40.0% of the whole growth period; during the heading-milking stage, the evapotranspiration of monoculture maize is up to 289.6 mm, accounting for 48.2% of the whole growth period. The growing season of monoculture maize is relatively short, during the whole growth period, its total evapotranspiration is also lower than the monoculture alfalfa and multi-storey cropping alfalfa; the water demand rules show a single peak, the consumption intensity during heading-milking stage is maximum. The evapotranspiration of maize//alfalfa belt-type multi-storey cropping during the whole growth is greater than the monoculture maize; and is closer to monoculture alfalfa; the water demand rules of herbage group is impacted by alfalfa mowing, its evapotranspiration intensity is considerably unstable, the fluctuation trend is similar with monoculture alfalfa.

Variation analysis of evapotranspiration of forage grass under multi-storey cropping conditions

Because the dynamic evapotranspiration and evapotranspiration trend of forage grass has changed, the evapotranspiration of maize//alfalfa multi-storey cropping forage grass should not be equal to the sum of evapotranspiration of both two plants, the degree of variation (variability) is calculated by the following formula:

$$C_v = \sum_{i=1}^{n} \frac{\sqrt{(x-\bar{x})^2}}{x} \qquad \text{(Eq.2)}$$

In the formula: C_v -variability; x -sample evapotranspiration; $\bar{x}$ -arithmetic mean of the two samples. The evapotranspiration indicators under monoculture conditions are taken as standard samples, the evapotranspiration indicators under multi-storey cropping are taken as comparison samples; C_v- the degree of variation of multi-storey cropping for monoculture.

The evapotranspiration variability calculated by *Equation 2* under the multi-storey cropping conditions are shown in *Table 4*. The results show that the evapotranspiration of forage grass group is not significantly variable from the evapotranspiration of monoculture maize and monoculture alfalfa, the variability is respectively 0.037 and 0.040, however, it is significantly variable, compared with monoculture alfalfa.

Evapotranspiration (ET) of monoculture maize under phased water shortage conditions

Under the maize monoculture conditions, the different water treatment has a significant impact on evapotranspiration. The treatment 4 is the water shortage at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58135822

heading-milking stage, the change in total evapotranspiration is the most obvious during the whole growth period, according for 75% of treatment 1. The treatment 2 is the water shortage at sprouting-jointing stage, the change in total evapotranspiration is minimum, according for 85% of treatment 1. In case of water shortage at a certain stage, the treatment may cause the increase of evapotranspiration at the next stage, there is a certain compensation effect, in this experiment, during the sprouting-jointing stage and heading-milking stage, the compensation effect for low moisture treatment is more obvious.

Table 4. *Analysis on variation of ET of maize & alfalfa under multi-storey cropping conditions*

Samples	Treatments	*ET* (mm)	C_v
Standard samples	1	600.6	0.0370
	6	726.7	0.0403
Comparison samples	14	660.5	

Water shortage at different growth stages on evapotranspiration of forage groups

It is found from *Table 5* that the evapotranspiration at various growth stages under different water treatments is less at the preliminary stage, increase at the interim stage, the late small variation, and then decreases at the later stage, which mainly result from the growth and development of maize plants and influence from environment meteorological factors, the moisture shortage also affects daily evapotranspiration intensity, thereby affects the evapotranspiration at the reproductive stage. Treatment 2 and 3 is the drought conditions respectively at seedling/jointing stage, at this time, the maize seedling size is less, the evapotranspiration is less. At the heading-milking stage, the evapotranspiration of fully-irrigated treatment is maximum, other treatments are water deficit at other growth stages, although after rewatering in this stage, evapotranspiration increases obviously, but is always lower than treatment 1, because the jointing-heading stage is the peak of the growth of maize silage, if water deficit exists during this period, the growth of plants will be seriously affected, resulting in a less silage maize leaf area index, the plant evapotranspiration is less than other treatments; on the other hand, even if the stage is not affected by the drought, but before the stage have been affected, resulting in poor plant growth, and the evapotranspiration intensity and evapotranspiration will be ultimately affected in the later stage of treatment.

Evapotranspiration of monoculture alfalfa under phased water shortage conditions

Table 6 shows, the alfalfa high evapotranspiration period is between in the first crop and the second crop, in the stage, the evapotranspiration accounts for 47.82% and 40.49% of total amount of the whole growth period, under full-irrigation conditions. The low moisture treatments in seedling (seedling establishment)-branching, branching-squaring, squaring-flowering, and other growth stages has a great influence on the total evapotranspiration during the whole growth period, compared to treatment 1, the low moisture treatment at the branching-squaring stage decreases by 20%; at seedling (seedling establishment)-branching stage, the total evapotranspiration of whole growth period changes less, however, it can decrease by 18%, compared with treatment 6.

Table 6. *Evapotranspiration of monoculture alfalfa and maize/alfalfa intercropping at different water treatments*

Trt	Crop 1		Crop 2		Crop 3		Total *ET* (mm)
	ET (mm)	Modal coefficient (%)	ET (mm)	Modal Coefficient (%)	ET (mm)	Modal coefficient (%)	
6	347.5	45.9	294.3	38.8	84.9	11.2	726.7
7	250.1	40.5	266.2	43.1	76.6	12.4	592.9
8	270.2	44.7	206.0	34.1	103.5	17.1	579.7
9	262.1	43.1	229.5	37.8	91.5	15.1	583.1
14	326.5	43.0	276.9	36.5	57.1	7.5	660.5
15	279.7	42.6	257.8	39.2	33.8	5.1	571.3
16	303.8	45.5	235.9	35.3	40.6	6.1	580.3
17	275.5	42.9	247.3	38.5	35.0	5.5	557.8

Evapotranspiration of 4//8 type at intercropping stage under water shortage conditions

Table 6 shows, as same as monoculture alfalfa, the alfalfa high evapotranspiration period is between in the first crop and the second crop under full-irrigation conditions, however, the evapotranspiration ratio in the second crop is higher than monoculture alfalfa, in the stage, the evapotranspiration accounts for 49.43% and 41.92% of total amount of the whole growth period. The evapotranspiration of maize//alfalfa multi-storey cropping forage grass should not be equal to the sum of evapotranspiration of both two plants, this shows that the planting pattern changes growth environment, the field evapotranspiration changes. Under full irrigation conditions, the low water treatment has a greater impact on branching-squaring and squaring-flowering stages; and has poor impact on emergence-branching stage.

Influence of different water treatments on forage yield

Table 7 shows, at different growth stages, different forages show various response to water stress, but which is eventually reflected by forage yield differences. Ass for monoculture maize, the influence of water shortages on yield reduction is the greatest at heading-milking stage, and is the lowest at sprouting-jointing stage. The influence of phased water shortage on the yield (grain) is in compliance with the following rules: Treatment 4 > Treatment 3 > Treatment 5 > Treatment 2, the maize requires less moisture at seedling stage; at the jointing stage, the impact of water deficit on yield is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58135822

greater, in case of water shortage at jointing period, the yield reduction rate is 47.2%; at the heading and milking stages, the maize transfers from vegetative growth to reproductive growth, leaf area index and evapotranspiration reach its highest value during the whole period, reproductive growth and metabolism is being vigorous; at flowering, pollination and milking stages, the output efficiency is the highest, lack of water has a greatest impact, the yield reduction rate is up to 51.7%; after soft dough stage, the influence of water deficit on yield decreases gradually. At different stages, the water deficit treatment does not significantly affect moisture production efficiency of monoculture maize, which is basically the same between Treatment 1 and Treatment 2, Treatment 3 is slightly lower than Treatment 5, the influence of Treatment 4 is maximum.

Table 7. *Analysis on forage yield under different water treatments*

Treatments	ET (mm)	Total yield (dry weight kg/hm^2)	Moisture production efficiency (kg/m^3)	Yield reduction rate (%)
1	600.6	13250.0	2.2	—
2	510.5	11316.7	2.2	17.1
3	438.4	9000.0	2.1	47.2
4	450.5	8733.4	1.9	51.7
5	480.5	10316.7	2.1	28.4
6	726.7	21150.0	2.9	—
7	592.9	16031.7	2.7	24.2
8	579.7	13472.6	2.3	36.3
9	583.1	14212.8	2.4	32.8
14	660.5	2636.8	0.399	—
15	571.3	2136.8	0.289	19.0
16	580.3	1706.9	0.294	35.3
17	557.8	1693.9	0.304	35.8

As for monoculture alfalfa, when the water shortage is implemented at emergence-branching stage (the lower limit of soil moisture content is lower than 50%), the impact on the yield is minimum, the yield reduction rate is 24.2%, indicating under normal emergence seedling conditions, appropriate water shortage does not impact later yield; the branching- squaring stage is a critical period of alfalfa physiological change, water shortage has the greatest impact on later yield, the yield reduction rate is 36.35%; during the squaring-flowering period, the influence of water shortage on the total yield decreases, the yield reduction rate is 32.8%. under different moisture treatment conditions, if the water supply is sufficient, the water production efficiency of monoculture alfalfa is the highest, and 6.89% higher than that of water shortage at sprouting-branching stage, 20.69% higher than that of water shortage at branching-budding stage, and 17.24% higher than that of water shortage at budding-- flowering stage.

As for the intercropping maize/alfalfa, alfalfa has a longer growth period, under non-full irrigation experimental design is mainly base on phased water supply in alfalfa growth period. By conversion to the crude protein content in maize/alfalfa final product within one year, it is available to conclude that the water shortages at squaring-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58135822

flowering stage has the greatest impact on crude protein yield under intercropping conditions under different water treatments, which is different with the maximum influence period from water shortage of monoculture alfalfa of branching-squaring stage, indicating two kinds of forages jointly change the rules of nutrition production of the whole groups of plants in farmland.

Conclusions

As the main dairy forage, maize and alfalfa are completely different in water demands. During the whole growth period, the water demand rules of maize is a single peak parabola; during a growing season, the water demand rules of alfalfa shows multiple peaks as times of mowing increase; The evapotranspiration of maize//alfalfa multi-storey cropping forage grass should not be equal to the sum of evapotranspiration of both two plants, the rules of water demand change greatly, showing a wavy undulating state. compared to evapotranspiration of monoculture maize and monoculture alfalfa, the variation of evapotranspiration of maize//alfalfa multi-storey cropping forage groups is not very significant.

As for monoculture maize, the influence of phased water shortage on the yield is maximum at the jointing-heading and heading-milking stages (moisture sensitive period); the influence of phased water shortage is minimum at emergence-jointing stage; as for monoculture alfalfa, during the squaring-flowering and branching-squaring period (moisture sensitive period), the influence of phased water shortage on the yield is maximum; at emergence (seedlings establishment)-jointing stage, the influence of phased water shortage is minimum; as for 4//8-type multi-storey cropping, at the branching-jointing stage of alfalfa, the influence of phased water shortage on the yield is maximum, which is greatly different with monoculture alfalfa.

In future studies, in order to meet the requirements of large-scale popularization and application of multi-storey cropping, further test deepening, technology integration and demonstration of various technologies still need to be implemented., technological maturity and farmers' planting level need to be improved, and technological maturity and farmers' planting level need to be improved.

(Received 11th Jan 2019; accepted 8th Mar 2019)

Abstract. This paper takes some typical points at downstream of Jinsha River in China as examples for the overall evaluation of greenhouse gas emissions. In reference of previous literature, this study adopted the combination of headspace balance method and model estimation to obtain the partial pressures of carbon dioxide and methane in surface water and exchange fluxes of CO_2 and methane. Additionally, this paper also used field measuring instruments to measure the physical and chemical variables. The Spearman correlation index based on SPSS software are applied to analyse the relationship between between the partial pressures and fluxes of CO_2 and methane and environment variables. Experiments' results showed that mean value for partial pressure of CO_2 ($p(CO_2)$) was (1785.87 ± 451.18) μatm, ranked medium in worldwide rivers. In contrast, the average value for $p(CH_4)$ was (22.63 ± 11.48) μatm ranked relatively low in worldwide rivers. Among all sampling sites, the $p(CH_4)$ for Linjiaba, Shaonvping, Lizhuang located in reservoir area were higher than that for other sites. And the diffusion of CO_2 flux was in medium level compared with other major rivers in the world, at (1.71 ± 0.55) mmol/(m^2·h), while that of CH_4 flux kept in low level at (0.0009 ± 0.0005) mmol/(m^2·h), and all benthic flux of CO_2 and CH_4 were positive indicated the Jinsha River was the source of producing greenhouse gas., the trend of the partial pressure and flux almost remained the same. Moreover, $p(CO_2)$ in surface waters showed positive correlations with alkalinity (TA) and dissolved organic carbon(DOC), and $p(CH_4)$ showed significant positive correlations with Chl-a and temperature. CO_2 flux showed positively correlation with the $p(CO_2)$, DOC, alkalinity (TA), and CH_4 flux is positively related to $p(CH_4)$, wind speed. Other environmental factors showed vague effects on the fluxes.

Keywords: *carbon input, environmental indicators, greenhouse gas, greenhouse effect, river*

Introduction

Although the water area takes up for approximately 2% of global inland area, it largely influences the global carbon cycle (Guo et al., 2011). As the crucial connection between terrestrial ecosystem and marine ecosystem which are two main carbon carriers, river has become vital part of global carbon cycle (Ludwig et al., 1996). The carbon output from rivers is closely responsible for the change of coastal environment, marine carbon cycle and the global climate system. However, in recent years, human activities accelerate land erosion-deposition, which to a large extent stimulates the disturbance and redeposition of carbon pool in land ecosystem, and strengthens carbon transport from rivers to ocean. About 1 Gt carbon containing 60% inorganic carbon and 40% organic carbon is estimated to be transported from river to sea (Ludwig et al., 1996; Zhang et al., 2013; Cole et al., 2007). Meanwhile, river releases and absorbs carbon dioxide and methane though air-water interface, of which the amount of released CO_2 can reach at least 10^7 t/a (Li et al., 2013; Degens et al., 1991). These two typical gases emission significantly contributes 80–85% of greenhouse effect (Clarke et al., 2007). This percentage has not changed for the last 20–30 years, but the total radiative forcing which causes the increase in the planet's temperature has increased consistently

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58235839

over this time window (Getoff, 2006). The primary effect for greenhouse effect gives Planet Earth its hospitable average temperature of c. 17 °C, and the smaller secondary effect which has been in existence for only 250–300 years and is caused by an increase in concentration of greenhouse gases (Yao and Gao, 2005). As a result, measuring CO_2 and CH_4 benthic flux among water-air interface in river in a right way contribute to a better understanding the role that river play in regional or global carbon cycle and a more systematical grasp of carbon budget in river basin. Considerable researches about gas fluxes in the last decades on water-air interface almost adopted eddy covariance method, model estimation method, remote sensing inversion, etc (Zhao et al., 2011b). Among these methods, field monitoring usually employs model estimation method for its simplicity, flexibility and practicality. Precisely, Model evaluation method applies the Fick law to evaluate the flux in accordance with Gas concentration gradient between air and water interface where difference of gas concentration between two medias Mass Transfer Coefficient are critical (Urabe et al., 2010; Jonsson et al., 2007; Huang and Wang, 2009).

Jinsha River is the upper reaches of the Yangtze River flowing though east northern of The Yunnan-Guizhou Plateau and west southern part of Sichuan Highland to the Minjiang River in Yibin City. Its length is 2326 km and its basin acreage which takes up 26% of the Yangtze River is 47.3×10^4 KM^2. In addition, it means annual discharge is 4750 m^3/s. Due to the large area covered by Jinsha River, systematic and correct measure of greenhouse gas budget is critical for carbon cycle research. What should be noted is the processes of gas exchange between water-air interfaces are not only impacted by wind speed and temperature, but also related to depth and acreage of waters. Adopting the model estimation method to measure the CO_2 and CH_4 benthic flux, while there were few researches, should take the following factors into consideration, while there were few researches. In this paper, aiming at the downwards of Jinsha River from Panzhihua City to Yibin City, the research obtained the live data of CO_2 and CH_4 partial pressure in surface water and environmental parameters for field monitoring. Then the research used thin boundary layer method to estimate benthic flux of greenhouse gas and elementarily analyze the correlation between the environmental parameter and the partial pressure as well as the benthic flux. In downstream of Jinsha River, Wudongde hydropower station and Baihetan hydrogen station are being constructed, and Xiluodu hydrogen station and Xiangjiaba hydrogen station have been put into effect. The operation of newly-built hydropower stations will impact the carbon cycle in this area. A research on greenhouse flux on water–air interface is critical to illustrate variation change of carbon cycle after constructing plants and give information for reliability of hydropower energy system.

Materials and methods

Research objective

We researched at the downwards of Jinsha River (N24°29'—28°53' to E100°57'—104°38') from Panzhihua City (the junction of Yalong River and Jinsha River) to Yibin City (the junction of Min River and Jinsha River) in China, of which the length was 768 km and and fall of water level was 719 m. From the upstream to downstream, a series of sampling positions were Geliping (GLP), Longjiedu (LJD), Jiaopingdu (JPD), Geledu (GLD), Yanziyan (YZY), Linjiaba (LJB), Shaonvping (SNP), Lizhuang (LZ), of which the locations were shown in *Table 1* and *Figure 1*. Among 8 sampling sites,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58235839

Shaonvping and Yanziyan are located in the reservoir area in front of Xiangjiaba hydropower station and Xiluodu hydropower station respectively, and Linjiaba site is located at the reservoir area between these two hydropower stations. We collected samples by taking local boat along the waterway in January 2016. Due to the rapid flow in Jinsha River, we gathered the water samples as well as relative environmental indicators in central of waterway. The scenes for sampling at Shaonvping, Gelefu, Yanziyan, Lizhuang are shown in *Figure 2*.

Measure method for CH_4 and CO_2 in water-air interface

To measure water-air interface gas partial press, recent research mainly adopted following two methods: static closed chamber- Gas chromatography method and the headspace equilibrium method and thin boundary layer method. However, on the condition of wind blows and flowing water, the disturbance caused by friction between the chamber and surface water may cause extra emission of greenhouse gas which will influence the accuracy of experimental result from the former method (Pumpanen et al., 2004). And this method is labor-intensive and it is unfit for large-scale and long-term observation (Tremblay et al., 2005; Kolb and Ettre, 2006). As a result, the static closed chamber technique only suits static water. Considering that the rapid flow of Jinsha River, long distance between sampling spots and poor weather condition during experiments, we use the latter method to observe the water-air interface greenhouse gas emission in the downstream of Jinsha River.

The principle of headspace equilibrium method

The principle of headspace equilibrium method is to obtain partial press of testing gas in water before equilibrium by measuring the concentration of the gas in upper space when gas concentration in water and air stay balance after rapid shake in the glass bottle filled with water sample and inert gas. The calculation is show as follows (Goldenfum, 2010):

$$p_{(Gas)} = \frac{(p_{final} \times K_{equilibrium}) + ((\frac{HS}{5}) \times \frac{(p_{final} - p_{initial})}{V_m}}{K_{sample}} \quad \text{(Eq.1)}$$

where the $p_{(Gas)}$ illustrates partial press of testing gas (μatm), and $p_{initial}$ and p_{final} denote testing gas partial press in upper part of bottle before and after equilibrium (μatm), and *HS/S* represents The volumetric properties for the gas mixture (mol/L), V_m demonstrate the molar volume of gas, K_{sample} and $K_{equilibrium}$ show solubility of testing gas at weather in bottle when sampling and experimenting respectively (mol/(L·atm)). And Henry coefficient of different gases can be calculated by following equations (Weiss, 1974; Weast and Astle, 1987):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58235839

$$\ln K_0(CO_2) = -58.0931 + 90.5069 \times (\frac{100}{T_K}) + 22.294 \times \ln(\frac{T_K}{100}) + s \times (0.027766 - 0.02588 \times (\frac{T_K}{100}) + 0.0050578 \times (\frac{T_K}{100})^2) \quad \text{(Eq.2)}$$

$$\ln K_0(CH_4) = -115.6477 + \frac{155.5756}{(T_K/100)} + 65.2553 \times \ln(\frac{T_K}{100}) - 6.1698 \times (\frac{T_K}{100}) \quad \text{(Eq.3)}$$

$$V_m = 1 \times 0.082057 \times (273.15 + T) \times \left(\frac{101.325}{p}\right) \quad \text{(Eq.4)}$$

where T is temperature when sampling (°C) and p is atmospheric pressure when sampling (kpa). 2.2.2 Water-air interface gas benthic flux

The water-air interface gas benthic flux mainly impacted by partial press of gas in surface waters and gas transfer coefficient which is influenced by flowing speed, blowing speed and weather, etc. According to Fick Law, for freshwater bodies, the water-air interface gas benthic flux is obtained as follows (Weast and Astle, 1987):

$$Flux = k_x \left(C_{water} - C_{equilibrium} \right) \quad \text{(Eq.5)}$$

with *Flux* as greenhouse diffusion flux (mmol/(m^2·h)), k_x as gas exchange coefficient (cm/h), C_{water} as the gas concentration in water (mmol/L), $C_{equilibrium}$ as greenhouse gas saturation concentration in site weather and atmospheric pressure (mmol/L).

And k_x is estimated worldwide mainly by following empirical equation adopted by Jähne et al. (1989):

$$k_x = k_{600} \left(\frac{600}{Sc} \right)^{0.67} \quad \text{(Eq.6)}$$

with k_{600} as exchange coefficient of sulfur hexafluoride (SF_6) gas (cm/h). Considering sampling spots are being constructing or have been constructed hydraulic power plant, we choose the exchange coefficient for CO_2 and CH_4 for lakes and reservoir eco-system from empirical formula (shown as *Equations 7* and *8,* respectively (Cole and Caraco, 1998; Macintyre et al., 2006)

$$k_{600} = 2.07 + 0.215 \times U_{10}^{1.7} \quad \text{(Eq.7)}$$

$$k_{600} = 2.07 + 0.215 \times U_{10}^{1.7} \quad \text{(Eq.8)}$$

U_{10} illustrates wind speed on 10 m above the water (m/s). It is usually acquired by following formula using wind speed U1 above water body measured at site (Crusius and Wanninkhof, 2003).

$$U_{10} = 1.22 \times U_1 \quad \text{(Eq.9)}$$

where U_1 denotes instantaneous wind speed above water level from meteorological station (accuracy is 0.1 m/s).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58235839

And *Sc* denotes Schmidt constant at t °C. For freshwater, it can be calculated as follows (Roehm et al., 2009; Wanninkhof et al., 1992):

$$Sc(CO_2) = 1911.1 - 118.11t + 3.4527t^2 - 0.04132t^3 \quad \text{(Eq.10)}$$

$$Sc(CH_4) = 1897.8 - 114.28t + 3.2902t^2 - 0.03906t^3 \quad \text{(Eq.11)}$$

Then, greenhouse gas saturation concentration in water sample will be achieved by that partial press of greenhouse gas multiply by Henry coefficient shown as follows (Morel, 1982; Anderson, 2002; Zhang et al., 2009):

$$C_{equilibrium} = K_0 \times p(Gas) \quad \text{(Eq.12)}$$

In *Equation 12,* K_0 denotes Henry coefficient which is defined as gas solubility (mol/(L·atm)) and *p(Gas)* show atmospheric pressure when experimenting (μatm).

The calculation procedure for greenhouse gas partial press and flux

The $p(CO_2)$ and $p(CH_4)$ in water were calculated within headspace equilibrium method though Agilent 7820A gas chromatograph according to Henry coefficient, water temperature, atmospheric pressure, volumetric property of gas and liquid in headspace bottle (5/7). And k_x is in connection with Schmidt constant from water weather and U_{10} obtained from *Equation 11* (m/s). The downstream of Jinsha River was rarely impacted by farmland, wetlands and human, we determined the mean concentration of CO_2 and CH_4 in atmosphere as 390.5 ppm and 1.803 ppm respectively with reference to Gui's and Zhang's research on the Yellow River an d the Yangtze river (Zhang et al., 2009; Gui, 2007). The whole process of calculation for greenhouse gas measurement by Headspace equilibrium method and Thin Boundary Layer Equation (TBL) method were shown in *Figure 3*. All field measuring apparatus had been calibrated standardly.

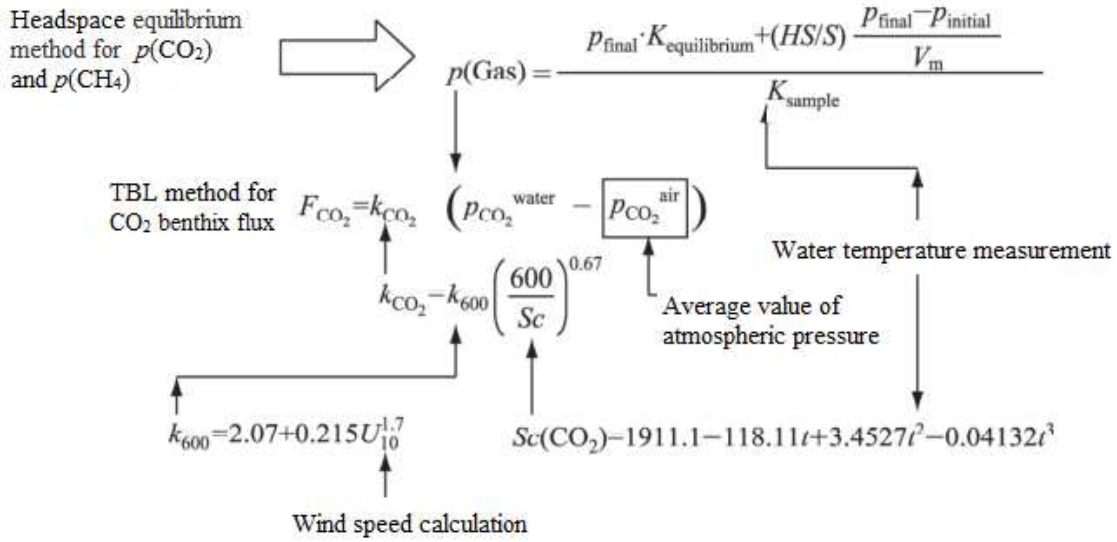

Figure 3. *The process of calculation for greenhouse gas*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58235839

Researching material and methods for sampling

Water sample was collected at 0.5 m depth by water sampler where headspace bottle was place inside to seal when submerging at each spot, and the water samples and headspace bottles were preserved at low temperature.

For environmental parameters measurements, pH, electrical conductivity and salinity were measured by YSI Multi-parameter instrument, temperature and atmospheric pressure were measured by handheld digital atmospheric pressure gauge, alkalinity (TA) was accessed from titration with standard sulfuric acid solution by microtiter from HACH Company (accuracy is 1.25 μl), the effective intensity of photosynthesis was measured by LI-COR19OSA Light quantum instrument, the solar radiation intensity came from the illuminometer, water temperature and Dissolved Oxygen (DO) were obtained by site measurements with YSI ProODO Dissolved oxygen meter (accuracy is 0.1 °C, 0.01 mg/L respectively), Chlorophyll-a(Chl-a) adopted acetylacetone spectrophotometric method, concentration for Dissolved Total Nitrogen (DTN) and dissolved inorganic carbon (DIC) were measured by Shimadzu® TOC-V total carbon analyser from filtrates though What-man GF/F fibrous glass filter paper heated for 4 hours at 450 °C (Bates et al., 2011). Concentration for dissolved total phosphorus (DTP) measurements adopted Potassium persulphate- spectrophotometric method.

Researching method for analysis

The statistical analysis and calculation of this study data are proceeded by SPSS ® or Origin ®. And the spearman correlation analysis are adopted to understand the linear correlation between data changes and chlorophyll - a regression analysis relating to p (CO_2), p (CH_4), CO_2 and CH_4 fluxes and various physical and chemical indicators (pH, TA, DO, DOC, etc.), water temperature. The significant correlation are judged by the value for coefficient p shown as follow, when value for p which are below 0.05 means significant correlation and when value for p which are below 0.01 means extreme significant correlation.

$$\rho = \frac{\sum_i (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_i (x_i - \bar{x})^2 \sum_i (y_i - \bar{y})^2}}. \quad \text{(Eq.13)}$$

Result and analysis

Partial press of CO_2 and CH_4 in surface water and water-air interface benthic flux

The partial press of carbon dioxide $p(CO_2)$ and methane $p(CH_4)$ in surface water in the downstream of Jinsha River in January 2016 are shown in *Figure 4*. Along the flowing orientation, $p(CH_4)$ approximately grew. The highest $p(CH_4)$ appeared at lZ sampling site (45.62 μatm), while the lowest point showed at GLD sampling site(12.01 μatm). The average value of $p(CH_4)$ was 22.63 ± 11.48 μatm. $p(CO_2)$ showed no definite change. The highest and lowest points are GLD (2491.23 μatm) and LJB (1030.11 μatm) respectively, and the mean value of $p(CO_2)$ was 1785.87 ± 451.18 μatm. The value of $p(CH_4)$ at YZY, LJB, SNP three sampling sites were relatively low.

The water-air interface benthic flux of carbon dioxide and methane in surface water at all sampling sites in the downstream of Jinsha River in January 2016 are shown in *Figure 5*. The flux of CO_2 and CH_4 were all positive which means the downstream of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58235839

Jinsha river was the source of greenhouse gas emission. The mean value of CH_4 and CO_2 were 0.0022 ± 0.0002 mmol/(m^2·h) and 2.27 ± 0.48 mmol/(m^2·h) respectively. The streamwise flux variation for each gas was similar to partial pressure variation of that gas. Because the TBL model method only concerned about the benthic partial press of gas and did not concern about the bubble diffusion which was the main diffuse means for CH_4, the measurement results of CH_4 flux might be smaller than actual level.

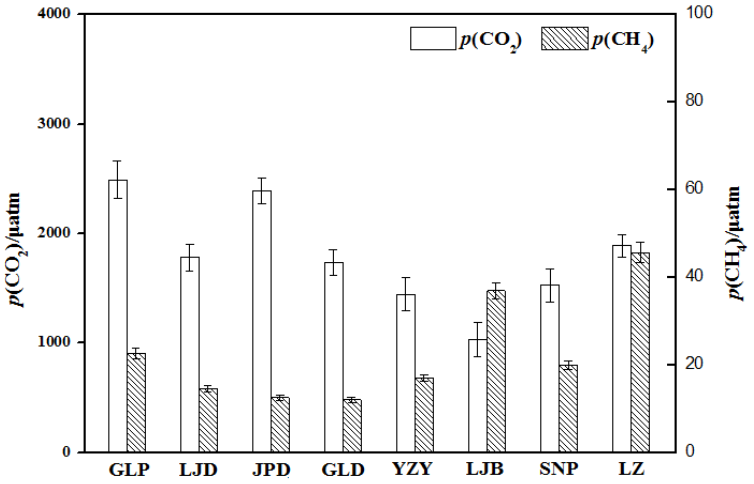

Figure 4. *Variation of streamwise of surface water of $p(CO_2)$ with $p(CH_4)$*

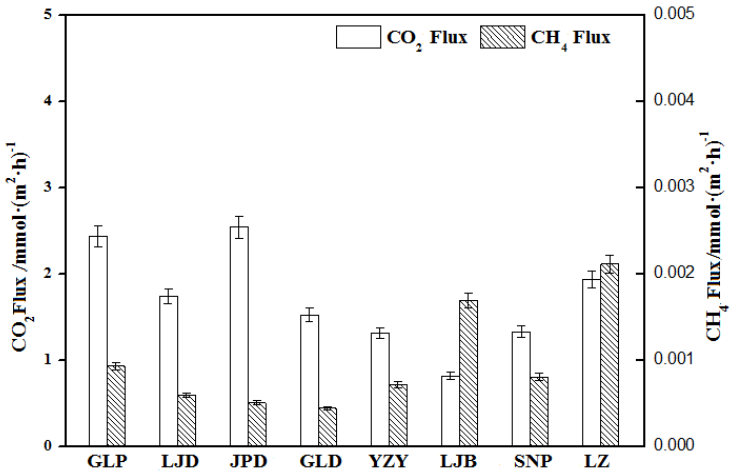

Figure 5. *Variation of streamwise of exchange flux of CO_2 and CH_4 between water and air*

Variation of environmental indicators

Water temperature and pH

The water temperature and pH variation along the river flowing route is shown in *Figure 6*. In January 2016, water weather changed a little in all sampling sites. The mean temperature was 14.7 ± 1.5 °C. The highest water weather was measured at GLP site, at 17.4 °C, in contrast, the water weather at GLD site was lowest, at 12.8 °C. The pH of surface water was almost same. The mean pH value was 7.14 ± 0.22 which

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58235839

demonstrate the surface water of downstream of Jinsha River in winter was neutral. The pH value at LJD site was highest at 7.43 while the lowest pH value was at YZY site, at 6.78. And there was no obvious change tendency in all sampling sites on the flowing direction.

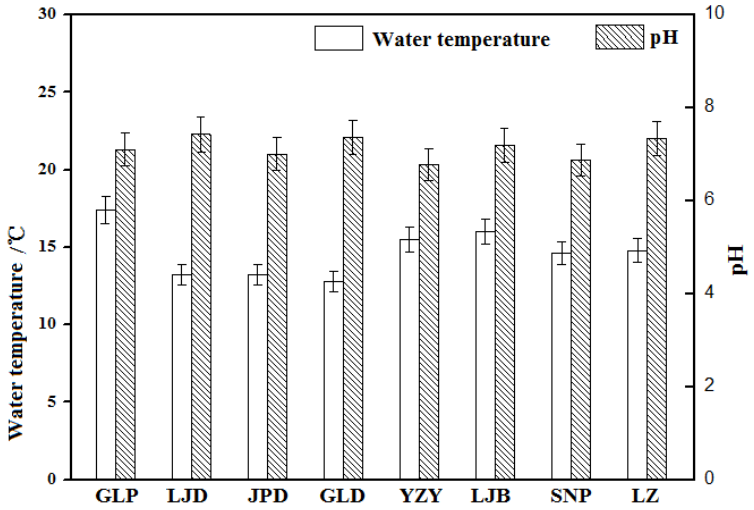

Figure 6. *Variation of streamwise of water temperature and pH in the water*

TA and Chl-a

The changes of TA and Chl-a along the river flowing route is shown in *Figure 7*. The highest Chl-a appeared at LJB site (30.456 $mg \cdot L^{-1}$), and Chl-a values in YZY, LJB, SNP sampling sites were relatively high. Because SNP, YZY, LJB site are located at the reservoir area of Xiangjiaba and Xiluodu hydropower stations. In reservoir area, the flowing speed is lower than the other area, and water capacity is larger. As a result, the reservoir area is suitable for growth of phytoplankton, and Chl-a was relatively bigger than that in other area. On the other hand, TA showed no obvious change mode, and the value of TA changed a little in all sampling sites.

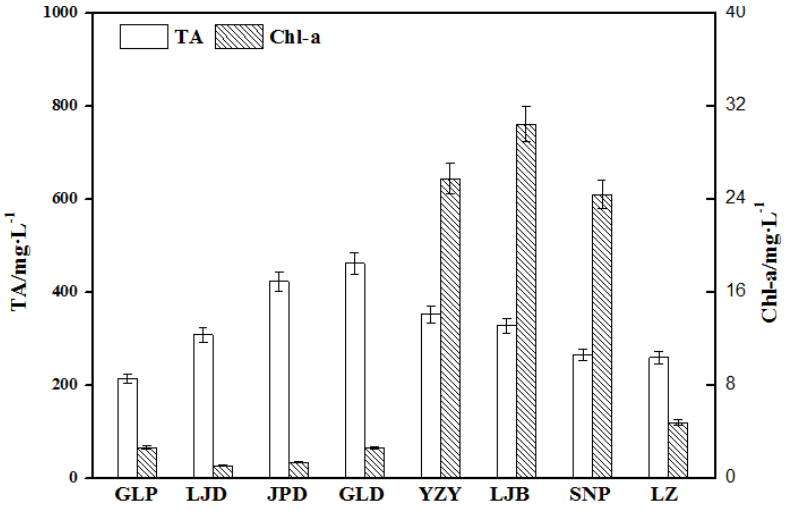

Figure 7. *Variation of streamwise of TA and Chl-a in the water*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58235839

DTN and DTP

The changes of DTN and DTP in 8 sampling sites along the river flowing route are shown in *Figure 8*. The fluctuation of DTP was similar to that of DTN among all sampling sites. The value of DTP and DTN in LJD were both highest, at 0.39 $mg \cdot L^{-1}$ and 5.3709 $mg \cdot L^{-1}$, respectively, in contrast, Chl-a in LJD site was lowest. And DTP and DTN in YZY, LJB and SNP were relatively low while Chl-a in these three sites were comparatively high. This proved phosphorus and nitrogen were absorbed adequately by phytoplankton.

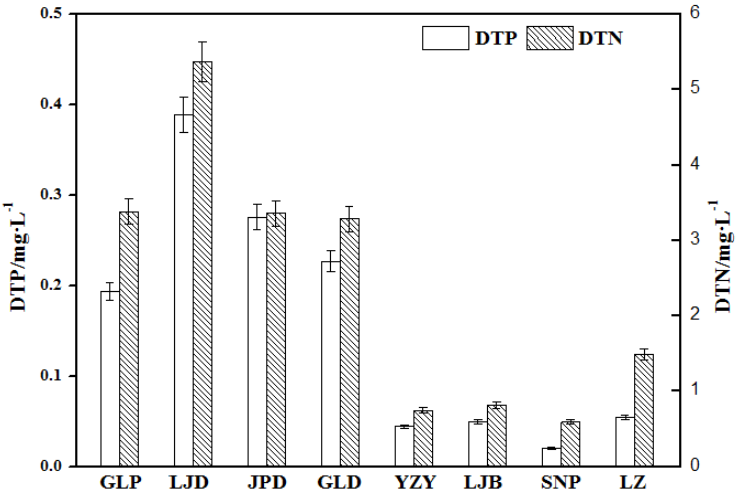

Figure 8. *Variation of streamwise of DTN and DTP in the water*

DO and DOC

The distribution of DO and DOC at all sampling sites in downstream of Jinsha River along the river flowing route are shown in *Figure 9*. DO in surface water generally climbed streamwise, companying with some decrease in last three sites. The average value for DO in water was (9.53 ± 1.00) $mg \cdot L^{-1}$, the highest and lowest DO were measured at SNP site (11.22 $mg \cdot L^{-1}$) and LJD site (7.94 $mg \cdot L^{-1}$) respectively. DOC in water varied a little along the flowing route which showed no obvious law. The mean value for DOC in January 2016 was (3.37 ± 0.14) $mg \cdot L^{-1}$, DOC in LJB and LZ sampling sites were highest 7 (3.60 $mg \cdot L^{-1}$) and lowest (3.19 $mg \cdot L^{-1}$) respectively among all sites in downstream of Jinsha River.

Discussion

The fluctuation of measured parameters on the streamwise

In the research, we focus on the partial pressure and flux of carbon dioxide and methane as well as the physical and physicochemical indicators at several sampling sites. From the experimental result, some changes appear along the river flowing direction, especially at last three sites near the reservoir. $p(CH_4)$ and flux of methane showed generally the same tendency of change, which have both increased at these three sites. This phenomenon indicates that these three sites have large water capacity contributing to low flowing speed, the stable water environment give rise to forming

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58235839

strong microbial community construction. As a result, water provides suitable and better environment for microbial community construction. In addition, neighbour reservoir contains amount of organic matter after submerging the surrounding ecosystem, and these substances are the best nutrients for microorganism in surrounding area. After decaying and decomposing process, methane is generated and emitted (Wang, 2017; Jin and Wei, 2008). Similarly, Roehm and Tremblay (2006) found that there was a significant correlation between the concentration of methane between the environment in the deep water of the reservoir and environment in the downstream rivers ($R^2 = 0.80$ and 0.70). It is also estimated that about 70% of methane and 40% of carbon dioxide emissions have occurred in the river downstream of the Petit Saute reservoir in Guiala, France for more than a decade (Friedl and Wuest, 2002). In conclusion, existence of reservoir is proved to impact the greenhouse gas emission and ecosystem in surrounding water environment.

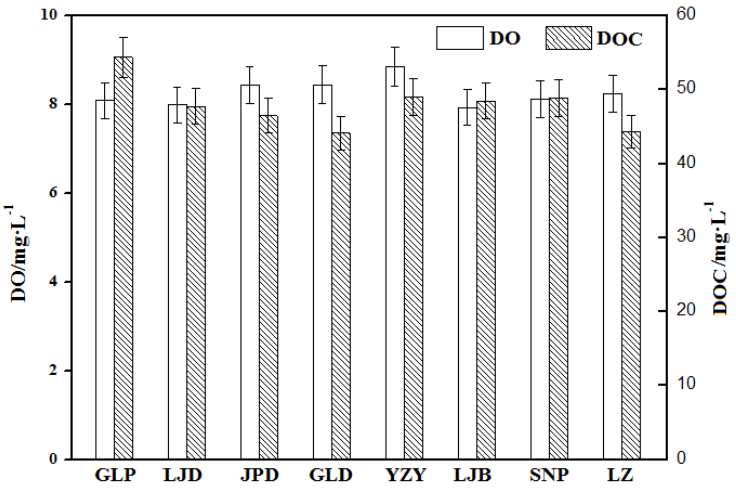

Figure 9. *Variation of streamwise of DO and DOC in the water*

Partial physical and chemical indexes also changed in these three sites. The concentration of Chl-a increased while DTN and DTP showed the reverse trend. The large capacity of water shapes better environment for photosynthesis contributing to the rise of concentration of Chl-a. Studies have shown that nitrogen content and nitrogen use efficiency of most plant leaves are positively correlated with photosynthetic capacity, which is one of the inherent physiological and ecological characteristics of plants (Evans, 2002; Cheng et al., 2012). Therefore, in the three sampling sites where photosynthesis effects increase, plants' utilization of ammonia nitrogen became stronger, so that DTN in water decreased (Wang and Xu, 2005). In terms of other estimators, the flux and partial pressure of carbon dioxide, water temperature, pH, TA and DOC showed no significant fluctuation law along streamwise orientation.

The correlation analysis between the partial press and flux of CO_2 and CH_4 and environmental indicators

We raised Spearman connection analysis method to illustrate the relationship between $p(CO_2)$, $p(CH_4)$, CO_2 flux, CH_4 flux and environmental indicators. The result given in *Table 2* showed that $p(CO_2)$ in surface water has significant positive correlation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58235839

with DTN, DTP and negative correlation with DO, Chl-a, DOC. This proved the photosynthesis of phytoplankton in water was stronger than its respiration. The stronger photosynthesis worked, the more Chl-a was measured, the more CO_2 were fixed which decrease $p(CO_2)$ in water, the more nitrogen and phosphorus DTP and DTN in water was absorbed, the more DO and DOC were produced. The CO_2 flux demonstrated positive correlation with $p(CO_2)$, wind speed and negative correlation with DO, Chl-a, DOC which resemble $p(CO_2)$. And the wind blow would enhance the diffusion of CO_2.The $p(CH_4)$ showed negative correlation with Chl-a, TA and positive correlation with wind speed and water temperature. It is determined that the higher water temperature decreased the solubility of CH_4 in water, and naturally, $p(CH_4)$ increased when CH_4 diffused into surface water. In addition, relatively higher temperature and vigorous growth of phytoplankton provide a suitable metabolism environment for methanogen that contribute to producing CH_4 (Hong et al., 2004). Meanwhile, wind blowing will give rise to diffusion of CH_4 in surface water. The CH_4 flux showed positive correlation with $p(CH_4)$, wind speed, water temperature and negative correlation with Chl-a, TA which was similar to correlation of $p(CH_4)$. What can be proved is the larger value of $p(CH_4)$ indicated the larger CH_4 flux.

Table 2. *Correlations between $p(CO_2)$, $p(CH_4)$, flux of CO_2, flux of CH_4 flux and environment factors*

Comparison of Jinsha River with other worldwide rivers for greenhouse gas concentration and flux

Comparison for CH_4 concentration and flux in Jinsha River and other rivers

Methane in general river mainly stem from direct produce, release from sediment and input of water enriching CH_4 in surrounding. Considering particulate organic carbons take minority of total suspended particulates, a small amount of CH_4 produced directly at site comparing to other two producing methods. Relative research indicated that concentration of CH_4 in surface water of downstream of Jinsha River was relatively low no matter in summer and in winter, because not only methane produced a little at site, but also a few human lived on the riverside of Jinsha River, and input of CH_4 from branch of Jinsha River is relatively low. In reference of previous researches, considering the wide river basin and large covering area of Jinsha River, we chose several typical

DOI: http://dx.doi.org/10.15666/aeer/1703_58235839

large rivers to make comparison. *Table 3* showed $p(CH_4)$ and CH_4 flux in the surface water of the world rivers. Average concentration of CH_4 in surface water was (39.35 ± 20.32) nmol·L^{-1}, lower than other river worldwide. And average value for CH_4 diffusion flux in Jinsha River was (23.36 ± 0.67) μmol/(m^2·d), and it was lower than other river. It might be caused by measure method and calculation equation that need further research.

Table 3. *The p(CH_4) and exchange flux of CH_4 in the surface water of the world rivers*

Comparison for CO_2 concentration and flux in Jinsha River and other rivers

CO_2 in worldwide majority river were oversaturated where $p(CO_2)$ were measured at 2000 to 8000 μatm and $p(CO_2)$ in some tributary even surpassed 10000 μatm (Cole and Caraco, 2001; Richey et al., 2002). In recent years, there were some researches about $p(CO_2)$ in river. Gui's research demonstrates $p(CO_2)$ was 790-1600 μatm in mainstream of Yellow River in fall and Zhang's research showed $p(CO_2)$ was 860-1600 μatm in mainstream of Yangze River in a whole year (Gui, 2007; Zhang et al., 2009). Because these rivers are the typical worldwide rivers, through comparing the carbon dioxide emission in these rivers can understand the CO_2 emission level in Jinsha River. *Table 4* illustrated $p(CO_2)$ and CO_2 flux in the surface water of the these rivers. From *Table 4,* the average value of $p(CO_2)$ in surface water in downstream of Jinsha River was 1785.87 ± 451.18 μatm that ranked medium comparing to worldwide other river such as Amazonian rivers, Hudson River. And average value of CO_2 diffusion flux on water-air interface was $(1.71 \pm 0.55$ mmol/(m^2·h) ranked medium when comparing with other worldwide rivers.

There are four hydropower stations being constructed and constructing in downstream of Jinsha River: XIangjiaba hydropower station and XIluodu hydropower station have been put into production since 2014, Baihexi hydropower station will begin working in 2020, and Wudongde hydropower station is going to be in operation by 2021. The operation of hydropower stations and reservoir storage might impact carbon

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58235839

cycle in Jinsha River. It is vital to discover the impact of operation of hydropower station study upon greenhouse gas emission in downstream of Jinsha River, and it also plays crucial role of researching in carbon cycle development in this area. From our study, at Yanziyan site, Shaonvping site and Linjiaba site that located in reservoir district, $p(CH_4)$ and CH_4 exchange flux were relatively higher than other sites, while $p(CO_2)$ in these sites were lower than other sites and CO_2 flux showed no obvious change in these 3 sites. It can be proved from current data that the construction and operation of hydropower station did not cause severe greenhouse effect, and this need further research.

Conclusion

A systematic and correct acknowledge the greenhouse gas concentration and benthic flux in river can get a better understanding of the role river played in carbon cycle. And the construction of hydroelectric station may influence the carbon flow in eco system in surrounding area. There are 4 newly-built hydroelectric stations on the downstream of Jinsha River, the major river in China where measurement of CO_2 and CH_4 partial press and flux will illustrate the effect of hydroelectric plant upon carbon cycle and demonstrate whether hydroelectric plant will enhance the greenhouse effect. Considering the rapid current in Jinsha River, we adopted the headspace equilibrium method with combination of TBL model methods to obtain the partial press and concentration of carbon dioxide and methane.

At first, the brief introduction of research objective, Jinsha River and the specific sampling sites were illustrated. Then we reported the principle of headspace equilibrium method to obtain partial press and TBL model estimation method for benthic flux based on the Fick Law with gas transfer coefficient considering the impact of flow speed, wind speed and temperature. And we conclude the calculation procedure for partial press and flux from *Equations 1* to *12*. Moreover, environmental indicators measure method, apparatus and experimenting material were listed to show the measurement procedure.

In result and analysis part, firstly, we demonstrated the partial press and flux of CH_4 and CO_2. The $p(CH_4)$ generally climbed with the mean value of (22.63 ± 11.48) μatm showed the methane increasing in reservoir sites. The $p(CO_2)$ showed no obvious changing trend along the flowing route with the mean value of (1785.87 ± 451.18) μatm. And the flux of CH_4 and CO_2 variation trend was similar to $p(CH_4)$ and $p(CO_2)$ respectively, and them were both positive proved Jinsha River was the source of greenhouse gas emission. Then the variations of environmental indicators including water temperature, pH, Chl-a, TA, DTP, DTN, DO and DOC were displayed to show the differences between the natural sampling site (GLP, LJD, JPD, GLD, YZY) and sampling sites in reservoir area (LJB, SNP, LZ). From the fluctuation, Chl-a and flux and partial pressure of CO_2 increased in reservoir area while DTN and DTP dropped in reservoir area, and TA, DO and DOC showed no obvious variation which indicated phytoplankton grew prosperously would absorb N and P in suitable water temperature. And in winter, pH was neutral in downstream of Jinsha River. It is acknowledged the existence of reservoir will influence the surrounding water environment. Furthermore, the discussion part showed the correlation between partial press and flux of greenhouse gas and environmental indicators by Spearman correlation analysis method. The result came out that $p(CO_2)$ in surface waters showed positive correlations with alkalinity

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58235839

(TA) and DOC, and $p(CH_4)$ showed significant positive correlations with Chl-a and temperature. CO_2 flux showed positively correlation with the $p(CO_2)$, DOC, alkalinity (TA), and CH_4 flux is positively related to $p(CH_4)$, wind speed. And $p(CO_2)$ and flux for CO_2 was ranked as medium while $p(CH_4)$ was ranked as low comparing to other worldwide rivers.

All in all, $p(CH_4)$ and CH_4 diffusion flux were relatively higher in reservoir area, $p(CO_2)$ was lower in reservoir area than that in natural area, and CO_2 diffusion was not obvious in reservoir area. So it can be demonstrated that the construction and operation of hydroelectric stations impact not much at greenhouse effect and this need more research to complement.

Abstract. This study examined the best option for remediating soil contaminated with crude oil through the addition of the inorganic nutrients C:N:P (yeast extract-glucose, NH_4Cl-$NaNO_3$ and K_2HPO_4-K_3PO_4), in order to increase the degradation of TPHs in the soil. To the contaminated soil a physicochemical characterization was made to know the initial conditions of the inorganic nutrients. The controlled conditions in the biostimulation strategy were 20 days of incubation under uncontrollable ambient temperature conditions. Responses measured after the experiments were residual TPHs, surface tension, respiratory activity and microbial counting. After an incubation period of 20 days, the best treatments found were Y5, which contains the nutrient source glucose-$NaNO_3$-K_3PO_4, and Y4 (yeast extract-NH_4Cl-K_2HPO_4), with degradation efficiencies of 14.0 and 12.8%, respectively. Biostimulation with inorganic nitrogen and phosphorus increased the metabolic activity of indigenous microorganisms in the soil and thereby increased the degradation of petroleum hydrocarbons. The Y5 and Y4 treatments can be considered as suitable for use as a biostimulation strategy in soils contaminated with TPHs.
Keywords: *bioremediation, inorganic nutrients, crude oil, soil remediation, bacterial population*

Introduction

A vital raw material for the operation of industries and private businesses, oil has become the most important non-renewable resource for modern society (Costa et al., 2012). However, it is a potential source of pollution in the seas, soil and air (Liu et al., 2010), causing major environmental problems worldwide. The degradation of organic pollutants, such as petroleum hydrocarbons, is limited by the assimilation capacity of the native flora of the soil. In some cases, natural attenuation cannot sufficiently eliminate xenobiotics from the soil due to the potential effect of soil conditions, such as organic matter content, soil particle size and microbiota density (Abed et al., 2015). Bioremediation is a technique that uses the metabolism of microorganisms to transform

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58415850

hydrocarbons into CO_2 and H_2O. It has been found that significant optimization of remediation parameters and increased microbial activity occur when strategies, such as biostimulation, are employed (Coulon et al., 2012).

This strategy entails the addition of nutrients to the indigenous community of microorganisms to incentivize metabolic action and improve the degradation of the pollutant being treated (Abed et al., 2014; Taccari et al., 2012). It should be noted that the application of this type of technique is recommended when the soil to be treated lacks the nutrients necessary for bioremediation. While bioaugmentation has resulted in higher rates of degradation in some cases (Ma et al., 2015; Taccari et al., 2012), the stimulation of indigenous microorganisms has resulted in the significant reduction of hydrocarbons in the soil (Suja et al., 2014; Silva et al., 2009). Thanks to biostimulation, groups of microorganisms native to the soil, such as archaebacteria, contribute directly or indirectly to the elimination of petroleum hydrocarbons (Ghoreishi et al., 2017; Ghosal et al., 2016). Therefore, in some cases, bioremediation mechanisms are stimulated by increasing the growth of indigenous hydrocarbon-degrading microorganisms (Milic et al., 2009); however, in others, remediation is ineffective as the degradation effect requires too much time (Couto et al., 2010; Bento et al., 2005) due to the lack of limiting nutrients that accelerate the remediation carried out by indigenous microorganisms (Atlas and Hazen, 2011).

Research on biostimulation has been conducted on indigenous microorganisms from different types of soil, with different sources of nutrients applied to improve microbial activity and degrade petroleum hydrocarbons (Abed et al., 2015; Hassanshahian et al., 2014; Taccari et al., 2012). However, this research was conducted on a tropical soil lacking nutrients and with a low density of indigenous microorganisms. Therefore, this study aimed to evaluate both the efficiency of total petroleum hydrocarbons (TPHs) degradation by applying biostimulation with the addition of various sources of nutrients (carbon, nitrogen and phosphorus) and the effect of the production of biosurfactants in the soil.

Materials and methods

Selection of the study area and soil sampling

Soil with a history of spills with petroleum hydrocarbons was collected in the municipality of Poza Rica, Veracruz, located at 20º 32" north latitude and 97º 27" west longitude, at an altitude of 50 m.a.s.l., at a depth of 5 at 40 cm. Seven simple samples from different points in the contaminated site were collected, around 10 kg were taken per sample, the samples were collected before noon to avoid moisture loss and transported under shade. In the laboratory, all samples were mixed to form a composite sample. The soil is categorized as clay-sandy with conglomerate materials. The region has a warm climate, an average annual temperature of 24.2ºC, average annual precipitation of 1,010 mm and relative moisture of 76 to 80% (INEGI, 2015).

Physicochemical characterization of the soil

Different physicochemical parameters of the soil were taken to verify that it was a soil type viable for the application of biostimulation. Each parameter was taken in triplicates (*Table 1*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58415850

Table 1. *Physical and chemical properties of the soil*

Parameter	Value	Method
Moisture (%)	32.64 ± 0.46	Gravimetric
pH	7.85 ± 0.01	Potentiometric
Density (g/cm^3)	1.09 ± 0.03	Pycnometer
Total nitrogen (%)	0.25 ± 0.00	Micro-Kjeldahl
Assimilable phosphorous (mg/kg)	n/d	Bray I
Organic matter (%)	11.14 ± 0.26	Oxidation with chromic acid and sulphuric acid
Texture	Clay-sandy	Hydrometer
TPHs (mg/kg)	50,000 ± 852	Gravimetric
Total bacteria (CFU)	1.04 x 10^4 ± 3.21 x 10^2	CFUs
Total fungi (CFU)	1.06 x 10^3 ± 3.06 x 10^1	CFUs

Note: n/d: not detected, ±: standard deviation.

The characterization of the contaminated soil revealed an unfavorable proportion between the main nutrients, namely nitrogen and phosphorus. According to Tindal (2005), the TPHs content shows that this a highly contaminated soil, with a slightly alkaline pH and a moisture content close to 30%. The presence of petroleum hydrocarbons causes higher proportions of C, resulting in a deficiency of both N and P (Atlas and Hazen, 2011). According to Abed et al. (2014), the concentration of indigenous microorganisms is low due to the N and P deficiency, as these nutrients are limiting factors in the growth of microorganisms. Given the low microbial mass, it was decided to apply nutrients to the soil in order to increase both microbial density and the degradation of TPHs.

Experimental development

From the composite sample we proceeded to make an experimental design of 2^3 (*Table 2*), they were taken 2 kg of soil in wet base and placed in trays.

Table 2. *Representation of factors and levels, the experimental matrix for the 2^3 factorial design, the experimentation plan, and the responses measured*

Factors (Independent Variables)						**Levels**	
Sources of:				-1 (g.kg^{-1})		+1 (g.kg^{-1})

The experimental design consists of 8 biostimulation treatments with different nutrients in order to obtain the best combination and apply to a bioremediation process of the sampling site. In addition, two controls (C1 and C2) were added, C1 contained contaminated soil sterilized and C2 was prepared with the same soil without addition of nutrient alone with the native microflora. For each treatment three replicates were made. The selection of inorganic nutrients was made according to Hassanshahian et al. (2014), with some modifications. The controllable parameters were: 20 days of incubation; humidity at 30%; and, soil contaminated with 50,000 mg/kg of TPHs, placing the samples under shade. The uncontrollable conditions in this work were the temperature that was presented throughout this design being of an average within 20 days of 30 ± 3 °C. The response variables that were measured after treatment were residual TPHs, surface tension, respiratory activity and the number of colony forming units (CFU) of microorganisms.

Measurement of response variables

Determination of TPHs

The extraction of TPHs from the soil was carried out according to Dias et al. (2012), with some modifications. In a conical centrifuge tube, to which 1 g of moisture base soil, 2 g of Na2SO4 and 10 ml of dichloromethane were added, mixed and vortexed for 45 seconds, and then centrifuged at 6,000 rpm for 15 minutes. This procedure was repeated 3 times for each sample and the supernatant was then collected and concentrated in a rotavapor at 740 mbar and 40°C until a volume of 2 ml was obtained. Once the extract had been concentrated, it was analyzed in both a Thermo Scientific Nicolet 380 FT-IR and a Smart Orbit spectrophotometer. Given the complex matrix of the soil, its extraction efficiency was evaluated, with a concentration of 2-fluorobiphenyl added to the soil prior to carrying out of the TPH extraction process.

Surface tension

The surface tension was measured using the hanging drop method in a model 200-00 Standard Goniometer with DROPimage Standard software (Ramé-Hart Instrument Co., EEUU) and Young-Laplace software, which is used to describe the shape of the drop under equilibrium conditions (Berry et al., 2015).

Respitatory activity (CO_2)

CO_2 evolution was measured using a Gow-Mac series 580 gas chromatograph, with an Alltech concentric column (CTR1) and a thermal conductivity detector coupled to a computer analyzing the samples via the Primary Computing Integration (CPI) Chromatography Data System program, version 6. The results were expressed as a percentage of CO_2. The working conditions of the system were as follows: 100°C detector; 30°C column; 40°C injector; 125 mV detector current; Helium as a mobile phase; 55 ml.min-1 flow for the mobile phase; and, 40 lb/in^2 pressure for the mobile phase.

Microbial count

For the microbial count, nutrient agar was used for bacteria (Bioxón, México) and rose bengal agar (Disco, USA) for fungi. The microorganism count was assessed by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58415850

applying the plate count method on the CFUs, in which 1 g of soil was weighed and diluted in 9 ml of sterile saline water (0.9% NaCl w/v). A series of successive 1 ml dilutions were made in 9 ml of sterile distilled water (10^1 to 10^8) from the colloidal suspension obtained, with each dilution stirred before the subsequent dilution, and with each dilution inoculated in triplicates. The samples inoculated for bacteria growth were incubated at 37°C for 48 to 72 hours, while the Petri dishes inoculated for fungal growth were incubated at 28°C for 7 days in the dark (Gong, 2012).

Statical analysis

The data were analyzed to detect significant differences ($P<0.05$) among the treatments, using one-way analysis of variance (ANOVA). Minitab version 18 software was used to carry out the statistical analysis. The means were compared using LSD and Tukey tests.

Results and discussion

Removal of TPHs

The initial concentration of TPHs for all treatments was 50,000 mg/kg. *Figure 1* shows the results obtained for the removal of TPHs via the different treatments used in the experimental design, with their respective controls (C1: contaminated sterile soil; and, C2: natural attenuation). A decrease in non-significant TPHs was observed for C1, representing a loss of contaminant via chemical oxidation. C2 represents the soil with native flora, in which treatment a very minimal degradation rate was observed after 20 days of incubation, which is due to the low concentration of indigenous microorganisms present in the soil and the scarcity of nutrient sources. After an incubation period of 20 days, it was observed that the best treatments for the removal of TPHs were Y5> Y4= Y3, with residual concentrations of 43,000> 43,666 and 44,000 mg/kg, respectively.

The LSD and Tukey statistical tests show significant differences among the treatments ($P\leq0.05$), with the best TPH degradation percentage obtained being 12 to 14% in 20 days. These results coincide with Wu et al. (2016), who obtained 23.45 and 28.26% TPHs removal in bioaugmented and biostimulated systems, respectively, with an initial concentration of 46,000 mg/kg. This shows that the addition of inorganic nutrients such as N and P improve the action of indigenous microorganisms taken from contaminated soils and optimize the efficiency of soil remediation (Nikolopoulou and Kalogerakis, 2010). Stimulating the populations of indigenous microorganisms is vital for efficient TPHs degradation because the process requires many different bacterial species, as one single species is not capable of metabolizing more than two classes of compounds, in this instance hydrocarbons (Wu et al., 2013). Karamaladis et al. (2010), achieved 51.5% TPHs degradation, obtaining a concentration of 34,000 mg/kg after 20 days of incubation. This result is caused by the fact that lower concentrations of TPHs lead to the degradation of contaminants at a higher level (Sharma, 2012), which, in turn, generates a less toxic habitat for indigenous microorganisms and, thus, leads to higher microbial density and improved TPHs degradation (Wu et al., 2013). The results obtained here via biostimulation are significant compared to natural attenuation, which may be due to the C: N: P adjustment applied in this research, which stimulates both microbial growth and TPH degradation (Atlas and Hazen, 2011). This is consistent with previous studies, which found that the biostimulation of a soil contaminated with TPHs

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58415850

obtained superior results than bioaugmentation (Abed et al., 2014; Taccari et al., 2012; Kauppi et al., 2011).

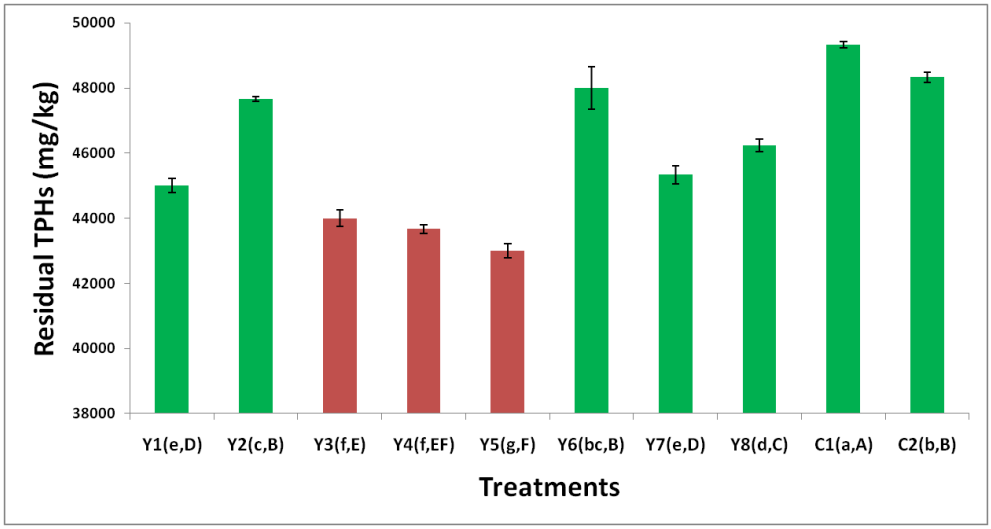

Figure 1. *Removal of soil TPHs by applying the different biostimulation treatments. (a,A): Uppercase and lowercase letters within the parentheses correspond to the LSD and Tukey tests, respectively, (P≤0.05). The dark red bars show treatments with significant degradation of TPHs*

Production of biosurfactants

The presence of biosurfactants was analyzed by means of the change in the surface tension of the extract in the soils using an extracting solution, the surface tension of which was measured and it was considered as the initial tension of the systems as well as the medium of culture of 72.30 mN/m at a temperature of 25ºC according to Soares et al. (2017). *Figure 2* shows the significant differences found for the treatments with respect to the surface tension values obtained (P≤0.05).

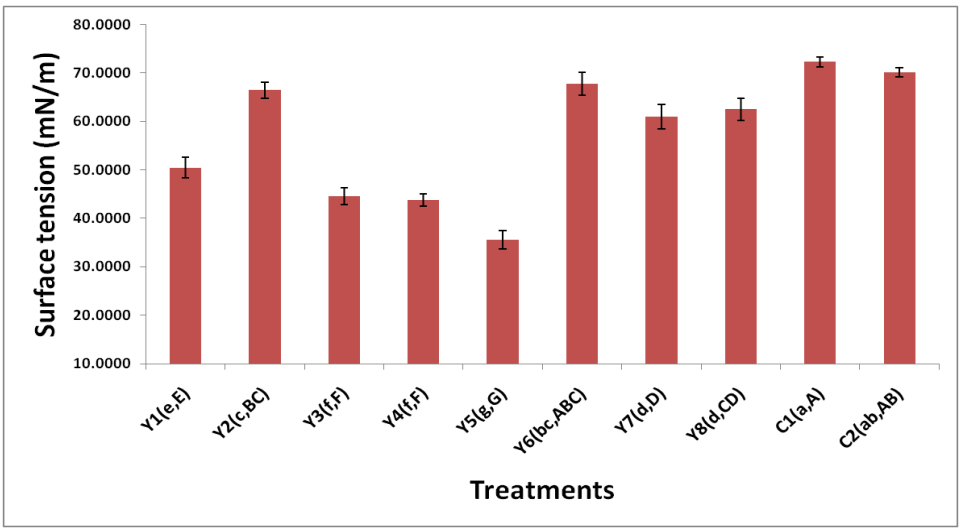

Figure 2. *Surface tension in the different biostimulation treatments. (a,A): Uppercase and lowercase letters within the parentheses correspond to the LSD and Tukey tests, respectively (P≤0.05). Culture medium γ=72. 30 mN/m at 25ºC*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58415850

The LSD and Tukey tests show that there are significant differences between treatments ($P \leq 0.05$), with the treatments with the greatest surface tension change found to be Y5>Y4=Y3, with 35.63>43.82 and 44.50 mN/m, respectively. These changes in surface tension confirm the production of biosurfactants by indigenous flora (Lin et al., 2009). The decrease in surface tension also has a direct relationship with the removal of TPHs, as it indicates a higher level of biosurfactant production, which enables the increased availability of petroleum hydrocarbons, thus generating a higher level of TPHs degradation.

Metabolic activity

This The metabolic activity of the microbial community was measured by the production of CO_2, with each treatment measured on days 1, 3, 5, 10, 15 and 20. The results obtained are shown in *Figure 3* and reveal variable respiratory activity across all treatments. The results show an active microbial community (Diploick et al., 2009), while the treatments with the highest CO_2 production level were Y5= Y4> Y3, a finding which is directly related to the study of biosurfactant production and TPHs degradation.

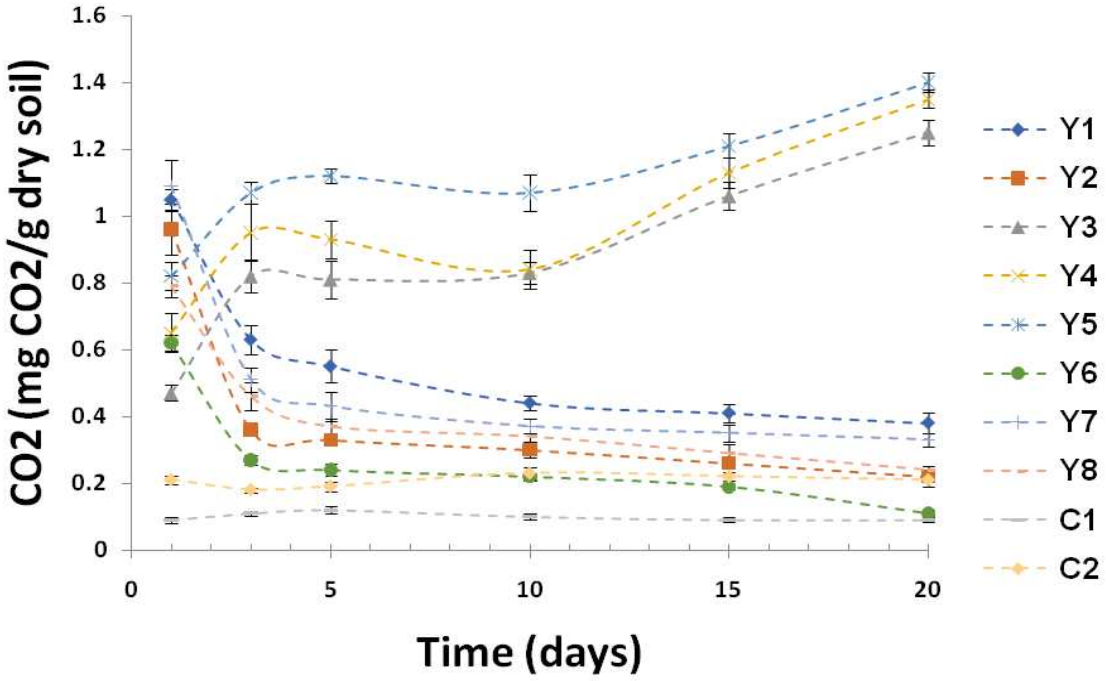

Figure 3. *Release of CO_2 over 20 days of incubation*

To verify that the production was caused by the action of the microbial community, a count of microorganisms was performed, which again found that the Y5=Y4>Y3 treatments had a higher microorganism population density, ranging from 6.36 to 9.83 x 10^7 CFU, compared to the initial concentration shown in *Table 1* (1.04 x 10^4 CFU) (*Figure 4*).

This proves not only that the bacterial populations were benefited by biostimulation with nutrients, but also that the populations of fungi presented greater population growth. Moreover, this study has observed a synergy effect between the bacterial and fungal populations, which improves the degradation of TPHs.

Conclusions

Based on previously obtained results with contaminated tropical soils, we can conclude that the success of bioremediation strategies depends on the properties of the contaminants, the nature of the nutrient products and the characteristics of the environment. Although several previous studies demonstrated the effectiveness of biostimulation, the present work could not demonstrate this fact since it took longer incubation time to be able to achieve a wider margin of degradation. Although in general, the treatments Y5 (Glucose-$NaNO_3$-K_3PO_4) and Y4 (yeast extract-NH_4Cl-K_2HPO_4) proved to be more effective than the other treatments to stimulate the degradation of the hydrocarbon. In this particular situation, the biostimulation strategy evidenced a better performance of the natural bacterial community, which constitutes a promising alternative for the restoration of tropical soil contaminated with hydrocarbons.

(Received 14th Jan 2019; accepted 26th Feb 2019)

Abstract. Population genetics is a subject of modelling the variations in gene and allele frequencies resulting genetic diversity between and within the population. The molecular marker assisted approaches in juxtaposition to computational biology have become powerful tools to explore the genetic pattern and diversity of a particular population. Therefore, population genetics of shisham population in terms of their diversity and genetic pattern was investigated. Twenty-one ISSR markers were used to investigate 30 shisham genotypes collected from Sindh, KPK and Balochistan. Genetic diversity analysis showed 337 loci were amplified with percent polymorphic loci, 99.41. Maximum diversity was found between genotypes SKP3 and KPK P3, however, genotypes TTP1 & TTP2 was found to be more similar. Principal Coordinate analysis depicted, first II coordinates accounted for 40.69% total genetic variation in 2-D plotting. AMOVA predicted high level of percent genetic variance within population (99%). Population genetic structure prediction using admixture model of Bayesian inference showed selected shisham population shared three gene pools (K = 3), with diverse genetic pattern that were grouped as distinct or even sharing maximum genetics. These findings could either be helpful for tagging and shaping scattered shisham population of Pakistan or a practical step toward identifying dieback disease resistant shisham germplasm.
Keywords: *molecular characterization, macropropagation, genetic structure, genetic diversity, dendrogram*

Introduction

Population genetics of trees is an imperative approach for characterizing, conserving and improving their dispersed population in a well-arranged manner. Evolutionary processes are the fundamental forces, which bring heterogeneity, existed in trees population. For exploring the forest biodiversity, their genetic study using molecular markers is of great impact (Tereba et al., 2017). Molecular markers have been employing to evaluate the genetic diversity based on allelic frequency present between and among the tree species (Zaya et al., 2017). These markers with the aid of computational biology well describe the genetic relationship of population at species as well as cultivar levels. These DNA markers, which determine the genetic relatedness in terms of diversity without environmental influence, are ISSR (Inter Simple Sequence Repeat), SSR (Simple Sequence Repeat), RAPD (Randomly Amplified Polymorphic DNA) etc. However, inter-SSR markers were identified as new and technically simple molecular marker technique that with small DNA template give results with robust and excellent repeatability (Nilkanta et al., 2017; Sheng et al., 2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58515861

Therefore, for determining the genetic diversity of *Dalbergia sissoo* (Shisham, tali) population of Sindh, KPK and Balochistan, ISSR marker analysis was made. Due to the fact that *Dalbergia sissoo* is economically the most important timber tree in Asia (Subedi et al., 2017). However, there is no well-defined categorization of its existed genotypes. Hence, ISSR based identification and tagging of diverse population of shisham from Punjab (Pakistan) has been attempted by Ijaz et al. (2018). In Dalbergia species SSR markers are not available, and characterization of shisham population in other countries has been documented using RAPD and ISSR markers (Bal and Panda, 2018). As literature supports that ISSR markers reveals high polymorphism rate with more reliability in comparison to RAPD markers (Wu et al., 2018), ISSR markers were used to study population genetics of shisham collected from Sindh, KPK and Balochistan (Pakistan).

Materials and methods

Germplasm collection and macropropagation

For the collection of healthy shisham germplasm, surveys were conducted across the three provinces of Pakistan viz., Sindh, KPK and Balochistan. Branch cuttings (3-5) were taken from healthy shisham trees and placed in differently labelled sampling bags. The selected shisham population size remained 15 from Sindh, 10 from KPK and 5 from Baluchistan (*Table 1*). Sandy loam soil was used to fill polythene bags (5-7" in length) after sterilization with 37% formalin solution. Cuttings from shisham trees (7-9 cm) with 3-5 nodes were planted in soil filled polythene bags and kept in green house for macropropagation (*Fig. 1*).

Molecular analysis

DNA of selected samples was isolated using modified CTAB method (Ijaz et al., 2018). Twenty one (21) ISSR markers were used for the amplification using PCR reaction conditions described by Ijaz et al., 2018. Polymerase Chain Reaction was performed on 96 well thermal cycler (peq STAR). The PCR products were resolved on agarose gel (2.5%) and visualized on gel documentation system (Bio Rad, USA). Band counting was scored as "1", for presence and "0" for absence on excel sheet. Data was analyzed using different software packages (STRUCTURE v. 2.3.4, PopGen 32 v. 1.32, PAST v. 3.16, DARwin6 v. 6.0, GenAlExe v. 6.501 and Power Marker v. 3.25) available for genetic diversity and population genetics studies.

Results

ISSR marker based PCR products with reliability of DNA bands (depending on SSR motifs) were obtained (*Fig. 2*). In three province of Pakistan, these 21 ISSR markers amplify 337 loci in total among 30 selected shisham genotypes, of which recorded polymorphism percentage was 99.41 accounted for 335 polymorphic loci. Total amplified alleles were 5252 that ranging from 57 (ISSR-17) to 321 (ISSR-5), while an average alleles per primer were 250.09. However, average number of alleles per locus ranged as 10.28 (ISSR-14) to 21.89 (ISSR-9). The high level polymorphism was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58515861

exhibited from 8.60 (ISSR-15) to 18.61 (ISSR-14). To check marker diversity PIC (Polymorphic Information Content) was calculated, that ranged from 0.2493 (ISSR-14) to 0.4321 (ISSR-1) with average of 0.3435. However, the calculated value for gene diversity was ranged 0.3045 (ISSR-14) to 0.4986 (ISSR-1) with mid value of 0.4142 (*Table 2*).

Genetic diversity analysis

Genetic diversity was performed using two distance matrix based clustering analyses i.e. unweighted pair group method with arithmetic mean (UPGMA) based dendrogram using PAST v.3.16 (Euclidean matrices) and Unweighted Neighbor-Joining (NJ) based dendrogram using DARwin6 (bootstrap method). The UPGMA based hierarchical clustering of 30 shisham genotypes showed four major clusters (I, II, III & IV) (*Fig. 3*). The cluster I comprised of KPK genotypes, KPK P3, KPK P4, KPK P5, KPK P6, KPK P7, KPK P8, KPK P9 & KPK P10 (KPK genotypes). Cluster II, being the largest, included Sindh genotypes, TTP1 & TTP2 (Thatta genotypes), HP1, HP2 & HP3 (Hyderabad genotypes), NFP1 & NFP2 (Naushahro Feroze genotypes), KPP1 & KPP2 (Khairpur genotypes), JSP1, JSP2 & JSP3 (Jamshoro genotypes), SKP1 & SKP2 (Sukkur genotypes). Balochistan genotypes, BLP1, BLP2, BLP3, BLP4 & BLP5 were grouped in cluster III. While cluster IV was observed to be distinct one which comprised of KPK P1, KPK P2 (KPK genotypes) and SKP3 (Sukkur genotype, Sindh). The whole dendrogram was rooted by the three genotypes of cluster IV. Despite this dendrogram, Neighbor Joining (NJ) based clustering (using Darwin6 software) with 1000 bootstraps, also supported the UPGMA results (*Fig. 4*). Somehow, same clustering pattern was observed among selected genotypes of three provinces which validated the results as well.

DOI: http://dx.doi.org/10.15666/aeer/1703_58515861

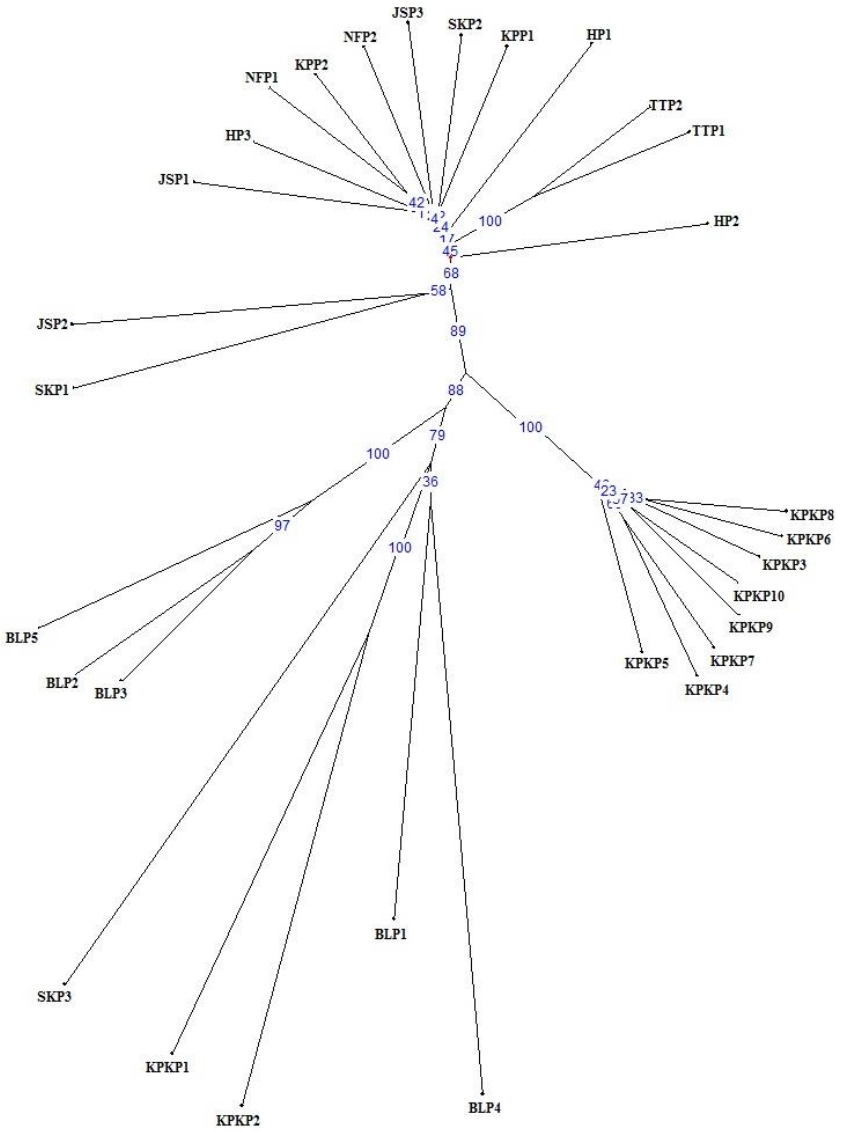

Figure 4. *A dendrogram using DARwin6 software, based on unweighted neighbor joining (NJ), showing hierarchical clustering of 30 representative shisham genotypes from three provinces, Pakistan.*

The similarity index retrieved from PopGen 32 also corelated with the results of dendrogram. The overall Nei's genetic distance ranged from 0.1594 to 1.1168. The maximum Nei's genetic diversity value of 1.1168 was scored by SKP3 and KPK P3 genotypes. Moreover, Sukkur genotype (SKP3) showed diversity value of 1.0197 and 1.0104 with KPK genotypes, KPK P6 and KPK P8, respectively. However, Thatta genotypes (TTP1 & TTP2) scored least Nei's genetic diversity value of 0.1594. These diversity values and the cladding of 30 genotypes were in accordance to each other. In addition, the values for total genetic diversity (H_t), number of alleles (na), effective number of alleles (ne), Nei's gene diversity (h) and Shannon's information index (I) was also computed by PopGen32. The values for H_t, 0.3705, na 1.9941, ne 1.6487, h 0.3705 and I 0.5469 were recorded on an average with standard deviation of 0.0169, 0.0769, 0.2968, 0.1301 and 0.1580, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58515861

Principle Coordinate Analysis (PCoA) was executed on Darwin6 program package to determine the spatial representation among and within selected shisham population based on genetic differences (*Fig. 5*). These results were in concurrence to the UPGMA based and NJ based clustering of selected genotypes. The two dimensional (2-D) plotting of 30 genotypes were observed from three provinces. These results revealed that first two coordinates (coords) accounted for genetic variation, 21.62% (Coord I) and 19.07% (Coord II). The genotypes found in intermixed as well as in scattered form. The SKP1, SKP3 (Sukkur genotypes, Sindh) and JSP2 (Jamshoro genotype, Sindh), BLP1, BLP2, BLP3, BLP4, BLP5 (Balochistan genotypes) KPK P1, KPK P2 (KPK genotypes) were showed to be scattered while all other genotypes were more or less closely related.

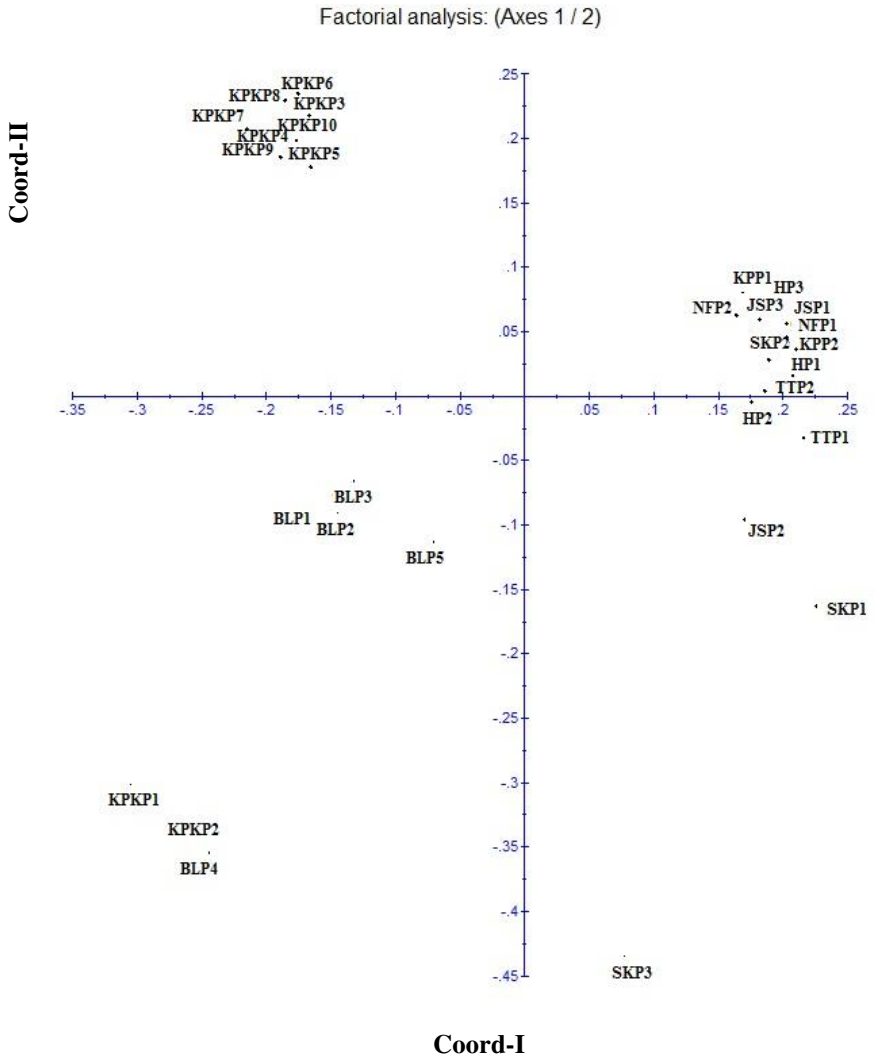

Figure 5. *PCoA based 2-D plot of 30 shisham genotypes from Sindh, KPK and Balochistan, Pakistan*

Analysis of molecular variance analysis (AMOVA) was performed using MS-Excel based program GenAlExe, on the whole ISSR data score of shisham genotypes without grouping by region or geographical location (*Table 3*). This analysis was performed to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58515861

understand the relationships within and among the populations (*Fig. 6*). AMOVA revealed high percentage credited to intra-population variation (99%) while the remaining in inter-population variation (1%). Therefore, in total, proportion of variation among shisham populations of three provinces was lower than within the populations, suggesting the collected shisham genotypes are highly diverse to each other but of same origin.

Table 3. *Calculated variance for inter and intra populations with percent of the variance of each source to the total variance*

Source	Degree of freedom (df)	Sum of square (SS)	Mean sum of square (MS)	Est. var.	Var. %
Among pops	2	185.800	92.900	1.032	1%
Within pops	27	2253.000	83.444	83.444	99%
Total	29	2438.800		84.476	100%

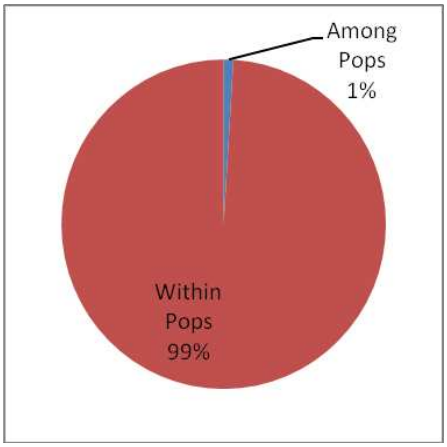

Figure 6. *Percentile of molecular variance among and within studied shisham populations*

Population genetic structure

The pattern of genetic structure among shisham population among three provinces has been observed using computer program STRUCTURE. The STRUCTURE HARVESTER suggested shisham population into appropriate subpopulation (K). The K was set from 2-5 with 10,000 burn-in and MCMC. Whereas the estimation of subpopulations was done by delta K (ΔK) value. For selected genotypes from three provinces (30 genotypes) the ΔK value was recorded as highest at K = 3, which conferred the shisham population into 3 subgroups (*Fig. 7*) (*Table 4*). This result depicted the sharing of three gene pools among investigated genotypes (*Fig. 8*).

Discussion

Genetic diversity has of tremendous importance for any plant or tree species to survive in their natural habitat by providing the knowledge about novel strategies for their conservation. In recent years, DNA molecular markers proved to be a vital strategy for the assessment of inter and intra population interactions as well as variation which greatly contributed in conversation of endanger species (Gudeta, 2018). ISSR regions are present between the SSR motifs that are ubiquitous in genome of higher organism and have ability to discriminate the genotypes (Ijaz and Khan, 2009; Ijaz, 2011).

In the present study, 21 ISSR markers primers produced 337 loci among 30 selected shisham genotypes for which polymorphism percentage was recorded to be 99.41% accounted for 335 polymorphic loci. Similar study was conducted in Punjab population of Pakistan in which 21 ISSR markers showed 83.32% polymorphism among 60 selected shisham population (Ijaz et al., 2018). The UPGMA based clustering grouped this population of 30 genotypes in to four clusters and minimum Nei's genetic identity was observed as 0.3273 in SKP3 and KPK P3 while maximum showed to be 0.8487 in KPP2 and NFP2, KPP1 and KPP2, KPK P9 and KPK P10.

DOI: http://dx.doi.org/10.15666/aeer/1703_58515861

PCoA value was calculated through Drwin6 which showed to be 21.62% in first coordinate and 19.07% in second coordinate. However, for PCoA, in the study conducted by Ijaz et al. (2018) revealed the shisham populations of Punjab province, Pakistan showed 16.23% and 13.83% in coordinate I and coordinate II respectively. The delta K value was calculated by using STRUCTURE HARVESTER which was observed as K = 3 which revealed that 30 shisham genotypes were sharing three genetic pool, similar results were observed for Punjab shisham population (Ijaz et al., 2018) and for bamboo tree (Nilkanta et al., 2017). As for AMOVA, 99% and 1% variation was observed within and among population respectively. Similar results were observed in bamboo (Nilkanta et al., 2017) and pistachio (Meimand et al., 2017).

Conclusion

Maintenance of genetic diversity of forest trees is also of critical importance worldwide for its preservation, propagation and commercial cultivation. However, in the case of shisham (*Dalbergia sissoo*) cultivars and accessions there are no identified cultivars and accessions that have been identified as diverse and closely related as well as resistant and susceptible. Genetic diversity assessment of shisham would enable scientists to understand phylogenetic relationships among different genotypes, their geographical distribution and linkage of certain morphological traits with DNA markers linked to the genes controlling them. The information thus obtained may also be helpful in solving the problem of shisham. The research findings will be important in the development towards tagging and identifying *D. sissoo* germplasm on a molecular basis and a practical step for the sustainable management of diseases in shisham.

Acknowledgement. We highly acknowledge “Punjab Agriculture Research Board (PARB), Pakistan” for providing funds under the PARB project no. 952 “Resistance gene analogues based molecular identification for dieback disease resistance in shisham (*Dalbergia sissoo)*” to conduct this research work.

Conflict of interests. I declare that the submitted manuscript is our own work, which has not been published before and even is not currently being considered for publication elsewhere. And there is no conflict of interests.

Abstract. Information regarding the stability of genotypes is critical in expanding the adaptability of released genotypes. But, this information regarding the basmati (scented) rice genotypes cultivated under north Indian conditions are not well known. Therefore, here we have evaluated the twenty-two basmati rice genotypes for stability, based on important traits, and different production system. Genotypes were evaluated for two consecutive Kharif seasons under open field conditions in a randomized complete block design (RCBD). The genotypes were evaluated under four production systems namely, transplanted rice (TPR), system of rice intensification (SRI), direct seeded rice (DSR) in both settings, i.e. wet DSR (W) and dry DSR (D). The stability of genotypes was determined via Eberhart and Russell model, additive main effects and multiplicative interaction (AMMI), and genotype × environment interaction (GGE) biplot model. The stability and adaptability studied using Eberhart and Russell model, AMMI and GGE biplot identified Basmati-370 as the most stable genotype for biological weight; Pusa RH-10 for filled spikelet; CSR-30 for spikelet Number; and Traori Basmati for test grain weight. TPR was the most desirable test environment followed by SRI and DSR (W). Further, we have identified HKR 08-417 as the most suitable genotype for all of the production systems. Overall, this study provides information regarding stable basmati rice genotypes under the north Indian conditions.
Keywords: *rice, G × E, GGE, AMMI, stability model, Eberhart and Russell, SRI, DSR*

Introduction

Rice (*Oryza sativa* L.) production is vital for the growing population (Zhang, 2007; Wu and Cheng, 2014). Although, rice is grown worldwide over an area of around 163.24 mha with a production of around 740.95 mt. besides its productivity is around 4.54 t/ha (Anonymous, 2016). In India rice is cultivated over 43.99 mha which results in the production of 109.69 mt., with a productivity of 2.49 t/ha (Anonymous, 2017). The productivity of rice in India is around half of the world average. This low productivity of rice in the Indian subcontinent is a result of several factors like less water availability, the frequent occurrence of droughts, weed competition, insect pest, and diseases (Silalertruksa et al., 2017; Sreekanth et al., 2017). The rice production areas in India are highly diverse with different production systems due to the area specific soil and climatic features (Singh et al., 1997). Moreover, the improper commercialization of high yielding varieties for non-conventional systems of rice production like system of rice intensification (SRI), direct

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58635885

seeded rice (DSR) etc. leads to below average yields under non-conventional systems (Wanjari et al., 2006).

Based on the aroma, rice is divided into two categories namely, basmati (scented) and non-basmati (non-scented) type. Basmati rice is comprised of long slender grain, pleasant aroma and fluffy rice texture (Ashfaq, 2015; Hinge et al., 2016). The scented aroma of basmati varieties is only perceived when basmati rice varieties are grown on the northwestern foothills of Himalayas (Bhattacharjee et al., 2002; Jena and Grote, 2012). Still, most of the basmati genotypes are limited to the environment of their developed institutes, due to less in-depth study regarding the performance of elite verities under diverse environments from their developed institutes (Kamoshita et al., 2008). The researchers are primarily focused on configuring the input demand for the transplanted rice-based production system (Lin, 1994). The new production systems/non-conventional strategies like, SRI, DSR (are intended for the optimum yield per amount of input supplied (Jain et al., 2018).

Genotype × Environment interactions (GEI) plays a pivotal role in the positioning of genotypes from their native to non-native environment, which further hampers the plant breeding advancement (Pham and Kang, 1988). A genotype is termed as stable if it performs statically across different environments. Whereas, the theory of biological stability consider the concept of less variance for yield and yield related characters across unrelated environments (Becker and Leon's, 1988). Rice breeders and agronomists give little attention to biological stability concept (Xu, 2016).

A number of stability analyses models are used to determine the contribution of G × E interaction (GEI), also, to identify genotypes which perform superior under several environments (Génard et al., 2017; Malosetti et al., 2013). Stability model is defined in terms of mean value, regression coefficient, deviation from the regression, and principal component analysis (PCA) (Bernardo, 2002). Stability models like Finlay and Wilkinson (1963), and Eberhart and Russell (1966) are based on two parameter regression coefficient (bi), and deviation from regression (S^2di). Whereas, the additive main effects and multiplicative interaction (AMMI) model is a combination of the main effect due to analysis of variance and their interactions (GEI) (Gauch, 1992).

Yan et al. (2000) created a biplot strategy known as GGE biplot which graphically indicates the genotype (G) primary effects and genotype × environment interaction (GGE). The G and GE are the two fundamental source of variation for genotype evolution under diverse environment. The GGE biplot analysis represents the G+GE of different environment records acquired by plotting the two (or more) PCA score of G × E interaction. The GGE biplot analysis allows the analysis of many characteristics of genotypes and environments (Samonte et al., 2005). Selection and identification of stable and high yielding genotypes over the different environments have been a continuous task to rice breeders (Balestre et al., 2010). Therefore, in our study, we have compared the Eberhart and Russell methodology, AMMI biplot, and GGE biplot analysis of the twenty-two popular basmati rice genotypes under north Indian conditions. Further, these approaches are applied under four different production systems transplanted rice (TPR), SRI, DSR (W) and DSR (D).

Materials and methods

Plant material and experiment layout

Experimental fields were settled at Regional Research Station, Kaul, India (29.98° N latitude and 79.66° E longitude) (*Fig. 1*). Field trials were conducted over two Kharif (July

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58635885

to October) seasons in 2014-2015 and 2015-2016 respectively. During both of the years, the nursery was sown in June, for both TPR and SRI. After that, the seedlings were field transplanted in July for TPR and SRI. Whereas, the direct sowing of DSR (D) and DSR (W) was performed in June. Plants were harvested in the month of October for data analysis. The weather during the entire crop period is presented in *Figure 2*. The soil was analysed as a composite sample from the top 0-15 cm (Bandyopadhyay et al., 2012). The soil was sandy loam with the with different percentage of sand (81.4%), slit (7.3%), and clay (11.3%). All plant production related practices were followed based on the package of practices for rice cultivation.

The experimental materials comprised of popular basmati rice genotypes (*Table 1*). These genotypes were laid out in a randomized complete block design (RCBD) with three replications, using four production systems namely, TPR, SRI, DSR (W) and DSR (D) (*Table 2*). Each experimental plot consisted of five rows of 2 m long with 0.20 m row spacing (*Fig. 3*).

Characterization and data analysis

In total seven characters were studied as the mean of five randomly chosen plants per plot. Biological weight is measured as the weight of plant biomass. The biological weight (g) per plant was recorded after harvesting and drying of mature plants. Whereas, the harvest index was determined as the ratio of grain yield/biological yield × 100. Test grain weight (g) was determined from the random sample of 1000 filled grains for each replication. Whereas, the number of spikelet per panicle were determined from a random sample of twenty panicles after harvesting. The percent of filled spikelet was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58635885

estimated as the percentage of grain filled spikelet to the total number of spikelet. While the days to 50% flowering were recorded based on the date of sowing to 50% flowering on a plot basis. Similarly, days to 75% maturity were recorded from the date of sowing until the day when a minimum 75% grains per panicle showed maturity.

The data analysis was performed using the software package PBTools version 1.4 (http://bbi.irri.org/products) and R Statistics (R Core Team, 2017). Unweighted Pair Group Method with Arithmetic Mean (UPGMA) method of hierarchical clustering was applied to the twenty-two genotypes in order to visualize how genotypes are related to each other based on all of the studied descriptors. The AMMI model (Gauch, 1988) is a combination of Additive (ANOVA) and multiplicative interaction (Principal component analysis). The Genotype × Environment interaction was evaluated by considering the first two PCA. The statistical model can be represented as:

$$Y_{ij} = \mu + g_i + e_j + \Sigma\, \lambda_n \alpha_{in} \gamma_{jn} + \theta_{ij} \quad \text{(Eq.1)}$$

where:
Y_{ij}: mean yield of i^{th} genotype in the j^{th} environment;
μ: general mean;
g_i: i^{th} genotypic effect;
e_j: j^{th} location effect.
λ_n: eigenvalue of the Principal Component Axis n;
α_{in}: and γ_{jn} are the i^{th} genotype, j^{th} environment Principle component analysis (PCA) scores for the PCA axis n;
θ_{ij}: residual n is the number of PCA axes retained in the model.

Whereas GGE biplots are a combination of both G (Genotype) linear effect and G × E interaction and it is based on sites regression linear, bilinear model (Kang, 1993; Cornelius et al., 1996; Crossa and Cornelius, 1997; Crossa et al., 2002).

Results

Genotypic performance of different traits

A diverse range of variation in the means was detected for yield and yield-related traits for all of the 22 basmati rice genotype in a different production system. During the two seasons; wide-ranging genotypic fluctuation or variation was detected and ranged for biological weight (32.49 to 44.26); harvest Index (%) (27.54 to 41.17); test grain weight (19.62 to 29.95); number of Spikelet (57.49 to 109.71); filled spikelet (%) (73.06 to 87.62); 50% flowering (86.00 to 108.40); 75% maturity (107.60 to 137.60) among different genotype under study as shown in *Table 3*. Considering the two season average mean, genotypes G22 recorded the highest number of spikelet per plant, whereas, genotype G16 recorded the highest biological weight per plant. Genotype G2 was short duration with lowest unfilled grain and highest test grain weight in all the production system (*Table 3*). Further, using the Unweighted Pair Group Method with Arithmetic Mean (UPGMA) technique the clustering results of the twenty-two basmati rice genotypes are presented in *Figure 4*. More related genotypes were clustered together. Genotype G2 clustered apart from rest of the genotypes. Whereas, seven genotypes clustered together, while, the remaining fourteen genotypes were together (*Fig. 4*).

Pooled analysis and stability analysis

Interpretations on the yield-related traits for two-year data were then subjected to pooled analyses by using Eberhart and Russel (1966), Additive Main Effect and multiplicative interaction (Gauch and Zobel, 1989) and GGE Biplot (Yan and Kang, 2003). In the analysis, the environment defined by every arrangement of location or Kharif season with the production system. First Analysis of variance was conducted for each location (environment) then combined analysis of two-year data was subjected to stability analysis using PB tools and R software. The pooled analysis results showed that the genotypic and environmental variances were significant ($p < 0.05$) for all the traits. Similarly, the mean sum of squares due to G × E interaction was significant for all of the seven traits studied. Furthermore, the partitioning of the combined environment, and genotype × environment variance into linear and non-linear components showed that environment linear and combined deviation was significant given in *Table 4*.

The stability model proposed by Eberhart and Russell (1966) was adopted to analyse the data over different environments and in this model is the most popular technique of studying Genotype × Environment interaction and genotypic stability. It used two parameters (bi and $S^{-2}di$) to define stability. $S^{-2}di$; is primarily used to rank the relative stability of cultivars. The indication is that bi may be utilized to depict the standard response to the goodness of environmental conditions though S-2di measures the predictability. According to this model, a stable variety is one that has a high mean (Xi), unit regression coefficient (bi=l) and the deviation from regression as small as possible ($S^{-2}di = 0$). The stability analysis revealed the genotypes in case of with significant regression coefficient (bi) and non-significant deviation from the regression ($S^{-2}di$) Genotype G21 (50% flowering) and G17 (filled spikelet (%)) exhibited non-significant $S^{-2}di$, regression coefficient significantly greater than one and mean higher than the population mean was found suitable for a better environment (E6 and E5). Genotype G2 in biological weight, G18 and G21 in a filled spikelet (%), G2 and G12 in Number of spikelet with regression coefficient significantly less than one and non-significant deviation from regression and mean higher than the population mean was identified suitable for unfavourable environments E1, E2, E3, E4. Genotype G9 and G19 were

Genotypes or general genotypic adaptation

GGE and AMMI biplots described stability across genotypes or general genotypic adaptation. Comparative position of diverse genotypes on the biplots is based on its projection onto the O-axis in AMMI Biplot and GGE biplot. Biplots can identify GEI effects on each trait which contribute towards yield. AMMI1 biplot interpreted results by main effect and IPCA1 of both genotype and environment revealed that genotypic differences were important in term of direction and magnitude along both axis (X axis and Y axis). AMMI biplot represent that shift along the X-axis reflected changes in main effects, however, shift along the Y-axis reflected differences in interaction effects and adaptation of a genotype to specific environment showed by high PCA score, IPCA scores nearly to zero gave information about stable genotype in different environments. The AMMI biplot analysis is provided in *Table 6*.

AMMI analysis (*Figs. 5, 6, 7, 8* and *9*) showed that genotype G22 for filled spikelet (%); G20 for number of spikelets; G18 for test grain weight; G8 for Harvest index.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58635885

Environment E5, E6 were more responsive for the traits Biological weight, number of Spikelets, Test Grain Weight, filled Spikelet (%) and environment E7 was responsive for traits filled Spikelet (%), Test grain weight, Harvest index. From the AMMI biplot was concluded that environment interaction was extremely diverse and entirely the four Production systems were extremely interactive for most of the yield-related traits. Environment E5, E6 seemed to be a favourable environment for all the yield-related traits; E7, E2 for filled spikelet (%), Test Grain Weight, Harvest Index. Environment E1 and E3 unfavourable for Harvest Index, Test grain weight, number of spikelet and filled spikelet (%).

Specific genotypic adaptation

Specific genotypic evaluation centred on two GGE biplots "which-won-where pattern" biplot and adaptation biplot displayed specific genotypic adaptation to limited environment condition or the adaptability of genotypes for each environment. The biplot *Figure 10* represents a polygon where some of the genotypes were placed on the crests, while the rest were surrounded by the polygon. As the genotypes placed on the peak had the longest detachment from the biplot origin and they were expected to be the most responsive. The genotypes on the crests could be called the ideal/vertex genotype. In the present study, the genotypes G15 in E1 and E5 are the vertex genotype, which had the highest test grain weight. The genotype G20 is only apex genotype for environment E4 and Genotype G14 for E2 and E6 environment. None of the environments fell in the sectors with genotypes G1, G7 and G3 that these genotypes were not appropriate for growing in these environments.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58635885

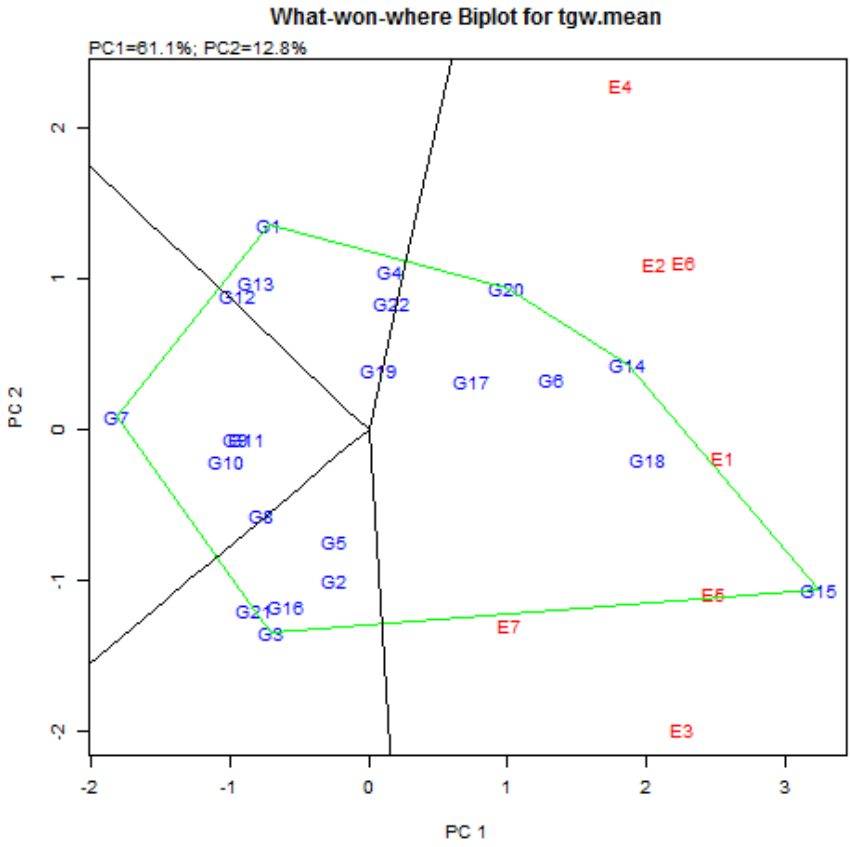

Figure10. *Polygon views of the GGE biplot based on symmetrical scaling for "which-won-where" pattern of rice genotypes in three environments "which-won-where pattern biplot test grain weight (g)"*

In case of biological weight (*Fig. 11*) Vertex genotypes are G4, G5, G10 and G1 at E6, E5, E7 and E1 respectively. In case filled spikelet (*Fig. 12*) Vertex genotypes are G22, G2, G12, G18 and G15 at E2, E4, E7, E1 and E3, E5 respectively.

In *Figure 13* average tester coordinate (ATC X-axis) or the performance line passes through the biplot origin with an arrow indicating the positive end of the axis. The average biological Weight of the genotypes is estimated by the projections of their markers to the ATC X-axis. Genotypes G2 and G5 had the highest biological Weight and genotype G15 had the poorest biological Weight. Mean biological weight of the genotypes were in the following order: G2 > G5 > G14 > G1 > G10 > G9 > G11 > G22 > G2 > G16 (*Fig. 13*). The performance of genotypes G10 and G1 were the most variables (least stable), whereas genotypes G4, G9 and G22 were highly stable with high biological weight.

The discriminating power vs representativeness view of the GGE biplot as shown in *Figure 14* indicated that environments E1 and E5 with the most extended projection from the biplot origin were found large discriminating power of the genotypes (i.e., provided information regarding differences among genotypes). On the other hand, E2 and E3 with its shortest vector from the biplot origin was found less discriminating of the different genotypes. Environments E2, E3, E4 and E6 were found to be more representative of other test environments because they have smaller angles with the AEAs (*Fig. 14*). E6 was therefore identified as an ideal environment that has both discriminating abilities of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58635885

the genotypes and representative of the other test environments. Therefore, environment E6 can be used to effectively select superior rice genotypes that can perform consistently across environments.

Ranking genotypes relative to the ideal genotypes

An ideal genotype is one that has both high mean yield and high stability. The centre of the concentric circles (*Fig. 15*) represents the position of an ideal genotype, which is defined by a projection onto the mean-environment axis that equals the longest vector of the genotypes that had above-average mean biological weight and by a zero projection onto the perpendicular line (zero variability across environments). Therefore, genotypes G21 and G16 which fell into the centre of concentric circles, were ideal genotypes in terms of higher yield ability and stability, compared with the rest of the genotypes. In addition G6, G7, G22, G9, G2 located on the next concentric circle, may be regarded as desirable genotypes.

Ranking environment relative to the ideal environment

The GGE biplot way of measuring representativeness is to define an average environment and use it as a reference or benchmark. The average environment is indicated by small circle (*Fig. 16*). The ideal environment, represented by the small circle with an arrow pointing to it, is the most discriminating of genotypes and yet representativeness of the other tests environments. Therefore, E1, E2 and E3 were the most desirable test environment followed by E7.

Discussion

Due to the Cultivation of rice under several agroecological zones and in different production systems the evaluation of rice genotypes for stability and adaptability is of prime importance (Bose et al., 2012). The changes in environmental conditions significantly affect rice production (Bose et al., 2014). Therefore, here we have identified stable rice genotype to sustain with innovative production systems like the system of rice intensification, and direct seeded rice using stability models. Previously, researchers have used GGE biplot analysis mainly for assessment of varietal stability cultivar evaluation and mega-environment evaluation (Kang, 1993; Yan and Hunt, 2001; Yan and Kang, 2003; Dehghani et al., 2006; Navabi et al., 2006; Blanche et al., 2007; Ding et al., 2007; Jalata, 2011; Mohammadi et al., 2012; Rakshit et al., 2012; Amiri et al., 2015). The simultaneous selection for stability and high mean results in the selection of better genotypes with non-significant stability variance, and it enhances the quality of selection (Nassir, 2013). Pooled analysis study stipulates that a significant basis of variation in the basmati rice genotypes was due to genotype by environment interaction. In the present study, two-year data under four production system of rice was primarily subjected to stability analysis of the traits.

The GGE and AMMI1 biplots recognised Genotype G21 most stable genotype for biological weight; G22 for Filled spikelet (%); G20 for Number of spikelets; G18 for Test Grain weight; G8 for Harvest index was identified as most stable genotypes. Similarly, it has been proved that for multi-environment trails both GGE and AMMI biplots were important for judging stable and adaptable genotypes (Hagos and Abay,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58635885

2013; Stojaković et al., 2010; Mitrovic et al., 2012; Rad et al., 2013). Genotypes G21 and G16 were ideal genotypes for biological weight. Further, E1, E2 and E3 were the top three most desirable test environments. Whereas, the GGE biplot analysis has identified E3 as the ideal environment having a long vector length (discriminating ability) and a small angle (representativeness) and G18 as a superior genotype across environments. Similar research finding by Khalil et al. (2011).

This study uncovered that the GGE biplot hence clarified better Genotype + Genotype-Environment interaction than the AMMI1 biplot so that better precise explanation of the GGE of the basmati rice genotype in a diverse production system. This might likely be due to the truth that in spite of the fact that, the AMMI1 biplot (Zobel et al., 1988) has been demonstrated to be exceptionally effective in identifying significant sources of variation of Genotype × Environment interaction effects and has moreover been pronounced as either superior or equal GGE biplot analysis (Gauch, 2006), but it isn't capable to successfully show the virtual execution of each genotype in each environment i.e., does not have the foremost critical property of a true biplot. As a result, the performance of a given genotype in a given environment cannot be precisely visualized even in case it completely shows the data.

Also, Yan et al. (2007) concluded that the GGE biplot is predominant in the AMMI1 biplot in mega-environment analysis and genotype assessment, as it clarifies more G+GE and pinpointed that, the AMMI1 biplot is way better seen as a tool for displaying conclusions instead of as a tool for finding which-won-where designs. Contrastingly, the GGE biplot was criticised by Ebdon and Gauch (2002) and Gauch (2006) for not being able to uncover which-won-where designs in case more than two PCs are required to surmise the information.

Conclusion

We showed the significance of Genotype × Environment interaction by evaluating the genotypic potential of twenty-two basmati rice genotypes using stability models. Basmati rice genotypes were compared for their stability under different production systems (both conventional and non-conventional) for yield-related traits. Results from the analysis with Eberhart and Russell model, AMMI and GGE biplots showed Genotype G21 as the most stable genotype for biological weight; G22 for filled spikelet (%); G20 for number of spikelets; G18 for test grain weight; and G8 for harvest index. Whereas, among the different environments E7 was the most desirable test environment followed by E5 and E4. Overall, a summary list of best genotypes under all of the four production system is provided in *Table 7*. Further, the HKR 08-417 (G14) was determined to be stable under all of the production systems.

(Received 16th Jan 2019; accepted 28th Feb 2019)

Abstract. We investigated how abandonment of mountain meadows influences bumblebees, true bugs and grasshoppers in two years in the Eisenwurzen region (Austria). We surveyed abandoned (20-40 years old) and annually mown unfertilized meadows. Bumblebees were observed in 20 m^2 plots, bugs were collected by sweep netting and grasshoppers identified with a soundscape approach. The insect groups were analysed in relation to plant species richness, flower cover, vegetation cover and the surrounding landscape. Bumblebee species richness and richness of long-tongued species were significantly higher in managed meadows. Similarly, we found significantly more phytophagous bug species in managed meadows, whereas grasshoppers showed no difference between meadow types. Bumblebee species richness and abundance, the abundance of phytophagous bugs and total grasshopper species richness were associated with total flower cover. Surrounding forest area negatively affected bugs, while open landscape positively affected bugs, both regarding species richness and abundance, number of phytophagous species and individuals and individuals overwintering as egg. Species assemblages of the three insect groups did not significantly differ between meadow types. Extensive management is important to preserve bumblebee and bug richness. However, abandoned meadows, which are not yet re-grown into forest can still act as suitable habitats for the three insect groups.
Keywords: *extensive management, management cessation, grasslands, Bombus sp., Heteroptera, Orthoptera*

Introduction

More than 40 % of the earth´s terrestrial surface is covered by grasslands (Suttie et al., 2005). In Central European landscapes, they represent valuable ecosystems harbouring a high plant diversity (Dengler et al., 2013; Chytrý et al., 2015). Semi-natural grasslands were maintained for hundreds of years by local farmers and traditional land-use systems (Maurer et al., 2006; Fischer et al., 2008; Poschlod et al., 2009; Hejcman et al., 2013; Price et al., 2015). In Austria, 60% of the agriculturally used area is made up of grasslands, 90% of which are not ploughed for at least 20 years (Pötsch et al., 2005). Changes in farming practice and intensity have led to a reduction

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58875908

of semi-natural grasslands throughout European landscapes (Wesche et al., 2012). Main causes of this reduction are agricultural intensification and abandonment (e.g. Strijker, 2005; Baur et al., 2006a; Gellrich et al., 2007; Tasser et al., 2007; Prévosto et al., 2011; Graf et al., 2014). The reasons for the abandonment of extensively managed mountain meadows are manifold. Rey Benayas et al. (2007) identified some of the main drivers of land-use abandonment and mentioned socio-economic factors like rural depopulation and ecological factors like slope, altitude and accessibility as factors for management cessation. Especially, slopes with a high inclination are more often abandoned (Tasser et al., 2007; Niedrist et al., 2009). Land-use abandonment, and the consequent process of secondary succession (Komac et al., 2013), leads to forest-regrowth (Gellrich et al., 2007; Prévosto et al., 2011). Abandoned meadows undergo several successional stages (Tasser et al., 2007). Some of these stages remain stable for decades and abandoned grassland remains open for a long time (Walcher et al., 2017). Usually, regular mowing or grazing is necessary to maintain semi-natural grasslands without encroachment of woody vegetation (Hannson and Fogelfors, 2000; Maurer et al., 2006).

While there is a great body of evidence regarding the effects of abandonment on plants, knowledge regarding insect species is scarce. The effects of human-induced land-use changes strongly depend on the insect taxa being considered (Bonari et al., 2017; Lessard-Therrien et al., 2018). Therefore, studies taking different insect groups into account, are important in order to understand the consequences of management measures and to develop conservation strategies (Van Noordwijk et al., 2017).

The three insect groups investigated in the present study are scarcely studied in mountainous grasslands, and especially data on true bugs in mountainous grassland ecosystems are largely missing. This is surprising because bumblebees, bugs and grasshoppers are suitable organisms to study the effects of land-use abandonment in grassland ecosystems. The reduction of foraging resources and loss of suitable nesting sites are the main causes for bumblebee decline (Carvell, 2002; Goulson et al., 2005; Carvell et al., 2006; Nieto et al., 2014; Goulson et al., 2015). Long-tongued bumblebee species, in particular, often have specialized diets and are known to be in decline in many European countries (Goulson et al., 2005; Kosior et al., 2007). The true bugs are a diverse group, including generalist and specialist species, which are assumed to react differently to land-use changes such as abandonment. Along with grasshoppers, they respond sensitively to altered environmental conditions (Schwab et al., 2002; Frank and Kuenzle, 2006; Fartmann et al., 2012) and are suitable indicators for land-use changes (Duelli and Obrist, 2003; Fartmann et al., 2012). Especially, grasshoppers require specific habitat conditions (Baur et al., 2006b). They are particularly affected by the cessation of management (e.g. Marini et al., 2009; Uchida et al., 2016).

In the present study, we aimed at investigating how abandonment impacts richness and abundance of bumblebees, true bugs and grasshoppers. Therefore, we compared extensively managed annually mown meadows (no fertilizer application) with abandoned meadows in an Austrian region. The Eisenwurzen region is one of the largest nature reserve areas in Austria. This area contains a range of semi-natural habitats and is facing severe challenges due to abandonment (Haberl, 2009). We investigated the three insect taxa for the same reasons as in Walcher et al. (2017), but collected an additional year of data and one additional meadow per treatment. Data sampling over multiple years in mountainous grassland ecosystems is highly important in order to possibly give recommendations for management schemes and conservation strategies in the future. Thus, in the present study, we picked up the highly topical issue

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58875908

of land-use abandonment by conducting a 2-years research in such an important nature reserve area.

We hypothesized that (i) species richness and assemblages of the three insect groups differ significantly between meadow types and, (ii) surrounding landscape structure and vegetation parameters significantly influence the three insect groups.

Methods

Study region

The study was carried out in 2015 and 2016 in the Styrian part of the Eisenwurzen region (Austria). Sampling was carried out once in June (between 16th and 18th of June) and once in August (between 16th and 18th of August) in both years. The mean annual temperature in this region is 6.9°C and the mean annual precipitation is 1 087 mm. Eight southerly exposed meadows – four extensively managed and four abandoned – were selected in the three municipalities St. Gallen, Stainach, and Pürgg (*Fig. 1, Table 1*).

Photos of the studied meadows give an impression of managed (*Fig 2 a* and *b*) and abandoned (*Fig 2 c* and *d*) meadows.

Due to technical problems with the soundscape method, we could only survey grasshoppers in three managed and three abandoned meadows, making a total of six meadows (n=6). The annually mown, non-fertilized managed meadows are usually

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58875908

mown at the beginning of August. In both years, 2015 and 2016, the meadows were mown mid-July. Thus, sampling in August took place four weeks after the last cut, thus ensuring new plants in flower for the second sampling round in August. Meadows are usually mown manually with bar mowers or, on very steep parts of the meadows, using a scythe. Abandoned meadows are between 20 and 40 years old and were used extensively before cessation of management. Information about former and current management of the investigated meadows and age of abandoned meadows was gathered by interviewing the land owners. The meadows were located at an average elevation of 670 m above sea level. The size of managed meadows ranged from 1095 to 4500 m^2, while the size of abandoned meadows ranged from 573 to 3370 m^2. The sizes of managed and abandoned meadows were not significantly different ($F=0.959$, $p=0.365$; ANOVA). We measured the percentage of surrounding open landscape (pastures, extensively and intensively used meadows) and the percentage of forest cover (closed forest) within a 500 m radius around the centre of each meadow, using ArcGIS (orthophotos, updated in 2017, ArcGIS basemap).

Insect sampling

We sampled bumblebees and bugs in June and August 2015 and 2016 and grasshoppers in August 2015 and 2016. We assessed richness and abundance of bumblebees in four rectangular 20 m^2 (4 * 5) plots at each meadow. Sampling plots were selected randomly in the centre of the meadows. In order to guarantee standardisation of the sampling method, we selected distances of 3, 9 and 27 meters between the plots. Sampling was performed for 15 minutes per plot, summing up to 1 hour of observation time, and individual bumblebees were counted and identified on-site at the species level using an identification key by Gokcezade et al. (2015). However, single individuals had to be collected for complete confident identification in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58875908

the lab. Furthermore, we grouped bumblebees into long- and short-tongued species and individuals. This classification is important because tongue length plays a major role in food plant selection.

For true bug sampling we carried out sweep-netting along defined transects. The distance between two transects was 15 metre. Specifically, we conducted 90 sweeps per meadow subdivided into 3 * 30 sweeps covering an area of total 90 m^2 (3 transects of 15 metre length * 2 m width of the transect). Collected bugs were identified using identification literature of Wagner (1952, 1966, 1967) and Strauss (2010). We gathered information on food preference (zoo- and phytophagous) and overwintering strategy (overwintering as egg or imagoes) from Wagner (1952, 1966, 1967).

To assess number of grasshopper species, we used digital recorders (Olympus LS-12, Olympus Europa SE & CO. KG, Hamburg, Germany) and connected them to bat detectors (Batbox III D, Batbox Ltd. Steyning, UK). We adjusted a frequency of 27 kHz on the detectors with a bandwidth of 16 kHz. We installed both devices on 80 cm high platforms. The records, which were conducted between 10 a.m. and 5 p.m., were afterwards analysed at the office by comparing them with acoustic material (e.g. Roesti and Keist, 2009). The recording range was approximately 30 meters. No analysis of grasshopper abundance can be made with the soundscape approach. All identified grasshoppers were assigned to Ensifera and Caelifera according to Baur et al. (2006b). All samples were taken during suitable weather conditions (low wind, sunny conditions, temperatures above 20°C, dry vegetation).

For bumblebee and true bug sampling, we carried out sampling in the meadows successively and not parallel. However, to avoid that the meadows were always sampled at the same time of the day, we investigated meadows, which were sampled in June in the morning, in August in the afternoon 2015. In the following year (2016) we sampled the meadows vice versa to 2015. A sketch showing the experimental setup of insect sampling is shown in *Figure 3*.

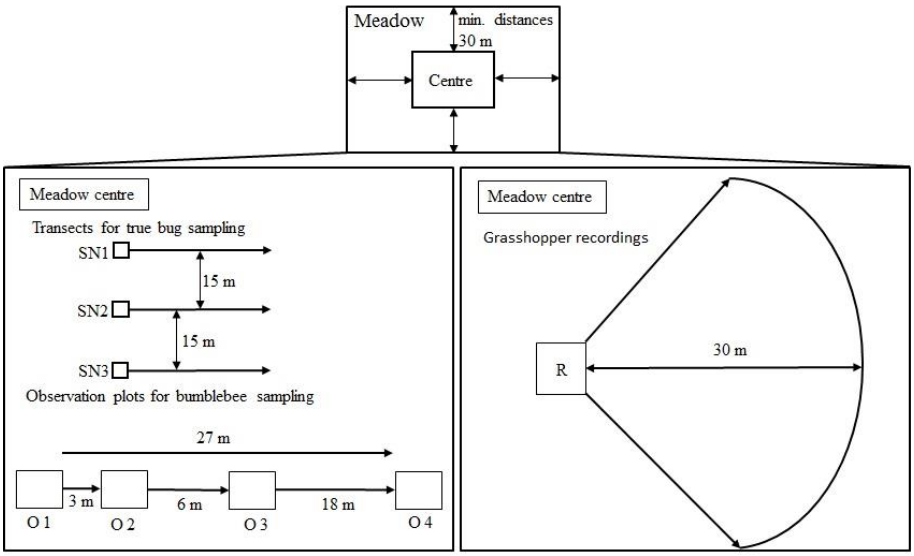

Figure 3. *Sketch showing sampling locations within one meadow. SN1-SN3 denotes transects for sweep sampling of true bugs. O1-O4 denotes observation plots for bumblebees. R denotes location of the recording devices. Measurements were carried out in the centre of each meadow keeping distances of minimum 30 meter to adjacent habitats*

DOI: http://dx.doi.org/10.15666/aeer/1703_58875908

Plant sampling

To estimate the influence of vegetation parameters on the three insect groups, we examined vegetation cover as well as total flower cover and diversity of vascular plants in each meadow. Sampling was carried out in June and August 2015 and 2016. We selected four 1 m^2 plots in the centre of the meadows. For the purpose of vegetation assessments, we placed a 1 * 1 m frame on the ground and identified each plant to the species level. We recorded percentage of vegetation cover (including living biomass, necromass and open soil) and percentage of flower cover within the total plot area (1 m^2). We subdivided individual plant species into plant species providing open or hidden nectar flowers, which is an especially important vegetation parameter for bumblebees and their different tongue-length.

Statistical analysis

We used Shapiro-tests to check for normal distribution, and Bartlett- and Fligner-tests to check for homogeneity of variances of the data. We used generalized linear mixed models (GLMMs) to investigate the management effect on species richness and abundance of the three insect groups. Management was chosen as a fixed factor, and month (June and August) and year (2015 and 2016) as random factors. We investigated overdispersion in GLMMs by including an observation-level random effect (Harrison, 2014; Meyer et al., 2017). GLMMs were performed using the R-package *lme4* (Bates et al., 2015). We conducted generalized linear models (GLMs) to investigate differences between management types regarding tongue-length of bumblebees, feeding and hibernating strategy types of true bugs, suborders of grasshoppers, effects of vegetation parameters (vegetation and flower cover, plant species richness, plants providing hidden and open nectar flowers) and the structure of the surrounding landscape (open landscape and forest) on the three investigated insect groups. To test for over- or underdispersion, we used the *P__disp()* function (R-package "msme" version 0.5.1, Hilbe and Robinson, 2014) and the *dispersion.test()* function in R (R-package "AER", version 1.2-4, Kleiber et al., 2015). We specified quasi-poisson errors to correct for over- or underdispersion in GLMs (Crawley, 2013). Before calculating GLM models, we investigated possible correlations between plant parameters and surrounding landscape structures. Since plant parameters and surrounding landscape structures were correlated, we decided to test them in single GLM-models. Furthermore, the point-biserial correlation coefficient r_{pb} was computed to detect possible significant associations of any individual species of the three insect groups with the two meadow types. This procedure calculates the strength (R-function *strassoc()*) and significance (R-function *signassoc()*) of possible associations. Both functions are included in the package "indicspecies" version 1.7.5 in R (De Cáceres and Jansen, 2015). Two-sided permutation tests were conducted to assess significant associations. We calculated confidence intervals and bootstrapped data 999 times with replacement (Walcher et al., 2017).

We analysed possible differences in species composition of the three insect groups conducting a principal coordinate analysis (PCO). We included month and year as random factors, similar to the univariate analysis. A permutational ANOVA (PERMANOVA) was conducted to evaluate significant differences in species assemblages of the three insect groups. We permuted residuals 9999 times under a reduced model. Furthermore, by conducting the SIMPER-routine (similarity

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58875908

percentages), we investigated how individual species contribute to the differences between meadow types.

We used the version 6.1.13 of the software Primer including PERMANOVA+ (PRIMER-E Ltd. Plymouth, UK) to conduct PCO, PERMANOVA, and SIMPER routines. We performed all other statistical analysis in R, version 3.1.3 (R Core Team, 2015).

Results

Bumblebees

In total, we collected 98 bumblebee individuals of 13 species (*Bombus sp.*, *Appendix A*). Twelve species with 64 individuals were found in managed, and 8 species with 34 individuals in abandoned meadows. We identified three cuckoo bumblebees (*Bombus* [*Psithyrus*] *sp.*). Further, we distinguished between 5 long- and 8 short-tongued species.

Managed meadows harboured a significantly higher total bumblebee richness and higher numbers of long-tongued species (GLMM, z=2.479, p=0.0132 and z=2.147, p=0.0318 respectively; *Fig. 4 a* and *b*).

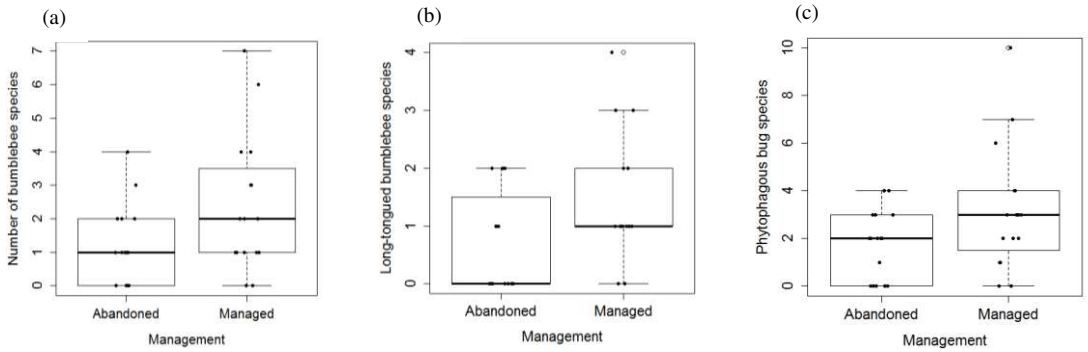

Figure 4. *Response of (a) total bumblebee species richness, (b) long-tongued bumblebee species richness and (c) phytophagous bug species richness on management. Boxplots show the median and the 25 % and 75 % percentiles. The dashed lines indicate the 10 % and 90 % percentiles. Outliers are indicated by (○). Data points are included as jitter-overlay*

Higher total flower cover increased total bumblebee species richness and abundance, and both number of short- and long-tongued species and individuals (*Table 2*, *Fig. 5a-f*).

Higher plant species with hidden nectar flowers significantly increased total bumblebee species richness as well as number of long-tongued species (*Table 2*, *Fig. 6 a* and *b*).

No relationship was found between number of bumblebee species and individuals, abundance of short-and long-tongued species and individuals and total plant species richness, surrounding landscape (open landscape and forest cover), vegetation cover and number of plant species with open nectar flowers. The point-biserial correlation did not show a significant association between individual bumblebee species and meadow types.

There was no significant difference between meadow types regarding bumblebee species assemblages (PERMANOVA, main-test: p = 0.145). We found an average

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58875908

similarity of 15.30 in annually mown meadows (SIMPER-analysis). 92.17% of the similarity was described by *B. lapidarius*, *B. hortorum*, *B. humilis* and *B. terrestris*. *Bombus humilis*, *B. pascuorum, B. hypnorum* and *B. terrestris* explained 91.42% of the similarity of 7.22 in abandoned meadows. Both meadow types revealed a dissimilarity of 91.49. *Bombus humilis*, *B. hortorum*, *B. lapidarius*, *B. pascuorum* and *B. terrestris* described 70.34% of the dissimilarity.

Table 2. *Generalized Linear Models (GLM, significance level: p<0.05) showing the effects of vegetation parameters on the three insect groups. The table shows the relationships between flower classes and bumblebees and the relationship between surrounding landscape structure, true bugs and grasshoppers. P-values which are significant are highlighted in bold (n.s: not significant, (-) indicates a negative effect, (+) indicates a positive effect, Res.dev. = Residual deviance, df = degrees of freedom)*

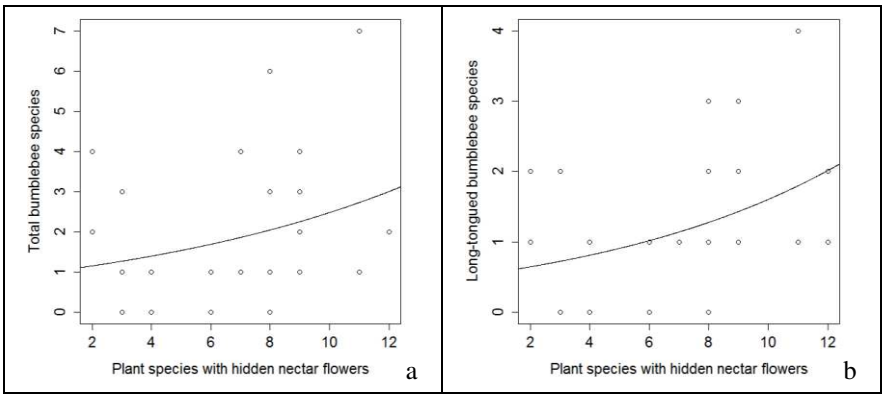

Figure 6. *Relationship between plant species with hidden nectar flowers and (a) total bumblebee species and (b) long-tongued bumblebee species. Fitted lines were drawn through the scatterplot using the predict-function in R*

True bugs

In total, we found 281 bug individuals of 32 species (*Appendix B*). We found 165 individuals of 27 species in managed, and 116 individuals of 13 species in abandoned meadows. Twenty-nine species were classified as phytophagous and three species as zoophagous. We classified 12 species as overwintering as eggs and 20 species as overwintering as imagos. We did not further include zoophagous bug species in the analysis due to the underrepresentation of this trophic group.

Managed meadows harboured significantly higher phytophagous bug species than abandoned meadows (GLMM, z=1.970, p=0.0488; *Fig. 4c*). Richness and abundance of true bugs, number of phytophagous bug species and individuals and individuals hibernating as eggs decreased with an increasing amount of forest cover in the surrounding landscape (*Table 2*). A larger proportion of open landscape in the surrounding landscape positively affected total number of individuals, individuals overwintering as eggs and species and individuals belonging to the phytophagous trophic group (*Table 2*). Increasing flower cover increased the number of phytophagous individuals (*Table 2*, *Fig. 5g*). No individual bug species was associated with either annually mown or abandoned meadows.

True bug species assemblages did not significantly differ between meadow types (PERMANOVA, main-test: p=0.565). The average Bray-Curtis similarity in the SIMPER-analysis in managed meadows was 7.19, with *Leptopterna dolobrata*, *Carpocoris purpureipennis*, *Orthops kalmii*, *Dolychoris baccarum*, *Graphosoma lineatum* and *Halticus apterus* explaining 91.58% of the similarity. Abandoned meadows revealed a similarity of 9.13. 91.11% of the similarity was due to the species *Nabis rugosus*, *Leptoperna dolobrata*, *Polymerus microphtalmus* and *Graphosoma lineatum*. We found an average dissimilarity of 92.30 between meadow types, where 62.70% of the dissimilarity was explained by the species *Leptopterna dolobrata*, *Nabis rugosus*, *Halticus apterus*, *Polymerus microphtalmus* and *Carpocoris purpureipennis*.

Grasshoppers

We detected a total of 15 grasshopper species in both meadow types (*Appendix C*). We found 12 species in managed and 13 species in abandoned meadows. We found eight Caelifera species and seven Ensifera species.

There was no management effect on total species richness or on richness of Caelifera and Ensifera. Increasing total flower cover increased total grasshopper species richness (*Table 2*, *Fig. 5h*). Caelifera were significantly negatively affected by higher amounts of forest cover in the surrounding landscape (*Table 2*). We found *Stenobothrus lineatus* to be significantly associated with managed meadows.

Grasshopper species assemblages did not differ between meadow types (PERMANOVA, main-test: p=0.257). 94.01% of the similarity of 61.63 in managed meadows was due to the species *Chorthippus biguttulus*, *Stenobothrus lineatus*, *Pseudochorthippus parallelus*, *Metrioptera brachyptera*, *Roeseliana roeselii* and *Euthystira brachyptera*. 84% of the similarity of 53.42 in abandoned meadows was explained by the species *Euthystira brachyptera*, *Pholidoptera griseoaptera*, *Gomphocerippus rufus*, *Pseudochorthippus parallelus*, *Roeseliana roeselii*, and *Chorthippus biguttulus*. The average dissimilarity between meadow types was 52.36, with *Stenobothrus lineatus, Metrioptera brachyptera, Pholidoptera griseoaptera, Gomphocerippus rufus, Chorthippus biguttulus, Roeseliana roeselii, Barbitistes serricauda* and *Pholidoptera aptera* explaining 67.13% of the dissimilarity.

Landscape structure and vegetation parameters

Managed meadows comprised a significantly higher total plant species richness as well as a higher total flower cover compared to abandoned meadows (F=38.17, p<0.001 and F=6.06, p=0.019, respectively, ANOVA). Similarly, managed meadows harboured a significantly higher number of plant species with hidden nectar flowers (F=88.05, p<0.001). Vegetation cover as well as number of plant species with open nectar flowers did not differ between habitat types. Surrounding open landscape and surrounding forest cover were significantly negatively correlated (R^2=-0.96; p<0.001). Flower cover significantly increased with increasing numbers of plant species (R^2=0.44; p=0.012). Number of plant species were significantly positively correlated with number of plants with hidden nectar flowers (R^2=0.74; p<0.001) and number of plants with open nectar flowers (R^2=0.37; p=0.037). Numbers of hidden nectar plants marginally significantly increased with increasing flower cover (R^2=0.34; p=0.057). A list of the recorded plant species, the mean values for vegetation and flower cover and mean numbers of plant species providing open and hidden nectar flowers are given in *Appendix D*.

Discussion

Our results showed a positive effect of extensive management on total bumblebee species richness, particularly on long-tongued bumblebee species. This positive effect is mainly attributable to the higher total flower cover and the higher number of plant species which provided hidden nectar flowers in the investigated annually mown meadows. As a consequence of abandonment, it is likely that plant species richness decreased (e.g. Stampfli and Zeiter, 1999; Pykälä et al., 2005), which subsequently led to a reduction of floral resources (Maurer et al., 2005). In our study, there was also a positive association between total flower cover and plant species richness. This illustrates the importance of maintaining extensively managed, species-rich meadows to preserve local bumblebee richness. In addition, these meadows provide an adequate supply of suitable foraging resources throughout almost the entire activity period of bumblebees, except for the time between mowing and the emergence of new flowers. The importance of providing flower-rich habitats for bumblebees has already been

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58875908

stressed by numerous authors (e.g. Dramstad and Fry, 1995; Carvell et al., 2006; Ahrné et al., 2009). Similar species assemblages between meadow types suggests the provision of a sufficient amount of suitable foraging plants in abandoned meadows (Walcher et al., 2017). Further, bumblebees are highly mobile organisms which use a wide range of habitat types (e.g. Darvill et al., 2004; Westphal et al., 2006; Carvell et al., 2017), and both meadow types lay within their flight range.

Managed meadows contained significantly higher numbers of phytophagous bug species compared to abandoned meadows. Effects of management on several bug species were also shown in other studies (e.g. Di Giulio et al., 2001). Due to a reduced plant species richness in abandoned meadows we assume that suitable host plants for phytophagous bug species might be lost during the process of secondary succession (Tasser and Tappeiner, 2002). The managed meadows provided a range of suitable host plants for many bug species, as many of them were polyphagous species using a range of different plant species and families (e.g. Di Giulio and Edwards, 2003; Wachmann et al., 2004, 2007, 2008). True bugs were positively related with surrounding open landscape, revealing the importance of this landscape factor for the observed bugs (Torma et al., 2017). Most of the examined bug species in the present study are associated with open grassland habitats (e.g. Wachmann et al., 2004, 2007, 2008). This might explain the positive relationship with surrounding open landscape, because these species can utilize the supplementary resources in the surrounding meadows depending on their food specialization (Torma et al., 2017). In addition, these habitats can also be regarded as suitable refuges during mowing of the extensively managed meadows or as supplementary overwintering habitats. Most of the detected species were found in both habitat types. True bugs are usually very mobile organisms with a high dispersal potential (Bröring and Wiegleb, 2005; Yanhui et al., 2007; Reynolds et al., 2013). In addition, many of the bug species found in both managed and abandoned meadows were generalist species which do not depend on a specific habitat (e.g. Di Giulio et al., 2001; Wachmann et al., 2004, 2007, 2008). This and the ability to migrate over long distances might explain the lack of differences in species assemblages between both habitat types. The positive relationship between bug species and total flower cover confirms the results of some other studies (Frank and Kuenzle, 2006; Zurbrügg and Frank, 2006). Around 70% of the collected bugs are reported to feed or stay mainly on inflorescences (Wachmann et al., 2004, 2007, 2008). This explains the positive relationship between bugs and flower cover in the present study. In general, both managed and abandoned meadows are beneficial for various bug species, while abandoned meadows, which are not yet regrown with woody plants, are still a valuable habitat for many bug species inhabiting open landscapes.

Several studies on grassland habitats revealed a negative influence of land-use abandonment on grasshoppers, in which abandonment led to a decline in grasshopper species richness (Marini et al., 2009; Uchida and Ushimaru, 2014; Uchida et al., 2016). Our results, on the other hand, supports the findings of other studies (Bonari et al., 2017; Walcher et al., 2017), in that grasshoppers did not show any response to land-use abandonment. Most of our observed grasshopper species are considered to be habitat generalists. Therefore, we assume that they are well adapted to the habitat conditions of both managed and abandoned meadows. Interestingly, there was a positive relationship between total grasshopper species richness and flower cover. We interpret this as an indirect effect of management, as there is no evidence in literature of grasshoppers using inflorescences as a direct food source. Zahn et al. (2010) showed a positive correlation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_58875908

between grasshopper abundance and total flower cover. More likely, the factor flower cover is an indicator of habitat conditions and vegetation development in the two management types. Managed meadows are particularly important habitats for some of the observed grasshopper species. For example, *Stenobothrus lineatus* was found to be a characteristic species of the managed meadows. This species requires regularly mown meadows with a low sward height and some places of bare ground (Behrens and Fartmann, 2004). However, abandoned meadows were characterized by taller vegetation and the presence of certain bushes and small trees. In general, Ensifera prefer more structured habitat types containing trees and shrubs (Baur et al., 2006b; Marini et al., 2009) and some of the Ensifera species were exclusively or almost exclusively detected in abandoned meadows. A species which showed a particular preference for abandoned meadows was *Tettigonia cantans*. This species requires well-structured habitat types with dense vegetation (Baur et al., 2006b). The negative relationship between Caelifera and surrounding forest cover is due to the fact that none of the observed Caelifera species would choose closed forest as habitat type, since they are known to have an affinity for open habitats. There was no difference between species assemblages in managed and abandoned meadows. This result is in contrast to other studies (e.g. Fartmann et al., 2012; Walcher et al., 2017) who found that species assemblages differed between successional stages of grasslands. Most of the grasshopper species we observed have no special preference for a specific habitat type (Baur et al., 2006b) but are more sensitive to vegetation characteristics (Gardiner et al., 2002). It can be assumed that most of the observed grasshopper species found suitable microhabitats in both meadow types, and thus contain similar species assemblages.

Conclusion

Extensive management of meadows turned out to be an important management scheme to sustain bumblebee and true bug richness in the nature reserve Eisenwurzen region. High plant richness in the extensively mown meadows was associated with high flower cover, which contributed to high richness and abundance of the three insect groups studied. Both types of meadows harboured a similar composition of the three insect taxa. This shows that abandoned meadows, as long as they are not yet re-grown into forest, can act as suitable habitat for many of the observed species. However, a conversion into closed forest would deteriorate habitat conditions which are suitable for most species inhabiting open habitats. Thus, a regular removal of shrubs and trees is required for the maintenance of this meadow type.

Acknowledgements. We want to thank the land owners and farmers for their permission to investigate insects and plants on their meadows. Thanks to the Austrian Academy of Sciences (project: Healthy Alps) for supporting this study.

Abstract. In this study, it is aimed to determine the variation of some leaf characters of *Platanus orientalis* L. depending on the climate type. For this purpose, in a country dominated by three climate types (Terrestrial, Black Sea and Mediterranean), leaves samples of *Platanus orientalis* trees were collected. Scaled images were obtained with the help of electron microscope (SEM = Scanning Electron Microscope) of collected leaf samples. Thus, with measurements made on these images, stoma length (μm), stoma width (μm), por length (μm), por width and stoma density (1 mm^2 area). The obtained data were evaluated as statistic and the change of these characters according to climate type and city was evaluated. In addition, by applying correlation analysis to the data, it was attempted to determine the relations between the subject characters and climate data. As a result of the study, no significant effect of the climate could be detected on the characteristics examined. This situation can be interpreted that morphological characteristics are shaped by many environmental factors and genetic structure besides climate. The authors suggest an increase and diversification in studies on the subject in order to determine how and under which conditions micromorphological characteristics are shaped. For this reason, it can be shown that the subjects of the study are collected from the individuals which were primarily raised for landscaping, and the practices in landscape studies change the micro ecological conditions in a clear way.
Keywords: *climate, correlation, flora, plant, landscape plant*

Introduction

In parallel with the rapid increase in urbanization across the globe, green areas are destroyed. However, the increase in the average global incomes and awareness levels of people has led to more efforts and legislations to preserve and increase green areas wherever possible. This is evident in major cities around the world where local authorities are planning to turn their cities greener by announcing schemes and plans to plant six and seven-figure trees in the short and long terms. The importance of plants and trees cannot be overstressed. Their environmental and social benefits such as reducing air and noise pollution, balancing the climate, and contributing to the ecosystem are just a few of many (Cetin and Sevik 2016a,b; Cetin et al., 2017). Furthermore, they perform many functions such as being an economic resource, reducing the speed of the wind and supporting wildlife (Kantarcı et al., 2011; Özel,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59095921

2008; Ertuğrul et al., 2014). In fact, one of the factors that affect the value of properties in cities nowadays is the amount of green areas and their proximity to them (Tilki et al., 2008; Erna, 2009; Ökmen and Yurtsever, 2010; Yiğit et al., 2014; Öztürk et al., 2017).

When designing open green places in urban areas, plant species, composition, cultivar, and even form are of great importance besides their sizes. In addition to their functional purposes, plants are desired to be aesthetically valuable, and more often that not, people tend to prefer non-native plants. As a result of this, plant species are used outside of their natural distribution areas, which is a situation frequently encountered in landscape architecture. They are confronted with stress factors arising from different habitats (Sevik and Cetin, 2016; Sevik et al., 2017, 2018; Cetin and Sevik 2016a,b; Cetin et al., 2017; Turkyilmaz et al., 2018a, b, c).

It is possible that the stress that may occur in plants as a result of their cultivation in the climatic conditions they are not accustomed to, may affect their micromorphological features that are not visible as well as their morphological features that are visible (Sevik and Cetin, 2015; Sevik et al., 2017, 2018; Cetin et al., 2018a, b; Kaya et al., 2018) because Turkey is under the influence of three main climates, which are quite different from each other. These climate types include the Black Sea climate type, continental climate type, and Mediterranean climate type. The effects of these climate types are combined with topographical conditions, resulting in many different types of local climates (Cetin et al., 2018a; Akkemik, 2014). According to the results of the study, the micromorphological characteristics of the areas working on the climate of the cities of the climate conditions or even the microclimate conditions of the areas of the plant is more effective than the main climate type. In this study, it has been shown that the environmental conditions affect the micromorphological characteristics of the leaves. The results of the study show that the local and micro-conditions are more effective on the micromorphological characteristics of the leaves than the main climate type. In landscape studies, there are many plants grown in the area where all three climate types are dominant. These plants are not morphologically different from each other. However, there is not enough information about how they differ in morphometric and micromorphological terms. However, these changes can provide insight into many issues, from the stress level of the plant to the habitat and the adaptation level (Sevik et al., 2017). However, in order to determine how these micromorphological changes should be interpreted, it is necessary to determine under what conditions these changes are shaped.

In this study, it was aimed to determine the change in some micromorphological characteristics in *Platanus orientalis* individuals grown in different climate types dominant in Turkey.

Materials and methods

Materials

The study was performed on the leaves of Platanus orientalis L. Plane tree (Platanus orientalis L.) belonging to Platanaceae family and is known for its grandeur and longevity. *Platanus orientalis* is one of the most common plane varieties in the world and it is the most widespread plane tree growing in Turkey. The common name of this variety is oriental plane. Among plane trees, it was the first variety to be discovered. The oriental plane is widely used as an ornamental tree, especially in urban areas and is also cultivated sometimes for timber (Guler et al., 2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59095921

Each of the city areas from each of the leaves collected from each leaf and each leaf was made from one to three pieces. Leaf specimens are collected from mature trees but it can be stated that the trees are at least 50-60 years of age.

Platanus orientalis (Oriental plane) leaves were collected from the areas dominated by the three climate types prevailing in Turkey. The Black Sea climate, which is one of the climate types prevailing in Turkey, is defined as wet and humid every season, while the Mediterranean climate has dry and hot summers as well as warm and rainy winters. In continental climate, summers are hot and dry, while winters are cold and snowy (Karakus, 2018). However, there are huge differences between the climate data of the cities in the regions where these climate types are dominant. The general climate characteristics of the cities included in the study were examined separately, and average temperature (Ta), average maximum temperature (Tmax), average minimum temperature (Tmin), average sunshine duration (ASD), average number of rainy days (ANRD), monthly average total precipitation (MATP), maximum temperature (MaxT) and minimum temperature (MinT) values obtained from the records of the General Directorate of Meteorology are presented in tables (URL, 1). The average meteorological data of the cities included in the study are given in *Table 1*.

Table 1. *Annual average meteorological data of the cities included in the study*

	Black Sea climate type			**Mediterranean climate type**			**Continental climate type**		
Cities	**Bartın**	**Samsun**	**Rize**	**Çanakkale**	**Antalya**	**İzmir**	**Ankara**	**Kayseri**	**Van**
T_a (°C)	12.8	14.5	14.3	15.0	18.6	17.8	11.9	10.7	9.2
T_{max} (°C)	19.0	18.2	18	19.6	24.1	22.6	17.8	18.0	14.9
T_{min} (°C)	7.6	11	11.1	10.7	13.7	13.4	6.2	2.9	3.6
ASD (hrs)	67.2	61	49.4	87.0	100.3	94.5	80.3	83.5	92.8
ANRD	140.0	135.6	172.5	83.6	75.1	77.7	102.3	107.2	93.0
MATP (mm)	1040.5	717.5	2304.1	616.2	1066.9	695.9	387.2	384.9	388.5
MaxT (°C)	42.8	39	38.2	39.0	45	43	41	40.7	37.5
MinT (°C)	-18.6	-9.8	-7	-11.5	-4.6	-8.2	-24.9	-32.5	-28.7

Ta (°C) = average temperature (°C); Tmax (°C) = average maximum temperature (°C); Tmin (°C) = average lowest temperature (°C); ASD = average sunshine duration (h); ANRD = average number of rainy days; MATP = monthly average total precipitation (mm); MaxT= maximum temperature (°C); MinT = minimum temperature (°C)

Upon examining the results of the table, it is observed that there are big differences between the meteorological data of the cities. The most significant difference is the amount of precipitation which is very important for plant development. While the annual average precipitation in Rize province is 2304.1 mm, this figure decreases to 384.9 mm in Kayseri, where the continental climate is dominant. There is approximately a 6-time difference between the two figures. A similar situation is observed between the temperature values. It is noteworthy that there are huge differences between the cities, especially in minimum temperatures. For example, the minimum temperature is -4.6 °C in Antalya, where the Mediterranean climate type is observed, while this figure is -32.5 °C in Kayseri where the continental climate is observed (*Fig. 1*).

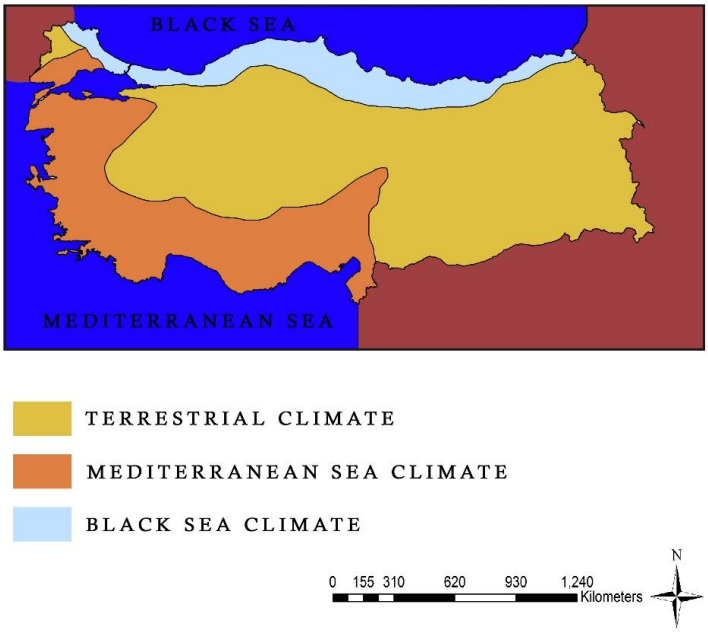

Figure 1. *Showing climate type in Turkey*

Method

Within the scope of the study, plane leaves were collected from the parks in the centers of the provinces at the end of September. A total of ten pieces of leaves were collected from each city and each leaf was made up of three pieces. Leaf specimens were collected from mature trees. The areas where the samples were collected are also shown in the map (*Fig. 2*). The GPS coordinates of the sampling of cities are following: Bartin 41° 38' 15.3744" N 32° 20' 1.7268" E; Samsun 40° 50' 12.5"N 34° 52' 28.9" E; Rize 41° 1' 31.8468" N 40° 31' 3.5976" E; Canakkale 39° 27' 12.0"N 26° 03' 48.9"E; Ankara 38° 40' 11.9"N 30° 50' 03.2"E; İzmir 37° 49' 06.9"N 26° 13' 48.7"E; Antalya 36° 05' 32.8"N 29° 15' 36.4"E; Kayseri 37° 39' 00.5"N 34° 53 '41.3"E; Van 37° 43' 48.4"N 42° 39' 42.8"E

Figure 2. *The locations of cities where the leaves samples were taken*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59095921

The samples of the mature leaves collected were pressed and brought to the laboratory. Samples were taken from the leaves brought to the laboratory and examined under an electron microscope. With the help of a Scanning Electron Microscope (SEM), scaled images were obtained from the lower side of the leaf blades and areas close to the middle sections. Files with the ".jpeg" extension were created from the obtained images. The points, where the measurements that were made using the "ImageJ" computer measurement program in order to perform micromorphological measurements of the leaves after these processes were completed, are shown in *Figure 3*.

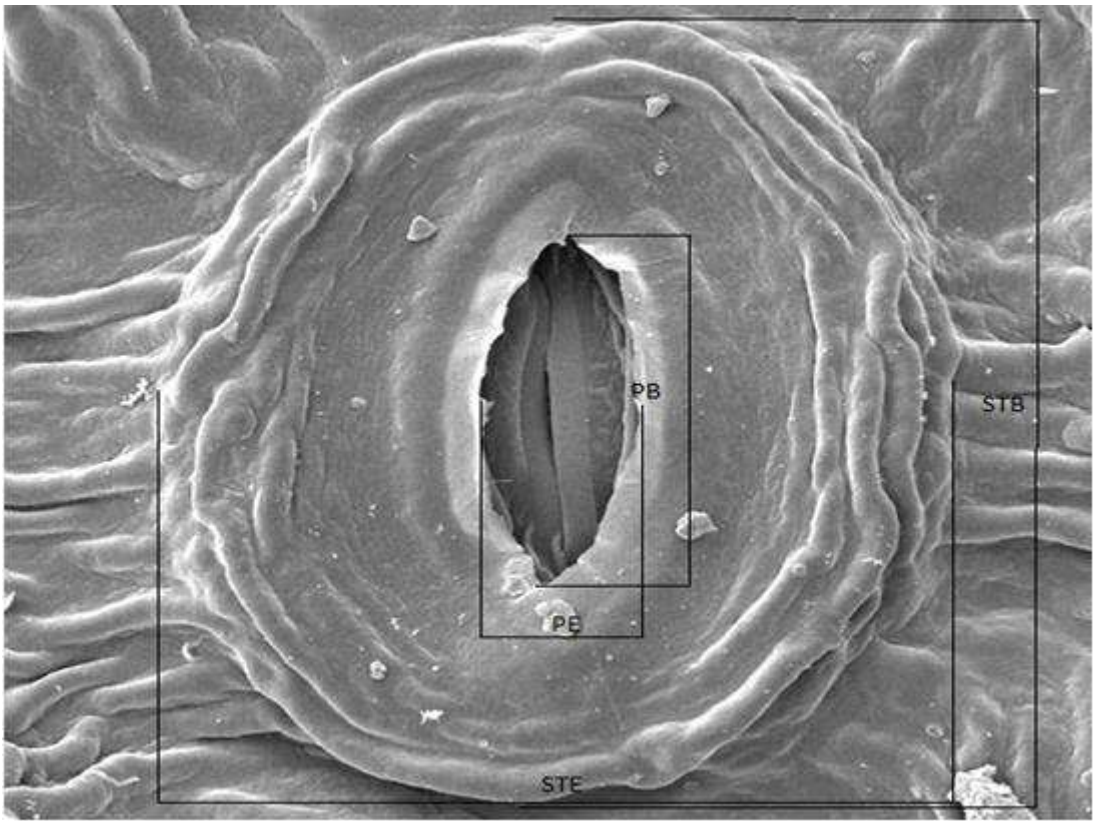

Figure 3. *Measurement of micromorphological characteristics. STL: stoma length, STW: stoma width, PL: pore length, PW: pore width, STD: stoma density (1 mm^2 in area)*

The data were analyzed with the help of SPSS packaged software, and the variance analysis and Duncan's test were applied to the data. As a result, correlation analysis was applied to the data in order to reveal the correlation of the characteristics with each other and with the climate parameters. The correlation coefficient varies between 0 and -1 or +1 and determines the direction of the correlation. If the sample correlation coefficient is equal to 0, it means that there is no linear connection between the two variables. As this value increases, the correlation between the two variables begins to increase and reaches the highest level when it is 1 (Cohen, 1988). According to Cohen, the correlation between the two variables is weak if the correlation coefficient is between 0.10-0.29 and moderate between 0.30-0.49 and strong between 0.50-1.0. The correlation analysis results obtained in the study were interpreted, and whether the correlation between the characteristics and climate parameters was statistically significant, the correlation direction and strength were interpreted.

Results

Change in micromorphological characteristics depending on climate types

Together with the results of the variance analysis and Duncan's test performed in order to determine the change in micromorphological characteristics of the species grown in different climate types depending on the climate type, the average values of the micromorphological characteristics based on the climate type are presented in *Table 2*.

Table 2. *Change in micromorphological characteristics depending on climate type*

Climate Type	Characters				
	STL (µm)	STW (µm)	PL (µm)	PW (µm)	STD (µm)
Continental	30.776	25.364 b	14.764	7.037	391.56
Mediterranean	28.687	21.956 a	13.382	6.441	313.78
Black Sea	29.105	24.448 ab	13.279	6.842	340.00
F Value	1.303 ns	3.736*	2.064 ns	0.414 ns	1.480 ns

*Significant level is at 0.05. The letters a, b, c, etc. means according to Duncan test results; show that the group is located. The means of following abbreviations are STL: stoma length; STW: stoma width; PL: pore length; PW: pore width; STD: stoma density

Upon examining the table values, it is observed that there is no statistically significant difference between climate types with at least 95% confidence level in terms of characteristics other than STW. On the other hand, there are significant differences at a 99% confidence level between the climate types in terms of STW. As a result of Duncan's test, two homogeneous groups were formed. The lowest value (21.956 µm) was obtained in the Mediterranean climate type, while the value obtained in the Black Sea climate type (24.448 µm) took place in both homogeneous groups. The value obtained in the continental climate type (25.364 µm) took place in the last homogeneous group.

Change in micromorphological characteristics depending on cities

Variance analysis was performed to determine the micromorphological characteristics of the species collected from the aforementioned cities. The F value and significance level obtained as a result of the variance analysis and the groupings consisting of the average values and Duncan's test are presented in *Table 3*.

Upon examining the table values, it is observed that there are statistically significant differences between the cities with at least 95% confidence level in terms of all characteristics except for STD. In terms of STD, there are no statistically significant differences between the cities at least 95% confidence level.

According to Duncan's test results, STL values were collected in three homogeneous groups. As a result of Duncan's test, Antalya with the lowest value (23.481 µm) took place in the first homogeneous group, while Bartın, Kayseri, and Samsun took place in the second homogeneous group, and Ankara and Çanakkale with the highest value (33.163 µm) took place in the third homogeneous group. Izmir, Rize, and Van took place in both the second and third homogeneous groups. In terms of STW, Antalya with the lowest value (17.669 µm) formed the first homogeneous group, while Ankara with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59095921

the highest value (27.274 µm) formed the last homogeneous group together with Van, Samsun, Çanakkale, and Rize. Bartın, Kayseri, and Rize formed the second homogeneous group.

Table 3. *Change in micromorphological characteristics depending on cities*

Climate	Provinces	STL (µm)	STW (µm)	PL (µm)	PW (µm)	STD (µm)
Mediterranean	Antalya	23.481 a	17.669 a	10.522 a	4.506 a	301.33
	İzmir	29.536 bc	21.765 b	14.473 bc	6.675 bcd	349.33
	Çanakkale	33.045 c	26.435 c	15.152 c	8.142 de	290.67
Black Sea	Samsun	28.756 b	27.049 c	14.309 bc	8.764 e	378.67
	Bartın	28.402 b	20.773 b	13.359 bc	5.597 ab	321.33
	Rize	30.158 bc	25.521 c	12.168 ab	6.167 abc	320.00
Continental	Van	31.433 bc	27.164 c	14.872 c	7.120 bcde	457.33
	Kayseri	27.732 b	21.655 b	13.551 bc	5.952 ab	290.67
	Ankara	33.163 c	27.274 c	15.867 c	8.039 cde	338.67
	F Value	5.924***	18.324***	3.979**	5.051***	0.727ns

*Significant level is at 0.05; **significant level is at 0.01; ***significant level is at 0.001 level. The letters a, b, c, etc. means according to Duncan test results; show that the group is located. The means of following abbreviations are STL: stoma length; STW: stoma width; PL: pore length; PW: pore width; STD: stoma density

PL values were collected in three homogenous groups based on cities. Antalya which had the lowest value (10.522 µm) took place only in the first homogeneous group, while Ankara (15.867 µm), Çanakkale (15.152 µm) and Van (14.872 µm) which had the highest values were only in the last homogeneous group. Rize which had the second lowest value (12.168 µm) took place in the second homogeneous group, while other cities, Bartın, Kayseri, Samsun, and Izmir took place in both the second and third homogeneous groups. The cities were gathered in five homogeneous groups in terms of the PW value. Antalya which had the lowest value (4.506 µm) took place only in the first homogeneous group, while Samsun which had the highest value (8.764 µm) took place only in the last homogeneous group. Regarding the other cities, Bartın and Kayseri were included in the first and second homogeneous groups, Rize was included in the first, second and third homogeneous groups, Izmir was included in the second, third and fourth homogeneous groups, Van was included in the second, third, fourth and fifth homogeneous groups, Ankara was included in the third, fourth and fifth homogeneous groups, and Çanakkale was included in the fourth and fifth homogeneous groups.

As a result of the variance analysis of the STD characteristic based on cities, it was determined that the change in the STD values based on cities was not statistically significant at least 95% confidence level. Therefore, Duncan's test was not applied to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59095921

the change in STD characteristic based on cities. When the change in STD based on cities is examined, it is observed that the values vary between 290.67 units/mm^2 and 457.33 units/mm^2. The lowest STD value was obtained in Çanakkale, while the highest STD value was obtained in Van.

Results of the correlation analysis

Correlation analysis was performed to determine the correlation between micromorphological characteristics and climate values, and the results are presented in *Table 4*.

Table 4. *Results of the correlation analysis related to micromorphological characteristics*

	STL (µm)	**STW (µm)**	**PL (µm)**	**PW (µm)**	**STD (µm)**
STL	0.740**				
PL	0.730**	0.594**			
PW	0.397**	0.618**	0.562**		
STD	0.110	0.128	0.115	0.150	
T_a (°C)	-0.347*	-0.450**	-0.329*	-0.188	-0.326
T_{max} (°C)	-0.450**	-0.665**	-0.359*	-0.342*	-0.323
T_{min} (°C)	-0.240	-0.267	-0.285	-0.079	-0.308
ASD (hrs)	-0.128	-0.326*	0.037	-0.156	0.056
ANRD	0.046	0.223	-0.124	0.021	-0.020
MATP (mm)	-0.159	-0.120	-0.429**	-0.276	-0.214
MaxT (°C)	-0.497**	-0.777**	-0.318*	-0.457**	-0.236
MinT (°C)	-0.233	-0.211	-0.325*	-0.081	-0.303

*Significant level is at 0.05; **significant level is at 0.01; ***significant level is at 0.001 level. The means of following abbreviations are STL: stoma length; STW: stoma width; PL: pore length; PW: pore width; STD: stoma density

Upon examining the table values, it is observed that the correlations between all characteristics other than STD are statistically significant. Only the correlation of STD with STL was statistically significant. It was determined that all of the correlations between micromorphological characteristics were positive, only the correlation between STL and PW was moderate and the correlations between the other characteristics were strong.

When the correlation between climate data and micromorphological characteristics is examined, it is observed that no correlation of STD with the climate parameters is statistically significant. In addition to this, it is observed that the correlation of MaxT (°C) and T_{max} (°C) with all micromorphological characteristics and the correlation of T_a (°C) with micromorphological characteristics other than PW are statistically significant. In addition to these, it was determined that the correlation of MinT (°C) with PL, the correlation of ASD (hrs) with STW, and the correlation of MATP (mm) with PL were statistically significant.

It is noteworthy that the statistically significant correlations found between climate data and micromorphological characteristics are all negative. The strongest correlations among these are between STW and ANRD, and T_{max} (°C). While these correlations are negative and strong, other correlations are moderate and strong.

Discussion

The plants used in the study were collected from plants that were planted for landscaping in city centers. In landscape studies, practitioners may change micro-environmental conditions to a certain extent. This situation causes species to be cultivated outside of their natural distribution areas (Cetin et al., 2018a). In this case, the effects of the dominant climate type in the area where the plant is grown are limited. For example, in this study, there was no correlation found between the amount of precipitation and the characteristics examined at the expected level. However, there is a very strong correlation between precipitation, namely water status, and plant development (Sevik and Cetin, 2015; Biber and Kara, 2012; Li et al., 2015; Marathe and Babu, 2017; Dixon et al., 2015).

Studies on the micromorphological characteristics of plants indicate that the water status and stomatal characteristics are closely related (Yang and Wang, 2001; Zhang et al., 2006; Liu et al., 2006). The fact that there was no significant difference between the characteristics examined and the climatic parameters in this study is probably due to the alteration of micro conditions by maintenance work on plants in landscape applications because irrigation applications, climatic, fertilizing applications, edaphic, spraying and pruning applications may also change biological conditions significantly.

In the studies, it is stated that the morphological and micromorphological characteristics of plant leaves are related to stress conditions. Factors such as high and low temperatures, salinity, oxygen shortage, and light stress as well as water status can significantly affect plant growth performance and characteristics (Kulaç, 2010; Xu and Zhou, 2008; Sevik et al., 2016; Topacoglu et al., 2016; Sevik and Karaca, 2016; Zhao et al., 2001; Romero-Aranda et al., 2001). Therefore, stomatal characteristics may change depending on many environmental conditions such as light, humidity, drought, and CO_2 (Banon et al., 2004; Beerling et al., 1997). In fact, it is stated that stomatal characteristics may change depending on factors such as traffic density because many unpredictable environmental factors may affect the growth, development and morphological characteristics of plants by creating stress effects (Sevik et al., 2017, 2018; Cetin et al., 2018a, b; Turkyilmaz, 2018a, b, c).

Plants do not easily encounter stress factors due to the climate in their natural habitats. However, since the plants used in landscape studies are cultivated outside of their natural habitat, they are more likely to encounter climate-induced stress conditions. The damages and effects on plant morphology caused by stress factors vary depending on the type, tolerance, and adaptability of the plant (Madhova Rao, 2005; Kadıoğlu, 2004).

Besides the mentioned conditions, the effect of external factors on plants can also affect plant development and its morphological characteristics. Factors such as pruning, hormone applications, spraying, shading and fertilization were demonstrated to be effective on the morphological and micromorphological characteristics of the plant (Knecht and Orton, 1970; Ferris et al., 1996; Pearson et al., 1995; Guney et al., 2016; Sevik and Cetin, 2016; Aydemir Özcan, 2017).

In addition, one of the factors that determine the reaction of the plant to the environmental conditions is the genetic structure. Morphological and physiological characteristics in plants are shaped by the interaction of genetic structure and environmental factors. Therefore, there are many factors affecting morphological characteristics. Many factors such as precipitation, temperature, stress factors, light, air pollution and soil structure affect the morphological characteristics of plants (Gratani,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59095921

2014; Peguero-Pina et al., 2014; Jochner et al., 2015; Majeed et al., 2015; Jud et al., 2016; Ren et al., 2018). The response of the plant to these factors is closely related to the genetic structure of the plant (Sevik et al., 2016, 2017). Plants of the same species can react differently to different stress conditions (Topacoglu et al., 2016). This is related to the genetic structure of the plant. As a matter of fact, it is stated that there may be significant differences between morphological and micromorphological characteristics of the plants grown in the same environment besides their growth performance (Sevik et al., 2016, 2017; Hrivnák et al., 2017).

Conclusion

As a result of the study, it was determined that there were huge differences between the data obtained from the cities located in the regions where the same climate type is dominant. For example, while the lowest value for STL was obtained in Antalya province, the second highest value was obtained in Çanakkale. On the other hand, the lowest value for PL was obtained in Antalya, while the second highest value was obtained in Izmir. However, three of the cities of Antalya, Çanakkale, and Izmir are located in areas where the Mediterranean climate type is dominant.

The results of the correlation analysis also support these results. According to the results of the correlation analysis, there was no correlation between the climate parameters and micromorphological characteristics at the expected level. Similar results were obtained for morphometric characteristics. It may be interpreted that factors other than climate are more effective on micromorphological and morphometric characteristics.

As a result of the study, no significant effect of the climate could be detected on the characteristics examined in the study. The possible causes are explained above. This situation can be interpreted as morphological characteristics are shaped by many environmental factors and genetic structure besides climate. In this case, it can be suggested to increase and diversify studies on the subject in order to determine how and under which conditions micromorphological characteristics are shaped in particular. In these studies, the diversification of the effects of environmental and genetic factors and examination of the changes caused by only one factor may provide more accurate data.

If a plant with high water demand is grown in a dry area, its water needs can be met by regular irrigation. Therefore, the micro conditions in which the plant is grown may be quite different from the main climate type. A similar situation applies to edaphic factors. Thus, micro-environmental conditions in plants used for landscaping can be quite different from the edaphic and climatic conditions of the region, and the micro-environmental conditions can strongly affect the growth performance of the plant. Therefore, it is difficult to determine the effect of climate on micromorphological characteristics of the plant in the studies conducted on the plants collected from these areas. Therefore, future studies to be carried out on natural plant species if they cannot be conducted in control environments may lead to more accurate data for determining the effect of climate on the micromorphological characteristics of the plant.

(Received 21st Jan 2019; accepted 27th Feb 2019)

Abstract. With the accelerating process of urbanization, the contradiction between the shortage of land resources and the expansion of cities has become increasingly prominent. Many cities have expanded the area of development by "cutting mountains and building land". Taking Lanzhou city of China, a typical valley-type city as the study area, land use change data obtained from remote sensing imagery in 1995, 2000, 2005, 2010, and 2015 were quantified by land use transfer matrix, land use change intensity index, ecosystem service value, and regional eco-environmental quality index method. The study on the characteristics of land use change and its impact on the ecological environment in Lanzhou City shows that the land use change in Lanzhou City during the period of 1990 to 2015 years is mainly reflected by the decrease of cultivated land and grassland, the increase in construction land and unused land area; The quality of eco-environment in Lanzhou City was negative developed from 1990 to 2015. The spatial expansion caused by urbanization had the most profound impact on land use types; the minimum value of eco-environmental index of all counties in Lanzhou City appeared in 2015, and Grassland and Farmland occupied by a large amount of construction land is the main reason for the deterioration of ecological environment quality. Based on the study, we expected to provide reference for the development and construction, and ecological environment protection of similar areas, especially the cities with extremely shortage of land resources such as the typical river-valley cities in the future development.
Keywords: *land creation, ecological environmental effect, land use, TM image, Lanzhou City of China*

Introduction

The fundamental national condition that China has Limited Farmland per Capita has led to a strong contradiction between supply and demand for land resources. Nowadays, the process of urbanization in our country is accelerating, and cities are rapidly expanding. However, limited land resources and urban expansion space have limited the expansion of cities. Especially in the valley-cities, the expandable area is relatively limited due to the restrictions of the terrain. Under the background of increasingly conspicuous contradiction between limited land resources, increasing population and land use demand, some cities in our country carry out the project of "Bulldoze Mountains to Build New City" to expand the urban area, thus obtaining better development space. For example, Yan'an expands the scale of the city through the method of "Foundation in the mountains" and builds a Yan'an New Area (Cui, 2015); the "industry terrace" project was implemented in Fujian, Guizhou, etc. (Huang, 2014; Jiang et al., 2007). The main method is to combine "truncating the mountain" and filling land with flat land in order to expand the area; the new district of Lanzhou and Gaolan county in Gansu Province have expanded the area of development by "truncating the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59235934

mountain". However, various scholars have different opinions on whether the "Bulldoze Mountains to Build New City" is feasible or not. Cui (2015) believes that the construction of Yan'an New District will continue to expand land for urban construction, at the same time, it causes changes in land use types, destruction of vegetation resources and ecological environment. Li et al. (2014) considered that the "cutting the mountain and building the city" project was not mature in terms of economy, technology, and ecological protection. Liu and Li (2014) considered that the implementation of the government's plan, "Cutting off hilltops and moving mountains to build city in Yan'an", is feasible and provides references for other cities. That because detailed planning, hydrology and water resources, have demonstrated from all sides of ecology by experts.

"Bulldoze Mountains to Build New City" will cause changes in the land use types. Changes in land use types (Li et al., 2017; Tan et al., 2010) will have an impact on the regional ecological environment. The quality of the ecological environment will directly affect human well-being and the sustainable development of the region (Chang et al., 2017; Ma et al., 2015; Liu et al., 2005, 2009; Terefe et al., 2017). Domestic and foreign scholars have studied the impact of changes in land use types on the value of ecological services. For example, such as Terefe et al. (2017) believed that the reduction of forest land in Ethiopia has resulted in huge losses in ecosystem service value; Lawler et al. (2014) studied land use change in the United States. The impact of changes on ecosystem services suggests that changes in land use have promoted the fixation of carbon but led to the destruction of ecological environment. Xie et al. (2008) studied the land use changes in the suburbs of Tongchuan City on the eco-environment with the value of ecosystem services as indicators. Zhou et al. (2017) studied the effect of ecosystem service value of valley-city in Lanzhou, and concluded that the invading of farmland ecosystems by land for urban construction led to a drastic decline in ecosystem service value in Qinwangchuan basin. However, ecosystem service value is used to measure the quality of the ecological environment as an important indicator (Rong et al., 2017; Zhang et al., 2017; Hu et al., 2008).

As a typical valley-city, Lanzhou City has limited land resources, urban development is restricted, and the contradiction between growing population and demand for land is becoming increasingly prominent. In the past two decades, many cities such as Qinwangchuan and the new district of Lanzhou have carried out a number of "Bulldoze Mountains to Build New City projects", thereby expanding the urban land area. Therefore, the thesis uses Lanzhou City as an object of study to use the Landsat image data from 1990 to 2015 to analyze the characteristics of spatio-temporal changes in land use, and estimate the value of ecosystem services, continue to evaluate the impact of land use changes on ecology caused by "Bulldoze Mountains to Build New City".

Material and methods

Background of the study area

Lanzhou City, the capital of Gansu Province, is the political, economic and cultural center of Gansu Province and it is also an important central city in the northwestern China. It is located in the upper reaches of the Yellow River and is located at longitude 102°36'-104°34' E and latitude 35°34'-37°07' (*Fig. 1*), with an average elevation of 1500 m. It belongs to the loess hilly and gully region, temperate semi-arid continental monsoon climate, and large temperature difference between day and night, less

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59235934

precipitation (Guo et al., 2016). Lanzhou is an important support for the Western Long Hai-Lan Xin Economic Zone. The core of the upper Yellow River economy is mainly composed 34 towns and 27 villages. It currently governs five districts such as Chengguan District, Qilihe District, Anning District, Xigu District, and Honggu District and three counties including Yuzhong County, Gaolan County and Yongdeng County The total land area of Lanzhou City is 1311.9 thousand hm^2. Due to the constraints of the canyon topography and the two mountains in the north and the south, Lanzhou's urban space development is greatly constrained. The geographical space is relatively narrow and its integrity is poor. It is a typical valley-city in China (Zhang et al., 2013). The human settlement environment formed by this influence is special.

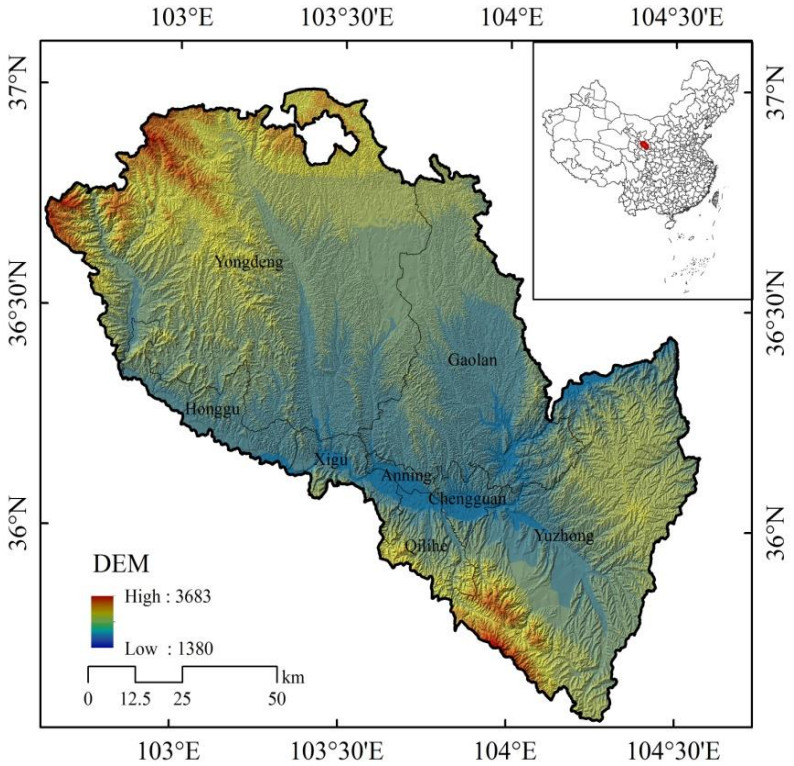

Figure 1. *The location of study area*

Data sources and processing

The research data used in this paper includes:

Remote Sensing Data: Landsat remote sensing images of Lanzhou City were selected in 1990, 1995, 2000, 2005, 2010 and 2015. The coordinates are 130/35, 131/34, and 131/35, and the spatial resolution is 30 m. All these data are from Geospatial Data Cloud (http://westdc.westgis.ac.cn).

Through radiation correction and FLAASH atmospheric correction, the processed remote sensing images were stitched and cropped to obtain remote sensing images in the study area from 1990 to 2015. By classification, the land use type map was obtained. In this study, the overall accuracy (OA), and another discrete multivariate index KAPPA (K) coefficient are used in accuracy assessments. The OA and K statistics can be calculated as *Equations 1* and *2,* respectively (Wei et al., 2010):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59235934

$$OA=\frac{\sum_{i=1}^{k} n_{ii}}{n} \quad \text{(Eq.1)}$$

$$K=\frac{n\sum_{i=1}^{k} n_{ii}-\sum_{i=1}^{k} n_{i+}n_{+i}}{n^2-\sum_{i=1}^{k} n_{i+}n_{+i}} \quad \text{(Eq.2)}$$

where, n is the total number of observations; k is the number of rows in the matrix, and n_{ii} is the number of observations in row i and column i; n_{i+} and n_{+i} are the total numbers of pixels in i-th row and i-th column, respectively. The results of statistics and accuracy analysis are shown in *Table 1*.

Table 1. *The classification supervision accuracy evaluation*

Year	2015	2010	2005	2000	1995	1990
Kappa coefficient	0.8699	0.8384	0.8248	0.8735	0.9024	0.9231
Overall accuracy	89.38%	90.16%	85.96%	91.25%	92.25%	85.59%

From *Table 1*, we can see that the classification accuracy of land use types in Lanzhou City during the period from 1990 to 2015 is all above 85.5%, which satisfies the accuracy requirements for follow-up studies.

Boundary data: National Geographic Center released.

Research methods

Land use change intensity index

The land use intensity index refers to the change in certain land-use types per unit area in the study area during a certain period of time. The land use change index (Xie et al., 2008) is calculated as *Equation 3:*

$$K_i=\frac{U_{ai}}{U_{bi}}\times\frac{1}{T}\times 100\% \quad \text{(Eq.3)}$$

where K_i denotes the i-th land use type change intensity index in the study area, U_{ai} denotes the i-th land use type area in the initial stage of the study period, U_{bi} denotes the i-th land use type area in the end of the research period, and T denotes the initial period of the study and the end of the study period. The time is apart and the unit is year.

Calculation of ecological service value

Xie et al. (2005) divided China's ecosystem services into nine categories such as climate regulation, water conservation, and food production, and formulated a table of ecological service values per unit area of different terrestrial ecosystems in China to calculate the ecological service value of the research area in different periods. The formula is as *Equation 4:*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59235934

$$\mathrm{ESV} = \sum_{i=1}^{n} A_i \times VC_i \quad \text{(Eq.4)}$$

ESV is the total value of ecological services of different land-use types (yuan), *i* refers to land-use types, A_i refers to the area of the *i*-th land-use type in the study area (hm^2), and VC_i is the unit ecological service value of the *i*-th land-use type (Yuan/hm^2·a).

Eco-environmental quality index

Taking into consideration the ecological environment quality and area ratio of land use types in various regions, the eco-environmental index are used to quantitatively characterize the overall situation of the ecological environment quality in a certain region. The expression (Zhang et al., 2018) is as *Equation 5:*

$$\mathrm{EV}_t = \frac{\sum_{i=1}^{n} A_i C_i}{\sum_{i=1}^{n} A_i} \quad \text{(Eq.5)}$$

where A_i, C_i is the area and eco-environmental index of the *i*-th land-use type in the period *t*, and *n* is the number of land-use types in the area.

Results and discussion

Analysis of land use change

(1) Overall land use change from 1990 to 2015

Based on the remote sensing imagery data from 1990 to 2015, using a combination of supervised classification and artificial visual interpretation, the land use type map of Lanzhou was interpreted, as shown in *Figure 2*.

The overall classification accuracy of different periods is between 85.59 and 92.25%, which meets the research needs. Overall, in the past 20 years, the land use structure in Lanzhou City underwent significant changes, mainly reflected in the increase in construction land and unused land, and the corresponding reduction in the area of cultivated land and grassland. From the point of view of spatial distribution, the increased construction land mainly shows two situations of agglomeration and scattered distribution. The increased construction land is mainly distributed in Gaolan County and Yongdeng County, that is, the construction of Lanzhou New District in December 2010 is consistent; The border between Anning District and Gaolan County is mainly the construction of Poly Xiuling Mountain, which is in line with the situation of the field investigation. Judging from the time series, the land for construction increased from 1990 to 2015. With 2010 as the demarcation point, the area of construction land in 2015 increased significantly.

In order to further study the characteristics of land use structure in Lanzhou City from 1990 to 2015, the area and proportion of each type of land use were calculated separately. The results are shown in *Table 2*.

	Proportion (%)	29.16	6.85	60.50	0.52	2.58	0.40
2005	Area (km^2)	3816.61	899.11	7993.48	68.17	369.81	55.73
	Proportion (%)	28.91	6.81	60.54	0.52	2.80	0.42
2010	Area (km^2)	3788.53	918.96	7993.81	68.39	377.95	55.26
	Proportion (%)	28.69	6.96	60.55	0.52	2.86	0.42
2015	Area (km^2)	3642.95	909.63	7917.97	70.04	558.40	103.91
	Proportion (%)	27.59	6.89	59.97	0.53	4.23	0.79
1990-2015	Net variable (km^2)	-210.56	8.72	-94.12	1.33	243.33	51.29
	Change rate (%)	-1.6	0.07	-0.71	0.01	1.84	0.39

From *Table 2*, we can see that during the period from 1990 to 2015, grassland was the main type of land use in Lanzhou, accounting for about 60% of the total area; in 2005, as the boundary, it decreased first and then increased. In 2015, it decreased drastically, and its value was 94.12 km^2. This is mainly caused by cutting mountains and land; arable land accounts for about 30% of the total area of land use. Since 2005, the area of cultivated land has been decreasing, which has decreased by nearly 210.56 km^2 compared with that of 1990. Construction land has been on an increasing trend. Compared with 1990, it has increased by 243.33 km^2 with a rate of change of 1.84%. Unused land and forest lands have been fluctuating. The change of Forest land was relatively small, while unutilized land increased nearly more than doubled in 2015. That is mainly because the land, which used for construction has not been used yet, increased obviously after the bulldoze mountains.

(2) Land use transfer characteristics and change intensity analysis

From the spatial distribution and structural characteristics of land use, we can see that the land use structure of Lanzhou City has undergone significant changes from 1990 to 2015. Therefore, the land use transfer situation in Lanzhou City from 1990 to 2015 was analyzed. The results are shown in *Table 3*.

From *Table 3*, it can be seen that various types of land use types have changed from 1990 to 2015. The types of land converted into construction land are the unused land <water area <woodland <grassland <cultivated land, and the area of water and unused land converted into construction land is 0.93 km^2 and 0.3 km^2 respectively; the area of cultivated land converted into construction land is 179.02 km^2, accounting for 73.34% of the conversion area. The conflict of the shortage of land resources and the large area of land for urban construction leads to create land from mountains, which caused the majority of grassland and a little few of the farmland reduced. This is similar to Lanzhou New District and Poly Lingxiushan. The Country Garden, which is still under

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59235934

construction, has close ties with other construction projects. On the other hand, due to the need for the construction of educational resources, large-scale arable land has been lost, such as Pengjiaping, Qiujiawan and so on.

Table 3. *Land use transfer matrix of Lanzhou city during 1990-2015 (unit: km^2)*

		2015					
		Farmland	**Forestland**	**Grassland**	**Water area**	**Construction land**	**Unused land**
1990	**Farmland**	3614.73	19.96	18.24	1.77	179.02	19.78
	Forestland	1.05	883.70	0.26	0.15	15.19	0.55
	Grassland	26.70	5.39	7898.95	0.52	48.63	31.89
	Water area	0.21	0.01	0.00	67.56	0.93	0.00
	Construction land	0.00	0.57	0.03	0.03	314.33	0.10
	Unused land	0.25	0.00	0.48	0.00	0.30	51.59

In order to further reveal the changes of land use types in Lanzhou City during the past 25 years, the change intensity of land use types in Lanzhou City during different research periods was calculated and the results are shown in *Table 4*.

Table 4. *The intensity of Land use change of Lanzhou city during 1990-2015 (unit: %)*

Year	Farmland	Forestland	Grassland	Water area	Construction land	Unused land
1990-1995	-0.06	0.01	-0.01	0.20	0.87	0.55
1995-2000	0.05	0.06	-0.05	-0.37	0.70	-0.54
2000-2005	-0.17	-0.11	0.01	0.02	1.74	1.18
2005-2010	-0.15	0.44	0.00	0.07	0.44	-0.17
2010-2015	-0.77	-0.20	-0.19	0.48	9.55	17.61
1990-2015	-0.22	0.039	-0.047	0.08	3.09	3.90

According to *Table 4*, from 1990 to 2015, the intensity index of land use change in forest land, water area, construction land, and unused land is positive, indicating that the overall area is increasing. In terms of different time periods, except for the intensity index of land use change during the period from 1995 to 2000, the rest is negative, indicating that the area of cultivated land has decreased during the past 15 years, and has decreased significantly from 2010 to 2015; The intensity index of construction land use change is positive, that is to say, the area of construction land in Lanzhou has increased at different degrees in the past 25 years. From 1990 to 2015, the positive value of the unexploited land use change index (19.34%) was much greater than the negative value (0.71%), and the unutilized land increased significantly. Most of the land obtained through the cut-to-earth land reclamation project has not yet been put into use in 2010-2015. Construction has led to a significant increase in unused land.

Eco- services value measurement and analysis

(1) Land use transfer characteristics and change intensity analysis

According to the research of Xie et al. (2005) in China's terrestrial ecosystem service value-equivalent factor table and correction factors of different provinces, the ecological

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59235934

service value of different land-use types in Lanzhou City is estimated, as shown in *Table 5*.

Table 5. *The intensity of Land use change of Lanzhou city during 1990-2015 (unit: million yuan)*

Year	Forestland	Grassland	Farmland	Water area	Construction land	Unused land	Total value
1990	73156.2	215583.8	98958.4	11737.8	491.5	82.1	400009.7
1995	73208.4	215470.4	98643.8	11852.5	512.8	84.4	399772.4
2000	73422.5	214925.2	98873.2	11633.5	530.7	82.1	399467.1
2005	73010.2	215083.0	98010.7	11645.5	576.9	86.9	398413.2
2010	74622.5	215091.8	97289.8	11684.4	589.6	86.2	399364.2
2015	73864.4	213051.2	93551.3	11965.7	871.0	162.1	393465.7

From *Table 5*, we can see from the total value of ecosystem services, the total value of ecosystem services in Lanzhou City decreased and then increased from 1990 to 2015. The total value of ecosystem services continued to decline during 1990-2005, which was reduced by 1596.5 million yuan. From 2005-2010, the total value of ecosystem services showed an increasing trend. From 2010-2015, the total value of ecosystem services declined drastically 5898.5 million yuan.

From the single type of land use, the ESV for forest land is similar to the change in the total value of ecosystem services in Lanzhou City. From 1990 to 2005, there was a trend of "increase-decrease-increase", of which in 2010 and 1990, the forest ecosystem service value peaked in 1990 and 2010 at the highest and lowest values, which were 74622.5 million yuan and 73156.2 million yuan respectively. In the past 25 years, the ecosystem service value of grassland and farmland showed a decreasing trend. The maximum values all appeared in 1990, and the minimum values all appeared in 2015. This is mainly due to the large number of Bulldoze Mountains to Build New City projects destroyed in Lanzhou City. Grassland and farmland have resulted in a significant reduction in the area of these two types of land use, which has led to a reduction in the value of ecosystem services. Due to the needs of urban construction, the area of construction land continues to increase. As a result, the ecosystem service value of construction land continues to rise. The speed of land creation is faster than the speed of construction. As a result, the area of unused land continues to expand, leading to a significant increase in the value of ecosystem services of unused land from 2010 to 2015.

(2) Regional comprehensive ecological environmental quality change

According to *Equation 3,* the eco-environmental indices of land use types in Lanzhou and its counties are calculated to analyze the impact of land use changes on the eco-environmental quality. The results are shown in *Table 6*.

From *Table 6*, we can see that the overall eco-environmental quality of Lanzhou City is basically stable, but it shows a downward trend. In addition to the increase trend from 2005 to 2010, the eco-environmental quality index of Lanzhou during the four periods of 1990-1995, 1995-2000, 2000-2005, and 2010-2015 both showed a downward trend. The ecological quality indices have been significantly reduced. The statistical analysis

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59235934

of the changes in eco-environmental index in all counties and counties of Lanzhou City in the past 25 years was the largest in Anning District, followed by Chengguan District, and Gaolan County ranked the third; the minimum eco-environmental index values of all counties appeared in 2015, including grassland and the large amount of cultivated land occupied by construction land is the main reason for the decline in the quality of the ecological environment.

Table 6. *The ecological environment quality index of Lanzhou city during 1990-2015*

	1990	**1995**	**2000**	**2005**	**2010**	**2015**
Chengguan District	0.3283	0.3273	0.3273	0.3204	0.3218	0.3091
Qilihe District	0.3502	0.3508	0.3507	0.3493	0.3498	0.3465
Anning District	0.3145	0.3128	0.3128	0.3022	0.3021	0.2932
Xigu District	0.3499	0.3479	0.3482	0.3469	0.3463	0.3454
Red Ancient District	0.3341	0.3341	0.3339	0.3336	0.3333	0.3306
Yongdeng County	0.3491	0.3490	0.3490	0.3489	0.3495	0.3481
Gaolan County	0.3330	0.3331	0.3327	0.3330	0.3339	0.3280
Yuzhong County	0.3394	0.3392	0.3390	0.3387	0.3387	0.3378
Lan'Zhou City	0.3426	0.3425	0.3424	0.3421	0.3425	0.3401

Conclusions

(1) From the land use type spatial distribution map, we can see that the area of construction land has increased significantly. It is mainly located in Yongdeng County and Gaolan County, and is used for the construction of Lanzhou New District and Poly Xiuling Mountain.

(2) In 2015, construction land and unused land increased rapidly. The project of "land creation" led to the conversion of large areas of farmland and grassland into construction land, which was mainly used for urban construction and educational resource construction.

(3) From the total value of ecosystem services, the total value of ecosystem services in Lanzhou City decreased and then increased from 1990 to 2015. From 2010 to 2015, the total value of ecosystem services declined drastically and its value was 5898.5 million yuan.

(4) During the period from 1990 to 2015, the overall eco-environmental quality in Lanzhou City was relatively stable, but overall it showed a deteriorating trend. Within the local area of each county, the quality of ecological environment changed significantly. Among them, the influence of cultivated land and grassland on the ecological environment quality played a leading role.

(5) This paper lacks the improvement research on the existing evaluation methods. How to consider other factors to the quantitative calculation of the ecological environment index, and accurately assess the effect of the land use changes on ecological environment. The influence of different scales and different land use classification systems on the evaluation results remains to be further studied in the future.

Abstract. The Banana infecting viruses have an importance in the movement and propagation of plant germplasm, especially in areas where banana is propagated vegetatively. During field surveys 118 banana leaf samples have been tested by DAS-ELISA, PCR and RT-PCR have shown malformation, necrosis, chlorotic streak and mosaic symptoms collected from Mediterranean Coast Line (Adana, Antalya and Mersin provinces) of Turkey in 2015 and 2016. For diagnosis of CMV, BBTV, BSV, TMV, PVY, WMMV, PRSV, BCMV and TSWV pathogens that cause severe crop loss in banana plantations firstly, serological tests have been conducted using DAS-ELISA immune kit. Further identification and confirmation studies by PCR and RT-PCR from leaf samples exhibiting mild chlorotic streaks and mosaics on leaves, typical infection of *Banana streak mosaic virus* (BSV) and *Cucumber mosaic cucumovirus (CMV)* were used. Their symptoms were truly matched in PCR (BSV & CMV) and DAS-ELISA (CMV) analyses. Disease incidence was consequently estimated between 17.79% (CMV) and 4.23% (BSV). This is the first molecular evidence for BSV or BSV mixed with CMV in banana in Turkey. Sequence information of PCR products were obtained from Hoplotypes and searched on BLAST system of NCBI. Phylogenetic analyses have informed the origin and ecology of CMV in bananas which were infected by vegetables grown inside the banana greenhouses The banana BSV isolate was in the same group isolates that were obtained in Kenya, Congo, Australia, China and India.
Keywords: *molecular ecology of banana viruses, BSV, CMV, PCR, DAS-ELISA*

Introduction

Banana (*Musa spp.*) is an economically important fruit, which is grown in tropical and subtropical climates and are widely consumed in both fresh and preserved form. Production is not only concentrated in the Mediterranean area of Turkey, but it is also produced worldwide (FAO, 2015). Around the world, roughly 145 million tons of bananas are grown each year (Baggaley, 2017). In Turkey according to the Ministry of Food, Agriculture and Livestock, 369009 tons of banana fruit was produced at the Mediterranean Coast Line (Adana, Mersin and Antalya provinces) in 2017. Additionally, an increase (14.4%) in banana production has been forecasted for this year (TUIK, 2017). There are many factors decreasing the quantity and quality of banana production more likely than in other fruit crops. One of the most important restrictive factors including plant diseases and pests, are viral agents. Among the important agronomic traits, virus resistance is one of the major breeding objectives, as several diseases caused by viruses have great economic impact on production.

Banana bunchy top virus (BBTV), *Banana streak virus* (BSV), *Cucumber mosaic virus* (CMV), *Banana bract mosaic virus* (BBrMV), *Banana mild mosaic virus* (BanMMV), *Banana virus X* (BVX) are major banana infecting viral agents (Tripathi et al., 2016). Morphology, taxonomy, symptomatology, cytopathology, epidemiology, diagnosis and sanitation of these *Musa spp* infecting species were reviewed by Teycheney and Lescot (2004). Furthermore, *Water melon mosaic virus, Papaya ringspot virus, Tobacco mosaic virus, Bean common mosaic virus, Tomato spotted wilt virus*, Potygroup and *Potato virus Y* could cause diseases in bananas. Nevertheless, based on the symptoms observed, Gambley and Thomas, (2001) has been underlined some viral infections.

Banana buncy top virus was first recorded in Fiji in 1889, and has spread broadly in banana production areas. It has been transmitted by sucker, and black aphid (*Pentalonia nigronervosa*). Also tissue culture propagation has an importance on transmission, due to noneradicated infections. The *Banana buncy top virus* can cause major economic yield loss. Another major threat is *Banana streak virus* that can cause leaf streak disease, it is a member of genus *Badnavirus*, and was first recorded in 1986. There are two main distinct strains of BSV (Lockhart and Olszewski, 1993). The Onne strain of BSV, now renamed BSV-OL (R Hull, personal communication), in Africa, Central and South America. The other strain is called as the Cavendish strain of BSV (BSV-Cav), which has been found in commercial banana plantations in Australia. BSV is transmitted by *Planococcus citri* (Risso) and possibly other species of mealybug (Lockhart and Jones, 1999). The characteristic symptoms of BSV infection are mainly chlorotic and necrotic streaks on the leaves. Other symptoms may include narrowing and thickening of the leaf, internal pseudostem necrosis, splitting of the base of the leaf sheaths and detachment of leaves, overall stunting of the plant, smaller bunches and abnormally shaped fruit with a thinner peel that is prone to splitting. The symptoms are probably diverged by factors such as environmental conditions, and host and virus genotypes (Lockhart and Jones, 1999).

BSV is transmitted by infected mother plants and through tissue-culture propagation of infected explants and by several mealybug (Hemiptera: Coccoidea: Pseudococcidae) species, but not mechanically (Lockhart and Jones, 1999). Mealybug species which have been confirmed as vectors include the citrus mealybug, *Planococcus citri* Russo (Lockhart and Olszewski, 1993), *Pseudococcus comstiki* Kuwana (Su, 1998), both the pineapple mealybug *Dysmicoccus brevipes* Cockerell and the sugarcane mealybug *Sacchirococcus sacchari* Cockerell (Kubiriba et al., 2001b), and the vine mealybug *Planococcus ficus* Signoret (Meyer et al., 2008).

Sison et al. (2017) underlined that BSV can be transmitted to uninfected banana by mealybugs of *Musa* sp. (*Pseudo-coccus elisae* and *Dysmicoccus brevipes*), *Manilkara zapota* (unreported), *Anonna muricata, Ananas comosus (Dysmicoccus brevipes)* and *Nephelium napaceum*. Infection transmission proficiency and mean effect seriousness was eminently most astounding utilizing the vectors from the last two yields. Mealybugs assume a noteworthy job in the characteristic spread of the infection. Since bananas in the Philippines are likewise planted close by the previously mentioned harvests, the board systems ought to tend to decrease the number of inhabitants in these mealybug species from fields.

The prevalent infection by CMV (Cucumovirus), has been classified by serology and symptomology (mosaic, line patterns and ringspot at leaf), and has three subgroups (IA, Ib and II) regarding coat protein gene. Interveinal chlorosis is also caused by CMV

strains. If strain severity is higher, plant mortality may become by CMV infections. CMV has been transmitted by sucker, and aphids. Eradication, certified material and vector management are important strategies to overcome the menace. CMV has many host species even ornamentals in Turkey (Koç. et al., 2016; Karanfil et al., 2016)

The aims of the paper are to determine the presence and distribution of common banana viruses, including BSV, BBTV and CMV in the Mediterranean Area of Turkey. Existence of banana viruses has not yet been explored by reliable* laboratory assays (i.e. more sensitive current techniques for detection and characterization such as serological (DAS-ELISA) and molecular (PCR) methods) other than those used in this study in our country.

Materials and methods

The research was conducted in the Mediterranean Coast Line of Turkey in 2015-2016 years. A total of 118 samples were collected from suspected plants in banana plantains at different locations in the line. During the surveys, small and shapeless malformed leaves, light colored areas resembling mosaic with streaks of necrotic areas of the leaves and small bunchy formations were observed on plants. Surveys were conducted during the growing season and only symptomatic samples were collected randomly throughout the area in Turkey (*Fig. 1*).

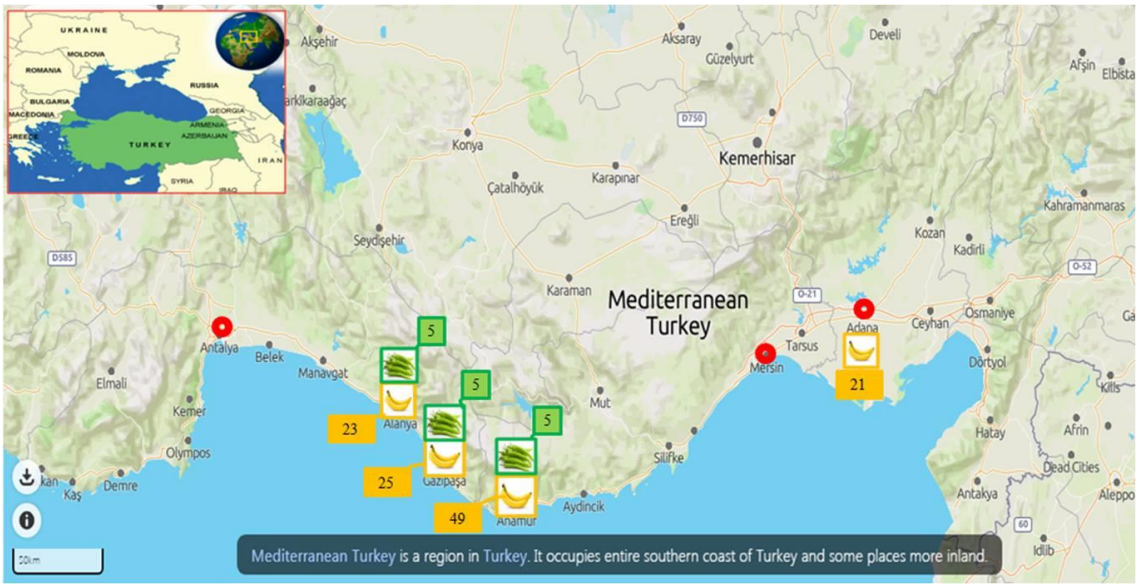

Figure 1. *Origin and number of samples per site from sampling area. (https://www.countryreports.org/travel/Turkey.html; https://mapcarta.com/Mediterranean_Turkey/Map)*

Green pepper plants, has been sampled which are grown for non commercial purposes at suitable places of the banana plantations. The typical symptom showing banana and pepper plants PCR product used for analyses.

DOI: http://dx.doi.org/10.15666/aeer/1703_59355951

Serological tests

The samples, were labelled and placed in separate plastic bags, they were brought to the Virology Laboratory placed in ice bucket and kept at 4 °C. All samples were processed within 24 h.

Double antibody sandwich enzyme linked immunosorbent assay (DAS-ELISA)

For the identification of viruses infecting *Musa spp*., leaf samples were tested by DAS-ELISA using polyclonal antiserum specific to the following viruses: BBTV (*Banana bunchy top virus*), CMV (*Cucumber mosaic cucumovirus*), TMV (*Tobacco mosaic tobamovirus*), TSWV (*Tomato spotted wilt orthotospovirus*), PVY (*Potato Y potyvirus*), BCMV (*Bean common mosaic potyvirus*), WMV-2 (Watermelon mosaic 2 potyvirus), PRSV (Papaya ringspot virus) *Potygroup* and Orthotospovirus Etc. specific antisera purchased from Agdia USA, Bioreba AG, Switzerland and Loewe® Biochemica GmbH, Germany, respectively.

Tests involved detection of viruses in infected young leaves and were carried out according to Clark and Adams (1977). Polystyrene microtiter plates were coated with 1:200 dilution of gamma globulin. The leaves of infected young plants were grounded in the extraction buffer (phosphate buffered saline, PBS, pH 7.0). Plant samples were applied at a dilution of l/5 (Wff) in PBS (pH 7.0), containing 0.05 volumes Tween-20, 0.2% polyvinyl pyrolidone (PVP-40) and 2% bovine serum albumin (BSA). IgG-conjugate was applied at the concentration of 1 ul/200 ul (Agdia and Loewe) and 1 ul/1000 ul (Bioreba). Alkaline phosphatase conjugate was used at a 1/1000 dilution.

Results were acquired spectrophotometrically at 405 nm wave length with a Medispec ESR 200 ELISA microplate reader. Also, negative controls (healthy samples), twice the mean value of healthy specimen were considered as positive. Positive controls of all viruses were supplied in lyophilized form with the kits and were resuspended in the sample buffer as recommended by the manufacturer (Agdia, Inc.).

Total RNA isolation, reverse-transcription polymerase chain reaction (RT-PCR) and phylogenetic analysis

Total RNA extracts (Dellaporta et al., 1983) of BSV, CMV and BBTV suspected banana samples were used in a PCR and RT-PCR (Reverse-Transcription Polymerase Chain Reaction) with BSV5466 5'-AGAGTGGGTTTCATCAAGTAGC and primer BSV 6196 5'-GAATTTCCCGCTCGCATAAG). The primer number indicates 731 bp positions (one cycle of 94 °C denaturation for 4 min, 30 cycles each at 94 °C for 30 s, gradient temp 58 °C for 30 s and 72 °C for 30 s followed by one cycle of final extension for 10 min.) in the BSV genome (Cherian et al., 2004); partially 513 bp CMV CP genes were cloned by sense CMVf TAACCTCCCAGTTCTCACCGT and antisense CMVr CCATCACCTTAGCTTCCATGT primers (95 °C, 45 s.; 52 °C, 30 s; and 72 °C, 45 s and final extension 72 °C for 10 min totally 35 cycles) according to Buzkan and Yüzer (2009); CP.F1 5'ATGGCTAGGTATCCGAAG 3' and CP.R1 5'CCAGAACTACAATAGAATGCC 3'primers, designed for BBTV virus indexing, were cloned partially 530 bp (denaturation for 5 min at 94 °C, then 35 cycles of: 1 min at 94 °C, 1 min at 57 °C, 90 s at 72 °C, and then a final extension for10 min at 72 °C.) by Mahadev et al. (2013). CP genes of each viruses have been subjected to processing at PCR thermocycler by using Thermo Scientific Verso 1-Step RT-PCR Hot-Start Kit according to manufacturer's protocol.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59355951

Standard PCR for DNA viruses and RT-PCR for RNA viruses were used and total RNA was isolated from leaf tissue by the RNeasy Plant Mini Kit (Qiagen).

Analysis of PCR products

PCR reaction mixture (Ten microlitres) was combined with gel loading buffer and analyzed on a 1.5% agarose gel containing 0.5 mg/ml of ethidium bromide and photographed (Sambrook et al., 1989). 100 bp DNA ladder (thermo) or Bio Marker^{TM} Low (Bio Ventures, Inc.) were used on each gel to determine the length of the amplified product. PCR-amplicons run at 100 V for 70 to 80 min, and the gel was stained with ethidium bromide.

Phylogenetic analysis

The PCR products were obtained and directly sequenced by Commercially Sequencing Service. Sequences were compared via databank BLAST on NCBI server (www.ncbi, nlm.nih.gov). Dnasp5 program was conducted for diversification, genetic distance and neighbourhood analyses. According to these analyses, a phylogenetic tree has established by MEGA 7 Program and Neighbours joining method.

Results

Type of symptoms

Mosaic and chlorotic streaking along the veins of the leaves, leading to necrosis, are common.

Virus infected leaves in the fields reduced in size and light colored yellowish necrotic leaf margin areas resembling to mosaic with streaks occured (*Fig. 2*); There were also, leaf mosaics, necrotic streaks, small narrowed and shapeless malformated leaves (*Fig. 3*), bunchy head formation and general discoloration were observed on the plants (*Fig. 4*). Leaf mosaics, marginal necrosis on banana plants are shown in *Fig. 5*. During harvesting, the plant was cut from the beginning to the end of line. The agricultural worker has not changed or sterilized all cutting equipments. Therefore, all harvested plants could have shown severe disease symptoms. This is clearly indicated that mechanically harvesting will spread the viruses.

Occurrence and detection of viruses by ELISA

As a result of DAS-ELISA, positive results were obtained from CMV (*Cucumber mosaic virus*). While one samples gave suspected BBTV value by DAS-ELISA. In performed serological analyses, 21 out of 118 (with 17.79% incidence) tested samples produced positive reaction with the specific antiserum to CMV. However, none of the

DOI: http://dx.doi.org/10.15666/aeer/1703_59355951

BBTV (*Banana bunchy top virus*), TMV (*Tobacco mosaic tobamovirus*), TSWV (*Tomato spotted wilt tospovirus*), PVY (*Potato Y potyvirus*), BCMV (*Bean common mosaic potyvirus*), WMV-2 (*Watermelon mosaic 2 potyvirus*), PRSV (*Papaya ringspot virus*) *Potygroup* and Orthotospo viruses have had strict positive reaction.

CMV is a member of the genus *Cucumovirus* and the family of *Bromoviridae* and have been reported on banana worldwide previously.

There is no commercial antiserum available to study BSV with immune test analyses. BSV can be tested with PCR analyses using DNAs obtained from banana plants.

The RT-PCR amplification

In order to verify the infection, RT-PCR analyses have been done. The target RNA regions (CMV; 513bp and BSV; 731bp) on coat protein partial genes of both viruses, identical for detection, were amplified in the RT-PCR assay. The Amplified RNAs, symptomologically selected from two samples, were yielded an expected product of 513 bp (*Fig. 6*) on agarose gel (2%) electrophoresis. Consequently, RT-PCR results confirmed infections of CMV in DAS-ELISA for positive plants. Additionally, 731 bp cDNA bands of BSV, 5 samples with 4.23% incidence via PCR, were observed. A mix infection by CMV+BSV was verified among them. However, none of the samples that were tested on suspicion of BBTV symptom (Banana bunchy ball virus) did not give positive PCR reaction. Symptoms may be related to zinc deficiency.

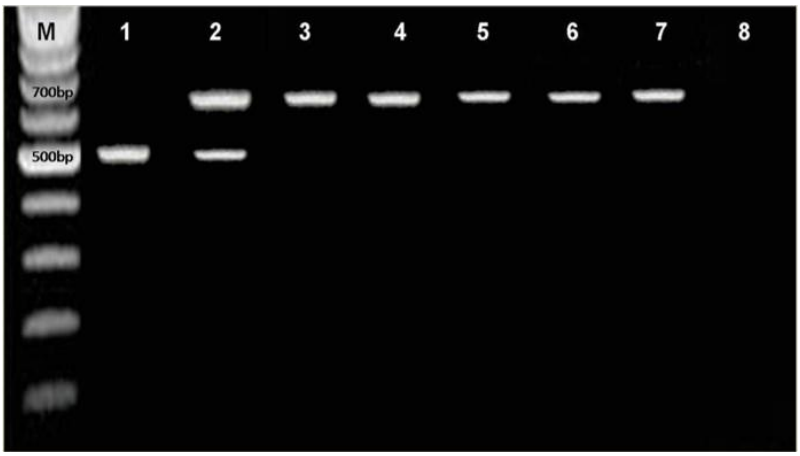

Figure 6. *First lane M DNA ladder; RT-PCR product of 513 bp of CMV CP (Lane 1, Lane 2); RT-PCR product of 731 bp of BSV CP (Lane 3 to Lane 7); Also Lane 2 stand as mix infection by CMV+BSV positive samples of Musa spp. in Turkey. Lane 8 negative control on agarose gel (2%)*

In the light of the observed symptoms, DAS-ELISA and PCR were conducted against nine viruses. Positive results were obtained only against CMV and BSV among all viruses (*Tables 1* and *2*). In addition to species specific ELISA, *Potygroup* and *Orthotospo* group specific polyclonal antiserums were not given positive results for all collected samples.

Phylogenetic analysis

Sequence and phylogenetic analyses have been shown that banana CMV and pepper CMV isolates are viruses with exactly the same haplotype. Banana and pepper plants include same CMV isolate sequences (*Fig. 7*) and the virus isolate has spread from pepper to banana. Virus infestation may also occur mechanically or via aphid vectors.

Phylogenetic tree was performed by MEGA 7 Program and Neighbour joining method from 2 symptomologically selected banana and pepper plants. The banana sample (TRAnCMVB, accessed as new record to NCBI system with accession number: MH931390) is a Banana CMV isolate (*Fig. 7; Tables 3* and *4*). A different haplotype was determined by RT-PCR and sequences. The results of comparison with isolates from other countries were submitted to NCBI system as new records. The results were clarified that these isolates have similar homology with pepper CMV isolate as TRAnCMVP (accesed as new record to NCBI system with accession number: MH931391) (100%-Turkey) and HE971674.1 pepper isolate (88%-Tunisia); KC559757.1 melon isolate (87% Bosnia and Herzegovina); KT270571.1 melon isolate (88% Serbia) and KJ789892.1 squash isolates (87% South Africa) were grouped into Ia (*Fig.7; Tables 3* and *4*). This result shows that the pepper and banana isolates are the same.

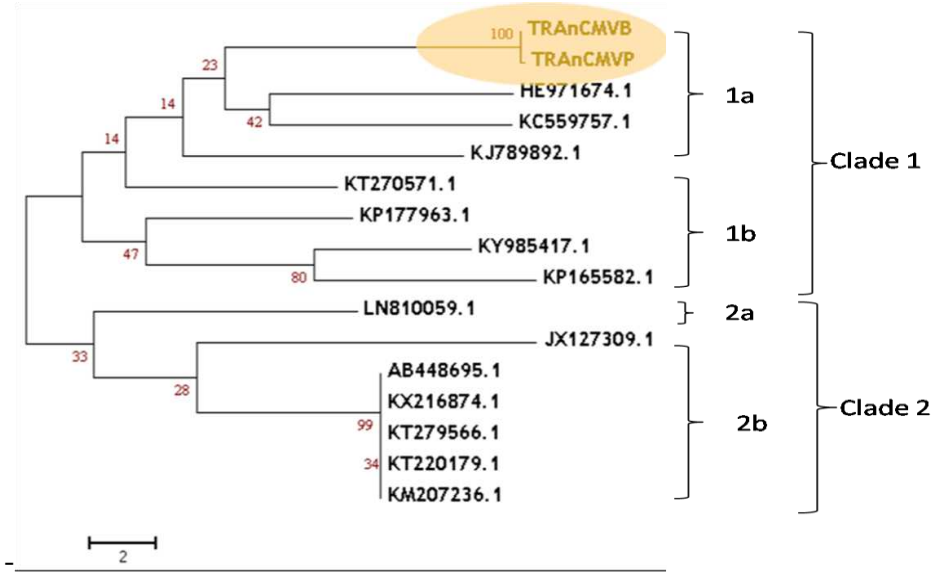

Figure 7. *Phylogenetic tree of Turkish Antalya Banana CMV haplotype had branched with Group 1a*

Another phylogenetic tree was performed by MEGA 7 Program and Neighbour joining method for one BSV banana isolates as TRAnBSV (accesed as new record to NCBI system with accession number: MH931389) (*Fig. 8; Tables 5* and *6*). Two different haplo group (CladeI and CladeII) were determined by sequences. This different isolate was compared with the isolates of other countries. Their results were submitted to the NCBI system as new records. The results were clarified that this isolate have similar CladeIb homology with AM905905.1 (97% - Kenya) and KU759865.1 (98% - Democratic Republic of Congo).

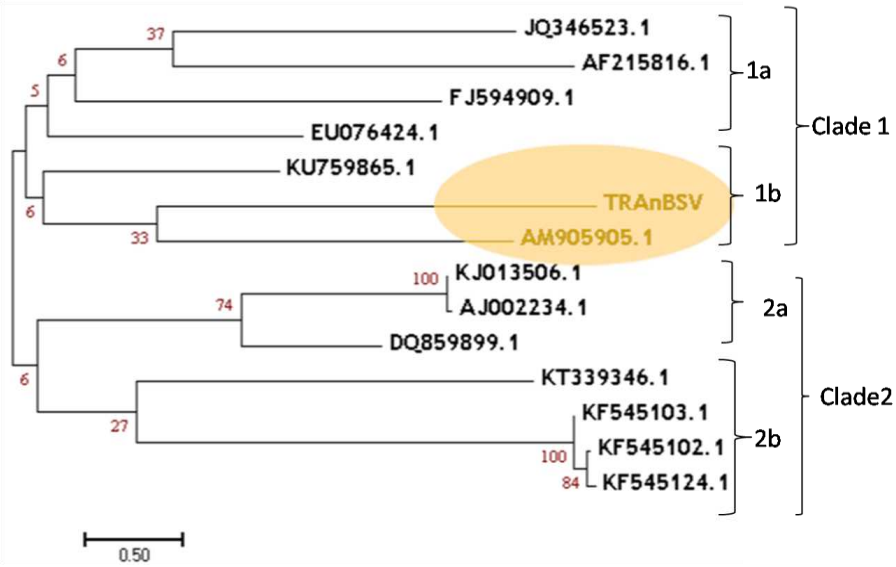

Figure 8. *Phylogenetic tree of Turkish Antalya Banana BSV haplotype had branched with Group 1b*

Discussion

The Mediterranean coast line is an important agricultural production area and all kind of commercial ships are visiting for trade. This study revealed the natural distribution and occurrence of banana viruses in this area. Our results pointed out that the sanitary conditions in banana growing fields are very important in Turkey to prevent the spreading of common plant viruses. CMV is the most widely spread virus, infecting banana crops in Turkey, it belongs to the genus Cucumovirus and it is transmitted by aphids. Management of these vectors are difficult. The symptoms on collected plants have been assigned to CMV and BSV by mixed infection. CMV infection causes typical leaf mosaic symptoms, mosaic may become necrotic when mixed infection occurs with BanMMV or BSV (Teycheney et al., 2005). These results fit with our results where our collected samples from Antalya samples generally showed a severe mosaic and became necrotic, when had CMV mixed infection with Banana streak mosaic virus (BSV). Similarly, Daniells et al. (2001) pointed out BSV infection have caused yield losses and severe mosaic symptoms. Discrete dark spots may appear on the petiole of the infected plants, pseudostem splitting, fruit bunch emerges from pseudostem, cracks on the skin of fruits occur, which become impossible to commercialize (Teycheney et al., 2005). The most characteristic symptoms of BSV infection are chlorotic and necrotic streaks on the leaves which have been recorded from Turkey BSV banana isolates by Lockhart and Jones (1999). Severe symptoms are correlated with high virus titres (Dahal et al., 1998a, b; 1999). With increasing concern about BSV, there is relatively little information on the effect of virus infection on yield of bananas. In one study in the Ivory Coast, the reduction in yield of cv. Poyo bananas (*Musa* spp. AAA group, Cavendish subgroup) was estimated to be from 7% to 90%, depending on the severity of symptoms (Lassoudière, 1974). Banana streak infections (BSVs) involve a complex of badnaviruses from the family Caulimoviridae known to contaminate Musa sp. around the world (Bhat et al., 2016).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59355951

The study was focused on BSV due to first occurrence on banana, cultivated in Turkey; Although BSV has a narrower host range than CMV, the BSV may survive in various banana plantains that are imported materials and cuttings as a reservoir. In addition, the presence of vector mealybug in the greenhouse and outside, and the lack of biological and chemical control agents, increase the risk of infection. These results allow CMV to be spread more by aphids from cultivated vegetable crops such as; pepper, melon, squash, tomatoes, are cultivated by farmers in the local area or near the banana greenhouse to meet household consumption need. It also originates progressively from different weed species and occurs after infection with infected seedlings or inoculum sources. Previous studies have found CMV in Turkey (Yılmaz, 1976). The destructive effect of CMV on Turkish banana production has been detailed by same researcher. If It's not well controlled. The current results have verified the previous results that banana plants infected with CMV could be limiting banana production. But overall, CMV has a low impact on production as it can be well controlled (Teycheney et al., 2005)

This is the first report of BSV and BSV+CMV mix infection infected banana in the Eastern Mediterranean Coastline of Turkey. Also it confirms reliable laboratory molecular methods that previous reports include of CMV on banana using serological, symptomologicaly and biological indexing in Turkey by Yılmaz (1976), Sertkaya (2016) and Tohumcu and Kamberoğlu (2018). BSV have been transmitted not only by mealy bug but also by sucker. Also tissue culture propagation has an importance. It can cause major economic yield loss. Eradication, Certified Material and Vector Management are important strategies to overcome the BSV.

In Cuba, Higginson et al. (2016) focused on some BSV strains on tetraploid banana cvs. FHIA 23. Banana leaf tests were gathered at arbitrary from symptomatic or potentially non-symptomatic plants in four FHIA 23 plots situated in El Mambí in Ciego de Avila area, Bayamo in Granma, Quivicán in Mayabeque and Santo Domingo in Villa Clara areas. Gathered samples were prepared and recorded for the nearness of BSV species BSOLV, BSGFV, and BSIMV by multiplex immunocapture PCR (M-ICPCR), An aggregate of 84 tests were gathered. Just a single plant at El Mambí was symptomatic with indications comprising of slight chlorotic leaf streaks. While BSOLV and BSGFV species were recognized in 12% of the 84 filed FHIA 23 tests, the species BSIMV did not show up in any example of this cultivar. Contaminated FHIA 23 tests were just recognized in the eight-month manor of El Mambí in Ciego de Avila. 17% (9/52) of the examples were distinguished contaminated by BSOLV in this area, including the plant showing chlorotic leaf streaking. An extra FHIA 23 non-symptomatic example of the same area was contaminated by BSGFV.

We have hypothesized that the BSV might come with ornamental plants which are relatives of banana plants. It is not able to coincidence that the BSV appeared in the banana grown area which is also a very popular place for the ornamental plants at the Eastern Mediterranean Coastline of Turkey. The CMV is commonly seen all over vegetable and fruit grown regions. Our results have clearly indicated that the virus could come from vegetable grown areas to banana grown places.

Bunchy top symptoms can be recorded on young suckers Infected plants are dwarfed and their emerging leaves are small and narrow with brittle, yellow edges. The leaves grow upright and have a stunted, bunched appearance similarly to the results of Teycheney et al. (2005). But there is no obvious result from ELISA and symptomologically suspected samples against Banana bunchy top virus in Turkey.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59355951

This paper also indicates that uncontrolled distribution of Banana plants in countries will create the viral problems.

The PCR technique was standardized and successfully applied for CMV and BSV detection. PCR-based detection methods will have the advantage of amplifying the target nucleic acid present even at very low level and it is an attractive technique for the early diagnosis of plant viral agents (Mahadev et al., 2013). Sison et al. (2017) reported four episomal BSV species either in single or mixed infections in the Philippines by Moleculer assays.

Molecular analyses have distinguished that there is one CMV haplotype present in Turkey according to their sequences alignments at NCBI system. Sequence alignments have shown Turkey's banana CMV haplotypes (TRAnCMVB) have similar homology with pepper CMV isolate from Turkey as TRAnCMVP and HE971674.1 pepper isolate from Tunisia; KC559757.1 melon isolate from Bosnia and Herzegovina; KT270571.1 melon isolate from Serbia (that could have same origin with Bosnia And Herzegovina) and KJ789892.1 squash isolates from South Africa clustered into Ia although isolates belong to different geographic origins.

To verify BSV banana isolate as TRAnBSV two different haplo group (CladeI and CladeII) were determined by sequences. Results were submitted to the NCBI system as new records, were clarified that this isolate have similar CladeIb homology with AM905905.1 from Kenya and KU759865.1 from Democratic Republic of the Congo. It is concluded that as evidence by phylogenetic analysis, both all CMV and BSV isolates are not identified as belong to new population or groups.

Both CMV and BSV Turkish isolates which are focused on in this study, have been placed to the NCBI system with new accession numbers (NCBI, 2018).

The results have indicated that all exported plant materials can be distributed through any quarantine regulation.

Conclusion

Further studies should be planned for identifying respective vectors and unknown epidemiological features and characteristics of the viruses (Islam et al, 2016). There are new viruses perpetuating in weeds and adjacent crop species in plantains. Novel management strategies for diseases will be devised upon these studies to protect sanitized and resistant plants, often depends on the virulence of pathogen (Razukas et al., 2007). Therefore, the infection pathway and transmissibility of major viruses could be prevented. This can be done by determining the virus ecology and molecular origin, which were another outcome of this study.

Thomas et al. (2015) description of virus diseases emerging from mass spread of contaminated plant materials or from mealybug transmission from neighbouring contaminated plants is obscure. Regardless, it is important to perform more precise and valid analytical strategies to screen the condition of planting material. On the off chance that in vitro culture is utilized, the meristem micropropagation joined with cryotherapy methods will guarantee the evacuation of tainting infections. Sison et al. (2017) determined some preventions, such as host resistance and removal of infected plants, against BSV infections are suitable control practices.

Banana bunchy top virus (BBTV), banana streak virus (BSVs) and cucumber mosaic (CMV) infections are announced to be contaminating bananas habitually all around the world. Successful control of their spread relies upon strong discovery of these infections

DOI: http://dx.doi.org/10.15666/aeer/1703_59355951

in engendering stock, planting material, contaminated nursery plants, and through strict quarantine Zhang et al. (2018).

Tripathi et al. (2019), reported a strategy to inactivate the eBSV by editing the virus sequences, named as CRISPR/Cas9 is a novel approach, as well as editing of endogenous banana streak virus in the B genome of *Musa* spp. Seventy-five percent of the altered plants stayed asymptomatic in contrast with the non-altered control plants. This examination prepares for the improvement of B genome germplasm and its utilization in rearing projects to deliver cross breeds that can be comprehensively spread.

All positive samples detected in this study, have been eradicated. Thus, it was tried to maintain or protect the country's disease free status with the definite destruction of the sources of infection, which were detected on a limited or limited level to comply with agricultural quarantine legal measures.

This report is the primary step to initiate research on the impact of the virus in banana production and germplasm exchange.

(Received 31st Jan 2019; accepted 21st Mar 2019)

Abstract. Perennial bay laurel (*Laurus nobilis* L.*)* is a dioecious economic plant. Its leaves and fruits are considered as important non-wood forest products that are used in food, pharmaceutical, and cosmetic industries. However, it is not possible to distinguish males and females at an early age and this can hinder its multiplication in a planned way. The aim of the present study is to determine the sex of bay laurel at an early stage by analyzing the nuclear DNA (Deoxyribonucleic acid) contents using flow cytometry. The findings of the study showed that the male DNA content is ≥ 7.95±0.13 pg and the female nuclear DNA content is ≤ 7.84±0.10 pg. After sex determination, female green axillary buds were cultured on MS (Murashige and Skoog) medium containing different combinations including BAP (6-Benzylaminopurine), NAA (1-Naphthaleneacetic acid) and GA3 (Gibberellic acid) for 42 days to induce micropropagation of the buds. The results indicated 100% shoot regeneration with 2.5±0.85 shoots per explant on MS medium containing 6.6 µM BAP, 5.4 µM NAA, and 0.6 µM GA3. Each randomly selected 45 female shoots were rooted on MS medium containing 4.90 µM IBA (Indole-3-butyric acid) for 12 weeks. Only 16 among them induced roots. However, 13 female plantlets, upon their transfer to pots, showed continuing viability and successful acclimatization to external conditions. Distinguishing sex of bay laurel plants at an early age and establishment of a rapid propagation protocol could offer a significant benefit in breeding and plant production.
Keywords: *bay laurel, Laurus nobilis L., DNA content, dioecious plant, micropropagation, acclimatization, sex determination, adult plants*

Introduction

The family of Lauraceae has 45 genera and 2850 known species worldwide (Maarten and Christenhusz, 2016). Different ploidy levels have been described, in Laurus with tetraploidy (2n = 4 x = 48), as the most frequent karyotype (Ehrendorfer et al., 1968). Bay laurel has spread over Tropical Asia, America, Africa, and Mediterranean countries (Darlington and Wylie, 1955). It can resist temperatures as low as -15°C in natural distribution areas (Lanzara, 1978). The hairless dark green leaves and black fruits are highly aromatic due to the presence of oil-filled cavities (Villar, 1986). Both fruits and leaves contain different types of essential oils with different quantities in them. These contain 25-30% green, aromatic oil consisting of a variety of fatty acids, including glycerides of acetic, oleic, linoleic, stearic, palmitic, myristic, and lauric acids, and free acetic acid oil (Panza et al., 2011). Both, its fruits and leaves are significantly important in pharmaceutical, food and cosmetics industries (Ercan, 1983). The dried leaves exclusively used to flavor foods as they produce about 1.3% essential oils containing 45% eucalyptol, 12% terpenes, 8-12% terpinyl acetate, 3–4% sesquiterpenes, 3% methyleugenol, and other α- and β-pinenes, phellandrene, linalool, geraniol, and terpineol. Their concentrations are inconsistent and differ with the antagonistic stage of plant growth. Generally, the highest oil percentage is obtained from dried leaves during mid-summer harvest (Tanrıverdi et al., 1993; Konukçu, 2001; Kilic et al., 2004). Therefore, early identification of the plants is of significant importance. The strategies

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59535964

to multiply male and female plants have significant importance and could be planned at an advanced stage of growth and with a purposeful and positive contribution to the economy of Turkey (Ercan, 1983). Anatolia and Balkans are considered as the origin of bay laurel. Nowadays, it grows in all of the Mediterranean countries (Algeria, Turkey, Italy, Greece, Morocco, Portugal, Spain, Albania, Romania and in the Greek islands in the Aegean Sea, on the eastern coasts of Libya, the western part of Syria, Israel, Palestine), Northern Europe (Belgium, France), The Black Sea coast of Russia, Georgia, Crimea, and Mexico at altitude of 600-800 m above sea level in temperate regions (Göker and Acar, 1983; Demir et al., 2004). The bay laurel Essential Oils (eugenol, cineol and geraniol), account for the distinctive spicy aroma and are extracted from its fruits and leaves (Konukçu, 2001). It is also considered in manufacturing perfumes and soap in many parts of the world (Tanrıverdi et al., 1993; Dhifi et al., 2018). Phenotypic sex determination is practically not possible during the early stages of the development of dioecious plants. It is possible to determine the ploidy level of plants by using flow cytometry for measuring the amount of nuclear DNA in plants. The data Information about genome size is a very important factor in determining the biodiversity of a large number of biological fields (Zonneveld, 2005). The flow cytometry could be used for plants' early sex determination studies. The identification and sex determination of dioecious plants could provide a significant advantage in production, multiplication, and breeding of plants (Bennett and Smith, 1976; Tuna, 2016). Therefore, the purpose of this study is to develop a protocol for sex determination of bay laurel seedling after their germination and establish micropropagation protocol in female sapling through axillary stem buds.

Materials and Methods

Plant material

The fresh bay laurel seeds were purchased from Yalova seed vendor in the open market. The number of chromosomes was determined as 48 in different studies. These seeds were stored at room temperature for 2 weeks and were, then, germinated at + 4°C for 6 weeks. All treatments of sex determination, regeneration and rooting experiments were carried out in Department of Agricultural Biotechnology and Department of filed crop Tekirdağ Namik Kemal University, Tekirdag, Turkey.

Sterilization and germination

The seeds were first rinsed with 2% solution of Tween 20, followed by sterilizing with 20, 40, 60, 80, and 100 percent commercial bleach (containing active 5% NaOCl – Ace, Turkey), and ensued by 4× 4 times rinsing with bidistillated and sterilized water. Seeds with 100 less pericarp were, then, germinated on MS medium (Murashige and Skoog, 1962) and supplemented with 30 g/l sucrose in glass tubes (1 seed/test tube) of adjusted pH to 5.7±0.1 For germination, these seeds were cultured in Sony versatile environmental chambers under 24 ± 1ºC using 16 hours' light/ 8 hours' dark photoperiod.

After seed germination, the leaf samples of *in vitro* germinated plants were taken for sex determination analysis by flow cytometry. Adult male and female plants were also analyzed for the purpose of comparison along the freshly germinated seedlings for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59535964

comparison purpose and validate the results. The regeneration studies were initiated by taking green shoot buds from respective female seedlings.

Flow Cytometry and Sex Determination

Fully developed bay laurel leaf samples were taken from 2-month-old seedlings and were cultivated under *in vitro* conditions; barley *(Hordeum vulgare)* 2C DNA=10.65 pg was used for estimation of genome size in *Laurus nobilis* in flow cytometry with the fluorescing DNA stain 4',6-diamidino-2-phenylindole (DAPI) as per manufacturer's instructions (Thermofisher Scientific Waltham, Massachusetts USA). The nuclear DNA quantification studies were set up using 3 replications.

Estimation of nuclear DNA content

The 10-15 mg samples were taken from the leaf tissues of barley grown by the standard *in vivo* and leaf tissues of bay laurel germinated by *in vitro* conditions; they were cultured in Petri dishes on MS medium afterwards. By adding 1 ml of A stock solution (20 ml $MgSO_4$ buffer, 20 mg Dithiothreitol, 500 µl DAPI stock, 550 µl TritonX-100) to the petri dish (Arumuganathan and Earle, 1991; Noirot et al., 2002), the plant tissues were decomposed with razor blades until they were crumbled away in the solution. The solution was filtered (30-33 µm) and followed by micro-centrifuging. The Supernatant, formed in the bottom of the micro-centrifuge tube, was dissolved in 400 µl B solution (5 ml solution A, 10 µl RNAse and DNAse free). Thereafter, the prepared samples were incubated in 5 ml glass tubes for 15 minutes at 37ºC temperature. The samples were analyzed by flow cytometry (Partec) device (Tuna et al., 2001; Savas Tuna et al., 2017). The absolute DNA content of 58 germinated bay laurel seedlings was calculated by using the values of the fluorescence intensities of the M1 peaks at the selected standard and the following formula, as a picogram (Zonneveld et al., 2005; Aydın Akbudak et al., 2018), was used for this purpose:

$$\text{Sample DNA content } 2C = \frac{\text{mean of sample peak (M1)}}{\text{mean of sample peak (M1}_i\text{)}} * \text{Standard DNA content } 2C \quad \text{(Eq.1)}$$

The data used in the formula was obtained from flow cytometry analyses. The separation of the male and female plant, by measuring their DNA content quantities, were conducted and the results were later compared with the results of Parlar (2017).

In vitro Micropropagation

The plant is difficult to multiply due to high oxidation of phenolic compounds (25-30% essential oil in female plants compared to males with 1.3% essential oils only. The idea was to use female plants that are more prone to necrosis and compared to male plants with lesser concentrations of essential oils and phenolic compounds. Therefore, axillary bud explants from the female seedlings, grown under *in vitro* conditions, were cultured on MS medium containing different combinations and concentrations of BAP, NAA and GA3.

Rooting and acclimatization

The growing shoots were re-cultured on MS medium containing 4.4 µM BAP. The 45 regenerating shoots were rooted in MS medium containing 2.24, 4.90 and 7.35 µM

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59535964

IBA in sterile glass jars. At this stage, the bay laurel seedlings (5-10 cm in length) were washed with tap water without harming the leaves and roots. These were transferred to sterilized peat moist in 500 ml paper cups. The pots were covered with transparent polythene bags and were left to grow in an environmental chamber. The bags were gradually perforated at the end of the second week to increase air circulation and to reduce the humidity 40-50% at +25±2°C (Dewir et al., 2015). This was done to adapt the plants to external conditions. The polythene bags were completely removed later and the plants were left to grow and harden in the environmental chamber. These plants were watered with liquid MS medium once in a month.

Statistical analysis of regeneration studies

All treatments of regeneration and rooting experiments used 15 explants (unless otherwise mentioned) which were divided equally into three replicates containing 5 explants each (3 replications x 5 explants = 15 explants); treatments were repeated twice afterwards. Statistical analysis of the data was carried out by using IBM SPSS18 (Statistical Package for the Social Sciences) computer software. The means were separated by using the Duncans Multiple Range Test and the percentage values were subjected to "arcsine transformation", before carrying out the statistical analysis (Snedecor and Cochran, 1982).

Results

Surface Sterilization and Germination of bay laurel

Out of different commercial bleach concentrations used for sterilization of bay laurel seeds, 60-100% commercial bleach concentration showed the most optimum results with 80% seed germination and development of no fungus or bacterial contamination of the seeds. However, the 80-100% commercial bleach concentration had negative impacts on the growth and development of seeds. The results are given in *Table 1*.

Table1. *Effects of different concentrations of Sodium of Sodium hypochlorite (NaOCl) on contamination and germination of with pericarp and without pericarp seed of Laurus nobilis L.*

Concentration of in percentage Sodium hypochlorite (NaOCl) (%) for sterilization of Seeds with pericarp	Contamination percentage (%)Seeds with pericarp	Germination percentage (%)Seeds with pericarp

The contamination percentage had a range of 26.57–90%, however, the concentration was decreased by each increase in the commercial concentration of commercial bleach on seeds with pericarps. No seed germination was noted irrespective of the commercial bleach concentration treatment and control treatment. The contamination percentage had a range of 0.00–77.08% and decreased with each increase in the concentration of commercial bleach on seeds without pericarps. No contamination was noted on seeds treated with 60-100% commercial bleach. The study indicates seed sterilization and their germination behavior with and without pericarps. The contamination rate was lower and the germination percentage was higher on the seeds. On pericarps removal, germination percentage had to be ranged between 0-80%.

Flow cytometry and sex determination

In seeds without a pericarp, 60% NaOCl concentration was applied and 58 stable bay laurel seeds were germinated. The DNA content and average of bay laurel was calculated by in flow cytometry with the fluorescing DNA stain 4',6-diamidino-2-phenylindole (DAPI) analysis with Partec device on the Fully developed bay laurel leaf samples of these seedlings The obtained DNA content of 58 bay laurel seedlings and 50 samples each from known male and female plants were taken as control treatment and were, then, compared with the studies. The number of chromosome 2n = 2x = 48 in the female and male plants, in the average DNA content of the plant, showed a 0.05 difference between male and female plants. It was observed that the male DNA contents of the male and female plant were slightly, a small margin of 0.11 pg, higher than the female plants. According to Parlar (2017), determined DNA contents of 84 male and female plants, were separated into independent groups by being subjected to t-test analysis, whereby the DNA content of the female plants was reported as 7.84±0.10 pg and the DNA content of the male plants was 7.95±0.13 pg. The results of this study showed that the DNA content of bay laurel, ranged between 7.04–8.14 pg, was divided into two groups; the male plants had nuclear DNA content of ≥ 7.95±0.13 pg and the female ones had nuclear DNA content of ≤ 7.84±0.10 pg. The result of this study showed that 43 out of the 58 seedlings were females and 16 of them were males (*Fig. 1*). The DNA content of the previously known males of ≥ 7.95±0.13 pg and females of ⩽ 7.84±0.10 pg also showed the same threshold level in their DNA contents.

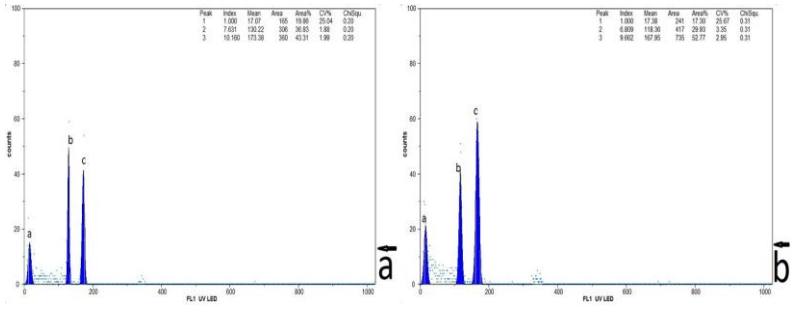

Figure 1. *Comparative schematic representation of Laurus nobilis histograms showing flow cytometry analysis of isolated nuclei of male and female plants (a) peak a- fragmented nuclei, chromosomes, plastids and other organeller, peak b- M1, L. nobilis, male seedlings DNA content of 7.99 pg , peak c- M2 nuclear DNA content of Barley (H. vulgare) (b) peak a- fragmented nuclei, chromosomes, plastids and other organeller, peak b- M1, female seedling nuclear DNA content of 7.51 pg, peak of L. nobilis, peak c- M2 nuclear DNA content of Barley (Hordeum vulgare)*

In vitro Micropropagation

The axillary bud explants, obtained from 2-month-old female bay laurel seedlings, germinated under *in vitro* conditions using by flow cytometry, were transferred to MS medium containing different doses and combinations of BAP, NAA, and GA3. The shoot regeneration was noted on all shoot buds irrespective of their concentrations and combinations of BAP+NAA+GA3. The best shoot regeneration was noted on MS medium as containing 6.6 µM BAP+ 5.4 µM NAA+ 0.6 µM GA3 (*Fig. 2a, b*).

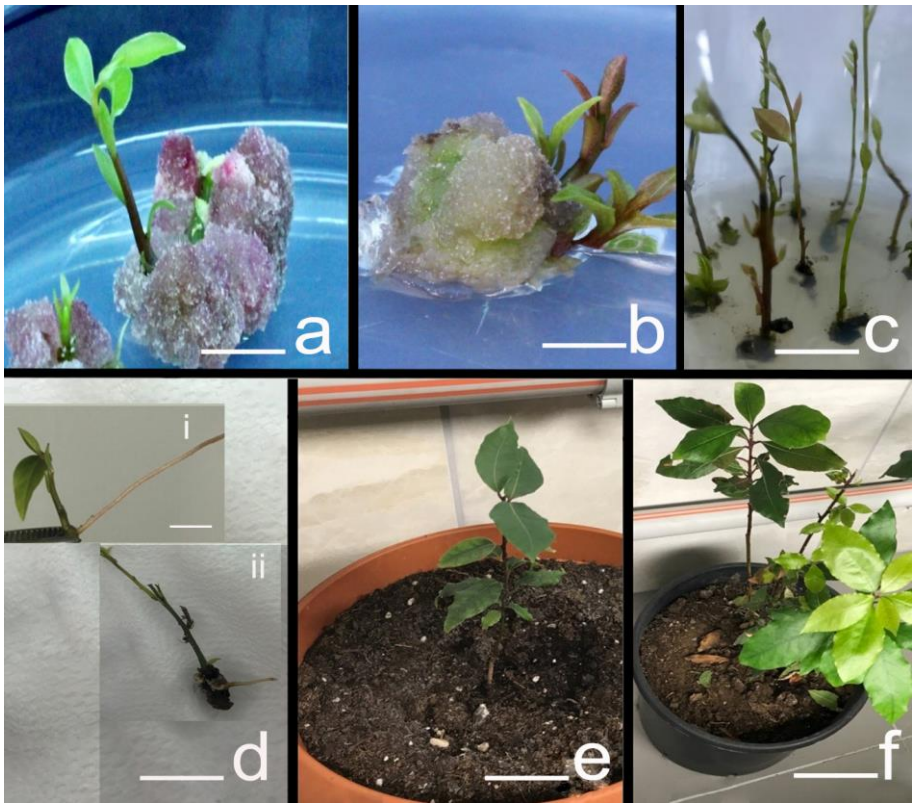

Figure 2. *In vitro regeneration from female shoot buds on axillary bud explants of L. nobilis (a)) induction of shoots on axillary buds induced calli of female using 6.6 µM BAP+ 5.4 µM NAA+ 0.6 µM GA_3 (c) rooting of in vitro regenerated shoots using 4.90 µM IBA (d) rooted shoots of female shoots (e) the saplings transferred to pots after 3 months in environmental chamber (d) the saplings ready for transfer to fields with profuse growth of leaves. bar in frame (a,b) 1.1 cm (c)1.25 cm (d-i) 1cm (d-ii) 1.2cm (e) 1.5 cm (f) 2cm*

After 42 days (2 × subcultures), the data were collected by testing the growth of the regenerating female shoots. The shoots regenerating on the explants, after their excision as single female shoots, were transferred to MS medium for 28 days. The Analysis of variance results showed that shoot regeneration percentage (%), the average number of shoots per explant, and their shoot length showed significant differences among treatment means. The maximum number of shoot induction per explant was obtained as 2.5±0.85 on MS nutrient medium containing 6.6 µM BAP+5.4 µM NAA +0.6 µM GA3. In terms of shoot percentage, the best results were obtained on the MS medium containing 8.8 µM BAP +2.7µM NAA +0.6 µM GA3. The longest shoots were obtained on MS medium containing 6.6 µM BAP+ 5.4 µM NAA + 0.6 µM GA3 (*Table 2*).

Rooting and acclimatization of bay laurel shoots

In vitro regenerated female shoots of 3-5 cm long that was rooted on 4.90 µM IBA (*Fig. 2c*). The first indications of rooting appeared after 4 weeks on MS medium containing 4.90 µM IBA. The increase in the number of roots was very evident after 12 weeks, with the highest rooting on MS medium containing 4.90 µM IBA (*Fig. 2d-i and 2d-ii*) on female shoots. Out of 45 female shoots used for rooting only 16/90 (17.77%) of them induced roots. The other concentrations of IBA were not suitable for rooting compared with this concentration. 2.24 µM IBA was non-inducing and 7.35 µM IBA showed necrosis and burning on the treated shoots. The number of roots increased when the rooted plantlets were cultured on MS medium. Prolonged culture of shoots on 4.90 µM IBA containing medium tended to induce callus formation that had negative effects on root growth and development.

Out of 16 rooted female plantlets, as mentioned above, only 13 could be acclimatized to external conditions after their transfer to pots (*Fig. 2e*). After the hardening period of 3 months in the environmental chamber, these female plants were ready for transfer to the fields (*Fig. 2f*).

Discussion

Sex determination cannot be ensured phenotypically at the first stage of the development of dioecious plants like bay laurel, in general. The literature reports no studies relating to sex determination in bay laurel at the seedling stage with highly limited *in vitro* micropropagation studies. It is highly significant to determine the sex and production protocols in bay laurel for the establishment of planned breeding and production programs.

The elimination of micro-organisms from the tissues has great importance in *in vitro* cultures of plants. During seed or tissue sterilization, surface contact of NaOCl must be adjusted to the level that it doesn't have any hazardous effect. This depends on the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59535964

careful adjustment of the concentration of disinfectant, duration of application, and the surrounding temperature. The researchers report high sterilization and germination of seeds without pericarps. The contamination rate was lower and the germination percentage was higher on the seeds if the pericarps were not removed. It was also found that diluted 30% commercial bleach (5% NaOCl) is suitable as a sterilizing agent of bay laurel seeds without pericarps. Additionally, that high-frequency of seed germination was highly affected by seed health during sterilization. The optimization of appropriate seed sterilization procedure is a prerequisite for carrying out any tissue culture experiment. The high (40-100% concentration) dose of commercial bleach was hazardous to the health of the seeds and resulted in a reduction of seed germination. The results of the study are in agreement with previous studies (Sari et al., 2006; Şenyay, 2008; Erkmen, 2009; Chaari Rkhis et al., 2011; Cavusoglu et al., 2014). These studies suggest that sodium hypochlorite exhibits a broad spectrum of anti-microbial activity and effectively disinfect or inactivate bacterial, fungal, and viral organisms adhering to the surface of explants. Contrary to Chourfi et al. (2014), who has reported germination of laurel seeds using kinetin and IAA (indole acetic acid), NAA on WMP (woody plant medium), this study did not need any phytohormonal treatment to germinate seeds.

Sex determination

DNA content was determined by using flow cytometry method on the leaf samples taken from bay laurel seedlings germinated under *in vitro* conditions and as a result of this study, it was determined that DNA content of bay laurel changes between 7.04 to 8.14 and it was showed that 43 out of the 58 seedlings were female and 16 of them were male. DNA content of male and female plant are not significantly different in statistical terms but is different numerically. The results were confirmed by finding the amount of DNA on adult male and female plants. Therefore, it is assumed that the method of determining sex would work. Sex determination was performed by comparing the DNA content of the plant following (Parlar, 2017). Doležel and Göhde (1995) have confirmed the sex determination of chalk plants by using flow cytometry. They used young leaves of two different chalk plants (*Melandrium. album* and *Melandrium. rumrum*), and noted that the nuclear DNA content of cells of female plants was lower compared to the DNA content in the cells of male plants. The nuclear DNA content of male and female plants differed at arate of 3.7% (Costich et al., 1991). It was shown that the DNA content of male *Silene latifolia* plants was larger compared to the DNA content of female plants. Furthermore, the researchers reported a difference in AT/GC contents of the males and females. Whereas Vagera et al. (1994) have shown androgenesis under *in vitro* conditions, by using ripe microspores of *M. album*. Supermales were crossed with normal female plants under *in vitro* conditions, to obtain female plants. Flow cytometry analysis was positively used for the determination of sex and the ploidy level. However, the researcher (Cepeda-Cornejo et al., 2012) did not find any significant differences between male and female individuals in terms of DNA during content sex analysis study of four *Chamaedorea* palm species.

Micropropagation

Micropropagation studies on axillary buds showed the induction of an average number of shoots per explant. The best regeneration was noted on MS medium containing 8.8 µM BAP, 2.7µM NAA, and 0.6 µM GA3. The results are supported by the findings of Stanica et al. (1992), who used axillary buds of one-year bay laurel,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59535964

lateral shoots of 2-3 cm in length, apical meristems, and 1 node fragments of developing shoots as explants. They took explants' starting material at 6 different times between February and May and regenerated them on MS medium containing 0.01 mg/l NAA + 0.3 mg/L BA + 250 mg/L Ascorbic acid + 1 mg/L MS medium containing adenine sulphate, and DKW nutrient media containing 0.2 mg/L IBA + 1 mg/L BA. They found that MS medium showed induction of callus at the rate of 62%. This was ensued by shoot formation on DKW medium. On the contrary, Souayah et al. (2002) reported that the best shoot development in axillary buds occurred on 1/3 × MS medium containing 1 mg/L BAP + 1 mg/L GA3. Callus development was observed in medium containing BAP and NAA; it was reported that the addition of activated coal to nutrient medium enhanced the development of root and callus. Cobo et al. (2019) reported that the significantly higher numbers of shoots per bud in mortio (*Vaccinium floribundum Kunth*) were observed on mWPM (modified Woody Plant medium) with 3.0 mg/L 2iP (N6-isopentenyladenine) or with 5.0 mg/L 2iP + 0.1 mg/L NAA (1-naphthaleneacetic acid).

In decade-long studies of *in vitro* regeneration, conducted by Boza and Altun (2013), the rate of shoot, root, and callus induction was examined on shoot tips, buds, and nodal cuttings; *in vivo* were taken from laurels located in the Turkish provinces of İzmir and Aydın. They used MS medium, DKW medium (Driver and Kuniyuki, 1984), and Heller and WPM (Woody Plant Medium) containing NAA, BAP, IBA; Kinetin plant, in different concentrations and combinations, could be used for micropropagation of the plant. They recommended that MS medium, having 0.3-4 mg/l BA and 0.5-5 mg/l NAA for the rooting of the micropropagated shoots. The rooting from woody plants is difficult due to the carry over effect of cytokinins (Huetteman and Preece., 1993). Although no study reported the rooting of bay laurel under *in vitro* conditions, the results are supported by the findings of Chourfi et al. (2014), Grigoriadou et al. (2002) on olive, Spahiu et al. (2013) on peach using IBA, and Sriskandarajah et al. (1982) on apples using 10 µM NAA or 750 µM IBA; all of them used IAA, IBA or NAA for rooting of woody shoots of different plants.

Rooting and acclimatization

The rooting and acclimation stages on plants affect the plants' development quality after acclimatization (McClelland, 1990). Adaptation studies of rooted bay laurel plants to external conditions are rare. The study confirms successful acclimatization of female bay laurel, when the humidity around the plants was gradually reduced to 50% and the first indications of rooting appeared after 4 weeks on MS medium containing 4.90 µM IBA. The increase in the number of roots was very evident after 12 weeks, the results are supported by Grigoriadou et al. (2002), who acclimatized *in vitro* regenerated Chondrolia chalkidikis plants to a soil substrate containing peat moss and perlite (1:4) with 90% success. Binet et al. (2007) found that shoots of olive were successfully adjusted to external conditions after rooting (Nas, 2004) and reported that IBA applications in different concentrations to different hazelnut species have positive impacts on *in vitro* rooting. Khater and Benbouza (2019) have reported that the highest root numbers and lengths in *Juniperus thurifera* L. were produced on 1/2 MS medium supplemented with IBA and NAA (5.0mg L^{-1} each) and During transfer to acclimatization, rates of plant losses of 50% occurred.

Conclusion

It is important to develop mass production technologies, suitable for different purposes, for non-wood forest products, especially bay laurel. For instance; in order to obtain bay laurel leaves and Essential Oils, generally female plants are preferred or male plants have the inside track to be grown due to being easier in terms of shaping and due to female plants being crumbled and causing pollution in landscape studies. With the results achieved from the study are, especially; it is considered that it would be possible to conduct early sex determination studies on perennial and diecious plants like bay laurel. it is assumed that optimization of *in vitro* micropropagation methods will help conscious commercial cultivation and easy breeding of bay laurel.

(Received 2nd Feb 2019; accepted 21st Mar 2019)

Abstract. This research was carried out to quantify the amount of defected fruits, outlining the causes of defect, and their negative economic impact, in terms of total fruit loss (US$), production cost (US$), total area of cropping land (hectare), and irrigation water (m^3) of *'Samani', 'Hayani', 'Bent Aisha', 'Oreebi'*, and *'Zaghloul'* soft date palm (*Phoenix dactylifera* L.) cultivars grown in North Delta, Egypt. Random fruit samples were taken at harvest date of each cultivar from Rasheed and Baltim districts and divided into two sets; sound fruit (free of visible defects) and defected/discarded fruit. The defected fruits set was classified based on the type of defect into; misshape, unpollinated fruit (shees), decay and mold, dirt, discolored, dry fruit, insect damage, over-ripped fruit, shrivelling, under size, unripe fruit, no calyx, and mechanical injuries. Each type of defect was calculated as a percentage of the total weight of the defected fruit. Fruit loss was determined as follow; *'Hayani'* (19.66–26.77%), *'Samani'* (23.03–25.33%), *'Oreebi'* (16.79–25.00%), *'Bent Aisha'* (9.66–15.68%) for 2015/2016–2016/2017 seasons respectively, *'Zaghloul'* (5.55%) for 2016-2017. Total monetary loss based on the farm price was about 8,641,908–9,232,793 for the studied cultivars. Total loss in terms of cropping land was about 1,771–1,939 ha with a total loss of 1,511,616–1,654,890 in production cost and 11,2–12,3 million (m^3) of the irrigation water. Fruit without calyx was the main defect of all the studied cultivars, except *'Oreebi'* during both seasons.
Keywords: *postharvest loss, date defects, losses cost evaluation, irrigation water loss, fruit loss*

Abbreviations: EGP: Egyptian pounds, MALR: Ministry of Agriculture and Land Reclamation

Introduction

Date palm (*Phoenix dactylifera* L.) is one of the key fruits in dry and semidry regions (Chao and Krueger, 2007). Egypt considers the highest country for date production over the world with 1590414 ton (FAO, 2019), around 18% of the global date production. There are three types of date fruits, soft, semi-dry and dry, about 45% of date fruits in Egypt are soft (MALR, 2018). The most common soft types in Egypt are *'Hayani', 'Zaghloul', 'Samani', 'Bent Aisha'*, and *'Oreebi'*, (they present around 43% of the soft types in Egypt) (MALR, 2018). In cooperation with FAO and other international agencies, Egypt has developed, in September 2016, strategy for the development of date palm and dates sector. One of its main pillars is to enhance dates export through high quality fruits (FAO, 2016). An important step to produce and maintain high quality date fruits and reduce loss and waste is to know the volume and types of defects (El-Habbab et al., 2017). Yahia et al. (2014) concluded that some of the vital means to produce good quality dates and to maintain its postharvest quality include: selecting the right type of male clones for pollination, developing appropriate date palm mechanization, especially for pollination and harvesting, adequate use of the cold chain, packaging and packages,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59655974

food safety measures, insect control and prevention of re-infestation during postharvest processes. The results of FAO (2011) study pointed out that roughly one-third of food produced for human consumption is lost or wasted globally. The types of food loss and waste in low-income countries are primarily linked to the limited financial resources, low managerial and technical capacities in harvesting performances, storage and cooling facilities in hard climatic conditions, inferior infrastructure, packaging and marketing systems. Yahia et al. (2014) reported that only about 10% of the world production of dates is handled in global trade due to various factors including inadequate handling practices and insufficient information for small farmers, who are the main producers. They also pointed out to the need to investigate and refine several subjects such as: improvements of harvesting systems; safe means for insect and pathogen control; adequate packaging and storage conditions; and more biochemical studies on sugar interactions, tissue softening, and browning. In Arabian Peninsula countries, fermentation, insect infection, birds and mechanical damage are the common types of postharvest loss of dates; the produced dates do not fulfil International Regulations and Standards required for export. Elsayed and Abdel Gleel (2013), in Egypt, had reported that, the average dates loss of ten-year (2000–2010) at harvesting were 10-15% and 8.1% during postharvest processes, this is due to mechanical (harvesting, sorting, grading, and transportation) or biological (pests and insects) reasons. El-Habbab et al. (2017) investigated dates loss at harvest time of three cultivars in four locations in Saudi Arabia, that include shees & besr, bird's damage, falling, insects and dust mite. They found that the loss varied from location to location as well as within cultivars in the same location. The average level of loss during the marketing stage was about 5-10% in most varieties and locations except Ajweh in Riadh (2.7% only). Lemlem et al. (2018) found that conventional procedures of date palm production were applied in Afar Regional State, Ethiopia and constrained with high incidence of insect pests. They recommended training sessions on good agricultural practices and to improve management, and postharvest handling practices. As a result of thirty years working on postharvest loss prevention, Boye and Muck (2015) concluded that a series of prerequisites including reliable funding over extended period, continuity in science-based programs and project approaches, considerations of technical and socio-economic factors are needed for implementing sustainable postharvest loss prevention. Identification of main causes of date defects and determination its percentage might contribute in filling the information gap of support to overcoming the weaknesses of date palm sector identified in Egypt date palm strategy (FAO, 2016), specifically weak tendency towards good agricultural practices to produce high quality dates.

The objectives of this work were to evaluate the cost, magnitude and type of main defects for some soft date palm cultivars at harvesting date, in North Delta, Egypt.

Materials and methods

The work was carried out in two main areas for soft date production in Egypt, Rasheed and Baltim districts which are located in North of Behira and Kafr El-Sheikh governorate respectively, at the North of Nile Delta, Egypt, on date palm fruits (*Pheonix dactylifera*, L.) of *'Samani', 'Hayani', 'Bent Aisha',* and *'Oreebi'*, soft cultivars during 2015/16 and 2016/17 seasons and on *'Zaghloul'*, only 2016/17 season. Three random crates samples, 16 kg each, which represent about 5% of total harvested amount daily that, weighs around 1000 kg of above-mentioned cultivars at commercial harvesting

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59655974

date of each cultivar usually practiced in the farm for many years. Each sample was examined and separated into two sets, sound fruits (free of visible defects) and defected/ discarded set, the percentages of sound and discarded fruits were calculated.

The defected fruit set was examined and separated according to the type of defect; each defect in the discarded set was calculated as a percentage of the total weight of the defected fruit set. The following are the types of defects were used for the examination and separation: 1) Misshape, the fruit was considered misshaped when it shows abnormal/irregular characteristic of the cultivar. 2) Unpollinated dates (shees), dates not pollinated as evidenced by thin flesh, immature characteristics and no pit in unpetted dates (Codex Stan 143-1985). 3) Decay, dates that are in a state of decomposition and very objectionable in appearance, (Codex Stan 143-1985). 4) Dirt, dates contaminated with sand, soil, dust or other field debris and particles are not easy to be removed. 5) Discolored, when the color of dates does not present the possess characteristic color for the cultivar 6) dry dates, 7) Insect damage, dates damaged by insects or mites or contaminated by damage and contamination the presence of dead insects or mites, fragments of insects or mites or their excreta (Codex Stan 143-1985). 8) Over ripped, fruits transformed from Bisr into Rutab stage 9) Shrivelling, date loses the moisture content causing wrinkling in fruit surface. 10) Under size, when number of fruits in half kg are more than 23 fruits for *'Samani' and 'Zaghloul'* cultivars and more than 100 fruits for *'Oreebi', 'Hayani'* and *'Bent Aisha'* cultivars (Codex Stan 143-1985). 11) Unripe dates, dates which may be light in weight, light in color, have shrivelled or little flesh or a decidedly rubbery texture (Codex Stan 143-1985). 12) Without calyx, 13) Mechanical injuries, any type of mechanical cracked or mashed or bruises on fruit surface. The data were managed as a randomized complete block design with three replicates (n = 3). Data were analyzed by Assistat software version 7.7, program **last** update was on 08/10/2014 according to Little and Hills (1972). Means were compared using Duncan's new multiple-range test at P value $\leq 0{\cdot}05$ (Duncan, 1965).

Financial value of defected date fruits (loss) at harvesting in Egyptian pounds (EGP): was calculated for each cultivar as follows:

$$\text{Production (ton)} \times \%\text{ of loss at harvesting} \times \text{Farm get price/ton (US\$)} \quad \text{(Eq.1)}$$

Loss in cropping-land (area used to produce lost amount of dates) Fed, was calculated as follows:

$$\text{Total production area (hectare)} \times \%\text{ of loss at harvesting} \quad \text{(Eq.2)}$$

Loss of production cost was calculated as follows:

$$\text{Loss in cropping-land (hectare)} \times \text{production cost (US\$)/Fed} \quad \text{(Eq.3)}$$

Loss of irrigation water (m^3) used to produce the lost amount of date fruits of each cultivar as follows:

$$\text{Loss in cropping-land (hectare)} \times \text{Water requirements per Fed } (m^3) \quad \text{(Eq.4)}$$

Results and discussion

Amount of sound and defected (loss) date palm fruits at harvesting time

The results in *Tables 1* and *2* showed that, the percentages of the sound, non-defected fruits at harvesting time and total discarded percentage/defected fruits of *'Samani', 'Oreebi', 'Hayani', 'Bent Aisha'* and *'Zaghloul'* cultivars during 2016 and 2017 seasons. The sound date palm fruits percentage was 84.32, 83.21, 76.97, and 73.23% for *'Bent Aisha', 'Oreebi', 'Samani'*, and *'Hayani'* in 2016 season, respectively. While during second season (2017), it recorded 94.50, 90.34, 80.34, 75.00% and 74.67% for *'Zaghloul', 'Bent Aisha', 'Hayani', 'Oreebi'* and *'Samani'* respectively. Regarding the defected fruits, *'Hayani'* cultivar showed that, the highest fruit loss at harvesting time was 26.77 percentage during 2016 season more than one quarter of its production, followed by *'Samani'* cultivar (23.03%), the differences were not significant. On the other hand, lossing fruits of *'Oreebi'* and *'Bent Aisha'* cultivars were 16.79 and 15.68% during harvesting time in the same season, respectively, with no significant differences between them. The losses of both cultivars at harvested time were significantly lower than *'Hayani'* and *'Samani'* cultivars.

In 2017 season, loss fruit of *'Samani'* and *'Oreebi'* cultivars were almost equal quantities; 25% of the produced fruits at harvested time and the differences between them was not significant followed by *'Hayani'* 19.66 and *'Bent Aisha'* 9.00%, respectively. While the lowest fruit loss was recorded by *'Zaghloul'* cultivar (5.50%).

The obtained results showed that loss at harvested of soft dates is substantial. These results are in consistent with those of Kader and Rolle (2004) who found that the magnitude of fruit losses depends, among other factors, on the nature of the commodities and the conditions of the produce at the time of collections. This also accords with FAO study in 2011 and Yahia et al. (2014), they reported that, low technical capacities in harvesting performances is one of the reasons of fruit loss, also El-Habbab et al. (2017) concluded that, the level of loss at harvesting time differs from area to area and from cultivar to another. Similar findings were observed on orange (Salama et al., 2015). So, the management practices of harvesting process play significant role in reducing loss during this stage and next stages in dates supply chain. The relatively low loss of *'Zaghloul'* could be attributed to the differences between growers in practicing harvesting techniques and processes.

Type of soft date fruit defects (loss) at harvesting time

Results in *Tables 1* and *2* present the percentages of different types of defects in the discarded fruit set. Fruits without calyx (*Fig. 1*) are the main defect of all studied cultivars in both seasons except *'Oreebi'* cultivar, it was discoloration in both seasons. In the first seasons 2016 (*Table 1*), *'Hayani'* cultivar, showed the highest without calyx defect (41.70%) followed by *'*Bent Aisha*'* (39.93%), the difference between them were not significant, while *'*Samani*'* cultivar (20.48%) was significantly lower than both. *'Oreebi'* cultivar showed the lowest significant without calyx defect. In the second 2017 season (*Table 2*), *'Hayani'* cultivar, also showed the highest without calyx defect (56.29%) followed by *'Bent Aisha'* (55.38%) and *'Samani'* (53.78%) cultivars respectively, the differences between them were not significant. *'Zaghloul'* cultivar (31.08%) was significantly lower than *'Hayani'*, *'Bent Aisha'* and *'Samani'* while *'Oreebi'* showed the lowest significant difference. This is could be attributed to the harsh way of fruit separation from the strands, which led mostly to the separation of part

DOI: http://dx.doi.org/10.15666/aeer/1703_59655974

of the fruit flesh with the cap (calyx), as shown in Photo 1. Fruits without calyx (cap) are more subjected to microorganisms and insect's infestation.

A B C

Figure 1. *Severe losses occurred due to careless rough handing of dates by farmers. A) rough way of separating the fruits from the branches (strands) using stick, B) separation of part of the fruit flesh with the cap (calyx), C) strands full of caps*

Discoloration defect was significantly the highest in *'Oreebi'* cultivar during both seasons, 69.83% and 55.52% respectively. In the first season, the difference between *'Bent Aisha'*, *'Hayani'* was not significant while *'Samani'* was significantly higher than both. In the second season, there was no significant difference neither between *'Hayani'*, *'Zaghloul'* and *'Samani'* cultivars nor *'Hayani' 'Bent Aisha'* and *'Samani'* while the difference between *'Zaghloul'* and *'Bent Aisha'* was significant.

During the both seasons, unpollinated dates (shees), decay, dirt, insect damage, unripe fruit and mechanical injuries defects for all cultivars were low and ranged from around 0.00 to almost 5.00%. The same was also observed for dry dates defect except for *'Bent Aisha'* cultivar in the first season, 5.64% significantly higher than the rest of the studied cultivars. Over ripening defect showed the same lower trend except for *'Oreebi'* cultivar in the first season (11.80%), it was significantly higher than the other studied cultivars. Shriveling defect showed also the same lower trend except for *'Bent Aisha'* cultivar during the first season (7.31%) and *'Hayani'* (9.13%) in the second season, significantly higher than the rest of the studied cultivars.

Results showed that the main causes of fruit loss at harvest under North Delta conditions were fruit without calyx (cap) for *'Samani'*, *'Bent Aisha', 'Hayani'*, and *'Zaghloul'* cultivars and discoloration defect for *'Oreebi'* cultivar. Fruit of the studied cultivars were less susceptible to insect damage, decay, dry dates, misshape, and unpollinated fruit (shees). These results are in consistent with those of Kereth et al. (2013) who stated that mechanical damages were the main type of fruit defect at harvest (79%) in Tanzania. El-saedy (2011) found that the fallen cap (calyx) of *'Hallawy'* and *'Zaghloul'* fruit triggered a high increase in polyphenol oxidase and peroxidase activity that resulted in negative effect on fruit weight loss, peel anthocyanin content, soluble solids, malic acid and total phenol content, which in turn led to quick fruit deterioration during cold storage at 1 °C. This is pointed out to the need of improving harvest methods, Yahia et al. (2014) and Kader and Awad (2009) reported that in Arabian Peninsula countries, mechanical damage are the common types of postharvest loss of dates. El-Habbab et al. (2017) stated that dates loss at harvest time of three cultivars in four locations in Saudi Arabia, include shees & besr, birds damage, falling, insects and dust mite which is not the case for the studied soft dates cultivars under North Delta conditions. Elsayed and Abdel Gleel (2013), in Egypt, have reported that, the average

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59655974

dates loss of ten-year (2000–2010) at harvesting were 10-15% and 8.1% during postharvest processes, this is due to mechanical (harvesting, sorting, grading, and transportation) or biological (pests and insects) reasons.

Financial value of the defected (loss) date fruits at harvesting

The Total value of dates loss of the studied cultivars during 2016 and 2017 were 9,232,793 and 8,641,908.89 (US$) based on farm gate price of 2014, (*Table 3*). The results showed that, the highest value loss in both seasons were corresponding to *'Hayani'* cultivar, 6,546,601.99 and 4,634,720.74 (US$) respectively, followed by *'Samani'* cultivar 1,986,639.19 and 2,185,044.32 (US$) for both seasons respectively. *'Zaghloul'* ranked the third with 1,215,153.39 US$ in 2017 followed by *'Bent Aisha'* 497,908.44 and 306,747.16 US$ for 2016 and 2017 respectively.

Loss of irrigation water and cropping-land and production cost (EGP) as a result of fruit defects (Loss) of some soft date palm cultivars at Harvesting

The irrigation water that has been used to produce the lost percentage of date fruits at harvesting, is considered an important lost as well taking into consideration that Egypt suffers from water shortage (Omar and Moussa, 2014). It was 5,242,919, 3,987,674, 1,325,155 and 666,340 m^3 for *'Hayani', 'Samani', 'Oreebi'* and *'Bent Aisha'* in 2016 respectively. In 2017, it was 4,385,922, 3,711,768, 1,973,132, 1,804,411 and 410,513 *'Samani', 'Oreebi', 'Hayani', 'Zaghloul'* and *'Bent Aisha'* respectively (*Table 4*). These differences due to the differences in the cultivated areas. The average water loss was 11,222,087 and 12,285,744 m^3 for 2016 and 2017 respectively. This amount of water was used to irrigate around 14% and 15% of date palm cropland during 2016 and 2017 seasons.

Water requirements for date palm vary from region to another according to climate conditions as well as the irrigation method, where it is 15,000–35,000 m^3/ha in Algeria,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59655974

23,600 in Tunisia, 13,000–20,000 in Morocco, 15,000–20,000 in Iraq, where it is 22,300 m^3/ha in Egypt (Albaker, 1972; Liebenbag and Zaid, 2002; Kassem, 2007).

Table 4. *Estimated loss of irrigation water (million m^3), cropping land (ha) and production cost (US$) because of defected fruits (loss) at harvesting of some soft date palm cultivars in North Delta, Egypt during 2016 and 2017 seasons*

Cultivar	Total[1] cultivated area (ha)	Loss (%)[2]		Loss in cropping-land (ha)[3]		Production cost Loss (US$)[4]		Loss of irrigation water (million m^3) (water requirement equal to 6333.18 m^3/ha)[5]

[3]Calculated by *Equation 2,* from columns 1 & 2
[4]Calculated by *Equation 3,* based on production cost/Fed equal to 15,185 EGP, source: Ministry of Agriculture and Land Reclamation, Economic Affairs Sector (EAS), 2017
[5]Calculated by *Equation 4.* Water requirements for Date palm in North Delta Region = 2661 m^3/Feddan and 6333.18 m^3/ha as One Feddan (Fed), equal to 0.39 ha. Source: Hassanien et al. (2012)

Conclusion

1. The percentages of fruit loss was 19.66- 26.77, 23.03–25.33, 16.79–25.00, 9.66–15.68, and 5.55% for 'Hayani', 'Samani', 'Oreebi', 'Bent Aisha' and 'Zaghloul' cultivars respectively.
2. The total financial value of date fruit loss was based on farm price (US$), which was 9,232,793 and 8,641,908 US$.
3. The total loss in terms of cropping land was 1764.44–1931.38 ha with a total loss in production cost = 3.59 - 3.93 million US$ and a loss in irrigation water = 11,2–12,3 million m^3.
4. The main fruit defect of 'Hayani', 'Samani', 'Bent Aisha' and 'Zaghloul' at harvesting in north delta area is Fruits without calyx (cap), while for 'Oreebi' cultivars is discoloration.
5. At harvesting, defects because of insect damage, decay, dry dates, misshape, and unpollinated fruit (shees) were low and ranged from around 0 to 5%.
6. There is a need for training programs on good agricultural practices of dates.

(Received 7th Feb 2019; accepted 29th Mar 2019)

Abstract. This study was conducted in the vine sapling production unit of "Kazova Vasfi Diren Agricultural Enterprise" located in central town of Tokat province in Turkey. The article attempted to graft five wine grape cultivars (Narince, Chardonnay, Merlot, Syrah, Öküzgözü) with five different American grapevine rootstocks (1103 Paulsen, 5BB, 41B, 110 R, 140 Ru) in order to combat mainly Phylloxera, but also provide protection against nematodes, lime and salinity-like soil-borne problems. Sapling yields of different cultivar/rootstock combinations were investigated. While the greatest sapling yield was observed in Narince/1103 Paulsen combination (98.03%), the lowest sapling yield was observed in Chardonnay/110R combination (43.64%).
Keywords: *vine rootstock, grapevine sapling, omega grafting, stratification room, sapling yield*

Introduction

Phylloxera (*Viteus vitifolii* Fitch.) was first encountered in France in 1863, then spread to European and Turkish lands. This pest feeds on the roots of culture vines and causes the termination of several grape cultivars (Yayla, 2008). Therefore, viticulture through direct rooting of scions of the local grape cultivars will not be economical. Laliman observed that some American grapevine rootstocks were resistant to Phylloxera, thus resistance to Phylloxera was achieved through grafting culture cultivars on these rootstocks (Winkler et al., 1974). For an economic viticulture, it is more appropriate to establish vineyards with vine saplings grafted on American grapevine rootstocks. American vine rootstocks are not only resistant to Phylloxera, but also serve alternative solutions for the problems related to nematodes, lime, salinity and the other soil-borne problems (Çelik et al., 1998).

Success of grafting is generally understood as callus layer formation between the rootstock and scion tissues and full-bonding and cohesion of them into a single plant (Janick, 1986; Çelik, 2007). In vine sapling production, sapling quality and final take ratios are largely dependent on whether or not the vines from which grafting materials were taken are free of pests and diseases, nutritional status of grafting materials, pre-grafting storage conditions of the rootstocks and scions, grafting method, attention paid to grafting, time of grafting, ambient conditions at stratification and following stages of grafted scions, mulching treatments, care and maintenance conditions after planting and the most important of all, cultivar/rootstock combinations (Kısmalı, 1978; Çelik and Ağaoğlu, 1982; Eriş et al., 1989; Kelen, 1994; Baydar and Ece, 2005).

Bhujbal (1993) used 1103P, 41B, SO4, Dogridge and Salt Creek rootstocks and Thompson Seedless cultivar and reported the best rooting and the greatest final take ratio for 1103P rootstock.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59755985

Dardeniz and Şahin (2005) grafted Uslu and Yalova İncisi grape cultivars on 1103P, 5BB, 41B and 140 Ru rootstocks and reported the greatest final take ratios as 44.61% and 37.47% for Uslu cultivar respectively grafted on 41B and 5BB rootstocks.

Ağaoğlu and Çelik (1982) grafted Hamburg Misketi, Hafızali and Hasandede grape cultivars on Kober 5BB and 99R rootstocks and reported total final take ratios varied as between 20-60%.

Kavak (2006) investigated the effects of Mycorrhiza and humic acid treatments on sapling final take ratios and reported the greatest grafting success (70.00%) for Yalova İncisi/1103P combinations and the lowest success ratio (52.67%) for Kalecik Karası/1103 P and Kalecik Karası/Fercal combinations.

Günen (2008) compared combinations of Cabernet Sauvignon and Syrah cultivars with five different rootstocks under open-field and greenhouse conditions and reported that ambient growth was significant. The greatest success was reported for Cabernet Sauvignon cultivar/1103 Paulsen combination as 90.08% in the first year and as 63.33% in the second year and for Syrah cultivar/1103 Paulsen combination as 91.67% in the first year and as 60.42% in the second year.

In this study, open-root sapling production was performed to assess the compatibility problems of commercially valuable wine grape cultivars of Narince, Chardonnay, Merlot, Syrah and Öküzgözü grafted on 1103 P, 5 BB, 41 B, 110 R and 140 Ru rootstocks commonly used in Turkey to propose solutions for Phylloxera, nematode, lime and salinity-like soil-born problems.

Material and method

This study was conducted in 2017 at the vine sapling production facility of Kazova Vasfi Diren Agricultural Enterprise in central town of Tokat province in Turkey (*Figure 1*). The 1103 P, 5 BB, 41 B, 110 R and 140 Ru American vine rootstocks and Narince, Chardonnay, Merlot, Syrah and Öküzgözü wine grape cultivars were used as the plant material of the study.

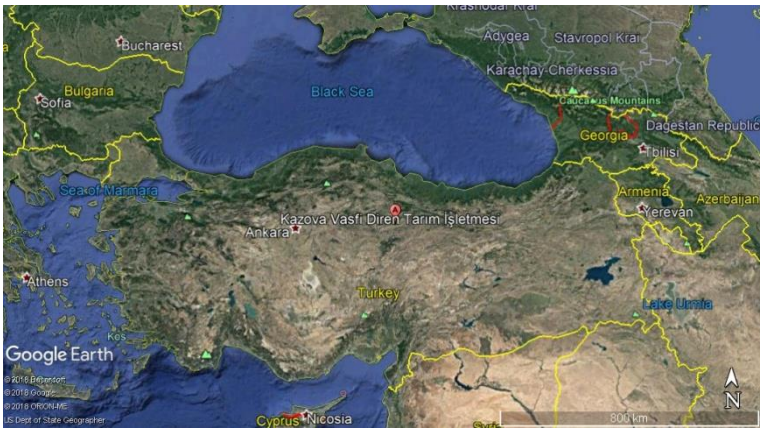

Figure 1. *Study site*

Shoots were taken from well-lignified mid-sections of annual branches, they were cut into single-bud scions and classified based on their thickness (7-8 mm, 9-10 mm and 11-12 mm thick) (Roux, 1988). Scions were treated with perlite moistened with water with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59755985

500 g/l Fenhexamid active ingredient against grey mold disease (*Botrytis cinerea)*. Treated scions were then placed into plastic bags and stored in a cold storage at +4˚C temperature for 2 months until the time of grafting (*Figure 2*).

Scions were cut into 30 cm long pieces as to have a single bud at the bottom and classified based on their thickness (7-8 mm, 9-10 mm and 11-12 mm thick). As can be seen in *Figure 3*, all buds were blunted except for the bottom one. Scions were then tied in bunches of 100 scions, placed into aseptic sacks and stored in a cold storage.

Figure 2. *Processes applied to grafting scions*

Figure 3. *Processes applied to rootstocks*

The scions (washed from the perlite over them) and rootstocks taken out of cold storage were kept outside (in a closed place) for three days. Rootstocks were kept in water-filled barrels and pools for two days (48 hours) and scions of the cultivars were kept in these places for one day (24 hours) (*Figure 4*). Just 6 hours before the end of this processes, 50% Benomyl was added only to holding water of scions to prevent the development of fungal diseases.

In this study, 37 500 grafted scions were produced [5 wine cultivars (Narince, Chardonnay, Merlot, Syrah and Öküzgözü) X 5 American Vine Rootstocks (1103 Paulsen, 5 BB, 41 B, 110 R and 140 Ru) X 3 replications X 500 grafted scions in each replicate] with omega bench grafting technique. Right after grafting, about 6 cm top section of grafted scions were coated with commercial paraffin prepared by using 1-5% wax, Vaseline, resin, bitumen, tar, mineral oil as well as efficient rate of fungicide and auxin and melted at 82°C. Following paraffin coating, grafted scions were taken into germination media and they were stacked into poplar shavings in Richter crates as recommended by Cangi et al. (2000) (*Figure 5*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59755985

Richter crates were then taken into stratification room for callusing. Stratification room conditions were arranged as 28-29°C temperature, 85-90% relative humidity and ventilation at every 6 hours (Çelik, 1982). The grafted scions left in Richter crates in stratification room for 21 days were taken out and placed in a closed facility for 2 days. Richter crates were opened, cleaned and second paraffin coating was applied to scions with full overall callusing. Grafted scions were placed into water pools for 12 days (a night) and they were removed from the water and rested for 2 days (*Figure 6*).

Figure 4. *Pre-grafting processes applied to rootstocks and scions*

Figure 5. *Omega grafting, paraffin coating and placement into Richter crates*

Figure 6. *Processes applied after stratification room*

Before to take the grafted scions to the field on 25th of April, they were subjected to 2000 ppm IBA (indole-3 butyric acid) and planted onto previously mulch-covered seed beds at 20 x 10 cm (row spacing x on-row plant spacing) spacing (*Figure 7*).

Figure 7. *Plantation of grafted scions to the field*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59755985

Following the defoliation, saplings were removed from the field on 23rd of November. Saplings offered for sale were counted and sapling yield (final take) (%) for five wine grape cultivars and five American vine rootstock combinations was calculated as the ratio of number of saplings offered for sale to number of grafted scions.

$$SY = \left[\frac{NSOS}{NGS}\right] x100 \quad \text{(Eq.1)}$$

where; SY= Sapling Yield (%), NSOS= Number of Saplings Offered for Sale, NGS= Number of Grafted Scions.

Statistical analysis

Experiments were conducted in randomized plots design with 3 replications. Following the analysis of variance, means were compared with Tukey's multiple range test at 1% significance level. JMP software was used in statistical analyses. Significant differences were indicated with the small letters by the data.

Standard delusion (SD)

Standard delusion calculations were performed to compare all experimental data in themselves.

Results and discussion

The results obtained for different cultivars are provided in *Tables 1, 2, 3, 4 and 5*. There were significant differences in number of saplings offered for sale and sapling yields of the cultivars ($p<0.01$).

In Narince cultivar, the greatest number of saplings offered for sale and sapling yield (491.33 and 98.27%, respectively) were obtained from 1103 P combination and the lowest values (265.33 and 53.07%) were obtained from 110 R combination (*Table 1*).

Table 1. *Sapling yields for Narince cultivar with different rootstocks (Mean ± SD)*

CULTIVAR	ROOTSTOCKS	NGS	NSOS	SY (%)
NARİNCE	**1103 P**	500	491.33±2.60 a	98.27±0.52 a
	5 BB	500	424.00±2.08 c	84.80±0.42 c
	41 B	500	457.00±3.21 b	91.40±0.64 b
	110 R	500	265.33±1.45 e	53.07±0.29 e
	140 Ru	500	294.67±2.91 d	58.93±0.58 d

The means indicated with different letters in the same column are significantly different according to Tukey's test at $p<0.01$. NGS: Number of Grafted Scions, NSOS: Number of Saplings Offered for Sale, SY: Sapling Yield

In Chardonnay cultivar, the greatest number of saplings offered for sale and sapling yield (399.00 and 79.80%, respectively) were obtained from 1103 P combination and the lowest values (218.67 and 43.73%) were obtained from 110 R combination (*Table 2*). The differences between 5 BB and 41 B rootstocks were not found to be significant.

In Öküzgözü cultivar, the greatest number of saplings offered for sale and sapling yield (376.67 and 75.33%, respectively) were obtained from 1103 P combination and the lowest values (248.67 and 49.73%) were obtained from 110 R combination (*Table 5*).

In a previous study comparing different cultivar/rootstock combinations under Isparta conditions, grafted vine saplings were produced through omega bench grafting and the greatest final take values were respectively reported for Razakı/SO4 combination (97.22%), Alphonse Lavallèe/SO4 combination (98.33%) and Italia/1103 Paulsen combination (98.04%) (Baydar and Ece, 2005). In present study, the greatest final take values (yield) of all cultivars were reported for 1103 Paulsen combination.

Table 5. *Sapling yields for Öküzgözü cultivar with different rootstocks (Mean ± SD)*

CULTIVAR	ROOTSTOCKS	NGS	NSOS	SY (%)
ÖKÜZGÖZÜ	**1103 P**	500	376.67±0.33 a	75.33±0.07 a
	5 BB	500	355.67±2.60 b	71.13±0.52 b
	41 B	500	367.33±2.33 ab	73.47±0.47 ab
	110 R	500	248.67±1.45 d	49.73±0.29 d
	140 Ru	500	322.00±2.31 c	64.40±0.46 c

The means indicated with different letters in the same column are significantly different according to Tukey's test at $p<0.01$. NGS: Number of Grafted Scions, NSOS: Number of Saplings Offered for Sale, SY: Sapling Yield

The greatest number of saplings offered for sale (491.33%) was obtained from Narince/1103 P interaction and the lowest value (218.67%) was obtained from Chardonnay/110 R interaction. The greatest sapling yield (98.27%) was obtained from Narince/1103 P interaction and the lowest value (43.73%) was obtained from Chardonnay/110 R interaction. While the greatest number of saplings offered for sale and sapling yields were observed in scions grafted on 1103 P rootstock and the lowest values were observed in scions grafted on 110 R rootstock. The differences in relevant values of Chardonnay/5 BB, Chardonnay/41 B, Merlot/41 B, Öküzgözü/1103 P, Chardonnay/140 Ru and Merlot/110 R interactions were not found to be significant (*Table 6*).

İşçi and Altındişli (2006) cleft-grafted different grape cultivars on rooted American vine rootstocks in place and reported final take ratios in 41 B and 110 R rootstocks respectively as 83 and 100% for Yuvarlak Çekirdeksiz cultivar, as 77 and 83% for Red Globe cultivar, as 84 and 80% for Buca Razakısı cultivar, as 100 and 81% for Trakya İlkereni cultivar and as 96 and 87% for Alphonse Lavallèe cultivar. Similar different values were also observed in this study for different cultivars.

Alço et al. (2015) investigated the grafting room performance of different cultivar/rootstock combinations and reported grafting room performance of Cardinal, Merlot and Cabernet Sauvignon grape cultivars grafted on 110 R rootstock respectively as 96.50, 98.75 and 98.75% in 2012 and as 97.75, 96.25 and 86.25% in 2013. Researchers reported the grafting room performance of the same grape cultivars grafted on 5 BB rootstock respectively as 99.50, 99.75 and 99.50% in 2012 and as 74.25, 70.50 and 86.75% in 2013. Present values obtained for Merlot/110 R and 5 BB combinations were lower than those values.

Günen and Altındişli (2017) compared combinations of Cabernet Sauvignon cultivar with three different rootstocks in open field and undercover conditions. Researchers indicated that growth ambient did not have significant effects on grafting success ratios

DOI: http://dx.doi.org/10.15666/aeer/1703_59755985

and reported the greatest grafting success for 1103 Paulsen rootstock as 90.08% in the first year and as 63.33% in the second year, the lowest grafting success for 110 R rootstock in the first year (53.18%) and for 99 R rootstock in the second year (23.34%). Present findings were parallel to those results obtained for 1103 R rootstock.

Çelik and Gider (1991) grafted Alphonse Lavallèe and Cardinal grape cultivars on 1103 Paulsen, 5 BB and S04 rooted rootstocks and indicated that grafting success varied with the cultivar/rootstock combinations and reported the greatest grafting success (98.08%) for Cardinal/1103P combination. Present findings were similar with those findings.

Eroğlu (2014) grafted Alphonse Lavallèe and Red Globe grape cultivars on 110 R and 1103 P rootstocks and investigated the effects of different biological preparates on sapling performance. Researcher reported grafting success in 110 R and 1103 P rootstocks respectively as 97.00 and 99.00% for Alphonse Lavallèe cultivar and as 97.60 and 97.90%

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59755985

for Red Globe cultivar. While present findings were lower than those findings on 110 R and were parallel to findings on 1103 P rootstock.

Çoban and Kara (2003) investigated sapling quality of combinations of four different grape cultivars and three different American vine root stocks and reported sapling performance of Lival, Ribol, Danam and Datal cultivars respectively as 51.0, 60.0, 61.0 and 70.0% in 5 BB rootstock, as 45.0, 65.0, 60.0 and 65.0% in 99 R rootstock and as 48.6, 50.0, 60.0 and 60.0% in 110 R rootstock.

Çakır and Yücel (2016) investigated grafting performance of Narince and Kalecik Karası grape cultures on 1103 Paulsen rootstock and reported callus formation ratios as 77% in Narince and as 60% in Kalecik Karası grape cultivar.

Yağcı and Gökkaynak (2016) investigated sapling performance of Sultani Seedless grape cultivar on different rootstocks (110 R, 140 Ruggeri, 1613 C, 5 BB and Ramsey) and reported total sapling performance respectively as 51.5, 40.4, 50.3, 57.3 and 50.2%. While present findings were lower than those findings on 5 BB rootstock, they were parallel to findings on 110 R rootstock.

Conclusion

With the intrusion of Phylloxera pest into vineyards, local viticulture practices have become impossible in Turkey. Therefore, growers had to establish their vineyards with American vine rootstocks resistant to Phylloxera, well-adapted to ecological conditions and with a good affinity to grape cultivars to be grown. This study was conducted through omega bench grafting of five different wine grape cultivars (Narince, Chardonnay, Merlot, Syrah and Öküzgözü) on five different American vine rootstocks (1103 P, 5 BB, 41 B, 110 R and 140 Ru) compatible with different soil characteristics of Turkish vineyards. While the greatest sapling yield (98.03%) was observed in Narince/1103 Paulsen combination, the lowest yield (43.64%) was observed in Chardonnay/110R combination. Present findings provide significant background information against potential incompatibilities in grafted vine saplings. Before to decide on any combinations, compatibility and affinity of the available rootstocks to the cultivar, adaptation of the rootstocks to local ecological conditions, effects of the rootstocks on yield, quality, growth, development and nourishment of the cultivar all should be well put forth. Such attributes of the rootstocks should be taken into consideration while recommending rootstocks to growers for the cultivars they wish to grow. Such appropriate recommendations will have great contributions to success and yield in viticulture activities of the growers.

(Received 7th Feb 2019; accepted 29th Mar 2019)

Abstract. Cockroaches, *Blatta lateralis* Walker (Orthoptera: Blattidae) have been one of the important groups of insect pests in urban environments. In this study, it was investigated that the effects of different native diatomaceous earths samples against Turkestan cockroach, *Blatta lateralis* Walker (Blattodea: Blattidae) nymph in the laboratory conditions. For this purpose, three different diatomaceous earths (Turco000, Turca004 and Turco020), obtained from domestic sources, were tested in seven different doses (0.50 g/m^2, 0.75 g/m^2, 1 g/m^2, 1.25 g/m^2, 1.50 g/ m^2, 1.75 g/m^2 and 2.00 g/m^2). It was concluded that the increase in the application dose increased the mortality. Turco020 caused 100% mortality rate at the end of the 28th hour at the application dose of 1.25 g/m^2. Similarly, the dose of 1.25 g/m^2 of Turco004 and the dose of 0.75 g/m^2 of Turco000 at the same treatment period produced 100% mortality. Based on the statistical analysis, a positive interaction between particle size and biological activity was detected. These results showed that the diatomite obtained from local sources have an important role in the control of this household pest.
Keywords: *Turkestan cockroach, bioactivity, native, control, particle size, efficiency, household pest*

Introduction

The Turkestan cockroach, *Blatta lateralis* Walker (Blattodea: Blattidae), also known as the rusty red cockroach, red runner cockroach or simply rusty red, red runner is native to a large area of the Middle East extending from Libya eastward to Central Asia including Afghanistan, Pakistan, Uzbekistan, and southern Russia (Alesho, 1997). In addition, Kim and Rust (2013) reported that this species has become an important invasive species throughout the southwestern United States. The adults of Turkestan cockroach are three cm tall and adult females are shorter than male. The Turkestan cockroach females produce between two and 25 ootheca or egg capsules over their life span. Each ootheca contains about 18 eggs. The species becomes adult after five molts, the nymphal developmental period at 26.7ºC is about 224 d. Five generations of Turkestan cockroaches require about 3 years (Kim and Rust, 2013).

Because of the species cause water and food contamination, transfer pathogens that cause diseases in human to induce allergic reactions and diseases (Shahraki et al., 2013). There is also a risk of damage to common household plants and crops that Turkestan cockroach feeds on once the cockroach reaches pest extents (Kim and Rust, 2013). In addition, Cranshaw (2011) reported that this species was known as a nuisance invader of homes in the United States. The use of insecticides is primarily preferred for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59875994

the control of cockroaches. However, alternative control methods have gained importance due to reasons such as the use of insecticides in indoor areas, threatening human and environmental health and developing resistance of cockroaches to insecticides. Some of the strains have shown resistance to up to 8-12 insecticide (Cochran, 2000; Kambayi et al., 2006).

In this context, there is growing interest in diatomaceous earth, which is known to be particularly effective against indoor pests (Faulde et al., 2006a; Alves et al., 2008; Hosseini et al., 2014; Islam and Rahman, 2016; Akhtar and Isman, 2016; Ertürk et al., 2017; Agnew and Romero, 2017; Atay et al., 2018). The mode of action of DE is generally accepted as desiccation affect on the insects (Faulde et al., 2006b). The effect primarily depends on its physical properties. There are different mechanisms of action such as abrasion of the cuticle, absorption of cuticular waxes, damage to the digestive tract, blockage of the spiracles and tracheae, and surface enlargement combined with dehydration (Ebeling, 1971; Faulde et al., 2006b).

The effectiveness of DEs for killing and controlling insect populations can vary depending on geographical origin, formulation process, oil absorption capacity, and chemical/mechanical modification of DEs, test conditions used and the species being tested (Quarles, 1992; Faulde et al., 2006b). This study was carried out to determine the efficacy of insecticidal activity of DE, which is obtained from domestic sources, against *B. lateralis* nymphs under laboratory conditions.

Material and methods

Rearing of Blatta lateralis

Turkestan cockroach nymphs were produced in 30 L plastic containers with 5 cm high peat at the base. A mixture of wheat flour and milk powder was used as a nutrient and water-absorbed paper for water needs (*Figure 1*). The colony was maintained in the climate room at 25 ± 2°C, 65 ± 5% relative humidity and 12:12 (L:D) photoperiod.

Diatomaceous earth

Diatomaceous earth (DE)'s used in this study were acquired from a local commercial company operating in Ankara-Kazan and Beypazarı counties (Beg-tuğ Mineral). The particle sizes of the diatomaceous earth were ranged 1-10 µm, 10-30 µm, 43-65 µm, for Turco000, Turco004 and Turco020, respectively. Local diatomaceous earth mainly composes of SiO_2 (83-95%) and other minerals were found oxidized form of calcium, aluminum, iron in small amounts.

Bioassay tests

Turco000, Turco004 and Turco020 local diatomaceous earth were weighed in seven different doses (0.50 g/m^2, 0.75 g/m^2, 1 g/m^2, 1.25 g/m^2, 1.50 g/ m^2, 1.75 g/m^2 and 2.00 g/m^2) and added to 20 cm^2 glass bottles (Hosseini et al., 2014). Five of Turkestan cockroach nymphs in the same period (60-day-old) were placed into glass bottles. Honey was applied to the inner edges of the bottles to feed of the insects, the mouth of the bottle was covered with insect proof mesh and incubated at 25 ± 2°C and 65 ± 5% r.h. conditions. At the end of the fourth, eighth, 12, 16, 20, 24, 28, 32 and 36 hours live and dead insects were counted and recorded. In the experiment, the control group

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59875994

weren't treated with the DE. Trials were set up with randomized block design with 18 replications.

Figure 1. *Rearing of Blatta letaralis in laboratory condiditons*

Statistical analysis

Contact toxicity test results were first converted into percent mortality and then were subjected to arcsine ($n = \arcsin\sqrt{n}$) transformation and ANOVA. Variance analysis was carried out with transformed data and additionally, the differences among treatments were analysed by means of Tukey multiple comparison tests ($p < 0.05$). All statistical analyses were conducted with MINITAB® Release 16 package program.

Results

It was determined that different doses of Turco020 showed activity in varying proportions against Turkestan cockroach nymphs (*Table 1*).

In all of the studied periods 2.00 g/m^2 showed significant activity on the mortality of the nymphs. After four hours of treatment, the dose of 2.00 g/m^2 had a mortality rate of 72.33%, at the end of the eight hours treatment mortality rate reached 100%. The dose of 1 g/m^2 caused 97.39% mortality rate at the end of the 24th hours and took place in a different statistical group from the control. All doses showing with significant activity were in a different statistical group than the control group. The doses of 0.50 g/m^2, 0.75 g/m^2 and 1 g/m^2 did not provide 100% mortality rate in any time period.

Turco004 showed similar bio-activity together with Turco020 on Turkestan cockroach nymphs (*Table 2*). The lowest dose and the shortest duration time in terms of 100% mortality were 1.25g/m^2 dose and 28 hours of treatment, respectively. However, based on the treatment time, 2.00g/m^2 dose gave 100% mortality rate at the end of the 12th hour. This dose was statistically different from the control group. The doses of 1.25g/m^2, 1.50g/ m^2, 1.75g/m^2 and 2.00g/m^2 gave 100% mortality rate different application time period.

Turco 000 having the smallest particle size, showed that dose-dependent activity in varying proportions. In terms of the highest activity and the shortest application time, the dose of 0.75 g/m^2 provided 100% mortality at the end of the 28th hours. Besides, at the end of 12th hours, complete mortality was obtained at doses of 1.25 g/m^2 and above (*Table 3*). All doses and times showing significant bioactivity were in a different statistical group with the control group.

Discussion

In this study was tested the effectiveness of the native diatomaceous earth, which is a biorational control method, for the Turkestan cockroach nymphs that are important indoor and outdoor pest, in terms of an alternative control method to the chemical compounds. In the trials, the insecticidal properties of local diatomaceous earth were initially tested in different doses and times against Turkestan cockroach nymphs and in this aspect, this study is a first in literature. Results from contact bioassays revealed that nymphs of the Turkestan cockroachs are sensitive to the diatomaceous earth at different rates. The most toxic formulation was Turco000 with the highest mortality rate and minimum exposure time (*Table 3*). It is known that the effect of the particle size on the effectiveness against insects is significant; smaller particles are significantly more effective than larger ones (Korunic et al., 2011). Similarly, Turco004 and Turco020 were less effective because of the having larger particle size than Turco000. The results we found supporting Bhan et al. (2014) findings showed that developed temephos and imidacloprid containing polyethylene glycol encapsulated nanopesticide with the melt-dispersion method and find more active against larvae of *Culex quinquefasciatus* (Diptera: Culicidae).

It is generally known for the diatomaceous earth that high relative humidity content effects the rate of mortality due to the desiccation (Fields, 1998; Subramanyam and Roesli, 2000; Fields and Korunic, 2000; Mewis and Ulrichs, 2001; Athanassiou et al., 2011; Frederick and Subramanyam, 2016). In our study, we used 65 ± 5% r.h. conditions in terms of determining the effect of the r.h. for the toxicity test. However, this relative humidity value needs to be diversified in future studies. Faulde et al. (2006a) revealed that seven kinds of DE formulation have been showing different toxicity at 25 g DE powder per m^2 to the adults of German cockroach, *Blattella germanica* (L.) (Orthoptera: Blattellidae) in a humid climate (85% r.h.), complete populations were eliminated within 10 days with FS 90.0S White, FS 90.0S, and FS 95.0 DE formulations tested. Our findings showed that the doses of 1g/m^2 of Turco000 killed the Turkestan cockroach nymphs at the end of the 16th hour's treatment. It is estimated that morphological differences of different types of cockroaches and the origin of the diatomaceous affects the mortality rates of insects at several rates.

The reactions of biological stages of insects to diatomaceous earth are also different. It is known that larval or nymphal stages of insect more susceptible to the DE formulations. Older larvae or nymph stages are significantly more resistant than young larval periods (Vayias and Athanassiou, 2004). Although the adult cockroach was not used in this study, it can be said that the nymphal periods of Turkestan cockroach are more sensitive to diatomaceous earth. Similarly, Hosseini et al. (2014) reported that the dose of 25 g/m^2 of DE completely kills the nymphal stages of German cockroaches at 72 hours, while LC_{50} and LC_{90} values for adults determined as a 12.9034 g/m^2 and 626.0942 g/m^2, respectively. Vayias and Athanassiou (2004) stated that all larvae of *Tribolium castaneum* Herbst, 1797 (Coleoptera: Tenebrionidae) were killed at the dose of 1.5 g/kg of SilicoSec whereas this rate was 50% in adults after 48 hours exposure period.

As a result, cockroaches emerge as a problem in terms of hygiene in areas where human activity and habitats are intense. Cockroaches are the potential carrier of human diseases, a pathogenic organism such as bacteria, protozoa, fungi, and helminths (Tatfeng et al., 2005; Baumholtz et al., 2008). In addition, increased awareness of side effect of the synthetic pesticides to the society, the resistance statues of insects against

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59875994

pesticides, has also led to the need to investigate safe control methods for the cockroaches that can be used in the integrated pest management system.

Conclusions

Diatomaceous earth can be regarded, as have strongly insecticidal properties against Turkestan cockroach. The results show that there is a negative correlation between particle size and activity. In view of these findings, native diatomaceous earth should be investigated in different humidity and temperature conditions against an invasive species Turkestan cockroach adults and nymphs.

Abstract. The AMMI (additive main effect and multiplicative interaction) and GGE (genotype, genotype x environment) biplot analyses were used to evaluate and identify stability and yield of Triticale genotypes at three different locations throughout two years (2014-15-2015-16). The AMMI analysis of variance showed significant genotype, environment and GE interaction and indicated 1.31, 98.40 and 0.28% of total variation, respectively. The GGE bi-plot analysis indicated 78.19% of the total variation (PC1 (priciple component) 50.01%, and PC2 26.08%). This study has been useful to discriminate genotypes with superior and stable yield evaluated by the AMMI analysis and yield stability index incorporating the AMMI stability value and yield capacity in a single non-parametric index. The AMMI analysis indicated that G4, G8 (candidate) and G6 were found to be quite promising genotypes. In the GGE biplot analysis genotypes were investigated in two mega-environments, and the first mega-environment covered E3, E5 and E6, and the second mega-environment covered E1, E2 and E4. The genotypes G6, G8, G9 and G11 were the wining genotypes in ME (mega-environment) I, G3, G4 and G12 and in ME II. The GGE and AMMI biplot approaches let us to describe the best genotypes, and G8 to be stable and high yielding for both ME, G6 only for ME I, G4 only for ME II and can be recommended to release as a cultivar.
Keywords: *stability, interaction, yield, multi, approach*

Introduction

In order to ensure an adequate and balanced diet of the growing world population, food production should be increased in parallel. This is possible through the development and application of new cultivation techniques and also by the development of more efficient and high quality plant species. For this purpose, Triticale (x *Triticosecale Wittmack*), was developed as a new species, a hybrid of wheat and rye, used as an alternative cereal crop for growing in marginal areas (Kendal and Sayar, 2016). This new species is known that it is tolerant to diseases, pests, dry conditions, acid and problematic soils and it was determined that it could replace cereal forage crops. Triticale is mostly used in animal feeding and it is also evaluated as grain, roughage, silage and straw. The feed value of triticale is equivalent to corn, wheat, barley, rye and sorghum or better than them, while in feed rations, it can be preferred instead of corn, wheat, barley, rye and oats. Triticale is used primarily as animal feed,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59956007

and in recent years it has also been used in human food and ethanol production (Oral, 2018).

Triticale cultivation in the world has shown an increase of over 40% in the last a decade years. The area of cultivation of triticale is 3.8 million ha, and the production is around 14.7 million tons in the world, and this rate is increasing day by day (Anonymus 2; Ayalew et al., 2018). In Turkey, statistical data related to triticale production have started to be given after 2004, and in 2016, about 38.000 ha area was planted and about 125.000 tons of product was obtained from this area. However, in our country, Triticale is the highest yield in cereals and grain yields approximately 3360 kg per hectare (Anonymous 1; Kizilgeci, 2019). Therefore, triticale is gaining more and more attention both in the world and in our country.

The exploiting of heredity instability is one of the very significant issues in terms of breeding strategies and this situation can only be explained by phenotypically phrase (Rad et al., 2013). In order to explain the phenotypic variations, it is highly dependent on the effect of the environments. Explaining this diversity is upwards sophisticated by the fact that all genotypes don't react in the same way as change in circles and the two environments do not have exactly the same conditions (Neisse et al., 2018). If the performance of genotypes changes in different location, then the interaction of the genotype location is an important factor in plant breeding strategies. Therefore, analysis of any variance combined can measure GEI and identify main effectiveness, however it is not enough to declare the GEI effectiveness. A convenient analytic pattern like the additive main effects and multiplicative interaction (AMMI) can cure both the additive main effect and multiplicative interaction constituent utilize the ANOVA (analysis of variance) and IPCA (Interaction Principal Components), respectively (Kilic, 2014; Mohammadi et al., 2018). The GGE biplot exploits the PCA approach to investigate the multi environment data and allow the visual presentation of the relationship among genotypes, environments and interaction as well as.

The aim of this study were to (i) analyses the effect of GEI on grain yield of 12 triticale genotypes by two new biplot models (AMMI and GGE) (ii) identifying high yielding and stable triticale genotype(s) across locations and (iii) to detect appropriate genotype(s) for every location or environment.

Material and Methods

The ten spring triticale advanced lines and two local check were evaluated in three locations across two years (2014-2015 and 2015-2016 growing seasons). The information of genotypes showed in *Table 1*. The trials were planted following a randomized complete block design with four replications at each location. The information about test location is given in *Table 2*. Each parcel was set in a six row plot of 6 meter length and 1.2 m diameter with plant spacing of 20 cm. Sowing of trials were done in autumn and sowing density was used 500 seeds in per m^{-2}. The fertilization of planting time, 60 kg N ha^{-1} and 60 kg P ha^{-1} were used, and 60 kg N ha^{-1} was used to each plots at tillering time for all plots. The grain yield was recorded from each plot after harvesting of the materials and measured extrapolated to ton/ha.

The described growing seasons 2014-2015

The rainfall was the same with long term in all location and it was enough for germination of plant after sowing time in October, the triticale had good weather in

DOI: http://dx.doi.org/10.15666/aeer/1703_59956007

winter days. Seasonal conditions were favorable for triticale cultivation in the development period in March and April in all location. Therefore, the expected high yield was obtained in all location of 2014-15 growing season. All location had good growing season, but in Ceylanpınar location the rainfall is very low than other location and it was partially heat stress during after heading time, in Adiyaman location during the spring period there was partially heat stress, In Diyarbakir location, conditions were more favorable than other locations.

	E6	Ceylanpınar	366	36° 84' N	40° 05' E	217.0

The described growing seasons 2015-2016

The rainfall of second season was late in planting time and it was low, in development of plant time, when we compare it with long term rainfall of locations. On the other hand; the temperature was high. Genotypes were exposed to drought in Ceylanpınar location. In the Adiyaman location, it was partially exposed to temperature stress. In Diyarbakır, heat stress was effective after heading period in April. Therefore, the grain yield of 2014-2015 season was suitable than 2015-16 growing season in all locations. The conditions of Ceylanpınar location is usually hard than other location, because the total of rainfall of seasons usually is low (*Table 2*).

Statistical analysis (AMMI and GGE)

The AMMI analysis was carried out using the adjusted mean values of grain yield to detect the relation among genotypes, locations and GEI over model designated by Zobel et al. (1988). The adopted method uses PCA to decompose the multiplicative effects of GEI into a number of IPCA. The two models (AMMI and GGE) analysis were carried out by Genstat software (version 12). The Additive mean effect and multiplicative interaction model analysis is based on the following formula; $\mathbf{Y}_{ger}$ $=\mu+\alpha g+\boldsymbol{\beta}_e+\boldsymbol{\Sigma}_n\boldsymbol{\lambda}_n\boldsymbol{\gamma}_{gn}\boldsymbol{\delta}_{en}+\boldsymbol{\varepsilon}_{ger}+\boldsymbol{\rho}_{ge}$; where, Yger is the monitored grain yield of genotype (g) in environment (e) for replication (r); Additive parameters: μ is the grand mean; αg is the deviation of genotype g from the grand mean, βe is the deviation of the environment e; Multiplicative parameters: λn is the singular value for IPCA, γgn is the genotype eigenvectorfor axis n, and δen is the environment eigenvector; ε_{ger} is error term and ρ_{ge} is PCA residual.

AMMI Stability Value (ASV) is the space from the origin to the coordinate point in a two dimensional plot of to IPCA scores (Purchase, 1997). Because the IPCA1 score contributes to the sum of squares of GEI, a weighted value is needed. This weighted value was calculated for each genotype and each environment according to the relative contribution of IPCA1 to IPCA2 to the interaction sum of squares as follows:

$$ASV = \sqrt{\left[\left(SSIPCA1 + SSIPCA2\right)\left(IPCA1Score\right)2\right] + \left(IPCA2Score\right)2} \qquad \text{(Eq.1)}$$

Where, / SS_{IPCA1} / SS_{IPCA2} is the weight given to the IPCA1-value by dividing the IPCA1 sum of squares by the IPCA2 sum of squares (Purchase, 1997).

Genotypic stability index (GSI) incorporate mean and stability index in a single criteria and calculated as: GSI = RASV+RY where, RASV is the rank of ASV and RY is the rank of mean yield of genotypes across environments. This index considered the rank of AMMI stability value to rank genotypes based on grain yield across environments.

On the other hand; data were graphically analyzed to interpret GEI to identify stable and adaptive genotypes using the GGE biplot described by Yan and Tinker (2006).The GGE biplot methodology (Yan et al., 2000) was applied for analysis of GE interaction of grain yield. The GGE biplot model is based on the following formula:

$$K(Yij)=\mu+ \beta j+ K \sum \delta k\gamma ik\eta jk \; k+1 \qquad \text{(Eq.2)}$$

where $E(Yij)$ is the expectation value of genotype i in environment j; μ is the grand mean; βj is the environment effect; K stand for the number of principal the environment effect; K stand for the number of principal components (PC) needed to provide an adequate explanation of G + GE; is singular value for the kth PC; and stands for the δk γjk ith genotype score and stands for the jth environmental score for the kth PC. Singular value ηjk partitioning is achieved by providing a scaling factor f to obtain alternative genotype ($c_{ik}=\delta^f{}_k$ and environment scores. The symmetric scaling (f = 0.5) was used in γik) ($d_{jk}=\delta^1{}_k{}^{-f}\,\eta jk$) visualizing which-wins-where pattern of MET data, due to its compliance with most of the features related to other benchmarking methods (Yan, 2002).

Result

The AMMI analysis

The variance of AMMI analysis showed that genotype, environment, GEI and IPCA (Interaction principle component analysis) had significant ($p<0.01$) effect on triticale grain yield of 12 genotypes tested in six environments (*Table 3*). The environment main effect accounted for 98.40% of total variation, compared with 1.31% for genotype and 0.28% for GE interaction effects in the analysis of combined variance (*Table 3*). The quantity of genotypic effect was about two times greater than the GEI effect, which indicates different possible presence of MEs in the METs data. The major differences between the circles influenced the average of squares and caused the grain yield of each environment to change. The multiplicative variance of the treatment sum of squares due to interaction was partitioned into the fourth interaction principal components and the only one of them significant effect. The first PCs accounted for 56.75%, the second for 17.56%, the third for 17.11%, and the fourth only 8.55% of G+GE total variation for triticale data. Except the first IPCA-I, the remaining three IPC axes were non-significant and contributed 43.22% of the GEI (*Table 3*).

In the AMMI model, the figure interpret by two direction and x-axis represents the genotypes and environment main effect and y-axis represents the effects of interaction (*Fig. 1*). The genotypes and environment indicated much more variability in both main effect and interaction. The environment located above the *y*-axis mean that they are desirable and high-efficient, whereas the environments, which are located under of *y*-axis mean that they are unffavorable and low-yielding (Kendal and Tekdal, 2016). According to these definitions, in the AMMI (*Fig. 1*) indicated that grain yield of the first year (7.244 t/ha) is higher than in the second year (3.979 t/ha) in all locations (*Fig. 1 and Table 4*). When we evaluate the locations based on grain yield average, all locations were located above average (y axis) in the first crop season (2014-15), while all location were located under average (y axis) in the second crop season (2015-16). This implies that grain yield of first year in all locations were higher than the second year. On the other hand, when we evaluate the environments independently, the highest yield average is obtained from E1 and the lowest yield average is obtained from E6.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59956007

According to the location averages, Diyarbakir location (6.529 t/ha) is found to be more efficient than the other two locations in both years (*Fig. 1 and Table 5*). The AMMI (*Fig. 1*) also shows the stability of genotype based on mean grain yield of multiple environments. The genotypes located near the *x*-axis and on the right of the *y*-axis mean that they are stable and high-efficient, whereas the genotypes, which are located far from *x*-axis and left side of *y*-axis mean that they are unstable and low-yielding (Crossa et al., 1990). Accordingly, G7, G4 and G8 placement of near *x* axis and on the right of the *y*-axis, therefore it mean that these genotypes are quite stable and yielding. Moreover; G1, G3, G10 (check) and placement of far from x axis, so these genotypes are unstable across environments. The AMMI (*Fig. 1*) biplot showed that G4, G6 and G8 are quite yielding, while both of check used in the study (G5 and G10) are poorest genotypes across test environments (*Table 4*).

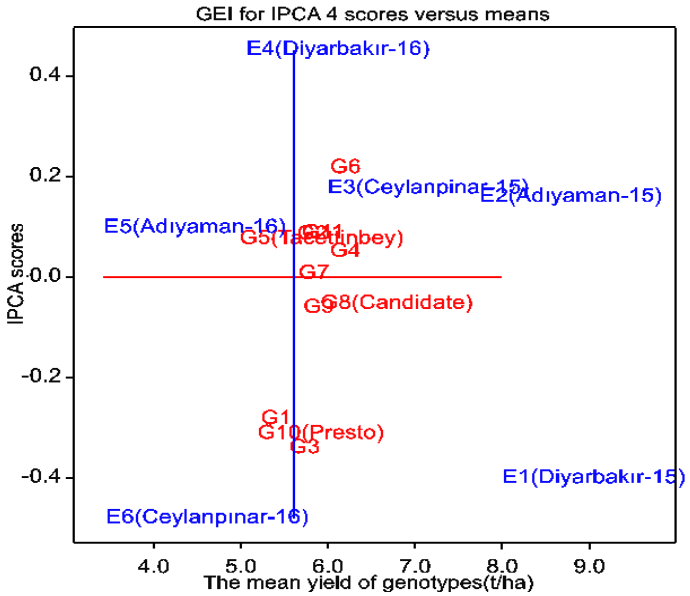

Figure1. *The AMMI shows the stability of genotype based on mean grain yield of multiple environments. The genotypes located near the x-axis and on the right of the y-axis mean that they are stable and high-efficient, whereas the genotypes, which are located far from x-axis and left side of y-axis mean that they are unstable and low-yielding. G1-G12 is the codes for the triticale disomic addition lines and G5 and G10 used as the control, respectively. E1- E3 are environment codes for 2014-15, E4-E6 for 2015-16 growing season*

The GGE Biplot analysis

The mean grain yield across two years (2014-15-2015-2016) in three location (Diyarbakır, Adıyaman, Ceylanpınar) of 12 triticale genotypes were showed in *Table 5*. These table data was used to generated a GGE biplot (*Fig. 2-Fig. 6*), although the genotype is compatible with biplot, it represents only 78.19% of the variation. In the present study, the first two IPCAS were used to portray genotype by environment interaction and placement on the (*Fig. 2-Fig. 6*). The GGE biplot provides good explanation of the pattern, regarding first two IPCs.

The relationships among and between genotypes and environments visualize in *Fig. 2*. A biplot such a graph to be interpreted bi-directionally has the following comments (Yan et al., 2000; Yan and Tinker, 2006). 1) The cosine of the angle between the vectors of the two environments approaches the Pearson correlation between them. Therefore, an angle of less than 90° shows a positive correlation, an angle greater than 90° shows a negative correlation and an angle of 90° shows zero correlation. 2) If the vector of a environment is longer than other vectors, the variation of this environment on genotypes is higher than the other environments, if the vector length of any environment is very short than other traits vector then the variation of this environment is very low. 3) The angle between the vector of any genotype and any environment gives information about the state of the genotypes to environments.

If the angle is quite sharp and narrow indicates that the genotype is desirable for that environment if the angle is too large then the genotype is undesirable for that environment. 4) The length of the vector of a genotype indicates the strength or weakness of the genotype for all environments. According to these explanations there are high correlation among E3, E5, E6 and G6 is desirable for these environment, while there are high correlation E1, E2 and E4 and G6 is desirable genotype for these

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59956007

environments, and G8 (candidate) is desirable for all environments (*Fig. 2 and Table 6*). In *Fig. 3*, five sectors are created, with two sectors each of them consisting of three environments. These sectors stand for different MEs, because the winning genotypes for each sector are those positioned at the vertex we can say that G4 is wining genotype for sector II (E3, E5 and E6), G6 for sector I (E1, E2 and E4).

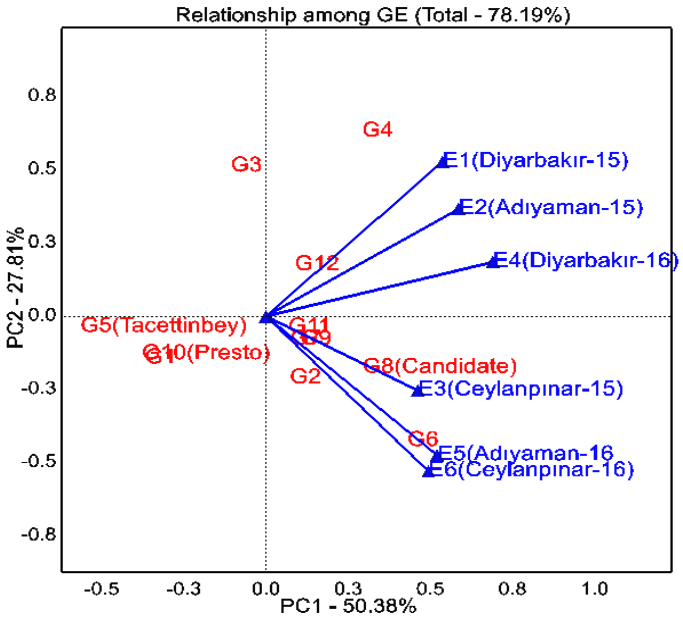

Figure 2. *The GGE biplot which shows the relationships among test environments. The correlation coefficient between any two environments is approximated by the cosine of the angle between their vectors. Acute angles indicates a positive correlation, obtuse angles a negative correlation and right angles no correlation. G1-G12 is the codes for the triticale disomic addition lines and G5 and G10 used as the control, respectively. E1- E3 are environment codes for 2014-15, E4-E6 for 2015-16 growing season*

Table 6. *The first four AMMI selections for per environmts, variance and IPCA scors*

Env	Mean	Score	1	2	3	4	IPCAe[1]	IPCAe[2]	IPCAe[3]	IPCAe[4]	Variance
E1	7.996	-0.79	***G4***	***G3***	***G8***	***G7***	-0.78881	-0.44311	0.14583	-0.40141	0.6423

E6	3.450	0.57	***G6***	***G8***	***G9***	***G2***	0.57021	0.16753	-0.02109	-0.48096	0.2598

Similar situation (two mega- environment) occured among environments presented in *Fig. 4*. The stability of genotypes also showed in *Fig. 5*, and generated by GGE biplot. The AEC is showing the stability genotypes based on across environment. The similar results indicated on *Fig. 6*, and G8 and G6 are favorable genotypes because they located near of center ideal center of biplot. The result showed that G8 (candidate) is quite stable and yielding, G6 and G4 are yielding as well as. The biplot showed that the selection of genotypes can be done both on specific and general goals.

Discussion

The multiple environments experiments aims to identify superior genotypes for different conditions. Due to the unpredictable environmental factors, different models (GE, GEI, GGE, AMMI) were developed to elucidate the effect of genotype, environment or interaction, and are still used in breeding studies (Kendal and Sayar, 2016; Kendal et al., 2016). In addition, The AMMI and GGE biplot techniques have been used for a long time by many researchers to understand the effect of genotype, environment and GEI based on grain yield (Yan and Tinker, 2006; Kendal and Dogan, 2015; Akcura et al., 2016; Oral et al., 2018). The AMMI analysis was used to identify the stability and superiority of genotypes, favorable and yielding environments based on multiple environments (Tekdal and Kendal, 2018). In the study AMMI analysis indicated that G4 and G6 were yielding genotypes, while G7 and G8 (candidate) were stable in tested environments. On the other hand, the study showed that the grain yield is fluctuation depend on factors of environmental and years. In addition, some locations (Diyarbakır) have proven to be highly yielding, some other locations (Ceylanpınar) have proven to be low-yielding even if the year conditions change. Some studies on AMMI commented that this model can be used to describe a two-way table of GE means. When the GE means are independent and homoscedastic, ordinary least squares (OLS) gives optimal estimates of the model (Gauch et al., 2008), this model could be used to evaluate genotypes at different locations over the years in breeding program (Sadeghzadeh et al., 2017). The magnitude of environment effect was higher than genotype effect (Rad et al., 2013). İn triticale the locations that are both descriptive and representative are good test locations for the selection of adapted genotypes (Bilgin et al., 2018). Acording to GGE biplot biplot showed that the selection of genotypes can be done both on spesific and general goals. In the study, two mega-environment were occured in the test environments and G4 was the best yielding in the poorest environments or years, and G6 for yielding crop seasons or environments, while G8 (candidate) is stabile for general testing environments. According to results of a study indicated that an ideal genotype should have both high mean yield and high stability within a mega-environment (Yan and Tinker, 2006). In studies conducted in different years or environments, if there is no difference between two or more environments and within the same circle, this is called mega environment and it is recommended to work in one of these environmental groups in later studies. Fortunately, more than two mega-environments are often sufficient to allow GE to capture a sizeable portion of the interaction signal (Gauch, 2013; Hongyu et al., 2015). According to the results of the AMMI and GGE biplot models had similar results in view of specific adaptability to environmental conditions. Nevertheless, contrary results were obtained for environmental contribution to the stability of genotypes (Lule et al., 2014; Shahriari et al., 2018). Both AMMI and GGE were able to efficiently explore the variability present in MET data due to genotype-environment interaction and both models proved to be approximately equivalent, leading to substantially the same conclusions about the genotypes with the highest yield and stability (Neisse et al., 2018).

Conclusion

The results of study revealed that grain yield of triticale was highly influenced by environment effect followed by genotypic effects and GEI contributed the least. This study demonstrated that AMMI model was found effective for determining the yielding

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_59956007

and stabilite triticale genotypes and discriminating ability and representativeness of the test environments. Acording of the study, G4 and G6 showed specific ability, while G8 general adaptability in test environments. Moreover; G4 can be reccomend for yielding (mega-env II), while G6 for low-yielding (Mega-env. I) seasons or environments. On the other hand, G8 can be registared as variety for study area, because this genotype is quite stable and yielding among genotypes in test environments. Both AMMI and GGE biplot model were proved to be approximately equivalent, leading to substantially the same conclusions about the genotypes with the highest yield and stability.

(Received 11th Feb 2019; accepted 28th Mar 2019)

Abstract. Food-borne diseases caused by pathogenic bacteria (especially *Escherichia coli*) are one of the main causes of mortality in some developing countries. Hospitals are one of the potential places from where food-borne diseases might spread. The food handlers working in the hospital have a major role in the distribution of pathogenic bacteria because they are directly involved in the hospital's food chain. This study aimed to determine bacteria contamination among 30 food handlers based on some influencing factors, such as education level, work experience, worker's behavior, and hygiene training at a public hospital in South Sumatra, Indonesia. To study the correlation between some factors with the level of *E. coli* contamination, the bivariate analysis was performed. The results of the bivariate analysis revealed that there was a significant relationship between the education level and work experience of the food handlers with the level of *E. coli* contamination (p-value ≤ 0.05). In the other hand, there was no significant relationship between behavior and hygiene training with the level of *E. coli* contamination (p-value ≥ 0.05). This study indicates the importance of socialization about food hygiene and regular rectal swab test for food handlers to ensure their health level.
Keywords: *Escherichia coli, rectal swab, hygiene, infection, bivariate analysis*

Introduction

Food handlers working in hospitals are people who directly involved in the food chain processing until the food distribution to the patients. The role of food handlers in spreading diseases is the contact between food handlers suffering infectious diseases with the food source itself. Subsequently, the food is consumed by the patient and causes nosocomial infections.

Food handlers who work in the food service sector with poor personal hygiene are the potential source of pathogenic organism infection (Acikel et al., 2008; Mukhopadhyay et al., 2016; Anjum et al., 2017; Gemeda et al., 2018). The food contamination occurs during food chain process including preparation, production, processing, and the food distribution (Permenkes RI, 2011; Anuradha and Dandekar, 2014; Mukhopadhyay et al., 2016). The risk of bacteria contamination to the food

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60096015

handlers depends on their health status, personal hygiene, knowledge, and the hygiene practice (Esparar et al., 2010; Dahiru et al., 2016).

Foodborne disease is defined as illness resulting from the consumption of contaminated food; food can be contaminated with microbial pathogens or a toxic substance (Unicomb, 2009). Most of the foodborne diseases happen because the food handlers have transmitted the bacteria or viruses through improper food handling and poor sanitation. The hands of food-handlers can serve as vectors in the spread of foodborne diseases due to poor personal hygiene or cross-contamination. Recent days, the food-borne diseases become a major health problem in developing countries, such as Ethiopia (Girma et al., 2017; Gemeda et al., 2018), Nigeria (Dahiru et al., 2016), Iran (Heydari-Hengami et al., 2018), and Indonesia (Chantika, et al., 2016; Kurniasih et al., 2015). The global incidence of food-borne diseases is difficult to estimate, but it was reported that in 2005 there were 1.8 million people killed from diarrheal diseases. This case can be linked to food and drinking water pollution (WHO, 2007, 2008).

As located in a developing country, the health problem is one of the concerning issues in Palembang, South Sumatra-Indonesia. The public hospital in South Sumatra serves many patients every day. Based on the preliminary research, the supervision of food hygiene and sanitation by the Environmental Health Department and the Nutritional Departments should be improved to ensure the public hospital sanitation. In the other hand, the Department of Infectious Disease only evaluates adherence of the hygiene activities in the food sanitation. Therefore, further study is required to perform the synergistic responsible of the three departments for food sanitation and hygiene. The food processing at a public hospital in South Sumatra should be improved to ensure the quality of food services, especially for patients.

Commonly, the parameter of hygiene is the presence of *Staphylococcus aureus* bacteria, while the parameter of sanitation is *Escherichia coli* contamination. This research is focused on *E. coli* contamination which is found in food handlers due to the poor sanitation of the hospital's workers (Hanekom et al., 2010; Kurniasih et al., 2015; Switaj et al., 2015; Dahiru et al., 2016; Nasrolahei et al., 2016). *Escherichia coli* or commonly abbreviated as *E. coli* is one of the common gram-negative bacteria. In general, these bacteria can be found in the human colon and feces (Switaj et al., 2015; Nasrolahei et al., 2017). Most of *E. coli* is harmless, however, *E. coli* type O157: H7 can cause bloody diarrhea because produces verotoxins (Lourenco et al., 2011; Switaj et al., 2015).

This study was to overview the *E. coli* contamination among food handlers at a public hospital in South Sumatra and also analyzes the factors affecting *E. coli* contamination among food handlers at the Nutrition Department at a public hospital in South Sumatra. In addition, this research also offers an effort to reduce the risk of *E. coli* contamination in the food handlers.

Materials and methods

This study was a cross-sectional design including data collection simultaneously with a descriptive quantitative approach, bacteria investigation, and factors that influence the health rate of food handlers at a public hospital in South Sumatra. The study was conducted to determine bacteria contamination among 30 food handlers at a public hospital in South Sumatra, as the population in this study. The dependent variable was *E. coli* contamination on food handler's sample. The independent variables were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60096015

education level, work experience, behavior, and hygiene training. The education level was divided into two sub-variables, which consisted of a middle (senior high school) and low (elementary and junior high school). The work experience was divided into two sub-variables which consisted of more and less than 3 years. The worker's behavior was divided into two sub-variables which consist of following and not following Standard Operation Procedure. The hygiene training was also divided into two sub-variables, which consist of attending and not attending the training related to the hygiene process.

Interviews were conducted with all food handlers working at the hospital. Total of 30 respondents was interviewed and 30 samples of rectal swabs were obtained from the corresponding workers for further testing. Preparation of the bacteria samples follows the WHO standard (WHO, 2003) using a rectal swab for *E. coli* bacteria (Esparar et al., 2004). Swab sampling and laboratory identification were analyzed in the Laboratory of Environmental Health Center Palembang.

Bivariate analysis was carried out to investigate the quantitative distribution of independent and dependent variables. Bivariate analysis was also performed to examine the correlation between each of the independent variables and the dependent variable. This was achieved by comparing the p-value to study the level of significance (Emzir, 2009). The factors investigated were education level, work experience, behavior, and hygiene training for staff at a public hospital in South Sumatra.

Results

The *E. coli* contamination shows the sanitation rate of the hospital's employees. *Table 1* shows that 36.7% of the food handlers staff at a public hospital in South Sumatra are positively contaminated with *E. coli*, while 63.3% of them are not indicated to be contaminated with *E. coli*.

Table 1. *Analysis of E. coli contamination among the food handlers a public hospital in South Sumatra*

No	Results	Food handlers	
		Quantity	Percent (%)
1.	Not contaminated	19	63.3
2.	Contaminated	11	36.7
	Total	30	100

Bivariate analysis was carried out on the characteristics of respondents and risk factors for *E. coli* exposure, especially those with a probability value less than 0.05 ($p < 0.05$). The analysis results will describe the risk factors for *E. coli* contamination without considering the existence of other independent variables. The bivariate analysis was carried out by making a double crosstab (2×2), the respondent's characteristics, and the risk factors which estimated to affect the *E. coli* contamination.

Table 2 shows the correlation between education levels and *E. coli* contamination. The p-value is 0.015 or $p \leq 0.05$ indicating that there is a significant correlation between the education level and *E. coli* contamination incident.

Table 3 reveals a correlation between work experience and *E. coli* contamination incident. The obtained p-value is 0.02 or $p \leq 0.05$ indicating the significant correlation between work experience and the *E. coli* contamination.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60096015

Table 4 shows correlation between food handler's behavior and *E. coli* contamination. The p-value is 0.37 or $p \geq 0.05$ indicating no significant correlation between worker's behavior and the *E. coli* contamination.

Table 5 shows the correlation between training related to the food handler's job and *E. coli* contamination. The p-value is 0.15 or $p \geq 0.05$ indicating that there is no significant correlation between the training profile and *E. coli* contamination incident.

Discussion

E. coli contamination is exclusively coming from fecal. It is transmitted through the fecal contamination of food and water, as well as cross-contamination, and by human contact during the food preparation. Meanwhile, the primary contamination source is the consumption of contaminated food, such as undercooked food or raw milk. For this reason, Lambrechts et al. (2014) proposed that *E. coli* contamination of the hands of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60096015

food handlers as an indicator of a hand-washing efficiency. The hands of ready-to-eat food service food handlers have been the main vector for spreading food-borne diseases. Furthermore, Howes et al. (1996) stated that improper food handlers practice contributed up to 97% of foodborne illnesses in food service establishments and homes. Even, the study of Wilson et al. (2017) revealed that food poisoning originated from the catering industry contributed 70% higher than that caused by other sectors.

Factors affecting *E. coli* contamination of food handlers include the knowledge and the food handling process. The food handler's responsibilities include providing the foodstuffs, storing the foodstuffs, processing the food, and distributing the food to patients or other hospital staffs. Our investigation reveals that there are still less than 50% of food handlers at a public hospital in South Sumatra who work not in accordance with the SOP. The reason given by workers regarding this problem is they are not familiar and they feel uncomfortable when using the work equipment (apron, gloves, head cover, etc.).

A total of 63.3% of food handlers are not indicated in *E. coli* contamination, while 36.7% of food handlers are indicated *E. coli* contamination. In general, 75% of the food handlers worker a public hospital in South Sumatra have a high school education background, 33.3% of them still have work experience less than 3 years, 26.7% of them do not follow the SOP in their work, and 33.3% of them have never attended the formal training related to their work.

These results are in accordance with the previous study conducted by Lazarevic et al. (2013). They revealed that the most general isolated bacteria in food handler's cases are *E. coli*. Another study by Nasrolahei et al. (2016) showed that there were 29.2% of 220 respondents contaminated with *E. coli* bacteria. Oundo et al. (2008) studied *E. coli* contamination of food handlers in three different locations in Kenya. They got 1.2% samples in Diani, 4% samples in Malindi, and 1.8% samples in Nairobi are contaminated by *E. coli*.

By finding a significant relationship between work experience, the food handler's behavior, and the *E. coli* contamination; special attention is required to improve the employee's behavior. The effort to reduce contamination of *E. coli* bacteria at a public hospital in South Sumatra is by providing socialization or related training about hygiene implementation as well as regular health checks for the food handlers. Because 36.7% of food handlers at a public hospital in South Sumatra are infected with *E. coli*, it is necessary to have rectal swab test intensively to check the health level of the food handlers. This suggestion is in accordance with several studies conducted by El Derea et al. (2008), Lazarevic et al. (2013), Ngivu (2016), Sande et al. (2014), Sharif et al. (2013, 2015), and Zaglool, et al. (2011).

Conclusion

A total of 36.7% of food handlers at a public hospital in South Sumatra are indicated to have *E. coli* contamination. The results of the bivariate analysis show that some factors including the education level and work experience significantly affected the risk of *E. coli* contamination. In the other hand, there is no significant correlation between the behavior of the food handlers and hygiene training with the *E. coli* contamination level. This study revealed the importance of socialization about food hygiene and regular rectal swab test for food handlers to reduce the risk of *E. coli* contamination among the food handlers. Future studies may include investigation of other bacteria and

(Received 12th Feb 2019; accepted 28th Mar 2019)

Abstract. Turkey is one of the best areas for beekeeping because of its geography, climate, and the diversity of flora and fauna. Beekeeping is a traditional and socio-economic activity which is performed throughout Anatolia and has a place in our culture. Besides this, bee-keeping is very important to protect biodiversity and pass it onto the next generations, and also to provide and enhance food security. There are more than 100,000 families with 6.6 million colonies in Turkey. With all those, bee-keeping contributes to Turkish economy around US$ 5-6 billion, not only through bee products but also pollination. As a part of the national policy, ORKÖY (the office of forest-village relations) provides micro-credits to villagers, who live in and around forested areas. In this study, ORKOY branch office distributed 30 beehives to 80 villagers with beekeeping certificates (in 2016 and 2017) and let them put their hives in the "honey forest" which was established in the region by the Forest Directorate. Face-to-face surveys, interviews and observations were conducted with 80 participants who benefited from beehive support and "honey forest." At the end of the study, socio-economic effects and welfare improvement of local people through beekeeping and producing of bee products are analyzed in the northwest of Turkey.
Keywords: *honey production, villagers, socio-economic, social forestry, Turkey*

Introduction

Nowadays, the world population and the amount and quality of the produced goods and services do not increase at the same rate. The increase in the population increases demands and expectations, and thus it increases the expectations of people from agriculture and forest areas. Forests have versatile benefiting opportunities in terms of variety and quantity. The concept of "agricultural forestry" (agroforestry) was defined for the first time in the 1980s by some international organizations such as FAO. Agricultural forestry is the research and development of the possibilities of multi-faceted utilization from the same plot of land and the planning of agricultural and forest-related products, mostly animal husbandry, in the same field together. In this context, beekeeping and production of bee products are among the best examples of agricultural forestry practices. When the effect of bees on pollination is considered, it is observed that the beekeeping sector is also supported by forestry institutions to conserve biological diversity in forests, prevent erosion by the development of forest areas, and increase the quality of honey and honey products (OGM-1, 2018; FAO-1, 2018).

The first findings on obtaining bee products by human beings were found in nest paintings in the Mesolithic rocks which are thought to be about 8000 years old. In 1919, in the Arana Cave in the city of Valencia in Spain, the Mesolithic rock paintings dated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60176029

to 6000 BC and demonstrating a human figure harvesting honey from the bee colony in the tree cavity were determined. Similar depictions, older than the Mesolithic period, were also found in the rock paintings in India. Based on these depictions dating back to many years ago, it could be stated that the history of beekeeping traces back to 16,000 years ago (Genç, 2003). Furthermore, according to the information on the tablets, the ancient Egyptians used honey in food, medicine, and religious ceremonies 4000 years ago. The Sumerians, who lived in Mesopotamia, are known to accept honey as medicine in 3000 years BC (Bakan, 2009; Nakamura, 2009).

Literature review

In a study conducted in Japan, a significant decrease in the number of bees detected due to environmental factors, infectious diseases, and pesticides (Kohsaka et al., 2017). Beekeeping, which is an important way to protect biodiversity and to transfer it safely to future generations, is also very important in terms of providing food security in the world and increasing its diversity. However, with the extinction of bee colonies in the world in recent years, food security and continuity of the ecosystem have become endangered (Phillips, 2014). Therefore, beekeeping is a strategic sector that needs to be supported as a state policy.

With its different climate and soil types, flowering opportunities for different trees throughout the year, large flora areas, topographic structure, highlands, meadows and pastures, various fruit species, industrial plants (such as sunflower and cotton), forage crops and legume fields, trees of many species such as chestnut, pine, acacia, linden, spindle, eucalyptus, rhododendron, etc., shrubs, maquis shrublands and mixed forests, Turkey represents a magnificent country in terms of natural resources required for beekeeping, honey variety, and quantity. Because of these features, beekeeping has been one of the ancient and common production varieties in Anatolia (Sıralı, 2015).

Since beekeeping is an activity that requires knowledge but does not need muscle power and intensive workforce, children, the elderly or women who cannot be sufficiently effective in other production works can be directed to beekeeping activities. Furthermore, since it is an activity generating revenue in a short time, it is also an activity with high socio-economic importance which enables the income of people living in forests or adjacent villages to increase. Therefore, beekeeping is regarded as an alternative source of livelihood for people from all sociologically different segments, such as nuclear families, retirees, farmers with little or no land, teachers or village imams (OGM-2, 2018).

Beekeeping can be performed in two ways. Beekeeping, which is performed without changing the location of hives throughout the year, is called stationary beekeeping. Migratory beekeeping is a way of beekeeping in which bee colonies are carried to areas with more favorable nectar and pollen resources throughout the year and in which productivity is higher (Özkırım, 2018). Migratory beekeepers carry about half of their bee colonies in winter to the coastal areas of the Mediterranean, Aegean, and Black Sea regions. These beekeepers, who travel around Turkey throughout the season and change places of their hives three times a year, move primarily to the Central Anatolian plateau with the beginning of April, then to high plateaus in the summer months, and finally to the areas in Muğla and İzmir for pine honey production since September (TAB-1, 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60176029

Since the beekeeping activity produces directly or indirectly the foods needed by people by playing a significant role in the pollination of plants, whether it is stationary or migratory beekeeping, it is also indispensable for herbal product agriculture. Approximately 85% of pollination in flowering plants in nature occurs through honey bees (Ghamdi et al., 2017).

Honey is composed of many components, such as approximately 82% carbohydrate, 17% water, 0.7% minerals, and 0.3% proteins, vitamins, phenolic compounds, free amino acids, and organic acids (Karabagias et al., 2014; Ozmen and Alkın, 2006; Islam et al., 2012). As a result of beekeeping activities, products such as honey, pollen, propolis, royal jelly and bee venom, which are very important for people and used in the treatment of various diseases, are produced. A method of treatment with bee products, which is called "Apitherapy," has become a rapid trend in the world, especially in China. Among these products, propolis is known as a potent antibiotic, and royal jelly is known as an energy supply and hormonal source. Honey and pollen also have high nutritional value and are known to be effective in the treatment of diseases and infections (OGM-3, 2018; TAB-2, 2018).

The quality and quantity of nectar sources depend on the season, environmental, meteorological conditions, blooming stage of the plant, and even time of the day (Farkas and Zajacz, 2007). There are about 200 kinds of components in honey. Honey is a versatile consumption product which has high nutritional value and which displays easy digesting, disease-protective and therapeutic properties due to vitamins, minerals, flavonoids, phenolic and organic acids, amino acids and enzymes in its content. Moreover, in a study conducted, heavy metals were determined in honey samples, and it was stated that bee products could be an effective and cheap method in the prevention of environmental pollution as an indicator substance (Ozmen and Alkın, 2006; Spilioti et al., 2014).

Regarding its source, honey is divided into two as nectar honey (flower honey) and secretion honey (pine honey). Flower honey is obtained from many forest trees, shrub floras, and shrub species such as chestnut, linden, acacia, rhododendron, and from herbaceous plants inside the gaps in forests or on the edges of forests, and depending on the season, flower honey can be obtained in all parts of Turkey (DPT, 2018). Pine honey is obtained in Muğla and its vicinity, in the Mediterranean region where Calabrian pines are intense, and its source is pine, oak and abies species. Approximately one-fourth of the honey produced in Turkey is pine honey (DPT, 2018; Subaşı, 2004).

Beekeeping in the world and Turkey

According to the figures of FAO, the total number of beehives in the world is around 79.9 million, and approximately 1 million 592 thousand tons of honey is produced annually from these beehives. One-fourth of the total honey produced in the world is the subject of trade. When countries in the world are ranked according to the number of their hives, India ranks first with 11.5 million hives. However, China, which has 9 million hives, is the most honey-producing country in the world, with approximately 466 thousand tons of honey produced per year. After China, Turkey ranks second with 114 thousand tons, Argentina produces 80 thousand tons, Ukraine 74 thousand tons, and the Russian Federation produces 68 thousand tons of honey. China and Argentina are prominent in the export of honey, while the American and European Union countries are prominent in the import of honey (FAO-2, 2018; Karasın and Kaptan, 2015).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60176029

The countries, where honey production per hive is more than the world average of 22 kg, are Canada with 56 kg/hive, China with 52 kg/hive, Mexico with 39 kg/hive, Argentina with 27 kg/hive, and the USA with 26 kg/hive. In Turkey which ranks 12th in the world with its 15 kg of honey production per hive, despite the great hive presence, production per hive is low since the efficiency of honey production is low. With the highest number of hives in the world, India is the last among the world countries with an average of 4 kg of honey production per hive (Sıralı, 2015).

There are different principles and rules on this subject in each of the 12 countries that perform 80% of the export of honey and bee products in the world; therefore, production at international standards is not possible. For example, while the most important factor in the European countries is honey's being GMO-free, in North America, filtered, pasteurized, and liquid honey is preferred. In the Middle East, people consider crystallized honey as fake honey and do not prefer it (Kuvancı et al., 2017).

In Turkey, beekeeping is a socio-economic activity that has been traditionally performed in every region of Anatolia and has become a part of the culture. Turkey is the homeland of approximately 70% of honey-giving plant species and 22% of bee breeds. In Turkey, more than 100 000 families have a total of 6.6 million bee colonies. 10% of these families earn a livelihood solely from beekeeping, and 30% of them continue beekeeping as a side income activity. The remaining 60% are engaged in beekeeping activities as a hobby (TUIK, 2018).

According to the data of TÜİK (Turkish Statistical Institute) (2017), 114 thousand tons of honey is produced annually in Turkey. Twenty thousand tons of this amount are pine honey, and 100% of it is produced in forest areas. When it is considered that such varieties of honey as chestnut honey, linden honey, acacia honey, rhododendron honey, thyme honey are also produced in our forests besides pine honey, honey can be stated to be a significant "non-wood forest product." The first ten provinces in Turkey in terms of honey production are Muğla, Ordu, Adana, Aydin, Sivas, Antalya, İzmir, İçel, Erzincan and Samsun provinces, respectively, and about half of the honey production is provided from these provinces (Sıralı, 2018).

In Turkey, to increase the sources of income of forest villagers by encouraging them to perform beekeeping, the General Directorate of Forestry has put 270 "honey production forest" lands into the service of beekeepers across the country. Moreover, with the protocol signed between the Ministry and the Beekeepers Association, it was decided to make water ponds in forest areas and to plant fire-resistant plants that give honey in fire lanes and forest roads. While 85% of honey production takes place in forest areas, only 15% takes place in agricultural areas (OGM-1, 2015).

Beekeeping contributes to the economies of countries directly as an agricultural activity and indirectly by contributing to plant production. Beekeeping is also important as a not land-dependent activity because in rural areas it can alone be a livelihood source for families without land (Kuvancı et al., 2016).

According to the 2017 data of TÜİK, 114, 471 tons of honey was produced in Turkey, and the revenue of US$ 24,720,000 was obtained with the exportation of 1,236 tons of this production. If the honey remaining in the country is considered to be sold at a minimum sales price of US$ 20 per kilogram, the total value will be about US$ 2,264,700.000, and the total contribution of the produced honey to the country's economy will be about US$ 2 billion 289 million. When this figure, which is obtained only with the honey data from beekeeping products, includes products such as pollen, beeswax, and royal jelly, the contribution of beekeeping products to the country's

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60176029

economy is determined to be approximately US$ 3 billion in a year. Considering that the contribution of beekeeping to the economy by pollination is at least 10-12 times of the income obtained from beekeeping products, it can be stated that beekeeping makes an essential contribution to Turkey's economy annually at about US$ 30-35 billion (TUIK, 2018).

The objective of this study is to determine whether the support of government policies, such as ORKOY credits, establishing honey forests and providing education on beekeeping, helps villagers to improve their social, cultural, and economic welfare.

Materials and methods

Within the scope of the activities carried out by Kastamonu Regional Directorate of Forestry ORKÖY Branch to support forest villagers, the social and economic individual project types that can be applied in forest villages were determined pursuant to the regulations with regard to "providing support for the social and economic development of forest villagers for the protection, development, and expansion of forests", and the study program was created. Within this context, in the years 2015 and 2016, in the areas with the stand area of pure and mixed chestnut (Castanea sativa Mill.) within the borders of Kastamonu Regional Directorate of Forestry, face-to-face surveys, interviews, and observational studies were conducted with 80 individuals benefiting from the support of "scientific beekeeping." While determining the beekeepers to be included in the study, attention was paid to the fact that they were forest villagers who had not received ORKÖY support before, had a certificate of beekeeping, and resided in the region. To analyze the socio-economic structure of chestnut honey producers and to determine honey and other beekeeping products' contributions to the social and cultural life of local people and their effects on the welfare level, the survey questions were asked to the people of the region.

Chestnut, which is called Castanea (Castanea sativa Mill.) in Latin, is from the family of Fagaceae. It grows in all temperate regions of the North Hemisphere. Although 10-12 species of chestnut are known to be in the world, the species that grows naturally in Turkey is Anatolian chestnut (*Castanea sativa* Mill) (Conedera et al., 2016). Chestnut tree, as a valuable species with its fruit and wood, is of great importance for its region from ecological, economic, social and cultural aspects (Doğanay, 2007).

In this study, to analyze the socio-economic structures of chestnut honey producers in Kastamonu, the contribution of chestnut honey production and beekeeping activities to the local people was determined by face-to-face surveys and interviews. First of all, the participants' demographic characteristics, product mix, production quantities, sales price, and obtained revenues and perceptions and opinions about beekeeping were attempted to be determined with the questions prepared for this purpose. While preparing the questions, a literature survey was conducted on the subject, and the opinions of the participants were obtained with 30 closed and open-ended questions. In the survey, apart from the questions regarding the study, questions related to the demographic characteristics of participants such as age, gender, education, etc. were also included. After the questionnaires were transferred to the computer in Excel format, in the analyses of the collected data, straight and cross-analyses were performed using SPSS (Statistical Package for Social Sciences) statistical program, and the results were presented and interpreted with the help of graphs (Orhunbilge, 2014).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60176029

Results

About 85% of the local people who deal with beekeeping in the study area are aged between 31 and 60 years. Beekeeping activities are mostly conducted by men in the region, and although women are involved in these activities together with men, they prefer to remain in the background. Furthermore, most of the people engaged in beekeeping (75%) are primary school graduates.

40% of the beekeepers, who participated in the study, stated that their total annual income is between US$ 4,000-5,000, and 45% stated that it is over US$ 5,000. According to the land amount owned by the beekeepers to whom the survey was applied, while 80% have 0-15 acres of land, only 8.5% have 26 acres of land and more.

Of the participants benefiting from beekeeping-related support, 32.5% have been engaged in beekeeping for 6-10 years, 21.3% for 11-15 years, and 25% for over 16 years. It was found out that almost all of the beekeepers were performing the beekeeping activity with one or two people, and these people were mostly their spouses or children, in other words, their family members.

Upon examining the ownership status of lands where beekeeping activities were carried out, 90% of the participants stated that they carried out beekeeping activities on their land, 10% in forest area or honey forests. 65% of the beekeepers participating in the study stated that beekeeping education was insufficient and that the relevant ministries and NGOs should attach importance to the subject of training.

Upon examining the number of hives owned by beekeepers including 30 hives provided by ORKÖY, it was found out that 50% of the beekeepers have 1-50 hives, 33.7% have 51-80 hives, 5% have 81-100 hives, 6.3% have 101-130 hives, and 5% have 130 hives and more. In 80% of the hives, there are 9 and more frames. In the region where half of the beekeepers have a maximum of 50 hives, before increasing the number of hives, the number of colonies under controlling and registration can be increased by determining the flora of the region. Thus, studies not only on yield but also on quality will be useful for beekeeping and will increase the amount of production.

Within the scope of the study, the beekeepers were asked about their seasonal expenses per hive, and 75% of the participants stated that their expenses were US$ 20-35, and 15% stated that the expenses were US$ 40 and above.

It was stated that the maximum amount of harvest received (*Fig. 1*) by the beekeepers participating in the survey from one hive was between 7-10 kg with a rate of 80%, in case the meteorological conditions in the region were good and the chestnut tree nectar at the end of May and the beginning of June was optimal. In the case of adverse climate conditions, the minimum amount of harvest from one hive was recorded to be between 1 and 3 kg at a rate of 95%.

80% of the 80 beekeepers who received hives stated the sale price of the produced honey as US$ 20-25 and 17.5% stated it as US$ 25-40. Regarding the marketing method of the produced beekeeping products, 98.8% of the participants stated that they sell the produced honey directly to consumers, and very few of them stated that they sell it to intermediaries. Beekeepers (96%), who did not experience any problem with the marketing of produced beekeeping products, stated that the customer was ready in the market.

While 37.5% of the participants who carry out beekeeping activities and benefit from ORKÖY support are members of beekeeping cooperatives, 62.5% do not have cooperative membership. 53.8% of the beekeepers benefited from the support granted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60176029

for two years in 2015, and 46.2% benefited from it in 2016, and the number of applications for support in the second year was higher than in the previous year.

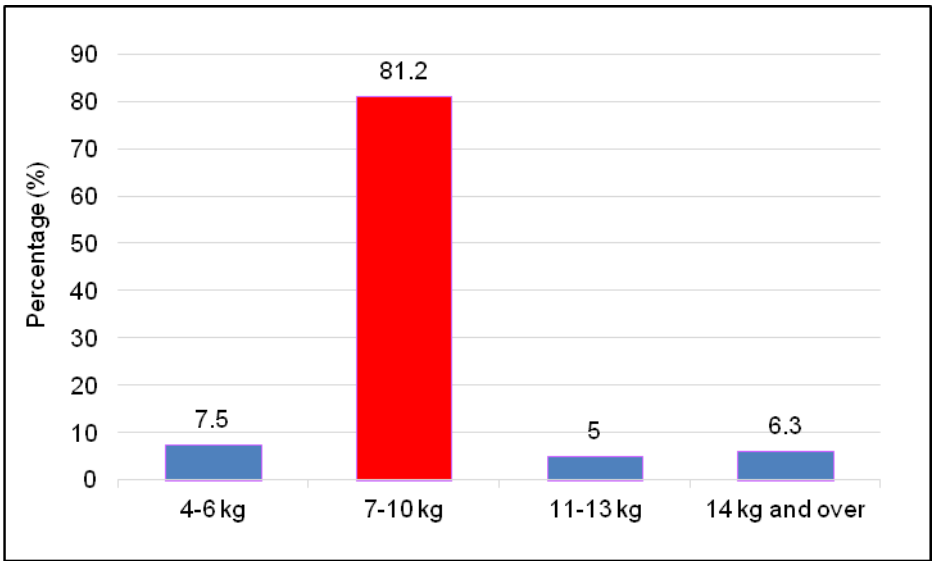

Figure 1. *Maximum honey harvest under good meteorological conditions (kg)*

76.2% of the beekeepers benefiting from the ORKÖY support stated that they generated profit and 20% stated that they did not make any profit or loss. The beekeepers were asked whether they wanted to use the ORKÖY support again, and 81.2% of them stated that they wanted to take advantage of it again and 18.8% stated that they did not want to take advantage of it again. When the participants were asked whether they had heard the term "honey forest," 51.2% stated that they had not heard it and 48.8% stated that they knew it. When the beekeepers were asked about the "future of beekeeping," 81.2% stated that they were hopeful about the future, 10% stated they were hopeless, and 8.8% stated that they did not have a positive or negative opinion.

In the comparison of the land amount owned by the beekeepers with their annual income, an increase was observed in the income levels as the amount of the land they owned increased (*Fig. 2*). As the land amount owned by the beekeepers increased, the number of their hives also increased.

When the relationship between the educational level of the beekeepers participating in the study and their cooperative memberships was examined, it was observed that while 22 primary school graduates and 7 secondary school graduates were not members of cooperatives, 38 primary school graduates and 7 secondary school graduates had cooperative membership. Accordingly, no relationship was determined between educational level and cooperative membership.

Upon examining the desire of the participants who carry out beekeeping activities and have benefited from the ORKÖY support to reuse the support according to their profit/loss status, it was determined that 53 individuals generated profit and could reuse the support, 8 individuals did not want to reuse the support although they generated profit, and 11 individuals did not make any profit or loss but could reuse the support. Therefore, any relationship between making profit or loss and ORKÖY support was not determined.

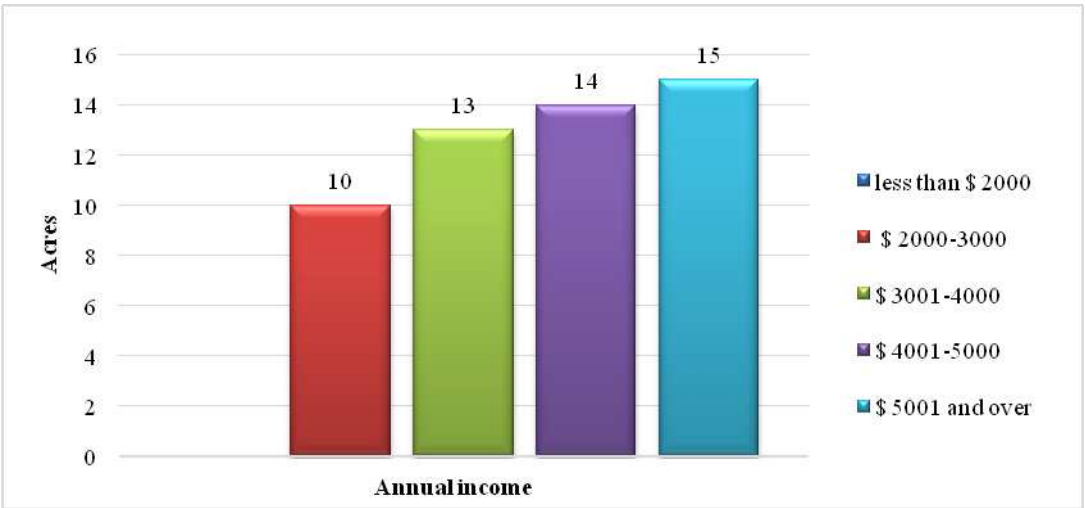

Figure 2. *The relationship between the amount of the land owned and total income*

Beekeepers who carry out beekeeping activities with the ORKÖY support sell honey directly to consumers at an average price of US$ 21-25 (*Fig. 3*). There is no sale of honey to intermediaries, factories or on export markets in the region.

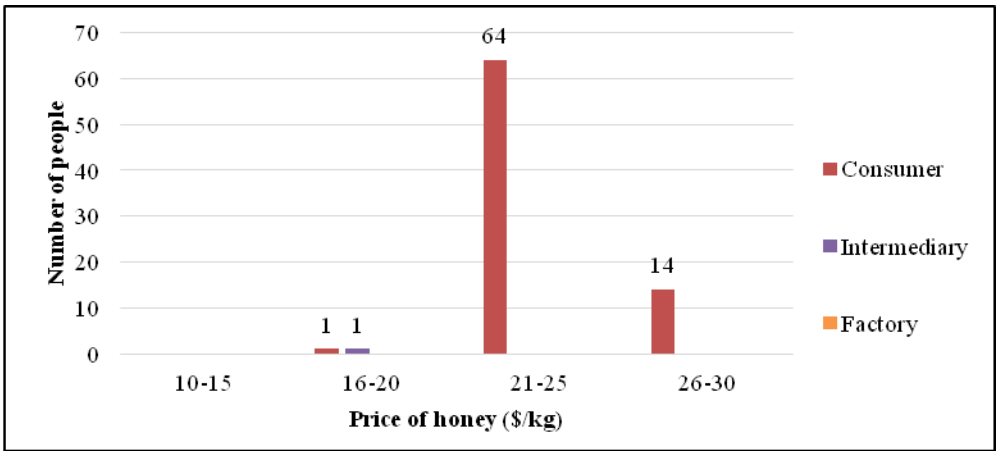

Figure 3. *The relationship between the sale price of honey and the marketing method*

Of the beekeepers who said that beekeeping-related training was sufficient, 17 beekeepers said that they learned beekeeping from the family, four beekeepers said that they learned it from other beekeepers, and four beekeepers said that they learned it in the course. Of the beekeepers who stated that the training was insufficient, 22 beekeepers stated that they learned beekeeping from the family, 16 beekeepers stated that they learned it in the course, and 14 beekeepers stated that they learned it from other beekeepers (*Fig. 4*). In general, the participants stated that they learned beekeeping from their families that beekeeping training was insufficient, and that beekeeping could not be learned from sources such as TV, books, and brochures, and that productivity could be increased through more visual and practical training.

Upon examining the relationship between the beekeeping activity and the total annual income, it was observed that the individuals who participated in the study did not

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60176029

produce beekeeping products such as propolis, pollen, beeswax, royal jelly, and bee venom, but produced only honey. Providing the necessary support, carrying out studies, and attaching importance to educational activities related to the subject to produce other beekeeping products in addition to honey in the study area will be effective in increasing the income and welfare of the people in the region.

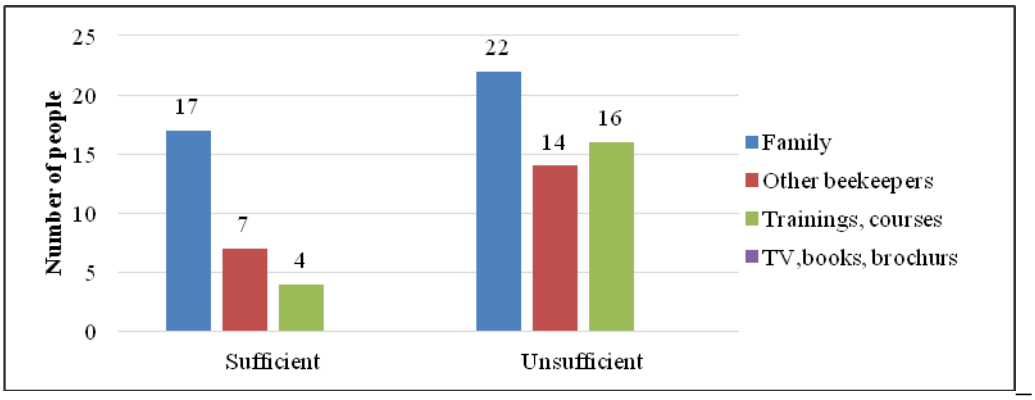

Figure 4. *Sufficiency of beekeeping training according to the beekeeping learning style*

Discussion

The production power of the honey bee, which offers valuable products for human life and health, has become much more critical with the increase in the world population. Besides its importance in the universal dimension, beekeeping also offers essential opportunities concerning the local development of forest villagers, since it is a field that provides middle or high-income opportunities with low investment and labor force. As Ayan et al. concluded in a study (2014), beekeepers/forest villagers have to have organic, brand name and certified bee products to increase their income.

In a study conducted by Önal and Bekiroğlu in 2011, the participants stated that they found the support provided by ORKÖY positive and that the economic and social village development projects implemented in the region increased the welfare level of the villages (82). Similarly, in this study, the villagers dealing with beekeeping stated that they were satisfied with ORKÖY support (96%), that their welfare level increased with the received support, and that they wanted the support to be repeated. In the same study by Önal and Bekiroğlu (2011) who emphasized the importance of being organized as a cooperative in rural areas, it was stated that the fact that villagers have a say in their works and the sales of products in the market and an increase in their efficiency should be provided through cooperatives. In this study, the ratio of becoming a member of a cooperative was determined as low as 37.5%, and it was stated that by increasing this ratio beekeepers would receive a say on the regional and national scale. Although in Turkey there are Provincial Unions established in the provinces and TAB (Turkey Beekeepers Association) that was established at the national level; locally, the memberships of beekeepers to these associations are inadequate.

Training of beekeepers/villagers on sustainable beekeeping is very important to improve their income level and sustainable usage of forest resources, in addition to providing food security (FAO-1, 2018). In our study, 52 (65%) out of 80 beekeepers stated that practical training and experience are important for sustainable beekeeping and sustainable usage of natural resources.

DOI: http://dx.doi.org/10.15666/aeer/1703_60176029

In the study conducted by Kuvancı et al. in the Eastern Black Sea Region (2017), it was stated that the average age of beekeepers was high, and to give momentum to this sector, the entrepreneurship and dynamism of the young people were needed. Similar results were also obtained in the study conducted in Kastamonu, and it was determined that 61% of the participants performing beekeeping activities were in the 40-60 age range. This result also indicates that the young population in villages migrates to cities due to unemployment. Again, the opinions in the same study which argued that the mix of goods related to beekeeping products should be diversified and that the level of income in the region should be increased by producing high value-added products show parallelism with the results of our study.

In another study conducted in the Netherlands, it was determined that producers, who perform plant production, pay beekeepers bee rent to provide pollination in plants and that they generate 3.5 times more of yield from bees' contribution to plant production in return (Hilmi et al., 2011). In Turkey, there is no study carried on this subject. The subject of making payment to beekeepers by determining the contribution of beekeeping to plant production should be put on the agenda by both the Ministry of Agriculture and Forestry and the Beekeepers Association.

Because of the low yield in the production of honey per hive, Turkey could not reach its beekeeping potential and the desired position in the world honey trade yet. Although the colony presence has increased by 41% over the last decade, the prices of bee products remain high due to reasons such as insufficient bee product variety, the lack of added value, unorganized marketing, and consumer demand. Although Turkey is in the second rank in the world in the amount of honey production, it could not reach the deserved position in the export of honey products due to imbalances in prices and supply amount (TUIK, 2018).

As it is stated by Seijo and Jato (2001), chestnut trees are a very important nectar and pollen resource to produce bee products both by quality and quantity. That is why *Castanea Sativa* Miller trees are important for beekeepers in northern Turkey economically, ecologically, and socially.

Conclusions

The fact that beekeeping activities have reached the targeted level will provide benefits such as the continuation of biodiversity, the development of citizens living in rural areas and the increase in their welfare level, the increase in the economic input to the region, the decrease in migration from the village to the city, the development of the relationship between forests and public, the decrease in illegal activities in forests, and many other ecological, social and economic aspects.

Since beekeeping is not a land-dependent branch of agriculture, it can solely be a source of income for farmers with little or no land. It is possible to state the main reasons which make beekeeping activities attractive as the opportunity to carry out beekeeping activities with limited resources in budget and capital, low maintenance and management costs, opportunity to generate income in a short time, opportunity of the easy sale of bee products due to the high demand in the market, and chance to procure materials that are necessary for beekeeping such as hives, bees, breeding bees, etc. within the country.

The forest ecosystem is not just areas which provide the industrial wood product. The products and services provided by forest ecosystems are more needed nowadays

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60176029

than in the past due to reasons such as population growth, quality of life, changes in consumer preferences, and the decrease in natural resources. To meet the people's increasing expectations from forests in a sustainable manner, each element of forests should be operated within the framework of efficiency principles.

Due to its rich plant diversity, Turkey has a great potential for the production and export of quality honey and other bee products obtained as a result of beekeeping activities. Although Turkey takes the second place in honey production in the world, we do not produce and export value-added honey products such as vax, pollen, propolis, and bee milk. It is necessary to conduct studies on how to produce those products and how we can market them worldwide instead of consuming them locally or nationally. To contribute more to the economy and environment, studies should be carried out on beekeeping activities to develop joint action plans with the Ministry of Food, Agriculture and Livestock, the Ministry of Forestry, universities, producer unions, cooperatives and exporting companies according to the results of these studies.

For the purpose of the national and international recognition of "chestnut honey," which is produced with great devotion by the local people in Kastamonu, has its unique aroma and taste, and determination of its standards, the process of branding was initiated by the local government, and an application for "geographical sign" registration was made.

Abstract. The study was conducted to evaluate the quality of durum wheat grain. For this reason, genetic resources are crucial for the identification of parents and the enrichment of the gene pool that can be used in the development of new varieties for better nutrition of people. For this purpose, 131 populations of landraces, 9 promising line and 5 new varieties were used. The experiment was set up in randomized blocks with 7 replications, according to the augmented (increased) experimental design in 2015-2016 growing season. In the study, we examined total nitrogen content, protein ratio, CIE (Commission Internationale Eclairage) wheat color analysis (L* brightness, b* jaundice, a* redness) of 145 genotypes of durum wheat seeds. According to analysis of variance, highly significant differences ($P < 0.05$ or $P < 0.01$) were determined for total nitrogen, protein content and CIE L* value, while differences were not significant for b* value and a* value. The superiority of the genotypes was determined by the first two principal components (IPC1 (principle component) and IPC2) in order to create a two-dimensional GT biplot. The sum squares of the first two components were accounted by 45.34% (PC1) and 40.03% (PC2) for genotypes. The GT (genotype x trait) biplot indicated that 9 (nine) sectors occurred among genotypes and quality parameters. On the other hand, three groups occurred among the quality parameters based on the genotypes. The scatter plot demonstrated that there is a high correlation between b* jaundice, and a* redness. The results showed that cultivars and more landraces have general adaptability for all quality parameters, while some genotypes (G79, G78), (G22, G102), (G3) and (G121, G5) showed specific adaptation for N (nitrogen), PC (protein content) and L*, a* and b* values, respectively. According to the biplot techniques, G36 came forward with the N, P and a* value and desirable landraces, G5 for b* value, G30 stable line for all quality parameters, while (G128, G61) and the majority of promising lines (L4, L6) did not come forward with any quality parameters. The results of the study indicated that the majority of landraces can be used as parents to improve the quality of durum wheat varieties. The study indicated that GT biplot can be used to evaluate the genotypes graphically to select the best genotypes for parents to use in breeding programs.
Keywords: *GT biplot, quality parameters, Southeastern Anatolia, Turkey*

Introduction

Global biodiversity and plant genetic diversity compose of the genetic resources which are crucial for the identification of parents and the enrichment of the gene pool that can be used in the development of new varieties for better nutrition of people. For this reason, landraces are very important as genetic resources for identity of parents to improve gene pool and develop new quality varieties for better people's health. Nowadays, quality of durum wheat is most substantial for healthy fed in Middle East countries, because majority of people are fed from durum wheat product (bulghur,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60316049

macaroni, bread). Therefore, landraces are considerable for breeding program of durum wheat, because most people care to use the healthy-products (bulghur, macaroni, and bread) of wheat. Upon domestication, it was estimated that initial diversity was reduced by 84% in durum wheat (Jaradat, 2013).

Turkey is located at a unique position from the view point of plant genetic diversity. Due to both in terms of environmental conditions and in terms of culture is very suitable for wheat cultivation. Turkey is one of the Centers of Origin of wheat and wheat has been grown around 8.5 million ha with production of around 20 million tons annually (http://www.tuik.gov.tr/PreHaberBultenleri.do?id; Karaman, 2019). The total 50% of durum wheat is produced in Southeastern Anatolia region where is center (Karacadag) origin of durum wheat. Southeastern Anatolia region follows the Southeastern Taurus Mountains and the valley of the Tigris River. Frequency of durum wheat exceeds 60%, with a high diversity of morph types dominated by murkiness (Morgounov et al., 2016).

The nutrient content of wheat grain can vary from genetic resources (landraces population, wild wheat, the orjin of cultivars) to regions and continents. Domestication and deep selecting in breeding progression significantly influenced to the depletion of nutritional content and in minimizing the genetic diversity of crops. An analysis of the nutritional value, especially micronutrients in the CIMMYT (International Maize and Wheat Improvement Center)-developed germplasm displayed that a declining trend in the micronutrient levels of the varieties (Velu et al., 2014; Pandey et al., 2016).

Nowadays, over three billion people suffer from “malnutrition”, a locution used to define shortage of micronutrients (FAO, 2013). At the present time, nutrient shortcoming is a problem both common in developing countries, but extensive in developed countries where diet is mainly dependent on cereals. Therefore, the durum wheat program need to progressive revelation studies of nutritional in breeding. Throughout the last century, the input of high-yielding cultivars, led to the loss of genetic diversity. Wheat landraces are comprised of complex, variable, genetically dynamic and diverse populations, for both biotic, abiotic stresses in their environment and micro-macronutrient.

On the other hand, durum wheat breeding programs should have focuses on the develop of new varieties for high quality which are important for modern pasta and bulgur industry, because of changing consumption habits and undernourishment places where this is based on durum wheat. To achieve this goal, durum wheat landraces keeps its importance inside genetic diversity in Middle east and Southeastern Anatolia region. Because local durum wheat populations have adequate quality characteristics (nitrogen content, protein ratio, wheat color analysis (L* brightness, b* jaundice, a* redness) for the development of new varieties that can be used in the pasta and bulgur industries. For this reason, durum wheat breeders have recently given more importance to the durum wheat landraces in order to raise the quality criteria in durum wheat.

Among quality criteria seed quality is one of the important factor effecting plant growth, yield and nutrient uptake by the plants. For a good and healthy growing start seed quality is important. Seed quality is one of the best criteria for cereal productions and qualified seeds led to about 25 to 40 percent yield increase. During the early stage, plants meet their nutrient and energy demand from the reserves in their seeds mostly. So, huge nutrient stocks in the seeds are vitally important for plants to be able to survive their growth healthy (Erdal et al., 2017).

The aims of the present study were to assess the importance of the local durum of wheat landraces that are about to disappear in nature and constitute the source of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60316049

gene for durum wheat in terms of quality criteria to determine the parents which can be used in durum wheat breeding programs.

Materials and methods

Plant material and experimental arrangement

The study was conducted using a total of 131 populations of landraces; 9 promising landraces and 5 new varieties were used. The populations of landraces were collected from Southeastern Anatolia region of Turkey where is centers for origin of durum wheat. The cultivars are used registered by International Agricultural Research and Training Center during last decades. The varieties used in the study both have good quality criteria and very common cultivating in this region. The coordinate data of the used genotypes indicated in *Table 1*. The meteorological data showed in *Figure 1*. The map to overview of the areas of collected landraces of durum wheat presented in *Figure 2*.

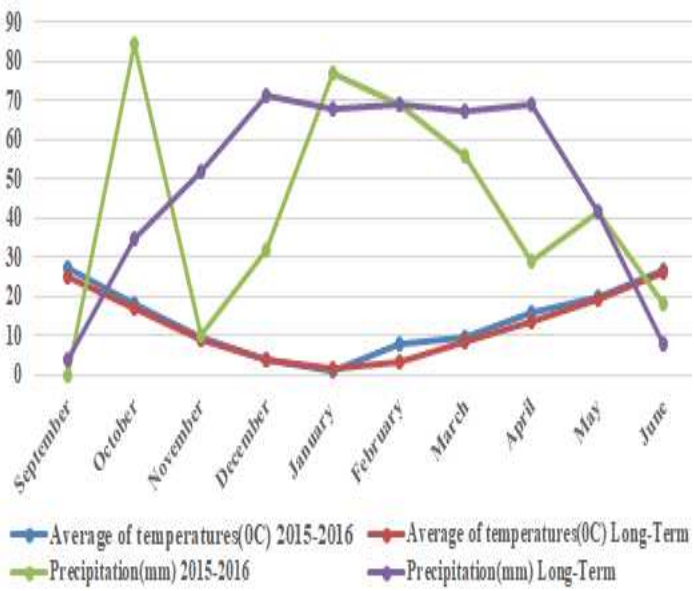

Figure 1. *The values of meteorological data of 2015-16 season and average of long term in research area*

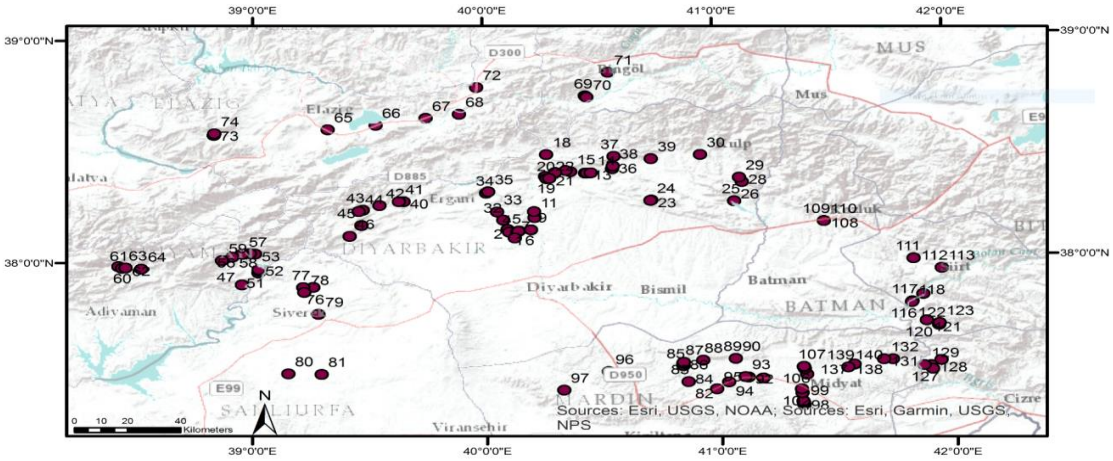

Figure 2. *The map to overview of the areas of collected landraces of durum wheat used in the research*

The experiment was set up in randomized blocks with 7 replications, according to the augmented (increased) experimental design in Diyarbakır conditions in 2015-2016 growing season. The seeding rates were 450 seeds m^{-2}. Plot size was 0.4 m^2 (20 cm × 1 m) consisting of 2 rows spaced 20 cm apart. Sowings were made by hands. The fertilization rates for all plots were 60 kg N ha^{-1} and 60 kg P ha^{-1} with sowing time and 60 kg N ha^{-1} was applied to plots at the early stem elongation. Harvests were made using Hege 140 harvester.

In the study, we examined total nitrogen content, protein ratio, wheat color analysis (L* brightness, b* jaundice, a* redness) of 145 genotypes of durum wheat seeds. All analysis was done in the lab of Department Enginering Food of Karamanoğlu Mehmetbey University.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Total nitrogen content (N%)

Data were recorded for grain protein content. It was estimated from a random sample of 100 gm of hand-threshed seeds of each genotype per samples. The seeds were milled and total Nitrogen percent (N%) was determined by Kjeldahl method as described in the manual by Sertsu and Bakele (2000).

Total protein content (%)

Data were recorded for grain protein content. It was estimated from a random sample of 100 gm of hand-threshed seeds of each genotype per samples. The seeds were milled and total Nitrogen percent (N%) was determined by Total nitrogen (N) contents of the samples were measured using a nitrogen analyzer (Velp Scientifica, Dumas Nitrogen Analyzer - NDA 701, Italy) running on a Dumas incineration method (AACC Method 46-30) and protein contents calculated using a 5.7 nitrogen-protein conversion factor AACC, 2000). There is a linear relationship between protein ratio and total nitrogen (Nuttall et al., 2017).

L, a* and b* color*

Wheat samples of 300-g grain portions were cleaned and tempered overnight to 16.5% moisture and milled on a QC-109 laboratory mill into semolina as described by Petrova (1993). L* and color (a*, b*) values were measured (AACC Method 14-22) using Hunter colorimetric (Color Flex A60-1010-615, Hunter Lab, VA, USA) of samples ground using a 1 mm size sieve (AACC, 2000). Yellow pigment content of wheat, semolina and pasta disc was determined according to ICC method 152 as β-carotene from a standard curve. Semolina color was measured by the CIE 1976 (Commission Internationale de l' Eclairage) L*a*b* color system. L* indicates lightness, a* represents redness, and b* represents yellowness of color. The colors of semolina and flours are expressed using the L* a* b* color system. L* is a measure of brightness, it can ranges from 0, completely non-reflective or black and 100, perfect white or total reflection. Bread wheat flours have reading values around 90, while semolina has lower values. The b* value is the blue-yellow chromaticity coordinate, it can go from -60, pure blue, to +60, pure yellow. Usual b* values for bread wheat flours are around 9.5. For semolina the higher the b* value the more yellowness. Good quality durum has a b* of approx. 27.3 or more. The b* value is the red-green coordinate.

Statistical analyses

The data obtained from the study related the investigated quality parameters were analyzed by using the JMP 5.0.1 statistical software package (SAS Institute, 2002), and the differences between means were compared using a least significant difference (LSD) test at the 0.05 probability level (Steel and Torrie, 1980). GT biplot analyses were carried out using GT biplot software to assess quality parameters (Yan and Thinker, 2006). In multi-traits (MT) for genotypes, biplots were constructed by plotting the first two principal components (PC1 and PC2) derived from centered quality criteria data to singular value separation. Also, with the GT biplot analysis graphs in the study: It was aimed at revealing relation among examined traits and genotypes means by scatter plot (*Fig. 3*), and grouped quality parameters and performance of each genotype at each trait (*Fig. 4*), which-won-where of sector analysis (*Fig. 5*), the stable and high

Results

The analysis of augmented (increased) experimental design revealed highly significant differences among the 145 genotypes of durum wheat for total nitrogen percent (N %), protein content L*(lightness color of semolina) ($p < 0.05$), while it was not significant for a* (represents redness color of semolina) and b* (represents yellowness color of semolina), as shown in *Table 2*. Moreover, significant interactions among the tested genotypes indicated that the genotype**s** had difference genotypic structures in terms of examined quality parameters. Usually, the wheat breeders interested in the landraces with high genotypic main effect (high values than average) and with low fluctuation in examined parameters (stable). The results variance analysis of sum of squares of quality parameters showed in *Table 2*.

The results of the data reviewed

The total nitrogen (N) percent of genotypes ranged from 2.07% (G1) to 3.18% (G79) and the mean of total nitrogen percent of genotypes was found 2.65% (*Table 4*). The results of the total nitrogen percent indicated that 79 genotypes have higher values than the five standards used as the control in the study. On the other hand; Güneyyıldızı and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60316049

Zühre varieties were the best on total nitrogen percent of among standards which used in the study. The landraces which collected in same province of Southeastern Anatolia Region showed different performance on total nitrogen percent, but the landraces which collected in Diyarbakır city (Dicle, Hani and Lice province) and Siirt city (Eruh province) had good results of total nitrogen percent respectively. Moreover; the landraces (G59-G64) collected in Gerger province of Adıyaman city had low value of total nitrogen percent. The results of total nitrogen percent showed that Southeastern Anatolia Region of Turkey is one of the Centers of origin of durum wheat showed a unique position from the view point of genetic diversity of durum wheat by landraces. Therefore, it is possible to can select the best landraces which have the best results in the study to improve the total of nitrogen and enrich the gene pool and develop quality varieties.

Table 2. *The variance analysis of sum of squares of quality parameters*

Source	df	N (%)	PC (%)	CIE (Semolina color results)

LSD: least significant effect, CV: Coefficient of variation, d.f.: degree of freedom *: Value significant at 0.05 probability level, ns: not significant, N (%): total nitrogen, PC (%): Protein content

The protein content of 145 genotypes varied from 12.22% (G77) to 18.11% (G79) and the average of the genotypes was found 15.14% and nearly 80 genotypes (all of them are landraces) had high value of protein content% (*Table 3*). The consequence of protein content showed that more than half of landraces have high protein content results than 5 varieties which used in the study as check. However, Güneyyıldızı and Zühre varieties were the best on protein content of among standards. These two varieties registries (2010) the last time in the region and they are used in farming area, because of high quality parameters. There was diversity on protein content among landraces which collected in same province, but the landraces showed good performance which collected in Şanlıurfa (Siverek) Diyarbakır city (Dicle, Hani and Lice province) and Siirt city (Eruh province) on protein content respectively. Moreover; the landraces (G61-G64) collected in Sincik province of Adıyaman city had low value of crude protein content. The outcome of protein content indicated that Centers of Origin of durum wheat (Southeastern Anatolia Region of Turkey) is one of the unique positions from the view point of genetic diversity of durum wheat by landraces. On the other hand the study showed that there is high and positive correlation (*Fig. 3*) between protein content and total nitrogen percent of genotypes. Range of protein contents defined in this study was in accordance to that reported by Simmonds (1989), reported that average protein content of durum wheat may vary from 9-18%. Matsuo and Irvine (1970) reported that wheat with 13% or higher protein content made a satisfactory

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60316049

pasta, whereas a protein content lower than 11% gave a pasta with poor cooking quality. The results of our study showed that majority of landraces had high value of protein content that made a satisfactory pasta (= and >13%).

Table 3. *The result of correlation analysis among quality parameters*

		N (T. Nitr.)	P. content	L* brightness	a* redness
CIE	L* brightness	0.13ns	-0.25ns		
	a* redness	0.19*	0.17**	-0.47**	
	b* yellowness	-0.08ns	-0.25ns	-0.58**	0.69**

**: Value significiant at 0.01, *: Value significant at 0.05 probability level, ns: not significant, N %: total nitrogen

L value, brightness of semolina color* of 145 genotypes ranged from 71.11 (G122) to 89.12 (G13) and the average of the genotypes was found 81.29 value and nearly 30 landraces had high value on CIE L* brightness of semolina color than the best variety which used in the study as control% (*Table 4*). On the other hand, the results demonstrated that Güneyyıldızı and Zühre varieties were the best on L* brightness of semolina color of among standards. These two varieties released last time, because of high value L* brightness of semolina color. The results indicated that there is high diversity among local populations collected in the region. Especially, the landraces which collected in the Hani, Lice provinces which located the north of Diyarbakır city where consist of Karacadağ mountain which Centers of Origin of durum wheat were the best among genotypes with regard to L* semolina color. Furthermore, the first genotypes (landraces) which collected in around Diyarbakır city plain places and the genotypes which collected in Kulp province were very poor on L* semolina color. The result of study showed that there was high genetic heterogeneity among durum wheat landraces and it can be support to improve genetic pool for breeder of durum wheat.

a value, redness of semolina* color of 145 genotypes varied from 0.35 (G13) to 3.85 (G41) and the average of the genotypes was found 2.32 value. The results indicated that there is high negative correlation (-0.47**) between a* redness of semolina color and L* brightness of semolina color (*Table 3* and *Fig. 3*).

b value, yellowness of semolina* color of 145 genotypes ranged from 6.76 (G13) to 22.13 (G6) and the average of the genotypes was found 16.44 value (*Table 4*). The results indicated that there is high negative correlation between b* and L* and high positive correlation between b* and a* semolina colors (*Table 3* and *Fig. 3*).

Graphically the association between genotypes and quality parameters

Principal component analysis was used to show the distribution of genotypes based on quality traits. The two dimensional PCA score plot, derived from multi-traits and accounted for 85.38% (45.34% and 40.03% for PC1 and PC2, respectively) of the total variation (*Figs. 3-7*). The scatter plot showed that three groups were occurred among quality traits and genotypes showed a wide distribution on traits, and also it was showed high correlation between b* jaundice, a* redness (*Fig. 3*). The results showed that cultivars and more landraces have general adaptability for all quality parameters (*Fig. 4*), while some genotypes (79, 78, etc.), (22, 102, etc.), (3..) and 121, 5, etc.) showed specific adaptation for N, PC, L*, a* and b* respectively (*Figs. 5* and *6*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60316049

According to the biplot techniques, G36 came forward with the N, P and a* and desirable landraces, G5 for b*, 30 stable line for all quality parameters, while (128, 61, etc.) and majority of promising lines (L4, L6) came not forward with any quality parameters (*Fig. 7*). The study indicated that GT biplot can be used to evaluate the genotypes as graphically to select the best genotypes for parents to use in breeding program (Oral, 2018).

Discussion

Nowadays, a number of study have focused on nutrient shortcoming in people who are fed from durum wheat product and to improve the quality of new varieties which came from hybrids made genetic resources in successful breeding programs (Akcura, 2011; Aktas, 2016; Mohammed et al., 2011; Pandey et al., 2016; Kendal and Sener, 2016). For this purposes the durum wheat landraces is very important and these days, they have been largely replaced, in their centers of diversity by monocultures of pure genotypes. This genetic erosion resulted in significant loss of valuable genetic diversity for quality traits (Jaradat, 2013). To improve the quality of new durum varieties, landraces keeps its importance inside genetic diversity in Middle east and Southeastern Anatolia region. Because landraces have adequate quality characteristics for the development of new varieties that can be used in the pasta and bulgur industries. For this reason, durum wheat breeders have recently given more importance to the durum wheat landraces in order to raise the quality criteria in durum wheat (Tekdal et al., 2014; Kilic et al., 2012).

The genotypes used in the research showed high variability in the maintenance of all the quality parameters examined. The still prefer of some wheat landraces shows that they have more competitive advantage on quality parameters relative to modern varieties and it is very imported that modern durum wheat cultivars are superior among cereals to providing high quality protein for billions of people around the world (Jaradat, 2013). Therefore, the need is urgent to improve nutritive quality (Koshgoftarmanesh et al., 2010). The wide variation of genotypes of durum wheat quality parameters were described by more researchers (Tekdal et al., 2014; Kiliç et al., 2012; Kendal and Sener, 2016). The researchers working on durum wheat in different

years and places have provided some results in support of our study on the quality of durum wheat. To summarize of these studies; as in most grain quality traits in wheat, protein content is known to be affected by genetic and environment mainly location (Bement et al., 2003). However, durum wheat is richer in protein, as this is crucial for pasta making (Nuttal et al., 2017), in Mediterranean areas, durum wheat has a significantly higher average grain N concentration under the same climatic conditions (Cossani et al., 2011). As a result of the study, grain color and protein content that are durum wheat quality traits were related with bulgur quality properties. Therefore both quality properties can be used indirect selection criterion to develop high quality bulgur genotypes (Tekdal et al., 2014). Durum wheat is a good source of protein and grain protein content of 13% for durum is a standard in quality throughout the grain industry (Riley et al., 1998). On the other hand; in the pasta industry, high protein content are required to process semolina into a suitable final product because the protein content is responsible for the cooking quality of pasta products (Reddecliffe, 2001). Durum wheat is used in bulgur sector, because it has bright yellow color and contains more protein than other wheat varieties (Bayram, 2000).

Color content has to be increased to avoid artificial coloration, which is reported to be a major problem for pasta and bulgur consumers and industrialists with pasta wheat breeding programs (Schulthess, 2013). In recent years, efforts to obtain yellow bulgur and pasta in the direction of consumers' demands mechanical annealing operations were introduced (Oner, 2002). The color of pasta and bulgur is a result of the relative proportions of pigments in the wheat grain. The color of durum wheat and flour came from the carotenoid pigments (Reddecliffe, 2001). The color of pasta and bulgur is the most important factor that consumers associate with quality and consumers believe that pasta and bulgur with a golden appearance has higher quality than sallow pasta. High yellow pigment content is desirable to ensure that the pasta has an intense amber color (Clarke et al., 1998; Tekdal et al., 2014). The L* value gives an idea of the yellow color and value the brightness of the product in durum wheat, and is considered as an important quality criterion (Sahin et al., 2006). Genotypes with high b* and L* values indicate that the quality of durum wheat increases and studies have shown that the yellow b* value is 86.6% and the L* value is under the genotype effect of 12.6% (Coşkun et al., 2010; Hailu and Mereker, 2008). Yellow pigment concentration in durum wheat is determining particularly in the commercial and nutritional quality of end-products and very important criterion in the assessment of semolina quality (Digesu et al., 2009). The semolina yellow pigment concentration is defining factor for amber color of the commercial value of durum wheat pasta (Blanco et al., 2011). Pasta quality was assessed by determining color (L*, a* and b* values) furosine, and quaking quality (stickiness, bulkiness, firmness (Marconi et al., 2002). The colour relationship between wheat fractions were that in all groups, the flour colour values (CIE L*, a*, b*) were well defined by those of the whole-meal fraction, and this was attributed to the predominance of the flour fraction in the wheat grain. It is, therefore, possible to extrapolate colour values from the easily accessible, whole-meal samples, to those of the flour fraction, which is the main portion consumed (Humphires et al., 2004).

Principal component analysis (GT Biplot) graphically showed that there is high correlation between genotypes and quality parameters and also relation among quality parameters (*Figs. 3-7*). The GT biplot mainly allows the visualization of any crossover GT interaction, which is very important for the breeding program (Goyal et al., 2011; Kendal and Sener, 2015; Sayar and Han, 2015). The GT (genotype-trait) biplot provides

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60316049

an excellent tool for visualizing genotype × trait data (Adjabi et al., 2014). In the biplot, a vector was drawn from the biplot centered to each marker of the traits to facilitate visualization of the relationships between genotypes and traits, and the angle of vectors among traits. If the angle of the vector was less than 90°, there was a positive correlation between genotypes and traits. If the angle was equal to 90°, they were not correlated. There was a negative correlation if the angle was less than 90° (Yan and Kang, 2003). In this study, there was a positive correlation between CIE a* and CIE b*, and total N and PC, while negative correlations among CIE a*, b* and L* (*Fig. 3* and *Table 3*). Nuttall et al. (2017) reported that there is linear correlation between total nitrogen and protein content, Tekdal et al. (2014) reported that there is negative correlation between CIE L* and CIE a* values and positive correlation between CIE a* and CIE b* values. On the other hand, there was high and special correlation among some genotype and quality traits. We can select the G6, G5 and G121 for CIE b* and G3 for b* and G25, G98 for L*and G78, G79 for total N and PC (*Fig. 4*). Kendal et al. (2016), The GGE biplot also ranks the traits for their ability to discriminate among genotypes. Sectors of the biplot formed COI groups based on the winning genotypes in each group of traits. So in the study, the features which examined were in four sectors and located in three different mega-traits. CIE a*, CIE b* located in sector 1 and total N and PC located in sector 2, while CIE L* only located in sector 3 (*Fig. 5*). On the other hand, CIE a*, CIE b* located in group 1 and CIE L* only located in group 2, total N and PC located in group 3 (*Fig. 5*). The GT biplot method provides considerable flexibility, allowing plant breeders to simultaneously select genotypes for quality and stability (Sabaghnia et al., 2013). Haile et al. (2007), the main goals of breeding programs is one of that producing durum wheat genotypes with high and stable grain protein content in Principal component analysis. In the study showed that G30 is stable genotype for all quality parameters, while G5, G14, G61 and majority of other genotypes were not stable for quality parameters (*Fig. 6*). Yan and Tinker (2006), the GGE biplot was accurate in interpreting the comparing genotypes and traits. The genotype with both high mean performance and high stability for all of the traits was called an ideal genotype (Kendal and Sayar, 2016; Karaman, 2019). Therefore the center of the concentric circles (i.e., ideal genotype) was the AEA in the positive direction. Genotypes located closer to the ideal genotype were more desirable than others. In the study, G36 located the center of ideal circle, it means that this genotype is ideal and desirable for all quality parameters (*Fig. 7*). On the other hand, G61 and G128 located under means line and far from center of circle, it means that these genotype are undesirable for all parameters. The results of the study indicated that majority of landraces can be used as parents to improve the quality of durum wheat varieties.

Conclusion

The study showed that durum wheat landraces still is very importance to raise the quality criteria in durum wheat for breeding programs. The results showed that cultivars and more landraces have general adaptability for all quality parameters, while some genotypes showed special adaptation and G79, G78, for N and PC, G22, G102 for L*, G3 for a* and G121, G5 for b*. Moreover, G30 was stable and G36 was ideal for all quality parameters. According to the biplot techniques indicated that there is high correlation between CIE a* value and CIE b* value and between N and PC, while negative correlation with these traits to CIE L* Therefore the study showed that

DOI: http://dx.doi.org/10.15666/aeer/1703_60316049

majority of landraces can be used as parents to improve the quality of durum wheat varieties on special or general quality parameters.

Abstract. The increasing average air temperatures and the change of climate elements pose negative threats to human and its life. Human beings develop different methods and plans to eliminate and minimize the threats that occur. Satellite imagery is the tool of these methods and plans. Through existing satellite imagery, land surface temperatures and land uses are determined by remote sensing methods to provide sustainable planning. Surface temperatures of the land are such a parameter that concerns the climate, fauna, flora and interaction of human beings with the environment. This study aimed to establish the bond between the surface temperature of the land and the different land uses. The data was collected from Erzurum province, which is located in Turkey, with a surface area of 25066 km^2. Thermal Band data obtained from four different dates which represents the four seasons and Coordination of Information on the Environment (CORINE) Land Cover (CLC) maps were digitized and interpreted statistically in Geographic Information Systems (GIS) package program. The results showed that forest areas 12.2°C, water surfaces 13.8°C, agricultural areas 17.9°C, open areas 15.7°C and residential areas 18.7°C has average surface temperature values. Statistically, the bonds between land uses and other variables were evaluated using Chi-square Automatic Interaction Detector (CHAID) analysis. As a result, this study will contribute planners and decision makers develop climate-sensitive strategies and policies regarding basin planning and urban planning.
Keywords: *thermal band, CORINE, CHAID analysis, surface temperature, land use, Turkey*

Introduction

Scientifically proven that temperatures have increased over the current century and this increase will continue in the future (Becker et al., 2012; Fearnside, 2015). In climate change scenarios for the years between 1990-2050 some hypotheses were developed and according to these hypotheses, it is asserted that the temperature will increase by 2-2.9°C on a global basis (van der Knaap et al., 2018). Climate change causes increased temperature, irregular precipitation and therefore a significant change in the climate cycle (Alexander et al., 2006; van Haren et al., 2013; Rajczak and Schar, 2017). Climate change with increased temperature forces people to live in places close to different land use areas in order to sustain their comfortable lives. The differences in land uses arise as a result of a mechanism created by the human and natural processes. Land changes over existing ecosystems has led to the emergence of surface temperature differences (Arnfield, 2003; Wu et al., 2012; Gonzalez et al., 2013). It has also caused a decrease in water quality and quantity due to varying climate in different land uses (Felzer, 2012; Tong et al., 2012; Seung-Hwan et al., 2013; El-Khoury et al., 2015). Recently, scientists are working on large areas with thermal band analyses

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60516067

based on remote sensing methods, while generating future scenarios and hypotheses (Zhan et al., 2011; Chen et al., 2014; Cho et al., 2018). Monitoring global climate change and its impacts with remote sensing methods has made it possible to make urban climate assessments (Zhang et al., 2004; Weng, 2009; Masiello et al., 2015). At the same time, the surface temperature, which is the basic climate parameter, has a great importance. Surface temperature is one of the physical parameters of land surface processes from local scale to global scale (Li et al., 2013). The surface temperature, surface radiation, and therefore the energy, has a great proposition in terms of its optimal use (Voogt and Oke, 2003; Yang et al., 2012; Feng and Myint, 2016). It is also stated in previous studies that the effect of surface temperature that directly influences the air temperature as a result of the division of anthropogenic effects is of great importance at spatial scale (Chrysoulakis et al., 2013; Song et al., 2017). Given the importance of surface temperature in terms of location and environmental sciences, temporal change provides a remarkable source of information (Li et al., 2013). The surface temperature of the land represents a unit of climate change from the "Land Surface Temperature" (LST) remote sensing platforms (Gallego-Elvira et al., 2016; Rosas et al., 2017). To monitor the effects of global warming and climate change, it is necessary to make assessments in different land uses (Zhang et al., 2004; Masiello et al., 2015; Blasi et al., 2016).

In thermal satellites, land surface temperature measurements are somewhat difficult because satellites are influenced by both surface temperatures and atmospheric conditions (Prata et al., 1995). In order to avoid measurement constraints, it is possible to achieve atmospheric correction of the thermal data with well developed split window approaches using two TIR bands (Becker and Li, 1990). With a swath width of 2,330 km, The Moderate Resolution Imaging Spectroradiometer (MODIS) satellite module is capable of displaying every single point in the world every day or two with the help of 36 different spectral bands (Xia et al., 2018). Indeed, the MODIS satellite provides a choice for scientific studies in order to be able to work on a regional scale between land uses and surface temperature (Justice et al., 2002; Jacob et al., 2004). Using MODIS satellite data, the linkages between the seasonal temperature distributions of the areas and land uses within the study area boundaries were investigated. The main purpose of this study is to investigate the compatibility of the thermal comfort with the environment in different land uses. As study site, Erzurum Province, which accommodates 3 different basin areas and topographic structure ranging from 850-3500 m, were selected. The results of the study will contribute planners and decision makers develop climate-sensitive strategies and policies regarding basin planning and urban planning.

Material and Method

Erzurum Province (approximately 25066 km^2, 40°15″-42°35″′E, 40°57″-39°10″N), which is located in Turkey, has a terrestrial climate. The average air temperature is -7°C in January and 16.2°C in July. The average annual air temperature is 6.1°C and is below -4.4°C from December to March. The average annual precipitation is 39.6 mm, and the wet season is from April to January. Short summer and a long winter lead to a high thermal exposure for the city. Land topography in the study area is constantly changing. Topography, which varies from 3200 m to 780 m, supports the formation of different climatic areas (*Figure 1*).

Land Use Classification of the Study Site

The land use classification map of the study area was created as a result of the digitization of Corine level 3 1/25000 scaled raster maps which obtained from Provincial Directorate of Agriculture (*Figure 2*). There are 44 different category of Corine level 3 in Turkey (İT, 2004). Within the Erzurum province, there are 27 sub-categories regarding to Corine level 3. These categories are reduced by simplifying to level 1 (Yildiz et al., 2018). As a result of this classification, the study site is divided into 5 different categories, including open areas, agricultural areas, forests, water surfaces and residential areas (*Figure 2*).

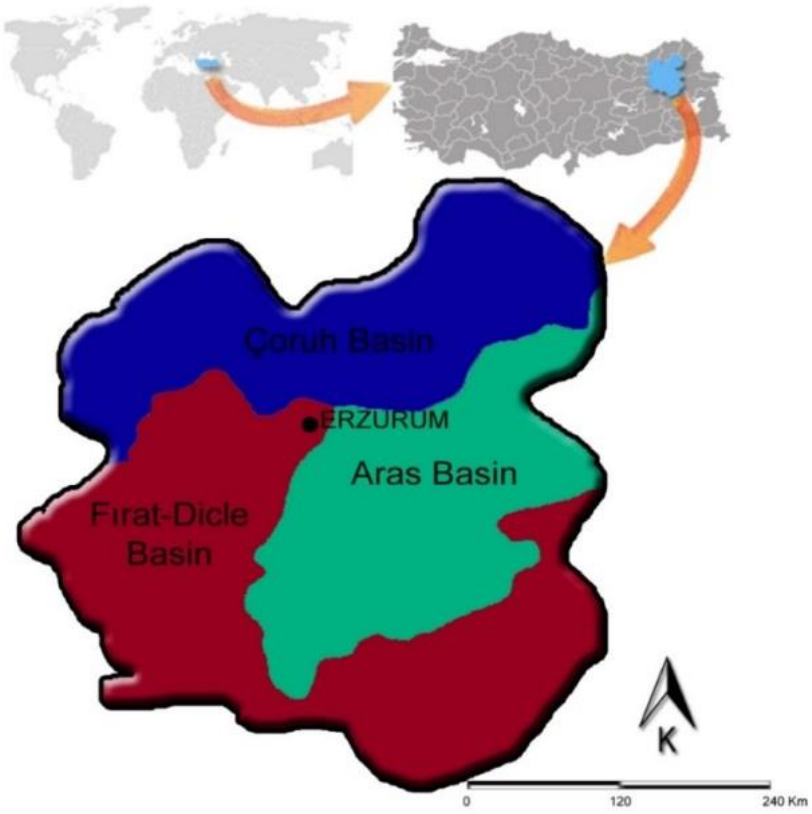

Figure 1. *The study site*

Thermal Satellite Images of the Study Site

In the lower scale land surface temperature (LST) studies, researchers mostly use Landsat-7 and Landsat-8 thermal sensors (Mallick et al., 2008; Mallick et al., 2012; Yildiz et al., 2018). Although the Landsat data sets that provide highly reliable and precise results in lower scale studies have also used in the upper scale, some problems can occur due to the area occupied by each raster data set and the bandwidth. For instance, in the upper scale LST studies if you use Landsat data set, four or five raster images are needed to define your study site, but MODIS data set, one raster image is enough to define it. This is one of the reasons why we used the MODIS data set in this study. Another reason why we preferred the MODIS satellite, because the satellite completes its tour around the globe in one day, offering unique opportunities for users.

DOI: http://dx.doi.org/10.15666/aeer/1703_60516067

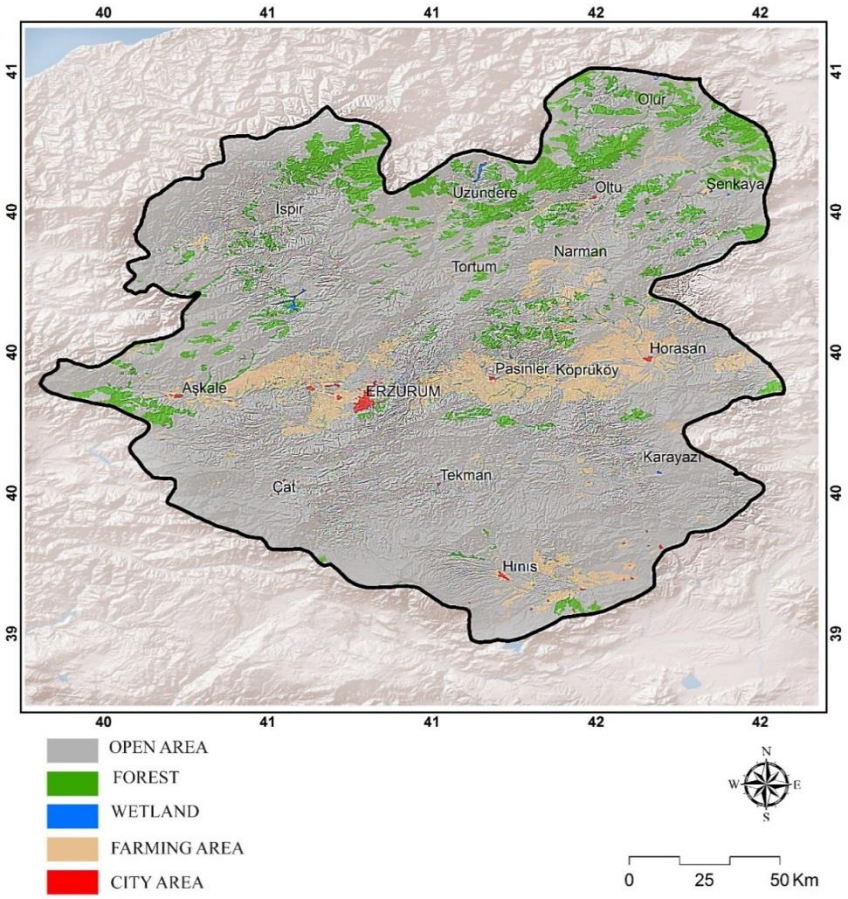

Figure 2. *Land use classification map of the study site*

Thermal images for the study site have 1000 m spatial resolution and 21st Band of MODIS satellite thermal infra-red data, 3,929 µm-3,989 µm, is used. In order to verify the surface temperature of the radiation intensity of the obtained data the Stefan-Boltzmann law was used (Montvay and Pietarinen, 1982; Narimanov and Smolyaninov, 2012; Rosas et al., 2017).

$$Ts = \sqrt[4]{\frac{T_m^4 - (1-\epsilon)T_{sky}^4}{\epsilon}} \quad \text{(Eq.1)}$$

where

- T_m= Surface temperature measured by radiometer.
- Ts= Surface temperature.
- T_{sky}= Sky temperature.
- ϵ = Surface emissivity.

Thermal infra-red images of the validated data were obtained by processing the ARC-Gıs 10.2 Package program with a controlled classification method (Eastman, 2001) (*Figure 3*). Pixel spacing has been utilized when controlled classification is performed. The 255-bit RGB-size thermal image indicates the highest bit range of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60516067

350 Kelvin degrees and 200 Kelvin degrees at the lowest 1-bit size. The following equation has been used to convert the RGB image to degrees Celsius. Data from the 2nd band of the MODIS satellite were digitized with the following formula (https://worldview.earthdata.nasa.gov).

$$°C = \left[T_{min} + \left(\frac{T_{max} - T_{min}}{255}\right) xRGB\right] - 273.15 \quad \text{(Eq.2)}$$

where

- °C: Celsius.
- RGB: Value at point of measurement.
- T_{max}= Maximum Kelvin degree indicated by thermal band.
- T_{min}= The minimum Kelvin degree indicated by thermal band.

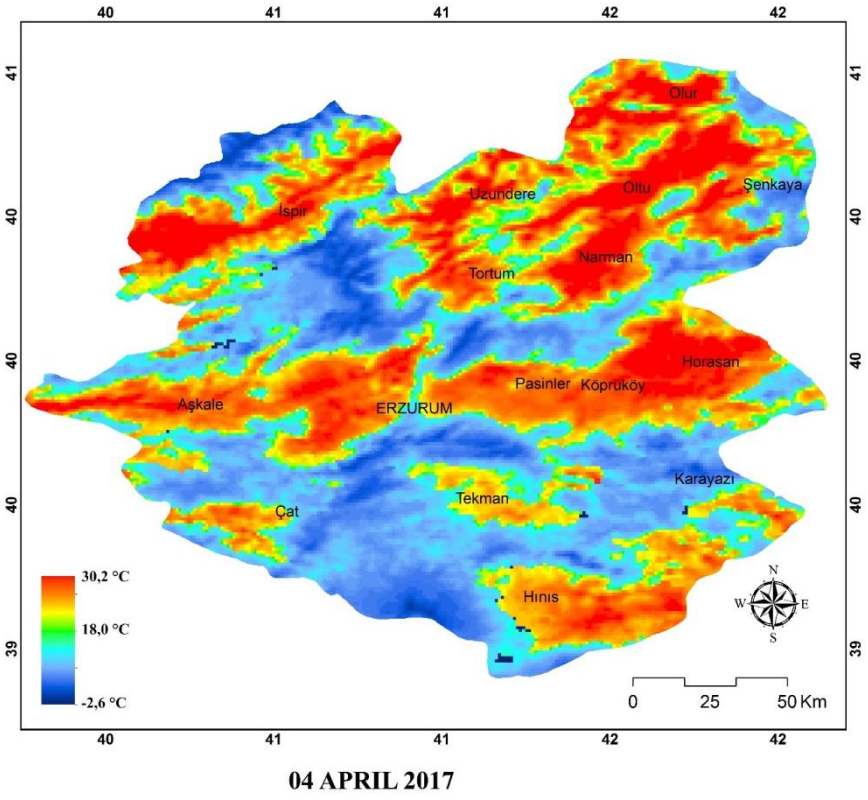

Figure 3. *Thermal Band Analysis of the study area on 4 April 2017*

In this study, four different dates were selected for thermal data. The selected dates are equal to the average temperatures of the seasons in which they belong. The average temperatures of the winter, spring, summer and autumn seasons were obtained from the General Directorate of Meteorology Affairs. The thermal data set of each day was obtained from the MODIS satellite.

Landsat satellites pass through a point every 16-days (Feng et al., 2013). The thermal band analyses of the MODIS satellite are obtained on a daily basis, especially on land surface temperatures (LST) (Rawat et al., 2018). The data obtained from the MODIS satellite is not suitable for use at lower scales due to the resolution, but in the upper

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60516067

scales or in the wide range of fields, the MODIS satellite offers different opportunities in terms of LST (Rawat et al., 2018). Our study was conducted in a large area of approximately 25,066 km^2 which is categorized as upper scale class

Three different watershed structures were taken into account when receiving thermal temperature data for different land classification in the study site. Thermal temperature values were obtained from 10 different locations of each different land use. Besides, 4 different time intervals were determined to be compatible with the study on a seasonal basis. These time intervals were matched with data from the General Directorate of State Meteorology. As a result of this pairing, each date carries similar qualities with the average temperature of the season.

Statistical Analysis of the Data of the Study Site

Decision trees are a widely used method for data mining and machine learning. The Chaid analysis technique is a decision tree algorithm that summarizes the relationships of arguments with each other and the dependent variable in a tree-shaped diagram. In the tree model, decision-making points are called nodes. In this model, the diagram begins to branch with the root node, which encompasses all relationships and is the most complex node. After that, the arguments are separated into the child nodes, which are heterogeneous among each other, homogeneous each time. When adequate homogeneity is ensured, the division stops, and these nodes are called terminal nodes. In the Chaid analysis, which is a Non-parametric test, dependent and independent variables can be continuous, discrete, or categorical and does not require preconditions and assumptions, such as normalcy and linearity required by parametric tests. When the tree diagram is divided into nodes, if the dependent variable is categorical, the chi-square statistic or if it is continuous the F-test are used (Akin et al., 2017). The reason for the selection of Chaid analysis in this study is that two of the independent variables are categorical (land use and month) and one is a constant variable (altitude). The determination coefficient (R^2) between the observed temperature values and the expected temperature values was calculated as 0.82. Minimum parental node count 20, child node count 10, maximum tree depth set as 3 and statistical analysis was done in SPSS 17.0 package program.

$$R^2(\%) = \left[1 - \frac{\sum_{i=1}^{n}(Y_i - \hat{Y}_i)^2}{\sum_{i=1}^{n}(Y_i - \bar{Y})^2}\right] * 100 \qquad \text{(Eq.3)}$$

Results

The thermal band Analysis taken on April 4, 2017 showed that open areas have minimum -1.15°C maximum is 32.4°C surface temperature and the surface temperature difference 33.6°C is measured. Forests surface temperature is minimum 1.2°C, maximum of 18.0°C and the temperature difference is 16.8°C. For water surfaces the temperature minimum 1.2°C, maximum 29.4°C and the difference is 28.2°C. Surface temperature parameters for agricultural land use minimum 4.2°C, maximum of 27.6°C and the temperature difference is 23.4°C. Residential areas; the surface temperature is similar to other land uses; minimum 2.4°C, maximum 29.4°C and the difference is 27°C (*Table 1 and Figure 3*). If we handle the study site on the basin scale, it is determined that the surface temperature is colder than the Çoruh Basin on the east of the Araz Basin and the Euphrates-Tigris Basin on April 4.

For the thermal band analysis taken on June 17 2017, when we examined in terms of the land uses, open area sampling points are maximum 30.6°C, minimum 20.4°C and the difference is 10.2°C. Forests minimum surface temperature is 18.0°C, maximum of 27.6°C and the temperature difference is 9.6°C. The temperature of the water surfaces is minimum -3.5°C, maximum 31.8°C and the total difference is 35.4°C. In terms of agricultural areas are observed at a minimum temperature of 24.6°C, while the temperature difference is observed at a maximum of 33.0°C. The total temperature difference in agricultural land use is 8.4°C. Similarly, the surface temperature observed at minimum 24.6°C in the residential area is 31.2°C and the difference is 6.6°C (*Table 2 and Figure 4*). On the basin scale, the surface temperature of the Aras Basin is seen to be significantly higher than the other 2 basins. In some points, air corridors in the form of deep canyons in basin bases cause wind mobility to cool down the surface cover and this is an evident in the north-west strip of Aras Basin and in the northern of the Çoruh Basin.

Table 2. *The values of thermal band analysis results of the study area on June 17 2017*

Points	Open Spaces (°C)	Forests (°C)	Water Surfaces (°C)	Agricultural Areas (°C)	Residential Areas (°C)

The study site was examined in the thermal band Analysis taken on October 6. 2017. The minimum 20.6°C, maximum 28.8°C is measured for open areas is and a total surface temperature difference is 8.2°C. For forests surface temperature is minimum 12.6°C maximum 30.0°C and the temperature difference is 17.4°C. On water surfaces minimum temperature is 17.4°C maximum 28.8°C and the total difference is 8.4°C.

When we examine the thermal band analysis on 2 December 2017; a maximum of 9.8°C is observed at open areas sampling points. While a minimum of -3.5°C with a difference of 13.4°C, a minimum temperature of -4.1°C is determined when a maximum surface temperature of 6.0°C in the forest areas. The temperature difference is 10.2°C. On the water surface, the minimum temperature is -9.5°C, maximum -4.1°C and the

DOI: http://dx.doi.org/10.15666/aeer/1703_60516067

total difference is 5.4°C. For the agricultural areas a minimum temperature is -4.7°C and a maximum temperature 9.0°C. The total temperature difference in agricultural areas is 13.8°C. In the same way, the minimum surface temperature of the residential area is -7.75°C, maximum surface temperature is 6.0°C and the difference is 13.8°C (*Table 4 and Figure 6*).

When we examined the thermal band images on the basin scale on December 2 2017; Erzurum Province is covered with snow cover in general. However, the thermal band analyses show in areas where there is little or no snow cover. The surface temperature is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60516067

higher than other areas (*Figure 6*). Coruh Basin has a lot of elevation differences in terms of topographic properties. Therefore, there are some formations of micro-climatic areas due to these characteristics. Micro-climatic areas are seen to be warmer in terms of surface temperature. On the other hand, Aras Basin and Fırat-Dicle basin consist of very flat areas in terms of topography. Flat areas are very cold because they are covered with snow cover in terms of surface temperature. However, in some rugged areas of the Aras Basin. The surface temperature is partly warmer than other areas (*Figure 6*).

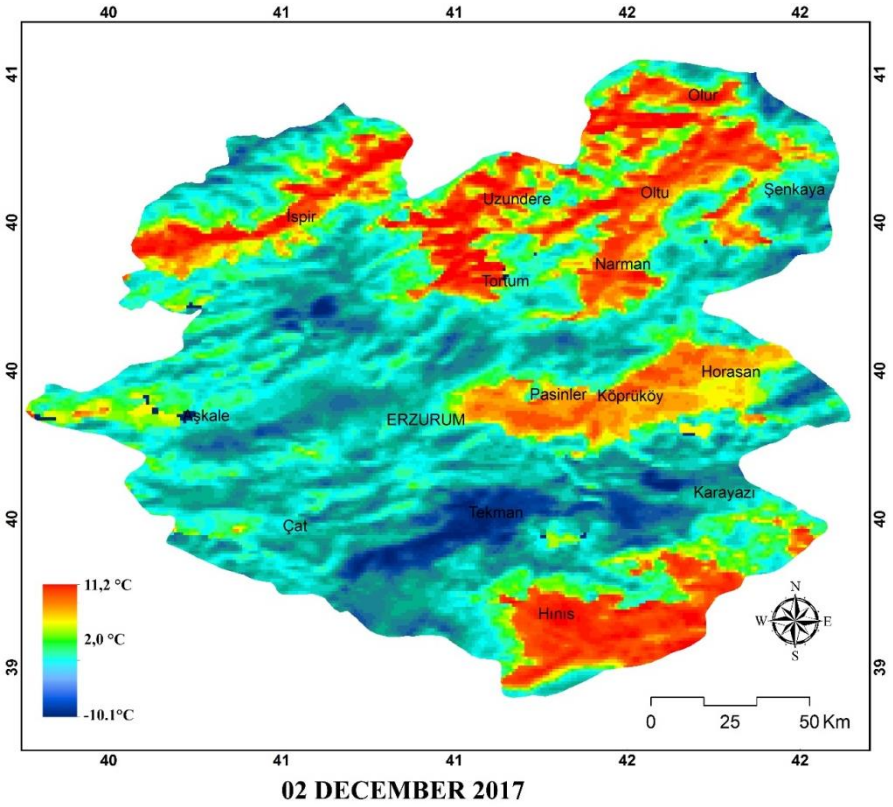

Figure 6. *Thermal band analysis of the study area on 2 December 2017*

In the study area, sampling points were obtained from 10 different locations, homogeneously distributed for each different land use. MODIS satellite sensors with a spatial resolution of 1000 m cause a large standard deviation in small areas. Therefore, while obtaining the data, sampling area was considered. The sampling areas sizes ranges from 2.3 km^2 to 14 km^2. The areas are not smaller than 1 km^2; hence it resulted in low standard deviation of LST data from the MODIS satellite sensors. In addition, the thermal data was obtained from the 4 different stations of the General Directorate of Meteorology Affairs for the accuracy of the sensor data used in the study (*Table 5*). On the basis of the resulting data, the difference of average surface temperature between stations was 1.9°C.

In the statistical analysis of this study, the effects of land use, month, and altitude were examined from the factors affecting the surface temperature. Because month and land use factors used as categorical, altitude factor used as continuous variables, CHAID analysis was preferred, which is a method use both categorical and continuous

DOI: http://dx.doi.org/10.15666/aeer/1703_60516067

variables. Beside this, the values of the altitude continuous variable divided into homogenous subgroups are automatically performed.

Table 5. *Temperature values obtained from thermal band analysis and meteorology stations*

Date/Place		4 Apr 2017 (°C)	17 Jun 2017 (°C)	6 Oct 2017 (°C)	2 Dec 2017 (°C)

According to the results of the statistical analysis, the most effective factors on the temperature of the months of June and October formed a homogeneous group in itself, and the temperature average is 23.9°C. It is determined that the month of December (0.6°C) with the lowest temperature average has an altitude effect (*Figure 7*).

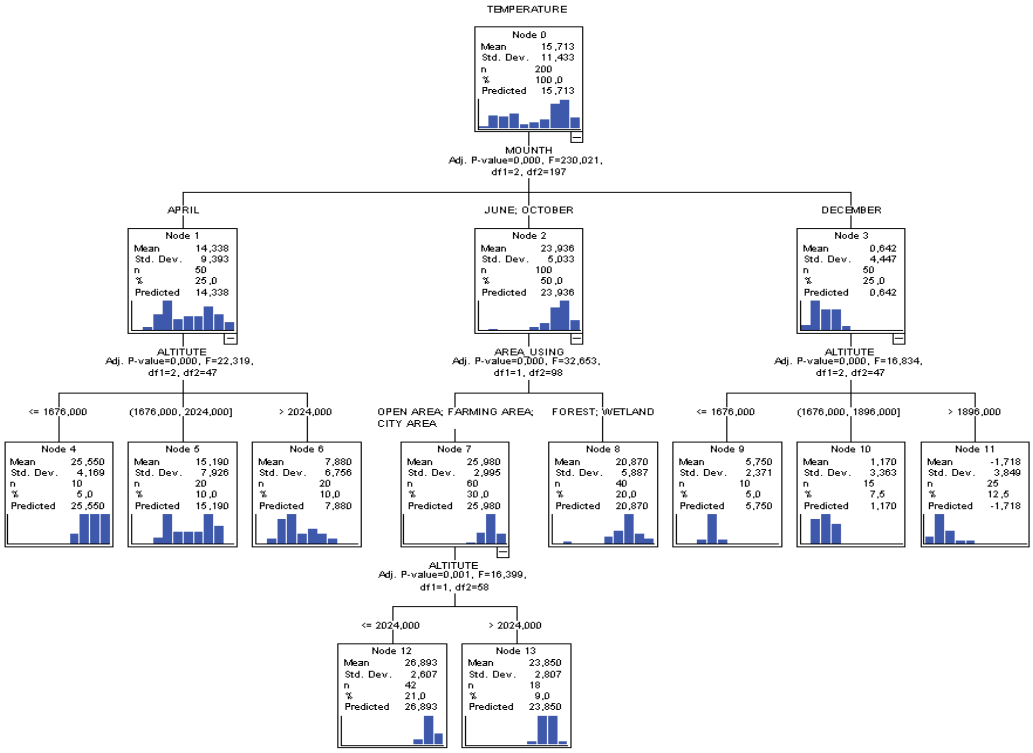

Figure 7. *Statistical analysis of thermal band data*

The altitude is divided into 3 heterogeneous groups while forming a homogeneous group in itself. While the average temperature of December is 5.7°C at a height lower than 1676 m. the temperature is between 1676-1896 m is 1.1°C and the temperature in the altitude above 1896 m is determined as -1.1°C (*Figure 7*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60516067

P < 0.00 has been effective in the land uses on the months of June and October. Among all land uses categories, open spaces and residential areas created one group. Forests and water surfaces created another group. Average surface temperature in open areas and residential areas is 25.9°C. In the other group, the surface temperature of the forest and water surfaces is 20.8°C (*Figure 7*).

The group formed by the open areas, agricultural areas and residential areas has been affected by height and the surface temperature of the area, which is less than 2024 m in altitude, is 26.89°C over 2024 m is 23.8°C. In the month of April only altitude was effective. The surface temperature at a height lower than 1676 m is 25.55°C, while the temperature is between 1676-2024 m is 15.1°C and over 2024 m is 7.8°C (*Figure 7*).

Overall, the most effective factor on the surface temperature was the month which comprise June, October, April and December. June and October were creating a homogeneous sub-group with the average surface temperature 23.9°C. On the other hand, April with a range of 14.3°C and December with a range of 0.6°C were creating separate group. The highest average surface temperature was seen at node 12. On this node, the average surface temperature obtained from 42 different observation points when open areas, farming areas and city areas and the altitude were lower than 2024 m for June and October as 26.9°C.

Discussion

One of the biggest problems facing seasonal determination of surface temperature is to distinguish between seasonal and sudden changes (Verbesselt et al., 2010; Ghazaryan et al., 2016; Muro et al., 2018). As a matter of fact seasonal timelines are divided into consideration of the 1-year urban meteorology data of 2017. It is also stated in previous studies that the measured value between 2 different single points to determine the surface temperature change is not an ecological indication (McVicar and Jupp, 1998). This study was evaluated by taking 10 different points in 5 different categories in 4 different time intervals on the province-scale. Surface temperature is used as an ideal tool for temporal analysis in the basin and other scales. although the resolution of the MODIS satellite in thermal band analyses is low quality (Neteler. 2010).

The reason for the selection of Chaid analysis in this study is that two of the arguments (land use and month) are categorical and one (altitude) is a constant variable. The determination coefficient between the temperature values observed and the expected temperature values (R^2) was calculated as 0.82. In another similar study the value of correlation between the two variables (R^2) was calculated as 0.65 (Muro et al., 2018).

Areas with the highest average surface temperature in the study site were determined as residential areas and they had a surface temperature of 18.7°C. At the same time the forest surfaces 12.2°C water surfaces 13.8°C agricultural areas 17.9°C and open areas 15.7°C were determined to have an average surface temperature. When the bonding between land uses and average surface temperatures is examined an average surface temperature difference was observed as 3.4°C between open areas and forests. Similarly, in previous studies, this difference was between 12 and 1.8°C (Falahatkar et al., 2011; Li et al., 2012; Mallick et al., 2012). In some studies, the difference between water surfaces and forests temperatures was found to be less important (Van and Bao, 2016). Indeed, in this study surface temperature values were close to each other in the water surfaces and forests. However, in another group study the difference between the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1703_60516067

forests and water surface temperatures was observed over 10°C (Falahatkar et al., 2011). In different studies the causes of different surface temperatures in similar land uses are topographic status of land structure, change in land use and humidity (Yuksel and Yilmaz, 2008). In this study, we have done on the provincial scale accommodates within the boundaries of 3 different basins. Even on the inside of these basins the land heights and climatic conditions are constantly differentiating from each other. Therefore, it causes different surface temperature values in the same land use.

Conclusion

In our study, we investigated the link between different land surface covers and surface temperature (LST) statistically. As a matter of fact, in the scientific studies that were made before, the method of statistical multi-linear regression analysis and correlation calculations were used for determining links between land surface temperature and land use (Choudhury et al., 2018; Wang et al., 2018). The point that makes our study different from other studies; we have been annotated with CHAID analysis by adding height and 4 different time zones in order to determine links between land surface temperature and land use. The reason for choosing CHAID analysis is that the month and land use factors used as the categorical variables, and the altitude factor used as continuous variables. In addition, using thermal band images in different time periods has supported the consistency of the links between LST and the land use.

In this study, Erzurum Province located in the eastern part of Turkey were investigated and also the 3 basin examples within the provincial boundaries were discussed. According to the results of the statistical analysis of the study, the most effective factor on surface temperature is the month of June and October in which a homogeneous group and the temperature average of this group is 23.9°C. It is determined that the month of December (0.64°C) with the lowest temperature average has an altitude effect.

If we look at the land use categories, the average surface temperature in the open areas and residential areas is 25.9°C. in the other group, the surface temperature of the forests and water surfaces is 20.8°C. When we discussed the study results in the basin scale, the surface temperature was higher at Coruh basin than Aras and Dicle basin due to altidute.
