The population of the study area has increased with an annual average growth rate of about 3% over the last three decades (Bekele et al., 2018b). The average number of a family is about seven in a rural area. According to data from CSA (CSA, 1994, 2007), the total population of three districts in CRV namely: Arsi Negele, Adami-Tulu-Jido Kombolcha, and Dugda had increased by about 86% in 2016 from its figure in 1994. About 85% of the population is still known to live in a rural area (CSA, 2007).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_76937713

For the vast majority (85%) of the population in the region, smallholder mixed rain-fed agricultural production is the main economic activity (Melka et al., 2015). There are also a few portions of the rural community who are still engaged in the agropastoral livelihood system. Despite significant attempts made to promote irrigated agriculture over the last two decades in the area, agricultural productivity is still subsistent due to erratic rainfall, recurrent drought, and limited technological applications. Due to this, the majority of the rural population is food insecure and still dependent on external relief aid programs (Bekele et al., 2018b).

Data used and sources

Long-term meteorological data (30-36 years) and socioeconomic data are the two main data sources used in this study. According to Maharjan and Joshi (2013), temperature and precipitation are widely used to assess climate change and its subsequent impacts. Hence, for climate variability and change analysis, long-term historical temperature and rainfall data were mainly used in this study. Data was specifically obtained from four selected Gaging Stations in CRV namely Meki, Ziway, Bulbula, and Arsi Negele (*Table*) which are monitored by Ethiopian National Meteorological Agency (NMA). All the stations are found along the rift-floor of the CRV and selected based on proximity to study Districts which were vulnerable to climate change and land use change in recent decades. The 1981-2017 database period was selected to make it match with the period for which land use/cover change was analyzed in previous work by the authors (Bekele et al., 2018a). Data for rural farmers' perception towards climate variability and its effect on their historical land use change was generated through formal households' interview and discussion with focus group and key informants — detail as explained in Bekele et al. (2018b). Accordingly, about 297 survey households were randomly selected and interviewed from two study districts namely Arsi Negele and Adami Tulu-Jido Kombolcha.

Table 1. *Data sources and period for rainfall and temperature*

Station	Latitude	Longitude	Elevation (m.a.s.l.)	Database period	
				Rainfall	Temperature
Arsi Negele	7°21'	38°39'	1800	1981-2016	1988-2017
Bulbula	7°43'	38°43'	1700	1981-2016	NA
Meki	8°09'	38°49'	1400	1981-2016	NA
Ziway	7°56'	38°43'	1640	1981-2016	1981-2017

m.a.s.l. = meter above sea level, NA = data not available (Source: NMA)

Data processing and analysis

Analysis of mean, standard deviation, coefficient of variation, precipitation concentration index, and standardized precipitation index

The daily time series rainfall and temperature data from each station and for the respective year were checked for homogeneity, outliers, discontinuities, and errors during analysis. Suspected outlier data were cross-checked with data from neighboring stations for typographical errors and corrected when found. Missing data value was filled by using data from a neighboring station. The inter-seasonal/annual trend of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_76937713

rainfall and temperature was examined for the study period and each station by processing data using the climatic analysis software, INSTAT version 3.36 following the guideline given by Stern et al. (2006). Mean values, standard deviation (SD), a coefficient of variance (CV), Precipitation Concentration Index (PCI), and standardized precipitation index (SPI) were employed for the analysis. The formula in *Equation 1* was used to calculate the SD for rainfall and temperature variability. Rainfall variability is also statistically described by using CV and PCI (Bewket and Conway, 2007). The CV is calculated as the ratio of the SD to the mean in a given period (*Eq. 2*), and the PCI values were calculated using *Equation 3* as given by Oliver (1980). SPI, also known as Standardized Rainfall Anomaly (SRA), *is simply the difference of precipitation from the mean for a specified period divided by SD, where the mean and SD are determined from recorded data* (McKee et al., 1993). The SPI values of the rainy season were calculated using the formula given in *Equation 4* as in Agnew and Chappell (1999) and Bewket and Conway (2007).

$$SD = \sqrt{\left[\sum_{i=1}^{n} \frac{(x_i - X)^2}{n}\right]} \quad \text{(Eq.1)}$$

$$CV = \frac{SD}{X} * 100 \quad \text{(Eq.2)}$$

$$PCI = \left[\frac{\sum P_i^2}{(\sum P_i)^2}\right] * 100 \quad \text{(Eq.3)}$$

$$SPI = \frac{P_t - P_m}{SD} \quad \text{(Eq.4)}$$

where, SD = standard deviation, CV = coefficient of variation, x_i = individual temperature/rainfall observation, X = mean rainfall/temperature, n = number of years considered, PCI = Precipitation Concentration Index, P_i = the rainfall amount of the i^{th} month, SPI = standardized precipitation index, P_t = annual rainfall in year t, P_m = long term mean annual rainfall over a period of observation.

Analysis of onset and cessation of rain, probability of dry spells, and length of growing season

Previous studies in dryland areas of Africa, including Ethiopia, defined the 'onset of rain' (a successful planting date) as *the first occasion after March 1st when the rainfall accumulates for three consecutive days and rainfall is at least 20 mm and no dry spell of more than ten days in the next 30 days* (Sivakumar, 1988; Simane and Struik, 1993; Tesfaye and Walker, 2004). Studies elsewhere described a 'rainy day' as a day receiving rainfall amount of >= 0.85 mm (Barron et al., 2003; Stern et al., 2006), whereas in this study the value given by Ethiopian National Meteorological Agency (NMA, 2001) (i.e., >=1 mm) was used as a reference for rainfall start which was also used by Seleshi and Zanke (2004). A first-order Markov Chain Model was applied by using INSTAT version 3.36 to analyze the onset of wet and dry spells as described by Stern et al. (2006). This model assumes that the probability of rainfall on a given day depends on whether rainfall did or did not occur on the previous day (Biazin and Sterk, 2013). To get an overview of drought at the study area for the whole year, probabilities of the maximum dry spell lengths over the next 30 days from planting was calculated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_76937713

(Tesfaye and Walker, 2004). For this study, a 'dry day' is a day receiving less than 1 mm of rain and a 'dry spell' is any consecutive number of days defined as 'dry'. The end of the rainy season or cessation was determined by using the water balance dialogue in the INSTAT climatic guide (Stern et al., 2006) and defined as a day after 'first September' when the soil water drops to 10 mm m^{-2}. Consequently, the length of the growing season is simply the difference between the rainfall onset date and cessation date (Sivakumar, 1988; Tesfaye and Walker, 2004; Stern et al., 2006). Frequency (F) of dry spells was computed using *Equation 5* below as in Sivakumar (1992).

$$F(D < x) = \frac{N(D_i)}{M} X\ 100 \quad \text{(Eq.5)}$$

where, $N(D_i)$ is the number of years a dry spell of length < x started in a prescribed 10-day period i, and M is the total data period (year).

Analysis of effect of climate change vulnerability on land use change

Studies show that drought vulnerability is much affected not only by climatological events but also by land use type and social contexts. For instance, Biazin and Sterk (2013) analyzed drought vulnerability based on locally perceived criteria of drought and found that the pastoral way of life was more vulnerable to severe drought than the mixed farming (livestock and crop combined) system. Based on these previous vulnerability findings, past historical land use type and future preferences of farmers who are currently engaged in two different land use system (agropastoralist versus mixed farming) were assessed by using a semi-structured questionnaire. The detail about household socioeconomic survey is explained in Bekele et al. (2018b). Accordingly, the study analyzed the change in land use of farmers during the study period, the main reason for changing, and their future preferences (either to continue as agropastoralist, mixed-farmer or other). Additional evidence for land use history was also collected from key informants and experts who were working in the study area for a long period. Finally, simple descriptive statistics were used to evaluate such climate change-induced farmers' historical land use change.

Results

Rainfall variability and change

Seasonal and annual rainfall characteristics

Rainfall of the study area showed both temporal and spatial variability over the study period. *Table* and *Table* summarizes the long-term statistics of spatial and seasonal rainfall for four selected sites in CRV while *Figure* illustrates a time series of bar graph that shows inter-seasonal and inter-annual total rainfall variability. The average precipitation of the driest month (19.2 mm) and wettest month (106.1 mm) was observed for November and August respectively. Mean annual total rainfall was below average for about 44% of the study years. The mean annual total rainfall is lowest (708 mm) at Bulbula and highest (769 mm) at Arsi Negele. The CV for rainfall is higher at Arsi Negele (43%) and lower at Ziway (20%). On the other hand, monthly rainfall distribution is less concentrated (PCI = 9) at Bulbula and more concentrated (PCI = 14) at Meki.

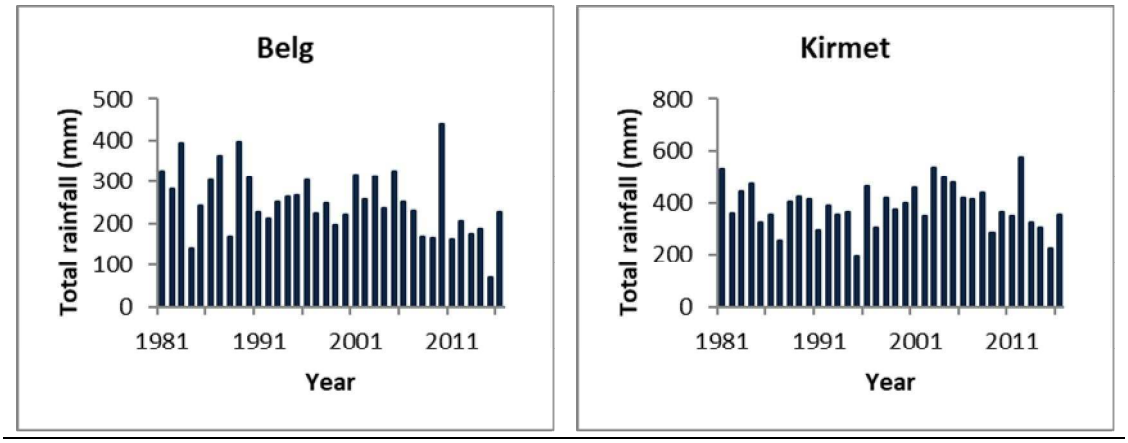

Figure 3. *Long-term seasonal total rainfall at CRV*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_76937713

Rainfall variability along the sites is also observed for both rainy seasons (*Table*). The overall mean seasonal rainfall ranged from 252 mm in *Belg* season (FMAM) to 386 mm in *Kirmet* season (JJAS). The coefficient of rainfall variation is higher for *Belg* season (47%) than for *Kirmet* season (35%). The long-term *Belg* season minimum rainfall ranged from 27 mm at Arsi Negele to 75 mm at Ziway, while the long-term maximum rainfall of the same season ranged from 413 mm at Ziway to 635 mm at Bulbula. Mean rainfall of the *Belg* season was lowest (234 mm) at Meki and highest (272 mm) at Arsi Negele. During this season, rainfall is more variable (CV=55%) at Arsi Negele and less variable (CV=43%) at Ziway. On the other hand, the minimum rainfall of the *Kirmet* season ranged from 70 mm at Arsi Negele to 182 mm at Ziway, while the maximum rainfall of the same season ranged from its 661 mm at Ziway to 1001 mm at Arsi Negele. The lowest (253 mm) and highest (461 mm) mean *Kirmet* rainfall was recorded for Bulbula and Meki sites respectively. *Kirmet* season rainfall is more variable (CV=53%) at Arsi Negele and less variable (CV=20%) at Ziway.

Standardized Precipitation Index (SPI)

The Standardized Precipitation Index (SPI) (*Figure*) shows an overall picture of average (normal), above average (wet) and below average (dry) years, while *Table* gives the classification of SPI based on McKee et al. (1993). SPI values ranged from (-)2.34 to (+)2.42 for *Belg* season and (-)2.23 to (+)2.21 for *Kirmet* season. As can be seen from *Figure*, both seasons experienced dry and wet years over the last 36 years.

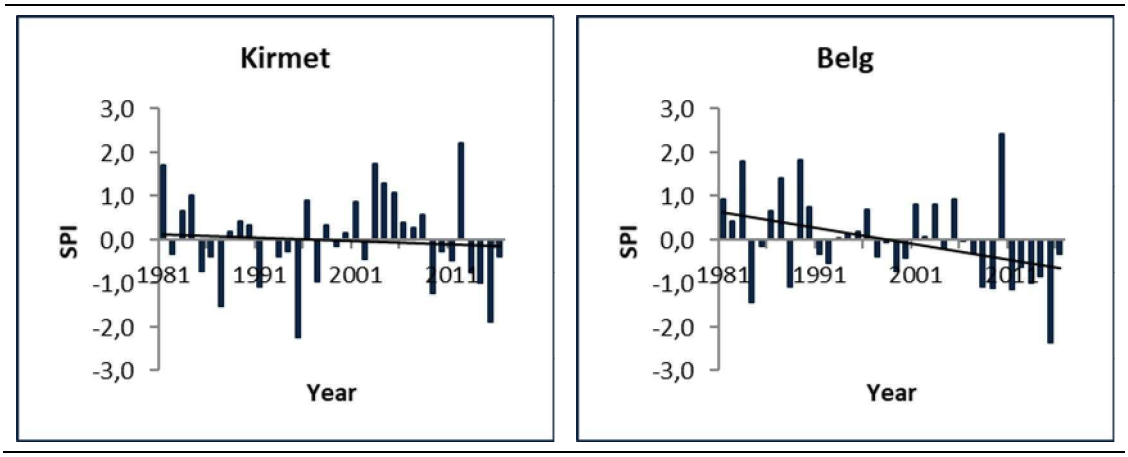

Figure 4. *Standardized Precipitation Index (SPI) of the growing season in CRV*

For instance, out of the 36 database years considered, rainfall was below average (dry years) during 20 years (56%) of *Belg* season and 18 years (50%) of *Kirmet* season. On the other hand, the linear trend line in *Figure* indicates that the total annual rainfall showed a general decreasing trend since 1981 during both seasons. According to the SPI classification given by McKee et al. (1993), rainfall of about 44% and 50% of the study years fall in the category of *no drought/normal* for *Belg* and *Kirmet* seasons respectively (*Table*). For the *Belg* season, the 'extreme drought' year was 2015, whereas for *Kirmet* season the 'severe drought' and 'extreme drought' years were 1987 and 2015, and 1995, respectively.

DOI: http://dx.doi.org/10.15666/aeer/1704_76937713

Table 4. *Drought evaluation in CRV based on McKee et al. (1993)*

Season	Drought class	Drought/normal years	Frequency	Percentage of frequency
Belg	Extreme drought	2015	1	2.8
	Severe drought	-	0	0
	Moderate drought	1984, 1988, 2008-2009, 2011	5	13.9
	Mild drought	1985, 1991-1992, 1997-2000, 2004, 2006-2007, 2012-2014, 2016	14	38.9
	No drought	1981-1983, 1986-1987, 1989-1990, 1993-1996, 2001-2003, 2005, 2010	16	44.4
	Total		36	100
Kirmet	Extreme drought	1995	1	2.8
	Severe drought	1987, 2015	2	5.6
	Moderate drought	1991, 2009	2	5.6
	Mild drought	1982, 1985-1986, 1993-1994, 1997, 1999, 2002, 2010-2011, 2013-2014, 2016	13	36.0
	No drought	1981, 1983-1984, 1988-1990, 1992, 1996, 1998, 2000-2001, 2003-2008, 2012	18	50.0
	Total		36	100

Rainfall onset, cessation, and length of growing season

The onset (start) and cessation (end) date of rainfall for the main rainy season, averaged for the study site is shown in *Figure*. The average rainfall onset date of the study area is 25 June. Out of the 36 database years considered, for 15 years (42%), rainfall started later than the average onset date (June 25). On the other hand, the average rainfall cessation date in CRV is 17 September. For 20 years (56%), out of the 36 years, rainfall stopped earlier than the average cessation date (September 17). The average length of the crop growing season (i.e., the difference between cessation date and onset date) is as shown in *Figure*. The average growing season in the study area is about three months (84 days), and the median value is 85 days. 1985, 1987, and 1995 were years with a growing season of less than 60 days, whereas 1982, 1988, 1996, 1998, 1999, 2000, and 2012 were years with more than 100 days of growing season.

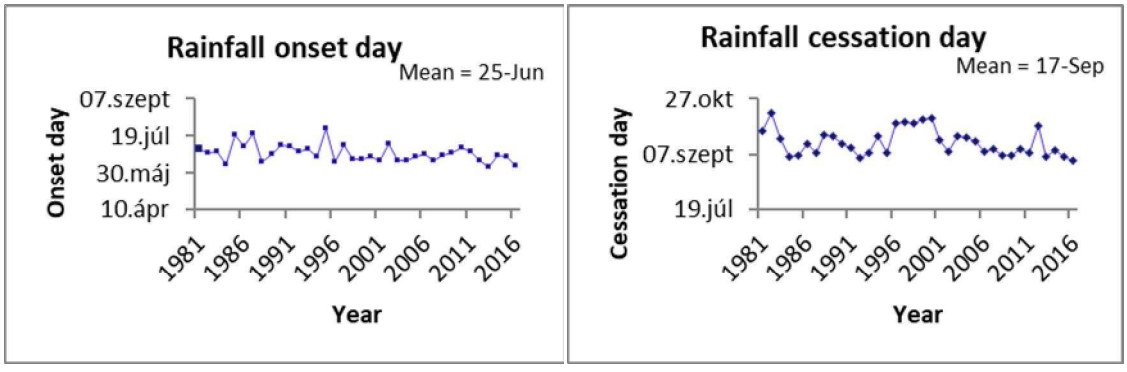

Figure 5. *Rainfall onset and cessation day variability in CRV*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_76937713

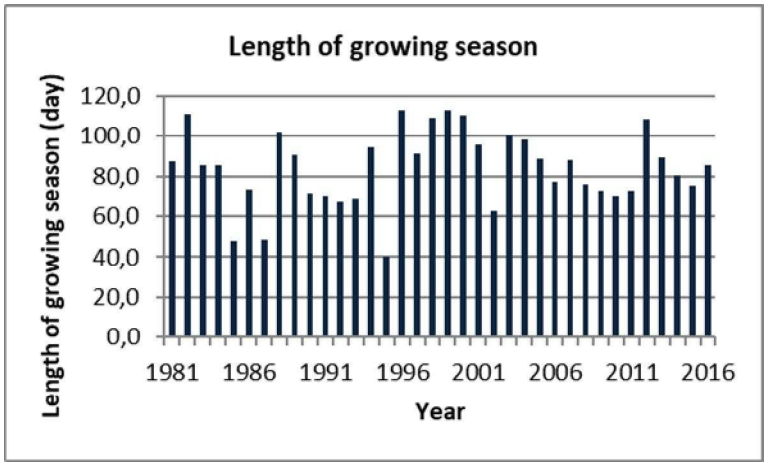

Figure 6. *Length of the growing season in CRV*

Number of rainy days and probability of dry spells

Figure depicts the trend of rainy days (days with rainfall >=1 mm) and dry spells (days with rainfall < 1 mm) for *Belg* and *Kirmet* seasons and respective study years. The average number of rainy days in the study area is 23 and 38, while the average number of dry spells is 97 and 84 for *Belg* and *Kirmet* seasons respectively. As presented in *Figure*, the number of rainy days showed a general decreasing trend, whereas the number of dry spells showed a generally increasing trend since 1981 for both *Belg* and *Kirmet* seasons.

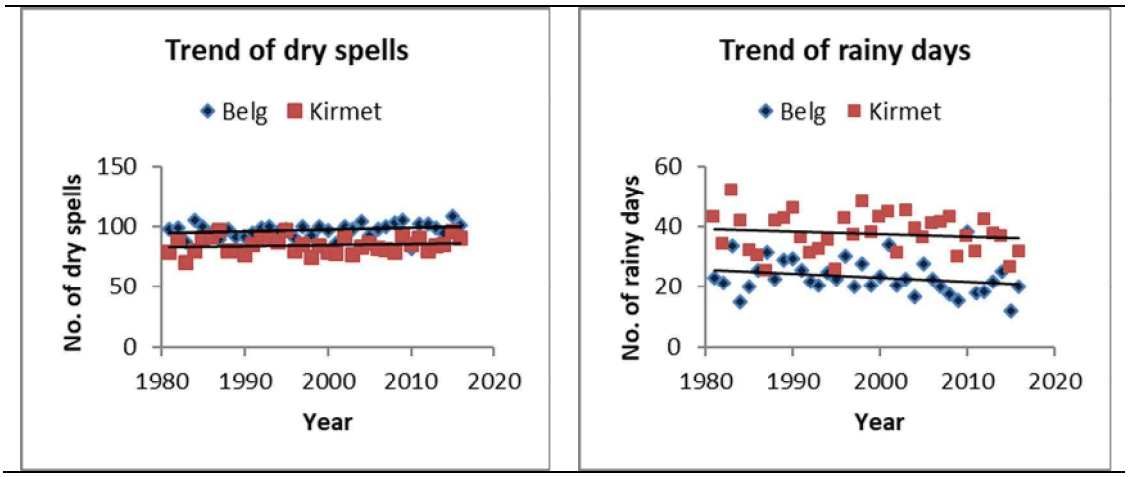

Figure 7. *Trend of number of rainy days and dry spells in CRV*

For example, for *Belg* season, the average number of rainy days was declined from 25 during 1981-1990 to 20 during 2007-2016 (18% decline), whereas for the same period, average number of dry spells was increased from 95 to 99. Similarly, for *Kirmet* season, during the same period, the average number of rainy days was declined from 39 to 36 (8% decline), whereas the average number of dry spells was increased from 83 to 86. On the other hand, the probability of dry spells was found to be higher during *Belg* season than during *Kirmet* season of the study years (*Figure*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_76937713

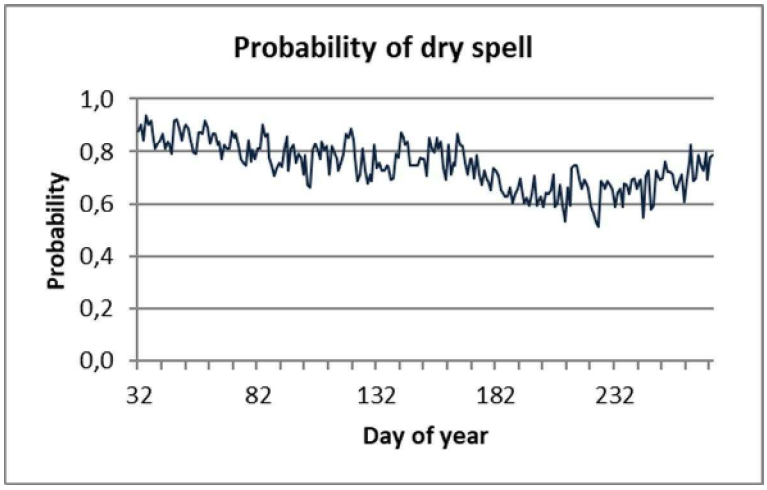

Figure 8. *Trend of the probability of dry spells in CRV*

Temperature variability and change

Results indicated that the temperature of the study area has shown minor inter-annual and inter-station variability over the study periods (*Table* and *Figure*). The average minimum temperature of the coldest month (10.7°C) and the average maximum temperature of the hottest month (28.8°C) was observed for December and March respectively.

Table 5. *Temperature characteristics at four stations in CRV*

Station	Minimum temperature			Maximum temperature		
	Mean	SD	CV	Mean	SD	CV
Arsi Negele	12.20	2.22	18.19	26.57	0.88	3.32
Bulbula	ND	ND	ND	ND	ND	ND
Meki	ND	ND	ND	ND	ND	ND
Ziway	14.14	0.89	6.28	27.36	0.97	3.55
Study site	13.24	1.26	9.51	27.12	0.55	2.03

SD = standard deviation, CV = coefficient of variation, ND = no data available

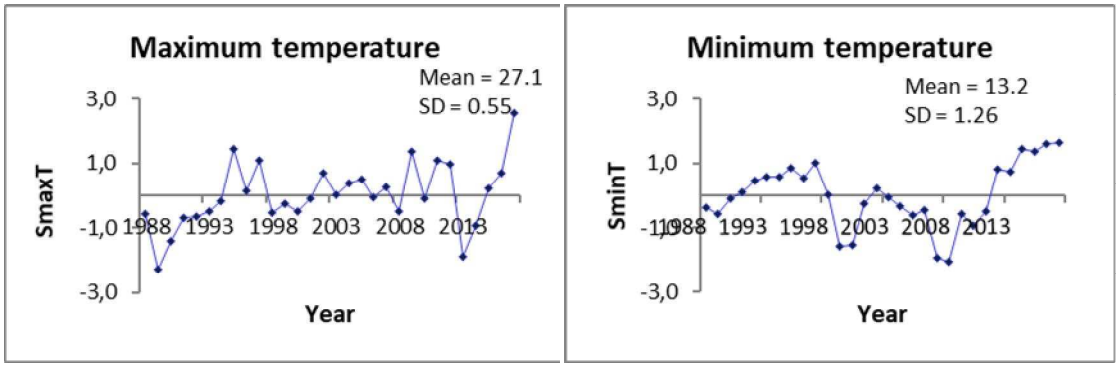

Figure 9. *Variability in minimum and maximum temperature in CRV: SminT = standardized minimum temperature, SmaxT = standardized maximum temperature*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_76937713

Both minimum and maximum temperature values are higher at Ziway than at Arsi Negele. The minimum temperature ranged from its lowest value (10.6ºC) in 2008 to its highest value (15.3ºC) in 2017, while the maximum temperature ranged from its lowest value (25.9ºC) in 1989 to its highest value (28.5ºC) in 2017. The minimum temperature had risen above the average value for 15 years (50%) out of the 30 years considered. Similarly, the maximum temperature was above average value for 16 years (53%) of the data years. On the other hand, both minimum and maximum temperatures showed a relatively continuous increment after 2013.

Effect of climate variability on farmers' land use change

Table indicates how farmers of the study area have shifted/wish to change their land use system through time in order to adapt to the impacts of climatic and environmental changes over time. About 15 and 35% of respondents in CRV claimed that they had been pastoralists and agropastoralists respectively before the government change in 1991. However, currently, only 9% of respondents claimed as being agropastoralists and none of them claimed as fully pastoralist. This indicates about 82% of farmers who were pastoralists and agropastoralists before three decades had changed their land use to mixed farming and other livelihood activities. On the other hand, as indicated in *Table*, though the majorities (about 90%) of the farmers wish to continue as a mixed farmer, none of them wish to continue either as pastoralist or agropastoralist in the future. The rest 10% of respondents have a wish to shift their livelihood to other activities like off-farm jobs, mini trading, and cattle fattening.

Table 6. *Farmers land use change through time (N=297)*

Type of land use	30 years before (%)	Current (%)	Future wish (Yes, %)
Pastoralist	15.00	0.00	0.00
Agropatoralist	35.50	9.10	0.00
Mixed farming	48.50	89.00	90.10
Other activity	1.00	1.90	9.90

The major factors that forced farmers to change their land use system through time are as listed in *Table*. This change in land use is more observed in communities whose livelihood is more vulnerable to climate change for example, in pastoralists and agropastoralists than in mixed farming communities who are less vulnerable. According to 40% of respondents, climate variability is the main factor forcing farmers to change their land use system which was followed by the shortage of land due to population growth (30%), as a second driver of change.

Table 7. *Forcing factors of farmers' land use change (N=297)*

Factors	Number of respondents (%)
Climate change	40
Population growth and shortage of land	30
Access to market and infrastructure	15
Institutional and policy changes	10
Others	5

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_76937713

Improvements in access to infrastructure and market from time to time and institutional changes following the subsequent government changes in 1974 and 1991 in Ethiopia were also mentioned as substantial factors that contributed for such land use changes in the study area.

Discussion

Results indicated that rainfall in the study area experienced a high inter-seasonal, inter-annual, and inter-station variability over the last 36 years. For instance, mean annual total rainfall was below average for about 44% of study years, and the CV of rainfall is about 20% and above for all seasons and sites. This long-term rainfall variability was also confirmed by the perceived results of the discussion with farmers and experts of the study area (Bekele et al., 2018b). As per the classification given by Hare (1983), total rainfall of CV < 20% is classified as less variable; CV of 20-30% as moderately variable, and CV of > 30% as highly variable and vulnerable to drought. According to this classification, the overall rainfall in CRV can be categorized in the threshold of 'moderately variable', even though inter-seasonal/station variations are 'highly variable'. On the other hand, the overall PCI value for the study site is about 11, which indicates that the monthly rainfall distribution of the study area is highly concentrated. According to Oliver (1980), PCI values of less than 10, 11-20, and above 21 are indicators of 'uniform', 'high concentration' and 'very high concentration' monthly distribution of rainfall respectively.

This result is in line with results of previous studies on climate variability in the region (Biazin and Sterk, 2013; Getachew and Tesfaye, 2015; Muluneh et al., 2017) and studies in other parts of Ethiopia (Seleshi and Zanke, 2004; Bewket and Conway, 2007; Cheung et al., 2008; Viste et al., 2013) who reported the prevalence of seasonal rainfall variability and drought in the country over the last decades. Besides climatic fluctuations, there are studies reported the non-stationarity in hydrological variables particularly stream flow and lake level in the Rift Valley Lakes Basin of Ethiopia (Wagesho et al., 2012; Getnet et al., 2014). This affects the available water which, in turn, affects land use. However, other studies reported the absence of significant variation particularly in terms of total annual rainfall as opposed to farmers' usual perception of the presence of total rainfall shortage in the country in recent decades (Rosell, 2011; Kassie et al., 2013; Adimassu et al., 2014). In addition to seasonal variation, Ethiopian precipitation exhibits great spatial variation due to high altitudinal variation over the country (Viste et al., 2013). Coupled with the semi-arid climate and hence moisture-deficient soil of the CRV, variability in rainfall is one of the challenges to the sustainable production of the rain-fed agriculture in the region (Kassie et al., 2013; Gizachew and Shimelis, 2014; Getachew and Tesfaye, 2015), in Ethiopia (Mideksa, 2010), and other semi-arid and dry sub-humid areas in Sub-Saharan Africa (Barron et al., 2003; Viste et al., 2013; Fekadu, 2015; Serdeczny et al., 2017).

In the study area, out of the 36 study years considered, total rainfall was below average (i.e., negative anomalies) for about half of these years. According to the threshold suggested by McKee et al. (1993), SPI values of less than zero are indicators of the presence of drought. SPI and probabilities of drought occurrence are commonly used in evaluating trends of rainfall over a long period (McKee et al., 1993; Agnew and Chappell, 1999; Agnew, 2000; Bewket and Conway, 2007; WMO, 2012; Viste et al., 2013). This is because using SPI has advantages in that other input parameter is not

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_76937713

needed except precipitation, it can be compared for varied climatic zones and timescales, it gives drought early warning and helps to evaluate the severity of the drought, and it is less complex than the other indices (Agnew, 2000; WMO, 2012). In addition, in areas where data accessibility is limited, Viste et al. (2013) recommend using precipitation-based drought measurements. On the other hand, SPI has weaknesses in that it requires the data to be normally distributed and also its output is affected by the time of the base data period used (Agnew and Chappell, 1999; Agnew, 2000; Ali and Lebel, 2009; WMO, 2012). In addition, there exists a confusion on the definition of the term 'drought' as its impacts can be evaluated in terms of meteorological, climatological, hydrological, agricultural, ecological, and economic aspects (McKee et al., 1993; Agnew, 2000; Viste et al., 2013). However, meteorological drought is the main form of drought, and there is a consensus that drought occurs when rainfall is 'below average' (Agnew and Chappell, 1999).

For a moisture-deficient, semi-arid climate, and a rain-fed dependent agriculture like the one in CRV of Ethiopia, the time of the start of rainfall (onset), the time at which rainfall stop (cessation), and the length of the growing season are very important climatic phenomenon that affects not only the crop cultivation calendar, but also the final yield of production (Seleshi and Zanke, 2004; Segele and Lamb, 2005). Hence, such rainfall analysis has important applications in initiating weather-responsive farming for drought-prone areas like the Sahel and East Africa (Sivakumar, 1988, 1992). As seen from the result, out of the 36 years considered, *Kirmet* season rainfall in the study area started after the average time of onset for about 42% of the years, and it ceased ahead of the average time of a stop for about 56% of the years. This shortens the length of the growing season which directly affects crop productivity due to moisture deficiency in the soil before crop grain filling time. Studies show that there exists a significant relationship between the length of the growing season and the date of onset of rain (Sivakumar, 1988). Early onset of rain is usually followed by a prolonged growing season and vice versa. As pointed in Bekele et al. (2018b), during the discussion, farmers also blamed that late onsets and early cessations of rainfall are the main reasons for the reduction of their crop yield in recent decades.

The average ratio of rainy days to dry spells for the rainy season in the study area is about 1:3. This indicates that the number of dry spells is three times that of rainy days. The number of dry spells showed a generally increasing trend while the number of rainy days has experienced a generally decreasing trend since 1981 for both *Belg* and *Kirmet* seasons. On the other hand, the probability of dry spell occurrence was found to be less during *Kirmet* season than during *Belg* season. Previous studies also reported the presence of frequent drought in Ethiopia. For example, the years 1972-1975, 1980-1982, 1984, 1987, 1990-1992, 1999-2000, 2002-2003, and 2008-2011 were the periods of severe drought episodes while the years 1973/74, 1984/85, and 2009 were the nationally widespread and worst drought years in Ethiopia (Jury, 2010; Gebrehiwot et al., 2011; Viste et al., 2013). It is important to match the crop phenology with the dry-spell lengths to meet the crop water requirements in the semi-arid and arid regions where moisture is available for a relatively short period during the year (Sivakumar, 1992). Hence, for the choice of a particular crop or variety, such information on the length of dry spells for a given region could be used as a guide.

Similar to rainfall, the temperature (particularly of minimum temperature) has shown an inter-annual variability and a generally increasing trend in recent years. It is evident that an evapotranspiration rate will increase with an increase in temperature which, in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_76937713

turn, will contribute to crop productivity decline due to a shortage of available soil moisture in drought-prone areas. Studies in different parts of the country also reported a slight increase in temperature over recent decades (Rosell, 2011; Fazzini et al., 2015; Getachew and Tesfaye, 2015). Local communities and experts relate such an increase in diurnal temperature to massive losses in vegetation coverage of the region due to deforestation over the last decades (Bekele et al., 2018b). An increase in temperature could also be ascribed to global warming effect due to an accumulation of greenhouse gases from intensive agricultural production (Maharjan and Joshi, 2013).

This study finally considered how climate change vulnerability shapes farmers' historical land use. Climate change perception survey results indicated that the variability in climate, particularly the occurrence of recurrent drought, is one of the factors that force drought vulnerable farmers to modify/change their land use system through time. Previous studies also indicate that land use change in CRV is driven by the interaction of frequent drought, socioeconomic and institutional dynamics, and access to market and infrastructures (Biazin and Sterk, 2013; Bekele et al., 2018b). Such climate change-induced change in land use is taken as a means of adaptation strategy to overcome climate change and its impacts (Dale, 1997; Reid et al., 2000; Ahmed et al., 2016). Besides such permanent changes in land use, farmers also use other short-term climate change adaptation mechanisms like changing cropping time, changing crop variety, using off-farm income sources, and selling cattle to overcome critical drought years. Studies show that coupled with climatological changes, the degree of drought vulnerability is also affected by the type of land-uses and social contexts (Biazin and Sterk, 2013). For instance, Biazin and Sterk (2013) in their study found that the pastoral way of life was more vulnerable to severe drought than the mixed farming (livestock and crop combined) system. This indicates that due to drought vulnerability farmers try to shift from a land use system that is more vulnerable to drought (e.g., pastoralist) to a land use system that is less vulnerable (e.g., mixed farming) through time. Another study by Ahmed et al. (2016) in western Africa also confirmed that the increase in agricultural land use in the region was primarily climate-driven.

Conclusions

Rainfall and temperature data analysis are in common practice to describe climate change and variability. Such analysis not only helps to evaluate the variation exists along spatial and temporal scales but also to see its impacts on the agrarian community. In this study, descriptive statistical tools were used to show long-term inter-seasonal, inter-annual, and inter-site rainfall and temperature variations, and its impacts on land use change in a drought-prone CRV region of Ethiopia. Results indicated that there existed a high inter-seasonal and inter-annual rainfall and temperature variability over the last three decades. For example, total annual rainfall was below average for about 44% of the 36 years data period. Late-onset and early cessation of rainfall were observed for the majority of the database period. The number of rainy days generally showed a decreasing trend while the number of dry spells showed a generally increasing trend since 1981. Standardized Precipitation Index of the crop growing season also showed negative anomalies (i.e., less than average) for the majority of the study years considered. Extreme and severe drought years were also noted for both rainy seasons (*Belg* and *Kirmet*).

DOI: http://dx.doi.org/10.15666/aeer/1704_76937713

In line with meteorological evidence for drought, vulnerable farmers in the study area well perceived such recurrent drought occurrence over the last three decades and they blamed the change in climate as one of the important forcing factors to change their land use system through time. Majority of the farmers who had been pastoralists/agropastoralists before three decades are currently already changed their land use system to mixed farming, and the rest also have a wish to change in the future. In general, it is evident that climate change plays a significant role in driving historical land use change in drought-prone areas like East Africa. Hence, future policies need to consider strategies that strengthen the adaptation capacity of farmers to overcome drought impact while combating anthropogenic activities that aggravate climate change, for instance, land degradation, in Sub-Saharan countries.

It is believed that for a climate change-prone and rain-fed dependent agriculture, like in East Africa, up-to-date local climatic trend information is quite crucial to practice climate-responsive agricultural management activities like cultivation, water management, health management, and to reduce drought-induced catastrophes. However, this study might have limitations in that we used data from limited meteorological stations and hence future studies better incorporate data from the wider stations in CRV lakes basin. In addition, missing data observed in each station might affect the accuracy of the results to some extent and hence a cross-comparison of the results with reference data elsewhere, for example, World Climate Research Program Global Precipitation Climatology Center (GPCC) might be important. The role of climate change vulnerability in governing land use change also need further detail study. Future studies also need to address the adaptation strategies of farmers to overcome climate change, and the barriers hinder the success of such efforts.

Acknowledgements. The authors are indebted to thank the National Natural Sciences Foundation of China [Grant No. 41571176] and Sino-Africa Cooperation and Exchange Special Program [Fund No. 2018-AF-22) for financial support in conducting this study. We are grateful to thank the Chinese Government Scholarship Council (CSC) for giving the first author a chance to pursue his Ph.D. study in China. Special thanks also go to the Ethiopian National Meteorological Agency (NMA) for providing rainfall and temperature data and all the rural farmers of the three Districts: Dugda, Adami Tulu-Jido Kombolcha, and Arsi Negele, who took part during the field survey. The anonymous referees and editor are thankful for their valuable comments on the initial version of this manuscript.

(Received 12th Mar 2019; accepted 1st May 2019)

Abstract. The grazing rate of three zooplankton species; *Daphnia carinata*, *D. lumholtzi* and *Ceriodaphnia* cf. *quadrangula* on six algal species at three concentrations are described in this paper. The effect of food density on ingestion rate was assessed by adding a suspension of algae to the tumblers and following the changes in concentration in the tumbler as the cladocerans consumed the suspension. Samples were taken and algal densities were measured every 15 minutes with a spectrophotometer. This study aimed to examine the role of cladoceran as grazers of algae under laboratory conditions. *D. carinata* removed algal cells at higher rates than the other two species when feeding in unialgal suspension. Quantitative differences in rate of food intake were found in suspensions of *Ankistrodesmus falcatus*, *Scenedesmus obliquus*, *Chlorella vulgaris*, *Chlamydomonas reinhardtii*, *Anabaena circinalis* and *Microcystis flos-aquae*. The small cells contributed by far the greatest fragment of green algae ingested by grazers. Filamentous *A. circinalis* and colonial *M. flos-aquae* can also be utilized by the grazers though the species was previously reported to have lethal toxic effects on cladocerans. Therefore, a management strategy using cladocerans for controlling undesirable cyanobacteria in aquatic ecosystem is contemplated to be necessary in the future.
Keywords: *grazing, zooplankton, Daphnia, Ceriodaphnia, ingestion rate*

Introduction

Zooplankton grazing is currently facing a crucial phase as the changes in the grazer population translate into changes in ecosystem properties, particularly in the phytoplankton biomass (Horn, 1981; Elser, 1992). Thus, it has attracted a lot of attention among scientists and has inspired them to conduct more research and experimental investigations into the plankton ecology. Measuring feeding rates of herbivorous zooplankton is important in order to understand the interaction between phytoplankton and zooplankton. Even though zooplankton grazing has been studied in laboratories worldwide, in Australia, little information is available on the subject. Zooplankton grazing directly affects the phytoplankton structure and changes the algal growth rates (Lampert et al., 1986). Algal losses in the aquatic ecosystems are caused by many factors such as grazing, sinking, parasitism, and nutrient levels (Tilman et al., 1982; Finkel et al., 2010). However, this paper focuses on zooplankton grazing through measurements in the laboratory as this approach has been known to be the best to estimate the increase and decrease of the algal population. The most important advantage of the laboratory method is the food type, food concentration quality and densities of grazers can all be defined by the researcher. Comprehensive laboratory determination of cladocerans feeding rates is essential to define the role of these important grazers in the freshwater ecosystems.

DOI: http://dx.doi.org/10.15666/aeer/1704_77157725

Food uptake of suspension feeders can usually be described by the ingestion rate (IR). Ingestion rate or feeding rate is expressed as the amount, number or biomass of food cells consumed by an animal in a time interval (Wirtz, 2013). Zooplankton ingestion rate increases with food concentration. It increases up to about 100,000 cells mL^{-1} after which, a plateau will be reached; body length will increase and the body temperature will rise up to 20°C (Burns and Rigler, 1967).

In terms of food, zooplankton require high quality food with appropriate size range, to allow them to grow healthily in their ecosystem. Therefore, food size is an important factor related to cladoceran feeding. Nonetheless, not all phytoplankton cells are suitable for ingestion. Often, they refuse to feed on algae that are inedible, toxic and are in the form colonies or filaments. Furthermore, the biochemical composition, the cell wall thickness and the digestibility of algae may affect the growth and the species composition of cladoceran. Several studies have shown that different species of cladoceran have different preferences in terms of food (Bogdan and Gilbert, 1984; Knisely and Geller, 1986). Consequently, food size preferences affect their body size (Urabe et al., 1996).

In general, this study aimed to examine the role of cladoceran as grazers of algae under laboratory conditions. More specifically, it was the aim of the study:

- To determine the grazing rates of three different species of cladoceran and density of unialgal populations;
- To determine if cladocerans' algal grazing is size selective;
- To compare the feeding preferences of cladocerans between green and blue green algae.

Materials and Methods

Two medium cultures have been used in this study; AlgaBoost f/2 from AusAqua Pty. Ltd. as green algae medium culture and BG - 11 based on Rippka et al. (1979) for blue-green algae culture. Algae collection was obtained from cultures maintained by the SAW and Commonwealth Scientific & Industrial Research Organisation (CSIRO). Six species of algae were used in the grazing experiments, namely *Ankistrodesmus falcatus*, *Chlamydomonas reinhardtii*, *Scenedesmus obliquus*, *Chlorella vulgaris*, *Anabaena circinalis* and *Microcystis flos-aquae*. Algae were cultured by the method described by Hoff and Snell (1987) and Kilham et al. (1998).

Cell biovolume is the most common approach used to estimate biomass of phytoplankton. The calculation of biovolume was based on geometric approximation, calculated from microscopically measured linear dimensions (Hillebrand and Sommer, 1996). Altogether, 360 cells from each species were measured and the cell sizes were grouped into various size classes. Then, the median of measured linear dimensions of the biovolume were calculated as proposed by Hillebrand et al. (1999), not as a median or mean value of a set of individually calculated biovolumes. In this experiment, the value was expressed in cell volume, rather than cell concentration as the unit will standardize the different sizes of algae.

Wild *Daphnia carinata*, *D. lumholtzi* and *Ceriodaphnia* cf. *quadrangula* were collected from Myponga and South Para Reservoirs and reared or cloned over at least 30 generations in the laboratory. Cladocerans collected from the wild were placed in Petri dishes under a dissecting microscope for sorting. Each organism was separated using T-pipette and transferred into six well plates containing filtered lake water. The

DOI: http://dx.doi.org/10.15666/aeer/1704_77157725

entire set up was placed in a lighted cabinet at 20°C and light regime for 10:14 hr light and dark. To maintain the uniformity of algal cells, the plates were gently agitated by hand twice a day. The plates were incubated in a lighted cabinet at approximately 1000 – 1500 lux and checked daily for clonal neonates. At least five individuals were present in the cell, the population was then transferred into a 50 mL falcon tube filled with filtered water and algae culture using a 10 µL pipette. Cultures in falcon tubes were incubated at the same temperature and light regime as indicated above. Cultures were then replenished once a week by removing 25 mL of media and adding 25 mL of 1:1 filtered lake water and algae. Once the culture was established, it was transferred to approximately 6 L aquarium containing lake water (*Fig.1*). The zooplankton were fed with a mixed culture of algae (*Ankistrodesmus falcatus*, *Scenedesmus obliquus* and *Chlorella vulgaris*) every two days (*Fig. 2*).

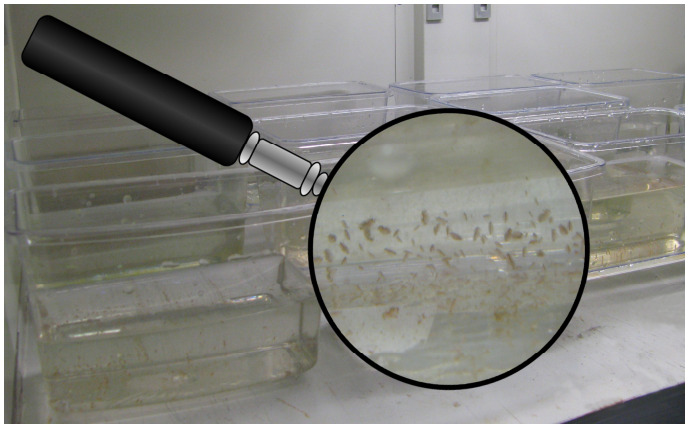

Figure 1. *Zooplankton culture*

Figure 2. *Algae culture*

In the grazing experiments, individuals with the largest adult length (*Daphnia carinata*, 3.4 – 3.8 mm; *D. lumholtzi*, 1.2 – 1.3 mm; and *Ceriodaphnia* cf. *quadrangula*, 0.65 – 0.75 mm) were used. The animals were acclimatized to the experimental temperature of 20°C for 24 hours before experiments in 50 mL of filtered lake water. Then, five adults were transferred to the 50 mL tumbler filled with filtered

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77157725

lake water (*Fig. 3*), enriched with an appropriate suspension of algae (Ismail et al., 2015). Five tumblers without animals served as the control sample. The experiments were run for two hours in a temperature-controlled cabinet at 20°C in the laboratory at 980 – 1045 lux.

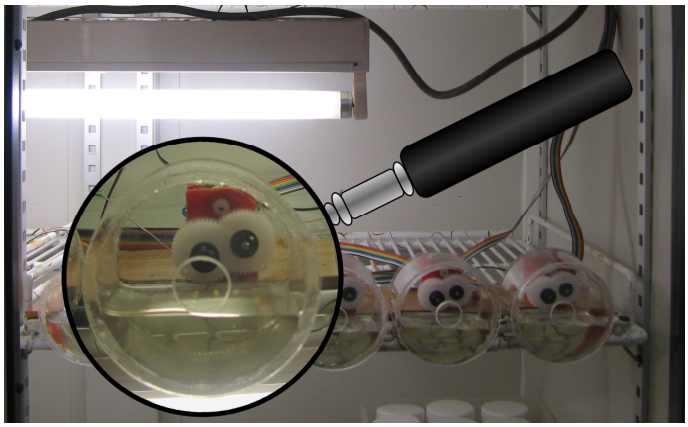

Figure 3. *Rotating tumblers filled with filtered lake water, enriched with an appropriate suspension of algae*

The effect of food density on ingestion rate was assessed by adding a suspension of algae to the tumblers following the changes in concentration in the tumbler as the cladocerans grazed the suspension down. Ingestion rate of cladocerans were measured every 15 min. All counts were made in five replicates using a spectrophotometer (Model 340). The instrument was adjusted to the desired wavelength such as 470 nm for green algae and 645 nm for cyanobacteria. Ingestion rate was calculated according to the formula in Frost (1972). There were three different cell concentrations at which ingestion rate was measured. Each concentration was replicated five times. The initial concentration of algae was the same for all species used which were 1.5 x 10^6 μm^3/mL, 3.0 x 10^6 μm^3/mL and 4.5 x 10^6 μm^3/mL. The tumblers were rotated at 1.5 rpm throughout the 2-hr experiment to minimize the sedimentation of algae. The ingestion rate was analysed using 3-way ANOVA to test the effects of the three cladocerans species, three food types and three concentrations for the eight time intervals. Significant differences among groups were tested using Tukey HSD test.

Results

The results of the grazing experiments on unialgal suspension were graphically presented in *Figures 4 and 5*, which show experiments from three different cell volumes on six algal species. All three species of Cladocera had a significant effect on the ingestion rate ($p < 0.05$), while all food concentrations showed a significant difference ($p < 0.05$), except at food volume of 3.0 x 10^6 μm^3/mL and 4.5 x 10^6 μm^3/mL ($p > 0.05$). The results displayed large fluctuating patterns for *A. falcatus* (*Fig. 1*), *C. vulgaris* (*Fig. 4*) and *M. flos-aquae* (*Fig. 5*), while small fluctuating trends occurred on *S. obliquus* (*Fig. 4*) and *C. reinhardtii* (*Fig. 5*). On the contrary, Cladocera grazing on *A. circinalis* showed low and almost constant trend throughout the experiment, which means that the rate was small compared with those of the other species of algae

DOI: http://dx.doi.org/10.15666/aeer/1704_77157725

(*Fig. 5*). The results of the 3-way ANOVA did not show any significant difference in the Cladocera, algae and concentration ($p > 0.05$) (*Table 1*). Based on the fact that at $p < 0.05$, the ingestion rate of algal species varied significantly between the algal concentrations for the eight time intervals.

Discussion

This paper focused on the outcomes of grazing rates of three cladocerans species in six single species of algae. The selection of zooplankton and algal species was based on the most common species found in Myponga and South Para Reservoirs. The mean body size of adult animals cultured in the laboratory was larger than those of the ones collected from the reservoirs, probably due to biotic factors such as predation, competition, and disease. To gain the maximum grazing rate, adult size was chosen for the experiments as representatives of all the body sizes present in the culture tanks.

In terms of quality, the six species of algae used were divided into two categories. The first one consisted of *A. falcatus*, *S. obliquus*, *C. vulgaris* and *C. reinhardtii*; all of them are edible algae. The other category included *M. flos-aquae* and *A. circinalis*, which are potentially toxic blue-green algae that require the cells to break away from the colony and filament before ingestion. In fact, cultured *M. flos-aquae* grew in smaller colonies than in their natural habitat. This observation corroborates that of Benndorf and Egerer (1981), which say that *Microcystis* change cell size and/or colony size in the culture. However, results obtained from the experiments may not be representative of their grazing behaviour in their natural environment.

In this experiment, 2-hr incubation periods for all zooplankton species were chosen. This was based on the pilot study, which showed that the zooplankton started to produce offsprings after two hours of incubation. Thus, it would not be relevant to measure feeding rates over longer periods because they might result in measurement bias. Moreover, within a 2-hr period, the animals' guts were believed to be full, thus they would produce faecal while they are simultaneously feeding. Further work on *D. magna* by Lotocka (2001) revealed that the intestines of adult individuals fed with mixture of *S. microspina* and *C. kessleri* were completely filled with food within 45 min while 50% of their guts would be full when exposed to *Aphanizomenon flos-aquae* after 30 min. Although the duration of this experiment was considered shorter than the findings in past literatures, the results are believed to be sufficiently accurate to determine the feeding rate of zooplankton on the selected foods. Even though in

previous literatures various grazing methods have been applied, this study chose to measure them via spectrophotometer, as this is the common method to measure cell density. Moreover, the method is simple, quick and yields reliable results. However, the accuracy of the results can be improved by using more replicates of samples, cautiously.

In this study, zooplankton ingested at large amount of food at the beginning of the experiment. Indeed, a higher ingestion rate was expected at the first part of the time interval due to the 24-hr starvation period before the incubation. Acclimatization time was set for 24 hr prior to carrying out the grazing experiment, as some cladocerans would die when starved for more than 24 hr. Subsequently, all the starved animals were exposed to a single alga species in different concentrations. Apparently, the animals tested fed at reduced rate at low concentrations, but fed at their maximum rates when exposed to the high concentrations of algae. Ingestion rate was dependent on the density of food until a certain critical concentration, after which the ingestion rate became constant. Previous literatures supported this general pattern (Rothhaupt, 1990; Navarro, 1999). The results of ingestion rate for six species of algae at three cell concentrations affirmed the model by McMahon and Rigler (1965) and agreed with the ILL value obtained by Kersting and Leeuw (1976). Although the observations of algal concentrations may not be sufficient to establish this result absolutely, the result was reliable and able to show how the feeding behaviours changed in different cell concentrations.

D. carinata ingestion rate was higher than that of *D. lumholtzi* and *C.* cf. *quadrangula* for both blue-green algae *M. flos-aquae* and *A. circinalis*. However, the ingestion rates were significantly lower in *A. circinalis* filamants, compared with *M. flos-aquae*. This may be due to the ability of the grazers to break the small colonies of *M. flos-aquae*, making them easier to graze compared with 50 – 100 μm of *A. circinalis* filaments during ingestion. Some scientists (Geller and Muller, 1981; Gliwicz and Lampert, 1990) pointed out that it could possibly be due to the size restrictions and rejection, while Infante and Litt (1985) and Hartmann and Kunkel (1991) concluded that the reasons were excessive handling time and poor interception of filaments when compared with non-filamentous algae. Further evidence from observations by Kirk and Gilbert (1992) showed that the presence of *Anabaena* filaments causes an increase in post-abdominal rejections in the large *Daphnia pulex*. Therefore, the findings of the present study are in accord with those of previous studies that reported lower grazing rates of *A. circinalis*.

On the other hand, in this study, *C.* cf. *quadrangula* ingested at the lowest rate when exposed to the single *A. circinalis* suspension, and followed by *D. lumholtzi*. Thus, clearly the ingestion rate decreased with increasing body size. This has been confirmed by investigations that indicated that small cladocerans are more able to avoid *Anabaena* cells than larger cladocerans, probably due to their smaller size, which forbids them to ingest the large *Anabaena* filaments (Kirk and Gilbert, 1992).

Even though the algae were potentially toxic species, the observation on ingestion rate in unialgal suspension of *M. flos-aquae* showed that the three species of Cladocera ingested the potentially toxic form of algal colony (Ismail et al., 2015). Many studies (Fulton, 1988; DeBernardi and Giussani, 1990; Kirk and Gilbert, 1992; Repka, 1996; Kurmayer and Juttner, 1999) have shown subtle toxic effect on fecundity and survival rate of zooplankton fed on cyanobacteria. However, the consequences were not considered in the short-term experiments. Some authors demonstrated that food size affects the differences in the ability of zooplankton to graze on algal species (Persson,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77157725

1985; Borsheim and Andersen, 1987; Urabe et al., 1996). Ingestion rates of *A. falcatus* (2.3 µm), *C. vulgaris* (3.3 µm) and *M. flos-aquae* (1.9 µm) by the three species of Cladocera were confirmed to be faster than those of *S. obliquus* (4.2 µm), *C. reinhardtii* (4.4 µm) and *A. circinalis* (5.8 µm). Undoubtedly, the three species of Cladocera preferred to graze on smaller sized cells. The cell size of *S. obliquus*, *C. reinhardtii* and *A. circinalis* might be too large for ingestion or to pass through their mouth gapes. According to Gliwicz (1980), the uptake of large particles by zooplankton is limited by the opening width of carapace gap.

Under laboratory conditions, *M. flos-aquae* grow in smaller colonies than in their natural ecosystems. Moreover, the suspension has been dispersed with strong shaking before the experiments to obtain the maximum ingestion rate. Apparently, the grazers can handle small colonies of *M. flos-aquae* efficiently compared with the filamentous form of *A. circinalis*. Possibly the cells of *M. flos-aquae* are more easily separated and ingested than the filamentous form of *A. circinalis*.

Despite the factor of particle size, differences in the grazability of algal species might be due to several other factors which can be considered, such as cell wall characteristic (Horn, 1981), flagella (DeMott, 1982), spines (Schnack, 1979), gelatinous sheath (McNaught et al., 1980), taste (Poulett and Marsot, 1978) and digestion (Porter, 1976). Knisely and Geller (1986) pointed out that smooth-walled species such as *Chlorella* would be possibly swept away after they are first captured. On the other hand, *A. circinalis* is a poor food for zooplankton due to the toxic strain that might affect the growth and the reproduction of Cladocera.

Furthermore, the results of this present study showed that ingestion rate varies with body size. The result is in agreement with those of other studies, which supported the size-efficiency hypothesis described by Brooks and Dodson (1965) which says that larger zooplankton body sizes provide a greater filtering capacity. The largest animal tested, *D. carinata* ingested at the highest rate among all algal species compared with the intermediate-sized *D. lumholtzi* and the small-sized species of *C.* cf. *quadrangula*. This outcome agrees with the results obtained by Geller and Muller (1981) who indicated that smaller sized grazers may have smaller carapace gaps and mesh sizes.

As observed in the experimental results, feeding behaviour of zooplankton depends on several factors when they are offered as food, algae as a single diet in terms of size, structure, quality and concentration as food. Besides, differences in body size certainly influence grazing efficiency between zooplankton species. Therefore, a combination of these factors may increase or decrease grazability despite the abiotic factors during the experiment.

Conclusion

The ingestion rate varies depending on the cladocerans' body size and species. In terms of feeding efficiency, larger cladocerans can ingest larger food items than smaller species. Algal size and concentration are major factors affecting the ingestion rate of cladocerans. Different sized algae were grazed at different efficiencies. Feeding on small and large particles appears to be qualitatively different. *D. carinata* ingested the largest food items most efficiently followed by *D. lumholtzi* and *C.* cf. *quadrangula*. The success of *D. carinata* may be explained partly by its ability to feed effectively on a variety of food organisms with a wide spectrum of cell sizes.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77157725

A. circinalis has the lowest rate of ingestion among all grazers. However, all the Cladocera tested do feed on colonies of *M. flos-aquae* at a comparable rate. In the present study, zooplankton feed on both green algae as well as potentially toxic algae, hence, may control the algal biomass in the water column.

In conclusion, the study has determined the feeding rate of zooplankton under laboratory culture conditions, which has been assumed to be close to the natural environment, even though the food concentrations and temperatures varied in both situations. The information on the ingestion of cladocerans can provide useful knowledge for practising efficient management and ideally, for the sustainability of the ecosystem. Undeniably, the results presented here are still limited and considered as preliminary to yielding a better understanding of the grazing and selectivity behaviours of zooplankton in drinking water reservoirs. Thus, it is hoped that future studies will uncover additional information and render some improvements such as using more species of zooplankton and algae at more varied cell concentrations.

Acknowledgements. Appreciation and thanks are due to Peter Baker, Peter Hobson, Steve Amos and Hossain Siddiqui for generously provided cultures of the algae and for advice on maintaining laboratory cultures.

Abstract. In this study, the concept of functional feeding groups was used to classify zooplankton community into functional groups among three seasons (spring, summer and autumn). A total of 30 zooplankton species were sampled in the Tuanjie Reservoir and identified into seven functional groups. Environmental factors and zooplankton functional group biomass were both varied in spatially and seasonally. Water transparency (SD), dissolved oxygen (DO), pH, N:P and dissolved iron (Fe^{3+}) were higher in autumn while total phosphorus (TP), chemical oxygen demand (COD_{Mn}) and dissolved copper (Cu^{2+}) were higher in spring, and temperature (T) and ammonium nitrogen (NH_4^+-N) were higher in summer. Zooplankton functional groups biomass was higher in summer, followed by spring and autumn. In spring, zooplankton functional group only dominated by group PF, while in summer and autumn dominated by group PF and RF. Spearman and RDA results showed that SD, conductivity (COND), DO, NH_4^+-N, nitrate nitrogen (NO_3^--N) and COD_{Mn} were the major factors influencing zooplankton functional groups in Tuanjie Reservoir.
Keywords: *seasonal dynamics, zooplankton functional groups, abundance and biomass, northeast of China*

Introduction

Zooplankton is found in almost all kinds of waterbodies. Compared with other aquatic animals, they are small in size, numerous in numbers and have strong metabolic activities. They feed on phytoplankton, bacteria, fragments and other organisms. Zooplankton also participates in the decomposition and circulation of organic matter in the water ecosystem through excretion and secretion, energy transfer from the primary producers to higher consumers (Wetzel, 2001). Variation of zooplankton can influence the structure of other nutrient levels in water ecosystems (Beaugrand et al., 2000; David et al., 2005; Lobry et al., 2008; Steinberg and Condon, 2009). The zooplankton community structure, their abundance and biomass is influenced by top-down and bottom-up control (Jeppesen et al., 2003), and is one of determinants for water quality (Jeppesen et al., 2011). This is due to the interaction between biological organisms and environmental factors (Ejsmont-Karabin and Karabin, 2013).

Traditional methods of zooplankton classification are usually based on the taxonomy system. However, it is difficult to reflect the aquatic ecological function. Therefore, ecologists have put forward the concept of functional groups, species characteristics of the functional group more closely in touch with environment, through the study of functional groups, can more directly reflect the ecological process of ecological

DOI: http://dx.doi.org/10.15666/aeer/1704_77277740

environmental impact of aquatic biological communities (Hood et al., 2006). In recent years, the use plankton functional groups have been applied in several studies of biogeochemical models (Anderson, 2005). Zooplankton is divided into three functional groups: mico-, meso- and macrozooplankton (Quéré et al., 2010). By using the concept of functional groups, zooplankton community composition can be used to model the ecosystem process of the aquatic ecosystem and it is also conducive to analyzing the seasonal variation of zooplankton community (Sun et al., 2010).

Tuanjie Reservoir was built in 1981 with the aim of supplying drinking water to the local village people. The main sources water of the reservoir is Muling River, which is the largest tributary of the Ussuri River on the left bank of the border between China and Russia. In this study the concept of functional feeding groups was used to reveal the seasonal variation of zooplankton functional groups in relation to environmental factors in Tuanjie Reservoir. Understanding the variation of zooplankton functional groups biomass in relation to environmental factors is very important to better understand the environmental factors that significantly structure the zooplankton community in the reservoir. This study aims at: (1) identifying and classifying zooplankton species of Tuanjie Reservoir into functional group, and (2) to determine the seasonal and spatial dynamics of the biomass of zooplankton functional groups and their relationship to environmental factors. We hypothesized that seasonal and spatial change in biomass of zooplankton functional groups will be strongly influenced by environmental factors.

Materials and methods

Study area

Tuanjie Reservoir (130°8'-130°11'E, 44°01'-44°04'N) is located in the southeast of Heilongjiang Province Northeastern China (*Fig. 1*). The reservoir was built in 1981 in order to control floods, provide water for irrigation, fish farming, power generation and for aesthetic value. Tuanjie Reservoir has a surface area of 445 km^2, a capacity of 8.63×10^7 m^3 and it shaped like big "Y". The region where located the reservoir is influenced by temperate continental monsoon. The average annual evaporation and precipitation of the reservoir are 950 mm and 534 mm, respectively. The annual mean temperature is 1 °C, which ranged between -44.1 °C to 37.6 °C. In winter, the surface water of the reservoir is covered by ice.

Field sampling and laboratory analysis

Based on the reservoir shape, 5 sampling sites (*Table 1*) were selected for sampling on spring (May), summer (July) and autumn (September). Samples were collected from top (0.5 m from the surface water), middle and bottom (0.5 m from the waterbed) of water column according to the different water depth among sites inside the Tuanjie Reservoir (*Fig. 1*). At every sampling site, water temperature (T), pH, conductivity (COND), dissolved oxygen (DO) was measured in the field using a portable multi-probe (YSI 6600, YSI Inc.). Water transparency (SD) and depth (D) were measured using Secchi disk and longline method. Triplicate water samples for chemical analyses were collected at each sampling sites and put on acid-washed plastic bottles, placed in ice box and transported to laboratory for analysis. The concentration of total nitrogen (TN), total phosphorus (TP), N:P ratio (N:P), ammonium nitrogen (NH_4^+-N), nitrate nitrogen (NO_3^--N), chemical oxygen demand (COD_{Mn}) and dissolved iron (Fe^{3+}) and dissolved

DOI: http://dx.doi.org/10.15666/aeer/1704_77277740

copper (Cu^{2+}) were measured according to the standard methods for China (MEP, 2002).

S2	N44°03'36"	E130°10'48"
S3	N44°03'00"	E130°09'36"
S4	N44°04'12"	E130°10'36"
S5	N44°04'48"	E130°10'48"

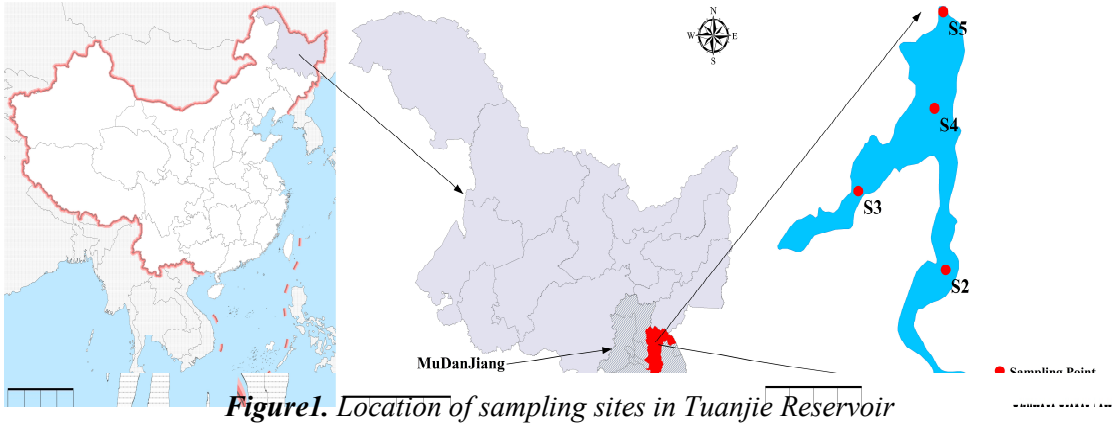

Figure1. *Location of sampling sites in Tuanjie Reservoir*

Zooplankton samples (20 L water filtered through 64 mm mesh size) were fixed with formaldehyde solution (4% concentration). Protozoa and rotifera samples were obtained by taking 1 L subsamples to form the 20 L pooled sample. The samples were preserved with Lugol's iodine and formaldehyde and allowed to sediment in 1 L jar for at least 48 h. The supernatant water was carefully removed and the residue was then collected and made to a known volume of 30 mL (Thompson et al., 2013). Identification and counting of the zooplankton specimen were using an inverted microscope at 400× magnification following the species keys (Chen, 1974; Chiang and Du, 1979; Yeatman, 1959). We calculated zooplankton functional group biomass by using dry weight (mg) obtained from length-weight relationship of the filtered water volume (L) (Zuo et al., 2003).

Zooplankton functional groups classification

Zooplankton species in Tuanjie Reservoir were classified into seven functional groups mainly according to body size/length and feeding mode (Benedetti et al., 2018; Ma et al., 2019; Mwagona et al., 2018). The seven functional groups are: group PF (protozoa filter feeders), group RF (rotifera filter feeders), group SCF (small copepods and cladoceran filter feeders, body size < 0.7 mm), group MCC (middle copepods and cladoceran carnivore, body size 0.7~1.5 mm), group MCF (middle copepods and cladoceran filter feeders, body size 0.7~1.5 mm), group LCC (large copepods and cladoceran carnivore, body size > 1.5 mm) and group LCF (large copepod filter feeders, body size > 1.5 mm).

DOI: http://dx.doi.org/10.15666/aeer/1704_77277740

Data analysis

Statistical analyses were carried out using the SPSS 19.0 software. Variation and correlation of environmental factors and biomass of zooplankton functional groups in different seasons were analyzed by using One-way ANOVA and Tukey's honesty significant difference (HSD) tests, and Spearman analysis, respectively. Relationship between zooplankton functional group biomass and environmental factors was done using CANOCO 4.5 software (Microcomputer Power, New York, USA). Before analysis, the biological and abiotic data were transformed by $\log_{10}(x + 1)$ to satisfy the normal distribution. We found that the detrended corresponding analysis (DCA) of the largest gradient length of the four axes was 1.889 (< 3). Therefore, linear ordination method of the redundancy analysis (RDA) was used to reveal the relationship. Monte Carlo simulations with 499 permutations were used to test the significance of the environmental factors in explaining the biomass of zooplankton functional groups data in the RDA.

Results

Seasonal variation of environmental factors

The mean values of environmental factors presented among seasons are shown in *Table 2*. Most of the factors varied significantly (One-way ANOVA and Tukey HSD test). The mean values of D, COND, TN and NO_3^--N were not statistically significant difference among the seasons ($P > 0.05$). While the mean values of DO, pH, NH_4^+-N, COD_{Mn}, Fe^{3+}, Cu^{2+}, T, TP, N:P and SD varied significantly with seasons ($P < 0.05$). The minimum mean values of DO, pH, N:P and Fe^{3+}were observed in summer, while their maximum values were observed in autumn except for COD_{Mn}. On the contrary, the maximum mean values of T and NH_4^+-N were observed in summer and minimum presented in autumn.

Table 2. *The seasonal variations (mean ± SE, n = 32) of environmental factors: water transparency (SD), depth (D), conductivity (COND), dissolved oxygen (DO), pH, water temperature (T), total nitrogen (TN), total phosphorus (TP), N:P ratio (N:P), ammonium nitrogen (NH_4^+-N), nitrate nitrogen (NO_3^--N), chemical oxygen demand (COD_{Mn}) and dissolved iron (Fe^{3+}) and dissolved copper (Cu^{2+}), P-value from One-way ANOVA and a, b, c mean differences between the seasons were tested by post-hoc test using Tukey HSD ANOVA*

Variation of zooplankton functional groups in Tuanjie Reservoir

A total of 30 zooplankton species belonging to 25 genera and four taxonomic groups including protozoa (33.33%), rotifera (36.67%), cladoceran (16.67%) and copepods (13.33%) were identified in the Tuanjie Reservoir (*Table 3*). The biomass of zooplankton functional groups showed seasonal and spatial variation (*Figs. 2* and *3*). Summer recorded the highest number of zooplankton species (20) followed by spring (19) and autumn (17). In summer, the dominant zooplankton functional group was PF mainly comprised by *Paramecium* (43.81%) and *Didinium nasutum* (37.55%), and RF which was presented by *Keratella cochlearis* (3.27%) and *Polyarthra trigla* (2.03%). While in spring, the dominant zooplankton functional group PF was presented only by *Paramecium* (74%). In autumn, the dominant zooplankton functional group PF was contributed by *Paramecium* (44.82%) and that of group RF was *Keratella cochlearis* (26.89%).

Correlation of zooplankton functional groups and environmental factors

The Spearman correlation analysis of zooplankton functional group biomass and environmental factors were listed in *Tables 4* and *5,* respectively. Group PF influenced RF, and group LCC influenced SCF and LCF. The feeding relationship of zooplankton functional groups has been proved by the results. Meanwhile, most environmental factors were correlated with zooplankton functional groups. Like group LCC, was significantly influenced by SD ($r = 0.374$), T ($r = 0.347$), NH_4^+-N ($r = 0.494$) and COD_{Mn} ($r = -0.541$). Groups MCF was negatively correlated with NO_3^--N ($r = -0.419$) and COD_{Mn} ($r = -0.541$). Other side, COND was positively correlated with group PF ($r = 0.407$), RF ($r = 0.392$) and SCF ($r = 0.477$). However, the DO and NH_4^+-N was only significant positively correlated with group MCC ($r = 0.386$) and LCF ($r = 0.410$) respectively.

RDA analysis between zooplankton functional groups and environmental factors

The results of Monte Carlo test showed that the first canonical axis and all canonical axes were significant ($F = 13.521$, $p = 0.002$; $F = 1.130$, $p = 0.002$; 499 random permutations). The eigenvalues of the four axes were 0.429, 0.033, 0.015, 0.004, respectively (*Table 6*). The functional groups-environment correlations for Axis 1 and Axis 2 were 0.686 and 0.691, respectively. The first two axes account for 46.2% of functional groups-environment variables relation (axis 1: 42.9%, axis 2: 3.3%) and 98.8% of the functional groups variables (axis 1: 91.7%, axis 2: 7.1%). Axis 1 was mainly positive correlated with pH ($r = 0.728$) and DO ($r = 0.683$) and negatively correlated with T ($r = -0.672$). Axis 2 was positively correlated with NH_4^+-N ($r = 0.602$), SD ($r = 0.481$) and negatively correlated with COD_{Mn} ($r = -0.658$), Fe^{3+}($r = -0.501$). Groups PF was positively related with pH, COND and COD_{Mn}, and negatively related with T, NH_4^+-N, NO_3^--N and Cu^{2+}. Group RF, SCF, MCF, LCF and LCC were positively related with NH_4^+-N and SD, and negatively related with COD_{Mn}, Fe^{3+}, DO, $Cu^{2+}$and NO_3^--N. Nevertheless, the group MCC was not related with most of environmental factors (*Fig. 4*).

Table 6. *RDA results of zooplankton functional group biomass*

Axes	Eigenvalues	Species-environment correlations	Cumulative percentage variance of species data	Cumulative percentage variance of species-environment relation

3	0.015	0.563	46.8	100
4	0.004	0.468	46.8	100

Discussion

Zooplankton, as an important part of the food chain in the aquatic ecosystem, is mainly composed of free-living protozoa, rotifera, cladocera and copepod. Zooplankton is very sensitive to environmental changes and hence considered as good indicator. Many previous studies focused on zooplankton community structure in relation to environmental factors (Bachiller et al., 2018; Coz et al., 2018; Jeppesen et al., 2011; Li et al., 2014; Matsuzaki et al., 2018; Neumann-Leitão et al., 2018). Recently, using functional groups to reveal the reaction of environmental factors are considered as a new method (Ma et al., 2019; Mwagona et al., 2018; Shi et al., 2015; Sun et al., 2010). Functional groups are species with similar morphological and physiological traits (Reynolds et al., 2002). In marine ecosystems, six functional groups have been classified according to zooplankton species individual size and feeding habits from the yellow sea (Sun et al., 2010). In Western English channel, the researchers analyzed the food web using three zooplankton functional groups (Araújo et al., 2006). On the other hand, in freshwater ecosystems, six and eight zooplankton functional groups have been confirmed in Small Xingkai Wetland Lake and Xiquanyan Reservoir in Heilongjiang Province, Northeast of China, respectively (Ma et al., 2019; Mwagona et al., 2018). In our study, we identified 30 species belonging to seven zooplankton functional groups in Tuanjie Reservoir, including group PF, RF, SCF, MCC, MCF, LCC and LCF.

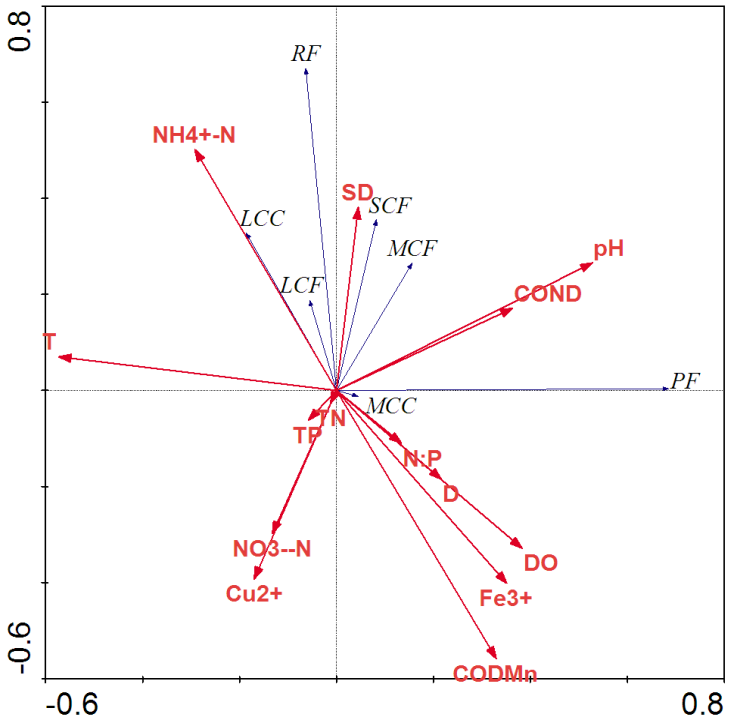

Figure 4. *RDA bioplot of zooplankton functional groups and environmental factors, water transparency (SD), depth (D), conductivity (COND), dissolved oxygen (DO), pH, water temperature (T), total nitrogen (TN), total phosphorus (TP), N:P ratio (N:P), ammonium nitrogen (NH_4^+-N), nitrate nitrogen (NO_3^--N), chemical oxygen demand (COD_{Mn}) and dissolved iron (Fe^{3+}) and dissolved copper (Cu^{2+}). PF (protozoa filter feeders), RF (rotifera filter feeders), SCF (small copepods and cladoceran filter feeders), MCC (middle copepods and cladoceran carnivore), MCF (middle copepods and cladoceran filter feeders), LCC (large copepods and cladoceran carnivore), LCF (large copepod filter feeders)*

Composition and variations of zooplankton functional groups in Tuanjie Reservoir

Seasonal and spatial variations of zooplankton biomass were demonstrated in aquatic ecosystems by Dube et al. (2017). In this study, the biomass of zooplankton functional groups varied significantly differences among seasons and sites. The mean values of biomass reported in spring (0.91 mg/L), summer (1.70 mg/L) and autumn (0.79 mg/L) were higher than those recorded by Mwagona et al. (2018) in the oligotrophic Xiquanyan Reservoir during spring (54.25 µg/L), summer (245.81 µg/L) and autumn (196.54 µg/L) and also higher than those found by Ma et al. (2019) in Small Xingkai Lake during spring (0.28 mg/L) and autumn (0.72 mg/L) in the same province. Mwagona et al. (2018) found that low nutrients level, which unable to meet the demand of the growth of zooplankton. While, Ma et al. (2019) noted that nutrient-rich level could promote the zooplankton breeding, and high turbid with low transparency also may contribute to zooplankton avoid predators.

As shown in *Figure 2,* during spring and summer seasons, zooplankton biomass was both dominated by protozoa filter feeders (group PF) accounting for 90.68% and 84.8% of total biomass, respectively. In spring, group PF mainly composed of *Paramecium sp.* (74%), while in summer mainly composed of *Paramecium sp.* (43.81%) and *Didinium nasutum* (37.55%). Group PF (protozoa filter feeders) are filter feeding on bacteria, algae and organic detritus and found in all sampling sites and water layer. We found

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77277740

that the biomass of group PF in summer was significantly higher than that in spring probably due to higher temperature and nutrients contributed to algae growth of their food resources (Duggan et al., 2001; Špoljar et al., 2010), and higher water transparency help them locate prey more clearly and predation activities more easily (Ma et al., 2019). Besides, *Didinium nasutum* could use their flagella enhance swimming ability in favor of avoiding predators and harvesting suitable light and food for growth, therefore became an dominant species (Bovo-Scomparin and Train, 2008). In autumn, zooplankton biomass was dominated by protozoa filter feeders (group PF) and rotifera filter feeders (group RF) accounted for 53.17% and 34.34% of total biomass, respectively. Group PF mainly composed of *Paramecium sp.* (44.82%) and group RF mainly composed of *Keratella cochlearis* (26.89%). This could be due to higher temperature in summer was suitable for rotifera breeding in large numbers (Galkovskaja, 1987), so they formed a dominant species in autumn. Another reason could be some environmental factors such as nutrients and turbidity can influence rotifera community structure in autumn (Armengol et al., 1998; Ma et al., 2019), and finally, it leads to the change of the structure and composition of zooplankton community. Moreover, other zooplankton functional groups preyed by their predators such as *Hypophthalmichthys molitrix* and *Aristichthys nobilis*, and some competitive interactions between those functional groups lead to relative low biomass among sampling sites and seasons in the reservoir during study (*Fig. 3a* and *b*).

Driving factors of zooplankton functional groups in Tuanjie Reservoir

There are so many driving factors influence the zooplankton community structure in aquatic ecosystems (Li et al., 2014; Ma et al., 2019; Mwagona et al., 2018; Shi et al., 2015; Sun et al., 2010). Among zooplankton functional groups, group MCF was positively correlated with group RF, and group LCC were both positively correlated with group SCF and LCF, which could due to intraspecific competition (*Table 4*). However, between environment and zooplankton, water depth did not affect the distribution of zooplankton functional groups (*Table 5*). Similarly, there was seemingly no significant variation in the abundance patterns of the dominant zooplankton taxa in response to changing pH value (Morgan, 1985a). The Spearman correlation results showed that pH was not related with the biomass of zooplankton functional groups in Tuanjie Reservoir (*Table 5*). The fluctuation of pH value in the freshwater ecosystem was primarily the result of enhanced primary productivity (Morgan, 1985b). Further studies also proved that the density of zooplankton individuals is influenced by the primary producers phytoplankton biomass (Trevisan and Forsberg, 2007).

On the other hand, this present study showing that nitrogen and phosphorus can usually be considered the main limiting nutrient (Fasham et al., 1990; Shumka et al., 2018). While in our study, both Spearman correlation and RDA results showing that the zooplankton functional groups were not affected by TN, TP and N:P ratio in Tuanjie Reservoir (*Table 5; Fig. 4*). That could be due to trophic level weakened their effect on plankton community in the reservoir, because an increase in trophic state can caused an increase in the total numbers of crustaceans (Ejsmont-Karabin and Karabin, 2013). The Spearman correlation and RDA results both showed that NH_4^+-N was positively influence group LCC and LCF, and NO_3^--N was negatively influence group MCF (*Table 5; Fig. 4*).

Metallic element concentrations were strongly correlated with plankton structure and biomass composition (Long et al., 2018). Such as iron (Fe) considered as important

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77277740

nutrient affecting the growth of phytoplankton (Alderkamp et al., 2015). Some phytoplankton species can take up Fe through their specialized transport mechanisms (Morel et al., 2008). Some researchers also found that zooplankton could directly obtain enough Fe to maintain growth (Baines et al., 2016). Similarly, copper (Cu) plays an important role in the physiology of natural plankton communities (Semeniuk et al., 2009). In Tuanjie Reservoir, there was no relationship among metal ion (Fe^{3+}, Cu^{2+}) with the biomass of zooplankton functional groups, which results consistent with RDA (*Table 5, Fig. 4*). We suspect that could be the zooplankton functional groups affected by the top-down and bottom-up control in the food webs (Carvalho, 1994; Prowe et al., 2012; Sinistro, 2010; Stephen, 2010; Sun et al., 2013). This proof confirmed a complex interaction between Fe and Cu physiology in plankton communities (Semeniuk et al., 2016). Besides, the primary correlated factors included chlorophyll a levels, cyanobacterial toxin levels, and temperature, suggesting that both phytoplankton biomass and composition play important roles in zooplankton dynamics (Srifa, 2010).

In addition, turbulence and turbidity of water column intensified the competition among zooplankton species (Zhou et al., 2018). These environmental factors should be considered as the new influencing variables in Tuanjie Reservoir for further studies in the future.

Conclusion

In this study, a total of 30 zooplankton species belonging to protozoa, rotifera, cladoceran and copepod were identified and classified into seven functional groups including PF, RF, SCF, MCC, MCF, LCC and LCF. Both environmental factors and zooplankton functional groups biomass in Tuanjie Reservoir varied seasonally and spatially. SD, DO, pH, N:P and Fe^{3+}were significant higher in autumn, while TP and T was higher in spring and summer. Zooplankton functional group biomass was higher in summer (0.62 mg/L), followed by spring (0.33 mg/L) and autumn (0.29 mg/L). In spring group PF was the dominant functional group, while in summer and autumn group PF and RF were both the dominant functional group. SD, COND, DO, NH_4^+-N, NO_3^--N and COD_{Mn} considered as the major factors influence zooplankton functional groups in Tuanjie Reservoir. Group PF was positively correlated with pH and COND while negatively correlated with T. Groups RF, SCF and LCC were positively influenced by NH_4^+-N and SD, while negatively influenced by COD_{Mn}, Fe^{3+}, DO, $Cu^{2+}$and NO_3^--N.

Acknowledgements. We thank to the leaders and workers from Muling city Fendou Reservoir construction headquarters for their assistance and support during field sampling work. The study was supported by programs of the National Key Research and Development Program of China (Grant No. 2016YFC0500406).

Abstract. The aim of the study was to evaluate the sediment prediction performance of Revised Universal Equation (RUSLE) and Musgrave Equation at the Ekinli pond catchment, North central part of Turkey. Ekinli pond was built in 1977 for irrigation purposes. The accumulation of sediment in the ponds negatively affects their functions. There are many dams located within the study area whose operations have been adversely affected by excessive reservoir sedimentation. Accurate estimation of sediment deposition is important in the design of a pond. The calculated amount of sediment volume deposited in the Ekinli reservoir was 21600.75 m^3 and the average sediment yield was 514.3 m^3 y^{-1} between 1977 and 2018. In the Ekinli basin, the availability of bathymetry measurements between 1981 and 2006, provided the appropriate conditions to validate the results of the predicted sediment yield since the deposited sediment volume could be quantified as 552.3 m^3 y^{-1}. The measured and estimated sediment amounts for the Ekinli reservoir have shown an excellent accordance. In the 42-year time period, 6.74% of the water storage capacity of the pond has been lost. From 1977 to 2000, the entire basin was grassland and 38% of the basin area has been afforested. The landuse change reduced a little the amount of sediment in the reservoir. The Mann–Kendal and Theil–Sen Slope estimator statistics indicated a decreasing trend of sediment amount.

Introduction

Generally, arid and semi-arid ecosystems, where limited rainfalls, floods, droughts and high population restrict rainfed crop production. For the solution of the problem, ponds present a significant contribution as a water conservation structure. The benefit of ponds is to keep water during periods of peak flows, thus preventing flood disasters, and then permit gradual release of water during periods of lower flows.

Pond construction involves high costs and environmental risks. In spite of this, they are built by taking into consideration of the benefits. All ponds negatively affect surface and subsurface hydrology, the aquatic environments of rivers, natural life. But those effects are often negated by the stated purpose of pond as being flood control, irrigation, drinking water supply and other functions. The expected life of a pond is essential for the evaluation of its function, viability, and the economic feasibility. The most important threat on the life of a pond is sedimentation. Deposition of sediment reduces reservoir's active water storage volume and hereby shortens its useful life. It has been reported that the reservoir capacity of world are decreasing each year about 0.5–1.0% (World Bank, 1998; World Commission on Dams Report, 2000). Soil erosion stands as the major factor controlling sedimentation of reservoirs in semi-arid regions (Wang et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

al., 2016); soils are usually shallower with sparse vegetation, low soil structural stability, non-negligible slopes and intense rainstorms (Cheviron et al., 2011; Gourfi et al., 2018). The useful life of reservoirs is limited by the excess sediment accumulation within the pond (Alighalehbabakhani et al., 2017). Several important factors such as climate change, glacial processes, and human induced activities (urbanization, deforestation, and changes in farm practices) in the watersheds can cause in accelerated soil erosion rates (Jordan et al., 2014; Toy et al., 2002).

There are several erosion models to estimate soil erosion in a field or a basin. One of them is USLE/RUSLE model (Wischmeier and Smith, 1978; Renard et al., 1997). The RUSLE, an empiric model, is a revised form of USLE model. The USLE/RUSLE is one of the most widely used soil erosion model worldwide, as well as in Turkey. Since this model is an erosion model, it needs sediment delivery ratio (SDR) to use in sediment calculations (Jobin et al., 2018). The RUSLE/SDR model has been widely used to evaluate soil erosion and sediment yield in numerous locations due to high efficiency and ease of implementation (e.g., Poirier et al., 2016; Gelagay, 2016; Yan et al., 2018; Ebrahimzadeh et al., 2018; Das et al., 2018; Wijesundara et al., 2018).

The RUSLE model is used with a calibrated SDR to obtain a simulated suspended sediment yield, which was compared with the observed values in 42 catchments of Morocco. The long-term observed values of sedimentation in all selected reservoirs in Morocco showed an annual mean sediment yield of 1.51 million m^3. A very strong positive relationship was determined between sedimentation in reservoirs and the corresponding drainage areas. The combination of RUSLE and SDR gave a very strong correlation with the observed suspended sediment yield (Gourfi et al., 2018).

The bathymetric measurement technique can be used to measure sediment yield in a reservoir by subtraction of the pre topographic elevations from current topographic elevations of a reservoir. This technique gives a possibility to compare between simulated sediment estimation to real sediment data in a reservoir.

In the Great Lakes watershed, the sediment accumulation rates of twelve reservoirs were evaluated using the Soil and Water Assessment Tool (SWAT). The estimated sediment accumulation rates by SWAT were compared on radionuclide dating of sediment cores and bathymetric survey methods. Based on the sediment accumulation rate, the remaining reservoir capacity for each study site was estimated. Evaluations of the anthropogenic impacts including land use change and pond construction on the sediment yield were assessed in this research. The regression analysis indicated a strong correlation between sediment yield and drainage area (Alighalehbabakhani et al., 2017).

In the present work, potential soil erosion of Ekinli basin and the sediment accumulation rate within the Ekinli reservoir was assessed by Revised Universal Equation (RUSLE) and Musgrave Equation, using the Geographic Information System (GIS)-based approach for reservoir sediment storage and post and pre-construction pond capacity. The objectives of this study are:

- The validation of applied sediment estimation method by comparing the sediment yields measured with the bathymetric surveys and calculated by some equations.
- To estimate the yearly sediment accumulation rate in the reservoir and predict the remaining capacity of the pond.
- To determine the effect of the partly afforestation on sediment yield in Ekinli basin.

DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

- To investigate the trends of rainfall and sedimentation and estimate the steepness of the slope used the Mann-Kendall for testing trend and Sen's slope estimator to determine trends of variables in Ekinli basin from 1977 to 2018.

Materials and methods

Study area

The study is carried out in the Ekinli basin in the North central part of Turkey, The reservoir was built in 1977 and its basin area is 591 ha. The Ekinli basin is located 49 km away from Tokat city (*Fig. 1*).

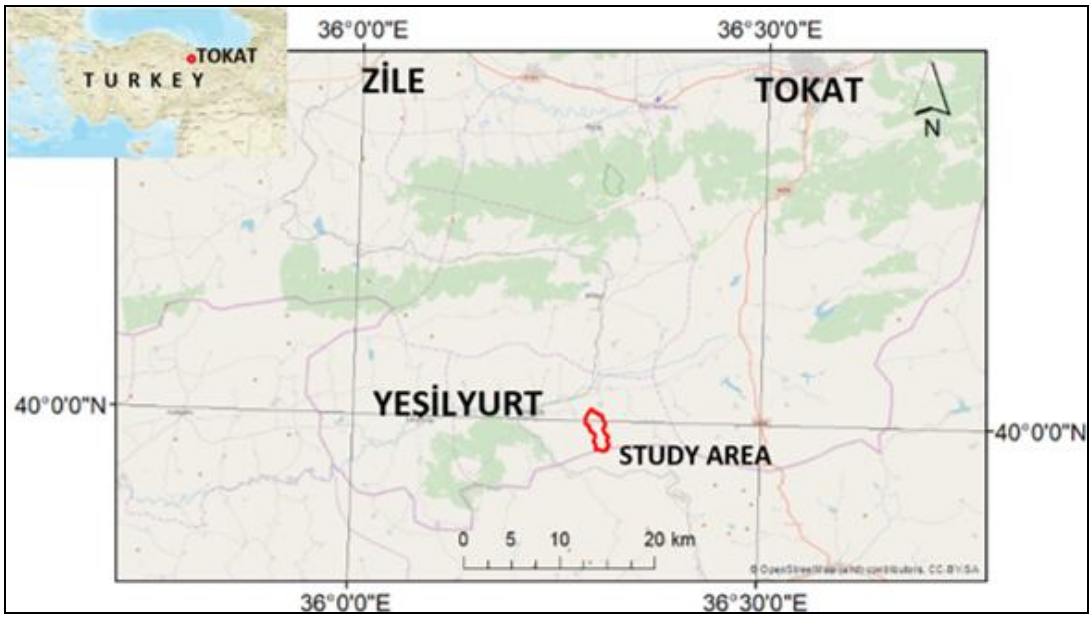

Figure 1. *The location of the study area*

The Ekinli reservoir at the Cayderesi outlet is a sub-unit of the Yesilirmak basin. Ekinli reservoir basin is located between 36°17'30"-36°18'00" latitudes and 40°00'30"-40°01'00" longitudes. The minimum and maximum elevation is 1118 m and 1440 m respectively and the average elevation is 1271 m. The digital elevation model (DEM) of Ekinli Basin is given in *Figure 2*.

The climate is semi-arid, and the annual precipitation is 419.6 mm. Approximately 49% of the annual precipitation falls between March and June. The mean annual temperature is 8.1 °C, the highest monthly temperature is in August (19.1°°C) and the lowest is in January (-2.1°°C). The mean annual evaporation is 1108 mm. The average snowy days are 22.6 in the basin.

The soils in the basin are calcareous brown forest soils with A and C profiles. Soils are generally vulnerable to degradation with steep slopes and lower vegetation density. The slope varies between 0 and 45% with an average of 26.15%.

The basin area was completely grassland up to 2000 year. In 2000, 38% of the basin area is converted to forestland. Currently, 38% of the basin area is forestland and 62% is grassland (*Fig. 3*). Some properties of Ekinli basin and reservoir are presented in *Table 1*.

Soil and sediment sampling and analyses

The coordinated soil samples from 150 locations were taken in June 2015 at the basin (*Fig. 3*). Sediment sampling was done in October when the pond was rather empty. Total 36 sediment samples were taken from crest to river discharge point through a line. Approximately 1000 cm^3 of disturbed soil was collected from 0.2 m depth, then sieved from 2 mm. The disturbed soil samples were used to determine soil organic matter and particle distribution. The undisturbed soil samples were obtained from 0 to 0.20 m by using a steel ring (0.05 × 0.05 m) to determinate saturated hydraulic conductivity and soil bulk density.

Soil organic matter was determined by Walkley-Black methods (Nelson and Sommers, 1982). Soil texture was analyzed using the hydrometer method (Gee and Bauder, 1986). Very fine sand content was measured by sieving (Soil Survey Staff, 1999). Saturated hydraulic conductivity was measured in the undisturbed cores (Black, 1965). Bulk density was determined by the core method (Blake and Hartge, 1986).

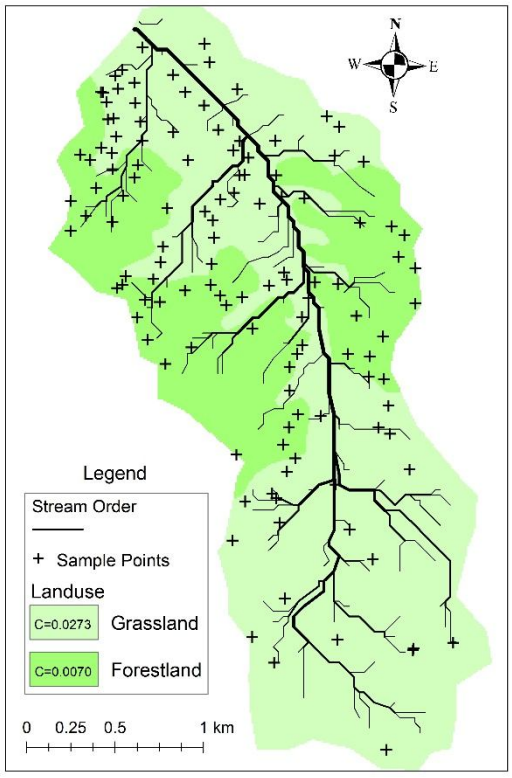

Figure 3. *Sample points, landuse and cover management factors map*

Bathymetric measurements

Bathymetric measurements of Ekinli reservoir were done three times in 1981, 1987 and 2006. The depth measurements of Ekinli reservoir were performed at 292 fix gridded points (10 × 20 m) in1981 and 1987 years. At these periods, the study was carried out at a limited number of fixed measurement points due to technical difficulties. For this purpose, iron bars were placed along both sides of the pond in order to precisely determine the fixed points. Iron bars were connected to each other by ropes during the measurement times. These ropes enabled the measurements on the same line

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

in both measurement periods. The depth measurements were performed with the 10 m interval for each line. The first two periods of measurement were done by previous researchers using a boat and a plumb. The last measurement was carried out at 11366 points with LAZ 4100 echocaunder in 2006 by our research team. The points were measured by a freely movement of a zodiac boat in the pond.

The water storage volume of the pond was calculated for each measurement period by Surfer Software (Surfer, 1997). According to each bathymetric measurement periods, the reservoir water storage capacities were calculated.

Soil erosion and sediment yield calculation

The RUSLE erosion model and Musgrave Equation were employed for the calculation of soil loss and sediment yield for the study of basin. Required all calculation were done in geographic information system (GIS) environment within ArcGIS Version 10.1 (ESRI, 2011).

The factors used in the Revised Universal Soil Loss Equation (RUSLE) were used to estimate the average annual soil loss (Renard et al., 1997). According to RUSLE, soil erosion is directly affected by a region's rainfall erosivity, soil erodibility, slope length, slope steepness, land use type and supporting practices. Hereby, mean annual soil loss in per unit of area is estimated from six erosion factors according to *Equation 1*.

The RUSLE is as follows:

$$A = R \times K \times L \times S \times C \times P \quad \text{(Eq.1)}$$

where A is computed soil loss (ton ha^{-1} y^{-1}); R is the rainfall-runoff erosivity factor (MJ mm ha^{-1} h^{-1} y^{-1}); K is a soil erodibility factor (t h ha MJ^{-1} mm^{-1}); L is the slope length factor (dimensionless); S is the slope steepness factor (dimensionless); C is a cover management factor (dimensionless); and P is a supporting practices factor (dimensionless).

The rainfall erosivity is determined by the various characteristics of a rainfall event, such as rainfall intensity and duration, the kinetic energy of raindrops, their size (diameter), and velocity (Petan et al., 2010). The unit rainfall energy, as proposed by the RUSLE methodology, is defined by the following equation (*Eq. 2*) and is calculated for each time interval as follows (Brown and Foster, 1987).

$$e_m = 0{,}29\,[1 - 0{,}72\exp(-0{,}05\,i)] \quad \text{(Eq.2)}$$

where e_m is unit rainfall energy (MJ ha^{-1} mm^{-1}); i is rainfall intensity during the time interval (mm h^{-1}).

The calculation of RUSLE R factor required pluviograph records. In Ekinli basin, only daily pluviometer rainfall depth data was available. The Modified Fournier Index (MFI) of Arnoldus (1980) is widely used worldwide to calculate rainfall erosivity which is not available pluviograph data. The MFI is a parameter of rainfall erosivity and makes use of mean monthly and annual rainfall depth data (*Eq. 3*). The equation is expressed as:

$$MFI = \sum_{i=1}^{12} \frac{p_i^2}{P} \quad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

where pi is monthly rainfall depth (mm); p is annual rainfall depth (mm).

Soil erodibility (K) is the sensitivity of a soil to erosion by runoff and raindrop impact. The higher K value is the greater the susceptibility of the soil to rill and sheet erosion. Soil erodibility factor was estimated using *Equation 4* given by Foster et al. (1991).

$$100K = 2.1M^{1.14}10^{-4}(12-a) + 3.25(b-2) + 2.5(c-3) \quad \text{(Eq.4)}$$

where K is soil erodibility (t h ha MJ^{-1} mm^{-1} ha^{-1}); M is the particle-size parameter; a is percent organic matter, b is soil structure code (very fine granular: 1, fine granular: 2, medium or coarse granular: 3, and blockish, platy, or massive: 4), which was determined in the field; c is soil profile permeability class (rapid: 1, moderate-to-rapid: 2, moderate: 3, slow-to-moderate: 4, slow: 5, and very slow: 6).

Slope length is defined as the distance from the point of origin of runoff to the point where deposition occurs. The slope length factor (L) was calculated with the help of *Equation 5* (Mc Cool et al., 1987).

$$L = (\lambda/22.1)^m \quad \text{(Eq.5)}$$

where L is slope length factor (dimensionless), which is field slope length (m); m is a coefficient that depends on slope steepness, being 0.5 for slopes exceeding 5%, 0.4 for 4% slopes and 0.3 for slopes less than 3%.

The slope steepness is a site slope, usually expressed as a percentage. The percent slope was determined from DEM with the help of *Equation 6*.

$$S = 10.8sin\theta + 0.03 \quad s < 9\% \qquad S = 16.8sin\theta - 0.05 \quad s \geq 9\% \quad \text{(Eq.6)}$$

where S is slope steepness factor (dimensionless) and ɵ is slope angle in degree.

In the RUSLE, the subfactor C were calculated by *Equation 7*. In this method, a factor called soil loss ratio (SLR) for given conditions is calculated by using 5 different subfactors.

$$SLR = PLU * CC * SC * SR * SM \quad \text{(Eq.7)}$$

where PLU is the prior land use subfactor, CC is the canopy subfactor, SC is the surface cover subfactor, SR is the surface roughness subfactor, and SM is the soil moisture subfactor.

Once the SLR's have been calculated for each time interval, they are multiplied by their corresponding percentage of annual EI (Wischmeier and Smith 1978). These values are then summed and divided by the total percentage of annual EI value for the entire time period (*Eq. 8*) (Renard et al., 1997).

$$C = (SLR_1 * EI_1 + SLR_2 * EI_2 + \cdots\cdots + SLR_n * EI_n / EI_t) \quad \text{(Eq.8)}$$

where C is average annual or crop value; SLR_i is the value for time period i; EI_i is percentage of the annual or crop EI occurring during that time period; n is number of periods used in the summation; and EI_t is sum of the EI percentages for the entire time

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

period. The cover management factor (C factor) represents a combined effect of interrelated cover and management variables.

Erosion control practices factor (P) is determined to be the ratio between the soil losses expected for a certain soil conservation practice and that of up-and-down slope ploughing (Liu et al., 2001). The support practice factor (P factor) represents a combined effect of support practices and management variables. They are also known as structural methods for controlling erosion. In an area, if conservation practices are not followed P value should assign as 1.

RUSLE is a soil erosion model and is not capable to estimate sediment amount directly. The calculated soil loss amount, according to RUSLE model was multiplied by sediment delivery ratio (SDR) of the basin. Thus, calculated soil loss of the basin area has been converted to sediment amount. Therefore, the SDR of the basin is calculated by Renfro Method (*Eq. 9*).

Renfro (1975) developed an equation relating SDR with the drainage area. It is based on Maner's (1962) equation and the sediment yields observed in 14 watersheds in the Blackland Prairie Area in Texas. The model shows a good relationship between SDR and the drainage area ($R^2 = 0.92$). The equation is expressed as:

$$\log(SDR) = 1.7935 - 0.14191 * \log(A) \quad \text{(Eq.9)}$$

where A is drainage area (km^2).

The RUSLE equation is only capable of calculating sheet and rill erosions, and cannot calculate bed load. Therefore, for a more realistic calculation, it is necessary to add stream bed load to the calculations made with these equations. To obtain a more realistic sediment estimation, the amount of sediment calculated by the Musgrave Equation (Sevinç, 1993) was added to the amount of sediment calculated by the RUSLE equation. The Musgrave equation (*Eq. 10*) is given by:

$$E = U * D * A * Y \quad \text{(Eq.10)}$$

where E is stream bed load ($m^3\ y^{-1}$); U is length of waterway (m); D is eroded coastal height (m); A is active erosion rate of riverbank (%) and Y is horizontal advance distance (m).

In the meteorological variables, parametric and non-parametric approaches have been used over the years. The most frequently used tests for identifying the variations in meteorological variables have been nonparametric. The most popularized approach among them is Mann–Kendal test (Kendall, 1975; Mann, 1945). The Mann-Kendall nonparametric test was used to test for trend (*Eq. 11*). This test is calculated as (Mohtar et al., 2015; Yurekli, 2015):

$$S = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} \mathrm{sgn}\left(x_j - x_i\right) \quad \text{(Eq.11)}$$

where n is the number of event, Xj and Xi are the observed events, and sgn is the sign function.

The variance is given by *Equation 12*:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

$$\sigma_S^2 = 18^{-1}\left[n(n-1)(2n+5) - \sum_{i=1}^{m} t_i (t_i - 1)(2t_i + 5) \right] \quad \text{(Eq.12)}$$

where n is the number of events, m is the number of tied events, t_i is the number of events that are tied. For sample size greater than 10 the test can be given in *Equation 13*:

$$Z_{MK} = \begin{cases} \dfrac{S-1}{\sqrt{\sigma_S^2}} & \text{if} \quad S > 0 \\ 0 & \text{if} \quad S = 0 \\ \dfrac{S+1}{\sqrt{\sigma_S^2}} & \text{if} \quad S < 0 \end{cases} \quad \text{(Eq.13)}$$

For increasing rainfall trends, the values of Z_{MK} is positive while for decreasing trends the value of Z_{MK} is negative.

Sen's estimator for slope is a nonparametric test for the steepness of the trend. For N pairs of data is given in *Equation 14:*

$$Q_k = \frac{x_j - x_i}{j - i} \text{ for } k = 1,..., N \quad \text{(Eq.14)}$$

where Xj and Xk are the values at times j and k (j > k) respectively. The N values of Qk are ranked from smallest to largest. According to condition that N is odd or even, the median concerning with total N values of is calculated by *Equation 15:*

$$Q_{med} = \begin{cases} Q_{\left[(N+1)/2\right]} & \text{if N is odd} \\ 2^{-1}\left\{ Q_{\left[(N)/2\right]} + Q_{\left[(N+2)/2\right]} \right\} & \text{if N is even} \end{cases} \quad \text{(Eq.15)}$$

The confidence interval for Q_{med} was obtained to determine the significance of the slope.

Results and discussion

Bathymetric measurements

In the Ekinli reservoir, three bathymetric measurements were conducted in 1981, 1987 and 2006. The three-dimensional map of the pond according to last bathimetric measurement in 11366 measurement points is given in *Figure 4*. We considered 1120 m sea level for volume computations in all bathimetric measurements. The amount of the sediment volumes stored in the pond was calculated on the basis of x, y and z coordinates. The sediment amounts accumulated in the pond during the bathymetric measurement periods are given in *Table 2*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

Table 2. *The change in the water storage volume of the Ekinli pond and the amount of sediment accumulation*

Years	Water storage capacity, m^3	The amount of sediment accumulated in the pond, m^3	Annual average sediment amount		Water storage capacity, %
			m^3 $year^{-1}$	mm $year^{-1}$	
1981	54873.6	0.0	-	-	100.00
1987	50626.2	4247.7	707.95	0.12	92.26
2006	45246.5	9627.1	534.84	0.09	82.46

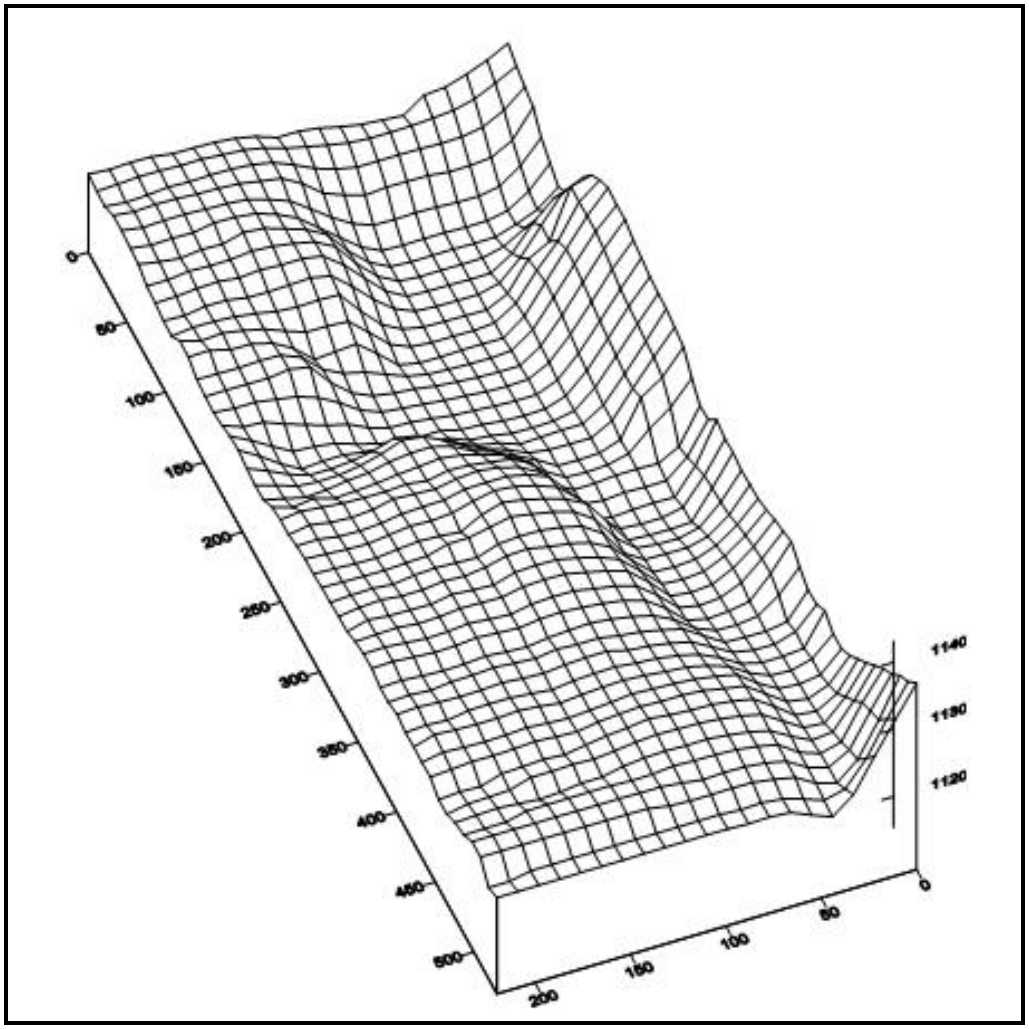

Figure 4. *Three-dimensional view of the pond (m)*

In 1981, the water storage capacity of the pond was calculated as 54873.6 m^3 according to 1120 m sea level by Surfer software. The water storage capacity of the pond decreased gradually due to accumulation of sediment amount during the experimental period. The water storage capacity of the pond decreased by 92.26% between the years 1981 and 2006. Considering the decrease in water storage capacity, a total of 4247.7 m^3 and 9627.1 m^3 sediment accumulated in the pond in 1981-1987 and 1987-2006 years respectively. The average sediment accumulation was 707.9 m^3 $year^{-1}$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

in 1981-1987 and 534.8 m^3 $year^{-1}$ in 1987-2006 periods, respectively. The decrease in the annual average sediment amount accumulated in the pond between 1987 and 2006 can be attributed to the afforestation of the Ekinli basin. The annual sediment volume to reach the reservoir is estimated as 589.4 m^3 y^{-1} when the pond was planned. The estimation of sediment for pond planning is quite accurate according to the results of the bathymetric measurements.

Sediment properties

A total 36 surface sediment samples of reservoir base were taken from crest to river discharge point to determine average sediment bulk density and sediment size distribution. The mean bulk density of sediment was measured as 1.48 g cm^{-3}. The highest clay and silt contents in the sediments were observed near the crest. The sand content was lower than 30% at this location. The clay content of sediments was measured over 25% up to 160 m from the crest. After this distance the clay content was below 5%. The silt content of the sediments was greater than 40%, from 0 to 150 m. Maximum sand content was observed at a distance of between 200 and 400 m from the crest (*Fig. 5*). Through the reservoir larger suspended particles generally sedimented earlier when reach to the pond compared to the fine particles which usually measured around the crest.

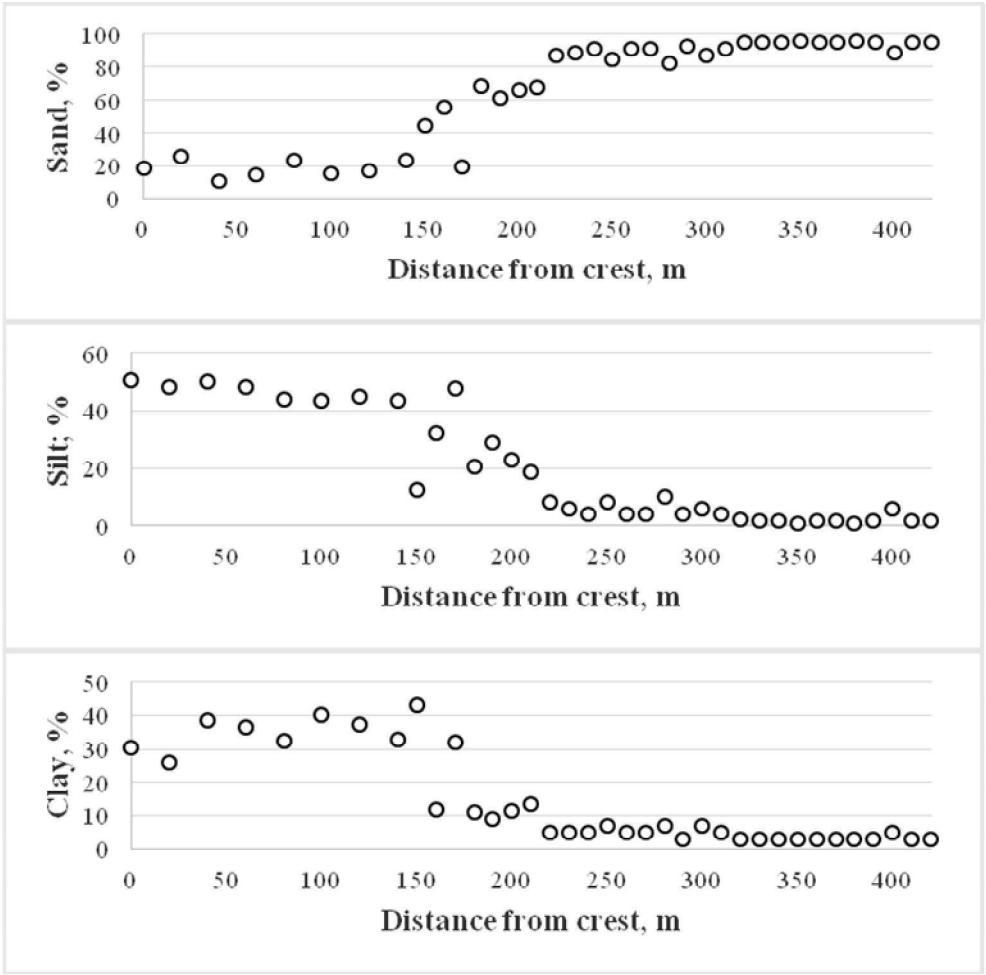

Figure 5. *Sediment size distribution according to distance from crest*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

Estimation of gross erosion of Ekinli Basin

Gross erosion includes sheet, rill, gully and channel erosions. The RUSLE estimates sheet and rill erosion only. For this reason, gully and channel erosions were modelled by Musgrave equation in the study (*Eq. 9*). The amount of sediment deposited in the pond was estimated by combining RUSLE and the Musgrave methods.

RUSLE erosion model calculations

As the required input parameters of RUSLE were obtained and prepared in ArcMap for soil loss calculation.

The rainfall erosivity (R) factor

Several studies showed that rainfall erosivity is one of the most sensitive factor for soil erosion (Ganasri and Ramesh, 2016). In Ekinli basin there were not pluviograph records hence, Modified Fournier Index (MFI) was used for the calculation of R factor. Using the MFI data, Tokat city pluviograph records were used to obtain a more realistic R-factor calculation. Tokat is 49 km away from the research site and pluviograph records for 18 years are available. The linear regression relationship equation was obtained between R factor and MFI values of Tokat province by 18 years data (*Fig. 6*). The regression analysis indicated a good correlation between R factor and MFI values. The R^2 which represents how close the data are to the regression line is 0.61. For the erosion studies with high level of uncertainty in the linear model, the R^2 of observation and parameter data were found as 0.61 which is adequate for the study.

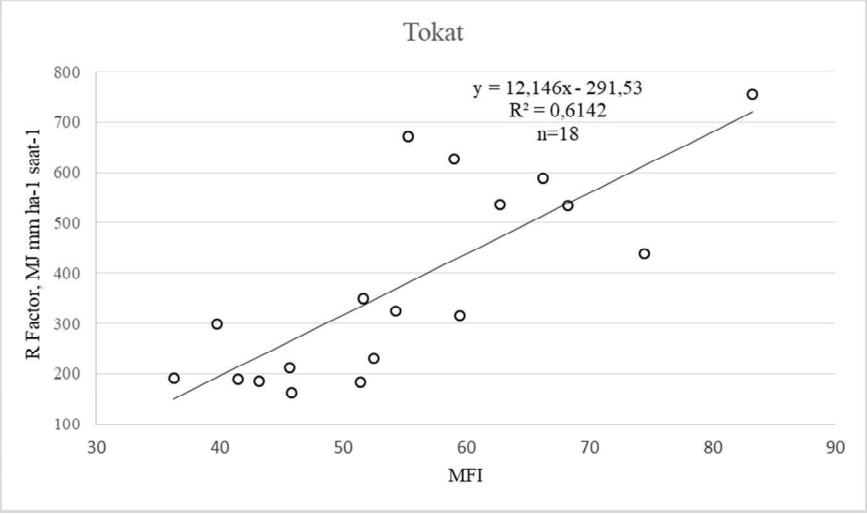

Figure 6. *Relationship between R factor and MFI values of Tokat*

The linear regression relationship equation between R factor and MFI of Tokat province were applied to Ekinli basin MFI values, which has been calculated from monthly rainfall data. Such regressions using local research areas have been used in literature where no rainfall intensity data are available (Gelagay and Minale, 2016; Zeng et al., 2017). Thus, the annual R-factor values of Ekinli basin were obtained (*Table 3*). The mean, lowest and highest R Factors values were 415.32, 98.12 and 800.09 MJ mm ha^{-1} h^{-1} y^{-1} respectively.

The K factor

To estimate the soil erodibility (K factor) values indirectly, soil physical features (texture, very fine sand, organic matter, saturated hydraulic conductivity and structural properties) were obtained in topsoil of 150 sampling points in the basin (Wischmeier and Smith, 1978). The soil erodibility characteristics of the Ekinli basin were determined with the help of *Equation 4*. Coordinated K factor point values of study area have been converted to K factor surface map by ArcMap software (*Fig. 7*).

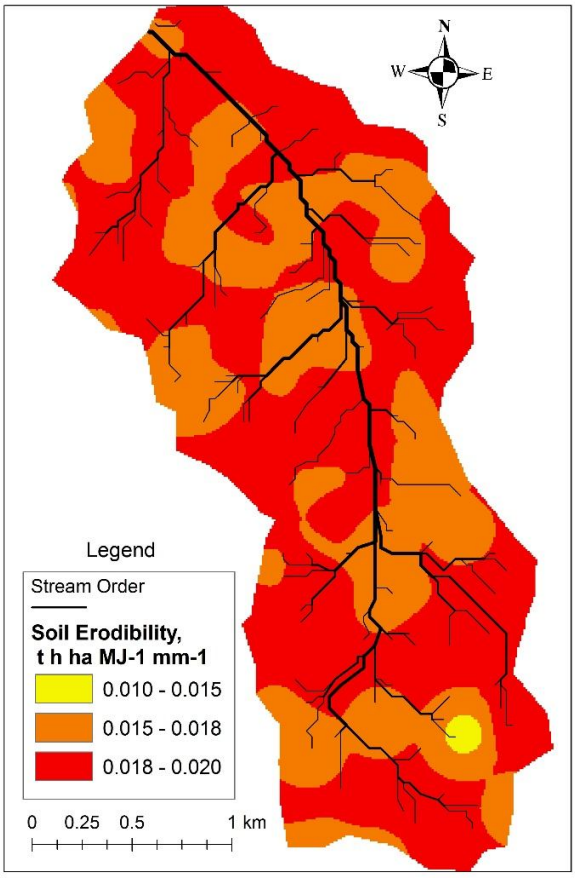

Figure 7. *The soil erodibility map*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

The spatial distribution of soil erodibility factor map ranged from 0.010 to 0.020 t ha h ha^{-1} MJ^{-1} mm^{-1}.

The LS factor

The slope length factor (L) and the slope steepness factor (S) illustrate the contribution of topography on soil loss. The L factor equals to 1 for 22.1 m slope length, and the S factor equals to 1 for 9% slope. L and S factor layers were directly calculated from DEM of the study area by the help of *Equations 5* and *6* in ArcMap (*Fig. 8*). The values of slope length and slope steepness factor (LS) varied from 0 to 22.04 with a mean value of 2.26; the highest values were recorded in areas with high altitudes and slopes, while flat lands had the lowest values.

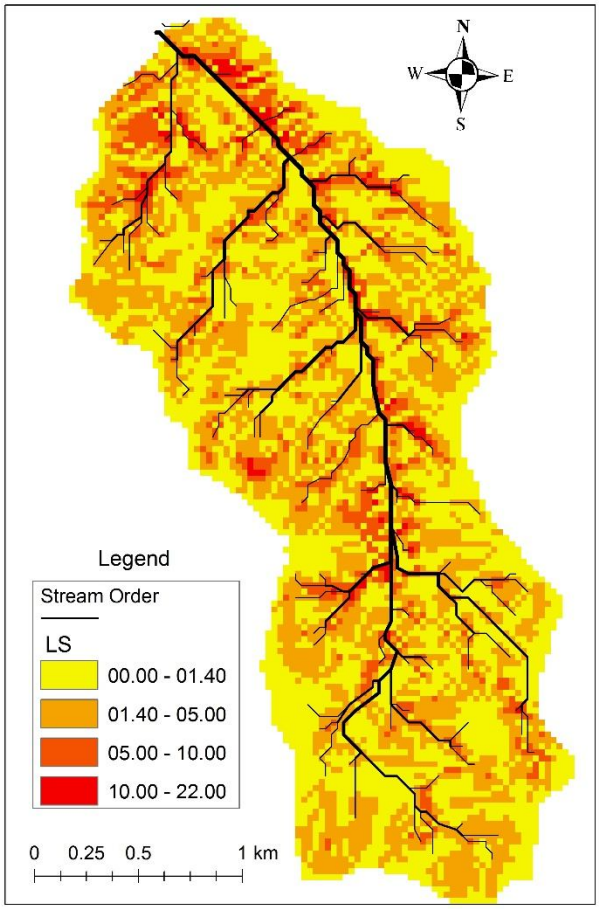

Figure 8. *The topographic factor of RUSLE map*

The C factor

In RUSLE, C factor represents the effects of plants, soil cover, soil biomass, and soil disturbing activities on erosion. The C factor values were determined by C factor calculation procedure (Renard et al., 1997) based on the field works. Field measurements were done in grassland and forestland separately. Various measurements and vegetation samplings were carried out at both locations in 15 days periods, excluding snow-covered days. A total of 18 field studies were carried out to obtain the

DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

C factor values. Some of the data were mass densities of live and dead roots, mass density of incorporated surface residue in the upper depth of soil, fraction of land surface covered by canopy, crop height, surface roughness, percent residue covers and dryweight of crop residue. As a result, SLR value was calculated for different time periods for forest and grassland by the help of *Equation 7* (*Table 4*). Weighted average values was also calculated and annual average C factor was determined according to *Equation 8* for the time frame corresponding to the annual erosion index (EI) value percentage. The annual C values were calculated as 0.007 and 0.0273 for forestland and grassland of the basin respectively (*Fig. 3*).

The P factor

The P factor is computed for individual support practices that are used in combination to reduce erosion. Such practices include terracing, contour tillage, and strip farming. In the case of rare conservation structures in a region, usually P Factor value of 1 is assigned (Tamene et al., 2015). There were no significant conservation measures so we used 1 value for soil loss calculation.

Soil erosion map of basin

Layers were created in GIS environment for each RUSLE equation factor. Thus, the annual potential sheet and rill erosion were calculated for the basin from 1977 to 2018. The average soil loss map is presented in *Figure 9*. The values of soil loss varied from 0 to 4.22 ton ha^{-1} y^{-1} with a mean value of 0.36; the highest values recorded in areas with high altitudes and slopes, while flat lands had the lowest values.

Sediment delivery ratio of Ekinli basin

The sediment delivery ratio (SDR) is commonly used in erosion and transport studies to describe the extent of sediment storage within the basin. Ekinli basin with small drainage area and the short distance of fields to the streams created a high SDR potential. Thus, the soil particles of reaching the water channel system are high. In order to calculate the SDR of the basin Renfro Equation (*Eq. 9*) was used and provided 48.31% value.

Stream bed load calculation by Musgrave equation

The waterway length of Ekinli basin is 4500 m. Since there has been active erosion on both sides of the waterway, total coastal length was considered as 9000 m. Eroded

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

coastal height is 1.5 m and active erosion rate is 48.31% while horizontal advance distance is 0.051 m. According to *Equation 10,* stream bed load of Ekinli basin was calculated as 332 m^3 y^{-1}. This calculated value was added to the amount of sediment computation by RUSLE and the annual total amount of sediment reaching to the pond was determined (*Table 5*).

The sediment accumulation of reservoir was calculated as 21600.75 m^3 for 42 years study period. The minimum (370.03 m^3) and the maximum (775.69 m^3) sediment amounts were calculated in 2008 and 1984 respectively.

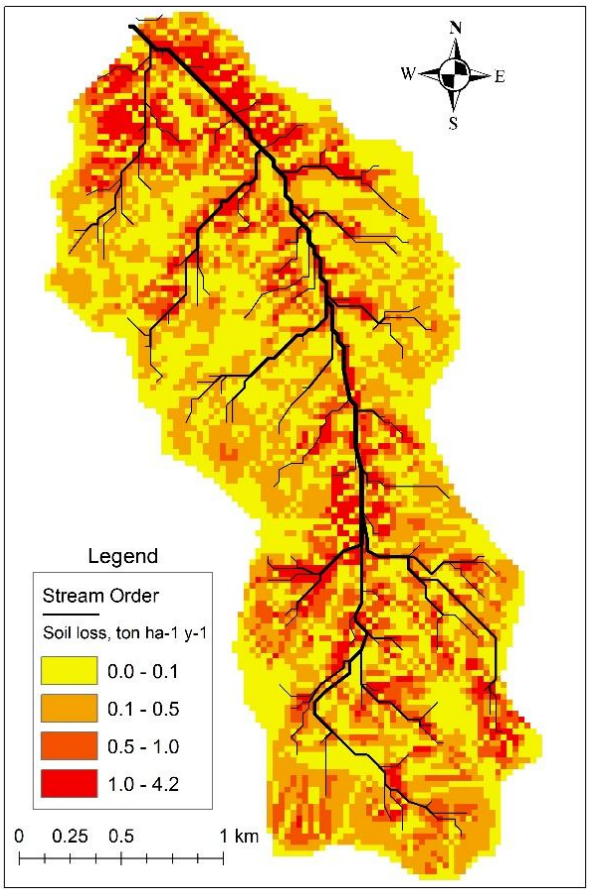

Figure 9. *Potential soil loss map of basin according to RUSLE method*

Comparison of sediment yield of Ekinli basin measured by bathymetry and computed by RUSLE and Musgrave method

In our study, the calculated sediment yield was compared with the results of bathymetric measurements. Thus, the accuracy of the calculations was tested. Because the last bathymetric measurement was carried out in 2006, the measurement values performed on this date do not provide sufficient information about the current water storage capacity of the pond. However, it gives valuable information about the validity of the calculations.

The effect of sedimentation on pond is only possible when the basin sediment yield is accurately modeled. Measured and calculated basin sediment yields are compared in *Table 6* by comparing two different bathymetric measurement periods.

*This value was calculated as: calculated mean soil loss by RUSLE (ton ha^{-1} y^{-1}) × basin area (591 ha) × bulk density of sediment (1.48 g cm^{-3}) × sediment delivery ratio (% 48.31)

** This value was calculated as: calculated total sediment amount by RUSLE (m^3) + calculated stream bed load by Musgrave equation (m^3)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

Table 6. *Comparison of measured and calculated sediment yields in Ekinli basin*

Period	Measured		Calculated		Variation
	Total, m^3	Average, $m^3\ y^{-1}$	Total, m^3	Average, $m^3\ y^{-1}$	m^3
1981-1987	4200	600.00	4217.06	602.44	+17.06
1988-2006	9600	505.26	9540.57	502.14	-59.43

According to the bathymetric measurements, the amounts of sediment deposited in the basin for the periods between 1981-1987 and 1988-2006 were 4200 m^3 and 9600 m^3, respectively. At the same period, the calculated sediment yield of the Ekinli basin was 4217.06 m^3 and 9540.57 m^3 respectively.

The first bathymetric measurement period was identified 7 years of sediment accumulation. The average sediment yield was 600 $m^3\ y^{-1}$ in this period. Calculated sediment yield was very close to the measured sediment yield during the same period. The predicted sediment yield was only 17.06 m^3 higher than the actual measurement results.

The second bathymetric measurement period was identified 19 years of sediment accumulation. The average sediment yield was 505.26 $m^3\ y^{-1}$ during this period. At the same period, the calculated sediment yield was also very close to the measured sediment yield. The predicted sediment yield was only 59.43 m^3, lower than the actual measurement results.

The measured and estimated sediment amounts for the Ekinli reservoir represented an excellent adaptation. According to this result, it is possible that the estimation of adaptation is also being quite accurate for non-measured years.

The effects of sediment accumulation on the water storage capacity of the pond

The sluice way height of the pond was planned according to 14735 m^3 volume for the 25-year duration, considering the amount of sediment accumulation in the reservoir. For the planning calculations, the dead volume of the pond is expected to be filled in 2001. According to our sediment calculation results, the dead volume of the pond was filled in 2004. The results of the bathymetric measurements confirmed that the dead volume has been filled in the planned period. The bed of reservoir elevated with sediment accumulation over time and the sluice way remained below the current pond floor. However, the special design of the sluice way intake and the whirlpool effect by water movement have ensured seamless water flow from reservoir for irrigation up to date.

In 2017 the open channel irrigation system was canceled and the pipe system was switched to irrigation. Thus, the irrigation area of the pond was expanded.

The cumulative sediment accumulation in the reservoir from 1977 to 2018 is presented in *Figure 10*. According to our calculations, a total of 21600.75 m^3 sediments were deposited in the reservoir for 42 years. According to pond planning calculation, our computation and bathimetric measurements, the mean sediment accumulation were 589.4 m^3, 514.3 m^3 and 552.3 m^3 respectively. According to these comparisons, all three computations showed a perfect fit.

Considering the amount of sediment calculated with the help of RUSLE and Musgrave equation, 6.74% of the total volume of the pond has been filled with sediment. 623 years are required for the pond to be filled completely with sediment.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

RUSLE has been used and accepted by many researchers for erosion prediction because of its high reliability in erosion prediction studies (Ullah et al., 2018). The calculated and measured sediment yields in the basin were very low. The methods used in the study were successful on the prediction of even low sediment yield. Presence of forest and lower mean annual rainfall in the upstream may contribute to comparatively lower erosion rates (Fayas, 2019). In the study area, grassland and forestland had low rainfall erosivity. Therefore, the sediment accumulation calculated in the pond was low.

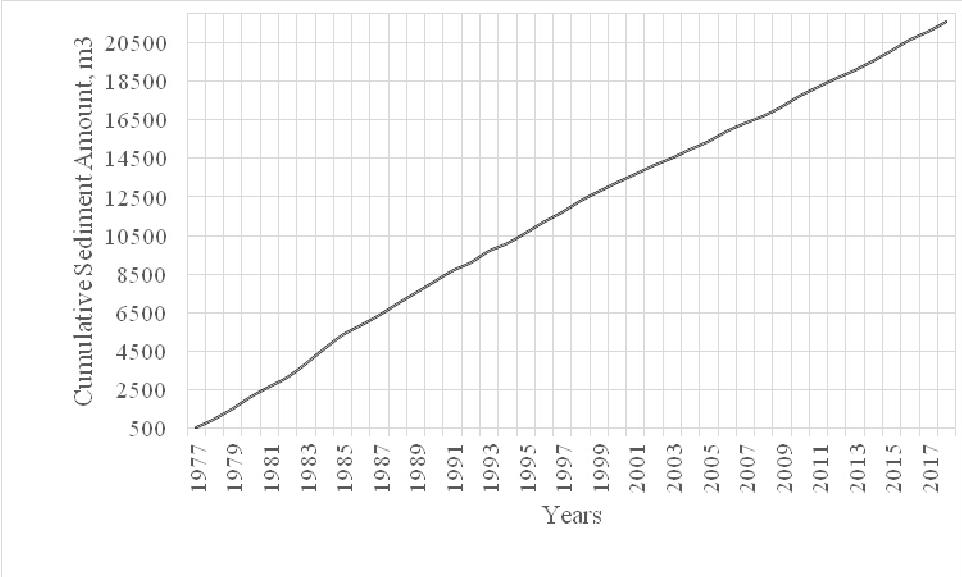

Figure 10. *Cumulative sediment accumulation (1977-2018)*

The effect of landuse chance on sediment yield

At the pond planning, the entire Ekinli basin was grassland. So the effects of forestation on sediment yield were not considered when the pond planned. As a result of the afforestation activities carried out in 2010 in the basin, 38% of the basin area was converted into forestland from grassland. The effect of this landuse change on sedimentation with the help of RUSLE equation was investigated. For this purpose, sediment accumulation was calculated by using RUSLE equation and Musgrave Equation for both situations (whole basin is grassland or 38% forestland and 62% grassland) for the years 2000-2018 (*Fig. 11*).

C factors values for grassland and forestland were calculated by the help of *Equations 7, 8* and the C value was used to detect of landuse change effect on sediment yield. According to these calculations, forestland was more effective in reducing erosion than grassland. The partial afforestation of the basin caused the sediment yield to drop from 9519 m^3 to 8801 m^3 between 2000 and 2018. The difference affected only 1.08% of sediment deposition over a 19-year period. The low difference could be the result of forestland and grassland which have a very close effect on reducing soil losses. Many studies have shown that the changes in land-use or vegetation have a large impact on soil erosion and sedimentation (Diyabalanage et al., 2017; Ganasri and Ramesh, 2016; Zhang et al., 2017; Chen et al., 2019). Conversion of a land from farmland to grassland or forestland is expected to contribute lower sedimentation. In a small basin in Poland, the increase in grassland and forestland at the catchment about 90% and 10%

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

respectively and a decrease in cultivated land as 82% reduced soil erosion by 74% as being calculated using the Revised Universal Soil Loss Equation (Strugała, 2019). The aforestration of Ekinli basin extended the life span from 603 to 623 years.

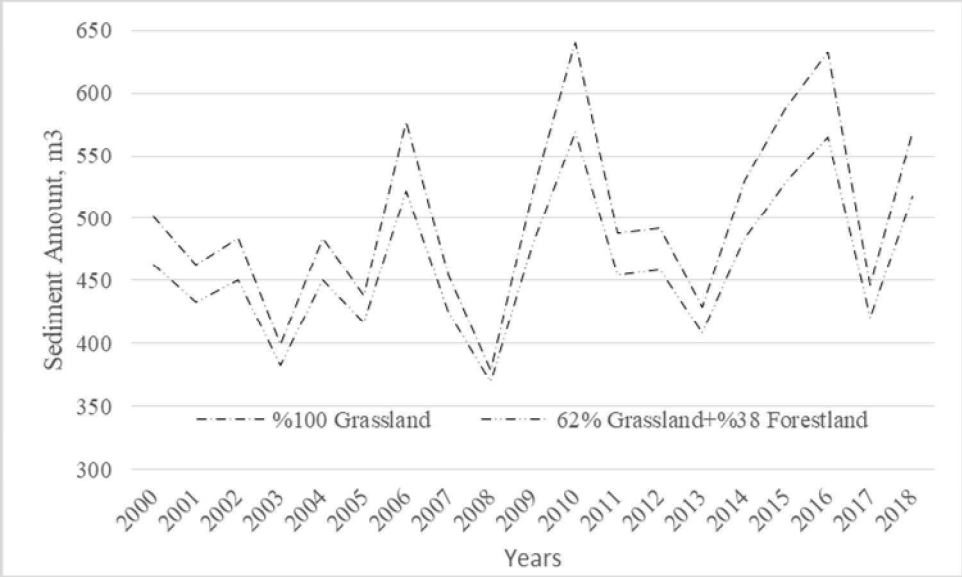

Figure 11. *The effect of this landuse change on sedimentation*

Trend and slope analyses

The Mann-Kendall test and Sen's slope estimator were used for rainfall, R factor and sediment amount of Ekinli basin. The Mann-Kendall statistics for trend and Sen's slope estimator result is given in *Table 7*. The Mann-Kendall statistics showed significant trend for sediment. The Sen's slope estimator had negative slope. The H_o hypothesis related to no monotonic trend was rejected for sediment data sets.

There were not a trend for rainfall and R factor in the basin. The calculated p value for sediment is smaller than the critical p value from the table of the standard normal distribution.

Although there was no trend for rainfall and rainfall erosivity, the trend for sedimentation was attributed to landuse change after 2000 in the basin.

Table 7. *Trend and slope results for Ekinli basin (1977-2018)*

Parameters	z	p-value	Sen	CI for Sen
Rainfall, mm	-1.41	0.08	-1.562	(-3.848, -0.657)
R Factor, MJ mm ha^{-1} h^{-1} yr^{-1}	-1.52	0.06	-3.511	(-8.193, -1.163)
Sediment, m^3	-2.77	0.00	-3.002	(-5.282, -0.919)

Conclusion

The silt accumulation of dams is complex event that affects negatively water storage capacity of pond. The economic life of the ponds are necessary for their sustainability since the most important event effecting the life of the ponds is sedimentation. The agricultural importance of the region has led to the construction of many small ponds.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77417763

The calculations of reasonable sediment amount by the help of RUSLE/SDR and Musgrave equation can be helpful for the new planning of small ponds. This study showed that the GIS systems combined with RUSLE and Musgrave equation is a practical, reliable, inexpensive and relevant method for assessing sediment amount in a basin. The results of the study revealed that the sediment estimation was considerably valid for the basin.

The dead volume of the pond is filled in 2004. Hence, the aquatic life of pond could be under the risk especially in the irrigation seasons. The water storage capacity of the pond decreased by 6.7% due to sedimentation thus the irrigation potential in the area also decreased. In case the sediment accumulated in the pond would have been spread all over the basin, it would correspond to a soil layer of 3.65 mm thickness.

The RUSLE equation can be used successfully in sediment calculations. The biggest limitation of this equation is the accurate calculation of the sediment delivery ratio. In addition, calculation of gully and stream erosion by using different methods that the RUSLE equation cannot calculate will provide a more accurate sediment estimation. Even in the lower sedimentation such as grassland and forestland uses the estimation of model was very accurate compared to the results of bathymetric measurements.

According to the results, land use changes from pasture to forest have a poor effect on sediment yield. In order to provide a control on the intensive sedimentation, conversion from cropland to grassland or forestland will be more effective on sedimentation.

(Received 13th Mar 2019; accepted 3rd May 2019)

Abstract. This trial was realized in the greenhouses of Uludag University Yenisehir Vocational School in Bursa province of Turkey between 2009 and 2010 to investigate effects of water deficit on yield and quality parameters of tomato during four crop growth stages. In this trial, fourteen irrigation treatments in four growth periods (vegetative, flowering, yield formation and ripening) of tomato (*Lycopersicon lycopersicum* L. var. Hazar F1) were constituted and the yield and quality parameters found from these treatments were evaluated. The layout of the experiment was a completely randomized block design with three replications for each of the fourteen irrigation treatments tested. According to the content of the treatments, the irrigation amount water applied to the plants varied between 0 and 554 mm in the first year, and between 0 and 556 mm in the second year. Water consumption of tomato in the first year ranged between 300 and 725 mm and in the second year ranged between 340 and 746 mm. Yield, fruit weight, diameter, height and dry matter ratio were determined statistically significant. In 2009 and 2010 years, the maximum yield were found as 92.2 t ha^{-1} and 93.4 t ha^{-1} in $V_{100}F_{100}Y_{100}R_{100}$ treatments, while the minimum yield were found as 2.0 t ha^{-1} and 4.0 ha^{-1} in the $V_0F_0Y_0R_0$ treatments, respectively. Water- yield relationship factors (k_y) in 2009 and 2010 years were found as 1.05 and 1.06, respectively. The maximum WUE and IWUE values were obtained from vegetative and ripening periods. Vegetative and ripening periods may be suggested as the maximum efficient irrigation periods for the tomato applied with drip irrigation under unheated greenhouse conditions.
Keywords: *tomato, deficit irrigation, WUE and IWUE values, yield and quality parameters of tomato, irrigation planning*

Introduction

Decreases in water resources together with increasing impacts of global warming and climate changes and increasing demands of increasing population make effective utilization of water resources a must. Increasing demands of sectors also deplete the ground water resources, pollute water ecosystems and developing new water resources is getting more and more expensive each day. Since about 75% of water resources of Turkey is allocated for agricultural purposes, effective water utilization and water saving in irrigation are the most critical issues to be considered. Pressurized piped systems and especially drip irrigation should be widespread for effective water utilization in agriculture (Cakmak and Gokalp, 2011).

Van Straten et al. (2010) stated that the greenhousing is worldwide the fastest growing sector of all agricultural production activities. There are two essential causes for this. First, the plant grows in greenhouse differently from the external environment, in this way supplying in a sort of way of abri from the flat-out effect of the exterior air conditions. This allows the production of crops at that specific place. Second, the greenhouse allows to be produced of many crops. Thus, grower allows the farming to come true as desired. It also offers advantages such as higher crop yield, longer production period, better quality and less use of chemicals. The output unit of area in greenhouses is much higher than that in field agriculture. This situation permits the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77657781

grower to direct the farming in a desirable aspect. It causes to higher crop yield, extended production period, better quality and less use of chemicals. The value added per unit surface area in greenhouse crops is much higher than that in field agriculture.

China, India are United States are the world's three biggest tomato producers with 57, 19, 15 million tons, respectively. United States is the largest tomato exporting country. Turkey is one of the significant tomato producer with Turkey 12 750 000 tons (fourthly in the world) in the world (FAOSTAT, 2017).

Papadopoulos (1992) pointed out the tomato is a major vegetable that has reached immense demand over the last hundred years. Tomato contains vitamins of A and C and is very useful for human heath. Tomato fruit is the best source of lycopene and lycopene is a cancer hampering antioxidant. Hence, tomato is very important in developed countries and its production is production is being tried to increase. Greenhouse cultivation is the optimum option for tomato producer because of higher quality of tomato. In addition, the crop is protected from insect, disease and pest. Moreover, the size of all fruit stays uniform because of optimum environment. Water is vital input for tomato to remain alive in greenhouse. Water is saved by the drip irrigation and plant gives better yield and quality.

Sezen (2005) found that surface irrigation is not suggested due to low irrigation efficiency originated from salinity and drainage problems in irrigated areas. From a different viewpoint, traditional irrigation systems where excess water inputs and poor drainage occur, cause environmental problems such as salinity and water logging. In irrigation methods where irrigation water is used efficiently do not have the problems of conventional irrigation methods (Buyukcangaz et al., 2007). Thus, the use of less water consuming irrigation methods is of great importance with regard to irrigation planning (Anonymous, 2005). The objective of irrigation planning is to prevent the soil moisture level falling below the critical line for a specific soil and crop condition. This may enable to avoid the harmful effect of water stress by means of estimating the earliest date (Ritchie and Johnson, 1990).

Irrigation planning with drip irrigation relies on approaches connected with evapotranspiration estimations (Bar-Yosef and Sagiv, 1982; McNeeish et al., 1985; Clough et al., 1990; Hartz, 1993) and permissible soil-water depletion (Bogle et al., 1989). *Ky* represents the declines in the yield as a result of each deficit level in water consumption. *Ky* values usually difficult to create accurately. *Ky* values are affected by regional conditions, soil properties, crop physiology and cultural practices. A suggested *Ky* value for irrigation planning must be high enough to avoid the water stress caused by the needs and specific local situations. It remains low enough for effective water management (Yuan et al., 2003). Some studies have been realized to investigate the effect of deficient irrigation on tomato. The purposes of this experiment were to obtain a prospectus for tomato growers and to determine drip irrigated tomato response to deficit irrigation regimes in Bursa conditions.

Materials and methods

The study was realized in Yenisehir Vocational School, Bursa of Turkey in 2009 and 2010 years. For practical purposes, plastic greenhouse (8 m x 40 m) was used. In the study place, wintertimes are cold and summertimes are hot. The average annual rainfall and temperature values for the region where the greenhouse experiments were made in 2009 and 2010 were 531.3-804.4 mm and 13.3-14.6 °C, respectively. While the average

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77657781

minimum temperature for 2009 and 2010 were -3.6 - (5.9) °C between January and December, the average maximum temperature in August was measured as 30.6 and 34.6 °C (Anonymous, 2011a). Maximum and minimum temperature values in greenhouse during the plant growing period (92 days) were 38-38 °C and 0.9-1.3 °C, respectively in 2009-2010 years (*Figs. 1* and *2*). The highest and lowest relative humidity values in greenhouse in 2009 and 2010 years were found as 88-87% and 39-39%, respectively (*Fig. 3*). In addition, the highest and lowest radiation values in greenhouse in 2009-2010 years were measured as 1974-1542 W/m^2 and 335-139 W/m^2, respectively (*Fig. 4*) (Anonymous, 2011b).

SL: sandy loam

Hazar F1 variety was used in the study. Hazar F1 is a mid-early type and its fruits are around 15-25 g. Hazar F1 has a strong plant structure. The fruits of Hazar F1 are oval, bright, charming and are resistant to waiting and transporting. This variety has a wide adaptability and high efficiency. In addition, this variety is tolerant to early leaf blight. In the experimental area, an irrigation well was utilized as the source and the water was of the class C_1S_1 after the analysis done. NPK 15-15-15 fertilizer was sprinkled on the soil by hand before planting the seedlings as bottom fertilizer. The application depth of the fertilizer ranged from 15 to 20 cm depending on the soil structure and the root depth of the plant grown. NPK 15-15-15 fertilizer was utilized to trial plots while the tomatoes were being planted, and 750 kg of NPK 15-15-15 fertilizer per hectares were utilized. The urea form of the nitrogen was applied to the plots together with the irrigation water. The first manure was applied as 250 kg/ha (% 46 N) in the flowering stage and the second fertilizer was utilized as 250 kg/ha in yield formation stage together with the irrigation water. Furthermore, in 2009 and 2010 years, 250 kg of magnesium nitrate manure per hectares (11 – 0 – 0 + 16 MgO - Nitrogen % 11 and MgO % 16) were used in the flowering and early yield formation stages to support the generative development.

The experimental blocks were formed with three replications and 14 trial treatments were randomly scattered. The size of the experimental plots was 4 m^2 (2.0 m × 2.0 m). The distances between the plots were 0.80 m and blocks were placed with 1.5 m distances. The tomato seeds were sown in viyols on 01 April 2009 and on 04 April 2010 in the experimental years. The tomato seedlings were transplanted to the plots on 02

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77657781

May 2009 and on 05 May 2010. The seedlings were grown with 50 cm intervals on the same row and with 50 cm intervals between the plant lines. Into each plot, 25 plants were planted.

Some quality parameters of tomato are yield, fruit weight, diameter, height and dry matter ratio. The fruit weight was determined by weighting 15 plants in the harvest part and fruit diameter and height were calculated by gauging the weighted fruit with a ruler and by taking the average of these values. The dry matter ratio was obtained after they were dried at 65 °C in a drying oven for 48 h and fruit dry matter ratio was calculated. The detail of the experimental plot is shown in *Figure 5*.

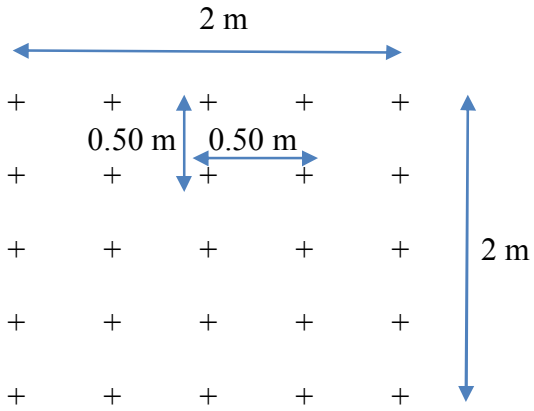

Figure 5. *The detail of a plot*

In different growth periods of tomato (vegetative, flowering, yield formation and ripening) fourteen deficit irrigation treatments were formed depending on full or deficit irrigation treatments. 75-50-25% of the deficit irrigations were applied in different growth stages of the plant, while 100% of irrigation water was used in full irrigation treatment. In line with this planning, irrigation treatments were planned like this: $V_{100}F_{100}Y_{100}R_{100}$, $V_{75}FYR$, $V_{50}FYR$, $V_{25}FYR$, $VF_{75}YR$, $VF_{50}YR$, $VF_{25}YR$, $VFY_{75}R$, $VFY_{50}R$, $VFY_{25}R$, $VFYR_{75}$, $VFYR_{50}$, $VFYR_{25}$, $V_0F_0Y_0R_0$ (*Table 2.*).

The irrigation equipment in greenhouse used in the study was given in *Figure 6*.

a b

***Figure 6. a** Drip irrigation system. **b** Main and lateral pipes*

In the trial, the plants were irrigated by drip irrigation method and water was used an irrigation well. Some features of the irrigation water were given in *Table 3*. The irrigation water has low-sodium risk and medium EC and its class is C_2S_1 class. C2S1 irrigation water quality class has low sodium and medium electrical conductivity (salinity). Water in the C2S1 quality class can be used for be irrigated medium and highly resistant plants to salinity. In addition, C1S1 quality class water can be used in all plants and soil without creating harmful alkalinity. A study has been conducted on irrigating tomato by using C2S1 quality class water (Ashraf and Ewees, 2008).

***Table 3.** Specific properties of irrigation water*

Water source	$EC_{25}x$ (10^6)	Na^+	K^+	Ca^{2+}	Mg^{2+}	PH	Class	SAR
		(me L^{-1})						
Deep well	715	2.3	2.56	9.25	5.7	7.12	C_2S_1	0.85

In four growth stages the soil moisture contains of the soil was followed before and after irrigation with a gravimetric method in every 30 cm up to 120 cm depth.

The water balance equation was used to calculate evapotranspiration (ET) (*Eq. 1*).

$$ET = I + P - R_f - D_p \pm \Delta S \quad \text{(Eq.1)}$$

where ET represents the evapotranspiration, I shows the irrigation water amount during the period (mm), P is the total precipitation, R_f is the amount of the surface flow (mm), D_p indicates the deep drainage (mm) and ΔS is the soil water content at the beginning and end of the period (mm/120 cm). Before planting seedlings, water was given to the crop by the drip irrigation method. Total precipitation (P) and surface flow (R_f) were omitted due to the plant production in the greenhouse. The soil water in the deeper than 120 cm was taken as the deep drainage (D_p) and the deep drainage (Dp) was neglected.

The intervals of lateral were equal to the plant row intervals in the trial. Therefore the percentage of wetted area was calculated by the equation as follows (*Eq. 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77657781

$$P = \frac{Sd}{Sl} 100 \quad \text{(Eq.2)}$$

where P is the percentage of wetted area, Sd and Sl are the interval of dripper and the intervals of lateral, respectively. The amount of irrigation water to be applied in each irrigation (*Eq. 3*) was found by the equation given below.

$$dn = \frac{(FC - WP) Ry}{100} \gamma t \, D \frac{P}{100} \quad \text{(Eq.3)}$$

where dn is the amount of irrigation water to be applied in each irrigation, FC and WP are the field capacity and wilting point, respectively. γt is the soil bulk density, D is wetted soil depth, P is the percentage of wetted area.

In this trial, the relationships between yield and ET was described by Steward Model (*Eq. 4*) (Stewart et al., 1975; Doorenbos and Kassam, 1979). The equation can be given as:

$$\left(1 - \frac{Ya}{Ym}\right) = ky\left(1 - \frac{ETa}{ETm}\right) \quad \text{(Eq.4)}$$

where Y_m (t/ha) and Y_a (t/ha) are maximal and actual yield, respectively, ET_m (mm) and ET_a (mm) are maximal and actual evapotranspiration, respectively. The yield response factor is shown as k_y. WUE values were determined to assess irrigation efficiency in treatments. WUE and IWUE terms refer to contribution of irrigation water to effective use of plant production stages (Bos, 1980). WUE was calculated by dividing the fruit yield by seasonal evapotranspiration (ET). IWUE was predicted as (Zhang et al., 1999):

$$IWUE = \frac{(Y1 - YNI)}{I} \quad \text{(Eq.5)}$$

where Y_1 is fruit yield of irrigated treatments (t ha $^{-1}$) and Y_{NI} is the fruit yield of non-irrigated treatment (t ha $^{-1}$) and I is the amount of irrigation water (mm). The water content of the soil up to 120 cm depth was calculated before the seedlings were planted into the soil. Before starting irrigations, moisture level of the soil was completed to the level of field capacity in all treatments. Irrigation was begun on May 02 in 2009 and May 05 in 2010 and it was repeated every 7 days. The irrigation water amounts for the four growth stages were given in *Table 4*. Crop evapotranspiration for growth periods of tomato are given in *Table 5*.

Yield and quality parameters were evaluated. Variance analysis of yield and quality parameters were evaluated according to LSD multiple comparison test ($p < 0.05$). Variance analysis was done with the values of yield productivity and quality parameters by using MSTAT-C and MINITAB software (Steel and Torrie, 1980).

Results

In 2009 and 2010 years, the highest irrigation water was found in $V_{100}F_{100}Y_{100}R_{100}$ treatment as 554-556 mm and minimal irrigation water was found in $V_0F_0Y_0R_0$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77657781

treatment as 0-0 mm respectively. Crop water use of tomato (ET_c) increased with the increment in the water amount. ET was found as 300-735 mm in 2009 and as 340-746 mm in 2010 in $V_{100}F_{100}Y_{100}R_{100}$ and $V_0F_0Y_0R_0$ treatments, respectively. The irrigation water and yields are presented in *Table 6*.

Crop water production functions (ky and R^2 values) obtained for each growth stage (vegetative, flowering, yield formation, ripening) and total growing season in 2009 and 2010 were given in *Table 7*.

Linear relationships between ET_c with Y_a, and IW with Y_a were observed for 2009 year. The relationship equation is as follows; $Y_a = 0.2185ET_c - 58.437$ with $R^2 = 0.9402$ and $Y_a = 0.1576IW + 2.2813$ with $R^2 = 0.99$ (*Figs. 2* and *3*). Linear relationships between ET_c with (Y_a), and IW with Y_a were observed for 2010 year. The relationship equation is as follows: $Y_a = 0.228ET_c - 67.477$ with $R^2 = 0.9115$ and $Y_a = 0.1569IW + 3.4724$ with $R^2 = 0.99$ (*Fig. 7*).

When the results were taken into consideration, yield was substantially affected by irrigation applications (*Figs. 2* and *3*) the maximum values of yield were found as 92.2 t ha^{-1} and 93.4 t ha^{-1} in $V_{100}F_{100}Y_{100}R_{100}$ treatment for 2009 and 2010 years, respectively (*Tables 8* and *9*).

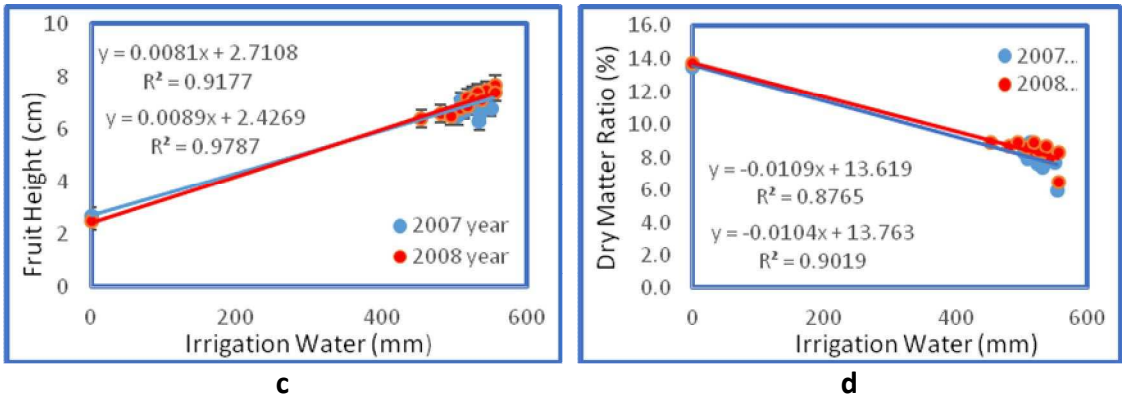

Figure 8. *Relationship between irrigation water and fruit weight, diameter, height and dry matter ratio*

Crop yield response factor (k_y)

The linear relationship between relative crop evapotranspiration and relative yield decrease is given the ky value. It is regarded as the yield response to the relative crop evapotranspiration. In another saying, it represents the declines in the yield as a result of each deficient level in water depletion. Seasonal ky values were determined as 1.05 (2009 year) and 1.06 (2010 year) (*Fig. 9*). Ky value increased with the increase in the water deficit. This result was relatively small with regard to seasonal crop yield response factors in four different crop growth stages of the tomatoes, while it was consistent with the crop yield response factors in each growth factors given in literature. The difference between these two results may refer to the differences between the empirical, climatic and seedling quality.

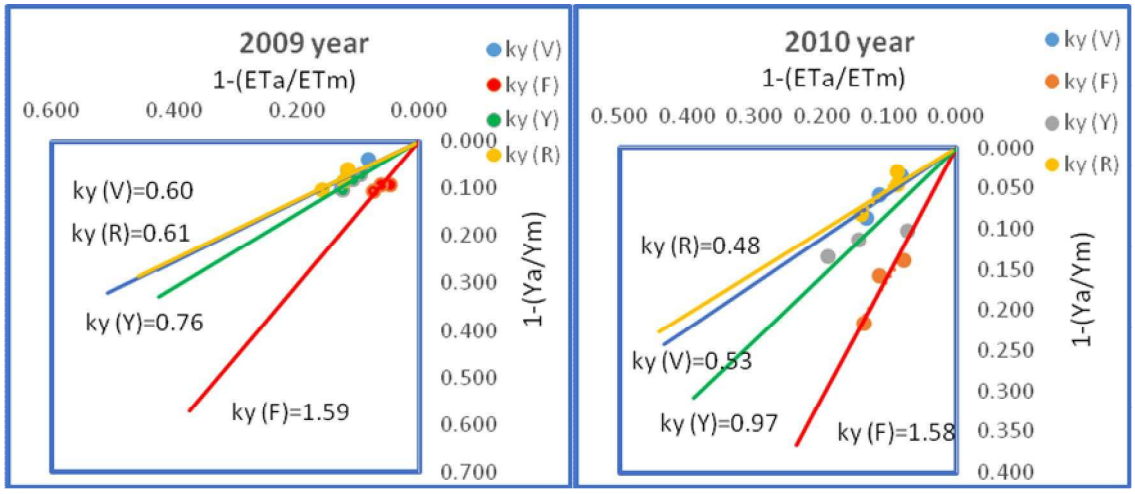

Figure 9. *The relationship between relative yield decrease and relative evapotranspiration deficit for the experimental years*

Water use efficiencies

WUE and IWUE values of the 2009 and 2010 years appeared differently in different treatments (*Table 10*). The maximum WUE values for 2009 year were found as 0.13,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77657781

0.14, 0.13 – 0.14, 0.13, 0.14 kg mm^{-1} and were found 0.13, 0.13, 013 - 0.13, 0.13, 0.13 kg mm^{-1} from V75FYR, V50FYR, V25FYR and $VFYR_{75}$, $VFYR_{50}$, $VFYR_{25}$ treatments for 2010 year, respectively. IWUE values for 2009 year were found as 0.17, 0.16, 0.16 – 0.17, 0.16, 0.16 kg.mm^{-1} and were found 0.17, 0.17, 0.16 – 0.16, 0.17, 0.17 kg mm^{-1} from V75FYR, V50FYR, V25FYR and $VFYR_{75}$, $VFYR_{50}$, $VFYR_{25}$ treatments for 2010 year, respectively. When WUE and IWUE values were taken into consideration, the maximum WUE and IWUE values were obtained in vegetative and ripening periods and the lowest value was obtained from flowering and yield formation periods. In other words, the maximum yields were obtained from vegetative and ripening periods and the most water saving was supplied with deficit irrigation only in the vegetative and ripening periods of the tomato.

Discussion

In this experiment, irrigation treatments considerably influenced yield, fruit weight, diameter, height and dry matter. In both experimental years, the maximum amounts of water applied to the crop were 554-556 mm for from $V_{100}F_{100}Y_{100}R_{100}$ while the seasonal evapotranspiration (ETa) values were changed between 725-300 and 746-340 mm for $V_0F_0Y_0R_0$ treatment. Total water amounts varied from 400 to 600 mm depending upon climate and length of growing season (Doorenbos and Kassam, 1979). Water applied for tomato ranged from 415 to 800 mm under different controlling sistems (Mahajan and Singh, 2006). Ayas (2015) stated that irrigation water amount applied for tomato varied from 65 to 564 mm in different treatments in the province of Bursa of Turkey. Kirda et al. (2004) reported that total seasonal evapotranspiration by tomato for spring and fall planted varied from 274 to 447 mm and irrigation water applied varied from 173 to 456 mm. Hanson and May (2011) determined that applied water ranged from 582 to 1018 mm. Berihun (2011) also reported that two days irrigation interval was used and a factorial combination of three levels of water (namely 315, 440 and 565 mm) combined with three mulch treatments. Wan et al. (2007) specified that for three years, evapotranspiration of tomato was 607 mm/season for drip irrigation with saline water. Seasonal evapotranspiration varied from 405 to 946 mm and irrigation amount applied from 271 to 832 mm in the province of Eskişehir in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77657781

Turkey between 1998 and 2000 years (Cetin et al., 2002). These results are notably in accordance with the irrigation water amounts and crop water consumption values obtained from previous studies (Kuscu et al., 2014; Ayas, 2015; Gatta et al., 2015; Biswas et al., 2015; Linker et al., 2016).

The tomato yield ranged between 92.2-2.0 and 93.4-4.0 t ha^{-1} for 2009 and 2010 years, respectively. Yield was decreased as the irrigation water amount reduced. As a result, the effect of deficit irrigation was found significant on total yield. This result was compatible with those of (Liu et al., 2013; Kuscu et al., 2014; Saadi et al., 2015; Ayas, 2015; Gatta et al., 2015; Biswas et al., 2015; Nangare et al., 2016). As in yield, some quality parameters of tomato (fruit weight, diameter, height and dry matter) showed a similar response to deficit irrigation.

As for fruit weight, there was influence of deficiency irrigation on single fruit weight with respect to quality parameters. As observed in yield, the fruit diameter and weight gave similar response to deficit irrigation. The highest quality parameters were obtained from $E_{100}V_{100}Y_{100}R_{100}$ treatments every two experiment years. The non-irrigated ($V_0F_0Y_0R_0$) treatment had lower values than all irrigation treatments. The result of study were in conformance with (Akhtar et al., 2014; Kuscu et al., 2014; Ayas, 2015; Biswas et al., 2015; Nangare et al., 2016). Since $V_{100}F_{100}Y_{100}R_{100}$ treatments had higher fruit weight than the other treatments, the lowest dry matters have been found at $V_{100}F_{100}Y_{100}R_{100}$ treatments when the highest dry matter values were observed at $E_0V_0Y_0R_0$ treatments in both years of the experiment. As a result, we may say that as the amount of irrigation water decrease, the number of dry matter increases. These values are similar to those of previous studies (Birhanu and Tilahun, 2010; Ayas, 2015; Gatta et al., 2015; Candido et al., 2015).

The maximum WUE and IWUE values were found as 0.14-0.19 and 0.14-0.19 for 2009 and 2010 years, respectively. The maximal WUE and IWUE values were obtained in vegetative and ripening periods and the lowest value was obtained from flowering and yield formation periods. When the results concerning WUE values were in comparison to the findings of different researchers, they were in agreement with those of the other studies (Alomran et al., 2012; Mukherjee et al., 2012; Kuscu et al., 2014; Ayas, 2015; Cantore et al., 2016).

The variety of tomato, climate of the region, soil properties and effective use of water also influence yield and quality parameters of tomato. As explained by Davis et al. (2008), it may be attributed to the variety and applied cultural practices handling under different climate and geographical conditions. Crop yield response factor (k_y) for 2009 and 2010 year were calculated as 1.05 and 1.06 for tomato, respectively. The specified values of k_y (1.05-1.06) which is bigger than 1.00 shows that tomato is responsive to the water. The factor of k_y also matches up with the values obtained by researchers who studied on similar issues (Doorenbos and Kassam, 1979; Kuscu et al., 2014; Ayas, 2015; Cantore et al., 2016).

Conclusion

According to the results of the study, irrigation water were applied 554 and 556 mm in $V_{100}F_{100}Y_{100}R_{100}$ treatment applied of full irrigation in 2009 and 2010 years. The plant water consumption of tomato was determined as 300-725 mm and 340-746 mm for $V_0F_0Y_0R_0$ treatment 2009 and 2010 years. The factors of k_y for the different irrigation levels ($V_{100}F_{100}Y_{100}R_{100}$, $V_{75}FYR$, $V_{50}FYR$, $V_{25}FYR$, $VF_{75}YR$, $VF_{50}YR$, $VF_{25}YR$, $VFY_{75}R$,

DOI: http://dx.doi.org/10.15666/aeer/1704_77657781

$VFY_{50}R$, $VFY_{25}R$, $VFYR_{75}$, $VFYR_{50}$, $VFYR_{25}$, $V_0F_0Y_0R_0$ treatments) in 2009 and 2010 years were calculated as 1.05 and 1.06 for tomato, respectively. The factors of k_y (1.05 and 1.06) values are bigger than 1.00 showed that the tomato was susceptible to water. The crop yield response factors (k_y) were close to each other in both years of the study. The highest yield decreases in all treatments were in *$V_0F_0Y_0R_0$* treatments, while the lowest yield decreases were in *$V_{100}F_{100}Y_{100}R_{100}$* treatments. In our trial, it was studied out that irrigation treatments considerable influences yield, fruit diameter, weight, height and dry matter ratio.

In this study, it was studied out that irrigation applications considerably influences yield, fruit weight, diameter, height and dry matter. In both years of the study, the highest yield was 92.2 t h^{-1} and 93.4 t h^{-1} and it was observed in $V_{100}F_{100}Y_{100}R_{100}$ treatment. The lowest yield was observed as 2.0 t h^{-1} and 4.0 t h^{-1} in $V_0F_0Y_0R_0$ treatment. Yield decreased considerably as a result of the diminishment in the water amount. Relative yield decreases in the irrigation treatments in 2009 and 2010 were 4.1%, 6.7%, 11.1%, 10.0%, 10.3%, 11.8%, 7.5%, 9.0%, 11.4%, 6.3%, 9.2%, 11.5%, 4510.0% and 3.7%, 6.3%, 9.5%, 16.0%, 18.8%, 27.6%, 11.5%, 12.8%, 15.5%, 3.1%, 4.7%, 8.9%, 2235.0%, respectively. WUE and IWUE values of vegetative and ripening periods were the maximum of all the treatments.

As a result of a possible deficit irrigation in a semi-humid climate condition, it is necessary to plan carefully and it is possible to say that the levels and times of the deficit irrigation were significantly effective on tomato yield. If deficit irrigation treatment is obligatory, water deficiency should be planned only for vegetative and ripening periods of tomato. The water deficiency should not be applied in flowering and yield formation periods and irrigations in these periods should be exactly applied. In addition, in the irrigation planning to be applied in similar climatic conditions may be benefited from crop yield response factor (ky) values. The results used to determine the amount of reduction in yield in response to the water deficiency applied to the plant may be used in studies related to tomato. It can be recommended that vegetative and ripening periods is most suitable periods for the deficit irrigation practices for tomato irrigation by drip irrigation.

(Received 17th Mar 2019; accepted 3rd May 2019)

Abstract. Organic agriculture is an integrated form of agriculture combines techniques of ancient knowledge with current science and targets to exclude inorganic fertilizers, growth regulators and pesticides. Generally organic products are accepted as healthier and better tasting. This opinion is more common for fruits and vegetables. Series of studies on comparison of organic and conventional fruits and vegetables have been performed but comparison of analytical quality parameters lacks in previous studies especially fatty acids and volatile aroma compounds. This study compares pomological parameters, some selected chemical properties, fatty acid composition and volatile aroma compounds of organic and conventionally grown Ferragnes and Ferraduel almond cultivars. Results indicated significant differences between cultivars and growing systems suggesting a better overall market quality for organic kernel samples. Total oil and linoleic acid was lower in organic samples, whereas oleic was higher (82.4% in both cultivars) when compared with conventional samples (78.9% for Ferragnes and 75.8% for Ferraduel). Most of the aroma compounds detected in this present study are new record for almond aroma-active compounds. In an overall view, organic samples resulted with higher contents of aroma compounds.
Keywords: *composition, kernel, quality, Prunus amygdalus, taste*

Introduction

The most widely cultivated nut crop of Mediterranean area is the almond. World almond production was more than two tons, and The United States was the leading producing country (1.029.655 tons) followed by Spain (255.503 tons) and Turkey was the fifth country with the production of 90 thousand tons (FAO, 2019). Almond growing areas have significantly increased in last decades, and this increase is due to increasing demand for almond thanks to its natural and healthy food ingredients. Many reports have been published on nuts as a beneficial food source for human consumption, and considered as an essential balancing component in diets especially because of rich nutritional value. Even though almond contents high amount of fat, it has high amounts of unsaturated fatty acids (both mono and poly) and fiber (Sánchez-Bel et al., 2008).

Main quality aspects of almonds are their chemical composition, fatty acids composition, aroma compounds, protein and ash content, etc. Varying mainly depending on genetic background and ecological factors, but also cultural practices, general chemical composition of an almond is fat, proteins and carbohydrates in the percentages of 50-60, 20-25 and 20, respectively (Sánchez-Bel et al., 2008).

Today, agricultural practices are designed by knowledge of intense research, and especially studies on organic agriculture including organic fertilization have strong effects on the capacity of food production. Therefore, many studies have been performed to observe the increase in yield and quality of the almond in ecological agriculture and organic fertilization (Heeb et al., 2006; Lester et al., 2007; Sánchez-Bel

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77837793

et al., 2008). Organic farming benefits biodiversity (Bengtsson et al., 2005; Hole et al., 2005), and have the potential of increasing yield in some cases, especially with better water use efficiency and less carbon sequestration and pesticide use (Pretty et al., 2006; Wood et al., 2006). On the other hand, organic growing has the disadvantages of higher input and lower yield for the farmers (Guichard et al., 2001). In terms of consumer acceptance, organic foods are better welcomed, since consumers assume organic crops as higher quality (better tasting and more nutritious) rather than those conventionally grown crops (Ekelund and Tjarnemo, 2004; Gąstoł et al., 2011). Indeed, there are various reports on health benefits of organic crops (Lester et al., 2007). For that reason, organic crops growers ask higher prices for their crops to balance the relevant disadvantages. However, this demand of the growers is generally met by displeasure of traders and consumers.

Previously, some comparison studies about organic and conventional almond were published. Venkatasubramanian (2011) conducted a retail level study and compared some nutritional quality aspects of organic and conventional market foods including almond snacks. Sánchez-Bel et al. (2008) compared organic and inorganic fertilizers on potted almond trees, cv. Guara. A profitability comparison study was performed for organic and conventional almond orchards (Anonymous, 2011). On the other hand, a number of studies compared organic and conventional fruits based on sensory tests (Bourn and Prescott, 2002). But, previous studies about comparison of organic and conventional grown almond fruit quality are limited, especially for fatty acid composition and volatile aroma compounds.

In the previous studies, generally two methods of investigating differences between organic and conventional products have been applied which are cultivation and retail market studies. Both of them are focused on advantages and disadvantages. The approach used in this study is the compositional analysis of crops obtained from farm and cultivation rather than purchasing products from market. Farm and cultivation studies differ from retail market studies with the information available on cultivar, environmental conditions, harvest and post-harvest influences etc. Therefore, retail studies are reported as representative of the growing system in broad sense (Magkos et al., 2006).

For all of those reasons, in order to evaluate flavor related aroma compounds and various quality aspects of organic and conventional growing in almond this study was conducted to compare final quality of almonds grown organic and conventionally.

Materials and Methods

The study was conducted in Konuklu Village located in Besni County of Adıyaman Province, Turkey (37°36'11.13"N and 37°56'00.15"E) in 2018 which was a normal year in terms of climatic conditions for the area (*Table 1*). Plant materials of the study consisted of 8 years old organic and conventionally grown trees of Ferragnes and Ferraduel cultivars grafted on wild almond (*Prunus amygdalus* var. amara). Organic and conventional trees were grown in two nearby orchards that eliminate climatic influences. Pest management, weed control and soil cultivation were done as required. Drip irrigation and fertigation were utilized, and no nutrient deficiencies and water stress were observed during the season.

The study was conducted according to randomized block design including the plantation and fruit sampling, and from each genotype representing fruit samples were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77837793

collected as required at harvest maturity stage (Anonymous, 2014). Fruit samples were subjected to hull separation and obtained nuts were sun dried for 4 days until 7% moisture level. Totally 10 kg of nuts (kernel with shell) samples were collected from each cultivar in each orchard. After two months of preservation of dried nuts at room temperature, pomological properties, chemical composition, fatty acid composition, and volatile aroma compounds of collected fruit samples were examined.

Pomological Evaluations and Sensory Analysis

With this regard, nut weight (NWE), nut length (NLE), nut width (NWI), nut thickness (NTH), kernel weight (KWE), kernel length (KLE), kernel width (KWI), kernel thickness (KTH), kernel/nut ratio (K/N), and Unit Kernel Number, number of kernels in 28.35 g (UKN), were measured. Nut and kernel width (mm), height (mm), and thickness (mm) were measured using digital calipers. Nut and kernel weight (g) were measured by precision scales (0.1 g), and kernel/nut ratio was calculated by division of these values. As part of market quality evaluation of the samples, consumer acceptability was also assessed by sensory analysis. For this aim, five judges (one a regular almond consumer, two almond growers, and two agriculture professionals) compared organic and conventional kernel samples in terms of their size & shape, color, and flavor.

Chemical composition

Total oil, total protein, total ash, and moisture were detected in terms of chemical composition. Total oil content was analyzed by extraction of oil with n-hexane (60 C) for 6 h using Soxhlet extractor (Anonymous, 2000). Total protein content was calculated by multiplication of total N content which was detected according to Kjeldahl method with 6.25 (James, 1995). Total ash were determined by burning almond kernels for 24 hours at 200°C and 6 hours at 600°C, respectively (Baymış, 2008). Kernel moisture content was measured according to the weight difference after heating the samples in an oven at 105°C for 24 hours (USDA, 1970).

Fatty acid composition

Fatty acid composition was evaluated by determination of palmitic acid, palmitoleic acid, stearic acid, oleic acid, linoleic acid contents. The fatty acid methyl esters were detected in a gas chromatograph (Shimatzu, QP2010 ULTRA) with a flame ionization

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77837793

detector and Rtx-5 MS capillary column according to Anonymous (1993). Obtained results were expressed as percentages of each fatty acid with regard to total oil content.

Volatile aroma compounds

Volatile aroma compounds were detected semi-quantitatively. Semi-quantitation (peak measurement) was done using another gas chromatograph (Agilent GC7890A) with a flame ionization detector and DB-5 ms capillary column (60 m×0.320 mm i.d. and 1 μm, film thickness) and 2-methyl-3-heptanone (internal standard) was used as internal standard. Peaks were identified by comparing retention times and mass spectra of eluted compounds with those of the Wiley library (Wiley7, Nist 05, J. Wiley & Sons Ltd., West Sussex, England).

Statistical calculations

Pomological parameters were measured in four replicates and obtained results were analyzed according to Duncan's test ($P \leq 0.05$) using SPSS 23.0 for Windows software. Data of compositional analyzes represents the average of multiple parallel measurements. Semi-quantitation was performed by comparing relative peak areas observed using FID detection, divided by the concentration in solution and compared again to that of 2-methyl-3-heptanone using headspace analysis.

Results

Fruit samples of almond trees grown organic and conventionally were evaluated in terms of pomological traits, sensorial quality, chemical, fatty acids and volatile aroma compounds composition. Pomological and sensorial evaluations were presented in *Table 2* and, results of the chemical, fatty acids and volatile aroma compounds compositions were shown in *Table 3, Table 4* and *Table 5*, respectively.

Pomological Evaluations and Sensory Analysis

Significant differences for all evaluated pomological parameters, except NLE which was not significantly differed between cultivars and growing systems. Although differences between nut and kernel sizes were significant between cultivars, they were not found significant between organic and conventional samples. NWE and KWE were significantly changed between organic and conventionally grown Ferraduel cultivar. NWE and KWE of organic Ferraduel samples were higher than conventional samples (4.9 and 4.6 g, 1.3 and 1.2 g, respectively). Both kernel and nut weight parameters were significantly changed between cultivars. Similarly, differences of K/N results were significant between cultivars but not between growing systems. On the other hand, UKN was significantly varied both between cultivars and between organic and conventionally grown Ferraduel cultivar. UKN of conventionally grown Ferraduel cultivar was higher than organic samples (23.8 and 21.4, respectively). Results indicated heavier nuts and kernels for organic samples of Ferraduel cultivar comparing to those conventional samples. Sensorial evaluations approved no difference between organic and conventional kernels in terms of size & shape, but indicated that organic kernels were slightly darker and richer in flavor. Results of the pomological evaluations are presented in *Table 2*.

DOI: http://dx.doi.org/10.15666/aeer/1704_77837793

Chemical Composition

Highest total oil content was found in conventional Ferragnes samples (46.7%), whereas organic Ferraduel samples presented the lowest total oil content (41.1%). Highest total protein and moisture were found in organic Ferraduel samples. The lowest values for these contents were found in conventional Ferragnes (20.7% for total protein, and 4.5% for moisture). While ash content was not significantly varied between organic and conventional samples, in both cultivars organic kernels presented lower total oil, but higher total protein content and moisture when compared to conventional samples. Ferragnes was higher in total oil content, whereas Ferraduel was higher in total protein and moisture. Proximate chemical compositions results are presented in *Table 3*.

Fatty Acid Composition

As part of fatty acid composition, the most significant differences were found in oleic and linoleic acid contents. Oleic acid contents were higher in organic samples, whereas linoleic acid contents were lower in both cultivars. Highest oleic acid content was found in organic samples which were the same in average for both cultivars (82.4%). Conventional Ferraduel samples were found with highest linoleic acid content

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77837793

(15.3%) followed by conventional Ferragnes samples (12.7%). Palmitic, palmitoleic and stearic acid contents were also higher in organic samples of both cultivars, and among the cultivars these values were higher in organic Ferraduel samples (7.9, 0.8, 2.7%). Fatty acid compositions of the samples included in the study are presented in *Table 4*.

Table 4. *Fatty acid compositions (percent) of almonds at organic and conventional orchards*

%	Ferragnes		Ferraduel	
	Organic	Conventional	Organic	Conventional
Palmitic Acid (C16:0)	6.4	5.9	7.9	6.0
Palmitoleic Acid (C16:1)	0.7	0.6	0.8	0.7
Stearic Acid (C18:0)	2.1	1.9	2.7	2.2
Oleic Acid (C18:1)	82.4	78.9	82.4	75.8
Linoleic Acid (C18:2)	8.4	12.7	6.2	15.3

Volatile Aroma Compounds

A total of 39 volatile aroma compounds were identified in almond kernel samples included in the study. The volatile aroma compounds consisted of ketones (17), terpenes (6), alcohols (5), esters (5), alkanes (4), and aldehydes (2). When all of the volatile compounds were classified according to absence in organic or conventional samples, most of the compounds were found higher in organic samples. Indeed, overall volatile compound contents were calculated as 1519 and 1193 µg/kg for organic and conventional samples of Ferragnes cultivar, 1417.4 and 1325.2 µg/kg for organic and conventional samples of Ferraduel cultivar.

Among the detected volatile compounds Butanal, Butyl acetate, Ethylbenzene, p-Chlorotoluene, 4-Octanone were found in higher concentrations in organic samples when compared with conventional samples in both cultivars. Pentadecane, 2-methyl-2-phenyl- was only detected in organic samples of both cultivars. On the other hand, some of the volatile compounds were detected in organic samples of one of the cultivar, while not found in other cultivar. 6-Hepten-3-one, 4-methyl-, 2.3-Dimethyl-1-butene, 3-Heptanone-5-methyl-, 2.6-Decadiene-4.5-diol-6-ethyl-, Decyl decanoate, Gamma-decalactone were detected in organic samples of Ferragnes, but not found in conventional Ferragnes samples and both of the Ferraduel samples. Similarly, Ethanone-1-(1-methylcyclopentyl)-and m-Cymene were detected in organic samples of Ferraduel, but not found in the rest of the samples. Butyl valerate and 3-Chloropentane-2.4-dione were not detected in conventional samples of Ferragnes cultivar but found in the rest of the samples.

The volatile compounds that found higher in conventional samples were butanol, 2-Methyl-3-heptanol, 2.5-Dimethyl-3-hexanone, isobutyric acid. On the other hand, 2.4-Dimethylpentane and 2-Hepten-4-one-2-methyl- were only found in conventional samples of Ferragnes, and similarly Octane-2.4.6-trimethyl-, diethyl phthalate, and gamma-undecalactone were only found in conventional samples of Ferraduel. While 3-Methyl-2-pentanone was not detected in both of the Ferragnes samples, it was detected in both organic and conventional samples of Ferraduel, and was found higher in concentration in organic samples when compared with conventional ones. Results of the volatile aroma compounds are presented in *Table 5*.

Discussion

Almond cultivars included in this study were investigated in terms of pomological parameters under conventional growing conditions. Gülsoy and Balta (2014) reported an almond selection study included Ferragnes cultivar grown at Aydın city of Turkey. They reported NWE, NLE, KWE, KLE, and K/N as 3.4 g, 33.4 mm, 1.1 g, 25.5 mm, and 32.6, respectively. Parlakçı (2007) performed an adaptation study in Şanlıurfa city of Turkey and included Ferragnes and Ferraduel cultivars. They reported NWE, NLE,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77837793

KWE, KLE, and K/N as 3.3 g, 32.6 mm, 1.2 g, 25.1 mm, and 31.1 for Ferragnes, and 3.7 g, 33.4 mm, 1.2 g, 25.7 mm, and 31.0 for Ferraduel, respectively. Results of these studies were similar each other but slightly lower than this study that probably caused by climatic differences caused by the year and environment.

Only a few previous studies have performed on comparison of chemical differences between organic and conventional almond. Venkatasubramanian (2011) compared commercial food samples of nuts from organic and conventional growing in terms of some sensory characteristics and chemical properties. Even though organic samples were found slightly darker and richer in flavor based on the sensory evaluations of this study, Venkatasubramanian (2011) reported a lighter color for organic almond, and no difference in terms of flavor. The difference of the flavor differences may be caused by fatty acid and volatile aroma compounds compositions. On the other hand, Venkatasubramanian (2011) reported higher protein, but lower fat and moisture content for organic samples when compared with conventional ones. These results are in accordance with total oil results of this current study but in opposite way for protein and moisture content. Relevant differences could be caused by multiple factors including cultivar, environmental differences, post-harvest processing, packaging, storage conditions etc. (Valdés et al., 2015). Yildirim et al. (2016) investigated total oil content of some almond cultivars and reported total oil contents as 61.3% for Ferragnes and 58.2% for Ferraduel. Houmy et al. (2016) measured total oil content of Ferragnes and Ferraduel kernel mixture and reported the value as 59.0% in average.

Sánchez-Bel et al. (2008) compared fatty acid composition of almond kernels sampled from trees fertilized with organic and inorganic fertilizers, and found no difference between the treatments in terms of fatty acid composition. However, current study resulted with significant differences especially in oleic and linoleic acid contents. Yildirim et al. (2016) investigated fatty acid compositions of conventionally grown Ferragnes and Ferraduel cultivars and indicated results in accordance with the results of conventional samples included in this present study. The differences between results of the studies would mainly are caused by growing conditions, and also cultivar difference. Samman et al. (2008) reported an inconsistently varied trend in the fatty acid compositions of edible oil samples of different crops grown organic and conventional including olive, coconut, canola, sesame, and sunflower.

Almonds are one of the most preferred nuts which are a regular part of the human diet since thanks to high nutritional value, and also sensory properties (Sathe et al., 2008; Gonçalves et al., 2018). Consumer preferences are related to nut quality which is associated with attractiveness such as color, size and shape (Kader, 2008), but aroma also play key role in market acceptability (Aceña et al., 2009; Shakerardekani et al., 2013). For this reason, evaluation of aroma compounds is important for determination of final quality of the products. Xiao et al. (2014) analyzed aroma compounds in raw almond samples and detected totally 41 volatile compounds from the groups of alcohols, aldehydes, ketones, and pyrazines. Erten et al. (2017) investigated aroma-active compounds in raw, dry roasted and oil roasted almonds and detected totally 59 aroma compounds including aldehydes, ketones, Nitrogen-containing compounds, Sulfur-containing compounds, acids, furanones, and other unknown compounds. Previously reported studies on volatile compounds in almonds showed that there are a large variety of compounds active in aroma specification of almonds that varies in absence and concentration in depending on various factors (Valdés et al., 2015; Erten, 2016). Erten et al. (2017) also suggested further studies for the identification of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77837793

potentially important unknown aroma compounds in almonds. In furtherance of this suggestion of the authors, most of the aroma-active compounds detected in this present study (all compounds except acetone, butanal, 2-Phenyl-2-propanol, ethylbenzene, and 3-Heptanone) were not reported by previous studies in almonds (Erten, 2016; Kesen et al., 2018).

Conclusions

This study was conducted to compare organic and conventional almond samples of two different cultivars. Overall physical quality evaluations indicated not a worse even better market quality potential for organic samples of both almond cultivars. Consistent differences were found between fatty acid compositions of organic and conventional samples both of the cultivars. In conclusion, together with various aroma-active compounds detected, organic samples were found richer in total amount and the range of compound diversity.

Abstract. With the acceleration of urbanization and the change of land use, the urban heat island effect has been significantly enhanced, leading to the rise of urban temperature, changing local air circulation, and influencing local microclimate. For investigating the temporal and spatial rules of the urban heat island effect in Xi'an City, China, this study combined Landsat TM, ETM remote sensing image, and surface meteorological station observation data to probe the trend of the urban heat island intensity in Xi'an City from 1993-2013 and to analyze its influencing factors. The results show that, from 1993 to 2009, the heat island intensity presented an increasing trend, with a temperature rise rate of 0.38°C/10y, while the heat island intensity showed a decreasing trend from 2009 to 2013. There was a positive correlation between heat island intensity and the urban area in Xi'an city. By a comprehensive analysis, the expansion of the urban land area, the heat island intensity followed a constantly increasing radius of influence are the main reasons.
Keywords: *urbanization, heat island intensity, urban land, forest land, farmland*

Introduction

Urban heat island refers to a phenomenon of increasing urban surface and atmospheric temperature in comparison to peripheral non-urban environments as a result of urbanization (Peng et al., 2013; Soltanifard et al., 2019). Urban heat island intensity typically measured by the mean difference between urban temperature and suburban temperature. According to existing publications, due to the urban heat island effect, the urban temperature of a city is typically 2-5°C higher than its peripheral suburban temperature (Ackerman, 2010). In recent years, with the acceleration of urbanization, the original use patterns of natural land have changed considerably, and the construction of buildings, roads, and other impermeable surfaces (Estoque et al., 2017) have further fragmented the urban landscape, increased the urban area and population, and enhanced the urban heat island effect (Alberti et al., 2004; Ciren et al., 2012; Zhou et al., 2017). Before 1980, the urban-suburban difference in annual mean minimum temperature of Shijiazhuang City had been rising by 0.26°C/10y; after 1980, it has been rising by about 1.7°C/10y (Yang et al., 2013a). On the temporal and spatial change characteristics of the heat island effect of Nanjing City, since 1985, the heat island intensity and scope have both increased, and the area affected by the grade-4 heat island effect in the built-up areas has increased by 107.88 km^2 (Yang et al., 2007). Beijing City, the capital of the People's Republic of China, reported that the area

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77957806

affected by urban heat island effect has constantly increased (Wang et al., 2006). In the Athens region, during the research period, the difference between its urban temperature and its suburban temperature was very significant, with a rising rate of 0.2°C/10y (Founda et al., 2015). The enhanced urban heat island effect has severely influenced both biodiversity and human life (Wu et al., 2014). Thus, in the context of changing patterns of urban land use, exploring the change rules and trend of the urban heat island effect has become one of the hotspot issues related to urban development under global climate change (Dong et al., 2011; Zhang, 2013a; Zhang et al., 2013b).

Studies on the urban heat island effect mainly conducted according to three methods: the ground meteorological data observation method, the remote sensing monitoring method, and the numerical simulation of the boundary layer (Yang, 2013b). Early studies mainly completed through an atmospheric temperature comparison between the urban and suburban areas of a city in the same period or of its different development stages (Song et al., 2009). With the development of remote sensing science and technology, the remote sensing monitoring method has become the primary method for investigating the heat island effect. In particular, aerospace sensors used to observe urban underlying surface temperature and other factors, while thermal infrared remote sensors are used to measure urban land cover temperature, thus obtaining heat distribution maps of different land covers via calculation and analysis (Yang, 2013b). For instance, remote sensing image for the inversion of land surface temperature and reported that changes in land use and land cover constitute the major drive behind the change in land surface temperatureb (Jiang et al., 2010). Other scholars (Chen et al., 2006; Qian et al., 2006; Xiao et al., 2007; Buyadi et al., 2013) reported that the increase of urban land area has led to a rise of land surface temperature, enhancing the urban heat island effect. The land surface temperature obtained through inversion via thermal infrared remote sensing can cover the land surface by a large scale, thus ensuring the relatively high spatial continuity and spatial resolution of the results (Voogt et al., 2003; Arnfield, 2003; Chen et al., 2012). However, given that the thermal infrared remote sensing phenomenon of the land surface is more significant during the daytime than during the nighttime, the results obtained with this method differ from the results calculated by atmospheric temperature data (Chen et al., 2012). It is thus clear that the data integration of aerial remote sensing and ground monitoring provides an effective method of researching the urban heat island effect.

With the acceleration of urbanization in China and the consequent increase of urban heat island intensity and expansion of heat island effect scope, accurately assessing and monitoring the development of the urban heat island effect has become particularly important at this point (Weilin et al., 2017). For explore the relationship between the urban heat island effect in Xi'an City and land use, land cover change (LUCC), this study integrated the remote sensing imaging technique and ground-measured atmospheric temperature data, probed into their relationships from both temporal and spatial scales, and analyzed the main controlling factors of the urban heat island effect through statistical comparison.

Research Contents and Methods

Research area

The study area, the Xi'an city, the People's Republic of China, located in the middle of the Guanzhong Basin, consisting of nine districts and four counties (geographical

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77957806

coordinates: 33°49′N-34°45′N, 107°40′E-109° 49′E). Xi'an city, situated between the Weihe River on the north and the Qinling Mountains on the south and adjoining, with the Taibai Mountain on the west and the Weinan City on the east. It is a temperate continental climate, with an annual mean temperature of 13.00°C and annual mean precipitation of 604.2 mm. It's maximum north-south width, and east-west lengths are about 116 km and 204 km, respectively. The total area of the city is 10,108 km^2.

Data sources

The temperature observation data came from the surface meteorological stations distributed in the urban districts and in Chang'an District, Lantian County, Gaoling County, Lintong County, Huxian County, and Zhouzhi County (*Fig. 1*). In particular, the annual mean temperature data of 1993, 1995, 2000, 2006, 2009, and 2013 were used to investigate the changing trend of heat island intensity; monthly mean temperature data were used to explore the spatial rules of heat island intensity change.

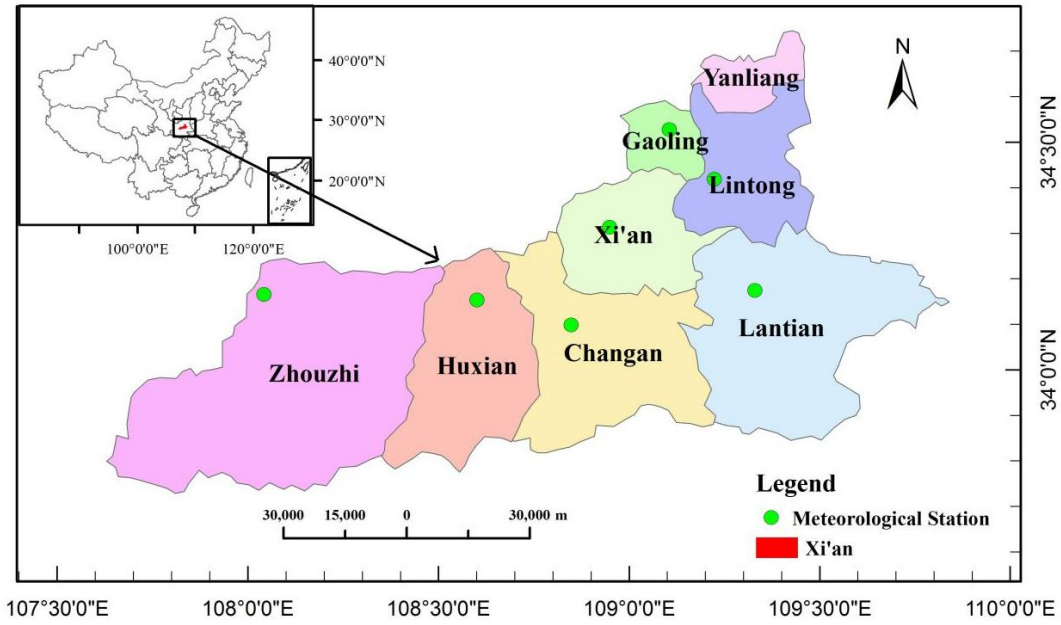

Figure 1. *Xi'an Administrative Region*

The remote sensing images were derived from the Geospatial Data Cloud of the Chinese Academy of Sciences (CAS), and Landsat TM and ETM remote sensing image data were selected from six years, i.e., 1993-6-18, 1995-6-8, 2000-5-20, 2006-7-24, 2009-6-30, and 2013-6-29.

Data processing

(1) The ENVI5.1 software used for the interpretation of remote sensing images and the supervised classification method was used to classify these images. According to national standards (Classification of land use status, GB/T 21010-2017), there are a total of six land use types, i.e., urban land, forest land, grassland, farmland, water area, and unused land. Based on the areas of various land use types obtained through statistical methods, a comparison conducted between acquired data and data from the statistical

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77957806

yearbooks, with the purpose of ensuring that the acquired data all fall within the allowable error range.

(2) Calculation of urban heat island intensity was done with the following formula:

$$\Delta T_{u-r} = T_u - \frac{1}{n}\sum_{i=1}^{n} T_r \quad \text{(Eq.1)}$$

where, ΔT_{u-r} is the urban heat island intensity; T_u is the annual mean temperature of downtown districts; T_r represents the annual mean temperature of suburban areas, covering six districts (counties), i.e., Chang'an District, Lantian County, Gaoling County, Lintong County, Huxian County, and Zhouzhi County; and n represents the number of suburban meteorological stations (n = 6).

Statistical analysis

The correlation between heat island intensity and various land cover types was analyzed according to the multivariate stepwise regression analysis and using SPSS software.

Results

Spatial change of the heat island effect in Xi'an City

Fig. 2 shows the temporal and spatial change rules of the temperature of Xi'an City. As can be seen from the interpretation of the remote sensing images during 1993-2009, the area of urban land showed a significantly increasing trend, and the area of downtown Xi'an City significantly increased as well. In the mountainous terrain of the Qinling Mountains to the south, and affected by human activities, the farmland and urban land of the intermontane valley region all increased, further fragmenting the forest there. The water area in this region accounted for a small proportion and did not present any significant change trend. Correspondingly, as indicated by the isothermal diagram of Xi'an City, with the expansion of urban land area, the isothermal diagram became more concentrated, pointing toward an increase of temperature gradients.

For comparatively analyze the changes in the urban heat island effect, this study calculated the change values of urban heat island intensity with time (*Eq. 1*). Affected by urban expansion and human activities, the mean temperature of Xi'an City increased significantly (*Fig. 3*). From 1993-2009, its urban heat island intensity presented a significantly increasing trend and increased from 0.42 in 1993 to 1.0 in 2009, and the five-year mean temperature rising rate of the city was 0.19°C/5y. Thus it is clear that after 2009, the urban heat island intensity index presented a decreasing trend. To discuss the cause of such a decrease, we evaluated the data of the statistical yearbooks of Xi'an City. According to statistical data from 2009 to 2013, the population of the city increased from 8.4346 million to 8.5881 million, and its urban land area was also constantly increased. However, it's forest land area remained unchanged. The improved urban landscape construction and increased green area weakened its heat island intensity to some extent (Huang et al., 2012). Furthermore, the climatic environment and local weather conditions also influenced the urban heat island effect, including inversion intensity, cloud cover, wind speed, wind direction, relative humidity, precipitation, and sunshine duration(Wang et al., 2006; Liu et al., 2008; Huang, 2011).

The relationship between heat island intensity and land use change of Xi'an City

To further analyze the relationship between heat island effect and land use in Xi'an City, remote sensing images were used to extract the urban land area, farmland area, forest land area and water area in the period of 1993-2009 to comparatively analyze their changing trends with time. *Fig. 4* depicts the change trends of the proportions of the urban land area, farmland area, forest land area, and water area in the total land area of Xi'an City with time. In summary, the urban land area of Xi'an City presented an increasing trend from 0.086 in 1993 to 0.100 in 2013. Xi'an's farmland area decreased from 0.316 in 1993 to 0.242 in 2013, while it's forest land area presented an increasing trend from 0.344 in 1993 to 0.503 in 2006. However, from 2006-2009, the water area showed a decreasing trend before 2000, an increasing trend observed after 2006.

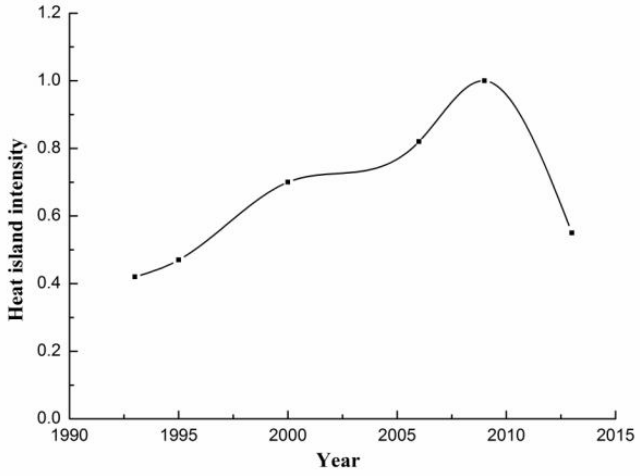

Figure 3. *Change trend of the urban heat island intensity of Xi'an City*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77957806

Correlation between land use area change and heat island intensity of Xi'an City

Multivariate stepwise regression analysis was employed to analyze the correlation between the change of land use and heat island intensity, as well as to quantitatively investigate the correlation between heat island intensity and the areas of various land use types. The analysis results presented in *Table 1*.

Table 1. *Relationship between land use change and heat island intensity of Xi'an City*

Land use types	Urban land	Farmland	Forest land	Water area
Coefficient of correlation	0.985	-0.965	0.938	-0.223

The analysis results show a positive correlation between heat island intensity and urban land area (coefficient of correlation = 0.985), suggesting that the increase of urban land area exerted a very significant influence on the heat island intensity. A positive correlation was observed between heat island intensity and farmland area, as the decrease of farmland area would enhance the heat island effect. A positive correlation also observed between heat island intensity and forest land area, which is inconsistent with the results reported in other studies (Zhang et al., 1988; Liu, 2007; Liu et al., 2011). It's might because Xi'an City leans on the Qinling Mountains on the south and its forest land mainly distributed in the mountainous terrain of the Qinling Mountains. However, the airflow motion of Xi'an City mainly influenced by the northwest monsoon climate. In other words, the forest land of the mountainous terrain of the Qinling Mountains exerted no significant influence on the heat island effect of Xi'an City (Miao, 1998; Wang et al., 2008; Miao, 2014). A negative correlation found between heat island intensity and water area. However, the correlation was not strong, mainly because the water area in this region only accounted for a small proportion. After 2006, the water area showed an increasing trend, but small-area urban water bodies still exerted no significant regulatory effect on urban temperature (Liu et al., 2011).

To this regard, this study introduced multivariate stepwise regression analysis to investigate the relationship between the proportions of the urban land area, farmland area, forest land area, and water area in the total land area of Xi'an City and its heat island intensity. The results of stepwise regression shown in *Table 2*, and the regression model acquired:

$$Y = 85.912X_1 - 6.913 \quad \text{(Eq.2)}$$

where Y represents heat island intensity, and X_1 represents the proportion of urban land area in the total land area.

Table 2. *Stepwise regression analysis results*

Model	Unstandardized coefficient		Standardized	t	Sig.
	B	Standardized coefficient	Trial version		
Constant	-6.913	0.769	0.985	-8.992	0.003
Urban land	85.912	8.693		9.883	0.002

All correlations were statistically significant ($p<0.01$)

Discussion

During recent years and with the acceleration of urbanization, China's large and medium-sized cities have witnessed an enhanced urban heat island effect (Weilin et al., 2017). Zigong City, in Sichuan Province, P. R. China, experienced relatively fast urbanization from 2000 to 2009, and the significant increase of urban land area changed the nature of the urban surface, thus enhancing the heat island effect (Deng et al., 2015). Guo et al. (2015) explored the thermal environmental characteristics and heat island intensity of urban villages in Shenzhen City and discovered a significant heat island effect in these villages. Using remote sensing images, Yao et al. (2013) analyzed the temporal and spatial change characteristics and causes for the heat island effect in Hefei, and the results show that the spatial distribution and extension of heat islands matched the layout of the city's built-up areas in the period of 1995-2010. Furthermore, the scope of heat islands continuously expanded with the development of Hefei city. In Shenyang City, P. R. China, compared to 2001, the year 2010 saw a significantly expanded urban heat island area (Wang et al., 2015). Heat island intensity, being closely related to LUCC, population, greening, and urban landscape environment, which is also influenced by the sum of climatic environmental and local weather conditions. In particular, local weather and meteorological conditions constitute the external cause, while land use change incurred by population growth, urbanization, and industrialization constitute the internal cause (Peng et al., 2013). Focused on the influence of the urbanization development of City on the heat island effect, Wang et al. (2010) found that the urban heat island effect of Shanghai City has gradually enhanced during recent years, mainly due to the increase of population density and the increase of built-up areas to a very large extent. Feng (2011) investigated the heat island effect in the metropolitan circle of Xi'an City and found the heat island effect in all the typical towns in its metropolitan circle to varying extents. In Liaoning Province, among the six cities, five suffered from an enhanced heat island effect (Li et al., 2012). Also, many other domestic cities experienced a heat island effect to varying degrees, and with the warming of the global climate and the acceleration of urbanization, the heat island effect gradually enhanced in China (Ran, 2010; Li, 2012). From the above results, we can say that the heat island effect poses a significant threat to human life and health. Therefore, it is of vital importance to decrease heat island intensity. Judging from the research results of this study, the urban heat island effect of Xi'an City presents an enhancing trend, mainly as a result of the increased urban area.

According to existing research, a negative correlation exists between the urban heat island effect and forest land area (Yang et al., 2007, 2014; Dai et al., 2009; Liu et al., 2011; Chen et al., 2012). However, according to our research, there is a positive correlation between urban heat island intensity and forest land area of Xi'an City. We think mainly due to two reasons. Firstly, Xi'an City leans to the Qinling Mountains on the south and its forest land mainly distributed in the mountainous terrain of the Qinling Mountain. However, the forest land area accounted for an extremely small proportion of the total land area of Xi'an City and did not change significantly. Therefore, the forest land in the mountainous terrain of the Qinling Mountains exerts no significant influence on its heat island intensity. Secondly, the prevailing wind in the Xi'an region is an easterly-westerly wind, and the Qinling Mountains on the south only block the entry of southerly airflow but exert no significant influence on the climate or general circulation of Xi'an City. The relatively weak correlation between heat island intensity and water area is due to the area of urban water bodies in Xi'an being relatively small and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_77957806

absorbing only a small proportion of surface heat. Consequently, water area exerts no significant influence on urban temperature.

Urbanization represents an inevitable trend of development all over the world, signifying the progress of human civilization (Li, 2006). The increasingly rapid urbanization has increased land surface temperature will no doubt intensely influence the mass and energy flows of the urban ecosystem, change its structure and functions, produce a series of eco-environmental effects, and impact urban climate, urban hydrology, urban soil physicochemical properties, urban atmospheric environment, urban biological habits, urban material cycle, urban energy metabolism, and urban residential health (Bo et al., 2005). The heat island effect is one of the extremely severe problems caused by urbanization. An extreme weather environment, particularly an extreme thermal environment, exerts a considerable influence on both mortality and morbidity. As an extra factor in the thermal environment, the heat island effect not only threatens human health but also increases mortality; furthermore, intensifies air pollution and increases energy consumption (Ketterer et al., 2014). Thus, to weaken the heat island effect, in the development process of its urbanization, Xi'an City should strengthen urban landscape construction, increase the extent of green and water area, control the increase of urban land area, and seek more rational patterns, scale, and spatial distribution of land use.

Conclusions

This study integrated the remote sensing imaging technique with ground-measured atmospheric temperature data, probed into the relationship between the urban heat island effect and LUCC from both temporal and spatial scales, and analyzed the main controlling factors of the urban heat island effect via statistical comparison. The mainly results as follows:

(1) From 1993 to 2009, the heat island intensity of Xi'an City presented an increasing trend, with a rate of temperature rise of 0.193°C/5y. However, from 2009 to 2013, its heat island intensity showed a decreasing trend, which might be related to both landscape construction and greening and the entire climatic environment.

(2) The heat island intensity of Xi'an City mainly influenced by urban land area, farmland area, increasing urban land area and decreasing farmland area. The city's heat island intensity increased. The stepwise regression analysis model for the correlation between heat island intensity and the urban land area in Xi'an City is $Y=85.912X_1-6.913$.

Abstract. On 12 May 2008, a devastating mega-earthquake of magnitude 8.0 struck the Wenchuan area, northwestern Sichuan Province, China. Following this earthquake event, many areas in the affected areas were susceptible to geological disasters, such as debris flows, landslides and other secondary disasters. To better understand the mechanism of the formation processes of geological disasters, and to reduce the economic loss caused by the disasters, a comprehensive analysis is required. With the aim of obtaining the characteristics of unfavourable geological bodies, and analysing their stability, we choose the Gengda Township as an example (there are many unfavourable geological bodies distributed in this area, including landslides and deformation bodies). Field investigations and computational models are employed to analyse the stability of the unfavourable geological bodies. Through preliminary analysis and model calculation, the following conclusions can be drawn: under natural conditions, the stability factor of the landslide ranges from about 1.02–1.03, which means that the landslide is in a basically stable or less stable condition. Under the effect of continuous heavy rainfall, the stability factor of the landslide will be significantly reduced, and the corresponding value ranges from 0.9–0.96, which signifies that the landslide is in an unstable condition. For No 1 and No 2 deformation bodies (named by local inhabitants), the stability varied from less stable to unstable, and basically stable to unstable, respectively. On the basis of the results of the calculation, some countermeasures are proposed to mitigate the effects of these disasters probably caused by geological bodies.
Keywords: *case study, stability, model calculation, safety factor, transfer coefficient method*

Introduction

The 2008 Wenchuan Earthquake in Sichuan Province, China generated many unfavourable geological bodies, which can provide a huge amount of loose deposits, which have caused a dramatic increase in debris-flow occurrence in subsequent years (Hu et al., 2016; Tang et al., 2009; Zhuang et al., 2013). The epicenter Wenchuan Earthquake was in Wenchuan County, Sichuan (31°1'15.60"N, 103°22'1.20"E). As a consequence of the severe shocks, most valleys and slopes were destabilized and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78077819

numerous geo-hazards, such as landslides, collapses, and unstable slopes, were triggered in the earthquake-affected area, which covered 50 badly affected counties and ten worst-affected counties in Sichuan province, SW China (Chen et al., 2009; Lee et al., 2017; Wang et al., 2017). The earthquake-stricken area is also the key area for torrent and debris flow mitigation in Sichuan. It was observed that the availability of masses of loose materials was the most important contributing factor for debris flows. Therefore, rock avalanches and landslides induced by the earthquake would supply abundant solid materials to form subsequent debris flows (Chen et al., 1989; Jiayuan, 1995; Postance et al., 2017; Sun et al., 2016). Gengda township is located in the worst-stricken area, Wenchuan earthquake not only caused a lot of casualties and economic losses, but also induced numerous secondary geological disasters, which including collapses, landslides and debris flows (Ni et al., 2012). As triggered by the Wenchuan earthquake, abundant rock falls and landslides were deposited in the gully drainages, which could provide a large amount of loose solid materials that might be directly turned into debris flows or easily entrained by debris flows. The abundant loose solid materials produced by an earthquake is usually recognized as the most important factor contributing to the occurrence of debris flow. Furthermore, the threshold of trigger factors, such as rainfall, significantly decreases after earthquake events. Thus, areas affected by the Wenchuan earthquake were prone to geological disasters (Ni et al., 2011; Zhuang et al., 2010; Kang and Kim, 2016; Shima et al., 2016).

Through field investigations, the lithology, seismic activity, and tectonic movements of the study area can be determined and consist of the following: exposed strata mainly concentrated in the Quaternary alluvial layer (Q_4^{al+pl}), the eluvial layer (Q_4^{el+dl}), colluvium (Q_4^{col}), and the landslide deposition layer (Q_4^{del}). Moreover, the bedrock in the study area is fragmentized due to the effect of tectonic movement and weathering, which can greatly facilitate landslide movement in subsequent rainfall conditions.

The study area is located in Huaxia tectonic belt, which belongs to Longmenshan tectonic system, and the tectonic movement is extremely complex. Due to the effect of strong tectonic movements, the bedrock becomes loose and can thus provide favourable conditions for the development of collapse, landslides, and other geological disasters.

On 12 May 2008, a devastating mega-earthquake of magnitude 8.0 struck the Wenchuan area of northwestern Sichuan Province, China. The focal mechanism of the earthquake was successive massive rock fracturing at 15 km depth at Yingxiu. Seismic analysis confirmed that the major shock occurred on the Beichuan–Yingxiu Fault and that aftershocks rapidly extended in a straight northeast–southeast direction along the Longmenshan Fault zone. The total number of fatalities approached 15000, with a significant number resulting from seismically triggered geohazards (Cui et al., 2011). The study area is located in Longmenshan seismic zone. Several earthquakes hit this area before the 12 May 2008 Wenchuan earthquake, including the 1933 Diexi earthquake (with a magnitude of 7.5), the 1657 Wenchuan earthquake (with a magnitude of 6.5), and the 1976 Pingwu earthquake (with a magnitude of 7.2). The study area influenced by these earthquakes reached degree V.

In order to mitigate the disasters that were caused by unfavourable geological bodies after the Wenchuan earthquake, field investigations and calculation models are employed in this paper to analyse the stability of the unfavourable bodies. After analysis, the stability of the unfavourable bodies can be identified, and the corresponding engineering countermeasures can be proposed. Thus, the magnitude of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78077819

the disasters caused by the unfavourable bodies can be significantly reduced, and the security of the inhabitants living adjacent to the unfavourable bodies can be guaranteed.

Materials and methods

Study area

Wenchuan earthquake of 12 May 2008 which caused numerous coseismic landslides. After earthquakes of this magnitude, most valleys and slopes are destabilized and conditions for debris flows and landslides are amplified. These hazards are typically very active during the following 10-20 years. As a consequence of the severe shocks, most valleys and slopes were destabilized and numerous geo-hazards, such as landslides (*Fig. 1*), collapses (*Fig. 2a*), and unstable slopes (*Fig. 2b*), were triggered in the earthquake-affected area, which covered 50 badly affected counties and ten worst-affected counties in Sichuan province, SW China (Chen et al., 2009). The Gengda township is located in an earthquake-stricken area; due to the effect of seismic activity, many slopes located in the Gengda township are seriously affected. Thus, in the subsequent rainy seasons, these unfavourable bodies can be transferred into secondary disasters in response to heavy rainfall. The main objective of this paper is twofold. First, through field investigation, the fundamental data of the study area and the distribution of the unfavourable bodies can be identified; then, computational models are employed to compute the safety factor of each slope, which could allow us to analyse the stability of the slopes distributed within the study area. On the basis of the model calculations, the risk of each slope can be mapped, and preventative engineering can be designed. Thus, the threat caused by the unfavourable bodies can be greatly reduced.

Characteristics of the unfavourable geological bodies

The unfavourable geological bodies in the Gengda township mainly fall into the following four types: landslides, slippery bodies, deformation bodies, and perilous rock. These unfavourable geological bodies cause a great risk to the security of the nearby inhabitants. Moreover, many facilities are also under their threat (*Table 1*). In order to compute the safety factors of the unfavourable geological bodies, field investigations were conducted meticulously. Through these investigations, the fundamental data of the study area could be obtained, including meteorological data, geological conditions, topography, rainfall data, tectonic and earthquake history, hydrological conditions, and human activity. With the help of the data obtained through field investigations, the stability of the bodies can be analysed preliminarily. Then, calculation models are employed to compute the corresponding safety factors of he bodies. By comparing the calculation results to preliminary analysis results, the stability of the unfavourable geological bodies can be reasonably analysed.

Methods

In this paper, two basic approaches (field investigations and model calculations) are employed to explore the stability of the unfavourable bodies. The field investigations can help us acquire data that are closely related with the unstable bodies, which will be useful and can greatly facilitate the subsequent model calculation processes. Based on the fundamental data of the study area and the results of model calculations, a comprehensive stability analysis of each body can be performed.

Field investigations

The field investigations were conducted from the period between June 2009 and July 2009, and these work lasted for around one month. Our investigations are primarily concentrate in Gengda township, Wenchuan prefecture, Sichuan Province. During the processes of investigations, we mainly collected the data with regard to rainfall conditions, geological conditions, topography, etc. The main purpose of the field investigations concerned the following main issues: an initial consideration of the distribution, scale, geological conditions, and triggering factors of each unstable body, followed by a preliminary analysis of the formation mechanism of each unstable body alongside an evaluation of its stability. These results can be compared with subsequent model computations, which can help us to draw reasonable and accurate conclusions. These conclusions can provide a reliable geological basis for designing preventative engineering measures for each unstable body. With the help of Wolong Reserve Management Bureau, Wolong Land Resources Bureau, and Wolong township government, field investigations were conducted and lasted for around one month. The scope of the investigations not only concentrated on the unstable body itself but also included the adjacent zone (within a 20 metre radius) and the area susceptible to these unstable bodies. Through the field investigations, it was possible to acquire the fundamental data of the study area, which are described in the following sections.

Model calculations

Since most slopes and other deformable bodies distributed within the study area mainly consist of soil, the deformation of the slope is mainly governed by the weak interface with maximum shear stress. Therefore, we can use the Transfer Coefficient Method (GB 50330-2013) to compute the safety factors of the slopes. Following this method, and to facilitate the subsequent deducing processes, the soil is initially divided vertically into several strips (*Fig. 3*) and each strip is taken as a rigid body while taking the interaction forces between the strips into consideration at the same time. The deducing results can be employed to calculate the safety factor of each strip from the slope, and the safety factor of the whole slope can be determined. On the basis of the above description, we assumed that the residual sliding force was parallel to the sliding surface, and then the driving moment and the resisting moment exerted on individual strips can be calculated, as shown by the stress analysis diagram in *Figure 3*.

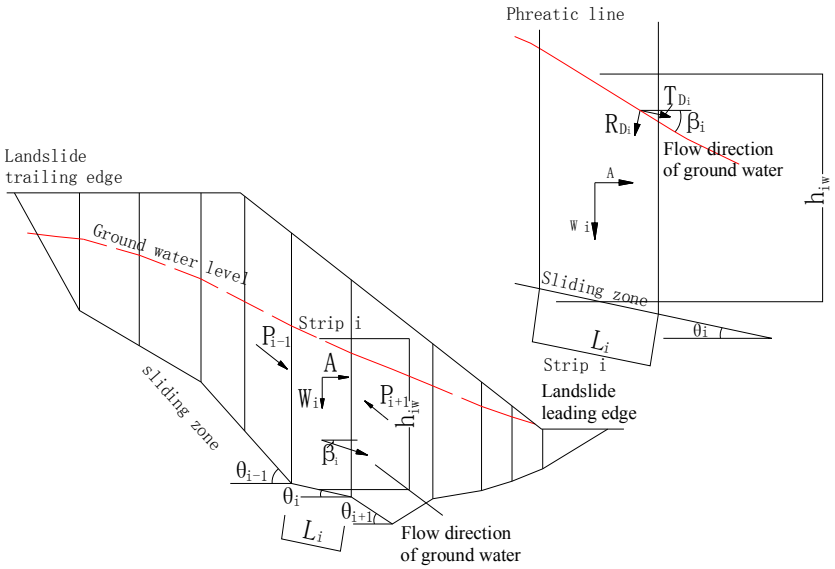

Figure 3. *Calculation model of transfer coefficient method*

(1) The computational formula for computing the safety factor is expressed as follows:

$$K_f = \frac{\sum_{i=1}^{n-1}((W_i(1-r_u)\cos\theta_i)tg\phi_i + C_iL_i\prod_{j=i}^{n-1}\psi_j) + R_n}{\sum_{i=1}^{n-1}(W_i(\sin\theta_i + A\cos\theta_i)\prod_{j=i}^{n-1}\psi_j) + T_n} \quad \text{(Eq.1)}$$

$$R_i = (W_i((1-r_U)\cos\theta_i - A\sin\theta_i) - R_{Di})tg\phi_i + C_iL_i \quad \text{(Eq.2)}$$

$$T_i = W_i(\sin\theta_i + A\cos\theta_i) + T_{Di} \quad \text{(Eq.3)}$$

$$\prod_{j=i}^{n-1}\psi_j = \psi_i\psi_{i+1}\cdots\cdots\psi_{n-1} \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78077819

Ψ_i is the residual sliding force transferred from strip i to strip i + 1 ($j = i$); that is:

$$\Psi_i = \cos(\theta_i - \theta_{i+1}) - \sin(\theta_i - \theta_{i+1}) \tan\phi_{i+1} \quad \text{(Eq.5)}$$

where W_i is the weight of the i-th strip; T_i is the sliding force of the i-th strip; R_i is the resistance force of the i-th strip; θ_i is the inclination of the sliding surface of the i-th strip; β_i is the angle between the sliding surface and the ground water (here, ground water denotes the water level below the i-th strip); ψ_i is the cohesion forces of the i-th strip; ϕ_i is the internal friction angle of the i-th strip; L_i is the length of the sliding surface of i-th strip; A is the coefficient of earthquake acceleration in the area where the seismic fortification grade is level 6, A is equal to 0.05; R_{D_i} is the component of seepage force perpendicular to the sliding surface, and R_{Di} is equal to $N_{Wi} \tan\beta_i \sin(\alpha_i - \beta_i)$; T_{Di} is the component of seepage force parallel to the sliding surface, and T_{Di} is equal to $N_{Wi} \tan\beta_i \cos(\alpha_i - \beta_i)$; N_{Wi} is pore water pressure, and N_{Wi} is equal to $\gamma_W h_{iW} L_i$; r_U is the ratio of pore pressure, and $r_U = \frac{v_w \times \gamma_w}{v_s \times \gamma_s} \approx \frac{s_u}{s_t \times 2}$, where v_w is the volume of the strip below water level, v_s is the total volume of the strip, s_u is the area of the strip below the water level, s_t is the total area of the strip, and γ_w and γ_s represent the unit weight of the water and strip (sliding body), respectively.

(2) The computational formula for computing the residual sliding force is expressed as follows:

$$P_i = P_{i-1}\Psi_{i-1} + K_s \times T_i - R_i \quad \text{(Eq.6)}$$

where P_i is the sliding thrust of the i-th strip (kN/m); P_{i-1} is the residual sliding force of i-th strip (kN/m); and K_s is the designed safety factor, with a value of 1.15 here.

Climatic and geological settings

Climatically, the study area falls into the subtropical humid climate zone; during winter the area is significantly affected by the Qinghai-Tibet Plateau climate, while in summer it is mainly dominated by the southwest and southeast monsoon climate. The mean annual precipitation is 930.2 mm, and the rainfall is mainly concentrated during the period from May to September, which contributes more than 78% of the total precipitation throughout the year. According to the rainfall contour diagram of Sichuan province illustrated in the manual of flood calculations for small and medium-sized basins, the rainfall data for 10 min and 1, 6, and 24 h can be acquired and the corresponding amounts are 10, 20, 65, and 120 mm, respectively. Some slopes in the study area have been loosened by the effect of seismic activity, which will result in instability under subsequent heavy rainfall conditions (Tang et al., 2011). The rainfall data from 2000 to 2009 were gathered, as shown in *Table 2*, and the historical rainfall histogram is shown in *Figure 4*.

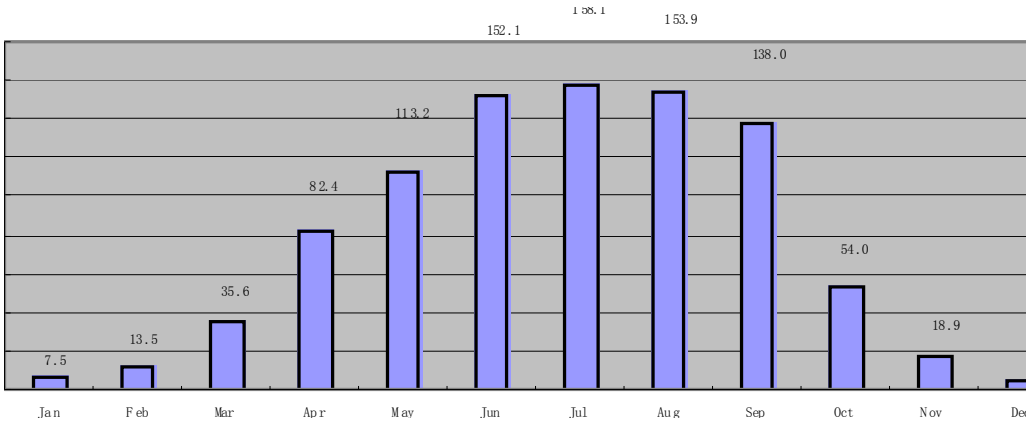

Figure 4. *Histogram of historical average rainfall (mm)*

Determination of the load condition parameters for model calculations

Through field investigations, the influential factors of the unstable bodies in the study area were studied meticulously. By analysis we found that the slopes in this area are mainly affected by the own weight of the slope, rainfall, and seismic activity. Based on these influential factors, we determined the load conditions and computed the safety factors under different load conditions. The load conditions were mainly grouped into three types: condition 1 represents the effect of the own weight of the slope, condition 2 represents the combined effect of the own weight of the slope and rainfall conditions (34 mm/h), and condition 3 represents the effect under the own weight of the slope, rainfall conditions (34 mm/h), and seismic activity.

During field investigations, we conducted some in-situ bulk density tests (we dug a hole in the field, measured the size of the hole in order to calculate the volume of the soil, and weighing the weight of the soil that was dug out, thus the unit weight can be figured out. Use similar method, we can also determine the saturated unit weight of the soil), and obtained the corresponding data, then combined with local rock-mass unit weight the unit weight of the slope body can be determined, the value of unit weight and saturated unit weight of the slope body is 17.1 and 25 kN/m^3, respectively. Soil strength

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78077819

parameters can be obtained by laboratory experiments (direct shear tests in the laboratory were conducted to identify strength of the soil collected from study area), by experiments the shear strength under fast shear and under fully saturated shear can be acquired simultaneously, their corresponding value shown in *Table 3*.

Table 3. *Shear strength of sliding body under different conditions*

Parameters / Landslide	Shear strength under natural conditions		Shear strength under fully saturated conditions	
	C (kPa)	Φ (°)	C (kPa)	Φ (°)
Sliding body and No 1 deformation body	8.5	29	7.5	28
No 2 deformation body	3.5	23.5	2.5	22

Results and discussion

According to the principle of the Transfer Coefficient Method, the unfavourable bodies in the study area can be vertically divided into several strips. Through preliminary analysis, we found that strips 6 and 7 are the most dangerous sliding bodies in the whole landslide, strips 1 and 2 are the most dangerous sliding bodies in No 1 deformation body, and strip 5 is the most dangerous body in No 2 deformation body. The stability calculation diagrams are shown in *Figure 5a-c*.

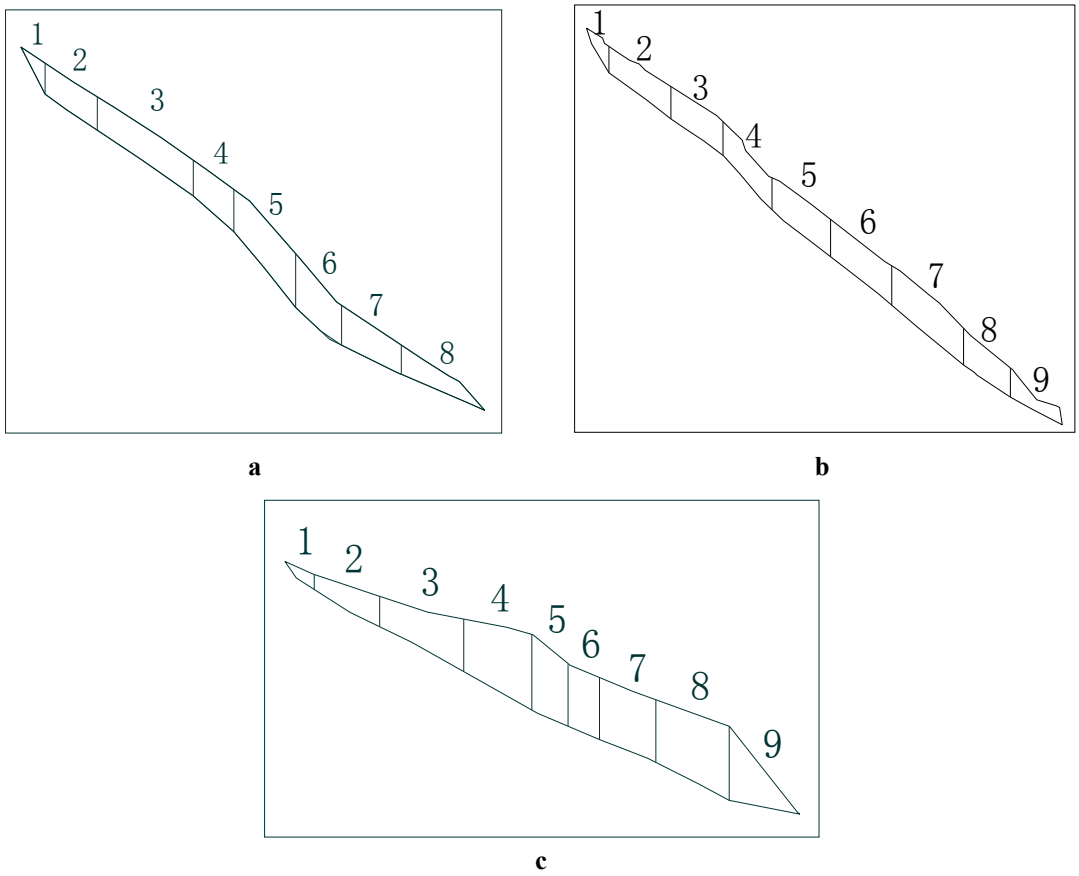

Figure 5. *Stability calculation diagram of* ***a*** *strip 1 of No 1 deformation body (profile);* ***b*** *strip 2 of No 1 deformation body (profile) and* ***c*** *strip 5 of No 2 deformation body (profile)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78077819

On the basis of Section 4, the calculation can be conducted and the calculation results can be obtained. Then the safety factors of strips 6 and 7 of the landslide, strips 1 and 2 of No 1 deformation body and strip 5 of No 2 deformation body can be obtained under different load conditions, as shown in *Table 4*. For No 1 deformation body, under the influence of the own weight of sliding body, the safety factor is 1.04, and under the effects of the own weight of sliding body and rainfall (34 mm/h), the safety factor is 1.03, results of the analysis can also be applied to landslide and No 2 deformation body.

Table 4. *Model calculation results. Conditions 1, 2 and 3 represent the effects under the own weight of landslide, the effects under the own weight of landslide and rainfall (34 mm/h), the effects under the own weight of landslide, rainfall (34 mm/h), and seismic activity*

Load conditions unstable bodies and strips		**1**	**2**	**3**
		Safety factor	**Safety factor**	**Safety factor**
Landslide	6	1.02	0.9	0.61
	7	1.13	0.96	0.66
No 1 deformation body	1	1.04	0.89	0.62
	2	1.03	0.89	0.63
No 2 deformation body	5	1.1	0.92	0.60

According to "Landslide Prevention Engineering Design and Construction of Calculation Specification", on the basis of the classification of landslide stability, the stability state under different stability factors can be determined, as shown in *Table 5*. With the help of *Table 5*, the safety factors under three different load conditions can be set as 1.30, 1.10, and 1.05, respectively. Then the residual sliding thrust can be calculated, and the calculation results are shown in *Table 6*.

Table 5. *Classification of landslide stability (Kst is the designed safety factor) Conditions 1, 2 and 3 represent the effects under the own weight of landslide, the effects under the own weight of landslide and rainfall (34 mm/h), the effects under the own weight of landslide, rainfall (34 mm/h), and seismic activity*

Stability factor of the slope	$K_s < 1.00$	$1.00 < K_s \leq 1.05$	$1.05 < K_s \leq K_{st}$	$K_s \geq K_{st}$
Stability status	Unstable	Less stable	Basically stable	Stable

According to landslide engineering investigation specifications, the stability of landslides can be subdivided into four classes. If the stability factor of a landslide under certain load conditions is larger than the safety factor, we can state that the stability of the landslide matches the stability criteria well. Based on this principle, the following conclusions can be drawn:

Under natural conditions, the stability factor of strip 6 is 1.02; thus referring to *Table 5*, the landslide is in the less stable state. Through field investigations, we found that many cracks developed at the location of strip 6. Moreover, under continuous rainfall, the stability factor decreased to 0.9, which means that the landslide is unstable under such conditions, which is in good agreement with the preliminary analysis. Under natural conditions, the stability factor of strip 6 is 1.13; referring to *Table 5*, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78077819

landslide is in the basically stable state. Similarly, under continuous rainfall, the stability factor decreased to 0.96, i.e. the landslide is unstable under such conditions, which is in good agreement with the real situation.

Table 6. *Calculation results of the residual sliding thrust*

Unfavourable bodies and strips		Load conditions	Safety factor F_s	Stability factor F_{st}	Residual sliding thrust E（kN/m）
Landslide	No.6	Condition 1	1.02	1.2	479.22
		Condition 2	0.9	1.10	800.28
		Condition 3	0.61	1.05	2230.20
	No.7	Condition 1	1.13	1.2	87.77
		Condition 2	0.96	1.10	274.38
		Condition 3	0.66	1.05	945.36
No 1 deformation body	1-1′	Condition 1	1.04	1.2	222.72
		Condition 2	0.89	1.10	433.78
		Condition 3	0.62	1.05	1139.49
	2-2′	Condition 1	1.03	1.2	348.58
		Condition 2	0.89	1.10	634.06
		Condition 3	0.63	1.05	1580.44
No 2 deformation body	5-5′	Condition 1	1.10	1.2	55.34
		Condition 2	0.92	1.10	147.33
		Condition 3	0.60	1.05	511.87

Under natural conditions, the safety factors of strips 1 and 2 of No 1 deformation body are 1.04 and 1.03, respectively. Referring to *Table 5*, the No 1 deformation body is in the less stable state. These findings agreed well with preliminary analysis. Under continuous rainfall, the stability factors of strips 1 and 2 both decreased to 0.89, meaning that the No 1 deformation body is unstable under such conditions, which is in good agreement with the real situation.

Under natural conditions, the safety factor of strip 5 of No 2 deformation body is 1.10. Referring to *Table 5*, the No 2 deformation body is in the basically stable state. This agreed well with the preliminary analysis. Under continuous rainfall, the stability factor of strip 5 decreased to 0.92, meaning that the No 2 deformation body is unstable under such conditions, which is in good agreement with the real situation.

Based on this analysis, the following conclusions can be drawn. The stability of the landslide and deformation bodies varied as the load conditions changed. From condition 1 (i.e. under the effect of the own weight of the slope) to condition 3 (i.e. under the effect of the own weight of the slope, rainfall, and seismic activity), the stability of the landslide varied from basically stable to less stable and finally to unstable; the stability of the No 1 deformation body varied from less stable to unstable; and the stability of the No 2 deformation body varied from basically stable to unstable. Due to the discrepancy of the slope in the study area, the deformation and stability variations have some differences; under some circumstances, partial failure may occur in the stable state.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78077819

Conclusions

By means of field investigation ands model calculations, the following conclusions can be drawn. The stability of the unfavourable bodies was mainly affected by the 12 May 2008 Wenchuan Earthquake and subsequent rainfall infiltration. Continuous heavy rainfall plays a crucial role in slope stability analysis. In addition, human activity and weathering have also influenced the stability of unfavourable geological bodies in the study area.

Under natural conditions, the stability factor of the landslide ranges from about 1.02–1.03, which means that this landslide is in the basically stable or less stable condition. Under the effect of continuous heavy rainfall, the stability factor of the landslide will be significantly reduced, and the corresponding value ranges from 0.9–0.96, which means that the landslide is in the unstable condition. For No 1 and No 2 deformation bodies, the stability varied from less stable to unstable, and basically stable to unstable, respectively.

At present, some of the unfavourable bodies are in the less stable state, under the effect of continuous heavy rainfall, seismic activity, or other influential factors; some geological bodies will probably change to the unstable state. Considering the property of the landslide itself, a cut slope is recommended as a preventative and mitigation measure. For the No 1 deformation body, anti-slide piles are recommended as prevention and mitigation measures. Due to the small volume and simplicity of the No 2 deformation body, it is recommended to clear it directly.

Abstract. Nowadays, the domestic mineral resources are short, and the ecological environment is becoming worse and worse. Besides, the trade protectionism is on the rise, and the international trade environment is uncertain and unsafe. This paper simulates the potential old scrap generated from actual aluminum products consumption of seven end-use sectors during 1996-2017 on the basis of Weibull distribution. The object is to facilitate the exploitation and cyclic utilization of old scrap and "urban mines". During this period, the building and construction (B&C) and transportation (T) sectors are still the most and second consumers, accounting for 30% and 17% of the total consumption. Most aluminum products haven't entered into the scrapping stage yet, and only one fifth of consumed aluminum (about 52 Mt) became old scrap. In the in-use reservoir, B&C and T sectors take up about 60% due to their longer lifetime intervals. If the potential old scrap will be recycled efficiently, then the secondary aluminum produced by the scrap can meet around nine years' consumption demands at current consumption level. Therefore, the cyclic utilization of old scrap prompts resources saving, energy conservation, emission reduction and may remove the impacts of international trade instability.
Keywords: *aluminum resource, scrap generation, in-use stock, recycling and cyclic utilization*

Introduction

Aluminum, a popular metal, and its alloys are applied widely all over the world. They are raw material sources of tens of thousands of products, and the production amount of aluminum nowadays is more than the sum of other nonferrous metals (Halvor, 2014). However, it has been produced in commercial quantities for just over 100 years (USGS, 2016) since the first electrolytic aluminium plant established by Pittsburgh, USA. So to speak, aluminum is a comparatively new industrial metal (USGS, 2016). In 1956, the world's aluminum production yield exceeded copper, ranking first among non-ferrous metals because of its wonderful characteristics (Chen et al., 2009a; Luca et al., 2013; USGS, 2016): light weight; excellent corrosion resistance and durability; no low-temperature brittleness and magnetism; good electrical conductivity and reflectivity; high thermal conductivity, and the like. Aluminum metal, its alloys and by-products are usually used in building & construction (B&C), transportation (T), consumer durables

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78217835

(CD), containers & packaging (C&P), machinery & equipment (M&E), electrical engineering (EE), and other products. With the popularization of material lightweight requirement, aluminum metal and its alloys are more widely utilized, especially in national defense science field and some sophisticated industries such as aerospace engineering, medical apparatus and instruments, rail traffic and so on.

China, a populous and rapidly developing country, has the potential to influence the global material use (Wang et al., 2008). There is a significance increase in aluminum production and consumption amount after the reform and opening-up policy. During the period of 1991 to 2007, China's average growth rate of aluminum production and consumption was four times higher than the global average (Yue et al., 2014), especially after 2000, with the alumina and primary aluminum shares of global production rising from 9% and 13.2% in 2000, to 37.7% and 51.1% in 2008 (Chen et al., 2010, 2012). China has long been the world's largest producer and consumer of aluminium (Yue et al., 2015). Nevertheless, China's bauxite reserves are only about 3 percent of the world's, and its per capita reserves are also small, one-tenth of the global average (Chen et al., 2008). They are mostly unserviceable diaspore, which are characterized by high aluminum, high silicon and low aluminum-silicon ratio. These characteristics increase the difficulty to mine and smelt bauxite ores, and lead to weak productivity growth (Chen et al., 2009b; Liu et al., 2011, Liu and Müller, 2012). As a result, China relies heavily on importing bauxite. In the previous study, its external dependence increased continuously, from 1.9% in 1996 to 40% in 2016, among them 52.4% in 2007 and 54.3% in 2013 (Liu, 2017). The trade protectionism is on the rise, and the international trade environment is uncertain and unsafe. This situation is an obstacle to the realization of sustainable supply and sustainable economic and social development.

The supply structure of China’s aluminum metal in recent years is about: 80% for primary aluminum, 20% for recycled aluminum (Liu et al., 2016). And the average annual increase rate of secondary aluminum is above 25% after 1996 (Liu et al., 2016). Besides, the contribution degree of recycled aluminum supply is rising gradually (Liu, 2018). The energy required and pollution emission for producing secondary aluminum might be only 5-10% of that needed for smelting and producing primary aluminum (Melo, 1999). Remelting recycled aluminum can not only make up for the shortage of domestic bauxite ores, but also promote energy conservation and emissions reduction.

Review of literature

MFA is a systematic resource management means for stocks and flows of entire life cycle of materials within predefined anthropogenic temporal and spatial boundary (Brunner and Rechberger, 2004; Pauliuk and Müller, 2014; Nakamura and Halada, 2015; Maung et al., 2017; Wang et al., 2017). In recent years, it was extensively used in the research of noxious or specific chemical elements and in the fields of resources appropriate use and waste management. It usually divides the entire life cycle of elements into four main stages: Production (P); Fabrication & Manufacture (F&M); Use (U); and Waste Management & Recycling (WM&R) (*Fig. 1*).

Many experts and scholars use this approach to analyze non-ferrous metallic element such as iron (Wang et al., 2007), copper (Graedel et al., 2002; Spatari et al., 2002; Bertram et al., 2002; Rechberger and Graedel, 2002; Reck et al., 2006; Daigo et al., 2009), aluminum (Melo, 1999; Boin and Bertram, 2005; Hatayama et al., 2007; Dhalström and Ekins, 2007; Chen et al., 2009a,b, 2010; Chen and Shi, 2012; Chen and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78217835

Graedel, 2012; Buchner et al., 2014), zinc (Graedel et al., 2005; Reck et al., 2006; Guo et al., 2010), lead (Mao et al., 2008a,b), phosphorus (Liu and Chen, 2006a,b) and the like. For the last few years, on the one hand, the studies on a more micro level (small scale of area, some kind or some certain kind of product) are more and more extensive. On the other hand, the WM&R stage such as recovery amount, recovery rate, and recovery potential are hot topics (Hoyle, 1995; Gesing and Wolanski, 2001; Müller, 2006; Modaresi and Müller, 2012; Gu et al., 2016a,b).

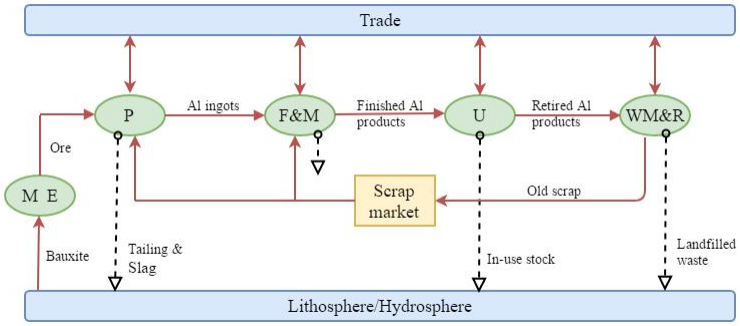

Figure 1. *Simplified aluminum life cycle diagram (M E: Mine Extraction, P: Production; F&M: Fabrication & Manufacture; U: Use; WM&R: Waste Management & Recycling)*

Among them, scrap generated from end-use sectors and in-use stocks of still existing in society are so complicated that researchers applied various methods to investigate them. McMillan et al. (2010) quantified aluminum in-use stocks and old scrap recycling and recovery in the United States for the period of 1900 to 2007 by a dynamic material flow analysis model and top-down approach. The in-use stock of aluminium in the State of Connecticut has been established by an extensive bottom-up study by Recalde et al. (2008), and the percentages of end-use sectors accounting for total stock have also been measured. Zhang et al. (2012, 2015a,b) mainly research on the flows and stocks of China's copper resource, and its spatial and temporal patterns by SFA, top-down, and bottom-up estimation. Yue et al. (2016) analyzed the iron in-use stocks in China by top-down and bottom-up methods, and related economic methods. Of course, estimation a sort of metal scrap and in-use stock of an industry is popular in researchers nowadays. The building stocks from urban to transnational scales was analyzed by Mastrucci et al. (2017) through bottom-up life cycle assessment, and Warrings and Fellner (2018) conducted a detailed material flow analysis for aluminum used in packaging & household non-packaging in 2013 in Austria. A MS (material stocks) accounting for 10 materials in 6 major infrastructures in Beijing, Tianjin and Shanghai were conducted by Huang et al. (2017).

Materials and methods

The aluminum products transform into retired products and generate old scrap after serving for society for a while. Nevertheless, their lifetimes are diverse for end-use products of different categories, and this study adopts the following lifetime intervals in *Table 1* on the basis of previous studies (Melo, 1999; Chen and Shi, 2012; Luca et al., 2013; Zhang et al., 2015a). Lifetime intervals of aluminum products are crucial for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78217835

quantifying potential aluminum scrap, and Weibull distribution is proved to be a good way to simulate the life span of products. This paper applies the classical Weibull distribution to simulate the lifetimes of aluminum products from cradle to grave, and this is the foundation of aluminum scrap generation model.

Table1. *Lifetimes of seven categories Al products assumed for this study*

	B&C	T	CD	C&P	M&E	EE	Others
Lifetimes							
Low (a)	23	10	5	1	10	10	5
High (b)	40	16	15	1	30	25	15

The probability density function (pdf) of the Weibull distribution function in this study can be expressed in *equation (1)*, and the scale and shape parameters are taken from some researchers as a reference (Melo, 1999; Chen and Shi, 2012; Luca et al., 2013; Zhang et al., 2015a; Wang et al., 2017). Thus it can be seen that the random variable T is described by three parameters: a location parameter a, a scale parameter α, and a shape parameter β; and the mathematical constraint conditions of this function are $a \geq 0, \alpha > 0, \beta > 0$.

$$f(t;a,\alpha,\beta) = \begin{cases} \alpha\beta^{-\alpha}(t-a)^{\alpha-1}\exp\left\{-\left(\frac{t-a}{\beta}\right)^{\alpha}\right\}, & if\ t > a \\ 0, & otherwise \end{cases} \quad \text{(Eq.1)}$$

If a product ends its service life in society and become to useless waste after t years, then the probability of it is given by *equation (2)*.

$$p_t = \exp\left\{-\left(\frac{t-a}{\beta}\right)^{\alpha}\right\} - \exp\left\{-\left(\frac{t+1-a}{\beta}\right)^{\alpha}\right\}, \quad a \leq t < b \quad \text{(Eq.2)}$$

The value range [a,b] of the distribution function is given by lifetime intervals in *Table 1*. In other words, 100% of the total area under the curve of the density function must be located within the ranges a and b. But the realistic situation is so complicated that not all of aluminum products will retire within b years. So, this study stipulates that the cumulative distribution probability is set as 99.7%, that is, 99.7% of the total area is under the density function curve within the lifetime interval [a,b]. The corresponding cumulative probability function IP and the distribution function $F_{(t)}$ is measured by *equations (3) and (4)*, and γ =99.7%.

$$IP(a \leq T \leq b) = 1 - \exp\left\{-\left(\frac{b-a}{\beta}\right)^{\alpha}\right\} = \gamma \quad \text{(Eq.3)}$$

$$F_{(t)} = 1 - \exp\left\{-\left(\frac{t}{\beta}\right)^{\alpha}\right\} \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78217835

Quantifying the scrap generation of end-of-life aluminum products is based on the Weibull distribution described above, and this paper adopts top-down method (McMillan et al., 2010; Park J-a et al., 2011; Yan et al., 2013; Müller et al., 2014; Chen and Graedel, 2015). The mechanism of scrap generation of end-of-life aluminum products is a very complex process, and this study simplifies it as: the finished aluminum products flow into society for multiple use, and they get retired after different given life spans. Therefore, the theoretical scrap generation of year n can be measured by *equation (5)*:

$$F'_{(n)} = \exp\left\{-\left(\frac{n-1}{\beta}\right)^{\alpha}\right\} - \exp\left\{-\left(\frac{n}{\beta}\right)^{\alpha}\right\} \quad \text{(Eq.5)}$$

Within this paper, the rate of theoretical old scrap generation in year n is assumed as $f_{(n)}$, the cumulative rate of which is $F_{(n)}$. Then $F'_{(n)}$ refers to the probability of old scrap generation of aluminum end-of-life products (Park J-a et al., 2011; Yan et al., 2013). Besides, α and β still represent scale parameter and shape parameter. There is a hypothesis that $T_{(t)}$ denotes the mount of realistic consumption of various aluminum-containing products in year t, and $P_{(n)}$ is defined as the corresponding old scrap generation amount in year n. So $P_{(n)}$ can be expressed as *equation (6)*:

$$P_{(n)} = \sum_{t=0}^{n-1} T_{(t)} F'_{(n-t)} \quad \text{(Eq.6)}$$

The temporal boundary of this paper is the period of 1996-2017, the spatial boundary is mainland China, of course, and the major research objects are simulated aluminum old scrap generation for sum and end-of-life sectors. Most of various data used in calculation stems from official statistics, for example, the Yearbook of Nonferrous Metals Industry of China and World Bureau of Metal Statistics. Some missing data, especially aluminum products consumption amounts of seven end-use sectors, are borrowed from some reports and articles (Chen et al., 2009a, 2010; Chen and Shi, 2012; Yue et al., 2014).

In order to strengthen the scientific preciseness and conciseness of research, there are some assumptions and explanations: (1) This study just considers actual consumption statistics and focuses on old scrap generation of studied period of 1996-2017. That is, this study ignores the generated scrap from the years before 1996 and after 2017. (2) The length of service life of aluminum products follows the Weibull distribution. (3) The losses to the environment during the transformation from this flow into other flows are excluded from consideration.

Results

Nowadays, China is the country that produces and consumes the most aluminum metal, and the average growth rates of them are well above the world average (Yue et

DOI: http://dx.doi.org/10.15666/aeer/1704_78217835

al., 2014). *Fig. 2* clearly describes this phenomenon and the variation trend of consumption amounts of seven end-use sectors.

The total consumption amounts of aluminum metal in China have maintained a trend of continuous increase since 1996, even during in global financial crisis, and the average growth rate reaches up to 14.58%. In China, the large-scale production and consumption of aluminum metal is relatively late, so the production and consumption of aluminum metal is very few before 1996. Besides, few consumption only generates fewer old scrap, and that is why the temporal boundary of this study begins in 1996.

Although the consumption amounts of seven end-use sectors all have been rising for decades, the consumption structure has also changed dramatically because of needs for economic and social development. From 1998 to 2000 was the period that has the most rapid changes in the consumption structure. Before 1998, the amounts of aluminum products in CD and EE fields were the most and second relatively, while the amount of aluminum products in B&C field was far more than any other sector in 2000, accounting for a third of total consumption. After 2000, the consumption structure of seven fields also changed, but not too much.

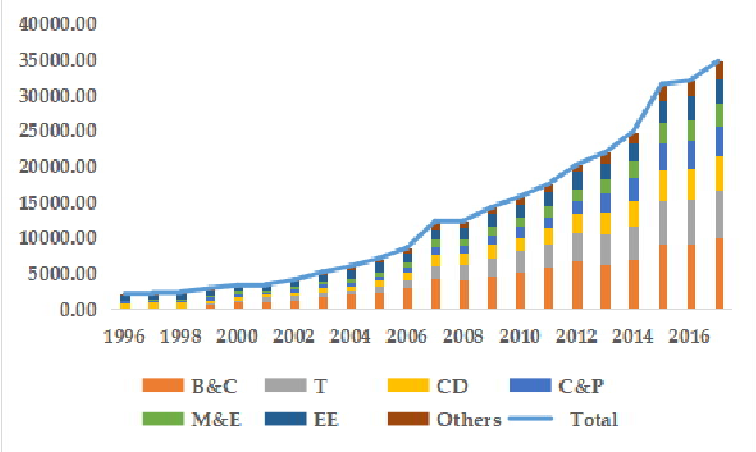

Figure 2. *Consumption amounts of total and end-use sectors (Unit: kt)*

The percentage of aluminum products in T sector was from less than 10% in 2000 up to 20% in 2017, nevertheless the percentage in EE sector was from about 20% in 2000 down to 10% in 2017. In the period of 1996-2017, the cumulative consumption amounts of seven end-use sectors are around 87.7 Mt, 49.2 Mt, 39.1 Mt, 30 Mt, 25.5 Mt, 34.2 Mt, 20 Mt, respectively, and account for 30%, 17%, 14%, 10%, 9%, 12% and 7% of total consumption. At present, the B&C and T sectors are the two sectors that consume most aluminum metal, and they account for a half of total consumption. This situation is closely related to the general background of China's economic development: higher urbanization rates and convenient, comfortable, plentiful life for more people.

Old scrap generation

Scrap generation of seven end-use sectors

As we all know, the lifetime of aluminum-containing products in B&C sector is relatively long due to its durability, so theoretically, the consumption in the period of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78217835

1996-2017 has not produced old scrap yet. The starting year and ending year of old scrap generation in B&C sector are 2019 and 2056, respectively (*Fig. 3*).

The total amounts of annual potential scrap from B&C sector rise smoothly and then fall gradually, the peak of which is at around 2043. Accordingly, the change trend of cumulative scrap amount is: increases slowly, increases rapidly and then remains at high position. The variation trends of potential scrap generation amounts annually and cumulatively from M&E and EE sectors are the same with B&C sector, but the lifetime intervals are completely different. The starting year and ending year of old scrap generation in M&E sector are 2006 and 2046, and they are 2006 and 2041 in EE sector. Besides, the peak of annual scrap generation amount in M&E and EE sectors are all in about 2028 (*Fig. 3*).

The consumption quantity of aluminum products in T sector increases more and more rapidly because of the macro social background and lightweight requirement. The period of old scrap generation in T sector is from 2006 to 2032, and the annual scrap amount increases gradually, then increases quickly and drops more quickly after reaching the peak around 2027. The change trends of potential old scrap in CD and Others sectors are similar to the situation in T sector. Moreover, the periods of old scrap generation in these two sectors are all from 2001 to 2031, and the peaks are at around 2022. The tendency of the cumulative curve in these three fields is similar to other three fields described above, but the CD and Others fields increase smoothly, not increase slowly and then increase rapidly before reaching the high position. There is a striking common point in in these three fields: the growth change of annual scrap generation amount is not so regular. This is because their actual consumption amounts don't increase all the time before the peak, and they change unsteadily, sometimes more and sometimes less. However, the annual scrap generation in B&C, M&E and EE fields increase little by little before reaching the peak.

Aluminum packaging materials can be said to be the most common aluminum products in life, but the mean lifetime of it is so short that the starting year and ending year of its old scrap generation are 1997 and 2018. This paper defined its lifetime interval as 1 year, therefore the annual scrap generation amount is closely related to the actual consumption of previous year. It's precisely because of its defined lifetime interval as well, the annual scrap generation amount augments all the time accompanying its consumption in the period of 1997-2018. Furthermore, the cumulative curve of C&P sector is very different from other six sectors, and it is always on the rise. This situation also has to do with its lifetime interval.

Annual and cumulative scrap generation

From the bars of various colors in *Fig. 4*, the scrapping time nodes and scrap generation amounts of aluminum products of each sector can be obtained. In the beginning, only the aluminum products in C&P sector enters the scrapping period, and the amount is nothing much.

Follow that, the aluminum products in CD, Others, T, M&E and EE sectors enter the scrapping periods successively, so there is a large growth in the annual scrap amounts. The latest aluminum products to enter the scrapping stage come from the B&C sector, and it's in 2019. However, the potential scrap decreases a lot in this year.

The fundamental cause of this phenomenon is that C&P sector is completely out of scrapping stage. Due to the plentiful aluminum scrap generated from B&C field, the total scrap has a big increase in amount.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78217835

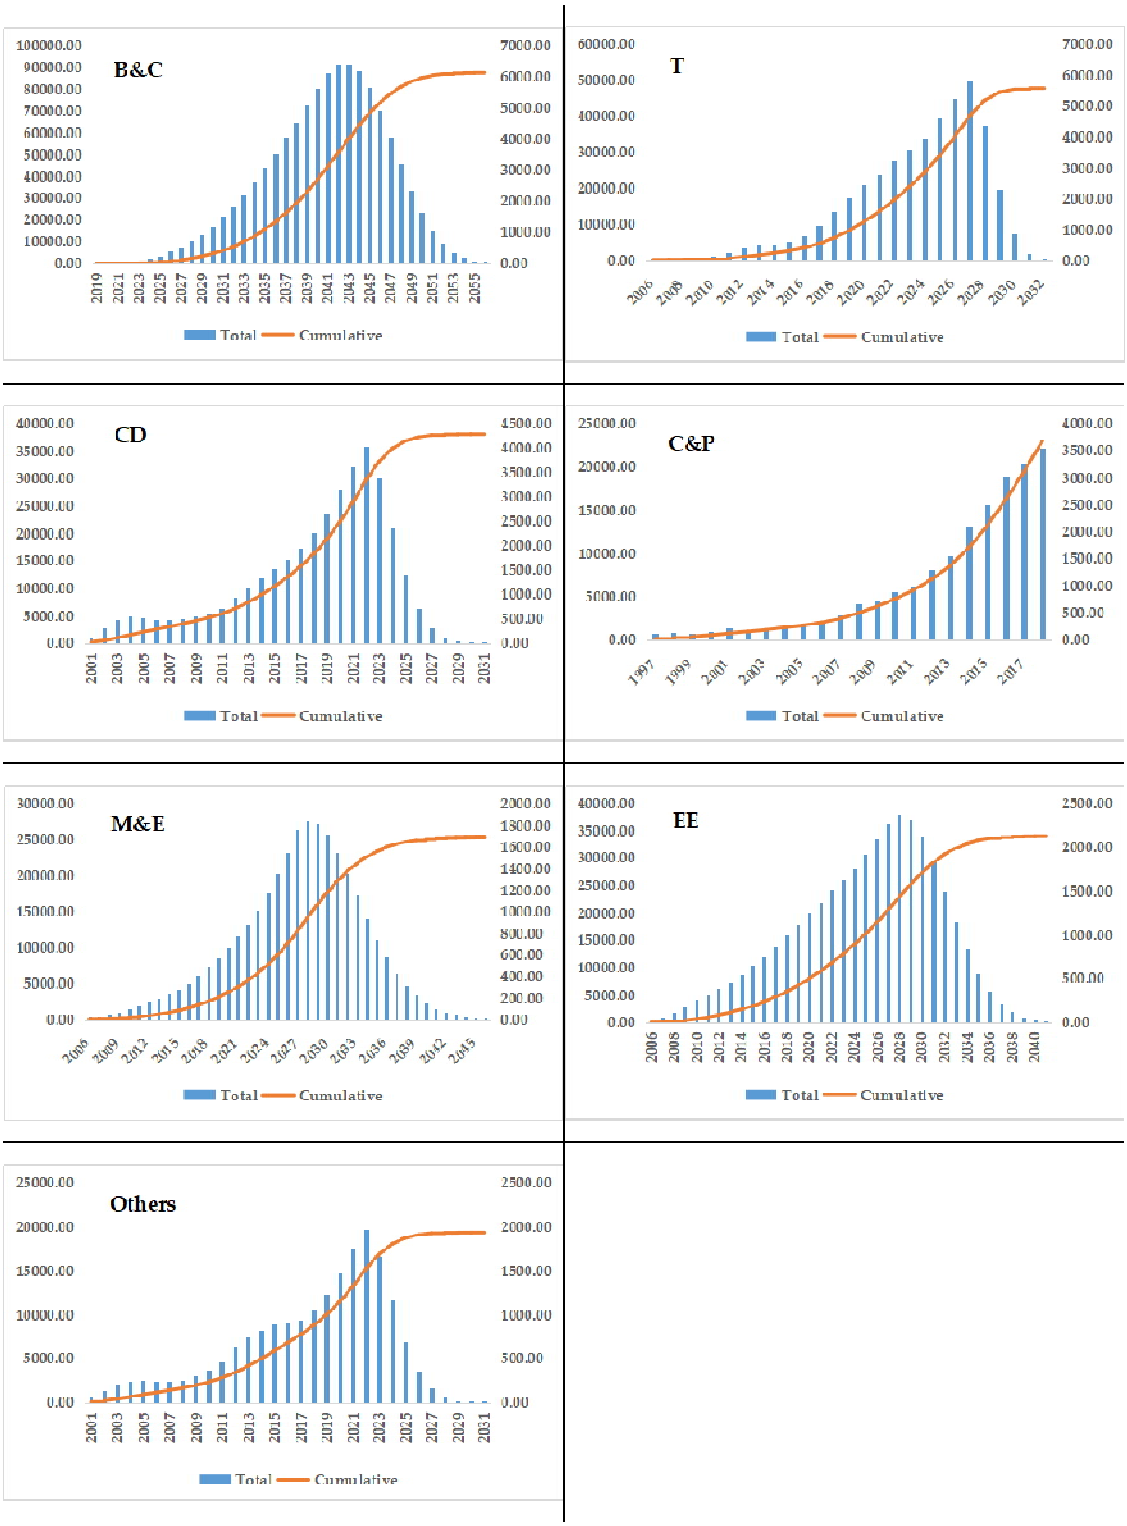

Figure 3. *Theoretical old scrap generation of seven end-use sectors (In all charts, the starting year is the first time that the various consumed aluminum products entered the scrap stage, and the ending year is the last time. "Total" denotes the total scrap amounts annually, and "Cumulative" denotes the cumulative scrap amounts within the lifetime intervals. The larger scale values on the left describe "Cumulative", and the smaller scale values on the right describe "Total". Unit: kt)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78217835

Then, the CD, T and Others fields also gradually exit the scrapping stage, so the potential scrap from these three fields is on the decrease until around 2030. For a while after that, the theoretical scrap generated from B&C, M&E and EE sectors is near the maximum or at the maximum, so the annual scrap generation amount continues to increase until the M&E and EE sectors exiting the scrapping period. In the end, there is B&C sector left, and the annual scrap generation amount is on the decrease step by step until it exiting the scrapping stage in about 2056. The complex old scrap generation amounts are attributed to the out-of-step of entering and exiting the scrapping stage of seven end-use sectors of aluminum products. There is no doubt that the cumulative amount increases continuously. The cumulative curve of the total potential old scrap in *Fig. 4* is analogous to the cumulative curves of those six end-use sectors in *Fig. 3*: rises slowly, then rises rapidly, and remains at the high position.

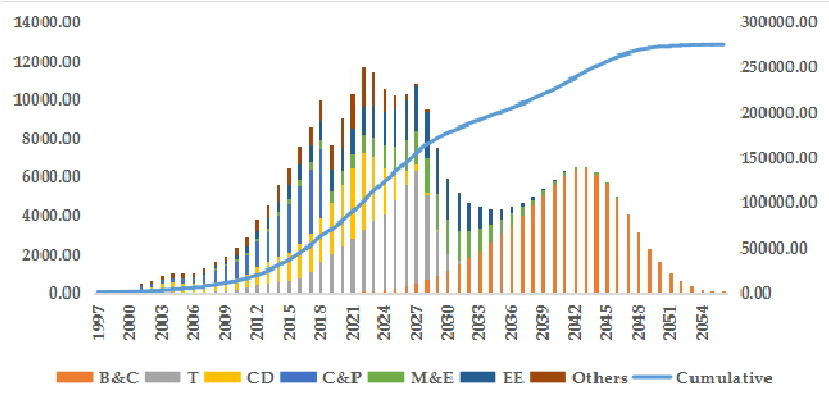

Figure 4. *Annual and cumulative scrap generated from seven categories aluminum products consumption. (The larger scale values on the right describe "Cumulative", and the smaller scale values on the left describe "Annual". Unit: kt)*

The total consumption of aluminum-containing products supports the twenty years' aluminum metal demands of the national economics. If most of the potential old scrap can be recycled, the secondary aluminum produced by it will meet nine years' consumption demands at current consumption level. It has a far-reaching significance for the country's sustainable development, and improves the ecological environment, reduces energy consumption and greenhouse gas emissions.

In-use reservoir

Theoretically, the cumulative old scrap generated from actual consumption in the period of 1996-2017 is 275 million tons, and the scrap generation amount before 2018 is about 52 million tons, accounting for one fifth or so. That is, there are four fifths of the theoretical old scrap still in the in-use reservoir, more than 220 million tons. The in-use stock is still under the ground to be mined, and will become the resource bank to support future consumption for economic development.

In in-use reservoir, there is no doubt that the largest proportion is in B&C field (*Fig. 5*), and 100% of them are still in anthropogenic cycle (*Fig. 6*) because they haven't entered into scrapping stage in the given period. It accounts for about 40% in the total in-use stock, and T sector followed by it. But the amount and percentage is only half of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78217835

it, far less than B&C field. Because it hasn't entered into a large-scale scrapping stage, most (90%) of aluminum-containing products in T sector is still in use stage. This situation is closely similar to M&E sector, however, it only accounts for about 10% in the total in-use stock. Besides, the slightly greater proportions in the in-use stock are EE and CD sectors, and the proportions are 13% and 11%, respectively. But 86.5% of electrical engineering products and 63.3% of consumer durables are in the use stage. The aluminum products amount consumed by others sector is less than other fields, nevertheless the in-use stock quantity is not the least due to its longer lifetime interval. In addition, 60.2% of aluminum metal in others sector is still serving the society in different positions. The least in-use stock magnitude occurs in C&P field, and its recycling period is very short. Although the year 2018 is its last recovery period, there are still 15.4% in the use stage. So the consumption quantity of aluminum packaging materials is large in last several years.

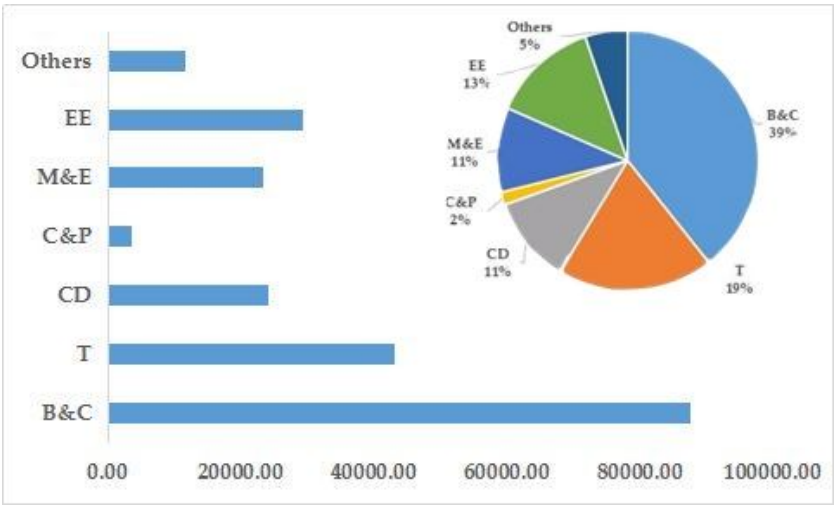

Figure 5. *The amounts and percentages of in-use stock in seven end-use sectors. (Unit: kt)*

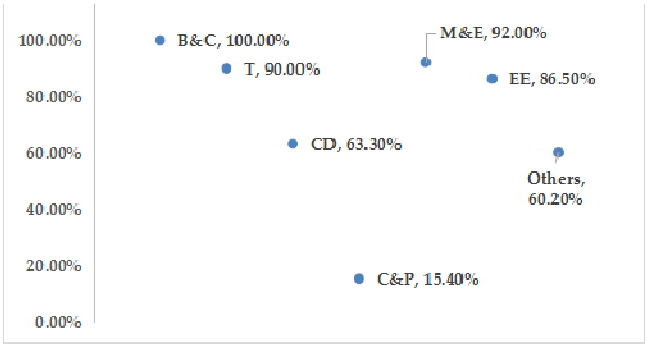

Figure 6. *The percentages of in-use stock in their theoretical scrap generation*

In general, the longer the lifetime interval, the more complex the scrapping process and the more uncertain the scrap generation. Therefore, the aluminum product consumed by B&C sector is more difficult to simulate its old scrap. On the contrary, the recovery rate of aluminum packaging materials is relatively high and is easy to calculate and utilize its old scrap. The research hot topics of old scrap and in-use stock

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78217835

management of aluminum products focus on the B&C, T and CD fields, and other fields are studied much less than them due to the lack of detailed statistics, a variety of products, complicated models to be established difficultly and so on. If the recycling system is relatively sound and perfect, like some developed countries, these in-use stock will be cyclic utilized in all walks of life in the future and achieve the proposed closed-loop for resource use. The closed-loop aluminum resource utilization, on the one hand, saves substantial primary ore consumption; and on the other hand, also saves energy consumption, reduces greenhouse gas emission and the influence of international trade environment.

Discussion

In real production process, there are so many kinds of aluminum-containing finished products and intermediate products to meet the actual demands, and the lifetime intervals of them are very different from each other even though the same kind of products. So the lifetime intervals are far more complicated than the simplified scrapping time assumed in this paper. For example, a car should become the retired product in its eighth year, then to be recycled, dismantled and other treatments. However, it may be scrapped in its fifth or tenth year due to the various reasons, or some components and parts are directly applied in other products, not recycled. In a word, the anthropogenic cycle course for serving the society of aluminum metal is not easy to investigate clearly, and in general varieties of scholars apply lots of methods and models to simulate it.

The research temporal boundary of this paper is the period of 1996-2017, and the scrapping interval of those aluminum products is relatively longer. But the aluminum products in other years also generate old scrap in this scrapping stage, nevertheless this study only pays attention to the old scrap generated from the period of 1996-2017. Hence the actual annual and cumulative scrap amounts are entirely different from the results in Section 3, and in the meantime, this is also not a dynamic study to some extent. Furthermore, the calculations of potential scrap in this study are only based on the actual consumption of sum and seven end-use sectors, but the scrap generation amount is restricted and affected by many factors. This is also what needs to be improved in later research course.

Besides, the aluminum metal in-use stock is not 100% recycled after the service lifetime, some of which will become post-consumer waste or waste left in the remelting course, and they will be delivered to the landfills, metallurgical waste residue storage sites or the ecological environment. In addition, the loss of resources in the recycling process is also large such as transport, classify, dismantle, remelt and other treatments. Therefore, the cyclic utilization of resource is easier said than done, and the joint efforts of responsible departments and the public are required to bear the responsibility for reducing the resource waste, energy consumption and greenhouse gas emission.

Conclusions

In addition to the various costs of importing raw materials, the trade wars are also getting more and more intense, and the international trade environment becomes very uncertain. These factors will drive the increasingly chaotic international trade order, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78217835

importing raw materials will be more and more difficult. Therefore, the focus of acquiring resources ought to turn to the homeland, and exploit and utilize the domestic resource (old scrap and "urban mines").

This paper simulates the potential old scrap generated from actual aluminum products consumption of seven end-use sectors during the period of 1996-2017 on the basis of Weibull distribution. The main results and conclusions are as follows. (1) The B&C and T sectors are still the most and second consumers. The cumulative consumption amounts of seven end-use sectors (B&C, T, CD, C&P, M&E, EE, and Others) are around 87.7 Mt, 49.2 Mt, 39.1 Mt, 30 Mt, 25.5 Mt, 34.2 Mt, 20 Mt, respectively, and account for 30%, 17%, 14%, 10%, 9%, 12% and 7% of total consumption. (2) Most aluminum products haven't entered into the scrapping stage yet. Only one fifth of consumed aluminum (about 52 Mt) became old scrap, and the rest are serving the society in the form of in-use stock. In the in-use reservoir, B&C and T sectors account for about 60% due to their longer lifetime intervals. (3) The percentages of in-use stock existing in those end-use sectors consumed in the period of 1996-2017 are 100%, 90%, 63.3%, 15.4%, 92%, 86.5% and 60.2%. The majority of aluminum-containing products delay for supporting the country's economic development, industrialization and urbanization. (4) If the recycling system and related supporting policies are improved and completed, the potential old scrap will be recycled efficiently. Then the secondary aluminum produced by the scrap can meet around nine years' consumption demands at current consumption level.

In recent years, the government established a number of renewable resource industrial parks or ecological industrial parks along with the increasingly serious resource situation and promised energy conservation and emission reduction requirements. This is the successful experience of developed countries, and makes the waste recycling and reuse form a complete industrialization development model. The government needs to formulate various policies for key support, mainly from tax policy, technology research and development support policy, land use policy and other related supporting measurements, to overall coordinate the development of the industry. This industry will recycle generated old scrap and in-use reservoir to support domestic production and consumption, and drive the aluminum industry away from importing bauxite and scrap gradually to reduce the influence of international trade environment. However, the realities of aluminum products consumption, usage, retire, recovery, treatment and the like are so tanglesome that this study simplified the calculation model, and still has many shortcomings. In later course of research, these shortcomings will be made up step by step.

Abstract. Gas is usually ignored in traditional studies of water movement processes in the vadose zone. However, a large number of simulation experiments show that gas is an important factor effecting water movement. In this paper, a two-dimensional sand tank model is built to observe the changes of gas pressure and negative pressure during rainfall events with different intensities and boundaries and investigate the interaction between gas and water to reveal the block effect of gas on water movement. The results show three main effects of gas affecting water infiltration. Firstly, the water infiltration causes the gas pressure increased, which results in the decrease of unsaturated hydraulic conductivity. Secondly, the gas will escape to surroundings even break through the overlying saturated layer if the infiltration causes the gas pressure to increase to a critical value. The movement of gas in the vadose zone is mainly in vertical under the condition of gas insulation boundary, while in both vertical and horizontal under the condition of gas exhaust boundary. Finally, according to the variations of gas pressure with depths in the central profile, the vadose zone is divided into three zones: gas escaping zone, gas pressure fluctuating zone and gas pressure fast-decreasing zone.
Keywords: *sand tank, rainfall intensity, gas pressure, infiltration, physical experiments, moisture content*

Introduction

Gas flow is usually ignored in research into water movement processes in the vadose zone, and it is generally assumed that gas can freely discharge or invasive, so the gas pressure and atmospheric pressure are balanced (Peng, 2002). In fact, water movement in the vadose zone is the result of the mutual displacement of gas and water in the vadose zone pores, especially during events of heavy rainfall infiltration and pressured water infiltration. Water infiltration causes the gas to be constantly compressed under the weight of water and the gas cannot dissipate within a short time period, resulting in an increase in gas pressure and a reduction in the infiltration rate (Jarrelt, 1978; Lei, 1988; Lu, 1994).

It was found that the water infiltration rate was smaller under gas insulation conditions than under free exhaust conditions, and that gas will break through the overlying layer to escape when the pressure reaches a breakthrough value in the one-dimensional soil column infiltration experiment (Wang, 1997). Others had also come to this conclusion (Peck, 1965; Toma, 1986; Grismerand, 1994. Weir and Kissling divided the soil column into three regions to describe the water phase and gas phase: an upper

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78377853

layer, a transition layer and a lower layer. Water-gas phase interactions mainly occur in the transition layer, where the existence of gas will affect the water penetration coefficient. Peng et al. (2002) found that the water infiltration rate obviously declined when the air flow rate at the bottom of the soil column was controlled instead of exhausting freely in a one-dimensional two-phase flow experiment. The flow movement to ambient infiltration zone and surface is due to gas pressure persistent arise and gas displacement by water is the main characteristic in infiltration process (Lei, 2009). Ghosh et al. (2012) made an experimental investigation on vertical gas–liquid counter-current two-phase flow and obtained nonlinear relationships between the developed flow regimes and input parameters. Jie et al. (2013) illustrated the essential of consideration of gas resistance. It was found that the calculated infiltration time considering gas resistance term in the stratified hypothesis model agrees with the measured value with low deviation degree and a very small fluctuation. Herrada et al. (2014) proposed a model to simulate infiltration into heterogeneous soils, with arbitrary initial water content distributions, subject to unsteady rainfall, and under the free draining condition. Li et al. (2015) obtained the results that the channel differential pressure on both sides brings obvious fluctuations when the liquid is infiltrated. It is the gas flow rate not the amount of liquid infiltration affects the fluctuation significantly in the amplitude of the pressure differential. Du et al. (2017) analyze the mechanisms of soil water and vapour transport in the desert vadose zone using the Hydrus-1D model. Xiao et al. (2018) created an artificial-intelligence system that identifies nanofluid gas-liquid two-phase flow states in a vertical mini-channel. Min et al. (2018) investigated the groundwater recharge and seepage velocity in the deep vadose zone under typical irrigated agricultural land-use types.

Most researchers focus on one-dimensional soil column infiltration experiments, studying the effect of the presence of gas in the vadose zone by controlling the air flow rate at the bottom of the column, with little consideration given to the existence of the overlying aquifer. Although pressure changes under infiltration conditions are analysed, the relationship between air pressure and moisture content are not presented. Research of two-dimensional problems of rainfall infiltration is relatively barely (Zhao, 2011). In this paper, based on a two-dimensional physical model, experiments are designed to investigate rainfall infiltration processes under conditions of four different rainfall intensities and two different boundaries. That the changes of gas pressure and the hydrodynamic filed under different rainfall intensities and boundaries are investigated. The gas pressure on the profile along the central line and at three typical points is chosen to make data analysis. The relationship between negative gas pressure and moisture content is also analysed.

Methods

Experimental equipment

The experimental equipment comprises a sand tank, a rainfall simulator and a rainfall collector, shown in *Figure 1*. The size of the sand tank is 130 cm × 120 cm × 30 cm. The rainfall simulator is a plate with circular holes (diameter is 0.2 mm). The size of the rainfall simulator is 50 cm × 30 cm × 20 cm.

The sand tank is the main body of the test device. It is made of a high-quality, water-resistant wood-based material, with a metal box at the bottom forming the saturated zone. The tank is fitted with intake pipes, drainage pipes and piezometric tubes.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78377853

Because the tank is symmetrical, so 19 gas pressure sensors (measuring range: -1000~1000 Pa; resolution: ±0.25% FS; manufacturer: Chang'an University and Huarui Transducer Technology Company) are installed in the front side of the sand tank, and 17 negative pressure sensors (measuring range: 0~-50 kPa; resolution; ±0.25%FS; manufacturer: Chang'an University and Huarui Transducer Technology Company) are installed in the back side of the sand tank. The effective rainfall simulation zone is 50 cm × 30 cm on the top of the setup. The experimental medium filled in the tank is silty sand. The joint parts of the device are well sealed to prevent water from flowing out of the device. Several air outlets with a diameter of 1 cm are installed at not only the left side but also the right side of the device for free exhaust. The origin of the coordinate system is at the left-bottom corner of the sand tank. The X axis increases positively to the right, and the Z axis increases positively upwards, so the coordinate of each pressure observation point is obtained. A markovian bottle is used to keep the phreatic level at 25 cm considering the base level at X axis.

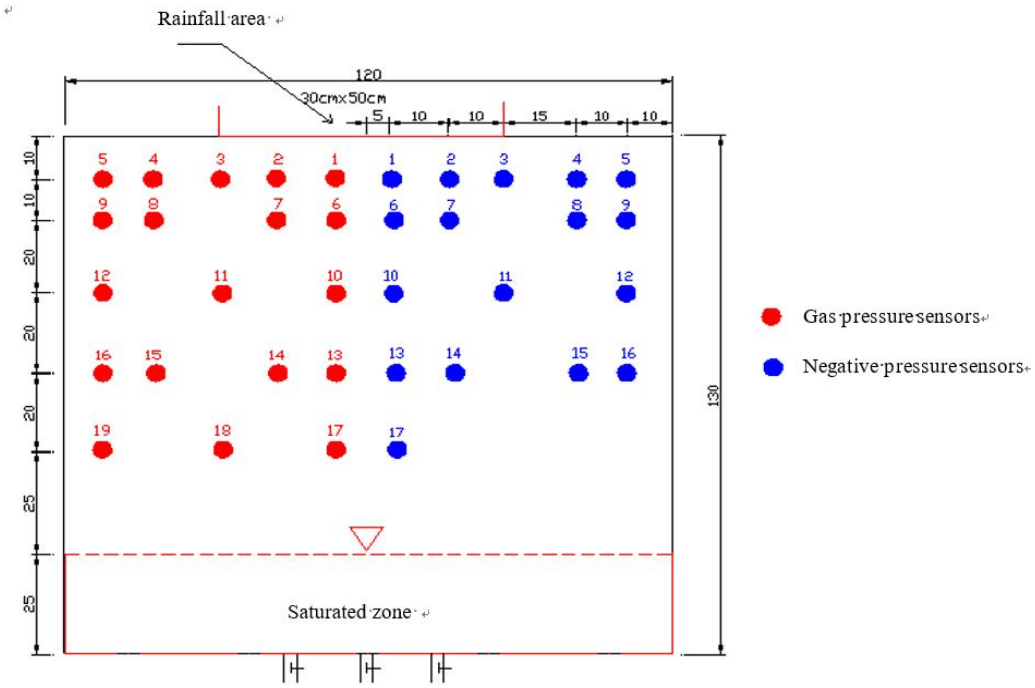

Figure 1. *Schematic diagram of experimental setup*

Experimental design

In order to analyze the affecting factors on water–gas phase flow migration law in the vadose zone, several different rainfall intensities and two different boundaries are set in the experiments. Two different boundaries are gas insulation condition and free exhaust condition. Gas insulation condition is that both the left and right boundaries of the sand tank model are closed and gas cannot be discharged (zero flux boundary). Free exhaust condition is that both the left and right sides of the sand tank model are partly open (flux boundary). The detailed experimental design is shown in *Table 1*. The rainfall duration is 30 min in each experiment. The groundwater level of saturated zone is kept at 25 cm. In each experiment, the negative gas pressure (matric potential) and the gas pressure and moisture content are measured and recorded continually.

Experimental results

Changes of the aerodynamic field under different boundaries

Distributions of the gas pressure field with a rainfall intensity of 58 cm/h (gas insulation boundary, presented in grey solid lines) and 53 cm/h (free exhaust boundary, presented in grey dotted lines) at different rainfall durations are shown in *Figures 2* and *3* respectively. The time varying maximum gas pressure of the central profile at X = 60 cm under different boundary conditions are presented in *Figure 4*.

Changes of the gas pressure with the depth

Take the gas pressure at the central profile along X = 60 cm for example, the time-varying relationships between the gas pressure and depth in the vadose zone under different rainfall intensities and rainfall durations are shown in *Figure 5*. The rainfall duration is 0, 11, 20, 26 min respectively for each line in each figure.

Changes of gas pressure at typical points

Three gas pressure observation points at different locations in the vadose zone are selected. The first point (1#) locates at the rainfall area. The second point (3#) locates at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78377853

the front of rainfall area and non-rainfall area. The third point (5#) locates at non-rainfall area. The changes of gas pressure values of the above three points are plotted in *Figure 6*.

DOI: http://dx.doi.org/10.15666/aeer/1704_78377853

The changes of gas pressure with time under different rainfall intensities are shown in *Figure 7*. It shows that the pressure fluctuates constantly around a mean value during a rainfall event. The mean value is 12.65 Pa when the rainfall intensity is 20 cm/h, while the mean value is 16.24 Pa when the rainfall intensity is 78 cm/h. The mean value of the pressure is greater when the rainfall rate is 78 cm/h than that when the rainfall rate is 20 cm/h. This proves that rainfall intensity has an important effect on the changes in gas pressure in the vadose zone.

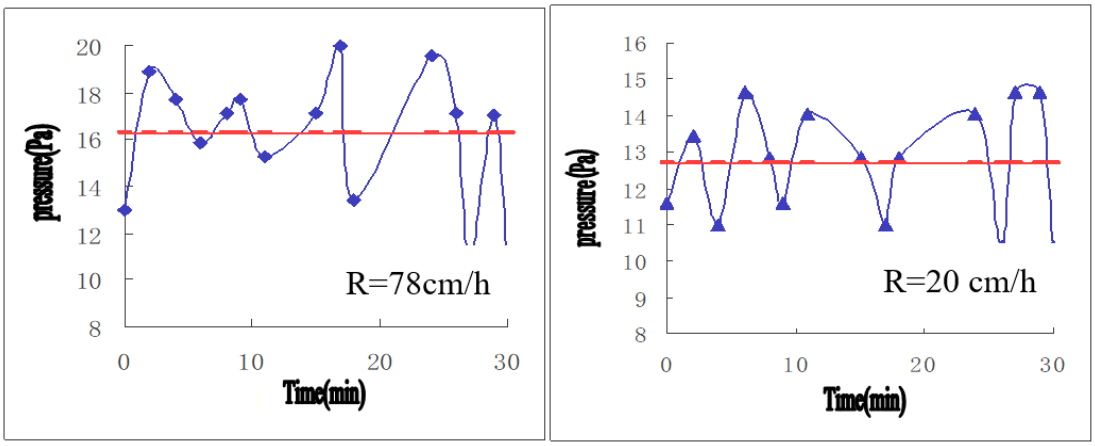

Figure 7. *Gas pressure variations with time in the vadose zone under different rainfall intensities*

Fluctuations in gas pressure are mainly related to unevenly distributed rainfall, surface disturbance, and the density of the experimental medium. These factors led to a change in the hydrodynamic field in the vadose zone, and to gas pressure fluctuations. It can be concluded that the water and gas phases are closely linked in the vadose zone and the mutual displacement processes should not be ignored.

Changes of the hydrodynamic field

The distributions of hydrodynamic fields under different rainfall intensities and different rainfall durations in the vadose zone are shown in *Figure 8*.

Figure 8 shows the downward migration of moisture in the vadose zone for different rainfall intensities. The hydraulic heads become increasingly concentrated in the vertical direction below the rainfall area as the rainfall time increases. The water flow usually moves vertically between the rainfall area and the groundwater table, and water infiltration in the vertical is much quicker than the percolation in the horizontal.

Contour plots of moisture content show the water infiltration process and the moving of wetting front. The figures showing the moving of the wetting front are presented in *Figure 9* for rainfall durations of 5, 20, 30 min and 15 min after the rainfall event respectively. The figure shows the distribution of moisture content within the vadose zone during a rainfall event. The red solid line represents the position of wetting front, at which the moisture content is approximately 20%. In addition, the movement of the wetting front shows a semi-oval shaped outward expansion. It can be obtained that for a rainfall duration of 29 min, the penetration distance of the water flow in vertical is about 50 cm, while the penetration distance in horizontal is only about 12 cm. This means the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78377853

vertical penetration of water flow is much larger than the horizontal penetration, which causes the differences of gas expansion and compression in the vertical and horizontal directions. The unevenly moving of wetting front in directions is one of the causes of complicated gas migration and gas pressure changes.

Water flow infiltration rate ($q_i = dL_i/dt$, i = x, z) in the vertical and horizontal directions can be derived from the distance moved by a moisture peak at different times, shown in *Figure 10* (line a and b). In addition, the surface infiltration flux is 78 cm/h. From Darcy's law, the rate of water flow infiltration can be calculated. At the sand surface:

$$R = -K_{w0}\left(\frac{h_1 - h_0}{\Delta z} - 1\right) \quad \text{(Eq.1)}$$

where h_0 and K_{w0} are the hydraulic head and infiltration rate of the surface node respectively. The calculation results from Darcy's law are shown in *Figure 10* (line c).

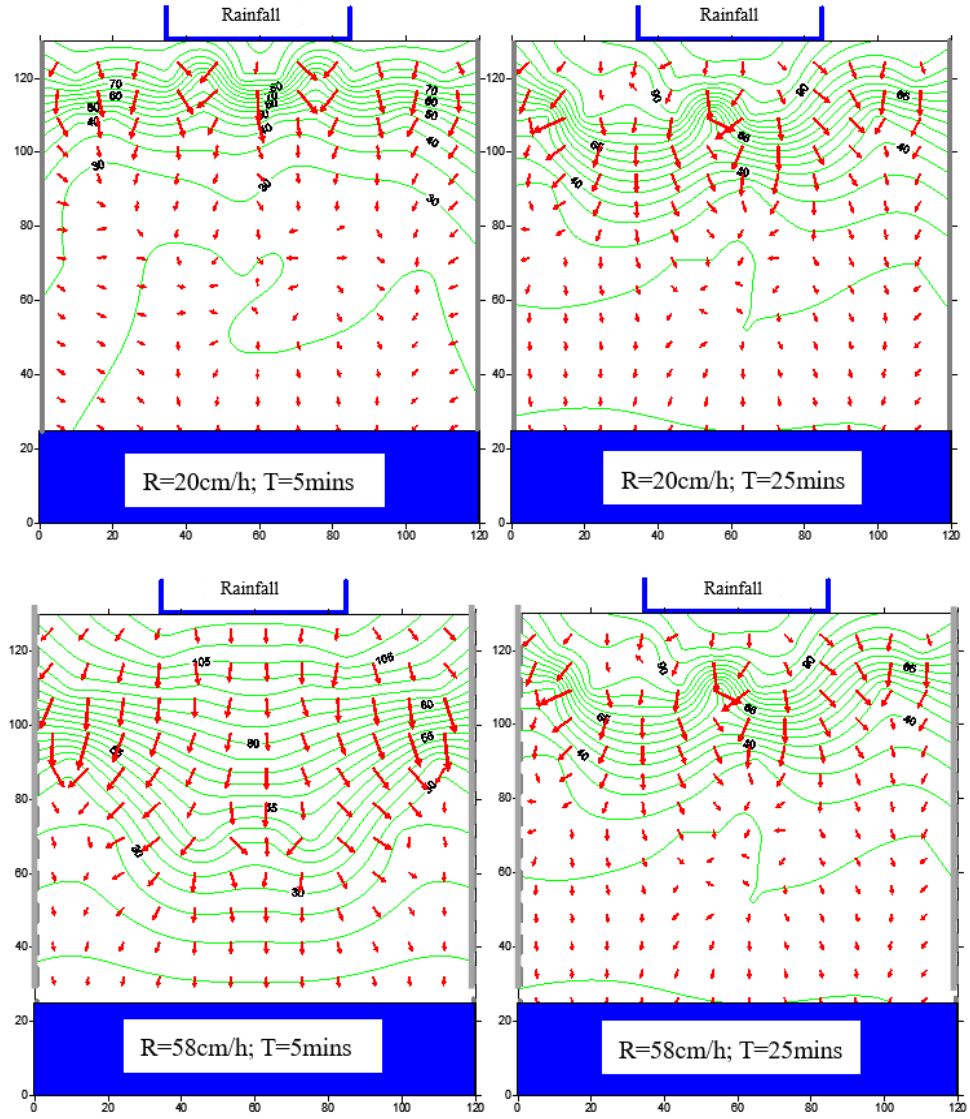

Figure 8. *Distributions of hydrodynamic field for different rainfall intensities and different rainfall durations (unit of hydrodynamic field: cm)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78377853

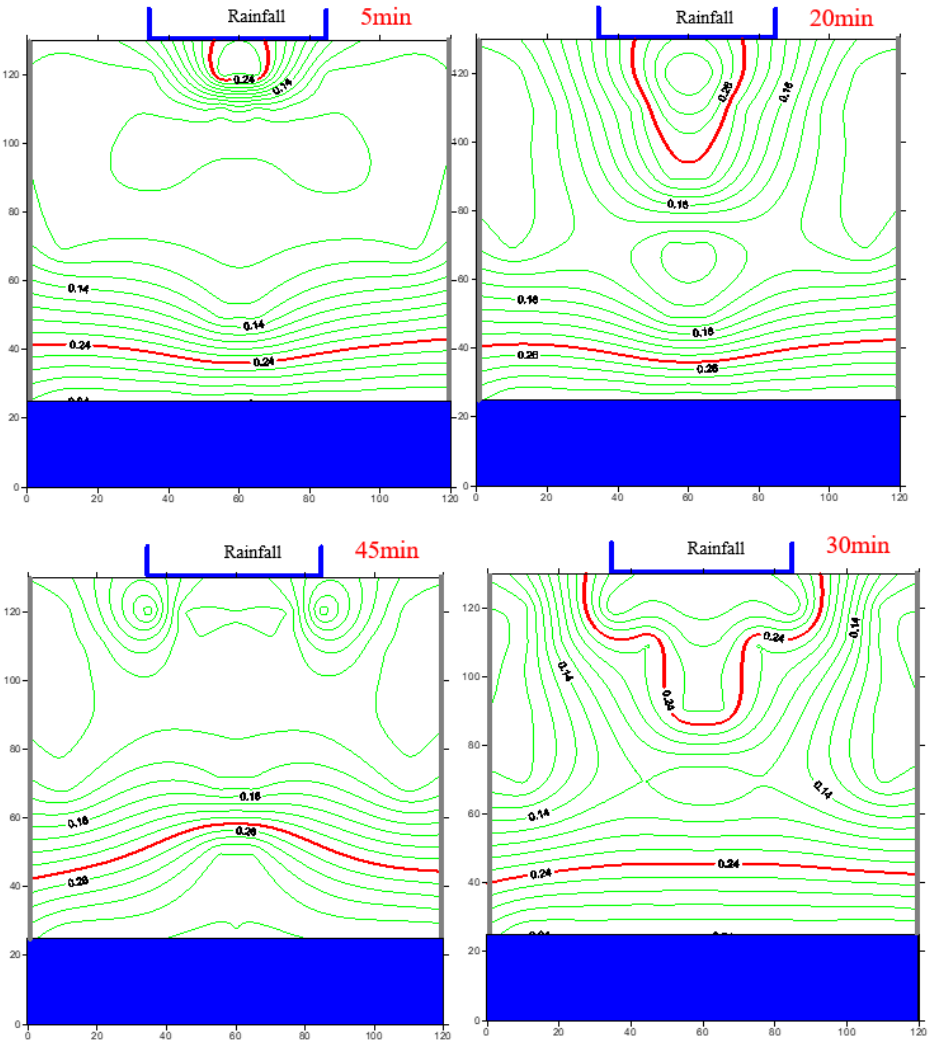

Figure 9. *Distributions of moisture content within the vadose zone at different times after the onset of rainfall (the rainfall duration is 30 min)*

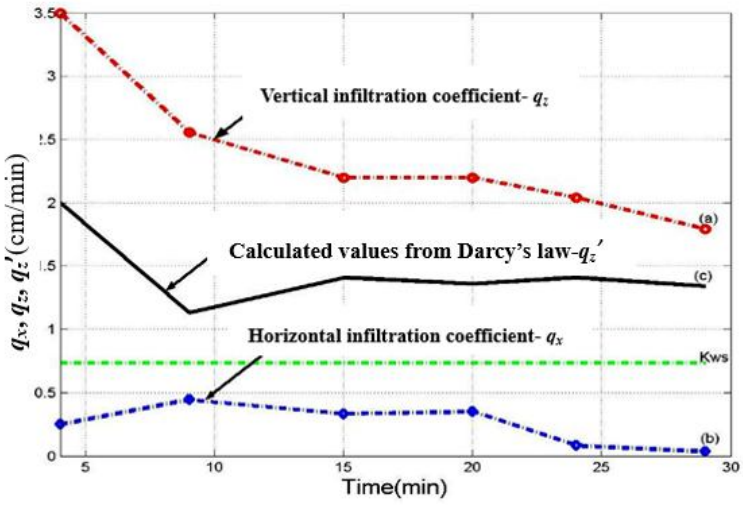

Figure 10. *Time series for the rainfall infiltration rates*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78377853

From *Figure 10,* we can see that water infiltration rate in the vertical (q_z) is significantly greater than that in the horizontal (q_x), that is $q_z >> q_x$. The calculated vertical infiltration rate from Darcy's law (*Fig. 10,* line c) is in accordance with the changing vertical infiltration rate derived from the movement of wetting front (*Fig. 10,* line a), but much larger. Early in the rainfall event, the flow infiltration rate is significantly greater than the saturated hydraulic conductivity K_{ws}. As the vadose zone soil porosity gradually become saturated, the vertical infiltration rate decreases, ultimately tending to the saturated hydraulic conductivity K_{ws}. The horizontal infiltration rate is much smaller throughout the rainfall event, and eventually tends to zero (*Fig. 10,* line b).

Distributions of moisture content in the central profile at X = 60cm

Negative pressure (matric potential) varies with moisture content. So the changes of negative pressure are a useful mean of indirect measurement of moisture content in the vadose zone. Water column height (in cm) is used to represent the values of the negative pressure. The changes of negative pressure with depths under conditions of different rainfall intensities and rainfall durations are shown in *Figures 11* and *12*.

The relationship between the gas phase and the water phase

Soil pores in the vadose zone are filled with either water or gas, so moisture migration resulting from rainfall infiltration is actually a mutual displacement process between the water and gas phases. The changes in moisture content cause the changes in gas pressure, while the negative pressure (matric potential) varies with moisture content, so there is a close relationship between air pressure, moisture content and negative pressure. The research of the relationship is important to understand the mechanisms of water and air migration in the vadose zone.

The time series of air pressure and negative pressure under conditions of different rainfall intensities are shown in *Figure 13*.

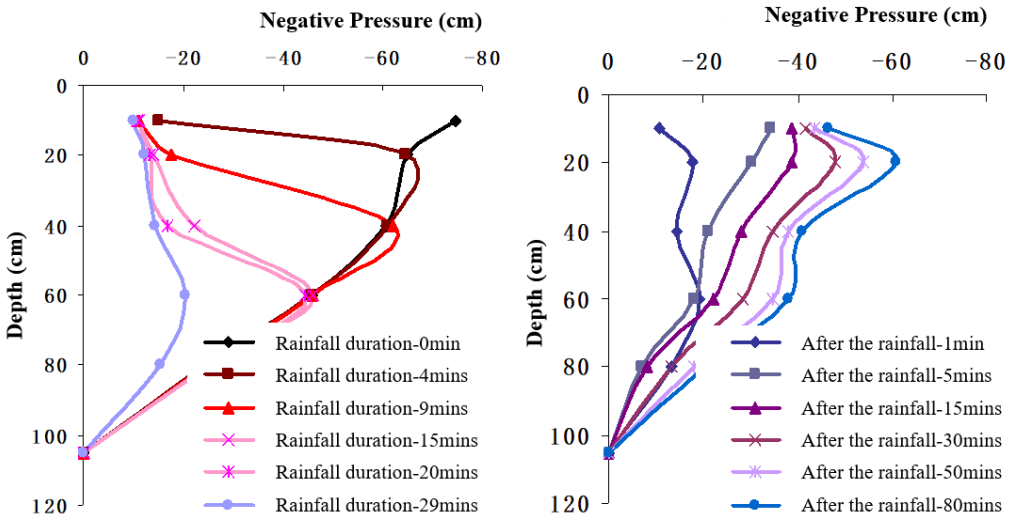

Figure 11. *Changes of negative pressure with depths in the vadose zone for a rainfall intensity of 20 cm/h*

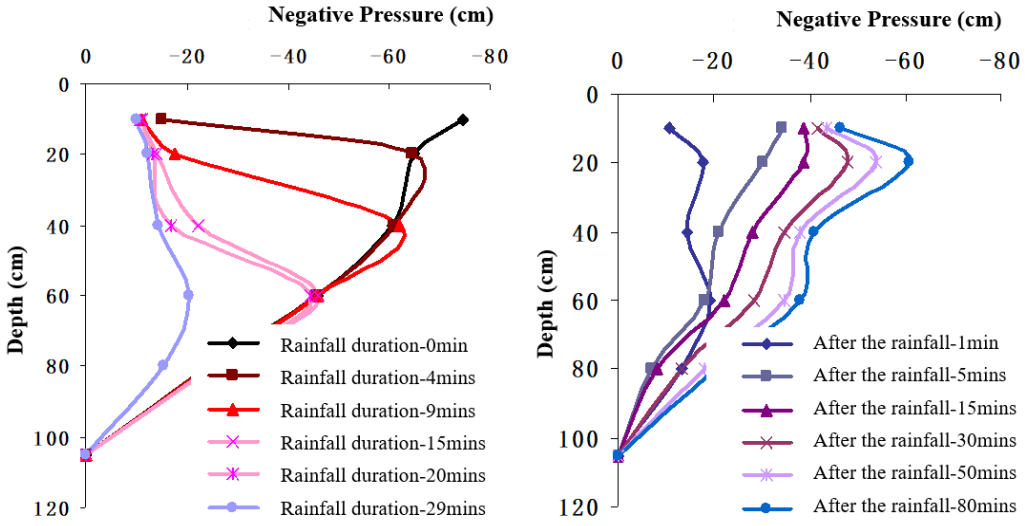

Figure 12. *Changes of negative pressure with depths in the vadose zone for a rainfall intensity of 78 cm/h*

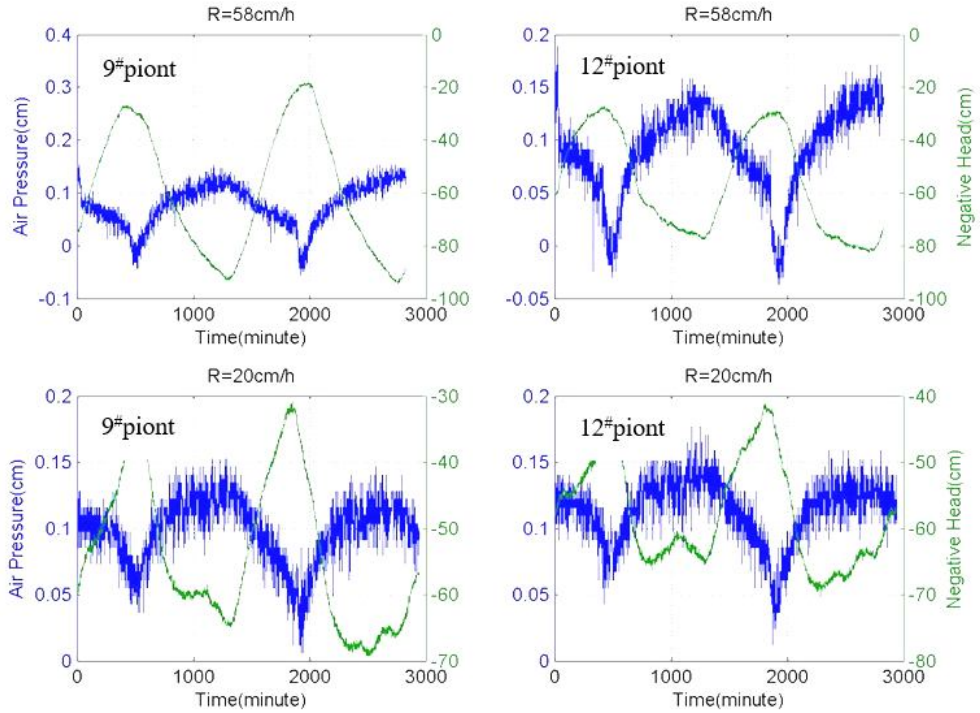

Figure 13. *Time series of gas pressure and negative gas pressure for different pressure measuring points under different rainfall intensities*

How the gas phase blocks water infiltration

The impact of the gas on the moisture migration. The mutual displacement relationship between the water phase and gas phase in the vadose zone is an important

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78377853

aspect of rainfall infiltration processes, and the blocking effect of the gas phase on water infiltration is particularly important. Using the groundwater recharge rate obtained from the rainfall infiltration experiments, Darcy's law can be expressed as the following equation:

$$q = -K_i\left(\frac{h_i - h_{i-1}}{\Delta z} - 1\right) \quad \text{(Eq.2)}$$

where h_i and h_{i-1} are the hydraulic head values for adjacent nodes near the groundwater table.

The unsaturated permeability coefficient *K(h)* can be obtained from *Equation 2*. The changes of *K(h)* with the pressure at node i are shown in *Figure 14*.

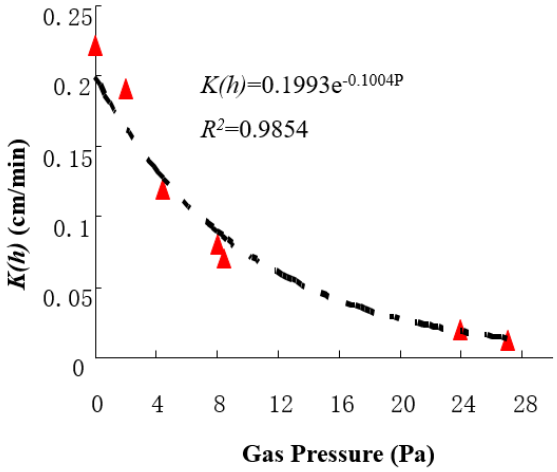

Figure 14. *The relationship between the unsaturated permeability coefficient K(h) and gas pressure*

The response time of rainfall recharge. Define the response time of rainfall recharge as the period between the time at which the rainfall infiltrates into the vadose zone to the time at which the infiltrated water begins to recharge groundwater. This response time is closely related to rainfall duration, vadose zone lithology and structure, surface vegetation cover and groundwater depth. The changes of the response time under different rainfall intensities conditions are depicted in *Figure 15*.

Discussion

Changes of the aerodynamic field under different boundaries

From *Figures 2* and *3,* it is found that the high pressure center, where the gas pressure increases quickly and the gas compression degree is the highest, is located just below the rainfall area, but not close to the groundwater table whether under the gas insulation boundary or free exhaust boundary. When the gas pressure increases to a critical level, the gas begin to escape to surroundings or even break through the overlying water layer to escape out of the sand surface as a result of the pressure gradient. Under gas insulation conditions, the gas cannot escape from the sides, and so

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78377853

is eventually released from the sand surface. And the maximum pressure of the compressed gas is about 38 Pa after 29 min rainfall (*Fig. 4*). The gas movement is mainly in vertical. Under the free exhaust condition, the gas escapes from both sides of the tank and exchanges with the air outside exhibiting significant horizontal movement besides vertical movement. The maximum gas pressure is about 32 Pa after 29 min rainfall (*Fig. 4*).

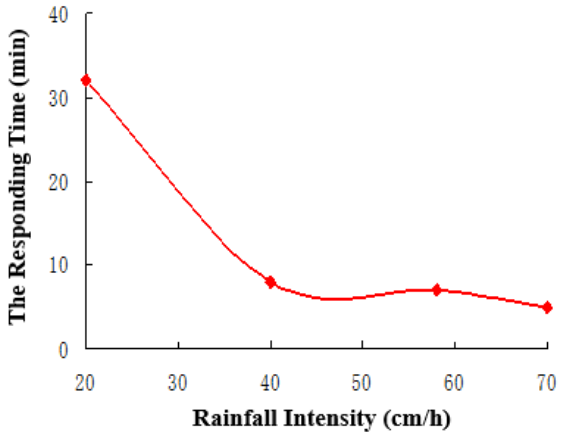

Figure 15. *The changes of the response time under different rainfall intensities conditions*

From *Figure 4,* it can be seen that the maximum pressure is larger under the gas insulation condition than that under the free exhaust condition during rainfall infiltrating. Almost at the end time of the rainfall, the gas pressure reaches a critical value, after which the gas breaks through the overlying water layer and escapes, causing the pressure to reduce rapidly. After rainfall (from 40 to 180 min), the maximum profile pressure decreases much more rapidly under gas insulation condition than that under free exhaust boundary condition. In addition, the pressure values under gas insulation condition keep lower than that under free exhaust boundary condition after rainfall. The above results demonstrate that the degree of gas compression under the gas insulation condition is much greater than that under the free exhaust condition. The boundary has a significant influence on the gas migration in the vadose zone.

Changes of the gas pressure with the depth

The gas pressure fluctuates strongly but approximately follows an "S" type with the depth from the surface to the bottom of the vadose zone either under a gas exhaust boundary or a gas insulation boundary. The difference is the location of the lower turning point. The location is at 60 cm under a gas exhaust boundary while it is at 20 cm under a 20 cm. The "S" type relationship between the gas pressure and depth divides the vadose zone into three zones. Zone I (at about 0–20 cm) is the gas escaping zone, where is close to the sand surface. The gas pressure in this zone decreases with the depth very slowly and reaches a minimum value at the depth of 20 cm. This is because this area reaches near-saturated in a comparatively short time during a rainfall event and the gas is quickly displaced by water. Zone II (at about 20-40 cm for gas insulation boundary; at about 20-60 cm for gas exhaust boundary) is the gas fluctuating zone. In this zone, the gas pressure increases quickly with the depth and reaches a maximum value at the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78377853

depth of 40 cm (gas insulation boundary) or 60 cm (gas exhaust boundary). The maximum value decreases with the rainfall intensity. The reason is that the infiltrating flow advances rapidly in this zone, resulting in great changes in moisture content. The sustained infiltrating flow causes the gas resistance. And the downward movement of wetting front causes the gas compressed, so the gas cannot dissipate in time. Zone III (40–80 cm for gas insulation boundary; 60-80 cm for gas exhaust boundary) is the gas pressure fast-decreasing zone. In this zone, the gas pressure decreases with the depth. The flow tends to be steady due to the large infiltration distance and the reduced infiltration rate. Gas here slowly dissipates and escapes in the effect of the wetting front. Only a small amount of gas is transported to the groundwater table. The turning point illustrates that the gas movement does not only occur in the vertical direction but also in the horizontal direction. The turning point is where the gas is compressed and dissipated. The increase of gas pressure prevents the water from infiltrating and causes a lower hydraulic conductivity.

Changes of gas pressure at typical points

Figure 6 shows that the gas pressure fluctuates with time continuously around a mean value, exhibiting peaks and troughs. This is because the water infiltration causes gas to be constantly compressed during rainfall events. The increase in pressure causes the gas to break through the overlying water layer, which forms a pore channel. Then the pressure begins to decay rapidly and the pore channel is quickly re-occupied by water. This process repeats in the whole infiltration process, so the gas pressure in the vadose zone is not increasing or decreasing continuously, but in a state of fluctuation. The shape of the gas pressure time series curve shows that the changes of gas pressure in the vadose zone is similar with the fluctuations of the atmospheric pressure (Li, 2010). Pore channels form in the vadose zone and connect with the outside atmosphere, so the gas pressure changes are primarily related to the ambient atmospheric fluctuations. This result is consistent with the phenomenon described by Buckingham (1904), who considered that fluctuations in gas pressure in the vadose zone were related to changes in the near-surface atmospheric pressure. Massmann (1992) explained the near-surface atmospheric pressure fluctuations in detail. Massmann believed that the main causes of it were firstly the effect of heat conduction and gravity, and secondly the regional scaled weather conditions.

Distributions of moisture content in the central profile at X = 60 cm

The results (*Figs. 11* and *12*) show that saturation state can be reached near the surface in a short period of time. At the onset of a rainfall, the moisture content is approximately the saturated moisture content and the negative pressure head is small. As the rainfall continues, the water-gas front moves downwards and the moisture content increases and the negative pressure head decreases. After the rainfall event, groundwater in the vadose zone is transported downwards under the influence of gravity. The negative pressure shows the trend of larger values at the lower depth and smaller values at the deeper depth.

Analysis of the relationship between the gas phase and the water phase

The results (*Fig. 13*) show that the air pressure and negative pressure fluctuates with time: the negative pressure increases (negatively) with the air pressure increases, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78377853

vice versa. The increase in gas pressure at a point in the unsaturated zone indicates the entry of gas into pores near that point and the discharge of water from the pores. This corresponds to a decrease in the moisture content at that point, and a consequent increase in negative pressure. Similarly, a decrease in pressure indicates the entry of water into a pore near that point, following the discharge of gas from the pore, which corresponds to a decrease in negative pressure because of the increase in moisture content.

Analysis of how the gas phase blocks water infiltration

The curve in *Figure 14* shows that the unsaturated permeability coefficient varies with gas pressure following the empirical relationship ($K(h) = 0.1993e^{-0.1004P}$). It is clear that the increase of the gas pressure results in the reducing of the unsaturated permeability coefficient during a rainfall event. It illustrates that increasing pressure will strongly attenuate the flow infiltration rate. For example, when the gas pressure reaches 270 Pa, the unsaturated permeability coefficient of water decreases from 0.22 cm/min to 0.03 cm/min. The effect of the gas phase on the unsaturated permeability coefficient gradually becomes weakened with the gas pressure increases, and the curve becomes flattened. Although this relationship does not provide a clear quantification of the relationship between gas pressure and the unsaturated permeability coefficient, it does clearly demonstrate how the increasing pressure has a blocking effect on the water flow, resulting in the water infiltration rate reduction.

Figure 15 shows that the response time decreases as rainfall intensity increases. The greater the rainfall intensity, the faster the flow infiltration rate, and the shorter time taken for the flow to reach the groundwater table. Although rainfall infiltration leads to gas compression and creates a partial block to the flow, this does not completely prevent the flow, and the response time is mainly determined by the magnitude of the rainfall intensity.

Conclusions

In order to obtain the mechanism of water infiltrating into an air block area in the vadose zone under conditions of different rainfall intensities and boundaries, a two-dimensional sand tank is made and lots of experiments are conducted. From the data analysis, the following conclusions can be drawn:

(1) The boundary has a significant influence on the gas pressure. The gas moves primarily in the vertical direction under a gas insulation boundary. However, the gas exhibits significant lateral diffusion besides vertical movement under a gas exhaust boundary. When the gas pressure reaches to a sufficiently high value, the gas escapes to the surroundings even break through the overlying water layer.

(2) The gas pressure fluctuates strongly but approximately follows an “S” type with the depths. So the vadose zone can be divided into three zones: Zone I is the gas escaping zone; Zone II is the gas pressure fluctuating zone; Zone III is the gas pressure fast-decreasing zone.

(3) The unsaturated permeability coefficient varies with gas pressure following an empirical relationship. The block effect of the gas phase on the unsaturated permeability coefficient gradually becomes weakened with the gas pressure increases.

Abstract. As one of the major water sources in Ningxia of China, it is of great importance to maintain healthy ecological environment of the Yellow River. In this essay, basin hydrological model is adopted to simulate the influences of prediction of climate changes on runoff in river basin, which is of great theoretical and realistic significance to flood and draught control plans as well as long-term exploitation and utilization of water resources in Ningxia Section of Yellow River Basin of China. Based on analysis of the changing characteristics of major climates and hydrological features in Ningxia Section of Yellow River Basin of China , distributed hydrological model SWAT (Soil and Water Assessment Tool) coupled with GIS is used in this study to simulate the yearly and monthly runoff volumes under 15 different climate changes, with the aim to explore the influences of climate changes to runoff. The results show that the runoff volume in the basin has negative correlation with the temperature but in positive correlation with the rainfall, and that the influence of the changes of rainfall in the basin on the runoff is greater than that of the temperature, which could provide basis for decision making of water resource management in Ningxia Section of the Yellow River Basin of China.
Keywords: *SWAT model, climate scenes, simulation, temperature, rainfall*

Introduction

As the environment in which human beings live, climate could affect human activities, which has been know by all. The influences of climate changes are comprehensive, multi-dimensional and multi-layered, with positive and negative influences co-existing. Generally, people concern more the negative influences. Global warming caused by carbon dioxide affects directly water supply and distribution in the world and has influenced the natural ecosystem in many areas of the world. Due to limited adaptability, natural ecosystem is easily to be destroyed severely and even irreversibly. Rainfall changes caused by climate warming is an essential factor to study the influences of potential climate on water supply, for rainfall is the fundamental source of fresh water on the earth. Water resources planning depends on mainly space-time distribution of rainfall and soil water. In the future, rainfall distribution would change obviously on the warmed earth and rainfall in many areas located in semi-arid subtropical zone would increase. Because global warming could cause profound changes of the global climate system, the coadaptation established between mankind

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78557863

and the ecological environmental system would be affected and disturbed significantly; therefore, global changes, especially climate changes, have attracted great concerns from governments of the world and the public.

Certain irrational activities of human beings have caused global warming in the world, which results in finally frequent draughts, floods and other natural disasters. In the past several decades, the global climate has had inconvenient changes, among which global warming has become an undisputed fact. Since IPCC (Intergovernmental Panel on Climate Change) was found in 1988, it has completed five evaluation reports on global climate changes (IPCC, 2013), among which it was pointed out in the fifth evaluation report: the average global surface temperature in the world between 1880-2012 rose 0.85ºC. Comparing the middle and late 21st century and the period from 1986-2005, the average global temperature will keep rising 1.0～ 2.0 and 1.0 ～ 3.7ºC. According to the observation results in the past hundred years in China, the average surface temperature in China in the 20th century had rose 0.5～ 0.8ºC, which showed similar trend of global warming. Climate changes could affect various fields and could change the conditions of global water circulation, which could result in spatial and temporal redistribution of water resource. In recent years, due to climate changes and the increase of human activities, about 31% annual runoff of 145 major rivers in the world shows rising tendency (9%) or descending tendency (22%) (Walling and Fang, 2003). Runoff of many major rivers in China declines, especially that in Haihe Basion and the Yellow River Basin (Wang et al., 2010; Bao et al., 2012; Feng et al., 2016). In recent years, many areas had floods or draughts often (Kunkelet al., 1999; Lindner et al., 2010; Zhang et al., 2015). For example, draught occurred in downstream of the Yellow River Basin, floods occurred in the Yangtze River Basin and Songhua River area respectively in 1997 and 1998, which had caused immense damages(Xu et al., 2010). Therefore, it is of great significance for understanding hydrological changing mechanisms and relieving future draughts and floods to know the reasons of the runoff changes in the changing environment.

Climate changes and human activities are two essential factors that could affect runoff changes. Climate changes affect runoff mainly through rainfall and potential evaporation (Chien et al., 2013; Zhao et al., 2015). A great number of studies have shown that global warming will aggravate global hydrological circulation (Huntington, 2006; Milliman et al., 2008). It has been predicated by the observation data and climate model studies that climate warming could result in significant increase of rainstorms (Wu and Lau, 2016). Many studies have used GCM and hydrologic model to evaluate the influences of climate changes on runoff (Eisner et al., 2017; Teklesadik et al., 2017). However, climate simulation factors could also affect runoff changes. The experiment adopted various factors (such as GCM model, project stage, emission scenes, downscaling method and deviation correction) to show the predicted flow is an factor for the modeling and that it is unnecessary to take all factors into consideration but to keep the overall design balance (Ringius et al., 1996; Aamery et al., 2016). Li et al. (2013) used two rainfall–runoff models to simulate the yearly and monthly runoff of southeastern Tibetan Plateau under the historical and future conditions of climate changes. Coles et al. (2017) studied the influences of climate changes on the hillslope runoff in the north of the Great Plains. Besides, with the increase of the population and the urbanization (Kuang et al., 2016), human activities, such as land use/cover changes (Rahman et al., 2015; Zhang et al., 2017; Yhang et al., 2019), operation of dam and reservoir, water and soil conservation projects as well as direct taking of surface water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78557863

and groundwater, all could cause great influences on water resources. Zhai et al. (2017) investigated the climates and runoff tendencies of seven typical basins in China from 1961 to 2014 and attributed the runoff change within three periods to climate changes and human activities of each basin. The problem of water resources has aroused concerns of various scholars; moreover, it has become the bottle-neck of economic development of many countries and areas. In recent years, many professional scholars have begun to study the influences of climate changes on water resources, which could provide scientific theoretical basis for rational development and utilization of water resources, disaster prevention and reduction, water loss and soil erosion as well as comprehensive planning of the basin and could offer relevant policy reference to the decision-makers.

In this paper, distributed hydrological model SWAT coupled with GIS is used in this study to simulate the yearly and monthly runoff volumes under 15 different climate changes, with the aim to explore the influences of climate changes to runoff, and it can provide decision-making basis for water resource management in the Ningxia Section of the Yellow River Basin of China.

Material and methods

Overview of the research area

The Yellow River enters the downstream of Zhongwei City, Ningxia province, running through the Yellow River irrigation area of Zhongning County, Qingtongxia City, Litong District, Lingwu City, Yongning County, Yinchuan City, Helan County, Pinluo County, Dawukou District and Huinong District and flowing in Inner Mongolia at Shizuishan. There are three hydrological stations along the mainstream of the Yellow River, i.e., Xiaheyan, Qingtongxia and Shizuishan hydrological stations. The Yellow River Basin within Ningxia is located in north latitude $36^{\circ}0'\sim39^{\circ}23'$, east longitude $104^{\circ}17'\sim107^{\circ}39'$, with the drainage area of 51400 km^2. The geomorphic type is alluvial plain of Yellow River, where the terrain is flat with various ditches. The altitude is 1100~2500. It is arid region of temperate zone with abundant sunshine. The average annual sunshine hours are within 2750～2950 h, the average annual wind speed is within 1.7～2.5 m/s. The temperature varies greatly, with abundant heat and longer frost-free period. The drainage basin belongs to continental climate, drought with less rainfall, with the average rainfall of 180～220 mm. The inter-annual rainfall changes decrease from north to south gradually; the difference of average monthly rainfall in the Yellow River irrigation area is relatively obvious but the annual distribution is non-uniform; the changes of inter-annual rainfall in the central arid area and the south mountainous area are relatively mild, showing seasonal variation. The inter-annual rainfall in the basin is distributed unevenly; the dry and humid seasons are obvious; rainfall of July to September covers 60%～70% of the annual total amount; the evaporation is high, with the annual amount of evaporation of 1100～1600 mm. The types of land use are mainly lawn and farmland, covering respectively 33.74% and 48.76% of the basin area, the woodland covering 3.60%, the water area covering 1.43%, the urban and rural industrial and mining land and the residential land covering 1.46%, and the unused land covering 11.01%.

Model calibration

SWAT (Soil and Water Assessment Tool) model was adopted as hydrological forecast model to simulate the hydrological circulation process in Ningxia section of the Yellow River Basin. This model could be used for short-term, middle-term and long-term hydrological forecast as well as for the evaluation of water resource regime in future climate scenarios. In the modeling process, the testing data of the meteorological and hydrological stations were taken as the input source to calibrate and test the model parameters. The simulation was based on the meteorological and hydrological data of Ningxia section from 1990 to 2012. With relative error R_e, correlation coefficient R^2 and Nash-Suttcliffe coefficient Ens as the standards, the sensitive parameters of the model were calibrated with the actually measured monthly runoff volumes within 2000-2006 and the model was validated with the actually measured monthly runoff volume within 2007-2012. The relative error R_e between the calibration period and the verification period was close to 10%, the correlation coefficient R^2 and Nash-Suttcliffe coefficientEns were larger than 0.86 and 0.85 during the calibration period, with good simulationresults. This suggests that this model is applicable to hydrological simulation of Ningxia section of the Yellow River Basin and could be used for quantitative and qualitative study of the basin under future climate changes. The DEM map of study area see *Fig. 1*.

Figure 1. *DEM Map of Ningxia Section of the Yellow River Basin*

Scene design of the climate changes

There are various reasons for climate changes, of which natural climate change caused by human activities affecting directly or indirectly global atmosphere is the key one. Climate change is naturally to cause the change of water circulation, redistribution of water resources in time and space as well as the change of quantity of water resource, which could in turn affect the development of ecological environment and the social economy. Global climate warming could cause rise of the seal level, gradual drop of groundwater level, melting of glacier and frequent occurrence of extreme climates. In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78557863

terms of hydrological circulation, climate change could change redistribution of water resources in time and space and could cause the changes of rainfall and evaporation, which could in turn affect the water balance of the overall basin. Rise of the temperature could accelerate the melting of glacier snow. Certainly, it could also affect other hydrological factors and then affect the runoff volumes of rivers as well as the hydrological process of the overall basin. Rainfall is the major influencing factor of water resource in the basin as well as the major water resource of the basin, that is, rainfall is the basis of the formation of runoff. Changes of rainfall plays significant roles in water resources quantity. It could influence directly water resources quantity of the basin and then the hydrological process of the basin.

Generally, there are two design methods of climate scenes: (1) Arbitrary scene setting: Based on the actual conditions of the study area, taking advantage of the interlocking combination of the supposed rainfall changes and the temperature rising scene, study the influences of climate changes on water resources with appropriate hydrological model. (2) Atmospheric circulation pattern (GCMs) method: This model forecasts the climate changes in the future based on the influences of different CO_2 emissions on climate changes (Feng et al., 2016), and analyzes influences of climate changes on water resources by coupling with hydrological model. However, because the grid interval of the GCMs model data is larger, the spatial resolution is low and the confidence degree is not high when it is used to analyze the influences of climate changes on water resources. So, this essay adopts arbitrary scene setting to establish the scene of climate change in the study area.

Entering the 1980s, the major problems concerned by the human society in the world is no other than global climate changes. There are sufficient evidences to show that with the increase of CO_2 and other greenhouse gases, the global climate is having sharp changes that have never had in history. It was pointed out in the fourth evaluation report of the first working group of Intergovernmental Panel on Climate Change (IPCC) that in the past 100 years from 1906 to 2005, the global climate became warm obviously and it was shown by the statistic results the surface temperature on the earth rose 0.74ºC. Especially, in the recent 50 years, the rising rate of the temperature was higher than the former 50 years, during which the temperature rose 0.65ºC; while 11 of the latest 12 years ranked in the 12 warmest years since 1850 (IPCC, 2013). In the past 100 years, the temperature in China rose 0.4～0.5ºC, slightly lower than the average of the world but in line with the general trend of climate changes. In the latest 50 years, the average temperature in summer in China has no obvious changes, but that in winter increased obviously, increasing 0.42ºC every 10 years. Since 1985, China has had continuously 16 nationwide warm winter, among which the winter in 1998 was the warmest, 1.4ºC warmer. Scientists have made prediction of the global climate in the future 100 years based on population growth, the environmental condition, globalization, economic development and technological progress, the result of which suggested that by the end of the 21st century, the average global temperature would increase 1.1～6.4ºC, the rainfall would transmit seasonally from south to north, among which the arid and semiarid areas would become drier with varying changing tendencies in different areas. Chinese scientist used different global climate patterns and regional climate patterns in China to study the climate changing scenes of China after CO_2 is increased. Supposing atmospheric CO_2 keeping increasing, it is expected the temperature would rise1.68ºC by 2020～2030; 2.22ºC by 2050; it is predicted the temperature could reach 2.94ºC in case the concentration of CO_2 doubles and the warming amplitude in the north is higher than

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78557863

the south. Temperature in Northwest China could rise, 1.9～2.3ºC, rise 1.6～2.0ºC in southwest and in Tibetan Plateau rise 2.2～2.6ºC. Rainfall shows rising tendency in many areas, with the south-eastern coast the largest, where the annual rainfall could increase 6.4%～11% (Jiang et al., 2008).

Based on the above predictions of the global and Chinese climate changes, 15 different climate scenes are set in this essay to reflect the influences of climate changes on runoff. The established climate changes in the future are: Change of the temperature on the original bases are 0ºC, +1ºC and +2ºC, while the changes of the rainfall are respectively -20%, -10%, 0%, 10% and 20% of the original. Specific combinations see *Table 1*.

Table 1. *15 different climate scene settings*

		Rainfall changes				
		P×(1-20%)	P×(1-10%)	P	P×(1+10%)	P×(1+20%)
Temperature changes	T	A11	A12	A13	A14	A15
	T+1℃	A21	A22	A23	A24	A25
	T+2℃	A31	A32	A33	A34	A35

Results and discussion

The actually measured temperatures and rainfall amounts are increased and decreased accordingly based on the above 15 scenes to generate the meteorological data corresponding to 15 climate scenes. Based on SWAT model established in Model calibration Section, the changed meteorological data are input in SWAT model to simulate the average monthly runoff volumes of tributary station and the simulation results of different scenes are as shown in *Table 2*.

Table 2. *Runoff simulation of 15 different climate scenes*

			Rainfall changes				
			P×(1-20%)	P×(1-10%)	P	P×(1+10%)	P×(1+20%)
Temperature changes	Average yearly runoff （ten thousand m^3）	T	7568.3	8567.1	9683.2	10987.5	12334.9
		T+1℃	7002.4	8011.7	9234.9	10468.8	11975.3
		T+2℃	6253.6	7498.8	8806.7	10023.4	11334.4
	Variation amount （ten thousand m^3）	T	-2114.7	-1115.9	0.2	1304.5	2651.9
		T+1℃	-2680.6	-1671.3	-448.1	785.8	2292.3
		T+2℃	-3429.4	-2184.2	-876.3	340.4	1651.4
	Changing rate （%）	T	-21.8%	-11.5%	0.0%	13.5%	27.4%
		T+1℃	-27.7%	-17.3%	-4.6%	8.1%	23.7%
		T+2℃	-35.4%	-22.6%	-9.0%	3.5%	17.1%

It could be seen from *Table 2* that the runoff in Ningxia section of Yellow River Basin changes with the temperature and the rainfall in the following rules:

(1) The runoff volume in the basin is in negative correlation with the temperature and in positive correlation with the rainfall. With the temperature unchanged and the rainfall increasing 10%, the runoff increases 1304.5 ten thousand m^3, increasing 13.5%; with the temperature unchanged and the rainfall increasing 20%, the runoff increases 2651.9 ten thousand m^3, increasing 27.4%, with the rainfall unchanged but the temperature increasing 1ºC, the runoff decreases 448.1 ten thousand m^3, decreasing 4.6%; with the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78557863

rainfall unchanged by the temperature increasing 2ºC, the runoff decreasing 876.3 ten thousand m^3, decreasing 9.0%. It could be seen thus rise of temperature could cause decrease of the runoff, the reason for which is rise of temperature could make the amount of evaporation greater; while increase of rainfall could make the runoff increase and the reason is that increase of rainfall could make the surface runoff yield increase.

(2) Rainfall changes in the basin have greater influences on the runoff than temperature. With the rainfall unchanged but the temperature increasing 2ºC, the runoff decreases 876.3 ten thousand m^3, decreasing 9.0%, which is in small scale; with the temperature unchanged by the rainfall increasing 20%, the runoff increases 2651.9 ten thousand m^3, increasing 27.4%, which is in large scale.

Runoff simulation under the condition with the rainfall unchanged but the temperature changed is as shown in *Fig. 2* and the runoff simulation under the condition with the temperature unchanged but the rainfall changed is as shown in *Fig. 3*.

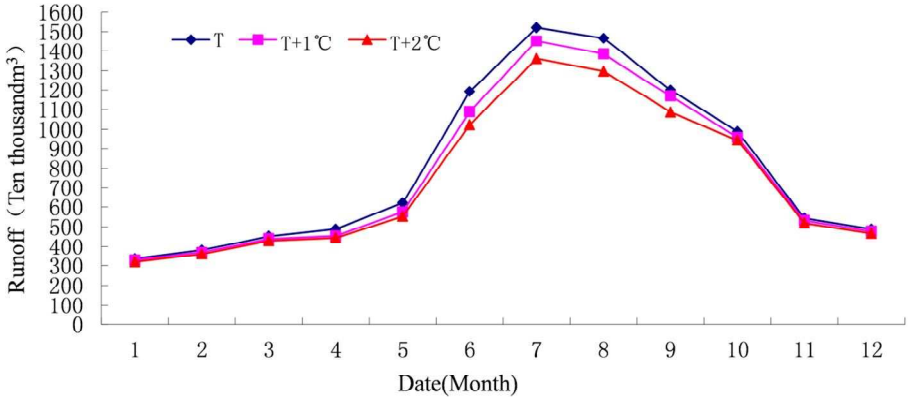

Figure 2. *Comparison between runoff volumes in climate scenes with the rainfall unchanged but the temperature changed*

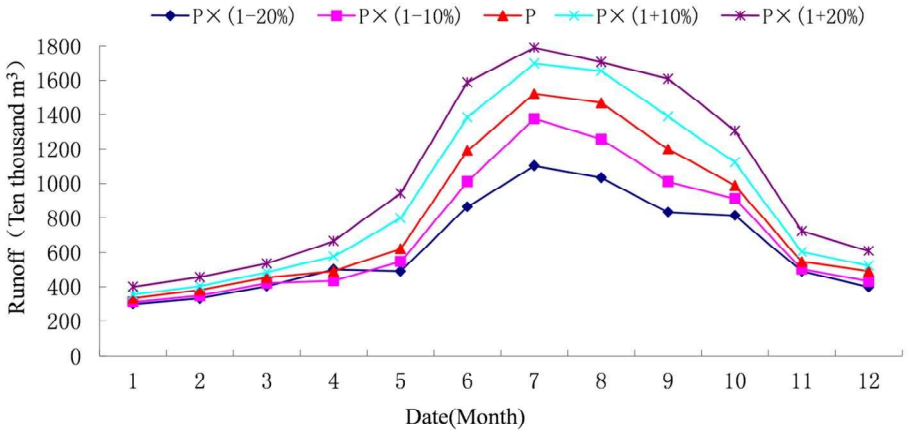

Figure 3. *Comparison between runoff volumes in climate scenes with the temperature*

It could be seen from *Fig. 2* with the rainfall unchanged, the runoff volumes show decreasing tendency. When the temperature rises, the evaporation amount would also increase so that the runoff decreases. It could be seen from *Fig. 3* with the temperature unchanged, the monthly runoff volumes and the rainfall changes have the same

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78557863

tendency, which begins to increase in spring and increases the most in summer; however, it decreases gradually in autumn but with the smallest increase in winter.

Conclusion

Distributed hydrological model SWAT coupled with GIS is used in this study to simulate the yearly and monthly runoff volumes under 15 different climate changes, with the aim to explore the influences of climate changes to runoff. The results show that the runoff volume in the basin has negative correlation with the temperature but in positive correlation with the rainfall, and that the changes of temperature has greater influences on the changes of rainfall but has little influences on the runoff. Its prediction of climate warming in the future has high credibility but the prediction of rainfall increase in the future is of certain degree of uncertainty; however, the influence of rainfall on runoff volume is more significant than that of temperature. Generally, it could provide some scientific basis for management and utilization of river basin water resources.

(Received 23rd Feb 2019; accepted 3rd May 2019)

Abstract. This study aims to investigate the subsurface gravel ditches and desulfurization gypsum (DG) as amelioration methods for alkalized solonchak soils in Gansu Jingyuan of China (37°02' N, 104°96' E). Three blind ditch spacing (6, 9 and 12 m) and three application rates of desulfurization gypsum (20, 22 and 24 t/hm^2) were used to alkalized solonchak soil and increasing the yield of Chinese wolfberry (*Lycium bararum* L.*)*, as compared with the control treatments without blind ditch and DG. The findings show that a larger blind ditch density and appropriate DG application rate contributes to discharge salts easily by reducing the migration distance for soil solutes moving. Under the treatment with blind ditches with 6-metre spacing and a 22 t/hm^2 DG application rate, the values of pH, exchangeable sodium percentage (ESP) and electrical conductivity (EC) of the soil layer up to 40 cm from the surface were decreased by 11.0%, 38.1% and 34.5%, respectively, than those of the control which had no blind ditch and DG treatment in the first year. The yield of Chinese wolfberry was increased by 228.8% than that of the control in the second year.
Keywords: *alkalinity, irrigation, leaching, soil salinity, alkalized solonchak*

Introduction

Saline-sodic soils cover an extensive land surface around the world (Qadir and Oster, 2004). One particular form of these soils is alkalized solonchak which is characterized by an excessively high concentration of sodium with high pH on the surface (Feng et al., 2017). According to a study (Kameli, 2017), the alkalized solonchak mainly distributes in Liaoning, Gansu and Xinjiang province of China.

Solonetz is also found in other regions such as central Asia and central Australia as well as patches in other continents (Driessen et al., 2000). The area of alkalized solonchak in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78657879

Gansu is approximately 21.18×10^4 hm^2 (Lin et al., 2016). The amelioration of saline-sodic requires a complex and long-term practice (Zhang et al., 2012a). The particles of this type of soils are dispersed and swelled after irrigation, causing the pores to close (Chi and Wang, 2014), which makes it difficult to be rapidly leached. Soluble salts accumulated in the soil surface cause changes in soil physical and chemical properties (Vance, 2008), which directly affect its ability for providing water, air and nutrients to plants (Heng et al., 2018) which is one of the main factors restricting the local agricultural production and ecological improvement.

The key to the amelioration of alkali soils is improving soil physical and chemical properties, providing a suitable soil environment for crops (De et al., 2014; Sakai et al., 2011). Presently, there are published reports on the amelioration of alkali soils with measures including planting saline-alkali tolerant crops (Mohsenian and Roosta, 2015), soil improvement by applying desulfurization gypsum (DG) (Mao et al., 2016), drip irrigation (Chen et al., 2015) and straw mulching etc (Xue et al., 2014). However due to a lower permeability of the alkalized solonchak soil, the leached salts from the upper layer may accumulate in the deeper layer resulting in secondary salinization occasionally, and in some cases the long improvement time and high cost make any single amelioration technique impractical and difficult to be extended.

The key ingredient in DG is $CaSO_4$ (Sakai et al., 2004), which increases Ca^{2+} concentration in the soil once it is applied. As the Ca^{2+} capacity of adsorption to soil colloids is stronger than that of Na^+ and the adsorbed Na^+ on soil colloids can exchange with Ca^{2+} in the soil solution, the increase in the Na^+ concentration in the soil solution results in an increase in alkalinity which damages soil aggregates. For this reason any improvement in soil aggregates and texture can effectively improve soil physical and chemical properties (Yu et al., 2015; Rhoton and McChesney, 2011).

Other experiments for the amelioration of saline-sodic show that the application of DG can decrease the soil pH and exchangeable sodium percentage (ESP) remarkably, but there is a problem associated with salt deposition within 60 cm of the soil layer (Lin et al., 2016). Due to the lower permeability of alkalized solonchak, the salts leached from the surface do not effectively discharge out of the soil, and instead they move to the land surface during evaporation. To facilitate salt leaching, mechanical means are effective which include the underground drainage facility to accelerate soil water movement and promote leaching of salts (Min, 2014; Christen and Skehan, 2001). The blind ditch is one form of underground drainage facilities which has advantages with a long lifespan and the benefit to farming operations without blocking the land surface (Pan and Zhao, 1998).

The blind ditches, backfilled with materials including straw and gravels etc., can accelerate infiltration of water and discharge saline water (Tao et al., 2016). It also allows soil water to dissolve salts sufficiently and drain it out of the soil through the blind ditches to reduce soil salinity/alkalinity which is an advantage over the traditional treatments that cannot discharge salts from the soil (Yu et al., 2012). The published research findings (Yang et al., 2015b) suggest that the blind ditch treatment on low-lying saline land with a clay layer can improve the soil permeability, increase the internal drainage ability and accelerate the salt mobility in the soil, resulting in a better leaching of ions such as Na^+, SO_4^{2-}, and Cl^- in the soil. Chinese wolfberry (*Lycium barbarum*) belongs to deciduous shrub with a high degree of economic value and medicinal value. It is mainly distributed in arid and semi-arid regions of northwest China. It has the characteristics of salt and drought tolerance and is very suitable to plant in saline-alkali soils (Liu et al., 2015).

DOI: http://dx.doi.org/10.15666/aeer/1704_78657879

At present, the blind ditch is used in Ningxia (Pan and Zhao, 1998) and on coastal saline soils in Jiangsu in China (Yang et al., 2015b). There are extensive reports on the amelioration of alkali soils through the application of DG (Sakai et al., 2011; Yu et al., 2015), but there are few published reports about the effects of blind ditches combined with DG on the physical and chemical properties of alkalized solonchak and ions. Research on the amelioration effects of alkalized solonchak on the spacing of blind ditches and the application rate of DG is still needed to apply this method more efficiently and cost effectively. The present study examines the application of DG and blind ditches on a farmland using gravels and straw as backfilling materials to investigate the effects on subsurface physical and chemical properties of alkalized solonchak in Gansu, China. The concentrations of salt ions and the yield of Chinese wolfberry under different treatments are examined. The outcomes of this study can provide a theoretical and technical guidance for the amelioration and utilization of alkalized solonchak in China.

Materials and methods

Site characterization

The experimental site is located in Dongsheng, Jingyuan county, Gansu Province (37°03'N, 104°96'E), China. The climate is typically arid continental with mean annual precipitations of 240 mm, which is mainly concentrated between July and September, and mean annual evaporation of 1,634 mm, up to 6-7 times the annual average precipitations. Annual average temperature is 9 °C. Seasonal drought is frequent in spring, the soluble salts accumulate in the upper soil profile during spring. The groundwater level changes from 1.3 to 1.8 m. The soil organic matter ranges from 5.12 to 8.97 g/kg, available nitrogen from 17.52 to 29.25 mg/kg, available P from 0.7 to 5.98 mg/kg, available K from 179.64 to 244.58 mg/kg. Other physical and chemical properties of the soil are listed in *Table 1*. Data in *Table 1* show that EC in the surface soil gradually decreases with the soil depth. ESP is over 21% and pH is above 8.5. The primary cation in the top 100 cm of the soil is Na^+ ion, whereas the primary anion is Cl^- ion.

Table 1. *Main physical and chemical properties of tested soils*

Depth cm	Ion ingredients cmol/kg								pH	EC dS/m	ESP %	Bulk density g·cm^{-3}
	Na^+	Ca^{2+}	K^+	Mg^{2+}	CO_3^{2-}	HCO_3^-	Cl^-	SO_4^{2-}				
0-20	4.21	0.27	0.08	0.23	1.19	1.01	1.42	1.25	9.1	2.89	28.5	1.52

Soil pH was measured using a Mettler Toledo S220-K pH meter. Soil EC value was measured using a Mettler Toledo S230. Exchangeable Na^+ was measured using an ammonium acetate-ammonium hydroxide-flam photometric method, and ESP was calculated as the percentage of exchangeable Na^+ and cation exchange capacity (CEC). The concentrations of K^+ and Na^+ were measured with a subtraction method. Ca^{2+} and Mg^{2+} were measured using the Ethylene Diamine Tetraacetic Acid (EDTA) titration

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78657879

method. Cl^- was measured using $AgNO_3$ titration. SO_4^{2-} was measured using the EDTA back-dropping method, and CO_2^{-3} and HCO^{-3} were measured using double indicator titration (Bigham, 1965). The application process is shown in *Figure 1*.

Figure 1. *Blind ditch and laying cushion*

Experimental design

The research was carried out between 2016 and 2017 with a unified leaching quota of 4.5×10^3 m^3/hm^2 (Yang et al., 2015a). According to previous reports (Yang et al., 2015b) and known characteristics of alkalized solonchak, three blind ditches were set up at spacing of 6 m, 9 m and 12 m, respectively. In this study, the spacing is the horizontal distance between two blind ditches. Three application rates were used at 20 t/hm^2, 22 t/hm^2 and 24 t/hm^2. A site without the blind ditch and DG was as the control site (CK), each treatment was repeated 3 times. The experimental design is shown in *Table 2*.

Table 2. *Experimental design*

Treatments	Blind ditch spacing m	Desulfurized gypsum application rate t/hm^2
CK	Non	Non
T1	6	20
T2	6	22
T3	6	24
T4	9	20
T5	9	22
T6	9	24
T7	12	20
T8	12	22
T9	12	24

CK means the control treatment

Ditches were dug with a ditching machine (Chain, CASE860) with a width of 30 cm and depth of 90 to 120 cm which have a slope gradient of 1% from the field to the drain. Gravels were laid at the bottom of each ditch with 20 cm, and then covered with 40 cm of straw as a filter, and finally backfilled with soils. The blind ditches were dug perpendicular to the drain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78657879

which was deeper than the ditch. Sheep manure was applied at a rate of 45 t/hm^2 uniformly at each site. According to the experimental design DG was applied between different treatments. Deep tillage was then performed to guarantee sufficient mixing. According to the previous studies (Yang et al., 2015a), the salts in the soil should to leach in total 3 times, the volume of leached water after the first operation was 1/2 of the leaching quota (ca. 2,250 m^3/hm^2) and the leached water was immersion for 24 h and then drained off the land surface. The volume of leached water after the second operation was 1/3 of the leaching quota (ca. 1,500 × 10^3 m^3/hm^2) and the leached water was immersion for 48 h and then drained off the land surface. Finally, the volume of leached water after the third operation was 1/6 of the leaching quota (750 m^3/hm^2). Chinese wolfberry seedlings were planted on 26 April 2016 with row spacing of 2.0 m and plant spacing of 1.5 m. The planted sites were irrigated once, respectively, during the May to November with 1.2 × 10^3 m^3/hm^2 (irrigation quota) water at every month.

Experimental methods

In order to analyze the amelioration effects, the soil samples were collected before the ditches were dug on 5 April 2016 and on 25 April 2016 in the first year, and on 25 April 2017 in the second year. Based on the principle of randomness and multipoint mixture, soil samples were collected using an auger by a random method in layers with spacing of 20 cm from the land surface. Samples were collected at 0 to 20 cm, 20 to 40 cm, 40 to 60 cm, 60 to 80 cm, and 80 to 100 cm in each treatment in triplicates. After the removing of gravel and crop residues, all soil samples were air-dried and passed through a 1 mm sieve.

The soil permeability was measured using a permeability cylinder, and the measured permeability is its value at a temperature 10 °C, expressed as K_{10} (mm/min) (Tian et al., 2013):

$$K_{10} = K_t / (0.7 + 0.03t) \quad \text{(Eq.1)}$$

where K_{10} (mm/min) is the permeability at 10 °C, K_t (mm/min) is the permeability at t, and t (°C) is the temperature of infiltrating water at the time of measurement.

On 30 May 2016, the survival rate of Chinese wolfberry seedlings was calculated, while the preservation rate was calculated on 2 May 2017. When the fruits of Chinese wolfberry were mature, the fruits were picked once every seven days. The fruits were collected in each plot and dried in a 45 °C oven, and the yield of Chinese wolfberry in every plot can be measured. The survival rate and preservation rate were calculated as follows:

$$\text{Survival rate} = \frac{\text{Actual alive number in the first year}}{\text{Seedling number}} 100\% \quad \text{(Eq.2)}$$

$$\text{Preservation rate} = \frac{\text{Actual alive number in the second year}}{\text{Seedling number}} 100\% \quad \text{(Eq.3)}$$

Data processing

Using an analytical approach of membership functions in fuzzy mathematics (Zhang, 2014), the membership values of various physical and chemical indexes were accumulated for different treatments and the average value was calculated. The values

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78657879

were then compared between different treatments to evaluate the improvement effects on alkalized solonchak.

The membership function X(u) of each index is determined using the following formula:

$$X(u)=\begin{cases}\dfrac{X-X_{\min}}{X_{\max}-X_{\min}} & \text{Positive correlation between index and improvement effect}\\ 1-\dfrac{X-X_{\min}}{X_{\max}-X_{\min}} & \text{Negative correlation between index and improvement effect}\end{cases} \quad \text{(Eq.4)}$$

where X(u) is the value of the membership function of an index for different treatments, X is the measured value of an index for different treatments, X_{max} is the maximum measured value of an index between all treatments, and X_{min} is the minimum measured value of an index between all treatments.

All the statistical tests were performed using SPSS software (version 19.0, USA).

Results

Soil permeability

The effect of different treatments on the permeability of soil from 0 to 40 cm is shown in *Figure 2*. It can be seen from *Figure 2* that the control site had a lower permeability compared to the other experimental sites, where its K_{10} was only 0.25 ± 0.02 mm/min in the first year. Each treatment significantly increased the soil permeability measured in terms of K_{10} values compared to the control site. The increase in treatment T2 by 308.0% (K_{10} = 1.02 ± 0.01 mm/min) is the largest while T7 increased the least (K_{10} = 0.55 ± 0.02 mm/min) in the first year. The permeability of the soil following the treatments in the second year was better in all treatments than the first year.

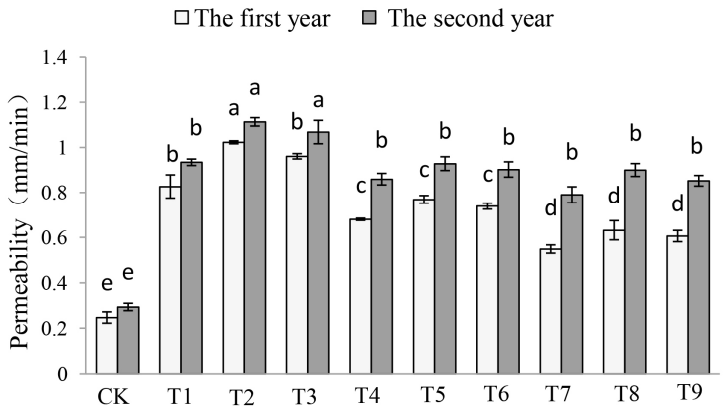

Figure 2. *Effect of different treatments on permeability of the soil from 0–40 cm, in which different letters indicate significant differences among treatments (P ≤ 0.05) and values = mean ± standard error, n = 3*

Regarding the blind ditch spacing, it is clearly to notice in *Figure 2* that, a 6-m blind ditch spacing treatments (T1, T2 and T3) have the highest values of soil permeability

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78657879

and followed by a 9-m spacing treatments (T4, T5 and T6), which have also superiority on a 12-m spacing treatments (T7, T8 and T9).

Respecting to the DG application rate, *Figure 2* shows that the DG application with a 22 t/hm^2 (T2, T5 and T8) gives rise to the highest soil permeability as compared with the other treatments (20 t/hm^2 and 24 t/hm^2 DG application rate). In addition, T2 in the second year shows the highest improvement in soil permeability (K_{10} = 1.11 ± 0.02 mm/min).

Soil pH

The effect of each treatment on pH of the soil from 0 to 40 cm is shown in *Figure 3*.

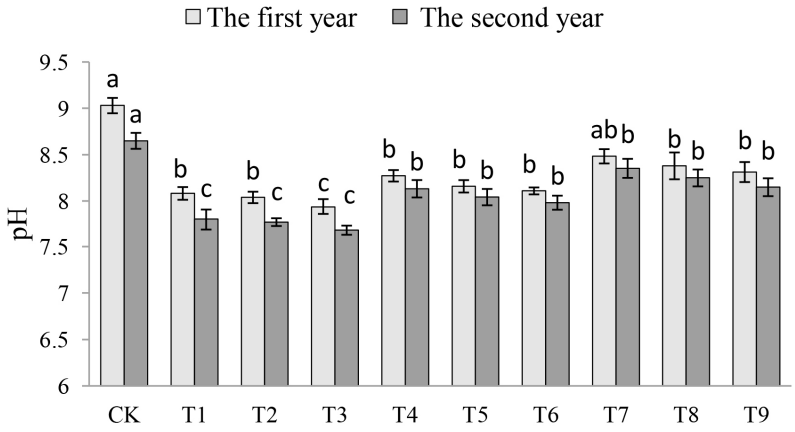

Figure 3. *Effects of different treatments on the pH of soil from 0–40 cm, in which different letters indicate significant differences among treatments (P ≤ 0.05) and values = mean ± standard error, n = 3*

Figure 3 illustrates that pH values of other treatment are lower than that of the control site except T7, and pH of T3 decreased by 12.1% compared to the control site in the first year. T3 in the second year has the minimum pH (7.7 ± 0.05). The pH of treatments with blind ditch spacing of 6-m, 9-m and 12-m in the first year on average decreased by 9.9%, 8.1% and 5.7%, respectively, compared to those before the treatments. In the second year, the pH of treatments with blind ditch spacing of 6-m, 9-m and 12-m on average decreased by 13.0%, 9.5% and 7.3%, respectively, compared to those before the treatments. It clear that the blind ditch with smaller spacing is more effective to reduce the soil pH compared to the other treatments.

Respecting to the DG application rate, *Figure 3* show that the DG application with a 24 t/hm^2 (T3, T6 and T9) produced the lowest pH compared to other treatments (20 t/hm^2 and 22 t/hm^2 DG application rate).

Exchangeable sodium percentage (ESP)

The effect of each treatment on the ESP of the soil from 0 to 40 cm is illustrated in *Figure 4*. It is seen from *Figure 4* that the ESP of each treatment is lower than that of the control site, and the ESP of T3 has the largest decrease of 51.0% than that before the treatment in the first year.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78657879

The ESP of treatments with blind ditch spacing of 6-m, 9-m and 12-m in the first year on average decreased by 47.5%, 40.5% and 37.4%, respectively, compared to those before the treatments. In the second year, the ESP of treatments with blind ditch spacing of 6-m, 9-m and 12-m on average decreased by 52.8%, 45.5% and 41.6%, respectively, compared to those before the treatments. Regarding the blind ditch spacing, it is clearly to notice in *Figure 4* that, a 6-m blind ditch spacing treatments have the lowest values of ESP, compared to 9-m and 12-m spacing treatments.

According to the DG application rate, *Figure 4* shows that the DG application with a 24 t/hm^2 (T3, T6 and T9) produced the lowest ESP compared to other treatments (20 t/hm^2 and 22 t/hm^2 DG application rate). In addition, T3 in the second year had the lowest ESP (11.8 ± 0.09%).

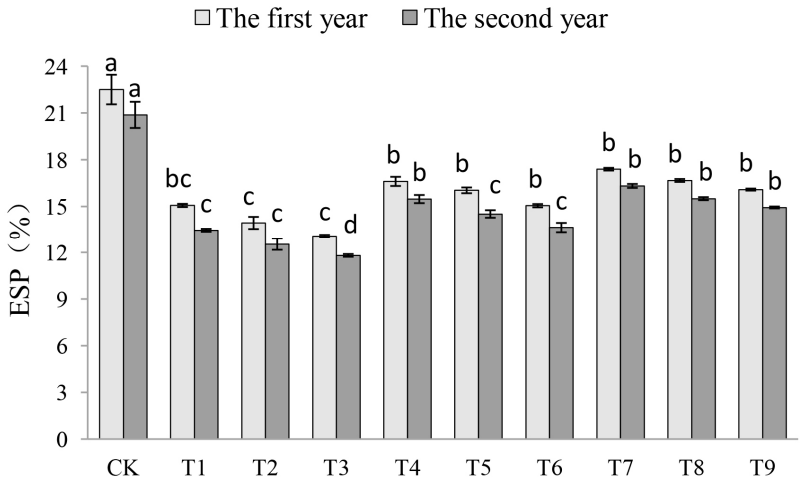

Figure 4. *Effects of different treatments on ESP of soil from 0–40 cm, in which different letters indicate significant differences among treatments (P ≤ 0.05) and values = mean ± standard error, n = 3*

Electrical conductivity (EC)

Before the soil improvement, the EC values of soil layers at 0 to 20 cm, 20 to 40 cm and 40 to 60 cm were 2.89 dS/m, 2.72 dS/m and 1.83 dS/m, respectively. The effect of each treatment on EC values in the soil layer from 0 to 60 cm is illustrated in *Figure 5*. As shown in *Figure 5a,* in the first year salts in the layers at 0 to 60 cm of each treatment were leached and the desalination effect on the land surface was significant. The EC values of the control site at 0 to 60 cm depth gradually increased with the soil depth in the first year. Salt accumulation indicated by an EC reading higher than its original value appeared at the depth of 40 to 60 cm. As to the data in *Figure 5b* for the second year, the EC value was highest at 0 to 20 cm of the control site. Treatments T1 to T9 did not appear to generate any secondary salinization. This is approved that, subsurface gravel blind ditches technique clearly leached the salts from soil layers and desalination effect on the land surface was significant.

In the first year, the EC of T2 at the 0 to 20 cm soil depth declined the most (75.1%) following the improvement. There were no significant differences for T1, T2, T3, T4, T5 and T6 at 0 to 20 cm, 20 to 40 cm and 40 to 60 cm soil depths in the first and second years. In the first year, the EC values of T1, T2, T3, T4, T5, T6, T7, T8 and T9

DOI: http://dx.doi.org/10.15666/aeer/1704_78657879

decreased by 40.1%, 45.4%, 42.3%, 33.7%, 37.4%, 35.4%, 19.5%, 23.9% and 22.0% at 0 to 60 cm, respectively, compared to the control site. In the second year, the EC values of T1, T2, T3, T4, T5, T6, T7, T8 and T9 decreased by 49.4%, 55.2%, 52.2%, 42.5%, 47.7%, 45.1%, 32.5%, 37.2% and 34.9% at 0 to 60 cm, respectively, compared to the control site.

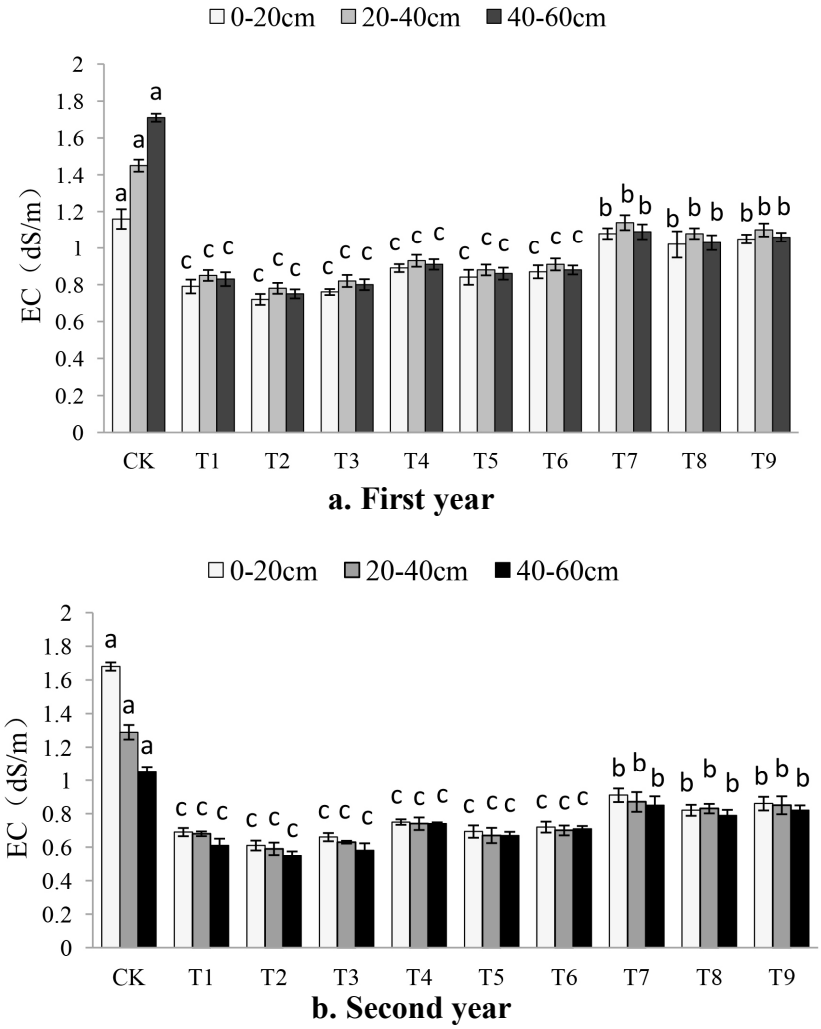

Figure 5. *Effects of different treatments on EC value of soil from 0–60 cm, in which different letters indicate significant differences among treatments ($P \leq 0.05$) and values = mean ± standard error, n = 3*

Soil salt ions

The effect of each treatment on ions is illustrated in *Table 3*. The concentrations of Na^+, Cl^-, CO_3^{2-}, HCO_3^- of the soil significantly declined following the treatment, and Mg^{2+}, K^+ did not change after the treatment while the concentration of SO_4^{2-} increased. The concentration of Ca^{2+} in each treatment was higher than that on the control site. The concentration of Na^+ declined over 60% in the first year following the treatment, and declined over 75% in the second year following the treatment compared to those before the treatments. The concentration of Na^+ in T3 had the largest decrease. CO_3^{2-} and HCO^{-3} of T3 decreased the most in the first year by 49.1% and 51.8%, respectively, compared

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78657879

to those before the treatments. In the second year, the concentrations of CO_3^{2-} and HCO_3^- of T3 were 0.01 cmol/kg and 0.04 cmol/kg, respectively, and continued decreasing compared with the first year.

In the first year, the concentrations of Cl^- in nine treatments were lower than 0.09 cmol/kg, Cl^- of T3 decreased the most by 95.4% compared to that before the improving treatments. In the second year, the concentrations of Cl^- in nine treatments were lower than 0.07 cmol/kg, and continued the decrease compared with the first year.

In the first year, DG was applied to increase the concentrations of Ca^{2+} and SO_4^{2-}, which had the greatest increase in T9, by 133.3% and 47.4%, respectively, comparing with before improvement. The data illustrated that the concentrations of Ca^{2+} in each treatment was higher than that on the control site, and the concentrations of Ca^{2+} and SO_4^{2-} of T1 were 0.25 cmol/kg and 0.72 cmol/kg, respectively, which were the lowest in the nine treatments in the second year. Compared to the control site, the difference in Mg^{2+} and K^+ concentrations of each treatment were insignificant in both first and second years.

Table 3. *Effect of different treatments on the distribution of salt ions in 0-40 cm soil layer (cmol/kg)*

Analysis of treatments on improvement effects of alkalized solonchak

Different expressions for evaluating the membership function values are used following a comprehensive analysis of the data from different treatments. The results are shown in *Table 4*. As shown in *Table 4*, T2 had the greatest improvement effect on alkalized solonchak among the nine treatments. The soil treatment effect had the following order of improvement: T2 > T3 > T1 > T6 > T5 > T4 > T8 > T9 > T7. The

DOI: http://dx.doi.org/10.15666/aeer/1704_78657879

results of T1, T2 and T3 show that under the condition with 6-m blind ditch spacing, an appropriate DG application rate will have better improvement effects. The results of T3, T6 and T9 show that with 24 t/hm^2 of DG application rate, the smaller spacing of blind ditches the better improvement effect.

Survival rate, height and yield of Chinese wolfberry

The crop yield is an important index for measuring the productivity of land, and *Table 5* lists the effects of different treatments on survival rate, height and yield of Chinese wolfberry. It can be seen from *Table 5* that the survival rate and preservation rate on the control site are lowest than other treatments. The seedling survival rate, preservation rate and the yield of Chinese wolfberry increased significantly in nine treatments compared to the control site in the first year. The yields of T1, T2 and T3 increased than those of T4, T5, T6, T7, T8 and T9. The yields of T1, T2 and T3 did not have significant differences. In the first year, the yield of Chinese wolfberry of the treatments with a 6-m blind ditch spacing was higher than those with 9-m and 12-m spacing. The treatment of T2 had the highest yield is 1.08 t/hm^2 in the first year, and increased by 78.7% in the second year than that for the first year.

Table 5. *Effects of different treatments on survival rate, height and yield of Chinese wolfberry*

Year	Treatment	Survival rate (%)	Preservation rate (%)	Height (cm)	Yield (t/hm^2)
The first year	CK	43.3 ± 2.36^b	-	68.3 ± 0.78^c	0.49 ± 0.01^c

The yield of Chinese wolfberry is the yield of dried fruits. Values = mean ± standard error, n = 3. Different letters indicate significant difference among treatments ($P \leq 0.05$)

Discussion

Alkalized solonchak has a high ESP, and under high alkaline conditions, the ion exchange with Na^+ during soil cementation results in the increased hydration of the cementing substance causing the soil to peptize and disperse easily in the presence of water (Ahmad et al., 2016). The macropores in the alkaline soils, once wetted, collapse to form fine pores leading to the impedance of soil water movement. The amelioration of saline-alkaline soils reduced both soil pH and ESP rapidly and effectively (Nan et al., 2016). As Ca^{2+} can flocculate soil colloids to form water stable aggregates which promote soil water movement (Morillo et al., 2002; Mahdy, 2011), the application of DG increases the concentration of Ca^{2+} in the soil which increases the capacity of adsorption to soil colloids more than that Na^+, thereby playing a role in improving the soil texture. The adsorbed Na^+ on soil colloids can exchange with Ca^{2+} in the soil solution, which decreases the exchangeable Na^+, thus decreasing soil ESP. Meanwhile, SO_4^{2-} is an acid radical with certain neutralization effects. The concentrations of CO_3^{2-} and HCO_3^- in the soil are important factors for determining the pH value of saline-alkaline soils (Chen et al., 2014). Consequently, a decrease in CO_3^{2-} and HCO_3^- in the soils content results in a decline in soil pH. However, DG is also a moderately soluble salt, which can increase the amount of salt in the soil if DG application rate is too much (Sakai et al., 2011). Therefore, in this experiment, the optimal application rate is 22 t/hm^2.

In order to enhance the treatment effects, the clay layer in the deeper soil must be disturbed to increase leaching. A clay layer between 60 cm and 80 cm at our experimental site was impervious to water, and collected the leached salts from the soil surface. In this arid region with little rainfall and strong evaporation, salts migrate through soil capillary forces to the surface of the soil leading to a higher EC value on the soil surface. The depth of our blind ditches is up to 120 cm, which broke the clay layer and promoted the migration of soil salts downward. The bottoms of the blind ditches are laid with gravels and straws to change the uniformity of soil texture, and to improve the soil water potential and permeability (Qu and Wang, 1997). Subsurface pipes can capture and drain infiltrating water to enhance desalinization and reduce the EC of the soil (Qu and Wang, 1997; Zhang et al., 2012b). Pores in gravels and straws are larger than those in the soil, and facilitate soil water movement. Our results are consistent with findings from other experiments on the improvement of soil structure with straws (Qu and Wang, 1997) and gravels (Zhang et al., 2012a).

The results presented here also show that soil water concentrates in straws forming a desalting zone after irrigation and expediting the desalting process (Zhen and Hao, 2010). We found that the application of gravels and straws not only accelerates the leaching of soil salts, but also prevents secondary salinization in the second year. Burying gravel and straw in a homogeneous soil can also improve soil aeration and crop

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78657879

growth and reduce the upward water movement. In addition, the organic acid released during the decomposition of straws can promote the dissolution of Ca^{2+} (Lu et al., 2017).

Cl^- has stable chemical properties with slow chemical reactions such as adsorption (Yang et al., 2015a). Yang et al. (2015a) found through an amelioration experiment of alkaline soil that with leaching, Cl^- easily accumulates in the soil deeper than 60 cm from the surface and is difficult to discharge through the soil layers again (Yang et al., 2015a). However, in our research, the concentrations of Cl^- for all treatments were significantly reduced, proving that the blind ditches help discharge Cl^-. The application of DG will increase the concentration of SO_4^{2-}, SO_4^{2-} and Na^+ producing Na_2SO_4 (Buckley and Wolkowski, 2014), which is leached to blind ditches by irrigation water and discharged from the soil.

Conclusion

With desulfurized gypsum which can effectively improve physical and chemical properties of alkalized solonchak, subsurface gravel blind ditches can further accelerate the leaching of salts from the soil and ameliorate the soil by improving its chemical and mechanical properties. Subsurface gravel blind ditches promoted the DG amelioration effect, which effectively improves the soil permeability and promotes salt leaching. The ESP, EC and the concentrations of Na^+, Cl^-, CO_3^{2-} and HCO_3^- in the soils are significantly reduced by the blind ditches and DG. Chinese wolfberry yield was significantly increased by the treatments. The best design scenario is one which has 6-m blind ditch spacing combined with a 22 t/hm^2 desulfurization gypsum application rate.

(Received 23rd Feb 2019; accepted 3rd May 2019)

Abstract. To understand the changing pattern of crack propagation and shear strength index of Yunnan laterite in China after dry-wet cycle, prepared the Yunnan laterite with certain moisture content and made the soil cake samples after compaction which underwent indoor spraying and air dry to simulate the dry-wet cycle caused by multiple precipitation and evaporation in the project, and the determination of crack width and direct shear test were carried out for samples with various numbers of cycles. The results indicated that the crack process of Yunnan laterite could be classified into three stages upon dry-wet cycle: crack developmental stage, crack progression stage and crack stable stage. The cohesion and internal friction angle of the samples were reduced as the crack propagation of continued, with the reduction amplitude of cohesion greater than that of the internal friction angle, and the reduction law of both in line with the logistic curve pattern.
Keywords: *Yunnan laterite, dry-wet cycle, shrinkage, crack width, shear strength*

Introduction

Yunnan is one of the most developed areas of laterite in China. Laterite is a red color-based soil formed by weathering, micro-agglomeration and soil-forming processes of iron-rich mother rocks in hot and humid climates (Huang et al., 1998). Yunnan laterite is a special kind of clay, showing the characteristics of high clay content, high liquid limit, large natural porosity ratio, low permeability coefficient, high dispersivity, weak expansibility and strong shrinkage (Liu et al., 2005). Due to the little knowledge of the basic properties of Yunnan laterite, quite a few engineering disasters related to laterite have occurred in Yunnan Province. For example, the development of shrinkage cracks in lateritic foundation led to the settlement of buildings caused by strength reduction, and mining groundwater resulted in the shrinkage and cracking of red soil slope, strength reduction, and landslides after rainfall.

Yunnan, a region with slow economic development in China, is faced with quite a lot of laterite problems with the commencement of a large number of railway and highway projects. At present, the study on Yunnan laterite is mainly focused on the basic physical and mechanical properties index (Huang et al., 1998; Liu et al., 2005; Yuan, 2002; He et al., 2008), chemical composition (Huang, 2002), and the effect of rainfall scouring laterite slope on its physical and chemical properties (Zhang et al., 2016). The study on the cracking mechanism of soils under dry-wet cycles is mainly concentrated in common clay (Sun et al., 2015; He et al., 2012; Rayhani et al., 2007, 2008) and expansive soils (Tang et al., 2011, 2012, 2013), and the engineering properties of Yunnan laterite are different from those of the two types of soil. The objective of this study is to understand the changing pattern of crack propagation and shear strength index of Yunnan laterite. The present study directly reflected the occurrence and expansion of cracks in Yunnan laterite during the dry-wet cycle by indoor simulating

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78817889

the reciprocating process of natural rainfall and evaporation and revealed that the decrease of laterite strength was caused by the occurrence and expansion of cracks. In this paper, an empirical formula reflecting the decrease in the shear strength index of Yunnan laterite with the increase in the number of dry-wet cycles, and the mechanism of the occurrence and propagation of cracks in Yunnan laterite after dry-wet cycles was also discussed.

Experiment schemes

The soil material was excavated from Luoyang Section of East Ring Expressway in Kunming on September 2. The excavation amount was about 80 kg. Yunnan laterite soil with the certain moisture content was prepared and compacted according to the heavy-duty II-1 standard (Ministry of Communications of the People's Republic of China, 2007), which was used to make soil cake samples. To stimulate the state of laterite after experiencing rainfall and evaporation cycles in nature, multiple dry-wet cycles were performed indoors to create cracks and expansion. The change pattern of cracks during dry-wet cycles was observed morphologically, and the maximum crack width and saturated shear strength index were determined after experiencing various numbers of dry-wet cycles. Shear strength index was measured by direct fast shear test.

The selected laterite was brown in dry and red brown after immersion with the clay particles of 41.25%, the granule particles of 47.93% and the sand particles of 10.82%, whose basic physical and mechanical properties were shown in *Table 1*. Using standard compaction test, the maximum dry density (ρ_{dmax}) and the optimal water content (ω_{op}) were determined as 1.62 g/cm^3 and 17.8%, respectively.

Table 1. *Basic physical and mechanical properties of lateritic soil*

Natural wet density ρ(g/cm^3)	**Specific density of solid particles** G_s	**Natural moisture content** ω(%)	**Liquid limit** ω_L(%)	**Plastic limit** ω_P(%)	**Plasticity index** I_P
1.76	2.64	29.2	52.0	28.0	25.0

In this experiment, the soil was prepared according to moisture content ω = 21%, and the prepared soil was sealed in plastic bags for 24 hours to ensure the uniform moisture content. The samples were then placed in the compaction cylinders (inner diameter of 100 mm and height of 127 mm) to compact, and the soil moisture content ω, dry density ρ_d and the compaction coefficient were 20.8%, 1.53 g/cm^3 and 94.4%, respectively. The soil in the compaction cylinder was slowly lifted by a jack, and the soil cake with the thickness of 20 mm was obtained by carefully cutting with a wire saw, using which a total of 72 samples were prepared. The 72 samples were divided into 9 groups with 8 in each group, and the dry-wet cycles of 0, 1, 2, 3, 4, 5, 6, 7 and 8 were carried out. A small portion of the soil cake was collected via using small ring knife (inner diameter of 61.8 cm and height of 20 mm) to determine the shear strength index.

The dry and wet in the cycles of the present study were not absolute dry and wet, but the stimulation of the humidification and dehumidification process of Yunnan laterite in nature. The control standard of "dry" was air dry of the soil cake in the lab for 48 h. The standard of "wet" was: (1) spraying the surface of samples by using a syringe with needle (with the distance from needle tip to sample surface of 1 cm and the spraying

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78817889

rate of 0.5 ml/s) until the surface was covered in water. Spray was continued after water was absorbed by samples until the water stayed at the same level after 5 min; or (2) spray was conducted until free water seeped from the bottom of the sample if the water sprayed to the sample surface was always absorbed completely within 5 min.

The experiment was performed in October in Kunming in which the minimum night temperature, the maximum day temperature and relative humidity were 12 °C, 26 °C and 43-58%, respectively.

Results and analysis

The surface cracks of Yunnan laterite samples were clearly visible after various cycles of dry-wet cycles. The expansion status of the cracks after 1, 2, 3, 4, 5 and 6 dry-wet cycles were as shown in *Figure 1*. Almost all the samples showed the development of annular microfracture after the first dry-wet cycle, and some samples showed a relatively wide crack during the first air dry process, which might be due to the weak structural plane resulted from the unequal stress during the sample preparation, so the cracks were formed during the first air dry process because of the uneven contraction distortion after dehydration. After multiple dry-wet cycles, the crack width was gradually increased and secondary cracks were formed. The initial annular crack gradually radiated to the periphery, and the maximum crack width reached the scale of millimeter after the fourth dry-wet cycle. The cracks expansion tended to be stable and the width was no longer increased after the sixth cycle. With the 100x visualizer of crack width (1 DIV/0.02 mm, Shangyu Jingnuo Instrument Factory, Zhejiang Province, China; *Fig. 2*), the maximum crack width after various numbers was determined which was shown in *Figure 3*.

Figure 2. *The visualizer of crack width (100x)*

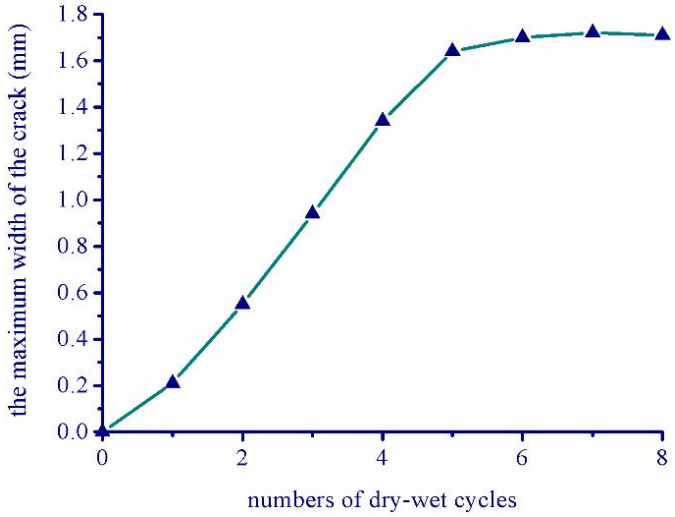

Figure 3. *The maximum crack width after dry-wet cycles*

Although the propagation of cracks is one of the contents of this study, for road engineering, more attention is paid to the shear strength attenuation of soil caused by cracks. The variation of soil moisture content during rainfall or evaporation in nature is not as dramatic as that of water saturation or oven drying. Therefore, the shear test was performed after each dry-wet cycle, and such shear strength index could reflect the effect of the crack development process on the strength of Yunnan laterite after the expansion-contraction cycle due to the dry-wet cycles caused by the external climate. The relationship of cohesive strength (c) and internal friction angle (φ) to the numbers of dry-wet cycles was as shown in *Figure 4*. Cohesion and internal friction angle are two indexes of shear strength of soil. Cohesion is the mutual attraction between the adjacent parts of the soil. This mutual attraction is the expression of the molecular force between the molecules of the same substance. cohesion is also the shear strength of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78817889

failure surface without any positive stress. The internal friction angle reflects the friction characteristics of soil, including the sliding friction caused by the rough surface of particles and the occlusal friction caused by the embedding, interlocking and disengaging of particles.

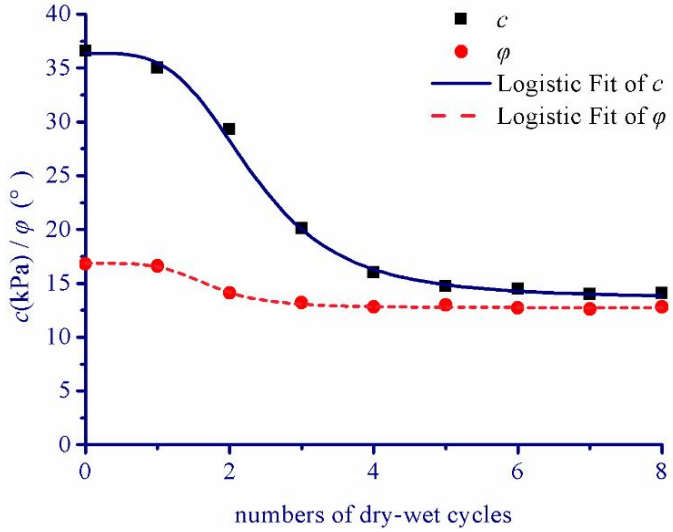

Figure 4. *The relationship of cohesive strength (c) and internal friction angle (φ) to the numbers of dry-wet cycles*

The results indicated that as the cycle increased, the cracks were formed from scratch and became larger, leading to the damage in the integrity of the soil and the gradual strength reduction of Yunnan laterite, which is consistent with the general knowledge of the variation pattern of shear strength in clay soil. Among these, the change in cohesive strength was most significant, which only retained 40% of its initial value after 5 cycles. Cohesion took on the trend of constant reduction due to successive crack development. Although some small cracks might close or partially close during humidification, the scars still existed, and the gradual increase in such damage of soil integrity resulted in looser soil and lowered strength. However, crack propagation followed the basic rule of being fast then slow, thus, the change to the number of dry-wet cycles of cohesion showed a form of being steep and then gentle as a whole. The internal friction angle of Yunnan laterite also decreased, but the altitude was much smaller than that of cohesive strength, showing 77% of the initial value after five dry-wet cycles. On one hand, the existence of cracks in the soil allowed Yunnan laterite to become fragmented. Furthermore, the expansion and shrinkage deformation led to loosen soil and reduced compactness, which tended to be stable after five cycles. Therefore, the decrease of internal friction angle at the beginning of dry-wet cycles might be related to the decrease of soil density caused by expansion and contraction.

Cracks lead to the decrease or lose of the cementation force between soil particles. Therefore, cohesion is significantly reduced, the further impact of crack propagation on it is not significant, and the main factor affecting the internal friction angle is the property of soil particles. Compared with cohesive strength, the reduction of internal friction angle entered stable stage with minimal variation.

Experiments revealed the expansion of cracks with increasing the numbers of dry-wet cycles, and the process of crack expansion was generally consistent with the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78817889

reduction in the strength of Yunnan laterite, and it was shown that the strength reduction was resulted from the crack propagation.

The relationship of cohesive strength c and internal friction angle φ to dry-wet cycle number exhibited inversed S-shape curve (*Fig. 4*), and it could be fitted via using the mathematical expression of logistic curve, which were:

$$c = \frac{A_1 - A_2}{1+\left(n/n_1\right)^p} + A_2 \quad \text{(Eq.1)}$$

$$\varphi = \frac{A_3 - A_4}{1+\left(n/n_2\right)^q} + A_4 \quad \text{(Eq.2)}$$

In *Equations 1* and *2, n* is the number of dry-wet cycles; A_1, A_2, A_3, A_4, n_1 and n_2 indicate the fitting parameters.

The above formula, as an empirical formula reflecting the rule that the shear strength index of Yunnan laterite is reduced with the increase in the number of dry-wet cycles, can be used to estimate the final value of shear strength index of laterite under the long-term action of sunshine and rain. The fitting results of the present study were as follows:

$$c = \frac{36.878 - 13.635}{1+\left(n/2.337\right)^{3.782}} + 13.635 \quad \text{(Eq.3)}$$

$$\varphi = \frac{16.854 - 12.745}{1+\left(n/1.733\right)^{4.487}} + 12.745 \quad \text{(Eq.4)}$$

Calculated by *Equations 3* and *4,* the ultimate reduction value of the shear strength of the laterite as the cycle numbers increased were c = 13.635 kPa and φ = 12.745°. The cohesive strength and internal friction angle were reduced to 37% and 76% of the initial value, respectively.

The simplified Bishop method is a quantitative analysis method for the stability of subgrade slope. The basic principle is: assuming that the slope has an arc sliding surface, the slope stability factor can be calculated by comparing the sliding moment produced by the sliding surface with the sliding moment produced by the sliding body. When calculating, the stability coefficient K is assumed first, and then the calculated value F_S of the stability coefficient is inversely calculated. Then the assumed value K is adjusted according to the calculated value F_S of the stability coefficient, and the relative error between K and F_S is repeated until the relative error between K and F_S is within the prescribed range. To intuitively demonstrate the effect of the decrease in the shear strength of Yunnan laterite caused by dry and wet cycles on the slope stability, the stability coefficient F_S was calculated (simplified Bishop method) for the homogeneous embankment (soil bulk density of 18.5 kN/m^3) with the height of 10 m, the width of 20 m and the slope ratio of 1:1 using the strength index obtained in the test, which was shown in *Figure 5*.

Discussion

According to the data, the developmental process of cracks in the Yunnan laterite samples upon dry-wet cycles can be classified into 3 stages: crack developmental stage, crack progression stage and crack stable stage.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78817889

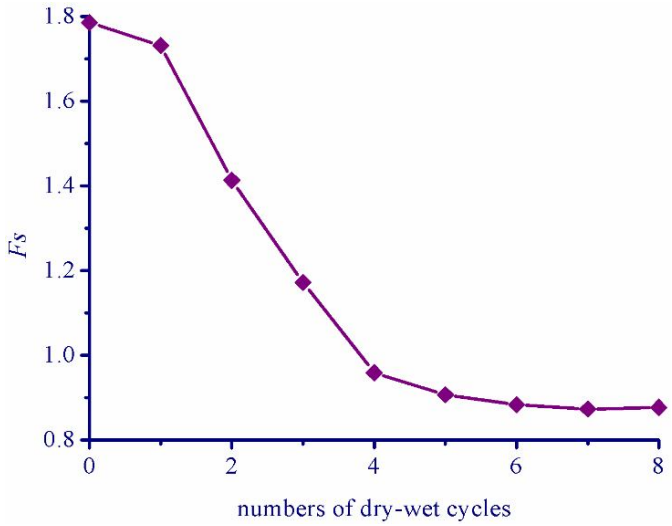

Figure 5. *The relationship of safety factor (F_S) and numbers of dry-wet cycles*

(1) Crack developmental stage. The first dry-wet cycle is the crack developmental stage. During this process, humidification of laterite samples occurs only in the original pores, the effect of humidification only lies in enabling the laterite to absorb water, and the effect of dehumidification only lies in emigration of partial moisture in the pores. However, such dry-wet cycle results in moisture gradient in laterite samples, and a large amount of moisture in the samples softens the connection between laterite particles, leading to the formation of micro-cracks in the samples, which creates favorable conditions for further expansion cracking and shrinkage cracking during later dehumidification. In the present study, the dry density of laterite sample was relatively high, so the swelling force caused in the process of humidification was also large, and the micro-cracks were produced after the first dry-wet cycle. It has been demonstrated that cracks were hard to form in the samples with relatively low dry density (Zhao et al., 2017).

(2) Crack progression stage. The 2^{nd}-5^{th} cycle is the crack progression stage. After the 1^{st} dry-wet cycle, the main effect of water absorption and humidification of laterite sample is to increase the thickness of water film between laterite particles, resulting in the swelling and cracking of laterite sample. The main effect of dehumidification is to reduce the thickness of water film between laterite particles, resulting in shrinkage and cracking of laterite samples, so the micro-cracks gradually develop into macro-cracks. With increasing the cycles, the thickness of water film among soil particles further increases, and the swelling and cracking laterite become more significant. During this development stage, the originally formed cracks have been further deepened and widened, and crack propagation has been achieved. In this process, crack propagation comes with the decrease in the shear strength index.

(3) Crack stable stage. Cycle beyond the 6^{th} is crack stable stage. During such a process, the main effect of water absorption and humidification of laterite sample is not to increase the thickness of water film between laterite particles and cause expansion cracking, but to fill the existing cracks, and the main function of dehumidification is to reduce moisture between laterite particles in existing fractures. Due to the large crack width and high moisture content, there is no water loss, shrinkage and crack deepening in a short time, which is not enough to form new cracks, so the expansion of cracks

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78817889

enters into a stable stage. In the repeated dry-wet cycles, the cracks are opened, closed and propagated under the combined effect of expansion and shrinkage, and they gradually reach a stable state after certain cycles. During this process, the attenuation of shear strength index in the soil samples also entered a stable period.

Although there are still some unreasonable factors in the method employed here, such as the artificial disturbance in sample preparation, the small size of sample, and the discrepancy between the simulated humidification and dehumidification and natural process, such a method is still preferable considering the difficulties in the present study on the cracking and strength of Yunnan laterite. Such a method makes it possible to study the crack initiation and propagation in Yunnan laterite caused by dry-wet cycles and the effect pattern of crack propagation on its strength by conventional geotechnical instruments, which provides a reasonable and effective basis for the analysis of laterite engineering problems in Yunnan. In the present study, the dry density of laterite sample was relatively high, and its compaction coefficient was similar to that of embankment. Therefore, the process of cracking during dry-wet cycles and the attenuation process of shear strength index are representative.

Conclusion and suggestion

(1) With a reasonable and simple experimental procedure, determined the crack width of Yunnan laterite and the variation pattern of shear strength index as the cracks expanded during dry-wet cycles. The data showed the phenomenon of the occurrence and expansion of cracks in Yunnan laterite upon dry-wet cycles, and revealed that the reduction in the strength of laterite was resulted from the occurrence and expansion of such cracks.

(2) The results indicated that either cohesive strength or internal friction angle exhibited certain decrease with the propagation of cracks which had a stronger effect on cohesive strength. An empirical formula was also presented showing the decrease of shear strength index of Yunnan laterite with the increase of dry-wet cycles as well as the development of cracks. Such a formula can be used to estimate the ultimate strength index of dense Yunnan laterite under long-term sunshine and rain.

(3) The mechanism of occurrence and expansion of Yunnan laterite after dry-wet cycles was discussed. During the crack developmental stage, the wetting process softens the connection between laterite particles, leading to the formation of microfractures after drying. During the crack expansion stage, the wetting process increases the thickness of water film between laterite particles to cause crack expansion of samples, whereas the drying process reduces the water film thickness between particles resulting in the shrinkage and cracking, and the micro-cracks gradually develop into macro-cracks. During the crack stable stage, because of the large width of cracks, the wetting process is to fill the cracks. The moisture content is relatively high during this stage, shrinkage and deepened cracks due to dehydration will not occur in a short time, and water loss is not enough to rip soil and form new cracks.

(4) In the future, investigations are needed to understand the pattern of crack propagation and strength attenuation of Yunnan laterite under various regulated conditions of dry-wet cycle and large-sized samples. For the foundation, embankment or slope of Yunnan laterite, more attention should be paid to the crack formation and strength degradation caused by rainfall and drought, especially with the large gradient of moisture content and uneven expansion. Because the effect of crack on the cohesive

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78817889

strength is more significant, the value of clay cohesive strength should be cautiously identified in engineering design, and the uniform moisture content is desired in the actual projects with Yunnan laterite.

(Received 23rd Feb 2019; accepted 3rd May 2019)

Abstract. Our research objective was to compare the eutrophication inhibition of reeds and lotuses on water body of wetland system of Yi River, evaluate ecological benefits of the two wetland systems, and reveal the response mechanism of water environmental factors, which not only has ecological theoretical significance, but also has extensive practical application value in the management and evaluation of wetland water ecosystem of Yi River. Three research sample plots were set up in Yimeng Lake of Yi River: reed water area, lotus water area and natural water area. In August (summer), October (autumn), December (winter) of 2018 and February 2019 (spring), subsurface water samples were collected and analyzed by laboratory detection for pH, chromaticity, total hardness, dissolved oxygen, BOD, COD, ammonia nitrogen, total nitrogen, total phosphorus, nitrate and chlorophyll a. Research results were as follows: 1) pH appeared as that of lotus water area > natural water area > reed water area, chromaticity appeared as that of natural water area > reed water area > lotus water area. Total hardness appeared as that of natural water area > lotus water area > reed water area, dissolved oxygen appeared as reed water area > lotus water area > natural water area. BOD appeared as that of lotus water area > natural water area > reed water area, COD appeared as that of lotus water area > natural water area > reed water area. Ammonia nitrogen appeared as that of reed water area > lotus water area > natural water area, total nitrogen appeared as that of natural water area > lotus water area > reed water area, total phosphorus appeared as that of reed water area > natural water area > lotus water area, nitrate appeared as that of natural water area > lotus water area > reed water area, and chlorophyll a appeared as that of lotus water area > natural water area > reed water area. 2) pH appeared as that of winter > spring > summer > autumn, chromaticity appeared as that of summer > autumn > winter > spring. Total hardness appeared as that of winter > autumn > spring > summer, dissolved oxygen appeared as that of spring > summer > winter > autumn. BOD appeared as that of spring > winter > autumn > summer, COD appeared as that of autumn > summer > winter > spring. Ammonia nitrogen appeared as that of winter > spring > autumn > summer, total nitrogen appeared as that of spring > summer > autumn > winter, total phosphorus appeared as that of winter > spring > autumn > summer, nitrate appeared as that of spring > summer > autumn > winter, and chlorophyll a appeared as that of autumn > summer > spring > winter. Our research conclusion is that reed can effectively increase dissolved oxygen and greatly reduce BOD, COD, total nitrogen, nitrate and chlorophyll a. Lotus can effectively increase pH, BOD, COD, chlorophyll a, and greatly reduce total phosphorus. It is recommended to increase reed community area and try to expand lotus community in the water areas with severe phosphorus load.

Introduction

Water eutrophication is an environmental problem that has aroused worldwide attention. A large amount of nutrients such as nitrogen and phosphorus of point source and non-point source pollutants enter the water body, which is an important cause of eutrophication (Schaffner et al., 2009; Zhang and Huang, 2011). The sensitivity of various water bodies such as rivers, lakes and reservoirs to eutrophication is closely related to hydrodynamic conditions and climatic conditions of the area where they are located. It is subjected to influence of hydrological, hydrodynamic, physical and chemical environmental factors and food web structures. Therefore, significant differences may exist between different water bodies and geographic locations (Li et al., 2012). Studies have shown that lakes and waters in the Asia-Pacific region are prone to eutrophication in various degrees, with 54% of water bodies exceeding the standard (Wang et al., 2012). Eutrophication degree of lakes in China is obviously higher than the average level in the Asia-Pacific region, and the water body over-standard-rate is up to 66% (Jin and Hu, 2010). At present, wetland water bodies like rivers and lakes have also entered the ranking of eutrophication, and the situation is increasingly serious (Ge et al., 2017).

Yi River, a large river in the Huaihe River Basin, is located in Southern Shandong and Northern Jiangsu, China, with geographical coordinates of 34°23′-36°20′N, 117°25′-118°42′E. About 574 kilometers long, it originates from Yiyuan County, Shandong Province, China, turns into Xinyi River (Yi River Diversion Canal) from Wulou Village, Peixian County, Jiangsu Province, China, and then flows into the Yellow Sea from Yanwei Harbor (Gao et al., 2008, 2009, 2010). Yi River is included in the "10th Five-Year Plan" on water pollution prevention and control in Huaihe River Basin for important control and monitoring. In the plan, the Chinese government points out that the plan is an important basis for the prevention and control of water pollution in the Huaihe River Basin of China, and that the economic construction activities in the Huaihe River Basin must meet the requirements of the plan. In 1997, the longest rubber dam in Asia was built in Xiaobudong, Linyi City section of Yi River, with a total length of 1,135 m. After the successive completion of the stepped rubber dam, water volume in Linyi City section of Yi River increased significantly, and the original shallow wetland conditions changed as demonstrated by cyanobacteria blooms of Yi River urban section in 2009, 2011 and 2015.

A large number of studies have shown that aquatic plants, especially wetland plants, have positive significance in reducing water eutrophication (Huang, 2015). Reed (*Phragmites australis*) wetland is the world's main type of wetland, with a wide distribution and large coverage (Wang et al., 2018). It can treat wastewater through physical, chemical and biological functions (Zeng et al., 2012). Landscape plants or tool species introduced into European urban wetlands are mainly reeds (Korboulewsky et al., 2012), while reeds and lotus (*Nelumbo nucifera*) are widely present in urban wetlands in China (Ge et al., 2017). Lotus and reed have different ecological effects on wetland restoration. Comparing eutrophication inhibition of the two on water body of wetland system of Yi River, evaluating ecological benefits of the two wetland systems, and revealing the response mechanism of water environmental factors not only has ecological theoretical significance, but also has extensive practical application value in the management and evaluation of wetland water ecosystem of Yi River.

Materials and methods

Research basin overview

The average annual precipitation of Yi River Basin is about 850 mm, and the average annual evaporation from water surface is about 1100 mm. There exists an urban wetland of about 3.6 square meters in Xiaobudong Rubber Dam and Jiaoyi Rubber Dam in Yihe City section, Taoyuan Rubber Dam and Liujiadaokou Hub - Yimeng Lake (Gao et al., 2008, 2009, 2010; Li and Gao, 2018).

Water sample collection and detection

In this field survey, three research sample plots were set up in Yimeng Lake of Yi River urban wetland: reed water area (35°107′N, 118°324′E), lotus water area (35°101′N, 118°351′E) and natural water area (35°081′N, 118°356′E). Three sets of duplicate plots were set for each plot, and three sets of duplicate water sample collection points were set for each plot, with one near shore, one in the center and one in the far shore. The sampling time was August 15 (summer), October 20 (autumn), December 16 (winter) of 2018 and February 14 2019 (spring). Sub-surface water samples (about 50 cm underwater) are collected for analysis and detection using 2.5 L clean water buckets.

In laboratory tests, pH, chromaticity, total hardness, dissolved oxygen, BOD, COD, ammonia nitrogen, total nitrogen, total phosphorus, nitrate and chlorophyll a were analyzed. pH was measured by a portable waterproof pH meter (08533797) using glass-electrode method (GB-6920-1986). Chromaticity was determined by dilution factor method according to GB/T 11903-1989. Total hardness was determined according to GB/T 5750.4-2006 by EDTA titration. Dissolved oxygen (DO) was determined by electrochemical probe method according to HJ 506-2009. BOD (5-day biochemical oxygen demand) was determined by 25 mL acid burette (B193) using dilution and inoculation (HJ 505-2009) method. COD (chemical oxygen demand) was determined by 50 mL acid burette (B192) using dichromate method (HJ 828-2017). Ammonia nitrogen (NH_3-N) and total phosphorus (TP) were determined by DR2008 visible spectrophotometer (1429121) using Nessler's reagent spectrophotometry (HJ 535-2009) and ammonium molybdate spectrophotometry (GB-11839-1989). Total nitrogen (TN) was determined by UV-1750ultraviolet-uisible spectrophotometer (A11605031003CS) using UV spectrophotometry (HJ 636-2012). Nitrate was determined by phenol disulfonic acid spectrophotometer according to GB/T 7480-1987. Chlorophyll a (Chla) was detected by acetone spectrophotometry according to HJ 897-2017.

Results and analysis

Water quality evaluation

According to the surface water environmental quality standard (GB 3838-2002), DO, BOD, COD, NH_3-N, TN and TP single indicators were used to evaluate the water quality of reed water area, lotus water area and natural water area of Yimeng Lake in different seasons. In China's surface water environmental quality standards, water quality grades are used to evaluate water quality. If the water level is high, that is the water quality is worse. I-II water is clean, IV water is contaminated, and super IV water is heavily polluted.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78917900

In terms of DO, the reed water area has type III water in summer, autumn, winter and spring; the lotus water area has type III water in summer, type IV water in autumn, and type III-IV water in winter and spring; the natural water area has type III-IV water in summer and spring, type IV water in autumn and type III water in winter.

In terms of BOD, the reed water area has type IV-V water in summer and spring, and type V water in autumn and winter; the lotus water area has type V-inferior V water in summer, type V water in autumn and winter, and type IV waster in spring; the natural water area has type V water in summer, autumn and winter, and type IV water in spring.

In terms of COD, the reed water area has type III water in summer, type III-IV water in autumn, and type IV water in winter and spring; the lotus water area has type IV water in summer and autumn, and type III-IV water in winter and spring; the natural water area has type IV water in summer and autumn, and type III water in winter and spring.

In terms of NH_3-N, the reed water area has type II water in summer and spring, type I-II water in autumn, and type III water in winter; the lotus water area has type I-II water in summer, and type II in autumn, winter and spring.

In terms of TN, all of the reed water area, lotus water area and natural water area have inferior type V water in summer, autumn, winter and spring seasons.

In terms of TP, all of reed water area, lotus water area and natural water area have type I water in summer, autumn and spring, and type II water in winter.

Seasonal dynamics of water environment factors

Statistical analysis was performed on all data using SPSS 17.0 Chinese version.

pH characteristics of reed water area, lotus water area and natural water area (*Fig. 1A*). show: that of lotus water area > natural water area > reed water area ($p < 0.01$) in summer; that of lotus water area > natural water area > reed water area ($p > 0.05$) in autumn, with that of reed water area significantly lower than that of lotus water area and natural water area ($p < 0.01$); that of natural water area > natural water area > reed water area ($p > 0.05$) in winter; that of lotus water area > natural water area > reeds water area ($p > 0.05$) in spring.

Chromaticity characteristics of reed water area, lotus water area and natural water area (*Fig. 1B*) show: that of reed water area = natural water area > lotus water area ($p > 0.05$) in summer, with that of lotus water area significantly lower than that of natural water area and reed water area ($p < 0.01$); that of natural water area > reed water area > lotus water area in autumn, with that of lotus water area significantly lower than that of natural water area and reed water area ($p < 0.01$); that of natural water area > reed water area > lotus water area in winter, with that of lotus water area significantly lower than that of natural water area and reed water area ($p < 0.01$); that of reed water area = lotus water area = natural water in spring.

Total hardness characteristics of reed water area, lotus water area and natural water area (*Fig. 1C*) show: that of lotus water area > reed water area > natural water area in summer ($p < 0.01$); that of natural water area > lotus water area > reed water area in autumn ($p < 0.01$), that of reed water area > natural water area > lotus water area in winter ($p < 0.01$); that of natural water area > lotus water area > reed water area ($p > 0.05$) in spring.

Dissolved oxygen characteristics of reed water area, lotus water area and natural water area (*Fig. 1D*) show: that of lotus water area > reed water area > natural water area ($p > 0.05$) in summer, with that of lotus water area significantly higher than that of natural water area ($p < 0.01$); that of reed water area > natural water area > lotus water area in

DOI: http://dx.doi.org/10.15666/aeer/1704_78917900

autumn ($p < 0.01$); that of reed water area > natural water area > lotus water area ($p > 0.05$) in winter, with that of lotus water area significantly lower than that of reed water area and natural water area ($p < 0.01$); that of reed water area > lotus water area > natural water area in spring, with that of reed water area significantly higher than that of lotus water area and natural water area ($p < 0.01$).

BOD characteristics of reed water area, lotus water area and natural water area (*Fig. 1E*) show: that of lotus water area > natural water area > reed water area ($p < 0.01$) in summer; that of natural water area > lotus water area > reed water area ($p < 0.01$) in autumn, with that of reed water area significantly lower than that of natural water area and lotus water area ($p < 0.01$); that of natural water area > lotus water area > reed water area ($p < 0.01$) in winter; that of reed water area > lotus water area > natural water area ($p < 0.01$) in spring.

COD characteristics of reed water area, lotus water area and natural water area (*Fig. 1F*) show: that of lotus water area > natural water area > reed water area in summer ($p < 0.01$); that of natural water area > lotus water area > reed water area in autumn ($p < 0.01$), with that of reed water area significantly lower than that of natural water area and lotus water area ($p < 0.01$); that of reed water area > lotus water area > natural water area in winter ($p < 0.01$)); that of reed water area > lotus water area > natural water area in spring ($p < 0.01$).

The characteristics of ammonia nitrogen in reed water area, lotus water area and natural water area (*Fig. 1G*) show: that of reed water area > lotus water area > natural water area ($p > 0.05$) in summer, with that of reed water area significantly higher than that of lotus water area and natural water area ($p < 0.01$); that of lotus water area > reed water area > natural water area in autumn ($p < 0.01$); that of reed water area > lotus water area > natural water area in winter ($p < 0.01$); that of reed water area > natural water area > lotus water area ($p > 0.05$) in winter.

The characteristics of total nitrogen in reed water area, lotus water area and natural water area (*Fig. 1H*) show: that of lotus water area > natural water area > reed water area in summer ($p < 0.01$); that of natural water area > lotus water area > reed water area in autumn ($p < 0.01$); that of natural water area > reed water area > lotus water area in both winter and spring ($p < 0.01$).

The characteristics of total phosphorus in reed water area, lotus water area and natural water area (*Fig. 1I*) show: that of reed water area > lotus water area > natural water area in summer, with that of reed water area significantly higher than that of natural water area ($p < 0.01$); that of reed water area = natural water area > lotus water area in autumn; that of natural water area > reed water area > lotus water area in winter, with that of natural water area significantly higher than that of lotus water area ($p < 0.01$); that of lotus water area > natural water area > reeds water area ($p > 0.05$) in spring.

Nitrate characteristics of reed water area, lotus water area and natural water area show (*Fig. 1J*) show: that of lotus water area > natural water area > reed water area ($p < 0.01$) in summer; that of natural water area > lotus water area > reed water area in autumn ($p < 0.01$); that of natural water area > reed water area > lotus water area in winter ($p < 0.01$); that of lotus water area > natural water area > reeds water area ($p > 0.05$) in spring.

Nitrate characteristics of reed water area, lotus water area and natural water area show (*Fig. 1K*) show: that of lotus water area > natural water area > reed water area in summer, with that of reed water area significantly lower than that of lotus water area and natural water area ($p < 0.01$); that of lotus water area > reed water area > natural water area in

Water environmental factor correlation

The correlation between water environmental factors of reed water area (see *Table 1*) shows: pH, total hardness, BOD, COD, ammonia nitrogen, total nitrogen, total phosphorus and nitrate are significantly positively correlated with each other ($p < 0.01$), and significantly negatively correlated with chlorophyll a ($p < 0.01$); chromaticity is significantly negatively correlated with total hardness and COD ($p < 0.01$).

Discussion

Studies in Wuliangsuhai Lake and Baiyangdian Lake show that lotus planting can significantly improve water quality and significantly inhibit the growth of algae in water bodies (He et al., 2013; Li et al., 2018), but attention should be paid to planting density as lotus has a hormesis effect on water algae (Li and Hou, 2007). For reeds with good water purification effect, Dawen River wetland N shows net release when the reeds die and rot in winter, while P shows a net accumulation (Liu and Liu, 2012), which is contrary to our research result. In eutrophic ponds, the increase of total phosphorus

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_78917900

decreases the relative abundance of annual plants without memory officer and increases the relative abundance of annual plants with memory officer (Arthaud et al., 2012). Eutrophication accelerates the decomposition of organic matter in plant litter (Deegan et al., 2012). Jinhewan Urban Wetland is the Driving Type of Total Nitrogen (Fan et al., 2012). Yihe urban wetlands with similar water environment background are also driven by total nitrogen.

Conclusion

Reed can effectively increase dissolved oxygen and greatly reduce BOD, COD, total nitrogen, nitrate and chlorophyll a. Lotus can effectively increase pH, BOD, COD, chlorophyll a, and greatly reduce total phosphorus. In view of the fact that the current urban wetlands in Yihe River are mainly driven by total nitrogen nutrients. We think that the main controlled nutrient parameters of urban wetlands in Yihe River should be total nitrogen. It is recommended to increase natural and artificial reed community area and try to expand lotus community in the water areas with severe phosphorus load.

(Received 23rd Feb 2019; accepted 3rd May 2019)

Abstract. In order to uncover the heavy precipitation percolation feature and formation mechanism intensity in the deep vadose zone called black box, the nonlinear dynamical system theory was introduced in this paper. By in-situ monitoring the water dynamics in Taihang piedmont deep aeration zone, the heavy precipitation infiltration-evaporation process, wetting front advancing process, water storage changing process were analyzed. The result showed that: (1) the deep vadose zone was a "balance-unbalance-balance" nonlinear dynamical system. And the water infiltration was a typical nonlinear process; (2) the forming mechanism comprised of the internal control parameter vector C determined by vadose zone lithology, and the external forcing terms G(t) determined by rainfall, evaporation and human activities ect.; (3) when the time, space scale is large enough, the non-autonomous system could be transformed into a free system and linear system.
Keywords: *deep vadose zone, soil water distribution, heavy precipitation, nonlinear infiltration, TDR100 system*

Introduction

A nonlinear system cannot be described by a linear mathematical model. In the system at least one part or all parts have nonlinear characteristics and have nonlinear interaction among them. The basic characteristics of nonlinear system lead to the diversity and multiple scales of dynamic process in the system, so the nonlinear system's study is more complicated than the linear system's study. The nonlinear system cannot satisfy superposition principle and its mass action is greater than the sum of partial actions. The interaction of many small nonlinear factors in the nonlinear system may generate unpredictable results. The continual dynamic system could be expressed by the following equations (Li, 2006).

$$\begin{cases} \dot{x}_1 = f_1[(x_1 \mathrm{K}\ x_n)(c_1 \mathrm{K}\ c_m)] \\ \dot{x}_2 = f_2[(x_1 \mathrm{K}\ x_n)(c_1 \mathrm{K}\ c_m)] \\ \qquad \mathrm{M} \\ \dot{x}_n = f_n[(x_1 \mathrm{K}\ x_n)(c_1 \mathrm{K}\ c_m)] \\ \qquad \mathrm{M} \end{cases} \qquad \text{(Eq.1)}$$

At least one of f1, …, fn is nonlinear function, C = (C1, C2, …, Cm) represents control parameter vector and F = (f1, f2, …, fn). So *Equation 1* can be considered a vector.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79017907

$$Z = F(X, C) \quad \text{(Eq.2)}$$

The system described by *Equation 2* has no external forcing and is a free system. If external forcing G (t) is introduced the system will be a forcing system which can be expressed by *Equation 3*.

$$Z = F(X, C) + G(t) \quad \text{(Eq.3)}$$

Equation 2 contains the time t so the system is known as non-autonomous system which can be expressed by *Equation 4*.

$$Z = F(X, C, t) \quad \text{(Eq.4)}$$

In *Equations 3* and *4,* G(t) and t are considered as a new state variable and the system can be conformed to free system.

The continual decline in groundwater level in Taihang Piedmont led to the depth of zone of aeration becoming greater (Baram et al., 2016). This is the typical nonlinear system under the interaction of precipitation, evaporation and human activity.

Every layer in the zone of aeration can be marked as Z1, Z2, …, Zn, f1, f2,…,fn are the nonlinear function of soil water potential or water content. The parameters of soil hydraulic properties can be expressed by C1, C2, …, Cm. The external forcing G(t) contains precipitation, evaporation, temperature and mankind's activity. The infiltration process of heavy precipitation takes place on the zone of aeration and be controlled by this nonlinear dynamic system, such as spatial variability (Dahan et al., 2017) inner the system. Meanwhile, the infiltration of heavy precipitation has an adverse effect on this nonlinear system, such as a new external forcing was added to the system over a period of time and cause the infiltration process analysis and simulation of nonlinear dynamic system more complicated (Gupta et al., 2018). Most of the traditional seepage researches in the zone of aeration separate the soil from the infiltration-evaporation process and less likely to carry the above two into a system (Turkeltaub et al., 2016) to explore the inner migration process and mechanism of black box.

In order to subtly study the soil hydraulic characteristics in the zone of aeration under various factors, this paper introduced the nonlinear dynamic systemic mathematic principle and take the heavy precipitation infiltrated into the zone of aeration and the soil as an entity (Min et al., 2017). And this paper analyzes the infiltration-evaporation process, moisture storage variation process, etc and tried to apply the nonlinear dynamic system to interpret the mechanism of the process.

Materials and methods

The study area

From 2012-2013, the study carried out in key field experimental base of the Ministry of Land and Resources in Zhengding, China. The study area has a temperate and semi-humid continental monsoon climate with clearly cut seasons. The annual average temperature is 12.9 °C, the average temperature in July is 26.5 °C and is the highest in a year and in January is the lowest with the temperature is -2.9 °C. The precipitation is focus on June-September and the annual average precipitation is 569.8 mm. The annual average evaporation is 1092.3 mm. The study time period was from April 15th to June

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79017907

5th. *Figure 1* showed that the heavy precipitation with 70 mm at April 18th, 16 mm at April 21th and 26 mm at April 24th and long-time evaporation process from April 24th to May 16th.

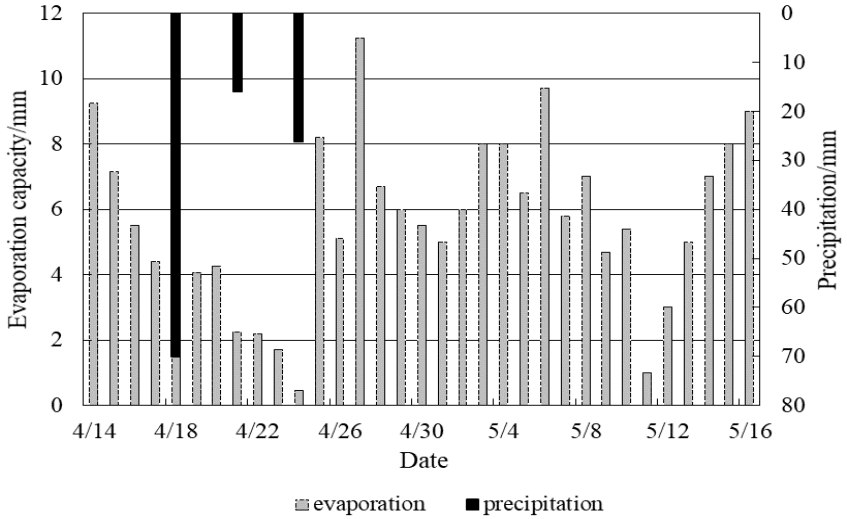

Figure 1. *Rainfall and evaporation (2012)*

Zhengding is located in the Piedmont Clinoplain in the midst of Taihang Mountain with the depth of shallow groundwater depth 36.1-49.1 m. The soil is composed mainly of silt clay and sandy clay, and specific gravity of soil is 2.2-2.74 g/cm^3 (Min et al., 2018).

Monitoring system layout

The study uncovered a typical multi-phase monitoring profile with 33 m depth, 2.5 m inner radius and 3.5 m outer diameter. The Time-Domain Reflectometry system developed by CAMPBELL Company in USA was applied to monitor the soil moisture. The detectors were installed on the inside of the typical profile. 36 CS630 were installed to measure the soil volumetric water content, 36 WATERMARK200-253/257 to measure the soil matric potential and 36 MODEL109 to measure the soil temperature. The buried depth of three kinds of detectors was the same. From the depth of 0.1 m, a detector was installed every 20 cm within 2 m and every 30~70 cm below 2 m. All the detectors were calibrated by the neutron probe and soil sampling.

The monitoring period was from August in 2011 and the monitoring interval was 0.5 h. The TDR systemic time was set up according to the Beijing time. At the same time the meteorological observation was carried out and its observation interval was 0.5 h. It includes 19 general meteorological data, such as precipitation, evaporation, the solar radiation, etc.

Results and discussion

The effect of lithology on infiltration

The control parameter vector $C = (C_1, C_2, \ldots, C_m)$ was internal effect factor of the nonlinear dynamic system. For the nonlinear dynamic system in the zone of aeration the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79017907

control parameters are determined by the lithology of every layer. Suppose that C1 was soil particle size, C2 was soil specific retention and C3 was hydraulic conductivity of soil, and among them C1 and C2 was a constant at a particular depth and C3 was a variable changing with the soil moisture content. The above three parameters had an effect on the nonlinear function and there had correlation among them. And the above three parameters were determined by the soil lithology characteristics.

The TDR system was applied to measure and analyze the soil matric potential during the three precipitation-infiltration process and evaporation process. Because the evaporation intensity was great during the April to June so the measurement value was the value at 20:00 of the day for the evaporation process was essentially completed. *Figure 2* shows that 12 detectors measure the soil matric potential daily at different depth of the profile.

According to the measured value at different times, the initial matric potential was significantly lower than the adjacent layers. The initial matric potential was measured under the longstanding stable weak-evaporation condition, and so the main influencing factor of the difference of the soil matric potential at different layer was the lithology. Besides, at April 22th, three days behind the precipitation, the matric potential drop rapidly by 20 cm and the falling speed was greater than other layers. This phenomenon illustrated that water retention capability of soil at 30 cm depth was poor and the soil permeability was high so this layer was the best water passage in relation to the other layers. At the 180 m depth there has the similar simulation.

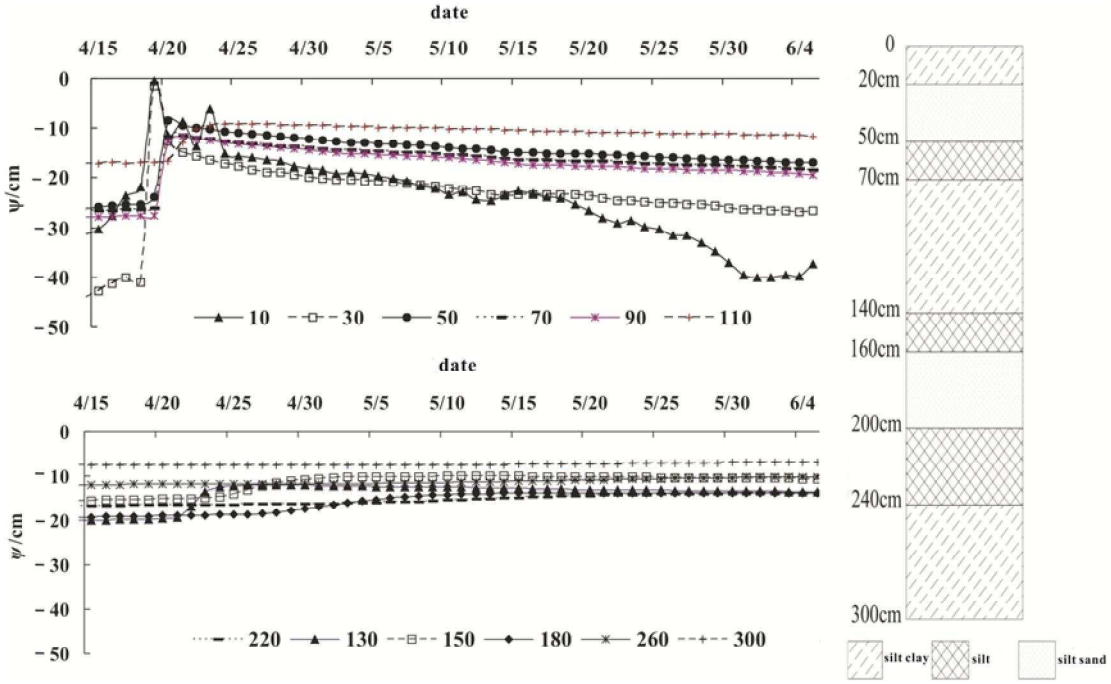

Figure 2. *Soil matrix potential variations of different depth*

The effect of lithology on soil water storage

The lithology has a significant effect on the soil water storage. The precipitation and evaporation changes the soil water storage and this process is a dynamic changing process. For the water storage compute of zone of aeration under one-dimensional

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79017907

condition, the soil volumetric water content at different depth can be measured, then accumulated the difference value of the soil water content at different time period and finally get the dynamic soil water storage. The CS630 detectors were applied to monitor the soil water content at different depth before heavy precipitation, 4 h and 720 h after precipitation. *Table 1* showed the soil moisture content dynamics at different time period by calculating changes in moisture content at each layer and then cumulated to get the total storage variation.

Table 1. *Soil moisture content dynamics and storage variations at different depth*

Moisture / Depth/cm	θ_1(0h)	θ_2(4h)	(θ_2-θ_1)	ΔW_1/mm	θ_3(720h)	(θ_2-θ_3)	ΔW_2/mm	(θ_3-θ_1)	ΔW_3/mm

300	0.045	0.045	0	0	0.045	0	0	0	0
Sum				77.6			5.7		71.9

The precipitation was 70 mm and lasted 4 h. θ_1, θ_2, $\theta_3$represented the soil volumetric water content 0 h, 4 h and 720 h after precipitation respectively, ΔW_1 represented the storage variation 4 h after precipitation at different depth, ΔW2 represented the storage variation between 4 and 720 h after precipitation at different depth, ΔW_3 represented the storage variation between 0 and 720 h after precipitation at different depth

In *Table 1,* the storage variation was up to 30.8 mm between 0 and 4 h after precipitation at 30 cm depth and was the maximum at the depth of 0-300 cm. that is because there were coarse soil particles and great porosity. The soil water storage can be increased rapidly during heavy precipitation and dropped quickly from 26% to 18% after 24 h. The high infiltration capacity of this layer was proved again. The storage variation simulation at 180 cm depth was similar to the above situation.

The above phenomenon was determined by the difference of the soil lithologic characters. For the high-content of sands at depth of 30 cm and 180 cm so the soil was named as silty sand according to the international standard. If the natural soil was not disturbed, it is difficult to monitor the mid-deep part of the vadose zone directly and accurately, so the hydrological cycle problem was settled from the point of lithology may be a new idea.

The effect of two and evaporation on infiltration and soil water storage

The nonlinear dynamic system was affected by the external forcing G (t) and was transformed to non-autonomous system. Its character was varying with the time significantly. Two precipitations, relative to the first heavy precipitation, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79017907

evaporation were consistent with this character. The shallow vadose zone approached saturation after heavy precipitation, the soil water content of deep- layers was increased and the permeability of unsaturated soil enhanced. So the two precipitations were easily to form the infiltration and increased the soil water storage. For the deep vadose zone two precipitations were hardly leaked to the groundwater level during the short time period. The process of evaporation varying with time was more significantly, especially at different layers. G (t) in the shallow non-autonomous system was nonlinear and below a certain depth was linear. In this paper the certain depth was 220 cm. When evaporation tends to be constant, G (t) was a constant and the system reached a new balance, the non-autonomous system was transformed to free system. The water storage of vadose zone reverted to the state before heavy precipitation and the storage was again determined by the lithology characteristics.

Conclusions

According to the analysis of the process of infiltration-evaporation, wetting front progradation, storage variation and dynamic variation of total water potential, the infiltration process occurring in the nonlinear dynamic system was typical nonlinear process. The formation mechanism of nonlinear infiltration process includes the inner control parameter vector C and the outer external forcing G(t). When the system suffering the heavy precipitation and evaporation becomes a non-autonomous system and the infiltration process will be determined by G(t) varying with time. When the system tends to be constant, the system becomes a free system and the infiltration process will be determined by the inner parameter vector C, such as the lithology of each layer in vadose zone. And further study is required to establish the specific range of soil particle sizes which can determine the lithology characteristics.

Abstract. In Lhasa area, the solar radiation intensity is relatively high, so in order to satisfy the indoor natural lighting quality, it is easy to cause overheating in the south-facing room and non-uniform heat in the north-facing room with lower room temperature. In this paper, Dest-h software is used to simulate and study the base temperature and average energy consumption of non-heating residential buildings under different window-wall ratio and partition wall conditions, trying to find out the structural measures and design methods to improve the indoor thermal uniformity.
Keywords: *solar radiation intensity, non-uniformity, Dest-h, base temperature, building energy consumption*

Introduction

As a cold area, Lhasa needs heating in winter according to the Code of Thermal Design of Civil Buildings in China. But heating is expensive because fuel and coal are imported from other areas. However, thanks to the strong solar radiation, the annual sunshine time of more than 3,000 h, and the annual total solar radiation of 7,000 MJ/m^2 (Xiao, 2010), Lhasa region has unique solar energy resources. Through literature review (Zhang and Liu, 2008; Li and Liu, 2017; Liu, 2017; Kang, 2012; Li, 2017) and field review in 2016-2017, it was found that the flat roof buildings sitting north and south are adopted most commonly in this area, maximizing the use of opening area of south-facing glass window or passive energy-saving technology with additional sunshine, so as to obtain more solar radiation heat, thereby increasing the indoor temperature of the room, and ultimately reducing the heating load demand of the building. Nonetheless, the contradiction between excessive heating area and strong solar radiation resources makes indoor thermal non-uniformity the most significant thermal comfort problem of residential buildings in this area. For example, in winter, the south-facing room is overheated during the day, residents need to open windows, and the north-facing room has a lower temperature all day, residents are unwilling to stay in it.

Based on the field test and simulation analysis of residential buildings in cities and towns in Tibet Plateau, Liu et al. (2011) put forward the basic theory and calculation method of low-energy building design suitable for the natural and climatic conditions of Tibet Plateau. In view of the abundant solar energy resources in this area, Yang et al. (2010) put forward a heating mode that is mainly passive solar heating, supplemented by active heating and other heating modes, and combined it with passive and active heating, in order to improve the indoor thermal environment quality and reduce building energy consumption. Liu et al. (2008) tested the indoor and outdoor temperature of traditional houses in Lhasa area, and concluded that increasing the area of south-to-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79097916

outdoor windows does not reduce the indoor minimum temperature, but can also improve the indoor average temperature and maximum temperature. Wang et al. (2012) tested and compared the indoor thermal environment of two residential buildings in Tibet using traditional building materials and modern building materials. It was concluded that the thermal insulation performance of traditional building materials in eastern Tibet was better than that of modern building materials. Wang (2018) divided the typical rural buildings in Tibet into space zoning modes, determined the structural parameters and thermal performance of the local typical building envelopes, and simulated and analysed the zoning modes. Domestic papers building thermal environment research in Tibet focuses, mainly on rural building envelope materials or indoor thermal environment energy-saving design, but there are few studies on indoor thermal heterogeneity, especially in urban residential buildings.

Aiming at the problem of indoor thermal non-uniformity in Lhasa area, the dynamic simulation of energy consumption of typical buildings in south and north rooms was carried out in this paper, according to the requirement of 65% energy saving in Lhasa area by means of Dest-h software simulation analysis, and the structural measures and design methods to improve the indoor thermal non-uniformity were explored in order to further improve the indoor thermal environment quality of buildings there.

Methodology

Climate parameters

In order to avoid the influence of weather instability on the accuracy of the calculation results, the typical meteorological year data (TMY) was used as the input condition, which is the hourly meteorological data of DeST software, and the number of air exchange is 0.5 times/h (Tianjin Eco-city Green Building Research Institute, Tsinghua University Building Energy Research Center, 2009). Room heat disturbance is determined by its use function. Indoor per capita calorific value was set at 53 W; lighting load was set at 60 W according to gross index input; the equipment load was set at 12.7 W/m^2 according to the average index input.

The slab buildings with two families sharing one staircase are the most representative residential building model in Lhasa. Usually, the buildings in this area are oriented to the south, with 6 stories and 3 m high. The plan is shown in *Figure 1*.

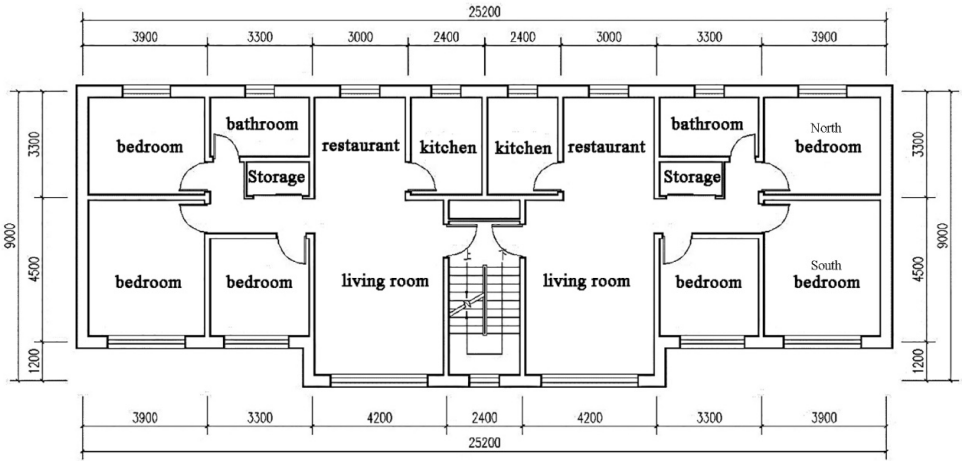

Figure 1. *Simulated model plan*

Building envelope parameters

The parameters of roof, exterior wall, interior wall, ground, floor, exterior window and exterior door are set at the limit value prescribed by the code (DBJ540001-2016, 2016). The thermal parameters of materials and components are selected from the *Code for Thermal Design of Civil Buildings*, as shown in *Table 1*.

Table 1. *Thermal parameters of building envelope*

Name of envelops	Materials of envelops	Heat transfer coefficient K W/(m^2·K)
Roof	20 thick lime mortar + 50 thick polyurethane insulation layer + 20 thick cement mortar + 100 thick reinforced concrete slab + 20 thick cement mortar	0.42
Exterior wall	20 thick lime mortar + 40 thick extruded polystyrene board + 370 thick lime sand brick wall + 20 thick cement mortar	0.53
Interior wall	20 thick cement mortar + 240 thick cement-sand brick wall + 20 thick cement mortar	2.0
Ground	Concrete floor	2.9
Floor	20 thick cement mortar + 60 thick lightweight aggregate concrete + 100 thick reinforced concrete slab + 20 thick cement Mortar	4.8
Exterior window	6 + 12 + 6 double glazed window	2.8
Exterior door	Solid wood door	2.0

Results

Window-wall ratio

The window-wall ratio is a key index affecting indoor thermal environment. It is stipulated in the *Design Standard for Energy Efficiency of Residential Buildings in Severe Cold and Cold Zones* that the window-wall ratio of residential buildings in Cold Area A is not more than 0.5 (JGJ 26-2010, 2010). However, there is no limit value of window-wall ratio in the *Standard for Energy-saving Design of Civil Buildings in Tibet Autonomous Region*. But Lhasa is a cold area with strong solar radiation. The larger the size of the window opening, the greater the heat loss in the room. For the north room, the window size only needs to meet the functional lighting requirements of the room. Therefore, the northward window-wall ratio is set to 0.12. For the south room, it is necessary to maximize the solar radiation heat, but also to prevent indoor overheating. As a result, the south-facing window-wall ratio range is 0.3-0.8.

With the same thickness of partition wall and different window-wall ratios, the dynamic simulation of energy consumption of typical buildings in south and north rooms was carried out by using Dest-h software. Results are shown in *Figure 2,* when the window-wall ratio in residential buildings is too large, that is, above 0.6, the average building energy consumption value has dropped to 0 w/m^2, the base temperature of the south room has reached 26.37 °C, and that of the north room is 19.96 °C, and the temperature difference between the two rooms is 6.41 °C. As shown in *Figure 3,* the base temperatures of the south room and north room increases with the increase of the south window-wall ratio. With the increase of the south window-wall ratio, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79097916

temperature fluctuation of the south room increases from 1.52 to 3.45 °C, and the temperature fluctuation of the north room increases from 0.8 to 1 °C. The temperature difference between the south room and north room increases from 4.31 to 7.28 °C, and the fluctuation also increases significantly. If only the south window is used to obtain the solar radiation, when the window-wall ratio is 0.4 and above, the average temperature of the room is above 16 °C, which basically meets the requirements of indoor thermal environment.

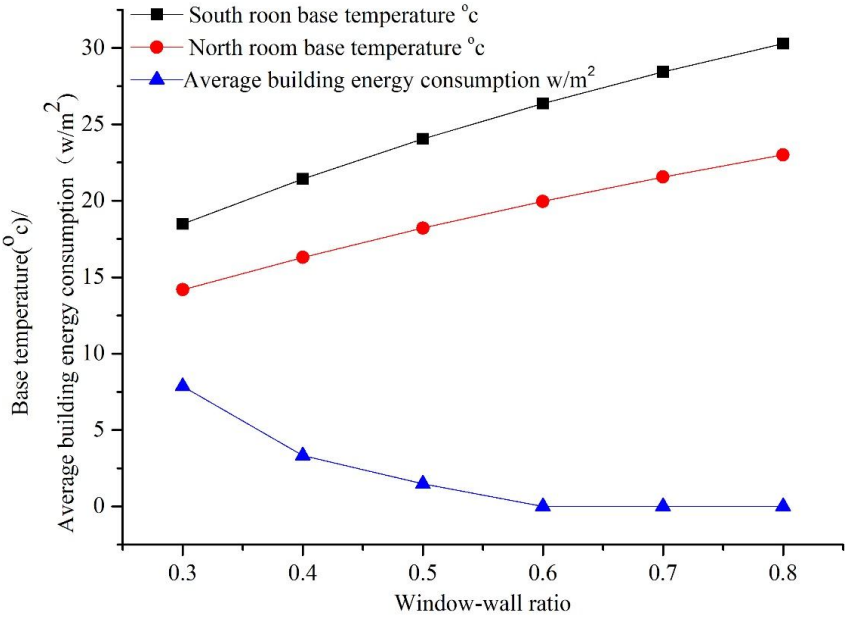

Figure 2. *The base temperature and average building energy consumption of south room and north room on the coldest day in Lhasa area with different window-wall ratios*

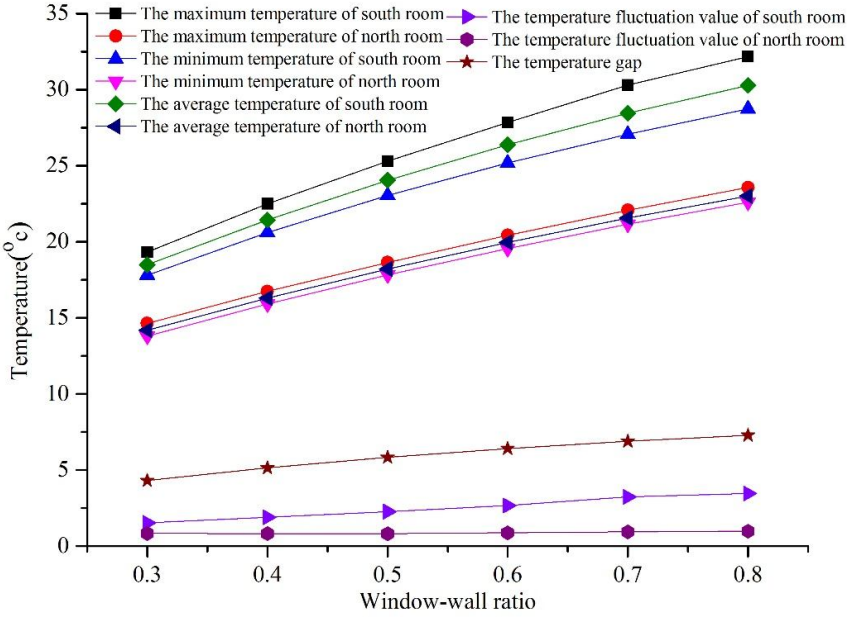

Figure 3. *The maximum, minimum, average temperature and temperature difference of south room and north room on the coldest day without heating (°C)*

DOI: http://dx.doi.org/10.15666/aeer/1704_79097916

Partition wall

Under different heat transfer coefficients, the base temperature of rooms facing south and north of residential buildings in Lhasa area was simulated and analyzed. The values of different heat transfer coefficients K and the corresponding partition construction methods are shown in *Table 2*.

Table 2. *Values of different heat transfer coefficients K and their corresponding partition construction practices*

Conditions	Heat transfer coefficient K[W/(m^2·K)]	Recommended practices of partition wall construction
Case1	0.7	200 thick aerated concrete block wall (0.723)
Case2	1.2	100 thick aerated concrete block wall (1.207)
Case3		370 thick porous brick wall (1.248)
Case4	1.6	240 thick porous brick wall (1.624)
Case5		370 thick lime sand brick wall (1.641)
Case6	2.0	240 thick lime sand brick wall (2.036)
Case7	2.3	120 thick porous brick wall (2.251)
Case8	2.6	120 thick lime sand brick wall (2.618)
Case9	3.2	50 thick plasterboard partition (3.23)
Case10	6.3	12 thick glass partition wall (6.3)

Under the same window-wall area ratio, different thickness of partitions and construction methods, the hourly room temperature comparison curves of south and north-facing rooms in winter solstice are shown in *Figures 4* and *5*. Even in the case of glass partitioning, although the thermal non-uniformity of rooms in the south and north directions decreases, there is still a temperature difference of 5.01 °C. The results show that after the passive energy-saving technology is maximized, the large temperature difference between the south and north-facing rooms still exists. Therefore, the main method to solve the problem of indoor thermal non-uniformity is how to make rational use of the south-facing heat collection area to store or transfer heat to the north-facing room.

Discussion

If only the south window is used to obtain the solar radiant, when the east and the west window-wall ratios are 0, the north window-wall ratios is 0.12, the south window-wall ratio is greater than or equal to 0.4. On the coldest day, the average temperature of the south and the north rooms is above 16 °C, which basically meets the requirements of indoor thermal environment. If the south window-wall ratio is greater than 0.4, the fluctuation value of base temperature in south room is greater than that in north room, and the fluctuation value of base temperature in north room is basically unchanged, which indicates that the heat from the south room is difficult to transfer to the north room. Therefore, it is considered to adopt a solar building form to solve indoor thermal non-uniformity when the south in south direction is greater than 0.4.

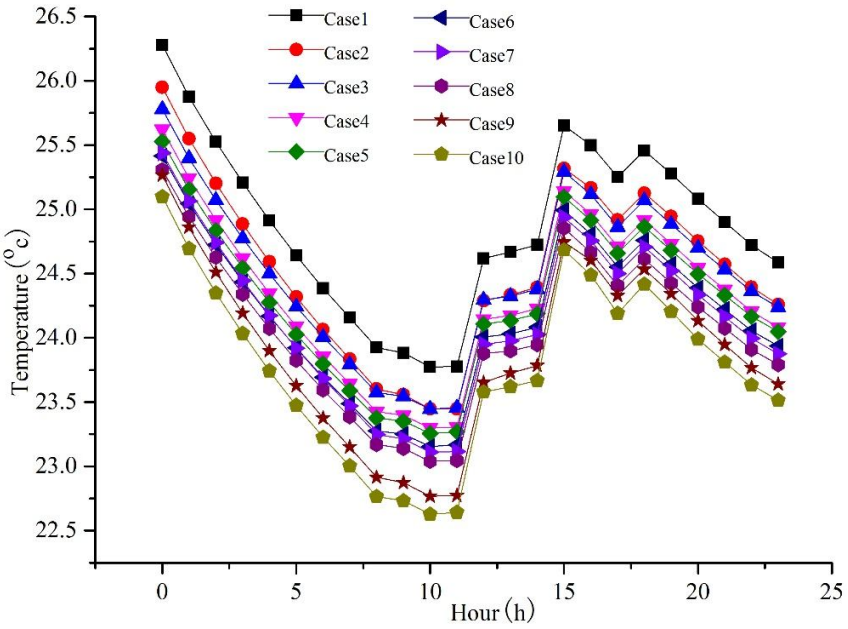

Figure 4. *Comparison of room temperature in south room under different partition conditions on winter solstice*

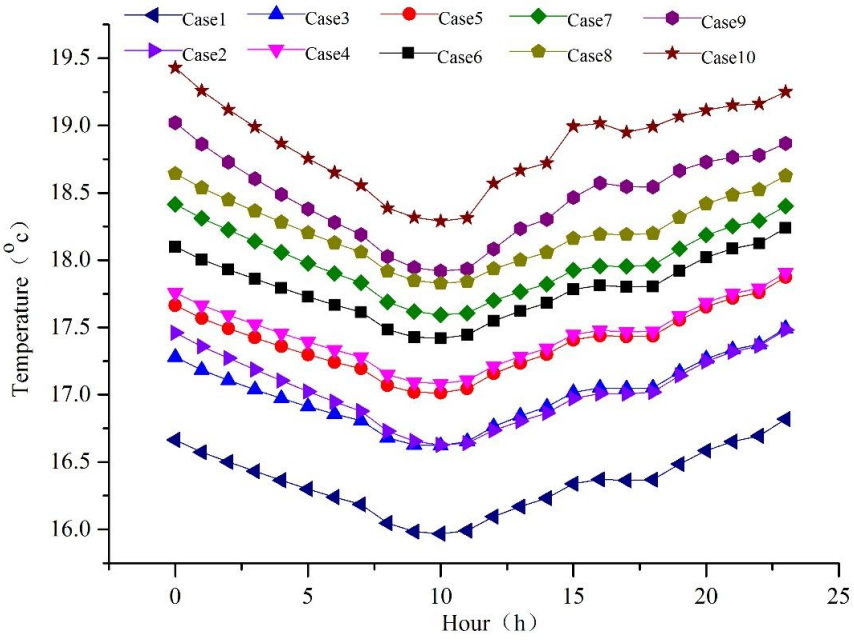

Figure 5. *Comparison of room temperature in north room under different partition conditions on winter solstice*

At present, the research focus of solar energy utilization in Lhasa area is on improving the efficiency of heat collection, which should be transferred to utilizing heat transfer to solve the non-uniformity of indoor temperature field. However, in the organic integration and utilization of building materials, building structures, building

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79097916

equipment and intelligent control methods, it still has the characteristics of simplification and one-sidedness. How to utilize the seasonality, randomness, periodicity and controllability of solar energy in different seasons, different periods and different heating areas to obtain the reasonable heat control, storage and use management of solar energy in time-sharing, zoning and seasons is an effective means to reduce energy consumption, improve indoor thermal comfort and solve the problem of non-uniformity of indoor temperature field.

In terms of installation mode, flat-plate solar collectors are mostly installed in fixed way in solar energy building, and wall-mounted type is adopted in order to ensure solar energy collection area in installation position. However, the former cannot adjust the angle of solar panels according to the change of all-day solar elevation angle, which leads to low efficiency of solar energy acquisition; the latter affects the facade design of buildings on the one hand. The latter on the one hand affects the design of building exterior facade, on the other hand has some potential safety hazards because it hangs directly on the wall surface. Therefore, the integrated design method of solar building with window solar energy system as heat storage component can be considered. At the same time, glass partition or light partition wall with large heat transfer coefficient should be adopted as indoor partition wall as far as possible.

Conclusions

In this paper, the indoor thermal environment and energy consumption of residential buildings in Lhasa under different window-to-wall ratios and partition conditions were simulated and analyzed. The results show that the indoor thermal environment of residential buildings in Lhasa still exhibits thermal non-uniformity under the condition of maximizing the use of passive energy-saving technology. When the east and the west window-wall ratios are 0, the north window-wall ratios is 0.12, the south window-wall ratio is greater than or equal to 0.4, glass partition or light partition wall with large heat transfer coefficient should be adopted as indoor partition wall as far as possible. On this basis, it is necessary to build window solar energy storage and energy-using equipment in combination with local climate, so that thermal energy can be transferred from south to north-facing rooms, reduce or avoid indoor discomfort, and reduce energy consumption.

(Received 23rd Feb 2019; accepted 3rd May 2019)

Abstract. To improve the precision of granular fertilizer mass measured via microwave Doppler technology, this study proposed a method based on RANSAC to predict granular fertilizer mass for fertilizer apparatus. The maximum value, the minimum value, and a random value in the sample data were selected to obtain the best-fitting line that contained most interior points using iterative method. The fitting result of LS method was also presented to compare with the proposed scheme. Simulation results and experimental results illustrate that RANSAC method has a higher prediction precision than traditional LS method and a better ability to reduce the effect of measurement error.
Keywords: *microwave Doppler, sensor, solid flow and mass, electric fertilizer distribution, opening degree*

Introduction

In recent years, grain system applied in agricultural production has been modernized and normalized in China. Solid flow meter is widely used in the field of variable rate fertilization, grain storage, and flour milling measurement. Online continuous measurement and the follow-up control of solid mass plays an important role in different agricultural industries, and creates a massive demand for solid flow and mass monitoring system. The precision of solid flow and mass measurement has a significant meaning on precision fertilization and energy saving. A large variety of methods used to measure solid flow and mass have been proposed in the past twenty years.

Invasive method and non-invasive method are the two common ways to measure solid flow and mass in delivery pipe (Yan and Stewart, 2000). Invasive method using apparatus with direct connection to the measuring object. Invasive instrument is regularly utilized to measure the flow of stive and corrosion without direct contact, which has a better stability, a higher precision and a longer service life. Hence the invasive method has been studied in the previous research of solid flow and mass measurement field (Zheng, 2010). Using Doppler frequency shift in the wave propagation, Doppler measurement is an invasive method, which includes laser Doppler measurement, ultrasound Doppler measurement, and photon Doppler measurement (Dimaczek et al., 1994).

Crame indicated the advantages of Doppler method applying ultrasound Doppler to different kinds of liquid metal flow measurement (Cramer et al., 2013). Shames et al. (2013) studied target location and signal of Doppler frequency shift (Shames et al., 2013; Karaboga and Latifoglu, 2013). Isa and Wu (2004) designed a solid flow

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79177925

monitoring system based on microwave Doppler radar sensor, and pointed out that the echo energy, which was transformed from solid flow signal using FFT (Fast Fourier Transform), and solid mass had a linear relation (Isa and Wu, 2004, 2006). Pang et al. (2018) investigated the relation between grain size and dielectric constant and proposed a real time invasive measurement for solid granule.

Random Sample Consensus (RANSAC) method builds a mathematics model to estimate parameters even if there is abnormal data in the data set (Hossein-Nejad and Nasri, 2016; Niedfeldt et al., 2017). Wang et al. (2016) presented a RANSAC method based on screening and matching, which has a high robustness in the environment of contamination and low computation complexity. Based on RLS model, granular mass was obtained via power spectral density in the previous studies, resulting in low sampling precision. As an iterative algorithm, RANSAC method is used to estimate the parameter of mathematics model in an outlier observation data. RANSAC method is usually applied in the field of spectral analysis and image processing. To the authors' best knowledge, RANSAC has been rarely used in the granule fertilizer mass measurement. To improve the accuracy of the granule fertilizer mass, RANSAC method is used to obtain the optimal linear function of the sample in this study.

The study focused on fertilizing mass measurement of granular fertilizer. Data set collected by Doppler sensor is the voltage of echo signal, and output of the mathematics model is the mass of granule fertilizer. A granular fertilizer applicator was developed in Heilongjiang Bayi Agricultural University to collect echo signal voltage by microwave Doppler radar sensor. The relationship of fertilizer apparatus open degree and granular fertilizer mass was investigated using Random Sample Consensus (RANSAC) algorithm. The fertilizer mass prediction model provides reference for the optimization of solid flow and mass measurement. Simulation and experimental results show that the RANSAC method used to predict the mass of granular fertilizer online has a high precision and stability. The presented method provides a scientific fundament for mass measurement of granular material, which has a great meaning of improving the grain quality and yield.

Materials and methods

Materials

In this research, this fertilizer is granular compound fertilizer diammonium phosphate, and the total nutrient of granule fertilizer: (N+P2O5)≥64.0%.This granular fertilizer is irregular granular and its surface is smooth, which is suitable for signal acquisition by microwave Doppler sensor.

Methods of the RANSAC Algorithm for granular fertilizer mass prediction

Structure of granular fertilizer applicator

Figure 1 shows the structure of the granular fertilizer applicator. The appliance is consisted of fertilizer box, electric fertilizer apparatus, microwave Doppler radar sensor, data collector, and a computer. Capacity of the fertilizer box is 20 L. Power of the fertilizer apparatus is 12V / 50W. Diameter of the fertilizer pipeline is 4 cm. Microwave Doppler radar sensor is installed outside of the pipeline 30 cm away from the release location of the granular fertilizer.

Algorithm description

For the granular fertilizer mass prediction model, voltage value of echo signal is taken as data set, unknown parameter of the sample model is granular fertilizer mass. The Voltage measured by Doppler sensor is linearly related to the opening degree of fertilizer apparatus. To improve the accuracy of the fitting line obtained by RANSAC method, the minimum value (X1, Y1), the maximum value (X2, Y2), and a random value (X3, Y3) are chosen in the establishment process of the initialized model. The three values are reserved in subset $\mathbf{M_i}$. The optimal linear model determined by the three feature points is given as *Eq.1*.

$$\mathbf{Ax + By + C = 0} \tag{Eq.1}$$

The distance from other point (Xi, Yi) to the optimal line is given as *Eq.2*.

$$d_i = \frac{|Ax_i + By_i + C|}{\sqrt{A^2 + B^2}} \tag{Eq.2}$$

If di<dh, (Xi, Yi) is inside the sample set $\mathbf{M_i}$, otherwise is outside the sample set. The inside point set is used to estimate a new line via least square (LS) method.

t is the probability of the inside point appearing in the sample set, which is expressed as *Eq.3*.

$$\mathbf{t} = \frac{n_{inliers}}{n_{inliers} + n_{outliners}} \tag{Eq.3}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79177925

The probability of at least one of the three points exiting outside the sample set is defined as *Eq.4*.

$$1 - t^3 \quad \text{(Eq.4)}$$

If none of the three points is inside point in k times random sampling, there is $(1 - t^3)^k$. The wrong solution is obtained as *Eq.5*.

$$P = 1 - (1 - t^3)^k \quad \text{(Eq.5)}$$

where, *k* is iteration step, which is the minimum number of random sampling. *P* is the probability of obtaining the right solution.

The probability of inside point *t* is a priori value, which has a crucial influence on the judgement of inside point and outside point. To ensure the probability *P* of the right solution, iteration step *k* must increase even if *t* is large. From *Eq.6*, *k* can be calculated if *P* is known.

$$k = \frac{\lg(1-p)}{\lg(1-t^3)} \quad \text{(Eq.6)}$$

Simulation results

Data acquisition

Data acquisition instrument developed at Heilongjiang Bayi Agriculture University was employed to measure the flow of large granular urea in the field experiment. Diameter of the urea granular fertilizer used in experiment was 2.00 mm-4.75 mm. The acquisition frequency was 500 Hz. Echo signal voltage of the granular fertilizer flow waveform was obtained. The waveform of 10%, 50% and 100% opening degree is shown in *Figure 2*.

The voltage of each 10 percent of the fertilizer apparatus opening degree was measured for six times. Mass of each 10 percent opening degree was also measured using electronic scale for six times. The acquisition time was 10 seconds, which was counted by a time relay to improve the timing precision. *Table 1* is the average mass. To indicate accuracy of the measurement, maximum error between acquisition value and average value is also presented in *Table 1*.

Granular fertilizer mass prediction based on LS

Table 2 is granular fertilizer mass in one-unit interval and quadratic sum of voltage amplitude at each 10% opening degree. $\frac{1}{n}\sum_{i=1}^{n} V^2$ is the average value of the echo signal voltage amplitude. *Figure 3* is the fitting line of voltage amplitude average value and mass of different opening degree in one-unit interval based on LS.

The predicting equation based on LS method shown in *Figure 3* is expressed as *Eq.7*.

$$y = 0.0885x - 0.0992 \quad \text{(Eq.7)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79177925

where, y is average value of the voltage amplitude, x is granular fertilizer mass in one unit interval. *Table 3* is the absolute error between actual value and LS prediction value.

The nonlinear error is given by Eq.8.

$$\epsilon_{LS} = \frac{|(\Delta y_L)_{max}|}{y_{FS}} \times 100\% \quad \text{(Eq.8)}$$

where, y_{FS} is full range output, $\Delta(y_L)_{max}$ is the maximum deviation in the measurement points.

The maximum deviation occurred when the fertilizer apparatus opening degree was 60%. According to *Eq.8*, the linearity degree ϵ_{LS} is 11.7%.

The predicting equation based on RANSAC method shown in *Figure 5* is defined as *Eq.9*.

$$y = 0.089945x\text{-}0.010418 \quad \text{(Eq.9)}$$

The maximum deviation occurred when the fertilizer apparatus opening degree was 100%. According to *Eq.9*, the nonlinear error ϵ_{LS} is 6.34%.

The nonlinear error of the RANSAC line, which is less than the nonlinear error of LS. To obtained a minimum sum of squared error, if there is large deviation point, the error

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79177925

of fitting method based on LS is large. As regards to RANSAC method, the points near the fitting line are selected by eliminating the large deviation point. Hence, the prediction accuracy with RANSAC is higher than LS.

Result

Figure 5 is the comparison of the actual value and prediction value. The well-fitted line demonstrates the effectiveness of the proposed RANSAC method. which is better fitting than the LS line. *Table 5* is the result of MSE and nonlinear error with RANSAC and LS method.

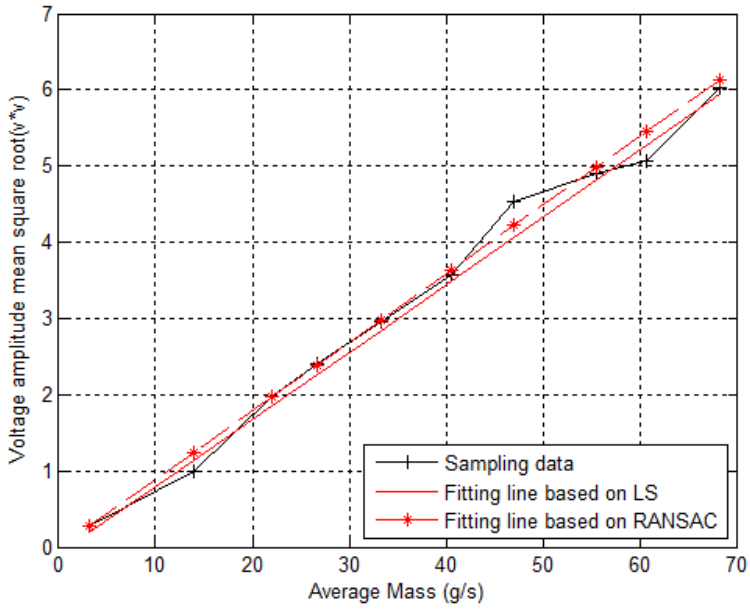

Figure 5. *Fitting lines based on RANSAC and LS*

Table 5. *Results of MSE and nonlinear error*

Fitting method	MSE	Nonlinear error
LS	0.45702	11.2%
RANSAC	0.37787	5.43%

Conclusion and discussion

The echo signal voltage of urea granular fertilizer was measured by Doppler sensor. The prediction model of granular fertilizer mass based on RANSAC was built. The proposed method was compared with LS algorithm. Simulation results demonstrate that the prediction accuracy with RANSAC is higher than LS.

The LS method considers the minimum square error of all location points in linear fitting. When there are several points with larger deviation, the fitting error is larger. Using RANSAC to estimate the Doppler signal, we can select consistent sets that conform to the straight line when fitting straight lines, automatically eliminate the larger error points, and improve the fitting accuracy. Subsequent research will further improve signal sampling accuracy, reduce computation time and improve operational efficiency.

Abstract. The scientific problem of fusion analysis for geospatial big data is to obtain the structure, composition, spatial distribution and variation law of geological bodies from interdisciplinary data. The key technology is to carry out a geospatial three-dimensional reconstruction and visualization, and perform spatial analysis, prediction and decision. Spatial distribution and variability analysis of Ordos sandstone uranium mining is an important concern for uranium formation research. This study is based on big sample data of typical drilling and constructs a digital frequency spectrum model reflecting uranium oxidation-reduction space and lithofacies combination relationship, to describe uranium change of Zhiluo formation strata combination and spatial coupling relationship with the surrounding rock. Modeling process involves a series of key assessments which are structure analysis for big sample data of typical drilling, scale calculation, digital frequency spectrum and variation function principle, geological interpretation. Using stratum as minimum geological unit by spatial frequency spectrum calculation, this study can directly make frequency spectrum synthesis calculation with different levels such as stratum combination, sedimentary facies combination and basin, so as to build geological spatial digital feature model, which can be used as a basis for quantitative analogy and extrapolation prediction in the northern sandstone uranium basin.
Keywords: *Geospatial big data, fusion analysis, big sample space scale, digital frequency spectrum, variation function*

Introduction

The geological space is the complex material accumulation body with mixed characteristics produced in the upper crust. The geoscience big data based on geological space has four characteristics: complexity, heterogeneity, periodicity and extensiveness. Processing analysis of geoscience big data belongs to complexly giant system. The scientific essence of geoscience big data research is to realize geological space abstraction through geological spatial distribution and variability exploration; to establish geoscience space model, and carry out geological process simulation, then implement geological space prediction and decision-making, which serves the two major geosciences needs of mineral resource prediction and geological hazard warning. Due to the particularity of the geological space, it brings more uncertainty and cannot fully (or very well) express geological entity information for space modeling of geological big data. The major theoretical and technical issues for complex analysis of geospatial big data include: discussion of multi-heterogeneity and synergy of geological big data, discussion of randomness and chaotic nature of geological space, science division of geological space, cross-fusion of geological big data, complex modeling,

DOI: http://dx.doi.org/10.15666/aeer/1704_79277941

spatial computing visualization, spatial prediction and spatial decision-making, etc. (Zhang and Zhou, 2017; Zhou et al., 2018, 2017).

Ordos continental uranium-bearing basin is giant accumulation area of uranium mining in north China, and Zhiluo formation in continental sedimentary construction is stratum combination with uranium-bearing specificity (Liu et al., 2013; Min et al., 2005; Jiao et al., 2016; Yang et al., 2015). Distribution variation of uranium mining space has a close relationship with sedimentary construction evolution, and borehole logging data is the important data set to reflect vertical lithology combination of the basin and the change of its physical properties; the logging data is divided into two types of direct uranium anomaly data and indirect associated data (Feng et al., 2016; Hao et al., 2015; Jiang et al., 2016; Liu et al., 2016; Yi et al., 2015). Application of logging data to depict digital features of uranium-bearing construction, which is not only very important for identifying change rule of uranium-bearing rock series of sedimentary facies and other sedimentary stratum combination, but also is important for identifying uranium-bearing characteristics of basin space (Ahmed and Arnous, 2015; Cai et al., 2015; Li et al., 2015; Luo et al., 2015). Therefore, the quantitative analysis of basin sedimentary facies, sedimentary construction, and uranium-bearing series is a hot and difficult problem for sandstone type uranium deposits assessment.

From the angle of geological analysis, basin sedimentary construction represents oxidation-reduction environment space of sedimentary environment and uranium element, and the smallest unit of sedimentary construction is stratum, different forms of stratum combination reflect overall characteristics of sedimentary facies and sedimentary construction, in general, geological information contained in these variation characteristics are drowned out by logging data (Guo and Xue, 2014; Wu, 2005; Zhao et al., 2015). Sometimes, it is impossible to directly extract uranium variation information from logging data, which objectively requires make systematic, comprehensive analysis about data structure and digital feature for logging data, and this is the objective of this study.

Uranium-bearing construction or lithofacies combination is constituted of different stratums. According to a certain space order relation, geologic body is constituted, and each stratum lithology has dependent and inheritance with overlying stratum, underlying stratum lithology in space, which in overall presents correlation and additivity (Li, 2012; Wang et al., 2014; Zhu, 2013). Therefore, digital feature model of basin sedimentary space should have structure and extensionality, and these are general principles which basin digital feature analysis should follow, which shows that analysis calculation of basin digital features depends on space order and logic recursive relationships of the construction, sedimentary facies, and uranium-bearing rock series.

Materials and methods

Every stratum geologic body in basin construction is deemed as independent monomer, and its thickness is L, logging data samples according to equal interval, so each stratum with different depth gets different number of samples, in special cases encryption interpolation processing for sample number of some stratum are made. Thereby a digital frequency spectrum model is established, the detailed process is as follows.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79277941

Sample capacity determination

The average depth of all boreholes in the Ordos basin is in the range of 500-700 m, the sampling interval in the logging is generally 5 cm, and interpolation processing can reach 1 cm. The number of logging samples for each borehole can reach at least 10000; logging parameters of each sample point respectively contain four items, which are natural gamma, caliper, density, and resistivity. These parameters also contain 25 lithology parameters, which are all nominal type geological data. According to sample matching scale analysis, four logging curves data have a unique representation under the target association significance of the uranium bearing could be informed. Therefore, four logging curves as main variable parameters were made, and radioactive r spectrum parameter was used as target variable, other three curve parameters as independent variables. First, causal relationship model between target variable and independent variables was established, and calculated independent weights of each variable under the condition with best curve fitting, and calculated correlation weight of target variable to satisfy the criterion of maximum correlation between independent variables combination and target variable. Next combination calculation for independent weights and correlation weight of each sample were made, and then obtained spatial scale value of the sample, thus formed the sample sequence.

The specific process was as follows:

Obtained borehole logging data matrix, and made the following translation transforms:

$$x_{ij} = \frac{x_{ij}^* - \boldsymbol{min}(x_{lj}^*)}{\sigma_j} \qquad 1 \le l \le n, \quad i = 1,2,\cdots,n, \quad j = 1,2,\cdots m \tag{Eq.1}$$

Here, x_{ij}^* was the original logging data, n was the sample size and constituted a computing matrix $X = (x_{ij})_{n\times m} = (X_1, X_2, \cdots, X_m)$, among $X_1, X_2, \cdots, X_m$ was the independent variables. In this study, $m = 3$; and target variable $Y = (Y_1, Y_2, \cdots, Y_n)'$.

The problem of this study was to compute independent weights of independent variable and correlation weight of target variable, so the following causal relationship model were established, as follows:

$$\begin{cases} y = b_0 + \sum_{j=1}^{m} b_j X_j \\ y = b_0 \, \boldsymbol{exp}[\sum_{j=1}^{m} b_j X_j] \\ y = b_0 \, \boldsymbol{exp}[\sum_{j=1}^{m} b_j X_j]^2 \end{cases} \tag{Eq.2}$$

In all above equations, least-squares solution or optimal simulation solution was strived, and chose most remarkable equation as regression equation, then calculated partial regression square sum of each independent variable: $V_j = \frac{b_j^2}{c_{jj}} \quad j = 1,2,\cdots,m$,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79277941

here, b_j was regression coefficients of remarkable regression equation, c_{jj} was main diagonal elements of inverse matrix of regression equation coefficient matrix, V_j would be defined as independent weights of corresponding variables X_j.

Considered the contribution of independent variables combination for target variable, correlation weight of target variable was calculated according to the following transformation: supposed constant α, β, and satisfied $\alpha + \beta = 1$, made:

$$q = \sum_{i=1}^{n} (\alpha y_i - \beta \sum_{j=1}^{m} V_j X_j)^2 \rightarrow \boldsymbol{min} \quad \text{(Eq.3)}$$

This meant that it had least fitting relationship between target variable and square for weighted residuals of independent variable combination, there had to be: $\frac{dq}{d\alpha} = 0$, and got:

$$\alpha = \frac{\sum_{j=1}^{m} V_j \overline{X_j}}{\overline{y} + \sum_{j=1}^{m} V_j \overline{X_j}} \quad \text{(Eq.4)}$$

Then defined sample space scale value of four logging curves were: $d_i = \alpha y_i + \beta \sum_{j=1}^{m} V_j \overline{X_j}$, $i = 1,2,\cdots n$ and gained spatial scaling sequence set: $D = (d_1, d_2, \cdots d_n)'$.

Samples spatial spectrum density calculation

For sample *D* sequence, according to the following process to calculate spatial spectral density of samples (Cui and Singh, 2016; Khalid et al., 2013; Lu and Liu, 2015; Ma et al., 2012; Mariotti et al., 2014; Silbert and Thomas, 2013), here had two cases:

Big sample scale sequence of individual geology body

Calculation procedure was as follows:

Supposed *D* sequence of a stratum sample scale as stable process, which had: $\{D(i), i \in R\}$.

Defined Fourier transform of $D(i)$ as spectral function, as follows:

$$F_D(\omega, I) = \int_{-I}^{I} D(i) e^{-j\omega i} di \quad \text{(Eq.5)}$$

Defined $S_D(\omega) = \boldsymbol{lim}_{I \to \infty} \frac{1}{2I} E\left\{ \left| F_D(\omega, I) \right|^2 \right\} < \infty$ as spatial spectral density of $D(i)$, this was distribution relationship of $D(i)$ about frequency ω ($\omega = 2\pi f$ is angular frequency).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79277941

Further defined autocorrelation function of $D(i)$ (Chen, 2009), there was:

$$\begin{aligned} R_D(i_1,i_2) &= E\left[D(i_1)D(i_2)\right] \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} D_1 D_2 f(D_1,D_2;i_1,i_2)dD_1 dD_2 \end{aligned} \quad \text{(Eq.6)}$$

This was autocorrelation function of $D(i)$, such as $D(i)$ is stable process, so $R_D(i_1,i_2)$ in unrelated to choice of location i_1 and i_2, only related to the size of $(i_2 - i_1)$. Supposed $i_2 - i_1 = \tau$, then autocorrelation function was represented as $R_D(\tau)$, therefore, which was also called as spatial variation function.

The relationship expression between spatial spectral density function $S_D(\omega)$ and spatial variation function $R_D(\tau)$:

$$\begin{cases} S_D(\omega) = \int_{-\infty}^{\infty} R_D(\tau)^{-j\omega\tau} d\tau \\ R_D(\tau) = \dfrac{1}{2\pi}\int_{-\infty}^{\infty} S_D(\omega)^{j\omega\tau} d\omega \end{cases} \quad \text{(Eq.7)}$$

Here, it meant that $S_D(\omega)$ and $R_D(\tau)$ were mutually Fourier inverse transform pair. $S_D(\omega)$ represented concentration degree index of space attribute set in the same geology body, which was domain function about frequency, this set was also called spectrum, and represented unique digital features of this geology body.

Big sample scale sequence of two geology bodies

Calculation procedure was as follows:

Above $D(i)$ sequence represented geology monomer, for scale sequence $D(i)$ and $H(i)$ of two geology bodies, cross-spectral density and cross-correlation function was calculated (Hotelling, 2012; Lei et al., 2011; Liang et al., 2011; Lv et al., 2011; Xie et al., 2011), this was:

$$S_{DH}(\omega) = \lim_{I\to\infty} \frac{1}{2I} E\left\{F_D(\omega,I)F_H(\omega,I)\right\} \quad \text{(Eq.8)}$$

Further there was:

$$S_{DH}(\omega) = \int_{-\infty}^{\infty} R_{DH}(\tau) e^{-j\omega\tau} d\tau \quad \text{(Eq.9)}$$

$$R_{DH}(\tau) = \frac{1}{2\pi}\int_{-\infty}^{\infty} S_{DH}(\omega) e^{j\omega\tau} d\omega \quad \text{(Eq.10)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79277941

It could be seen that these two were Fourier inverse transform pair. It should be pointed out that establishing of cross-spectral density and cross-correlation function should be carried out under the premise that two geology bodies should have spatial correlation.

Additive operation of big sample space spectrum density

When two or more than geology bodies need to make cumulative calculation of spectral density, the formula could be $Z = \bigcup_{i=1}^{p} D_i$, which expressed that P geology bodies superimposed. Therefore, combined spectral density after superimposing was $S_Z(\omega) = \sum_{i=1}^{p} S_{D_i}(\omega)$, and average variation function of the geology body after superimposing was $R_Z(\tau) = \int_{-\infty}^{\infty} S_z(\omega) e^{-j\omega\tau} d\tau$.

Synthesis calculation for stratum combination

It is well known, all substance has vibration frequency, but vibration frequency of irregular geology body such as geological space is unable to estimate, this study can only start from multiple observation data to estimate. In this sense, spatial frequency spectrum function is expressed as frequency domain function, which completely can satisfy superposition operation conditions, and it also has the function of transforming into spatial domain, so as to make variability analysis.

Stratum combination (construction, sedimentary facies and rock facies) analysis is an indispensable part for basin analysis. Spatial frequency spectrum of geology body belongs to non-dimensional measurement, which can be made additive operation in the mathematical sense. Spatial frequency spectrum of different geology bodies exists the difference in the magnitude and structure. Oxidation, oxidation and reduction, boundary classification of reduction space for basin uranium involves synthesis calculations problem of spatial frequency spectrum, therefore according to the different levels of stratum combination to make synthesis calculations of spatial frequency spectrum, and constitute the whole content for digital features analysis of stratum, sedimentary facies, sedimentary formation and even the whole basin.

About superposition conditions of stratum, apart from according to geological methods such as sedimentary facies analysis, etc., also judge from the cross-correlation function and cross-spectral density function defined by this study. Generally, higher cross-correlation function in two stratums can be considered to make spectrum synthetically calculation. Cross-correlation function can also be used as the basis for three-division space.

Results

Background

Logging data of ZKA-7 borehole in the A exploration line of Daying uranium area in Ordos basin is used in this study, the distribution of boreholes in the A exploration line is shown in *Figure 1*. Then trial calculation based on above models was make, the result is as follows.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79277941

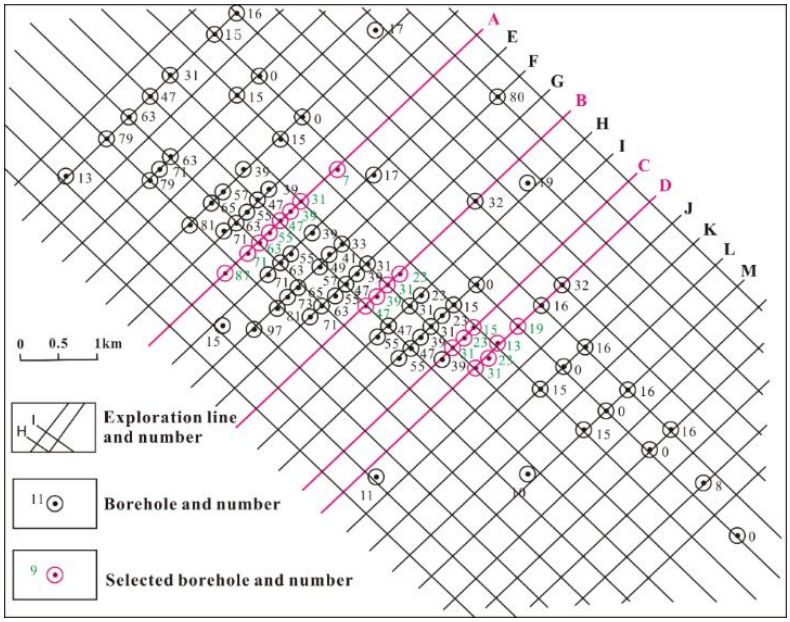

Figure 1. *Boreholes distribution in the A exploration line*

Spectrum density curves and spatial variation curves of each section interval for ZKA-7 borehole in the A exploration line are shown in *Figures 2* and *3*; 20-716 m variation comprehensive curve is shown in *Figure 4*. It should be noted that the depth markings on the figure do not correspond to the exact location, and it represents only the general characteristics of some section interval.

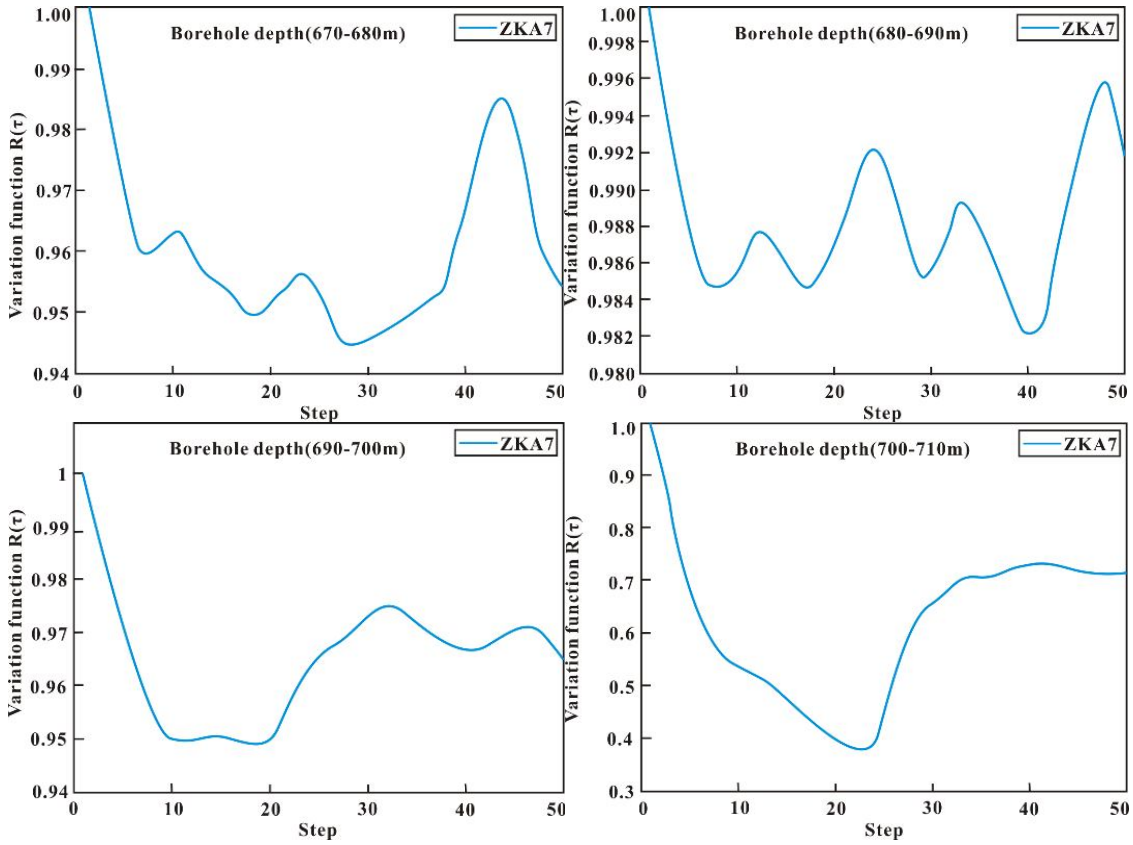

Figure 3. *Variation curves of A drill for 630-710 m*

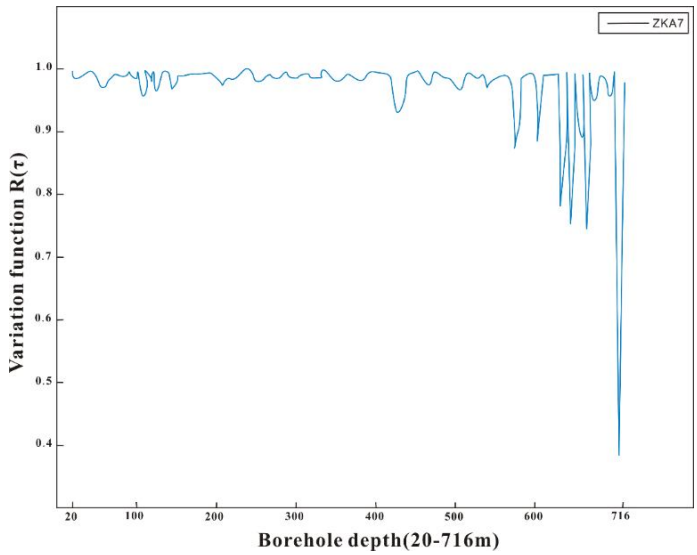

Figure 4. *Comprehensive variation curve for ZKA-7 borehole (20-716 m)*

In order to express the distribution of variation function $R_x(\tau_n)$ of all boreholes in A exploration line, specifically it will synthesize all variation curves of all boreholes in A exploration line, and finally generate variation comprehensive curve of the whole borehole, as shown in *Figure 5*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79277941

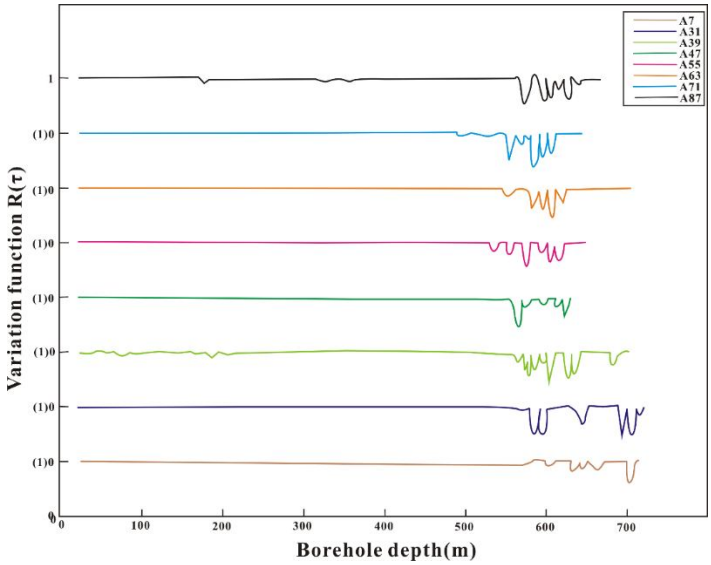

Figure 5. *Comprehensive variation curves for 8 boreholes in A exploration line*

In order to express the variation characteristics of lithologic assemblages of different strata at different depths, according to the statistical calculation of A borehole, 50 m is used as the interval standard, and the spatial spectrum density value of each section and the corresponding spatial variation value are calculated respectively. This part focuses on the section of 630-710 m with gamma anomaly characteristic.

Discussion

The spatial spectrum density curves represent the aggregate degree of the uranium mineralization factor (attribute set) combined by four parameters in the unit space measure (depth distance), which reflects the comprehensive intensity index of regional uranium mineralization, and call as generalized spatial attribute density (hereinafter referred to as density). This kind of parameters combination indicates a measure of the comprehensive information, which is more comprehensive than traditionally measured by single natural gamma or quantitative gamma, and the identified information is more reliable.

Due to the imbalance of geological actions in the region, resulting in the imbalance of comprehensive strength index or density distribution for the uranium mineralization, so the spatial distribution sometimes shows singularity characteristics, which is so-called anomaly phenomenon. The singularity characteristics or anomaly phenomenon is an important research content for spatial data distribution, and its scientific nature reflects the intensity change of geology action caused by regional environment, such as: magma intrusion with heat source intrude into the region is selective, so mineralization enrichment of the polymetallic elements formed during the process of magma emplacement is imbalanced.

From *Figure 2* it can be seen that distribution state of uranium mineralization factor density. Spectrum density curves of uranium mineralization factor for logging data about the entire borehole shows that the oscillation form, but oscillation frequency and density amplitude (ie, amplitude value, which is the corresponding function value) are different as different depth. Each spectrum density curve shows the frequency closer to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79277941

0 points, the greater the marginal density, where the marginal density can also be identified as the maximum density distribution of this section, and with the frequency increases, the density gradually decay, which is the unique characteristics of the model algorithm.

From the view of section, the amplitude of the spectrum curves for the 65 sections (20-630 m, 670-700 m and 710-716 m) in the calculation is smaller, usually fluctuates between 0.01 ~0.35, and the features of density variation is not obvious, and the scale average in these sections is also lower, as shown in *Table 1* and *Figure 4*. But the amplitude for the five sections (630-670 m, 700-710 m) is larger, fluctuates between 0.7 and 9, as the frequency changes with same interval, the change of the density is also larger, and original scale average for these sections is also higher (*Table 1*). The comparison shows: the amplitude of the spectrum curves, original scale average for these five sections are significantly higher than other 66 sections of the ZKA-7 borehole. This can be understood as that in areas where the density is high, the density changes significantly and original scale average is also high, the comprehensive intensity of uranium mineralization is stronger. It is shown that these uranium combinations under the conditions of the redox environment achieve the best state, very conducive to precipitation mineralization for uranium element.

On the other hand, it can be seen from the variation curves of different sections for ZKA-7 borehole, these curves can be divided into four categories: (1) the spatial variance with less fluctuates and high original scale; (2) the spatial variance with less fluctuates and low original scale; (3) the spatial variance with greatly fluctuates and high original scale; (4) the spatial variance with greatly fluctuates and low original scale.

The curves of these 66 sections (20-630 m, 650-660 m, 670-700 m, 710-716 m) in the ZKA-7 borehole belong to (2) and (4) categories, the internal variation has no big difference. Variability is more balanced with 10% fluctuations, which indicates that the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79277941

distribution for the uranium mineralization scale is more uniform, and the original scale average of these sections are relatively low.

The curves of these 4 sections (630-650 m, 660-670 m, 700 m) belong to (1) and (3) categories, the internal variation has big difference. Variability has abrupt changes with 60% fluctuations, which indicates that the distribution of uranium mineralization scale is not balanced, and original scale average of these sections is relatively high, which means that there are anomalies in the sections with such features.

The anomaly sections of the spectrum density curves and the variation curves corresponds to the location of the mineralization body of known geological exploration profile. It can be found that the mineralization anomalies also present in these anomaly sections, and there are distribution signs of metallogenic belt.

It can be seen from *Figure 5,* abrupt variability usually occurs in the lower section of Zhiluo Formation. According to the size of the original scale value, it can be judged that abrupt sections present strong uranium mineralization information, which indicates that these sections may be gathering zone of uranium mineralization. In order to better verify this explanation, according to the comprehensive distribution characteristics of the spatial variation curves of all boreholes, the anomaly area of A exploration profile was determined, that is, mineralized anomaly area. The determination area is aligned with the mineralized body location map of the known geological profile, as shown in *Figure 6*. It can be found that the mineralization anomaly region determined by the spatial variation characteristics has relatively better coincidence with the known mineralization zone. So, this determining method can be used as an attempt to determine mineralization anomaly.

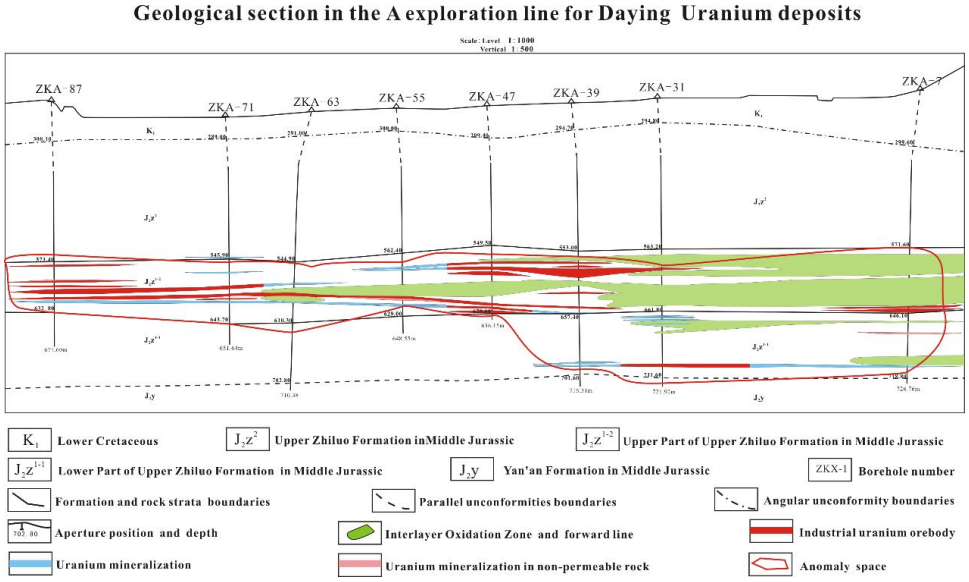

Figure 6. *Mineralization anomaly region delineated by the spatial variation characteristics*

Conclusion

The digital spectrum analysis of borehole logging data in Ordos Basin is essentially the fusion analysis of multivariate logging big data. The spatial spectrum density reflects the generalized density of geological elements set, which represents spatial concentration energy intensity of the geological properties. The spatial variation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79277941

function reflects the spatial variation trend of geological element set or uranium mineralization factor. From the digital point of view, these two indicators (spatial spectrum density and spatial variation function) describe the spatial distribution and variation characteristics of the uranium mineralization combination and even mineralization anomalies, which provides a quantitative basis for determining the mineralization anomalies by using the digital features of the geology body

Through the case analysis, it is known that the size of density amplitude and the intensity of density change for the spectrum curves reflect the impact intensity of comprehensive indicators of the geology action. In the case of a larger original scale average, it presents that density amplitude is larger, simultaneously, the zone with greater fluctuations indicates that the comprehensive intensity of uranium mineralization is stronger, and such sections are easy to gather uranium element to achieve the best condition, which is favorable for uranium precipitation mineralization.

The features of spatial variation curves reflect spatial variation degree of the mineralization combined information. The larger original scale average, the greater fluctuations degree and the sections with abrupt change mean that there is a stronger uranium mineralization anomaly information, which indicates that these sections are favorable for forming the uranium mineralization zone, then to determine the spatial range of ore-bearing for A exploration profile. In the four categories of variance curves recognition, (1) and (3) categories indicate the mineralization section, where (3) categories indicates greater significance.

The better coincidence between the mineralization body location map and the mineralization anomaly area determined by the features of spatial spectrum density and variation curves shows that the digital spectrum calculation based on fusion analysis of multiple logging curves can be used as the effective and tentative method for identifying determination anomaly information.

Because data science system is uncertain and the constituent components are unknown, this study only uses known data to describe the unknown information, and uses the correlation between the data to construct the information identification method. This is also the limitation of this study. In order to better improve the limitations, this study can replace the most basic transform method with others, and make the tests. Then it also encrypts the multi-dimensional data density to improve the accuracy and make the result information more refined. The construction of this study belongs to the accurate prediction of the behavior or state of the natural science system. Now, it has been applied in the accurate prediction of geological mineralization, and will develop in the direction of precision medical evaluation and ecological critical identification in the future, this is also the future direction for this study.

Abstract. A simple and rapid method based on ionic liquid liquid-liquid microextraction with room temperature ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate ([BMIM][PF_6]) coupled to electrothermal atomic absorption spectrometry (ETAAS) was developed for the speciation of arsenite (As(V))/ arsenate (As(III)) in environmental samples. In this method, As(V) can be extracted by [BMIM][PF_6] at pH 6.5 due to the formation of a hydrophobic complex, whereas As(III) remains in the aqueous solution. The As(V) and As(III) concentration were analyzed by ETAAS respectively. Various factors including pH, volume of [BMIM][PF_6], equilibrium temperature and time, effect of salt by single factor experiment design and orthogonal experimental design. Under the optimized conditions, the limits of detection (3σ) were 0.04 ng/mL and 0.35 ng/mL for As(V) and As(III), and its relative standard deviations was 3.5% and 2.9% respectively (n = 9, c = 20.00 ng/mL). The proposed procedure was applied without any chelating agent or dispersive agent. The method was validated against the certified reference materials (GBW08666), and successfully applied to determine As(V) and As(III) in real environmental samples.

Keywords: *As(V), As(III), ionic liquid, liquid-liquid microextraction, 1-butyl-3-methylimidazolium hexafluorophosphate, atomic absorption spectrometry, orthogonal experiment design, single factor optimization method*

Introduction

Arsenic is an abundant and high toxic element in the natural. The sources of arsenic can be divided into natural and man-made sources. The former is mainly arsenic in geological rocks, which is determined by the arsenic content in the soil, and the latter comes mainly from pesticides, fertilizers and mining smelters, such as lead arsenate and calcium arsenate, which are used to control insect pests of fruit trees or cottons; zinc methylarsonate used to control rice sheath blight, arsenic in medicament present in dentistry, used to kill nerve. Arsenic containing waste water, waste gas and waste residue were carried into the environment and raised environmental pollution, this pollution must be controlled by human beings. An important step in controlling this pollution is the determination of arsenic, and this involves the determination of arsenic speciation. Arsenic is divided into inorganic arsenic and organic arsenic, and their toxicity is very different. Inorganic arsenic and organic arsenic species have different toxicological behavior and biochemical activity. The As(III) is 10 times greater toxicity than As(V), and also seven times than methyl arsenate (MMA) and dimethyl arsenate (DMA) (Squibb et al., 1983). Many countries and regions have therefore established the maximum allowable limits of arsenic and its compounds in drinking water (United States Environmental Protection Agency, 2002; Ministry of Public Health of the People's Republic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79437955

of China, 2007). Arsenic speciation is of more significant than total arsenic determination for evaluating their toxicity on human beings, as well as monitoring environmental pollution.

The direct determination of arsenic species at very low concentrations is always an impossible task due to the insufficient sensitivity of method, as well as the complicated matrix interferences occurring in samples. Generally, a preliminary separation and preconcentration step is often required for this reason. Numerous separation/analysis methods with primary separation steps for the speciation of As(V) and As(III) have been proposed, such as high-performance liquid chromatography and inductively coupled plasma mass spectrometry (Li et al., 2017), flow injection analysis and chemiluminescence detection (FIA-CD) (Nellaiappan et al., 2018), solid phase extraction electrothermal atomic absorption spectrometry/atomic fluorescence spectrometry (SPE-ETAAS) (Tunçeli et al., 2015; Abdolmohammad-Zadeh et al., 2013; Pourghazi et al., 2015), liquid–liquid microextraction-electrothermal atomic absorption spectrometry (LLME-ETAAS) (Wang et al., 2018). LLME is one of the efficient techniques to separate and concentrate metal ions, our research team has developed this method for the determination of many metals (Wen et al., 2013, 2014; Wen and Zhu, 2014). There are many advantages for LLME, such as easy operation, fewer solvents and rapidness. However, the method involves the use of organic solvents which generally are toxic and hazardous to organisms and environment.

Ionic liquids (ILs) were deemed as new green solvents (Wen et al., 2014), they seem very promising replacements for the traditional volatile organic solvents in the sample preparation. The ionic liquid liquid-liquid microextraction (IL-LLME) has received considerable attention for its convenience and simplicity compared with traditional liquid-liquid extraction, including lower cost, higher enrichment factor, and lower consumption of toxic organic solvent (Stanisz et al., 2014). 1-butyl-3-methylimidazolium hexafluorophosphate ([BMIM][PF_6])-based microextration procedures were proved to be environmentally friendly and efficient for the preconcentration of heavy metal ions in biological and environmental samples (Arain et al., 2016; Sha et al., 2014). However, the application of [BMIM]PF_6] for the speciation of As(V) and As(III) based on IL-LLME has not been explored so far.

In this work, [BMIM][PF_6] was synthesized, and used to extract/separate inorganic arsenic. As(V) was extracted by ionic liquid directly, while As(III) remains in aqueous phase at pH 6.5, then, a new method for the determination of arsenic by LLME-ETAAS was established. The new method is simple to operate. The proposed procedure does not need any chelating agent, and it also does not require any dispersants, reduce the harm to environment in preliminary separation/preconcentration step obviously. All parameters are optimized by single factor experiment design; furthermore, the orthogonal experiment design is used to optimize the conditions based on the above results. Under the optimized experimental conditions, the developed method was applied for the determination of As(V)/As(III) of different samples with satisfactory results.

Experimental

Instrumentation and reagents

Instrumentation

A ZEEnit 700 electrothermal atomic absorption spectrometer (Analytik Jena Instrument Co., Ltd., Germany) equipped with a arsenic hollow cathode lamp, and a Zeeman-based background corrector were used for arsenic determination. The instrumental settings are listed as follows, wavelength: 193.7 nm, spectrum bandwidth:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79437955

0.8 nm, lamp current: 6.0 mA, matrix modifier: 0.1% $Pd(NO_3)_2$. All the absorbance measurements were performed by integrating peak areas. Operating parameters and electrothermal temperature program for arsenic determination were given in *Table 1*. Fourier transform infrared (FTIR) spectra were recorded by a TENSOR-27 Fourier transform infrared spectrophotometer (Bruker Corporation, Germany). A mode TDL80-2B centrifuge (Shanghai Anting Science Instrument Factory, Shanghai, China) was used to blend the mixture. pH measurements were made with a PHS-25B pH meter (Shanghai Precision & Scientific Instrument Co., Ltd., Shanghai, China) using a combined glass electrode. A digital constant temperature water-bath (Guohua Co., Ltd., China) was used to heat the mixture. Vacuum was achieved by a 2K-82B vacuum drying oven (Yichuan, Co., Ltd., China).

Table 1. *Instrumental conditions for arsenic species determination*

Step	Temperature (°C)	Heating rate (°C/S)	Hold time (S)	Argon flow rate (mL/min)
Drying 1	90	5	20	250
Drying2	110	2	20	250
Pyrolysis	300	250	10	250
Atomization	2100	3000	4	-
Cleaning	2200	500	4	250

Reagents

1-Bromohexane, N-methylimidazole, As(III) stock standard solution (1.00 g/L) was prepared by dissolving 0.1320 g dried As_2O_3 in 2.0 mL of 1.0 mmol/mL NaOH solution and adjusting the pH to 7.0 with 0.5 mol/L HCl. As(V) stock standard solution (1.00 mg/mL) was prepared by sodium arsenate. Working standard solutions were prepared by stepwise diluting the stock solutions just before use. N-Butylimidazole (98%, Shanghai Darui Fine Chemical Reagent Co., Ltd., Shanghai, China), KPF_6 (Aladdin Chemical Reagent Co., Ltd., Los Angeles, USA) and 1-bromobutane were used. Buffer solutions of acetic acid sodium-acetate (0.2 mol/L), polyethylene oxide pyridine, glycerol. A certified reference material for arsenic (V) GBW08666 was supplied by Research Center for Eco-Environmental Science, Chinese Academy of Sciences (Beijing, China). All chemicals and reagents used were of analytical reagent grade or higher purity and purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China) unless otherwise specified. Deionized water used throughout entire work.

River water sample: The river water sample near Yangzhou Thermal Power Plant was collected to study the circulation of inorganic arsenic, the river water sample was filtrated and diluted 10 times prior to detect.

Air sample: For the same reason as above, air sample was collected near Yangzhou Thermal Power Plant. 10 g polyethylene oxide pyridine was added into 10 mL glycerol, then mixed with 100 mL water, neutral filter paper was immersed in the mixture solution for 6 h, then the filter paper was dried under infrared light and packed into a sampler to collect 15.0 m^3 gas with the flow rate of 60 L/min. After the sampling, the filter paper was shredded and put into a 100 mL beaker. Instead of adding such as nitric acid to digest sample for the determination of total arsenic, only 20 mL water was added

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79437955

to the beaker in this word in order to prevent V(III) from being oxidized to As(V), then stirring violently for 10 min. The sample solution was filtered with quantitative filter paper, the filtrate was fixed to 100 mL. Finally, 1.0 mL solution was put it in a 100 ml volume bottle, then set the volume to scale, which was used for the determination of water-soluble inorganic arsenic. It must be pointed out that in the actual sample determination in this experiment the result of air sample determination refers to the concentration of arsenic in the 100 mL volumetric flask, not the concentration of arsenic in the air.

Soil sample: Soil sample collected was near Yangzhou Thermal Power Plant too. 20 mL water was added to 0.5 g soil sample, then the mixture was stirred violently for 10 min. After filter, the filtrate was moved into 100 mL volumetric flask, the solution was diluted 1000 times prior to detect. Similarly, in the actual sample determination in this experiment, the result of soil sample is that the data was diluted 1000 times, not the concentration of arsenic in the soil sample.

Procedure

Synthesis of IL (Huddleston et al., 2001)

1-Butyl-3-methylimidazolium chloride was prepared by reaction of equal molar amounts of 1-methylimidazole and chlorobutane in a round-bottomed flask fitted with a reflux condenser by heating and stirring at 70 °C for 48–72 h. The resulting viscous liquid was allowed to cool to room temperature and then was washed three times with 200 mL portions of ethyl acetate. The remaining ethyl acetate was removed by heating to 70 °C under vacuum. To prepare the ionic liquid, hexa-fluorophosphoric acid (1.3 mol) was added (slowly to prevent the temperature from rising significantly) to a mixture of 1-butyl-3-methylimi-dazolium chloride (1.0 mol) in 500 mL of water. After stirring for 12 h, the upper acidic aqueous layer was decanted, the lower ionic liquid portion was washed with water until the washings were no longer acidic. The ionic liquid was then heated under vacuum at 70 °C to remove excess water. The product was verified by IR spectrum, the results are in agreement with references.

Extraction procedure

A 0.30 mL [BMIM][PF_6] with 1.0 mL arsenic sample solution was added into a 5 mL glass marked centrifuge tube, and added 1.0 mL acetate/acetic acid buffer, and then diluted to 5 mL with deionized water. For optimization procedures, 20 ug/mL As(V) was used instead of water sample. The tube was first shaken violently, and then the mixture was heated in a water bath for obtaining a dispersion of the ionic liquid into the aqueous media. Finally, the tube was centrifuged at 4000 r/min, then the formation of two well-defined phases was achieved. The aqueous phase were manually removed to analysis the concentration As(III) by ETAAS, and the viscous ionic liquid phase was dissolved in 0.40 mL of methanol prior to ETAAS measurement.

Results and discussion

In the research, the optimization method of single factor experiment design is first used to optimize the experimental conditions, and on the basis of the optimization conditions of the single factor experiment method, the cross-effect of each factor is

DOI: http://dx.doi.org/10.15666/aeer/1704_79437955

considered comprehensively. Then, the experimental conditions was optimized by orthogonal experiment design.

Optimization of experimental parameters by single factor optimization method

Effect of pH

The effect of pH on the extraction efficiency of As(V) and As(III) was investigated separately over the pH range of 4.0–11.0. The results presented in *Figure 1* indicate that the quantitative recovery (>92.0%) of As(V) was achieved at a pH range of 4.0 to 7.0, while the extraction rate of As(III) was less than 7.0%. The reason for the selective extraction of As(V) maybe explained that As(V) was associated with positive ion of [BMIM][PF_6] by electrostatic interaction to form a hydrophobic complex compound, leading to the quantitative recovery of As(V).

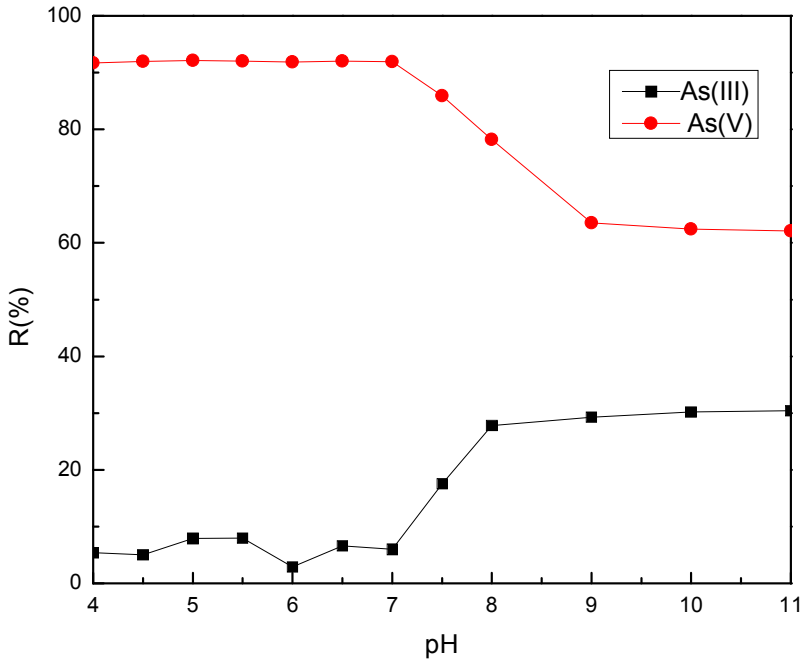

Figure 1. *Effect of pH*

As(V) and As(III) exist in both molecular and ionic forms depending on the pH value of the solution. The stability and speciation of inorganic arsenic compounds depend on pH of solution, as presented in *Figure 2* (Sullivan et al., 2010). In the range of pH 4.0-7.0, As(V) mainly exists as $H_2AsO_4^-$, which can be easily reacted with positive ion of [BMIM][PF_6] to form a stable compound:

$$C_6H_{11}N_2^+.PF_6^- + H_2AsO_4^- \rightarrow C_6H_{11}N_2^+.H_2AsO_4^- + PF_6^-$$

Therefore, the higher recovery rate of As(V) was obtained when pH ≤ 7.0.

However, As(III) tends to be as a neutral molecule(H_3AsO_3) when pH ≤ 7.0, it can not combine with the cation of [BMIM][PF_6], decreasing the recovery of As(III).

In order to selectively determine As(V) and avoid the interference of As(III), the pH 6.0 was chosen in the rest of the work.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79437955

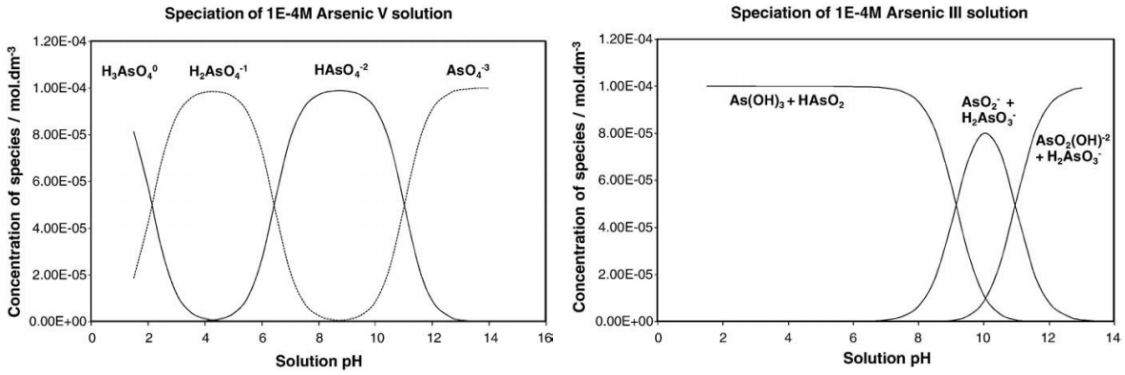

Figure 2. *Stability and speciation of arsenic compounds*

Effect of volume of [BMIM]PF$_6$]

Different volumes of [BMIM]PF$_6$] were investigated, and the results were shown in *Figure 3*. For As(V), the recovery rate increased with the increase of [BMIM]PF$_6$] amount from 0.1 mL to 0.3 mL, and the maximum recovery was obtained when the volume of [BMIM]PF$_6$] was 0.3 mL, whereas the recovery of As(III) was less than 7%. A 0.3 mL of [BMIM]PF$_6$] was selected.

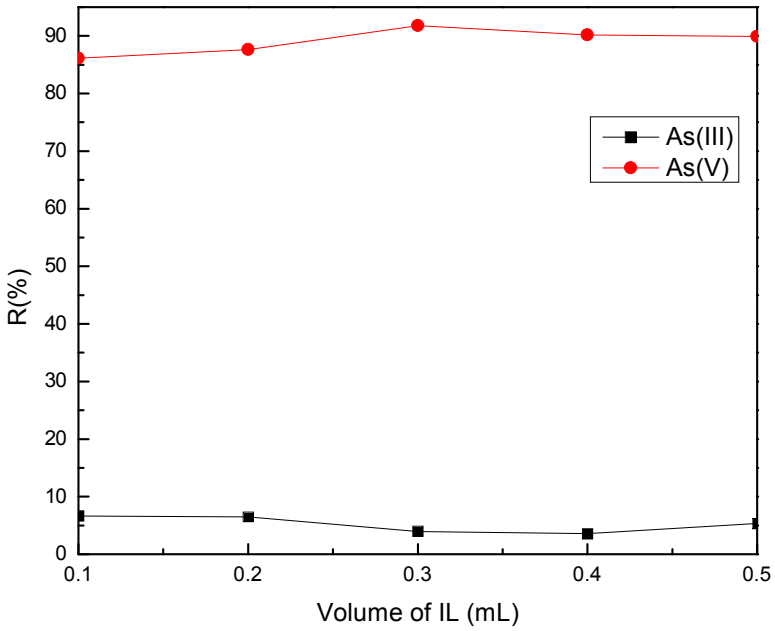

Figure 3. *Effect of the volume of [BMIM]PF$_6$]*

Effect of salt

The effect of salt was investigated with NaCl concentration ranging from 0 to 15% (W/V). As shown in *Figure 4,* the recovery ratio of As(V) decreased tardily with the addition of salts concentration, for the solubility of As(V) was increased with salts addition, as a result, the extraction ration decreased lightly when salts was added. Thus, salt addition was not adopted for further experiments.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79437955

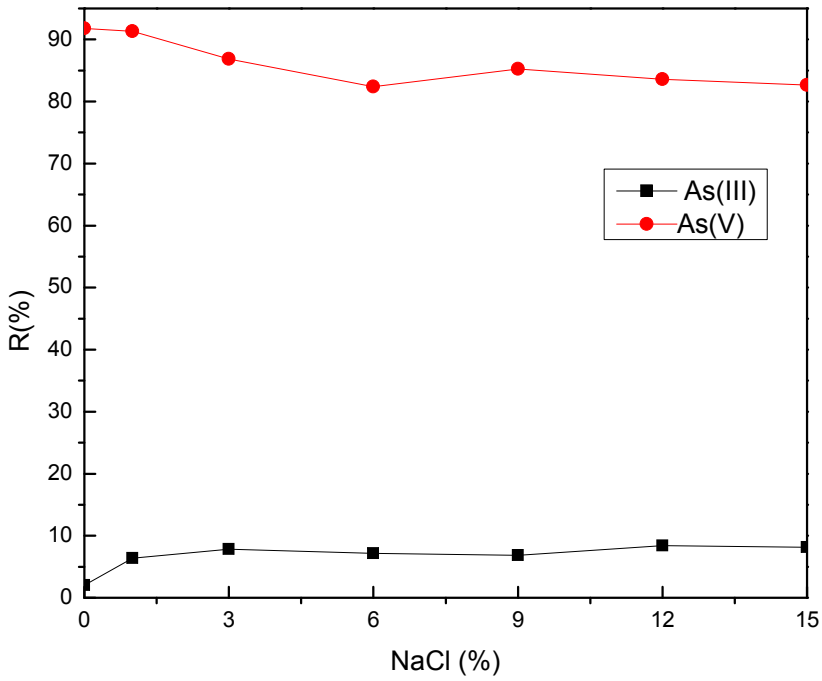

Figure 4. *Effect of salt*

Effect of extraction temperature

The effect of extraction temperature was examined in the range of 15-65 °C, as shown in *Figure 5*. Recovery ratio of As(V) was maximum at 45 °C; so 45 °C was selected.

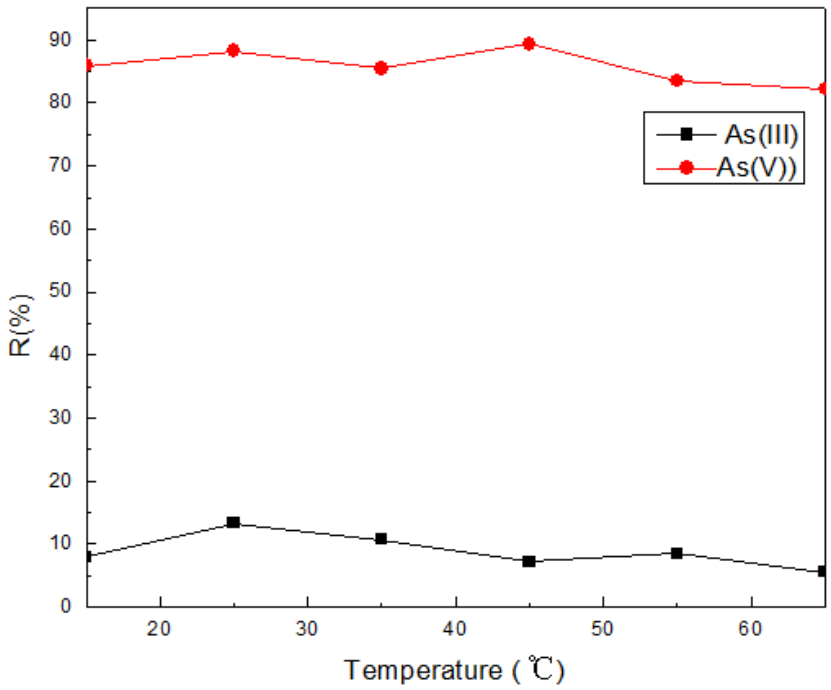

Figure 5. *Effect of temperature*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79437955

Effect of extraction time

The influence of extraction time was investigated in the range from 5 to 30 min. *Figure 6* shows that 20 min was sufficient for the quantitative extraction (90%) of As(V), while the extraction efficiency of As(III) was very low (below 10%) in the tested time range. Thus, the extraction time of 20 min was used.

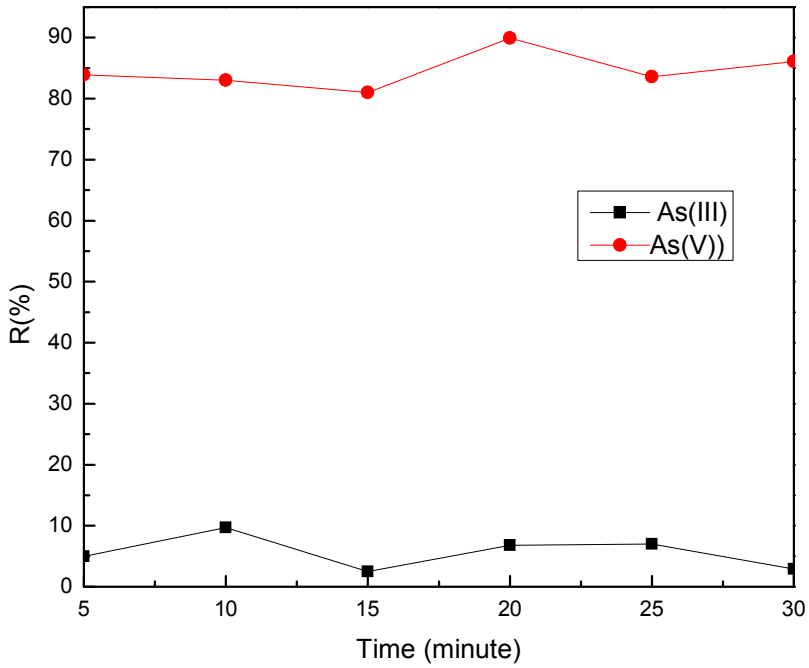

Figure 6. *Effect of the time of extraction*

Optimization of adsorption parameters by orthogonal experiment design

It is simple to use the single factor experiment method when optimizing the experimental conditions, but it must be assumed that the method can only be used when there is no interference between factors. If there is a cross-effect between factors, the use of this method may lead to a wrong result. In fact, factors are less independent of each other. Therefore, on the basis of single factor experiment, the orthogonal design is used to optimize the extraction conditions in this study. For there is little effect of salt on the extraction process, the effect of salt is not taken into account in orthogonal design. Above and below the optimum experimental conditions obtained by single factor experiment method, the orthogonal experiment design is used to optimize the experimental parameters, details are shown in the *Table 2.*

As can be seen from *Table 2*, the importance of the factors that affect the extraction rate of As(V) is significantly different, the order of factors is (from large to small): pH > volume of [BMIM]PF_6 > extraction temperature > extraction time. For As(III), there is little difference in the range of factors affecting the extraction. In pursuit of an increase in the extraction rate of As(V), the selected experimental conditions are as follows, pH:6.5, volume of [BMIM]PF_6: 0.5 mL, extraction temperature is 35 °C, and extraction time is 20 min, under this condition, the extraction rate of As(V) is more than 92% with the extraction rate of As(III) is less than 7%.

Interference

Interference of As(III)

The interference between As(III) and As(V) was evaluated. The results showed that no remarkable influences were observed on the determination of As(V)/As(III) at the concentration ratio of As(III) to As(V) within 20-fold, the good recoveries have been obtained and the two species can be separated.

Interference of other metal ions

To evaluate the potential interference of other metal ions, different foreign metal ions were added individually to a series of standard working solution containing 20.00 ng/mLAs(V)/As(III). A variation on the recovery higher than ±5% was considered as interference. The tolerance limits (metal ion/As, w/w) of foreign ions on the determination of As(III)/As(V) were summarized as in *Table 3*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79437955

Table 3. *Effect of interfering ions of As*

Interferences ions	Tolerance ratio (w/w)

K^+, Na^+, Cu^{2+}, Ni^{2+}, SO_4^{2-}, NH_4^+	200

Performance of the method

The proposed method was evaluated under the optimum conditions described above. According to the International Union of Pure and Applied Chemistry definition, the detection limits (3σ) of this method was 0.04 ng/mL for As(V) and 0.53 ng/mL for As(III).The relative standard deviations for six replicates extractions at 20.00 ng/mL level of As(V) was 3.5%, and As(III) was 2.9%. The preconcentration factor was 12.5-fold for As(V), which was calculated as the volume ratio of the sample solution (5.00 mL) to the [BMIM][PF_6] phase after the dilution with methanol (0.40 mL).

Comparison of the present method with others

Comparing the analytical features of the method with other studies (*Table 4*), the results demonstrates that this method is superior in terms of LOD of As(V). It should be noted in particular that no chelating reagent has been added to this method and no organic reagent has been used in the whole extraction process. Compared with other methods, this is less harmful to the environment, greener, more economical, and more environmentally friendly.

LOD: limits of detection

Method application

To validate the accuracy and precision of the proposed method, arsenic species were analyzed in a certified reference material for GBW08666. The results in *Table 3* shows that almost no As(III) was detected in the reference GBW08666, and the content of As(V) was in good agreement with the certified value of 14.39 ng/mL. Furthermore, the recovery results for As(V)/As(III) in the reference were in the range of 93.4–104.4%. That could be concluded that the method was feasible and accurate for the determination of As(V)/As(III) species.

DOI: http://dx.doi.org/10.15666/aeer/1704_79437955

The method was also applied to the determination of As(V)/As(III) in three kinds of samples. The results and the recovery for the spiked samples are given in *Table 5*. The As(V) extraction rate of standard addition is between 96.5% and 106.4% in the detection of various practical sample, while As(III) is between 97.2% and 106.8%.

Conclusion

In this paper, hydrophobic ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate was synthesized to extract and separate iAs species, The experimental conditions were optimized by single factor experiment and orthogonal design method. The whole process was carried out without any chelating/dispersive agent. The method sees to be simple, sensitive, and efficient. With the proposed procedures, satisfactory results of iAs species in different samples were obtained. The proposed method is recommended for iAs determinations in environmental samples.

Abstract. Contaminants from various anthropogenic activities such as agriculture, mining, and recreation negatively affect wetland water quality and vegetation health and composition. Phytoremediation is an effective, sustainable and eco-friendly pollution abatement method using green plants. *Arundo donax* L. and *Phragmites australis* (Cav.) Trin. ex Steud. are two morphologically similar reeds commonly used for phytoremediation in wetlands of South Africa. *Arundo donax* is however, a declared category '1b' weed under the National Environmental Management: Biodiversity Act (NEM:BA, Act No. 10 of 2004), requiring its immediate removal. Thus, determining the phytoremediation efficiency of the two reeds could help making the right choice between them for potential use in wetlands. Furthermore, the effeciency of wetlands depends on a robust monitoring system for phytoremediating plants to determine the appropriate time for biomass harvest before they die and release contaminants taken up in plant tissues back into the source through decomposition. Remote sensing can be used for mapping and monitoring of such aquatic macrophytes at species level effectively. Satellites imageries with high spatial and spectral resolutions not only are capable of detecting heavy metal-induced plant stresses, but also can effectively discriminate between morphologically similar species like *A. donax* and *P. Australis* and facilitate wetland managment.

Introduction

Phytoremediation is a relatively low-cost and environmentally friendly method of reducing environmental pollutants to harmless levels using green plants (Emmanuel et al., 2014; Kaewtubtim et al., 2016; Newete and Byrne, 2016). Based on the plant tissues involved in removal of pollutants and their specific sites of accumulation in the plants, phytoremediation is sub-categorized as phytoextraction, rhizofiltration, phytovolotalization, phytostabilization, phytodegradation, and rhizodegradation (Pilon-Smits, 2005; Newete and Byrne, 2016). Phytostabilisation refers to the process of plants stabilising pollutants in the soil to harmless levels; phytoextraction is when pollutants are transported and concentrated in the above ground plant tissues and involves subsequent harvest of aerial plant biomass; rhizofiltration is when plants, or

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79577972

microorganisms associated with the rhizosphere, remove contaminants from water; phytodegradation occurs when plant enzymes break down pollutants inside their tissues and convert them into harmless compounds; phytovolatilisation involves extraction of volatile compounds by plants which are released as volatile compounds through the leaves (Raskin, 1997; Wong, 2003). Phytoremediation can occur in both dry and wet environments. Phytoextraction is commonly used for cleaning contaminants from soil, rhizofiltration to clean contaminants from water medium, while phytostabilization, phytovolatilization and phytodegradation can be used to clean either from soil or water mediums (Frick et al., 1999; Wong, 2003; Yang et al., 2005). The degree of pollutant accumulation by plants tends to increase with the wetness of the environment (Aryal et al., 2016). Compared to conventional or engineering methods of cleaning polluted environments, phytoremediation is potentially cheaper, environmentally friendly, sustainable, and has the possibility of bio-recovering heavy metals (Yang et al., 2005).

According to Ramsar Convention Secretariat (2016) wetlands are "areas of marsh, fen, peatland or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish or salt, including areas of marine water the depth of which at low tide does not exceed six metres". Wetlands are essential to both humans and the ecological environment, and once their health and functions are disturbed, the effects are detrimental on all life forms supported by wetlands. Their functions include nutrient removal from water, trapping of sediments, pollutant trapping, control of erosion, stream flow augmentation, provision of habitat for wildlife, and recreational benefits (Bruneau, 2017; Luo et al., 2017). According to Zedler and Kercher (2004), wetlands account for approximately 6% of the world's land surface. Depending on their positioning, wetlands are subjected to impacts from human activities such as agriculture, mining and urban development. Impacts of mining on wetlands include water pollution from Acid Mine Drainage (AMD) and heavy metals, land degradation, vegetation biodiversity degradation, and destruction of a wide range of habitat for wetland wildlife (Gupta and Nikhil, 2016). From these, the major effect of mining activities on wetlands is AMD pollution, which emanates from seepage of both active and abandoned mining areas near wetlands (Newete and Byrne, 2016). Acid mine drainage is the outflow of acidic water from mining sites, and this is mainly due to the oxidation of iron pyrites (FeS_2) (Akcil and Koldas, 2006; Ochieng et al., 2010). Due to its low pH of usually 2 - 3, AMD dissolves mining ores, and thus contains, high concentrations of metals which include manganese, aluminum, iron, nickel, zinc, cobalt, copper, and cadmium (Bell et al., 2001; Coetzee et al., 2006). AMD pollution from wetlands can also end up in streams, rivers and dams, which supply potable water for humans (McCarthy and Humphries, 2013). This makes the water quality unsuitable for human consumption and adds a toll to the costs of water purification. Research has shown that low pH and high concentrations of heavy metals negatively affect wetland species composition (Ochieng et al., 2010). Destruction of wetland vegetation or alteration of vegetation composition will also affect wild animals which use the plants as habitats. However, some aquatic plant species have adapted mechanisms to survive in such conditions (Deng et al., 2004; Papazoglou et al., 2005; Vymazal and Březinová, 2015), thus, they can be used as bio-indicators to evaluate the presence and amount of heavy metal contaminants in wetlands. These plants have an extensive root system and root surface area that enhances contaminant uptake by adsorption of metal cations onto the negatively charged root surfaces (Newete et al., 2016; Newete and Byrne, 2016). The subsequent harvest of the phytoremediating plants with a cocktail of organic and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79577972

inorganic contaminants from polluted wetlands means an improvement of the existing water quality. Thus, many artificial wetlands are constructed for treatment of wastewater using green plants (Liu et al., 2007; Vymazal and Březinová, 2015). Among the common emergent macropytes used in wetlands are *Phragmites australis* (Cav.) Trin. ex Steud. (Vymazal and Brezinova, 2016), *Arundo donax* L. (Elhawat et al., 2014), *Phalaris arundinacea Scirpus* spp. and *Typha* spp. (Papazoglou et al., 2005; Newete and Byrne, 2016). From these, *P. australis* is the most commonly used and studied plant species (Vymazal and Brezinova, 2016). This could be because it is a cosmopolitan plant species which is widely distributed across the world (Adams and Bate, 1999). *Arundo donax* L., which is morphologically similar to *P. australis*, is another such species with wide geographical distribution in many polluted wetland systems of South Africa outside its natural habitat (Rouget et al., 2004). *Phragmites australis* also known as common reed, is native to South Africa (Adams and Bate, 1999), while *A. donax*, known as the Spanish or the giant reed, is a declared Category 1b weed in South Africa (Henderson, 2001; Department of Environmental Affairs, 2016). Although the two reeds have proved to be effective as tools of phytoremediation in wetlands, their capacities to uptake heavy metals have not been compared under similar and controlled conditions.

Although the efficiency of metal uptake by phytoremediating plants depends on plant species, size of plant biomass particularly large root surface area in aquatic macrophytes, type and amount of elements targeted for removal (Newete and Byrne, 2016), it is equally important to monitor the level of such pollutants' removal from the polluted environment and accumulation in the plant tissues. This is because it allows subsequent management of the phytoremediating plants by determining the appropriate time for harvest of plant biomass and safe disposal (Carson et al., 2018). The conventional method of determining metal accumulation in plant tissue in the laboratory is often expensive, destructive and labour intensive (Van Deventer and Cho, 2014). Thus, there is a need for effective and non-destructive method to monitor heavy metal uptake by various wetland plants. Remote sensing has the potential to be that method. This is because the spectral reflectance by green vegetation depends, *inter alia*, on the amount of specific biochemical in plant leaves (Gates et al., 1965; Zwiggelaar, 1998). Remote sensing has extensively been used to monitor the effect of individual metal pollutants on plants using their effects on chlorophyll and net photosynthesis (Sridhar et al., 2007).

There is a large number of literature reviews on phytoremediation (Raskin et al., 1997; Pilon-Smits, 2005; Laghlimi et al., 2015; Rizwan et al., 2017) and for wetlands (Matagi et al., 1998; Usharani and Vasudevan, 2016; Newete and Byrne, 2016; Leguizamo et al., 2017). However, only few of them focused on wetland phytoremediating plants. This study will therefore, review the efficiency of phytoremediation by emergent aquatic macrophytes in wetlands with specific reference to two morphologically similar reeds, *P. australis* and *A. donax*, in South Africa. It will also investigate the potential of remote sensing technique in monitoring heavy metal accumulation by the plants effectively.

Reeds in South Africa

Reed is the general botanical term used for tall, grass-like plants that grow in wet places. They occur in reed beds. They are all members of the order Poales, but under different families. *Table 1* gives a list of some of the commonly known reeds.

Table 1. *Some of commonly known reeds in the world*

Family	Reed's common name and species name
Poaceae grass	Common reed *(Phragmites australis (Cav.) Trin. ex Steud.*)
	Giant reed (*Arundo donax L.*)
	Burma reed (*Neyraudia reynaudiana*)
	Reed canary-grass (*Phalaris arundinacea*)
	Reed sweet-grass (*Glyceria maxima*)
	Small-reed (*Calamagrostis species*)
Cyperaceae (sedge)	Paper reed or papyrus (*Cyperus papyrus*)
Sparganiaceae	Bur-reed (*Sparganium species*)
Typhaceae	Reed-mace (*Typha species*)
Restionaceae	Cape thatching reed (*Elegia tectorum*)
	Thatching reed (*Thamnochortus insignis*)

From the list in *Table 1*, *Cyperus papyrus*, *A. donax*, *Calamagrostis* species, *P. australis* and *Typha* species were identified in wetlands of South Africa (De Villiers et al., 2011). *Cyperus papyrus* is a tall perennial grass-like emergent plant. It is naturally found in KwaZulu-Natal, Mpumalanga and Limpopo provinces. It grows along the edges of rivers, seasonal or permanent pools, or swamps. The reed is unpalatable and has low forage quality, and thus does not support many plantivores (De Villiers et al., 2011). *Calamagrostis* is a perennial grass which inhabits vleis and marshes. It is sparsely distributed in Eastern Cape, Mpumalanga, Gauteng, North West and Northern Cape provinces of South Africa (De Villiers et al., 2011). *Typha* species is widely distributed in South Africa and it grows in wetlands and all aquatic habitats (Masoko et al., 2008; Ilfergane, 2016). The species forms large dense and dominant stands. *Arundo donax* and *P. australis* are tall, robust and perennial grass-like plants with hollow stems, and are widely distributed in Western Cape, Eastern Cape, KwaZulu-Natal, Mpumalanga and Gauteng provinces of South Africa (De Villiers et al., 2011). Morphologically the two reeds resemble each other. They are both aggressive invaders outside their native ranges (Lambert et al., 2010). The slight differences between them are shown in *Table 2*, extracted from Lusweti (2011). Images for *A. donax* (*Fig. 1*) and *P. australis* (*Fig. 2*) in Johannesburg, South Africa, extracted from google earth, are also shown below.

Table 2. *Morphological differences between Phragmites australis (Cav.) Trin. ex Steud. and Arundo donax L.*

Arundo donax L.	***Phragmites australis (Cav.) Trin. ex Steud.***
Very tall grass, 2 – 7 m tall	relatively tall grass, 1.5 – 3m tall
Relatively broad leaves, 10 – 80 mm wide	relatively narrow leaves 10 – 35 mm wide

Arundo donax L. is native to the Mediterranean Basin and the middle east in Asia, and some parts of Africa and southern Arabian Peninsula, while *P. australis* is a cosmopolitan species with wide distribution spanning the five continents (excluding the polar continents) of the world, and it is also known as native to South Africa

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79577972

(Henderson and Cillier, 2004). *Arundo donax* L. is a naturalised alien species in South Africa (Milton, 2004), and was introduced in the late 1700s for soil erosion control. It invades riparian areas across South Africa and its spread is facilitated by human activities such as building of dams and soil stabilisation (Canavan et al., 2017). Alien invasive plant species have negative impacts on indigenous plant ecosystems. They form dense stands which reduce biodiversity of indigenous communities, affect food-webs, and hence change ecosystem processes (Milton, 2004). *Arundo donax* L. is highly flammable and can alter fire regimes in invaded areas, thus changing the communities of native plants into a dense mono stand of *A. donax* (Lusweti, 2011). To address the invasive potential and negative impacts of *A. donax* in South Africa, biological control methods are being considered (Canavan et al., 2017).

Figure 1. *Image of the giant reed (Arundo donax). Source: US Department of State Geographer, Google earth, 2018.*

Figure 2. *Image of the common reed (Phragmites australis). Source: US Department of State Geographer, Google earth, 2018.*

Both *A. donax* and *P. australis* can adapt well in both dry and damp or wet areas, as well as in heavily polluted areas. As such, they are common in most wetlands. Their dense stands often crowds or shade other wetland vegetation. Their ability to uptake and accumulate nutrients and other pollutants makes them the most suitable macrophytes for phytoremediation in polluted wetlands (Bonanno, 2012; Aminsharei et al., 2017; Bello et al., 2018). As such the two plants have been used for phytoremediation in constructed and natural wetlands.

Phytoremediation by aquatic plants

Wetland vegetation is an important part of the wetland ecosystem, as it plays a major role in environmental sustainability (Adam et al., 2010). Naturally wetlands are sinks for many contaminants, and as such they accumulate materials resulting from both terrestrial and wetland disturbances like sediments, nutrients, salts, heavy metals and other contaminants (Kaplan et al., 2017). According to De Villier et al. (2011), 50% of wetlands in South Africa have already been destroyed due to anthropogenic activities such as agriculture, mining, and urban development. Disturbances from these activities negatively affect the native wetland ecosystems. As a result of this, wetlands are vulnerable to invasion, and presence of particular invasive macrophytes in a wetland may be an indicator of the status of the wetland medium and system (Zedler and Kercher, 2004). Most invasive macrophytes are hyper-accumulators and have the ability to absorb harmful substances and pollutants from the wetland medium into their plant tissues (Zedler and Kercher, 2004). High concentration of pollutants in plant tissues is an important indicator of water quality status in wetlands and other water systems (Deng et al., 2004; Allende et al., 2011). All forms of aquatic plants (emergent, submerged and floating aquatic species) are used for phytoremediation of polluted wetlands (Newete and Byrne, 2016). Nevertheless, emergent aquatic macrophytes like *P. australis* (and *A. donax* are more prevalent in most wetland systems and have proven to be more resilient and effective in removal of heavy metals (Sheoran and Sheoran, 2006; Yang et al., 2006). The degree to which plants accumulate heavy metals is determined by the individual plant uptake capacity and intracellular transportation within the plant (Yang et al., 2005). For example *P. australis* has the potential to accumulate Cd, Cu, Cr, Ni and Pb up to 0.1% of plant dry mass and Fe and Zn up to 1% plant dry mass (Kalra, 1998; Sasmaz et al., 2008). Research conducted by Yang et al. (2006) in Guangdon province, China, showed that *Typha latifolia*, *P. australis* and *Cyperus malaccensis* significantly removed 94% of Cd, 99.04% of lead (Pb), and 97.30% of zinc (Zn) from a constructed wetland. Vymazal and Březinová (2016) revealed that *P. australis* planted in constructed wetlands removed 59% Zn, 55% Cd and 38% Cr, from the inflow annual load of the metals into wetlands. Vymazal and Březinová (2016) also concluded that the plant shoots in constructed wetlands can sequester up to 55% Cr, 49% Zn and 71% Cd, of the total heavy metals removed by the *P. australis*. In another study 19 plant species, among which were *P. australis* and *Cyperus* species, were planted in a constructed wetland in China and irrigated with waste water containing concentrations of Zn, Cd and Pb at 5.0, 0.5 and 2.0 mg/L, respectively. The results showed that the plants had more than 90% removal efficiency for the heavy metals (Liu et al., 2007). Bello et al. (2018), in Saudi Arabia, investigated the capacity of *P. australis* in removing Cd, Pb and Ni in hydroponic experiments with 5 mg/L concentration for each heavy metal. The results showed that the capacity of heavy metal removal by *P. australis* was 93%, 95% and 84% for Cd, Pb and Ni, respectively. In another research conducted in Catania, Italy, the roots, stems, and leaves of *A. donax* were tested as potential bio-monitors of trace elements such as Al, As, Cd, Cr, Cu, Hg, Mn, Ni, Pb, and Zn. The results showed that *A. donax* had the capacity to significantly bioaccumulate the trace elements, with root/sediment Bioaccumulation factors of: Cr (0.08), Cu (0.05), Mn (0.02), Ni (0.1), and Pb (0.03) (Bonanno, 2012). Mojiri et al. (2015) investigated the effectiveness of *P. australis* for heavy metal uptake from municipal waste leachate. At the end of their experiment, the amount of Fe, Mn, Cu and Ni removed by *P. australis* were 25.049, 9.623, 6.112, and 0.900 mg/kg, respectively. The translocation factors were 0.34, 0.89,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79577972

1.30 and 1.01, respectively. Translocation Factor (TF) is the ratio of metal concentration in shoots to the metal concentration in roots, and measures the ability of a plant to translocate metals from roots to shoots (Mojiri et al., 2015). A plant has potential to be used for phytoextraction when its TF for a particular metal is above 1. Thus, according to Mojiri et al. (2015), it is apparent that *P. australis* has the potential for the phytoextraction of Cu and Ni, from wetlands, but not for Fe and Mn.

Aquatic plants are very useful in natural and constructed wetlands in the abatement of water contaminants and improving the water quality for domestic and agricultural purposes. *Table 3* is a summary of some literature showing the removal of heavy metals from contaminated wetlands by aquatic macrophytes.

Table 3. *Removal of heavy metal contaminants from wetlands by aquatic macrophytes*

Species	Metals purified	Place	Reference
Typha capensis and *Arundo donax L.*	Zn, Mn, Ni and Fe	Johannesburg, South Africa; Natural wetland	Van der Merwe et al., 1990
Cyperus vaginatus	Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd, and Pb	South Australia; Constructed wetland	Aryal et al., 2016
Typha domingensis, *Phragmites australis (Cav.) Trin. ex Steud.* and *Arundo donax L.*	Al, As, Cd, Cr, Cu, Hg, Mn, Ni, Pb, Zn.	Italy; Natural wetland	Bonanno, 2013
Phragmites australis (Cav.) Trin. ex Steud. and *Bolboschoenus maritimus*	Cr, Ni, Cu and Zn	Northeast Italy; Constructed wetland	Bragato et al., 2006
Bolboschoenus Maritimus	Al, Fe, Cu, Zn	Western Cape, South Africa; Natural wetland	Shuping et al., 2011

The efficiencies of *P. australis* and *A. donax* in heavy metal uptake have been studied by a number of researchers worldwide (Papazoglou et al., 2005; Bonanno, 2012; Kumari and Tripathi, 2015), including in South Africa (Van der Merwe et al., 1990; Zingelwa and Wooldridge, 2016). Kumari and Tripathi (2015) demonstrated the removal of Cu, Cd, Cr, Ni, Fe, Pb and Zn from urban sewage mixed with industrial effluents using *P. australis* and *T. latifolia*, as a cost effective and promising technology in India. Their resuts showed that *P. australis* perfomed better than *T. latifolia* for all the metals, and mixing the two plants increased the removal efficiency of the metals from the effluent. Papazoglou et al. (2005) investigated *A. donax* irrigated with tap water containing increased concentrations of Cd and Ni in Greece. At the end of the experiment the parameters measured, namely, stem height and diameter, number of nodes, fresh and dry weight of leaves, and net photosynthesis, were found not affected, indicating that *A. donax* tolerates high concentrations of Cd and Ni, and thus can be used for phytoremediation. Van der Merwe et al. (1990) measured the accumulation of Zn, Mn, Ni and Fe by *A. donax* and *T. capensis* under acidic and alkaline conditions in the Burgspruit catchment area near Germiston, Ekurhuleni, South Africa and concluded that the metal accumulation capacity of *A. donax* was higher than that of *T. capensis*. Zingelwa and Wooldridge (2016) studied the mineral element uptake and accumulation by *T. latifolia* and *P. australis* from waste water in constructed wetlands in South Africa. They found that *T. latifolia* accumulated more mineral elements (N, P, K, Ca and Al) than *P. australis*. However, only few or no studies compared the capacities of *A. donax* and *P. australis* in heavy metal accumulation under experimental or controlled environment. Bonanno (2013) compared the trace element bioaccumulation capacities

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79577972

of the two plant species under field or natural conditions, and the results showed that *P. australis* is a better heavy metal accumulator than *A. donax*. He measured the heavy metals Al, As, Cd, Cr, Cu, Hg, Mn, Ni, Pb, and Zn in *Typha domingensis*, *P. australis* and *A. donax* naturally growing along a stream in Italy. The results showed that the bioaccumulation capacities decreased in the order of root>stem>leaf in *T. domingensis*, and root>leaf>stem in *P. australis* and *A. donax*. Generally the bioaccumulation capacities for *P. australis* and *T. domingensis* were found to be higher than that of *A. donax*. Thus, if the native *P. australis* is more effective in removal of heavy metals than its counterpart *A. donax* in wetlands, it is imperative to promote the former species to eventually replace the notorious invader *A. donax* in wetlands. However, to ascertain this, future research should focus on comparing the heavy metal uptake capacities of the two plant species under controlled/experimental conditions. This is because they are widely distributed in many parts of the country and they both provide similar economic and ecological functions. They are useful as thatching, ornamental and musical-instrument (like flutes) materials and source of energy, and wildlife habitat (Bonanno, 2012; Shuai et al., 2016). However, because of their similar morphology, discrimination between the two species and monitoring their occurrence and their environmental foot prints in the field is difficult.

Methods of monitoring heavy metal uptake by aquatic macrophytes

While many aquatic macrophytes have proven to be valuable for phytoremediation, the process requires continuous monitoring to ensure timely harvest of plant biomass and thier replacement for continuous and effective removal of water contaminants (Carson et al., 2018). Appropriate tool of monitoring is required to determine the heavy metal accumulation in the phytoremediating plant tissues and their health status to avoid metal-induced stress and subsequent death of plant tissues before their harvest and removal (Vassilev et al., 2004). Traditional methods of monitoring heavy metal uptake by plants involve sampling plant tissues and sample preparation for laboratory analysis. For example tree-ring analysis, which involves chemical analysis of samples from successive growth rings, can be done to monitor patterns of heavy metal uptake by plants over years (Lepp, 1975). In the same manner samples of plant roots, stems, and leaves can be analysed in the laboratory to determine the heavy metal uptake ability by plants (Vymazal and Brezinova, 2016). However, for monitoring large areas, traditional surveys involve lots of plant sample collection and preparation, which may be difficult, expensive, too technical, time consuming and poses safety issues on chemical handling and disposal. Sampling of representative plant tissue could also be constrained due to inaccessiblity. Remote sensing is a modern and alternative technology for monitoring such wetland phytoremediating plants. It is also an effective, non-destructive tool for monitoring heavy metal accumulation by wetland plants (Van Deventer and Cho, 2014). Remote sensing can be used to acquire spatial and temporal variations of accumulated heavy metal concentrations over large and inaccessible areas, as opposed to the in-situ traditional methods which are limited to small and accessible areas (Liu et al., 2010).

Monitoring of heavy metal uptake by wetland plants with remote sensing

Remote sensing is the technology of obtaining information about an object without a direct contact to the object under observation. Monitoring of vegetation using remote sensing is possible because vegetation under different conditions and of different

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79577972

characteristics and quality has unique spectral characteristics in the electromagnetic spectrum (Knipling, 1970). The spectral response properties of vegetation are determined by the biochemical content (e.g. chlorophyll) and anatomical (e.g. canopy architecture) structure of their leaves or crowns (Curran, 1989). All vegetation has a spectral response curve, which is unique to each species. High chlorophyll levels result in increased absorption (reduced reflection) in the red region of the electromagnetic spectrum, and broadening of the absorption pit in the red (660–680 nm) (Horler et al., 1983). It also shifts the red edge reflectance slope (680–760 nm) and the point of maximum slope in the red edge known as the chlorophyll red edge position (REP) towards the longer wavelengths, referred to as a red shift (Horler et al., 1983). Accordingly, decreased chlorophyll results in increased reflectance in the red region, and a shift of the red edge slope and REP towards the shorter wavelengths, which is referred to as a blue shift. Increases in biomass increases reflection in the near-infrared (NIR) region (Rouse Jr., 1974). Various heavy metal concentrations also have significant effects on the spectral reflectance properties of leaves. According to Sridhar et al. (2007), Zn accumulated in plant leaves causes a blue shift in the REP and a decrease in NIR reflectance. Accumulated Cd also results in a blue shift of REP and overall increase of reflectance in the visible region (Sridhar et al., 2007). Lead results in increased reflectance in the NIR region (Clevers et al., 2004). Liu et al. (2010) studied the possibility of using a small scale hand held hyperspectral sensor to estimate heavy metal (Pb, Cu and Zn) concentrations in *P. australis*. The study revealed that heavy metal concentrations affected chlorophyll levels in the plants, which in turn determine the hyperspectral measurements for the plant leaves. It was also found that chlorophyll concentrations for the sampled leaves varied inversely with concentrations of Pb, Cu and Zn, and chlorophyll concentration accounted for about 30% of the variations in the three heavy metals, respectively. Linear combination of normalized band depths at wavelengths 537 (green), 667 (red) and 747 (near infrared) nm were found to explain 82% of the variation of chlorophyll concentration (Liu et al., 2010). Thus it was concluded that it is possible to use laboratory-based hyperspectral data to estimate concentrations of Pb, Cu and Zn in *P. australis* (Liu et al., 2010). In another study, Shakya et al. (2008) also concluded that high concentrations of heavy metals in plants determine their chlorophyll content, which can be measured by field hyperspectral data or hyperspectral images. Research by Li et al. (2008) investigated the biogeochemistry responses of vegetation *Rhus chinensis* Mill in a copper mine area to heavy metal contamination. The results showed that there was a significant correlation between copper concentration in leaves and leaf reflectance. Increased copper concentrations were found to: increase the leaf spectral reflectance by about 5% to 30%, cause a blue shift of about 5 to 15 nm, increase the red edge from 4.5534 to 8.9475 nm and decrease the chlorophyll absorption depth. Thus, remote sensing can be used to differentiate between healthy and stressed vegetation and to determine the level of specific heavy metals in plants. Some plants used for phytoremediation in wetlands like *P. australis* and *A. donax* are morphologically similar, and it is also important to be able to discriminate between such species using remote sensing.

Use of remote sensing to discriminate wetland plant species

Successful management of wetlands requires proper and up to date mapping and discrimination of wetland plants (Hirano et al., 2003; Davranche et al., 2010). While the physical methods of mapping and discriminating wetland vegetation are time

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79577972

consuming and have accessibility and many other logistical problems, remote sensing can be an effective alternative for such purpose. Discrimination of plant species using remote sensing is possible because different vegetation types reflect differently to electromagnetic radiation. Plant leaves of different plant species have different biophysical and biochemical characteristics, and these affect their leaves' spectral properties, and make it possible to discriminate between different plant species (Kurmar et al., 2001). Extensive research has been done using remote sensing to discriminate between plant species (Adam et al., 2010). For example, Dubula et al. (2016) proved the potential of remote sensing in discriminating invasive plant species in the Klipriviersberg nature reserve in Johannesburg, South Africa. Their research concluded that at both individual level and plot level, the near infrared region of the electromagnetic spectrum could be used to discriminate between *Asparagus laricinus* and other vegetation species in the nature reserve. Pu (2009) used spectrometry to identify 11 forest species. They concluded that two classification algorithms, Artificial Neural network (ANN) and Linear Discriminant Analysis (LDA) were effective in discriminating plant species using selected spectral variables that are linked to water content, pigments and other biochemical.

Even though remote sensing is proved as a practical and cheap method for discriminating plant species, there are some challenges involved when discriminating wetland plant species. It is not easy to detect and discriminate wetland vegetation types using optical remote sensing because of very high spatial and spectral variability, due to very short ecotones between wetland vegetation units (Adam and Mutanga, 2009; Zomer et al., 2009). Thus the selection of the appropriate spatial and spectral resolution and the best process to use to extract the spectral information is of paramount importance (Elhadi et al., 2009). According to the review paper by Adam et al. (2010), hyperspectral remote sensing, especially field spectrometry, is more appropriate and accurate in discrimination of wetland plant species compared to aerial photography and multispectral remote sensing such as Landsat TM and SPOT. This is because hyperspectral sensors have hundreds of narrow continuous spectral bands ranging between 400 to 2500 nm, which make them capable to provide more details on vegetation types (Zomer et al., 2009). In this regard, a research by Smith and Blackshaw (2003) confirmed that plant species discrimination using hyperspectral data yielded more accurate results than that of multispectral data. The research also indicated that the visible (400-700 nm) and the red edge (700-730 nm) bands were the regions significantly useful for plant species discrimination. Schmidt and Skidmore (2003) also concluded that increased spectral resolution improved accuracy in discrimination of vegetation species of similar structure in a wetland. The purpose of their research was to discriminate 27 wetland plant species, including *Phragmites australis* (Cav.) Trin. ex Steud. using field spectrometry. Their results showed that more than 75% of the possible pairs of plant species showed significant differences based on their spectral reflectance measurements. Furthermore, research by Vaiphasa et al. (2005) concluded that field spectral measurements of crown leaves of various mangrove species were efficient in discriminating mangrove species. In their research a field spectrometer, with 2151 bands ranging from 350 to 2500 nm, was used to measure leaf spectral reflectance of 16 mangrove species. Statistical analysis of the spectral measurements indicated that the 16 species were statistically different at most spectral locations. Adam et al. (2012) also used ASD spectrometry measurements to discriminate among four wetland vegetation species, *Cyperus papyrus* L., *P. australis*, *Echinochloa pyramidalis* and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79577972

Thelypteris interrupta in Greater St Lucia Wetlands Park in South Africa. Van Deventer and Cho (2014) also proved that field spectroscopy can be a quick and cheap method to assess the health and condition of vegetation affected by Acid Mine Drainage.

Conclusion

Arundo donax L. and *Phragmites australis* (Cav.) Trin. ex Steud., among other macrophytes, are very important in phytoremediation of heavy metal contaminated wetland systems. Their efficiencies in heavy metal uptake have never been compared under same and controlled environment. While the two species could be important phytoremediating plants, determining their efficiency could help their management as weeds, particularly considering the fact that *A. donax* is an infamous invader of the water system in South Africa. It will also help determine the effective plant of choice for phytoremediation in constructed wetlands. Remote sensing could be an effective method for monitoring of heavy metal induced stress in both plant species to facilitate their management before they die and release the contaminants removed from water and accumulated in plant tissue back to the source. Although the two plant species are morphologically similar, remote sensing can also effectively discriminate between them. Future research should compare the heavy metal uptake capacities of the two plant species under controlled/experimental conditions, and determine the best remote sensing analysis method to discriminate between the two species, and monitoring their heavy metal uptake capacities.

(Received 23rd Nov 2018; accepted 1st May 2019)

Abstract. Two sewage-enriched urban rivers within Chaohu Lake Basin in Southeast China were selected to study the seasonal variations in Nitrous Oxide (N_2O) concentrations, to improve the information of N_2O concentrations and emissions in the similar areas. The results indicate that N_2O concentrations ranged 16.12~1043.09 nmol/L and averaged 266.27 ± 250.28 nmol/L during the sampling period. N_2O was oversaturated in both rivers ranging 184~12084% (mean 2964%). The significantly higher level of N_2O concentrations and emissions were observed in cold months. It is indicated that the two rivers were net sources of atmospheric N_2O. N_2O emissions ranged 11.32~2920.38 μg $N\text{-}N_2O/m^2/h$ with an overall mean value of 743.57 ± 831.78 μg $N\text{-}N_2O/m^2/h$. A significant negative correlation exists between N_2O concentration and water temperature, which may be regulated by inverse tendencies between temperature and riverine nutrient loadings. Dissolved Oxygen (DO) is a predictor of N_2O in Nanfei River explaining 60% of variability in N_2O; while water temperature and NO_3^- are better predictors of N_2O in Ershibu River explaining 73% of variability in N_2O. The riverine N_2O may be produced by denitrification in Nanfei River while by coupled nitrification-denitrification in Ershibu River.
Keywords: *nitrous oxide, concentration, nitrification, flux, urban river*

Introduction

Nitrous Oxide (N_2O) is one of the most significant greenhouse gases contributing to the destruction of stratospheric ozone and climate change (Ravishankara et al., 2009; Wójcik-Gront et al., 2015; Pauleta, et al., 2019). The atmospheric N_2O has risen from about 270 ppb in the pre-industrial era to 319 ppb in the present, mainly due to human perturbations of the global nitrogen (N) cycle (Holland et al., 2005). As N inputs increase, potentially more N_2O is produced (Bouwman, 1995; Wójcik-Gront et al., 2015). In river networks, more than 0.68 Tg/yr of anthropogenic N inputs were converted to N_2O on the global scale, equivalent to 10% of the anthropogenic N_2O emission rate (Beaulieu et al., 2011; Quick et al., 2019; Luo et al., 2019). Therefore, more and more attentions have been paid to the emissions of N_2O from different sources as accurate information is required to determine the contribution of N_2O to global greenhouse gas fluxes (Khalil et al., 2002; Yang and Lei, 2018).

Among the many natural and anthropogenic N_2O sources, most are biological ones (Short et al., 2013). In aquaculture systems, N_2O can be produced by denitrification under anaerobic conditions, where NO_3^- was converted to N_2O and dinitrogen (N_2)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79737985

(Öquist et al., 2004). Under oxic conditions, N_2O is also produced as a by-product of nitrification where ammonium (NH_4^+) was oxidized to nitrite (NO_2^-), and subsequently to NO_3^- (Stein and Yung, 2003). Natural rivers have shown large temporal and spatial variations in their N_2O production and emissions due to the changes of topographic feature and environmental factors (Wilcock et al., 1998; Bansal et al., 2015; Quick et al., 2019). The exact mechanisms of aquatic N_2O production are related to the various specific environmental conditions, such as N species and loads, dissolved oxygen (DO) concentration, pH, and others. The classification of carbon source also influences N_2O emission from denitrification and nitrification. Controlling factors related to N_2O production and emissions in rivers are still needed to fully understand due to lack of *in situ* observation data. Thus, more investigation is needed to determine the underlying mechanism of seasonal variation in N_2O concentration in rivers.

Emissions of N_2O from riverine ecosystems take significant influences on the global climate change, since riverine ecosystems are very sensitive to human activities and often receive high loadings of nutrient and organic matter (Richey et al., 2002; Bansal et al., 2015; Yang and Lei, 2018; Quick et al., 2019). Much work has been dedicated to quantifying N_2O emissions from terrestrial ecosystems; however, emissions of N_2O from rivers and streams have received much less attention and remain a major source of uncertainty in the global N_2O budget. Similar to many developing countries, river N pollution is one of the most critical environmental problems in China (Richey et al., 2002; Yang et al., 2006, 2013; Wang et al., 2007; Luo et al., 2019). The related researches on China's greenhouse gas emission primarily focus on the estuary and coastal areas (Yang et al., 2006; Wang et al., 2007; Liu et al., 2015; Yang and Lei, 2018). However, few studies actually directly measure N_2O fluxes from N enriched rivers, and that information is sparse.

Chaohu Lake is a shallow lake in Southeast China, which has suffered from serious pollution resulting from substantial discharge of urban wastewater and agricultural runoff. It has been reported that, the annual mean concentration of Total Nitrogen (TN) and Total Phosphorus (TP) over 2001-2016 ranged 0.08-24.60 and 0.02-2.46 mg/L, respectively, meanwhile, the lake water quality showed no substantial improvement (Yang et al., 2013; Yang and Lei, 2018). The Nanfei River (NR) and Ershibu River (ER) are two urban tributaries of Chaohu Lake. These two rivers are narrow and short with low flow speed. Large amounts of N-enriched sewage inputs into the two rivers result in highly eutrophic river water. Significantly, small rivers are thought to be hot spots of nitrogen cycling (Alexander et al., 2000; Bansal et al., 2015; Quick et al., 2019) and can remove a large proportion of nutrient inputs (Wollheim et al., 2006; Luo et al., 2019; Quick et al., 2019), hence could be important sites of N_2O emissions. Therefore, this study aimed to determine: (1) the presence and extent of seasonal variations in river water chemistry, dissolved N_2O concentration and emissions in sewage-enriched rivers in the Chaohu Lake region; (2) the potential factors that regulate the seasonal N_2O variability.

Materials and methods

Sites description

The study was carried out in NR and ER, two tributaries of Chaohu Lake. The mean annual temperature and precipitation of this region is 15.5 °C and 950 mm respectively. The NR and ER are small rivers with a total length of 70 and 17 km respectively

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79737985

(*Table 1*). In this study, the sampling site was set up at the downstream of each river and located at urban areas (*Fig. 1*). The respective mean water depth of the sampling site is 1.8 m and 3.2 m in NR and ER, and the respective mean flow speed is 0.2 and 0.3 m/s. In recent years, the sewage loading of NR and ER have significantly increased as a result of the effects of local development, which may have become atmospheric N_2O sources. Increases in riverine N and organic matter discharge also stimulate microbial processes and associated algae blooming in Chaohu Lake.

Table 1. *Physical characteristics of the study rivers*

River	River length (km)	Mean flow speed (m/s)	Mean water depth (m)	Dominant land use (%)	Sampling location
NR	70	0.2	1.8	Urban (> 70)	Daxing port
ER	17	0.3	3.2	Urban (> 80)	Longtang bridge

Sample collection and chemical analysis

Triplicate surface water (0.2 m depth) samples were collected monthly during Jan. and Dec. in 2017 for the measurement of NH_4^+, NO_3^-, TP, BOD_5, COD_{Mn}, SO_4^{2-}, and Cl^-. Dissolved oxygen (DO), pH, and water temperature were measured *in situ* using a portable meter (HQ30D, USA). Samples for dissolved N_2O analysis were collected in 60-ml serum bottles sealed with a butyl-rubber stopper, and preserved after the addition of a few drops of saturated mercuric chloride solution to prevent their biological activities. Water samples were stored in ice box during transport and analyzed within 24 h.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79737985

The respective concentration of NH_4^+, NO_3^-, TP, BOD_5, COD_{Mn}, SO_4^{2-}, and Cl^- in water samples was determined according to the standard methodology of GB3838-2002 promulgated by the China central government. The headspace-equilibrium method was used for measurement of initial sample dissolved N_2O concentrations in river water (Huttunen et al., 2002; Liu et al., 2015; Quick et al., 2019; Luo et al., 2019). Twenty milliliters of highly purified N_2 (purity > 99.999%) was injected into the serum bottle using an airtight syringe and a 20-ml water sample was displaced. Bottle headspace N_2O concentrations were directly analyzed using a gas chromatograph (HP5890 II) equipped with an electron capture detector (ECD) after the bottles were vigorously shaken for 4 h. Initial N_2O concentrations (C_w) in water samples were calculated (Johnson et al., 1990; Yang and Lei, 2018). The equilibrium concentration (C_e) of N_2O in river water with atmosphere was calculated using Henry's first law. Dissolved N_2O saturation, expressed in %, was calculated by comparing C_w and C_e.

N_2O emission flux

N_2O emission flux across the water-air interface was estimated using the two-layer model:

$$F = k \times (C_w - C_e) \quad \text{(Eq.1)}$$

where F is the N_2O emission flux (μg $N\text{-}N_2O/m^2/h$); C_w and C_e is the measured and equilibrium concentration of N_2O (nmol/L), respectively; k (cm/h) is the gas transfer coefficient, calculated by the equation accounting for both wind speed and flow speed (Borges et al., 2004; Liu et al., 2015):

$$k = [1 + 1.719(w/h)^{0.5} + 2.58\mu_{10}](S_c/600)^{-1/2} \quad \text{(Eq.2)}$$

where w and h are flow speed ($m\ s^{-1}$) and depth (m) of river water column, respectively; μ_{10} (m/s) is the instantaneous wind speed at the 10 m height; Sc is the Schmidt number for N_2O calculated by the equation proposed firstly by Wanninkhof (1992): $S_c = 2301.1 - 151.1t + 4.7364t^2 - 0.059431t^3$, where t (°C) is in situ river water temperature. In this study, wind speed data was gained from the Hefei Meteorologic Bureau, Anhui Province.

Results

Water chemistry

NH_4^+ and NO_3^- concentrations varied considerably over the sampling time, ranging 1.97~23.75 (mean12.24 ± 5.13) and 0.05~6.98 (mean3.54 ± 4.45) mg/L (*Fig. 2a, b*), respectively. NH_4^+ and NO_3^- concentrations indicated a generally higher level in cold months ($P < 0.001$). Difference in mean NH_4^+ and NO_3^- concentrations was not significant between the two rivers ($P > 0.05$). DO concentration ranged 0.20~7.70 mg/L with an overall mean of 2.61 ± 2.14 mg/L (*Fig. 2c*). In NR, DO concentrations were generally lower than 2 mg/L. Similar to the patterns of NH_4^+, TP concentrations (ranging 0.20~2.37 mg/L, mean 1.16 ± 0.53 mg/L) showed the marked temporal variations and reached the lowest value in July in both rivers (*Fig. 2d*). Water temperature ranged 11.0~33.3°°C (*Fig. 2e*), significantly negatively related with DO ($P < 0.05$). The pH value of river water ranged 6.60~8.56 and decreased dramatically after August (*Fig. 2f*).

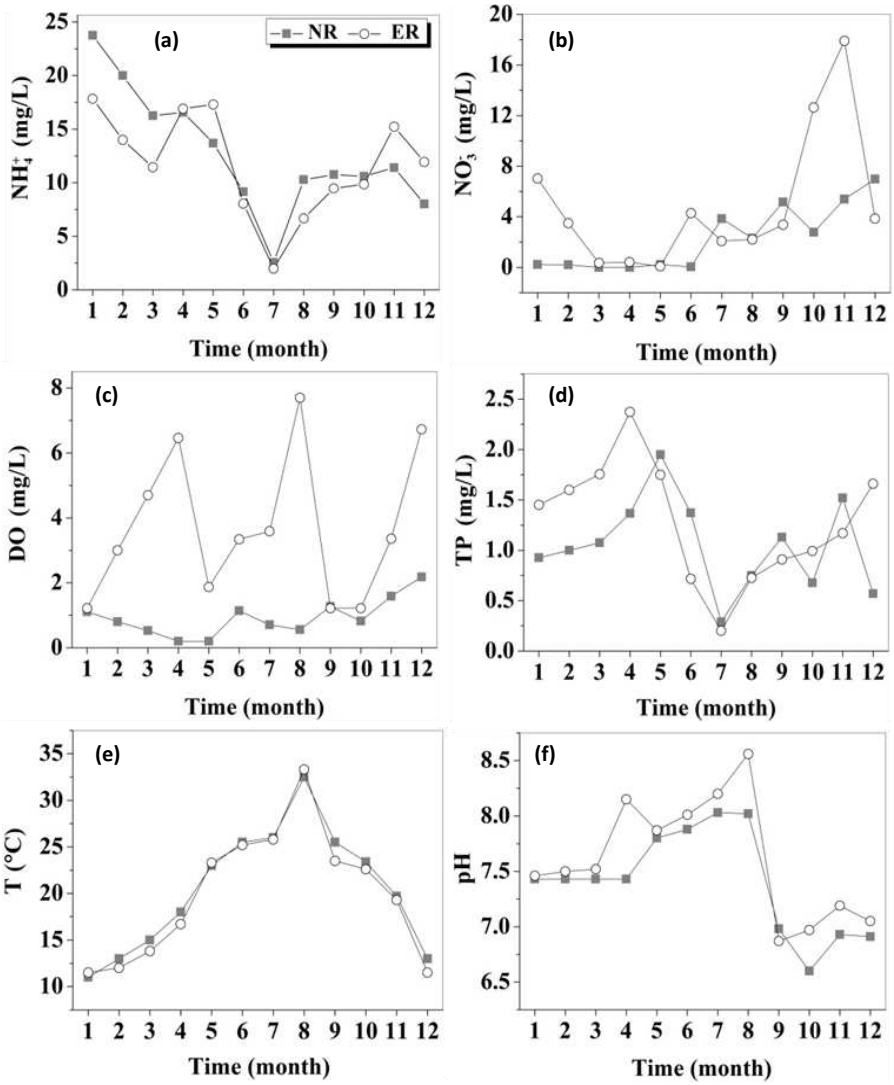

Figure 2. *Seasonal variations in NH_4^+, NO_3^-, DO, TP, water temperature (T), and pH value of Nanfei and Ershibu River*

Monthly concentrations of BOD_5, COD_{Mn}, SO_4^{2-}, and Cl^- in water samples are shown in *Table 2*. BOD_5 and COD_{Mn} concentrations ranged 3.6-23.1 and 7.5-20.4 mg/L, with an overall mean of 9.80 ± 5.37 and 11.97 ± 4.44 mg/L, respectively. Significantly higher BOD_5 and COD_{Mn} concentrations were investigated in spring and winter ($P < 0.001$). SO_4^{2-} and Cl^- concentrations ranged 45.65~332.50 (mean 101.43 ± 79.06) and 28.55~277.14 (mean 107.16 ± 56.57) mg/L, respectively, generally lower in summer.

Compared to other rivers in this region, the NR and ER showed extremely high level of NH_4^+, NO_3^-, TP, BOD_5, COD_{Mn}, SO_4^{2-}, and Cl^- concentrations. The long-term dynamics of water quality in Chaohu river nets were observed over 13 years (Yang et al., 2013; Yang and Lei, 2018), indicating that NH_4^+, COD_{Mn}, and TP concentrations in the Fengle and Hangbu river which drained agricultural runoff averaged 0.25, 0.07, 4.17 mg/L and 0.31, 0.10, 3.47 mg/L, respectively. Based on the latest investigation, the respective mean SO_4^{2-} and Cl^- concentration was 29.8 and 23.5 mg L^{-1} in Fengle River, and 57.1 and 37.9 mg/L in Hangbu River.

Dissolved N_2O concentration and emission flux

Overall, N_2O concentration ranged 16.12~143.09 nmol/L and averaged 226.27 ± 250.28 nmol/L (*Fig. 3a, b*). A clear seasonal variation in N_2O concentration was found in each river. Consistent seasonal trends were apparent between rivers. In general, the higher N_2O concentrations were observed in colder months. Difference in mean N_2O concentration was not significant between the two rivers ($P > 0.05$). During the sampling period, both rivers were oversaturated in N_2O with a range of 184~12084% (mean 2964%).

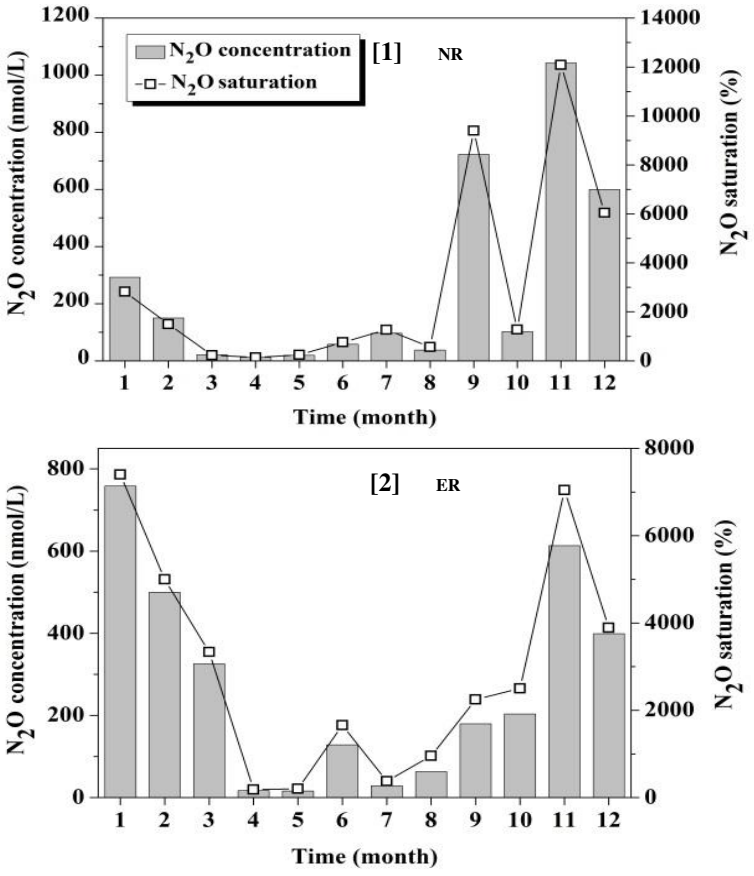

Figure 3. *Seasonal variations in N_2O concentration and percentage saturation*

DOI: http://dx.doi.org/10.15666/aeer/1704_79737985

This study indicates that NR and ER were net sources of N_2O across all the seasons sampled. N_2O emission fluxes also followed a distinct seasonal patter ranging of 11.32~2920.38 μg N-N_2O/m^2/h (mean 743.57 ± 831.78 μg N-N_2O/m^2/h) (*Fig. 4*). Significantly lower N_2O emission fluxes were investigated in summer.

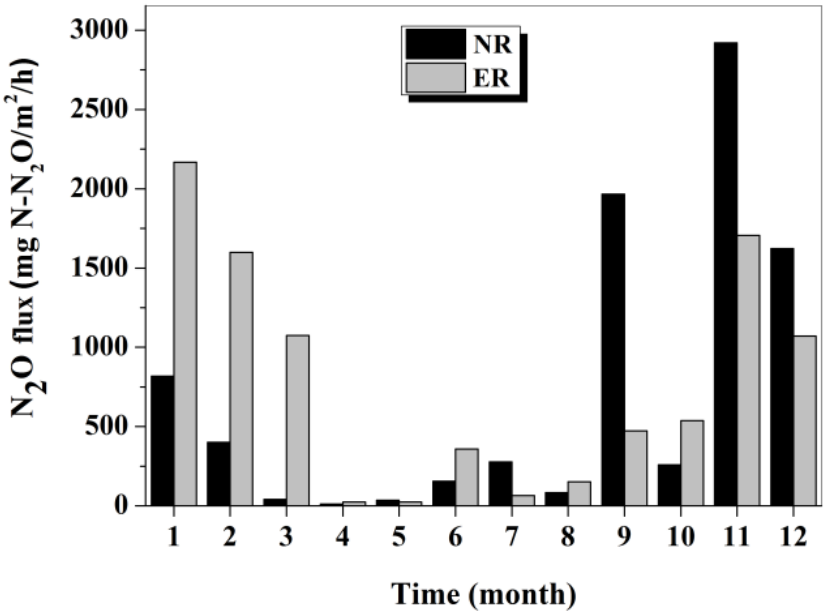

Figure 4. *Seasonal variations in N_2O emission flux*

Discussion

Compared to some literatures on the temporal and spatial variation of water pollution in the Zhegao River of Chaohu Lake basin (Chu et al., 2011; Yang et al., 2013), in which NH_4^+, NO_3^-, and TP showed an annual mean concentration of 1.13, 0.63, and 0.11 mg/L respectively. However, low NO_3^-/Cl^- ratios (ranging 0.000~0.21, mean 0.04) were observed both in NR and ER in this study; this result further indicates that high riverine N concentrations in these rivers can be strongly attributed to the direct discharge of untreated sewage. Based on the measurements, the contribution of N_2O flux in colder seasons accounted for 90% of the annual budget, similar to results from two subtropical reservoirs (Liu et al., 2011, 2015), with lower fluxes of N_2O appearing in summer. However, different seasonal variation patterns on water surface N_2O emissions were also reported from the Three Gorges Reservoir in China (Zhu et al., 2013; Zhao et al., 2012). Some sewage-enriched rivers showed higher dissolved N_2O concentrations and were net atmospheric sources of N_2O. Xin'an Tang river (Taihu Lake basin of China) receiving high untreated sewage inputs indicated high N_2O concentration and emission flux with respective mean value of 0.48 μg N-N_2O/L and 56.1 μg N-N_2O/m^2/h (Xia et al., 2013). The overall mean saturation and emission was 770% and 1.91 mg N-N_2O/m^2/d in the Shanghai city river network (Yu et al., 2013), respectively. The urban rivers in Tianjin city (Haihe basin of China) showed high N_2O concentration and emission rate in winter with respective mean value of 88.9 nmol/L and 71.4 N-N_2O/m^2/h (Hu et al., 2013; Liu et al., 2015). Thus, given the rapid progress of global urbanization, it is urgent to better understand the effect of urban rivers on global N_2O budget.

Seasonal variation in N_2O concentration and its potential control

Seasonal variations in N_2O concentration in two sampling rivers were observed in the study. Generally, the significantly higher N_2O concentration was observed in colder months. It has been reported that, seasonal patterns of trace gas concentration and emission in aquatic systems were governed by seasonal variability in temperatures affecting water availability, production of substrate precursors and microbial activity (Whalen, 2005; Quick et al., 2019). For example, water temperature positively correlated to N_2O saturation and explained 70% of the seasonal variance of N_2O saturation in a large and impounded river (Beaulieu et al., 2010). However, a negative correlation between water temperature and N_2O concentration was investigated in this study ($P = 0.03$) (*Fig. 5*). Some studies (Sun et al., 2013; Liu et al., 2015) also found a similar seasonal pattern in N_2O concentration and emission in the Yellow River estuary. It is indicated that this seasonal pattern of N_2O concentration in the NR and ER was mainly regulated by the inverse tendencies between temperature and riverine nutrient loadings during the study period. Small river discharge and high riverine nitrogen concentration was generally investigated during the cold seasons in this region. This combination of decreased water discharge and increased nutrient loadings is likely to have sustained high N_2O concentration in cold seasons. The correlation between NO_3^- and N_2O concentration was significant in NR but not significant in ER. These results suggested that N_2O may be produced by denitrification in NR while by coupled nitrification-denitrification in ER, which could be further proved by the significant negative correlation between DO and N_2O concentration in NR and significant positive correlation in ER. However, N_2O concentration was not significantly correlated with NH_4^+ and NO_3^- based on the data collected.

It is suggested that none of the environmental variables stood out as a clearly superior predictor of N_2O when considered them alone, though several of them showed some predictive value with respect to dissolved N_2O concentration. Herein, a stepwise multiple regression that include DO, NH_4^+, NO_3^-, TP, BOD_5, COD_{Mn}, water temperature, and pH was conducted to assess predictors of N_2O concentration. The results showed that DO is a better predictor of N_2O in NR explaining 60% of variability in N_2O, indicating N_2O production was limited by DO concentration; while water temperature and NO_3^- are better predictors of N_2O in ER explaining 73% of variability in N_2O, indicating N_2O production was NO_3^- limited. Based on all of the observation data, water temperature and NO_3^- are better predictors of N_2O explaining 43% variability in N_2O. Other investigations also found similar relationships between NO_3^- and N_2O concentration in urban rivers (Wang et al., 2015; Quick et al., 2019). However, Yu et al. (2013) reported that N_2O production was greatly controlled by DO and NH_4^+ level in some urban rivers. As discussed above, river N_2O may be produced by denitrification in NR while by coupled nitrification-denitrification in ER. Meanwhile, we thought that, high NH_4^+ come from the decomposition of organic nitrogen in urban effluents in urban rivers, while NH_4^+ cannot be oxide to NO_3^- rapidly under hypoxic conditions. As a result, river N_2O production was NO_3^- limited based on the data collected.

Uncertainty of N_2O emission flux

There are many models for gas emission estimation. However, the overall accuracy of model-based gas estimation in rivers remains uncertain, since models were developed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79737985

in different settings and gas transfer coefficients (k) estimated with these models have not satisfied all field conditions (Kremer et al., 2003; Pauleta et al., 2019). In open waters, k is usually parameterized as a function of wind speed. It is reported that the primary driving mechanism that regulates k is presumed to be near-surface turbulence from low to moderate wind speeds; while at higher winds, bubble-mediated exchange produced by breaking waves may play significant roles on k (Borges et al., 2004). It is also reported that bottom-generated turbulence that is transported to the surface can significantly affect gas transfer especially in deep flowing waters (Nimmo-Smith et al., 1999; Zappa et al., 2003; Luo et al., 2019). Thus, choices of the models for estimation of k took a considerable bearing on the estimated gas emissions. Gas transfer velocity was directly measured in some studies to improve accuracy of estimating N_2O emission, as is however beyond this study.

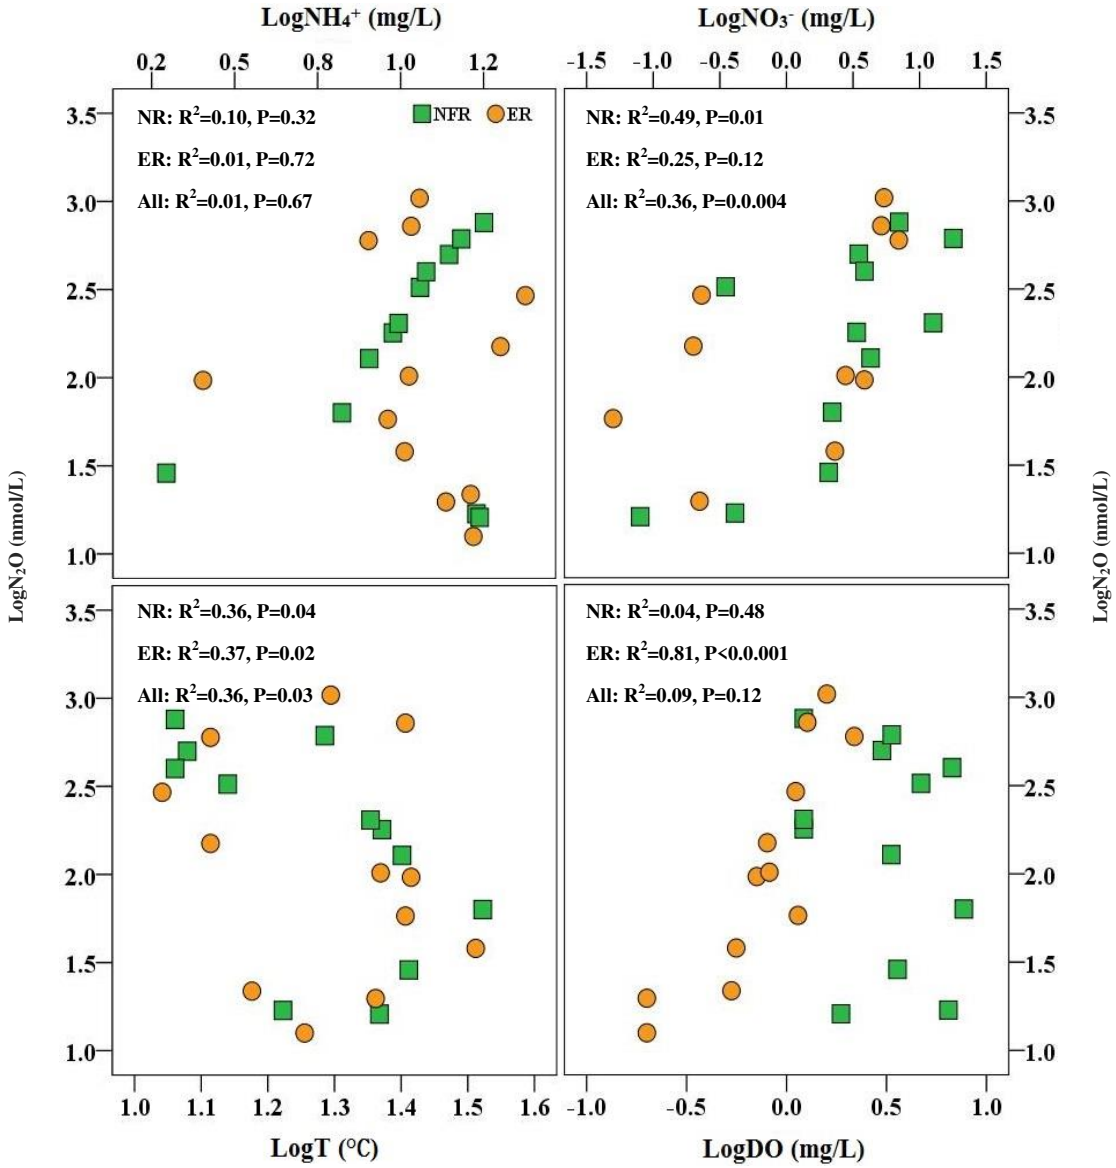

Figure 5. *Simple linear regression analysis of normalized N_2O concentration with (a) normalized NH_4^+, DO, (b) normalized NO_3^-, (c) normalized water temperature (T), and (d) normalized DO for sampling rivers*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79737985

Herein, 5 wind-based models (Liss and Merlivat, 1986; Wanninkhof, 1992; Raymond and Cole, 2001; Liu et al., 2015; Yang and Lei, 2018) and 2 wind-currents based models (Borges et al., 2004; Clough et al., 2007; Luo et al., 2019) were selected to compare the disparities in k_{N2O} and eventually N_2O fluxes among models. The results showed wide disparities in gas transfer velocity estimates between different models. Overall, k_{N2O} ranged 0.03~29.05 cm/h and averaged 4.26 ± 4.22 cm/h (*Fig. 6*). LM86a gave the lowest estimates while CL07 gave the highest estimation results. BO04 model expressed by *Equation 2* gave an intermediate k_{N2O} value (mean 4.77 ± 1.61 cm/h) relative to the other selected models. Generally, estimated k_{N2O} using wind-based models indicated lower level than wind-current based model. Thus, studies that applied wind speed value only to estimate N_2O emissions in rivers may be grossly underestimating emissions and their contribution to the global budgets. The results also indicated that providing a range for the model-based N_2O emissions might be more reliable than providing a single flux value by using a single model.

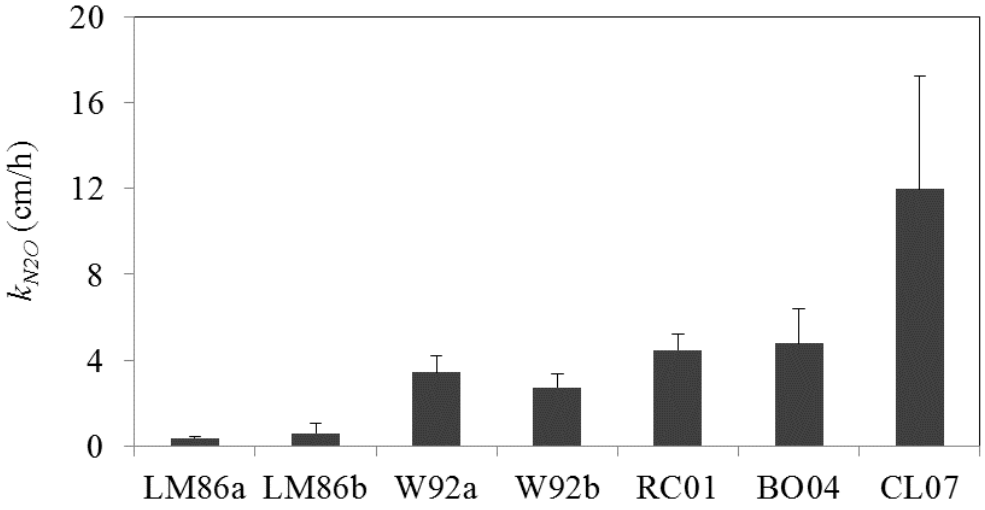

Figure 6. *Comparison of gas transfer velocities estimated*

Conclusions

Seasonal variation in N_2O concentrations and emissions of two urban rivers receiving sewage effluents in Chaohu Lake basin of China was investigated, to provide information on N_2O concentrations and emissions in the similar areas. The sampling rivers were oversaturated in N_2O and were net sources of atmospheric N_2O. Generally, significantly higher N_2O concentrations and emissions were observed during cold seasons. The simple linear regression analysis showed a negative correlation between N_2O concentration and water temperature based on the data collected, which may be regulated by the inverse tendencies between temperature and riverine N loadings during the study period. The results for the predicted production of riverine N_2O showed that DO is a better predictor of N_2O in NR explaining 60% of variability in N_2O, indicating N_2O production was limited by DO concentration; while water temperature and NO_3^- are better predictors of N_2O in ER explaining 73% of variability in N_2O, indicating N_2O production was NO_3^- limited. The riverine N_2O may be produced by denitrification in Nanfei River while by coupled nitrification-denitrification in Ershibu River.

DOI: http://dx.doi.org/10.15666/aeer/1704_79737985

Although further investigation is clearly needed to answer the question of how best to proceed before any unquestionable conclusion can be drawn, deriving quantitative estimates and the relative implications such as those presented in this study, is helpful to advance the policy debate. In the future, impacts of economic activities and land use on the concentration and emission of nitrous oxide in urban nitrogen-enriched rivers would be the crux in the relative study.

(Received 9th Dec 2018; accepted 10th Apr 2019)

Abstract. Tibetan plateau is an area of global ecological and cultural significance often called the third pole of the earth, world water towers and roof of the world. The plateau provides forage to 95% of world's total yak population and supports the largest pastoral population (9.8 million) of the globe. The plateau is vulnerable to climate change which threatens grassland resources, watersheds, livestock and pastoral population. As the pastoralists are the key custodians of the plateau, this study examined their climate change perceptions and analyzed their adaptation strategies in Tibetan Plateau, China. The results showed that majority of the pastoralists were aware of the climate change issues in the plateau. It was found that pastoralists have noticed changes in climate variability leading to grassland degradation and poor animal health and productivity. TV Programs about climate change and weather forecast programs were among the key tools for developing pastoral perception about climate change. The demographic characteristic of the pastorals like education, age and household size proved to contribute in the development of climate change perceptions among pastorals ($P \leq 0.05$). The study found that livelihood diversification, having mixed livestock breeds, cultivation of high yielding and drought tolerant forage varieties, grassland fencing and controlled grazing were among the most practiced adaptation strategies in the Plateau. Pastoralists are the key stakeholders of the Plateau. Therefore, their capacity needs improvement to adapt climate effects and work with the government institutions for the betterment of the plateau and their improved livelihood so that it can create win-win situation for pastoralists and government managers as well.
Keywords: *global warming, climatic variability, pasture utilization, mitigation measures, diversification*

Introduction

Global warming is changing climate rapidly, with adverse effects of excessive and uneven rainfall, floods and droughts with impacts on forests, environment, agriculture and humanity. Therefore, climate change is thought as one of the major threats to the earth's environment and to human race. Pastoralism is internationally significant for the

DOI: http://dx.doi.org/10.15666/aeer/1704_79878009

communities it supports, the food stuff and environmental services it provides, the economic benefits it grants to some of the world's areas with the highest poverty rates and the long-lasting civilizations, it has helped survive to this day (Nori and Davies, 2007). Unluckily, threats relating to human populations, development, changes in land use and climate are challenging experts and managers to maintain and conserve these socially, culturally, economically, and ecologically precious assets around the world (Nori and Davies, 2007; Asrat and Simane, 2018).

Adaptation to climate change has been an important research topic, especially in agriculture, ever since climate change has been commonly recognized (Adger et al., 2003). There have been several studies investigating factors that affect adaptation to climate change in agriculture sector (Apata et al., 2009; Bryan et al., 2009; Below et al., 2012; Deressa et al., 2009, 2011; Hassan and Nhemachena, 2008; Seo and Mendelsohn, 2008a, b; Asrat and Simane, 2018; Hyland et al., 2015 and Lasco et al., 2015). Most of them have been conducted in developing economies where agriculture plays an essential role. In Southeast Asian countries, there have been significant variations in the intensity and frequency of extreme weather events associated with the changes in climate. The understanding of adaptation, however, is still limited as far as those countries are concerned (Francisco et al., 2008).

Adaptation to climate change in the perspectives of rural livelihood

Many research findings have highlighted the significance of policies related to climate change adaptation that can involve to deal the climate change issues (Adger et al., 2003; Hulme and Shepherd, 2003; IPCC, 2001, 2014). Adaptation is an approach that helps to manage ecological systems and socio-economic in reference to climate change consequence (Gallopin, 2006; Smit et al., 1999). Adaptation is generally considered as a capability of a society to form social capital in collective way (Adger, 2003). The capability and efficiency of climate change adaptation relies on the vulnerability of people and natural systems to climate adverse effects. The vulnerability "is the susceptibility to be damaged from pressures related with environmental and social change without having any capacity to cope with" (Adger, 2006). Ability to adapt climate change is context specific and varies among nations, communities, social groups and individuals over time (Smit and Wandel, 2006).

To minimize the vulnerability of an individual and a society to changes in climate has close connections with rural livelihood improvements, as poor livelihood is known as a condition and determinant of vulnerability (Tanner and Mitchell, 2008). According to Sen (1999), poverty is linked to inadequate outputs related to health, nutrition and literacy, as well with weaker social relations, insecurity, low self-worth and non-helping attitude. Sen (1999) comments that the basic ability of people improves their ability to question, challenge, propose and control new actions. Poverty has also linkage to social justice and is explained as "an incapability to contribute, due to limited resources" (Whelan, 2007). Thus, a multidimensional viewpoint of poverty highlights a broader picture of deficiency, social variables, relationships and structural aspects (Curwood and Eckerle, 2009; Frye, 2008).

The climate change and livelihood perspectives in the study area

In China, Grasslands occupy two thirds of the Tibetan Plateau's area (Cui and Graf, 2009), and climate change impacts on the plateau ecosystem have already been observed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79878009

(Fu et al., 2012). The Tibetan Plateau is sensitive to global climate change because average air temperatures have increased at much higher rates (0.16 °C/decade) than Northern Hemisphere as a whole (Liu and Chen, 2000; Zheng et al., 2002). (IPCC) The Intergovernmental Panel on Climate Change projects that by 2050s, temperatures on plateau will increase more than 3 °C (IPCC, 2007), although precipitation changes on the plateau will likely be variable (Niu et al., 2004; Li and Kang, 2006; Xu et al., 2008).

Tibetan communities are dealing with the highly variable climate and winter snowstorms for many years. Traditionally, to live with the harsh climate, the Tibetan herders have developed a range of sophisticated strategies. These included migratory grazing over time and geographic space, flexibility in migration patterns and underlying social norms (e.g., reciprocity and trust), making use of diverse environment (e.g., seasonal pastures) and plant species, and the exchange of products from livestock and substance essential for daily living through local markets. Diversifying herd composition according to grassland vegetation is also employed to minimize the risk of livestock loss in harsh winters (Miller, 2002). These strategies helped them to lessen the damages during climate hazards and to have an efficient use of grassland resource base.

In the scenario of changes in climate, herder communities on the Tibetan Plateau would like to face more risks due to climate change. In order to improve Tibetan grassland social-ecological systems herders that are highly prone to climate changes should be capable to counter these changes. Governments are required to support and take advantage of adaptation strategies that are already being practice in a proven way further built up ability of herder communities to adapt. Thus, examination of historical adaptation mechanism based on livelihood and associated local institutional facilitators are important for this goal.

Strengthening of institution and changes in policies can support adaptation process by removing or introducing subsides and insurance systems, by supporting and inducing income diversification and early warning systems and other forecasting and crisis-awareness systems. However, it is significant that pastoralist should help to devise these actions. Keeping in view climate change scenario, this study documented the socioeconomic profile of the pastoralists. The study also recorded the climate change perceptions and adaptation strategies by the pastorals. The data generated and recommendations made through this study would help policy makers, scientist and managers to improve grasslands and pastoral livelihood in Tibetan Plateau. The specific objectives of the present study include: i) to document community perception about climate change and the factors responsible develop this perceptions; ii) to document activities adopted by the pastoral communities for climate change adaptation and how they diversify their activities for sustainable livelihood; iii) to document the recommendations made by the pastoralists for improving capacity and efficiency for climate change adaptation.

Materials and methods

Study area

This research study was accomplished in Daiqian Village of Zhuaxixiulong Township of Tianzhu County of Tibetan Autonomous Region of Gansu Province, China and Dawu Village of MaqinGuoluo Prefecture Qinghai Tibetan plateau. The topography of Daiqian village is relatively diversified due to the topographic impact of Maya Snow Mountain to the south and Leigong Mountain to the north. Jinqiang River flows into the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79878009

valley from west to east. Different landforms and communities of various plants and grasses are scattered along the river. The Dawu Village is located at Maqin County of Guoluo Prefecture of Qinghai Tibetan Plateau of Qinghai Province (*Fig. 1*). The salient features of the Daiqian Village and Dawu Village have been described in *Table 1*.

Table 1. *Salient features of the selected villages*

Location	1. Daiqian Village: Tianzhu County of Autonomous Region, Tibetan Plateau of Gansu Province, China 2. Dawu village: MaqinCounty of Guoluo Prefecture, Tibetan Autonomous Region, Qinghai Province, China
Geographical location	1. N 37°14′, E 102°35′ 2. N 34°28′11″, E100°12′39″
Elevation	1. 3177 m above sea level 2. 4200 m above sea level
Climate	1. Mean annual temperature, -0.1 °C; Mean annual precipitation, 416 mm 2. Mean annual temperature, -0.6 °C; Mean annual precipitation, 513 mm
Households	1. 120 2. 180
Population	1. 600 2. 1075
Vegetation	1. Alpine meadows 2. Alpine meadows
Major livestock types	1. White Yak, Tibetan sheep and others 2. Yak, Tibetan sheep and others
Livelihood	Mostly dependent on grasslands for grazing their livestock for livelihoods

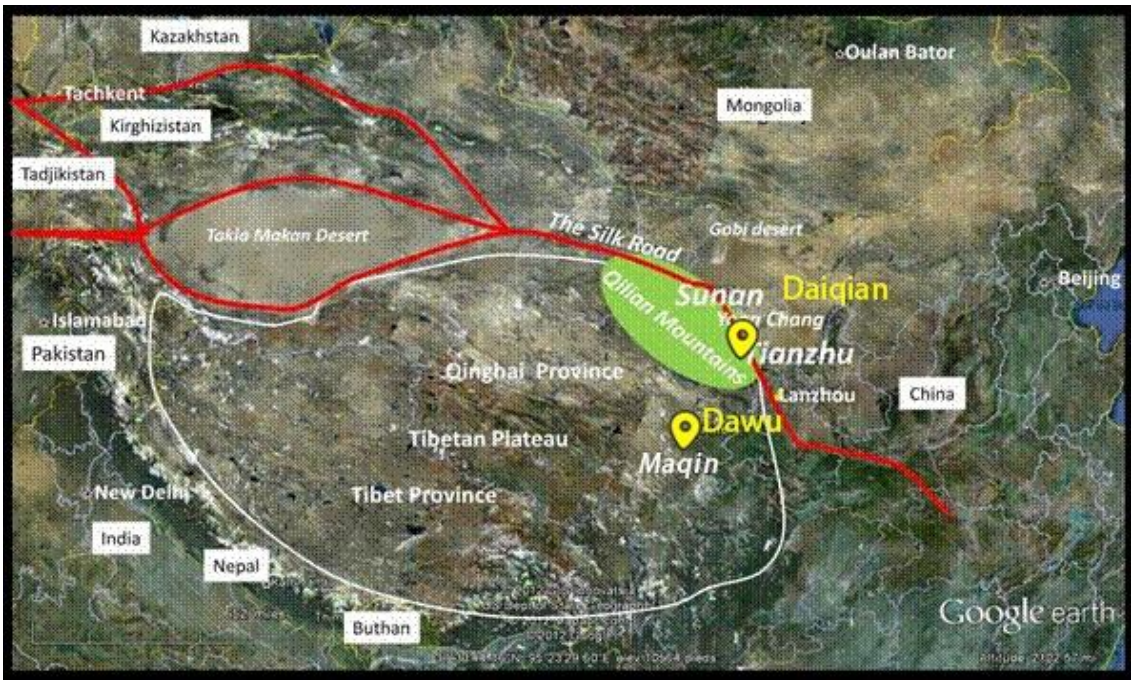

Figure 1. *Study area (Daiqian & Dawu). Red line is showing the Silk Road and green area is showing the Qilian Mountain. (Source: Google Earth®)*

Variation in climate parameters (temperature and precipitation) in study areas

The climate of the study area is cold temperatures and most of precipitations occur in the form of snowfall due to its location at high altitude and dry temperature zone. The last two decades climate data (1991-2012) of the areas (Tianzhou county and Maqin county) is given in *Figure 2*. Along with the variation in annual precipitation of both counties (Tianzhou county and Maqin county) is given in *Figure 3*.

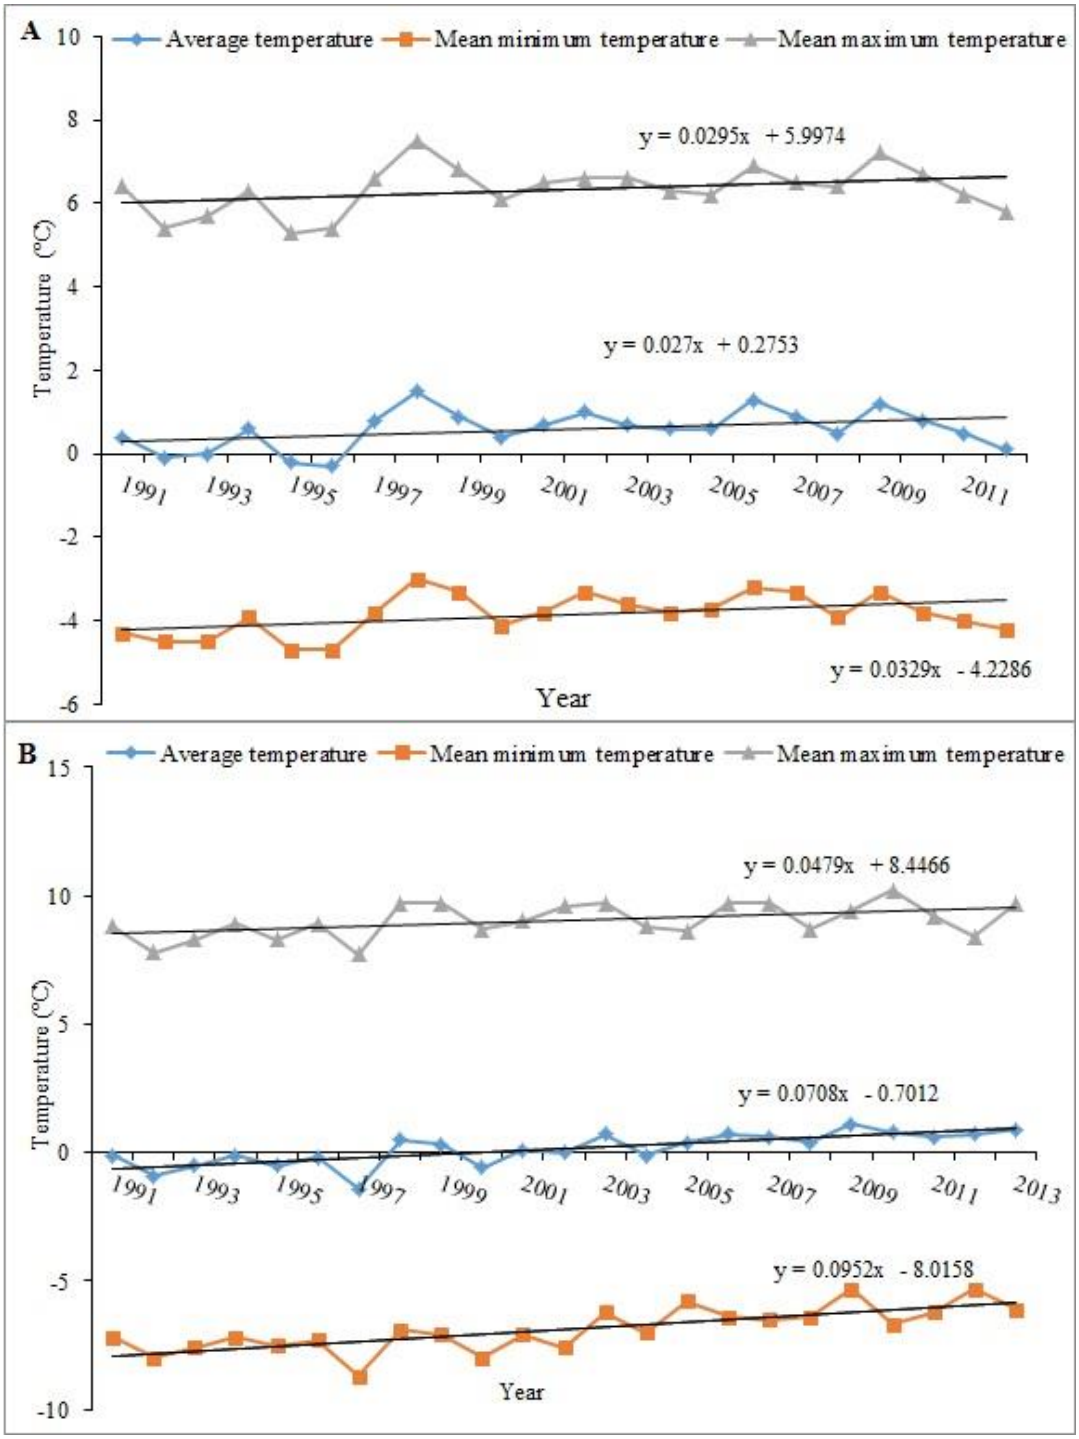

Figure 2. *Variations in annual temperature data. A) Tianzhu County 1991-2011. B) Maqin County during 1991-2013*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79878009

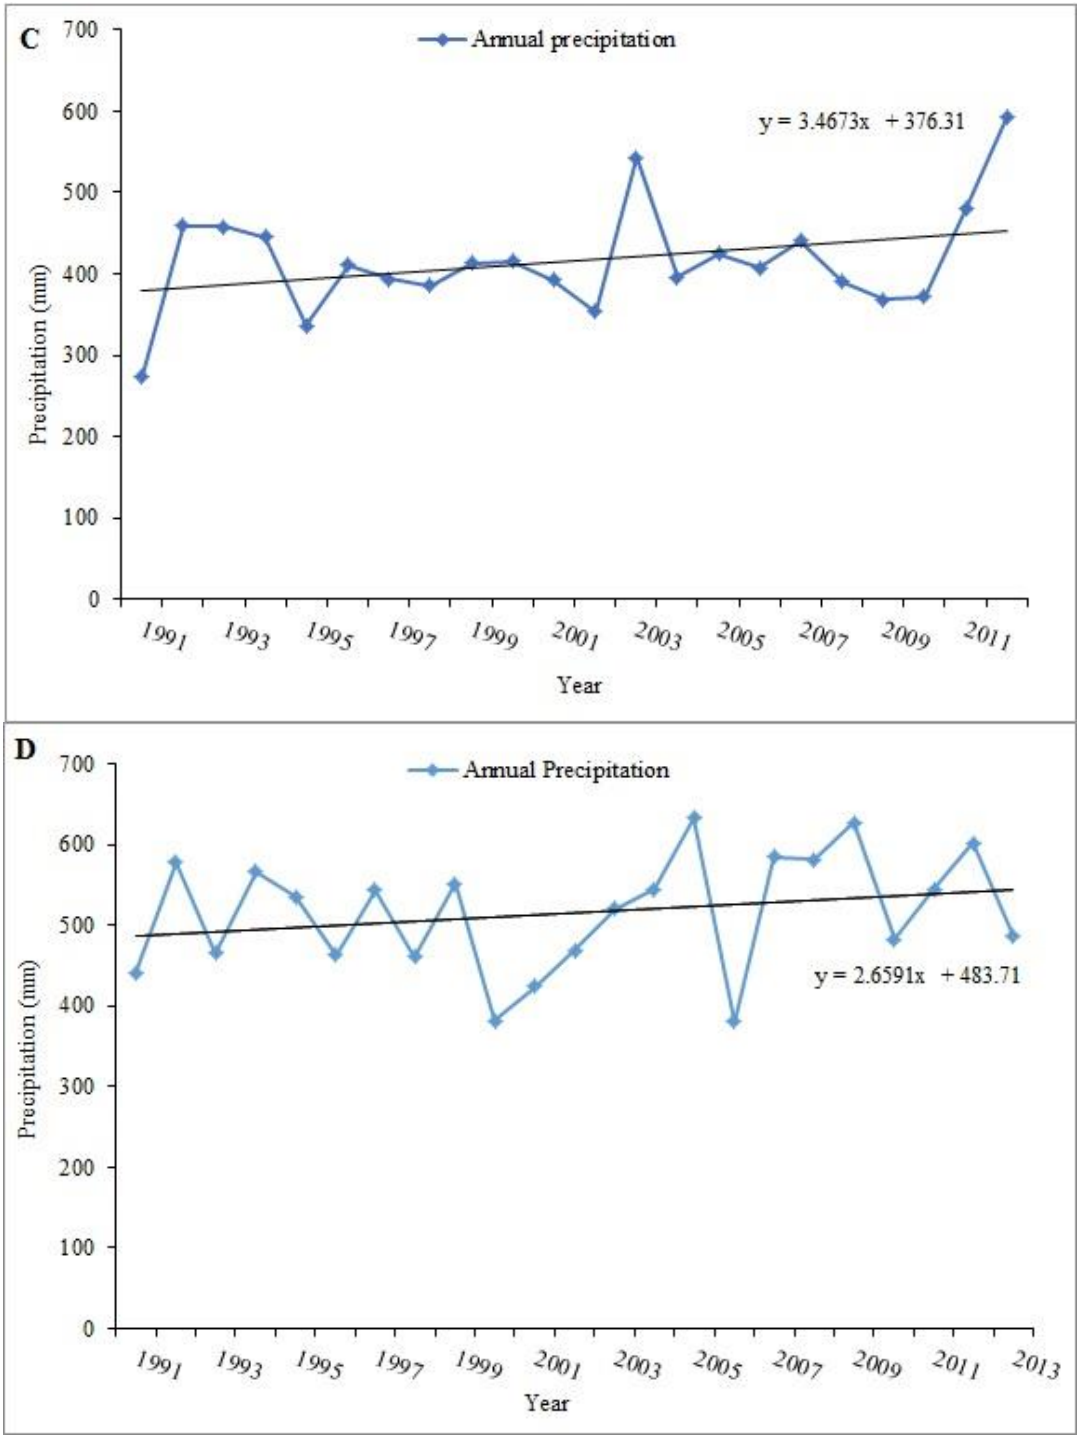

Figure 3. *Variation in annual precipitation data. C) Tianzhu County 1991-2011. D) Maqin County during 1991-2013. (The climate data of Tianzhu County and Maqin County are from http://data.cma.cn/data/cdcdetail/datacode/surf_cli_chn_mul_yer.html, by permission)*

Increasing temperature

Analyses of temperature variability over the last two decades in Tianzhou County have been given in (*Fig. 2A*). A gradual increase in average annual, mean maximum and mean minimum temperatures have been noticed in the study area. The trend line shows

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79878009

upward trend indicating a gradual increase in annual temperature from 1991-2013. For example, the mean maximum temperature ranges from 5.3 °C in 1995 to 7.5 °C in 1998. Similarly, year 1998 and 1995 had the highest mean minimum temperature -3.0 °C and lowest mean minimum temperature -4.7 °C, respectively. There is a sudden variation in temperature in Tianzhou County. The mean maximum temperature ranged from 7.2 °C in 2009 to 5.8 °C in 2012. In the same way year 2009 and 2012 had the highest mean minimum temperature -3.3 °C and lowest mean minimum temperature -4.2 °C respectively. In Maqin county (*Fig. 2B*) temperature is gradually increasing and is also highly variable. The mean maximum temperature in year 2010 and 2012 is 10.2 °C and 8.4 °C) respectively. In this county in 1997 had the lowest mean minimum temperature -8.3 °C) and 2009 and 2012 had the highest mean minimum temperature -5.3 °C).

Erratic precipitation

A noticeable variation in precipitation patterns over the last 22 years has occurred (*Fig. 3C*). In 1991 annual precipitation was recorded as the lowest 274 mm and in 2012 was recorded as the highest precipitation 592.8 mm during the last 22 years.

In Maqin County (*Fig. 3D*) the variation in annual precipitation is also noticeable. For example year 2005 had the highest annual precipitation 632 mm and year 2006 had the lowest precipitation 380 mm during the last 22 years. The trend line shows an increasing trend both in temperature and precipitation in both of the study areas; however the deviation in the lower or higher case is much prominent that may be due to climate change effects. However the impact of these extreme variations may be much pronounced on grasslands and livestock health that actually helps pastoralists to perceive these variations.

Pasture utilization and animal feeding calendar of a year

The grazing period for animals is from mid-June to mid-August. The summer pastures are far from pastoralists' houses and all of the animals have free access to the pasture for grazing in summer. A generalized pasture utilization and animal feeding calendar of the year is given in *Table 2*.

Table 2. *Major features of livestock production system of study areas*

	January	**February**	**March**	**April**	**May**	**June**	**July**	**August**	**September**	**October**	**November**	**December**
Animal's area	Winter pasture				Summer pasture				Autumn pasture	Winter pasture		
Grazing	-			+	++	+++			+	-		
Supplementation (forage)	Yes									Yes		
Supplementation (concentrates)	Yes											
Milking						Yes						
Calving period					Yes							
Lambing period			Yes									
Wool sales						Yes						
Animal selling period									Yes			
Planting period					Yes							
Harvest									Yes			

-No grazing, +light grazing, ++moderate grazing, +++heavy grazing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79878009

Data collection

The data was collected through questionnaire and interviewing (see *Appendix*). 30 households were selected from Daiqian Village while 40 households were selected from Dawu village. The snowball sampling method was applied to approach the respondents. Snowball sampling approach is more appropriate to access the populations which are difficult to locate. Pastoralists often have scattered homes far from one another in the mountains and hilly areas with no proper access. So keeping in view we used snowball sampling method in this research. Interviewing helps scientists to look into the features of a society and know about a particular social fact by respondents own opinion (Dutcher et al., 2004). All interviews with villagers were taken with the help of Chinese interpreters, and all respondents showed their willingness to give interview. The data collected thus was tabulated in excel program.

Data analysis

For the purpose to describe and have a fair understanding about the collected data, data were analyzed using sociological statistic software known as Statistical Product and Service Solutions (SPSS 13.0 version, 2004) and Microsoft Excel. Based on the statistical results of the research conclusions were drawn. Statistical analysis base on best fit model, relying on the null hypothesis (H0) that an effect does not exist whereas the alternative hypothesis (H1) is contrary to that (Field, 2009). The acceptance or declining of the null hypothesis base on the probability value (p-value), that is to be related to the confidence interval around the average value of a tested response variable. A 95% confidence level was considered in this study and then, if the p-value is below or equal to 0.05, the null hypothesis is declined. Descriptive statistics, binomial and chi-square tests were also applied in this data analysis.

Binomial test

To examine whether respondents perceive (category I) or not perceiving (category II) about the statement of climate change perception, we carried out a binomial analysis. This analysis was also used for frequencies for category I and II of the variables "perception", "impacts" as well "adaptations" that have been explained in *Table 3*. Binomial test also examines frequencies of every class of "Yes" and "No". In our research we examined either the frequencies of category I differs from the category II. In this case null hypothesis (H0) was created like "the frequency of category I (Yes) is higher than the frequency of category II (No)".

Chi-square test

In order to better understand the relationship between two categorical variables Pearson Chi-square test was applied. The analysis gives a judgment between the observed frequency level in a category and the expected frequencies by testing perfect random possibility (Field, 2009). A null hypothesis was created "there is no relationship between the two variables" and a substitute hypothesis (H1) describes "there is a relationship between the two variables". There is a key supposition in this analysis that expected frequencies must be more than 5. If every variable has only two categories, we should use Fisher's exact test. The Pearson chi-square tests results are not consistent every time, and can be considered investigative only.

Table 3. *Description of the variables changed to a categorical scale*

Variables	Description	Category I	Category II
Factors for developing climate change perception	The following helped to develop climate change perceptions • Personal observations • Government department • TV programs • Weather forecast	Yes/agree	No/disagree
Awareness of weather	Farmers awareness about the changes in climatic conditions • Temperature is rising • Rainfall is decreasing	Yes	No
Impacts on resources	Are there any adverse effects of climate change on grasslands and livestock? • Grassland degradation • Negative impacts on livestock health • Deaths in livestock	Yes	No
Adaptation	Are they adapting the climate changes? • Water harvesting • Forage cultivation • Good quality seed • Fencing • Controlled grazing • Mixed livestock breed	Yes	No

Results

Displayed results contribute a better insight of pastoralist's perceptions about climate change and their adaptation for these changes. It will help the governments to find the best possible incentives, measures and interventions to improve the adaptation practices and protect the natural, environmental and cultural resource on a sustainable base that has a unique global importance. Firstly, the participant's general demographic characteristics are described; containing gender, age, education, household including their socioeconomic profile about incomes and expenditures. Secondly, perception of the pastoralists including contributing factors leading to develop climate awareness in pastoralist has been described. Thirdly, measures taken by the pastoralists to adopt issues associated to climate change and diversification of livelihood have been discussed. Lastly, the recommendations made by the pastoralists to enhance climate change perception and adoption in Tibetan Plateau have been explained.

Demographic profile of pastoral community

Table 4 shows the demographic profile of the respondent pastoral communities of the Daiqian Village and Dawu Village. The respondents from Daiqian village consists of 66.33% male and 36.37% female while in Dawu village most of the respondent were men 92% and only 8% were the female respondents. The age of the respondents ranges from 30 to 70 years. Majority of the respondent (40%) in Daiqian village belonged to 40-50 years age group as compared the 50% of the Dawu village respondents belonged to age group of 30-40 years. In Daiqian village majority of the respondents (41.9%) got their education up to primary level while in Dawu village majority of the respondent

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79878009

were illiterate as the 85% of the respondent had no education. The household size of the respondents was divided into less than five members and greater than five family members. In Daiqian village majority of the respondent have family size of the ≤ 5 that counted about 73% while in Dawu about 50% of the respondents were having family member ≤ 5.

Table 4. *Demographic profile of pastoral communities of selected villages*

Variable	Category	Daiqian village	Dawu village
Gender	Male Female Total	19 (66.33%) 11 (36.67%) 30 (100%)	37 (92%) 3 (7.5%) 40 (100%)
Age (years)	30-40 41-50 51-60 61-70	8 (26.66%) 12 (40.0%) 8 (26.67%) 2 (6.66%)	20 (50%) 11 (27.5%) 2 (05.0%) 7 (17.5%)
Education	Illiterate Primary Elementary	12(40%) 13 (41.9%) 5 (16.1%)	34 (85%) 6 (15%) 0
Household size	≤ 5 > 5	22 (73.33%) 8 (25.8%)	21 (52.5%) 19 (47.7%)

Rural household resources and socio-economic characteristics

Rural household resources and socio-economic profile of the respondent communities of Daiqian village and Dawu village have been recorded in *Table 5*. Both of the villages have minimum household size of family members of 03 while on the other hand Dawu village have maximum number of family members up to 09 as compared to 07 members of Daiqian village. The mean pasture land holding size of Daiqian and Dawu is (13 ha) and (33 ha) respectively. The maximum land holding size for pasture is (38 ha) while in Dawu it reached to (133 ha). The mean mobility of the herder in Daiqian and Dawu village was recorded as 3 km. Mean annual income were found in Daiqian (7886 $), that were more in Dawu (8422 $). Similar trend was observed in mean annual expenditures in both villages. Mean livestock number was more in Daiqian as compared to Dawu village.

Table 5. *Rural household resources and socio-economic characteristics of study areas*

	Daiqian				Dawu

Economic profile of the selected respondent communities

Figure 4 explained the economic profile including the income sources and types of various expenditures incurred of the respondent communities of Daiqian and Dawu villages during the year. Major income sources included livestock sale, wool sale, caterpillar fungus sale, subsides and other including labor, sale of milk , dung etc while the major expenditures include buying livestock, daily living (food and other things), medical, livestock feed, vaccination and others. Livestock sale, subsidies were among the major income sources for both of the communities while living and animal feed were among the major expenditures of the respondent communities.

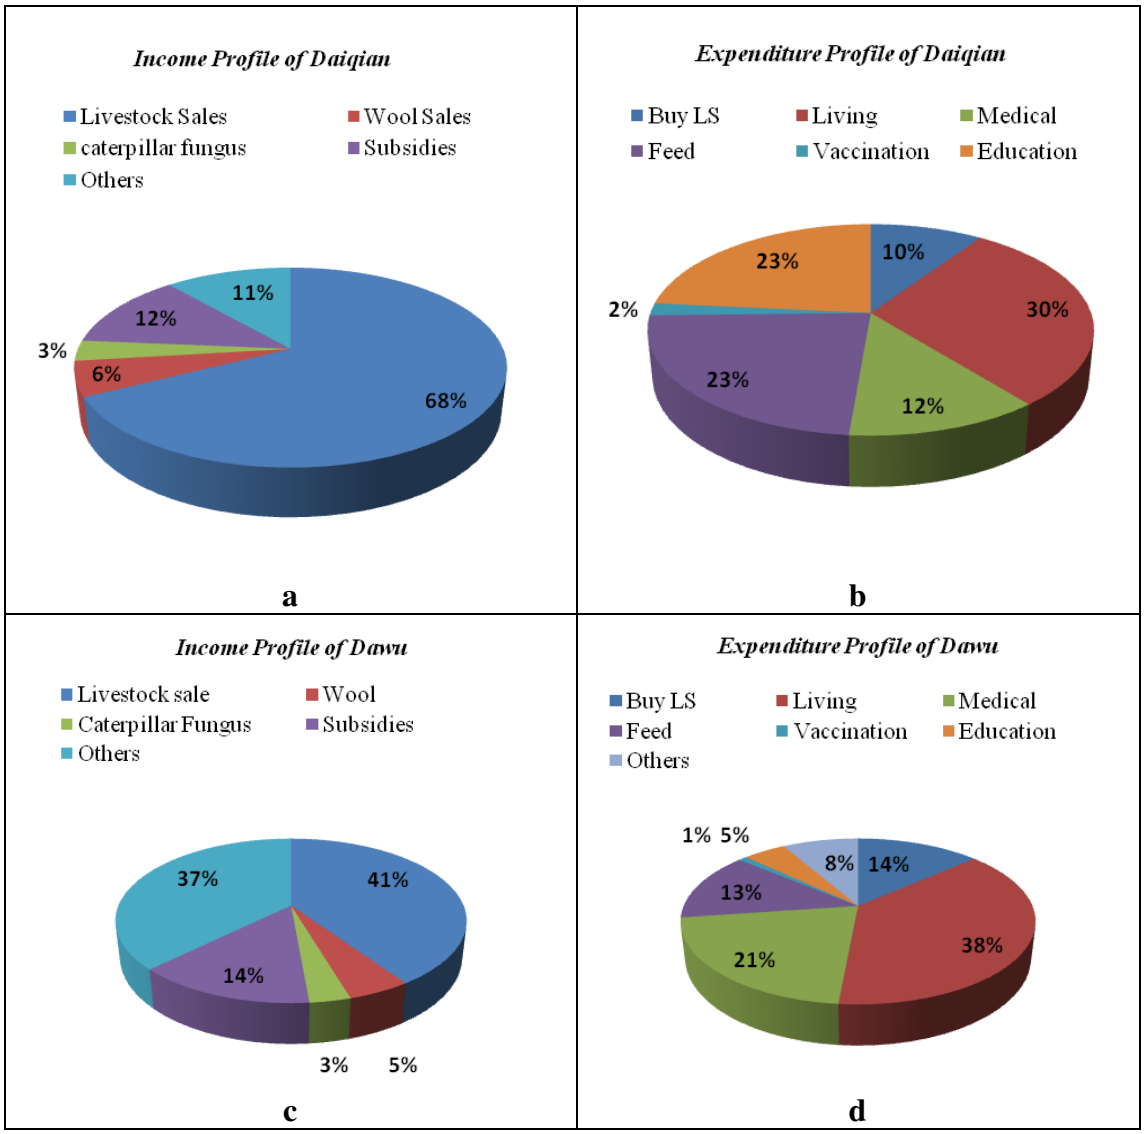

Figure 4. *Income and expenditure profile of the pastoral community*

Pastoralist's perceptions about climate change

The data presented in *Figure 5* has shown the responses of the pastoral communities about climate change perception. Responding to the question whether they know about

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79878009

climate change or not. 83.3% of the respondents belonging to Daiqian village were aware of the climate change issues while about 16.7% of the respondents were not aware of the climate change phenomenon at all. As compared to Daiqian, the pastoral community of the Dawu was less aware of the climate change. However majority of the respondents of Dawu village75% had the knowledge about climate change while 25% did not have awareness about climate change (*Table 6*).

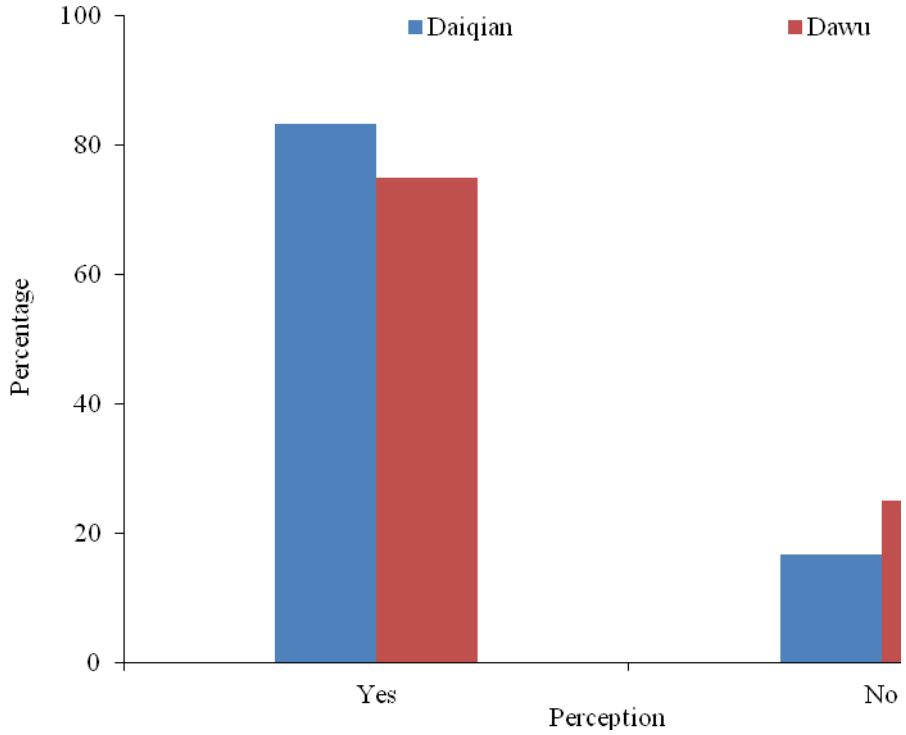

Figure 5. *Pastoralist's perceptions about climate change in selected villages*

Table 6. *Climate change perception and factors for perception development*

Variable	Statement	P value Daiqian	P value Dawu
Knowledge about climate change	Know about climate change	.000	.001
Factors for developing climate change perception	Personal observations	.043	.006
	Government department	.000	.000
	TV programs	1.000	.006
	Weather forecast	.000	.002

Majority of the respondents 72.5% in Dawu village were having a personal experience to judge the climate change issue while only 30% in Daiqian village have examined the climate change through personal observations (*Table 7*). The other factor contributing in the development of climate change awareness among pastoralist included Government Departments, weather forecast program, TV programs and multiple sources. Weather forecast program and TV program jointly contributed in developing perception among 13 (43%) and 16 (40%) of the respondents in Daiqian and Dawu respectively.

DOI: http://dx.doi.org/10.15666/aeer/1704_79878009

Table 7. *Different tools of climate change perceptions among respondents*

Sources of climate change perception	Daiqian	Dawu
	Frequency/percent	Frequency/percent
Personal observation/experience	9 (30.0%)	29 (72.5%)
From government department	2 (6.7%)	3 (7.5%)
Weather forecast	5 (16.7%)	10 (25.0%)
TV program	8 (26.7%)	6 (15.0%)
Multiple sources	15 (50.0%)	11 (27.5%)

Perceived impacts of climate change

After recording the pastoralists knowledge about climate change and tools helping to develop awareness about climate change, next to that pastoralist were asked about the perceived impacts of climate change. *Figure 6* shows, in Daiqian village, most of the participants (18%) perceived changes in climate in the form of rise in annual temperatures in the area (p = .043) while 29% of the respondents perceived changes in climate in the form of low rainfall and rainfall variations (p = .000). The other perceived negative impacts of climate change in Daiqian were low production of the grasslands (12.5%), poor animal health (15%) and death of animals (12.5%) (= .000). On the other side, 17.5 and 15% (p = .000) of the respondent in Dawu village increase in temperature and lower rainfall distribution respectively (*Fig. 6*).

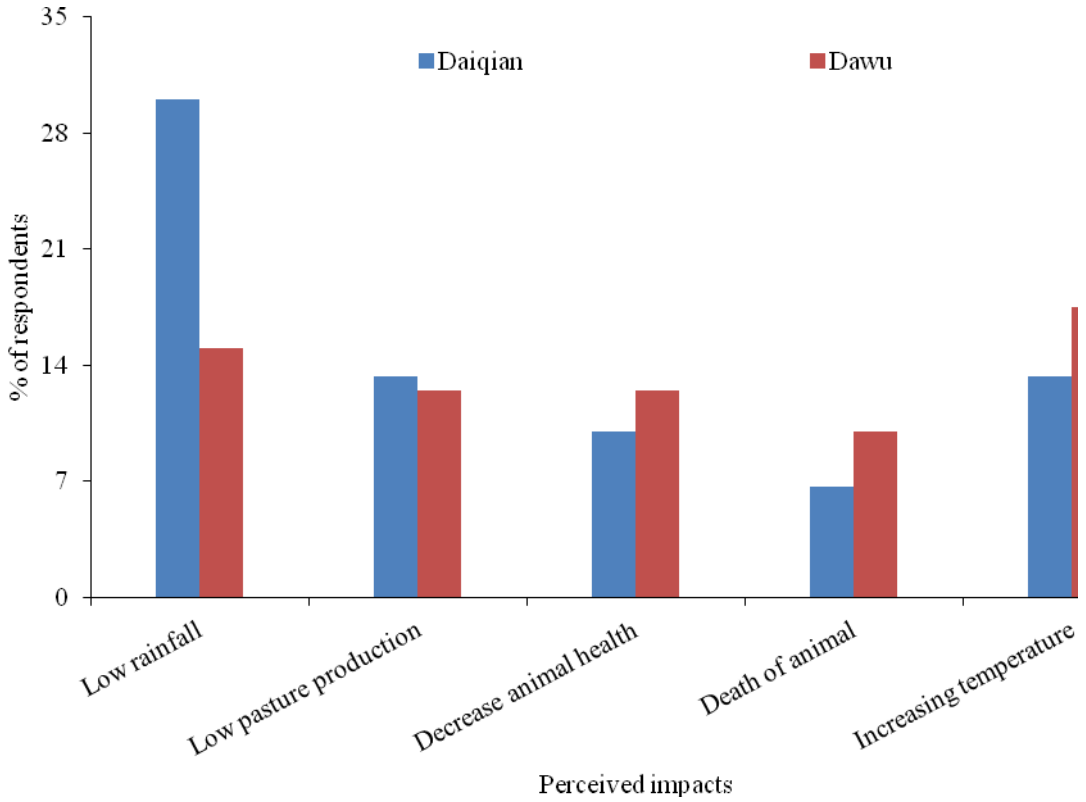

Figure 6. *Perceived impacts of climate change by pastoral communities*

DOI: http://dx.doi.org/10.15666/aeer/1704_79878009

Climate change adaptations

The data about adaptation measures being practiced by the pastoralists have been presented in *Figure 7*. In Daiqian village having mixed livestock was one of practice that being adopted by majority of the respondents of 86.7% ($p = .000$), the having mixed livestock not only helps to utilize the available grassland resources but also can be voided loss in case of any epidemic to one type of livestock. In addition smaller animal can be sold as and when needed due to shorter age of maturity and high prices to sustain the livelihood. In Dawu village about 57.5% were having the mixed livestock. Controlled grazing was being adapted by the respondents (60%) of both of villages equally to minimize the climate impacts on their daily life management scenario, Good quality seed for forage cultivation and fencing to pasture area were also recorded as the strategies to reduce climate change impacts on livelihood of the pastoralists.

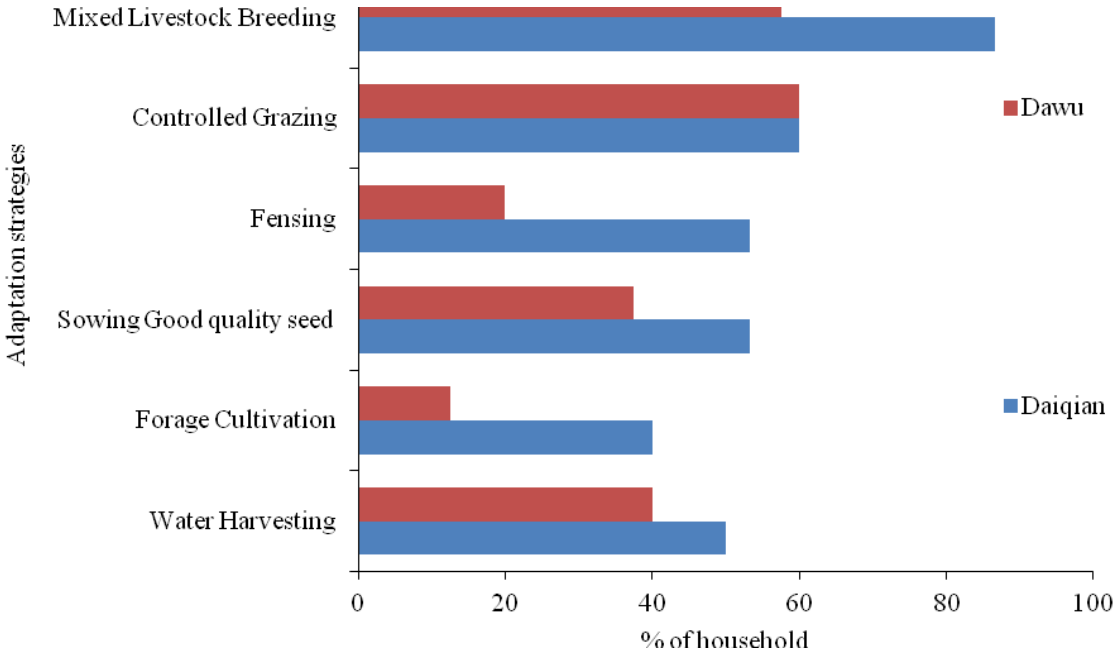

Figure 7. *Climate change adaptation measures by selected communities*

Relationship between demographic factors and climate change perception and adaptation

The demographic factor may have had an effect on the climate change perception, impacts and adaptation. It was tried to expose such relationship through chi-square tests. If these relationships are known, it will be easier to develop sufficient and area specific governmental intervention. *Table 8* describes the results about the relationship is significant or not. The data shows that only the age is one of the significant factors in Daiqian village that may influence their given answers significantly for developing the perception among the pastoralists. Similarly education is Daiqian village could possibly be helpful influencing the knowledge of the respondents about climate perceptions. Similarly household could positively be able to contribute in developing the perception of climate change knowledge in respondents.

Livelihood diversification

Livelihood diversification is considered as one of the effective tools that not only helps pastoralists to manage climate change effects but also supports sustainable livelihood by enhancing income levels of the pastoralists. While responding about livelihood diversification mixed livestock was considered as one of the major activity in both of the villages because it is not only utilizes the pastures in a better way but sheep and goats can be sold as and when needed to meet the urgent needs (*Fig. 8*). However in Daiqian village about 86.7% of the pastoralists were having mixed livestock to sustain their lives and meet their daily needs where in Dawu only 57.5% were having the mixed livestock. Almost all of the pastoralists were selling wools of their animal to earn some money. In addition collection and selling of caterpillar fungus, labors were also recorded as means to diversify pastoral income in Daiqian and Dawu villages.

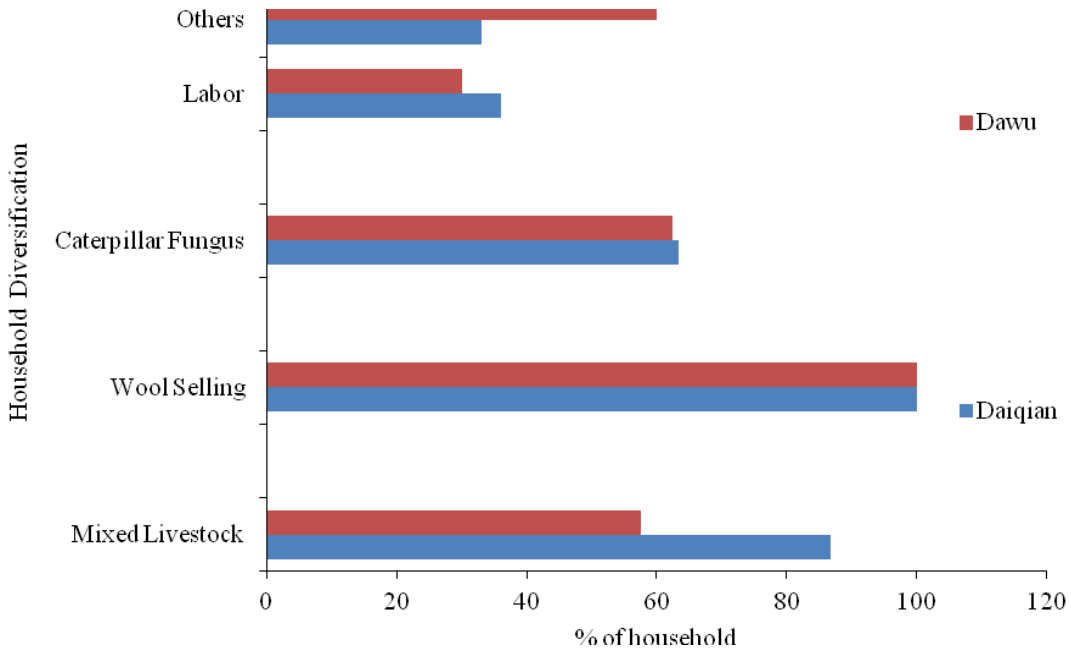

Figure 8. *Livelihood diversification measures by pastorals in Daiqian and Dawu villages*

Institutional set up and government policies

The pastoralists were asked whether they know about the institutional set up and government policies about different sectors in their villages. Responding to the

DOI: http://dx.doi.org/10.15666/aeer/1704_79878009

questions most of pastoralists in villages were aware about pasture management institution and policies *Table 9*. In Daiqian village 56.7% and Dawu village 60% of the villages were aware about the pasture management and related policies. Following to the pasture management, people were aware about the credit organizations in both villages as in Daiqian 46% and Dawu 15%. People in both of the villages were also having more or less information about NGOs, Water management and Agriculture management both villages.

Table 9. *Institutional set up and government policies*

Govt. Policies	Daiqian			Dawu		
	Yes	No	Don't know	Yes	No	Don't know

NGO's	30.0%	40.0%	30.0%	22.5%	67.5%	10.0%

Key recommendations by pastoralists to mitigate future effects

Pastoralists are the key custodians of the grasslands of the Tibetan Plateau. They can play a significant role in the conservation of this resource base if their opinion is given due consideration and noticed their needs in this regards. Keeping in view it was sought to put a question about their recommendation to not only conserve this resource but this unique diminishing social and cultural heritage of pastoralism (*Table 10*). The majority of the Daiqian respondents (26%) recommended that grassland degradation should be controlled. Secondly they recommended (20%) that their capacity should be built through training about pasture and climate change management as well as similar number of respondents recommended watering points for live stocks. In addition about 16.7% of the respondents suggested developing forage bases and introduction seed of drought and cold tolerant good forage varieties. In the case of Dawu village capacity building for pasture and climate change, establishment of watering points for grazing livestock in the pasture area, development of forage base with introduction of good variety seed were recorded (*Table 10*).

Table 10. *Key recommendations by pastoralists to mitigate future effects*

Recommendations by pastoralists	Daiqian (%)	Dawu (%)
Training of pasture knowledge and climate change scientific management	20.0	17.5
Awareness campaigns	13.3	10.0
The establishment of livestock water points	20	17.5
Strengthening governance about the protection of natural grassland	3.3	10.0
Increase grassland degradation control	26.7	10.0
Development of forage base and cultivate new varieties of drought resistant	16.7	17.5
Infrastructure for drinking water	6.7	5.0
Strengthen meteorological disaster forecast	10.0	17.5

Discussion

Farmer's perceptions about climate change

This study noticed some important findings about the perception. The study found that the participated pastoralists had knowledge about climate changes and its impact on their lives and associated resources. The findings are in line with the results of Thomas (2008) who found that farmers could recognize changes in climate and increased variability in natural climatic conditions due to climate change. In some sense, communication on climate change has been enormously successful. Across nations, almost everyone in study area has heard the issue and many can identify at least some important climate change impacts (Leiserowitz, 2007). In this study, communication way like electronic media, weather forecast information has been noticed as the tool to develop perception of the respondent about climate change. It is therefore, suggested that government institutions and policy makers could use media as a tool for developing climate change perception among masses. The awareness about climate change is related to age thus older pastoralists have better understanding about climate change that may be based on their experience to observe these changes. Pastoralists in Tibetan Plateau indicate a declined precipitation and increased temperatures with a short rainy spell. The comparable findings were reported by several other researchers as (Lema and Majule, 2009; Wongtschowskiet al., 2009; Zampaligréet al., 2013). Pastoral perceptions have been verified by the long term climate data examination that highlighted a decreasing tendency in rainfall pattern with a mild to highly worst drought frequency, and increase in temperature. The findings of (IPCC, 2007) observed a universal shortage in rainfall with increased temperatures along with a hint that there will be higher rainfall occurrence in some areas, while many other areas will receive insufficient rainfall. The Tibetan plateau may fall in the second scenario having low rainfall. However, if local people's native knowledge about prediction of weather changes has been interrupted, this may lead to inefficiency of local mitigation and adaptation strategies (Nyonget al., 2007). Agro-pastoralists understand that change and inconsistency in climatic conditions effects grasslands, water resources, animal vigor and productivity. Actually, the production of agriculture, grasslands and water resource are greatly associated with climatic parameters such as precipitation and temperature. Decline in rainfall causes a reduced pasture production (Lema and Majule, 2009; IUCN, 2010). Increase in temperatures accelerates evapotranspiration rate by plants which leads to condition of drought (IPCC, 2007). Pastoralists' perceptions about the impacts of global change on the pastures have also been noticed by Wongtschowskiet al. (2009) and Zampaligreet al. (2013). They concluded that forage availability, the soil quality and the pastures specie composition (e.g. biodiversity) is affecting by climate change.

Adaptation strategies and livelihood diversification

Transformation in livestock possessions and livestock management systems, are fundamental for adaptation of long term global changes (Deressa et al., 2009). It was noticed that mixed live breed holdings by the pastoralists is one of the major adaptation measures in the area. This can help to not only face issues related to climate aspects but also sustain livelihood prospects. The mix livestock breed helps not only to use different types of forage and livelihood sustainability, as sheep and goats are sold out as and when needed as compared to yak that needs long time for getting more money. For efficient and better adaptation of the impacts of climate change and variability

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79878009

pastoralists diversify their livestock species, cultivate supplementary forage and practice other measures (*Fig. 9*).

Figure 9. *Pictorial representation of some adaptation and livelihood practices by pastoralists of the selected villages*

The sheep and goat have a significant role in pastoral livestock production system by allowing the pastoralists to fulfill their instant socioeconomically requirements (Malonine, 2006). Diversification by means of forage production not only produces cereals for their own food but also feed for their livestock from crop straw residues. In addition, to perform diversification crop farmers also practice shifting cultivation, enlarge their cropland, and grow superior plant breeds. However, the increased frequency and harsh intensity of climate events (floods, droughts) and the rainfall variations are posing bigger threats to the pastoralists' adaptive capacity (Kandjiet al., 2006). Farmers become more vulnerable to climate changes if they don't have very good ability to adapt climate change effects for their resilience. The pastoralists were of the view that training should be imparted to them for building their capacities to perceive and mitigate climate change issues.

Conclusions

Pastoral perception of climate change and analysis of climate data both showed a decrease in rainfall and an increase in temperatures with a reduction of rainy season in study area. Personal experience and electronic media are main factors for developing climate awareness among local pastoralist, so these should be taken into consideration while launching campaigns and initiatives about climate awareness and adaptation in the plateau. Climate change and deviation have affected the accessibility of natural resources such as pasture, water, livestock production, and livestock health

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_79878009

deterioration. Due to strong negative effects on people's welfare and safety, climate change is a huge risk to pastoral safety. To adapt these impacts of climate change and variability pastoralists shifted from monoculture (yak) of livestock to mixed species (yak + sheep + goats) and diversification of income sources. Adaptation to climate change has to be included in disaster risk reduction policies and should be regularized into land plans policies at national, local and regional levels.

Keeping in view above concluding paragraph following recommendation are made:

- Migration, ethnicity and religious believes could be important factors to develop climate change adaptation among pastorals societies, it is therefore recommended that future studies may be conducted while addressing these parameters.
- Electronic media and weather forecast programs have been indicated by the pastoralist as an effective tool for developing awareness among the pastoralists. Government and policy institutions can strengthen these sources and develop an effective mechanism for their efficient use for developing knowledge about climate change in the area.
- Personal experience and education have a strong relationship with knowledge about climate change, so Government should consider these factors while developing mechanisms
- The development of cottage industry associated to livestock products can help pastorals to improve their livelihood. There are opportunities for organic meet production and its processing, commercial production of caterpillar fungus and cottage industry related to livestock products like wool products and cheese production. All these opportunities can help to improve their livelihood and also can enhance their adaptation to the adverse effects of climate change.
- In order to improve an efficient adaptation to climate change on the bases of long term, planned adaptation is necessary. Therefore, government should offer financial in it will reduce the financial risk for the farmer. But it should be given as a reward on the bases of the pastoralists' performance for adopting good practices for climate and resource conservation.
- Pastoralists are the key custodians of the grasslands of Tibetan Plateau so they should be given a central place while developing policies and initiatives for climate change mitigations and resource restoration in the area.

Abstract. Soil respiration is an important indicator of soil fertility and biological activity, which has impact on plant yield. The aim of the present study was the evaluation of soil respiration intensity depending on different soil treatment practices in cultivation of maize and to determine the effect of biology activity on soil respiration. The study was based on the long-term field experiment located at the Agricultural Experimental Station at the Institute of Soil Science and Plant Cultivation – State Research Institute in Grabów (Poland). Three objects were included in this research: maize cropped continuously (monoculture) with direct sowing, maize monoculture cropped continuously with full tillage and crop rotation (spring barley, winter wheat, maize) with full tillage. Research indicates that soil respiration depends on cultivation method used before the maize is sown. The analysis showed that soil respiration was correlated with its biological activity and biochemical parameters. The statistically strongest negative correlation was found between soil respiration and evapotranspiration, changes in carbon dioxide concentration and acid phosphatase activity, while strongest positive correlation was found between soil respiration and ammonifying bacteria. The simple regression analysis showed linear relationship between soil respiration and such parameters as: acid phosphatase activity and ammonifying bacteria.
Keywords: *monoculture, tillage practice, microbial and biochemical properties, dehydrogenase activity, acid phosphatase, soil moisture*

Abbreviations: Sr: soil respiration (g $CO_2 \cdot m \cdot h^{-1}$), E: evapotranspiration (g $CO_2 \cdot m \cdot h^{-1}$), ΔCO_2: changes in carbon dioxide concentration, ΔMb: changes in soil moisture, SM: soil moisture (%, v/v), SBD: soil bulk density ($Mg \cdot m^{-3}$), DHA: soil dehydrogenase activity DHA (ug formazan·g DM of soil·24 h^{-1}), AcP: acid phosphatase (ug p-nitrophenol·g DM^{-1} of soil·h^{-1}), AlP: alkaline phosphatase (ug p-nitrophenol·g DM of soil·h^{-1}), B + A: total bacteria and Actinomycetes number (10^7 CFU (colony forming units)·g DM^{-1} (dry matter) of soil, F: total fungi number (10^4 CFU·g DM^{-1} of soil), AM: ammonifying bacteria (10^4 CFU·g DM^{-1} of soil), OLIGO: total oligotrophic bacteria (10^6 CFU·g DM^{-1} of soil), KOP: total copiotrophic bacteria (10^6 CFU·g DM^{-1} of soil)

Introduction

Soil respiration refers to the production of carbon dioxide by soil organisms (Luo and Zhou, 2006). A small part of soil respiration (below 10%) results from the decomposition of resistant organic carbon particles (Hanson et al., 2000; Schlesinger and Andrews, 2000).

Soil capacity to produce CO_2 varies depending on soil structure, season, intensity and quality of agrotechnical tillage, soil water, cultivated plant, fertilizer etc. (Moraru and Rusu, 2012). Soil respiration leads to CO_2 emissions from soil to the atmosphere, in significant amounts for the global carbon cycle (Moraru et al., 2010).

Tillage practices influence soil physical, chemical and biological properties, which in turn may alter plant growth and yield (Czyż, 2011; Feiza et al., 2005; Gus et al., 2008;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80118022

Mark and Al-Kaisi, 2004; Moroizumi and Horino, 2002; Natywa et al., 2009; Ozpinar and Cay, 2006; Rashidi and Keshavarzpour, 2009; Ulrich et al., 2006). They also have a significant influence on biological activities (Swędrzyńska et al., 2013; Ghimire et al., 2014) and soil CO_2 efflux (Frank et al., 2006). The soil temperature and its moisture may be affected on soil respiration intensity (Box and Meentemeyer, 1993; Frank et al., 2006; Natywa et al., 2010).

Systems for soil gas measurements offer crucial information regarding production, consumption, and gas transportation, with major implications in quantitative and qualitative assessment of soil respiration and soil aeration (Moraru and Rusu, 2010).

Conventional tillage includes the largest number of soil treatment (Imadi et al., 2016). This method of soil cultivation allows a good aeration of the soil and increases its biological activity (Olesen et al., 2011).

Knowledge about the influence of soil microbial activity and physical properties on soil respiration is insufficient. This indicates a need to conduct research aimed at recognizing and understanding the responses of effect the microbial, biochemical and physical properties on soil efflux under various crop species.

The aim of the present study was evaluation of soil respiration intensity depending on different soil treatment practices and to determine the effect of biology activity on soil respiration.

Materials and methods

Location of experiment

The study was based on the long term field experiment located at the Agricultural Experimental Station (AES) of the Institute of Soil Science and Plant Cultivation – State Research Institute in Grabów (Mazowieckie voivodeship, Poland; 51°23'N; 21°38'E). The experiment has been running since 2004. Experiment involving maize cropped continuously and rotated with other crops. The experimental scheme involved three following treatments:

1. Maize monoculture with direct seeding (zero tillage) (A)
2. Maize monoculture with full ploughing tillage (B)
3. Cultivation in crop rotation with full tillage (C)

Experiment was conducted on a grey brown podsolic soil formed from light loam (USDA soil classification) classified as very good rye complex. The ploughing layer of soil was characterized by low magnesium content, medium potassium content, and high phosphorus content. The size of a plot was 27.0 m^2 at the set-up of the experiment and 21.0 m^2 at harvest. The experiment was established using a long strip design in four replications.

Maize cultivar Delphine, sown at the end of April or at the beginning of May, with a precision seed drill. The fertilization dose of nitrogen amounted to 140 kg $N \cdot ha^{-1}$ (70 + 70 at the six-leaf stage). The doses of phosphorus and potassium for maize were P_2O_5 - 80 $kg \cdot ha^{-1}$ and K_2O - 125 $kg \cdot ha^{-1}$. In the case of crop rotation, all plant species were grown. In all the years of the study, a full dose of manure was used for maize. It was cattle dung containing: 20-22% dry matter, 0.45-0.51% N, 0.12-0.17% P, 0.53-0.59%.

Cv. Antek of spring barley (sown at the first or second decade of April) and cv. Turnia of wheat were seeded. Annual fertilizer rates supplied to barley were 60 N, 35

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80118022

P_2O_5, and 50 kg ha^{-1} K_2O, and to wheat 120 N, 40 P_2O_5, and 70 kg ha^{-1} K_2O. In order to measure the effects of maize tillage prior to the onset and after termination of the trial we assessed pH in KCl and soil contents (mg per 100 g of soil) of P_2O_5 (CFA method), K_2O (FES method), MgO (AAS method), percentage of total nitrogen (CFA method). The results content yields of maize (plant height, weight of 1000 grains, parameters of maize cobs, plant density of harvest, grain yields of cereals) were published (Księżak et al., 2018).

Soil respiration measurement

Soil respiration (Sr) was measured twice by a model CIRAS-2 apparatus (PP-Systems, USA), portable infrared CO_2 analyzer equipped in Soil CO_2 Flux dynamic closed Chamber. The closed chamber is having a head space volume of 1.17 dm^3, enclose an area of 75.6 cm^2 and was kept inserted into the soil during the measurement. Soil respiration was estimated from the rate of increase in CO_2 in the closed chamber during a 60-s period. The measurements were conducted before sowing of maize (in term 15-25 of April depending on the year of the study) and after harvest (15-25 of October) in four replications. All measurement were done during day time (i.e. 9:00–13:00 a.m.) on rows. Concentration value of carbon dioxide expressed in g $CO_2 \cdot m^2 \cdot h^{-1}$. The measurement range of SRC-1 is 0-9.99 g $CO_2 \cdot m^2 \cdot h^{-1}$. The level of evapotranspiration (E), the differences in carbon dioxide concentration (ΔCO_2), changes in soil moisture (ΔM_B) were also determined.

Soil moisture measurement

The soil moisture (SM, %, v/v) and soil bulky density ($Mg \cdot m^{-3}$) measurements were made on 7 depth level: 0-5, 5-10, 10-15, 15-20, 20-25, 25-30 and 30-35 cm in four replication for each variant of soil tillage, which made by made by weighing and drying method, using cylinders with a volume of 100 cm^3. Soil for the determination of the physical properties was collected during the harvesting of maize for grain. For analysis used mean data of measurement from soil layer 0-30 cm and 30-35 cm.

Soil samples

Soil samples were collected according to Polish Standard PN-ISO 1038-6 (1998). The soil samples in three replicates were taken from the 0-20 cm layer and sieved through a 2 mm sieve and stored in a refrigerator (4 °C) until analysis.

Microbial and biochemical properties

The soil samples were examined for different microorganisms groups. Microbial and biochemical properties analysis was described by Gałązka (2017).

Statistical analysis

Statistical analyses were performed using the Statistica Program PL (10.0). The analysis were carried out using ANOVA method in a proper model for the experimental design. The 95% confidence limit ($P < 0.05$) was chosen to determine the significance of differences between soil respiration and studied parameters of soil chemical and biological properties.

Course of weather conditions were different in the years of study. In Grabów, the total precipitation during the growing period was higher in the first and the second year of the study than the average multi-annual precipitation (by 40 and 33%, respectively) (*Table 1*). In 2010, high precipitation occurred in August and September, while a rain deficit took place in June and July. In 2011, very abundant precipitation was recorded in July (3.5-fold higher than the multi-year average), while a shortage of rainfall occurred in June and August. The third year of the study (2012) was more favourable in terms of the quantity and distribution of precipitations. Same deficits were recorded in May and June (*Table 1*).

Results and discussion

Results of the study showed that the highest value of soil respiration, as before sowing as after harvest, was measured under maize cropped in monoculture with full ploughing tillage (C) (*Fig. 1*), while the least one, under maize cropped in the direct sowing system (A). Analysis of variance showed that treatments have significant effect on soil respiration (*Fig. 1*). So that, addition of soil simplification reduced CO_2 emission while addition of soil tillage have influence on soil respiration. The research results obtained by Lamptey et al. (2017) showed that zero-tillage significantly decreased soil respiration compared to conventional tillage. Hryńczuk and Weber (2004) reported higher values of soil respiration in cultivation with full tillage compared to direct sowing. Kordas (2007) and Kordas and Zbroszczyk (2012) reported higher soil biological activity after soil treatment simplification and the least one in traditional cultivation. These authors found that as soil is more simplificated, as biological activity and ability of soil respiration are higher. Analysis showed that higher soil respiration in all cultivation method was recorded after harvest of maize (second term). The differences between terms amounted 25%. Analysis of variance showed that the mean CO_2 emission was significantly influenced by seasons. In the studies by Amos et al. (2005), Lou et al. (2004) and Natywa et al. (2010), the strongest soil respiration activity was at springtime. Wielgosz and Szember (2006) noted a decline in soil respiration in the summer. Amos et al. (2005) and Lou et al. (2004) attributed this result to the increased root respiration as well as to the soil temperature and moisture conditions. Quemada (2001) reported that soil respiration was greatly affected by temperature and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80118022

water content. In his study the highest values were obtained in August when high temperatures and water content produced the highest respiration. These results were confirmed also by Frank et al. (2002), Bajracharya et al. (2000) and Mielnick and Dugas (2000). According to Sandor et al. (2011) beginning of summer could also offer good conditions for development of soil microbial biomass which in turn could reach the highest metabolic activity. As Lou et al. (2004) reported high soil temperature is positively correlated with CO_2 flux.

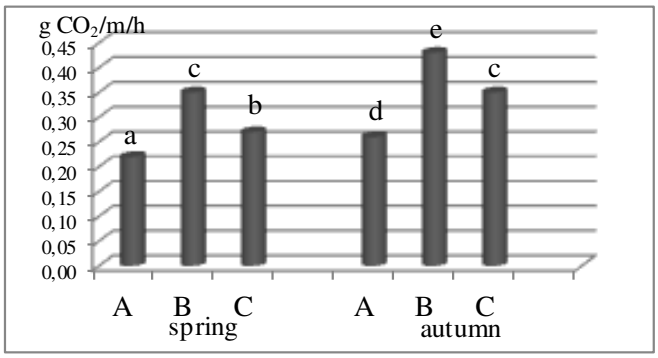

Figure 1. *Soil respiration (Sr) depending on method of soil cultivation (average of the years of the study). Values followed by a different letter are significantly different (P < 0.05)*

The evapotranspiration process was most strongly under maize cropped in monoculture in full tillage, but strongly the least under maize cropped in crop rotation. Significantly higher levels of this parameter were found in date after sowing (*Fig. 2*). The difference between two terms regardless soil tillage amounted to 81%.

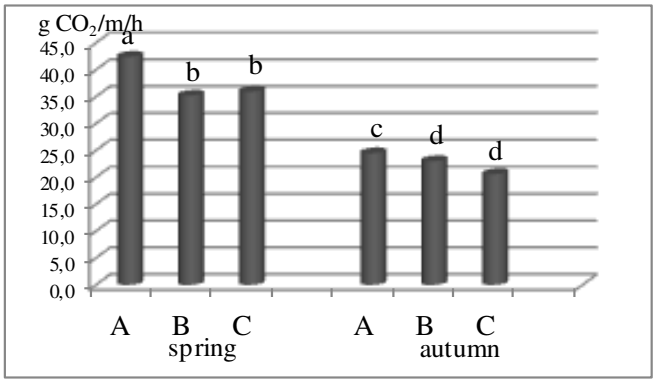

Figure 2. *Evapotranspiration (Sr) depending on method of soil cultivation (average of the years of the study). Values followed by a different letter are significantly different (P < 0.05)*

The differences in carbon dioxide concentration were highest in term after maize sowing. Compared method of soil cultivation, the highest changes in this parameter in both terms were found under maize cropped in monoculture (*Fig. 3*). While the least changes in the changes dioxide concentration were differentiated depend on season. In the first term the least value of this parameter were found under maize cropped in monoculture in full tillage, while in the second term in crop rotation.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80118022

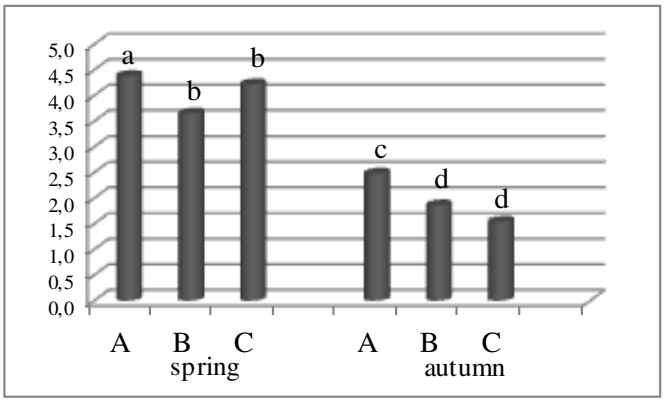

Figure 3. *Changes in carbon dioxide concentration depending on method of soil cultivation (ΔCO_2). Values followed by a different letter are significantly different ($P < 0.05$)*

The highest changes in soil moisture were recorded under maize cropped in direct sowing, while the smallest one in crop rotation (*Fig. 4*). A significant variability was recorded in the changes in soil moisture between method of soil cultivation. In the studies of Lamptey et al. (2017) soil water content increased under no-tillage soils compared with conventional treatment. According to Cook and Orchad (2008) to compare the effect on respiration, a measure of the soil-water status is required.

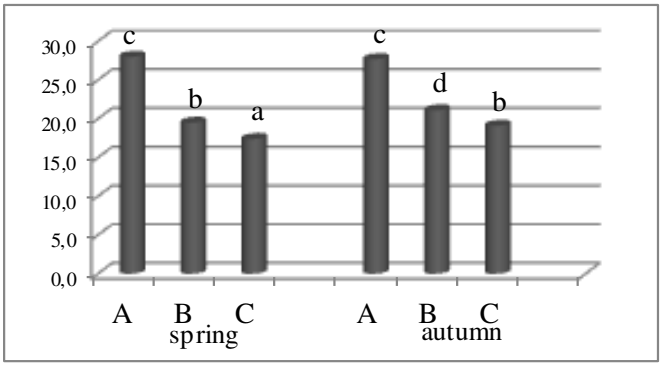

Figure 4. *Changes in soil moisture (ΔMB) depending on method of soil cultivation. Values followed by a different letter are significantly different ($P < 0.05$)*

The soil respiration was correlated with its biological activity and biochemical parameters (*Table 2*). The statistically strongest negative correlation was found between soil respiration and evapotranspiration (-0.495), changes in carbon dioxide concentration (-0.493) and acid phosphatase activity (-0.683), while strongest positive correlation was found between soil respiration and ammonifying bacteria (0.598).

Statistical analysis revealed also that no linear relationship was found between soil respiration and such parameters as: evapotranspiration and changes in carbon dioxide concentration (*Fig. 5a, b*) and biochemical parameters as: soil dehydrogenase activity and acid phosphatase activity (*Figs. 6* and *7*). According to Cook and Orchad (2008) to compare the effect on respiration, a measure of the soil-water status is required.

Dehydrogenase and phosphatase activities are good indicators of changes of soil parameters and widely used microbial parameters of soil biology (Wolińska et al., 2013). Phosphatase can be a good indicator of the mineralization potential of organic phosphorus and soil biological activity. In the studies of Gałązka et al. (2017) the dehydrogenase activity was is in correlation with the increased number of the most examined groups of microorganisms.

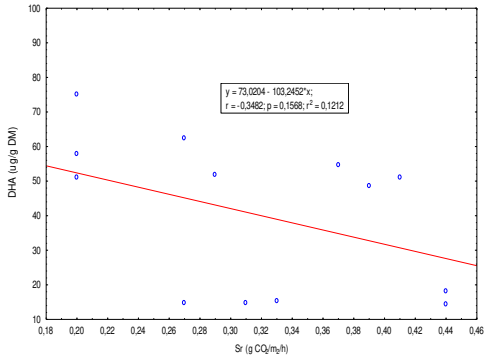

Figure 6. *Relationship between soil respiration (Sr) and soil dehydrogenase activity (DHA)*

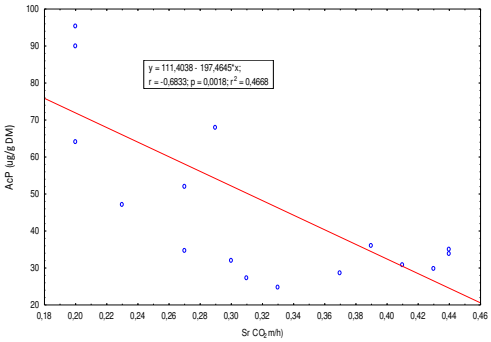

Figure 7. *Relationship between soil respiration (Sr) and acid phosphatase (AcP)*

Soil respiration was not significantly affected by the soil moisture and soil bulk density in 0-30 cm soil layer (*Table 2*). The simple regression analysis showed linear relationship between soil respiration and such parameters as: acid phosphatase activity and ammonifying bacteria (*Figs. 7* and *8*). The strongest relationships was found between soil respiration and acid phosphatase activity, which is confirm by value of coefficient of determination ($R^2 = 47\%$).

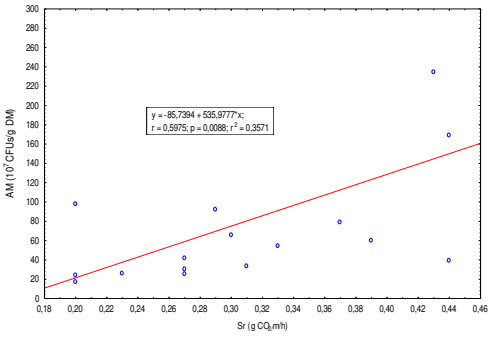

Figure 8. *Relationship between soil respiration (Sr) and ammonifying bacteria (AM)*

The available literature lacks studies on the effect of physical properties on soil respiration. Małecka et al. (2012) found that the no-tillage systems favoured the increase of soil moisture and density, as well as the reduction of capillary water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80118022

capacity, especially in the 0-10 cm layer. The studies of Morris et al. (2010) and Raczkowski et al. (2012) indicate the increase in the volume density of soils in the ploughed systems. In own studies, analysis showed that soil bulk density in 0-30 cm soil layer (SBD_1) was significantly affected total copiotrophic bacteria (KOP) (0.459), while soil bulk density in deeper layer (30-35 cm) was not affected any characteristics. Soil moisture in both deep soil layer: 0-30 cm and 30-35 cm (SM_1 and SM_2) was negatively influence on total copiotrophic bacteria (KOP) (-0.483 and -0.556 respectively). Soil moisture in 0-30 cm layer was negatively significantly influence on total fungi number (F) (-0.354) and total oligotrophic bacteria (OLIGO) (-0.486) (*Tab. 2*).

The continuous use of the no-tillage system with crop rotation usually results in an increase of the microbial biomass and decrease in soil respiration, therefore, displaying evident long-term effects on the increase of soil C contents (Valpassos et al., 2001).

Soil respiration refers to microbial decomposition of dead plant residues and soil organic matter (Kuzyakov and Gavrichkova, 2010), which is controlled by soil microbial activities and soil C content. According to Lou et al. (2011) soil microbial activities are influenced by soil physicochemical conditions, such as soil moisture.

Soil moisture was considered by Bonal et al. (2008); Luo and Zhou (2006) and Lou et al. (2011) to be the secondary important factor controlling soil respiration. According to Huang et al. (2014) soil respiration was negatively correlated with soil moisture at high soil moisture content (> 19). According to Zhang et al. (2016) soil respiration was negatively correlated with soil moisture and soil pH. While Chang et al. (2016) reported that soil respiration is mainly controlled by soil temperature and moisture. According to Pietri and Brookers (2009) soil pH also had been proved to be an important factor influencing microbial respiration. The results of Șandor and Opruța (2012) show a relationship between soil moisture and soil respiration. It was suggested (Mielnick and Dugas, 2000) that wet soil at deep depth may counteract the effect of surface dry soil on soil respiration.

Conclusions

The results of soil samples analysis (soil properties and microbial activity) would not provide a complete understanding of the relation between soil properties and soil respiration. However, the values may be used as indicators of changes on soil quality, and parameters such as respiration are sensitive indices to study the effect of crop systems in the soil microbiological environment. Among the studied soil treatments, zero-tillage system exhibited better results for bulk density, soil chemical properties. Our study did not present enough variety to go further in our conclusions, but it confirms the relevance of influence effects between factors.

This study demonstrated that tillage systems under maize influence soil respiration along with soil biochemical, physical and other microbiological properties. Further research is needed to determine the soil respiration in long-time period of field experiment under maize growth in different agricultural management practices.

(Received 6th Jan 2019; accepted 3rd May 2019)

Abstract. Forest areas occupied by Marantaceae show a significant regeneration deficit because of the bulk of foliar and subterranean biomass of these herbaceous plants. The present study evaluates the regeneration dynamics (< 10 cm diameter) of Marantaceae forests by counting and identifying pre-existing regrowth, then their subsistence rate, and finally comparing the potential of regeneration with that of mixed wood forests and that of the *Gilbertiodendron dewevrei* forests (De Wild.) J Leonard. At a confidence level of 95%, a highly significant difference ($F = 120.40$, $p < 2.2e\text{-}16$***) is observed between the averages. These averages are 68.36 ± 40.19 in the Marantaceae of Biaro, 105, 24 ± 84 in the Marantaceae of Yoko Forest Reserve, 435.8 ± 147.3 in the mixed forests and 620, 16 ± 175.55 in the *G. dewevrei* forests at (De Wild.) J Leonard. In addition, regeneration of Marantaceae has a very high mortality rate averaging at 23.22%. This pre-existing deficit and the high mortality rate significantly affects the forest dynamics of the Yoko Forest Reserve and its surroundings. The clear-cut technique of the aboveground and underground biomass of Marantaceae tested during this study is essential for any development of these herbaceous groups, it has increased by an average of $23.5 \pm 7.43\%$ in the plots of 2 m².

Keywords: *aboveground, underground, biomass, Gilbertiodendron dewevrei, Biaro*

Introduction

Regeneration is a vital process in forest ecosystems. It is at the base of the balance and demography of the plant population and the rejuvenation of the stand following the disappearance of mature trees by windfall or exploitation. These populations of the future result either from pre-existing regrowth or vegetative potential, or from pre-existing seeds or edaphic seminal potential, and finally, seeds arriving from the outside after opening of the cover or external potential (Alexander, 1982, 1989; N'dja et al., 2010).

Two meanings are attributed to the expression of natural regeneration. The first expresses the process in which the tropical forest reproduces itself naturally. It refers to the meaning of dynamics. The second, which is often used by foresters, corresponds to all the seedlings, strands and seedlings existing in a stand. It refers to the statistics of regeneration potential in a forest stand (Oldeman, 1990; Puig et al., 1989, 1992; Puig, 2001). More than 10% of the forests in the Yoko Forest Reserve are infested with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80238035

Marantaceae herbaceous plants. In that zone the regeneration of woody trees seems very limited. The foliage biomass of these herbaceous species is screened to limit the substantial penetration of the luminous flux into the soil and their very perennial rhizomes in the basements constitute real obstacles to the flowering of the seedlings in an area intended for sustainable conservation forest resources.

This study evaluates the dynamics of regeneration at counting thresholds (< 10 cm) of Marantaceae forests by counting and identification, then their mortality rate, and finally, compares the regeneration potential of these herbaceous plants with that of mixedwood forests and that of *Gilbertiodendron dewevrei* forests (De Wild.) J Leonard on the same topological sequence.

Materials and methods

Study area

The present study was conducted in the forests around Kisangani, specifically in the Yoko Forest Reserve located in the Tshopo province, the community of Bakumu-Mangongo, Ubundu territory and more particularly in experimental plots of Biaro (*Fig. 1*), in east of the Democratic Republic of Congo.

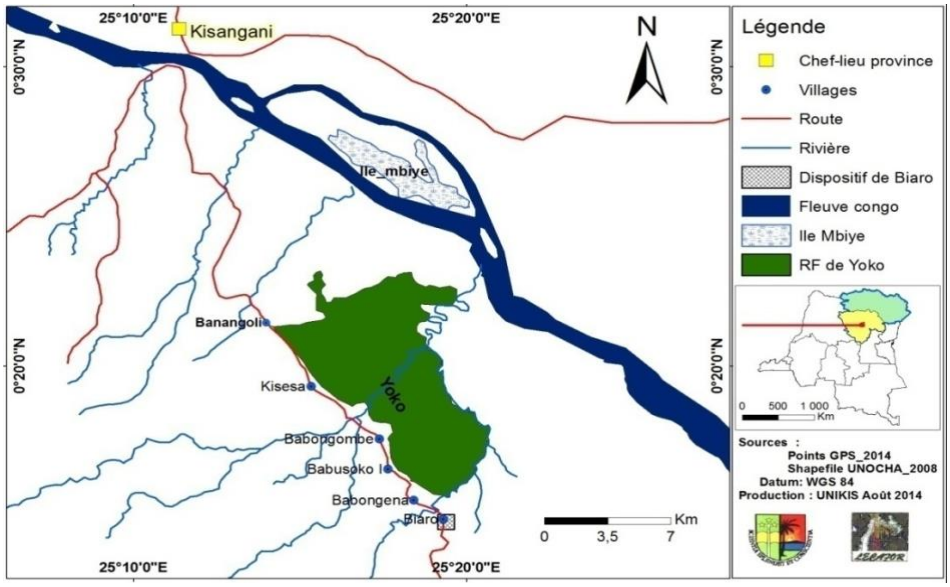

Figure 1. *Location of the Yoko Forest Reserve and the Biaro plots*

It is governed by the ordinance n° 52/104 of the 28/02/1959 of the Ministry of the Environment, Nature Conservation and Sustainable development. It is a private property of the Congolese Institute for the Conservation of Nature accordance to the ordinance - law no. 75-023 of July 1975 of the Ministry of the Environment establishing a public company of the State for the purpose of managing certain public environmental institutions as modified and supplemented by the ordinance-law n° 78-190 of May 05, 1988.

The Yoko Forest Reserve is located on North longitude: 00° 17’ 59” and East: 025° 17’ 4” between 400 and 500 m altitude. The Biaro device is located ± 10 km south of the Yoko Forest Reserve on North Longitude 00° 12.27’ 1” and East 025° 20.0’ 4” between 420-530

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80238035

m. The average temperature is 25 °C and the annual average rainfall is 1750 mm. It is located between 23 and 45 km points of the road and the Kisangani-Ubundu railway. The Yoko River, which crosses this concession, divides it into two blocks, of which the North block with 3,370 ha and the South block with 3,605 ha represent an overall area of 6,975 ha (Lomba and Ndjele, 1998). Vegetation in the reserve is composed of mixed forest, sometimes sparse, forests of Marantaceae and rattan, monodominant forests of *Gilbertiodendron dewevrei* (De Wild.) J. Leonard, and secondary forests (Lomba, 2012).

Methods

The equipment used consists of a vernier caliper to measure seedling diameters, metric ribbons to size plots and study plots, a GPS to collect geographic coordinates. The biological material is made from consisted of woody seedlings less than 10 cm in diameter. Full counting and identification of vegetative potential at counting threshold of diameter < 10 cm was carried out in the 50 m² plots stratified in 10 m² plots in the Marantaceae of the Yoko Forest Reserve and Biaro. To compare the pre-existing regrowth potential of Marantaceae with that of *Gilbertiodendron dewevrei* (De Wild.) J. Léonard and mixedwood forests, plots of identical size were delineated in these stands. The geographical coordinates of the sites in study are shown in *Table 1*.

Table 1. *Coordinates and altitudes of the study areas*

Study areas	Informations	Altitude (m)
Marantaceae Forest RF Yoko	N00° 18' 42.6'' E025° 17' 31.0''	435
Marantaceae Forest of Biaro	N00° 12' 05.9'' E025° 17' 20.05''	456
Mixed forest	N00° 18' 27.9'' E025° 17' 40.4''	466
Gilbertiodendron dewevrei Forest	N00° 18' 02.2'' E025° 17' 49.9''	456

Assisted regeneration was tested in the Marantaceae of the Yoko Forest Reserve. The technique consisted of clear cutting of aboveground biomass and rhizome extirpation in plots of 40 m² stratified in 2 m² plots. All seedlings were counted and marked. Two months later, a recount was done.

Data processing was based on the few botanical characterization indices (Doucet, 2003):

$$\text{Relative frequency of a species} = \frac{frequency\ of\ a\ species}{\sum frequencies\ of\ all\ species} \times 100 \quad \text{(Eq.1)}$$

$$\text{Abundance (\%)} = \frac{Number\ of\ individuals\ of\ the\ species}{Number\ of\ individuals\ of\ all\ species} \times 100 \quad \text{(Eq.2)}$$

$$\text{Dominance (\%)} = \frac{Basal\ area\ of\ the\ species}{Total\ basal\ area} \times 100 \quad \text{(Eq.3)}$$

$$\text{Relative importance: } I_r = \frac{D_r + D_{or} + F_r}{3} \quad \text{(Eq.4)}$$

DOI: http://dx.doi.org/10.15666/aeer/1704_80238035

The annual mortality rate (March 2013 - March 2014) is evaluated from the Madron relationship (1993): $TM(\%) = 100x[1 - Nt/No]^(1/t)$, where: TM = mortality rate, t = duration of the calculation period, N_0 = starting workforce and N_t = number of survivors after t years. Four plots of 200 m² divided into plots of 100 m² were delimited in the East, West and South of the forest reserve of Yoko Biaro were followed.

The comparison of the averages was done by the ANOVA test. As for the ANOVA, Tukey's post-hoc test at $p < 0.05$ was used to detect the differences between the different averages taken two by two. The Shapiro-Wilk test was used initially to check the normality of the data. The comparison of the two averages was done by Student's t-test. The comparison of the proportions between the diameter classes was carried out with the test of $\chi^2 = \sum_{i=1}^{k} \frac{(ni-ti)^2}{ti}$., where ni = number of individuals observed in class i; t_i = number of theoretical individuals in class i; k = class number of the qualitative variable ($k \geq 2$) and i = class number of the qualitative variable ($1 \leq I \leq k$).

The different tests and their significance were provided by the R version 2.10.0 software.

Results

Potential for woody seedlings of Marantaceae, mixedwood and Gilbertiodendron dewevrei forests (De Wild.) J. Léonard

The average densities of woody seedlings at counting thresholds of < 10 cm diameter, for a 95% confidence interval in Marantaceae forests, mixedwood forests and *Gilbertiodendron dewevrei* (De Wild.) J. Leonard forests are arranged in descending order (*Fig. 2*): 69.36 ± 40.19 6 < 105.24 ± 89 < 435.8 ± 147.39 < 620.16 ± 170.55 respectively, in the Marantaceae of the Yoko (MarRFY), the Marantaceae of Biaro (MarBia), the mixed forests and the forests to *Gilbertiodendron dewevrei* (De Wild.) J. Leonard (FDM and FDG).

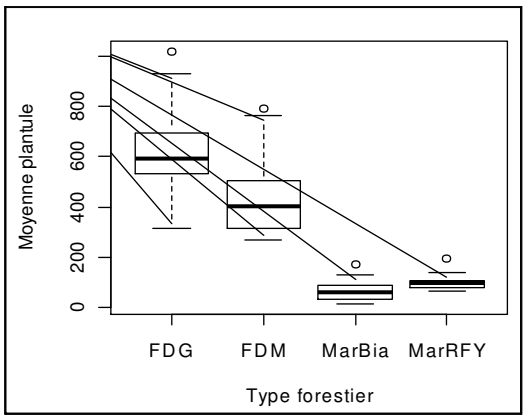

Figure 2. *Dispersion of seedling density values of Marantaceae, mixedwood and Gilbertiodendron dewevrei forests (De Wild.) J. Léonard*

The highly significant difference is observed between the different groups (F = 120.40, $p < 2.2e-16$***), and is not significant between the Yoko Forest Reserve of Marantaceae and the Biaro forest of Marantaceae (Tukey: $p > 0.05$), highly significant

DOI: http://dx.doi.org/10.15666/aeer/1704_80238035

between Marantaceae and mixedwood forests and between Marantaceae and *Gilbertiodendron dewevrei* forests (De Wild.) J. Leonard (Tukey: $p < 0.01$).

Mortality rate in Marantaceae forests

The mortality rate is studied in the East, West and South Marantaceae of the Yoko Forest Reserve and at Biaro (*Table 2*). In each site, two plots of 10 m² were monitored. A count was made in each plaza on March 10, 2012 and a recount on March 10, 2013.

Table 2. *Mortality rate of woody seedlings in Marantaceae forests*

Site	Number of seedlings		
	2012	**2013**	**Mortality rate (%)**
Ouest Marantaceaa RF Yoko 1	136	73	46.32
Ouest Marantaceaa RF Yoko 2	136	116	14.71
East Marantaceaa RF Yoko 1	44	26	40, 91
East Marantaceaa RF Yoko 2	94	66	29.79
South Marantaceaa RF Yoko 1	93	62	29.79
South Marantaceaa RF Yoko 2	115	93	19.13
Biaro 1 Marantaceaa	130	104	20
Biaro 2 Marantaceaa	64	61	20
Average	101.5 ± 34.26	75.14 ± 28.53	23.22 ± 12.26

The mortality rate varies from one site to another. It is higher in the Marantaceae of the Yoko Forest Reserve where it varies from 46.32% to 4.71% whereas it varies from 20.00% to 4.69% in Biaro.

Specific richness and index of importance of woody seedlings

The species richness and the importance index (*Table 3*) calculated in the different sites on equivalent areas equal to 2,500 m².

HNP = non-pioneering heliophile, TO = shade tolerant, HP = pioneer heliophile, Dr = relative density, Dor = relative dominance, Fr = Relative frequency, IVI = importance index

The most important woody seedlings vary from one site to another: *Barteria nigritiana* Hooke (IVI = 56.51) is more important in the northern *Marantaceae*, *Xylia ghesquierei* Robyns (IVI = 28.83) in the Marantaceae of the East, *Myrianthus preussii* Engler (IVI = 56.02) in the western Marantaceae, *Scaphopetalum thonneri* De Wild & Th Dur (IVI = 39.69) in the southern Marantaceae and *Thomandersia hensii* De Wild. & Th Dur (IVI = 64.67) is more important in the Marantaceae of Biaro.

The majority of regenerating seedlings in Marantaceae forests are shade tolerant (TO) species. Some light species appear intermittently in the sites (*Pycnanthus angolensis* (Welw.) Warb., *Rinorea oblongifolia (C.H Wild) Marquand ex Chipp, Xylia ghesquierei* Robyns *and Alchornea floribunda Mull.* Arg.

Diametric distribution dynamics of seedlings in Marantaceae forests

Diameter frequencies (*Table 4*) by seedling neck diameter class were measured in the Marantaceae of the North, South, East and West of the Yoko Forest Reserve and in Biaro on equivalent areas of 500 m^2 stratified in 5 plots (10 m × 10 m).

The frequency of seedlings per diameter class in five sites is low in classes > 1-1 cm, it goes up a notch in classes 1-2 cm, then an asymmetrical decrease begins to be observed from classes 2-3 cm. The independence test χ^2 applied to compare the diametric structures indicates that there is a "site" effect, ($\chi^2 = 308.81$, df = 32, $p < 0.01$). Calculating the contributions (%) of χ^2 from each diameter class to the total χ^2 statistic shows that the classes (1-2, 2-3, > 1-1, 3-4, 6-7 and 4-5) contribute the most to this difference.

Residue analysis shows that in classes (1-2 cm), the size of southern Marantaceae individuals is larger and contributes the most to the significant difference of χ^2 total obtained. The numbers of the Northern Marantaceae classes 2-3, 4-5 and 6-7 are larger

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80238035

and contribute the most to the significant difference of χ^2 total obtained. In classes (> 1-1) the numbers of western Marantaceae are larger and contribute the most to the significant difference of χ^2 total obtained. In the class (3-4), the number of Marantaceae de Biaro individuals is larger and contributes the most to the significant difference of χ^2 total obtained. To correctly interpret the degeneracy observed in the diameter classes, the frequencies of the five most important species were followed (*Fig. 3*).

MarRFYN = Marantaceae North Yoko Forest Reserve, MarRFYE = Yoko Forest Reserve East Marantaceae, MarRFYW = Marantaceae West Yoko Forest Reserve, MarRFYS = South Marantaceae Yoko Forest Reserve, MarBia = Marantaceae of Biaro

It is observed that shade tolerants (TO), which are mainly larger (*Table 3*), show a positive asymmetry for the most part. This is the case of *Barteria nigritiana* Hooker, *Scaphopetalum thonnerii* De Wild & Th. Dur, *Campylospermum sp*, *Trilepisium madagascariense* DC, *Turraeanthus africanus* (Welw. Ex C.DC.) Pellegr, *Olax Gambecola* Bailon, *Thomandersia hensii* De Wild. & Th. Dur. The species *Aidia micrantha* (K. Schum.) F. White has, in addition to the structure with positive asymmetry, an irregular frequency. It is the same for *Petersianthus macrocarpus* (P. Beauv.) Liben.

Non-pioneer heliophiles (HNP) exhibit variable behavior, sometimes a right-handed distribution or an irregular distribution. This is the case of *Pycnanthus angolensis* (Welw.) Warb. A symmetrically positive structure is also observed in *Rinorea oblongifolia* (C.H. Wright) Marquand ex Chipp and *Myrianthus preussii* Engler, the only pioneering heliophile *Alchornea floribunda* Mull. Arg presents, unlike all other species, an increase of the numbers in the initial classes > 1-1 cm and 1-2 cm, which decreases appreciably subsequently, from the intermediate classes. Finally, *Xylia ghesquierei* Robyns is the only species that has the classical L-shaped structure. A large number of individuals are observed in the initial classes, whereas it decreases as the diameter increases. It is the only species with good regeneration.

Assisted regeneration

The assisted regeneration (*Table 5*) was followed in 10 plots of 2 m² divided into two plots in the West, East and South sites of the Yoko Forest Reserve and Biaro.

IX	4	20	19
X	11	25	14
Averages	10.8 ± 43.51	28.9 ± 7.69	23.5 ± 7.43

After clear-cutting of Marantaceae biomass, the number of woody seedlings increased from an average of 10.8 ± 43.51 to 23.5 ± 7.43 for a confidence level of 95%.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80238035

The mean independence t-test indicates a highly significant difference between the initial density of the seedlings before clear-cutting and the density of newly planted seedlings after clearcutting ($t = 4.2257$, $df = 18$, $p < 0.0005131$***).

Discussion

Regenerative dynamics, mortality rate and neck diameter structure of seedlings in Marantaceae forests

The regeneration of woody plants in forests at Marantaceae is very low. For a confidence level of 95%, the average is 105.24 ± 89 woody seedlings in the Marantaceae of the Yoko Forest Reserve. This average is nearly 5 times less than that of the forests of *Gilbertiodendron dewevrei* (De Wild.) J. Leonard and 4 times lower than that of mixed forests. A lower average (47.67 ± 36.13) was observed in the Marantaceae of Biaro. It is 9 times less than that of *J. dewevrei* (De Wild.) J. Léonard forests and 6 times less inferior to that of mixed forests. A highly significant difference is observed between the different groups (Anova: $F = 120, 40$, $p < 2.2e\text{-}16$***). Considered in pairs, Tukey's post-hoc comparison of multiple averages test showed a highly significant difference between Marantaceae forests and *J. dewevrei* (De Wild.) J. Leonard forests and between them mixed forests ($p < 0.05$***).

In addition, an insignificant difference is observed between the Marantaceae of the Yoko Forest Reserve and the Marantaceae of Biaro ($p > 0.05$). Similar results were observed in Odzala where the regeneration density was very low, ie 10 to 70 stems per 100 m² was observed in the dense Marantaceae forests and 804 to 984 stems per 100 m² in the dry Marantaceae dry forests (Gillet et al., 2008). This deficit justifies the ability of these herbaceous plants to easily dominate the acquired space to the detriment of woody regeneration for long periods (Lejoly, 1996; Kouka, 2004; Gillet et al., 2008).

Several factors allow Marantaceae to compete with other plants to form persistent monodominant shrubs, namely, (i) the production of a dense leaf layer, (ii) the rapid recovery of rhizomes after each disturbance. These powerful branched rhizomes allow them, from a single strain, to extend considerably the scale of their vegetative apparatus and thus to occupy vast spaces, (iii) they arouse the underground competition and the competition for the light with young plants and (iv) their clonal growth (De Foresta, 1990; Brncic, 2002; Vande Weghe, 2004). This resource rivalry prevents the growth of seedling potential and is the cause of a significant mortality rate of 23.23% on average in the Marantaceae of the Yoko Forest Reserve and Biaro.

The inhibition impact of these herbaceous plants does not only affect ligneous plants. In Odzala, Bruguière et al. (2000) and Mbayu (2009) observed a decrease in density of small primates at the same time of 40% with 2.99 troops per km (all species combined). The heaviest monkeys, *Lophocebus albigena* (white-cheeked mangabe) and *Cercopithecus nictitan* (monkey-hog), which preferentially use high forest layers, were more sensitive to canopy opening. Therefore, these impacts suggest that colonization of Marantaceae in a forest area negatively and non-discriminatorily impacts all diversity and may even block the regeneration process (Nepstad et al., 1991).

The frequency degeneration of the pre-existing regrowth in the Marantaceae of the Yoko Forest Reserve and Biaro attests that there is a net "site" effect ($\chi^2 = 308.81$, $dof = 32$, $p < 0.05$). Residue analysis after χ^2 total showed some classes contributed significantly to this difference, this is the case of classes 1-2 cm in the South, 2-3 cm, 4-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80238035

5 cm and 6-7 cm and the class > 1-1 cm west of Yoko Forest Reserve and 3-5 cm class in Biaro. In all cases, it is observed that the extreme classes 1-1 cm, 4-5 cm and 8-9 cm have a low density compared to the intermediate classes 1-2 cm and 3-4 cm). This positive asymmetry distribution suggests a weak regeneration apparently related to disturbances in the environment (Puig, 2001). Such a structure is different from the structure observed in humid dense forests where the frequencies of individuals in classes ranging from 1 to 10 follow the exponential type law (Puig, 1989 et al, Puig, 1992; N'dja, 2010).

The 5 most important species that were tracked for frequency in the diametric classes showed that shade-tolerant species (TOs) had a positive asymmetric structure. This is the case of *Barteria nigritiana* DC, *Scaphopetalum thonnerii* DC, *Campilospermum sp*, *Trilepisium madagascariense* DC, *Turraeanthus africanus* (Welwc ex C.DC.) Pellegr., *Olax gambecola* Muell. Arg, *Thomandersia hensii* De Wild. & Th. Dur. The species *Aidia micrantha* (K. Schum.) F. White has in addition to the bell structure, an irregular structure. The irregular structure is also observed for the species *Petersianthus macrocarpus* (P. Beauv.) Liben. On the other hand, non-pioneer heliophiles (HNP) show a very variable behavior, sometimes an irregular structure, this is the case of *Pycnanthus angolensis* (Welw.) Excell, sometimes a positive asymmetric structure in *Rinorea oblongifolia* (CHWright) Marquant ex Chipp, *Myrianthus preussii* Engler and *Alchornea floribunda* Mull. Arg. have, unlike other heliophiles, an increase in numbers in the initial classes>1-1 cm and 1-2 cm which decrease significantly from intermediate classes. The species *Xylia ghesquierei* Robyns is the only species with an exponential-like structure characteristic of dense moist forest species (Rollet, 1974).

The analysis of the structure of a tropical rainforest shows this structural variability according to species, genera or families. This variation reflects in most cases the temperament of the species (Puig, 2001). This behavior is explained by the fluctuation of the luminous flux in the mass of Marantaceae leaves. The ligneous trees show variable behavior in the light. At a young age, they have specific peculiarities relating to their growth and gregariousness. This behavior would lead to types of structures much more varied than the general structure of the L-shaped stand more or less erect, truncated or asymmetric bell, S more or less stretched, or having a spread distribution and almost independent of the diameter (Puig, 1992).

Light plays a fundamental role in the germination of the seminal potential of the soil and the growth of pre-existing recruits. The variations in its intensity and the composition of its spectrum influence the growth, production and productivity of forest ecosystems and indirectly its structure. The decrease in intensity that occurs varies depending on the canopy, the leaf motion and the angle of incidence of the sun's rays (Hall et al., 1981; Puig et al., 1989; Clark, 1990).

Assisted regeneration in Marantaceae forests

Forests in Marantaceae are considered ecosystems whose regeneration and evolution are extremely slow and deficient due to the almost inextricable coverage of their surface leaf masses and rhizomes in the soil (Brugière et al., 2000; Brncic, 2002). Nevertheless, the clear-cut regeneration of aboveground and underground biomass of these giant herbaceous plants in a few plots during this study increased the density of pre-existing recruits. Overall, for all species combined, an increase in woody seedlings averaged 23.5 ± 7.4%. This increase suggests that the seminal potential of the soil that was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80238035

dormant beneath the Marantaceae mass of leaves found an optimal luminous flux that allowed it to begin germination (Rey, 1997).

Assisted regeneration was tested in the Marantaceae in Congo Brazza by Gillet in (2013) in order to reinvigorate the deficient regeneration of pre-existing heliophilous species inventoried and identified and then cleared of neighboring competing vegetation. Similarly, nursery seedlings were introduced to maintain linear density in all 4 m. This silviculture has resulted in remarkable performances. The species *Canarium schweinfurhii* Engl, *Ricinodendron heudoloti*i (Baillon) Pierre ex Hecke, *Terminalia superba* Engler & Diels *Nauclea diderrichii* (De Wild. & T. Durand) Sea, followed for a year, showed an average growth of between 124 cm and 154 cm. The most successful planted species was *Triplochiton scleroxylon* K. Schum, which grew at a height of 95 cm in a single year.

Numerous interventions based on silvicultural improvement for the management of natural stands have been carried out. These are natural forest interventions in which the silviculturist sought to promote the growth of valuable species in order to valorize and order the forest for its good management (Dupuy, 1989). In Yangambi in the Tshopo Province, several tests were carried out by INERA since colonial times. However, as everywhere in Africa, methods for natural regeneration with more than one canopy opening provided very uncertain results because of the variability of application conditions, the problem of light dosing, the costs of the work, the number of intervention and spread of work over time. But these operations, which remain the only way to develop dense tropical forests, have been abandoned in the process (CTFT, 1989).

In this study, testing of assisted regeneration in Marantaceae forests was not intended to favor any category of species. It was essentially a question of observing the behavior of the potential of the pre-existing recrudescence of the seminal potential in the face of light. The results showed that the forests at Marantaeae abound with an important seminal potential that was waiting for light to initiate their germination. In addition, the potential for pre-existing regrowth exhibited an optimal growth performance after the addition of the luminous flux for two less tests. But it will be necessary to point out that for this prosperous regeneration, it will have to go beyond the carpet of the herbaceous plants which approach them thus to try to slow their development by an optimal closure of the tree cover (Gillet, 2003).

Conclusion

The impact of Marantaceae forests on woody regeneration in the Yoko Forest Reserve and surrounding area is significant. These herbaceous plants substantially inhibit the regeneration and growth of the potential of pre-existing recrudescence and seminal potential. This impact results in a significant reduction in the density of woody seedlings compared with mixed forests and *Gilbertiodendron dewevrei* (De Wild.) J. Leonard forests. In addition, under the conditions of highly increased competition, growing recruits have a significant mortality rate of around 23.22% on average. The few species that regenerates in these herbaceous Marantaceae are mostly shade tolerant and some heliophiles with a structure unfortunately bell or irregular attesting a weak regeneration.

The assisted regeneration test carried out in this study allowed the penetration of an optimal luminous flux which triggered the germination of the seminal potential and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80238035

stimulated the growth of pre-existing recruits. This silvicultural technique is the means of management to reinvigorate regeneration in the Marantaceae forests of the forest reserve.

For future research conducted in and around the Yoko Forest Reserve, we suggested that:

- Studies of permanent assisted regeneration are undertaken based on species growth and silviculture of fast-growing species is practiced and assisted in infested areas.
- Soil and dynamics studies on the annual rate of occupation of the herbaceous species are initiated and conducted.
- Anthracological studies are densified and systematically deepened in the different forest groupings of the Yoko Forest Reserve and surrounding areas to understand the history of the stands in the region.

Agroforestry techniques are popularized and monitored in the riparian communities of the Yoko Forest Reserve and surrounding areas. This integrated land management practice will help contain the practices of clearing that favor the proliferation of hegemonic herbs throughout the region to the detriment of forest dynamics.

(Received 9th Jan 2019; accepted 22nd Feb 2019)

Abstract. The present study evaluates physicochemical variables, perform a microbiological analysis as well as determine heavy metal concentrations in the water and muscle tissue of fishes from the Cachorros River. The analysis of metal concentrations in the estuarine water revealed high levels of Fe and Al, with values above the limits established by Brazilian legislation. The concentration of total coliforms and thermotolerant coliforms tended to be higher in the rainy season. Regarding metal concentrations in the muscle tissue of fishes, high levels of Pb and Cd were found, especially in carnivorous and detritivorous species, with values above the limits established by national legislation. Two-factor analysis of variance revealed that only Pb demonstrated a significant interaction between seasonality and the feeding habits of the fish fauna, with higher concentrations of this metal in the dry season among detritivorous species in comparison to herbivorous species. The present findings demonstrate the contamination pattern that has been occurring in the Cachorros River, as evidenced by the concentration of trace metals in both the water and muscle tissue of fishes, which are an important source of protein as well as an economic resource for the population of this river basin.
Keywords: *estuarine fish, metal levels, microbiological contamination, physicochemical variables, health risk*

Introduction

A large portion of the world's population lives in urban centers near estuarine coastlines, which places anthropogenic pressure on water resources due to the demands and wastes of such populations (Cunha et al., 2005; Carmo et al., 2011; Barbosa, 2006). It is estimated that approximately 75% of the world's population will be living within 160 km of a coastline by the year 2025 (Moura, 2009). Thus, urbanization and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80378047

industrialization have made the issue of the contamination of aquatic environments increasingly critical (Simões, 2007; Curcho, 2009). In Brazil, disorderly urbanization, the increase in the population and the indiscriminate construction over of natural areas have led to progressive environment degradation, which is directly associated with the health status of populations that reside around affected areas (Sanches Filho et al., 2013).

Estuaries and coastal regions are often used for the disposal of urban and industrial effluents, leading to the contamination of freshwater and marine life by diverse pollutants. From the public health standpoint, the degree of contamination of these ecosystems poses a risk to the river communities that use such water for the purposes of aquaculture, recreational fishing and leisure activities (Castro, 2009).

Pollution by trace metals constitutes a major source of contamination in aquatic environments. These elements are non-biodegradable and tend to accumulate in the tissues of living organisms, the consequences of which include the decimation of the biota and the intoxication of living beings throughout the food chain, which can eventually reach humans (Castro et al., 1999). Trace metals are chemically highly reactive, which explains the difficulty in finding these metals in their pure state in nature, since concentrations are normally very low and associated with other chemical elements.

Estuarine pollution can be evaluated by an analysis of trace metals found in the water, sediment and aquatic organisms. The characteristics of teleost fish, such as the rate at which they accumulate metals, abundance, sampling ease and adequate size for tissue analysis, make these organisms effective indicators of pollution in estuarine environments.

According to Lins et al. (2010), the close relationship between water quality and numerous illnesses that affect populations is widely known. It is therefore necessary to determine the source, mechanism of action and consequences of contaminants in aquatic environments. Exposure to industrial waste can affect human health in the form of headaches, nausea, skin irritation and lung irritation as well as serious reductions in neurological and hepatic functions (Moraes and Jordão, 2002). Thus, there is a need for research directed at the acquisition of knowledge regarding the environmental transformations that stem from the contamination of aquatic ecosystems as well as implications regarding the health of surrounding communities to assist in decision-making processes and the formulation of effective management policies.

The aims of the present study were to evaluate physicochemical variables, perform a microbiological analysis and determine heavy metal concentrations in the water and muscle tissue of fishes from the Cachorros River in the city of São Luís, state of Maranhão, Brazil.

Materials and methods

A large part of the watersheds on São Luis island concentrate industrial activities developed in the city of São Luís, state capital of Maranhão in northeastern Brazil. The Cachorros River is the largest estuarine river basin in the southeastern portion of the island, covering an area of 63.7 km² (*Fig. 1*), most of which is in the rural zone and near large industrial enterprises, such as the Itaqui Port Complex, ENESA and VALE, as well as smaller enterprises, such as slaughterhouses and mining activities. The river empties into the Coqueiro Strait in front of the ALUMAR port, where materials used in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80378047

the production of aluminum (bauxite, coke, tar, coal and lye) are unloaded and alumina loading operations occur (Castro, 2009).

The estuary of the river is considered extremely important to the populations of the villages Parnauaçu, Cajueiro, Porto Grande, Limoeiro and Taim that conduct fishing activities and use the estuary for other purposes, such as navigation and recreation (Carvalho, 2011). The watershed also has mineral reserves for use in civil construction, such as sand and clay, which supply the internal market. However, mineral extractions are in need of greater control in terms of public power, as these raw materials are removed without planning or authorization (Castro and Pereira, 2012).

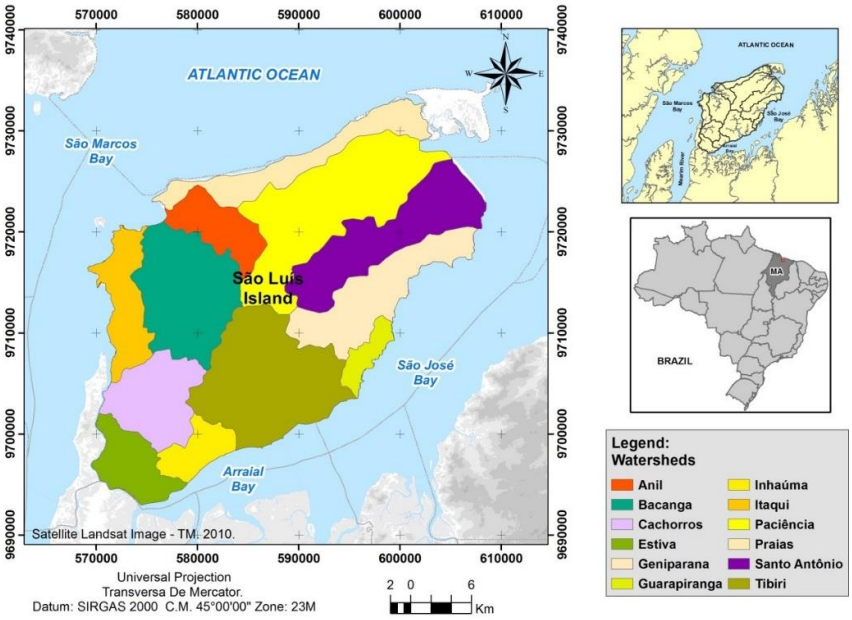

Figure 1. *Map of watersheds on São Luís Island, Maranhão, Brazil*

The evaluation of water quality involved the determination of physicochemical variables, a microbiological analysis and the determination of concentrations of heavy metals (Al, Fe, Zn, Cu, Cd and Pb). Four sampling campaigns were conducted in the rainy and dry seasons. Sampling was performed bimonthly from April to November 2014 at three points spatially distributed along the salinity gradient (*Fig. 2*). The coordinates of the sampling points were determined using of a Global Positioning System: Point 1 – 0571470/9704228; Point 2 – 0574746/9704786; and Point 3 – 0576841/9704838.

At each sampling point, water temperature (°C), pH, dissolved oxygen ($mg.L^{-1}$) and conductivity ($mS.cm^{-1}$) were recorded using a HANNA HI 9828 multi-parameter kit. Turbidity (UNT) was determined using a HANNA HI 93703 turbidimeter and water transparency (cm) was determined using a SECCHI disc. Water samples were also collected 50 cm from the surface in duly labeled 500-mL glass recipients for the subsequent determination of dissolved metals. Nitric acid (1 mL) was added to each sample to maintain the physicochemical properties of the water (APHA, 2012). The samples were placed in a cooler with ice and transported to the lab for storage under refrigeration. For the subsequent analyses, an aliquot (100 mL) was removed from each sample and placed on a hot plate for chemical digestion until reaching a volume of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80378047

20 mL. Five mL of nitric acid were added every 15 min to facilitate the digestion. The samples were diluted to 100 mL with de-ionized water and filtered with a fiberglass filter with a porosity of 0.45 μm. Readings were performed in an atomic absorption spectrophotometer with a graphite furnace (SpectrAA24OZ). Other water quality variables were determined following the Standard Methods for the Examination of Water and Wastewater (APHA, 2012). The collection methods and preservation of the samples followed the ABNT NBR 9897 and ABNT NBR 9898 guidelines, which stipulate the conditions for the sampling of domestic and industrial liquid effluents, sediments and water samples from receiving bodies of water.

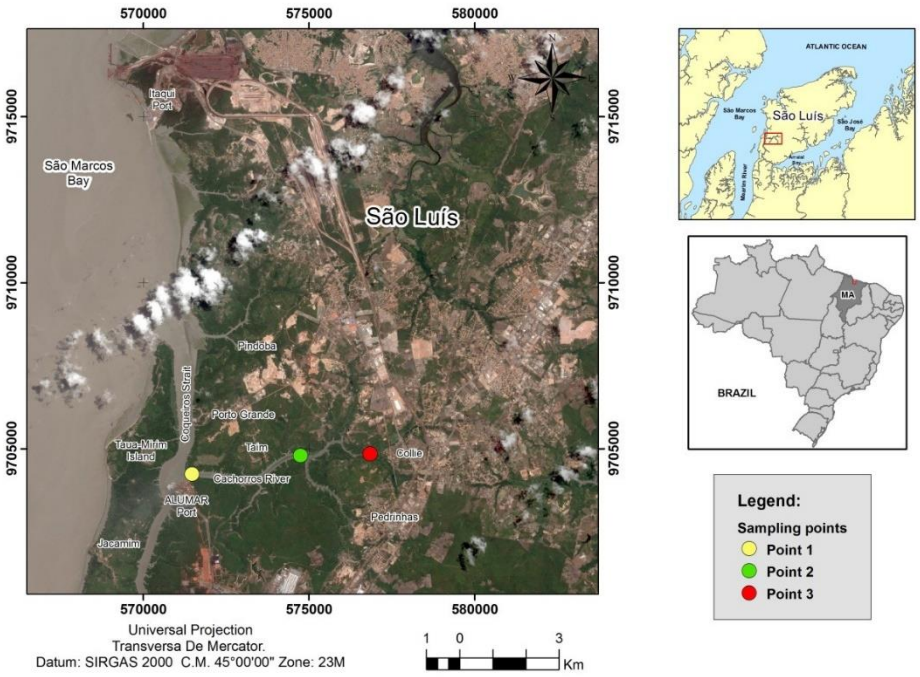

Figure 2. *Map of sampling points*

For the microbiological analysis, water samples were collected approximately 50 cm from the surface, placed in sterilized beakers with a capacity of 250 mL and transferred in coolers to the Microbiology Lab of the Federal University of Maranhão (Brazil). The multiple tube method was used for the determination of the most probable number (MPN) of total and thermotolerant coliforms as well as the identification of *Escherichia coli* following the methods established by the American Public Health Association (APHA, 2005).

Fish species were acquired from local fishermen, stored in plastic packages and transported under refrigeration to the lab. The muscle tissue was removed and weighed to form five replicates of approximately 4 g each. The samples were dehydrated for 24 h at 105 °C and digested with nitric acid + water ($HNO_3 + H_2O$) (1:1) and 150 μL of octanol ($C_8H_{18}O$) following the recommendations proposed by Carvalho et al. (2000). The extracts were analyzed at the Soil Lab of Maranhão State University (Brazil) using atomic absorption spectrophotometry for the trace metals Al, Fe, Zn, Cu, Cd and Pb. The determination of the elemental concentrations was performed through analyses of the ash obtained by dry digestion after complete decomposition of the muscle tissue, as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80378047

adapted from Jones and Case (1990) and Perkin-Elmer (1973). The solutions were analyzed in an inductively coupled plasma atomic emission spectrophotometer (model 720-ES, VARIAN). Specific calibration curves were used for each element and all analyses were conducted in triplicate. The blank reading was performed ten times to calculate the quantification limit (LQ) and the detection limit (LD) of the equipment, which were calculated considering the mean white signal plus 10 times the standard deviation (SD) for LQ and the mean white signal plus 3 times standard deviation (SD) to LD,, according to definition and criteria established by the IUPAC (1997). The entire analytical procedure was tested for both measurement precision and accuracy in order to assess the degree of reliability which can be allocated to the data generated by this investigation. The precision of the method was established by a calculation of the between assay variation coefficients from data of ten independent analyses.

One-way analysis of variance (ANOVA) was used for the spatiotemporal comparison of the variables. In cases of significant values, Tukey's test was used for the association between sampling months and points. Levene's test was used to assess the equality of variances. Feeding habits of the species were defined based on information in Fishbase (Froese and Pauly, 2009) and two-way ANOVA was employed to determine possible associations between the concentration of metals in the muscle tissue of the fishes and both local seasonality and trophic level.

Results and discussion

The distribution of dissolved metals in estuarine environments depends on the behavior of physicochemical variables and their controlling mechanisms. Many studies have demonstrated that the partition of trace metals between particulate and dissolved phases depends on factors such as pH, salinity, temperature, redox potential, dissolved organic carbon and the composition of suspended particulate matter (Hatje et al., 2003). The samples from the Cachorros River demonstrated quite homogenous physicochemical aspects on the spatial scale, with no statistically significant differences among the sampling points (ANOVA; $p > 0.05$). On the temporal scale, a differentiation pattern was found for nearly all physicochemical variables ($p < 0.05$). These differences mainly occurred when comparing the rainy months (April and June) to the dry months (September and November). *Tables 1* and *2* display descriptive statistics and the results of Tukey's test for the physicochemical variables in the study area on both temporal and spatial scales, respectively.

Table 1. *Mean and standard deviation (± SD) values and coefficient of variation (CV) for physicochemical variables in Cachorros River according to sampling month*

Variable	April		June		September		November	
	Mean ± SD	CV	Mean ± SD	CV	Mean ± SD	CV	Mean ± SD	CV
Water temperature (°C)	29.9 ± 0.17^{a}	0.58	29.3 ± 0.15^{b}	0.52	28.7 ± 0.2^{c}	0.69	28.2 ± 0.51^{c}	1.02

In the water column, concentrations of dissolved trace metals tend to vary by several orders of magnitude due to the large number of variables involved in the dynamics of the process, such as daily and seasonal variations in water flow, local discharges of urban and industrial effluents, variations in pH and redox conditions, detergent concentrations, salinity and temperature (Förstner and Wittmann, 1983). Despite these variations, the determination of concentrations of dissolved metals in water is a useful tool for the evaluation of the degree of contamination of a given ecosystem that has been employed by researchers throughout the world (Garbarino et al., 1995; Hurley et al., 1995, 1998; Marjanovic et al., 1995; Watras et al., 1995; Smith et al., 1996; Mastrine et al., 1999).

The analysis of metals in the estuarine water of Cachorros River revealed Fe and Al with values higher than the limits established by Brazilian legislation throughout all sampling months and points. The concentration of Cu was high at all sampling points only in September. Concentrations of Pb, Cr and Cd remained below the detection limit throughout the study (*Table 3*).

Table 3. *Concentrations of heavy metals ($mg.L^{-1}$) in Cachorros River (limits established by CONAMA Resolution 357/05 in bold)*

According to Schenone et al. (2014), fishes are good indicators of pollution by trace metals and can be used for the identification of the potential risk for human consumption. Fishes living in polluted waters can accumulate toxic trace metals through the food chain to levels that can compromise human health.

The determination of the concentration of metals in the muscle tissue of fishes caught in Cachorros River revealed Mn and Cd only in the dry season, occurring in three species. Mn was only detected in *M. curema*, whereas concentrations of Cd were found in the muscle tissue of both *C. acoupa* and *S. herzbergii* at levels above the limit established by Collegiate Board Resolution 42/13, which imposes greater restrictions in comparison to other Brazilian resolutions. Levels of Zn and Cu were higher, but below the limits established by Brazilian legislation. Zn was found in all species sampled and Cu was found in all except *G. luteus* and *M. curema*. Higher concentrations of these elements were found in the rainy season. Pb was the only metal analyzed with values above the limits established by all Brazilian legislation, with significantly higher values in the dry season for all species.

Although there are no national laws regulating the concentrations of Fe or Al in the muscle tissue of fishes, high values were found in both the rainy and dry seasons. Fe levels were highest in *G. luteus* and *C. microlepidotus* in the rainy season, whereas the highest level in the dry season was found in *M. curema*, with concentrations twofold higher in comparison to the other species. It was not possible to analyze Al in the rainy season, but the results were notably high in the dry season, especially for *M. curema* and *C. microlepidotus*, both of which had concentrations greater than 180.0 mg.kg^{-1} (*Table 5*).

Two-way ANOVA was used to determine significant differences in metal concentrations in the muscle tissue of fishes as a function of season (dry and rainy) and feeding habit (detritivorous, carnivorous and herbivorous). The only significant interaction between factors regarded Pb, as concentrations of this metal were higher in the dry season in detritivorous species in comparison to herbivorous species (*Table 6*).

Knowledge on seasonal variability in the concentration of trace metals in the water and muscle tissue of fishes in estuarine environments is extremely useful to understanding the effects of human actions on transitional ecosystems and the toxicological impact on populations that depend on these fishing resources. Marine fishes constitute an important source of protein and are a representative component of the human diet for a multitude of people who live in the rural zones of coastal cities (Mziray and Kimirei, 2016). The gradual increase in industrialization and urban expansion of the Industrial District of the city of São Luís, which potentiates the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80378047

introduction of undesirable amounts of pollutants in the aquatic environment, underscores the need for studies on the determination and quantification of trace metals in different compartments and trophic levels of the aquatic biota.

Besides industrial expansion, the estuarine region of Cachorros River is submitted to other forms of environmental pressure, such as domestic sewage, effluents from agricultural activities and livestock farming and the extraction of sand. However, according to Coimbra (2003), these factors have less importance when compared to the potential risks of contamination due to industrial activities, which affect the quality of aquatic ecosystems, posing potential risks to organisms and an important portion of the local human population that depends on fishing resources as a source of income and food.

Conclusion

The physicochemical variables of the water (temperature, pH, salinity and dissolved oxygen) only demonstrated temporal differences, thereby confirming seasonality as the determinant factor of such variations.

Concentrations of Al and Fe were high in both the water and muscle tissue of the fishes analyzed, although such concentrations could be attributed to natural processes, such as the breakdown of rocks and the transport of soils.

Concentrations of Cu and Pb were high in the water and muscle tissue of fishes, respectively, which raises concerns regarding the potential for the biomagnification of these elements and serious public health risks.

The interaction of season and feeding habits was significant with regard to the concentration of Pb in detritivorous species.

Escherichia coli in the water in June, September and November reveals contamination of a fecal origin due to the absence of adequate sanitation in the rural communities surrounding the Cachorros River.

Besides, further studies are needed to evaluate the extent of heavy metal contamination in sediment and other structures such as gills and liver, as well as whether feeding behavior, habitat preferences and life history patterns could influence heavy metal in fish. This study suggests a contamination of water resource due to the anthropogenic sources and a competent surveillance and monitoring program becomes extremely necessary to any attempt of managing the coastal areas in urbanized regions.

(Received 22nd Jan 2019; accepted 8th Mar 2019)

Abstract. This study highlighted the structure, species composition and biomass carbon stock in the *Abies Pindrow* dominant community in Dir Kohistan, temperate region of Pakistan. The results showed that stem density varied between 3 ha^{-1} in *Acer ceasium* to 273 ha^{-1} in *Abies pindrow*, with a total stand density of 350 trees ha^{-1}. The importance value index (IVI) varied between 2.27 (*Acer ceasium)* and 62.22 (*Abies pindrow*). The mean basal area was recorded at 132.15 m^2 ha^{-1}. The average stem volume was measured at 120 m^3 ha^{-1}. The mean stem and total tree biomass carbon was 639 and 967 t ha^{-1} respectively. Similarly, the understory vegetation and litter, dead wood and cone biomass carbon was found 1.43 t ha^{-1} and 12.02 t ha^{-1} respectively. Soil carbon (0-30 cm) was calculated by using Walkey-Black methods multiplied by mean soil bulk density measurements. The average soil organic carbon was calculated 70.75 t ha^{-1}. The Total average carbon stock of the community was calculated at 568.63 t ha^{-1}. These results provide the evidence that, *Abies Pindrow* dominant community has a greater potential of sequestering carbon. Upon proper carbon management the ecosystem might be included in the carbon trading of Kyoto protocol.
Keywords: *soil, temperate region, structural attributes, growing stock, biomass, carbon, Kumrat Valley*

Introduction

Forests sequester and accumulate more carbon than any other terrestrial ecosystem and are a significant natural 'brake' on climate change (Pan et al., 2011; Espírito-Santo et al., 2014; Manan et al., 2018). Forest biomass contained a significant amount of carbon and can accumulate continuous carbon through their life spin (IPCC, 2006; Ahmad et al., 2014, 2015). Various anthropogenic activities e.g. industrialization, deforestation, forest degradation and burning of fossil fuel, has caused an increase in the level of carbon in the atmosphere and disrupted the global carbon cycle (Sharma and Rai, 2007; Ahmad et al., 2014; Manan et al., 2018). However, nature has its own mechanism of sequestering and storing the carbon in its "reservoirs" or "sinks''. The removal of carbon for decreasing the CO_2 level is need of the time (Wani et al., 2014, 2016). Forest plays an important role in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80498058

the global carbon cycle as carbon sinks of the terrestrial ecosystem (Coulston et al., 2015; Calfapitera et al., 2015). Forest contained about 4 billion ha of the globe with 861 ± 66 Pg stock carbon (Wani et al., 2014; FAO, 2015).

The Intergovernmental Panel on Climate Change (IPCC) identified five carbon pools of the forest ecosystem, namely the above-ground biomass, below-ground biomass, litter, woody debris and soil organic matter (Nizami, 2012). Among all the carbon pools, the above-ground biomass constitutes the major portion of the carbon pool (Ahmad et al., 2014). Estimating the amount of forest biomass is very crucial for monitoring and estimating the amount of carbon that is lost or emitted, as well the forest's potential to sequester and store carbon (Ahmad et al., 2018; Manan et al., 2018; Saeed et al., 2019). The IPCC and the Kyoto protocol (KP) identified forest as one of the important tool for the mitigating climate change through managing forest carbon for climate change strategy (Hosonuma et al., 2012). Concerns regarding the climate change mitigation, the international community stresses on the national and regional monitoring of forest carbon under the IPCC proposed guidelines (Böttcher et al., 2008).

Pakistan, being a member, to the IPPC and KP, the measurement of periodic and annual budgeting of the stored carbon in their forest is their obligation. In Pakistan various researcher outline the carbon stock of different forest like in temperate region (Ahmad et al., 2014; Ahmad et al., 2015; Ahmad and Nizami, 2015; Manan et al., 2018; Ahmad et al., 2018), in subtropical region (Nizami, 2012; Manan et al., 2018; Amir et al., 2018) and in planted forest. However, the carbon stock potential as well the species composition of the dominant Abies Pindrow community is not worked out yet. Looking into consideration this study was designed with the objectives to figure out the soil analysis, forest structure, species composition and biomass carbon of the *Abies pindrow* forest of Dir Kohistan, Pakistan.

Materials and methods

Study area and research design

Dir Kohistan is located to the North West side of Khyber Pakhtunkhwa province Pakistan. Geographically Dir Kohistan is mountainous with elevation ranges from 2000 to 6000 m (Ahmad et al., 2018). The *Abies pindrow* community occurred with in elevation range of 2500 to 3000 m along with latitude 35° 34' to 35° 43' and longitude72° 10' to 72° 16'. The mean annual precipitation in area ranges from 1000 to 1500 mm, while the mean temperature ranges from 0.6 to 25 °C (Ahmad and Nizami, 2015). Geologically most of the rocks are diorites, nitrites, and schist is the principle types of rocks. The underground rocks are mostly quartzite, schist, shale, slate, and granites. Soil is rich in organic matters and acidic in nature (Ahmad and Nizami 2015; Ahmad et al., 2018). For the related data collection, 14 sample plots, each of size 0.1 ha were laid out randomly in the forest (*Table A1* in the *Appendix*). The species composition and their related attributes, the growing stock, and biomass carbon in the respective pools were assessed (*Fig. 1*).

Species composition and related attributes

The species composition and their related attributed like stem density, relative density, basal area, relative basal area, frequency, relative frequency and importance value index were measured using *Equations 1-6* given below.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80498058

$$\textbf{Density (D)} = \frac{\text{Total number of individual of a species in all the sample plots}}{\text{Total number of sample plots taken}} \quad \text{(Eq.1)}$$

$$\textbf{Relativedensity (D3)} = \frac{\text{Total No,individual of a species in all quadrates}}{\text{Total No.of individuals of all species in all quadrates}} \times 100 \quad \text{(Eq.2)}$$

$$\textbf{Average cover per species, (C)} = \frac{\text{Total cover (square feet) of a species}}{\text{Number of plants of a species}} \quad \text{(Eq.3)}$$

$$\textbf{Relative Cover of Species (C3)} = \frac{\text{TotalCoverSqftofallPlantsofallSpp}}{\text{TotalCoverSqftofallPlantsOfallSpecies}} \quad \text{(Eq.4)}$$

$$\textbf{Frequency (F)} = \frac{\text{Number of quadrats of occurrence of a species}}{\text{Total number of quadrats used by sampling}} \times 100 \quad \text{(Eq.5)}$$

$$\textbf{RelativeFrequency (F3)} = \frac{\text{Frequency of a species}}{\text{Total frequency of all species}} \times 100 \quad \text{(Eq.6)}$$

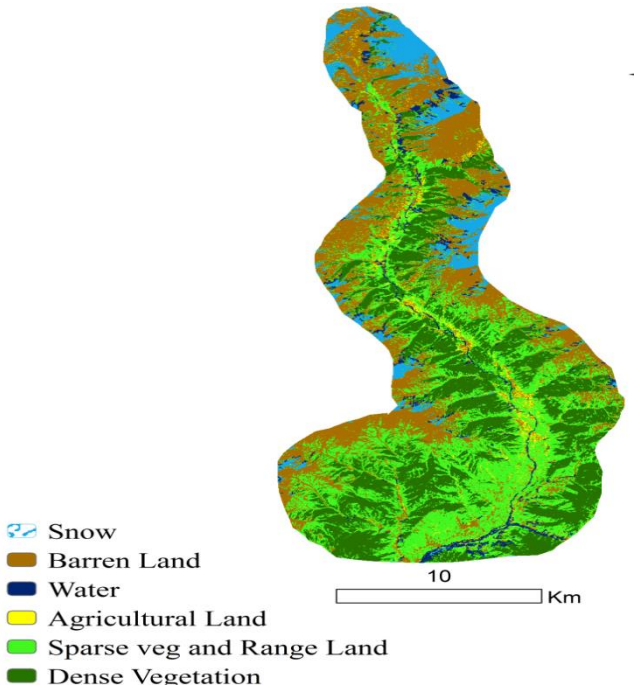

Figure 1. *Study area*

Importance value index (IVI)

In mixed forest, data of density, cover and frequency of a species do not give a clear data about the main species. It was estimated by adding the value of relative cover, relative density, and relative frequency and to dividing it by 3 given the importance value index (IVI) of the species. IVI for a forest stand were calculated as the total of the relative density, relative frequency and relative cover (Curtis, 1959).

$$\text{I.V.I} = \frac{\text{D3} + \text{C3} + \text{F3}}{3} \quad \text{(Eq.7)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80498058

Biomass carbon estimation

For upper storey vegetation biomass carbon, in each plot diameter and tree height was measured. The stem volume was measured from the relationship of diameter (cm) and height (m) following formula:

$$\text{Tree volume } (m^3) = \pi/4d^2 \times h \times FF \quad \text{(Eq.8)}$$

Stem biomass (kg) was calculated from the relationship of stem volume (m^3) and basic wood density (Kg/m^3). Basic wood density was sourced from available literature (Haripriya, 2000; Ahmad et al., 2014; Manan et al., 2018,). The following formula was used to estimate stem biomass:

$$\text{Stem biomass (kg)} = \text{Stem volume } (m^3) \times \text{Wood density } (Kg/m^3) \quad \text{(Eq.9)}$$

To estimate total biomass, biomass expansion factor was used. The BEF ratio of 1.51 for conifers and 1.55 for broad leaved was used to find out total biomass of a tree (Haripriya, 2000; Ahmad et al.,2018; Manan et al., 2018).

$$\text{Total biomass (Kg)} = \text{Stem biomass (Kg)} \times BEF \quad \text{(Eq.10)}$$

For the measurement of understory vegetation, dead wood, cone, and litter biomass carbon, sub plots each of 1 m^2 size were laid out. From the each sub plot, the understory vegetation was harvested destructively and dead wood, cone and litter were collected and their fresh weight was measured. The collected samples were oven dried for 48 h at 72 °C and their dry weight was taken as their biomass (Ahmad and Nizami, 2015; Ahmad et al., 2018; Manan et al., 2018).

The carbon values were assessed from the biomass of the respective pools. The conversion factor of 0.5 was used to convert biomass into carbon that has been used widely around the Globe (Brown and Lugo, 1982; Malhi et al., 2004; Nizami, 2012; Ahmad et al., 2014; Amir et al., 2018; Saeed et al., 2019). For soil carbon assessment, soil samples were collected from each plot at the depth of 30 cm. The soil organic carbon was measured following (Walkely, 1934). The soil carbon in t ha^{-1} was assessed from the soil bulk density, depth increment and soil organic carbon following (Ahmad and Nizami, 2015; Saeed et al., 2018; Ahmad et al., 2018).

Results and discussion

Species composition and growing stock

The results regarding the species composition and related attributed are given in *Table 1*. The results clearly figure out that *Abies pindrow* is the dominant tree species with the maximum species compositional attributes while the minimum values for these attributes were recorded for *Acer cesium*. Over all the results showed that the stem density varied between 3 ha^{-1} (*Acer caesium*) and 276 ha^{-1} (*Abies pindrow*) with a total stem density of 350 trees ha^{-1}. The results of frequency in *Table 1* explained that along with *Abies pindrow*, *Taxus baccata* and *Picea smithiana* were found throughout the community. Regarding the growing stock (volume m^3 ha^{-1}) details are given in *Table 2*. The results in *Table 2* showed that the total growing stock in the community was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80498058

recorded at 1720 m^3 ha^{-1}. Regarding the relationship between basal area (m^2 ha^{-1}) and growing stock (m^3 ha^{-1}), the results in *Figure 2* showed a strong positive linear correlation with R^2 value of 0.98. The highly positive correlation of basal area and growing stock indicated that growing stock is the function of basal area (Nizami, 2012; Ahmad et al., 2014; Ahmad and Nizami, 2015; Saeed et al., 2019; Amir et al., 2018).

Table 1. *Species composition and related attributes*

Species	D ha^{-1}	RD %	BA ha^{-1}	RB %	F %	RF %	IVI
Abies pindrow	276	77.23	112.39	85.12	100.00	27.31	63.22

Biomass carbon

The total tree biomass value varied between 5 and 800 t ha^{-1} (*Table 2*) with overall value of 967 t ha^{-1}. The relationship of basal area (m^2 ha^{-1}) and biomass is presented in *Figures 3* and *4*. The value of R^2 suggested a very strong correlation between basal area and biomass. The basal area and biomass have a functional relationship and with increase in the basal area the biomass also increases (Nizami, 2012; Saeed et al., 2018). Under storey vegetation were mostly consist of grasses, forbs and shrubs. The average biomass of under storey vegetation was 2.87 t ha^{-1}. The biomass carbon of the upper story vegetation was 484 t ha^{-1}. In the total tree biomass carbon, the contribution of *Abies pindrow* was 82.64%. In the under storey vegetation, the mean carbon stock was 1.43 t ha^{-1}. Similarly, the carbon stock in litter, dead wood and cones was recorded as 12.02 t ha^{-1}. The soil carbon varied from 52.13 to 81.78 t ha^{-1} (*Table 3*) with mean value of 70.74 t ha^{-1} (*Table 4*).

Table 3. *Soil bulk density and soil organic carbon stock tons* ha^{-1}

Plot	Bulk density (0-15 cm)	Bulk density (15-30 cm)	SOM %	SOM %	Total SOM%	T otal SOC%	SOC tons ha^{-1}
1	1.01	1.05	3.14	0.98	4.12	2.38	73.07
2	1.009	1.04	3.39	1.19	4.58	2.65	80.46
3	1.009	0.93	3.16	1.02	4.18	2.42	73.43

Table 4. *Total carbon stock in forest ecosystem*

S. No	Carbon pools	Average carbon stock (tons ha^{-1})
1	Upper storey vegetation carbon stock	484
2	Under storey vegetation carbon stock	1.43
3	Litter, dead wood and cones carbon stock	12.02
4	Soil carbon stock	70.74
Total average carbon stock		568.63

Overall the results in *Table 4* showed that the *Abies pindrow* community stored 568.63 t ha^{-1} carbon. The upper storey vegetation hold maximum carbon followed by soil, whereas the understory vegetation hold the minimum carbon. In compression the current carbon values in the biomass gives higher estimates from the reported values from Himalayan temperate regions (Sharma et al., 2010, 2011; Wani et al., 2014). This higher value might be the results of the presences of larger tree particularly of *Abies pindrow*. We found trees up to 150 cm in diameter that resulted in the maximum carbon value in the community. However, the soil carbon was found low from the reported value of Sharma et al. (2011) and Wani et al. (2014). This may be due to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80498058

management practices. The forest are managed forest and during management operations the dead wood are removed from the forest floor and upon the removal of the deadwood the forest floor have little deadwood stuff, resulting low soil carbon (Barbati et al., 2007).

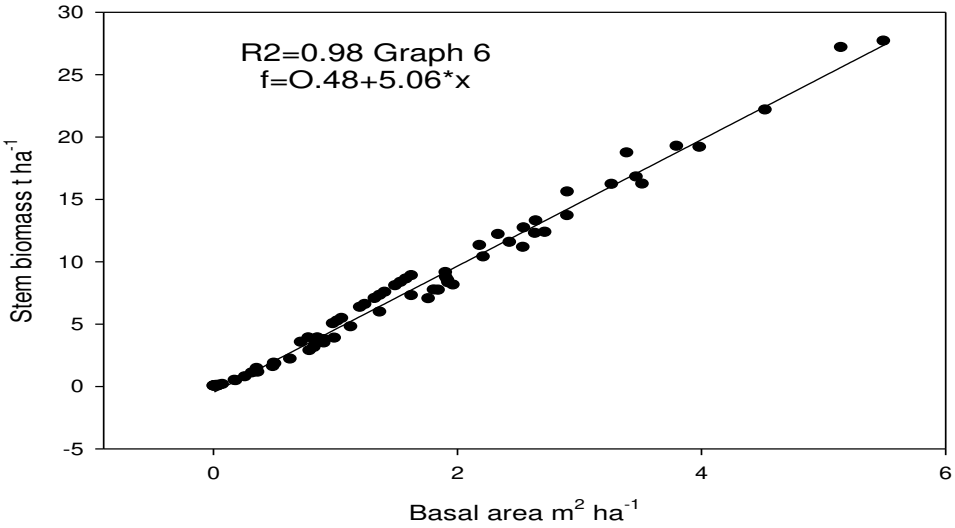

Figure 3. *Relationship between stem biomass (t ha^{-1}) and basal area m^2 ha^{-1}*

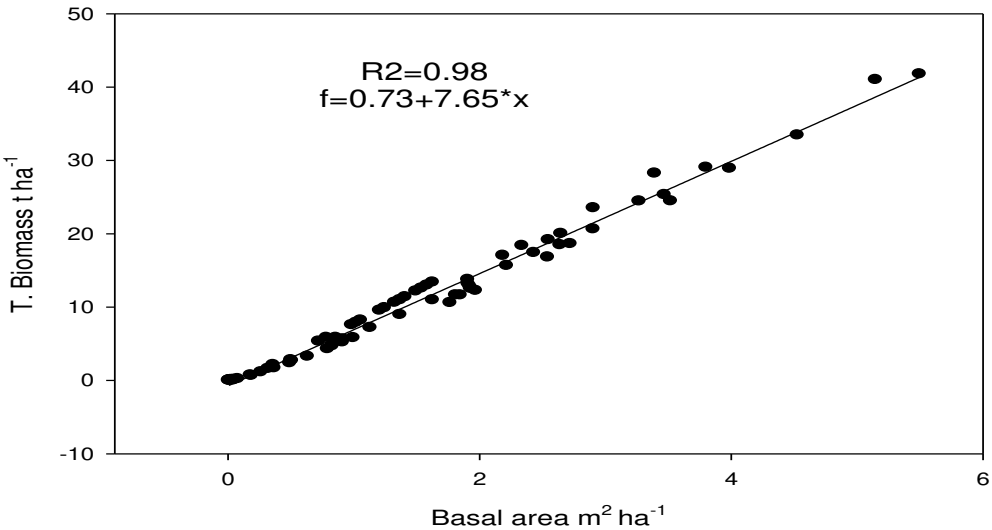

Figure 4. *Relationship between stem biomass (t ha^{-1}) and basal area m^2 ha^{-1}*

Soil carbon stock

Soil carbon in tons ha^{-1} was calculated from the relation of soil organic carbon (SOC %), Soil bulk density (gm/cm^3) and thickness of horizon (cm). Soil carbon was estimated by the use of different chemical solution like M K_2 Cr_2O_7 and H_2SO_4. Composite soil samples were collected at 0-15 and 15-30 cm depths from each inventory plot, using an auger. Soil carbon concentration (g C/g of soil) was established using the Walkey-Black titration method. Data collection for desired objectives was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80498058

recorded using standard procedures (FAO, 2005). The result of study showed that soil organic carbon stock decrease with increasing soil depth. The high value of organic carbon content showed that there is fast decomposition rate in forest litter in suitable environment. The soil organic carbon is affected due to different environmental factors geographic location along with slope. The average soil organic carbon was 70.75 ± 11.26 t ha^{-1} with average soil bulk density 0.99 ± 0.032 was recorded.

Soil PH

Soil pH was measured by using soil pH meter (Mc Lean, 1982). The average pH was recorded 6.19 ± 0.12 the minimum soil pH was recorded 5.93 while maximum was 6.33 with coefficient variance. The result of the study shows that the soil was strongly acidic.

Conclusion

The presented finding in this study revealed that the *Abies pindrow* community having the greater carbon sequestration potential. However, the forest faces greater pressure in term of grazing, fuel wood collection and timber harvest. In this regard activities like Reduction in timber harvest, promotion of aforestation, reforestation, and the development of Hydropower should be imitated from the preservation and conservation of the forest.

Abstract. Various types of wastes are the main sources of heavy metal within a landfill system including metal waste components such as food cans, scrap metal, household hazardous waste and electronic waste such as batteries and old computers. The procedure that occurs inside the waste cells quickens that procedure for substantial metal draining from the waste component. This study comparing soil samples taken from four different sites in Selangor of closed non-sanitary (Sungai Kembong) and sanitary (Ampar Tenang, Air Hitam and Kubang Badak) landfills at different depths (0-30 cm, 30-60 cm and 60-90 cm) and radiuses (5-10 m, 10-15 m and 15-20 m), for ten heavy metals (Al, Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd and Pb) to find the risk of heavy metal movement from the upper layer cell into the deeper layer. The data were analysed using ICP-MS (Perkin Elmer NexION 300X). Al and Fe displayed higher concentration at most of the sites with different volume of concentration at different depth and radius. Most of the sites consistently showed higher contamination in deeper soil than the upper layer of the soil.
Keywords: *urban pollution, landfill, inorganic pollutant, laterite soil, leachate, municipal solid waste*

Introduction

It is estimated that approximately 0.5 to 4.5 kg of solid waste per person per day is produced at different regions of the world (Bakare et al., 2005; Swati et al., 2014). Land degradation, which caused by human activities, creates significant adverse effects on the environments and ecosystems worldwide (Thomaz and Luiz, 2012; Bai et al., 2013; Li et al., 2013; Chen et al., 2015). Thus, solid waste becomes an important and emerging environmental problem. The most common ways to manage such waste disposal are landfills and incinerators. At the time being, it is up to 95% total of municipal solid waste (MSW) collected is disposed of in landfills worldwide (El-Fadel, 1997; Swati, 2014). Landfilling is the major MSW disposal method used in modern cities (Wong, 2015).

Due to the problems of environmental pollution and the shortage of urban land, landfill becomes a major issue in any urban management in the world (Hoornweg and Bhada, 2012). As consequences, ex-landfills are turned into another beneficial alternative to the urban population. At present, there were 143 closed landfills in Malaysia

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80598067

(SWCorp, 2017). The number of the closed landfills had increased each year from 115 in 2003 to 131 in 2012 and it has been expected to become 296 when all the existing landfills closed their operation in 2020 (Simis et al., 2016). For the time being, there are about 160 operating landfills and 143 closed landfills, which make altogether 303 landfills in total that, are available in Malaysia. It has been expected more than 70.0% of the future ex-landfills to be located in urban areas and become the major concern of the local population within the ex-landfill areas (Chun-Yang and Talib, 2006).

Based on Act 672 under Solid Waste and Public Cleansing Management Act 2007, every ex-landfill must undergo waste recovery through new technology such as waste to energy facilities, construction and demolition recovery facilities, organic waste facilities, landfill closure, and integrated waste management. However, the existence of the ex-landfill within the neighbourhood reported creating issues of foul odours, leachate, and landfill gas pollution. The local communities have reported it and they claimed to have declined health and quality of life (Simis and Awang, 2015). These concerns probably have become more pragmatic when recent intensive studies demonstrated the increment of human health risk caused by exposure to toxic chemicals, such as dioxins and related compounds, and heavy metals in these dumping sites (Agusa et al., 2003; Minh et al., 2003).

Landfills containing hazardous materials are under critical observation today for potential hazards, resulting in the need for thorough risk analyses along with the soil and groundwater that have been contaminated with chemicals leaching from landfills. Several reports have been published which are documented on the leachate characterization and its effect on groundwater pollution (Boels and Fleming, 1993), but little information is available on the effect of landfills on soil contamination and its toxicological effects. Damaging human activities cause pollution. Thus, more information and assessment of land pollution are needed to overcome the problems occurred (Kardanpour et al., 2015; Mahmoud and El-Kader, 2015).

Based on the previous study, most organic chemical substances will eventually either be degraded through biochemical reactions in the landfill or be leached out of the landfill with water movement. However, the majority of heavy metals will remain in the landfill because heavy metal migration is very limited compared to the number of metals accumulated in the landfill (Oygard et al., 2004; Riber et al., 2005), especially in anaerobic processes. The slow movement of heavy metals is the result of heavy metals being subjected to strong sorption on soil particles, precipitation under anaerobic conditions, and chelation with inorganic and organic ligands in landfills (Bozkurt et al., 1999, 2000). Heavy metals occur naturally at low concentrations in soils. They are considered soil contaminants due to their widespread occurrence, as well as their acute and chronic toxicity (Youn-Joo, 2004).

High concentrations of heavy metal such as As, Cd, Cu, Pb, and Zn in soils have often been reported in a number of countries. It was reported by Bhattacharya (2012), that no significant adverse impacts of As upon human health in Bangladesh, India, and China. It is claimed that millions of people are potentially at risk from As poisoning. Similar to As, Cd accumulation in the offal of grazing animals in New Zealand and Australia made it unsuitable for human consumption. Besides, it affected access to meat products to overseas markets (Loganathan et al., 2008). There are also concerned about the urban development of horticultural sites which contained toxic levels of heavy metals in soils that resulting from excessive use of fungicides and herbicides (Pietrzak and Uren, 2011).

Materials and methods

Study area description

Twelve points at 4 different sites of closed landfill located at Selangor, Malaysia namely; Ampar Tenang sanitary landfill (2°49'13.3"N 101°40'47.6"E), Sungai Kembong non-sanitary landfill (2°53'08.8"N 101°49'17.0"E), Air Hitam sanitary landfill (2°52'22.4"N 101°38'53.8"E) and Kubang Badak sanitary landfill (3°23'01.6"N 101°24'54.2"E) were selected for this study. The site selection was based on the types of the landfill and the size of the landfill located in Selangor state. *Table 1* indicates the landfill sites info with the area covered, wasted collected, total year of operation and the current status of the landfill studied.

Table 1. *Selected landfill sites with the area covered, waste collected per day, total year operation and current status*

LANDFILL SITES	AREA (ACRE)	WASTE COLLECTED (TONE/DAY)	TOTAL YEAR OPERATION	CURRENT STATUS	SOURCE
Air Hitam Sanitary Landfill	100	1500	16	Closed	Othman et al. (2016)
Kubang Badak Sanitary Landfill	30	400	10	Closed	Yahaya et al. (2016)
Ampar Tenang Sanitary Landfill	10	100	9	Closed	Yusoff et al. (2013)
Kampung Sungai Kembong Inert Waste	38.5	83	5	Closed	Yahaya et al. (2016)

Soil sampling

Soil samples were collected at different points (0-200 mm depth, approx. 1000 g) were taken by using soil auger (Eijkelkamp Agrisearch). The soil then was sealed in a polyethylene bag and labelled. The soil was dried in an oven for 70ºC for 3 days to a week depending on the moistness of the soil. Then samples were ground by using agate mortar until becoming small particles. Then it was sieved using a 2 mm mesh to remove stones and plant materials. Then samples were stored at room temperature before being digested using Microwave Digestion Ethos D (Milestone, 2001). Heavy metals, Al, Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd, and Pb were then analysed by using ICP-MS (Perkin Elmer NexION 300X).

Determination of Heavy Metals in Soils

0.5 g of soil samples were accurately weighed into a container made of PFA perfluoroalkoxy polymer and digested through a microwave digestion system using the digestion method as described by Zhao et al. (1994). Soil samples were air-dried and sieved. Soil samples were passed through a 2 mm sieve and ready for further analysis. Dried and the ground sample was mixed with 10 ml of concentrated nitric acid (HNO_3 65%) and digested. Acid was added for each soil samples and then the digestion tubes were placed in a rotor segment by using a torque wrench. The segments were inserted into the microwave cavity and connected with the temperature sensor. The mixture temperature was adjusted to ±175ºC and 1,200 Watt of power for 30 minutes using Microwave Digestion (Milestone Start D) as detailed in Method US EPA 3051. The digestion was completed after the last solution was clear and no brownish fumes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80598067

were released from the digestion vessel tubes. When digestion was completed, samples were removed and diluted. The soil digests were adjusted to the final volume of 50 mL with deionized water. This solution is further 1:1 diluted for the analysis of components by ICP-MS and divided into triplicate each into 15 ml tubes.

Data analysis

All the experiments were carried out in triplicates and data presented as mean values of three independent replicates. Data were further analysed using analysis of variance (ANOVA). Statistical analysis for all experiments was performed by using SAS through factorial analysis of variance followed by Tukey's test with significant different at $P<0.0001$.

Results and discussion

Ampar Tenang sanitary landfill

The results in *Fig. 1* showed heavy metal concentration in a closed sanitary landfill with a radius of 5 to 10 m, 10 to 15 m and 15 to 20 m at different depth 0 to 30 cm, 30 to 60 cm and 60 to 90 cm of Ampar Tenang sanitary landfill.

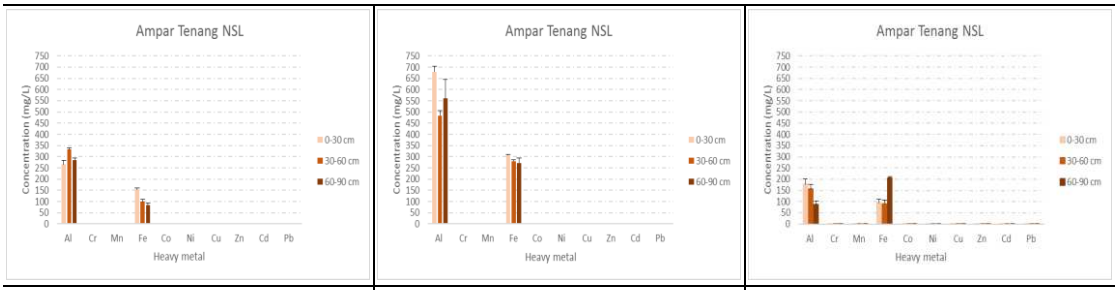

Figure 1. *The pattern of 10 heavy metal concentration depicted Ampar Tenang sanitary landfill at different soil depths (0-30 cm, 30-60 cm, and 60-90 cm) and radiuses (A: 5-10 m, B: 10-15 m and C: 15-20 m) of the closed landfill*

Results of heavy metal showed that Al and Fe concentration is higher at all point of Ampar Tenang landfill. Among the analysed heavy metals, Al and Fe concentration at radius 10 to 15 m had the highest concentrations. Each showed 679.088 mg/kg, 483.627 mg/kg and 560.437 mg/kg for Al while 306.678 mg/kg, 280.216 mg/kg and 272.183 mg/kg for Fe. Concentration for the radius 5 to 10 m and 15 to 20 m also almost equal within each depth. The heavy metal concentration at radius 15 to 20 m showed Al range between 87.711 mg/kg and 177.155 mg/kg while for Fe the concentration range between 90.317 mg/kg and 204.819 mg/kg. Meanwhile, radius 5 to 10 m showed Al concentration higher than Fe concentration. Each at 265.645 mg/kg, 332.441 mg/kg, and 284.904 mg/kg for Al and 152.911 mg/kg, 99.968 mg/kg and 84.924 mg/kg for Fe.

Sungai Kembong non-sanitary landfill

The results in *Fig. 2* showed heavy metal concentration in a closed non-sanitary landfill with a radius of 5 to 10 m, 10 to 15 m and 15 to 20 m at different depth 0 to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80598067

30 cm, 30 to 60 cm and 60 to 90 cm of Sungai Kembong non-sanitary landfill. Results of heavy metal showed that Al and Fe concentration is higher at all point of Sungai Kembong landfill. Among the analysed heavy metals, Fe concentration at radius 15 to 20 m showed 364.243 mg/kg, 534.058 mg/kg and 559.114 mg/kg. Fe concentration at radius 15 to 20 m and 5 to 10 m also showed high concentrations. Each showed 170.397 mg/kg, 316.408 mg/kg and 436.530 mg/kg for radius 15 to 20 m while 337.625 mg/kg, 342.236 mg/kg and 289.030 mg/kg for radius 5 to 10 m. The Al concentration showed the highest reading for radius 5 to 10 m at 160.216 mg/kg, 185.739 mg/kg and 239.069 mg/kg compared to Al concentration at radius 10 to 15 m and radius 15 to 20 m. For radius 10 to 15 m, the concentration for Al range between 160.216 mg/kg, 185.739 mg/kg and 239.069 mg/kg. Meanwhile, for radius 15 to 20 m showed a range between 28.183 mg/kg and 43.081 mg/kg.

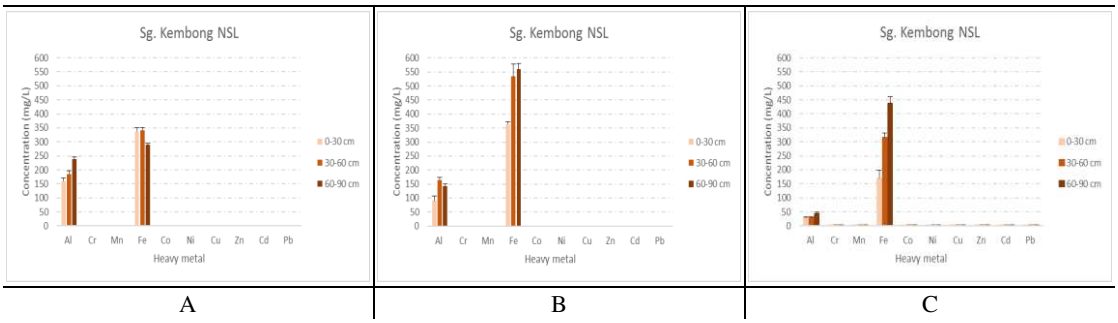

Figure 2. *The pattern of 10 heavy metal concentration depicted Sungai Kembong non-sanitary landfill at different soil depths (0-30 cm, 30-60 cm, and 60-90 cm) and radiuses (A: 5-10 m, B: 10-15 m and C: 15-20 m) of the closed landfill*

Air Hitam sanitary landfill

The results in *Fig. 3* showed heavy metal concentration in a closed non-sanitary landfill with a radius of 5 to 10 m, 10 to 15 m and 15 to 20 m at different depth 0 to 30 cm, 30 to 60 cm and 60 to 90 cm of Air Hitam sanitary landfill. Results of heavy metal showed that Al and Fe concentration is higher at all point of Air Hitam landfill. Among the analysed heavy metals, Al concentration at the radius 10 to 15 m showed the highest concentration. Each showed 235.604 mg/kg and 460.756 mg/kg and 422.434 mg/kg. Meanwhile, radius 5 to 15 m and 15 to 20 m showed 87.317 mg/kg, 75.733 mg/kg and 68.102 mg/kg for radius 5 to 10 m and 19.247 mg/kg, 42.861 mg/kg and 28.097 mg/kg for radius 15 to 20 m. For Fe concentration, the highest concentration depicted by radius 15 to 20 m; 523.195 mg/kg at 0 to 30 cm depth. Fe concentration at radius 10 to 15 m showed almost equal concentration at a different depth. Each showed 337.115 mg/kg, 270.938 mg/kg and 330.970 mg/kg. Meanwhile for radius 5 to 10 m, Fe concentration showed lower concentration at 107.231 mg/kg, 137.143 mg/kg and 136.536 mg/kg for each different depth.

Kubang Badak sanitary landfill

The results in *Fig. 4* showed heavy metal concentration in a closed sanitary landfill with a radius of 5 to 10 m, 10 to 15 m and 15 to 20 m at different depth 0 to 30 cm, 30 to 60 cm and 60 to 90 cm of Kubang Badak sanitary landfill. Results of heavy metal showed that Al and Fe concentration is higher at all point of Kubang Badak landfill.

DOI: http://dx.doi.org/10.15666/aeer/1704_80598067

Among the analysed heavy metals, Fe concentration depicted the highest concentration at the radius 15 to 20 m, 10 to 15 m as well as radius 5 to 10 m of the radius. Each showed 471.797 mg/kg, 260.469 mg/kg and 103.413 mg/kg at radius 15 to 20 m; 676.043 mg/kg, 618.660 mg/kg and 524.594 mg/kg at radius 10 to 15 m and 255.221 mg/kg, 268.966 mg/kg and 353.415 mg/kg at radius 5 to 10 m. However, Al concentration showed the highest concentration depicted by radius 10 to 15 m and 5 to 10 m. Each showed 359.564 mg/kg, 407.121 mg/kg and 289.186 mg/kg at radius 10 to 15 m while 332.316 mg/kg, 391.556 mg/kg and 342.372 mg/kg at radius 5 to 10 m. Meanwhile, Al concentration at radius 15 to 20 m showed 172.183 mg/kg, 121.184 mg/kg and 91.807 mg/kg. Other heavy metal despite Al and Fe showed the lowest concentration at all radius and depth.

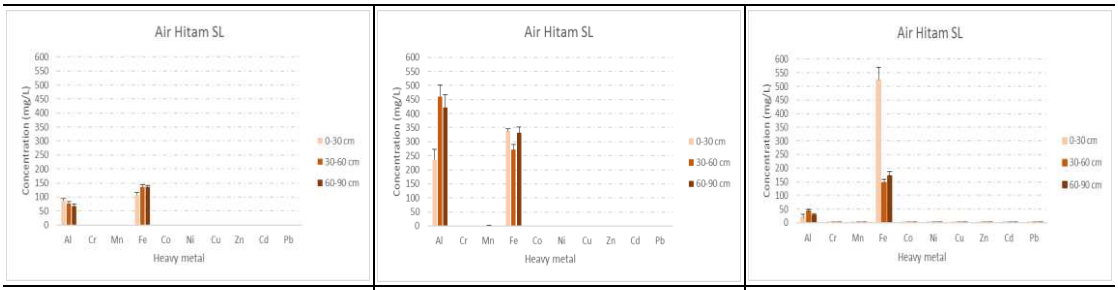

Figure 3. *The pattern of 10 heavy metal concentration depicted Air Hitam sanitary landfill at different soil depths (0-30 cm, 30-60 cm, and 60-90 cm) and radiuses (A: 5-10 m, B: 10-15 m and C: 15-20 m) of the closed landfill*

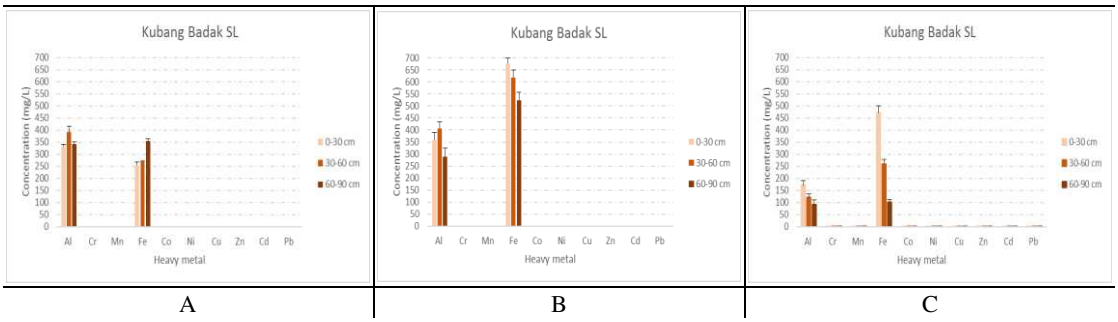

Figure 4. *The pattern of 10 heavy metal concentration depicted Kubang Badak sanitary landfill at different soil depths (0-30 cm, 30-60 cm, and 60-90 cm) and radiuses (A: 5-10 m, B: 10-15 m and C: 15-20 m) of the closed landfill*

Analysis of variance confirmed the findings by exhibiting highly significant differences (P<0.0001) between the radius, depth, and heavy metal concentration at three different radiuses, three different depths, and ten heavy metals concentration. This clearly demonstrates that environmental factors and landfill area background can have an important influence on the accumulation of certain heavy metal and its content. Al and Fe concentration showed the highest pattern on all 4 closed landfill sites. Research by Elwali et al. (2008), showed that the most common heavy metal contaminations at the landfill area vary from iron (Fe), cadmium (Cd), copper (Cu), zinc (Zn) and nickel (Ni). Furthermore, various studies reveal very high contaminants levels in the

DOI: http://dx.doi.org/10.15666/aeer/1704_80598067

groundwater underneath the non-engineered waste disposal sites in Selangor (Bahaa-eldin et al., 2010; Suratman and Sefie, 2010; Taha et al., 2011). The subsurface soils were considerably polluted by heavy metals where wastes were dumped directly on top of the unlined natural formation (Mohd et al., 2013). This is probably the reason for the high concentration of the river alluvium soil beneath the landfill that has the highest metal concentrations of Cu, Zn and Pb (Elwali et al., 2008). Based on the shallow and fluctuation of the periodic water table, water infiltration during the rainy season, acidic soil environment and local groundwater flow direction were the main reasons that enhanced the contamination migration through the soil formation into the groundwater (Elwali et al., 2008). Although the contamination present in the solid waste applied a significant impact on the groundwater, it has to be stressed that different metals behaved differently. Heavy metal binding properties of these soil constituents differ with the charges of the soil material and the ionic valences. As a result, different depths of the sample soil from landfill depict different capability of heavy metal binding. In addition, the rate and amount of pollutant penetration through the soil is also influencing the concentration of heavy metal present in the landfill environment.

Conclusions

The effects of the heavy metals content and composition, radiuses, depths and localities interactions have not been studied in the landfill area. Despite significant results in our understanding of heavy metals contamination distribution profiles at different soil depths and radiuses at closed landfill area, type of soil, the control mechanisms regulating the type of heavy metals distribution and accumulation and soil chemical reaction still remain an enigma. Each factor had an effect on the heavy metals content and profile; however, the most influential factor appeared to be a type of soil. Recommendations for future researches are by identifying the key factors controlling heavy metals distribution and accumulation in a different type of soils a greater understanding of landfill pollution mechanism in response to interactions with environmental factors will emerge.

(Received 24th Jan 2019; accepted 3rd May 2019)

Abstract. Landfilling is more preferable in Malaysia compared to another disposal method due to low cost, and availability of land. Other than solid waste, the percolation of water into the landfill leads to leachate formation. The migration of waste in leachate form may accelerate the heavy metal contamination of the soil one of the major concerns in landfilling. This study aimed in comparing soil samples taken from five different sites in Selangor of inert waste (Sungai Kertas, Kuang and Dengkil) and sanitary (Tanjung Dua Belas and Jeram) landfills at different depths (0-30 cm, 30-60 cm and 60-90 cm) and radiuses (5-10 m, 10-15 m and 15-20 m), for ten heavy metals (Al, Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd and Pb) to find the risk of heavy metal movement from the upper layer cell into the deeper layer of the soil block. All the data were analysed using ICP-MS (Perkin Elmer NexION 300X). Al and Fe displayed high concentration at most of the sites especially at the deeper depth of the soil.
Keywords: *urban pollution, landfill, active sanitary landfills, inorganic pollutant, leachate, municipal solid waste*

Introduction

According to Agamuthu et al. (2014) and Yusoff et al. (2013), there is a total of about 251 landfills of different sizes and ages recognized officially in Malaysia. Out of these, 111 were closed and 150 are active landfills. These active landfills include 77 open dumpsites, 49 open-tipping sites, 19 landfills without leachate treatment, 10 landfills with leachate treatment, and 6 are sanitary (engineered). In Malaysia, proper disposal of solid waste at sanitary landfills constitute only a small portion of a whole and was built recently compared to open dumps which constitute around 90% of all the waste disposal sites (Agamuthu and Fauziah, 2011; Sharifah and Latifah, 2013).

Selangor as one of the most developed states in Malaysia has produced the highest MSW per capita due to the high standard of living (Agamuthu, 2001; Leete, 2002). Studies reported that Selangor is responsible for one-third of the total amount of solid waste generated in Malaysia with 3,923 tons daily (Riber et al., 2005; Ismail and Manaf, 2013; Sharifah and Latifah, 2013). Twelve landfill sites from a total of 20 landfill sites in Selangor (closed and operating) are considered as open dumpsites with level 0 sanitary

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80698077

classification, which generate the highest risk of contamination and leachate migration. In addition, all 20 landfills are located in 5 main river basins where the Sungai Selangor Basin has the highest number of operating landfills (three) and four closed landfills. The classification is as followings; Level 0: Open dumping; Level I: Controlled tipping; Level II: Sanitary landfill with a bund and daily soil cover; Level III: Sanitary landfill with leachate recirculation system; and Level IV: Sanitary landfill with leachate treatment facilities.

Sanitary landfilling and open dumping are commonly known across the world as disposal of municipal solid waste (MSW) method. Sanitary landfilling is predominantly practiced in developed nations while open dumping is common in low-income and developing nations (Yahaya, 2016). An open dump is a primitive and non-sanitary waste disposal site where indiscriminate wastes are improperly tipped or dumped in a pre-existing hole or on the side of a hill without proper maintenance (Agamuthu, 2001; Blight, 2008). As an alternative, a sanitary landfill utilizes the principles of engineering to ensure the protection of the environment and public health while providing safe long-term disposal of solid wastes (American Society of Civil engineers, 1959). In Malaysia, municipal solid waste is disposed of in both the newer sanitary landfills and older open dumps.

The increasing of waste generation due to this municipal solid waste, however, shortens the span of a landfill. Thus, more and more new areas have to be converted into disposal sites. The negative impacts of MSW landfill on the environment cause a wide range of concern. It includes the risk of explosion, odor problem, leachate seeping into surface and groundwater system, as well as, soil contamination due to heavy metal sourced from disposed waste (Fauziah and Agamuthu, 2005). Contaminated soil remediation is reported as one of the most expensive technologies in environmental management.

Based on the previous study, most organic chemical substances will eventually either be degraded through biochemical reactions in the landfill or be leached out of the landfill with water movement. However, the majority of heavy metals will remain in the landfill because heavy metal migration is very limited compared to the number of metals accumulated in the landfill (Øygard et al., 2004; Riber et al., 2004), especially in anaerobic processes. The slow movement of heavy metals is the result of heavy metals being subjected to strong sorption on soil particles, precipitation under anaerobic conditions, and chelation with inorganic and organic ligands in landfills (Bozkurt et al., 1999, 2000). Heavy metal contamination is mainly due to the subsequent migration of leachate from and within the landfill's waste cell. The natural process taking place within the boundaries of the waste cells accelerate the process of heavy metal leaching from the waste component. Various types of wastes are the main sources of heavy metal within a landfill system. This includes metal waste components such as food cans and scrap metal and the indiscriminate dumping of household hazardous waste and electronic waste such as batteries and old computer. The release of heavy metal into the adjacent environment is a serious environmental concern and a threat to public health and safety.

Material and methods

Study area description

Five active landfill sites (3 non-sanitary landfills and 2 sanitary landfills) located at Selangor, Malaysia namely; Sungai Kertas non-sanitary landfill (3°15'52.5"N

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80698077

101°41'05.1"E), Kuang non-sanitary landfill (3°15'31.4"N 101°33'50.0"E), Dengkil non-sanitary landfill (2°52'12.2"N 101°38'54.1"E), Tanjung Dua Belas sanitary landfill (2°43'48.9"N 101°36'21.7"E) and Jeram sanitary landfill (3°11'23.8"N 101°21'54.3"E) were selected for this study. The site selection was based on the types of the landfill and the size of the landfill located in Selangor state. *Table 1* indicates the landfill sites info with the area covered, wasted collected, total year of operation and the current status of the landfill studied.

Table 1. *Selected landfill sites with the area covered, waste collected per day, total year operation and current status*

Landfill Sites	Area (Acre)	Waste Collected (Tone/Day)	Total Year Operation	Current Status	Source
Kampung Sungai Kertas Inert Waste	14.19	130	7	Active	Othman et al. (2016)
Kuang Inert Waste Landfill	27	50	11	Active	Tengku Ibrahim et al. (2017)
Dengkil Inert Waste Landfill	145	400	25	Active	Othman et al. (2016)
Tanjung 12 Sanitary Landfill	160	1000	20	Active	Yahaya et al. (2016)
Jeram Sanitary Landfill	160	2500	16	Active	Othman et al. (2016)

Soil sampling

Soil samples were collected at different points (0-200 mm depth, approx. 1000 g) were taken by using soil auger (Eijkelkamp Agrisearch). The soil then was sealed in a polyethylene bag and labeled. The soil was dried in an oven for 70ºC for 3 days to a week depending on the moistness of the soil. Then samples were ground by using agate mortar until becoming small particles. Then it was sieved using a 2 mm mesh to remove stones and plant materials. Then samples were stored at room temperature before being digested using Microwave Digestion Ethos D (Milestone, 2001). Heavy metals, Al, Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd, and Pb were then analysed by using ICP-MS (Perkin Elmer NexION 300X).

Heavy metals digestion and analysis

0.5 g of soil samples were accurately weighed into a container made of PFA perfluoroalkoxy polymer and digested through a microwave digestion system using the digestion method as described by Zhao et al. (1994). Soil samples were air-dried and sieved. Soil samples were passed through a 2 mm sieve and ready for further analysis. Dried and the ground sample was mixed with 10 ml of concentrated nitric acid (HNO_3 65%) and digested. Acid was added for each soil samples and then the digestion tubes were placed in a rotor segment by using a torque wrench. The segments were inserted into the microwave cavity and connected with the temperature sensor. The mixture temperature was adjusted to ±175ºC and 1,200 Watt of power for 30 minutes using Microwave Digestion (Milestone Start D) as detailed in Method US EPA 3051. The digestion was completed after the last solution was clear and no brownish fumes were released from the digestion vessel tubes. When digestion was completed, samples

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80698077

were removed and diluted. The soil digests were adjusted to the final volume of 50 mL with deionized water. This solution is further 1:1 diluted for the analysis of components by ICP-MS and divided into triplicate each into 15 ml tubes.

Data Analysis

All the experiments were carried out in triplicates and data presented as mean values of three independent replicates. Data were further analysed using analysis of variance (ANOVA). Statistical analysis for all experiments was performed by using SAS through factorial analysis of variance followed by Tukey's test with significant different at $P<0.0001$.

Results and discussion

Sungai Kertas Inert Waste non-sanitary landfill

The results in *Fig. 1* showed heavy metal concentration in an active non-sanitary landfill with a radius of 5 to 10 m, 10 to 15 m and 15 to 20 m at different depth 0 to 30 cm, 30 to 60 cm and 60 to 90 cm of Sungai Kertas non-sanitary landfill. Results of heavy metal showed that Al and Fe concentration is higher at all point of Sungai Kertas landfill.

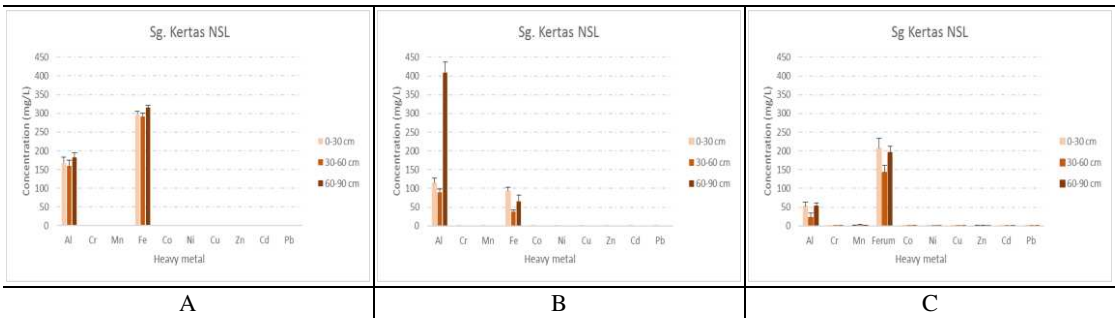

Figure 1. *The pattern of 10 heavy metal concentration depicted Sungai Kertas non-sanitary landfill at different soil depths (0-30 cm, 30-60 cm, and 60-90 cm) and radiuses (A: 5-10 m, B: 10-15 m and C: 15-20 m) of the active landfill*

Among the analyzed heavy metals, Al had the highest concentrations up to 409.786 mg/kg within active non-sanitary soil heavy metal concentration. Compared altogether between these three radiuses of Sungai Kertas non-sanitary landfill, the heavy metal concentration at radius 5 to 10 m showed the highest result for Fe; 297.023 mg/kg, 291.954 mg/kg and 314.758 mg/kg. The lowest results showed by Al at radius 15 to 20 m; 52.089 mg/kg, 22.256 mg/kg and 53.188 mg/kg meanwhile Fe at radius 10 to 15 m showed 93.175 mg/kg, 38.714 mg/kg and 65.584 mg/kg.

Kuang Inert Waste non-sanitary landfill

The results in *Fig. 2* showed heavy metal concentration in an active non-sanitary landfill with a radius of 5 to 10 m, 10 to 15 m and 15 to 20 m at different depth 0 to 30 cm, 30 to 60 cm and 60 to 90 cm of Kuang non-sanitary landfill. Results of heavy metal showed that the highest concentration is depicted by Fe. The concentration is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80698077

higher at the centre and the middle point of Kuang landfill. Compared altogether between these three radius of Kuang non-sanitary landfill, heavy metal concentration showed the highest result for Fe at the radius 15 to 20 m; 593.954 mg/kg, 546.171 mg/kg and 570.699 mg/kg and radius 10 to 15 m; 433.383 mg/kg, 235.407 mg/kg and 230.230 mg/kg. The lowest results showed by Al at radius 10 to 15 m; 22.311 mg/kg, 36.557 mg/kg and 32.934 mg/kg well as radius 5 to 10 m; 44.811 mg/kg, 29.436 mg/kg and 36.277 mg/kg.

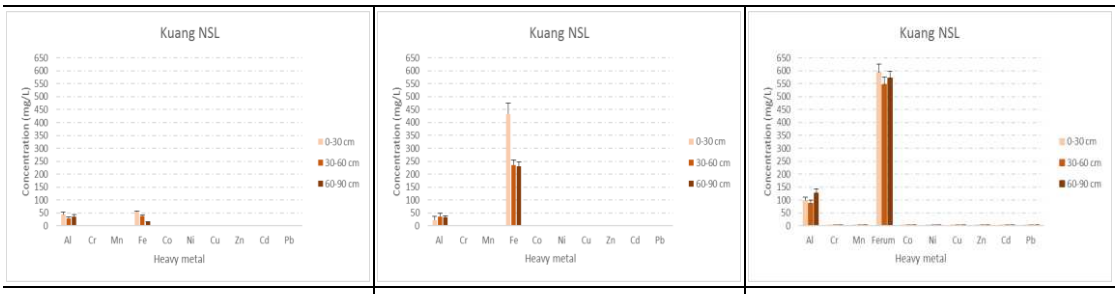

Figure 2. *The pattern of 10 heavy metal concentration depicted Kuang non-sanitary landfill at different soil depths (0-30 cm, 30-60 cm, and 60-90 cm) and radiuses (A: 5-10 m, B: 10-15 m and C: 15-20 m) of the active landfill*

Dengkil Inert Waste non-sanitary landfill

The results in *Fig. 3* showed heavy metal concentration in an active non-sanitary landfill with a radius of 5 to 10 m, 10 to 15 m and 15 to 20 m at different depth 0 to 30 cm, 30 to 60 cm and 60 to 90 cm of Dengkil non-sanitary landfill. Results of heavy metal showed that the highest concentration is depicted by Al. The concentration is higher at radius 10 to 15 m of Dengkil landfill.

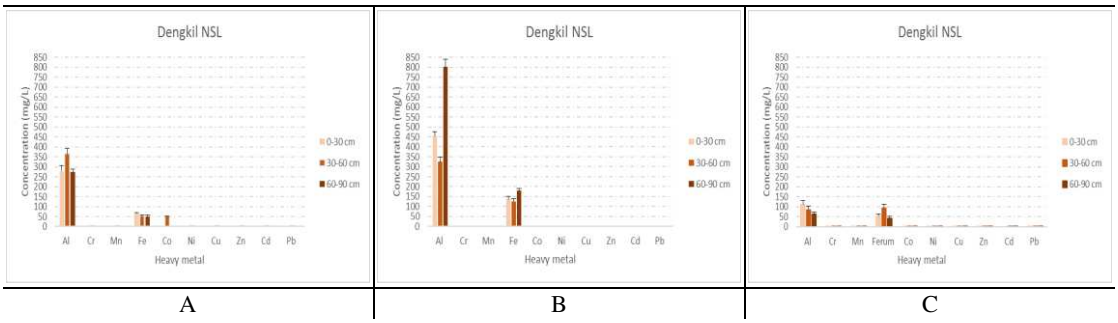

Figure 3. *The pattern of 10 heavy metal concentration depicted Dengkil non-sanitary landfill at different soil depths (0-30 cm, 30-60 cm, and 60-90 cm) and radiuses (A: 5-10 m, B: 10-15 m and C: 15-20 m) of the active landfill*

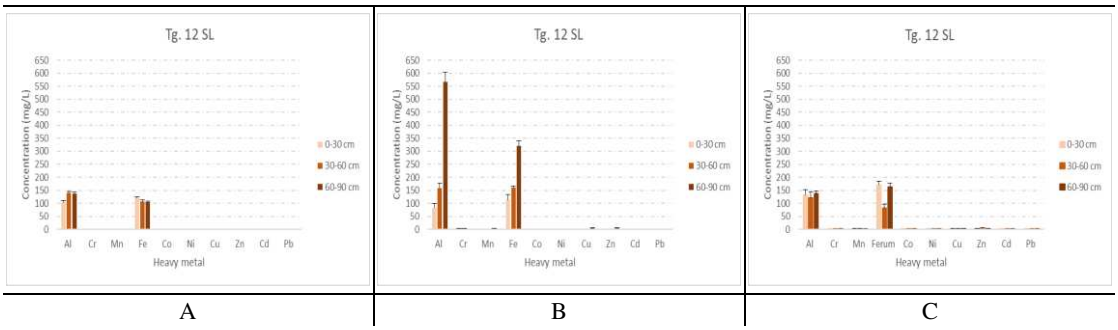
Compared altogether between these three radiuses of Dengkil non-sanitary landfill, heavy metal concentration showed the highest result for Al at radius 10 to 15 m; 455.457 mg/kg, 325.270 mg/kg and 800.804 mg/kg followed by radius 5 to 10 m; 278.700 mg/kg, 364.215 mg/kg and 275.386 mg/kg. The lowest results showed by Fe at all point. The highest concentration for Fe showed by radius 10 to 15 m;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80698077

137.191 mg/kg, 126.688 mg/kg and 178.860 mg/kg followed by radius 15 to 20 m; 54.143 mg/kg, 93.842 mg/kg and 41.216 mg/kg then radius 5 to 10 m; 65.457 mg/kg, 52.985 mg/kg and 51.282 mg/kg. There is a concentration of Co that showed up to 52.985 mg/kg at 30-60 cm depth for radius 5 to 10 m.

Tanjung Dua Belas sanitary landfill

The results in *Fig. 4* showed heavy metal concentration in an active sanitary landfill with a radius of 5 to 10 m, 10 to 15 m and 15 to 20 m at different depth 0 to 30 cm, 30 to 60 cm and 60 to 90 cm of Tanjung Dua Belas sanitary landfill. Results of heavy metal showed that the highest concentration is depicted by Fe and Al. The concentration is higher at radius 10 to 15 m of Tanjung Dua Belas landfill. Compared altogether between these three radiuses of Tanjung Dua Belas sanitary landfill, heavy metal concentration showed the highest result for Al at radius 10 to 15 m; 85.182 mg/kg, 159.445 mg/kg and 567.264 mg/kg followed by Fe; 113.967 mg/kg, 161.552 mg/kg and 321.409 mg/kg. The radius 15 to 20 m concentration also lead by Al and Fe. Each showed 133.694 mg/kg, 120.739 mg/kg, 137.235 mg/kg for Al concentration and 170.976 mg/kg, 83.036 mg/kg and 162.968 mg/kg for Fe concentration. Meanwhile, at a radius 5 to 10 m, the concentration showed almost equal between Al and Fe. Al concentration at radius 5 to 10 m; 104.207 mg/kg, 138.692 mg/kg and 136.317 mg/kg followed by Fe; 120.165 mg/kg, 106.395 mg/kg and 103.827 mg/kg.



A B C

Figure 4. *The pattern of 10 heavy metal concentration depicted Tanjung Dua Belas sanitary landfill at different soil depths (0-30 cm, 30-60 cm, and 60-90 cm) and radiuses (A: 5-10 m, B: 10-15 m and C: 15-20 m) of the active landfill*

Jeram sanitary landfill

The results in *Fig. 5* showed heavy metal concentration in an active sanitary landfill with a radius of 5 to 10 m, 10 to 15 m and 15 to 20 m at different depth 0 to 30 cm, 30 to 60 cm and 60 to 90 cm of Jeram sanitary landfill. Results of heavy metal showed that the highest concentration is depicted by Fe and Al. The concentration is higher at the radius 15 to 20 m of Jeram landfill. Compared altogether between these three radiuses of Jeram sanitary landfill, heavy metal concentration showed the highest result for Al and Fe at radius 15 to 20 m; each at 219.009 mg/kg and 232.830 mg/kg for 0 to 30 cm depth. Followed by Fe at radius 10 to 15 m; 239.127 mg/kg for 30 to 60 cm depth. Meanwhile, for Al and Fe concentration at radius 5 to 10 m showed almost equal readings at all depth. Each showed 32.632 mg/kg, 82.432 mg/kg and 52.744 mg/kg for Al and 104.709 mg/kg, 168.297 mg/kg and 151.001 mg/kg for Fe.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80698077

Analysis of variance confirmed the findings by exhibiting highly significant differences (P<0.0001) between the radius, depth, and heavy metal concentration at three different radiuses, three different depths, and ten heavy metals concentration. This clearly demonstrates that environmental factors and landfill area background can have an important influence on the accumulation of certain heavy metal and its content. Al and Fe concentration showed the highest pattern on all 4 active landfill sites. This might probably cause by the transportation of metals that may vary between relatively unpolluted systems and disturbed or polluted systems as well as the site context. Particulate transport is dominant in unpolluted systems where metal inputs are principally from the erosion of watershed substrates (Elder, 1989).

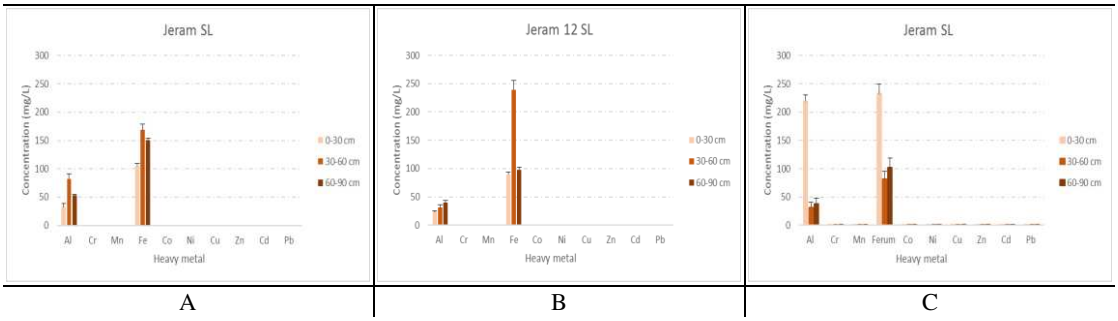


Figure 5. *The pattern of 10 heavy metal concentration depicted Jeram sanitary landfill at different soil depths (0-30 cm, 30-60 cm, and 60-90 cm) and radiuses (A: 5-10 m, B: 10-15 m and C: 15-20 m) of the active landfill*

In disturbed or polluted systems, for example, those affected by acid-mine drainage, point sources commonly deliver metals in a soluble phase or associated with organic matter, and the proportion of dissolved metals and their bioavailability tends to be higher (Solomons and Förstner, 1984). Leachate is still being produced even though most of the non-sanitary landfills in Selangor have been closed or still operating. This leachate production still occurs and badly affect the nearest water system and soil due to the location of the landfills near the water system as a source of water to the local residents. Therefore, environmental factors and landfill area background can have an important influence on the accumulation of certain heavy metal and its content. There are high contaminants levels in the groundwater underneath the non-engineered waste disposal sites in Selangor. The rate and amount of pollutant penetration through the soil is also influencing the concentration of heavy metal present in the landfill environment and finally lead to different capability depiction of heavy metal binding in the soil.

Conclusions

It can be summarised that heavy metal contents in Sungai Kertas non-sanitary landfill, Kuang non-sanitary landfill, Dengkil non-sanitary landfill, Tanjung Dua Belas sanitary landfill and Jeram sanitary landfill were accumulated by high Al and Fe. A few of the landfills had been exposed to Cr, Mn, Zn, Co, and Cu below 5.0 mg/kg. They are Sungai Kertas non-sanitary landfill, Dengkil non-sanitary landfill and Tanjung Dua Belas sanitary landfill. Kuang non-sanitary landfill and Jeram sanitary landfill showed only Al and Fe contaminations. In other words, there are particular locations as well as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80698077

depth and radius where specific heavy metals signature accumulates with high concentration levels and some with low level. This raises the importance and needs for an effective potential model system for future research to investigate in depth the environmental factors such as the type of soil and waste that influence heavy metals profile and distribution or controlling heavy metals accumulation.

(Received 24th Jan 2019; accepted 3rd May 2019)

Abstract. Urban parks planning and management is a crucial issue in the context of the urban environment and community development by creating space for social interactions, recreation, aesthetics and provide natural habitats. Apart from that, the value of the ecological functions such as air purification, storm water regulation and carbon storage are also crucial for biodiversity conservation within the urban context. This study provides a case study of the quantification of carbon sequestration rate by a selected urban park with a hybrid design landscape setting in Putra Heights, Mukim Damansara, Selangor. The carbon sequestration rate was calculated by biomass equations, using field data inventory, measurements, plan analysis and survey data analysis. This study aimed to discuss the influence of urban park green spaces, plant materials specifications and spatial design organization and pattern towards carbon sequestration rate. The significant outcome of this study is the determination of key factors that influenced the Carbon Sequestration Rate. This study proved that higher plants specification plays an important role in sequestering more carbon. The larger green area also contributes to higher carbon sequestration rate. These findings will become a novel landscape design approach to neutralize carbon emission with cost-effective and environmentally friendly.
Keywords: *carbon emission, air pollution, green technology, landscape design, urban landscape*

Introduction

Recently, urban greenery systems have been promoted as a climate change mitigation method (Velasco et al., 2016) as urban vegetation reduces the carbon dioxide (CO_2) concentration of the atmosphere through photosynthesis and by carbon storage via plant growth. The greatest available green spaces for city residents are urban parks (Ehnat, 2011; Gratani et al., 2016). Urban parks have been identified as one of the most important components of cities and had an evolving role in the life of city residents. Urban parks help decrease carbon emission levels in cities (Sadeghian, 2013). Trees act as a sink for CO_2 by fixing carbon during photosynthesis and storing carbon as biomass (Nowak, 2013). According to Shahidan (2015), plants can filter heat and reduce radiation thus cooling off the urban environment. Therefore, urban park due to its

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80798088

conditions that are covered with plants is more likely beneficial to reduce urban heat island effect. Urban heat island effect is caused by the large areas of heat-absorbing surfaces, in a combination of high energy use in cities (Sadeghian, 2013).

However, the rapid wave of urbanization in recent decades foresees the high potential for increasing energy demand and severe environmental concerns, simultaneously. Furthermore, it is expected that by 2020, 3 quarters of the Malaysian population will be living in urban areas (Tenth Malaysia Plan, 2010). According to the Department of Statistics Malaysia (2011), in tandem with Malaysia's rapid development, the proportion of urban population increased to 71.0 percent in 2010 compared with 62.0 percent in 2000. One of the state in Malaysia with a high level of urbanization was Selangor with 91.4 percent. A significant increase in the urban population in a short span of time creates various problems, especially environmental problems. Air and noise pollutions are generally considered as a major concern in urban areas.

The recent study by Shahbaz et al. (2015) found strong causal links between urbanization and energy consumption in Malaysia. Therefore, there is a possibility that the urbanization also has direct or indirect relation with carbon dioxide emission. Thus, having an urban park will help to mitigate climate change by functioning as a carbon sink to reduce air pollutant level and sequestering atmospheric CO_2. Carbon sequestration is defined as a method or process of moderating carbon dioxide in the atmosphere to stop it from being polluted (Singh, 2013). This method will contribute to mitigating global warming as it will capture and store carbon dioxide gas in a particular process (Rackley, 2010).

Although the impacts of urban trees thus have been studied rather extensively, at least through urban air quality models, there is a suggestion that research specifically on urban parks has been limited so far (Pataki et al., 2011; Yin et al., 2011). The case study for this research is Putra Heights Neighbourhood Park (*Fig. 1*) with hybrid design landscape setting located at Selangor, Malaysia. Thus, the objective of this research is to assess the influence of urban park green spaces, plant materials specifications and spatial design organization and pattern towards carbon sequestration rate.

Material and methods

Study area description

Selected site study area (*Fig. 1*) located at Neighborhood Park, Putra Heights, Mukim Damansara, Daerah Petaling, Selangor (3°01'13.1"N 101°34'31.7"E), a rapidly urbanized and populated city surrounded by highly developed residential areas with the Light Rail Transit (LRT) and ELITE highway located nearby. With the overall park area of 10.45 acres, this urban park serves as a recreational park to the surrounding neighbourhood area.

Site inventory and plan analysis

The first method applied was through site inventory and analysis. The girth of each plants species was measured conventionally at the breast height (GBH) i.e. near about 1.32 m above the ground surface as well as overall plants heights (Moumita, 2015). For calculating the total built-up area and green area of the park, the base map of Putra Heights Neighborhood Park was obtained from the authority. Plan analysis was

conducted to determine the overall park design structure, planting composition and also spatial design organization and pattern. Apart from that, the bill of quantities of landscape plants was also retrieved in order to identify the exact quantity of the plant materials and to identify the plant specifications including the overall height and breast height diameter of plants for determination of age. Next, the current carbon sequestration rate (CSR) on every planting species was calculated using the carbon calculator formula stated in *Table 1* below. In calculating the carbon sequestration rate of the selected site study area, there are few matters needed to be considered as the rate for carbon sequestration vary greatly depending on a few factors such as tree species, age/stage of tree, composition/density of tree, location/condition of the tree and type of soil (Othman, 2016).

Results and discussion

Carbon Sequestration Rate at Putra Heights Neighbourhood Park

Tables 2-6 and *Fig. 2* portrayed the amount of CO_2 sequestered by different types of plant's categories and species. The carbon sequestration value for all planting species from each planting categories was then calculated. The highest amount of carbon sequestration rate is from the turf category (*Axonopus compressus*). The total amount of CO_2 sequestered by this turfing species is 31530 $kgCO_2e$ compared to other plants categories such as trees (11438.83 $kgCO_2e$), orchard trees (272.80 $kgCO_2e$), palms (1264.57 $kgCO_2e$) and shrubs (943.19 $kgCO_2e$). From *Table 1*, it can be depicted that tree species of Samanea saman sequestered the highest total amount of CO_2 of

DOI: http://dx.doi.org/10.15666/aeer/1704_80798088

1937.93 kgCO_2e. Meanwhile, Neodypsis leptocheilos ranked as the highest sequester agent for palm category with the amount of 427.32 kgCO_2e. Eugenia oleana has been classified as the highest sequester agent under shrubs categories that sequestered 692.06 kgCO_2e.

Figure 2. *Planting plan at Putra Heights Neighbourhood Park*

From *Fig. 3,* it can be depicted that the highest value represents as an effective agent to sequester carbon is from turf category (31530 $kgCO_2e$). The amount is tremendously high compared to other planting categories. At this particular site, turfing category

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80798088

(*Axonopus compressus*) acts as a dominant Carbon Sequestration Rate (CSR) agent which contribute the highest CSR value due to the large coverage area for planted turfing. Meanwhile, trees category has become the second highest CSR agent that sequester 11438.83 $kgCO_2e$, followed by palms (1264.57 $kgCO_2e$), shrubs (943.19 $kgCO_2e$) and the least CSR value represented by orchard tree category which sequestered 272.80 $kgCO_2e$ of carbon dioxide.

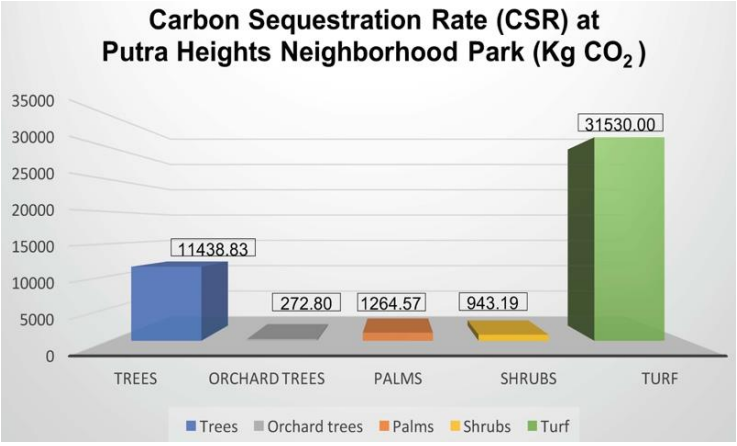

Figure 3. *Carbon sequestration rate produced by a different type of planting category at Neighbourhood Park, Putra Heights*

Total Park Area, Green Area and Built Up Area of Neighbourhood Park

In calculating the total park area, green area and built-up area of the park, the base map is obtained from the authorities (*Fig. 4*). The summary of the findings is presented in *Table 7*. According to *Table 7*, it can be found that the total park area is 42,288 m^2, covered majority by a green area with the percentage of 87% (36760 m^2) and covered only 13% with the built-up area (5528 m^2). According to *Table 8*, the green area consists of soft landscape plantings which categorized as trees, palms, shrubs and turfing while the built-up area consists of the parking area, hard landscape components such as pedestrian walkways, jogging track, open plaza, wakaf, courts and children playground. Putra Heights Neighborhood Park is perceived to have a greener area than built up area.

This formula is created in order to identify the minimum amount of carbon sequestration rate required in every 1meter square. For example, Malaysia's carbon emission is predicted at around 285.73 million tonnes by the year 2020 (Safaai et al., 2011):

$$\frac{285.73\ million\ tonnes}{330{,}803\ km^2} = \frac{x}{1\ km^2} \qquad \text{(Eq.1)}$$

1km^2 x 285730000 tonnes km^2 = x (330,803 km^2)

x = 285730000 tonnes km^2 / 330803 km^2

x = 863.746 tonnes per km^2 / 1000000

1m^2 = 0.000863 tonnes / 0.863 kg CO_2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80798088

From the calculation above, every 1 m^2 of Malaysia should sequester minimum of 0.863 $kgCO_2$ emissions. Next, the amount will be multiplied by the total area of the site. Hence, Putra Heights Neighbourhood Park sequestered 1.077 Kg CO_2 for every 1 m^2, which is more than the amount of CO_2 that it should sequester.

Factors Influencing Total Carbon Sequestration Rate

Results showed that different planting specification contributes to the different amount of carbon sequestration rate even though there are from the same plant's category. According to Mandal et al. (2016), the effect of carbon sequestration varies from the plant species, for instance, parks with trees and shrubs have the most efficient carbon sequestration effect. Therefore, the findings proved that higher plants specification contributes to greater CSR value. For example, as the trees grow older, the tree trunk becomes taller and the trunk diameter becomes bigger, the greater carbons are being absorbed by the plants provided with the plants are being maintained and taken care with the proper landscape maintenance practice applied. Apart from that, planting quantity also has interrelated to influence the total carbon sequestration rate. Results proved that planting with larger quantity and higher specifications have a greater capability to sequester the higher amount of carbon dioxide. The difference between the ability of each plants category to sequester carbon differs greatly as referring back to *Table 3.*

Furthermore, from the findings, it is also revealed that a larger green area contributes to the higher value of carbon sequestration rate. Therefore, the percentage allocated for the green area has very much influence on the total carbon sequestration rate. The larger green area, the higher value of CSR will be obtained. At this site study area, by referring back to the *Figure 3*, it is clearly seen that green area covered majority from the total park area with 87% allocated for the green area as compared to only 13% allocated for a built-up area. Thus, this percentage of green area covered mostly by turf planting had influenced the total carbon sequestration rate of the park. This assumption is supported by Almeida et al. (2018), stated that urban parks are critical components within the metabolism of cities as well as the core scenes for open-air leisure communal activities. Thus, the concerns for designing a contemporary urban park must consider the size and quality of the green areas aiming to improve the air quality conditions of the nearby urban settlement. On the other hand, landscape design setting or spatial design organization also influence the total carbon sequestration rate. Putra Heights Neighbourhood Park portrayed hybrid design landscape setting with the combination of linear design and curvilinear design landscape planting. Most of the trees, palms and shrubs were organized to be planted in a combination of linear and curvilinear planting according to its spatial functionality.

In summary, it can be concluded that there are key factors that influence the carbon sequestration rate and optimization in applying these factors can contribute to the optimum value of carbon sequestration rate in urban parks.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80798088

i. Planting quantity and specifications.
ii. Percentage of green area and built up area.
iii. Landscape design setting / spatial design organization.

Thus, this will become new design guidelines to the researchers, landscape architects and designer to consider before they start designing any open space or urban parks.

Conclusions

In urban parks, trees are considered as a green belt asset and function as sinks for excess CO_2 in the atmosphere. Trees played an important role in contributing to environmental change and many studies aware of the role of trees in urban environments. Carbon storage of urban trees can lead to a thorough understanding of the ability of urban trees in global carbon that relating to greenhouse emissions. From the findings of the present study, it is clearly shown that urban park green spaces, plant materials specifications and spatial design organization and pattern have greatly influenced the carbon sequestration rate in urban parks. From the context of this site study area, a higher percentage of the green area has much influenced to contribute greater CSR value. Furthermore, plant materials with higher specifications and larger quantities also contribute to the higher carbon sequestration rate. Besides, by having a hybrid design landscape setting also helps in optimizing the CSR value. Consideration of the optimization of these three key factors in designing or enhancing the existing urban parks will help to sequester optimum value or carbon sequestration rate. Thus, by applying these key factors as design guidelines during the design stage or before starting any developments will help the researchers, landscape architects and designers. By having an urban park with an optimum value of carbon sequestration rates will help to strengthen the ecosystem services, therefore, alleviating urban heat island and global warming. These findings will become a novel landscape design guideline to improve environmental quality with cost-effective and environmental friendly. Correlation between plant material group and type of design can be indicative of the carbon sequestration rate. In other words, there is a particular design where specific plant material group sequester high level of carbon. Thus for future research, this raises the importance and need for an effective potential model system to investigate in depth the environmental factors, type of design and plant material group that influence or controlling carbon sequestration rate.

(Received 24th Jan 2019; accepted 3rd May 2019)

Abstract. The need for urban parks became greater as cities expanded and the urban population rapidly grew. Therefore, having an urban park can facilitate a reduction in GHG emissions by alleviating some of the impacts of this dense development. Trees in the urban parks are an important factors reducing the amount of carbon dioxide accumulated in the urban area. The carbon sequestration rate was calculated with biomass equations, using field data collection, measurements and survey data analysis. This study aimed to calculate, predict and compare carbon sequestration rate of plant materials with linear and curvilinear design landscape setting. The decisive outcome of this study are the optimization of carbon sequestration rate by selecting the right plant material specifications with suitable landscape design setting. The findings revealed that the curvilinear design landscape setting sequesters more carbon per m^2 than linear design landscape setting. Plants with bigger girth and larger quantities contribute to sequestering greater carbon compared to smaller girth and fewer trees. These findings will become a green practice approached towards building a sustainable environment with better design solutions.

Introduction

Urban parks have been viewed as an important component of the urban fabric that benefits for community development by providing space for recreation and leisure. From a social perspective, green spaces provide health and a range of recreational and psychological benefits, create environmental awareness and encourage positive actions toward climate change (Pataki et al., 2011; Demuzere et al., 2014). A study conducted in Helsinki, Finland, indicated that nearly all (97%) city residents participate in some outdoor recreation during the year (Sadeghian and Vardanyan, 2013). Thus, the need for urban parks become greater as cities expanded and the urban population rapidly grew. According to Department of Statistics Malaysia (2011), in tandem with Malaysia's rapid development, the proportion of urban population increased to 71.0 percent in 2010 and this growth is expected to continue as total population increased over the years. One of the state in Malaysia with a high level of urbanization was Selangor with 91.4 percent.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80898101

A significant increase in the urban population in a short span of time creates various problems, especially environmental problems. Therefore, under the Paris Agreement, in accordance with decisions of the United Nations Framework Convention on Climate Change (UNFCCC) (Biennial Update Report to the UNFCCC, 2015), Malaysia has committed to reducing its greenhouse gas (GHG) emissions intensity of GDP by 45% by 2030 relative to the emissions intensity of GDP in 2005. Alternative ways that have been further studied to reduce these greenhouse effects in the atmosphere is through carbon sequestration technology (Wiedman et al., 2007). Carbon sequestration is the process through which CO_2 from the atmosphere is absorbed naturally through photosynthesis by the plants (Pandya et al., 2013). Trees in urban parks play an important role in the urban environment by sequestering a substantial amount of carbon dioxide from the atmosphere. Urban trees in air pollution reduction, mentioning their effects in terms of intercepting atmospheric particles and absorbing various gaseous pollutants (Yin et al., 2011). In both neighborhoods, the trees with the highest carbon stocks and sequestration rates are generally located along the main roads and in public parks (Velasco et al., 2016). Although the impacts of urban trees thus have been studied rather extensively, at least through urban quality models, there is a suggestion that research specifically on urban parks has been limited so far (Pataki et al., 2011; Yin et al., 2011). Hence, this study aimed to estimate, predict and compare carbon sequestration rate produced by plant materials through linear and curvilinear design landscape setting at two selected urban parks in Selangor. The chosen case studies for this research is differentiated between two urban parks with different landscape settings, which are linear and curvilinear design landscape setting.

Materials and Method

The first method of this study used field data collection through site inventory and analysis to estimate total carbon sequestration rate Two selected urban parks in Selangor with different landscape design settings were chosen as site studies which are Putra Heights Linear Park (3°01'13.1"N 101°34'31.7"E, linear design landscape setting) and Subang Jaya Urban Forest Park (3°03'19.0"N 101°34'15.0"E, curvilinear design landscape setting) (*Fig. 1*).

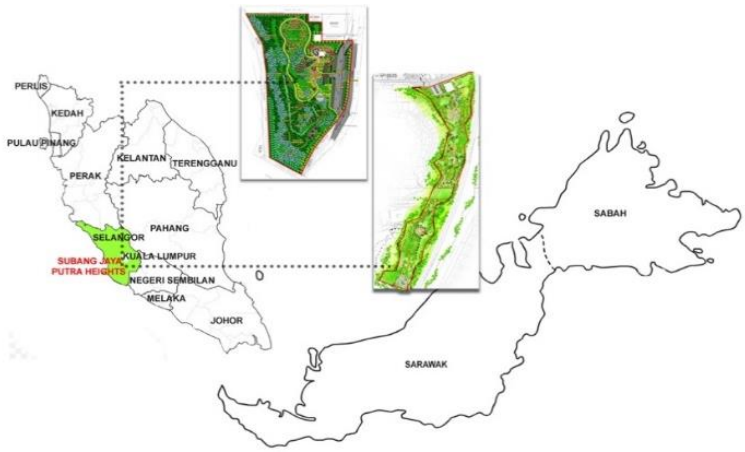

Figure 1. *Base map showing Subang Jaya Urban Forest Park with curvilinear design (left) and Putra Heights Linear Park (right), Selangor, Malaysia*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80898101

Both sites were selected for inventory and analysis process in acquiring data needed. Besides, for calculating the total green area and built up area of the selected site studies, the site plan for both urban parks was obtained from the authorities. Whereas, for calculating the exact numbers of trees and detailed plants specifications on site, bill of quantities is also collected from the authorities. The data needed in this study including plants specifications such as overall plant's heights, trunk diameter, plant's age, plant's quantity and area of the plants (for climbers and turfing). Next, the current carbon sequestration rate (CSR) on every planting species was calculated using the carbon calculator formula stated in *Table 1*.

Table 1. *The formula to calculate carbon sequestration rate (CSR)*

CSR formula for tree and shrub	CSR formula for turf, climber and groundcover
Total Green Weight (TGW): $0.25D^2H$ (1.2)	Total Dry Weight (TDW): 0.56 x area (m^2)
Total Dry Weight (TDW): TGW x 0.725	Total Carbon Weight (TCW): TDW x 0.427
Total Carbon Weight (TCW): TDW x 0.5	Total CO_2 Weight (TCO_2W): TCW x 3.6663
Total CO_2 Weight (TCO_2W): TCW x 3.6663	D = Diameter of the trunk; H = Height of the tree

Results and Discussions

Carbon sequestration rate at Putra Heights Linear Park (linear design landscape setting)

Fig. 2 showed the planting plan at Putra Heights Linear Park which depicted linear design landscape planting. *Tables 2-4* portrayed the amount of CO_2 that sequestered by different types of plant species categorized under tree, shrub and turfgrass at Putra Heights Linear Park.

Figure 2. *Planting Plan of Putra Heights Linear Park located in Selangor, Malaysia*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80898101

The highest amount of CO_2 sequestered by *Axonopus compressus* at 100,205.17 $kgCO_2e$. This amount is substantially high as compared to the other planting categories which are from tree and shrub category, sequestered at 9691.89 $kgCO_2e$ and 690.49 $kgCO_2e$, respectively. The main reason for this turfgrass becomes a dominant CSR agent because of the large coverage area planted with turfing at this particular site. Thus, it can be concluded that larger turfing area contributes to the greater amount of CO_2 that can be sequestered at one time. The tree species that sequestered the highest total amount of carbon at this site is *Samanea saman* (2176.79 $kgCO_2e$). The high CSR value of this species compared to the other tree species is due to higher plants specification used such as taller in height, bigger in trunk diameter, planted in larger quantity and had an older age (*Table 2*). According to Othman et al. (2016), the effect of carbon sequestration varies from the plant species, for instance, parks with trees and shrubs have the most efficient carbon sequestration effect. Meanwhile, *Eugenia oleana* ranked as the highest sequester agent for a shrub with the amount of 355.92 $kgCO_2e$. This value is slightly higher from the other one shrub species which is *Murraya paniculata* with the sequestered amount of 334.58 $kgCO_2e$. From *Table 3*, it can be clearly seen that even though the quantity of shrub for *Murraya paniculata* has a greater number planted on site (5000 nos), the total CSR value for this plant is still lower than *Eugenia oleana* which was only planted at 600 nos on site. Therefore, this finding revealed that plants specifications such as overall height and trunk diameter have very much influenced the total CSR percentage.

Fig. 3 indicates the relationship between planting categories and the total amount of carbon sequestration rate from each category. It can be depicted that the highest CSR value is from turfing category, followed by trees and shrubs category.

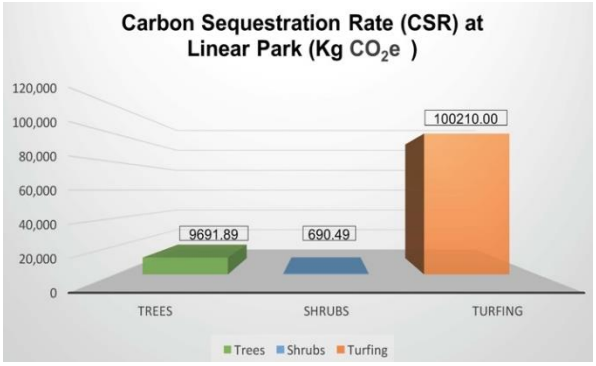

Figure 3. *Carbon sequestration rate based on planting categories at Putra Heights Linear Park (linear design landscape setting)*

Table 5 tabulated in detail distribution of plant's category, plant's quantity and CSR value obtained from each category. With the total numbers of 1615 nos of trees, 5600 nos of shrubs and 114,300 m^2 of planted turfing, the overall total of CO_2 sequestered by all plants in this site is 110,592.38 $kgCO_2e$.

Carbon sequestration rate at Subang Jaya urban forest park (curvilinear design landscape setting)

Fig. 4 illustrates the planting plan at Subang Jaya urban forest park which represents curvilinear design landscape setting. *Tables 6-11* showed the current carbon

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80898101

sequestration rate obtained at Subang Jaya urban forest park (curvilinear design landscape setting) based on plants categories and the total amount of CO_2 sequestered by each plant. It can be concluded that the highest value represented as an effective CSR agent to sequester carbon is from turfgrass category, which named *Axonopus compressus* and *Zoysia matrella* with the sequestered amount of 24,190 $kgCO_2e$ and 350 $kgCO_2e$, respectively.

Table 5. *Distribution of plant's quantity and carbon sequestration rate by plant's category*

Plant's Category	Plant's Quantity	CSR Value/ ($kgCO_2e$)
Trees	1615 nos	9,691.89
Shrubs	5600 nos	690.49
Turfing	114300 m^2	100,210.00
Total CSR ($kgCO_2e$)		**110,592.38**

Figure 4. *Planting plan of Subang Jaya urban forest park, Selangor*

At this particular plant's category, *Axonopus compressus* has become a dominant CSR agent because of the quantity planted is tremendously high compared to *Zoysia matrella.* Thus, this finding proved that quantities of the plant have very much influence on the CSR value. The total amount of carbon sequestration rate produced by turfgrass at this site is 24,540 $kgCO_2e$. The amount is tremendously high as compared to the other planting categories such as trees (2781.28 $kgCO_2e$), palm (170.84 kg CO_2e) and

DOI: http://dx.doi.org/10.15666/aeer/1704_80898101

tall shrubs (518.59 $kgCO_2e$) categories. Besides, for the shrubs and climbers categories have the same CSR value which is 310 $kgCO_2e$ each. The tree species that sequestered the highest amount of CO_2 is known as *Hopea odorata* (274.06 $kgCO_2e$) whereas for the palm species is *Livistonia rotundifolia* (170.84 $kgCO_2e$). Apart from that, as for the tall shrubs category, *Murraya paniculata* has the highest amount of CO_2 sequestered. *Labisia pumila* (90 $kgCO_2e$) and *Tristellateia australasiae* (100 $kgCO_2e$) have ranked the highest contributor of carbon sequestration for shrubs and climbers categories.

Fig. 5 showed the relationship between planting categories and the total amount of carbon sequestration rate from each category at Subang Jaya urban forest park. It can be depicted that the highest CSR value is from turfing category, followed by trees, tall shrubs, shrubs, climbers and palm category. At this particular period of time, turfing has become the dominant CSR agent due to the large coverage area for turfing. *Table 12*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80898101

tabulated distribution of plant's category, quantities and the CSR value that sequestered from each planting category. With the total number of 775 nos trees, 18 nos palm, 2000 nos tall shrubs, 366.66 m^2 of shrubs, 351.67 m^2 of climbers and 27,991 m^2 of turfing, total carbon sequestration rate for this particular site is 28,630.71 $kgCO_2e$.

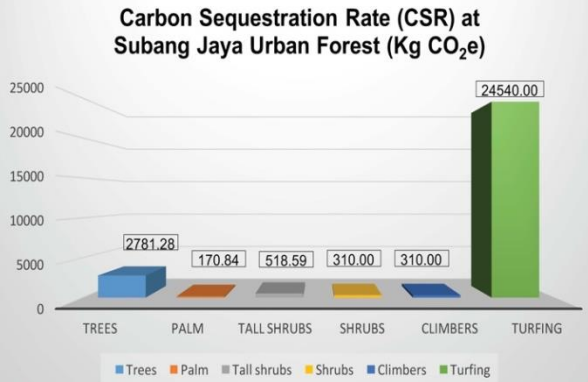

Figure 5. *Carbon sequestration rate based on planting categories at Subang Jaya urban forest park (curvilinear design landscape setting)*

Table 12. *Distribution of plant's category, plant's quantity, andcarbon sequestration rate value*

Plant's Category	Plant's Quantity	CSR Value/ $KgCO_2e$
Trees	775 nos	2781.28
Palms	18 nos	170.84
Tall Shrubs	2000 nos	518.59
Shrubs	366.66 m^2	310.00
Climbers	351.67 m^2	310.00
Turfgrass	27991 m^2	24,540.00
Total CSR ($kgCO_2e$)		**28,630.71**

Total Park Area, Green Area and Built Up Area

Fig. 6 illustrated the total park area, green area and built up area for both selected site studies. It has been found that the green area for Putra Heights linear park (114300 m^2) is enormously larger than Subang Jaya urban forest park (25,446.63 m^2). From the results, it can be concluded that a larger green area contributes to the greater value of carbon sequestration rate.

Fig. 7 showed the comparison of carbon sequestration rate obtained at Putra Heights linear park (linear design landscape setting) and Subang Jaya urban forest park (curvilinear design landscape setting). From the bar graph shown, it can be clearly seen that the Putra Heights linear park (110592.38 $kgCO_2e$) had sequestered more carbon compared to Subang Jaya urban forest park (28630.71 $kgCO_2e$). There are many factors contribute to this difference which will be explained on the next page.

Comparison of Carbon Sequestration Rate for Linear and Curvilinear Design Landscape Setting

Table 13 portrayed comparison between Putra Heights linear park character and Subang Jaya urban forest park character. There are four categories considered in doing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80898101

this assessment, which are a green area, landscape design setting, plant's category and quantity and also means trees specification. From the tabulated results, it is shown that Putra Heights linear park possessed higher amount in terms of green area, plant's category, and quantity and also mean trees specifications. Therefore, these factors have very much influenced the total CSR rate.

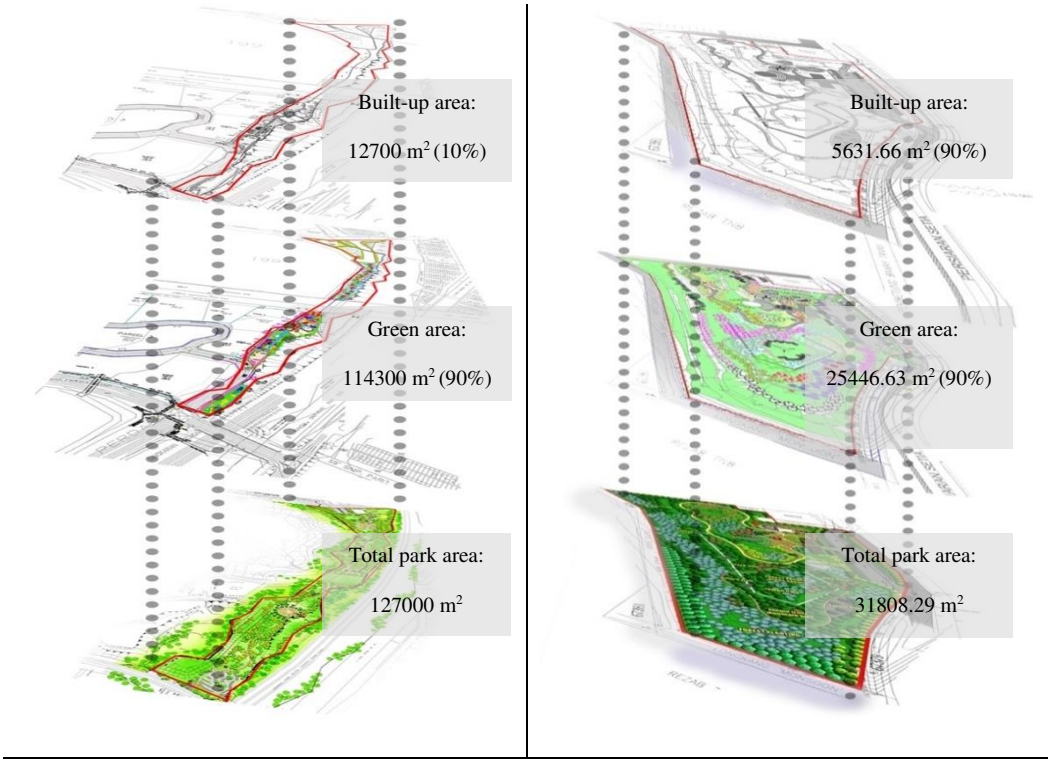

Figure 6. *Distribution of total park area, green area and built up area for both urban parks*

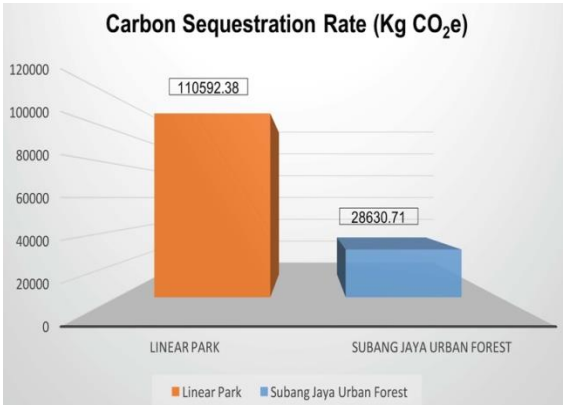

Figure 7. *Carbon sequestration rate based on planting categories at Subang Jaya Urban Forest Park (curvilinear design landscape setting)*

Optimizing the Carbon Sequestration Rate

According to Safaai et al. (2011), Malaysia's carbon emission is predicted at around 285.73 million tonnes by the year 2020. With the total land area of 330,803 km^2, every

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_80898101

1 m^2 of Malaysia should sequester minimum of 0.863 $kgCO_2e$ emissions. Next, the amount will be multiplied by the total area of the site. *Table 14* showed the distribution of total CSR and CO_2 sequestered per m^2 for both urban parks according to planting categories. Surprisingly, Subang Jaya curvilinear urban forest park sequestered 0.9 $kgCOe/m^2$, which is higher than Putra Heights linear park. Therefore, this finding revealed that curvilinear design landscape setting contributes to the greater amount of CO_2 sequestered per m^2. Both urban parks sequestered more than the amount of CO_2 that it should sequester. Apart from that, the amount of CO_2 sequestered per m^2 for trees category of Subang Jaya curvilinear urban forest park (0.09 $kgCO_2e$) is higher even though the total quantity of trees is lower compared to Putra Heights linear park (0.08 $kgCO_2e$). There are a few factors affected such as planting distance and spatial design organization. The total amount of CO_2 sequestered per m^2 for turfing category is nearly equal for both parks.

Table 13. *Comparison between Putra Heights linear park and Subang Jaya urban forest park landscape design setting*

	Putra Heights Linear Park	**Subang Jaya Urban Forest Park**

Conclusions

Plants in urban parks are important agents that sequester the CO_2 emission of the earth atmosphere. Thus, the sequestration of carbon by urban trees and other vegetation plays an important role in mitigating climate change and have a high potential in reducing urban air pollution. Carbon sequestration rates differ based on the species of tree, planting quantity and specifications, type of plant materials group, percentage of green area and built up area as well as landscape design setting or spatial design organization. Therefore, by selecting the appropriate planting materials with suitable landscape design setting will contribute to sequestering greater value or carbon sequestration rate. It can be concluded that curvilinear design landscape setting sequester more CO_2 per m^2 compared to the linear design landscape setting. Thus, the selection of landscape design settings also plays an important role in contributing to the higher CSR value. Moreover, a higher percentage of the green area has much influenced in contributing to the greater CSR value. By selecting the right plant materials with higher specifications and larger quantities will also contribute to the optimum value of carbon sequestration rate in urban parks. Therefore, having an urban park with an optimum value of carbon sequestration rates will help to strengthen the ecosystem services, as a result, alleviating urban heat island and global warming. These findings will become a green practice approached towards building a sustainable environment with better design solutions. Thus, for future research, the environmental factors such as locality, type of soil and seasonal climatic variation may have influenced the carbon sequestration rate. Clearly, a further study utilizing plant material grown under different environmental conditions is required to confirm this hypothesis.

(Received 29th Jan 2019; accepted 10th Apr 2019)

Abstract. This paper was the first to employ land use regression (LUR) with high-resolution geographical census data for Hebei, one of the most severely polluted regions in China, to evaluate its spatial distribution characteristics of $PM_{2.5}$ and NO_2 concentrations and identify influencing factors. To develop the LUR model, $PM_{2.5}$ and NO_2 concentrations recorded at 53 sites in Hebei were selected as dependent variables. Independent variables include buffer-related and location-based factors. At first, 169 independent variables were chosen in total. Then pre-processing of bivariate correlation was performed to prevent multicollinearity. Lastly, step-wise regression was processed to identify the impacting factors. Different to other cities which have been studied like Shanghai or Beijing, we find that the results showed that PM2.5 and NO2 concentrations were positively correlated with the industrial pollution sources in a buffer area. NO_2 concentrations displayed significant negative correlations with forestland within the distance of 1 km and from the coastline. This study showed that the introduction of high-resolution geographical data into the LUR model significantly improved the fitting. More importantly, our study identified industries within a 9 km-buffer as important influencing factors in Hebei and was also consistent with empirical observations. It provided data on effective buffers to support future policy-making and designations of residential areas.
Keywords: *land use regression, fine particulate matter, air pollution*

Introduction

Fine particulate matter with a diameter of less than 2.5 μm ($PM_{2.5}$) and nitrogen dioxide (NO_2) have been recognized as causes of adverse health effects (Duki et al., 2003; Roswall et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81038120

al., 2017; Chen et al., 2018; Yin et al., 2017). Empirical studies have shown a significant increase in the proportion of related diseases in regions affected by air pollution (Shekarrizfard et al., 2016; Su et al., 2008). Research by the World Health Organization (WHO) has shown that outdoor pollution caused 3.0 million extra deaths in 2012 (WHO, 2016). After three decades of rapid economic development, China has become the world's second largest economy (Morrison et al., 2015). At the same time, China is suffering from serious air pollution (Chambers et al., 2015; Chan et al., 2008; He et al., 2016; Hu et al., 2015; Wang et al., 2013; Fengwen et al., 2015; Song et al., 2017). There are emerging studies from various perspectives under pressures of urban and social development (Liu et al., 2017), but interdisciplinary research linking urban land use pattern, air pollution and meteorology at the regional level in China is lacking.

Many studies in Europe and North America have shown that land use patterns directly and indirectly influence air pollutant concentrations, and the optimization of land use patterns is feasible to alleviate air pollution problems (Briggs et al., 2000). In order to optimize land use, it is necessary to understand the impacts of its various influencing factors. There are numerous approaches to the quantitative assessment of the influence of land use on air pollution, such as diffusion models (Ciocănea et al., 2013) (for example, land use regression [LUR]), numerical simulations of the atmosphere (Chen et al., 2009), inversion of MODIS remote sensing images (Wu et al., 2016; Yao et al., 2017), and artificial neural network models (Jerret et al., 2005; Lu et al., 2003), etc. Jedynska et al. (2015) and Liang et al. (2016) respectively applied the LUR model on relationship of air pollutants, land use variables in Oslo, The Netherlands, Munich/Augsburg, and Catalonia of Europe and Houston of USA.

Among these tools, LUR has been proved to be feasible and appropriate of regions of China and other areas worldwide (Hoek et al., 2008; Ross et al., 2007). Therefore, LUR was chosen as the method to study spatial influencing factors in air pollution in this paper. As of the study areas, Hebei Province was selected because it is one of the most polluted area in China and worldwide, and in-depth research is needed to understand its pollution characteristics (He et al., 2016; Zhang et al., 2016).

LUR models are important methods for studying the relation between the spatial distribution of air pollutants and elements of geographical space. Usually, an LUR model is built by constructing a regression equation to analyze factors affecting air quality, in which data for air pollutant concentrations serve as the dependent variable while data for socioeconomic, land use, and meteorological factors, etc., serve as the independent variables.

After the Chinese government established national networks for monitoring air pollutants in 2013, relevant studies using LUR models gradually increased in number. Some researchers employed an LUR model to study land use and air pollution levels in Shanghai, one of the largest megacities in China (Liu et al., 2016; Meng et al., 2015). Although, Meng et al. (2015) was the first to combine aerosol optical depth (AOD), meteorological information and the land use regression (LUR) model to predict ground PM10 levels on high spatiotemporal resolution. However, in their studies, the resolution of land use data is not high.

Previous studies showed that the Beijing–Tianjin–Hebei region is one of the most seriously areas affected by the pollutant haze in China (Wang et al., 2015b; Gang et al., 2014; He et al., 2018). Beijing and Tianjin are two of the most important cities in China. Beijing is the capital of China, and Tianjin is an important municipality directly under the jurisdiction of the central government. Both cities have a high degree of urbanization and high levels of financial industry. Although the level of urbanization in Hebei Province is not high, its industry is dominated by steel and coal. The sources of pollution are therefore different, and the spatial patterns and influencing factors of pollution are also potentially different.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81038120

Some researchers have pointed out that the impact of motor vehicle exhaust emissions on the atmosphere is the most significant pollution source in Beijing and Tianjin, whereas in Hebei Province industry is the most notable contributor (Yang et al., 2018; Wang et al., 2017).

By the end of 2012, the total coal consumption of Hebei Province reached 271 million tons, which was much higher than the combined consumption of Beijing and Tianjin. Among 74 major cities in China, pollution by $PM_{2.5}$ in seven Hebei cities is the most serious (Wang et al., 2013).

An LUR model has been used to analyze the spatial distribution and influencing factors of air pollutants in Tianjin and Beijing and good results have been achieved (Chen et al., 2010; Wu et al., 2014). However, an LUR model has not been employed in Hebei Province alone in any recent researches. Because of the heavy industry-based industrial structure and complex geographical and meteorological environment, we focused exclusively on Hebei and used high-resolution land use data to employ LUR for the identification of influencing factors.

The purpose of this study is to conduct Land use Regression model to analyze the relationship between spatial characteristic and air pollutants in Hebei province. In comparison with previous studies, this paper improved both data fineness and model integrity in cooperation with multiple local and international institutes. Firstly, high-resolution (1 × 1 m) land use data from national geographical census data were used. Secondly, we set 20 buffer distances to refine the influencing factors that significantly influenced the concentrations of air pollutants. Finally, this study introduced meteorological data as a variable for a more comprehensive analysis on air pollution problems.

Data and methodology

Hebei Province was chosen as the study area because it is the most polluted region of China (Lu et al., 2015). In contrast to Beijing and Tianjin, Hebei has a more complex and diverse geographical environment and a much larger area. Furthermore, Hebei is relatively less urbanized and has more heavy industries. Hebei's unique characteristics need customized research designs, and it is necessary to conduct separate studies in Hebei alone. When we developed our LUR model, the $PM_{2.5}$ and NO_2 concentrations at 53 air quality monitoring sites were selected as separate dependent variables, and various influencing indicators (e.g., meteorological factors, land use types, road area, population density, monitoring enterprises, pollution sources, elevation, etc.) were selected as independent variables. The LUR model was analyzed with a statistical package (SPSS) and geographic information system (GIS) software (ArcGIS 10.1). A flow chart of the study is shown in *Figure 1*.

Research area

Hebei Province is a coastal province adjacent to two megacities in northern China, namely, Beijing and Tianjin. The Beijing–Tianjin–Hebei region is also one of China's largest urban agglomerations. Hebei consists of 11 cities, and its land area is approximately 188,500 km^2. The Yanshan and Taihang Mountains lie to its north and west respectively and the Bohai Sea lies to its northeast Hebei, as illustrated in *Figures 2* and *3*. At the end of 2014, the gross domestic product (GDP) of Hebei reached 2942.12 billion renminbi (RMB), its population was 73.83 million, and its average population density was 392 inhabitants/km^2 (National Bureau of Statistics, 2015).

DOI: http://dx.doi.org/10.15666/aeer/1704_81038120

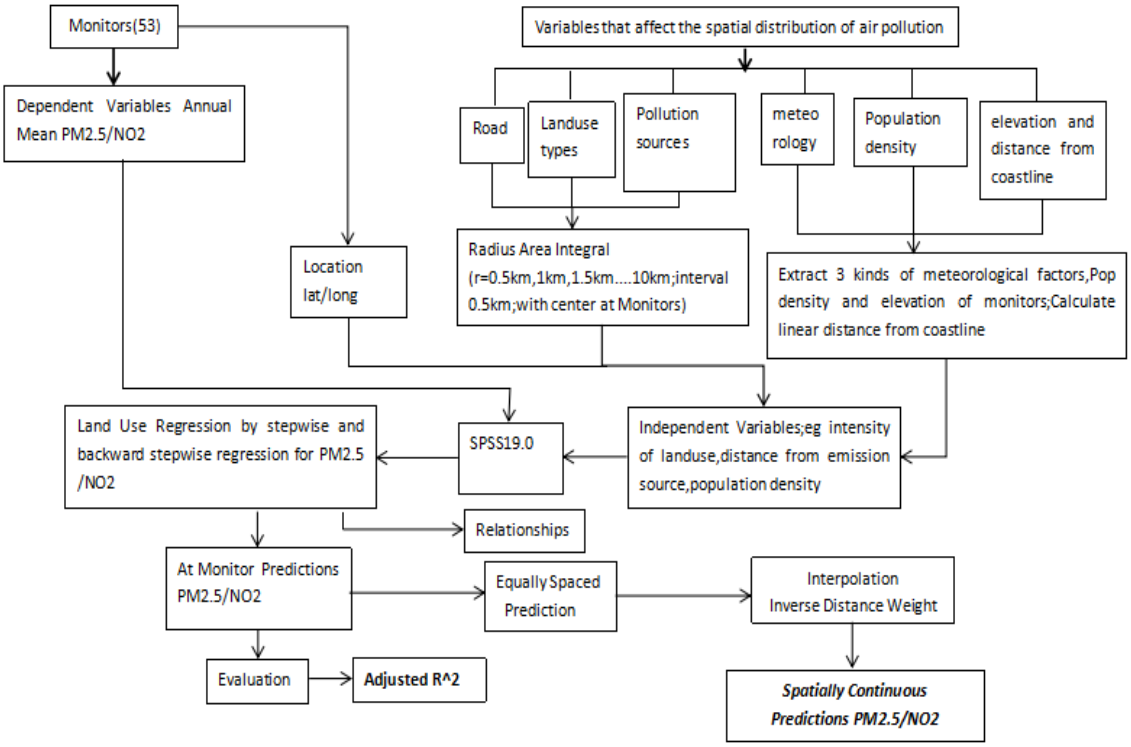

Figure 1. *Flow chart of our study*

The annual temperature at meteorological monitoring sites in Hebei Province in 2014 ranged is 13°C (Climate Bulletin of 2014 in Hebei Province), and the average wind speed is 2.5 m/s, calculated from data for 20 national meteorological monitoring stations in Hebei in 2014. The average wind speed in southern and western areas is lower than that in northern and eastern areas because the Taihang and Yanshan mountains to the west and north of Hebei block the prevailing northerly winds in winter.

LUR model setting

Dependent variables: $PM_{2.5}$ and NO_2

Hebei Province started to report $PM_{2.5}$ concentrations in 2012. In this study, we extracted hourly monitoring data for $PM_{2.5}$/NO_2 concentrations from the official website of China Environmental Monitoring Station (http://www.cnemc.cn) during the period from March 22, 2014 to March 22, 2015. In total, one-year observations from 53 national air quality monitoring sites in 11 cities of Hebei were collected, and the average annual values of $PM_{2.5}$ and NO_2 concentrations were used as dependent variables.

Independent variables

Independent variables were divided into buffer-related and location-based variables, of which the latter were specific to the 53 air quality monitoring sites. The buffer-related variables are comprised of six land use types, road areas, and the numbers of pollution-emitting industries in different buffer areas around each monitoring site, which were calculated for 20 different buffer distances (from 0.5 km to 10 km at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81038120

intervals of 500 m) from each monitoring site. Furthermore, the location-based variables included the longitude, latitude, distance from the monitoring site to the coastline, population density, and elevation, as well as meteorological elements, including air pressure, wind speed, temperature, precipitation, and relative humidity. In the LUR model, 169 independent variables were used, and each independent variable is described as follows.

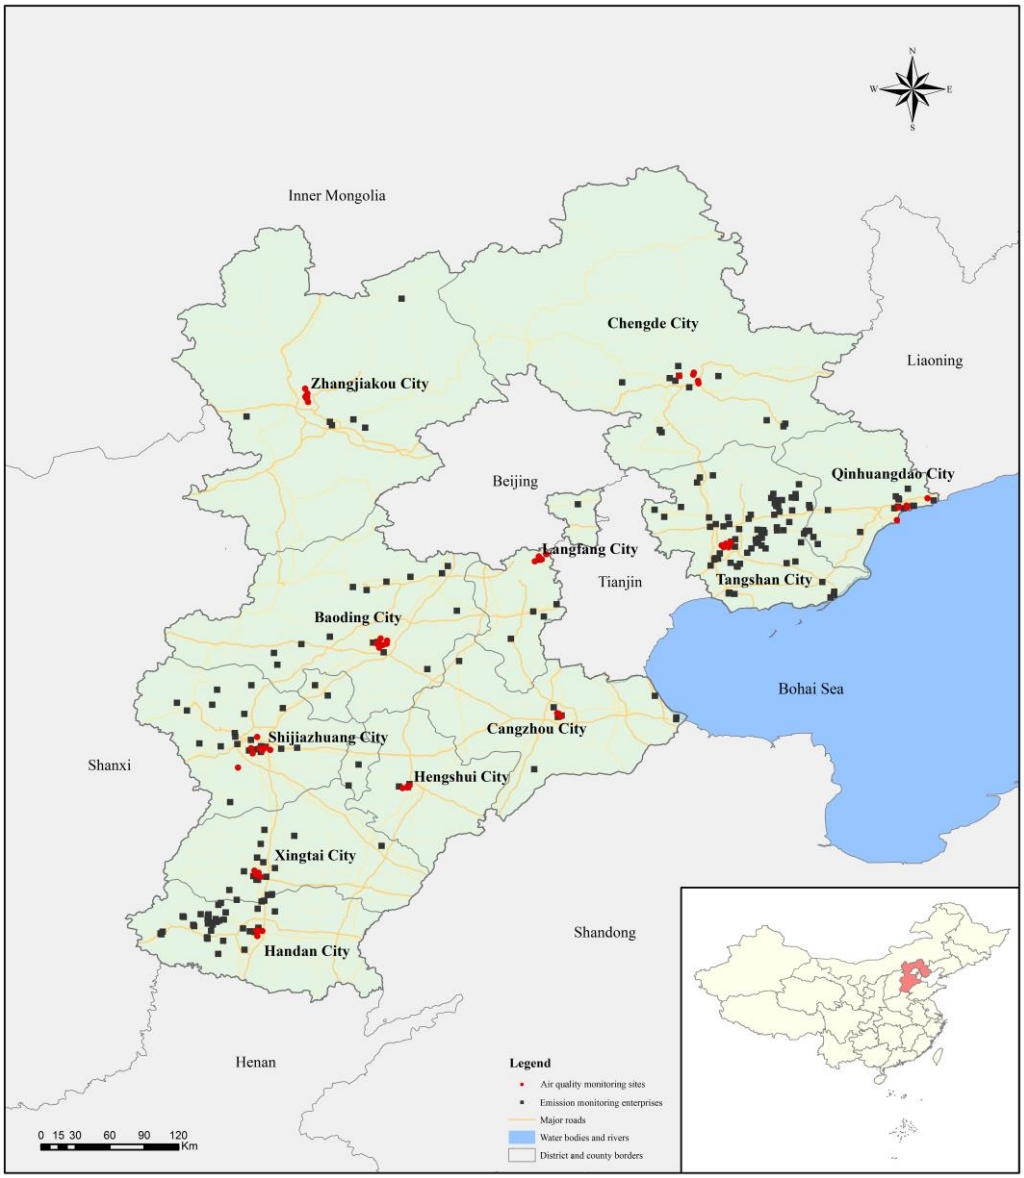

Figure 2. *Study area and monitor distributions*

Land use

The six land use types adopted are comprised of building land (including workplaces, residences, educational institutions, and buildings used for entertainment), forest land, farmland, bodies of water (rivers and lakes), greenhouses, and garden land. (A greenhouse is defined as a heating facility used to cultivate plants.) The areas occupied

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81038120

by each land use in each buffer zone were calculated separately. The land use data were derived from national geographical census data for Hebei Province with high resolution (1 × 1 m), which were collected by the Hebei Bureau of Geoinformation (http://www.hebsm.gov.cn/) in 2015. The variables were denoted as the land use type plus buffer distance as follows: build_buffer distance, fore_buffer distance, farm_buffer distance, wat_buffer distance, ghl_buffer distance, and gar_buffer distance. The explanation of abbreviation is shown in *Table A3* in the *Appendix*.

Figure 3. *Study area and ridgelines distributions*

Road areas

The areas of all road types in the different buffer zones in km^2 were calculated. The road area data were derived from high-resolution national geographical census data for Hebei Province from the Hebei Bureau of Geoinformation (http://www.hebsm.gov.cn/). The road types included national roads, provincial roads, county roads in rural areas, expressways, arterial streets, sub-arterial streets, and local streets in urban areas. We did not separate these road types in detail but uniformly calculated the areas of all types of roads in different buffer zones, which were denoted as rdar_buffer in this paper.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81038120

Population density

Population density data in inhabitants/km^2 were extracted from the database of China's population distribution provided by the Data Center for Resources and Environmental Sciences, Chinese Academy of Sciences. We used the GIS to extract the raster values of the 53 air quality monitoring sites in Hebei Province as population density variables from the population distribution dataset for the Chinese population grid (1 × 1 km), which was calculated by Fu et al. (2013). In comparison with the census data, the above-mentioned data have higher resolution and are better for revealing spatial differences in population density, because the relative error is kept under 10% (Fu et al., 2010).

Distance to the coastline

The straight-line distance (m) between each air quality monitoring site and the nearest coastline was measured on a map of Hebei Province with the GIS. The measurement of the distance to the coastline served to determine the effects of the deposition of pollutants in the sea and the dilution of pollutants by sea breezes.

Geographical features of air quality monitoring sites

The geographical coordinates of each air quality monitoring site (including its longitude and latitude) were recorded, which were obtained from the Environmental Monitoring Center of Hebei Province. Elevations were extracted from the data of a digital elevation model of Hebei with a worldwide resolution of 30 m.

Industrial sources of air pollution

This study considered 241 enterprises that carried out national emission monitoring in Hebei Province in 2015, as listed on the website of the Ministry of Environmental Protection of China, as shown in *Figure 2* (http://www.zhb.gov.cn/). These included waste gas, coal, and thermal power plants, etc. We counted the number of these enterprises within each buffer zone, which was included as an independent variable in the model.

Meteorological data

We extracted meteorological data for 20 national meteorological monitoring stations in Hebei Province from the official website of the China Meteorological Administration. The mean values of five variables (air pressure, temperature, precipitation, wind speed, and relative humidity) in one year were calculated. By means of the kriging interpolation algorithm in ArcGIS 10.1, the values of the five classes of meteorological data for each air pollution monitoring site were taken as independent variables.

Statistical analysis

Pre-processing was performed to solve problems arising from multicollinearity between independent variables. Firstly, a bivariate (Pearson) correlation test was used to calculate the absolute strength of the correlation between all variables and the measured $PM_{2.5}$/NO_2 concentrations. Secondly, for land use factors, from two independent variables between which the correlation coefficient was greater than 0.6, only the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81038120

variable with a stronger correlation with the dependent variables was employed in the LUR model. In addition, the longitude, latitude, wind speed, population density, precipitation, pressure, temperature, and altitude were added directly to the LUR model.

After the pre-processing step, stepwise backward multiple regression methods were employed to test the remaining variables for their correlations with $PM_{2.5}$ and NO_2 concentrations. The adjusted R^2 and residuals were used to evaluate the goodness of model fitting. The global Moran's index and Durbin–Watson index were employed to test the assumption that the regression residuals were spatially independent. In the application of GIS model, Moran's (Anselin, 1983) and Durbin-Watson (Mcauliffe, 2015) indexes are generally used for spatial autocorrelation test of data.

Results and discussion

Descriptive characteristics of $PM_{2.5}$ and NO_2 concentrations

The average $PM_{2.5}$ and NO_2 concentrations at the 53 air quality monitoring sites in Hebei Province were 83.64 ± 29.45 μg/m^3 and 47.18 ± 12.10 μg/m^3, respectively. *Figure 4a* shows an inverse distance weighting (IDW) interpolation map derived from the annual average values of $PM_{2.5}$ concentrations. *Figure 4b* shows an IDW interpolation map derived from the annual average values of NO_2 concentrations. The maps indicate that the concentrations in the southwest were higher than those in other areas. In addition, there were significant differences in concentration between the north and south of Hebei along the Yanshan mountains. Areas under severe air pollution were mainly concentrated in the south of Hebei for both $PM_{2.5}$ and NO_2.

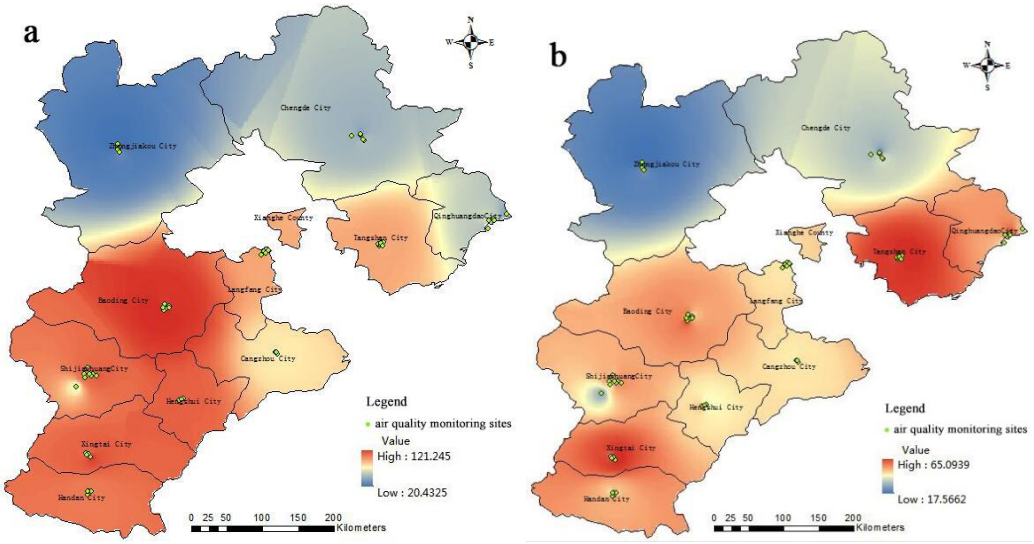

***Figure 4. a** Interpolation map of $PM_{2.5}$ concentrations (μg/m^3) based on observational data. **b** Interpolation map of NO_2 concentrations (μg/m^3) based on observational data*

Results of pre-processing for multicollinearity

There were initially a total of 169 indicator variables in this study; after filtering for multicollinearity between the influencing factors with reference to the modelling method proposed by Wu et al. (2014), 20 influencing factors remained for $PM_{2.5}$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81038120

concentrations (*Table 1*) and 19 influencing factors remained for NO_2 concentrations (*Table 1*), which were added to the LUR model at the outset.

LUR model results

$PM_{2.5}$ concentration modeling results

The adjusted R^2 in the regression model was 0.96 and the F-statistic was 157.71 ($p < 0.01$), which indicates that the LUR model had good fitness (*Table A1* in the *Appendix*). The value of the Durbin–Watson test statistic was 1.954, which indicates that there was no autocorrelation in the residual sequence. Eight independent variables were finally entered into the LUR model, namely, air pressure, precipitation, temperature, wind speed, longitude, elevation, farmland_500 m, and pollution-emitting industries within the 7.5 km buffer zone. The standardized regression coefficients for air pressure and precipitation were 0.94 and 0.23, respectively, which indicates that they

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81038120

were positively correlated with $PM_{2.5}$ concentrations. In contrast, the standardized regression coefficients for temperature and wind speed were -0.62 and -0.15, respectively, which indicates that they were negatively correlated with $PM_{2.5}$ concentrations. The results also show that the area of farmland within the 500 m buffer zone and emission monitoring enterprises within the 7.5 km buffer zone (Emission monitoring enterprises_7.5 km) were included as significant predictor variables, with standardized regression coefficients of 0.07 and 0.10, respectively. This indicates that the emission source of waste gas enterprises is the main contributor to the concentration of $PM_{2.5}$ pollutants, and the wind speed is the main factor to alleviate $PM_{2.5}$ pollution, which is similar to the conclusions of relevant study (Guan et al., 2017; Liu et al., 2018). Longitude and elevation were also influencing factors negatively correlated with $PM_{2.5}$ concentrations, with standardized regression coefficients of -1.14 and -0.29.

The final model explains 96% of the variation in the measured $PM_{2.5}$ concentrations. There was no apparent bias in the model, as shown in *Figure 5a* and *b*. The results for spatial autocorrelation are shown in *Figure 5c*. The z-score was 0.74, which is less than the critical value of 1.96, which means the probability that the residuals resulted from random factors is greater than 0.95. The value of Moran's index of 0.056 further indicates that there was no autocorrelation and justifies the assumption that errors were spatially independent.

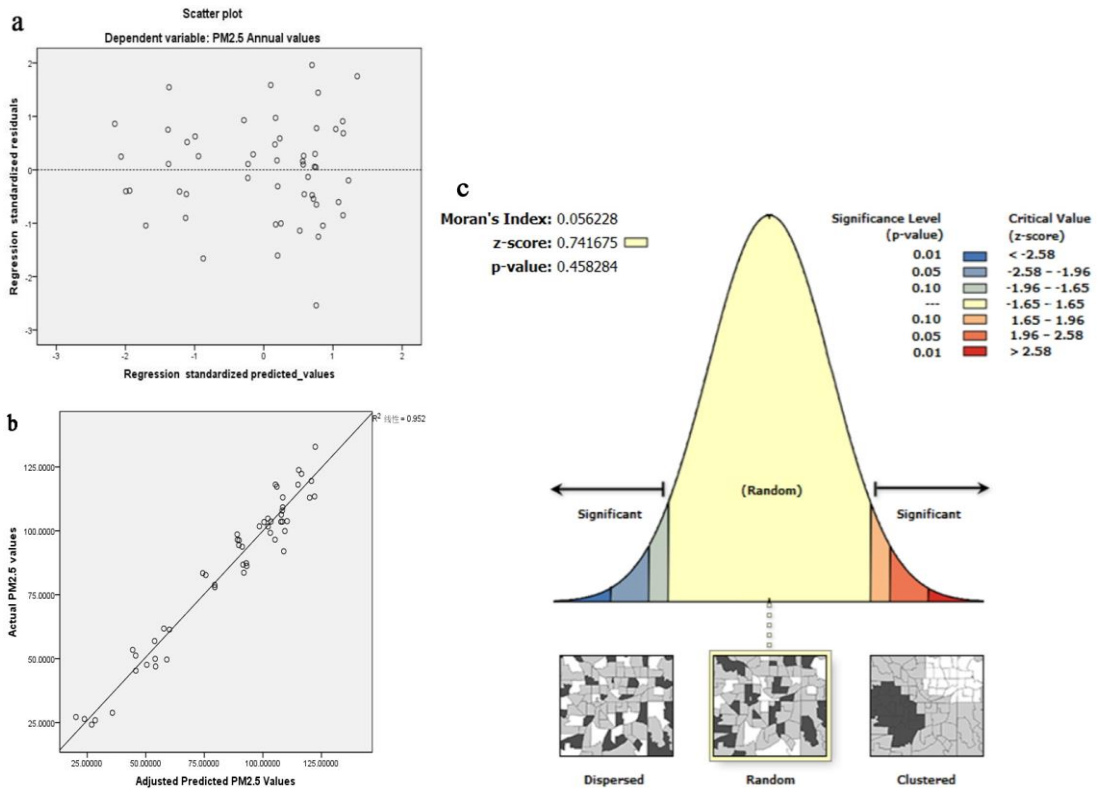

***Figure 5. a** Plot of residuals versus predicted $PM_{2.5}$ values. **b** Plot of monitored versus predicted $PM_{2.5}$ values ($\mu g/m^3$). **c** Results of spatial autocorrelation test for LUR residuals*

An interpolation map of measured values of $PM_{2.5}$ concentrations is shown in *Figure 4a*, and an interpolation map of LUR predictions of $PM_{2.5}$ concentrations is shown in *Figure 6a*. From these two figures, we can conclude that there existed

DOI: http://dx.doi.org/10.15666/aeer/1704_81038120

significant heterogeneity in the spatial distribution of $PM_{2.5}$ concentrations in Hebei Province. The variables of longitude and elevation were negatively correlated with $PM_{2.5}$ concentrations. Correspondingly, the LUR model results show that western areas were more heavily polluted than eastern areas and that southern areas were more heavily polluted than northern areas. The regression coefficients for the number of emission monitoring enterprises within the 7.5 km buffer zone and farmland within the 500 m buffer zone show that these variables were positively correlated with $PM_{2.5}$ concentrations.

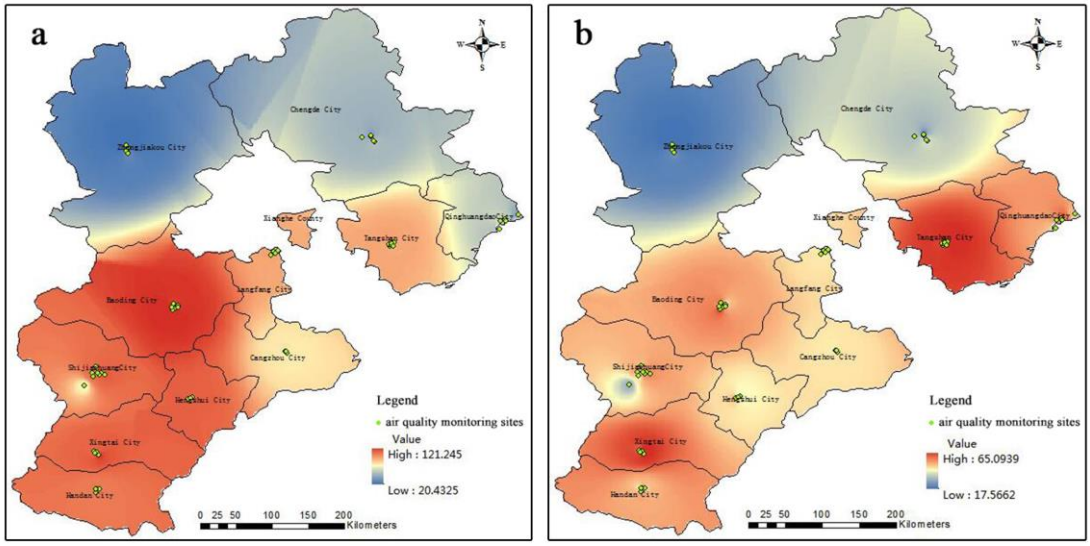

Figure 6. a *LUR predictions of $PM_{2.5}$ concentrations ($\mu g/m^3$).* ***b*** *LUR predictions of NO_2 concentrations ($\mu g/m^3$)*

This is due to the following reasons. Firstly, industrial emissions of air pollutants make a great contribution to $PM_{2.5}$ concentrations (Rohde et al., 2015). Secondly, the destruction of the soil structure and surface vegetation cover of farmland by human farming processes (Bogman et al., 2005; Goossens, 2004; Pattey et al., 2012) and the burning of biomass lead to the increases in $PM_{2.5}$ concentrations (Cheng et al., 2014). Therefore, we conclude that $PM_{2.5}$ concentrations are influenced by meteorological factors, certain land uses, and heavy industries.

Spatial distribution of NO_2 concentrations and influencing factors

NO_2 is the main air pollutant indicator that originates from transportation. In this study, we also developed an LUR model for NO_2 for comparison with the features of $PM_{2.5}$ pollution. The adjusted R2 in the regression model was 0.81 and the F-statistic was 25.31 ($p < 0.01$), which indicates that the LUR model was also highly predictive for NO_2 concentrations (*Table A2* in the *Appendix*). The value of the Durbin–Watson test statistic was 2.08, which is very close to 2, indicating that there was no autocorrelation in the residual sequence. Finally, nine independent variables were entered into the model, namely, distance to the coastline, latitude, forest land within the 1 km buffer zone, emission monitoring enterprises within the 8.5 km buffer zone, area of water within the 10 km buffer zone, wind speed, temperature, air pressure, and relative humidity.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81038120

An interpolation map of measured values of NO_2 concentrations is shown in *Figure 4b*, and an interpolation map of LUR predictions of NO_2 concentrations is shown in *Figure 5b*.

The main similarity was that for both $PM_{2.5}$ and NO_2 the number of emission monitoring enterprises and air pressure had a positive influence on pollution levels. There were also differences between the two models. In general, land uses were more influential in the NO_2 model than in the $PM_{2.5}$ model, whereas meteorological factors were more significant in the $PM_{2.5}$ model than in the NO_2 model. A possible reason is that $PM_{2.5}$ remains suspended for a longer time and could be transported over longer distances with the help of meteorological conditions in comparison with NO_2 (Liu et al., 2016). NO_2 is considered to be a local pollutant and is thus more influenced by local land uses (Liu et al., 2016). The results of the NO_2 model differed from those of the $PM_{2.5}$ model. Unlike the LUR model results for $PM_{2.5}$, the distance to the coastline and latitude affected NO_2 pollution but were not entered into the $PM_{2.5}$ model. Secondly, wind speed, temperature, and relative humidity were positively correlated with NO_2 concentrations but negatively correlated with $PM_{2.5}$ concentrations. Thirdly, forest land was helpful for NO_2 pollution reduction but did not exhibit significant effects in decreasing $PM_{2.5}$ concentrations. Besides, the adjusted R^2 for the NO_2 regression was lower than that for the $PM_{2.5}$ model.

There is a negative correlation between wind speed and NO_2 concentration in *Table 1*. This suggests that without being influenced by anything else, the higher the wind speed, the more favorable is the diffusion of NO_2 concentration. But in the LUR model, the influence factor coefficient of wind speed is negative, this may be because the influence of wind speed on NO_2 concentration may be interfered by other factors.

Discussion

A comparison was carried out with LUR results for similar regions. Owing to the lack of specialized research in Hebei Province using LUR, we chose previous studies of the Beijing–Tianjin–Hebei region as a whole to compare our results. Each study had a specific combination of influencing variables for the prediction of $PM_{2.5}$ concentrations, as shown in *Table 2*.

The results of the comparison showed that this study displayed the best fitness and the highest adjusted R^2. The primary reason was that Hebei Province and the cities of Beijing and Tianjin have distinct economic structures. Beijing and Tianjin are two of the most highly developed cities of China, with high levels of urbanization and much fewer polluting industries. Therefore, the fitness of the LUR model was lower when Beijing–Tianjin–Hebei as a whole was considered as the study region and the spatial characteristics were assumed to be the same in the model.

In all three sets of results, elevation was a common variable and was negatively correlated with $PM_{2.5}$ concentrations. Emission monitoring enterprises played an important role both in this study and in the model used by Gang et al. (2016), which had buffer zones of 9 km and 10 km, respectively. This consistency indicates that the influence of pollution-emitting industries on $PM_{2.5}$ concentrations was significant.

Our study was the first to consider the impacts of meteorological factors on pollutant levels. Our model showed that meteorological factors were even more significant for predicting $PM_{2.5}$ concentrations, and hence a comprehensive LUR including meteorological factors is valuable and more convincing.

Table 2. *Comparison of LUR results for $PM_{2.5}$ concentrations for the Beijing–Tianjin–Hebei region*

Authors	Study area	Buffers	Adjusted R^2	Influencing variables in the model
Our study	Hebei Province	0–10 km total, 20 different buffers, interval 500 m	0.96	Pressure, longitude, precipitation, temperature, elevation, wind speed, emission monitoring enterprises_9 km, farmland_0.5 km
Xu et al. (2016)	Beijing–Tianjin–Hebei region	0–10 km total, 22 different buffers	0.81	Temperature, elevation, emission monitoring enterprises_10 km, water_10 km
Jian-Sheng et al. (2017)	Beijing–Tianjin–Hebei region	100, 200, 300, 500, 1000, 2000, 3000, 5000 m	0.81	Elevation, water_2 km, relative humidity

Conclusions

Our LUR models indicate that the $PM_{2.5}$ and NO_2 concentrations in Hebei Province had significant spatial heterogeneity, and that the $PM_{2.5}$ and NO_2 concentrations in southern cities were higher than in northern cities.

In contrast to relevant research studies in Europe, America, and other areas in China, the distribution of $PM_{2.5}$ and NO_2 concentrations in Hebei Province is affected by pollution-emitting industries, whereas the road network is not the most significant variable. This is because Hebei is a developing region, whereas other areas of the Beijing–Tianjin–Hebei region are already developed. Specifically, Beijing's per capita GDP reached 99,995 RMB and the per capita GDP of Tianjin reached 105,231 RMB, whereas the per capita GDP of Hebei was only 39,984 RMB (National Bureau of Statistics, 2015).

In general, the model results for $PM_{2.5}$ concentrations demonstrate a gradually decreasing tendency from west to east, and the pollutant concentration is lower near the coastline than inland, which can be attributed to the influence of the onshore monsoon. The effect of dilution by sea breezes is consistent with the conclusions of a study performed in Shanghai (Liu et al., 2016).

The results show that the rational planning of land uses, such as the designation of land as industrial land or as green space, plays an important role in mitigating air pollution and can effectively reduce $PM_{2.5}$ and NO_2 concentrations.

Our study was the first to use high-resolution geographical data to study Hebei Province as the sole study area. Furthermore, our models made significant improvements with the use of meteorological factors, which were usually not incorporated into traditional LUR models. The results indicate the importance of meteorological factors. In addition, we identified the most distinctive characteristic of the spatial patterns of pollution in Hebei in comparison with developed cities, namely, the effective buffers around polluting industry. Our findings can be utilized for the planning of residential land and the design of buffers around heavily polluting industry and can help to reveal the land use factors with the greatest influences on $PM_{2.5}$ and NO_2 concentrations.

Some limitations of the LUR models used in this study should be recognized. Firstly, the total number of national monitoring stations in Hebei Province used in this study was 53. Although this conforms to the number of monitoring sites (40–80)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81038120

recommended by Hoek et al. (2008), most monitoring sites were located in urban areas and there was a lack of rural monitoring sites. Secondly, our study was limited by the availability of refined variables, including land use types, pollutant emission sources, real-time meteorological data, and transportation emission data. This is a common constraint that also existed in previous studies.

Further studies should be performed with more monitoring site data and more dynamic variables. In addition, empirical observations are needed to support our findings, such as the impact of buffers around industry, meteorological impacts, etc. As the most severely polluted region in China, Hebei Province needs more comprehensive study from an interdisciplinary perspective to identify the relevant problems, reasons, and solutions.

(Received 1st Feb 2019; accepted 16th May 2019)

Abstract. Pot experiments were conducted from May 2017 to October of 2017 at the cultivation base of the Resource and Environment College of the Shanxi Agricultural University in China. The physiological and photosynthetic characteristics of different cultivars treated with different Zn concentrations at different growth stages were investigated to determine the optimum spraying period and spraying concentration of Zn fertilizer ($ZnSO_4 \cdot 7H_2O$) in Millet plants (*Setaria italica* L.). Results showed that spraying low Zn concentrations (20, 40, and 60 $mg \cdot L^{-1}$) solutions decreased the malondialdehyde content, Ci (intercellular CO_2 concentration), and qN (non-photochemical quenching coefficient) but increased antioxidant enzymatic activities, pigment content, photosynthetic gas exchange parameters (except Ci), and chlorophyll fluorescence parameters (except qN). By contrast spraying high Zn concentration (80 and 100 $mg \cdot L^{-1}$) showed opposite effects. Moreover, 'Jingu 21' (susceptible variety, conventional cultivar) showed more remarkable variation higher than 'Zhangzagu10' (resistant variety, hybrids). Thus, low Zn concentration promoted plant growth, while high Zn concentration inhibited plant growth, which was most pronounced during the Millet booting stage. The optimal conditions were booting period and 40 $mg \cdot L^{-1}$ of Zn. Thus, a theoretical basis for the efficient use of Zinc Fertilizer in Millet is provided.
Keywords: *foxtail millet, growth stage, zinc fertilizer, antioxidant enzyme activity, photosynthetic gas exchange parameters, chlorophyll fluorescence parameters*

Introduction

Zinc is an essential element in human health and an indispensable trace element in animal and plant growth (Gartler et al., 2013). As the only metal element to be simultaneously present in six enzymes, Zn plays an important regulatory role in plant photosynthesis, protein and nucleic acid metabolism, auxin metabolism, biofilm stability, and cell division (Prasad and Hagemeyer, 1999; Kabata-Pendias and Pendias, 2001). In recent years, plants have taken away substantial amount of nutrients from the soil because of the growing area of crops and the gradually increased yield (Feng, 2010). In addition, the amount of organic fertilizer applied in the field has generally declined (Mutegi et al., 2012), and trace elements could not be replenished in time. Thus, the available Zn in the soil gradually decreased with the passage of time. This phenomenon resulted in the prevalent deficiency of Zn in crops (Carroll and Loneragan, 1968; Alloway, 2009). Zn deficiency can cause dwarf plants, short internodes, suppression of leaf expansion and elongation, leaflets, twisted leaves, and wrinkled leaf margins. Albino corn seedlings and stiff Miller of rice seedlings are due to Zn

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81218138

deficiency (Rengel et al., 1998; Singh and Yashbir, 2017). At present, the application of Zn fertilizer to crops is the safest, most convenient, and effective approach to augment the micronutrient Zn deficiency in humans. This process can also effectively improve the symptoms of Zn deficiency in crops (Noulas et al., 2018). However, excessive application of Zn will inhibit the growth of crops, cause poisoning (Mateos-Naranjo et al., 2014), and can lead to toxicity, such as nutrient imbalances, growth inhibition, leaf chlorosis, and photosynthesis impairment (Todeschini et al., 2011; Cambrollé et al., 2012).

Photosynthesis is an important factor in plant growth and an indicator to assess plant growth status (Moss and Musgrabe, 1971; Silveira and Carvalho, 2016). Chlorophyll fluorescence is an effective tool to sense and assess the impact of Zn on the photosynthetic apparatus, and this tool has been used extensively to investigate the effects of various substances in crops (Appenroth et al., 2001; Prasad et al., 2001; Frankart et al., 2002; Drinovec et al., 2004). Zn plays a significant role in the regulation of the stomatal aperture, which accounts for the possible role of Zn in maintaining a high K content in the guard cells (Sharma et al., 1995). Cambrollé et al. (2013) showed that an appropriate Zn concentration (60 mmol/L) could increase the net photosynthetic rate (Pn), but greater external Zn concentration (90–130 mmol/L) could negatively affect plant growth probably because of the recorded decline in the Pn. This process may be linked to the adverse effect of Zn on the photosynthetic electron transport.

Various grain industries have received increasing attention because of the improved human dietary structure (Ardiea et al., 2015). The millet (*Setaria italica* L.) originated from China and is an important strategic food crop in the country (Guo et al., 2018; Yuan et al., 2017). The millet is a traditional drought-resistant crop (Bai et al., 2009; Andersen and Nepal, 2017) and the preferred crop in drought-scarce areas in northern China. The main components of millet, including starch, protein, lipid, vitamins, and minerals, satisfy the various dietary needs of the human body (Usha et al., 1996). Low Zn availability affects crop yield and food production worldwide, and this phenomenon has led to the more efficient use of Zn in agriculture. The application of Zn fertilizer is an effective measure to increase nutrient Zn (Genty et al., 1989; Bouis and Welch, 2010; Gibson, 2006), but the safety of Zn to foxtail millet is ambiguous.

Studies on Zn fertilizers are mostly concentrated on rice (Jamalomidi et al., 2006), wheat (Khoshgoftarmanesh et al., 2006; Hacisalihoglu et al., 2003), and other crops (Gunes, 1996; Hu, 1991), but few reports have focused on millet production (Zong, 2011; Guo, 2014). In this experiment, millet was used to study the effects of different Zn concentrations on the growth of millet under different stages. Moreover, the optimal combination of conditions for the growth of millet was determined to provide a theoretical basis for the reasonable application of Zn fertilizer on millet.

Materials and methods

Site and plant materials

The pot experiments were conducted from May 2017 to October of 2017 at the cultivation base of the Resource and Environment College of Shanxi Agricultural University (37°42′ N, 112°55′ E) in Shanxi, China. The area has a mean annual temperature of 9.9 °C and a frost-free period of 176 days. The precipitation is concentrated, and the mean annual rainfall is 462.9 mm. The plant materials were ‘Zhangzagu 10’ (provided by the Zhangjiakou Academy of Agricultural Sciences of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81218138

Hebei Province, China.) and 'Jingu 21' (provided by the Institute of Millet Research, Shanxi Academy of Agricultural Sciences, China). The soil used was calcareous soil, with pH value of 8.51, organic matter content of 21.02 g/kg, alkali nitrogen content of 52.37 mg/kg, available phosphorus content is 21.98 mg/kg, available potassium content of 21.98 mg/kg, total N content of 1.180 g/kg, total P content of 1.261 g/kg, and total K content of 20.18 g/kg. The seeds were sown on May 31, 2017. After 20 days of thinning out the seedlings, five seedlings were left in each pot.

Treatment details and allocation

The experiment was conducted in a completely random design. The seeds of 'Zhangzagu 10' and 'Jingu 21' were separately sown in pots with a diameter of 32 cm and a height of 26 cm under normal water content, and each pot was filled with 10 kg of soil, the cultivation temperature was 22-35℃, relative humidity of atmosphere was 70-80%. The seeds were normally watered daily after germination to ensure the normal growth of the seedlings (by weighing method, the Moisture field was maintained at 13%-15%). Different concentrations of $ZnSO_4 \cdot 7H_2O$ solution were sprayed at the seedling stage (SL, 35 d after planting), booting stage (BT, 60 after planting), flowering stage (FE, 70 d after planting), and filling stage (FL, 90 d after planting). A control (no Zn application) was set simultaneously, and each treatment was repeated thrice. The Zn concentrations sprayed were 0, 20, 40, 60, 80, and 100 $mg \cdot L^{-1}$, and the corresponding samples were labeled as CK, Zn1, Zn2, Zn3, Zn4, and Zn5. After 7 days of Zn treatment, the physiological and photosynthetic characteristics were measured.

Determination of antioxidant enzyme activity

Fresh plant leaves (0.1 g) were placed in an ice-cooled mortar, and 1 $mg \cdot L^{-1}$ of 50 mM phosphate buffer (pH 7.8) was added. The leaves were ground on ice, transferred to a 1.5 mL centrifuge tube, and centrifuged at 12000 $\times g$ for 15 min at 4 °C. The supernatant was extracted to determine the superoxide dismutase (SOD), peroxidase (POD), and catalase (CAT) activities.

The SOD activity was determined using the nitroblue tetrazolium (NBT) photoreduction method (Gao, 2006). First, the NBT reaction solution was configured. The solution consisted of 50 mM phosphate buffer (pH 7.8), 13 mM L-methionine, 0.075 mM NBT, 0.002 mM riboflavin, and 0.01 mM EDTA. Then, 5 mL of the reaction solution was added to the blank and control tubes. A portion of 50 μL of the supernatant was taken from the test tube and mixed with 5 mL of the reaction solution. The control and test tubes were illuminated for 20 min under 4000 lx light conditions at 25 °C. The absorbance of the irradiated solution was measured at 560 nm, and a non-irradiated complete reaction mixture served as a control. The result was calculated by inhibiting 50% of the NBT photochemical reduction as an enzyme unit. SOD activity was presented as the number of units per gram of fresh weight (U/g FW).

The POD activity was determined by the guaiacol method (Gao, 2006). The supernatant (5 μL) was mixed with 3 mL of the reaction solution containing 3 mL of 0.1 mM phosphate buffer (pH 6.0), 28 μL of 30% H_2O_2, and 19 μL of guaiacol (0.1%). The absorbance of the complete reaction mixture was measured at 470 nm, and the 0.1 mM phosphate buffer (pH 6.0) served as a control. The change in absorbance every 3 min indicated the POD activity.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81218138

The CAT activity was determined by the UV absorption method (Gao, 2006). The supernatant (50 μL) was mixed with 3 mL of the reaction solution containing 2.7 mL of Tris-HCl buffer (pH 7.0) and 50 μL of 200 mM H_2O_2. The absorbance of the complete reaction mixture was measured at 240 nm. The decrease of 0.1 by A240 in 1 min was the enzymatic activity unit.

Determination of lipid peroxidation

The MDA content was determined by the thiobarbituric acid (TBA) spectrophotometry method (Zhao et al., 1994). Fresh plant leaves (0.4 g) were placed in an ice-cooled mortar, and 5 mL of 0.1% trichloroacetic acid was added. The leaves were ground on ice, and 5 mL of 0.5% TBA was added. The ground leaves were transferred to a 15 mL centrifuge tube. After boiling in water for 15 min, the leaves were cooled to room temperature and centrifuged at 3000 $\times g$ for 15 min. The absorbance of the supernatant was measured at 560 nm and 600 nm.

Determination of photosynthetic pigment content

The pigment contents of the leaves were determined using acetone extraction. Fresh plant leaves (0.1 g) were extracted in 10 mL of acetone (80%, v/v) and stored in the dark for 24 h (Gao, 2006). The absorbance of the supernatant was measured at 470, 646, and 663 nm (*Eqs.1-3*).

$$Ca = 12.21A663 - 2.81A646 \quad \text{(Eq.1)}$$

$$Cb = 20.13A646 - 5.03A663 \quad \text{(Eq.2)}$$

$$Cx.c = (1000A470 - 3.27Ca - 104Cb)/229 \quad \text{(Eq.3)}$$

Determination of photosynthetic gas exchange parameters

The Pn, transpiration rate (Tr), intercellular CO_2 concentration (Ci), and stomatal conductance (Gs) were measured using a CI-340 portable photosynthesis system (CID Bio-Science, Inc., USA, *Fig. 1*). The seedlings with uniform growth were randomly selected from each pot, and the photosynthetic gas exchange parameters were measured at 9:00–11:00 am on the 7th day after spraying the $ZnSO_4 \cdot 7H_2O$ solution. Photosynthetically active radiation (PAR) at the leaf surface was approximately 1000 ± 50 μmol/m^2/s. The temperature in the leaf chamber was 38 ± 2 °C, and ambient CO_2 concentration was 420 ± 30 μmol/mol.

Figure 1. *CI-340 portable photosynthesis system*

DOI: http://dx.doi.org/10.15666/aeer/1704_81218138

Determination of chlorophyll fluorescence parameters

Actual photochemical efficiency (ΦPSII), photosynthetic electron transport rate (ETR), photochemical quenching coefficient (qP), non-photochemical quenching coefficient (qN), and maximum photochemical efficiency (Fv/Fm) were measured using a portable chlorophyll fluorometer PAM-2500 (Walz, Germany, *Fig. 2*). Prior to measurements, the leaves were first treated in the dark for 30 min, and a beam of measurement light (less than 0.1 μmol) was irradiated on the fully dark-adapted leaves to obtain the initial fluorescence Fo. Then, saturated pulsed light (8000 μmol $m^{-2}s^{-1}$) was turned on to obtain the maximum fluorescence Fm under dark adaptation (Marwood et al., 2001). Afterward, the endogenous actinic light (600 μmol $m^{-2}s^{-1}$) was turned on. When the actual primary light energy capture efficiency ΦPSII had stabilized, the action light was turned off, and the far-infrared light was illuminated (Schreiber et al., 1986, 2003). The ETR was automatically calculated by the instrument (Mayer et al., 2008). The different parameters were calculated as follows (*Eqs.4-7*):

$$Fv / Fm = (Fm - Fo) / Fm \quad \text{(Eq.4)}$$

$$\Phi PSII = (Fm' - Ft) / Fm' \quad \text{(Eq.5)}$$

$$qP = (Fm' - Ft) / (Fm' - Fo') \quad \text{(Eq.6)}$$

$$qN = 1 - (Fm' - Fo') / (Fm - Fo) \quad \text{(Eq.7)}$$

Statistical analysis

The data were plotted using Microsoft Excel and analyzed by ANOVA using SPSS 17.0. Duncan's test ($P < 0.05$) were used to determine the significance of differences between treatment means.

Results

Effect of Zn on the antioxidant enzymatic activity of foxtail millet

After Zn treatment, protective enzymes SOD, POD, and CAT in both cultivars increased first and then decreased with the increase in Zn concentration, and the level of change in these enzymes differed between the cultivars and among periods (*Figs. 3-5*). Among the three protective enzymes, Zn treatment of the same cultivars reached maximum effect in Zn2 and reached a significant level compared with the control ($P < 0.05$). However, in 'Zhangzagu10', no significant difference in CAT was found between the control and Zn2 treatment during the SL stage (*Fig. 3*). However, the three enzymatic activities were lower in Zn4 than in CK, and the change was more obvious after Zn5 treatment. *Figures 3-5* show that Zn treatment of the two millet varieties was most obvious at the BT stage.

Compared with CK, during the BT stage, after 7 days of Zn2 treatment, the SOD, POD, and CAT activities of 'Jingu 21' increased by 28.2%, 61.1%, and 35.1%, respectively. By contrast, the corresponding values of 'Zhangzagu 10' increased by 11.3%, 15.5%, and 10.6%. After 7 days of Zn5 treatment, compared with CK, the SOD, POD, and CAT activities of 'Jingu 21' decreased by 17.2%, 20.4%, and 16.8%' respectively, while those of 'Zhangzagu 10' were reduced by 11.7%, 12.1%, and 12.6%' respectively (*Figs. 3-5*).

Effect of Zn on the MDA content of foxtail millet

The trend of MDA was opposite to that of the protective enzyme activity. The MDA decreased first and then increased with the increase in Zn concentration. MDA content reached minimum in Zn2 and then gradually increased until Zn4 treatment, during which the MDA content was higher than that in CK. *Figure 4* shows that the MDA content had the greatest impact during the BT stage.

Compared with CK, after 7 days of Zn2 treatment, the MDA activities of 'Jingu 21' in SL, BT, FE, and FL were decreased by 26.0%, 35.9%, 15.4% and 13.3%, respectively, while those of 'Zhangzagu10' were reduced by 14.2%, 16.7%, 11.7% and 10.7%, respectively (*Fig. 6*).

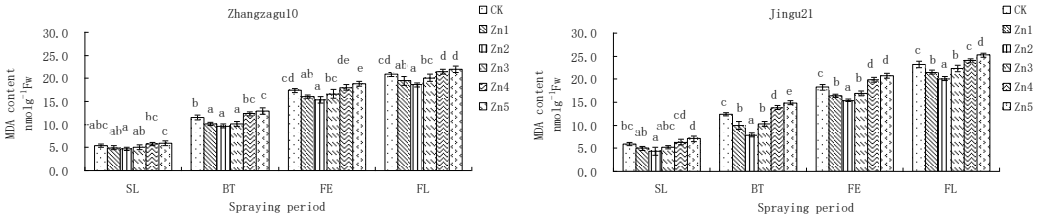

Figure 6. *Effects of Zn on the malondialdehyde (MDA) content in the leaves of 'Zhangzagu 10' and 'Jingu 21' at the different growth stages*

Effect of Zn on the pigments of foxtail millet

The average amounts of pigments in the leaves as affected by spraying period and spraying concentrations are presented in *Tables 1* and *2*. The pigment contents in the leaves of foxtail millet increased with increasing Zn concentrations until Zn2. However, the pigment contents declined at Zn4 and Zn5 treatments, and the levels were even lower than those of the CK. Although both cultivars showed similar trends in the different stages, the degrees of increase or decrease of chlorophyll contents in the cultivars were not identical. Chlorophyll a, chlorophyll b, chlorophyll, and carotenoid were most affected by Zn treatment during the BT stage.

Compared with CK, during the BT stage, after 7 days of Zn2 treatment, the chlorophyll a, chlorophyll b, chlorophyll, and carotenoid of 'Jingu 21' increased by 27.1%, 36.7%, 28.9%, and 9.7%, respectively, while those of 'Zhangzagu 10' increased by 13.3%, 27.8%, 15.9%, and 8.0%, respectively.

In addition to the carotenoid during SL of 'Jingu 21', these pigments reached significant levels. After 7 days of Zn5 treatment, compared with CK, chlorophyll a, chlorophyll b, chlorophyll, and carotenoid of 'Jingu 21' decreased by 11.6%, 31.3%, 15.3%, and 7.7%, respectively, while those of 'Zhangzagu 10' declined by 6.5%, 23.5%, 9.6%, and 6.5%, respectively. These values almost reached significant levels (*Tables 1* and *2*).

Effect of Zn on the photosynthetic gas exchange parameters of foxtail millet

After Zn treatment, the Pn, Gs, and Tr in both cultivars increased first and then decreased with the increase of Zn concentration. The change in these indices differed between cultivars and among periods (*Figs. 7-9*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81218138

Among these three indices, Zn treatment reached maximum effect in Zn2 and then gradually decreased. From the Zn4 treatment, these indices were lower than CK and reached a significant level between treatments. *Figures 7-9* show that the Zn treatment of the two millet varieties was most obvious during BT.

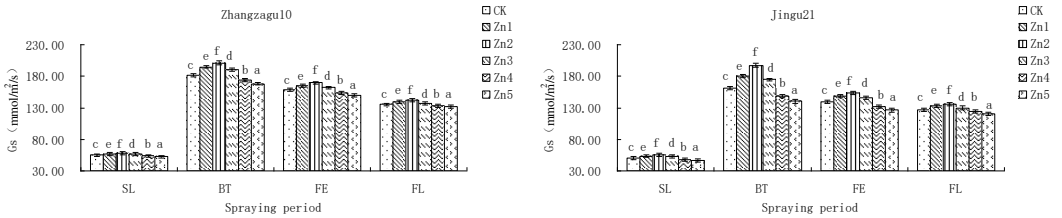

Figure 8. *Effects of Zn on stomatal conductance (Gs) in the leaves of 'Zhangzagu 10' and 'Jingu 21' at the different growth stages*

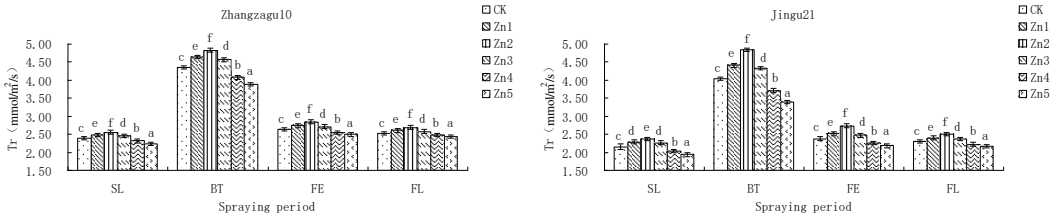

Figure 9. *Effects of Zn on transpiration rate (Tr) in the leaves of 'Zhangzagu 10' and 'Jingu 21' at the different growth stages*

During the BT stage, compared with CK, after 7 days of Zn2 treatment, the Pn, Gs, and Tr of 'Jingu 21' increased by 33.1%, 22.4%, and 20.0%, respectively, while those of 'Zhangzagu 10' increased by 19.9%, 10.5%, and 10.7%, respectively. After 7 days of Zn5 treatment, compared with CK, the Pn, Gs, and Tr of 'Jingu 21' decreased by 19.1%, 13.1%, and 16.0%, respectively, while those of 'Zhangzagu 10' declined by 14.6%, 7.7%, and 11.1%, respectively (*Figs. 7-9*).

As the Zn concentration increased, Ci decreased first and then increased, which was opposite to the trend of Pn. Among the different Zn treatments for the same period, the reduction of Zn2 treatment was the most obvious. *Figure 8* shows that, after Zn treatment, Ci had the greatest impact during the BT stage.

Compared with the control, after 7 days of Zn2 treatment, the Ci of 'Jingu 21' during SL, BT, FE, and FL decreased by 16.9%, 23.7%, 18.3%, and 13.8% respectively, while those of 'Zhangzagu 10' declined by 11.2%, 16.4%, 13.7%, and 9.5%, respectively (*Fig. 10*). During BT, the Ci of Jingu 21 was as follows: Zn5 > Zn4 > CK > Zn3 > Zn2 > Zn1. 'Zhangzagu 10' had the same trend. Although 'Zhangzagu 10' and 'Jingu 21' showed similar trends in the different concentrations, the degrees of increase or decrease in Ci for the cultivars were not same.

Values are mean ± SE (n = 3). Different letters in the same column indicate significant difference at the $P < 0.05$ level by Duncan's new multiple range test. SL, BT, FE, and FL represent the seedling, booting, flowering, and filling stages, respectively

Effect of Zn on the chlorophyll fluorescence parameters of foxtail millet

Tables 3 and *4* show that the chlorophyll fluorescence parameters of foxtail millet increased with increasing Zn concentrations until Zn2. Then, at the Zn4 and Zn5 treatments, the chlorophyll fluorescence parameters declined, even lower than those at CK, except the values of qN. These indicators showed the greatest impact on millet during BT and had greater effect on 'Jingu 21' than 'Zhangzagu 10'.

During BT, compared with CK, after 7 days of Zn2 treatment, the Fo, Fm, Fv/Fm, and Fv/Fo of 'Jingu 21' increased by 5.5%, 42.5%, 11.4%, and 50.4%, respectively, while those of 'Zhangzagu 10' increased by 4.9%, 27.6%, 7.6%, and 30.9%, respectively. After 7 days of Zn5 treatment, compared with CK, the Fo, Fm, Fv/Fm, and Fv/Fo of 'Jingu 21' decreased by 6.7%, 18.5%, 6.4%, and 18.3%, respectively, while those of 'Zhangzagu 10' declined by 5.2%, 13.9%, 4.3% and 13.1%, respectively (*Tables 3* and *4*).

Values are mean ± SE (n = 3). Different letters in the same column indicate significant difference at the $P < 0.05$ level by Duncan's new multiple range test. SL, BT, FE, and FL represent the seedling, booting, flowering, and filling stages, respectively

Compared with the CK, during the BT stage, after 7 days of Zn2 treatment, the Y2, ETR, and qP of 'Jingu 21' increased by 30.9%, 17.8%, and 23.1%, respectively, while those of 'Zhangzagu 10' increased by 15.0%, 9.9%, and 15.5%, respectively. After 7 days of Zn5 treatment, compared with those at CK, the Y2, ETR, and qP of 'Jingu 21' decreased by 25.8%, 10.2%, and 17.5%, respectively, while those of 'Zhangzagu 10' declined by 12.8%, 8.1%, and 15.2%, respectively (*Tables 3* and *4*).

After Zn treatment, the qN in both cultivars increased first and then decreased with increase in Zn concentration, and the level of change differed between cultivars and among periods, which was opposite to the trend of qP. In this index, the Zn treatment of the same cultivars reached the minimum effect in Zn2 and gradually increased. The levels of both cultivars from the Zn4 treatment were both lower than those in CK and reached significant levels with each treatment. *Tables 3* and *4* show that Zn treatment of the two millet varieties was most obvious during the BT stage.

Compared with CK, after 7 days of Zn2 treatment, the qN of 'Jingu 21' during SL, BT, FE, and FL decreased by 20.6%, 33.5%, 28.6%, and 13.7% respectively, while

DOI: http://dx.doi.org/10.15666/aeer/1704_81218138

those of 'Zhangzagu 10' declined by 14.2%, 28.4%, 16.6%, and 10.0%, respectively (*Tables 3* and *4*). During the BT stage, the qP of 'Jingu 21' was as follows: Zn5 > Zn4 > CK > Zn3 > Zn2 > Zn1, and 'Zhangzagu 10' showed a similar trend.

Table 4. *Effects of Zn on the chlorophyll fluorescence parameters of 'Jingu 21' at the different growth stages*

Discussion

Effects of Zn on the physiological characteristics

Although Zn is a micronutrient necessary for photosynthesis and plant growth at low concentration, Zn becomes toxic when its concentration reaches a threshold level (Cunha et al., 2008; Lin and Aarts, 2012). Jat et al. (2007) reported that Zn activates several antioxidant enzymes, such as SOD, POD, and CAT. Saeed et al. reported that SOD, POD, and CAT and free radical scavenging activities in cut-flowers remained maximum with the medium dose of Zn (6 mg Zn kg^{-1}). Thus, Zn applied at 6-8 mg kg^{-1} imparted greater beneficial effects on growth, production, vase life quality, and antioxidative activities in gladiolus cut flower and further higher application rates

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81218138

rendered non-significant improvement (Tariq et al., 2013). In this study, 40 $mg \cdot L^{-1}$ of $ZnSO_4 \cdot 7H_2O$ significantly increased the SOD, POD, and CAT activities of 'Jingu 21' and 'Zhangzagu 10' at different stages. However, 80 $mg \cdot L^{-1}$ of $ZnSO_4 \cdot 7H_2O$ resulted in SOD, POD, and CAT activities lower than those of CK (*Figs. 3-5*). Moreover, 40 $mg \cdot L^{-1}$ of $ZnSO_4 \cdot 7H_2O$ significantly decreased the MDA content, but 80 $mg \cdot L^{-1}$ of $ZnSO_4 \cdot 7H_2O$ increased the MDA content higher than that of CK (*Fig. 6*).

Zn plays an important role in the anti-lipid peroxidation of millet. The suitable Zn concentration can alleviate the peroxidation of membrane lipids and improve the antioxidant activity of foxtail millet (Kakade et al., 2009; Maurya and Kumar, 2014; Hajiboland and Beiramzadeh, 2008). Therefore, the application of a suitable concentration of Zn to foxtail millet will help improve its resistance to stress. The mechanism of the effect of Zn on energy metabolism needs further study.

Effects of Zn on pigments

Pigment is the most important part of photosynthesis. This parameter can reflect the ability of plant light energy conversion to a certain extent, and it will also protect the normal operation of photosynthetic apparatus to some extent (Nouet et al., 2011). The main factors in the pigments are chlorophyll and carotenoids, and Zn can prevent the oxidation of pigments (Cakmak 2000; Cherif et al., 2010). Pongrac et al. (2009) reported that an appropriate amount of Zn can increase the chlorophyll content of leaves, but excessive Zn reduces the chlorophyll content of leaves. This experiment shows that low concentration of Zn can increase the pigment content, while high concentration treatment will inhibit the pigment content. In 'Jingu 21', the pigment content was as follows Zn2 > Zn1 > Zn3 > CK > Zn4 > Zn5, and 'Zhangzagu 10' showed a similar trend (*Tables 1* and *2*). Excessive Zn affected the growth of the seedlings, causing a significant decrease in photosynthetic pigment content and yellowing of the leaves. This phenomenon may be due to the antagonistic effect of Zn and iron metabolism in plants, and the excessive Zn content inhibited the absorption of iron by plants (Wirén et al., 1996). Thus, an appropriate amount of Zn concentration can effectively increase the pigment content of the leaves (Kumar and Arora, 2000) and delay the rapid senescence of the foxtail millet.

Effects of photosynthetic gas exchange parameters

Photosynthesis plays a very important role in plants. This process is the source of plant yield, which is related to plant growth and development. This process involves photoreaction and carbon reaction to convert carbon dioxide and water into organic matter and oxygen, which are the basis for plant survival (Baron et al., 1995; Yruela, 2005). The Pn, Gs, Tr, and Ci are important indicators to affect the photosynthesis. Fernàndez-Martínez et al. (2014) reported that the photoprotective and antioxidant responses were enhanced with increasing Zn concentration, but high Zn concentration produced high toxicity levels for both clones and resulted in impaired biomass production, photochemical processes, and photosynthesis. The results showed that Zn treatment could increase Pn, Gs, and Tr and reached maximum levels in Zn2, gradually decreased. From the Zn4 treatment, these three indices were both lower than those at CK, but Ci showed an opposite trend of Pn (*Figs. 7-10*). Although the trends are similar at all times, but the degrees of increase or decrease were not the same. In summary, Zn had a regulatory effect on plant photosynthesis and exhibits different effects depending

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81218138

on the application concentration, period, and crop type (Sidhu, 2016; Camargo Gai et al., 2017).

Effects of chlorophyll fluorescence parameters

The chlorophyll fluorescence parameter is a set of variables or constant values used to describe the photosynthesis mechanism and photosynthetic physiological state of plants. This parameter reflects the "inherent" characteristics of plants and regarded as an intrinsic probe to study the relationship between plant photosynthesis and environment (Lahive et al., 2012). Information on the donor side, receptor side, and reaction center of PSII can be obtained using the chlorophyll fluorescence induction kinetics curve (Appenroth et al., 2001; Wen et al., 2002). Fv/Fm represents the primary light energy conversion efficiency of PSII. Previous studies suggested that Fv/Fm is a sensitive indicator of plant photoinhibition under stress conditions. This ratio is a measure of the maximum ability of primary light energy capture, reflecting the potential maximum photosynthetic abilities of plants (Krivosheeva et al., 1996). Fv/Fo represents the potential activity of PSII, which is more sensitive in reflecting changes in photon conversion efficiency during leaf senescence (Krivosheeva et al., 1996). In this study, the Fv/Fm and Fv/Fo values increased first and then decreased with the change in Zn concentration, indicating that low Zn concentration can enhance photosynthesis, but high Zn concentration can cause photoinhibition of foxtail millet or damage PSII complex. Y2 reflects the quantum conversion efficiency of photosynthetic electron transport and is the efficiency of PSII light energy capture in case of PSII reaction center shutdown (Longstaff et al., 2002). ETR reflects the apparent electron transfer efficiency under actual light intensity conditions (Longstaff et al., 2002). The results of this experiment indicate that as the Zn concentration increases, Y2 and ETR increased and then decreased. This phenomenon indicated that the low Zn concentration can enhance photosynthesis, but high Zn concentration inhibition of photosynthesis decreased the actual quantum yield of the PSII photosynthetic reaction center (*Tables 3* and *4*).

Photochemical quenching (qP) reflects the quantity of light energy absorbed by the PSII antenna pigment for photochemical electron transport. This parameter is a measure of the oxidation state of the original electron acceptor (QA). This parameter represents the proportion of the open part of the PSII reaction center, which can reflect the electron transfer rate of the electron photosynthetic chain and its efficiency in CO_2 fixation (Mu et al., 2016). Under the experimental conditions, 40 $mg \cdot L^{-1}$ of $ZnSO_4 \cdot 7H_2O$ significantly increased the qP of 'Jingu 21' and 'Zhangzagu 10' in different stages. However, from 80 $mg \cdot L^{-1}$ of $ZnSO_4 \cdot 7H_2O$, the qP was lower than that of the control (*Tables 3* and *4*). This result indicated that the low Zn concentration strengthened the electron transfer activity of PSII, while high Zn concentration decreased the open part of the PSII reaction center, which hindered the photosynthetic electron transfer. The parameter qN reflects the portion of the light energy dissipated in the form of heat that cannot be used for photosynthetic electron transport in the light absorbed by the PSII antenna (Mu et al., 2016; Mikulic and Beardall, 2014). The results showed that qN increased first and then decreased with the increase in Zn concentration. This parameter indicated that Zn concentration had an inhibitory effect on the heat loss of millet light energy. This process is beneficial to the accumulation of dry matter in foxtail millet.

DOI: http://dx.doi.org/10.15666/aeer/1704_81218138

Conclusions

In summary, low Zn concentration could promote plant growth and enhance plant antioxidant capacity and photosynthesis. However, high Zn concentration inhibited plant growth and leaf photosynthesis. 'Jingu 21' changed more than 'Zhangzagu10'. The combination of optimal Zn spraying period and spraying concentration for the foxtail millet growth was BT and 40 $mg \cdot L^{-1}$ of Zn. Thus, a theoretical basis for the safe application of Zn fertilizer on foxtail millet is provided.

The study did not test a larger number of genotypes cultivars and more soil fertility conditions because of the limited experimental conditions. The numbers of test materials and test sites were not sufficiently comprehensive. Multiple materials, multiple points, and multiple years of tests are required to provide a clear direction for the subsequent research.

(Received 13th Feb 2019; accepted 29th Mar 2019)

Abstract. A 42-day study was designed to determine the mineral composition of *Moringa oleifera* leaf meal (MOLM) and the response of Ross 308 broilers to dietary MOLM supplementation. Day-old Ross 308 broiler chicks (n = 500) were allotted to five treatments in completely randomized design with each group replicated five times with each replicate having 20 chicks. Birds received diets supplemented with MOLM at 0, 25, 50, 75 and 100 g/kg feed, respectively and assigned T1, T2, T3, T4 and T5. MOLM level that supported optimum variables was modelled using the quadratic function. At day 42, three birds per replicate were slaughtered to evaluate carcass and organ yields. Results of mineral assay indicate that MOLM was high in calcium, sodium, potassium, sulphur and iron. Daily feed intake (FI), average daily gain (ADG) and feed conversion ratio were the same among the groups with the exception of starter broilers on diet T1 that had higher ADG ($p < 0.05$) than those on the other diets. Final live weight (FLW), mortality and gizzard weight were influenced ($p < 0.05$) by MOLM supplementation. MOLM supplementation had no effect on other parameters measured. MOLM supplementation at 39.98 and 35.80 g/kg feed supported optimum FLW and ADG at starter phase and 46.88 g/kg feed MOLM supported optimum FLW at finisher phase. In conclusion, MOLM is a good source of nutrients and suitable for production of enhanced cut parts in broiler chickens.
Keyword: *alternative feedstuffs, broilers, optimization, production outputs, South Africa*

Introduction

The development of the broiler industry as a means of bridging the food and nutrition insecurity gap in most countries has been attracting great attention (Dieye et al., 2010). Unfortunately, the growth of the broiler sector in most developing countries are constrained by the spiralling feed cost due to rising prices of feed ingredients particularly protein supplements (Abbas, 2013). This spiralling feed cost is having negative impacts on the feed supply chain as well as the quality of the compounded rations. This rising price of feeds has been partly attributed to the competition between humans and animals for protein and energy concentrates. Therefore, it has become imperative that the potential of alternative protein feedstuffs that are not in direct competition with humans be fully harnessed in broiler nutrition (Ogbuewu et al., 2015, 2019). One of the best-suited alternative plant protein feed raw material for broiler feeding in the developing countries is the leaf of Moringa plant.

Moringa oleifera belongs to the family Moringaceae and thrives well during severe drought and heat. *Moringa oleifera* is one of commonest specie among the 14 species in the family and grows to a height of 7–12 m. It is native to India, but thrive well in the tropics (Nsofor et al., 2012). The leaves of moringa plant are high in essential amino acids, protein, minerals, vitamin A and fibre (Ustundag and Ozdogan, 2015) and could

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81398150

be incorporated in broiler feed. In addition, *M. oleifera* leaf meal contains 2.4% ether extract, 25.4% crude protein, 17.4% crude fibre and 5.9% ash (Alnidawi et al., 2016) as against 18.8% ether extract, 42.8% crude protein, 20% crude fibre and 5.5% ash in (Banaszkiewicz, 2000). *Moringa oleifera* leaf therefore is lower in protein than soybean but much higher in ash (minerals) value thus supporting the earlier reports of Ustundag and Ozdogan (2015) that *M. oleifera* leaf can partially substitute soybean and fishmeal in broiler rations without negative impacts of production data while lessening the prize of feed (Ebenebe et al., 2012). In addition, research has established that *M. oleifera* leaves are abundant in water and fat-soluble vitamins as well as lutein and β-carotene (Igwilo et al., 2014; Saini et al., 2014). Evidence also exists that *M. oleifera* leaf is a storehouse for a variety of essential bioactive elements such as saponins, flavonoids, and phenols among others (Saini et al., 2016).

Feeding trial conducted by Kakengi et al. (2007) in chickens fed *M. oleifera* leaf meal revealed enhanced feed and dry matter intake hence showing the palatability of the *M. oleifera* leaf meal based diets to the chickens. In view of this observation, other authors (Onu and Aniebo, 2011; Onunkwo and George, 2015) fed broilers diet containing 10% MOLM and noticed to boost feed utilization and weight gain in comparison with birds fed 0% MOLM. In experiment conducted in native chickens, Gadzirayi et al. (2012) observed reduced feed consumption and enhanced growth rate in birds that received MOLM at 5% as a substitute for soybean meal (SBM) when compared with the group fed SBM alone as the main protein source. Increased egg production and egg mass in laying hens fed 20% MOLM has been documented (Kakengi et al., 2007). Also, improved growth rate and blood constituents in goats and fish fed MOLM have been reported (Paul et al., 2013; Jiwuba et al., 2017).

Several publications have been documented on the use of Moringa leaves as a feed resource for livestock and poultry (Gadzirayi et al., 2012; Paul et al., 2013; Onunkwo and George, 2015; Jiwuba et al., 2017). However, there is no comprehensive data on the mineral assay of moringa leaves and such knowledge will allow farmers to optimize the nutritional value of this plant in animal production. Hence, it has become important to investigate the mineral constituents of leaf meal of *Moringa oleifera* plant and their influence on the production characteristics of meat typed chickens. The objectives of this feeding trial therefore, was to determine the mineral content of *M. oleifera* leaf meal and the effect of its supplementation on production physiology of Ross 308 broilers. The *M. oleifera* leaf meal supplementation level that supported optimum performance in Ross 308 broilers were also reported.

Materials and methods

Study site and preparation of Moringa oleifera leaf meal

The study was performed in a private broiler farm located at Plot 519 Zuurbekom, Gauteng province, South Africa in the months of December 2017 to January 2018. Gauteng province is located at the Highveld of South Africa and lies between latitude 26° 11' 42.8856" S and longitude 28° 2' 2.716" E. Fresh and tender leaves of *M. oleifera* were harvested in Grootfontein, a village near Polokwane in Limpopo province of South Africa and air-dried for 3-5 days to a moisture level of about 10%. Thereafter, the dried leaves were milled and stored in unused feedbags for determination of mineral content and diet formulation.

DOI: http://dx.doi.org/10.15666/aeer/1704_81398150

Mineral analysis

The mineral values were determined in triplicates in the Department of Animal Science Laboratory, North-West University-Mafikeng Campus, South Africa as described by AOAC (2000). The mineral constituents determined were calcium (Ca), phosphorus (P), potassium (K), magnesium (Mg), sodium (Na), sulphur (S), iron (Fe), chromium (Cr) and manganese (Mn).

Experimental procedures

Day-old Ross 308 broiler chicks (n = 500) were allotted to five treatments in completely randomized design with five replications with each replicate having 20 chicks. Birds received commercial mash diets (*Table 1*) supplemented with MOLM at 0, 25, 50, 75 and 100 g/kg feed, respectively and tagged T1, T2, T3, T4 and T5. Birds were procured from the National Chicks' Hatcheries located in the Boschkop area of East of Pretoria, Gauteng province, South Africa. The floor of each pen was swept, scrubbed with a strong brush, thereafter cleaned with water and later disinfected with Virkon® S. Pens were left open for several days after cleaning with Virkon® S as to break the breeding cycle of the pathogens that may have escaped the actions of the disinfectant. The floor of each of the pen was covered to a depth of 7 cm with fresh sawdust under a deep litter management system. The drinkers, feeders, and accessories were assembled and carefully positioned 7 days before the chicks arrived. In addition, pens were heated for 24 h via an infrared light before the chicks arrived. The starter diet (21.0% crude protein) and grower diet (19.0% crude protein) were formulated according to NRC (1994) standard to meet the nutrient requirements of the experimental birds. Feed and water were offered ad libitum and the investigation lasted for 42 days. All the biosecurity measures conformed to the rules and guidelines of the Ethics Committee of the University of South Africa and the South African Animal Disease Act 35, of 1984.

Table 1. *Nutrient content of the diets used in the experiment*

Nutrient* (%)	Starter (0-21 days)	Grower (22–42 days)
Crude protein	21.0	19.0
Lysine	1.30	1.15
Methionine	0.58	0.5
Moisture	12.0	12.0
Fat	2.5	2.5
Fibre	5.0	6.0
Calcium	1.2	1.2
Phosphorus	0.6	0.55

*As illustrated in feed label

Data collection

The initial live weights (LWs) of broiler chicks in each pen were taken at the beginning of the study and weekly thereafter to obtain the weekly LW and weight difference. The mean LW of birds on each pen was determined by dividing total LW by the number of birds in the pen. Feed consumption was determined by subtracting the leftover feed in the feeding trough the following morning from the quantities of feed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81398150

offered daily to the birds. Average daily gain in each pen was computed as the quotients of the LW at the end of the study less the live weights at the start of the study and the period the investigation lasted. Feed conversion ratio (FCR) was determined as the quotient of FI and ADG. At 42 days, 15 birds were chosen from each treatment, denied of feed for 12 h and thereafter, slaughtered to assess the carcass and organ weights. The carcass, organ and cut parts were weighed and expressed as a percentage of the live weight and carcass weight respectively following the procedures of Chukwukaelo et al. (2018).

Data analysis

Data collected were subjected to one-way analysis of variance (ANOVA), and differences in means where significant F-test ($p < 0.05$), Duncan's multiple range test (Duncan, 1955) method was used to separate the means (SPSS 24.0 package). The supplementation related responses in growth and production parameters to MOLM in Ross 308 broilers were modeled using the following quadratic optimization equation:

$$Y = a + b_1x + b_2x^2$$

where Y = growth indices (LW, FI, ADG, FCR and mortality), carcass, dressing percent, cut parts (breast, thigh and drumstick) or organ (liver, heart and gizzard) weight; a = the Y intercept; b = coefficient of quadratic optimization equation; x = MOLM supplementation levels and $-b_1 / 2b_2 = x$ value for optimum response. The quadratic equation was fitted to the experimental data by means of the nonlinear model procedure of SPSS 24.0. The choice of the quadratic regression model is because it fitted the model and the probability level for significance is 5%.

Results

Nutrient composition of experimental diet and MOLM

The results of the nutrient content of the treatment diets are shown in *Table 1*. The crude protein levels were 21.0% for the starter mash and 19.0% for the grower mash. *Table 2* presents the mineral composition of MOLM. The mineral content of the MOLM contains appreciable levels of beneficial minerals, including calcium, phosphorus, magnesium, sodium, potassium, iron, sulphur, chromium and manganese showing that MOLM is a source of mineral for livestock. The coefficient of variation (CV) values across sample measurements for the minerals were higher and ranged from 61.35–81.70%.

Growth performance of starter broilers

Table 3 presents the growth indices of starter Ross 308 broilers fed with diets supplemented with varying levels of MOLM. Broilers fed diet T1 recorded the highest FLW of 833 g, which was significantly different from birds on diets supplemented with MOLM at 25, 50, 75 and 100 g/kg feed. ILW and DFI had similar ($p > 0.05$) value in the groups. ADG decreased ($p < 0.05$) steadily with increasing supplementation levels of MOLM. Birds on diet T1 (0 g MOLM/kg feed) had better FCR when compared with birds that received diets supplemented with MOLM at 25, 50, 75 and 100 g/kg feed,

DOI: http://dx.doi.org/10.15666/aeer/1704_81398150

however, the difference was not significant ($p > 0.05$). Mortality rate was significantly ($p < 0.05$) higher for birds on diet T1 when compared with birds fed the other four diets.

Table 2. *Macro and micro mineral composition of MOLM (mg/kg)*

Parameters	Mean ± SD	CV (%)
Calcium	2687.41 ± 188.68	70.20
Phosphorus	120.73 ± 8.68	71.85
Magnesium	250.00 ± 17.88	71.51
Sodium	968.02 ± 6.03	62.32
Potassium	734.59 ± 45.10	61.35
Iron	316.98 ± 31.68	73.73
Sulphur	1144.09 ± 87.52	76.44

Growth performance of finisher broilers

The result of growth indices of finisher Ross 308 broilers fed with diets supplemented with varying levels of MOLM as shown in *Table 4*. Higher FLW ($p > 0.05$) was reported control birds fed MOLM at 0 g/kg feed than those fed diets supplemented with MOLM at 25, 50, 75 and 100 g/kg feed. Broilers fed MOLM supplemented diet at 0, 25, 50 and 100 g/kg feed had comparable ($p > 0.05$) ILW, DFI, and ADG values. Birds fed MOLM supplemented diet at 75 g/kg feed had the best FCR, although the difference was not significant ($p > 0.05$) compared with the groups fed the other four diets. Birds on 0 g/kg feed MOLM had the highest mortality ($p < 0.05$) when compared to the birds supplemented with 25, 50, 75 and 100 g/kg feed MOLM.

Relative carcass and organ weight of finisher broilers

The performance in terms of the relative weights of the carcass and organs are presented in *Table 5.* Birds fed diet with MOLM at 0 g/kg feed had higher live weight ($p < 0.05$) than those on diets supplemented with MOLM at 25, 50, 75 and 100 g/kg feed. Birds on diet with MOLM at 0 g/kg feed had higher non-significant ($p > 0.05$) carcass weight than those on diets with MOLM at 25, 50, 75 and 100 g/kg feed. Although, broilers on diets with MOLM at 75 g/kg feed returned the highest non-significant dressing percent ($p > 0.05$) relative to the birds on the other four diets. Cut parts and organ weights of broilers fed MOLM supplemented diets at 25, 50, 75 and 100 g/kg feed had the same values.

Table 5. *Relative carcass and organ weight values of finisher broilers fed MOLM supplemented diets*

Optimization functions

The results of the effect MOLM supplementation on FLW and ADG in Ross 308 broilers are presented in *Tables 6* and *7*. FLW and ADG were optimized at 2538.4 – 173.97 MOLM + 21.756 $MOLM^2$, $r^2 = 0.8994$ and 79.334 – 5.8806 MOLM + 0.8214 $MOLM^2$, $r^2 = 0.8960$ respectively in starter broilers while FLW was optimized at 3173.7 – 200.36 MOLM + 21.371 $MOLM^2$, $r^2 = 0.9928$ in finisher broilers.

Table 6. *Quadratic analysis of the effect of MOLM on FLW and ADG in starter broilers*

Variables	Formula	r^2	x-value	y-value	P-value
FLW	$Y = 2538.4 – 173.97x + 21.756x^2$	0.8994	39.98	2190.63	0.0100
ADG	$Y = 79.334 – 5.8806x + 0.8214x^2$	0.8960	35.80	68.81	0.0200

Table 7. *Quadratic analysis of the effect of MOLM on FLW in finisher broilers*

Variable	Formula	r^2	x-value	y-value	P-value
FLW	$Y = 3173.7 – 200.36x + 21.371x^2$	0.9928	46.88	2704.09	0.0384

Discussion

The objective of this feeding investigation was to determine the responses of Ross 308 broilers to commercial diets (starter and grower) mash supplemented with varying levels of MOLM. The starter diet contained crude protein level of 21.0% while grower contained crude protein level of 19.0% with similar levels of other essential nutrients that satisfied the bird's nutrient demands as endorsed by NRC (1994) for poultry.

Minerals are vital in poultry nutrition because they serve as cofactors for several biological processes. Calcium, an important mineral for bone growth, muscle, and neurological functions are high in MOLM with the order of macro mineral level being calcium (2687.41 mg/kg) > sodium (968.02 mg/kg) > potassium (734.59 mg/kg) > magnesium (250.00 mg/kg) > phosphorus (120.73 mg/kg) as determined in the current study. These observations are in harmony to the value recorded by Sena et al. (1998). Furthermore, the calcium, potassium, magnesium and phosphorus values determined herein were lower in general than the corresponding values of 16046.7, 17450, 2833.8 and 4827.4 mg/kg published by Olson et al. (2016) in Mexico. Freiberger et al. (1998) and Yaméogo et al. (2011) have noticed a higher calcium value (14,400 to 35,126 mg/kg) than the value determined in this experiment, and is therefore not clear what is responsible for this wide difference. Noteworthy too was the fact that the sodium content (117.4 mg/kg) reported by Olson et al. (2016) was about 99% units lower to what was determined in this experiment. These variations may be associated with such factors as soil composition, agro climatic condition, plant age and stage of maturity of the leaves, digestion protocols and analyzing techniques used as observed by Melesse et al. (2012) and Mbah et al. (2012). Phosphorus is another important macro mineral needed for rapid bone growth in meat-typed chickens. Such rapid bone growth requires adequate calcium and phosphorus supply (Williams et al., 2000).

Inadequate supply of both or one of the minerals as a result of the deficiency or excess of one of them interferes with homeostasis of the second one (Kebreab and Vitti, 2005), resulting in reduced growth rate and bone mineralization (Hurwitz et al., 1995).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81398150

The analysed leaf meal contained small amounts of phosphorus; however, this was not a problem since the leaves were used as protein supplement for broilers. The study plant also contains appreciable quantities of iron and sulphur. This high iron content could explain the improved blood values in chickens fed MOLM based diets (Ustundag and Ozdogan, 2015; Alnidawi et al., 2016) since they are needed for haemoglobin formation. Noteworthy is that MOLM has moderate potential as a good source of dietary minerals (calcium, potassium, sodium, iron, and sulphur) in animal nutrition. High sulphur content (1144.09 mg/kg) recorded in the current study for MOLM was in agreement with Lyon et al. (2017) who reported that *Moringa oleifera* tree has an exceptional power to take up and store in the leaves mineral sulphur, even when grown on soils with low in sulphur. The health and medical benefits of this finding is that MOLM may be used to enhance productivity in animals fed low sulphur diets. The coefficient of variation of mean mineral values as observed in the current study was high, thus suggesting that the means could not serve as reference mineral value for MOLM in the study location.

The results reveal that the final live weight of starter broilers on the control birds was significantly higher than the groups on diets supplemented with MOLM at 25, 50, 75 and 100 g/kg feed, but lower than the reference live weight of 929 g recorded for 21-day-old unsexed Ross 308 broilers (www.aviagen.com). Factors such as enhanced nutrition and improved housing conditions may have explained the observed disparity in starter phase. The present result showed that MOLM supplementation up to the rate of 100 g/kg feed showed no adverse influence on feed consumption. This compared favourably with the result of Divya et al. (2014) who also noticed non-significantly reduced feed intakes in broilers fed *Moringa oleifera* leaf meal based rations. This finding indicate that the level of MOLM supplemented in the current study is acceptable to the birds. However, the reason for the acceptability is not known. Although, one possible reason is anti-nutritional factors as similarly observed by Makkar and Becker (1996). The non-significant reduction in average daily gain as observed for birds fed MOLM supplemented diets in the current feeding investigation was similar to value recorded in broilers by Divya et al. (2014). There was no significant MOLM effects on feed to gain ratio in the present feeding investigation. The result of the percentage mortality revealed that MOLM supplementation significantly influenced mortality rate ($p < 0.05$) with birds on control experiencing the highest rate. Mortality was significantly low in treatment groups relative to the control group and this observation may be because of high levels of phytochemical compounds in moringa leaves, which have been reported to have medicinal and pharmacological property such as antiprotozoal, antibacterial and antifungal effect as well as immune stimulating actions in animals (Sharma and Paliwal, 2013). Furtherance to this, the coefficient of variation of mean growth performance values were small, indicating that the reported means could be used as reference value for broilers fed diets with varying supplementation levels of MOLM in the study location.

The non-significant carcass weight and dressing percent at 25, 50, 75 and 100 g/kg feed supplementation rates can be attributed to high quality of the MOLM supplemented diets and enhanced nutrient utilisation by the broilers (Hassan et al., 2016). The result of the weights of breast, drumstick and thigh suggested that MOLM supplementation positively influenced the development of the cut parts but did not maintain progressive pattern, which is in agreement with the earlier findings published by Hassan et al. (2016). This observation has shown the suitability of MOLM

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81398150

supplemented diets for enhanced cut parts development and production in broilers and therefore may be recommended for broiler production. The slight enlargement on the size of the liver of broilers fed MOLM supplemented diets at 25–100 g/kg feed could be linked to enhanced activity of this organ in a bid to detoxify the antinutritional factors that may be present in the experimental diet (Igwilo et al., 2007). The weight of gizzard at 25 and 100 g/kg feed was significantly increased and this corroborated with works of Ayssiwede et al. (2011), who recorded higher gizzard weights in indigenous chickens fed MOLM based diets. In addition, the coefficient of variation of mean carcass and organ parts were narrow, suggesting that the means could serve as standard value for Ross 308 broilers fed MOLM supplemented diets in the study region.

The results of the quadratic function showed that no single MOLM supplementation level optimized FLW and ADG in the current feeding experiment. The quadratic function showed that all the significant parameters had very high (89.6–99.3%) coefficients of determination (r^2). Handful of studies has used a quadratic model to ascertain the optimal levels of feed that supported optimum performance variables in chickens (Okoro et al., 2016 a, b). However, information on the use of quadratic analysis to determining the MOLM supplementation level that supported optimum production parameters in Ross 308 broilers is lacking in the literature. The results of the quadratic function in the current study corroborate the results of Okoro et al. (2016a, b) who observed that no single feed inclusion level optimized all production parameters in chickens. The results of this feeding experiment revealed that for starter broilers, FLW and ADG was statistically optimized at 39.98 and 35.80 g/kg feed respectively. However, the value of 39.98 g/kg feed MOLM that optimized final live weight at the starter phase was 6.9 g/kg lower than the value of 46.88 g/kg that optimized the final live weight at the finisher phase. The observed difference is expected since the starter diet was high in protein (21.0%) than the finisher diet (19.0%), thus the birds on the starter phase will tend to take less diet to meet their daily protein requirements when supplemented with MOLM which are reported to contains 25.4–42.8% crude protein by Banaszkiewicz (2000) and Alnidawi et al. (2016). The high r^2 value recorded for the FLW and ADG revealed the high strength of relationship of the two variables using the quadratic analysis. These observations have practical application when supplementing diets with MOLM for FLW and ADG in Ross 308 broilers as to reduce the wastage of feed supplements. The significant optimization influence on FLW and ADG n implied that their values could be predicted at a given quantity of MOLM supplemented in the broiler diet.

Conclusion

The information provided in the current investigation further support the potential of *Moringa oleifera* leaves as an alternative non-conventional protein feed resource in broiler chicken diets. Importantly, this is useful for smallholder poultry farmers who are compelled by the high prices of conventional protein feed resource such as soybean meal to rely on such alternative protein source for enhancing the productivity of their animals. In addition, *Moringa oleifera* leaves are good sources of minerals and is suitable for cut parts development and production of enhanced cut parts in the broiler chickens. It is therefore, recommended that supplementation rate of 100 g/kg feed MOLM may be well accepted by the Ross 308 broiler chickens.

(Received 13th Feb 2019; accepted 24th May 2019)

Abstract. In this article, the response of surface water quality to land use/land cover changes studied. We investigate the impact of land use changes on quality of water during three decades in the Razavi Khorasan Province of Iran. Detecting of LULC changes has done using Landsat satellite images belonging to the years 1987 (TM), 2001 (ETM^+) and 2015 (OLI). In the study area based on RS and GIS standard techniques, sixteen land use classes were defined: barren, rocky, residential, swamp, water, dunes, salt marsh, irrigated cultivation, garden, dry farming, desert, good rangeland, medium rangeland, poor rangeland, wooded rangeland, and watercourse. Also, the water quality data from 1987 to 2015 in the stream gauge station located at the outlet of the 36 catchments analyzed. In this study, 13 parameters included K, Cl, Ca, Mg, Na, CO_3, HCO_3, SO_4, EC, pH, TDS, SAR, and Hardness investigated. After removing variance, non-parametric tests performed and trends of water quality variables in the time series evaluated. Then, using a multivariate linear regression model was trying to link water quality variables to land use changes. Results demonstrated that the models estimate water quality parameters with an acceptable degree of accuracy (P-value < 0.05) except calcium, potassium, carbonate, and bicarbonate. The results showed the relationship between land use and the water quality indicators that can be applied in environmental protection and land use planning.

Introduction

Ecological and human health directly affect by water attribute and for this reason, the quality of water is as important as its quantity (Zamani et al., 2013). In the past few decades, surface water characteristics deteriorated in numerous countries. The major environmental worry is the deterioration of stream water quality due to unsustainable activities of human (Chen and Lu, 2014). Also, the quality of water is momentous to assess the health of a watershed and to make necessary management decisions to control current and future pollution (Walling and Fang, 2003). Water carries the particles from the land, as flows from the land surface and be enriched with different kinds of contaminants when flows from various types of land use (Tong, 1990). Rivers are vulnerable to land use and land cover (LULC) change and ubiquitous exploitation (Withers and Jarvie, 2008; Vörösmarty et al., 2010) and comprehending the relationship between land use and surface water quality is essential for effective water management (Ding et al., 2015).

Watershed is a topographic region of natural space that encompasses the correlation of water, its physical appearance, along with the related movement of elements connected with water resources usage. Thus, the best unit for water-related research at the regional scale is catchment (Li et al., 2012). The relevance between the quality of water in rivers and land use, despite its significance for the watershed, is not well described (Ding et al., 2016). Many studies derived that a significant relationship exists

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81518169

between the water quality parameters and land use and land cover at a basin scale (Kibena et al., 2014; du Plessis et al., 2014), while others demonstrated that are dependent on the depth of studies (Miserendino et al., 2011; Dabrowski et al., 2013; Namugize et al., 2018). Because of its reiterative data, digital format appropriate for processing, and precise geo-referencing approaches, satellite imagery is the most common data source for detection and mapping of land use changes (Minaei and Kainz, 2016). LULC change detection has become the main usage of RS data, due to repetitive coverage at short intervals and consistent image quality (Joorabian Shooshtari et al., 2012).

In relation to ecology, deforestation, desertification, urbanization, sustainable management of natural resources, identifying and modelling the impacts of weather events and climate change, etc land use change is monitored (Rafiee et al., 2009). Geographic Information System (GIS) provides many various methods to analyze and evaluate land use changes. These methods developed by using Remote Sensing (RS) and image processing techniques. For example, in the Beijing, (in China) (Wu et al., 2006) applied a combination of GIS and RS to find land use changes and found a significant increase in urban areas and a decline in rangeland from 1986 to 2001. Or in another research, in the north-western coastal region of Egypt from 1987 to 2001, (Shalaby and Tateishi, 2007) monitored land use changes used the post-classification method and maximum likelihood technique to generate the maps, detect land use changes and report on the effects of development projects in tourism and agriculture on vegetation cover region. In the west of Nile River (Egept), (Abd El-Kawy et al., 2011) applied Post-classification comparisons to investigate land use changes. And numerous similar studies conducted using GIS and RS combinations.

To specify whether the measured values of a variable increase or decrease during a period, generally trend analysis apply. Many methods are available for the quantification and detection of trends: regression analysis, T-tests, graphical methods, etc. Trend analysis method for water quality data should consider some of the specifications generally found in the water quality data (Zamani et al., 2013). Seasonality, non-normality, missing values, outliers, autocorrelation, and dependence on other variables such as river flow are some of these specifications (Zamani et al., 2013). (Esterby, 1996) provided a comprehensive review of statistical approaches that are using for trend analysis of water quality time series.

The intricate relationships of land use, water quality in various geographical regions under different scales are yet to be clarified, although there are some studies on the impacts of land use on water quality. The common procedures for predicting water quality in river basins based on land use types are still developmental. In a study, Huang explained the major participants to the increase of nutrients and sediments in freshwater ecosystems are increasing in agricultural and civil areas (Huang et al., 2016). Results in another study by (Mello et al., 2018), showed that organic matter and nitrogen were more influenced by the riparian zone composition, while fecal coliforms, phosphorus, sediment, and dissolved oxygen were affected by land use types at the watershed scale (Shi et al., 2017) in their research found that the land use composition in a riparian area is a superior predictor of water quality than in the whole basin, while (Zhou et al., 2012) showed that land use types at the basin scale can better account for the variability in river water quality.

Iran is among the arid and semi-arid countries of the world, and in most of its areas, there is a water shortage problem. Khorasan Razavi, besides the problem of water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81518169

shortage, has a problem with reducing water quality. As it follows from the review of previous studies, one of the factors of long-term change in water quality is the change in land use. However, according to the authors' information, in Khorasan Razavi Province, no research has been undertaken for linking the spatial and temporal changes in land use and quality of water. The purpose of this study is to answer three basic questions. First of all, is land use change in Khorasan Razavi province significant? Second, do these land use changes affect the quality of surface water resources? And eventually, are these changes in water quality predictable and can be modelled?

Material and methods

Study area and data description

Razavi Khorasan province with an area of 117966 km^2, located between 56° 13′ 40″ to 61° 17′ 07″ eastern longitudes and 33° 51′ 16″ to 37° 42′ 18″ north latitudes in the northeast of Iran (*Fig. 1*).

Figure 1. *Geographical location of Razavi Khorasan Province in Iran*

Two kinds of data applied in this research: land use data and water quality data. To study the dynamics of land use, it is needful to have maps that reflect the status of land cover at various periods. In this study, we used a set of Landsat satellite images from TM (1987), ETM$^+$ (2001) and OLI (2015) sensors to obtain land use maps of Khorasan Razavi Province. For complete coverage of the province in each year, 12 images (Overall 36) were used (*Table 1*). *Figure 2* shows the final image of 1987, which is a combination of 12 Landsat 5 images. For the 2001 image, the combination of 12 Landsat 7 images and for the 2015 image, the combination of 12 Landsat 8 images used (*Figs. 3* and *4,* respectively).

This study was performed to apply the river-basin based approach to analyze possible statistical and spatial correlations of LULC on the surface water quality. In this province, there are 70 hydrometric stations located at the outlet of the watersheds (*Fig. 5*). For this study, 36 stations with complete data of surface water quality in the years studied selected (*Table 2*). The water quality data for the period of 1987-2015 obtained from the Iran Water Resources Research Organization. This organization is a repository for water quality, quantity, chemical and physical data. Water quality variables, including calcium (Ca), potassium (K), chlorides (Cl), carbonate (CO_3), bicarbonates (HCO_3), magnesium (Mg), sulphate (SO_4), sodium (Na), electrical

conductivity (EC), potential of hydrogen (pH), sodium adsorption ratio (SAR), total dissolved solids (TDS), and total hardness (TH) were chosen. The data is measured on these stations daily. Since the changes in water quality due to land use changes do not change over a day, therefore, the multi-day average of these data was used in this study.

Long-term land use change detection

To find the impact of land use changes on water quality trends, land use changes during the study period investigated (Worrall and Burt, 1999). Using Erdas Imagine 2014 software and RS data, the LULC changes in Razavi Khorasan Province between the years of 1987, 2001 and 2015 were determined in the manner described below.

In the present study, in spite of the positive results of the research experience that used the Maximum likelihood method for categorization (Al-Ahmadi and Hames, 2009), three different supervised classification techniques including Maximum likelihood, Mahalanobis Distance, and Minimum Distance are applied for the classification of Landsat 8 (image of 2015). All non-thermal bands of the images used to generate spectral signatures for classification. For further separating and identifying the phenomena, false-colour images generated (Khoi and Murayama, 2010). These produced images helped to distinguish various types of land use in the study area.

The first step in performing a supervised classification method was to define areas used as training samples for each class. Using random point generation tool in ArcGIS, reference points randomly generated and the accuracy of the classification verified (Jensen, 2015). For this goal, the following steps were employed: first, using a GPS, 200 points were specified for the images of 2015, and after that, the actual ground points compared with the classified maps. Then, by applying GCP (ground control points) and visual interpretation, the overall accuracy assessment of the classified maps of 2015 (three maps that were prepared by the Maximum likelihood, Mahalanobis Distance, and Minimum Distance methods) determined (Schulz et al., 2010). The admitted RMSE between any two dates should not be more than 0.5 pixels (Lunetta and Elvidge, 1998), so the acceptable RMSE between the two images considered less than 0.5 pixels. The results of these three methods were compared and the best method for the classification was chosen.

Following the classification of imagery from the individual years, to specify changes in land use between the intervals (1987–2001 and 2001–2015), Post-Classification Comparison method applied (Erdogan et al., 2015). The post-classification technique supply 'from–to' change information and so, the type of LULC changes that occurred can be easily determined (Yuan et al., 2005). By applying extension X tools in ArcGIS 10.3, the extent of each land use types determined. Also, the transition matrix obtained by cross-tabulating the maps of 1987, 2001, and 2015. This matrix generally reported in the land use change detection studies (Dewan and Yamaguchi, 2009; Monteiro et al., 2011).

The area of watersheds for each of hydrometric stations delineated by applying ArcGIS software and it used as a foundation map for the analysis. Then the layers of the watershed used to clip 1987, 2001, and 2015 LULC coverage allowing calculation of the effective land uses. For analyzing the spatial distribution of various land use category and land cover transformation, the cross-tabulation method performed. Finally, using cross tabulations in ArcGIS software (Spatial Analyst Tools > Zonal > Tabulate Area), maps of land cover classes compared with each other, as the maps of 1987 and 2001, 2001 and 2015 crossed and aspects of changes extracted.

Long-term trend analysis of water quality

At hydrometric stations, water quality data are measured daily. In this study, given the fact that water quality data may change over the course of a few days due to short-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81518169

term or local changes, the multi-day average data was used to study the changes in surface water quality. According to *Table 1*, Landsat 5 images were captured in 1987 between June 16th and June 27th (12 days). Similarly, Landsat 7 images were captured in 2001 between May 29 and July 27 (63 days) and Landsat 8 images in 2015 between June 15 and June 29th (15 days). Therefore, the water quality data of the aforementioned days were averaged and used in subsequent calculations.

For example, in 1987, for the TDS parameter, there are 12 data in each sub-basin (12 days). The average of these 12 data was considered as the value of the TDS parameter in 1987 in each sub-basin. This was done for all 36 sub-basins and the TSD parameter value was obtained in 1987 (36 data for the TDS parameter in 1987). Also in 2001, for the TDS parameter, there are 63 data in each sub-basin (63 days). The average of these 63 data was considered as the value of the TDS parameter in 2001 in each sub-basin. This was done for all 36 sub-basins and the TSD parameter value was obtained in 2001 (36 data for the TDS parameter in 2001). The same way, in 2015, for the TDS parameter, there are 15 data in each sub-basin (15 days). The average of these 15 data was considered as the value of the TDS parameter in 2015 in each sub-basin. This was done for all 36 sub-basins and the TSD parameter value was obtained in 2015 (36 data for the TDS parameter in 2015). The same method was used for other parameters. Considering that 13 parameters were evaluated in this study, 1404 numbers were obtained for modelling.

The Mann-Kendall and Seasonal Kendall tests are the most common trend tests in hydro-meteorological studies for non-normal variables. While, the linear regression and analysis of covariance are some of the parametric methods, which is used for normally distributed variables (Zamani et al., 2013; Sheikhy Narany et al., 2017). We assessed the normality of data by means of the Kolmogorov-Smirnov and Shapiro-Wilk tests and then the appropriate method for trend test was chosen (Pratt and Chang, 2012).

Simulation and predicting of water quality data

The null hypothesis was water quality is not related to the land use changes at a watershed scale and the statistical analysis employed to test it. A rejected null hypothesis reveals that "there is a relationship between land use changes and water quality". In SPSS software, Spearman's rank correlation analysis applied to finding the relationships between land use types (as an independent variable) and water quality in the 36 hydrometric stations (as a dependent variable) (Tong and Chen, 2002).

For modelling, at first, the amount of land use area in 36 sub-basins extracted using ArcGIS software from the attribute table of each layer. Since some of the land use does not exist in all sub-basin so in modelling, was not used. For example, there is a poor rangeland area in all 36 sub-basins. According to the maps of 1987, 2001, and 2015, 108 land use values (for poor rangeland) are obtained. These data considered as parameter x and water quality data as a parameter y. But for land use that does not exist in all sub-basin (for example, residential land), the number of data for modelling would be less and may reduce correlation and not be used in modelling.

It is difficult and time-consuming to thoroughly analyze the data of one variable at a time. Because of identifying the relevance of the variables, the multivariate statistics are useful and apply for reducing the number of components in a dataset. Thus, the multivariate linear regression model used to investigate the statistical relationships of land use changes and water quality variables to making model. For this purpose, different types of land use as independent variables (Range, Garden, Residential, etc.)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81518169

and changes in each factor of the surface water quality considered as a dependent variable (TDS, EC, pH, etc). After reducing the number of factors, modelling done with fewer parameters and further simulation of surface water quality performed.

By using relationships between land use types in 1987, 2001, and 2015, the linear regression models created and applied for predicting land use types in the future. The time interval between the selected images for studying land use changes for the years 1987, 2001, and 2015 is 14 years. In order to make a more accurate estimate of land use changes, the time interval for the prediction of variations was chosen 14 years, so that the resulting data would be maximally consistent. Then, by using the regression model that provided for predicting water quality, and the area of land use predicted in 2029, each water quality parameter was simulated.

Results

Satellite imagery data were analysed with digital image processing methods and spatial analysis techniques to detect spatial-temporal changes in land use. A multitemporal Landsat satellite dataset formed the basis for the change detection procedure. The overall accuracy assessment of the classified maps of 2015 that were prepared by the Maximum likelihood, Mahalanobis Distance, and Minimum Distance methods was 87.3, 83.7, and 78.5, respectively. So, by applying the supervised maximum likelihood classification technique, the images classified (Schulz et al., 2010). Land use maps of Khorasan Razavi Province for the years 1987, 2001 and 2015 showed in *Figures 6, 7* and *8,* respectively.

In the Khorasan Razavi Province identified sixteen land use classes included: Barren (Ba), Rocky (Ro), Residential (Re), Swamp (Sw), Water (Wa), Dunes (Du), Salt marsh (Sa), Irrigated cultivation (Ir), Garden (Ga), Dry farming (Dr), Desert (De), Good rangeland (GR), Medium rangeland (MR), Poor rangeland (PR), Wooded rangeland (WR), Watercourse (Wc). The coverage of each land use class gave as the area (km^2) and percentage (%) for the years of 1987, 2001 and 2015 (*Table 3*).

Table 3. *Distribution of land use classes in 1987, 2001 and 2015*

Land use	1987		2001		2015	
	(km^2)	(%)	(km^2)	(%)	(km^2)	(%)
Barren	3716.2	3.2	3638.7	3.1	3638.7	3.1
Rocky	1325.9	1.1	1325.9	1.1	1325.9	1.1
Residential	380.5	0.3	477.1	0.4	569.9	0.5

Watercourse	154.4	0.1	154.4	0.1	154.4	0.1
Total	117966.0	100	117966.0	100	117966.0	100

In Khorasan Razavi Province, between 1987 and 2001, the highest incremental changes in the percentage of land use area were 378, 125 and 115 related to water area, residential and poor range, respectively. The maximum of incremental changes in the area was 5449 km^2 (poor range), 670 km^2 (irrigated cultivation) and 96 km^2 (residential). Also, the maximum decreasing changes in the area were 3794 km^2, 2271 km^2, and 77 km^2 related to medium range, good range, and barren, respectively. In this area, during 2001-2015, the highest incremental changes in the percentage of land use area were 473, 119 and 102 percent related to water area, residential and dry farming, respectively. The maximum of incremental changes in the area were 961 km^2 (poor range), 362 km^2 (dry farming) and 92 km^2 (residential). Also, the highest decreasing changes related to medium range (1411 km^2), dunes (119 km^2) and wooded rangeland (32 km^2), respectively.

In ArcGIS software, using land use maps of Razavi Khorasan province (1987, 2001 and 2015) and the surface of 36 catchments, land use changes in the watershed of hydrometric stations extracted. Thus, a total of 108 land use maps were prepared. Using linear regression models (*Table 4*), land use changes in the years 2029 estimated (*Table 5*).

findings, among the 16 types of land use, eight items showed the highest correlation. The eight items were Residential, Irrigated cultivation, Garden, Dry farming, Good rangeland, Medium rangeland, Poor rangeland, and Wooded rangeland.

Using Pearson correlation analysis, the correlation coefficient of these eight land use parameters versus water quality parameters were investigated. Results showed in *Table 6*.

Re: Residential, Ir: Irrigated cultivation, Ga: Garden, Dr: Dry farming, GR: Good rangeland, MR: Medium rangeland, PR: Poor rangeland, WR: Wooded rangeland

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81518169

Using the data in *Table 6* and the linear regression model, each water quality parameter was modelled (*Table 7*). The general formula was the linear equation including "y = (variable*x) + constant". The 'x' parameter value selected based on the highest correlation, in *Table 6*. For example, for predicting the parameter magnesium (Mg) the highest correlation belongs to residential land use ($R^2 = 0.902$), so the area of the residential land use used as 'x'. No models were available to predict the amount of potassium. Then, using the linear regression model was trying to estimate water quality variables in the years 2029 (*Table 8*). Results demonstrated that except calcium (Ca), Carbonate (CO_3) and Bicarbonate (HCO_3), the models estimate all other water quality variables with an acceptable degree of accuracy (P-value < 0.05).

Discussion and conclusions

One of the objectives of this study was to investigate the significance of land use change. The results showed that changes in the direction of a significant decline in good rangeland and a significant increase in poor rangeland that is in agreement with the findings by (Farazmand et al., 2018).

In the present study, three different supervised classification techniques including Maximum likelihood, Mahalanobis Distance, and Minimum Distance are applied for the classification. Results showed that the Maximum likelihood method gave the best results and that is in agreement with results found in other environments by Al-Ahmadi and Hames (2009) and Schulz et al. (2010).

The basic goal of this study was to linking LULC changes to surface water quality variation by using GIS and RS technique. Current methods of estimating water quality in river basins based on land-use patterns are still developing. In this study, we used 36 basins as a case study to consider the relationships between land use and water quality. The relation between water quality and land use types could be different at the various scales of rivers. However, through the analysis of the correlation between water quality variables and various land use types, different land cover patterns that could affect water quality can be recognized.

Our results proposed that Garden, Irrigated cultivation and Residential land uses can be a parameter affecting the water quality in the study area. Also, results represented that an overview of the relationship between land use and water quality could provide a combination of large-scale investigations and multivariate statistical techniques. The research showed that the concentration of Electricity Conductivity (EC), Sodium Adsorption Ratio (SAR) and Total Hardness (TH) varied in various sub-basins. Results

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81518169

demonstrated that in 8 out of 13 models can estimate water quality variables with a correlation coefficient of 60%, approximately.

The relevance of land use changes and water quality parameters is complex and site-specific, while the correlation coefficients vary among sub-basin. These results add to the body of research studies accomplished by (Du Plessis et al., 2014) in South Africa, (Wan et al., 2014) in China, (Kibena et al., 2014) in Zimbabwe and (Maimaitijiang et al., 2015) in the USA.

The findings of this research assist policymakers and watershed managers in developing catchment management plans to effectively protect water quality conditions. Therefore, figuring out the effects of changes in LULC is serious for retaining a favourite level of water quality and for restoring water quality in affected areas. However, consequence researches in similar environments can inform that changes in land use and land management practices are initial factors responsible for the variation of receiving water quality. One of the most regular approaches to test these relationships is to develop statistical correlations between water chemistry and current land use in the drainage basins of surface-water sampling points (Wayland et al., 2002). Considering the limitations of this study, the results are only valid in the study area. However, the results and methodology in this study still have implications for water quality management and land use planning in the future for the study area.

Recommendations

The results of this study propose that land use change is one of the main parameters causing water quality changes. It is suggested for making model use additional layers of parameters such as geomorphology, geology, soil, etc. to increase the accuracy and the coefficient of determination. Further study with a better design of spatial and temporal sampling regime may better clarify the complex nature of the relationship between land use and water quality. Future research for linking the finding of hydrological processes with different pollutant transfer processes is needed. Also, to obtain superior data on the linkages between land use patterns and water quality parameters, a water sampling point per sub-basin is required, as well as an increase in monitoring sites, so that information on smaller sub-catchments will be available.

Acknowledgements. The authors would like to thank the Khorasan Razavi Regional Water Authority for supplying funding for this PhD research (Contracted Number KOE-92075). We would further like to thank TAMAB for providing water quality datasets. We also thank the Kerman Graduate University of Advanced Technology for the structural support; and appreciate the classmate for helping with the statistical analyzing the water quality data.

(Received 18th Feb 2019; accepted 8th Apr 2019)

Abstract. Berries of *Juniperus drupacea* L. are important non-wood product used in traditional pekmez (fruit concentrate) production in Turkey. In this article, some chemical, nutritional and mineral properties of dried mature *J. drupacea* berries are reported. The materials were collected from Kahramanmaraş and Adana Provinces (Turkey). The results are given in the order of Kahramanmaraş and Adana; total dry matter 92.89 and 93.30%, water soluble dry matter 62.40 and 57.07%, protein 2.06 and 3.74%, lipid 5.49 and 3.84 g/100g, pH 5.53 and 5.65, titretable acidity 0.38 and 0.52%, K 14.5 and 17.3 g/kg, Ca 890.5 and 794.7 mg/kg, Na 67.0 and 68.1 mg/kg, Mg 439.2 and 543.6 mg/kg, Fe 33.8 and 65.8 mg/kg, Cu 4.4 and 5.5 mg/kg, Zn 16.5 and 18.1 mg/kg and finally Mn 4.7 and 5.1 mg/kg. In addition, holocellulose (carbohydrate) was determined as 14.29 and 16.01%, lignin (phenolic compounds) as 16.94 and 18.98% and ash (inorganic constituents) content as 4.00 and 3.38%. The soluble content of toluen/acetone/ethyl alcohol, hot water and cold water for Kahramanmaraş samples were 31.18, 67.08 and 60.74%. They were 37.56, 63.36 and 55.81% for specimens from Adana. The berries from Kahramanmaraş showed higher lipid, soluble solid, Ca and ash contents than those from Adana.
Keywords: *Syrian juniper, refractometer, protein, lipid, functional foods*

Introduction

One of the juniper species in Turkey is *J. drupacea* which naturally grows in Mediterranean countries such as Turkey, Syria, Lebanon and Greece. Within this general distribution area, in the mountainous parts of the Eastern and Central Mediterranean regions of Turkey, it has a significant distribution between 600 and 1750 m altitude (Gültekin, 2014). It covers 958.423 ha which is 4.29% of the total forest area of country (OGM, 2015).

In Turkey, from the fruits of *J. drupacea* "pekmez" (fruit concentrate) is produced traditionally by the local people and used to treat asthma and bronchitis. It is an important foodstuff for people with high energy needs, mainly consumed in the winter months (Seca et al., 2015; Güneş et al., 2017).

Functional nutritional science has been very important nowadays. As average life expectation and healthcare costs rice, the people has investigated to become healthier and improve the quality of life. Functional foods may be "an essential macronutrient, or an essential micronutrient. While a macronutrient (e.g. carbohydrates, fats, and proteins) must be ingested in large amounts in human diet, a micronutrient (e.g. vitamins or minerals) must be consumed in certain trace amounts. Bioactive compounds are considered as the source of functional food effectiveness. Bioactive compounds can be categorized as "phenolic compounds, proteins, peptides and lipids, and carbohydrates (Martirosyan and Singh, 2015).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81718178

Leaves, fruits, seeds and wood parts of junipers contain considerable chemical components. So, it takes important places in medicine, pharmacology and food industry. Juniper species are very miscellaneous and have been subject of researches by many scientists for it's oil, protein, reduced sugar, mineral, essential oil, phenolic compound content and antioxidant - antimicrobial activity properties (Nasri et al., 2011; Jalal et al., 2014; Hosseinihashemi, 2017; Salamon et al., 2017; Miceli et al., 2018).

Although there are many works about *J. drupacea* fruit concentrate (Özdemir et al., 2004; Akıncı et al., 2004; Kocakulak, 2007; İzgi, 2011), less studies related to its dried fruit physical, chemical and mineral features are provided with. In the present study, some chemical (holocellulose, lignin, toluene-acetone-ethyl alcohol solubility, hot-cold water solubility and ash content), nutritional (total dry matter, water soluble dry matter, protein, lipid, pH, titretable acidity) and mineral (K, Ca, Na, Mg, Fe, Cu, Zn ve Mn) components of dried mature fruit are identified.

Materials and methods

Materials

In this study, mature ripe juniper berries obtained from Kahramanmaraş-Andırın (KM) and Adana-Kozan (AA) in Eastern Mediterranean Region were used as experimental materials (*Figure 1*). The samples were collected in 2014, February-March and the information related to the places samples taken are given in *Table 1* and *Figure 2*. Thirty berries were collected from each of the 30 randomly selected trees and a total of 900 berries were collected in each province. The collected samples were then dried in the laboratory environment under open air conditions. The dried samples were broken and seeds removed, later the remaining parts were grinded in the Willey-mill, sieved and preserved in glass jars.

Methods

The methods used to identify the main chemical components of the juniper berry: Holocellulose, lignin and ash content was determined according to Wise's chlorite method (Wise and Karl, 1962), TAPPI T222om-02 (2002) and TAPPI T211om-02 (2002) standards, respectively. Solubility properties, including toluene-acetone-ethyl alcohol (4:1:1, w/w) and cold - hot water solubilities were determined according to TAPPI T204cm-97 (1997) and TAPPI T207cm-99 (1999), respectively.

Methods for determining nutritional properties of *J. drupacea* berries are: Total dry matter was determined by drying the samples to a constant weight in a 65^{o}C oven (AOAC, 1990). Soluble solid and pH values of the extract from the berries were determined by using a Hanna HI96801 refractometer and a pH meter (IFJU, 1968a, 1968b). Protein was calculated from the percentage of nitrogen found by using the Kjeldahl method (TS4895 EN ISO3188). Lipid content and titratable acidity of the samples were determined by the soxhlet extraction method, with hexane (AOAC, 1984) and by the titration method with, 0.1 N NaOH (IFJU, 1968c), respectively. All chemical analysis results were calculated relative to oven dry sample weight.

To determine the mineral components of juniper berry the samples were burned with HNO_3 (65%) and H_2O_2 (35%) solution in a microwave. Then, the absorbance of the extract was determined with the Atomic Absorbance Spectrophotometer, Perkin Elmer

Optima 2100DV ICP-OES coupled with AS93 auto sampler. The mineral content was calculated with a standard curve.

To evaluate the significant differences between the mean values of each of the properties, independent-samples t-test analyses (ISTTA) were used. All statistical analyses were conducted by means of SPSS Statistics software, and the results were considered significant at $p \leq 0.05$.

Figure 1. *Juniperus drupacea tree, leaf and fruit (Kocakulak, 2007)*

Table 1. *Information for locations where juniper berries collected*

Location	Latitude	Longitude	Altitude (m)
Kahramanmaraş-Andırın	37º45'	36º42'	943
Adana-Kozan	37º38'	35º50'	895

Results and discussion

The main chemical, nutritional and mineral composition of *J. drupacea* dried berries are shown in *Tables 1, 2 and 3*, respectively. In order to compare the provided results, the properties of juniper berries from Akseki-Antalya (AY) from Western Mediterranean Region are also shown in *Table 2* and *Table 3*. In addition to these, related properties of carob bean and raisins are given in the same tables, respectively.

Chemical and nutritional properties of J. drupacea dried berries

The major chemical components of natural lignocellulosic materials are holocellulose (total carbohydrate), lignin (phenolic compounds), ash (total inorganic constituents) and a very small fraction of so-called extractives (Fengel and Wegener, 1989; Chen, 2014). All these substances have an important place in human nutrition.

The average results and standard deviations of main chemical components of juniper berry from KM and AA are given in *Table 2*, the results of nutritional properties are given in *Table 3*. Juniper berry is a hard nut and cannot be consumed as a fresh fruit. So, general chemical properties of main components for softwoods and hardwoods are also given in *Table 2*.

As indicated in *Table 2*, the holocellulose mean ratio for juniper berry is 15.15% and this value is quite less than that in both softwood and hardwoods. With regard to lignin amount juniper samples (17.96%), it showed hardwood characteristics. Phenolic substances have important contributions to human health. These compounds have been reported to play an effective role in preventing cancer and cardiovascular diseases by preventing free radical formation in the body (Gil et al., 2000). The results also showed that fruits from AA junipers have more lignin (18.98%), in other words, more phenolic compounds than those from KM (16.94%).

It is possible to remove waxes, oils, resins, photosterols, non-volatile hydrocarbons, low molecular weight carbohydrates, salts and other water soluble components present

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81718178

in the sample with neutral organic solvents (TAPPI T204cm-97, 1997). According to the results obtained, the solubility content of toluene/acetone/ ethyl alcohol (34.37%) and the hot water (65.22%) - cold water (58.28%) of the samples were found to be fairly high when compared to softwood and hardwoods.

The ash content of juniper berry samples was determined as 3.69%. This value found to be 2.51 g/100g for Antalya samples, 2.40% for raisins and 2.5% for carob bean (Karkacıer and Artık, 1995; Akıncı et al., 2004; Kalkan et al., 2012). According to all these values, the amount of ash in KM and AA junipers berry found to be rather high.

When nutritional property mean values in *Table 3* compared, soluble solid content was 62.40% for the berries from KM and 57.07% for AA samples. This value has been reported as 33.68% for AY juniper berry and 64.68% for carob bean (Karkacıer and Artık, 1995; Akıncı et al., 2004). The highness of this value is desirable. Accordingly, KM and AA soluble dry matter is 77.4% higher than AY specimen, and shows similarity to that from carob fruit.

Considering *Table 3*, the protein (3.74%), pH (5.65) and titratable acidity (0.52%) values of AA samples were higher than those for samples from KM as 2.06%, 5.53 and 0.38%, respectively. The lipid amount of KM samples was found to be 43% higher than that from AA. According to data from literature survey, the value for protein was found as: AY juniper berries 2.45%, *J. communis* L. berries 4.28% and carob bean 4.05% (Karcıer and Artık, 1995; Akıncı et al., 2004; Bacém, 2018). According to results from the present work, titretable acidity value for juniper berries (0.45%SSA) is more acidic than carob bean (0.72%SSA).

Mineral composition of J. drupacea dried berries

Minerals have important place in human nutrition. The importance of these minerals, also known as trace elements, has been well understood in recent years, since when missed, causes diseases and major disorders in the human body (Bittencourt, 2018).

Mineral content and their ratio in KM and AA juniper berries are given in *Table 4*.

Table 4. *Mineral composition of J. drupacea dried berries*

Mineral composition	Determination			Literature	
	KM berries	AA berries	Mean	AY berries (Akıncı et al., 2004)	Raisins (Kalkan et al., 2012)
K (g/kg)	14.5 (b)	17.3 (a)	**15.9**	10.0	7.5
Ca (mg/kg)	890.5 (a)	794.7 (b)	**842.6**	1063.0	500.0
Na (mg/kg)	67.0 (b)	68.1 (a)	**67.6**	84.8	20.0
Mg (mg/kg)	439.2 (b)	543.6 (a)	**491.4**	477.0	70.0
Fe (mg/kg)	33.8 (b)	65.8 (a)	**49.8**	15.4	18.8
Cu (mg/kg)	4.4 (b)	5.5 (a)	**4.95**	29.2	3.2
Zn (mg/kg)	16.5 (b)	18.1 (a)	**17.3**	13.9	2.2
Mn (mg/kg)	4.7 (b)	5.1 (a)	**4.9**	9.0	-

*KM: Kahramanmaraş, AA: Adana, AY: Antalya

**Letters in parentheses represent statistical differences at the 95% confidence level

Results showed that the amount of K (17.3 g/kg), Na (68.1 mg/kg), Mg (543.6 mg/kg), Fe (65.8 mg/kg), Cu (5.5 mg/kg), Zn (18.1 mg/kg) ve Mn (5.1 mg/kg) from AA are higher than those in KM samples. In contrast, only the amount of Ca (890.5 mg/kg) in KM berries is higher than that in AA (794.7 mg/kg).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81718178

When the mean values of the results considered, KM and AA berries contain more K, Mg, Fe and Zn than AY berries and raisins. Inci et al. (2016) reported that *Juniperus communis* berries contained 61.2 g/kg K, 1.90 mg/kg Mg, 80.12 mg/kg Fe, 15.31 mg/kg Mn, 18.80 mg/kg Zn and 19.94 mg/kg Cu. When we compared berries of *J. drupacea* and *J. communis*, it is seen that *J. communis* berries has a higher mineral content.

Conclusion

When the data obtained within the scope of the study considered, it can be mentioned that juniper berries collected from Kahramanmaras Province, found to be more oily, with more soluble solids, extractive matter (hot and cold water solubility), ash and calcium content than those from Adana Province samples. However, dried berries from Adana Province contains more holocellulose, lignin, protein and mineral matters (K, Na, Mg, Fe, Cu, Zn, Mn).

When the data obtained within the scope of the study considered, it can be mentioned that juniper berry is a good source of minerals. It contains especially a fine ratio of Fe.

(Received 18th Feb 2019; accepted 10th Apr 2019)

Abstract. The paper analyses the impact of location of the vegetable cold store floor in relation to the ground level on heat exchange with the soil. The scope includes the analysis of indoor and outdoor temperature and soil temperature under the cold store and its surrounding, specification and adaptation of the cold store heat exchange model with soil, calculations for chosen variants in non-stationary conditions and a comparative analysis of cold store heat exchange with soil and soil temperature in chosen solutions. The paper used the results of field studies conducted in a cold store located in southern Poland. The said building was used to store carrots from 1 October to 30 June. Three calculation variants were used in order to determine in detail the impact of the chosen factors on heat exchange between the cold store and soil. The calculations were made based on the elementary balances method in WUFI®plus software. The calculation model was validated based on the results of field studies of indoor and outdoor temperature and soil temperature in 5 measurement lines at the depth of 0.05, 0.50, 1.00 and 1.50 m. The obtained validation results showed a very high correlation of measurement data and calculated data and an absence of significant differences. The calculation results for 3 variants showed statistically significant ($p < 0.05$) differences in both soil temperature and heat exchange with the soil.
Keywords: *cooling chamber, energy management, energy efficiency, microclimate, ground temperature*

Introduction

In order to preserve an adequate commercial, nutritional and biological quality, the picked fruit should be stored at a precisely specified temperature, humidity and with an appropriate gas composition and lighting in the store (Sun et al., 2004; Zhihang et al., 2006). Appropriate storage is intended mainly to reduce the intensity of microbiological, chemical, physical and biological processes causing unfavourable quality changes of the product (Łapczyńska-Kordon and Krzysztofik, 2008; Mazzeo et al., 2015). Such processes include breathing, transpiration, change of chemical composition, ripening and ageing, and damage caused by various pathogens. Changes in the fruit chemical composition take place at a various rate depending on many factors such as cultivation, fruit species and variety and, most of all, storage conditions (Wu et al., 2012; Phillips et al., 2016). Active cooling and controlled storage atmosphere is used to reduce the risk of deterioration of quantitative and qualitative factors (Liu et al., 2010; Ambaw et al., 2013; East et al., 2013). Other methods of preservation include application of edible coats, potentially not hazardous to humans, the main purpose of which is inter alia to prevent the fruit discoloration and to destroy harmful bacteria. The main benefit of such treatment is a significant extension of the shelf life of stored products (Soliva-Fortuny and Martin-Belloso, 2003; Albanese et al., 2007).

DOI: http://dx.doi.org/10.15666/aeer/1704_81798189

The heat exchange with soil is an issue that is well known and described in the literature. The studies in this area were conducted by inter alia Radoń et al. (2014), Nawalany et al. (2014, 2017), Aresti et al. (2018), Janssen (2002) and Deru (2001). Due to a large accumulation potential of soil, partially earth-sheltered buildings have a reduced demand for heating and cooling energy in comparison to non-earth-sheltered buildings, assuming the functional and spatial solutions in such buildings are similar (Dronkelaar et al., 2014).

The paper aimed at determining the impact of cold store floor location relative to the ground level on heat exchange between the floor and the soil.

Materials and methods

The field studies were conducted in a vegetable cold store in southern Poland. The said cold store has a set of rooms, with the manipulation area located at the head of the row of two cold rooms. The sorting and packing areas are located in the northern part of the building, and the cold rooms in the south-eastern and south-western part. The total building area is 232 m^2, including 58 m^2 of sorting and packing areas, 96 m^2 of right-hand cold room and 78 m^2 of left-hand cold room. The building has a steel frame structure on a 30-cm wide concrete foundation located 1.0 m below the ground level. Important for the heat exchange with the soil is the fact that the foundation is not thermally insulated. The chamber floors are made of 10-cm thick cement screed and feature a 4-cm thick thermal insulation of hard EPS. An organoleptic soil examination showed that the cold store surrounding includes a 40-cm thick humus layer, with a 1.5-m thick layer of silty clay below it. The outside walls and ceiling of the chambers are made of sandwich panels, comprising steel sheets galvanized and painted on both sides, and a 15-cm thick EPS core. Polyurethane foam was used at the joints of panels to eliminate thermal bridges.

The storage cycle in the examined facility lasted from 15 October to 30 June, with a technological interruption from 1 July to 30 September. The optimum temperature was kept by a 20 kW refrigerating unit. The cold rooms' dimensions were adapted to multiples of box pallets in which carrots were kept. The distance between the box pallets and walls and between the box pallet rows were 10 cm to 30 cm and 5 cm to 10 cm, respectively.

The field studies were conducted between 1 May 2009 to 30 June 2011, and the period from 1 May 2010 and 30 April 2011 was used for this paper. The studies included continuous measurements of indoor and outdoor air temperature and floor temperature at 1-hour intervals. The temperature was measured by twenty-two APATOR TOP 168 sensors based on a PT100 platinum resistor (0.1°C measurement resolution, 0.1°C measurement error). The sensors were connected to an HP 34970A recorder. The measurement results were used to validate the calculation model that was used in this paper. *Figure 1* shows the building layout and location of the measurement points.

Three calculation variants were applied to study the impact of cold store floor location relative to the ground level on the indoor microclimate and soil temperature under the cold store and in its surrounding: variant 1 - floor on the ground level, variant 2 - floor elevated +0.75 m above the ground level, variant 3 - floor sunk -0.75 m below the ground level. The simulation was conducted in WUFI®plus software which allows for calculating in a non-stationary approach using the method of elementary balances.

DOI: http://dx.doi.org/10.15666/aeer/1704_81798189

Prior to the calculation analysis, the software was validated based on actual measuring data. The starting point for the model validation was to build a discrete geometrical model divided into balance-differential elements. The model included measuring points corresponding to their actual location in the field-studied facility (*Fig. 2*).

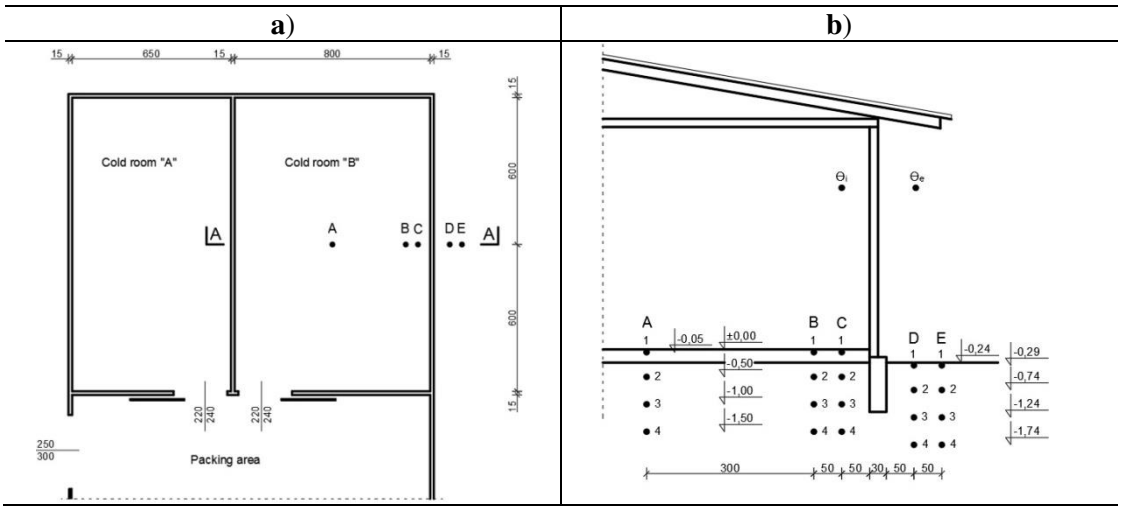

Figure 1. *Location of measurement points in the cold store: (a) plan; (b) section A - A: A, B, C, D, E - measuring lines, A1 - A4, B1 - B4, C1 - C4, D1 - D4, E1 - E4 - soil temperature measurement points, Θi, Θe - air temperature measurement points*

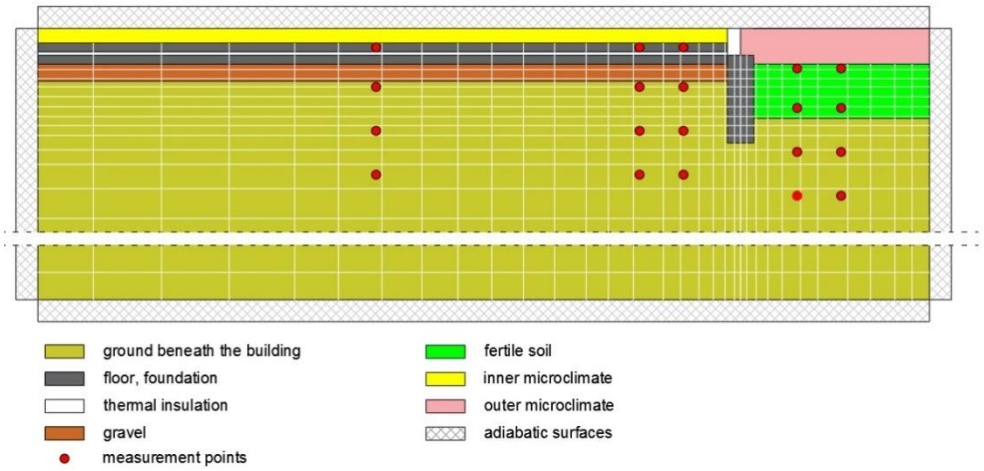

Figure 2. *Section of the modelled facility with division network and layout of soil temperature calculation points (model from WUFI®plus software)*

The physical parameters of the construction materials and soil used in the calculation model for validation are presented in *Table 1*. The minimum indoor air temperature used in calculations was $\Theta_{i,min}$ = 0°C, maximum indoor air temperature $\Theta_{i,max}$ = 4°C, minimum indoor air relative humidity $Rh_{i,min}$ = 80%, and maximum indoor air relative humidity $Rh_{i,max}$ = 99%. The natural air change was assumed at 0.3 h^{-1} and infiltration at 0.2 h^{-1}. The variant calculation analysis was based on climatic data for a typical

meteorological year (TRY) for Krakow, Poland, available in the WUFI®plus software database. Correlation analysis was performed for results obtained from all the measuring points, based on the Spearman's Rank Test (the data distribution was not normal). The data distribution normality was tested previously using the Shapiro-Wilk Test.

Results

Results of experimental studies

The indoor air temperature during the storage period (15 October - 30 June) was kept between 0.0°C and 4.0°C. During the technological interruption from the beginning of July to the end of September the indoor microclimate in the cold store changed passively depending on the outdoor microclimate; this caused the indoor temperature to increase to 15.3°C in August. The maximum outdoor air temperature in that period was 22.3°C. The indoor temperature fell abruptly in the last week of September after the cooling system had been activated to ensure the optimum temperature from the first day of the storage period - that is 1 October. From 1 October to 6 December the indoor air temperature was kept again at 4.0°C, with small, short-term drops. The drops were caused by a decrease of the outdoor air temperature and were in the 0.2 - 0.8°C range. In winter the average indoor air temperature in the cold store was in the 1.0 - 1.6°C range, and in the remaining months it was near 4.0°C (*Fig. 3*).

The floor temperature analysis in point A1 showed 4.2°C on the last day of the storage period. On the first day of the next storage cycle, the floor temperature was 11.6°C and decreased gradually. It was that in the analysed calculation variant determined the time necessary to reduce the floor temperature to the value from the end of the storage period is 18 days.

In points C1, B1 and A1 located in the soil under the cold store, the annual soil temperature amplitude was in the 13.9 - 14.3°C range. A larger impact of the soil on the stabilisation of thermal conditions is visible at the depth of 1.5 m. At the depth of 0.50 m, the annual temperature fluctuations were reduced almost twofold compared to the depth of 0.05 m. The impact of the cold store on the soil temperature decreases with depth. In points located in the facility surrounding, the annual soil temperature

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81798189

amplitude was from 14.5°C (point D2) to 15.1°C (point E2), and in points under the cold store it was from 7.5°C (A2), 6.5°C (B2) and 6.6°C in C2 (*Fig. 4*).

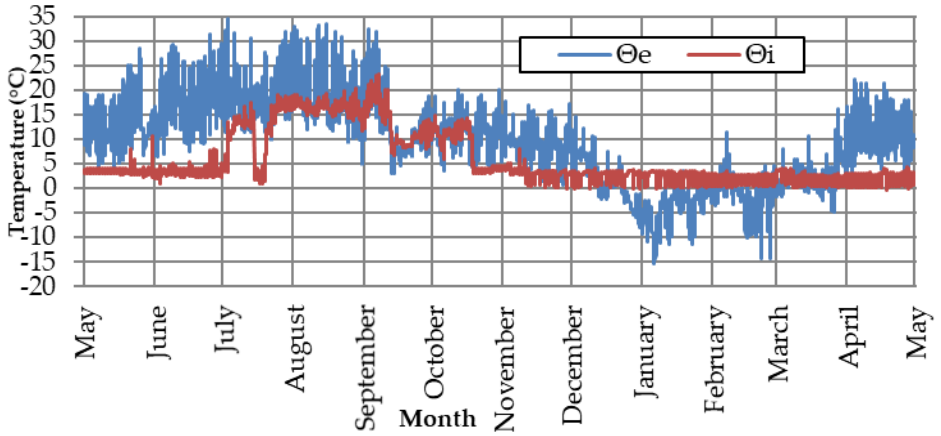

Figure 3. *Outdoor (Θe) and indoor (Θi) air temperature*

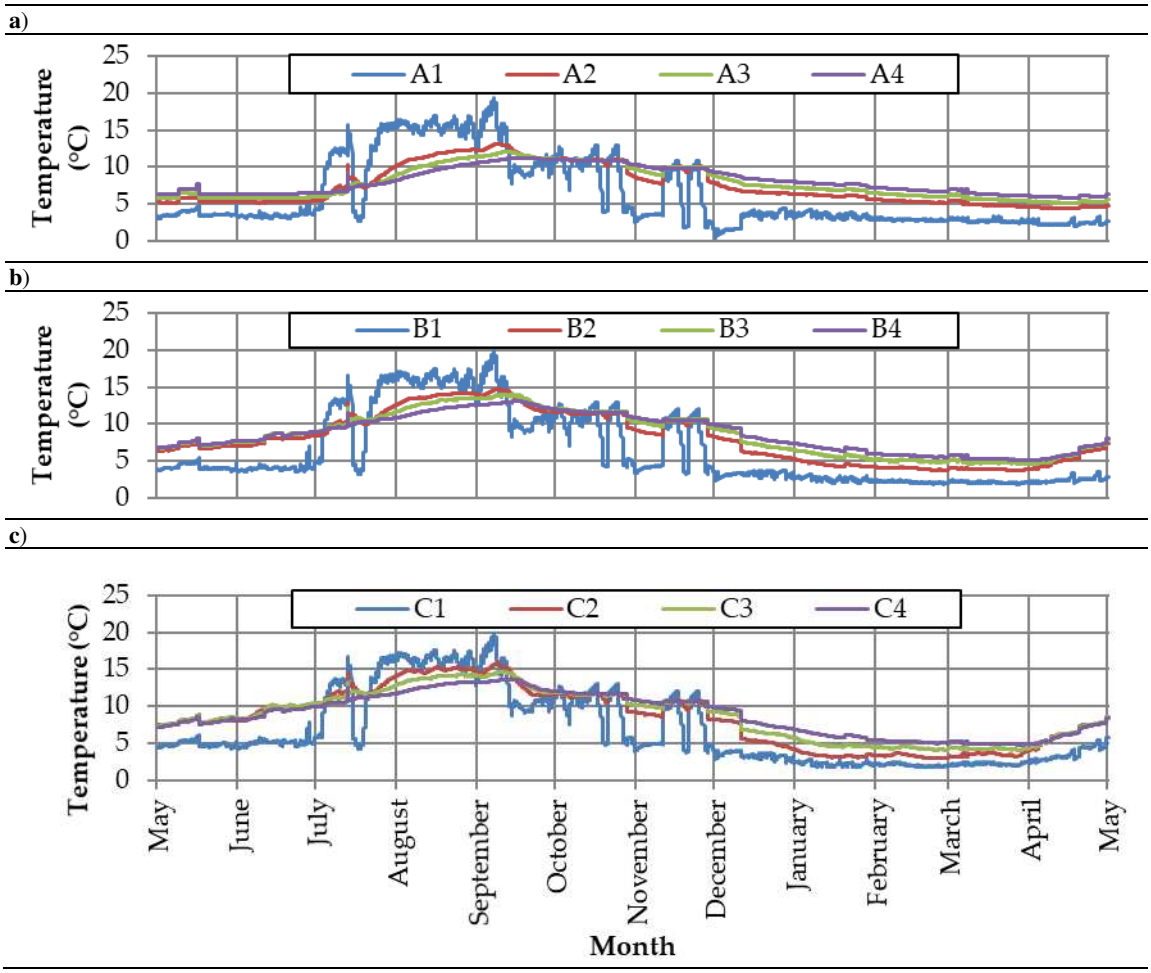

Figure 4. *Measured soil temperatures in lines A, B and C: (a) temperature points A1 (0.05m), A2 (0.50 m), A3 (1.00 m) A4 (1.50 m); (b) points B1 (0.05 m), B2 (0.50 m), B3 (1.00 m), B4 (1.50 m); (c) points C1 (0.05 m), C2 (0.50 m), C3 (1.00 m) and C4 (1.50 m)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81798189

The soil temperature in the cold store surrounding depended on the indoor and outdoor air temperature. The annual soil temperature amplitude in point E1 was 29.4°C, and at the depth of 1.5 m in the same measuring line (E4) it was 9.2°C. The calculation results showed the highest soil temperature in the measuring point E1 in June (18.8°C), and the lowest soil temperature (-10.6°C) was recorded in January in the same measuring point (*Fig. 5*).

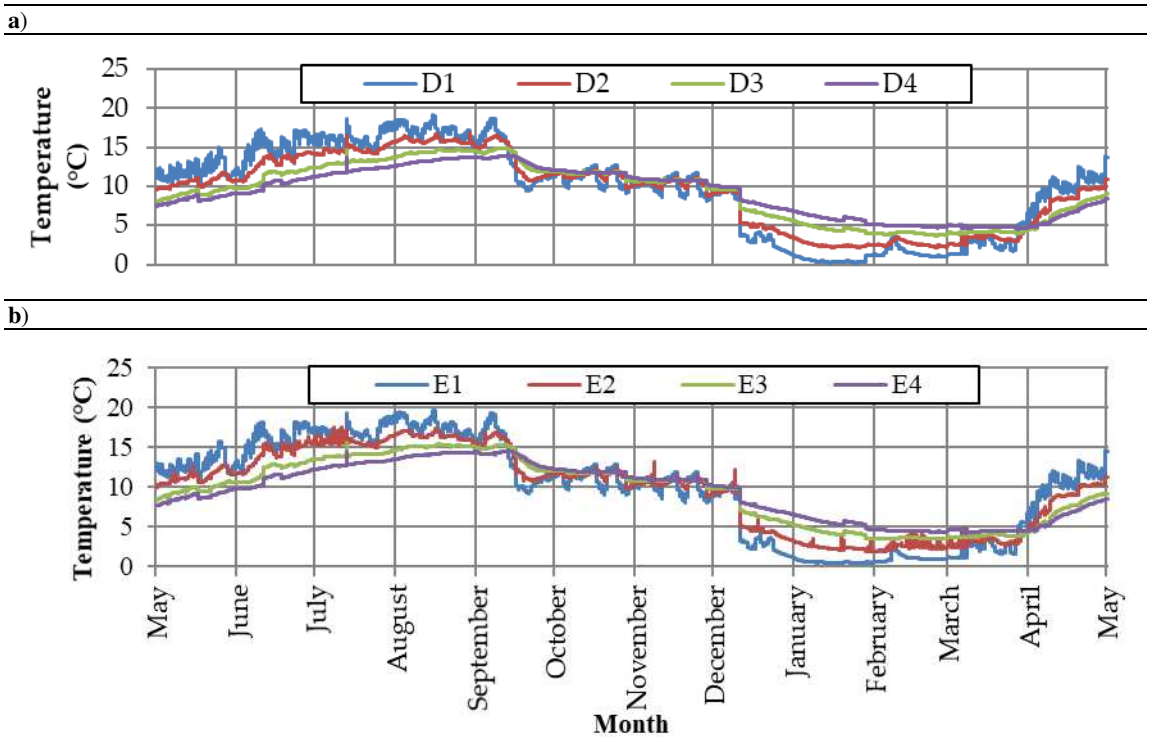

Figure 5. *Measured soil temperatures in lines D and E: (a) temperature points D1 (0.05m), D2 (0.50 m), D3 (1.00 m) D4 (1.50 m); (b) points E1 (0.05 m), E2 (0.50 m), E3 (1.00 m), E4 (1.50m)*

Results of generalising calculations

The calculation model was validated based on measured temperature inside and outside the cold store. In relation to the soil temperature, the measured temperature was a boundary condition of the third kind. The initial soil temperature was assumed at 8.8°C, which corresponds to the average annual outdoor air temperature for Krakow (TRY).

The highest correlation coefficient (0.95 - 0.99) was determined for measuring points E2, E3, E4, D2, D3, D4, C2, C3, C4, B2, B3, B4, A2, A3 and A4. Consequently, the conformity of calculation and measurement data at the depth of 0.50 m, 1.00 m and 1.50 m can be considered full. In the case of points E1 and D1, located 0.05 m below the ground level, and A1, B1 and C1 located under the floor, the correlation coefficient was 0.85 - 0.88, so the conformity of measurement and calculation data should be considered very high (*Fig. 6* and *Fig. 7*).

It should be emphasised that in winter the actual soil temperature at the depth of 0.10 m differed from the calculated values by 11.2°C in line E and 11.0°C in line D. The reason was the impossibility to account for the snow cover. The differences occurred, however,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81798189

only for a short time and were not significant for the entire period of study. The statistical significance of differences was tested using the Kruskal-Wallis ($p < 0.05$) test.

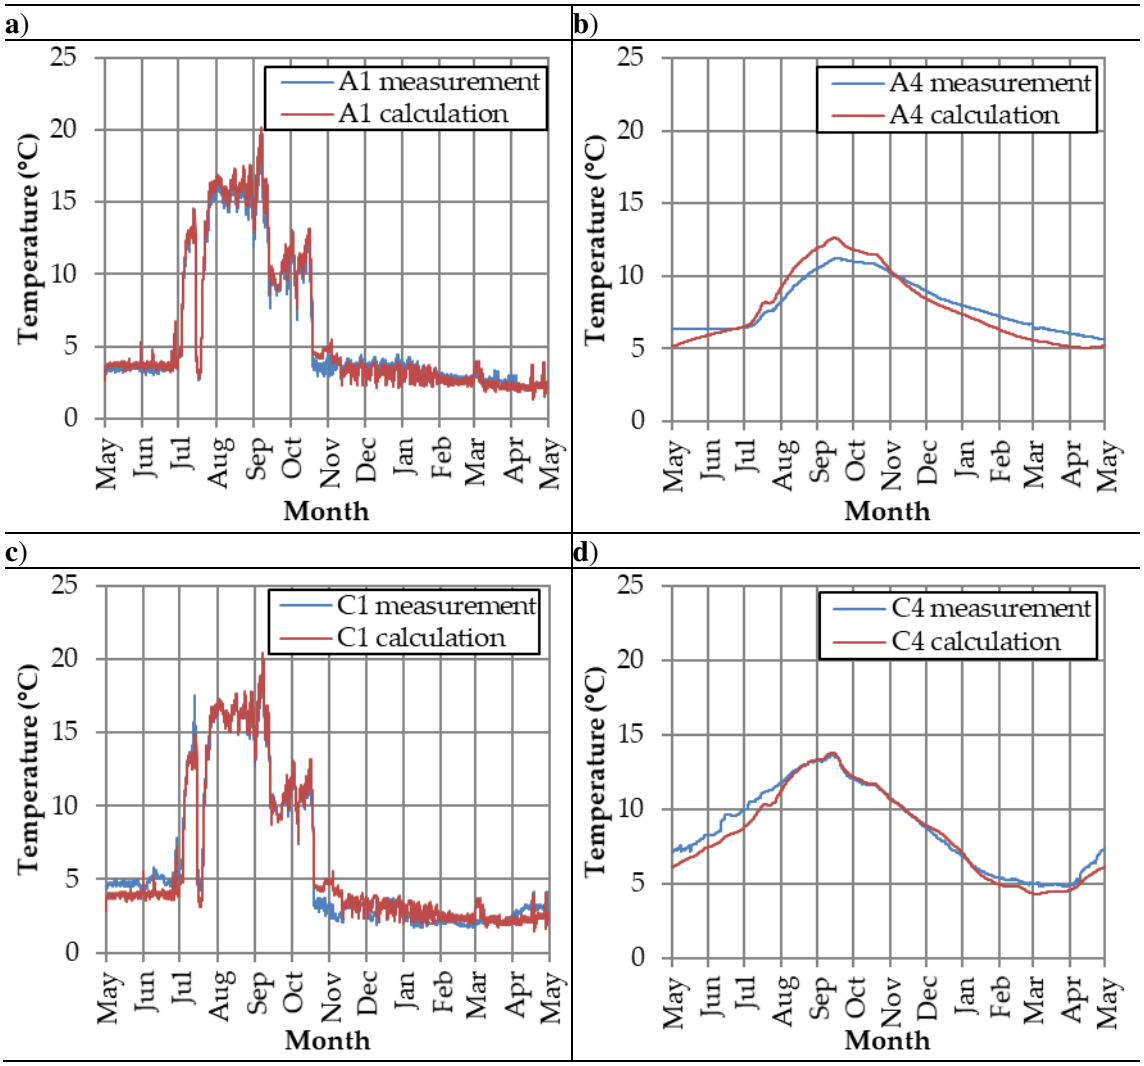

Figure 6. *Calculated and actual soil temperature: (a) A1; (b) A4; (c) C1; (d) C4*

The analysis of heat exchange intensity between the indoor air and the soil for the cold store with the floor at the ground level (variant 1) showed that the soil share in the total cold store energy balance was 16.6%. The highest energy gains from the soil were discovered in October (478.5 kWh). As a result of technological interruption in the summer, there was an intensive heat flow to the soil in July (588.1 kWh). The location of the cold store floor +0.75 m above the ground level (variant 2) reduced the soil share in the energy management to 8.2% relative to variant 1. The energy demand for cooling was 4920.5 kWh, and for heating 682.7 kWh. The analysis of variant with the floor -0.75 m under the ground level indicated that such variant significantly increases the soil share in the cold store energy balance relative to variant 1. During one year the soil share in the cold store energy balance for variant 3 was 32.8%. Similar to the two previously discussed variants, the highest heat gains were in October (891.5 kWh). The analysis of the balance of heat exchange with soil indicated high energy gains of 2054.6 kWh (*Fig. 8*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81798189

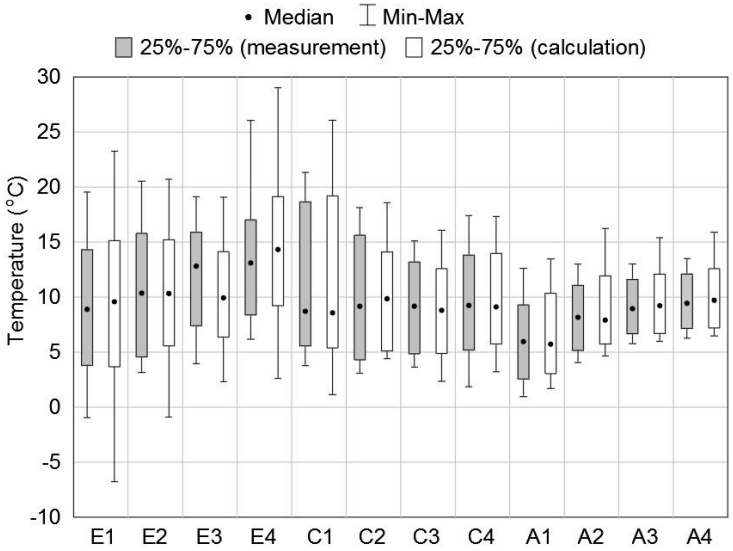

Figure 7. *Statistical agreement of the measured and calculated data, E1 – E4; C1 – C4; A1 – A4 – floor and ground temperature measurement points*

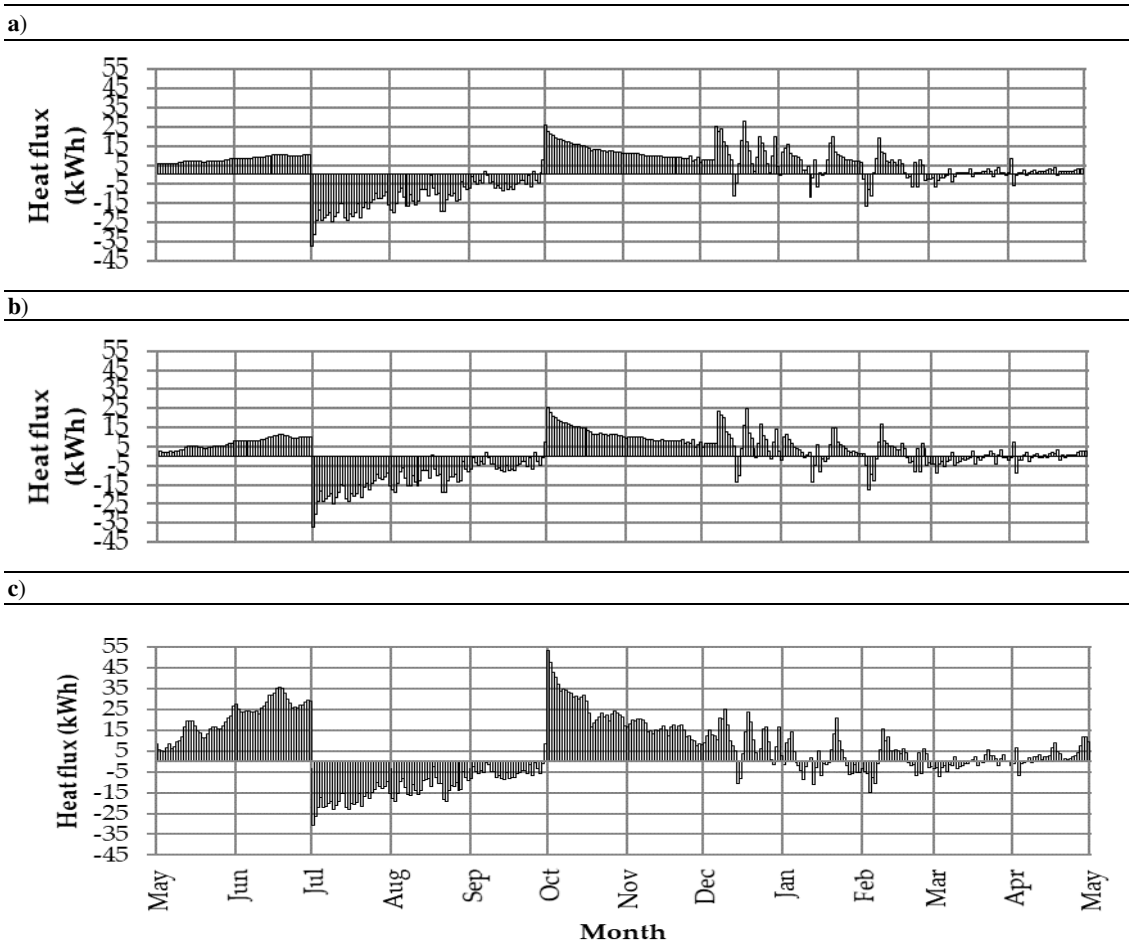

Figure 8. *Heat exchange between the cold store and soil: (a) variant 1; (b) variant 2; (c) variant 3*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81798189

The highest dynamics of heat exchange with the soil was determined in variant 3, with a 3-month cooling period from 1 October to 30 June and a 3-month technological interruption from 1 July to 30 September. The annual amplitude of the heat stream flowing through the soil in that period was 4849.4 kWh. The least soil share in the total cold store energy balance was found in variant 2 with the floor elevated +0.75 above the ground level (*Table 2*). The swap of the floor level relative to the ground level affects the decrease of the soil temperature under the cold store even by 4.0°C. Similar to the soil temperature, the data deviated from the normal distribution also in case of the cold store-soil exchange. The analysis of the significance of differences between the individual variants indicated that all the examined solutions significantly affect the heat exchange between the cold store and soil.

Table 2. *Calculation results of the heat exchange between the cold store and soil and the cold store energy demand for heating and cooling, annual balance for all variants*

	Variant 1	**Variant 2**	**Variant 3**
Heat gains from the ground (kWh·rok^{-1})	2259.1	1876.1	3452.0
Heat losses to the ground (kWh·rok^{-1})	-1319.7	-1417.7	-1397.4
Participation of the ground in cold store energy balance throughout the year (%)	16.6	8.2	32.8
Energy demand and for cooling (kWh·rok^{-1})	5141.4	4920.5	5745.5

The results show that the cold store floor elevated +0.75 m above the ground level decreases the cooling energy demand by 220.9 kWh per year compared to the variant with the floor at the ground level. The floor located below the ground level seems to be the least favourable option as it significantly increases the cooling energy demand. It should be noted that such a relationship occurs as a result of a unique storage technology. There is a 9-month storage period in the examined cold store, and the technological interruption takes place in the summer.

Discussion

The obtained generalising results of the simulation can be accepted as reliable and universal for all buildings of this type. Numerical analysis is one of the most accurate and frequently used methods in science (Janssen et al., 2004; Radoń et al., 2014; Nawalany et al., 2017; Dong, 2017; Bambara and Athienitis, 2018). However, the authors have not encountered such analysis for a vegetable cold store. Compared to other agricultural buildings, for example a greenhouses, a cold store has a significantly higher share of soil in the total energy balance of the building. In greenhouses, the soil share in the total energy balance is about 5% (Nawalany et al., 2014). The results presented in this paper indicate that in a cold store such a value is 16.6% in the case of the floor on the ground level. The studies (Bambara and Athienitis, 2018; Hyung-Kweon et al., 2018) indicate the need to verify the impact of the cold store thermal insulation at various floor location variants on the intensity of heat exchange with the soil and the soil share in the total energy balance of the building. An adequate building insulation can lead to even a 5-fold decrease of the soil share in energy gains and losses of the building (Nawalany et al., 2017; Dong, 2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81798189

Conclusions

The studies show that the cold store floor location has a significant impact on the heat exchange with the soil. When a cold store is partially earth-sheltered (floor 0.75 m below the ground level), the heat flow from soil increases even by 16.2% compared to the variant with the floor at the ground level. A floor elevated above the ground level (+ 0.75 m) decreases the heat flow from the soil by 8.4% compared to the variant with the floor at the ground level. The variants with the floor above and below the ground level significantly affect the cold store energy balance. The share of the foundation and floor in a partially earth-sheltered cold store is 32.8%, and 8.2% in an elevated cold store (+ 0.75 m). Significant differences can also be observed in the cooling energy demand. The most favourable variant is the one with the elevated floor in which the cooling energy demand is 4920.5 kWh/year. The least favourable variant is the one with the floor -0.75 m below the ground level as it increases the cooling energy demand to 5745.5 kWh/year.

Abstract. Chlorophyll a concentration [ρ(Chla)] in phytoplankton is used to understand algal biomass and the primary productivity of a water body. To investigate the seasonal dynamics of [ρ(Chla)] and their relationship with environmental factors Tiegang Reservoir at Guangdong China, continuous observation and analysis was carried out from April 2013 to June 2014. The distribution of algae had an obvious spatial heterogeneity, and the ρ(Chla) gradual increased from the southeast to the northwest of the reservoir. From April to early December 2013 and from late April to June 2014, the dominant algae was cyanobacteria. In other months, bacillariophyta were dominant. Chlorophyta were at a low level throughout the year. Multivariate analysis showed that water temperature (WT) was the primary driving factor of the spatio-temporal distribution of algae. The main environmental factors of cyanobacteria, bacillariophyta and chlorophyta were greatly different. Single environmental factors such as WT, total organic carbon (TOC), nitrate nitrogen (NO_3--N), and chemical oxygen demand (COD) were significantly related to the competitiveness of cyanobacteria and bacillariophyta. And they can be used as early warning indexs for cyanobacteria and diatom blooms. The dual synergistic effects of WT and other environmental factors on the competitiveness of cyanobacteria and bacillariophyta were analyzed. A combination of environmental factors at high risk for cyanobacteria or diatoms were found.
Keywords: *chlorophyll a, environment factors, seasonal variation, multivariate analysis, interspecific competitiveness*

Introduction

Shenzhen is the most densely populated city in mainland China. At the beginning of its establishment, the total population was 320,000 (Liu et al., 2013; Gu and Ma, 2013; Qin et al., 2014; Ng et al., 2011; Zhou et al., 2011). As of the end of 2016, the actual population had increased to 18 million, and the population density reached 9,015 persons/km, ranking first among the cities in mainland China. The influx of a large immigrant population placed unprecedented pressure on the water supply system and seriously polluted the water environment (Liu et al., 2013; Gu and Ma, 2013; Qin et al., 2014; Ng et al., 2011; Zhou et al., 2011). Although Shenzhen is located in the subtropical region, no large rivers or lakes exist in the territory. Therefore, rich rainfall cannot be effectively gathered, resulting in scarce water resources. So Shenzhen is experiencing a serious water shortage (Güneralp and Seto, 2008; Liu and Ma, 2011). In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

2015, nearly 90% of the city's drinking water needed to be imported from the Pearl River. Shenzhen water supply system is mainly composed of overseas water diversion engineering and local reservoirs. There are nearly 168 reservoirs in Shenzhen. After arriving at Shenzhen, overseas water was firstly stockpiled in local reservoirs and then was supplied to nearby water works. Therefore, water quality of those reservoirs has played an important role to the city's drinking water security. And how to ensure the safety of drinking water and to meet the people's increasing requirement for the quality of drinking water became important topics in the construction of ecological civilization in Shenzhen (Liu et al., 2013; Li et al., 2015; Lu et al., 2015).

Chl-a is an important pigment for the photosynthesis of phytoplankton (Liu et al., 2013; Li et al., 2015; Lu et al., 2015) and an important medium for absorbing and transmitting light energy. In environmental science, the concentration of chl-a in phytoplankton is used to understand algal biomass (Eisner et al., 2016; Tebbs et al., 2013; Bowes et al., 2012; Wainger et al., 2016) and the primary productivity (Lee et al., 2015; Mantyla et al., 2008; Bott et al., 2006; Morin et al., 1999) of a water body. Chl-a is used to evaluate the nutritional status (Qin et al., 2014; Naeher et al., 2016; Bell et al., 2014; Terauchi et al., 2014) of the water environment. The traditional chl-a detecting method is breaking the algal cell wall by grinding, repeatedly thawing or using microwave methods, and the total chl-a concentration is then detected by spectrophotometry (Pyo et al., 2016) without distinguishing the different algae. According to the difference of fluorescence characteristics of algae, the chl-a concentration of cyanobacteria, chlorophyta and bacillariophyta can be detected by PAM (pulse-amplitude modulation) chlorophyll fluorometer (Jakob et al., 2005; Beecraft et al., 2017; Ruth et al., 2010), which can reflect the algal biomass and provide strong technical support for studying the community structure of algae.

Reservoir is a typical non-stable water body that is influenced by nature and humans, and its hydrodynamic and ecological characteristics are distinct from those of a natural lake (Teeter et al., 2001). Tiegang Reservoir is the largest water supply reservoir in Shenzhen. Shenzhen has promoted water quality in recent years to improve the water pollution situation of the reservoir, but the total nitrogen (TN) level is still seriously above the standard, and the water quality is poor (grade V) (Zhu et al., 2018; Qin et al., 2014). To date, few studies on Tiegang Reservoirs are available, and most of them are focused on water quality, while studies of the algae community structure and seasonal changing pattern are lacking. Our research group carried out continuous monitoring of the chl-a concentration of cyanobacteria, chlorophyta and bacillariophyta and their main environmental factors from April 2013 to June 2014. The temporal and spatial distribution characteristics and evolution of chl-a in algae were analyzed, the high risk areas and periods of algal blooms were identified, and the relationship between environmental factors and algae was studied. This study provides technical support to explore the mechanism of algal blooms, to ensure the safety of drinking water and to improve the ecological civilization of water.

Materials and methods

The layout of the study area and sampling sites

There were a total of 10 sampling sites in Tiegang Reservoir (*Fig. 1*): the No. 1 site is near the inlet of Xili Reservoir, No. 2 is near the intake point of the water plant, No. 3 and No. 4 are in the running water area in the middle east reservoir (where water flow

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

velocity is fast), No. 5 and No. 6 are in the dead water area (where water flow velocity is slow), No. 7 is near the water intake point of Shiyan Reservoir, No. 8 is in the running water area in the western reservoir, No. 9 is near the Jiuwei River, and No. 10 is near the Liaokeng River. For each sampling site, the samples were collected within 3 layers from top to bottom; the surface layer is the water layer approximately 10 cm below the surface, the transparent layer is the water layer corresponding to the depth of the transparency measurement, and the bottom layer is the water layer approximately 10 cm above the sediment.

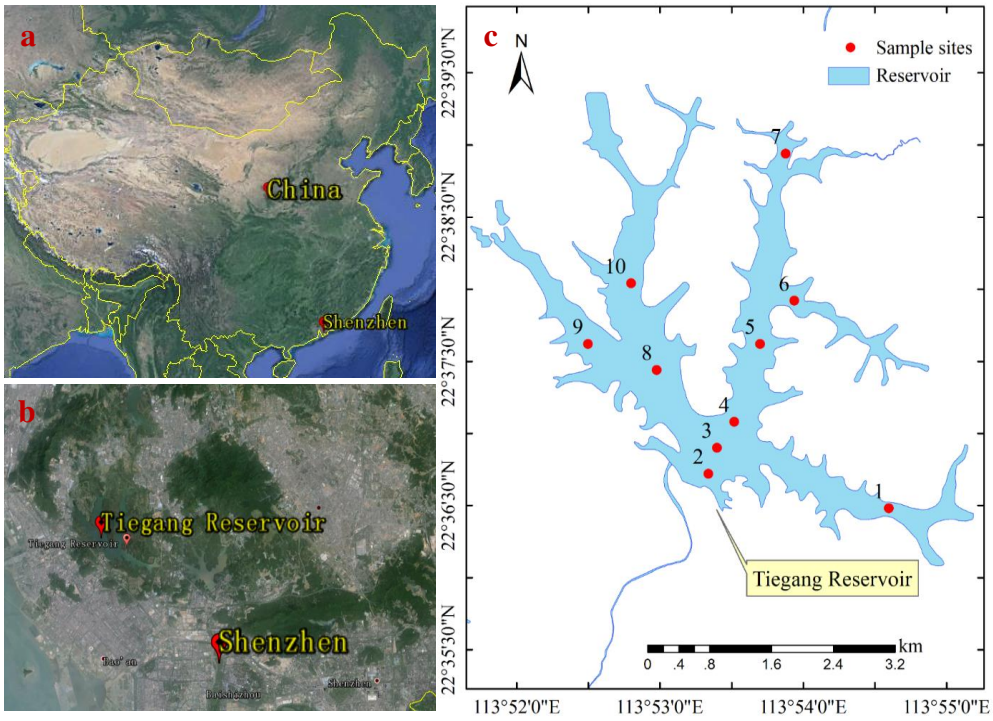

Figure 1. *The sampling sites at Tiegang Reservoir*

Sampling and analysis

The samples were collected using a ZPY-1 water collector and stored separately. The water samples were transferred to the laboratory within 2 h after collected and they were preservated at 4 °C. The chemiluminescence detection of the permanganate index (COD_{Mn}) and determination of ρ(Chla), total organic carbon (TOC), total nitrogen (TN), total phosphorus (TP), ammonia nitrogen (NH_4^+-N), nitrate nitrogen (NO_3^--N), iron (Fe) and silicate were carried out within two days. Chl-a was measured by using a modulated fluorometer (WALZ Phyto-PAM, Germany) that was periodically calibrated by acetone extraction spectrophotometry. The depth of the water, WT, pH, DO and turbidity were measured in-site using a multi-parameter water quality analyzer (YSI 6600V2, USA). The transparency (SD) was measured in-site using a secchi disk. COD was measured by the acidic potassium permanganate method; TP was determined by ammonium molybdate spectrophotometry (Shimadzu UV-2700 Ultraviolet-Visible Spectrophotometer, Japan); silicate was determined by silicon molybdenum blue spectrophotometry (Shimadzu UV-2700 Ultraviolet-Visible Spectrophotometer, Japan); TN, NH_4^+-N and NO_3^--N were analyzed by a flow analyzer (AMS-Alliance-Futura,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

French); and TOC was determined using a TOC analyzer (GE-Siever 5310C). The meteorological data, including temperature, air pressure, humidity, rainfall, evapoproportion n and sunshine hours, were provided by the Shenzhen National Climate Observatory. Three parallel samples were measured for each monitoring sample, and then the average value was taken as the final result.

Climatic periods

According to the weather characteristics, sampling time was divided into five periods. Pre-rainy period (PRP) was from April to June 2013 and 2014. Latter rainy period (LRP) was from July to September 2013. High temperature and rain free period (HTRFP) was from October to November 2013. Winter drought period (WDP) was from December 2013 to February 2014. Temperature jump period (TJP) was March 2013.

Data processing

The bivariate relationship between ρ(Chla) and the environmental factors was analyzed by Pearson correlation analysis on SPSS20. *Values in bold are different from 0 with a significance level alpha = 0.05. **Values in bold are different from 0 with a significance level alpha = 0.01. Time and space factors on environment factor and ρ(Chla) was analyzed by one-way ANOVA and two-way ANOVA that performed with SPSS20. The comprehensive correlation between the ρ(Chla) of the algae and the environmental factors was carried out using canonical correspondence analysis (CCA) on XLSTAT2010. The distribution chart of algal chl-a was generated on ArcMap10.2 by the Kriging interpolation method based on the mean of the ρ(TChla) of several months at each sampling site in the corresponding climatic period. Other graphics were prepared via using Origin9.0.

Results and discussion

Spatio-temporal evolution pattern of chl-a

Spatio-temporal evolution pattern of total chl-a

Figure 2 shows the seasonal changing pattern of ρ(TChla) in Tiegang Reservoir. The highest ρ(TChla) of Tiegang Reservoir in the sampling period was 145.06 μg L^{-1}, which appeared on the surface layer of the No. 9 sampling site on June 17, 2013. The peak period of chlorophyll a in Taihu Lake of China is from July 1 to 10 every year (Liu et al., 2019). Compared with Taihu Lake, the peak period of algae in Tiegang Reservoir is 2-3 weeks earlier. This is mainly because Tiegang Reservoir is located in the subtropical zone and its temperature is higher than that in the Taihu Lake Basin. The lowest ρ(TChla) was 4.72 μg L^{-1}, which appeared on the bottom layer of the No. 1 sampling site on January 27, 2014. The mean value was 38.53 μg L^{-1}, which was significantly higher than the value of 16.84 μg L^{-1} for the upstream reservoir - Xili Reservoir and lower than the value of 52.03 μg L^{-1} for the downstream reservoir - Shiyan Reservoir in the same period. These results indicate that the quality of the water from the Dongjiang River was significantly deteriorated after storage and transfer in the cascade reservoirs, and the water body had evolved from an oligotrophic state to a mesotrophic state.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

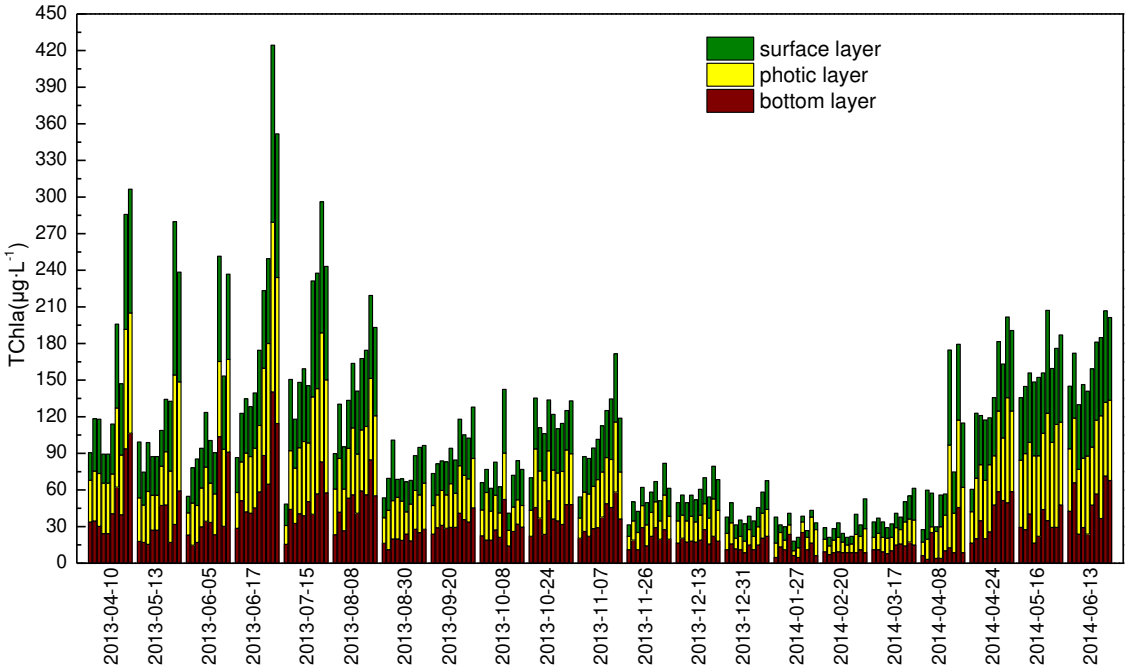

Figure 2. *Annual trend in total chl-a concentration. There are 10 columns every month and each column from left to right represents sampling sites 1 to sampling sites 10*

The temporal heterogeneity of chl-a in the algae of Tiegang Reservoir was evident: the algae began anabiosis in the temperature rising period in March 2013. The ρ(TChla) increased rapidly in April 2013 and reached 67.43 μg L^{-1} on June 17, 2013, which was the highest level for the year. From July to August 2013, the ρ(TChla) remained high, began to decline in September and remained at a medium concentration level in November, with an average value of ρ(TChla) in this period of 33.29 μg L^{-1}. From December 2013 to February 2014, the ρ(TChla) was at the lowest level of the whole year due to the low temperature, and the average value of ρ(TChla) in this period was 14.26 μg L^{-1}. From March to April 2014, the ρ(TChla) increased sharply due to the increased temperature and runoff pollution from the average of 14.4 μg L^{-1} on March 17 to 35.10 μg L^{-1} on April 8th. From May to June 2014, the reservoir again entered the high algae laden period.

The spatial heterogeneity of chl-a in the algae during the rainy season was obvious, especially from April 10 to August 8, 2013. The ρ(TChla) of the No. 9 and No. 10 sampling sites was approximately 1.5-2 times that of other sampling sites because these sites were close to the Jiuwei River and Liaokeng River and were affected by river basin pollution. From August 30 to September 20, 2013, at the end of the rainy season, the spatial heterogeneity of ρ(TChla) decreased because the pollutants in the watershed were rinsed by the heavy rainfall from April to July 2013, resulting in a significant decrease in the intensity of pollution. In August and September, although there was still heavy rainfall, the concentration of pollutants from the runoff was significantly reduced, and the concentration of algae in the inlet area from the rivers to the reservoir was also reduced due to dilution by the runoff. The spatial heterogeneity of ρ(TChla) at each sampling site in the periods of high temperature and rain free, winter drought and temperature jump was not clear. On April 8, 2014, with the arrival of the new rainy season, the ρ(TChla) of the No. 9 and No. 10 sampling sites in the northwest of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

reservoir was significantly increased, and the spatial heterogeneity of the ρ(TChla) in the reservoir was again observed.

The chlorophyll-a of algae has a certain spatial heterogeneity in the vertical direction. The distribution pattern of ρ(TChla) is the transparent layer > the surface layer > the bottom layer. The deeper the water, the more obvious this pattern became. At a water depth of 3-5 m, the algae showed a distribution pattern of the transparent layer > the surface layer > the bottom layer. At a water depth of 5-8 m, the ρ(TChla) of the bottom layer decreased rapidly, and its differences between the surface layer or transparent layer became enlarged. At a water depth of 8-15 m, the mean ρ(TChla) of the bottom layer was only approximately 3/5 that of the transparent layer. The spatial heterogeneity of chl-a in the vertical direction in a natural water body is mainly caused by the stratification of light and the water temperature (Nishijima et al., 2016). The deeper the water body, the greater the difference of the water temperature and light between the different water layers is and the more obvious the difference of ρ(TChla) should be. The ρ(TChla) of Tiegang Reservoir did not show a large difference between the bottom layer and the surface layer as in natural deep lake reservoirs, mainly because Tiegang Reservoir is a typical unstable water body affected by artificial water, with fast water flow and frequent exchange. This was especially true for the sampling sites at the intake points of the water plant and the downstream reservoir, which were 3-6 m under the water surface, thus promoting water exchange in the vertical direction and reducing the spatial heterogeneity of the algae in the vertical direction.

Spatio-temporal evolution pattern of chl-a and community structure of phytoplankton

Figure 3 shows the seasonal changing pattern of the chl-a concentration of cyanobacteria, chlorophyta and bacillariophyta in the surface layer, the transparent layer and the bottom layer of the water body. During the monitoring period, the mean value of the ρ(Chla) of cyanobacteria was 22.74 μg L^{-1}; the highest value was 98.95 μg L^{-1} in the surface layer of the No. 9 sampling site on June 17, 2013, and the lowest value was 1.57 μg L^{-1} in the bottom layer of the No. 1 sampling site on December 31, 2013. The highest monthly average was 43.98 μg L^{-1} in July 2013, and the lowest monthly average was 4.43 μg L^{-1} in January 2014. The mean value of the ρ(Chla) of bacillariophyta was 11.53 μg L^{-1}; the highest value was 49.27 μg L^{-1} in the transparent layer of the No. 10 sampling site on April 10, 2013, and the lowest value was 3.15 μg L^{-1} in the bottom layer of the No. 1 sampling site on January 27, 2014. The highest monthly average was 22.63 μg L^{-1} in April 2013, and the lowest monthly average was 4.18 μg L^{-1} in January 2014. The mean value of the ρ(Chla) of chlorophyta was 4.54 μg L^{-1}; the highest value was 18.66 μg L^{-1} in the surface layer of the No. 9 sampling site on June 17, 2013, and the lowest value was 0.18 μg L^{-1} in the bottom layer of the No. 2 sampling site on January 27, 2014. The highest monthly average was 9.24 μg L^{-1} in June 2013, and the lowest monthly average was 1.18 μg L^{-1} in February 2014.

The changing pattern of the ρ(Chla) of cyanobacteria was essentially the same as that of ρ(TChla) described in the previous section: rising in the early rainy season in 2013, reaching the highest level in June-August, decreasing to a lower level in September-November, reaching the lowest level in December 2013-March 2014 and rapidly rising in early April 2014 to reach a high in June 2014. Compared with the same period of the previous year, the ρ(Chla) of cyanobacteria was increased by 30%-50% from May to June in 2014, indicating that the diversity of algae in the reservoir decreased, and the risk of a cyanobacteria bloom further intensified. The ρ(Chla) of bacillariophyta reached

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

a maximum at March-April each year, which was slightly decreased in May-July and remained low from August to early October. From late October to early December, due to the sharp decrease of cyanobacteria, the interspecific competition was weakened; thus, the ρ(Chla) of bacillariophyta rose again. In late December to February, due to the cold weather, the ρ(Chla) of bacillariophyta was reduced again and was at the lowest level of the year. The ρ(Chla) of chlorophyta was relatively low, showing the overall characteristic of being high in the summer and autumn and low in the winter and spring.

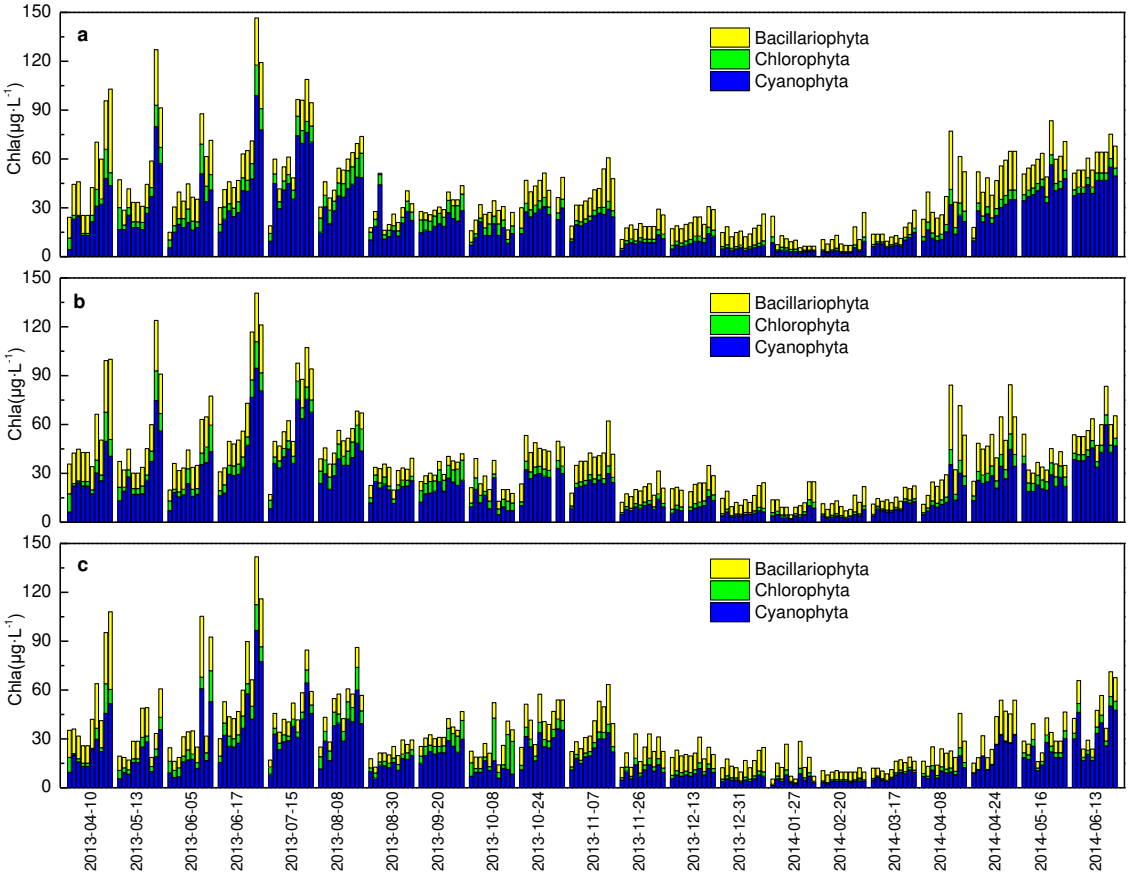

Figure 3. *Annual trend in chl-a concentration of cyonophyta, chlorophyt and bacillariophyta:* ***a*** *surface layer;* ***b*** *photic layer;* ***c*** *bottom layer. There are 10 columns every month and each column from left to right represents sampling sites 1 to 10*

Figure 4 shows the changing pattern of the algae population structure. The dominance of cyanobacteria in Tiegang Reservoir was apparent, accounting for 27.21%-72.58%, with an average of 54.49%. Bacillariophyta dominated in the winter and spring, accounting for 16.27%-61.82%, with an average of 34.17%. Chlorophyta was always at a low level, accounting for 7.21%-17.03% for the entire monitoring period, with an average of 11.38%. From April 2013 to July 2013, the proportion of cyanobacteria gradually increased from 49.28% to 72.58% and was maintained at approximately 65% until October. After December 2013, cyanobacteria rapidly decreased until the loss of dominance in December and finally reached the minimum in February 2014. In March 2014, cyanobacteria began to recover and reached 53.83% in late April to become dominant again; then, the proportion quickly rose to 71.28% in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

June. The changing trend of bacillariophyta was the opposite of that of cyanobacteria, which decreased from 43.41% in April 2013 to 16.27% in July 2013 and remained low in August-September. In October, the proportion of bacillariophyta rebounded rapidly to 46.99% at the end of December, becoming the dominant algae; this dominance was maintained until the beginning of April 2014 and reached a peak in February-March 2014. This was followed by a rapid decline under the impact of cyanobacteria recovery, falling to 21.47% in June 2014. The proportion of chlorophyta was low throughout the year, showing no obvious changing pattern in the proportion throughout the year. Compared with the same period of the previous year, the proportion of cyanobacteria in Tiegang Reservoir was increased in May-June 2014, and the proportions of bacillariophyta and chlorophyta decreased with the decreased diversity of algae. The algal population structure is a measure of the ecological diversity and stability of the water body (Pinckney et al., 2017; Tachibana et al., 2017; Tian et al., 2017). Tiegang Reservoir was dominated by cyanobacteria; the algal structure was relatively simple, with poor diversity, and the risk of a cyanobacteria bloom was rising.

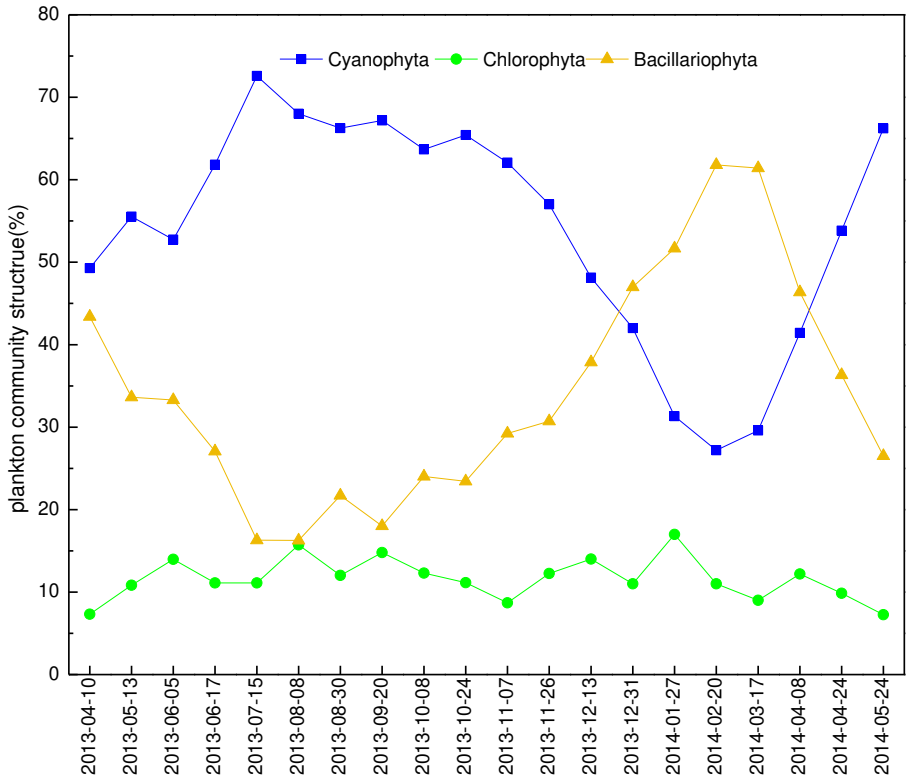

Figure 4. *Community structure of phytoplankton in Tiegang Reservoir*

Identification of the high risk area of an algal bloom

Tiegang Reservoir has a large capacity and a high spatial heterogeneity of ρ(Chla), showing the overall characteristic of gradual increases from the southeast to the northwest of the reservoir area (*Fig. 5*). From the perspective of time, the northwest and northeastern reservoir areas in the early rainy season and the northwest reservoir area in the late rainy season were at high risk of a cyanobacteria bloom, and the reservoir areas near the No. 9 and No. 10 sampling sites had a mild algal bloom in June-July 2013.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

There is a moderate risk of cyanobacteria bloom in the northeastern reservoir area in the late rainy season and the northwest reservoir area in the high temperature and dry period. The winter drought period and temperature jump period showed no risk of cyanobacteria bloom.

From the perspective of space, the No. 1 sampling site was at the inlet of Tiegang Reservoir from the Xili Reservoir, whose ρ(TChla) was 4.72-55.01 μg L^{-1}, with an average of 21.13 μg L^{-1}. The water quality was relatively good, and the algae concentration was low. The No. 2 sampling site was close to the water intake point from Tiegang Reservoir for the water plant. Because of the daily water supply to the water plant, the water exchange was most frequent in the No. 2 sampling site; therefore, the growth of algae was inhibited, with a mean ρ(TChla) value of 25.14 μg L^{-1}, showing good water quality. The No. 1 and No. 2 sampling sites were essentially free of algal blooms. The No. 3 and No. 4 sampling sites were located in the center of the reservoir, with good hydrodynamic conditions, whose mean values of ρ(TChla) were 28.50 μg L^{-1} and 28.16 μg L^{-1}, respectively, showing a relatively low risk of algal bloom. The No. 5 and No. 6 sampling sites were located in the dead water area, whose mean values of ρ(TChla) were 32.63 μg L^{-1} and 31.83 μg L^{-1}, respectively, showing a moderate risk of algae bloom in the rainy season. This was especially true for the No. 5 sampling site in June 2013, with a ρ(Chla) of 104.88-122.43 μg L^{-1}, showing a sign of mild algal bloom. The No. 7 sampling site was at the inlet from Tiegang Reservoir to the Shiyan Reservoir, whose ρ(TChla) was 4.07-96.17 μg L^{-1}, with a mean value of 69.01 μg L^{-1}, showing a moderate risk of algal bloom in the rainy season. The No. 9 and No. 10 sampling sites were close to the entry from the Jiuwei River and Liaokeng River, whose mean values of ρ(TChla) were 53.50 μg L^{-1} and 67.01 μg L^{-1}, respectively. The maximum values of ρ(TChla) were 145.06 μg L^{-1} and 119.62 μg L^{-1} in June 2013, respectively. Except for the winter dry storage period and the temperature rising period, the No. 9 and No. 10 sampling sites were at moderate or high risk of algal bloom in all other months, and the water supply safety was threatened, which needs to be addressed. The No. 8 sampling site was located at the intersection of the No. 9 and No. 10 sampling site waters, whose average annual ρ(Chla) was 39.42 μg L^{-1}, also showing a certain risk of algal bloom in the rainy season. Overall, most areas of Tiegang Reservoir are already in a mesotrophic state, and some areas are in the transition to a eutrophic state.

Multivariate analysis of chl-a and environmental factors

Pearson correlation analysis of chl-a and water quality factors

Table 1 shows the relationship between chl-a and water quality factors in the flood and drought seasons. The main correlation factors of cyonophyta, chlorophyt and bacillariophyta in different periods were different. The main correlation factors of cyanobacteria in descending order of the absolute value of the correlation coefficient for the rainy season were WT > transparency > turbidity > N:P > TP > silicate > TOC, in which transparency, N:P and silicate were negatively correlated. The main correlation factors of cyanobacteria in descending order of the absolute value of the correlation coefficient for the drought season were TOC > WT > NO_3^--N > TN > Fe > N:P, in which the NO_3^--N, TN, Fe and N:P were negatively correlated. The main correlation factors of bacillariophyta in descending order of the absolute value of the correlation coefficient for the rainy season were WT > TP > TN > TOC > NO_3^--N, in which the WT and TOC were negatively correlated. The main correlation factors of bacillariophyta in descending order of the absolute value of the correlation coefficient for the drought season were silicate > N:P > TN > transparency > NO_3^--N > Fe, in which N:P, TN, transparency, NO_3^--N and Fe were negatively correlated. The main

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

correlation factors of chlorophyta in descending order of the absolute value of the correlation coefficient for the rainy season were COD > transparency > TOC > NO_3^--N > DO > WT, in which transparency and NO_3^--N were negatively correlated. The main correlation factors of chlorophyta in descending order of the absolute value of the correlation coefficient for the drought season were TOC > WT > TP > N:P > pH > COD, in which N:P was negatively correlated. In general, the correlations between the three algae and the water quality factors in the drought season were significantly higher than those in the rainy season. This likely occurs because the algae concentration was significantly decreased by the dilution effect of the heavy rainfall (Bernal-Brooks et al., 2016) in a short time during the rainy season, leading to strong fluctuations in the chl-a concentration; therefore, the correlation with water quality factors was reduced.

Rainy season was from April to September 2013 and April to July 2014. Drought season was from October 2013 to March 2014. *Significant at the 0.05 level. **Significant at the 0.01 level. DO-dissolved oxygen. WT: water temperature, SD: transparency, COD: chemical oxygen demand, TOC: total organic carbon, TN: total nitrogen, NO^{3-}: N-nitrate nitrogen, TP: total phosphorus, N: P-the proportion of TN to TP

In particular, in the rainy season, the WT was positively correlated to cyanobacteria, with a correlation coefficient of 0.418, and was negatively correlated to bacillariophyta, with a correlation coefficient of -0.562. It was found that rising temperatures (1.4 – 6.8 °C) could increase cyanobacteria growth rates and increase cyanobacteria bloom occurrences (Davis et al., 2009; Wu et al., 2014; O Neil et al., 2012). The optimum temperature for microcytic species are 30–33 °C (Mowe et al., 2017). Fadel et al. (2015) investigated a freshwater reservoir in the Mediterranean and found that when the WT exceeded 25 °C, the cyanobacteria represented by microcystis began to multiply. It was found that the suitable temperature for the growth of bacillariophyta was 10–25 °C (Mitrovic et al., 2010), and the maximum growth rate occurred at 20 °C, and the growth rate of bacillariophyta was inhibited and the biomass began to decrease when the WT exceeded 25 °C (Jung et al., 2013). The WT of Tiegang Reservoir was 22.46–32.79 °C in the rainy season, with an average of 29.44 °C, and reached 28 °C in May. The higher WT is beneficial to the growth and reproduction of cyanobacteria, and it somehow inhibits the growth of bacillariophyta, which allows the cyanobacteria to gain an advantage over bacillariophyta. Therefore, the WT was positively correlated with cyanobacteria and negatively correlated with bacillariophyta in the rainy season. In the rainy season, the concentration of cyanobacteria was positively correlated with turbidity and negatively correlated with transparency, indicating that the rapid increase of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

cyanobacteria in the rainy season increased the water turbidity while reducing the water transparency and light intensity. The photosynthesis of algae is limited with reduced light intensity in a water body. However, some cyanobacteria have pseudo-vacuoles, which can float up to the surface water layer where the light intensity is higher, and they will subsequently not be inhibited by the weakening of light. Bacillariophyta are more widely distributed in the middle layers of water, and the high turbidity and low light intensity of the water body will therefore more significantly affect the growth of bacillariophyta. In the rainy season, TN was significantly correlated with bacillariophyta, and TP showed a certain correlation with both bacillariophyta and cyanobacteria, indicating that nitrogen and phosphorus are the important factors for algae growth. Tiegang Reservoir is a nitrogen-contaminated reservoir, with total nitrogen levels up to 1.64 mg L^{-1}, a surface water quality of grade V, and TP levels as low as 0.024 mg L^{-1}, belonging to the surface water quality of grade II. For algal growth, TN is relatively abundant, and TP is relatively scarce, and phosphorus is a limiting nutrient for algal growth. The N: P of Tiegang Reservoir in the rainy season and drought season was 69 and 54, respectively, and the N: P showed a negative correlation with cyanobacteria and bacillariophyta, indicating that a high N: P was not favorable for the growth of algae. This result is consistent with the findings of Smith (1983), who proposed the "N: P law" based on the study of 17 lakes; that is, cyanobacteria blooms can easily outbreak when N: P is lower than 29. The WT in the drought season was still the main influencing factor for all three algae, especially for chlorophyta and cyanobacteria, with correlation coefficients as high as 0.695 and 0.651, respectively. All three algae in the drought season showed significant negative correlations with water quality factors, including NO_3^--N, TN and Fe. There were two main reasons for this phenomenon. On the one hand, the ρ(Chla) of algae in the drought season significantly decreased with decreased temperature. On the other hand, water is lacking in the drought season, and the reservoir was operating at low water level; thus, the concentrations of water quality factors, including NO_3^--N and TN increased slightly. The transparency was negatively correlated with the three algae at each period to varying degrees, indicating that the growth of algae in the reservoir was not conducive to the transparency of the water body. The correlations between DO and the three algae in each period were not obvious because Tiegang Reservoir is a typical artificial water transfer and supply reservoir, with a highly frequent water exchange and a low stability of the water body. The average concentrations of dissolved oxygen in the rainy season and drought season were 8.89 and 9.12 mg L^{-1}, respectively, which are sufficient to meet the needs of algal growth.

Pearson correlation analysis of chl-a with the meteorological and hydrodynamic factors

Table 2 shows the correlation of chl-a with the meteorological factors and hydrodynamic factors in the flood and drought seasons. On the same day, the collected hydrodynamic factors and meteorological factors should be the same, and the data characteristics were different from those of water quality factors. Therefore, their correlations with the chl-a were analyzed separately. *Table 2* shows that there were significant differences in the main correlated factors of different algae in the same period and the same algae at different periods. The main correlated factors of different algae in different periods were different. In the rainy season, the main correlated factors of cyanobacteria in descending order of the absolute value of the correlation coefficient

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

were WT > evapoproportion n > pressure > runoff > sunshine hours > hydraulic retention times (HRT). The main correlated factors of bacillariophyta in descending order of the absolute value of the correlation coefficient were temperature > evapoproportion n > sunshine hours > runoff > HRT > pressure. The main correlated factor of chlorophyta was temperature. In the drought season, the main correlated factors of cyanobacteria in descending order of the absolute value of the correlation coefficient were water evapoproportion n > temperature. The main correlated factors of bacillariophyta in descending order of the absolute value of the correlation coefficient were evapoproportion n > pressure > temperature. The main correlated factors of chlorophyta in descending order of the absolute value of the correlation coefficient were humidity > evapoproportion n > pressure. Temperature showed a significant positive correlation with cyanobacteria and a significant negative correlation with bacillariophyta, which was consistent with the effect of WT on cyanobacteria and bacillariophyta. Rainfall is the main driving force of watershed pollution entering the reservoir. The rainwater washed the organic matter and nitrogen/phosphorus nutrient salt deposits from the watershed surface into the reservoir in the form of ground surface runoff (Abell and Hamilton, 2015). The runoff in the early rainy season showed a significant negative correlation with cyanobacteria and a negative correlation with bacillariophyta. The runoff in the late rainy season showed a slight negative correlation with all three algae. This occurs because the proportion of organic matter and nutrient salts in the runoff of the early rainy season were high, which could increase the organic matter and nutrient salts in the reservoir and promote the growth and reproduction of cyanobacteria. The water quality of the runoff in the late rainy season was better, which was mainly due to the increased amount of water in the reservoir, which diluted the organic matter, nutrient salts and algae. In the rainy season, HRT was highly negatively correlated with cyanobacteria, indicating that, in order to inhibit the excessive reproduction of cyanobacteria during the rainy season, the reservoir management department can reduce the water retention time by increasing the water supply and reducing the water level of the reservoir to prevent a cyanobacteria bloom. The pressure was negatively correlated with all three algae to different degrees, but the results do not indicate that the pressure has a significant direct effect on algal growth. This is mainly due to the significant negative correlation between air pressure and air temperature in meteorological regularity. Pearson correlation analysis also showed that the correlation coefficients of air temperature and air pressure in the flood and drought seasons were -0.859 and -0.936, respectively.

Canonical correspondence analysis (CCA) of chl-a and environmental factors

Canonical correspondence analysis of the relationship of the water quality, meteorological factors and hydrodynamic factors with algae ρ(Chla) in the rainy season and the drought season was carried out to investigate the comprehensive effects of the environmental factors on the growth of algae in the flood and drought seasons (*Fig. 6*). The arrow in the figure indicates the environmental factor, and the length of the arrow indicates the correlation between the algae and this environmental factor. The angle between the arrow line and the ordination axis indicates the correlation between this environmental factor and the ordination axis, and the smaller the angle is, the closer the correlation is. The quadrant of the arrow indicates the positive or negative correlation between the environmental factor and the ordination axis. In the rainy season, cyanobacteria, chlorophyta and bacillariophyta were located in the fourth, first and

second quadrants, respectively; in the drought season, cyanobacteria, chlorophyta and bacillariophyta were located in the second, fourth and first quadrants, respectively, indicating that the growth patterns of the three algae were different, and the environmental factors influencing the three algae varied widely. The eigenvalues of F1 and F2 in the rainy season were 0.022 and 0.008, respectively, and the explanatory rates were 72.61% and 27.39%, respectively. The eigenvalues of F1 and F2 in the drought season were 0.024 and 0.009, respectively, and the explanatory rates were 73.10% and 26.90%, respectively.

Rainy season was from April to September 2013 and April to July 2014. Drought season was from October 2013 to March 2014. AT: air temperature, BP: barometric pressure, SHD: sunshine duration, EC: evaporation capacity, RV: runoff volume, TR: total rainfall, HRT: hydraulic retention time. *Significant at the 0.05 level. **Significant at the 0.01 level

Figure 6 shows that the environmental factors with the highest correlation degree to algae were the meteorological factors, including the temperature, sunshine hours, pressure and evaporation, indicating that the spatio-temporal distribution and evolution of algae are mainly driven by changes in climate. Panels a and b show that the strongest environmental factor associated with algae in the rainy season and the drought season was WT, followed by air temperature, indicating that temperature is the primary driving factor for algal growth in Tiegang Reservoir. The environmental factors showing the maximum projection on the F1 axes of the two panels were both WT; thus, the F1 axis mainly reflects the change in WT. The number of sunshine hours and the amount of evaporation in both figure a and figure b showed positive correlations with algae. Light is the essential condition for the photosynthesis of algae, and the increase of sunshine hours is beneficial to the increase of algal biomass. The amount of evaporation reflects the loss of the reservoir water from liquid to gas; the greater the amount of evaporation is, the more the loss of the reservoir water due to evaporation, resulting in increased algal concentration. Air pressure was negatively correlated with algae and was highly opposite to temperature in figure a and figure b since pressure was negatively correlated with temperature in the meteorological regularity; thus, pressure was indirectly negatively correlated with algae, which does not indicate that pressure has a direct causal relationship with algal growth. The hydrodynamic factor HRT reflects the length of residence time of water in the reservoir, which was significantly correlated with algae in both figure a and figure b. This negative correlation was especially significant for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

cyanobacteria, indicating that frequent water exchange could inhibit the growth of algae. This finding is consistent with the result of the Pearson correlation analysis. TOC and COD represent the contents of organic matter in the water, whereas TN, ammonia nitrogen, nitrate nitrogen and TP reflect the contents of nutrient salts in the water. The TOC, COD, TN, ammonia nitrogen, nitrate nitrogen and TP were moderately correlated with algal concentration ns in figure a and figure b. Silicate was more closely related to algae in the rainy season, and the correlation in the drought season was not obvious. In the drought season, Fe was highly correlated with the F1 axis because Fe is an essential element of algal photosynthesis and metabolism and has an important effect on the biomass and growth rate of algae, especially bacillariophyta (Sugie et al., 2013; Okumura et al., 2013; Russo et al., 2015).

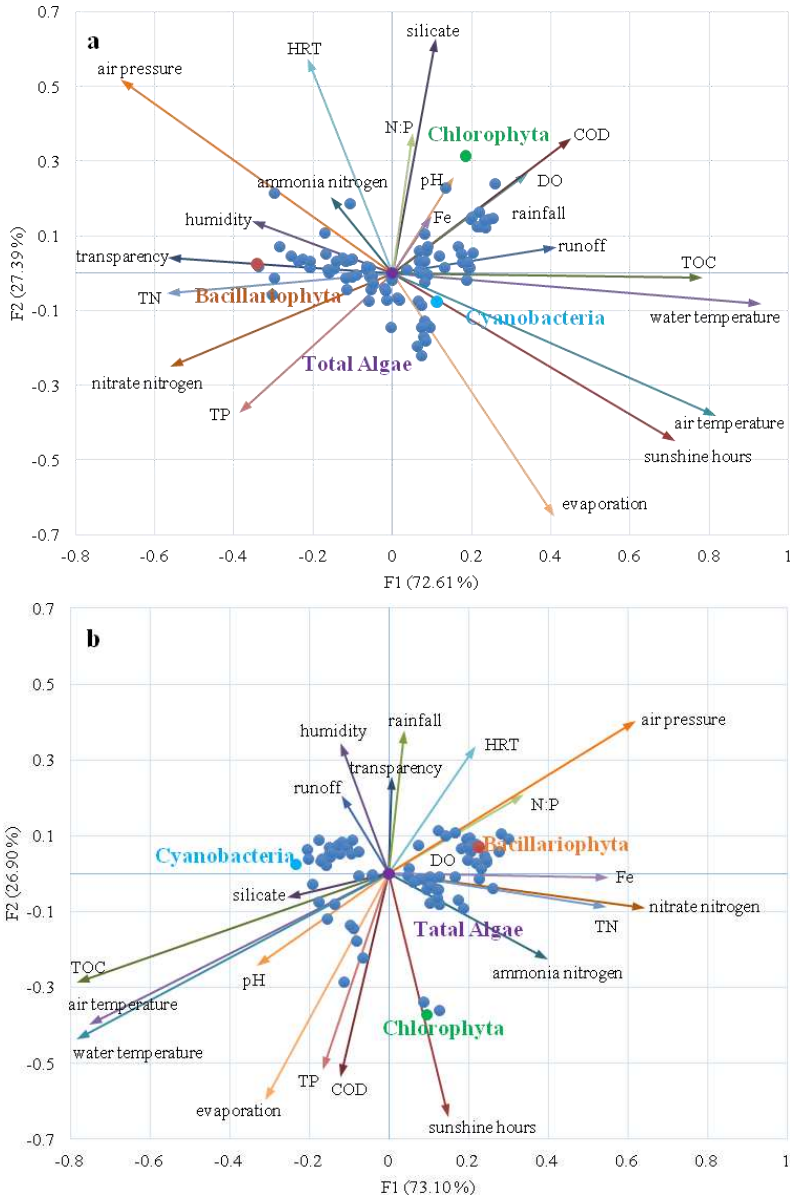

Figure 6. *Canonical correspondence analysis of environmental factors and phytoplankton:* ***a*** *rainy period;* ***b*** *drought period. The light blue, green, yellow and purple dots, respectively, represent cyanobacteria, chlorophyta, bacillariophyta and total algae; the dark blue dots indicate the sampling sites; and the arrows indicate the environmental factors*

Influence of environmental factors on the competitiveness of cyanobacteria and Bacillariophyta

Effects of single environmental factors on the competitiveness of cyanobacteria and Bacillariophyta

Chl-a proportions of cyanobacteria and diatom were used to characterize the competitiveness of cyanobacteria and bacillariophyta, thus describing the potential for growth and eruption. When the chl-a proportion was less than 40%, it meant that the outbreak risk was low. When the chl-a proportion reached 40%~60%, it meant that they had slight risk of outbreaks. When the chl-a proportion were more than 60%, it meant that they were at high risk of outbreaks.

Figure 7 shows when WT was lower than 17 °C, the proportion of cyanobacteria was between 30~40%, and the advantage was not obvious. With the increase of WT, the competitiveness of cyanobacteria increased gradually. When the WT was 21.5 °C, the proportion of cyanobacteria and bacillariophyta were both equal to 48%. The two were equal in competitiveness. There was a high risk of cyanobacteria blooming. When WT reached 28.8 °C, the proportion of cyanobacteria was over 60%, which completely occupied the dominant position. When WT exceeded 30 °C, the cyanobacteria proportion raised to 70%~80%, reaching the highest level. The linear fitting formula of cyanobacteria competitiveness and WT was calculated as *Equation 1*. When WT was below 17.2 °C, the diatom proportion was higher than 60%. Bacillariophyta occupied a dominant position. As the water temperature raised, the diatom proportion decreased gradually. When WT was 21.5 °C, the proportion of cyanobacteria and diatom was both 48%. When WT exceeded 24.3 °C, the diatom proportion fell below 40%, completely losing the dominant position. When WT exceeded 32 °C, the diatom proportion dropped to 10~15%, reaching the lowest level in the whole year. The linear fitting formula of diatom competitiveness and WT was calcuated as *Equation 2*.

$$[\text{Chla-cyanophyta}] = 11.94 + 1.68\text{WT}, R^2 = 0.81 \quad \text{(Eq.1)}$$

$$[\text{Chla-bacillariophyta}] = 107.60 - 2.76\text{WT}, R^2 = 0.49 \quad \text{(Eq.2)}$$

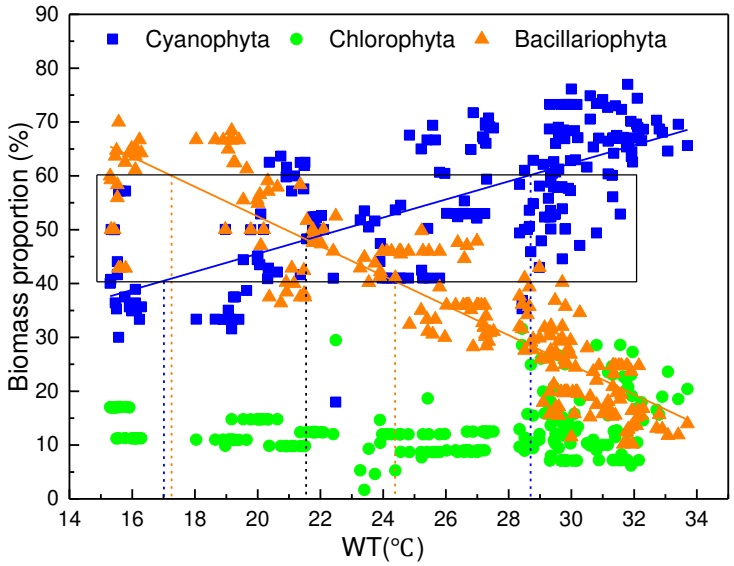

Figure 7. *Effects of WT on the competitiveness of cyanobacteria and bacillariophyta*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

Figure 8 shows when TOC was below 2.25 mg/L, the proportion of cyanobacteria was between 30~40%, and its advantage was not obvious. With the increase of TOC, the competitiveness of cyanobacteria increased gradually. When TOC was 2.62 mg/L, the proportion of cyanobacteria and bacillariophyta were both equal to 48%. The two were equal in competitiveness. When TOC reached 4.21 mg/L, the proportion of cyanobacteria was more than 60%, which fully occupied the dominant position. When TOC exceeded 5.0 mg/L, the cyanobacteria proportion raised to 65%~75%, reaching the highest level in the year. The linear fitting formula of cyanobacteria competitiveness and TOC was calculated as *Equation 3*.

When TOC was below 1.70 mg/L, the diatom proportion was higher than 60%. Diatom occupied a dominant position. With the increasing of TOC, the proportion of diatom decreased gradually. When TOC was 2.62 mg/L, the proportion of cyanobacteria and bacillariophyta was both 48%. When TOC exceeded 3.29 mg/L, the diatom proportion fell below 40%, completely losing dominance. When TOC exceeded 4.52 mg/L, the diatom proportion falls to 10%~20%, reaching the lowest level of the year. The linear fitting formula of diatom competitiveness and TOC was calculated as *Equation 4*.

$$[\text{Chla-cyanophyta}] = 26.11 + 8.22\text{TOC}, R^2 = 0.54 \quad \text{(Eq.3)}$$

$$[\text{Chla-bacillariophyta}] = 82.09\text{-}12.89\text{TOC}, R^2 = 0.69 \quad \text{(Eq.4)}$$

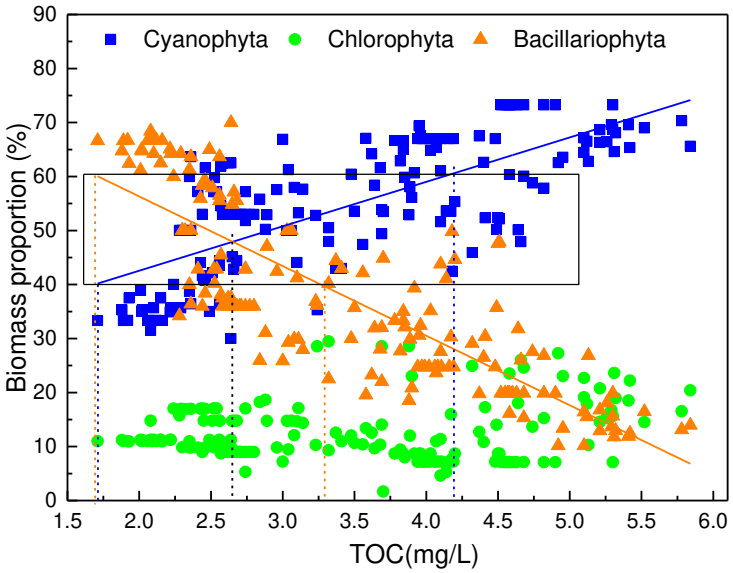

Figure 8. *Effects of TOC on the competitiveness of cyanobacteria and bacillariophyta*

Figure 9 shows when NO_3^--N was below 0.82 mg/L, the proportion of cyanobacteria was between 60~75%, taking full advantage. With the increasing of NO_3^--N, the competitiveness of cyanobacteria declined gradually. When NO_3^--N was 1.28 mg/L, the proportion of cyanobacteria and bacillariophyta were both equal to 46%. The two were equal in competitiveness. When NO_3^--N reached 1.53 mg/L, the proportion of cyanobacteria fell below 40%. Cyanobacteria completely lost dominance. The linear fitting formula of cyanobacteria competition and NO_3^--N was calculated as *Equation 5*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

When NO_3^--N was below 0.82 mg/L, the diatom proportion was below 30%, and the competitiveness was very low. With the increasing of NO_3^--N, the proportion of diatom raised gradually. When NO_3^--N was 1.28 mg/L, the proportion of cyanobacteria and bacillariophyta was both 48%. When NO_3^--N exceeded 1.4 mg/L, diatom occupied the dominant position. The linear fitting formula of diatom competition and NO_3^--N was calculated as *Equation 6*.

$$[\text{Chla-cyanophyta}] = 82.97 + 27.93\ NO_3^-\text{-N},\ R^2 = 0.28 \quad \text{(Eq.5)}$$

$$[\text{Chla-bacillariophyta}] = -2.59\text{-}39.04\ NO_3^-\text{-N},\ R^2 = 0.30 \quad \text{(Eq.6)}$$

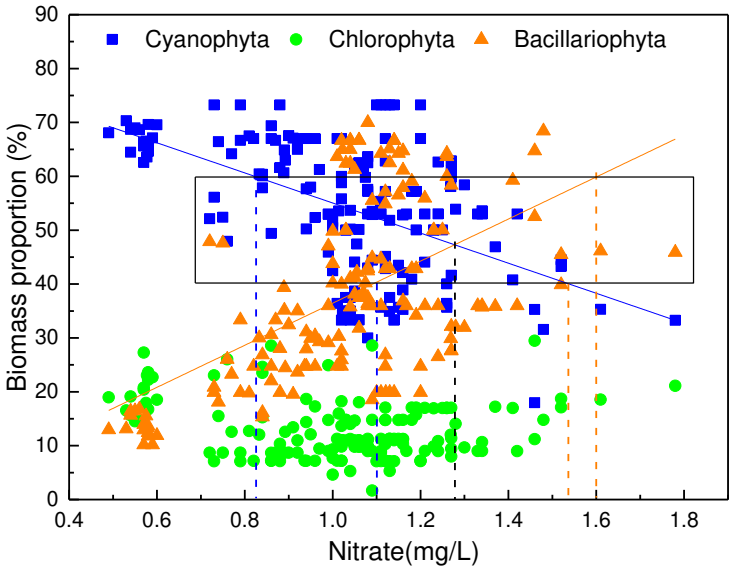

Figure 9. *Effects of NO_3^--N on the competitiveness of cyanobacteria and bacillariophyta*

Figure 10 shows when COD was 1.20~1.50 mg/L, the proportion of cyanobacteria and bacillariophyta was 30%~72%. When COD was 1.38 mg/L, the proportion of cyanobacteria and bacillariophyta were both equal to 49%. The competition between them was fierce and neither had obvious advantages. With the increase of COD, the dominance of bacillariophyta declined while the dominance of cyanobacteria increased. When COD was 1.82 mg/L, the proportion of bacillariophyta dropped below 40%, losing dominance, while the proportion of cyanobacteria rose further. When COD was 2.55 mg/L, the proportion of cyanobacteria was over 60%. Cyanobacteria completely occupied the dominant position, while the diatom proportion dropped to about 20%. From *Figure 9,* it can be found that the competitiveness of cyanobacteria is significantly higher than that of diatoms at lower nutrient saline levels. With the increase of nutrient concentration, the competitiveness of bacillariophyta increased significantly. This validates the research results of Onur. Cyanobacteria cell sizes are much smaller than diatom cells. Therefore the higher nutrient affinity and growth rate of the small s Cyanobacteria makes them better competitors (Onur et al., 2012). The linear fitting formula of blue-green algae competitiveness and COD was calculated as *Equation 7*. The linear fitting formula of diatom competitiveness and COD was calculated as *Equation 8*.

DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

$$[\text{Chla-cyanophyta}] = 36.14 + 9.44\text{COD}, R^2 = 0.17 \quad \text{(Eq.7)}$$

$$[\text{Chla-bacillariophyta}] = 73.42\text{-}18.15\text{COD}, R^2 = 0.31 \quad \text{(Eq.8)}$$

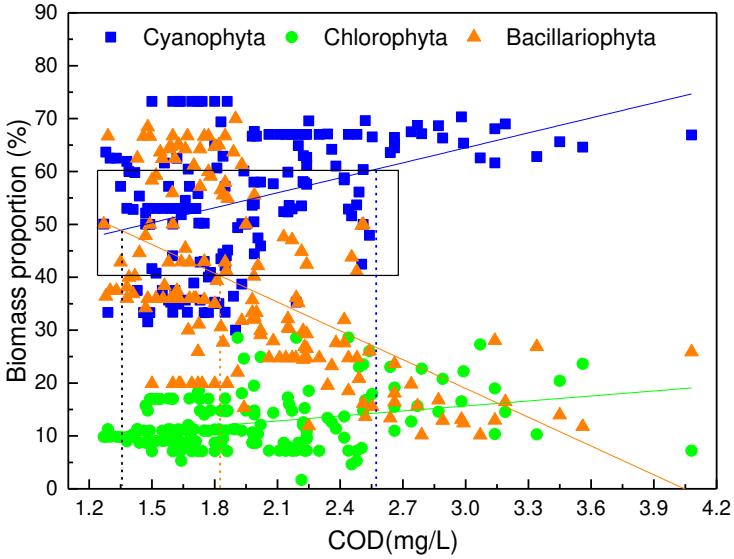

Figure 10. *Effects of COD on the competitiveness of cyanobacteria and bacillariophyta*

Therefore, environmental factors such as WT, TOC, NO_3^--N and COD were closely related to the competitiveness of cyanobacteria and bacillariophyta. So they can be used as an early warning index for algal bloom. WT 22 °C can be used as a primary WT threshold of cyanobacteria. When WT was more than 22 °C, the diatom dominance decreased, and the predominance of cyanobacteria rose rapidly. WT 28 °C can be used as the secondary WT threshold of cyanobacteria. When WT was over 28 °C, and the predominance of cyanobacteria was over 60%, and cyanobacteria blooming was most likely to occur. Similarly, the primary TOC threshold of cyanobacteria was 2.8 mg/L, and the secondary TOC threshold was 4.2 mg/L. The primary NO_3^--N threshold of cyanobacteria was 1.25 mg/L, and the secondary NO_3^--N threshold was 0.85 mg/L. The primary COD threshold of cyanobacteria was 1.25 mg/L, and the t secondary COD threshold was 2.55 mg/L.

Analysis of the effects of dual environmental factors on the competitiveness of cyanobacteria and bacillariophyta

The effects of single environmental factors on the competitiveness of cyanobacteria and bacillariophyta were analyzed in the previous section (*Figs. 11–14*). However, in the real environment of the reservoir, the growth of algae was influenced by synergistic effect of many environmental factors. WT was the most important environmental factor. Therefore, the dual synergistic effects of WT and other environmental factors on the competitiveness of cyanobacteria and bacillariophyta were further analyzed. Bubble charts were used and bubble size indicated the proportion of chl-a to cyanobacteria or bacillariophyta, which represented the competitiveness of cyanobacteria and bacillariophyta.

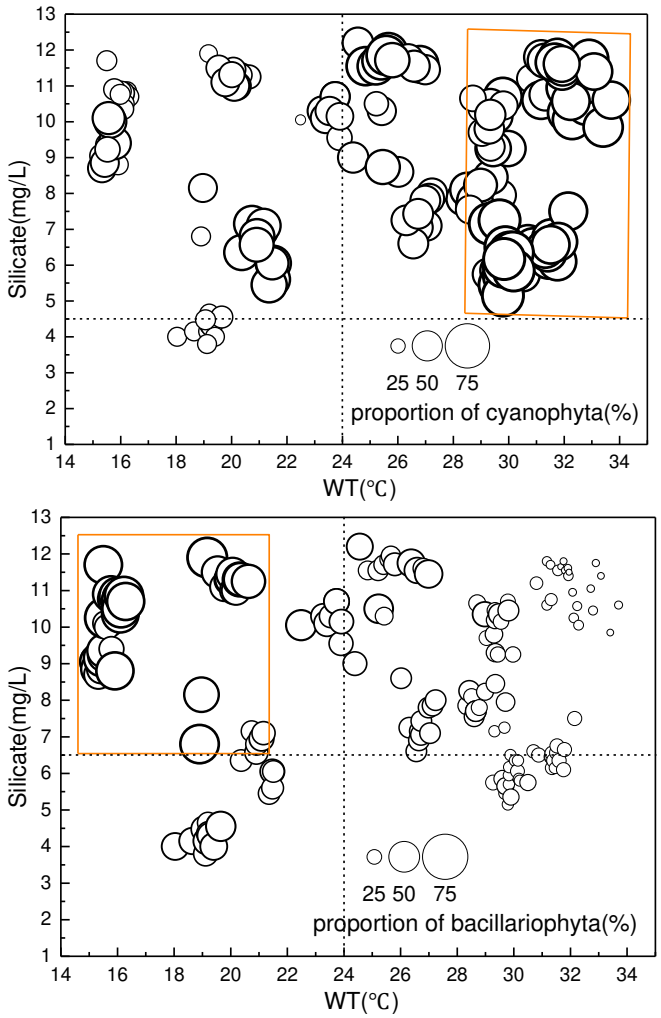

Figure 14. *Combined effects of Silicate and NO_3^--N on the competitiveness of cyanobacteria and bacillariophyta*

A combination of environmental factors at high risk for cyanobacteria or diatoms were found. WT (24.5~33.5 °C) and TOC (3.2~5.8 mg/L) were high risk factors for cyanobacteria outbreaks. WT (15.5~21.5 °C) and TOC (1.5~3.3 mg/L) were high risk factors for bacillariophyta outbreaks. WT (28.5~33.5 °C) and NO_3^--N (0.5~1.5 mg/L) were high risk factors for cyanobacteria outbreaks. WT (15.5~21.5 °C) and NO_3^--N (1.0~1.5 mg/L) were high risk factors for bacillariophyta outbreaks. WT (28.5~33.5 °C) and COD (1.7~3.5 mg/L) were high risk factors for cyanobacteria outbreaks. WT (15.5~20.5 °C) and COD (1.2~1.9 mg/L) were high risk factors for bacillariophyta outbreaks. WT (28.5~33.5 °C) and Silicate (5.0~11.8 mg/L) were high risk factors for cyanobacteria outbreaks. WT (15.5~20.5 °C) and Silicate (6.5~12.0 mg/L) were high risk factors for bacillariophyta outbreaks.

Conclusions

1) During the monitoring period, the average connection of algae [ρ(TChla)] in Tiegang Reservoir was 38.81 μg L^{-1}, which was in a mesotrophic state. The mean

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_81918217

ρ(Chla) values of cyanobacteria, bacillariophyta and chlorophyta were 22.74, 11.53 and 4.54 μg L^{-1}, respectively. From late December 2013 to early 2014, bacillariophyta was the dominant algae (46.37–61.81%), cyanobacteria was dominant in all other periods (48.13–72.58%), and chlorophyta was low throughout the entire year (7.25–14.80%). Compared with the same period of the previous year, the proportion of cyanobacteria was increased in the period of May-June 2014, and the proportions of bacillariophyta and chlorophyta decreased with the decreased diversity of algae, leading to the increased risk of a cyanobacteria bloom.

2) The temporal changing pattern of ρ(Chla) in Tiegang Reservoir is as follows: the early rainy season > the late rainy season > the high temperature and no rain period > the temperature rising period > the autumn and winter water storage period. The distribution of ρ(Chla) in the vertical direction is as follows: the transparent layer > the surface layer > the bottom layer. The spatial changing pattern of ρ(Chla) is a gradual increase from southeast to northwest. The No. 9 and No. 10 sampling sites are at the entry of the runoff to the reservoir, whose ρ(Chla) were significantly higher than that in other reservoir areas. The water quality of the No. 2 sampling site at the intake point of the water plant was good. The northwest reservoir area is at high risk of an algal bloom.

3) Pearson correlation analysis and CCA analysis showed that the spatio-temporal distribution of algae was mainly driven by changes in climate, for which the WT was the primary driving factor. The main environmental factors for cyanobacteria, bacillariophyta and chlorophyta were greatly different. Cyanobacteria is mainly associated with WT, TOC, sunshine hours, runoff and HRT; bacillariophyta is mainly associated with WT, silicate, TN, TP and HRT; and chlorophyta are mainly associated with TOC, COD, WT, NO_3^--N and sunshine hours.

4) Influence of environmental factors on the competitiveness of cyanobacteria and bacillariophyta was analyzed. Single environmental factors such as WT, TOC, NO_3^--N, and COD were significantly related to the competitiveness of cyanobacteria and bacillariophyta. The linear fitting formula of cyanobacteria competitiveness and environmental factors were calculated. The dual synergistic effects of WT and other environmental factors on the competitiveness of cyanobacteria and bacillariophyta were analyzed. A combination of environmental factors with high risk of cyanobacteria and diatom outbreaks was proposed.

Abstract. During periods of predation risk, prey adopt antipredator behaviours to maximise chances of survival, such as increased vigilance, reduced foraging time, shifting to safe habitat, and group formation. To effectively balance resource acquisition and antipredator behavior, prey animals make use of cues within their environment that provide them accurate information about the realistic threat of predation. Using camera traps, we tested vigilance and feeding behavioural responses of two naturally occurring ungulate species roe deer and moose to cues from naturally occurring brown bear and novel Amur tiger predators. We found that roe deer and moose vigilance and feeding behaviours were not affected by either visual or olfactory cues from predators, suggesting that ungulates in this system do not respond differently to novel predator cues. There are a number of potential explanations for this surprising lack of response to any predator cues: a) habituation to uninformative cues is important; b) ungulates might have relied more heavily on other cue types, such as auditory cues, or cues in combination; and, c) constraints on dispersal and/or resources may result in prey being forced to remain in high risk food patches, and continued prioritization of feeding over vigilance. We therefore, recommend that in the future studies regarding cues should involve a combination of cues at a similar location to increase predation risk to the animals to maximise prey response. To our knowledge, this is the first study to lay out the foundation of the ecological influences of captive Amur tiger on prey behaviors in the wild environment.
Keywords: *predators, ungulates, fear ecology, camera trap, antipredator, hanma, vigilance, foraging*

Introduction

Under predation risk, prey adopt predation avoidance behaviours to maximise their chances of survival (Blumstein, 2006), such as increased vigilance, change of foraging time, shifting to safe habitat, and group formation (Creel and Christianson, 2008; Li et al., 2011; Kuijper et al., 2014). Vigilance behaviors - which can be explained as the time a prey animal spends being alert, actively scanning for predators, and fleeing (Brown and Kotler, 2004; Creel and Christianson, 2008; Creel et al., 2014) - help prey animals adjust to predation risk (Li et al., 2011) through prioritizing predator recognition (Brown and Kotler, 2004). Predation risk determines the habitat pattern to be used by most prey species (Laundré et al., 2001; Hernández and Laundré, 2005), due to the fact that the presence of large predators builds a “landscape of fear” (Laundré et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82198234

al., 2001) meaning that prey perceive risk differently in different habitats and act and distribute themselves accordingly (Hernández and Laundré, 2005; Brook et al., 2012).

Prey species trade off activities such as foraging, moving between patches, mating, and vigilance behaviours – how this unfolds can have substantial effects on prey species life history trajectories (Lima and Bednekoff, 1999; Eccard et al., 2017). This balance of behaviours is likely to be skewed more towards antipredator behaviours in high predation risk habitat, with vigilance taking a higher priority (Blumstein, 2003). The optimal foraging theory states that under high risk conditions, foraging time is minimised (Lima and Bednekoff, 1999; Eccard and Liesenjohann, 2008). For example, under high predation pressure from predators like wolves (*Canis lupus*) and Lynx (*Lynx lynx*) (Eccard et al., 2017), ungulate species decrease foraging and increase vigilance (Eccard et al., 2017). This shows how fear effects can shape individual behaviours and even community significantly even than direct killing (Creel and Christianson, 2008; Creel et al., 2014).

In order to effectively balance resource acquisition and antipredator behavior (Brown and Cowan, 2000; Brown and Kotler, 2004), prey animals make use of cues within their environment that provide them accurate information about the realistic threat of predation (Hemmi and Pfeil, 2010). For example, experimental manipulation of apex predator cues, such as visual and odor cues or both, reduces foraging behaviors carried out by the dottyback fish, *Pseudochromis fuscus* (Palacios et al., 2016). In most cases predator odour cue results in minimized foraging activity (Nersesian et al., 2012) or total prey avoidance of the area (Apfelbach et al., 2005; Kats and Dill, 2016). In mammalian species, the use of predator odour cues may be especially prevalent given the importance of olfactory cue use in intraspecific communication (Wikenros et al., 2017). For example, roe deer *Capreolus pygargus* respond to lynx odour (urine) cue by either staying vigilant or avoiding predation risk areas (Eccard et al., 2017). In terms of informational content, however, predator visual cues may elicit stronger responses because they reveal immediate risk (Noell, 2013; Chamaillé-Jammes et al., 2014).

To improve our understanding of how the ecological community is structured, it is wise to learn how prey species assess and respond to risk from predators (Blumstein et al., 2000). Our previous work (submitted) has shown that predator cues alter the incidence of ungulate species in a landscape. However, ungulates do still exist in landscapes where perceived predation risk is high (i.e., in the presence of predator cues). Here, we test if these predator cues (visual and odour) result in altered prey behavior. We hypothesise that in the presence of cues, ungulates will display a) increased vigilance, and b) reduced foraging, in line with the findings of previous studies (Bridges, 2002; Brown and Kotler, 2004; Apfelbach et al., 2005; Nersesian et al., 2012; Creel et al., 2014; Cremona et al., 2014; Beauchamp, 2015; Olson et al., 2015; Eccard et al., 2017). We also test whether there is a difference in ungulate response to familiar and novel predators (Brown bear and Amur tiger, respectively). Prey that is not familiar with a predator (novel predator) due to lack of experience or non-evolutionary history might not respond or show a weak response (Banks and Dickman, 2007; Smith et al., 2008; Sih et al., 2010). Therefore, since there is no evidence for Amur tiger to have historically lived in the study area we would expect no or weak response from the prey to tiger cues. Since there are plans to train and rewild the Amur tiger (Wang et al., 2018), it is useful to know well about its ecological influence on prey foraging and vigilance behaviors. Lastly, we also test differences in response to cues between ungulates of different size classes (roe deer, and moose). As it is suggested that small

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82198234

and large body sizes mammal respond differently to predation risk (Riginos, 2015; Rogers, 2016); hence, we predict size-differences in predator response. This study will help our understanding of whether and how the presence of predator cues in an environment may further influence ungulate behavioural trade-offs beyond the differential use of the landscape, with possible consequences for fitness and population dynamics.

Material and methods

Study area

The study was conducted in Hanma National Nature Reserve, near to a small town of Genhe, Inner Mongolia, North East China (*Fig. 1*) (51°20′02″–51°49′48″N, 122°23′34″–122°52′46″E) (Guo et al., 2017) between July 2016 and July 2017. The National Forestry Administration Unit owns the reserve which is located in the Greater Khingan Mountains, being run as a nature reserve. Hanma has a total area of 1073 km^2, with no or very low human disturbance due to its distance from human settlements (Zhai Penghui, 2015; Guo et al., 2017). Habitat, vegetation and wildlife composition are described elsewhere (Zhai Penghui, 2015; Guo et al., 2017).

Experimental design and treatments

Design

In the current study, we tested the behavioural responses of two naturally occurring ungulate species roe deer (*Capreolus pygargus*) and moose (*Alces alces)*) to cues from naturally occurring brown bear (*Ursus arctos*) and a novel Amur tiger (*Panthera tigris tigris*) predators. We divided the study site into grids, randomly created using the fishnet method in ArcGIS 9.3 (Krivoruchko, 2011), which encompassed 2 different types of cue treatments.

Three grids contained visual cues: one grid containing cues of Amur tiger, one grid containing cues of brown bear, and a separate control grid. Treatments were kept separate in order to avoid cue treatment at one camera site affecting the behaviour of ungulates at nearby camera sites that may be of different treatments. The grid plot sizes were quantified as 3.2 km × 3.2 km, and each grid had 18 camera traps including control, 54 in total. Note that because brown bears are native in this habitat, we cannot conclusively confirm that our control grids contained no bear cues; however, as bears occur at low density in this area (Guo et al., 2017), we are confident that at least, our treatment increased perceived predator density in this area.

An odour cue experiment was initially designed in the same way (one grid containing tiger odour, and a control grid). However, after arriving at the site, we found some area (parts of the tiger odour cue experiment/group) were flooded with water and others with too big mountains with a dense forest harsh to be accessed. Due to this setback, we redesigned the tiger odour cue experiment with both of the two grids containing both treatment (tiger odour cue) and control in each half (See *Figure 1*) in order to set each treatment grid with its control over similar environmental conditions. Here, grid plots were smaller in size, i.e. (1.6 km × 1.6 km) compared to that of visual cues experiment due to the same logistical constraints. Each grid had eight camera traps, i.e. (8 x tiger feces, 8 x controls) × 2, making a total of 32 camera traps for the odour cue experiment.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82198234

In the assigned grids, we deployed a total of 86 camera traps (LTL ACORN scouting camera; Ltl 5210 5MP & Ltl 5210A 12MP, and Nighthawk Bestguarder SG-990V infrared sensor trigger self-timer digital camera). Cameras were set at least 1 km apart, and the positioning for each individual camera was decided based on different animal signs such as trails, droppings and near water sources. We set all the cameras with a video mode to record 20 seconds at an interval of 5 seconds when triggered.

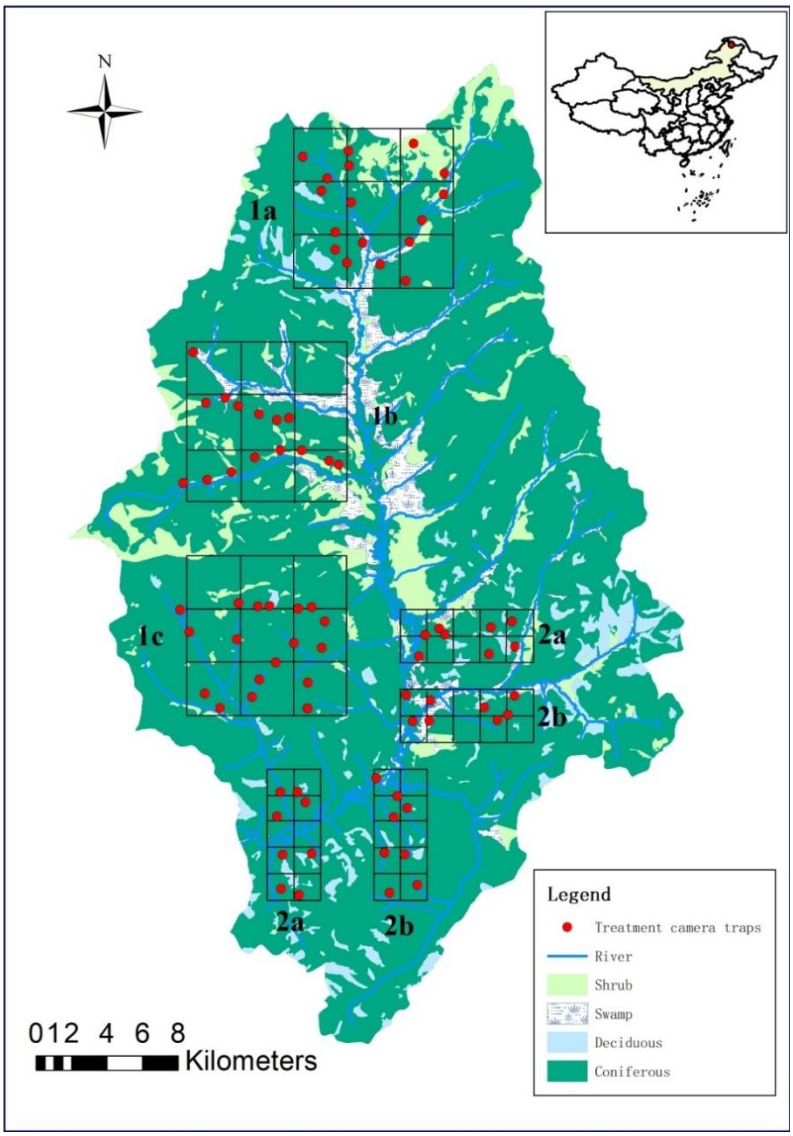

Figure 1. *A map indicating the location of the experimental area and different types of surrounding habitats. The number 1 represent visual cue experiment (i.e., 1a- tiger, 1b- bear, 1c- control), and number 2 represent the odour cue experiment (i.e., 2a- tiger, 2b- control). Tiger visual (1a) includes a 100 cm x 100 a 2D picture of standing tiger printed on a canvas which is tied to two opposite trees, with a camera tied to one of the trees; with everything similar at the bear visual (1c). For the control visual (1c), a canvas similar in settings as tiger and bear visual cues was printed to mimic the environment and tied to two opposite trees with a camera tied to one of the trees to record visitation incidences. The Grids in 2 (a&b) represent the tiger order cue experiment, a plastic bottle filled with tiger feces (i.e., 2a groups) and then a camera tied on a nearby tree to record the visitation rate; the same was done to odour cue control filled with soil (2b) groups*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82198234

Visual cue experiment

Predator visual cues (a life-size photo of a standing tiger, bear or vegetation like control were printed on a canvas; *Figure 2*. following studies by (Li et al., 2011; Fischer et al., 2017) were printed on canvas at a size of 100 cm x 100 cm. The canvas was suspended between two opposite standing trees at each camera site. Cameras were tied ~50 cm from the ground one of the trees to record animal behaviours (i.e., the camera faced away from the visual cue, in the direction of approaching ungulates).

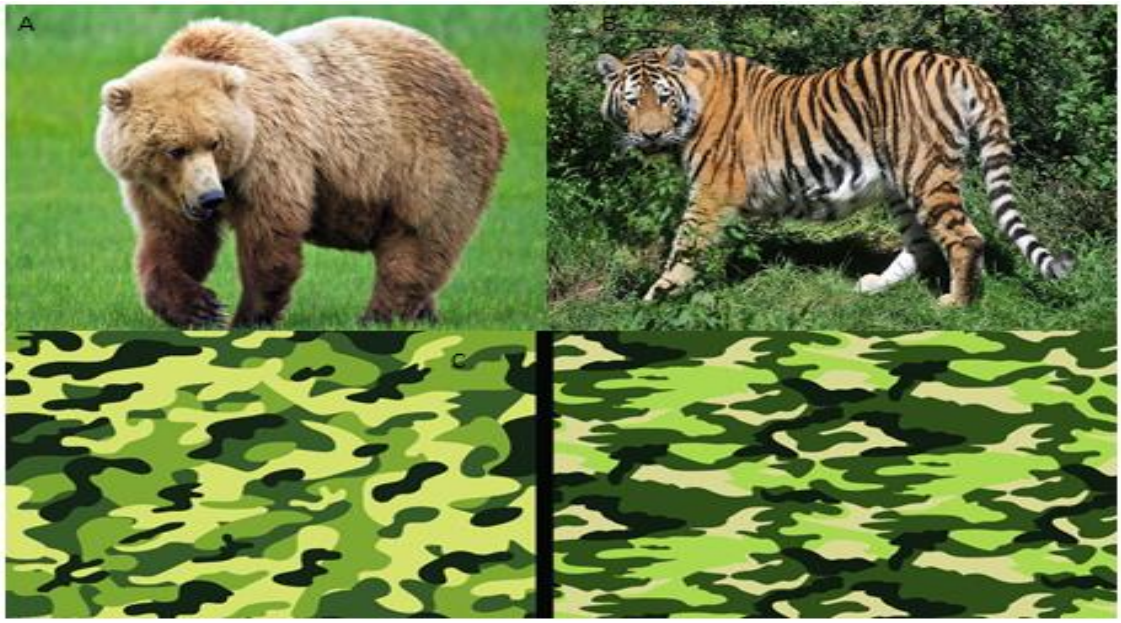

Figure 2. *Visual cues treatment and control. A- Is a brown bear photo representing bear visual cue, B- is Amur tiger photo reprinting tiger visual cue, and C- which is vegetation/habitat like photo represent control visual cue. They were both hanged on two different trees and a camera tied on one of the trees to record ungulates behavioral responses*

Odour cue experiment

As predator odour cue, we used Amur tiger fresh feces from Harbin Siberian Tiger Park, transferred into 150 ml plastic bottles (*Figure 3B*) which had small holes around to produce the odour. Feces were collected no more than one week before deployment and in the interim stored in laboratory refrigerators at -20°C to avoid quality loss. Bottles were tied to trees ~50 cm above ground opposite the camera trap and in the focus of the camera to record animal behavioural responses. As a control, we used soil which was filled in the same 150 ml plastic bottles and tied on the tree at the same settings as the odour cues (*Figure 3A*). Due to unavailability of fresh bear feces, we, unfortunately,, could not involve bear odour cues in this experiment.

Data collection

Cameras were deployed for 1 year, after which SD cards were collected, and cues were removed. Behavioural data were collected from the resulting videos using focal sampling and all occurrence methodology (Altmann, 1974; Martin et al., 1993; Margulis, 2016). For this study the behavioral data extracted were– vigilance and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82198234

foraging behaviours for ungulates which triggered the camera to record). All recordings which were activated inside 30 minutes of one another and contained similar animals were considered one visit. Ungulate species that were detected included roe deer, musk deer (*Cervus elaphus*), red deer, wild boar (*Sus scrofa*), and moose; however, due to low numbers, we only considered roe deer and moose further.

Figure 3. *Odour cue treatment and control; A- Represent a plastic bottle (150ml) field with Amur tiger odour cue control (soil), and B is the same bottle filled with Amur tiger odour cue (feces). All the bottles were similar, just differing in contents. The camera was located in front or nearby the bottler to be able to record animal behavioral responses when around the odour cue or control*

Behavioral coding, description, and classification

We classified behaviours into five main components following Heijtel and van Hooft (2014), Meng et al. (2008), and Li et al. (2011), to include vigilance and feeding behaviours (*Table 1*).

Table 1. *Behavioral classification used in this study*

Behavior	Description/definition
Vigilant - VG	Animal keeps a careful watch or looks for possible danger occurrence within the habitat. Usually, the eyes are wide open. It includes behaviors as stare, stand while head up, smell while staring, walk while head up, walk while turning head, turn head, turn ears, alert, stand, listen and turn the body
Feeding - FD	The animal is feeding/eating or drinking. It involves behaviors like forage, walk while foraging, water drinking, and suckling
Locomotion - LO	The animal is moving without any accompanying behaviors; it includes actions as walk, jump, trot, run and swim
Communication - CO	Animal express behaviors that help others to know their presence and also marking their territories. It includes behaviors like the smell, sniff, walk while smelling, rub and rub against a tree

We included other behaviours such as communication and locomotion in separate groups because we did not have explicit predictions about how predator cues might influence these behaviours and because we decided to focus on the foraging/vigilance trade off. Our analyses focused on feeding and vigilance behaviours, as the trade-off between anti-predator behaviour (vigilance) and self-maintenance behaviour (foraging)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82198234

is a key life-history concern in response to predation risk (Brown, 1999). We included other behaviours such as communication and locomotion in separate groups because we did not have explicit predictions about how predator cues might influence these behaviours and because we decided to focus on the foraging/vigilance trade off.

Statistical methods

From our camera traps, we obtained a total of 193 records from cameras in the visual cues experiment, and 399 records from cameras in the olfactory cues experiment. For the purposes of statistical analyses, we excluded records from species that had too few records overall, or where records were from too few cameras to be representative (N=41 records from musk deer (from only 2 cameras), in the visual cues experiment; N=15 musk deer and N=5 wild boar in the olfactory cues experiment). We also excluded records from moose in the analysis of the visual cues experiment, as all control records were from a total of only 2 cameras. As a result, analyses of the visual experiment consisted of 142 records of roe deer, and analyses of the olfactory cue experiment consisted of 209 records of roe deer and 170 records of moose.

The effects of predator cues (visual and olfactory) on the proportion time ungulates spent being vigilant (as defined in *Table 1*) and time spent feeding (as defined in *Table 1*) were tested using generalized linear mixed models using the *lme4* package in R (Team, 2015). For analyses of both the visual and olfactory cue experiments, the proportion of time spent vigilant/feeding was constructed as a paired column (created using the *cbind* function in R). The paired column containing time spent vigilant/time spent feeding in one column, and total time spent doing other behaviours (i.e., the total time the animal was recorded, minus the time spent vigilant/feeding) as a second column. This allowed us to account for variation in the total time recorded. Experimental treatment (in the case of the visual cue experiment: control, tiger cue, bear cue; in the case of the olfactory cue experiment: control, tiger cue) was set independent variable. Also included was the number of days the camera had been active at the time of recording (i.e., days treatment was in place) (this variable was logged to improve normality and scaling). Camera ID was set as a random term to account for non-independence of multiple records from the same camera. As the visual cue experiment contained the only deer, species was not included as a variable in this analysis. In the analysis of the olfactory cue experiment, an interaction term treatment*species was included as an explanatory variable to test whether treatment effects differed between species.

Results

Visual predator cue experiment

There was no effect of visual predator cue treatments on roe deer vigilance behaviour (treatment $X^2_2 = 0.15$, P = 0.93), or feeding (treatment $X^2_2 = 2.81$, P = 0.25) (*Figure 4*). Post-hoc analysis (Tukey test) revealed that there was no difference in proportion time spent vigilant or feeding specifically between the two predator cue treatments (tiger and bear visual cues: vigilance Z = 0.08, P = 0.99; feeding Z = -1.55, P = 0.27). Vigilant and feeding behaviours also were not predicted by the length of time (days) the camera and treatment had been in place (days camera activity vigilance: $X^2_1 = 2.45$, P = 0.12; feeding $X^2_1 = 0.79$, P = 0.37).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82198234

Olfactory predator cue experiment

We observed a significant interactive effect of treatment and species on time investment in vigilance behaviour (treatment*species X^2_1 = 22.8, P < 0.001). Post-hoc analysis (Tukey test) revealed that this effect was driven by roe deer having a higher base vigilance rate (i.e. were more vigilant than moose under the control treatment: Z = 3.56, P < 0.01) but a lower vigilance rate under the predator treatment, tiger odour (Z = -3.15, P < 0.01) (*Figure 5a*).

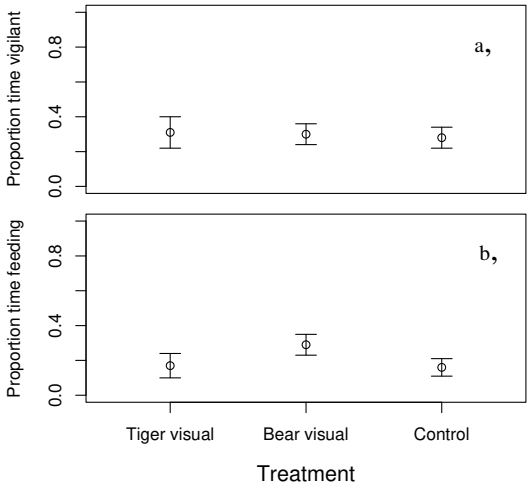

Figure 4. *The presence of predator visual cues did not influence time investment in a) vigilance and b) feeding behaviour in roe deer*

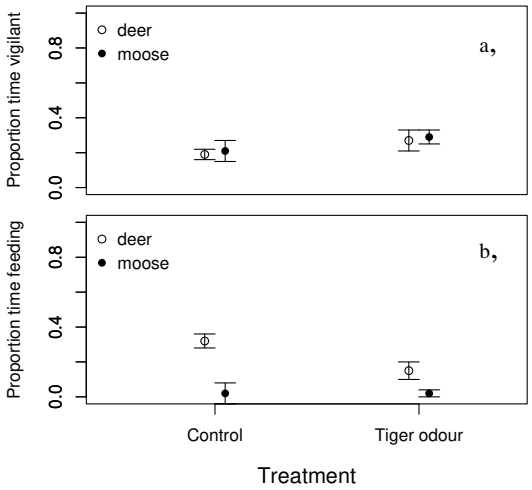

Figure 5. *Predicted effects from a model accounting for days of camera activity of predator odour treatment on a) vigilance and b) feeding in roe deer (open circles) and moose (filled circles). Effects of treatment differed significantly between species in both cases, but responses to predator odour within species were not statistically significant in both cases*

This interactive result suggests that moose responded more strongly to tiger odour. However, within-species effects of treatment were not significant, according to post-hoc tests (roe deer Z = 1.05, P = 0.72; moose Z = -2.05, P = 0.17).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82198234

We also observed a significant interactive effect of treatment and species on time investment in feeding (treatment*species $X^2_1 = 49.12$, $P < 0.001$) (*Figure 5b*). Post-hoc analysis (Tukey test) revealed that this effect was driven by differences between roe deer and moose feeding rates under the control treatment (moose feeding rate significantly lower, $Z = 5.94$, $P < 0.001$) (*Figure 6*). There was no significant difference between roe deer and moose in feeding rates under the predator cue treatment ($Z = -0.3$, $P = 0.99$). Again, within-species effects of treatment were not significant, according to post-hoc tests (roe deer $Z = 1.95$, $P = 0.21$; moose $Z = -2.25$, $P = 0.11$).

Both vigilance and feeding behaviours were significantly predicted by the length of time (days) the camera and treatment had been in place (days camera activity, vigilance: $X^2_1 = 164.34$, $P < 0.001$; feeding $X^2_1 = 11.86$, < 0.001).

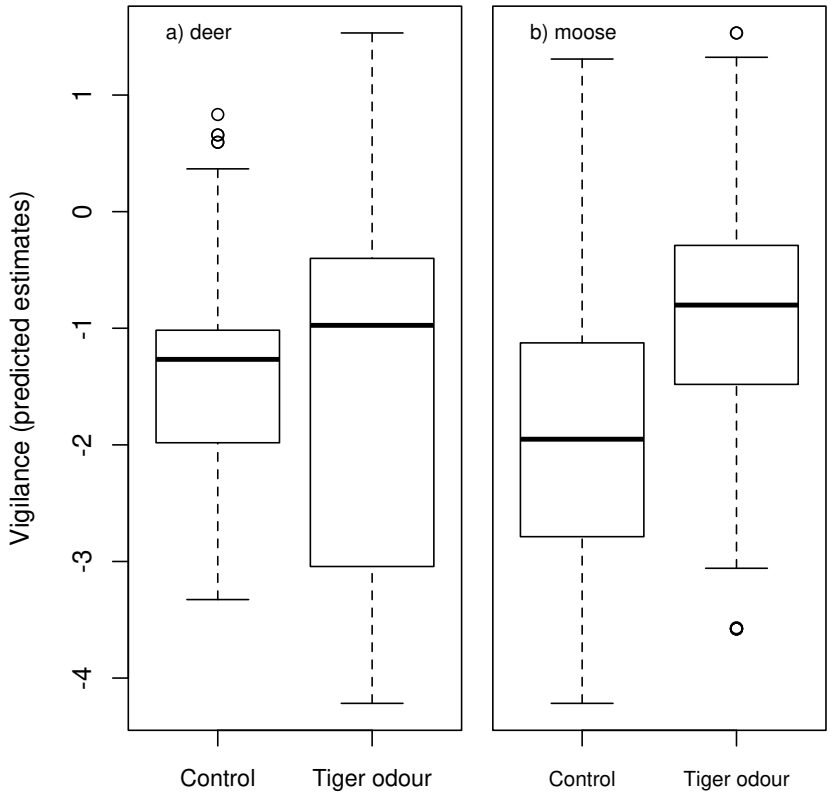

Figure 6. *Predicted effects from a model accounting for days of camera activity of predator odour treatment on vigilance behaviour in a) roe deer and b) moose. Effects of treatment differed significantly between species, with moose showing a stronger response than roe deer, though the strength of responses to predator odour within species was not statistically significant*

Discussion

Predator cues alter the incidence of prey species in a landscape, which is likely to have cascading effects on population dynamics throughout the system in line with hypotheses based on the "landscape of fear" (Suraci et al., 2016). Predator cues reduce prey species incidence in areas where predation risk is perceived as high: but prey species do continue to use high risk areas, albeit at lower levels. Understanding how behaviour changes where they do exist in those landscapes is important to gain a fuller

DOI: http://dx.doi.org/10.15666/aeer/1704_82198234

picture of the effects of predation risk on individual level fitness and population dynamics. In this study we tested the effects of visual and olfactory cues on ungulate vigilance and feeding behaviour tradeoffs, and show no significant changes in either vigilance or feeding behaviour according to predator-cue treatment, contrary to our hypotheses and previous work showing increased vigilance at the expense of feeding in a number of prey species (Creel et al., 2014; Cremona et al., 2014; Beauchamp, 2015; Olson et al., 2015; Eccard et al., 2017). The familiarity of the predator also had no effect on ungulate behavior. We suggest that these results indicate that when prey animals exist in high risk environments (perhaps due to constraints associated with dispersal, or food patch availability), they may display higher selectivity in cue use (i.e. ignoring cues that may be inaccurate) in order to maximise energy intake (Lima and Bednekoff, 1999; Eccard et al., 2017). Additionally, our results reveal differences in how species (roe deer and moose) respond towards predator cues, potentially because body size may effect on how species respond to predation risk (Rogers, 2016; Venter et al., 2017).

Ungulates did not reduce feeding and increase vigilance in the presence of predator cues

Prey animals use cues within their environment to inform their time allocation to antipredator and other behaviours (McCoy et al., 2012). Based on this, we expected that in the presence of predator cues, ungulates would increase their time spent vigilant, and decrease time spent foraging, in order to maximise survival in a perceived high risk environment. However, we found that roe deer and moose vigilance and feeding behaviours were not affected by either visual or olfactory cues from predators (*Figure 4*). There are a number of potential explanations for this surprising lack of response to predator cues, that we will consider in turn: a) habituation to uninformative cues is important, b) ungulates may rely more heavily on other cue types, such as auditory cues, or cues in combination, and c) constraints on dispersal resulting in prey forced to remain in high risk food patches and continued prioritization of feeding over vigilance.

First, it is possible that ungulates habituated to the cues presented over time as they learned that the cue was not actually associated with a live predator and did not pose a real threat. Using up to date and accurate information is essential since as suggested by (Karban et al., 2016) it becomes more costly to keep responding to unreliable cues, responding correctly to precise information enhances animal fitness. Our visual cue model accounted for the length of treatment and showed no effect of how long the treatment was deployed, where we might have expected to see a stronger response initially which declined when animals habituated. We, therefore, cannot conclusively say that this is why we see no overall effect of predator cues on behavior in response to visual cues. However, in the context of the olfactory cue, investment in both vigilance and feeding behaviours were significantly predicted by the length of time (days) the camera and treatment had been in place. The strong effect of length of treatment in the odour treatment is essential; it means that they stopped responding once the cue was out of date. This is strongly adaptive; animals do not want to keep using cues that are out of date because then they are wasting opportunities and energy based on wrong information (Karban et al., 2016). Perhaps they are choosier and more discriminatory in how they use cues to alter behaviours related to energy use/consumption, similar to what suggested by (Venter et al., 2006) that different animals respond differently to different threats (predator odour cues included).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82198234

Second, cues that influence habitat use and behaviour may be different; perhaps ungulates rely more on auditory cues, which may contain more accurate and up-to-date information, to adjust their behaviour. We think that we were not able to see the effect because (from the previous submitted study) we saw that these species are already using the landscape differently, so perhaps it might be that those using these areas have already adjusted their behaviours. Venter et al. (2017) suggested that ungulates depend less on visual cues when searching for food (relative to movement behaviors), possibly because it is easier to incorporate auditory cues while foraging with head down, than visual cues, which require the cessation of foraging to lift the head. Auditory cues may also be more likely to be accurate and up-to-date than olfactory cues (Shelton and Kumar, 2010). The effectiveness of olfactory/chemical cues varies with different factors such as weather, seasons, the frequency of use, amount of concentration, and food availability (Elmeros et al., 2011). Another reason might be odour cues might be less effective during harsh winter which characterizes the study area for most parts of the year. To make these cues more effective we in the future we suggest similar to (Knapp et al., 2004; Andreassen et al., 2005) that they should be used in combination with another cue at the same area to pose more risk to the area.

Ungulates did not respond differently to novel/familiar predator cues

The introduction of a novel predator in an area can have a significant impact on prey species, particularly if prey species do not respond appropriately to novel predator cues, or if there is a learning period (Dunlop-Hayden and Rehage, 2011; Polo-Cavia and Gomez-Mestre, 2014; Carthey et al., 2017). Given that in a previous study (submitted) in the same system novel predator visual cues influenced the incidence of prey species (incidence was more strongly predicted by familiar predator cue presence), we predicted that ungulates might similarly respond less strongly behaviourally to cues from a novel predator (Amur tiger) than to cues from a familiar one (brown bear) (Smith et al., 2008; Saxon-Mills et al., 2018). However, our results show no difference in the amount of time spent vigilant or feeding between the two predator cues treatments (tiger and bear visual cues), i.e., ungulates showed the same lack of response to both novel and familiar predator cues. This is different from what would have normally expected that ungulates (roe deer in this case) would have responded strongly to at least native bear cues and less to a novel tiger cue; but this result is similar to a study showing that mosquitos and flagfish failed to differentiate a chemical cue that comes from a novel predator (Cichlid) (Dunlop-Hayden and Rehage, 2011). It is possible that the fine-scale differentiation of native and novel predators depends on specific cues used by such prey (Dunlop-Hayden and Rehage, 2011), or potentially cues in combination (for example visual + chemical at the same place): Amo et al. (2004) also revealed that lizard increase more the antipredator behavior once exposed to combined cues (visual and chemical) of their snake predator might respond well to cues once they are combined. As well, Elmeros et al. (2011) found that chemical cues did don't repel deer unless integrated directly within the food.

Ungulates did not respond differently to novel/familiar predator cues

The olfactory predator cue had a significant interactive effect with ungulate species on time allocation on vigilance behaviour, driven by roe deer being more vigilant than moose under control conditions, but having a reduced response to the predator treatment, tiger odour (*Figure 5a*). We also observed a significant interactive effect of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82198234

treatment and species on time investment on feeding behavior (*Figure 5b*). It is necessary for prey to allocate time wisely for feeding in order to avoid predation risk at the same avoiding the effect of staying vigilant (e.g., poor fitness, malnourishment) (Lima and Bednekoff, 1999). It was primarily driven by the difference of feeding rate between roe deer and moose at the control treatment, with moose showing a significant lower feeding rate at the control treatment (*Figure 7*).

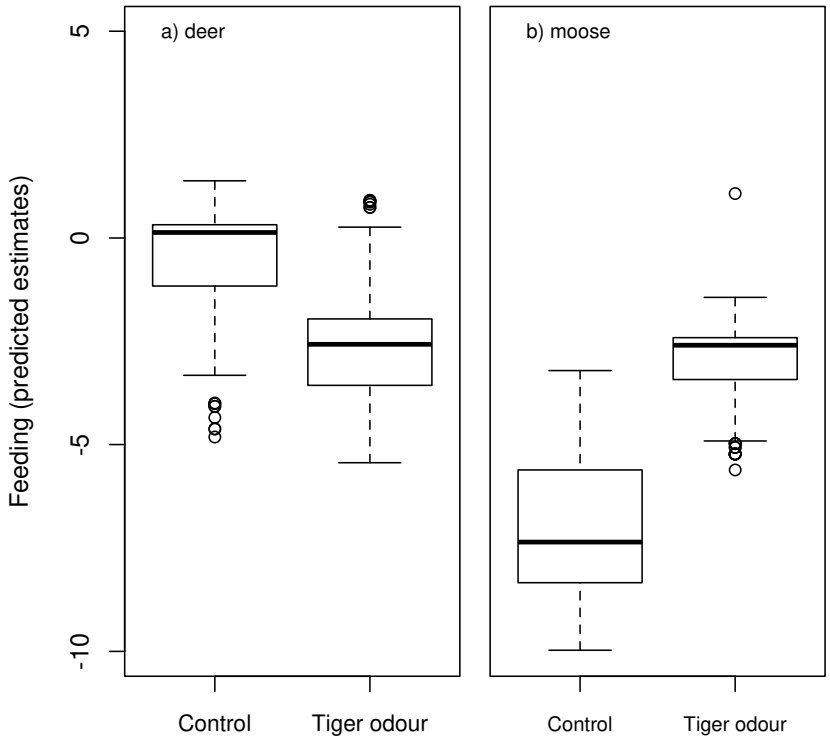

Figure 7. *Predicted effects from a model accounting for days of camera activity of predator odour treatment on feeding in a) roe deer and b) moose. Effects of treatment differed significantly between species, with moose showing a significantly lower feeding rate under control treatment than roe deer; the responses to predator odour within species were not statistically significant*

Nevertheless, treatment showed no significant effects within-species, partly may be due to the differences in the sense of odour cue perception (Padodara and Jacob, 2014) within these two species. It is possible that species like roe deer, due to their higher vulnerability to a greater number of potential predators (Rogers, 2016), are more vigilant under any circumstances, with the predator cue evoking a lessened response given that they are already at a reasonably high level of vigilance (beyond which, the benefits of increased vigilance may be minimal). Conversely, the stronger response of moose was surprising, since we would expect larger species to be less responsive to risk compared to those of smaller body size (Riginos, 2015), because large body species are a) less likely to be targeted by predators, and b) affected more by lack of food availability than predation risk. Our results emphases the importance of considering different prey species separately when investigating the effects of predation risk and cue use, as ecological and life history differences are likely to contribute to different outcomes of risk.

Conclusions

We have successfully shown that both familiar (brown bear) and novel (Amur tiger) cues have no significant influence on ungulates (roe deer and moose) vigilance and foraging behaviors in our study system. Also, our results demonstrate that when prey animals occur in a fearful environment due to limitations of factors like food availability, mating, and dispersal; they display selectivity or even ignore cue use so as to maximise energy intake (Lima and Bednekoff, 1999; Eccard et al., 2017). Likewise, our results tell the differences in how species respond towards predator risk, that small body size animals (roe deer) are potentially at high risk from various predators compared to large size (moose) which are mostly limited by food (foraging) (Rogers, 2016; Venter et al., 2017). Our results also indicate that due to differences in historical background, it is essential to consider each species differently when considering predation risk or cue use effects of different prey species. We further recommend that in the future studies regarding cues can involve a combination of cues (example; visual and order) at the same location to increase predation risk to the animals and see their response. Lastly, to our best level of understanding, this is the first study to lay out the foundation on the ecological influences of captive Amur tiger on prey behaviors in the wild environment.

(Received 24th Feb 2019; accepted 24th May 2019)

Abstract. The objective of this study was to assess patients' perceptions of the indoor environment of wards in a hospital in terms of architectural design, thermal comfort, indoor air quality (IAQ), lighting and acoustical parameters. The study attempted to determine the factors influencing the perceived indoor environmental quality (PIEQ) and explored the relationships between the perceived importance of indoor environmental quality (PI-IEQ) and health recovery, health satisfaction and therapeutic ambience of the hospital. A field study of the indoor environmental quality (IEQ) of 4 wards in the General hospital at Minna, Niger state, Nigeria was conducted, and responses from 271 patients were obtained. Structural equation modelling was employed for data analysis. The research identified the six IEQ factors that influenced PIEQ as architectural design features, thermal comfort, adaptive opportunities, lighting, IAQ and acoustics aspects. PIEQ had a positive influence on a ward being perceived as conducive for wellbeing. It was observed that health satisfaction had the most significant and positive influence on PI-IEQ. The second most positive influence was health recovery. Therapeutic ambience also had a positive influence on PI-IEQ but this was not significant.
Keywords: *architectural design, thermal comfort, adaptive opportunities, lighting, indoor air quality, acoustics, health recovery, health satisfaction, hospital ward*

Introduction

Indoor environmental quality (IEQ) as one of the features of green buildings and the sustainable environment has been drawing much attention, due to its high impact on the behaviour of the building users. An assessment of the (IEQ) of buildings is essential in determining success and failure. Buildings are designed and constructed to be occupied by people and the requirements for their occupancy must be made a prerequisite for their comfort. Therefore, the significance of sustaining better (IEQ) in buildings including hospital buildings should be a concern for architects, planners and stakeholders.

For buildings such as healthcare facilities, the issue of maintaining health and comfort should not be overlooked. In the practice of nursing, a healthy environment has been noted as having significant impacts on the health of the patient. This conforms to Al-Rajhi et al.'s (2010) notion who describe hospitals as diagnostic human treatment environments where activities such as care promotion, health education, training and research is undertaken. A hospital environment that contributes to healing does not only add to the patient's wellbeing, but also the wellbeing of the healthcare workers. It has been posited by Zborowsky and Kreitzer (2008) that hospital buildings which are comprised of adequate indoor environmental quality would attract, retain, and enhance the patient's healing process as well as the worker's efficiency. Therefore, a hospital facility should be designed to accommodate the maximum benefit to the occupants, namely patients, their family members, visitors, and healthcare workers. As such, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82358259

indoor environmental quality of a hospital facility is essential for its occupants. A poor (IEQ) create stressful feelings on the occupants' perception of their environment.

Similarly, research has shown that poor (IEQ) is associated with a negative impact on the occupants' physical and psychological health (Mahbob et al., 2011; Sadek and Nofal, 2013). Additionally, Sadek and Nofal (2013) remark that the impact of (IEQ) on patient's satisfaction affects psychological and physical dispositions. Thus, the design and settings of the indoor environment of hospitals should be designed to foster the emotional needs of patients, their families, and staff (Salonen et al., 2013).

The awareness for a healthy and comfortable work environment in buildings has not yet taken root or informed the design of healthcare facilities. This is because the pressure to create sustainable buildings has given more attention to the environmental aspects of the built form, and less to the health and wellbeing of occupants. Researchers, however, have begun to understand the need to focus on the sustainable environment for occupants (Smith and Pitt, 2011), and this should be the same for hospital facilities. Therefore, this paper identifies the influence of each factor affecting PIEQ and explores its relationship with health recovery, health satisfaction and therapeutic ambience on PI-IEQ.

Background

Architectural design features

Features of the hospital's architectural design include room size, design and furniture. Room size (dimensions, area and volume) is an essential factor that can affect the perception of patients. The design includes the shape of the walls, floor and ceiling. According to Kembel et al. (2014), hospital design and spatial configuration have an impact on patient recovery. Similarly, Scholz et al. (2019) suggest that room design influences patients' healing outcomes. For example, furniture in the hospital room, in particular flexible furniture has been shown to play a crucial role in meeting various health and recovery requirements (Huisman et al., 2012). Furniture criteria include type, design, postural comfort and ergonomics (Biancheri and Landi, 2017). In the context of health care settings, there are limited studies that have investigated the relationships between the spatial environment and patient recovery processes (Bosch and Lorusso, 2019). Other authors suggest that the configuration of the plan and the size of the hospital rooms may facilitate patient interaction and support medical care activities (Alfonsi et al., 2014; Mourshed and Zhao, 2012).

Thermal comfort

A thermally comfortable and healthy indoor environment for patients is essential for their optimum recovery. Thermal comfort describes the condition of the mind in terms of temperature satisfaction in a defined environment (ASHRAE, 2004a). Two important schools of thought exist in thermal convenience research; the heat balance approach (Fanger, 1970) and the adaptive thermal comfort approach (de Dear et al., 2013). Fanger (1970) introduced the concepts of the predicted mean vote (PMV) and predicted percentage of dissatisfied (PPD), which have been incorporated into the international standards (ISO, 2005) and ASHRAE (2004b). The adaptive principle opined that 'humans react in such a way that tends to lean towards ensuring that their comfort is reestablished when changes which affect their comfort level' occur (Nicol et al., 2012). The idea of adaptive thermal convenience, based on the adaptive principle and outcomes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82358259

of several field studies, has been incorporated into ASHRAE (2004b) and CEN 15251 (2007). Several studies have investigated the physical quantities that affect the indoor thermal comfort of wards and also the effects of thermal comfort on patients (Khalid et al., 2019; Sadrizadeh et al., 2018; Shi et al., 2018; Verheyen et al., 2011). Such researches were carried out in naturally ventilated (NV) and air-conditioned (AC) wards using the heat balance approach and adaptive comfort models. Over time, studies have revealed that no specific temperature is ideal for people living in a particular building enclosure. However, although 20-24 °C has been judged as the range that is acceptable for healthy daily living, priority must be given to personal preferences or sentiments expressed by individuals. The level of activities and the choice of clothes also impacts on the thermal comfort of an individual (Djongyang et al., 2010; Gou et al., 2018; Kamalha et al., 2013).

Research outcomes related to indoor thermal comfort deals with the thermal environment acceptability of hospital wards and their level of compliance with global best practices (Khodakarami and Nasrollahi, 2012). Khalid et al. (2019) showed that the wellbeing of patients largely depends upon their preferences in terms of thermal comfort and air quality, and this should be considered. For example, the assessment of thermal comfort in a Belgian healthcare facility is set at 95% despite 29% of the thermal surrounding not being in accordance with ASHRAE design ranges of temperature and relative humidity (Verheyen et al., 2011). This situation implies that the environmental conditions of hospital patient rooms recommended by ASHRAE are sometimes very tough for patients to adapt to and suggests that perhaps the range of environmental parameters should be broadened.

Studies have shown that sensation, comfort and preferences in tropical countries are at variance with global standards (ASHRAE, 2007; ISO, 2005), which implies that thermal tolerance confronted in warm, humid season is greater, due to adaptation and acclimatisation (Anam, 2018). Therefore, greater efforts aimed at improving relevant and contextual thermal comfort that can consider varied outcomes, preferences and adaptation measures, for non-air conditioned spaces in tropical locations are required. Additionally, humans strive better under a cooler temperature that higher temperature (USEPA, 2015). This indicates that a relative rise in temperature also leads to the corresponding vaporisation of particulate matter from indoor components including furniture, fittings and building materials thereby limiting indoor thermal quality (Toftum, 2010). A varied number of factors impact room temperature ranging from fenestration opening that can increase thermal challenges during summer (Norbäck and Nordström, 2008). The architectural decision to design a well-ventilated in-patient ward, by utilising the outdoor environment should be of principal consideration in tropical countries. Accurate and adequate fenestration for ventilation and positioning of ceiling fans should also be evaluated and considered.

Lighting

The indoor environments of hospital buildings are highly demanding, with ambient parameters that are dependent upon use patterns, activities and specific sanitary needs. As a result, guaranteeing adequate comfort conditions becomes a more important and pressing issue than energy consumption (Ulrich et al., 2008), which has been regarded as a crucial factor for designing healing environments (Huisman et al., 2012). A well-designed healing environment in healthcare can have a significant impact on health outcomes including reducing errors and infections (Joseph, 2006), improving patients'

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82358259

moods (Beute and Kort, 2014) and stress (Ulrich, 1991). Also, colour and lighting play a major part in the perceived health outcomes of patients (Dalke, 2006) in addition to adequate soundscape environments (Mackrill et al., 2014). This is achieved by providing high window-to-wall ratios that enhance daylighting parameters and result in visual comfort and energy savings in patients' rooms.

Improper use of roller shutters may darken the room to the detriment of health and wellbeing. Daylighting conditions, indoor illuminance levels and visibility from the room to the outside should be key considerations for work on energy retrofitting of hospitals (Calama-González et al., 2019). Choi et al. (2012) identified a significant relationship between indoor daylight environments and a patient's average length of stay in a hospital room. The study revealed that in addition to the seasonal weather factor, indoor illuminance and luminance ratios could potentially influence the design of hospital spaces. Benedetti et al. (2001) highlight the antidepressant effect of daylighting on occupants and conclude that direct exposure to natural sunlight may reduce a patient's length of stay in hospitals. Likewise, Raanaas et al. (2012) reveal that having views through the windows as opposed to partially or blocked views may help alleviate stress and shorten patients' stay in hospitals.

Indoor air quality

Hospitals represent a uniquely complex environment that differs from other commercial or residential buildings, given that its occupants are at a higher risk of health symptoms such as eye irritation, headaches, coughs, colds, dizziness, asthma, respiratory and cardiovascular diseases (Eames et al., 2009; Pérez-Padilla et al., 2010; Verde et al., 2015). Environmental microbes can contaminate the patient care environment and complicate recovery if users develop infections from common infectious agents. Therefore, good ventilation performance is important to achieve minimal exposure to infectious airborne microbes (Leung and Chan, 2006; Verde et al., 2015). Consequently, hospitals should be regarded as high-performance buildings in terms of environmental and air quality to enhance staff efficiency and maintain patients' healing process (Leung and Chan, 2006; Shrivastava et al., 2013; Verde et al., 2015; Wan et al., 2011).

Achieving clean indoor air quality within hospitals is important and requires a good understanding of how the ventilation systems, indoor occupants, type of medical activities, building materials, as well as spatial and seasonal variations affect indoor air pollution levels (Erdogan et al., 2010; Jung et al., 2015; Nimlyat and Kandar, 2015; Verde et al., 2015). Fenestration within the hospital building can allow for the inflow of polluted air from outdoor sources into the indoor environment of the hospitals. Likewise, evaporation of particulate matter from furniture, water and infiltration of radon and other gases from underlying soil and bedrock also contributes to the pollution of the indoor environment (John et al., 2010). Other factors that may contribute to poor IAQ include poor cleaning practices, poor moisture control (e.g. water leaks or persistent damp surfaces), human occupancy (e.g. odours) and poor building maintenance (Paevere et al., 2008).

Acoustics

The sound environment is a vital part of the overall environmental ecosystem, and sounds beyond the acceptable decibel level is unwanted (usually referred to as noise) and can be seen as a major environmental stressor in the clinical surrounding (Xie et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82358259

2009). The impact of sensory stimuli such as sound and light is a critical challenge in creating a suitable environment in hospital settings for patients and operators. Research has shown that noise in the hospital environment can inhibit sleep and patient's recovery (Gardner et al., 2009; Hofhuis et al., 2012; Monsén and Edéll-Gustafsson, 2005; Waye et al., 2013; Xie et al., 2009). This suggests that unpleasant or distressing sounds impact negatively on the rate of recovery of patients in the hospital and in some extreme cases worsen the health condition of the patients. This includes psychological and physiological effects such as altered memory, increased agitation, aggressive behaviour, depression, anxiety, psychiatric disorders and deciphering speech difficulties (Elmenhorst et al., 2012; Helton et al., 2009; Joseph and Ulrich, 2007; Ryherdet al., 2008; Short et al., 2011). According to Frumkin and Louv (2007), it could be argued that people are closely attached to the natural world, which suggests that contact with nature is beneficial to health and wellbeing. As such, nature sounds may also be introduced in the environment as a positive distraction, which has been shown to have a significant influence on patients' clinical and behavioural outcomes (Pati and Nanda, 2011; Shepley, 2006).

Adaptive opportunities

Adaptive opportunities as defined by Nicol et al. (2012) are 'the chances created by structures for occupants to provide adequate comfort themselves such as windows, blinds, fans, etc.' The feedback approach suggested by Nicol and Humphreys (1973), relating to deductions from research on thermal comfort field surveys, targets feelings of high temperature or cold as a significant function of the comfort control system. And also further opined that poor sensation conditions the occupants to evolve basic measures, mitigation and modification that helps to stabilise the system. This approach to thermal comfort is generally termed an adaptive model (Nicol et al., 2012).

Adaptive actions cover the physiological, social and behavioural dimensions that enable occupants to start depending on their thermal environment (Yan et al., 2017; Kim et al., 2018). Such adaptive actions, among others, include switching on fans, opening a window, switching on the air conditioners and so on. An adaptive approach to thermal comfort targets the behaviour of the occupants who try to achieve their comfort. Brager et al. (2004) defined the imperatives of individual control, as an avenue to enhance the performance and promote the thermal satisfaction of the users. Gou, Lau, and Chen (2012) evaluated the occupants' dimension of management on the comparative note against building use studies (BUS) benchmarking system. Their study reveals a significant correlation between occupants' control of heating, cooling and ventilation with the thermal comfort, overall comfort and productivity, which are important components of IEQ.

Theoretical predictions

Based on the literature review on the various dimension of IEQ and exploratory factor analysis (EFA), the factors that influence PIEQ were identified, and a model was developed to explore the influence of PIEQ on patient's perception of a ward being conducive. The model also explored the influence of health satisfaction, health recovery and therapeutic ambience on PI-IEQ of the hospital. The final research model (*Fig. 1*) and hypotheses are proposed as follows.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82358259

Hypotheses

Hypothesis 1 (H1): Patient satisfaction is enhanced with an enhanced level of PIEQ.

Hypothesis 2 (H2): An enhanced level of PIEQ of ward leads to an enhanced level of perception of the ward as being conducive for wellbeing.

Hypothesis 3 (H3): Health satisfaction, health recovery and therapeutic ambience has a positive influence of PI-IEQ.

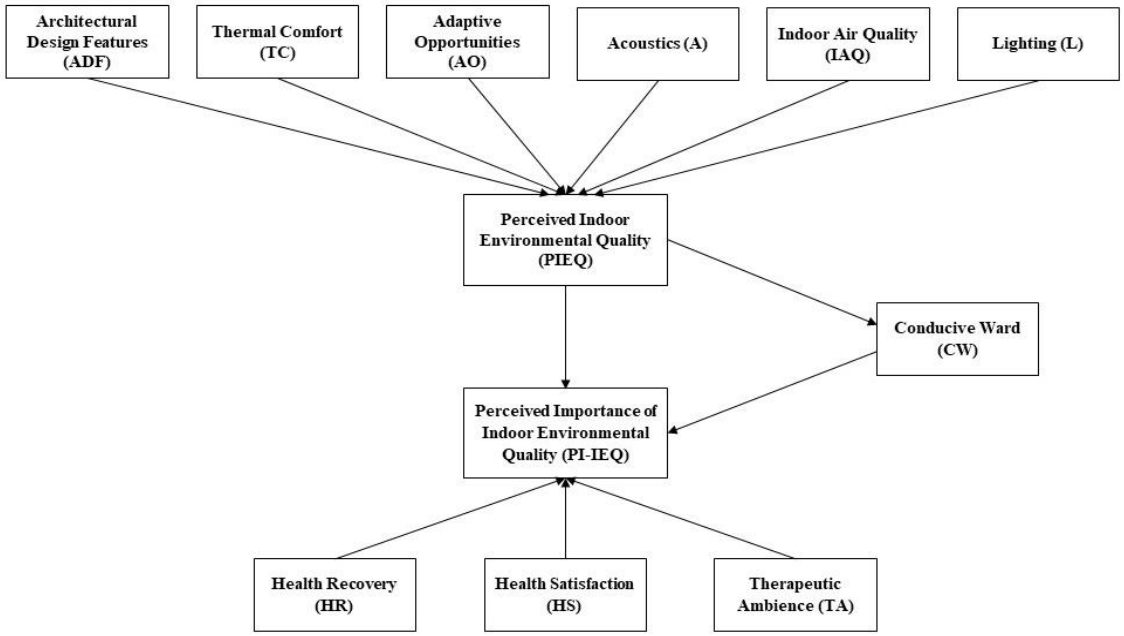

Figure 1. *Research model*

Research methods

The study area

This study is carried out in Minna, Niger State, which is the twelfth largest state in Nigeria. As demonstrated in *Figure 2,* Minna is situated at latitude 9°37' North and longitude 6°33' East. The northeast part of the city has a rock outcrop that acts as a physical constraint to development. Minna is 200 Kilometres from Abuja, the federal capital and covers 100,000 Hectares of land at the present development (Minna Master Plan, 1979). This increased the population of about 200,000 in 1991 to about 552,000 in 2017 (Sulyman et al., 2017). Minna as a city lies in North Central Nigeria, and it is in the Savannah region of the country. The average mean precipitation is 1,334 mm (52.52 inches) and the highest mean monthly rainfall is in September (300 mm or 11.7 inches), and the mean monthly temperature is between 33 and 27 °C (Nimet, 2010). Minna, in common with other cities in Nigeria experience both dry and rainy seasons. The dry season starts in October and lasts until April and has a strong north east trade wind known as the Harmattan wind or tornadoes. The wind is cool, dry, hazy and dusty. It brings about a cold environment with dryness. The rainy season starts at the end of April and lasts until mid-October and has a south west trade wind which brings about a warm, heavy wind that brings on the rain.

DOI: http://dx.doi.org/10.15666/aeer/1704_82358259

The study was conducted among the patients of general hospital Minna, Niger state in Nigeria. The collection of field data for this study was carried out in four selected wards of the general hospital. The questionnaire survey was conducted in four wards, namely the amenity ward, surgical ward, pediatric ward and emergency ward. The studied wards were located in different parts of the hospital (*Fig. 3*).

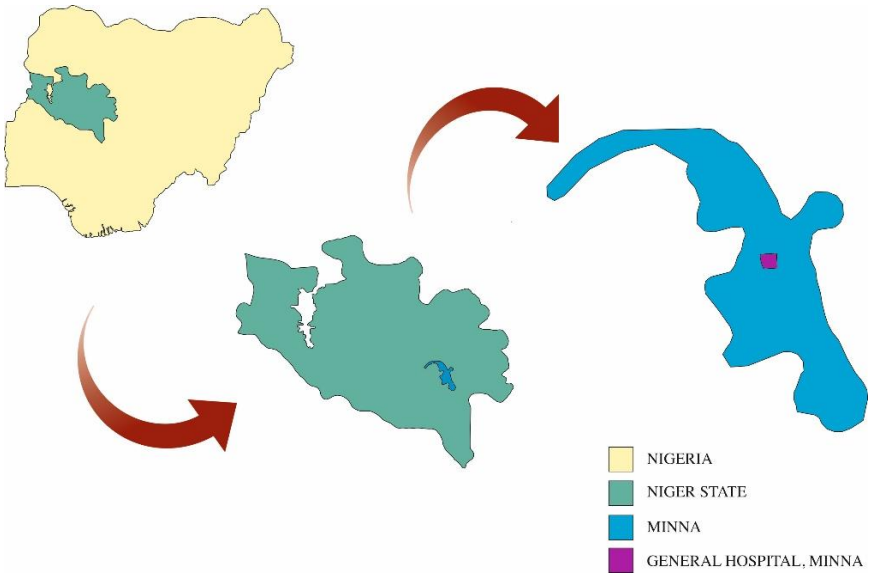

Figure 2. *Showing the map of Minna, Niger State, Nigeria*

Figure 3. *Existing site layout of general hospital Minna*

Objective and subjective data collection

Parameters such as temperature, relative humidity, illuminance, sound and CO_2 were recorded within each ward throughout the day using DrDAQ (USB) CO122/133 and REED SD – 9901. DrDAQ (USB) CO122/133 was used to measure temperature,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82358259

illuminance level and sound intensity level (Temperature range 0–70 °C, accuracy ± 0.3 °C, Light Intensity range 0 – 100 and sound level range 55–100dBA, accuracy ± 5dBA) while REED SD – 9901 was used to measure relative humidity and carbon dioxide concentration (Relative Humidity range 5 – 95%, accuracy ± 3%, Carbon dioxide range 0–4000 ppm, accuracy). The data loggers were placed on a table in the middle of the ward 1 m above the floor.

Questions related to each of the dimensions of the indoor environment (architectural design features, thermal, adaptive opportunity, lighting, acoustic and IAQ) were included in terms of adequacy, satisfaction, conduciveness and importance. A seven-point Likert-type scale was used to measure adequacy, satisfaction, conduciveness and importance. 300 questionnaires were distributed in four different wards on different days, during the period from February 2018 to April 2018. Out of 300 questionnaires distributed, only 280 were returned. Nine of the questionnaires were not used due to being incomplete. Therefore, a total of 271 questionnaires were used for the analysis.

Data analysis

Evaluating indoor conditions by means of surveys alongside measuring campaigns is a widely used approach that has been extensively tested (De Giuli et al., 2013; Sattayakorn et al., 2017; Verheyen et al., 2011). The objective data was collected using the above instruments and were compared to the recommended standards. The analysis of the patients' responses was carried out using SPSS version 23.0 and SmartPLS 3.0 version, frequently used for structural equation modelling (SEM) to test the fitness, estimate flexibility, and predicting both observed and latent variable influences on each other in a particular model.

Results and analysis of the objective data

The scientific measurement of the various climatic factors which affects the IEQ in the hospital ward was carried out using the identified instruments as shown in *Table 1*. These factors are temperature, relative humidity, sound, lighting and CO_2. The temporal resolution of the measurements from this study has been displayed in the *Appendix*. However, the measurement for illumination and light intensity in the various wards surveyed was pegged at between 6am and 8pm. This is so based on the noticeable challenge of power inefficiency in the study area. Nigeria has a serious energy supply deficit and this often applied to all class of infrastructure in the country (Olatunji et al., 2018). On the basis of this argument, the readings and measurements taken in the study area between 6am and 8pm is an aggregate of analysis between both natural and artificial lightning system, however beyond 8:00pm, lightening is basically dependent on artificial lightning which made reading difficult to examine because of the dearth in power supply, hence, the research considered lightening measure at periods when natural lighting can be relied upon in d absence of the artificial lightning. The outcomes of these measurements are included in *Table 2,* which presents the various averages shown on the table for temperature, relative humidity, sound, lighting and CO_2. The analysis shows that the average daily temperature for the various hospital wards examined were 33.8 °C for the surgical ward, 31.5 °C for the emergency ward, 34.1 °C in the amenity ward and 32.3 °C in the paediatric ward. The recommended standard of temperature ranges is between 23-26 °C (ASHRAE, 2006) and 24-33 °C (British Standards Institution, 2007).

Table 1. *IEQ mobile measurement station logger. (Source: Author's analysis, 2018)*

IEQ element	Instrument model	Resolution	Range	Accuracy
Air temperature	Mastech MS8209	0.1 °C @25 °C	0-70 °C	± 0.3 °C
Relative humidity	Mastech MS8209	0.10%	5 – 95%	± 3%
Light intensity	DrDAQ (USB) CO122/133	0.1	0 – 100	Manually calibrated
Sound level	DrDAQ (USB) CO122/133	1 dBA	55 – 100dBA	± 5 dBA
Carbon dioxide (CO_2)	REED SD – 9901	1 ppm	0 – 4000ppm	± 5%(> 1000 ppm)

Table 2. *Objectives measurements averages*

Month	Wards	Temp (°C)	RH (%)	Sound (dBA)	Lighting (lux)	CO_2 (ppm)
February	Surgical	33.8	55.5	43.5	371	510
	Emergency	31.5	55.0	44.9	402	496
	Amenity	34.1	54.9	46.1	410	495
	Pediatric	32.3	54.6	46.2	420	517
March	Surgical	33.8	54.5	43.8	403	490
	Emergency	33.6	54.9	45.1	397	498
	Amenity	33.9	55.2	45.7	399	487
	Pediatric	33.4	54.5	45.0	391	506
April	Surgical	34.1	54.1	43.8	402	497
	Emergency	34.0	54.8	45.0	402	493
	Amenity	33.0	54.6	46.0	403	506
	Pediatric	32.6	54.7	45.2	412	490

Temp = temperature; RH = relative humidity

Furthermore, the average daily minimum and maximum temperatures range from 23.1 °C and 33.4 °C within the various wards examined between February, March and April. It was observed that the weather condition of the city and the internal environment of the hospital wards examined differ considerably given the temperature recorded within the chosen month. This suggests that such wards will require an external input in terms of artificial ventilation to help make the internal environment of the hospital wards conducive for patients who are treated for various medical conditions.

Another indoor element examined in the measurement is the relative humidity of the hospital wards. The analysis shows that the average daily relative humidity of the hospital wards within February, March and April ranges from an average daily range from 41.2 to 68.2% daily within the months sampled. The average relative humidity of the wards measured is presented as 55.5% for the surgical ward, 55.0% for the emergency ward, 54.9% in the amenity ward and 54.6% in the pediatric ward. However the recommended guideline for relative humidity by ASHRAE (2004a) is 30-60%. Based on the data presented, relative humidity in the selected wards is within the recommended standard.

The sound level and acoustic properties of the hospital wards were also measured in the for the four wards sampled for this research. The measurement shows that the surgical ward has a daily average sound decibel of 43.5 dBA, the emergency ward is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82358259

44.9 dBA, the amenity ward is 46.1 dBA, and the paediatric ward is 46.2 dBA. This shows that most of the hospital wards are relatively noisy and unconducive for the patients. The daily sound level of the wards was measured at 26.6 dBA minimum and 69.7 dBA maximum. However, the recommended sound level should not exceed 40 dBA (WHO, 1999) and 60 dBA (ASHRAE, 2007). From the sound measurement carried out, it shows that the highest level of noise is recorded in the afternoons of February across the hospital wards. This situation shows a serious challenge for design as most of the wards are expected to be designed in such a way that these high noise levels are properly managed in order to achieve a good level of comfort for the patients.

The lighting conditions of the wards were also examined between February-April. The analysis shows that the surgical ward has a daily average light intensity of 371 lux, the emergency ward is 402 lux, Amenity ward is 410 lux, and the paediatric ward is 420 lux. However, the recommended guideline is 100-225 lux (CIBSE, 1989). This shows that most of the hospital wards are bright during the day time and are above the recommended standard.

The particulate matter is another element of the indoor air quality that was measured in this research. The measurement of the particulate matter shows a daily minimum of 258 ppm and 750 ppm. The measurement further showed that the surgical ward has a daily average CO_2 of 510 ppm, the emergency ward is 496 ppm, amenity ward is 495 ppm, and the paediatric ward is 517 ppm. This measurement given the daily measures shows that the level of CO_2 is within the acceptable range recommended of > 700 ppm (ASHRAE, 2010; British Standards Institution, 2007)

Structural equation model

Structural Equation Modeling (SEM) approaches are a second-generation multivariate technique that has been widely employed for investigating or testing the research model of several studies (Fornell and Bookstein, 1982). Using SEM is similar to the employment of Multiple Regression Analysis (Ali et al., 2018). In addition, SEM is used to predict the influence of the independent variable on the dependent variable of a particular research model. A two-stage analysis was conducted under the structural equation model in this study, first the assessment of the measurement model and secondly evaluating the structural model (Anderson and Gerbing, 1982).

Content validity

The content validity of the survey questionnaire in this current study was investigated in two ways. First, the questionnaire items were adopted from studies which has been used and tested. Second, the draft of the survey questionnaire was re-evaluated by some professionals in the field under the study to ensure content validity.

Internal consistency

The internal consistency of the constructs was tested using Cronbach's alpha (α). The general accepted reliability or internal consistency of the constructs should be greater or equal to 0.70 (Hair et al., 2010). As indicated in *Table 3*, the Cronbach alpha ranges from 0.75 to 0.972 indicating high internal consistency. The skewness and Kurtosis indices are also presented in *Table 3*, to assess the normality of the data. Lei and Lomax (2005) suggest less than an absolute value |2.3| for both skewness and kurtosis indices to ensure adequate data normality.

Convergent validity

Average variance extracted (AVE) composite reliability (CR) and factor loadings were used to measure convergent validity. Each factor loading is expected to be above a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82358259

0.70 threshold (Kurfali et al., 2017). All factors loadings were above 0.60. The recommended AVE values should be more than 0.5 while CR values exceed 0.7 for accepted convergent validity (Hair et al., 2010). As indicated in *Table 3*, AVE value ranges from 0.681 to 0.972 while CR value ranges from 0.869 to 0.986, suggesting significant level of approval (Sarstedt et al., 2014).

Discriminant validity

The discriminant validity is said to be attained if the square root of the Average Variance Extracted (AVE) for individual constructs are higher than the inter-factor correlation between the construct in the model (Chin, 1998; Hair et al., 2010; Kurfali et al., 2017) as boldly shown in the diagonal cells in *Table 4*. The general results in *Table 5* were within the endorsed values. The general results satisfy the discriminant validity recommendation of the model construct.

Table 4. *Correlation matrix of the constructs*

Diagonal elements are square roots of AVE (in bold)
A = Acoustics, AD = Adaptive opportunity, CW = Conducive ward, ADF = Architectural design features, HR = Health recovery, IAQ = Indoor air quality, L = Lightning, PI-IEQ = Perceived importance of indoor environmental quality, PIEQ = Perceived indoor environmental quality, TA = Therapeutic Ambience, TC = Thermal comfort

Evaluation of structural model and hypotheses

Generally, the CFI, NFI values are expected to be 0.9 and RMSEA $\leq$ 0.08 and SRMSR $\leq$ 0.05 (Hooper et al., 2008; Wong et al., 2014) to indicate a good model fit. As indicated in *Table 5*, the statistical results shown Chi-square/degree of freedom (χ^2/df) = 2.804, CFI = 0.964, RMSEA = 0.0432, P-value = 0.002, NFI = 0.950, and SRMSR = 0.0454. This suggested that the model for this current study has a good fit.

As indicated in *Table 6* and *Figure 4,* the result from the hypothesis H4, H12, H2, and H7 were all supported. That is Architectural design features ($\beta = 0.263$, $p = 0.022 > 0.05$), Thermal comfort ($\beta = 0.304$, $p = 0.000 < 0.05$), Adaptive opportunity ($\beta = 0.268$, $p = 0.010 < 0.005$) and indoor air quality ($\beta = 0.209$, $p = 0.002 < 0.05$) have a positive influence on the Perceived Indoor Environmental Quality of the studied hospital wards. However, H1 and H8 were not supported. Thus, Acoustics ($\beta = 0.122$,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82358259

p = 0.109 > 0.05) and lighting (β = 0.087, p = 0.375 > 0.05) also have no significant effect on perceived indoor environmental quality. Furthermore, Hypotheses, H9 and H10 were supported. The Perceived Indoor Environmental Quality was positive and had a significant influence on the conducive ward (β = 0.502, p = 0.000 < 0.05) and the perceived importance of indoor environmental quality (β = 0.268, p = 0.048 < 0.05). Also, H3 was not supported. That is, the conducive ward ((β = 0.048, p = 0.600 > 0.05) has no significant ınfluence on the perceived importance of indoor environmental quality.

Table 5. *Confirmatory factor analysis*

Fit indices	Recommended value	Research model
Chi square/degree of freedom (χ^2 /df)	≤ 3.00	2.804
P-value	≤ 0.05	0.002
Comparative fit index (CFI)	≥ 0.90	0.964
Normed fit index (NFI)	≥ .90	0.950
Standardized root mean square residual (SRMSR)	≤ 0.05	0.0454
Root mean square error of approximation (RMSEA)	≤ 0.08	0.0432

In addition, Hypotheses H5 and H6 were supported. Indicating that, Health Recovery (β = 0.223, p = 0.011 < 0.05) and Health Satisfaction (β = 0.264, p = 0.015 < 0.05) has a positive influence on the perceived importance of the indoor environmental quality. However, Hypothesis, H11 was not supported. This suggests that Therapeutic Ambience (β = 0.025, p = 0.761 > 0.005) has no significant influence on the perceived importance of indoor environmental quality. Lastly 59.4%, 34.9% and 25.2% of the variance in the perceived indoor environmental quality, perceived importance of indoor environmental quality and conducive ward are explained respectively as presented in *Figure 4.*

Table 6. *Summarised structural modelling results*

	Hypotheses	Path coefficient	T statistics	P values	Decision

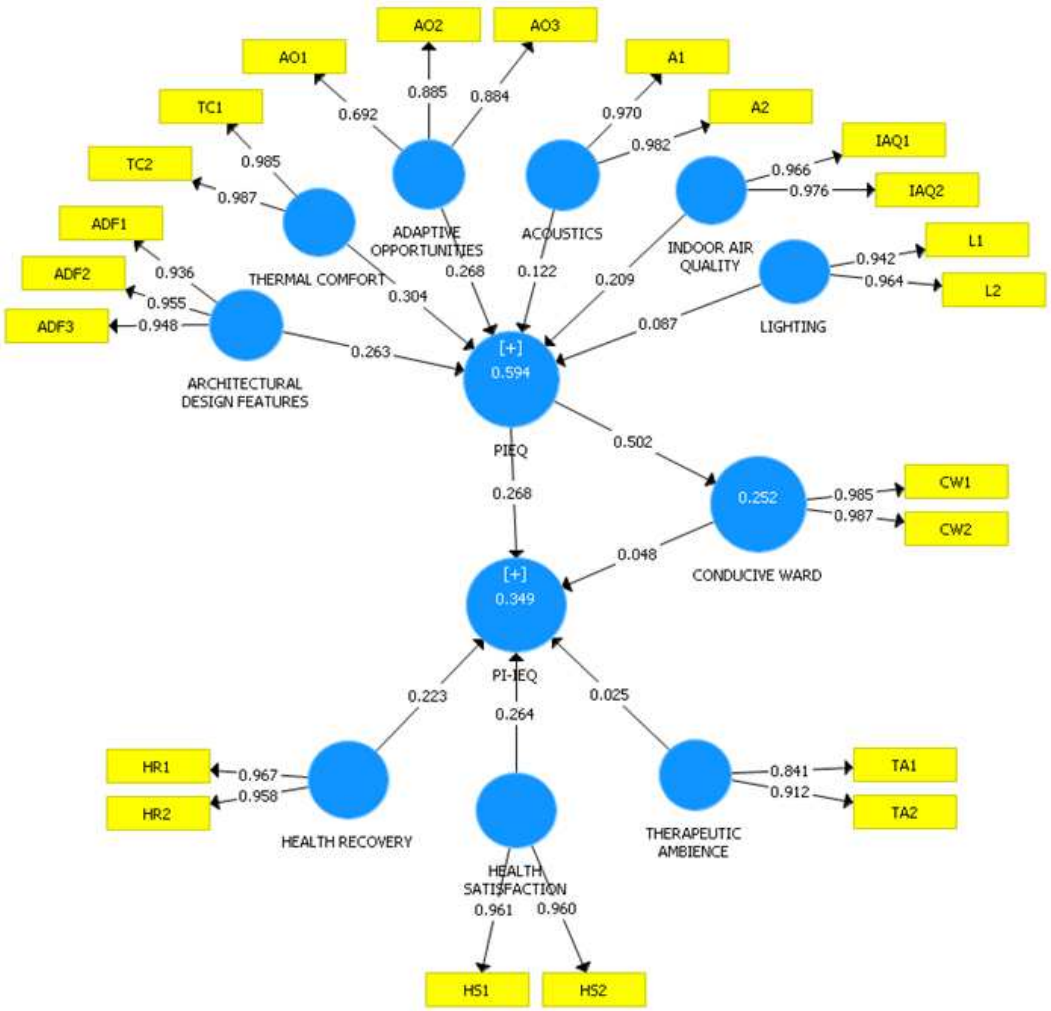

Figure 4. *Structural model evaluation*

Discussion

The six factors that influence PIEQ were consistent with the findings obtained from the literature review. Several types of research conducted indicate that patient's perception significantly relied on design features and ambient attributes (air quality, temperature, daylight, acoustics and artificial lighting) in hospital wards (Ghalib,2018; Gou et al., 2018; Iyendo et al., 2016; Salonen et al., 2013).

In this study, Adaptive opportunity in the context of IAQ and lighting includes the freedom to switch the ceiling fans, freedom to open/close the window shutter and freedom to switch fluorescent lamps. The provision of opportunities to control the patient's indoor environment improved the thermal and visual comfort and satisfaction with IAQ (Fisk, 2000). Occupants attempt to restore their thermal comfort by responding consciously or unconsciously to the thermal environment (Nicol and Humphreys, 2002) and by adjusting the personal environment conditions by opening/closing windows or switching fans on/off (de Dear and Brager, 1998).

Architectural design features were the third most influencing factor on PIEQ in this study (*Fig. 5*). Architectural design features in ward play an important role and health satisfaction of patients (Bosch and Lorusso, 2019; Devlin and Arneill, 2003; Douglas

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82358259

and Douglas, 2004). The beds in the studied wards are fixed and unable to be adjusted by the patients. A flexible bed that could be adjusted to the different comfort level of the patient contributes to the conducive space. The spaces between the beds are not sufficient for patients to move around and for staff to treat patients. The layout of the wards contributes to the health satisfaction of the patients depending on the arrangement of the beds in the ward (Bosch and Lorusso, 2019; Liu et al., 2018; Schweitzer et al., 2004). The number and size of opening influence the temperature, ambient air, and lighting in the ward which effect on the perception of the patients.

Figure 5. *Interior views of the selected wards*

In this study, visual comfort influence on patients in the wards is positive but not significant. Daylight levels in a ward depend upon the size of several windows, and their orientation and location within the building (*Fig. 6*). The orientation of the wards is the same, and also the acoustics of the wards was observed to have a positive influence on PIEQ which was not significant.

Interestingly, in this study, thermal conditions had the highest influence on PIEQ. As per Frontczak and Wargocki (2011), thermal comfort was accorded greater importance compared to visual and acoustic comfort and IAQ by the occupants, and it had a higher degree of influence on the overall satisfaction with IEQ compared to other indoor environmental factors. Studies have reported that temperature had the most influence on patients' perceptions of healing environments (De Giuli et al., 2013). All the selected wards in this study depend on the combination of cross-ventilation and the use of ceiling fans.

Conducive and comfortable wards that meet the needs of patients facilitate recovery and health satisfaction (Doyle et al., 2013; Hughes, 2008; Lim et al., 2019; Reiling et al., 2008). It was observed from this study that the higher the PIEQ, the higher the perception of the wards being perceived conducive. Rarely have researchers

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82358259

investigated the influence of health recovery, health satisfaction and therapeutic ambience on PI-IEQ. Interestingly, this study revealed that Health satisfaction had the most positive influence, followed by heath recovery. Moreover, therapeutic ambience had a positive influent but not significant.

Figure 6. *Exterior views of the selected wards*

Summary

Comfortable thermal environment helps to maintain patients' mood and improves the healing of patients. From the objective survey, the high temperature levels increases toxins rate from building materials and also reduce the recovery rate of the patients in the wards (Kameel and Khalil, 2003). This may increase the lenght of stay of the patients in the wards. Sound level affects comfort and well-being of patients according to Cunha and Silva (2015). The level of noise in this current study can lead to increase in the use of drugs, cardiovascular disease, sleep disruption and hearing loss of the patients. A similar study conducted in Nigeria revealed that most of the indoor environmental quality factors were either above or below the recommended standards (Nimlyat and Kandar, 2015). Temperature and lighting were above the recommended standard in the previous study.

On the other hand, the subjective survey indicated that thermal comfort had the highest influence on the perceived indoor environmental quality in this study. This conforms to the findings of other studies conducted in the tropics (De Giuli et al., 2013; Sattayakorn et al., 2017). Most patients in this study were not satisfied with the adequacy of openings, layout and bed space which contributes to the indoor environment as also reported in a study by De Giuli et al. (2013). Architectural design features such as layout, bed space and openings had significant influence on the PIEQ, as architecture has a role to play in IEQ of buildings (Biancheri and Landi, 2017;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82358259

Alfonsi et al., 2014; Mourshed and Zhao, 2012). Patients chose health satisfaction over health recovery and therapeutic ambience as factors influencing PI-IEQ. This implies that, health satisfaction is more important to the patient followed by the health recovery.

Conclusions, implications and limitations

In this study, objective physical measurements and a questionnaire based subjective survey were conducted to investigate the IEQ of four different wards in the General hospital at Minna, Nigeria. Objective measurements of IEQ include temperature, humidity, acoustics, air quality and illuminance. The measurement was recorded daily for three months. Two hundred and seventy-one (271) questionnaires were retrieved from the patients in different wards during the recording period.

From the Objective measurement, temperature, relative humidity, illuminance and sound level were all above recommended guidelines of WHO, British standards and ASHRAE. On the other hand, results from the subjective survey indicated that thermal comfort, adaptive opportunity, architectural features, air quality, lighting and acoustics positively affect the PIEQ. However, Acoustics and lighting do not have a significant influence on PIEQ in this study. An improved PIEQ of patients significantly increases the level of conduciveness of ward and also PI-IEQ of the ward. It was observed that health satisfaction health recovery and therapeutic ambience had a positive influence on PI-IEQ respectively.

Nigeria, being the most populous nation in Africa, has a large number of cases of widespread communicable diseases and an increasing population of more than 190 million. More than 30,000 Nigerians spend $1 billion annually on medical tourism because of the state of health services (Nigeria Investment Promotion Commission, 2019). With a need for more hospitals and proposals to add more wards to the existing hospitals to meet the growing demand of healthcare services, focus need to be accorded by health practitioners and architects to the design of hospital wards. This study added to the existing knowledge of healing environments, in terms of the outcome of the patient's perception of the hospital ward, particularly through PIEQ and PI-IEQ.

The objective data analysis was limited, as data was collected within three months of the dry season. There will be a need for data collection throughout the year in order to understand the role of other influential factors that may affect PIEQ evaluation in hospital buildings in general. Architectural design features were only limited to layout, the opening of windows and furniture (bed). Other design features such as material finishes, landscape elements, bed spaces etc. should be studied in detail to ascertain how they influence the PIEQ.

(Received 25th Feb 2019; accepted 15th May 2019)

Abstract. The present study was conducted to determine the biochemical characteristics of *Fraxinus ornus* subsp. *cilicica*, seeds, an endemic tree species of Turkey. Seeds were collected from three provenances (Düziçi-Osmaniye, Andırın-Kahramanmaraş, Pozantı-Adana). Seed reserve composition (total soluble sugars, reducing sugars, carotenoids, xanthophylls, total soluble proteins, total tocopherol, total soluble phenolics, flavanoids and oil content) and seed fatty acids contents were examined. Total soluble sugars content and total tocopherol contents of seed among provenances did not differ significantly but other seed constituents were different among provenances. The highest amount of fatty acids present in *F. ornus* subsp. *cilicica* seeds were linoleic and oleic acids. The present study is the first report dealing with various aspects of seed composition and should provide valuable information for this endemic species.
Keywords: *fatty acids, manna ash, taurus flowering ash, oil content, provenance*

Introduction

Fraxinus ornus (L.) (Oleaceae), also known as Manna ash (Fraxigen, 2005), can be used for numerous purposes for example, afforestation/reforestation of deforested areas, urban landscape design, forest restoration and manna production. Manna refers to white or faded yellow sugary substance that dried exudates collected from diverse natural sources and used in several locations around the world as a traditional sweet, emergency food or traditional medicine to treat trivial diseases (Harrison, 1950). Manna production for many years was the source of mannitol used as nutritive sweetener (Debord et al., 1987; Wisselink et al., 2002). Mannas have been known from the earliest times, particularly in Asia Minor, where some mannas are still regularly used in the preparation of local sweets.

Fraxinus ornus subsp. *cilicica* (Lingelsh) Yalt., localy named as Taurus flowering ash, is an endemic tree species of Turkey. The species has ornamental value because of its flower, foliage and interesting crown form (Dirr and Heuser, 1987). This species is an insect-pollinated tree (Verdú et al., 2007), fruits are winged, elongated and single seeded samaras borne in clusters (Bonner, 2008). It is distributed on southern parts of Turkey, mostly on Taurus and Amanos mountains in the East. Taurus flowering ash could reach 8-10 m height and sometimes reach up to 20 m height (Yaltirik, 1978; Browicz, 1982; Yilmaz and Tonguç, 2009). Taurus flowering ash mostly found in karstic areas on sunny southern slopes and grows from 350 m to 1500 m above sea level. Throughout its natural distribution areas, it is scattered generally as individual trees and rarely as clusters and groups. *F. ornus* subsp. *cilicica* wood is used to make shovel handles and therefore scattered populations of this species are under the threat of illegal harvest (Yilmaz and Tonguç, 2013a). However, there are no special conservation programs for the tree species in Turkey. In the last decades, there is an increasing awareness in using native local trees for reforestation and urban planting studies (Grey and Deneke, 1992; Ürgenç, 1998).

DOI: http://dx.doi.org/10.15666/aeer/1704_82618269

Forestry activities are long-term investments, therefore use of high quality seeds are critical to have successful seedling establishment. Factors in relation to the provenance and genetic diversity among the populations together with variety within origins should be taken into consideration because field performance of the seeds obtained from different origins of the same species might be varied greatly (Evans, 1982; Duryea, 1985). Though high quality seeds have fundamental importance for success in plantation forestry, chemical properties are yet more important. The term of high quality seeds for reforestation and urban planting studies refers to not only provenance but more importantly chemical composition of the seeds (Ayaz et al., 2011). While many studies deal with seed size, seed dispersal and seed size and seedling establishment, research on seed reserve contents of forest trees has been started studying recently (Brancalion et al., 2008; Soriano et al., 2011; Ataíde et al., 2013).

Although some studies on the seed morphology and physiology (Yilmaz and Tonguç, 2009; Yilmaz and Tonguç, 2013b) and seed fatty acid and mineral content (Ayaz et al., 2011) of endemic *Fraxinus ornus* subsp. *cilicica* species were carried out, there is no detailed studies on the seed chemical composition. The purpose of the present study was to obtain information regarding to the chemical composition of *F. ornus* subsp. *cilicica* seeds collected from three different provenances.

Material and methods

Seed collection

Fraxinus ornus subsp. *cilicica* seeds were collected from three provenances; Düziçi-Osmaniye, Andırın-Kahramanmaraş and Pozantı-Adana. The seeds were collected in October 2016 at least from 10 individual trees and were packed and transported to the laboratory. Seeds were air dried and 400 seeds were taken and seed wings were removed before the analysis. Taurus ash seed morphologies were analyzed in detail previously among the provenances and therefore they were not included in the present study (Yilmaz and Tonguç, 2009, 2013a). Seed provenances and their locality properties were given in *Table 1* and *Figure 1*.

Table 1. *Seed provenances and their localities used in the study*

Provenances	Latitude	Longitude	Altitude (m)	Mean annual rainfall (mm)	Mean annual temperature (°C)
Adana (Pozantı)	37°22’	34°53’	1150	916.9	11.1
Kahramanmaraş (Andırın)	37°32’	36°18’	950	1477.2	14.2
Osmaniye (Düziçi)	37°16’	36°30’	1400	1362.9	11.2

Biochemical analyses

All chemicals were purchased either from Merck-Millipore (Darmstadt, Germany) or Sigma-Aldrich Chemical Co. (St Louis, USA). Spectrophotometric measurements were made on a T80 spectrophotometer (PG Instruments, UK). Total soluble and reducing sugars were extracted as described by Tonguç et al. (2012). The total soluble sugars content was determined by the phenol sulfuric acid assay (DuBois et al., 1956) and the reducing sugars content was determined by Somogyi method (Somogyi, 1952). Glucose was used as standard and the results were expressed as mg/g dry weight. Total

DOI: http://dx.doi.org/10.15666/aeer/1704_82618269

carotenoids and xanthophylls contents were determined according to Association of Official Analytical Chemists (AOAC) (AOAC, 1984). 10 ml of acetone-hexane (4:6) solvent was added to 1.0 g pulverized seed samples and the mixture was shaken at 15 minutes and the upper phase was washed twice with 20% NaCl solution. Two phases were separated, and the aliquots were taken from the upper phase and read on a spectrophotometer at 436 and 474 nm wavelengths. The protein extraction was performed according to the method of Larson and Beevers (1965) and the total soluble protein content was determined following Hartree method (Hartree, 1972). Bovine serum albumin (BSA) was used as standard. Total tocopherol content was determined according to modified Emmerie-Engel method (Baker et al., 1980). Standard curve was prepared using α-tocopherol. Total soluble phenolics and flavonoid contents of the seeds were determined following procedures of Sakanaka et al. (2005). Standart curve was prepared using (+)-catechin solution and the results were expressed as mg/g dry weight.

The oil content and fatty acid composition of the seeds were determined using Nuclear magnetic resonance (NMR, Bruker mq-one, USA) and Gas chromatography (GC, Perkin Elmer Auto System XL, USA), respectively. The oil samples (50-100 mg) were extracted and converted to its fatty acid methyl esters (FAME) by the method of Maquard (1987). GC-MS analysis was performed as described by Tonguç and Erbaş (2012). Total free fatty acids content of seeds (%) was determined as oleic acid equivalents.

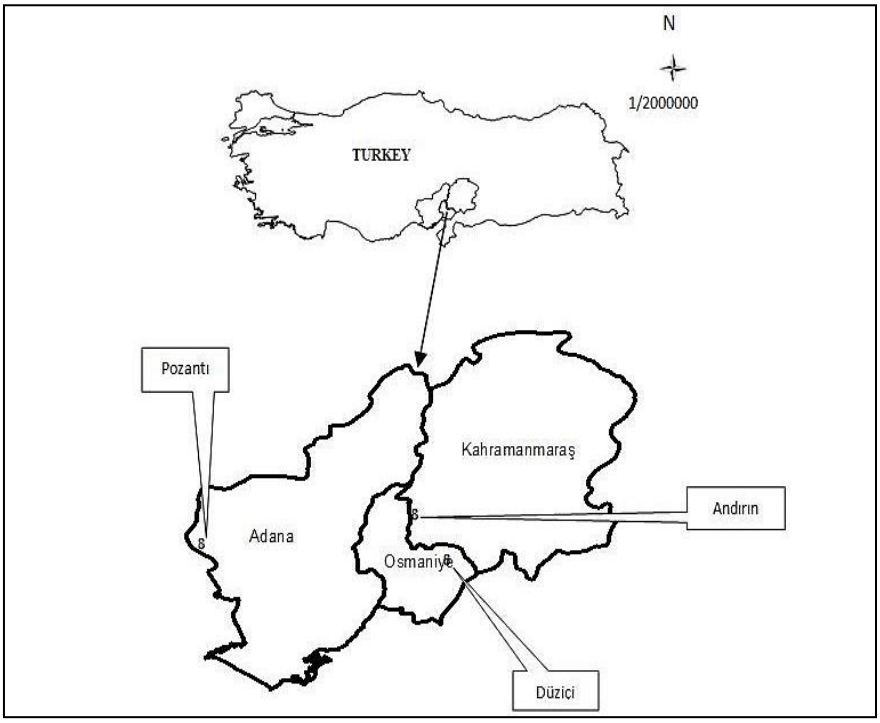

Figure 1. *Location map of seed collection sites*

Statistical analysis

Chemical compositions of provenances were measured 3 times independently and results were analyzed with the analysis of variance (ANOVA). To determine differences between the means, Duncan's Multiple Range test was performed.

Results and Discussion

Total of nine parameters related to seed reserves as well as fatty acids compositions were measured to determine chemical composition of *F. ornus* subsp. *cilicica* seeds from 3 provenances. The highest reducing sugars content was found from seeds collected from Adana (146.32 mg/g) followed by Kahramanmaraş (141.29 mg/g) and Osmaniye (138.52 mg/g), however reducing sugars content of the seeds collected from Kahramanmaraş and Osmaniye did no differ significantly. On the other hand, total soluble sugars contents was not statistically significant among the provenances (*Table 2*).

The highest total carotenes (0.894 mg/g) and xanthophylls (0.586 mg/g) contents were obtained from seeds collected in Osmaniye. Unlike reducing sugars content, *F. ornus* subsp. *cilicica* seeds from Osmaniye provenance had higher carotene (0.894 mg/g) and xanthophylls (0.586 mg/g) contents than *F. ornus* subsp. *cilicica* seeds collected from Adana and Kahramanmaraş.

Table 2. *Chemical composition of F. ornus subsp. cilicica seeds from different origins*

Provenance	Reducing sugars (mg/g)	Total soluble sugars (mg/g)	Carotenes (mg/g)	Xanthophyll (mg/g)	Total Soluble proteins (mg/ml)	Total tocopherol (mg/g)	Total soluble phenolics (mg/g)	Flavonoids (mg/g)	Total oil content (%)
Adana	146.32a*	200.24	0.776b*	0.517c**	10.06b*	76.16	5.95a*	2.22a*	23.83c**
Kahramanmaraş	141.29ab	199.96	0.763b	0.556b	9.10b	76.94	5.35b	2.18a	28.42a
Osmaniye	138.52b	199.52	0.894a	0.586a	11.47a	76.48	4.70c	1.89b	25.18b

The values on the same row followed by the same letter are not significantly different at $p<0.05$

Total soluble protein content was also differed significantly between the seed sources. Protein content was not significantly differed between Adana and Kahramanmaraş (*Table 2*). The highest protein content among the seeds was observed in Osmaniye provenance (11.47 mg/ml) and the lowest protein content was found in seeds from Kahramanmaraş (9.10 mg/ml).

Total tocopherol content of *F. ornus* subsp. *cilicica* seeds were close to each other and varied between 76.16-76.94 mg/g. While seeds from Adana had lower tocopherol content than the seeds from Kahramanmaraş and Osmaniye provenances, the difference was not statistically significant.

Total soluble phenolics content was significantly differed among the provenances and changed between 4.70-5.95 mg/g, and the highest soluble phenolics content was observed from the seeds collected from Adana provenance. Total flavanoid content ranged between 1.89-2.24 mg/g among the seed sources and was different between Osmaniye and Adana-Kahramanmaraş provenances.

Total oil content was also measured and statistically different variations were found among the seeds collected from Adana, Kahramanmaraş and Osmaniye provenances. Seeds from Kahramanmaraş had the highest oil content (28.42%) while seeds from Adana (23.83%) and Osmaniye (25.18%) had lower oil contents.

Fatty acid compositions of *F. ornus* subsp. *cilicica* seeds from different seed provenances were also examined. GC/MS analysis revealed 3 major fatty acids (C16:0 palmitic acid, C18:1 oleic acid, C18:2 linoleic acid) and 5 minor fatty acids (C16:1 hexenoicacid, C17:0 heptadecanoic acid, C18:0 stearic acid, C18:3 linolenic acid). Detected fatty acids accounted more than 97% of total fatty acids found in *F. ornus*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82618269

subsp. *cilicica* seeds. Majority of the fatty acids were unsaturated fatty acids and linoleic and oleic acids constituted the majority of the unsaturated fatty acids. Palmitic acid had the highest amount among the saturated fatty acids (*Table 3*).

Seeds contain carbohydrates, proteins and lipids as reserve molecules and they are usually accumulated as insoluble large macromolecules (Vidigal et al., 2016). These macromolecules are the fundamental constituent of seed biomass and are the source of energy playing important roles for the seedling during germination, early development and survival (Soriano et al., 2011; Wahid and Bounoua, 2013; Zhao et al., 2018). During the germination enzymatic pathways are activated upon imbibition to convert these molecules into smaller soluble units for energy production and synthesis of new molecules (Bewley et al., 2013). Other molecules, such as vitamins, carotenoids and xanthophylls, are also present in seeds in varying amounts. Presence of these molecules protects seeds from enzymatic and non-enzymatic lipid peroxidation during the storage and germination (Priestley, 1986). Information on chemical composition of seeds belong to wild species is scarce therefore some chemical parameters were determined for *F. ornus* subsp. *cilicica* seeds in the present study.

Table 3. *Fatty acid contents (%) of F. ornus subsp. cilicica seeds*

Fatty Acid		RT*	Seed Provenance		
			Adana	Kahramanmaraş	Osmaniye
C16:0	Palmitic acid	24.564	11.69	8.88	11.36
C16:1C7	7-hexenoic acid	25.234	0.31	0.75	1.24
C16:1C9	9-hexenoic acid	27.013	0.16	0.24	1.55
C17:0	Heptadecanoic acid	29.408	0.32	0.25	0.95
C18:0	Steraic acid	32.780	2.65	1.99	3.05
C18:1	Oleic acid	33.408	24.73	17.50	19.12
C18:2	Linoleic acid	34.916	57.56	66.67	56.33
C18:3	Linolenic acid	37.193	0.60	0.95	0.70

*Retention time

It has been reported that type and amount of seed reserves have influence on germination rate, germination percentage or both (Zhao et al., 2018). Different reserves have different influence on germination for example protein content was positively correlated with germination percentage in different tree speceies (Brancalion et al., 2006; Soriano et al., 2011; Wahid and Bounoua, 2013), yet total soluble sugars content was not have influence on germination percentage in *Pinus pinaster* (Wahid and Bounoua, 2013) and did not significantly different among the seeds of the different populations. Oilseed species such as sunflower and safflower seeds showed significant reduction of protein and oil reserves during the germination and early seedling growth, but total soluble sugars and reducing sugars did not decreased significantly (Tonguç et al., 2012; Erbaş et al., 2016). Seed germination parameters have been studied previously (Yilmaz and Tonguç, 2013a,b) but we did not investigate type of the reserves used during the germination and early seedling growth. Different species use different reserves for germination and *F. ornus* subsp. *cilicica* seeds are rich in sugars, proteins and lipids and their role in germination should be investigated further to ascertain their role during germination and seedling growth.

Environmental factors and seed provenances may influence seed morphology and reserve composition. In a previous stduy, seed morphologies of *F. ornus* subsp. c*ilicica* trees colleceted from 8 provenances were described (Yilmaz and Tonguç, 2009). While

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82618269

there were differences among the seed morphologies depending on provenances, only the mean temperature had influence on samara width among the studied parameters. In the present study, mean temperature of Kahramanmaraş was different to have an influence on seed morphology. Total soluble sugars and tocopherol amounts did not differ significantly between provenances, but other reserves of the seeds showed significant differences among the provenances. (*Table 2*). Effects of precipitation on seed lipid, protein and sugar contents on 19 tree species were reported. Lower rainfall increased seed protein content of 12 species while it reduced sugar content of seeds in 2 species. Lipid content of 5 species decreased and one species showed increased lipid content out of 19 tree species in Mexico (Soriano et al., 2011). Phenolics and flavonoids in the seeds have major roles for protecting plant species against insect feeding, herbivory and abiotic stresses such as drought, temperature flactuations, lipid peroxidation (Mierziak et al., 2014). Caratenoids and xhanthophylls are present in photosynthetic tissues and in seeds and protect plants from oxidative damage. Caratenoids in plant seeds also involved in abscisic acid production and seed dormancy (Howit and Pogson, 2006). Tocopherols are also present in seeds and their major role is the prevention of lipid peroxidation during seed storage and germination (Sattler et al., 2004). In the present study, amount of caratenoids and xanthophylls, and total phenolics and flavanoids was different among the seeds from the provenances, suggesting different mechanisms may have involved in the accumulation of these compounds. We have studied effects of storage temperature and seed moisture content of *F. ornus* subsp. *cilicica* seeds collected from 5 provenances (Yilmaz et al., 2014) but their effects on seed storability have not been investigated. The present study will be helpful to investigate seed storage compounds and seed storability of *F. ornus* subsp. *cilicica* seeds.

The present study is a preliminary study to determine some seed reservers of *F. ornus* subsp. c*ilicica* seeds and was conducted one year therefore it was not possible to identify. Influence of environmental factors on seed reserve composition at present. Multi year studies must be conducted to deliminate effects of environmental factors on seed reserve composition.

Seed fatty acid composition have also been investigated. Majority of fatty acids were mono and poly unsaturated fatty acids in *F. ornus* subsp. *cilicica* seeds. GC/MS analysis revealed 97% of fatty acids present in seeds therefore there are other undetected fatty acids and their amounts and types should be investigated further. Lajara et al. (1990) and Bozan and Kaplan (2007) stated that fatty acid profiles are affected by temperature, plant species, genotype and environmental conditions. Differences in fatty acid compositions might be due to lower altitude of seed source and therefore the warmer climate of Kahramanmaraş compared to other provenances (*Tables 1, 3*). Similar results were reported by Ayaz et al. (2011) that provenances in the cooler temperatures were tended to deposit higher levels of oleic acid for *Fagus orientalis* seeds.

Conclusion

The present study was conducted to quantify different seed reserves and chemical constituents in *F. ornus* subsp. *cilicica* seeds. Seed reserves such as seed oil content and 8 other seed reserves involving in different features of seed life and seed fatty acid contents have been investigated. Seven compounds present in seeds were differently accumulated in seeds dependeing on seed source. Total soluble sugars and total

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82618269

tocopherol contents among the provenances were not different. Eight different fatty acids have been detected in *F. ornus* subsp. *cilicica* seeds and majority of fatty acids were unsaturated fatty acids. Previous studies revealed that seed reserve accumulation depends on many factors such as environment and maternal plants, and seed provenances differ in their germination capabilities. Further studies would be necessary to conduct to investigate type of reserves accumulated in different seasons and used during the seed germination and their effects on germination capability among different seed provenaces of *F. ornus* subsp. *cilicica* seeds.

(Received 27th Feb 2019; accepted 1st May 2019)

Abstract. Riverine systems are influenced by historical and current land use practices linked to alterations in the riparian zone across multiple scales. This study aims to explore the trend of spatiotemporal land cover changes and configuration along a major headstream of the river Ganges in India. Geo-spatial tools were used to quantify the changes in the landscape across a time span of 22 years. Landscape configuration was quantified by applying class level metrics using the software FRAGSTATS. A loss of 18.3% and 5.5% in the dense forest class was perceived in the upland and the riverine areas respectively aided by conversion of large contiguous forests into smaller isolated patches. Markov analysis showed that the forests in the landscape still possess inherent resilience capacity as indicated by a probability of 47% conversion of open forest class to dense forest class in future based on current land-use practices. Land cover changes and forest fragmentation can have inevitable impacts on ecological functioning and species persistence. Monitoring these changes is fundamental in planning future strategies for riverine landscape management. The present study underpins the utility of remote sensing and GIS in building useful baseline data for inaccessible mountainous landscapes at both local and regional scales.
Keywords: *Bhagirathi basin, fragmentation, landscape change, landscape-level assessment, riverine landscape*

Introduction

Natural riverine landscapes are classic examples of ecotonal habitats characterized by a high level of heterogeneity. Multiple interactive pathways operating across various spatiotemporal scales determine the dynamic structure and function of these terrestrial-aquatic continuum habitats (Steel et al., 2010). River form linear corridor features in the landscapes they traverse; montane river systems characteristically being single-thread channels bordered by a narrow band of native riparian vegetation (Ward et al., 2002). Riverine forests grow along the riverbanks and their structural composition is unique and highly influenced by the river's fluvial activities (Naiman et al., 1993). They provide multiple ecosystem services (Tomscha et al., 2017; Sutfin et al., 2016); providing habitats to diverse organisms (Dybala et al., 2019) and maintaining a network of dispersal corridors (Naiman et al., 2005). Riverine forests support high densities and diversities of migratory birds by providing a critical habitat and the only edge cover available to them during migration (Naiman et al., 1993; Gergel et al., 2007).

Forests are losing their resilience capacity at an increasing rate, often irreversibly due to large-scale changes occurring at an unprecedented rate (Wilson, 1992). Forest fragmentation is a global concern, effects of which are well documented in climatic, biophysical and hydrological cycles (Ramanathan et al., 2005), biodiversity and associated ecosystem services (Xu et al., 2009). Fragmentation has impacts on the overall health of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82718289

forest ecosystem. Forest loss and changes in forest configuration impedes the survival of the forest dependent species (Villard et al., 1999; Bogaert et al., 2011). India is endowed with a forest cover of 21.34% (FSI, 2015) of its total landmass and is ranked tenth in the world in terms of the extent of forest cover (FAO, 2010). Although, escalating human population is increasing dependence on forested landscapes for space and resources leading to the degradation of forests, fragmentation being a major corollary (Roy and Roy, 2010). In the state of Uttarakhand, anthropogenic pressure has led to dwindling of forest cover with a loss of 268 km^2 area in a span of two (2013-2015) years (FSI, 2015) with individual case studies from different districts providing strong evidences in the same line (Rawat and Kumar, 2015; Rawat et al., 2013).

Hence, it is critical to assess the current condition of vegetation in a landscape for its conservation and designing future restoration programs (Egbert et al., 2002; He et al., 2005). Discerning the patterns of vegetation change within a landscape can provide a basis for future monitoring and addressing its management (Gould, 2000). Remote sensing offers the best tool to analyze, map, and monitor ecosystem patterns and processes. It facilitates possible data archives from present time to over several decades back due to its potential for observing the Earth's surface at different times (Ety and Rashid, 2019; Xie et al., 2008). Change is an inherent characteristic of a landscape driven by natural and anthropogenic drivers shaping its structure, function and dynamics. Detecting change is an important aspect for studying landscapes that are dynamic and continuously changing, where change is 'an alteration in the surface components of the vegetation cover' (Milne, 1988) or 'a spectral/spatial movement of a vegetation entity over time' (Lund, 1983).

This study aims to explore the use of geo-spatial tools in monitoring landscape changes for inaccessible areas in mountainous terrains across spatial and temporal scales. Advanced tools like FRAGSTATS (McGarigaI and Marks, 1994; Neel et al., 2004) and simulation models using Markov analysis were used to understand patterns of forest fragmentation and predicting future scenarios in the backdrop of current land-use patterns. The study is intended to a comparative understanding of Land-Use and Land-Cover (LULC) change and forest fragmentation events in riverine stands in contrast to the entire river basin.

Materials and methods

Study area

The river Ganga is the largest and longest river of India and a lifeline to millions of humans (supporting > 40% of the total population; sustaining 520 people per sq. km) (Census of India, 2001). It is also listed among 'the top 10 rivers of the world at risk' because of over-extraction of water resources (Wong et al., 2007). The mountainous catchment of the river Ganga is formed by the two Himalayan rivers - the Bhagirathi and the Alaknanda. The study area i.e. the Bhagirathi basin spreads across three administrative districts of Garhwal region viz., Tehri, Pauri, and Uttarkashi in the state of Uttarakhand, Western Himalaya (*Fig. 1*). We focused our study along the river stretch between Gaumukh, the origin of the Gangotri glacier (30°55'37.35"N lat. and 79°4'46.98"E long.) and Rishikesh (30°05'12.94"N lat. and 78°16'3.40"E long.), where the river enters the plains encompassing an elevational range of 4100 to 330 m above sea level. Due to enormous hydro-power potential, many operational and proposed hydro-electric projects exist enroute the Bhagirathi River (Rajvanshi et al., 2012). The characteristic species representing various vegetation types include *Shorea robusta, Mallotus philippensis, Acacia catechu, Bauhinia variegata, Toona ciliata, Celtis*

DOI: http://dx.doi.org/10.15666/aeer/1704_82718289

australis, Pinus roxburghii, Alnus nepalensis, Pinus wallichiana, Populus ciliata, Cedrus deodara and *Betula utilis* in association with a large number of shrubs and herbaceous flora. The climate of the state of Uttarakhand is primarily temperate except for the plains, with temperatures ranging from below 0 to 43 °C with an annual rainfall of 1550 mm (Government of Uttarakhand, 2014).

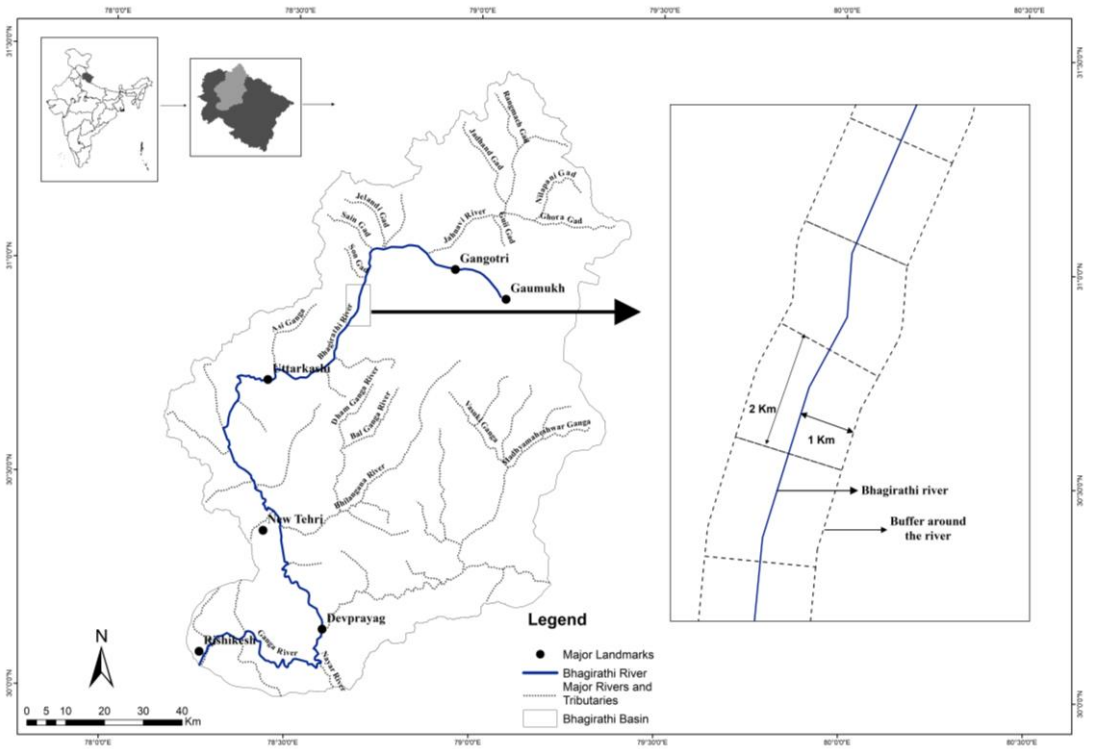

Figure 1. *Location of Bhagirathi river basin in the state of Uttarakhand in India and diagrammatic sketch (right side) represents the cross-section of riverine buffer (2 km long and 1 km wide) on either side along the Bhagirathi river*

Data procurement and processing

Past studies on LULC changes have been carried out by using remote sensing data sets (Halmy et al., 2015), such as MODIS (Alhamdan et al., 2017), Landsat (Osgouei and Kaya, 2017) and SPOT (McCarthy et al., 2018). Since, Landsat offers optimum spatial and spectral resolutions and multi-temporal archives to understand the changes over space and time, it is best suited for this study. Cloud-free Landsat satellite data of 30 m spatial resolution was downloaded from USGS Earth Explorer (www.earthexplorer.usgs.gov) for the month of May for the years 1993 and 2015. The imageries of the path and row 146/38 and 146/39 were subsequently mosaiced for further image interpretation (*Table 1*). Preprocessing was performed in Erdas Imagine 2013 and ArcGIS 10.1 before classifying the images, including radiometric correction and topographic normalization. Normalization algorithms aided in removing albedo variations and topographic effects associated with remote sensing data acquired for mountainous regions. To remove topographic effects resulting from the position of the sun and angle of terrain, an algorithm called Minnaert correction was used (Allen, 2000; Ge et al., 2008).

A reconnaissance field survey was undertaken before classifying the image and ground truth points were collected during subsequent field surveys across the entire river basin. Processed False Color Composite (using the spectral band combination of Near-infrared, Red and Green) for the years 1993 and 2015 were classified using unsupervised classification (ISODATA technique) beginning with 100 classes and then decreasingly grouping together into eight land cover classes namely, dense forest, open forest, shrubland, grassland, agriculture, barren land, river and snow. To validate the remotely sensed data, ground truth points were gathered from on ground surveys and Google Earth generated points to improve accuracy of classified LULC images. The classification accuracy for the images of the two years was measured using the agreement between predicted and observed (field validation points) categories of a dataset, while correcting for agreement that occurs by chance (Jenness and Wynne, 2005). It made use of overall accuracy (OA) of the model in terms of both predictive model and field surveyed sample points, to correct for chance agreement between the both. Around 270 ground truth points collected through extensive field surveys aided in improving the classification accuracy.

Landscape configuration and temporal change

We calculated the area under the eight land cover classes in ArcGIS 10.1 to understand current landscape configuration of the Bhagirathi river basin along with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82718289

temporal change across a period of two decades. Markov chain prediction using IDRISI GIS Analysis in TerrSet software was performed to develop the probability matrix for future transitions resulting from the cross-tabulation between the earlier and later times' land cover images. This matrix calculates the probability of a given class pixel to change into any other class or stay the same in the next time period. In a Markov Chain transition, the probability $p(y_t)$ that a phenomenon exists in state a_j if it was in state a_i at a previous time is denoted by the following equation:

$$p\langle y_t = a_j | y_{t-1} = a_i \rangle$$

A landscape is characterized by various land-use and land-cover configurations which is dynamic over time, hence depicts a Markov Chain matrix that encapsulates multiple transitions:

$$\underline{P} = [p_{ij}] = \begin{bmatrix} p_{11}, p_{12} \ldots p_{1n} \\ p_{21}, p_{22} \ldots p_{2n} \\ p_{n1} p_{n2} p_{nn} \end{bmatrix}$$

where $\underline{P} = [p_{ij}]$ is the probability of transitioning from one state i to a different state j or to multiple states (i_1, i_2,...i_j) (Wilson et al., 2018).

FRAGSTATS 4.2.1 was used to quantify the spatiotemporal changes in the structural characteristics reflecting the ecological process and consequent pattern in the landscape. We used class-level metrics to understand the status of forested areas at two scales, for the entire landscape and the riverine buffer (considering a distance of 1 km on either side). We investigated the change in forest class across the landscape using patch density (PD), largest patch index (LPI) and percentage of the landscape (PLAND) under the patch area metrics, the area of the patch (AREA MN) under the shape metrics, clumpiness index (CLUMPY) and aggregation index (AI) under the interspersion metrics. PD is expressed as the number of patches on a per unit area basis and is considered as general index of spatial heterogeneity of the entire class in a landscape mosaic. LPI at the class level quantifies the percentage of total landscape area comprised by the largest patch and is a simple measure of dominance. PLAND quantifies the proportion of particular patch type of a class in a landscape and approaches zero when the class becomes increasingly rare in the landscape. Area MN or mean patch size is a measure of fragmentation in a landscape as the smaller the mean patch size the more fragmented is the focal class in a landscape. Both AI and CLUMPY are calculated from adjacency matrix which means a single, compact patch type is achieved when the AI approaches maximum value while clumpiness index values varies between -1 to + 1 indicating maximum disaggregation or aggregation of the focal patch type (McGarigal and Marks, 1995). For further insights regarding changes in the riverine forest stands, we also analyzed patch properties along both the banks of the Bhagirathi river.

A total of 123 units of 2 km length each were created on the river (linear shapefile) with the aid of the Split tool in ArcGIS10.1 (*Fig. 1*). Thereafter, the Buffer tool was used to create a buffer of 1 km width on both sides of the river. Hence, we created 123 segments of 2 km^2 area on both sides of the river for performing FRAGSTATS analyses in the riverine buffer. With a special focus on understanding the pattern of forest fragmentation in these narrow linear habitats, we used class-level FRAGSTATS analyses. Metrics used for this analysis were identical to those used for comprehending spatiotemporal pattern of forest structure in the entire landscape for enabling a comparative understanding.

Results

Landscape configuration and temporal change

The entire river basin comprised of a total area of 11389 km^2. The overall accuracy of the classified images for the years 2015 and 1993 were 85.1% and 87.2%, respectively. The LULC pattern for the year 2015 indicated 24.1% of the land under dense forest class followed by, open forest (24.3%), shrubland (3.1%), grassland (5.6%), agriculture land (4.5%), barren land (7.1%), river (0.6%) and snow cover (30.6%). The dense forest markedly declined (18.3%) across the time span of 22 years, although the overall area under forests has relatively not undergone much change (*Table 2*). The open forest class showed an increase (18.3%) in the entire river basin. Agriculture class (increase of 2.5%) was found uniformly distributed in the entire landscape barring higher altitudes with a significant concentration along the rivers (*Fig. A1* in the *Appendix; Table 2*). The buffer of a width of 1 km encompassing an area of 409.9 km^2 varied in composition, although it reflected almost similar trends of landscape change as of the entire basin (*Table 2*).

Table 2. *An area-wise comparative analysis of spatiotemporal change (increase depicted as positive [+] and loss as negative [-]) of land cover between 1993 and 2015 in Bhagirathi basin (total area = 11389 km^2) and 1 km buffer along both the sides of Bhagirathi river (total area = 490.9 km^2)*

Land cover class	Basin			Buffer		
	1993	2015	% Change	1993	2015	% Change
	Area (km^2)	Area (km^2)		Area (km^2)	Area (km^2)	
Dense forest	4830.9	2746.2	-18.3	201.7	174.7	-5.5
Open forest	683.8	2768.1	18.3	55.9	109.7	11.0
Shrubland	508.4	358.7	-1.3	59.8	7.9	-10.6
Grassland	672.8	636.4	-0.3	67.7	52.7	-3.1
Agriculture	226.2	507.7	2.5	15.1	45.9	6.3
Barren land	1136.7	814.2	-2.8	62.2	54.3	-1.6
Snow	3282.0	3486.9	1.8	3.8	5.0	0.2
River	48.5	70.8	0.2	24.8	40.8	3.3

The study area depicted a decline in dense forest areas across the entire Bhagirathi basin (4830.9 km^2 to 2746.2 km^2) as well as in the riverine buffer (201.7 km^2 to 174.7 km^2) (*Table 2*). There was a substantial increase in the open forest class in both buffer areas and entire basin, whereas shrubland decreased significantly in the riverine buffer (10.6%). The area under river class increased markedly from 48.5 km^2 (1993) to 70.8 km^2 (2015) owing to land submergence by the Tehri dam, which became operational in the year 2008 and is conspicuous in the map (*Fig. A1*). Area under shrubland and grassland categories decreased across time, remarkably in the riverine buffer (Shrubland-10.6%, Grassland-3.1%). Agricultural land increased across the entire basin, comparatively more in the riverine areas. The riverine buffer units (*Fig. 2; Table A1* in the *Appendix*) depict the similar trends where dense forest showed mostly a negative change while open forest and river showed a positive change across a span of 22 years.

DOI: http://dx.doi.org/10.15666/aeer/1704_82718289

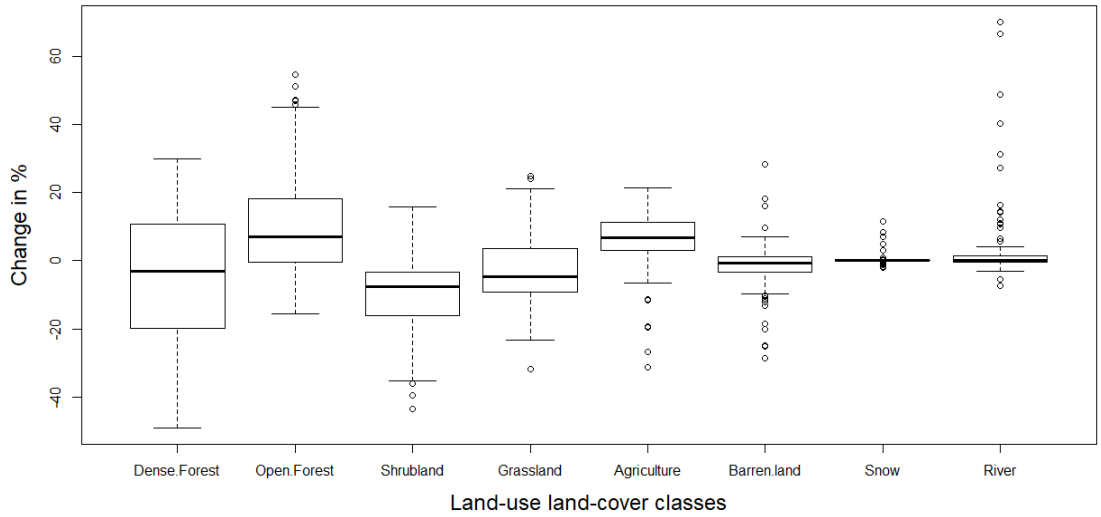

Figure 2. *Box and whisker plot illustrating the area-wise percentage change of Land use/Land cover categories from the years 1993 to 2015 in the 123 riverine buffer units (4 km^2 area) along both the banks of the Bhagirathi River*

Results of Markov analysis reveal that areas under open forest in the entire Bhagirathi basin still hold an equal probability (0.47) of reverting back to dense forest and vice-versa by the year 2037 (*Fig. 3*) depending on the current land-use practices. Area under grassland showed a significant probability of getting converted into open forest (40%). The probabilities of shrubland getting converted to open forest and vice-versa are comparatively similar and smaller in magnitude, while the probability of desertification (conversion of open forest into barren land) was found to be negligible (2%).

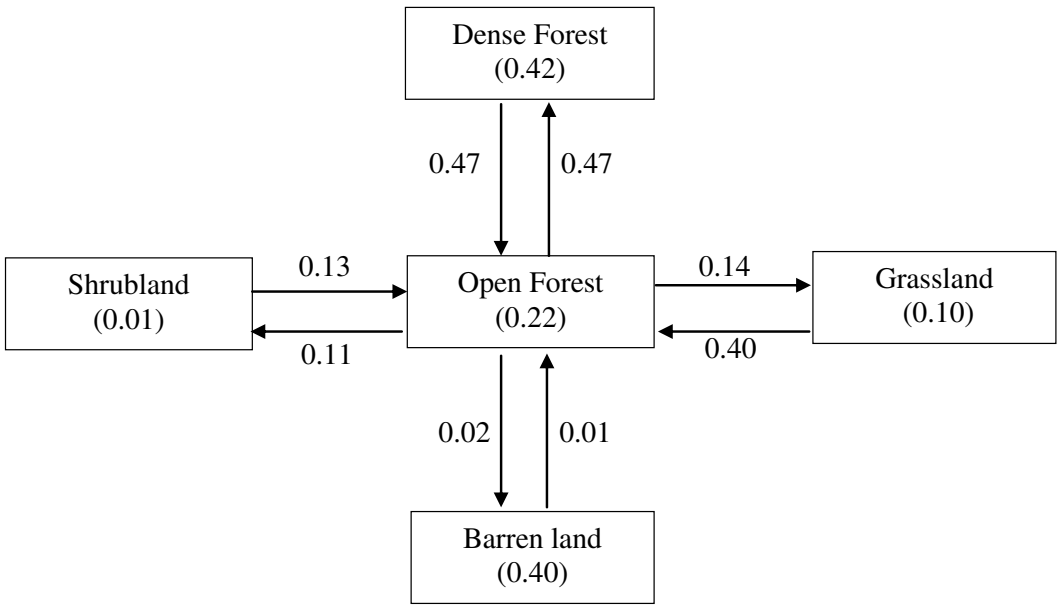

Figure 3. *Land cover/Land use transition probabilities as predicted for the year 2037 (22 years) using Markov analysis (values within box denotes self-replacement probability and values on arrows are their transition probabilities to other land-cover classes)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82718289

Forest integrity and intactness

Results of FRAGSTATS analysis indicate fragmentation events with an increase in the number of patches (1993: 30166 and 2015: 31978) and patch density (1993: 2.65 patches km^{-2}, 2015: 2.81 patches km^{-2}) and decrease in the Large Patch Index (LPI; 1993: 46.0% and 2015: 40.1%) for the forested areas in the Bhagirathi basin. Patch density is a fundamental aspect of landscape pattern and serves as a general index of spatial heterogeneity of the entire landscape mosaic. LPI essentially quantifies the percentage of total landscape area comprised by the largest patch and is a simple measure of dominance. The river basin has undergone a drastic increase in patch density with decreasing LPI in the basin, indicating the disintegration of existing forest patches into smaller fragments.

Proportion of Landscape (PLAND) values decreased in the dense forest class from 42.5% (1993) to 24.1% (2015) while simultaneously increasing in the open forest class from 6.0% to 24.3%, providing evidence for the process of conversion of dense forest to open forest (*Table 3*). Values for Aggregation Index (AI) has decreased moderately in the dense forest type indicating decrease in intactness. In contrary, AI values increased for the open forest class hinting towards decreasing distance between neighbouring patches of this class. The overall status of forests in the Bhagirathi basin portrayed more patchiness in the dense forest class with patches of open forest getting clustered together with time.

Table 3. *Comparative analysis of forest fragmentation using class metrics (dense forest and open forest) between the years 1993 and 2015 in the Bhagirathi basin*

Forest type	Year	PLAND (%)	NP	PD (number of patches/km^2)	LPI (%)	AREAMN (km^2)	CLUMPY	AI (%)
Dense	1993	42.49	44952	3.96	34.44	10.74	0.82	89.92
	2015	24.12	119856	10.43	1.9	2.29	0.65	73.4
Open	1993	6.02	109691	9.66	0.01	0.62	0.47	50.22
	2015	24.31	60486	5.32	4.41	4.57	0.68	75.65

NP: Number of Patches, PD: Patch Density, LPI: Large Patch Index, PLAND: Proportion of Landscape, AREA MN: Area Mean: CLUMPY: Clumpiness Index, AI: Aggregation Index

Although it is useful to consider forest fragmentation at the landscape level, the quality of the forest is best realized when focusing on a single habitat type i.e. smaller geographic extent. The forest communities along riverbanks are central elements of riverine landscapes undergoing maximum interactions at the terrestrial-aquatic interface. Results of FRAGSTATS analyses for 123 units along both the banks of the Bhagirathi river were noteworthy for the riverine forest cover (*Fig. 4*). There was minimal change in the patch density in the units 1-3 (*Fig. 4*) which belong to the high-altitude areas forming treeline, consisting stands of *Cedrus deodara* which have remained relatively intact temporally. This can be owing to the inaccessibility of these areas due to their remoteness and also because this forested land is protected under the Gangotri National Park. A similar trend exists for units 110-123, which lie around the town of Rishikesh where riverine stands comprise of late successional species like *Holoptelea integrifolia* and *Haldina cordifolia* which are well established and less prone to disintegration. Temporal fluctuations in patch density showed spatial patterns with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82718289

three distinct peaks. Increase in patch density in the higher elevation river reaches can be owed to the natural riverine vegetation in this belt (units from 15-30). Forest community here comprises of *Alnus nepalensis* and *Populus ciliata* both of which are early successional species and grow well on eroding slopes and open flat sites, respectively. LPI has considerably been constant across the entire riverine stretch (*Fig. 4*) with a little increase around the submergence zone of Tehri dam followed by an increase in patch density (units around 40-60) depicting the afforestation activities near Tehri dam in an area of 138.4 km^2 under Forest Department plantation scheme raised in the year 2010-11.

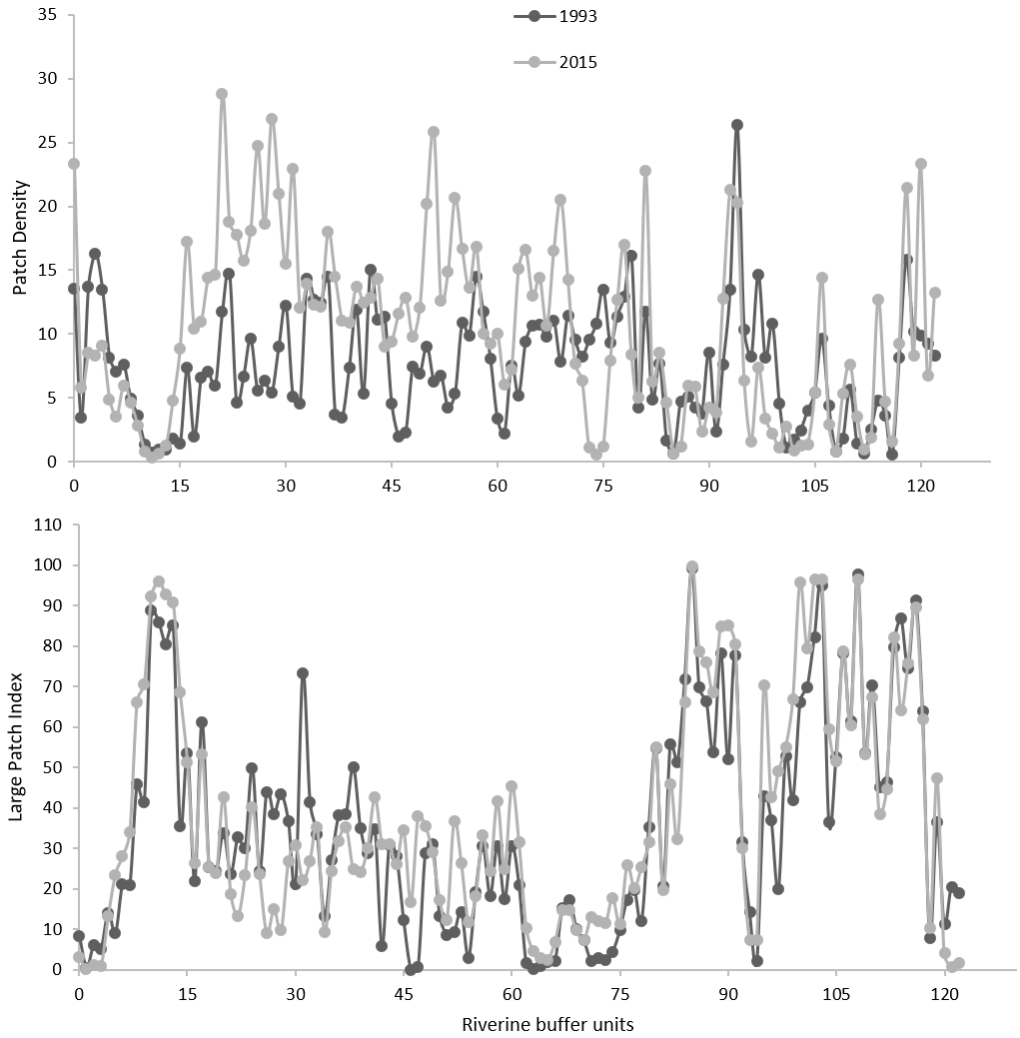

Figure 4. *Graphs comparing fragmentation events of the years 1993 and 2015 for two class level indices. (a) Patch density and (b) large patch index for forest class in the 123 riverine buffer units (2 km long and1 km wide) along both the banks of the Bhagirathi river*

Discussion

Spatiotemporal landscape change has been studied for varied applications including planning and management of urban sprawl (Vani and Prasad, 2019), understanding dynamics of vegetation cover change (Kaur et al., 2019), forest connectivity for wildlife (Areendran et al., 2017) and watershed planning and management (Wilson et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82718289

Riverine landscapes are fragile and dynamic in nature (Miles et al., 2004) and consist of plant species with narrow distribution ranges (Silva et al., 2008) which renders the characteristics of riverine vegetation to be markedly different in structure and function. This makes the riverine ecosystem more vulnerable to extreme events and natural disasters, and thus, an important landscape to understand and manage (Stella and Bendix, 2019). The Himalayan river systems are undergoing major modifications through changes in land use, climate and water resource development (Rajvanshi et al., 2012; Manel et al., 2000). A similar study was found useful for knowledge-based future land management practices in the Upper Awash basin, Ethiopia where river basins and sub-basins were considered as focal area to study the extent and the rate of landscape change (Shawul and Chakma, 2019). Our study is a pioneering attempt of landscape-level assessment, ascertaining forest fragmentation patterns by select metrics across a time-span of two decades containing a substantial amount of riparian stands, which are otherwise not protected by law (Roy et al., 2013). Results highlight considerable conversion of dense forest into open forest characterized by the proliferation of much smaller, less connected forest patches in the studied landscape. Although rates of forest fragmentation were found to be appreciable, the forests of the landscape exhibited marked resilience capacity as portrayed by the results of the Markov transition probability matrix (*Fig. 2*). A remote-sensing-based analysis of the forest cover in the Western Himalaya during the years 1985–2005 also indicated significant degradation in the forest cover during two decades as depicted by our study (Roy and Rathore, 2019).

The composition and spatial configuration of the landscape matrix have multiple cascading effects mediated by disproportionate edge and area ratios which can profoundly affect dispersal- colonization dynamics (Dunning et al., 1992; Gascon et al., 1999) and habitat use (Antongiovanni and Metzger, 2005; Norton et al., 2000) of animals. The magnitude of change in select landscape matrices used to quantify patterns of landscape composition and configuration can influence ecological communities dependent on these forest patches (Donovan, 1997; Rodewald and Bakermans, 2006). In our study, the decrease in the LPI in the basin with rise in the number of patches highlights internally driven dynamics within patches themselves (Woodroffe and Ginsberg, 1998; Chen et al., 1995). Results of Fragstats analysis brings forth the fact that patches under the dense forest category are undergoing isolation with time whereas patches of open forest are clumping together (*Table 2*). Fragmented vegetation reduces overall plant species richness, encourages edge species and discourages interior forest species (Solbrig, 1992), hence modifying the entire structure of communities (Haddad et al., 2015). Intact large patches of natural vegetation persist in areas protected by legal restrictions and forests in inaccessible terrains (high-altitude region) (*Fig. 3*). In future, patch level analyses can be performed to comprehend the underlying factors that have resulted in the distinct spatial patterns observed in the forest.

The Ganga basin has the highest dam density (1/18 of the river channel being dammed) followed by Brahmaputra (1/35 km) and the Indus (1/36 km) in the Indian Himalayan Region (Pandit and Grumbine, 2012). Due to the development of Tehri dam, Koteshwar hydropower plant and Kotli-Bhel hydropower project (under development in Bhagirathi basin), approximately 68.03 km (31%) of the Bhagirathi river is being diverted, whereas 85.4 km^2 (39%) of the riverine area has been submerged (Rajvanshi et al., 2012). Dams alter the natural flow of rivers and streams, thus changing the temperature and chemical composition of water which determines the distribution of riverine tree species (Bergkamp et al., 2000). A large number of dams along the course

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82718289

of the Bhagirathi river has resulted in modification of the native riverine vegetation owing to altered micro-climatic regimes and afforestation activities by Forest Department around the Tehri region highlighted by an increase in the LPI in this region (*Fig. 3*). Landslides are common in montane river networks and cause considerable loss to riverine forest stands on a regular basis. Hence, quantifying the landscape change in the riverine buffer is concerning in the backdrop of vulnerability to natural disasters.

Over the last several decades, riverine buffers have been employed as a conservation tool in an attempt to maintain natural processes and functions in running-water ecosystems and consequently protect native aquatic organisms (Richardson et al., 2005; Marczak et al., 2010; Kuglerová et al., 2014). Their biodiversity values render them as hotspots for adaptation to climate change in the near future (Das, 2014; Pandey et al., 1999). The current study is useful in filling the information gap for remote terrains, features predominant in the Himalaya, which are poorly researched due to inaccessibility. Such understanding is required for realization of the vulnerability of these systems, which are ever dynamic, and thus, necessitates the need to conduct the study at a broader scale of time and space.

Conclusion

India is endowed with a magnificent river basin network; water resources having an overriding influence on the socio-economic development of the country. This necessitates the establishment of baseline information for monitoring these systems and for developing local and national policies for guiding conservation programmes. Riverine landscapes are one of the most human-dominated areas eliciting increased developmental activities in and around the river. Dams which have comparatively larger-scale consequences, require machinery and manpower for building and maintenance, steering rapid growth of cities and settlements around; accelerating the process of habitat loss and forest fragmentation in riverine areas. Given their high productivity values and increasing degradation rates, periodic monitoring of forest fragmentation dynamics and change in land cover needs to be documented systematically and at regular time intervals. The use of satellite imageries with higher spatial/spectral resolution can aid in identifying the underlying drivers of landscape change and substantially add to such initiatives to better understand the magnitude and direction of landscape change and forest fragmentation. Delineating the rate of change from one class to another and using more comprehensive fragmentation index including patch-level analysis can aid in understanding the trends of future land use/land cover conversion to determine the resilience of these important riverine systems.

Riverine forests are fragile and have immense bio-diverse and socio-economic significance. Hydrologic alteration caused by river regulation alters the vital processes which establish and maintain riverine vegetation. The site-specific ecological consequences of natural and human induced changes remain challenging to predict and address. This is often associated with the difficulty in delineation of riparian buffers from the remaining landscape. Identifying intact forest patches of enhanced biodiversity values along the river can substantially aid in effective management and conservation. The overall trends that emerge from our study give a synoptic view of landscape change and forest fragmentation processes which can be beneficial in navigating conservation efforts towards biodiversity management at a large scale, and particularly in difficult mountain terrains predominant in the Himalaya. There is a dire need to conduct

DOI: http://dx.doi.org/10.15666/aeer/1704_82718289

scientific studies on the flora and fauna of such fragmented habitats. The research can further be upgraded by understanding the underlying drivers of landscape change and potential causes of the forest fragmentation. Hence, a combination of both anthropogenic and climatic drivers can give us a holistic understanding of the actual causes underlying the fragmentation of riverine landscape features in the future. Pertinent research aiming to understand the role of fragmented vegetation in species conservation and devising novel approaches of possible restoration programmes for such fluvial landscapes is vital for future conservation.

Acknowledgements. The authors are thankful to the Department of Science and Technology, Government of India for financial assistance under the grant (SERB No: F. No. SERB/SR/SO/PS/06/2010). Thanks are due to the Uttarakhand forest department and Dr. V. B Mathur, Dr. P. K Mathur, Dr. G. S Rawat and Dr. S. Sathyakumar, Wildlife Institute of India for their support. We are grateful to Kevin Moore and Kamna Pokhariya for their assistance in analyzing the remote sensing data.

(Received 18th Feb 2019; accepted 1st May 2019)

Abstract. The lysimeter experiment was carried out twice in consecutive two years (2014-15 and 2015-16) at Sakha Agricultural Research Station, Kafrelsheikh, Egypt to study the effect of three irrigation levels water (i.e., 100, 110 and 120% field capacity (FC), two rates of gypsum (G) (i.e., 50 and 100% G) and three sources of nitrogen (90 kg nitrogen (N), 10 t compost (C) and 7.5 t C + 45 kg N (CN) fed^{-1} (fed = 4200 m^2)) on grain yield of wheat, water relations and soil chemical properties. Water consumptive use (WCU) was markedly increased due to the increase of the level of irrigation, rate of gypsum (G) and CN source (7.5 t C + 45 kg N fed^{-1}). Irrigation with water amount equal to 120% FC recorded the highest values of WCU 1433 and 1570 m^{3}fed^{-1} in both seasons. Water productivity (kg grain m^{-3} water) for either water application (WA) in both seasons or WCU in the second season was decreased by increasing level of irrigation from 100 to 120% FC in the second season, while the inverse was true for WCU in the first season. The highest mean values of water productivity for WCU 1.816 and 1.791 kg m^{-3} were obtained with the irrigation level of 120% FC in the first season and 100% FC in the second season, respectively. Gypsum rate and N source have an effect on the productivity of irrigation water (WP) for WA and WCU, where the highest mean values for both the two irrigations efficiency were recorded under 100% G requirements and CN (7.5 t C + 45 kg N fed^{-1}). The interaction of 110% FC × 100% G × 7.5 t C + 45 kg N fed^{-1} produced the highest values of WP for WA (1.245 and 1.374 kg grain m^{-3} WA) in both seasons. Grain yield fedd.$^{-1}$ was increased significantly with the irrigation level from 100 to 120% FC in both seasons, G rate and CN source. Grain yield (GY) did not differ significantly due to the levels of irrigation water between 120 and 110% FC in both years. Application of 100% G and 7.5 t C + 45 kg N fed^{-1} at any irrigation level were among those treatments having high GY, being insignificant. The mean values of electrical conductivity (acidity; ECe) and soil sodicity (SARe) were affected by irrigation treatments, G rates and nitrogen sources. A stronger reduction in soil ECe and SARe were recorded under the irrigation level of 120%FC, 100% G and 10 t compost in both seasons. While the soils ECe and SARe were increased by application of chemical N fertilizer alone or with compost. Therefore, it can be concluded that irrigation with water amount equal to 110 or 120% FC, 100% G requirements and 7.5 t C and 45 kg N fed^{-1} was the best treatment for getting high GY, improving the soil chemical properties, nutrients availability and increasing the water productivity of salt-affected soil in North Delta of Egypt.

Introduction

Wheat (*Triticum aestivum*, L.) is a vital cereal across the globe and it is the most widely grown food cereal crop and its demand is increasing with the increasing population (Hossain et al., 2018; Jahan et al., 2019). It is considered a strategic crop and has played a major role on the national economy and it is one of the widely adapted cereals, grown in different environments (Barutcular et al., 2017; Yildirim et al., 2018). In Egypt, it is also the main food crop, as the current production of wheat does not meet the consumption demand. Recently US' Foreign Agricultural Service (FAS) in Cairo estimated that the wheat production in Egypt reaches 8.45 million metric tons (MMT) in the year in 2018-19, which was 4.3% higher than 2017-18 (Egypt Today, 2018; IndexMundi, 2018). Although in the year 2017, 60.2% of Egypt's total wheat consumption was imported. Concerning wheat consumption, FAS Cairo forecasts Egypt's total wheat consumption in the marketing year (MY) 2018-19 was 20 MMT, which was 1.5% more than the MY 2017-18 (Egypt Today, 2018; IndexMundi, 2018). Therefore, it is confirmed that the demand for wheat in Egypt is increasing day by day, but domestic production could not meet the current demand. As a result, to meet the food security of increasing population, the government of Egypt has taken several initiatives such as increase the area of production, development of high yield potential and stress resistance wheat cultivars, and also to find out improved management practices for reduction the imported percentage to be less than 50% (McGill et al., 2015; IndexMundi, 2018).

Wheat production depends on several factors including environmental condition, cultivars and management factors, such as irrigation and soil fertility. Among the management approaches, irrigation and fertilization and their interaction are considered the most important factors for increasing wheat production (Shaaban, 2006). For example, application of one irrigation increases the yield of wheat by more than 40%, whereas two to three irrigations with proper water and fertilizer management practices increase wheat yield by 50-100% (Hossain et al., 2006). However, to assist the efficient water use, plant-soil-water positive and negative interaction should be well understood under various environmental conditions, particularly in arid and semi-arid regions, where irrigation water is limit due to lack of rainfall (Musick et al., 1994; Wiedenfeld, 2000; Halitigil et al., 2000).

On the other hand, as Egypt is situated under the arid and semi-arid region of the Mediterranean environment, heat, drought and salinity are the major abiotic stress which decreases the productivity of wheat (Al-Naggar et al., 2015a, b; Abdelaal et al., 2018). Among the abiotic stresses, salinity is the most important one that adversely affects the productivity and quality of wheat through altering the physiological and biochemical activity of plants (Otu et al., 2018; Yassin et al., 2019) by accelerating osmotic stress and ion cytotoxicity in plants' cell (Chen and Jiang, 2010; Islam et al., 2011). It is anticipated that the consequence of soil salinity may be increased in future due to the scarcity of annual rainfall, rising of sea water, irrigation with saline water,

DOI: http://dx.doi.org/10.15666/aeer/1704_82918306

excessive use of fertilizers and absence of a good drainage system, particularly in the Mediterranean environment (El-Hendawy et al., 2005).

Therefore, to improve or reclaim the sodic soil for sustainable crop production, it is important for replacing the most of the Na^+ by the most favourable Ca^{++} followed by removal/leaching of salts derived by the reaction of the amendment from sodic soil. While many chemical compounds such as amendments are known in this respect of effective salts reclamation. For example, amendments directly or indirectly supply soluble Ca^{++} and improve the soil productivity by escaping Na^+ from saline soils. Sodic soil reclamation by using amendment will largely depend on the nature of the soil, effectiveness and cost considerations. Among the amendments, gypsum ($CaSO_4$-$2H_2O$) is a typical soil amendment, which replaces Na^+ ions by the calcium (Ca^{++}) ions (Hanay et al., 2004).

However, the presence of organic matter (OM) through the management of crop residues, using different types of organic manures in the soil is a fundamental option for maintaining soil fertility and productivity. It improves the physical properties, biological activity, water holding capacity and soil's aeration for better seed germination and seedling stand establishment (Edwards and Hailu, 2011). Considering the above important issues for the sustainability of crops production, the research was aimed to study the effect of different requirements of irrigation water, soil amendments and nitrogen fertilization on wheat yield, water relations and some soil chemical properties.

Materials and methods

Location and duration of the study

The lysimeter study was established during the wheat grown season of 2014-15 and 2015-16 at Sakha Agricultural Research Station, Kafr ElSheikh-Egypt. The location lies in 134 km north Cairo, Egypt under North Delta-Egypt. The location is situated at 31°07'N latitude and 30°57'E longitude. The study aimed to study the effect of irrigation water level, soil amendments and nitrogen fertilizer sources on wheat yield, water relations and some soil chemical properties.

Physical and chemical properties of lysimeters' soil

Soils in the North Delta of Egypt are characterized by saline and sodic. For determination of soils' chemical and physical soil properties, soil samples were taken from each lysimeter at the depth of 0-15, 15-30, 30-45 and 45-60 cm before sowing and after harvesting in both seasons (*Table 1).* Soil reaction (pH) was determined according to Cottenie et al. (1982), electrical conductivity (ECe) according to Page (1982) and sodium adsorption ratio (SAR) was calculated. Soil OM status was estimated though Walkally Black method according to Hesse (1971). Available N and K were determined according to Jackson (1967). Phosphorus (P) availability was observed according to Olsen et al. (1954), by following sodium bicarbonate method. Mechanical soil analysis was determined according to the international pipette method (Piper, 1950). Gypsum requirement was calculated according to Schoonover method (1952). Soil bulk density was measured by using the core sampling technique as described by Campbell (1994). The chemical composition of compost used in the study is amiable in *Table 2.* The

DOI: http://dx.doi.org/10.15666/aeer/1704_82918306

lysimeters were fertilized with 15.5 kg P_2O_5 feddan^{-1} in the form of calcium superphosphate (15.5% P_2O_5) during soil preparation.

Table 1. *Physical and chemical properties of the lysimeters' soil recorded before sowing during the 2014-15 season*

Meteorological information during growing seasons

The meteorological data on mean monthly temperature, relative humidity, wind speed and pan evaporation as well as rainfall in both seasons (2014-15 and 2015-16) from Sakha Station were recorded and presented in *Table 3*.

Experimental treatments and design

Treatments of the present study were arranged in a split-split plot design and repeated four times in both seasons. Where main plots were arranged in levels of irrigation, sub-plots were in rates of gypsum (G) and sub-sub-plots were in sources of nitrogen. Irrigation was done five times at all irrigation treatments: first irrigation was done at each of sowing, the second was tillering, third at jointing, fourth at heading and final one (fifth irrigation) were done at milking stages. Irrigation treatments were started

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82918306

after the sowing irrigation. Amounts of applied irrigation water were equal to 100, 110 and 120% of field capacity (FC) in the root zone (0-60 cm depth) of the plants. The second and third irrigation were increased 10 and 20% than FC as leaching requirement. Gypsum (G) requirements were used in two rates, i.e., 2.21 and 4.42 t fed^{-1} (for maintaining 50 and 100% G requirements). Nitrogen (N) sources were 90 kg N (N), 10 t compost (C) and 7.5 t C + 45 kg N (CN) fed^{-1}.

Experimental procedure and data collection

Seeds of wheat variety 'Sids 13' was seeded by hand in rows 12.5 cm a part at the rate of 50 kg seeds fed^{-1}, sown on 18 and 23 November in both years (2014 and 2015 seasons), respectively. While each lysimeter was included 8 rows. Phosphorus (P) and potassium (K) fertilizers were added according to the recommended doses of North Delta area of Egypt. For the source of N, fertilizer urea (46% N) was applied in two equal splits, before sowing irrigation and at the tillering stage. G and C were added before planting. The different agricultural practices were done as recommended. At harvest (158 and 154 days after sowing), the central of 6 rows were harvested and threshed to determine grain and straw yield. The weight of GY was adjusted to 14.5% moisture content.

Water measurements

Amount of irrigation water applied (WA) was measured by a portable pump equipped with a water meter for each lysimeter. Amount of irrigation water applied (WA) was determined according to Phocaides (2001) as follows:

$$WA = \frac{FC - \theta_1}{100} \times BD \times DS \qquad \text{(Eq.1)}$$

where, WA: water applied (cm^3); FC: soil moisture percentage at field capacity; Θ_1: soil moisture percentage before irrigation; BD: bulk density (g cm^{-3}) and DS: soil layer (cm).

Water consumptive use by growing plants was calculated based on soil moisture depletion (SMD) according to Israelsen and Hansen (1962):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82918306

$$Cu = SMD = \sum_{i=1}^{i=4} \frac{\theta_2 - \theta_1}{100} x Dbi\ x\ Di\ x\ 4200 \quad \text{(Eq.2)}$$

where, Cu: water consumptive use (m^3/fed.) in the effective root zone; Θ_2: soil moisture percentage after irrigation; Θ_1: soil moisture percentage before next irrigation; Dbi: soil bulk density (g cm^{-3}); Di: soil layer depth (cm) and i: number of soil layer (1-4).

Soil moisture (%) was determined by drying the soil samples at 105 °C to constant weight and the moisture content was calculated according to Singh (1980).

Water productivity (WP) was calculated as the ratio of GY with the amount of irrigation water applied (PIW) and water consumptive use (PW) according to Ali et al. (2007) as follows:

$$PIW = \frac{\text{Yield (kg/ feddan)}}{\text{Applied water } (m^3 / \text{feddan})} \quad \text{(Eq.3)}$$

$$PW = \frac{\text{Yield (kg/ feddan)}}{\text{water consumpitive use } (m^3 / \text{feddan})} \quad \text{(Eq.4)}$$

Statistical analysis

Data in the present study were arranged and all statistical analysis was subjected to analysis according to Gomez and Gomez (1984) by using "MSTATC" computer software package. Treatment means were compared by Duncan's Multiple Range Test at 5% level of significance (Duncan, 1955).

Results and discussion

Seasonal water applied

Applied seasonal water (WA) consisted of two sources such as irrigation water delivered to lysimeter and effective rainfall. In both seasons, the total amounts of the effective rainfall were recorded 446 and 393 m^3 fed^{-1}, respectively (*Table 3*). At the same irrigation treatment, lysimeters of all combinations between gypsum rates and nitrogen sources were received an equal amount of irrigation during the growing season.

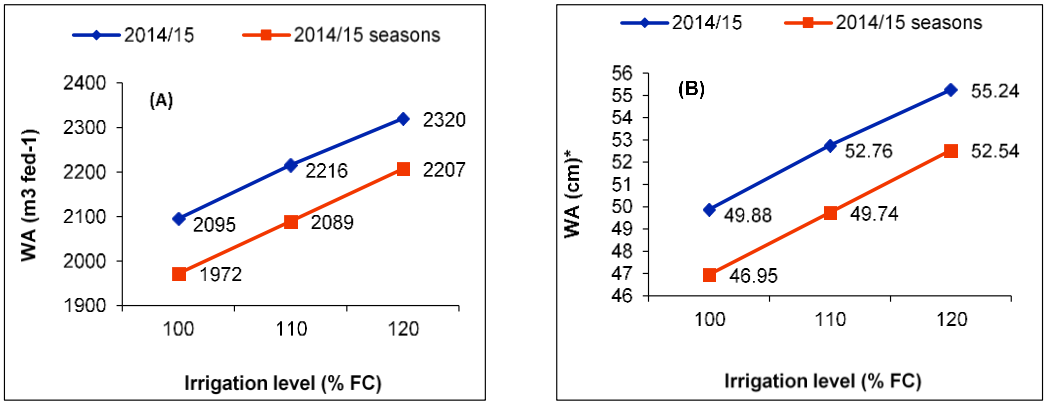
Figure 1 shows that the amounts of WA from sowing to harvesting of wheat were gradually increased by increasing the level of irrigation from 100 to 120% FC in both seasons. Wheat plants irrigated with the water amounts equal to 120% FC recorded the highest values of WA 2320 and 2207 m^3 fed^{-1} (55.24 and 52.54 cm) in the two seasons, while the 100% FC recorded the lowest levels of WA i.e., 2095 and 1972 m^3 fed^{-1} (49.88 and 46.95 cm) in both growing seasons, respectively. Such increased in the amount of WA by increasing irrigation level may be attributed to a considerable increase in vegetative growth and leaf area, which resulted in greater transpiration and in turn water requirement. These findings are in close harmony with the findings of Hossain et al. (2006), Sarker et al. (2007), Inamullah et al. (2011) and El-Agrodi et al. (2016).

Seasonal water consumptive use

Data in *Table 4* show that the amount of water lost as evapotranspiration (seasonal water consumptive use, WCU) was increased by increasing irrigation level in the two

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82918306

seasons. WCU was markedly increased by an increasing the amount of irrigation water from 100 to 120% FC in both seasons. The irrigation level of 120% FC recorded the highest values of WCU followed by 110 and 100% FC. As the soil moisture level increased the water consumptive use was increased due to more improved growth and perhaps luxury consumptive of water. Also, this may be due to an increase in leaching water by increasing the amount of water applied than field capacity.



** Fed=feddan= 4200 m2= 0.42 h

* 1 cm water = 42 m^3 fed^{-1}

Figure 1. *WA in m^3 fed^{-1} (A) and in cm (B) as affected by irrigation level in both seasons*

Incorporation of gypsum in the soil at the rate of 4.42 t fed^{-1}(100% of requirements) resulted in the greater WCU than the rate of 2.21 t fed^{-1} (50% of requirements) in both seasons. This may be due to more water applied for leaching the exchangeable sodium.

Source of N had a substantial effect on WCU in both seasons. Whereas, application of 7.5 t C + 45 kg N fed^{-1} (CN) exceeded the application of 90 kg N (N) or 10 t compost fed^{-1} (C) alone in WCU in both seasons. Nitrogen sources were arranged in descending order CN > N > C in this trait in both seasons. While, the application of C and chemical N fertilizer (urea), enhanced the availability of the nutrients in the soil solution. The available nutrients might have helped in enhancing leaf area, which thereby resulted in higher transpiration and more water consumptive.

The interaction between irrigation levels and gypsum rate exerted a substantial effect on WCU. Data show that WCU was increased by increasing each of irrigation level and G rate alone or together in both seasons.

The highest values of WCU 1454 and 1587 m^3 fed^{-1} were recorded by the irrigation level of 120% FC along with 100% G requirements, while the lowest ones 1349 and 1391 m^3 fed^{-1} were recorded by the irrigation level of 100% FC along with 50% G requirements in both seasons. The integration between chemical nitrogen (45 kg N fed^{-1}) and C fertilizer (7.5 t compost fed^{-1}) along with the irrigation level of 120% FC consumed greater water than the irrigation level of 100% FC and 10 t C fed^{-1} in both seasons (*Table 4*). The second order of interaction (irrigation level × G rate × nitrogen source) had a markedly effect on WCU (*Table 4*).

Increasing irrigation level and G rate increased WCU at the same nitrogen source. However, application of both compost and chemical N (7.5 t C + 45 kg N fed^{-1}), resulted in a markedly increased in WCU, as compared with application 90 kg N or 10 t compost fed^{-1} alone at the same combination of irrigation level and G rate. Wheat plants

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82918306

received 120% FC WA, 100% G and 7.5 t C + 45 kg N fed^{-1} recorded the highest values of WCU (1491 and 1603 m^3 fed^{-1}), while those received 100% FC WA, 50% G and 7.5 t C fed^{-1} recorded the lowest ones (1344 and 1394 m^3 fed^{-1}) in both seasons. Results demonstrated that water consumptive use increased as soil moisture content was highly maintained by increasing amount of water applied due to increasing leaching requirements. Also, the higher frequent irrigation provides a chance for more water consumption, ultimately resulted in increasing plant transpiration and evaporation from the soil surface. These results are in great harmony with those obtained by Ali et al. (2007).

Generally, WCU values were greater in the second season than in the first season (*Table 4*). This may be due to increase temperature and decrease relative humidity at the most growing months in the second seasons, which increased evaporation and transpiration and in turn more water consumptive.

Water productivity

GY per unit of applied irrigation water (WA) or water consumptive use (WCU) in kg grain m^{-3} water were used to determine water productivity. Data in *Table 4* show that WP (kg grain m^{-3} water) for either WA in both seasons or WCU in the second season was decreased by increasing irrigation level from 100 to 120% FC. The inverse was true in WP for WCU in the first season. The WP for WA and WCU was increased by increasing the gypsum (G) rate in both seasons. Application of 7.5 t C along with 45 kg N fed^{-1} recorded the highest values of WP for WA and WCU followed by 90 kg N and 10 t compost fed^{-1} alone in the two seasons. Incorporation of 100% G requirements and integration of compost with chemical nitrogen resulted in an increase in WP for WA and WCU through increasing GY in both seasons.

The first and second order of interaction had a substantial effect on WP for WA and WCU in both seasons. The relative ranking of the interaction among irrigation level, G rate and nitrogen source in was WP for WA and WCU inconsistent in both seasons. The interaction of 110% FC × 100% G × 7.5 t compost + 45 kg N fed^{-1} produced the highest values of WP for WA (1.245 and 1.374 kg grain m^{-3} WA), while the interaction of 110% FC × 50% G × 10 t compost fed^{-1} produced the lowest values (1.019 and 1.112 kg grain m^{-3} WA) in the two seasons. The interaction of 120% FC × 100% G × 7.5 t compost + 45 kg N fed^{-1} produced the highest values of WP for WCU (1.922 and 1.886 kg grain m^{-3} WCU) in both seasons. However, the lowest value of WP for WCU was 1.629 kg grain m^{-3} WCU recorded from the interaction of 100% FC × 50% G × 10 t compost fed^{-1} in the first seasons, while the interaction of 110% FC × 50% G × 10 t compost fed^{-1} recorded the lowest value 1.590 kg grain m^{-3} WCU in the second season. Results of the present study could be attributed to the great differences between GY of wheat as well as differences between water applied and water consumed also confirmed by the findings of Ali et al. (2007), Liu et al. (2013), Ali (2016) and El-Shawy et al. (2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82918306

Grain yield

Grain yield fed^{-1} was significantly increased by increasing the level of irrigation from 100 to 120% FC in both seasons (*Table 5*). While no significant difference was recorded for GY due to the levels of irrigation water of 120 and 110% FC in both seasons. This may be due to the increase in growth and yield components. In this connection, adequate water not only allowed the wheat plant to increase photosynthetic rate but also give extra time to translocate the carbohydrates in grains, which enhanced grain size and ultimately causes higher GY. This trend in agreement with Ali et al. (2007), Liu et al. (2013); Ali (2016) and Abdrabbo et al. (2016) and Rashwan et al. (2016). The high rate of G (100%) out yielded the low rate (50%) in GY in both seasons. This trend could enhance with Abdel-Fattah (2012), and Hafez et al. (2015). The combination of compost and chemical nitrogen resulted in a significant increase in GY compared with each of the two sources alone in both seasons. Application of organic (compost) and chemical N fertilizer to wheat enhanced the availability of nutrients in the soil solution. The available nutrients might have helped in the stimulation of various physiological processes including cell division and cell elongation of internodes resulting in more tillers formation, leaf numbers and photosynthetic area (leaf area), which resulted in more photosynthetic production and consequently increased dry matter accumulation and GY. Similar results were reported by Ayadi et al. (2012), Yousef et al. (2014), Mehasen et al., 2015), Abd El-Lattief (2016) and Gharib et al. (2016).

Means of each factor in grain yield columns designated by the same latter are not significantly different at 5% level using DMRT

All the first and second order interactions had a significant effect on GY in both seasons. Increasing irrigation level and G rate along with compost and nitrogen together substantially increased GY. Application of 100% G and 7.5 t compost + 45 kg N fed^{-1} at any irrigation level were among those treatments having high GY, being insignificant, in both seasons. These results go with those reported by Attia et al. (2013), Abdel-Fattah, 2012), Hafez et al. (2015) and Gharib et al. (2016).

Salinity and sodicity

Salinity (ECe) and sodicity (SARe) of the soil after harvesting as affected by irrigation level, G rate, nitrogen source and their interactions under wheat crop are shown in *Table 5*. The initial value of ECe before the experiment was 7.10 dS m^{-1} (*Table 1*). Data show that the values of salinity and sodicity were decreased after harvesting compared with those before the beginning of experiment at any studied treatment in both seasons. Increasing irrigation level, G rate and compost alone resulted in a substantially decrease salinity and sodicity of soil after harvesting. Data show that application N fertilizer alone or with compost increased these traits compared with compost alone at any combination between irrigation and G in both seasons. The lowest values of ECe (5.34 and 4.78 dS m^{-1}) and SARe (10.80 and 9.82%) were obtained from the irrigation level of 120% FC, 100% G and 7.5 t compost fed^{-1} in both seasons.

Application of 10 t compost alone with 100% G reduced Ec greater than 16% at any irrigation level in both seasons (*Figs. 2* and *3*). The highest values of reduction percentage 24.8 and 32.7% were recorded by the interaction of 120% FC × 100% G × 10 t compost fed^{-1} in the two seasons. The application of G and compost had a positive effect on the soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_82918306

properties and the present investigations have addressed the combined effect of compost and G on the saline-sodic soils under semi-arid conditions. The effect of G application on saline-sodic soil reclamation have shown that the soil receiving G at higher rate since it removes the greatest amount of Na^+ from the soil columns and causes a substantial decrease in soil electrical conductivity (EC) and sodium adsorption ratio (SAR) (Hamza and Andrrson, 2003; Rasouli et al., 2013).

Application of 10 t compost alone with 100% gypsum reduced SAR greater than 18% at irrigation levels of 110 and 120% FC in both seasons (*Figs. 2* and *3*). The highest values of reduction percentage 21.2 and 28.4% were recorded by the interaction of 120% FC × 100% gypsum × 10 t compost fed^{-1} in the two seasons.

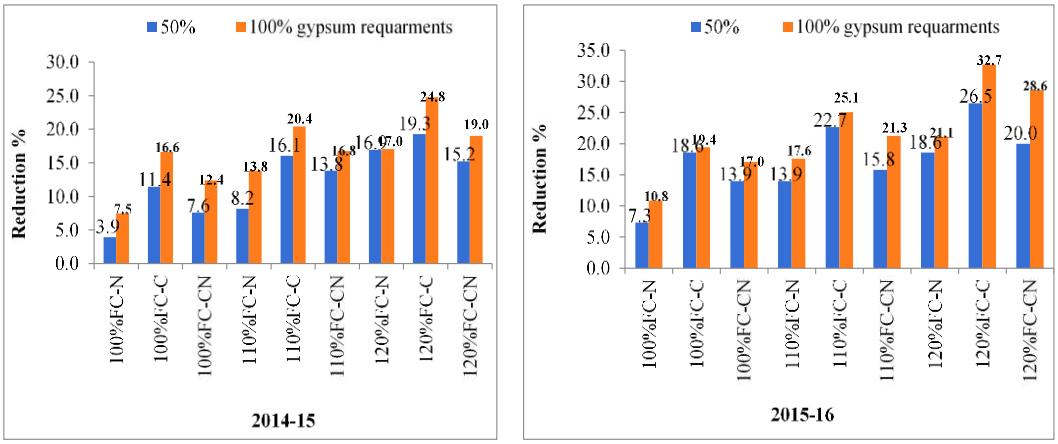

Figure 2. *The percent reduction of EC after harvest based on its initial value (7.10) as affected by the interaction of irrigation level, gypsum rate and nitrogen source in both seasons*

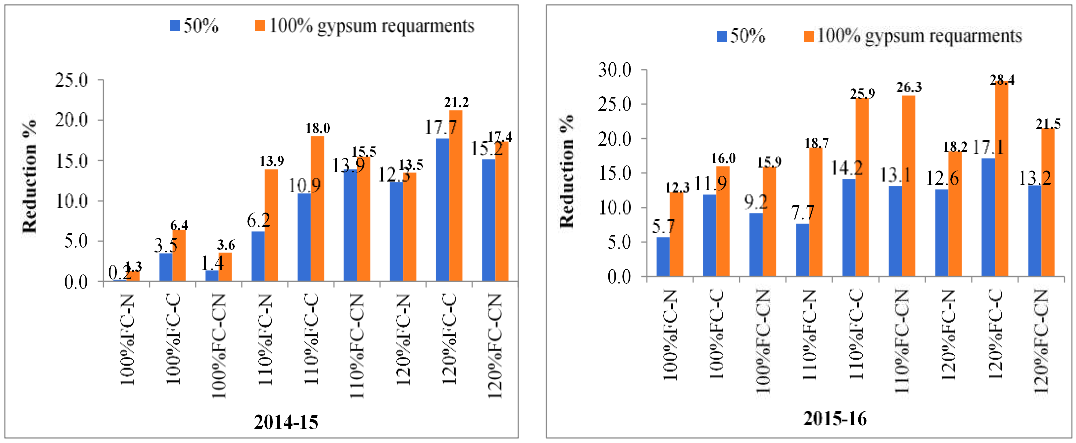

Figure 3. *The percent reduction of SAR after harvest based on its initial value (13.71) as affected by the interaction of irrigation level, gypsum rate and nitrogen source in both seasons*

Conclusion

In summary, it can be concluded that irrigation with water amount equal to 110 or 120% FC, 100% G requirements and 7.5 t C and 45 kg N fed^{-1} was the best treatment for getting high GY, improve the soil chemical properties, nutrients availability and increase water productivity of salt-affected soil in North Delta of Egypt.

Abstract. Heat and drought stresses are the most important abiotic factors that reduce crops productivity by affecting various physiological and biochemical processes. Thus, selecting cultivars with better drought or heat stress tolerance or breeding for stress tolerance will be helpful in enhancing crop productivity under harsh environments. This review elaborates the physiological basis of high temperature and drought stress tolerance in wheat which can be used as selection criteria in wheat breeding program. In addition, some agronomic selection criteria which are valid and useful in selecting stress tolerant wheat species and cultivars. The review also discussed the valid usage of stress tolerance indices (such as mean productivity (MP), geometric mean productivity (GMP), yield index (YI), yield stability index (YSI), relative productivity (RP%), stress susceptibility index (SSI), and the tolerance index (TOL)) to scan the genotypes against drought and heat stress. Beside these, exogenous application of stress signaling compounds, osmolytes, or certain inorganic salts play a vital role for alleviating adverse effects of abiotic stresses for sustainable wheat production. In addition, applications for soil amendments will also helpful in increasing wheat crop productivity under stressful conditions. All these strategies may be helpful to meet the food demands of the increasing population.
Keywords: *wheat, drought, heat stress, stress tolerance indices, agronomic approaches*

Introduction

Wheat (*Triticum aestivum* L.) is one of the leading cereals and used as a staple food for 1.2 billion people worldwide (Afzal et al., 2015; Iqbal et al., 2018). To feed the increasing population, the global demand for wheat is expected to increase up to 40% by 2050 to meet the food security (Rosegrant and Agcaoili, 2010; Abdelaal et al., 2018; Jahan et al., 2019). In view of the global climate change, drought ,salinity and heat stresses are the major abiotic constraints for wheat productivity and adversely affects the yield and quality through altering the physiological activity (Kosina et al., 2007; Otu et al., 2018; Yassin et al., 2019). Short or long-term exposure to heat and drought stresses can significantly affect the growth and yield, particularly at sensitive growth stages (Prasad et al., 2008). Hoegh – Guldberg et al. (2018) estimated that due to climate change and 2-3°C rise in global temperature, losses of wheat yield will increase by up to 30% by 2050. As water availability is a major factor limiting crop production in many parts of the world, the management practices focus on enhancing water use efficiency of the future crops (Majid et al., 2017). In addition, drought tolerance traits must be incorporated in crops anticipating the climate changing scenario (EL-Shawy et al., 2017). To cope climate change, selection of suitable varieties as well as optimization of irrigation water are needed for maintaining sustainable food supplies (Bernardi, 2011).

Various approaches are suggested to overcome crop losses due to drought and heat stresses such as stress management practices, breeding for developing stress-tolerant cultivars, use of physiological mechanisms in developing stress tolerant cultivars and exogenous use of chemicals which improve stress tolerance (Farooq et al., 2011; Hossain and Teixeira da Silva, 2012, 2013). Since most of the modern wheat varieties are not sufficiently tolerant to drought and heat (Alghabari et al., 2015), development of wheat cultivars that are tolerant to drought and heat is one of the main challenges for wheat breeders around the world (EL Sabagh et al., 2018a). The present review aimed to assess the current status of knowledge of the physiological basis of stress tolerance in plants, the applicability of this knowledge in developing stress tolerant crop cultivars,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

limitations or deficiencies in understanding mechanism of stress tolerance, and efficiency of different approaches in mitigating adverse effects of drought and heat stress on plants. In other words, the main objective of the present review is to rationalize the physiological breeding for drought and heat stress tolerance in wheat. This will help in deciding future directions in developing high yielding wheat cultivars under heat and drought stress conditions.

Impacts of drought and heat stress on phenology, growth, and productivity of wheat

A temperature above or below the optimum can hamper the growth and development of wheat crop by influencing various processes such as uptake of water and nutrients, however, such effects may vary with plant developmental stages (Wahid et al., 2007). Under high temperature, the crop completes its life cycle relatively faster which ultimately lead to decrease the final biomass and yield (Rahman et al., 2009; Nahar et al., 2010; Hakim et al., 2012; Hossain et al., 2009, 2011, 2012a, b, c, 2013, 2017,2018). In the Sub-Tropical region of South-Asia such as Pakistan, India, Bangladesh, delayed planting significantly reduces the days to maturity and grain filling period and grain yield of wheat (Mahboob et al., 2005). Similarly, Barutcular et al. (2016b, c; Yıldırım et al.,2018) noticed that delayed planting cause the exposure of wheat plants to high temperature and moisture stress that resulted in a reduction in growth and yield of wheat. In view of these reports, it is suggested that efforts should focus on identifying drought and heat resistant ideotypes and selection should be based on yield traits to increase the economic yield under heat and drought stress conditions. However, traits responsible for drought and/or heat resistance in wheat are not well defined. Drought tolerance in crop species can be defined as the ability of crop cultivar to produce satisfactory harvestable yield under water deficit conditions (Basu et al., 2016). However, yield stability is better to stress tolerance indicator under heat stress or water stress conditions (Fleury et al., 2010). In addition, a little progress has been made in identifying key mechanisms associated with high yield and stress tolerance against high temperature and drought stress (Ogbaga et al., 2018).

Drought and heat stress in relation to sowing time

Days to germination

Seed germination in wheat is one of the most critical growth stages that influence initial plant population, stand establishment, and finally yield of wheat under stress condition (Almansouri et al., 2001). Environmental factors such as seed-bed soil moisture, temperature, as well as seed vigour/quality, play an important role in seed germination and stand establishment of the crops (Khajeh-Hosseini et al., 2003). Since soil moisture availability and temperature both regulate seed germination, lower moisture and/or low soil temperature hinder or delay seed germination which results in unequal seedling establishment and ultimately reduce the final grain yield of crops (Hampson and Simpson, 1990; Hossain et al., 2012). Generally, in the arid and semi-arid region, seed germination in spring wheat occurs at the range of air and soil temperature of 20-30°C (Hossain et al., 2012a,b,c). However, late sown (LS) wheat crop takes longer time to germinate than sown at optimum sowing in temperate region (like Russia), due to reduced soil moisture and low temperature (<12°C) (Hossain and Teixeira da Silva, 2012; Hossain et al., 2012b; *Fig. 1*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

The impact of heat stress in combination with deficit soil moisture (drought stress) is the most critical to impact seed germination than the individual stress (Al-Karaki et al., 2007; Hossain et al., 2013). Similarly, Hossain and Teixeira da Silva (2012) found significant differences in days to germination among the three wheat varieties in OS (optimum sowing) and LS (late sowing) conditions (*Fig. 2*). They found that the days to germination were increased by 25 to 50% in late sown condition due to a low temperature at germination, while under OS, all varieties showed no variation in germination time (*Fig. 3*; Hossain and Teixeira da Silva, 2012). Likewise, while conducting a field experiment Chakrabarti et al. (2011) reported that air temperature greater than 15°C is appropriate for seed germination and seedling stand establishment of spring wheat.

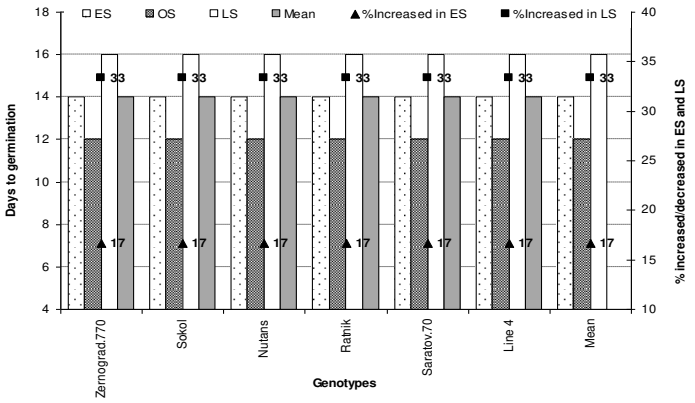

Figure 1. *Days to start germination of wheat and barley as influenced by low temperature in early sown and high temperature with drought stress in late sown condition in the arid region of south-eastern Russia; ES, early sowing; OS, optimum sowing; LS, late sowing (Source: Hossain et al., 2012b)*

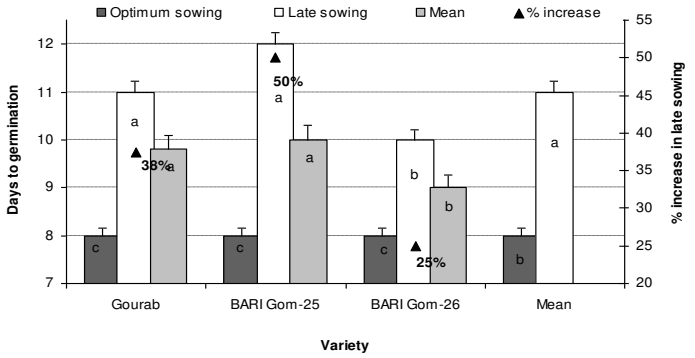

Figure 2. *Days to seed germination of three wheat varieties as influenced by late sown heat stress conditions in the north-western part of Bangladesh (Source: Hossain and Teixeira da Silva, 2012)*

Days to booting

The reproductive stages are the most sensitive to high temperature and drought stress (Foolad, 2005). Heat stress induced by late sowing of wheat reduced days to booting by 4-14% in variety 'Shatabdi', 'BARI Gom 27 and 'BARI Gom 28' in the north-western part of Bangladesh (Hossain and Teixeira da Silva, 2012; Hossain et al., 2017; *Fig. 4*). Similarly,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

Hakim et al. (2012) noticed that days to maturity in different wheat cultivars were significantly decreased under late sown condition (LS) as compared to optimum sowing (OS), which was probably due to heat stress at the reproductive phase. These reports suggested that number of days to attain specific phenological stage are affected by the change in sowing date and alterations in soil moisture availability and prevailing temperature. However, such effects were lesser for drought and heat stress tolerant wheat cultivars (Hassanuzzaman et al., 2013).

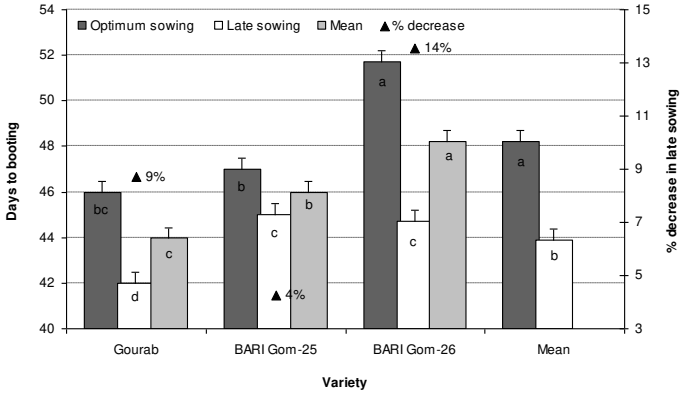

Figure 3. *Days to booting of wheat varieties as influenced by very late sown heat stress conditions in north-western part of Bangladesh. (Source: Hossain and Teixeira da Silva, 2012)*

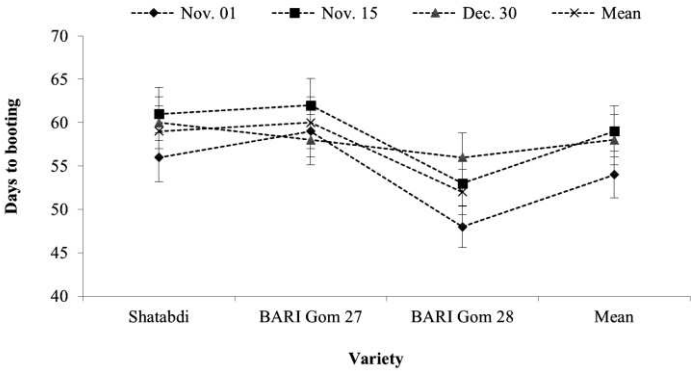

Figure 4. *Number of days to booting in three wheat varieties when sown on three different dates in North-Western Bangladesh (Source: Hossain et al., 2017)*

Days to first awn development

Ear emergence or first visble awn developmental stage is sensitive to heat stress. For example, Foolad (2005) reported that heat stress is most detrimental to wheat crops at the first awn development stage and this heat sensitivity in wheat continues up to 10 to 15 days after flowering. Hossain and Teixeira da Silva (2012) found a considerable genetic variation in days to first visible awn in late sowing wheat genotypes (*Fig. 5*). They further added that such variation in first awn development was associated with degree of sensitivity to heat stress.

Similarly, Reynolds et al. (2000) reported a reduction in the crop growth period in response to the shortage of favourable resources under heat stress, resulting in low total plant biomass, finally low grain yield. Nahar et al. (2010) also found a decrease in the life span of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

wheat under late sown induced heat stress condition in Bangladesh. In their study, in late sown condition, the maximum temperature at vegetative and reproduction phases were 25 to 27°C and 30 to 32°C, respectively. However, under environmental condition of south-eastern part of Russian, Hossain et al. (2012b) observed that wheat and barley genotypes took a long time until the first visible awn in early sowing as compared to optimum and late sowing, due to the delay of germination and a long period of vegetative growth due to the low of temperature *(Fig. 6).* They also reported that days to first awn visible was reduced by 19 to 25% (*Fig. 6*) in late sowing conditions, due to high temperature in combined with drought stress (Hossain et al., 2012b). From these reports, it is clear that soil moisture availability and high temperature shorten the time to visible awn, which might have been due to the adverse impact on plant metabolism and available resources.

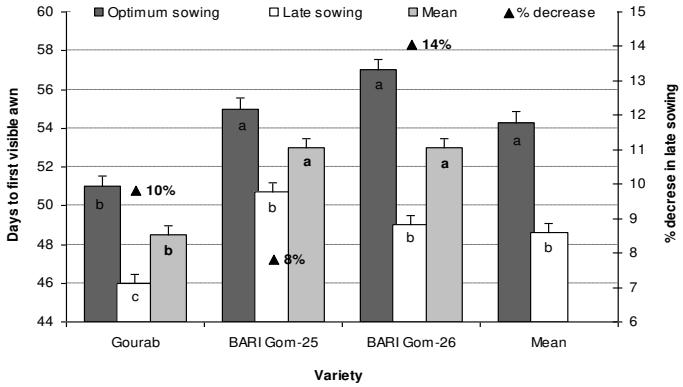

Figure 5. *Number of days to the first visible awn of wheat varieties sown at different dates. Due to different sowing times, wheat plants become exposed to different temperatures at a specific growth stage (Source: Hossain and Teixeira da Silva, 2012)*

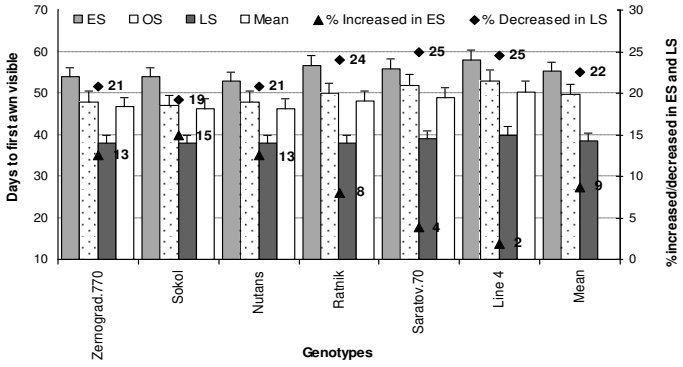

Figure 6. *Days to first awn visible of wheat and barley is influenced by low-temperature at early sown and high temperature with drought stress at late sown condition in the south-eastern part of Russia (Source: Hossain et al., 2012b)*

Days to anthesis

Development of flowers with visible mature anthers is called anthesis stage in wheat. Flowering is regulated by temperature, duration of light and dark (photoperiodic) and plant vigour. Change in temperature alters the time of flowering in wheat plants by changing sowing time. It has been observed that anthesis time can be modulated by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

15-20 days (Reynolds and Trethowan, 2007; Prasad et al., 2008). By optimizing sowing date, the temperature at the anthesis stage can be modulated in wheat plants which may favour fertilization. In the environmental condition of Bangladesh, Hossain and Teixeira da Silva (2012) carried out a field research in north-western part of Bangladesh with three wheat varieties sown at optimum (OS) and late sowing (LS) conditions and observed that all evaluated wheat varieties took less time to anthesis, due to the harmful effect of high temperature and drought and all varieties decreased the life span from 10 to 21% to complete anthesis (*Fig. 7*).

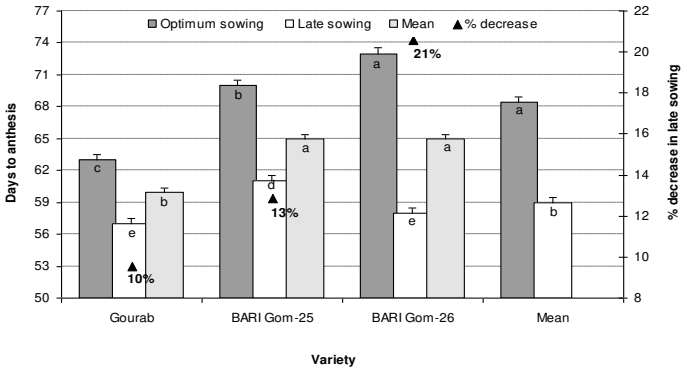

Figure 7. *Days required to anthesis of wheat varieties are influenced by the very late sown heat stress condition in the climatic condition of north-western Bangladesh (Source: Hossain and Teixeira da Silva, 2012)*

Similar results were also reported by Ubaidullah et al. (2006), who found that late sown wheat faced adverse effect of high temperature (25-33°C) stress at a reproductive stage under the condition of Pakistan that ultimately leads to decrease the yield of wheat. However, heat stress tolerant wheat cultivars had a lesser impact on yield. These reports suggested that exposure of wheat plants to episodes of high temperature at the initial stage of reproductive phase cause yield losses due to either shortening of plant growth period or due to adverse effects of high temperature on fertilization, or grain filling process. It is already well established that high temperature affects meiosis and gametogenesis in anthers which results in poor development of pollen grain and hence fertilization.

Days of physiological maturity

Under stress condition, most of the crops try to finish their developmental phases within a shorter period of time (Hakim et al., 2012; Hossain et al., 2012a,b,c, 2013). Araus et al. (2007) argued that environmental factors such as temperature and drought accelerate the time to reach different growth stages of wheat but this effect may vary with the type of cultivar and stress imposition at the specific phenological stage. Ubaidullah et al. (2006) found that heading, grain-filling and physiological maturity period of wheat crops in Pakistan were significantly different with the change in sowing time. Similarly, Prasad et al. (2008) found that late-sown spring wheat took fewer days to anthesis, grain-filling, and physiological maturity due to exposure to heat stress in India. The effect of heat stress on late-sown heat wheat crops was also confirmed by Hossain and Teixeira da Silva (2012) (*Fig. 8*) in the north-western climate condition of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

Bangladesh, where they observed that a temperature >30°C during grain-filling forced late-sown crop to mature earlier than the crop sown at the optimum time. These reports suggested that detailed understanding of differential sensitivity to varying temperature and soil moisture availability induced by different sowing times in different agro-ecological zones is necessary for selection of superior wheat genotypes.

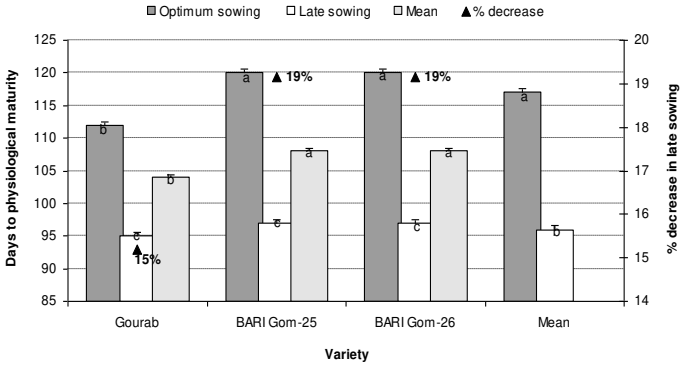

Figure 8. *Required days to physical maturity of three wheat varieties are influenced by very late sown heat stress conditions of north-western Bangladesh (Source: Hossain and Teixeira da Silva, 2012)*

Growth and development of wheat as affected by drought and heat stress

High temperatures along with low moisture availability particularly in late sown crop reduced the growth and yield of spring wheat in different agro-ecological regions of the world including the arid and semi-arid region of the Mediterranean environment. Heat stress in late sown induced accelerate leaf senescence, abscission of the shoot and cause poor root growth (Vollenweider and Gunthardt-Goerg, 2005; Martiniello and Teixeira da Silva, 2011). These reports suggested that the adverse effect of heat stress due to late sowing reduced the wheat growth and yield by affecting vegetative growth traits that are translated in to yield. Understanding the effects of heat and soil moisture availability on these agronomic traits and its relationship with wheat yield will help in devising management strategies to overcome this problem.

Plant population of wheat in relation to stress tolerance

Plant population of field crops generally depends on seed rate, genotypes, germination percentage and seed-bed environment, especially soil moisture and temperature (Khajeh-Hosseini et al., 2003; Hossain et al., 2013). Similarly, Wazid et al. (2004), Hossain et al. (2012a,b,c) and Mumtaz et al. (2015) observed that the number of plants m^{-2} was higher in early sown wheat genotypes followed by optimum sowing and late sowing. Planting density was strongly influenced by the availability of soil moisture and favourable temperature at germination. They also reported that plants m^{-2} reduced by 12-70% in late sowing due to low temperature and low soil moisture. Al-Karaki et al. (2007) reported that the combined effect of high air temperature and drought was critical for reducing the per cent seed germination, finally plant population was lower under combined stresses than the individual stress. Hampson and Simpson (1990) and Hossain et al. (2012b; *Fig. 9*) reported that soil moisture deficit postpones the germination rate of wheat, causes unequal plants per unit area, and finally reduce the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

seed yield and quality of wheat. Although above-mentioned reports suggested that temperature variation during seed germination affect plant density which results in lower yield, there are published reports which demonstrated that plant density 80-400 plants/m^2 did not show any change in yield because of other factors such as tillering (Fischer et al., 2019).

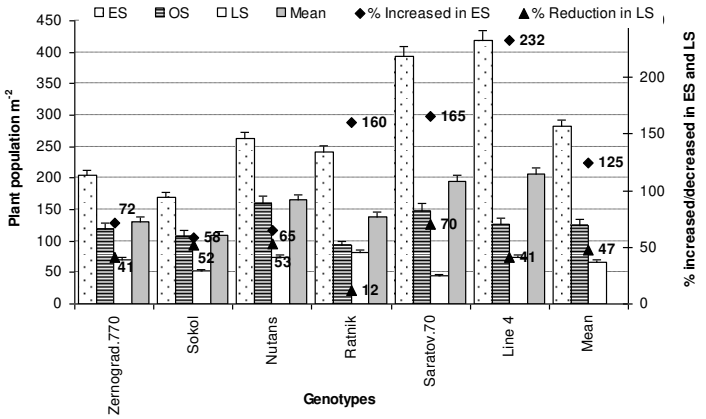

Figure 9. *Plants m^{-2} of all wheat & barley genotypes is affected by low (early sowing) and high temperature with drought (late sowing) in the environmental condition of south-eastern part of Russia (Source: Hossain et al., 2012b)*

However, the yield of spring wheat cultivars with erect growth habit planted at higher altitude is highly sensitive to plant density and row spacing. In addition, yield sensitivity to plant density and row spacing is moderate in winter wheat. However, at low soil moisture availability, optimum plant density become reduced (Fischer et al., 2019).

Tillering capability of wheat under heat and drought stresses

Wheat tillers generally grow from the axils of the main shoot leaves, the potential numbers of tillers depend on the type of species or its genetic makeup and prevailing temperature (Hossain et al., 2012a,b). Shifting in sowing dates (early or late sown) change temperature at a specific plant reduced the number of tillers (Patil et al., 2001; Singh and Pal, 2003; Subhani, 2010). While assessing the impact of different planting dates on tillering in wheat in a two-year experiment in Pakistan, Mumtaz et al. (2015) reported that late sowing reduced the number of tillers. They further added that the reduction in the number of tillers per unit area is positively associated with an increased temperature at the tillering stage. Upadhyay et al. (2015) stated that numbers of effective tillers were significantly superior for crop sown on 20th November followed by 10th December, to late sown on 30th October. The effective number of tillers decreased with early and delayed sowings, due to environmental stresses (Herbek and Lee, 2009; Hossain et al., 2012b; *Fig. 10*). Although a substantial amount of evidence is available that number of tillers per unit area is co-determined by cultivar characteristics, agronomic practice such as sowing date and environmental factors mainly thermal conditions, developing general consensus on phenological responses to changing sowing dates as climate warming is not an easy task because of different genetic makeup of different wheat cultivars.

DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

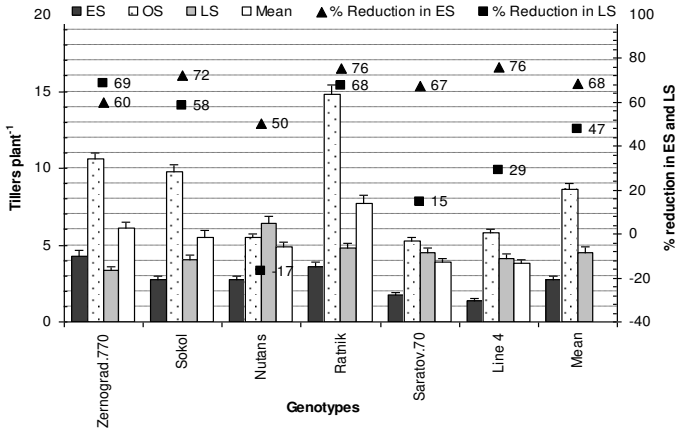

Figure 10. *Tillers plant^{-1} of all wheat and barley genotypes is influenced by low-temperature stress in early sowing and high temperature combine with drought in late sowing conditions (Source: Hossain et al., 2012b)*

Dry matter partitioning of wheat and barley genotypes as influenced by high-temperature

Under favourable environment, 80 to 90% of the carbohydrates is translocated to the grain and rest of 10 to 20% is reserve to wheat plant's (Spiertz and Vos, 1985). Ahamed et al. (2010) found that dry matter partitioning and yield in five wheat varieties was influenced by the heat stress (30 to 32°C) under late sowing. Hossain et al. (2012b; *Fig. 11*) found that most of the existing spring wheat and barley genotypes in the south-eastern part of Russia were highly sensitive to high temperature and drought in late sown condition, whereas in early sowing generally rainfed spring wheat and barley face low-temperature stress. Despite a higher plant population in early sowing, tillers production plant^{-1} was low due to low-temperature stress. This caused 10 to 42% reduction in dry biomass of early-sown crop. While, the late sown crop suffered 57 to 81% reduction in dry biomass due to high temperature (with low soil moisture and low relative humidity in air) that ultimately affected rate of seed germination (*Fig. 9*), tillers plant^{-1} (*Fig. 10*), and grain yield (Reynolds et al., 2000; Hossain et al., 2012b; *Fig. 11*).

Gupta et al. (2002) found the maximum dry weight in wheat genotypes under optimum sown conditions as compared to those of late sown conditions. The late sown wheat genotypes faced unfavourable conditions during germination to reproductive stages that ultimately lead to decreased final biomass accumulation of wheat cultivars. Similarly, Jat et al. (2013) found the maximum dry matter at optimum sown crops as compared to late sown crops. Ahamed et al. (2010) conducted an experiment with five wheat varieties ('Sourav', 'Pradip', 'Sufi', 'Shatabdi' and 'Bijoy') under two sowing times (at November 30 and December 30) and found the highest dry matter partitioning in 'Shatabdi' under heat stress environment but 'Prodip' and 'Sufi' produced the lowest dry matter partitioning, which indicated that dry matter partitioning of a genotype fully depend on genetic makeup of the specific variety. Similarly, Khichar and Niwas (2007) reported that delayed sowing resulted in a decrease in biomass and grain yields, due to the unfavourable environment during late sown conditions, especially high temperature and water deficit. Mondal et al. (2016) also reported that optimizing of sowing date can significantly enhance biomass yield of wheat. These reports suggested that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

environmental factors affect plant metabolism associated with translocation of photo-assimilates from source to sink.

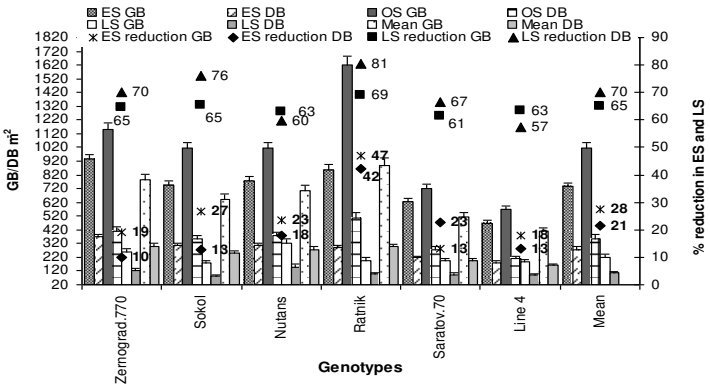

Figure 11. *Dry and green biomass of rainfed spring wheat and barley are affected by in early sowing low-temperature stress and heat stress in combination with drought stress in late sowing conditions in south-eastern part of Russia. GB-green biomass and DB-dry biomass (Hossain et al., 2012b)*

Plant height of wheat and barley genotypes as affected by high-temperature stress

Hossain et al. (2012b) observed a significant genotypic and environmental effect on the height of wheat genotypes under early and late sown conditions (*Fig. 12*). They also found that plant height in early and late sowing was lower, due to low-temperature in early sowing, while high temperature combined with drought in late sowing (Hossain et al., 2012b; *Fig. 12*). It is suggested that prevailing temperature at early growth stage regulated plant height probably through gibberellic acid biosynthesis or GA signaling response pathway.

Yield and yield attributes of wheat genotypes influenced by heat and drought stress

Tillers m^{-2}, spikes m^{-2}, grains $spike^{-1}$, number of fertile tillers m^{-2}, 1000-grain weight, spike length, spike weight, stem weight and awn length in wheat are considered most important yield contributing characters that are positively correlated with final grain weight of wheat and thus are the most important parameter for screening wheat genotypes in breeding programs (Forgone, 2009). However, drought and heat are the two significant environmental factors that limiting crop productivity through influencing the yield attributes of wheat (Prasad et al., 2008). However, interaction of environmental and genetic factors has a significant role in obtaining high productivity as reported by Shahin and Valiollah (2009). Maralian et al. (2010) observed that tillering and heading stages were sensitive to drought, and can reduce up to 37% grain yield. Mirbahar et al. (2009) reported that drought stress significantly decreased the spike length, spikelets per spike, grains $spike^{-1}$ and 1000-grain weight of wheat. The maximum reduction in all traits was observed in terminal drought, while post- and pre-flowering drought significantly influenced the 1000-grain weight (Abdoli et al., 2013).

Grain yield of wheat genotypes is strongly influenced by heat stress. Hossain and Teixeira da Silva (2012) found that the grain yield of wheat varieties significantly decreased when sown late compared with optimum sowing time (*Fig. 13*). Similarly, Barutçular et al. (2017) reported that cultivation of wheat under heat stress conditions

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

recorded significantly lower grain yield. The inhibited kernel weight at maturity was the result of high temperature which shortened the grain filling period (Wardlaw, 2002). The grain yield reduction in wheat was associated with delayed sowing, which exposed the reproductive phase of plants to high temperature (Mostafa et al., 2009). Menshawy (2007) found that delayed sowing reduced the grain yield by shortening the grain filling process, and kernels achieved maturity before completion of filling.

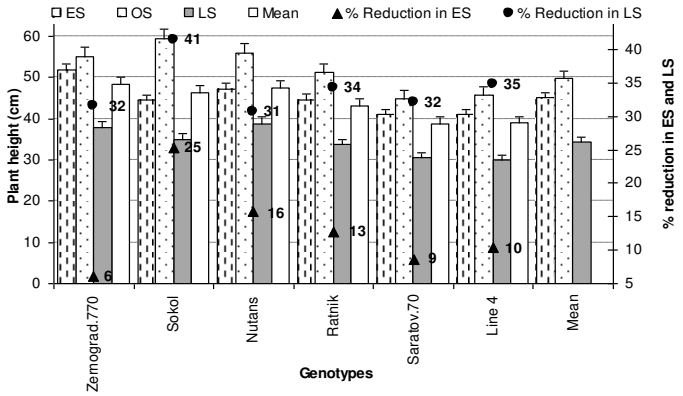

Figure 12. *Plant height (cm) of wheat and barley genotypes is influenced by low-temperature stress in early sowing and high temperature combine with drought stress in late sowing conditions (Hossain et al., 2012b)*

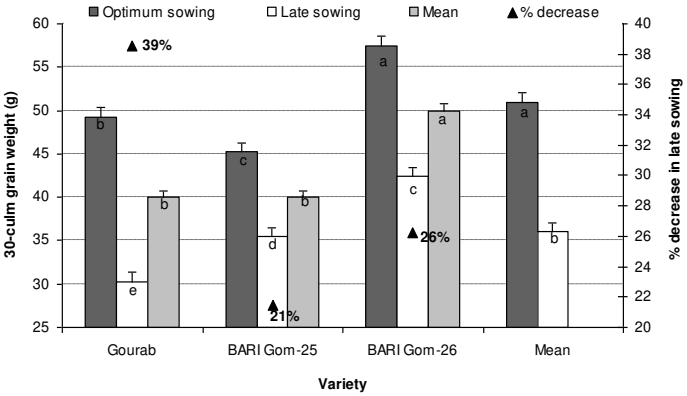

Figure 13. *Grain yield of wheat varieties is influenced by late sown heat stress condition (Hossain and Teixeira da Silva, 2012)*

Stone and Nicolas (1994) reported that high temperature during grain filling reduced grain weight and pre-anthesis decreased the grain number in wheat (Wardlaw et al., 1989; Wardlaw and Moncur, 1995). Subedi et al. (2007) found variation in grain yield and yield attributes among wheat genotypes grown at delay sowing comparing optimum sowing could be attributed through hampering of grain filling process that is high temperatures arisen at late sown wheat shortened the grain filling period.

The occurrence of drought stress along with the high temperature in the arid region is the most frequent after heading and grain filling that remarkably influences grain yield of wheat crop (Balla et al., 2011; Saleh, 2011). Hozayn and El-Monem (2010) reported that the decrease in growth and yield attributes of wheat might be due to water stress

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

during grain filling stage; while Zeidan et al. (2009) associated grain yield reduction in wheat with drought-induced photosynthetic inhibition.

Physiological and biochemical traits

High-temperature and water availability influence the photosynthetic capacity of plants including wheat (Chaves et al., 2009; Efeoglu et al., 2009). Chlorophyll content and stem reserves are very sensitive to high-temperature (Mohammadi et al., 2009). Singh (2009) observed the variation in the thermo-tolerance and physiological traits of wheat varieties under high-temperature stress. Hence, leaf chlorophyll content could be used as an indicator to determine the performance of the photosynthetic rate and reflect the photosynthetic potential (Hussain et al., 2018). Li et al. (2006) found that drought tolerance in wheat genotypes was associated with leaf chlorophyll content. Xia (2012) reported that heat, as well as drought stress tolerance, was positively associated with photosynthetic capacity. Recently, Ogbaga et al. (2018) suggested that developing thermos-tolerance in photosynthetic machineries such as in rubisco or rubisco activase will result in enhanced crop productivity. Stay-green plants have been used to select for yield stability and a selection criterion for heat stress tolerance in wheat (Joshi et al., 2007; Christopher et al., 2008). Reynolds and Trethowan (2007) reported that leaf chlorophyll content or stay-green was correlated with the leaf transpiration efficiency, which enhances the water use efficiency (WUE) under drought stress conditions. The studies on the stay-green trait of wheat genotypes are largely elusive (Rehman et al., 2009) and are yet to be evaluated for their association with stress tolerance in the wheat (Cao et al., 2015). Yeganehpoor et al. (2016) noticed that grain yield had a significant positive correlation with leaf area and chlorophyll content. Furthermore, chlorophyll content can simultaneously enhance grain yield, and plants with large leaves and higher chlorophyll content can also produce higher grain yield. These reports suggested that the amount of chlorophyll regulates the light harvesting capacity of plants which is sensitive to both heat and drought stress. In addition, photosynthetic pigment sensitivity to abiotic stresses is cultivar specific in wheat, thus could be used as selection criteria for selecting tolerant cultivars.

The reduction in the CO_2 assimilation rate in drought-stressed plants is mainly due to the reduction in leaf stomatal conductance (Chaves et al., 2009). Therefore, stomatal conductance could be used as a reliable indicator of growth rate responses to drought stress at the whole plant or canopy level (Munns et al., 2010). However, metabolism limitation to photosynthesis in drought or heat stressed plants are also well established. For example, the reduction in photosynthesis is the result of adverse effects on the metabolic process that lead to growth inhibition, stomatal closure with consecutive reduction of transpiration (Yordanov et al., 2003). Similarly, Zhang et al. (2009) reported that the soluble carbohydrate content was lower in stressed plants than that of well-watered wheat plants. Araus et al. (2007) reported that leaf physiological aspects such as water potential, chlorophyll content, photosynthetic rate, stomatal conductance, and transpiration rate are associated with the physiological adaptation of crops to environmental stress. Increase in transpiration lowers the plant water status which affects cell division and cell enlargement. For example, Manivannan et al. (2007) suggested that water deficit can significantly reduce leaf area development in wheat genotypes by arresting the cell enlargement. Similarly, Almeselmani et al. (2011) reported that relative water content (RWC) indicates the water status of the cells and have a positive correlation with production and stress tolerance. However, transpiration

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

through stomates regulates leaf or canopy temperature. For instance, when transpiration rate is low in wheat plants under drought stress conditions, the canopy temperatures of plants at both vegetative and anthesis stages were higher than in plants under control conditions (Siddique et al., 2000). Balota et al. (2007) proposed that low canopy temperature can be used as a selection criterion for drought tolerance in wheat.

Reactive oxygen species (ROS) are generated in chloroplast, mitochondria and in the cytoplasm upon explore to heat and drought stresses and can cause membrane damage (Larkindale and Knight, 2002). The reduction in the activity of ROS scavenging enzymes has been found under drought conditions (Ahmadi and Baker, 2001). Maria et al. (2008) reported that water deficit could significantly reduce phenoloxidase activity of wheat plants, however, such effect is lesser in stress tolerant genotypes. Although an increase in activities of one or more than two ROS scavenging enzymes may have a role in inducing stress tolerance, it is not necessary that higher activities of ROS scavenging enzymes are associated with stress tolerance. Membrane damage due to ROS generation can be assessed by measuring the extent of lipid peroxidation or leaf electrolyte leakage. Under stress, cellular membrane permeability of plants become increased and often correlated with reduced growth of wheat (Iqbal, 2009). The heat tolerant cultivars had lower leaf electrolyte leakage under heat stress (Thiaw and Hall, 2004) and selection based on low leaf electrolyte leakage can be used as selection criteria for enhancing heat and drought tolerance. Proline accumulation enhances membrane stability under heat or drought stress conditions (Ashraf and Foolad, 2007). The accumulation of proline with high rate in leaves under stressed occurs during the grain filling phase under moderate stress and the role of proline is correlated to a protective action against stress (Zhu et al., 2004). Sugar alcohols enhance the stability of membranes and protein to high-temperature denaturation (Heber and Santarius, 1973).

Correlation among yield attributes and stress tolerance

In the previous section, some physiological indicators for heat and drought stress have discussed. However, agronomic traits and their derived parameters can also be used as selection criteria in the breeding program. Here we describe the importance of agronomic criteria in brief. The relationship between the stress tolerance indices (STIs) and grain yield (GY) can be used to screen the wheat genotypes that are suitable to grow under stress conditions. A positive relationship between GY and each of (stress tolerance indices) MP, GMP, YI, YSI, and RP% were observed (Khan and Kabir, 2014). Mitra (2001) suggested that a significant correlation between GY and STIs of a genotype is suitable to grow under heat stress conditions. Such correlations also hold true for other stresses such as drought. Toorchi et al. (2012) and Khalili et al. (2012) reported that GY was positively correlated with each of GMP, MP, YI, and YSI under heat stress conditions.

The mean values of drought resistance index (DRI) are used for characterizing drought and heat stress tolerance and adaptation of genotypes to stress conditions. Drought stress index (DSI) was negatively correlated with grain yield under cool supplement irrigation. Moreover, heat stress index (HSI) was also positively correlated with grain yield under warm conditions inferring that heat stress was more effective for grain yield than drought stress under the warm environment. The higher values of DRI indicated more tolerance in wheat genotypes under stress environments and might be used as stress tolerant index (STI) in wheat breeding programs (EL-Shawy et al., 2017; Barutçular et al., 2016a, 2017). Since modern wheat varieties are not sufficiently

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

stressed tolerant, developing cultivars tolerant to heat is challenging for wheat breeders (Timsina and Connor, 2001). Rahman et al. (2009) found that stress resistance genotype had a higher value (%) of relative performance (RP %). Similarity, compared with RP% at late sown condition (high temperature and drought) genotype 'Nutans' (57%) performed better than 'Saratov.70' (18%), while at early sowing low-temperature stress condition, genotype 'Zernograd.770' (74%) was highly resistant to low-temperature stress and 'Saratov.70' (27%) was recorded as heat sensitive (Hossain and Teixeira da Silva, 2012; *Fig. 14*).

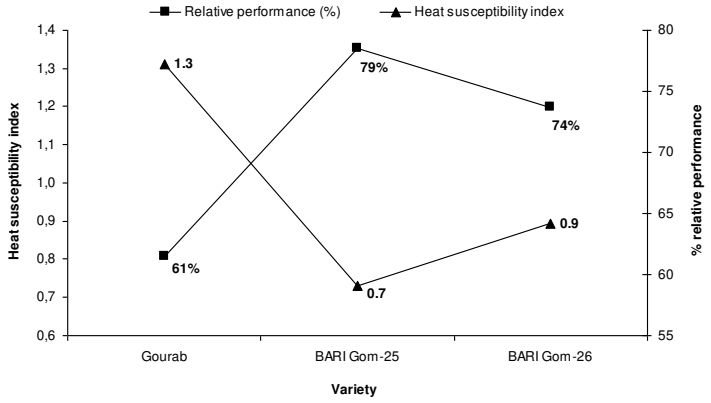

Figure 14. *Relative performance (%) and heat susceptibility index of three wheat varieties in very late heat stress condition, as compared with optimum sowing (Hossain and Teixeira da Silva, 2012)*

Similarly, Hossain et al. (2012a) found that three genotypes had SSI higher than 1.0 under late sowing condition (high temperature) indicating susceptible to stress, while other two genotypes (SSI <1, indicating tolerant to high temperature in combined with drought) (*Fig. 15*). A number of researchers suggested that stress tolerance indices (STIs), stress tolerance (TOL) (Rosielle and Hamblin, 1981), mean productivity (MP) (Clarke and McCaig, 1982), geometric mean productivity (GMP) (Ramirez and Kelly, 1998), stress susceptibility index (SSI) (Fischer and Maurer, 1978), and STI (Fernandez, 1992) can be used to identify high-yielding varieties with improved tolerance to stress.

Approaches to enhance drought and heat stress tolerance in wheat

Development and selection of wheat genotypes are aimed at enhancing yield under existing climatic conditions. Various strategies including seed dressing/coating, seed soaking, and foliar application of plant growth regulators, osmoprotectants and antioxidants have been used to enhance stress tolerance in wheat plants. Moreover, another organic compound like yeast extract (YE) is a natural source of several growth substances that positively effect to mitigate the deleterious influence of drought stress (Hammad and Ali, 2014). Barnett et al. (1990) found that YE has a significant role in regulating vegetative and reproductive growth of plant under stress condition. Nagodawithana (1991) found that exogenous application of amino acids or yeast on wheat lead to a significant improvement in all growth traits under stress conditions compared to control. El-Nabarawy (2001) reported that amino acids or yeast play a significant role in the synthesis of chlorophyll content. Furthermore, Wanas (2002)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83078332

recorded that the yeast improved the chlorophyll while delayed the degradation and senescence in plants. Osmoregulators protect plants through osmotic adjustment by maintaining membrane integrity, protecting the macromolecular structure, and stabilization of proteins and enzymes (Ashraf and Foolad, 2007; Hayat et al., 2012). There are several reports indicating that abiotic stress triggers the accumulation of proline in plant tissues (Slama et al., 2014). Moreover, exogenous application of proline caused an increase in endogenous level in plants subjected to water stress conditions and induced plant tolerance (Ashraf and Foolad, 2007; Ali et al., 2008). Glycine betaine (GB) plays an essential role in the protection of photosynthetic apparatus from photo-damage (Zhao et al., 2007), and involvement of GB in the regulation of the activities of antioxidant enzymes has been reported by Wang et al. (2010).

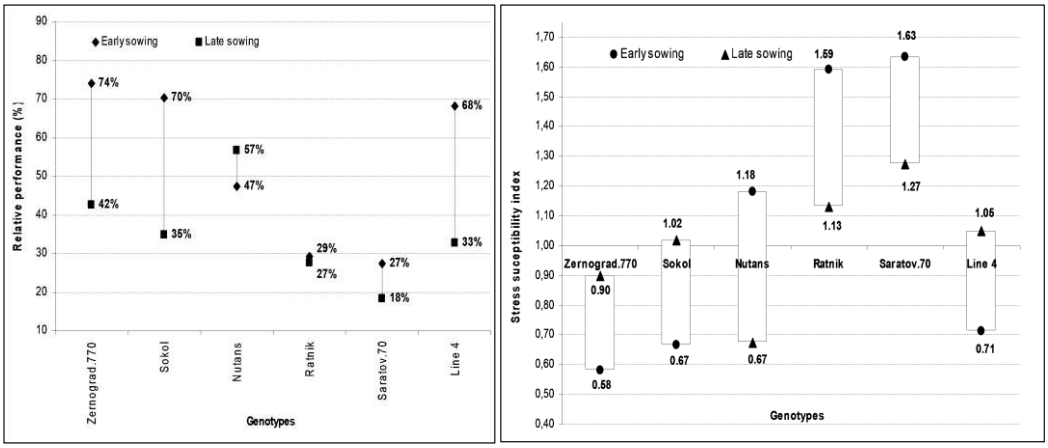

Figure 15. *Relative yield performance (%) and stress susceptibility index of different genotypes under ES-early sowing and LS-late sowing (Source: Hossain et al., 2012a)*

In addition to osmoprotectants, antioxidants are also being used to regulate stress tolerance such as salicylic acid, ascorbic acid etc. Salicylic acid (SA) is useful for the establishment of systemic acquired resistance in plants (Larkindale and Huang, 2005). Ascorbic acid (AsA), is an antioxidant that plays a beneficial role in cell growth and division, differentiation and metabolism in plants (Athar et al., 2009). Xu et al. (2015) observed that foliar application of AsA ameliorates the adverse effects of drought stress by controlling the stomatal closure, nutrient uptake, total chlorophyll content, protein synthesis, transpiration, photosynthesis, and plant growth. Bakry et al. (2012) applied AsA aiming to control pattern of growth and development coupled with improvement of systemic tolerance against different stressful environments of plants and they reported that AsA enhances plants growth to survive under stress conditions by changing plant structure and function.

Recently, selenium (Se) has been reported to counteract with the detrimental effects of various environmental stresses such as excess water stress (Wang et al., 2010), chilling (Hussain et al., 2016a,b), submergence (Hussain et al., 2016c) and high-temperature stress (Djanaguiraman et al., 2010). It may regulate water status (Kuznetsov et al., 2003), and increase biomass production (Nawaz et al., 2013) by the activation of antioxidant apparatus of water-stressed plants (Hasanuzzaman and Fujita, 2011).

Conclusion and future prospect

The drought and heat stresses may occur simultaneously under natural environments and cause huge crop losses. Thus, selecting cultivars with better drought or heat stress tolerance or breeding for stress tolerance will help in developing stress tolerant cultivars to enhance crop productivity under harsh environmental conditions. The present review synthesizes and elaborates the physiological basis of high temperature and drought stress tolerance in wheat which can be used as selection criteria in wheat breeding program. In addition, some agronomic selection criteria which are valid and useful in selecting stress tolerant wheat cultivars. In addition, to mitigate the adverse effects of these stresses on wheat, optimization of production technology package especially sowing dates, selection of appropriate irrigation at critical growth stages, and/or development of drought and heat-tolerant cultivars will help to sustain grain yield production. Application of natural bio-stimulants, especially amino acids lead to overcome the damaging effects and consequently lead to enhance the growth and yield of wheat under stress environments. In addition, exogenous application of signaling compounds, osmolytes, and certain inorganic salts play a significant role in alleviating stress. Any suitable combinations of these management strategies can enhance stress tolerance of wheat in the Mediterranean environment and similar eco-regions elsewhere. Beside these approaches, applications for soil amendments will also helpful in increasing wheat crop productivity under stressful environments. The review also discussed a positive and negative correlation between (grain yield) GY and stress tolerance indices (such as mean productivity (MP), geometric mean productivity (GMP), yield index (YI), yield stability index (YSI), relative productivity (RP%), stress susceptibility index (SSI), and the tolerance index (TOL)) to scan the genotypes against drought and heat stress. In the future, stress adversities might be minimized by improving tolerance in genotypes and by adopting better agronomic strategies. In the present review, field phenotyping for heat and drought stress tolerance in wheat discussed at length which is based on visual scoring, weighing biomass, stress tolerance indices and physiological traits. However, such practices are time consuming and labor intensive. With the advent of artificial intelligence, robotics, communication and immage processing large number of studies are focused on high throughput phenotyping using spectral sensors and algorithms to assess in depth genotypic variation at specific growth stages. Such advance phenoimic approaches not only helped in identifying physiological responses of crops to drought and heat stress, it will aid in developing stress tolerant crop cultivars. Global interest will increase in this area of research in future for agricultural sustainability.

(Received 1st Mar 2019; accepted 1st May 2019)

Abstract. Water-stress is one of the most adversarial environmental constraints limiting wheat growth and productivity. Seed priming is a promising approach to alleviate the adverse effects of water-stress on seed germination and early seedling establishment. In the current study, we evaluated the effectiveness of Glycine-betaine (GB) to improve seed germination and early seedling establishment of Wheat (Cultivar: Jimai-22) under water-stress conditions. The current study was conducted at the Engineering Research Centre of Plant Growth Regulator, College of Agronomy and Biotechnology, China Agricultural University, Beijing, China, during the year 2018-19. Water-stress significantly reduced seed germination characteristics, shoot/root fresh weight and dry matter accumulation, and relative water content (RWC). Moreover, water-stress aggressively increased the production of Proline, soluble sugars, Hydrogen peroxide (H_2O_2), and Malondialdehyde (MDA) and showed higher electrolyte leakage and reduced membrane stability. However, seed priming with GB significantly alleviated adversities of water-stress on seed germination characteristics and early seedling growth attributes; the effects were more pronounced with GB 50 and 100 mM seed treatment. Seed priming with GB counteracted the overaccumulation of proline, soluble sugars, H_2O_2, and MDA content and increased membrane stability and reduced electrolyte leakage with higher activity of antioxidant enzymes under water-stress treatment. Water-stress tolerance augmented by GB priming might be related to higher antioxidant activity and reduced reactive oxygen species (ROS) accumulation and lipid peroxidation, eventually lower electrolyte leakage and higher membrane stability, all these salient features of GB enhanced survival capability of wheat seedlings under water-stress conditions. The study is a valuable validation for enhancing water-stress tolerance via GB priming, which is of broad-spectrum interest for sustainable agriculture production.
Keywords: *seed treatment, Glycine betaine, seedling vigor, osmolyte accumulation, water-stress tolerance*

Introduction

Water-stress is a serious agronomic problem worldwide and is one of the most important factors reducing crop productivity (Farooq et al., 2012; Li and Liu, 2016). Successful and uniform seed germination is essential for healthy plant growth and development to enhance productivity potential as well as the quality of crop production (Conrath et al., 2006; Cheng et al., 2018). Uneven and delayed seed germination often result in poor seedling establishment. Therefore, it is essential to enhance seed germination and seedling vigor under osmotically stressed conditions. Seed germination and emergence are the primary steps in successful seedling development and crop productivity. Seed germination is defined as a sequence of events that start with the imbibition of dry seeds and that terminate with the elongation of the embryonic radicle (Bewley, 1997; Wolny et al., 2018).

Generally, seeds start the germination process under optimal environmental conditions (i.e., sufficient or optimal water, oxygen and temperature). However, seeds under sub-optimal conditions, such as water stress, salinity, and extreme temperatures, showed uneven germination and poor seedling development (Mahmood et al., 2009; Jisha et al., 2013; Nawaz et al., 2013; Hussain et al., 2016). Extensive research efforts have been carried out in order to improve the crop performance under water deficit conditions. Nevertheless, water deficit is still a major limitation to crop growth and productivity. Typically, seed germination and early seedling growth are less tolerant to environmental fluctuations as compared to mature plants. Thus, soil moisture stress during early growth may result in high mortality rates, leading to reduced crop performance (Chachar et al., 2016).

To enhance seed germination rate and seedling vigor under adverse environmental conditions. The pretreatment of seeds called seed priming is widely practiced in agriculture. Suitable priming treatment enhances seed germination and boosts seedling vigor in different crops. Research demonstrated that variety of chemicals shown potential to act under specific conditions as a defense priming agent against a range of different abiotic stresses (Beckers and Conrath, 2007), such chemicals includes: amino acids; Proline, Glycine-Betaine (Moustakas et al., 2011), hormones; Salicylic acid, Abscisic acid (Srivastava et al., 2010; Nazar et al., 2015), reactive oxygen-nitrogen–sulfur species (Seabra and Oliveira, 2016), mineral priming; Selenium, Calcium chloride (Iqbal et al., 2015) and even water; hydro-priming (Iqbal et al., 2015).

GB priming is an effective strategy to improve seed germination, emergence, and seedling growth of several crop plants, especially under stress conditions (Farooq et al., 2008; Atta et al., 2013; Zhang et al., 2014; Rakshit and Singh, 2018). GB could ameliorate the adversities of oxidative stress by detoxification of ROS both directly or by enhancing the activities of ascorbate peroxidase (APX), glutathione (GSH) and GSH/GSSG, Ascorbate (AsA), mono-dehydro-ascorbate reductase (MDHAR), dehydroascorbate reductase (DHAR), glutathione reductase (GR), glutathione peroxidase (GPX), catalase (CAT), and glyoxalase I (Gly I) in the different crops under adverse environmental conditions (Hasanuzzaman et al., 2014; Gupta and Thind, 2015). For example, Cheng et al. (2018) reported that GB priming increased the chilling stress tolerance of Cotton at the seedling stage, exhibited a higher net photosynthetic rate, improved antioxidant enzyme activity, and lower hydrogen peroxide content and less damage to the cell membranes. Water-stress significantly hindered seed germination and seedling growth, reduced starch metabolism, RWC, and increased cell electrolyte leakage. However, seed priming with GB improved the germination rate, root and shoot length, seedling fresh and dry weights, leaf and root scores, RWC, soluble sugars, and a-amylase activity as compared to unprimed seeds of Maize under chilling stress (Farooq et al., 2008). Similar improvements were also noted for Turfgrass under different stress conditions such as drought, salinity, and temperature (Zhang et al., 2014).

Seed priming has potential to promote uniform and synchronized seedling emergence and enhance the capability of seedlings to establish under unfavorable environmental conditions. Physiologically, seed priming strengthened the antioxidant activities of CAT, POD, SOD, and APX and as well as promoted the accumulation of compatible solutes including reducing sugar, proline, soluble sugars, free amino acids, and soluble proteins contents (Zhang et al., 2015). As a result, seed priming reduced lipid peroxidation and stabilized the cell membranes integrity, resulting in increased stress

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83338350

tolerance under water-deficit or excessive soil moisture environments (Zhang et al., 2015).

Seed priming with GB could play a significant role during germination and early seedling growth of wheat. Therefore, it is crucial that this method should be employed in wheat production to improve water-stress tolerance by seed priming with GB. In this study, we examined the effects of GB seed priming with different concentrations of GB to optimize suitable concentration and evaluate its effectiveness to improve wheat seed germination and seedlings development under water-stress conditions. We ensured that 50 to 100 mM concentrations of GB for seed priming 12 h were more advantageous for uniform and synchronised seed germination and successful seedling growth. For further insight into the phenomenon, we investigated the activities of different antioxidant enzymes directly involved in detoxification of ROS, triggered by water-stress.

Material And Methods

Growing conditions and treatment details

This study was conducted at the Engineering Research Center of Plant Growth Regulator, College of Agronomy and Biotechnology, China Agricultural University, Beijing, China, during the year 2018-19. The present study was aimed to evaluate the effect of GB seed priming on wheat seed germination and early seedling growth. Wheat (*Triticum aestivum* L.) cultivar "Jimai-22" was used in the current study. Jimai-22 is an inbreed hexaploid wheat cultivar, which is mostly planted by the wheat farmers in North China Plan (Li et al., 2015). To eradicate contamination during seed priming, wheat seeds of uniform size were surface-sterilized with 3% NaClO for 10 minutes. All the glassware and hydroponic solution used in this study were autoclaved before to use. The seed-priming treatments were hydro-priming (HP; distilled water), chemical priming (GB: 10, 25, 50 and 100 mM), and a non-primed control (NP) included for comparison. Wheat seeds were primed in the dark at 25ºC for 12 h with constant gentle shaking in a mechanical shaker. The proportion of seed weight to volume of priming solution was maintained as (w/v) was 1:5 (Hussain et al., 2016). After 12 h of priming treatment, the primed seeds were washed thoroughly with deionized water for 4-5 times, to remove priming agent from the surface of the seeds. The primed seeds were surface-dried using blotting paper and placed to an air- drying oven at 25°C for 48 h to minimize the moisture content to <10%. The experiment was designed in Completely Randomized Design (CRD) with three replications. After achieving required seed moisture content, 20 seeds per replicate were placed in 12.5 cm Petri dish on a double layer of filter paper No.102, moistened with 10 ml of distilled water considered as well-water (control) or with 10 ml of 10% PEG-6000 solution (water-stress). During the experiment, 10 ml of autoclaved distilled water or 10% (w/v) PEG-6000 solution was added to each petridish after every 24 h to maintain constant moisture. The radicle protrusion at 1 mm was recorded as the criterion for germination (Guo et al., 2017). The experiment was conducted in a controlled room (Environmental Growth Chamber, China Agricultural University, Beijing), which was set to maintain 22/18°C (day/night), 60% relative humidity, 12-h photoperiod, and 650 $\mu molm^{-2}$ s^{-1} photosynthetically active radiation at the canopy level. Seedlings kept for eight days under stressed and non-stressed conditions. Growing media solution was changed after every 48 h; the number of seeds germinated after every 12 h was recorded and final germination percentage was calculated when there was no more germination in reach treatment

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83338350

(day-4). All the seedlings were harvested after eight days of planting, five seedlings from each replicate were used for the root and shoot fresh and dry weight measurements, while the rest of seedlings were wrapped in an aluminum foil and exposed to liquid nitrogen and saved to -80°C for further biochemical studies.

Seed germination characteristics

The following germination characteristics were recorded according to AOSA (1983).
Final germination %

$$(G) = \frac{total\ seeds\ germinated}{total\ \ seeds\ planted} \times 100 \quad \text{(Eq.1)}$$

Germination rate index

$$(\mathrm{GRI}) = (\frac{G1}{1} + \frac{G2}{2} + \frac{G3}{3} + \cdots \frac{Gi}{i}) \quad \text{(Eq.2)}$$

where G1 is the germination percentage on day 1, G2 is the germination percentage on day 2; and so on.
Seedling Vigour Index

$$(\mathrm{SVI}) = \text{shoot lenghth} + \text{root length} \times \mathrm{G} \quad \text{(Eq.3)}$$

Root and shoot length measurement

Fifteen seedlings from each treatment were randomly collected (five for each replicate) for the measurement of the root and shoot length (by using a Vernier caliper) at the 8th day of planting.

Plant growth and biomass accumulation

For the measurement of fresh weight and dry matter accumulation, shoot, and root were separated and weighed for their fresh weight. The shoot/root dry weight was recorded in milligrams after drying in hot air oven (SANYO, Model, MOV-202, Japan) at 80°C ± 5°C for 72 hours. All the related traits were recorded after eight days of planting.

Relative water content (RWC)

The RWC was calculated by using leaves from randomly selected plants; the leaves were cut into about one cm discs and weighed to get fresh weight (FW). Later these leaf discs were soaked in distilled water for 4 h and turgid weight (TW) was recorded, leaves discs were then dried in an oven till constant weight at 80°C to obtain the dry weight (DW). RWC was calculated as

$$\mathrm{RWC\%} = \frac{FW-DW}{\mathrm{TW-DW}} \times 100 \quad \text{(Eq.4)}$$

Malondialdehyde (MDA) and Hydrogen peroxide (H_2O_2) content

Determination of lipid peroxidation in wheat seedlings was done by, Thiobarbituric acid (TBA) test, which determines MDA as an end product of lipid peroxidation (Heath

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83338350

and Packer, 1968). Plant material (500 mg) was homogenized in 5 ml of 0.1% (w/v) Trichloroacetic acid (TCA) solution. The homogenate was centrifuged at 10000× g for 20 min, and 0.75 ml of the supernatant was added to 1.5 ml of 0.5% (w/v) TBA in 20% TCA. The mixture was incubated in boiling water for 30 min, and then reaction stopped by placing the reaction tubes in an ice bath. Then the samples tubes were centrifuged at 10000×g for 5 min, and the absorbance of the supernatant was recorded at 532 nm by using UNICO UV-2800AH spectrophotometer (UNICO Instrument Co. Ltd., Shanghai). The value for non-specific absorption at 600 nm was subtracted. The following equation was used to calculate MDA concentration using its absorption coefficient (ε) and expressed as μmol Malondialdehyde g^{-1} fresh weight:

$$\text{MDA } (\mu\text{mol } g^{-1} \text{ FW}) = [(A532 - A600) \times Vt \times 1000/\varepsilon] \times Wt \quad \text{(Eq.5)}$$

where ε is the specific extinction coefficient (=155 mM cm^{-1}), Vt is the volume of total extract and Wt is the fresh weight of leaf sample, A600 and A532 is the absorbance at 600 and 532 nm wavelength.

The H_2O_2 concentration was determined according to Alexieva et al. (2001). 500 mg of wheat seedlings (shoot) samples were homogenized in an ice bath with 5 ml of 0.1% (w/v) TCA. The homogenate was centrifuged at 10000×g for 20 min, and 0.5 ml of the supernatant was added to 0.5 ml of 10 mM potassium phosphate buffer (pH 7.0) and 1 ml of 1Molar potassium iodide (KI). The absorbency of the supernatant was recorded on Spectrophotometer at 390 nm. The content of H_2O_2 was given on a standard curve.

Electrolyte leakage, and membrane stability index

Leaf membrane damage was estimated by the recording of electrolyte leakage (EL) as reported by Bajji et al. (2002) with slight modifications. Plant material (500 mg) washed with distilled water and then placed in 15 ml test tubes with 10 ml of deionized water and incubated for 4 h at 25°C. Subsequently, the electrical conductivity (EC) of the samples (R1) was recorded on the EC meter (DDS-12A; Shanghai Kangyi Co., Ltd., Shanghai, China). The samples were then autoclaved at 120°C for 20 minutes, cooled at room temperature and the final conductivity (R2) was recorded on the EC meter. The EL was defined as follows:

$$EL\% = \frac{R1}{R2} \times 100 \quad \text{(Eq.6)}$$

However, Membrane stability index (MSI) was calculated by using the following equation:

$$MSI\% = \frac{1-R1}{R2} \times 100 \quad \text{(Eq.7)}$$

Antioxidant enzymes extraction and assays

Antioxidant enzymes extraction was performed as described in Seckin et al. (2010) with slight modifications. Shoots of wheat seedlings were collected at the 8th day of planting, and immediately placed into liquid nitrogen, then stored at -80°C until used. Approximately 500 mg of leaf sample was rapidly extracted in a pre-chilled mortar on an ice bath with five mL of ice-cold 50 mM sodium phosphate buffer (pH 7.8)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83338350

containing 1 mM disodium diammonium acetate (EDTA-Na_2), 1% (w/v) polyvinyl pyrrolidone (PVPP) and 10 mmol / L magnesium chloride. Samples were centrifuged at 12,000×g for 25 min, and the supernatant was used for the determination of antioxidant enzymes activities. Likewise, catalase (CAT, EC 1.11.1.6) activity was estimated by monitoring the initial rate of disappearance of H_2O_2 by using spectrophotometer at 240 nm wavelength according to Cakmak and Horst (1991). Meanwhile, the activity of superoxide dismutase (SOD, EC 1.15.1.1) was determined using the method of Xue et al. (2008). Thus, the peroxidase activity (POD, EC 1.11.1.7) was determined by the guaiacol oxidation method (Nakano and Asada, 1981).

Osmolyte accumulation

Free proline content in shoots of wheat seedlings was extracted with 3% sulfosalicylic acid and centrifuged at 12,000×g. An aliquot was mixed with glacial acetic acid and acidic ninhydrin for 30 minutes at 100°C. The reaction was terminated in an ice bath, and chromophore was extracted with five mL of toluene. The chromophore-containing toluene was warmed to room temperature, and absorbance was recorded on a spectrophotometer at 520 nm (Bates et al., 1973).

Total soluble sugars were extracted from the shoots samples previously stored at -80°C. 500 mg of shoot sample with 5 ml distilled water incubated in hot-water bath at 100°C for 20 minutes, the extract were centrifuged at 12,000×g for 10 min; supernatant was transferred to 15 ml tube, and again 5 ml of distilled water was added into the sample tube and extraction was repeated, supernatants were collected together. The supernatant was mixed with anthrone reagent, heated for 7 min, the reaction was terminated by placing reaction tubes in an ice bath for 10 min and the absorbance was recorded on Spectrophotometer at 625 nm. Total soluble sugars content was recorded according to the method elaborated by Morris (1948) and expressed as mg g^{-1} fresh weight.

Statistical analysis

Statistical analysis and data computations were made using Microsoft Excel 2016 (Microsoft Corporation, Redmond, WA, USA) and Statistix 8.1 (Analytical Software, Tallahassee, USA). Significantly different treatment means were separated using the least significant difference (LSD at 0.05) test.

Results

Seed germination ability, synchronization and seedling characteristics

The seed germination response was varied among different water-stress and priming treatments (*Fig. 1*). Water-stress significantly arrested seed germination. However, seeds primed with distilled water (HP) as well as with different concentrations of GB had better seed germination percentage as compared to NP seeds under well-water and water-stress conditions. The maximum final seed germination % was recorded in seeds primed with GB 50 and 100 mM and had 13% higher seed germination % as compare to non-primed (NP) seeds under well-water conditions. Whereas under water-stress, a similar trend was observed and GB had maximum seed germination of 80% as compared to NP seeds of only 64%.

DOI: http://dx.doi.org/10.15666/aeer/1704_83338350

The germination rate index presented in *Fig. 1*, was also affected by water-stress and priming treatments; the higher germination rate was noted in response to GB priming treatments followed by HP. However, NP showed least germination index both under well-water and water-stress conditions.

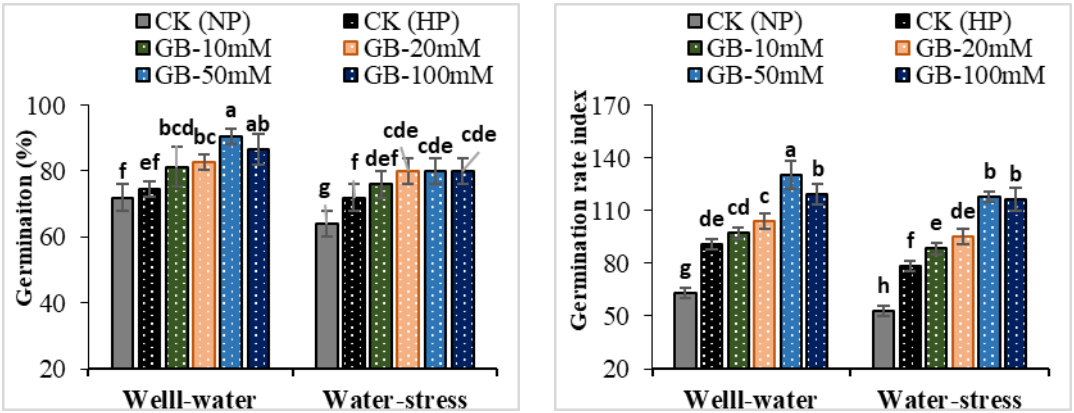

Figure 1. *Effect of different seed priming treatments on seed germination (a) and germination rate index (b) of wheat seeds under well-water (non-stressed) and water-stress (PEG-10%) condition. Bars showing the same letters are not significantly different at P ≤ 0.05 as determined by LSD test*

Shoot, root length

Under well-water conditions, the length of shoot and root was higher in primed seeds as compared to NP seeds. However, water-stress significantly affected seedling's shoot and root morphological characters (*Figs. 2 and 3*).

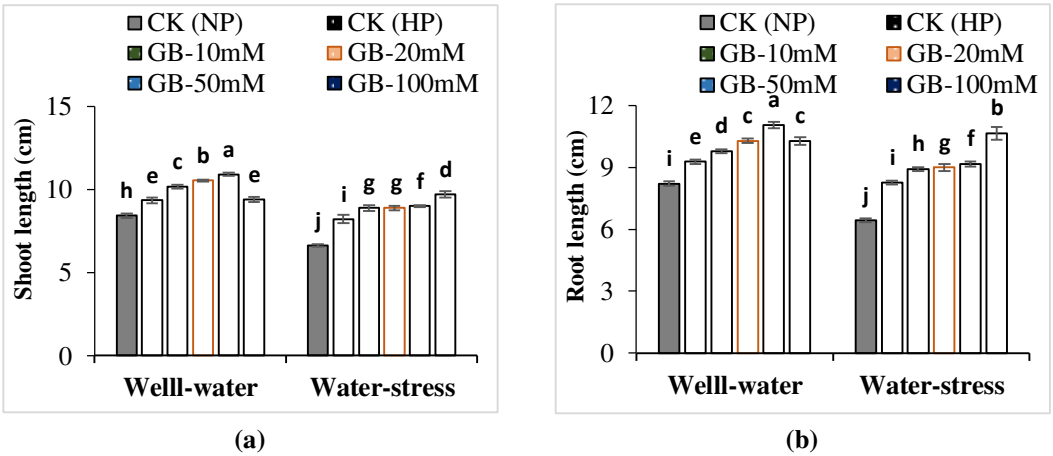

Figure 2. *Effects of different seed priming treatments on shoot length (a) and root length (b) of wheat seedlings under well-water and water-stress conditions. Control non-primed; CK (NP), Control hydro-primed; CK (HP), Glycine-betaine primed denotes GB. All values represent means ± standard deviations (SD) of three replicates. Bars showing the same letters are not significantly different at P ≤ 0.05 as determined by LSD test*

DOI: http://dx.doi.org/10.15666/aeer/1704_83338350

Under well-water treatment seeds primed with GB 50 mM showed contrasting results in term of shoot and root length and showed 29 and 35% higher shoot and root length as compared to NP seeds, however, HP seeds also had significant difference of 11 and 13% higher shoot and root length as compared to NP seeds under well-water treatment. Under water-stress, seeds primed with GB 100mM showed better seedling character in term of the shoot and root length and had 36 and 66% higher shoot and root length as compared to seedlings of NP seeds under water-stress conditions.

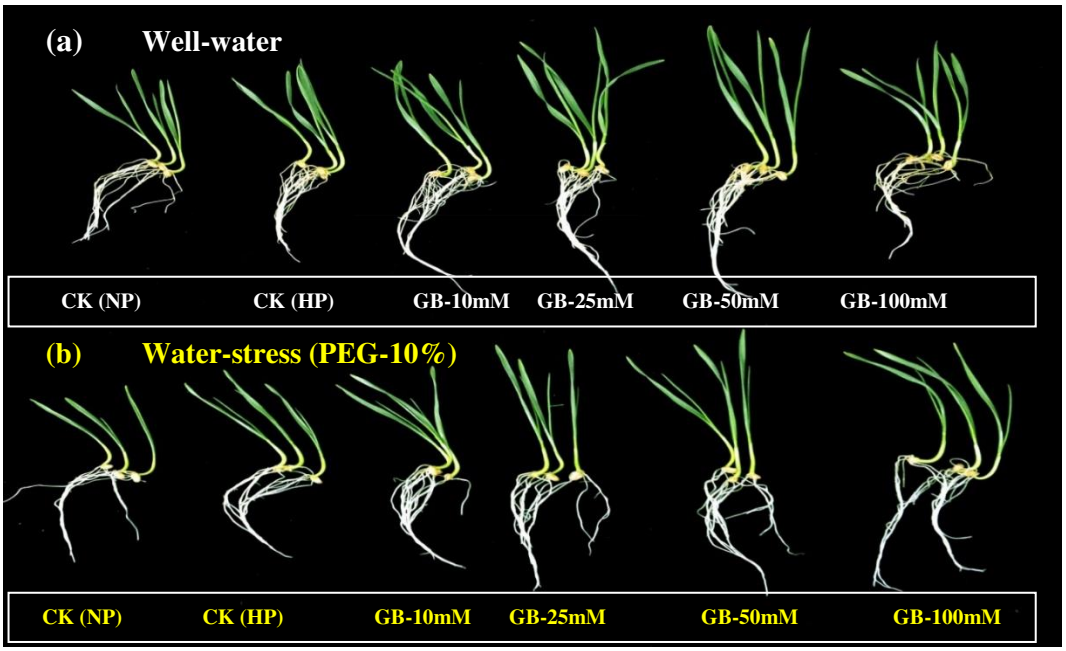

Figure 3. *Effects of different seed priming treatments on morphological characteristics of wheat seedlings under well-water (a) and water-stress (PEG-10) (b) conditions. Control non-primed; CK (NP), Control hydro-primed; CK (HP), Glycine-betaine primed denotes GB*

Shoot, root fresh weight, and dry matter accumulation

The response of wheat seedlings with respect to shoot and root fresh weight and dry matter accumulation were varied among different water and priming treatments (*Fig. 4*). The maximum shoot and root fresh weight were noted in 25 and 50 mM of GB primed seeds as compared to rest of GB, HP and NP primed seeds, however, under water-stress conditions seeds primed with GB 50 and 100 mM showed better performance as compared to seedlings of HP and NP treatments. Under the water-stress condition, NP demonstrated diminishing growth of the seedlings along with a significant decrease in dry weight of shoot and root (*Fig. 4*). Similar to seedling fresh weight, the dry weight of seedlings was also higher in 25 and 50 mM GB primed seeds and under well-water treatment. However, GB 50 and 100 mM were more effective under water-stress treatment and had higher dry matter accumulation as compared to HP and NP seeds.

Seedling vigor index

In the current study, water-stress significantly reduced the seedling vigor index as compared to the well-water treatment (*Fig. 5*). Irrespective of water-stress effects, seeds primed with GB significantly increase the seedling vigor index as compared to HP and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83338350

NP seed treatments. The more prominent increase in seedling vigor was revealed by GB 100 mM seed priming followed by 50, 25 and 10 mM under water-stress treatment.

Shoot relative water content (RWC)

There was a significant reduction in shoot RWC under water-stress as compared to well-water treatment (*Fig. 5*). Seed priming either with HP or GB considerably enhanced shoot RWC in water-stress treatment. The seedlings originating from the NP or HP seeds suffered a more significant decline in shoot RWC under water-stress treatment. However, seed priming with GB 50 and 100 mM significantly increased 4.7 and 3.8 % higher shoot RWC as compared to seedlings originated from NP seeds under water-stress treatment.

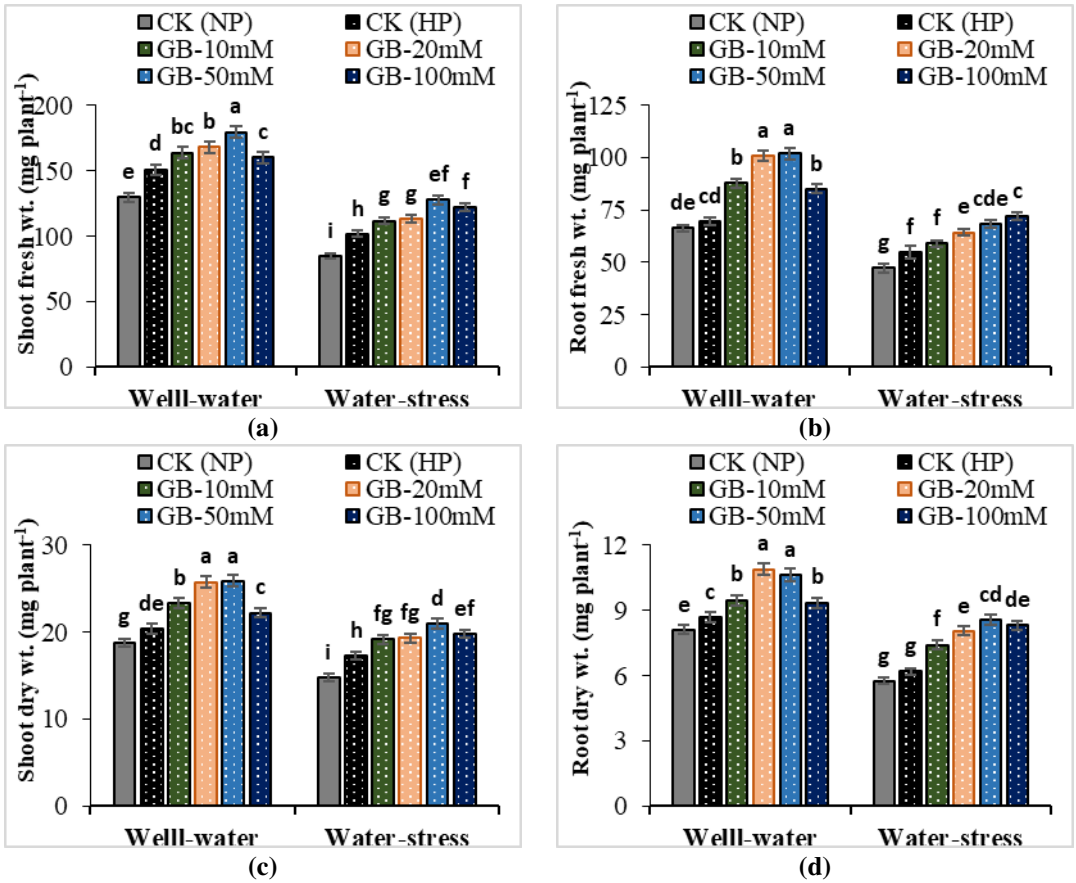

Figure 4. *Effects of different seed priming treatments on the shoot and root fresh (a and b) and dry (c and d) weight of wheat seedlings grown under well-water and water-stress conditions. Control non-primed; CK (NP), Control hydro-primed; CK (HP), Glycine-betaine primed denotes GB. All values represent means ± standard deviations (SD) of three replicates. Bars showing the same letters are not significantly different at $P \leq 0.05$ as determined by LSD test*

Lipid peroxidation and ROS accumulation

The rate of lipid peroxidation was recorded in term of MDA accumulation, induced by PEG-stress was found to be dependent upon water-stress treatment (*Fig. 6*). Under well-water conditions, the MDA accumulation was almost similar in all wheat seedlings originated from either NP, HP or GB treated seeds. Upon exposure to PEG stress, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83338350

MDA accumulation was increased in all priming treatments; however, in the seedlings of GB primed seeds, the increase was lower than that of NP and HP seed priming treatments.

The response of wheat seedlings originated from NP, HP and GB primed seeds were varied among water-stress treatments, and exposure to water-stress all priming treatments showed a significant increase in H_2O_2 accumulation (*Fig. 6*). However, all the seeds either primed with different concentrations of GB or primed with distilled water (HP) showed lower accumulation of H_2O_2 and presented better performance as compared to seedlings of NP seeds under water-stress condition. The seedlings from the seeds treated with 100 mM showed 18% lower H_2O_2 content compared with seedlings of NP seeds under water-stress treatment respectively.

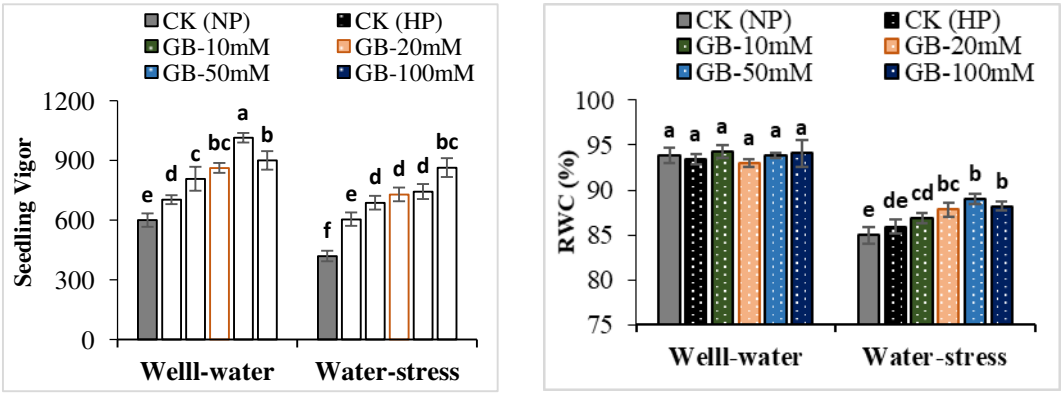

Figure 5. *Effects of different seed priming treatments on seedlings vigor (a) and RWC (b) of wheat seedlings grown under well-water and water-stress conditions. Control non-primed; CK (NP), Control hydro-primed; CK (HP), Glycine-betaine primed denotes GB. All values represent means ± standard deviations (SD) of three replicates. Bars showing the same letters are not significantly different at $P \leq 0.05$ as determined by LSD test*

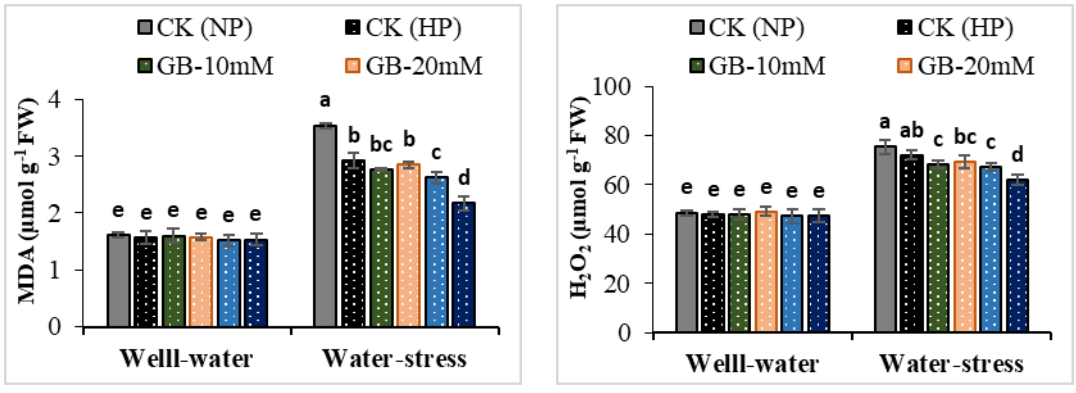

Figure 6. *Effects of different seed priming treatments on MDA (a) and H_2O_2 (b) content in wheat seedlings grown under well-water and water-stress conditions. Control non-primed; CK (NP), Control hydro-primed; CK (HP), Glycine-betaine primed denotes GB. All values represent means ± standard deviations (SD) of three replicates. Bars showing the same letters are not significantly different at $P \leq 0.05$ as determined by LSD test*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83338350

Membranes stability index and electrolyte leakage

Cellular membrane stability is reciprocal to electrolyte leakage, the higher electrolyte leakage, the lower membrane stability. Membrane stability was not changed among different priming treatments and had lower electrolyte leakage under well-water conditions. However, under water-stress treatment cellular membrane stability was significantly reduced as elucidated from a significant increase in electrolyte leakage in the wheat seedling originated from either primed or non-primed seeds (*Fig. 7*).

The most damaging effects of water-stress were observed in wheat seedlings originated from NP seeds as increased electrolyte leakage and lower membrane stability index values under water-stress (*Fig. 7*). However, seed priming either with GB or with water significantly reduced electrolyte leakage and increased cellular membrane stability index under water-stress treatment. The most contrasting results were obtained by seed priming with GB 25 to 100 mM concentrations and found lower electrolyte leakage and higher membrane stability index in wheat seeding originated from the seeds primed with high concentrations of GB and grown under water-stress conditions.

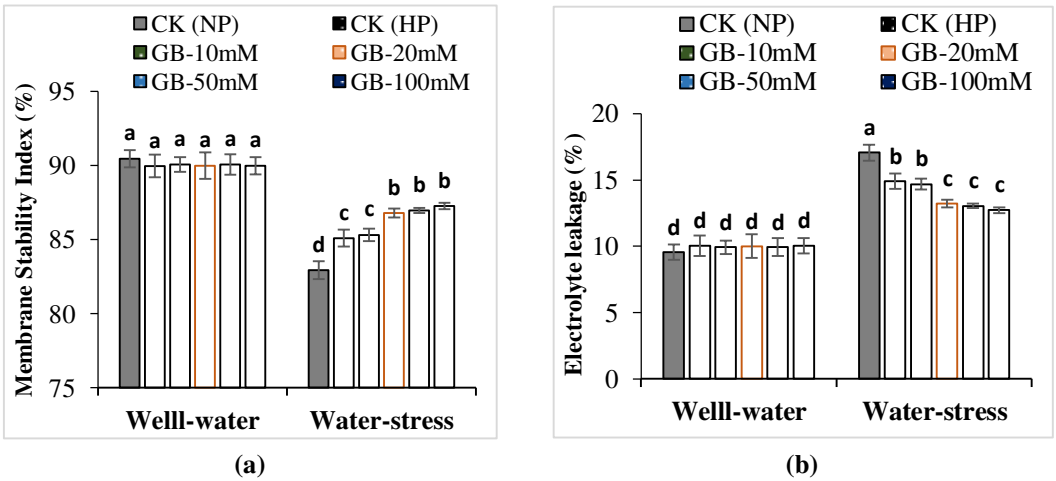

Figure 7. *Effects of different seed priming treatments on membrane stability index (a) and electrolyte leakage (b) of wheat seedlings grown under well-water and water-stress conditions. Control non-primed; CK (NP), Control hydro-primed; CK (HP), Glycine-betaine primed denotes GB. All values represent means ± standard deviations (SD) of three replicates. Bars showing the same letters are not significantly different at P ≤ 0.05 as determined by LSD test*

Activities of antioxidant enzymes

The activities of antioxidant enzymes (CAT, POD and SOD) were significantly higher in osmotically stressed seedlings and significant variation was recorded among different priming treatments, whereas, under well-water conditions, the activities of CAT, POD and SOD in the seedlings of GB and HP primed seeds were almost similar to seedlings of NP seeds (*Fig. 8*). Under the water-stress condition, the CAT activity was increased significantly in the seedlings of GB 50 and 100 mM primed seeds as compared to HP and NP seedlings. The activities of POD under water-stress, the seeding originated from GB 100 and 25 mM primed seeds showed 19 and 14% higher POD activity as compared to seedlings of NP seeds. However, seedlings originated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83338350

from 100mM GB and HP seeds showed 43% and 13% higher SOD activity as compared to seedlings of NP seeds under water-stress treatment (*Fig. 8*).

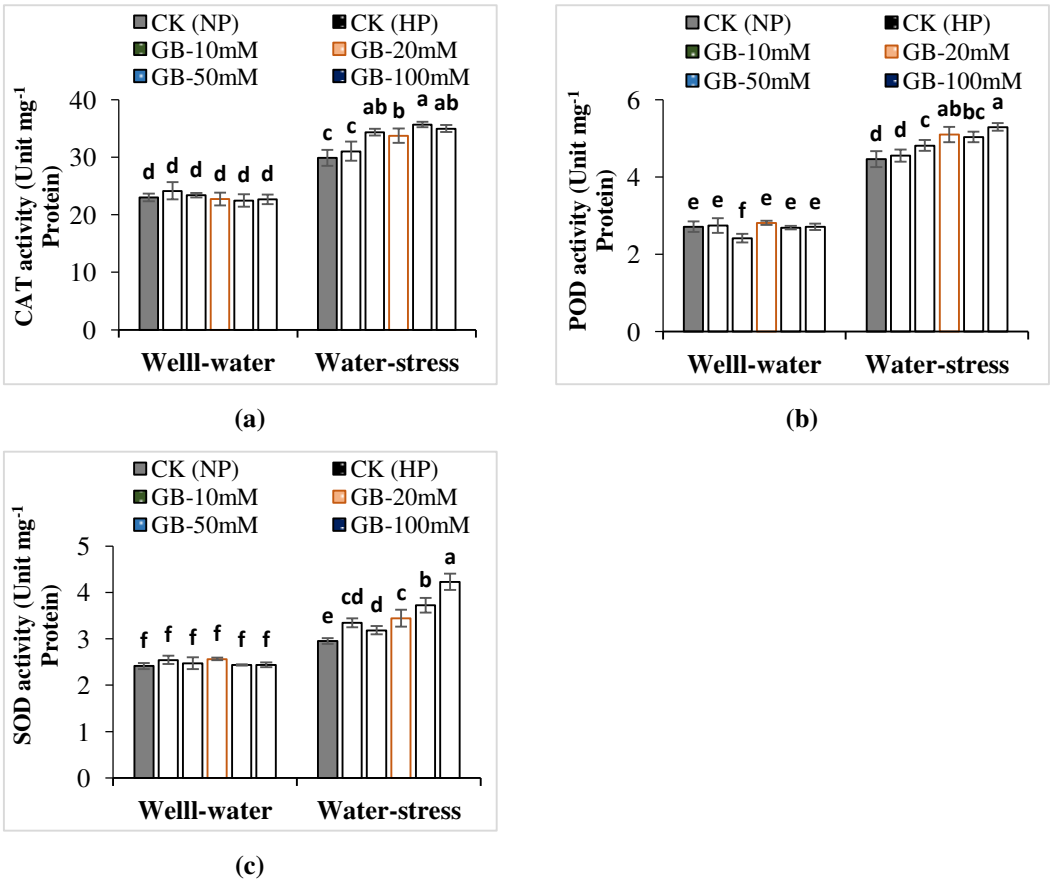

Figure 8. *Effects of different seed priming treatments on the activities of antioxidant enzymes; catalase (CAT) (a), Peroxidase (POD) (b) and superoxide dismutase (SOD) (c), in wheat seedlings grown under well-water and water-stress conditions. Control non-primed; CK (NP), Control hydro-primed; CK (HP), Glycine-betaine primed denotes GB. All values represent means ± standard deviations (SD) of three replicates. Bars showing the same letters are not significantly different at P ≤ 0.05 as determined by LSD test*

Osmolytes accumulation

The results represent proline and soluble sugars contents in wheat seedlings under well-water and water-stress treatments are presented in *Fig. 9*. The accumulation of proline and soluble sugars significantly enhanced by water-stress; for instance, there was an approximately 6-fold increase in the proline content of water-stressed seedlings of NP seeds as compared to NP seedlings of well-water treatment. In addition, the proline content remarkably decreased with seed priming treatments. Moreover, 33 and 44% lower proline accumulation were recorded in the seedlings originated from GB 50 and 100 mM primed seeds as compared to the seedlings of NP seeds under water-stress treatment. Similarly, the accumulation of soluble sugars content in wheat seedling was higher in water-stressed seedlings; however, more pronounced accumulation of soluble sugars was recorded in the seedlings of NP seeds. Seed priming significantly altered soluble sugars accumulation and 28 to 27% lower soluble sugars were accumulated in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83338350

seedlings originated from GB 50 and 100 mM primed seeds planted in water-stress treatment (*Fig. 9*).

Discussion

Results of this study revealed that seed treatment with an appropriate agent and its concentration could invigorate wheat seeds, subsequent in greater germination ability and better seedling establishment and higher seedling fresh weight and dry matter accumulation under well-water and water deficit conditions (*Figs. 1 to 4*). In the current study, faster and more synchronized and uniform seed germination and seedlings emergence were recorded with seed priming, as indicated by higher germination %, germination index (*Fig. 1*), shoot and root length (*Fig. 2*), fresh weight or dry matter accumulation (*Fig. 4*), and seedling vigor index (*Fig. 5*). Water-stress induced deleterious effects on seed germination and seedling growth were alleviated by seed treatment with GB, this improvement in synchronized seed germination and better seedlings establishment could be attributed from higher antioxidant activity and Maintainance of cellular membrane integrity. Our results are in agreement with the previous finding with Safflower, cotton, Turfgrass, and Wheat (Zhang et al., 2014; Salama et al., 2015; Alasvandyari et al., 2017; Cheng et al., 2018). Uniform and synchronized seed germination and early seedling establishment are the most critical stages for any crop. Water deficit may severely reduce seed germination capability, uniformity and dry matter accumulation (Jisha et al., 2013; Nawaz et al., 2013; Hussain et al., 2016). Consequently, the advantages of seed priming may be more helpful under sub-optimal soil water conditions compared with more favorable soil moisture conditions (Farooq et al., 2008; Mahmood et al., 2009; Zhang et al., 2014).

Water-stress induced growth decline has been previously reported by many researchers in different crops: Turfgrass (Zhang et al., 2014), Rice (Farooq et al., 2008) Sorghum (Zhang et al., 2015) and Wheat (Nawaz et al., 2013; Guo et al., 2017). Water-stress-induced reduction in plant growth and development is mainly attributed to a reduction in plant water potential, leaf RWC, photosynthesis and dry matter

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83338350

accumulation (Farooq et al., 2012). Our findings revealed that inhibitory effects of water-stress could be ameliorated by seed priming with GB appropriate concentration, our results demonstrated that seedling originated from seeds, primed with GB 50 and 100 mM had better shoot RWC under water-deficit conditions and had the ability to reduce adversities of water-stress (*Fig. 5*). The decline in RWC showed a loss of turgor, which restricted water availability necessary for proper plant growth and development. Water-stress tolerance is substantially associated with tissue water potential and antioxidant system, exogenous application of GB significantly reduced adversities of water-stress in seedlings of fine grain aromatic rice and improved leaf water potential and had higher antioxidant activity and better photosynthetic ability under water-deprived conditions (Farooq et al., 2008; Wani et al., 2013).

The cellular membrane stability was significantly affected by the overproduction of H_2O_2, and MDA content, which elucidated from the higher release of electrolytes from the cells under water-stress conditions. Furthermore, water-stress stimulated overproduction of H_2O_2 and MDA content in wheat seedlings (*Fig. 6*) represents a well-known indicator of oxidative stress. However, seed priming with GB alleviated adversities of water-stress, which were manifested in term of substantially improved membrane stability index, as noted from lower electrolyte leakage (*Fig. 7*) and reduced H_2O_2 and MDA production. Higher ion leakage and MDA production are considered as indicators of oxidative stress (Mahajan and Tuteja, 2005; Farooq et al., 2012). The oxidative stress often arises from the overaccumulation of ROS, especially H_2O_2. Overproduction of H_2O_2 is toxic to cellular structure and macromolecules, impairing normal cellular activities (Das and Roychoudhury, 2014; Mittler, 2017). The overproduction of ROS in plants is managed by a variety of antioxidant enzymes and lipids and water-soluble macromolecules. Of these antioxidant enzymes (CAT, POD, and SOD) are the key components of ROS scavenging mechanism under oxidative stress conditions (Das and Roychoudhury, 2014; Lou et al., 2015; Xu et al., 2018). Our results suggested that the activities of antioxidant enzymes significantly triggered in wheat seedling originated from the seeds treated with GB (*Fig. 8*). This increase in activities of antioxidant enzymes and reduced ROS mediated injuries in wheat seedlings as evident from the association between H_2O_2 and MDA and antioxidant enzymes system under water-stress but not under well-water conditions.

It is well-established phenomena that proline and soluble sugars content in plant tissues enhanced by a variety of environmental stress including water-stress (He et al., 2011; Wei et al., 2015). Accumulations of these osmolytes in maize hybrids were increased with the severity of drought stress (Anjum et al., 2017). Water-stress significantly triggered the accumulation of proline and soluble sugars in this study (*Fig. 9*). Our results revealed that seed priming with GB reduced overproduction of proline and soluble sugars under water-stress. The effects of GB seed priming on proline accumulation under water can be interpreted based on the argument that higher accumulation of endogenous proline does not contribute to the osmotic adjustment in plants under water-stress conditions (Borgo et al., 2015). Lower accumulation of endogenous proline in wheat seedlings are also reported in GB primed seeds under salinity stress (Salama et al., 2015). Moreover, higher accumulation of soluble sugars adversely affects plant physiological and biochemical activities in a concentration-dependent manner (Aldesuquy et al., 2012; Sami et al., 2016).

Conclusion

The results of the present study elucidated that the seed priming with GB did not simply accelerated germination-related processes but was also involved in other specific mechanisms that improved the seedling vigor and allowed the wheat seedlings to cope with the oxidative stress induced by water-stress. Increase in activities of antioxidants as governed by GB based seed priming can protect the degradation of enzymes from water- stress-induced ROS production and maintained cellular membranes stability. In addition to protecting from oxidative stress, GB seed priming was also involved in regulation of endogenous accumulation of proline and soluble sugars, RWC and antioxidant system in wheat seedlings, which may also be a remarkable demonstration of enhanced seed germination characteristics and seedling vigor under stressful environment.

Abstract. At-site Rainfall Frequency Analysis (RFA) is a crucial tool for designing of water related infrastructures. Partial Duration Series (PDS) and Annual Maximum Series (AMS) are the most popular techniques for RFA. PDS is capable of including more extreme events as compared to the AMS. Keeping in view the importance of at site RFA, in this study we identify suitable statistical model that best represent PDS and AMS extracted from daily rainfall records of 25 years in the vastly growing city, Rawalpindi, Pakistan. The most commonly used statistical distributions in RFA such as Generalized Pareto (GPA), Generalized Extreme Value (GEV), Generalized Logistic (GLO), and Pearson Type-3 (PE-3) distributions are used in this study. The parameters of these distributions are estimated by method of linear moments (LM). Anderson-Darling (A-D) testing criterion along with L-moment ratio diagram have been used to determine the best fit probability distribution. The findings of our study suggest that GEV as the best fit statistical distribution for PDS while GLO for AMS. Moreover, in this study we have also estimated quantiles for the best fitted probability distributions. The results revealed that PDS sample outperforms than AMS for various return periods. These estimates can be used in designing of water-related infrastructures such as culverts, bridges and other hydrological structures in the city.
Keywords: *frequency factor, goodness-fit test, linear moments, quintile estimation*

Introduction

Nowadays, climate change is one of the main challenge for mankind. Global warming occurs due to multiple changes in the climate such as changes in the intensity, duration, frequency and timing of extreme events including bolstering lengthening droughts, heat waves and occurrence of more precipitation. Like other countries worldwide, in Pakistan also, due to abrupt changes in the climate, several extreme changes in the weather have been observed in the form extreme rainfalls, droughts, irregular floods, glacier melting, sea-level rising, etc. (Rasul et al., 2012). In Pakistan, global warming has also putting severe impacts on hydrological parameters leading to cause an increase in precipitation for arid region including Rawalpindi city of Pakistan (Hassan et al., 2017). These heavy rains due insufficient water resources management cause flash floods in the city. Resulting disasters damage the economy of the country and create problems for citizens. In worst circumstances these disasters cause disruption of normal services like health care livelihoods and also loss of human lives. Reduction in flood risk, the mitigation of resulting damages is possible by human actions on the fluvial system, such as the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83518367

construction of reservoirs, culverts and other protection measures. Rainfall Frequency analysis using different probability models is one of the randomising approaches which could be used to estimates future rainfall with certain probability in order to mitigate the losses mentioned above. However, relatively small samples of annual maximum rainfall series put some limitations to the degree of statistical sophistication that can be engaged during at-site frequency analysis. The data of extreme events must reflect the variations expected in the quantity of interest. However, the values of many hydrological and hydrometeorological data vary in time giving alternating sequences of large and small values. So, usually, the larger values are greater than the mean values and make clusters in short time period followed by smaller values or null values sometimes. In the result of such temporal pattern, we get the typical configuration of a succession of exceedances over a specified threshold. The number and magnitude of such exceedances can be modeled by probability modeling. Such series are known as partial duration series (Naghettini, 2016).

For this study we have carried out RFA using two commonly known methods i.e. Annual Maximum Series (AMS) and Partial Duration Series (PDS) for the daily rainfall records of the city Rawalpindi, Pakistan. Rawalpindi is located in the north-south of the sub-mountainous region of the province Punjab. In recent decades, abrupt fluctuations in rainfall patterns are being observed particularly in northern Photohar regions. In the past years due to heavy rainfalls i.e., 1981, 1988, 1997, 2001, several tributaries have been affected badly in the city. A total of 11 major small tributaries of rain water pass through the city including the famous Lai-Nullah. The intensity amount of rainfall caused the water level of Lai-Nullah (the famous rainfall tributary in the city) particularly, other tributaries to rise remarkably and gave raise to heavy floods in the city. In the result of these floods, 74 human lives were lost, around 400,000 people were affected, 742 cattle heads were perished, 1,087 houses were completely 2,448 partially were demolished. The flash flood which drove by the monsoon rain in 2001 turn into a loss of US$ 250 million (Rasul et al., 2004). There are many factors causing this situation in these tributaries such as the illegal constructions along with these tributaries has squeezed the space for smooth flow of sewage rainwater collection of debris and also other construction materials being dumped in these rain water tributaries resulting in the rise of rainfall water to a precarious level. The accurate modeling in the form of at-site frequency analysis of these heavy rainfalls is of immense importance to mitigate future losses. Rainfall frequency analysis (RFA) with the passage of time is getting more attention worldwide. Extensive research works are being carried out in various parts of the world. According to Lang et al. (1999) two techniques, PDS and AMS are commonly used techniques in rainfall frequency analysis. AMS consists of single value, the maximum value per year of the daily records while PDS consists of all well-defined maximum peaks above a certain threshold level (Beguería, 2005). The dilemma in RFA is to select the proper series among AMS and PDS. The most regular objection with respect to use of annual maximum series is that it uses only one peak value in a year. On some occasions, the second largest event in a data may be greater than many AM events of the other years. On contrary, PDS modeling represents a complete description of extreme events (heavy rainfalls or floods), particularly when the issue of short length of data is under consideration (Lang et al., 1999). Fischer and Schuman (2014) explained that PDS modeling provide comparatively more data series per year as compared to AMS. The substitute makes possible to analyze events which are extreme still higher than annual maxima of others years and are not incorporated in the AMS technique. Lang et al. (1999) proposed to consider PDS modeling as a compromise between AMS analysis and classical

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83518367

time series modeling. A lot of studies are available around the globe address different aspects of PDS and AMS modeling techniques (see for example Nagy et al., 2017), where they discussed the technical questions concerning the use of the partial duration series (PDS) within the domain of flood frequency analysis while the study of Chang et al. (2015) presented a comparison of AMS and PDS for derivation of rainfall intensity-duration-frequency relationships in peninsular Malaysia. Berton et al. (2018) discussed the Improving peak flow estimation across the United States by using PDS. Agilan et al. (2017) proposed non-stationary rainfall intensity-duration-frequency relationship with a comparison between AMS and PDS. Gado and Nguyen (2016) presented regional estimation of floods for ungauged sites using scaling approach partial duration series. Vrban et al. (2018) evaluated the Stormwater Infrastructure using PDS and AMS Models. Guru and Ramakar (2016) presented a study on flood estimation in Mahanadi river system, India using PDS. Olsson (2019) debated the short-duration rainfall extremes in Sweden with a regional analysis paradigm. Pham et al. (2013) discussed the statistical properties of PDS with a case study of North New Zealand. Alahmadi et al. (2014) proposed the best fit distribution for PDS of daily rainfall in Madinah, western Saudi Arabia. Karim et al. (2017) evaluated the AMS and PDS for estimating frequency of small floods for 24 gauging stations in the Great Barrier Reef (GBR) lagoon catchments in north-eastern Australia. Keeping in view the importance of PDS frequency analysis, we have compared the performance of PDS frequency analysis with AMS frequency for Rawalpindi city, Pakistan.

Objectives of the study

- To provide comparative at-site rainfall frequency analysis of Rawalpindi city of Pakistan using PDS and AMS modeling techniques.
- To determine the best fit probability distribution for PDS and AMS and estimate their parameters using robust estimation method of L-moments
- Finally, to estimate the quantiles of the best fit probability distribution under PDS and AMS paradigms.

Materials and methods

Data description

The daily rainfall data for length of 25 years of Rawalpindi City, Pakistan is being retrieved from Pakistan Meteorology department. The data is measured in millimeters (mm). Each normal year contains 365 values of daily rainfall while a leap year contains 366 values. We have total of 9131 values with minimum value of 0 mm and maximum of 592 mm. There are total 6 leap years during the study period from 1990 to 2014. Each value has been recorded during 24 h in the city. The average rainfall during 25 years is 53.52 mm with a standard deviation of 24.041 mm. The distribution of daily rainfall is positively skewed with sharp peak. The basic statistics of the study sample is given in *Table 1*.

Table 1. *Summary statistics of basic data for the time period from 1990 to 2014*

Number of values	Minimum value (mm)	Maximum value (mm)	Mean value (mm)	Standard deviation (mm)	Coefficient of skewness	Coefficient of kurtosis
9131	0	592	53.52	24.041	13.137	83.780

Preliminary trend analysis

Preliminary trend analysis is also very important to know about the nature of the data. In order to identify the random behaviour of the time series test of serial correlation could be applied. This test must be applied before applying Mann-Kedall's (MK) test. MK test is normally applied for serially uncorrelated series. If a series is found to be serially correlated, we must do prewhitening to make it serially uncorrelated. The test statistic is given in *Equation 1* and its confidence interval is given in *Equation 2*.

$$R = \frac{1/(n-1)\sum_{t=1}^{n-1}(y_t - \bar{y_t})(y_{t+1} - \bar{y_t})}{1/n\sum_{t=1}^{n-1}(y_t - \bar{y_t})} \quad \text{(Eq.1)}$$

$$\frac{\{-1-1.645\sqrt{n-2}\}}{n-1} \leq R \leq \frac{\{-1+1.645\sqrt{n-2}\}}{n-1} \quad \text{(Eq.2)}$$

where R shows lag-1 correlation while $\bar{y}_t$ represents the average of the time series, n is the number of data points in the time series. The general rule is that if lag-1 correlation co-efficient R is found to be present in the interval as shown in *Equation 2*, we say that there is no significant correlation and declare that the desired series is free from serial correlation at given level of significance otherwise not. The Mann- Kendall's Test, also known as Kendall's tau statistic denoted by "S" by *Equation 3* is applied to find significance and direction of the trend. The null hypothesis will be that series at h with independent and identically distributed observations with two side alternative hypothesis. The constraints for the test are that k j ≤ n j ≠ k.

The test statistic "S" is defined as

$$S = \sum_{k=1}^{n-1}\sum_{j=k+1}^{n}\mathrm{sgn}(y_j - y_k), \quad \text{(Eq.3)}$$

where

$$\mathrm{sgn}(y_j - y_k) = \begin{Bmatrix} +1 \ if \ (y_j - y_k) > 0 \\ 0 \ if \ (y_j - y_k) = 0 \\ -1 \ if \ (y_j - y_k) < 0 \end{Bmatrix}$$

where y_k y_j represent the rank of the data. For the time series with mean of 0 and identical distribution, variance of S statistic can be calculated as in *Equation 4* (Adamowski and Bougadis, 2003):

$$V(S) = \frac{\left\{n(n-1)(2n+5) - \sum_{h=1}^{n} t_h(h)(h-1)(2h+5)\right\}}{18} \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83518367

where t_h shows the summation of t, equal to number of tied values to the extent of c. For sample size more than 10, the above statistic follows normal distribution, as given in *Equation 5*. We can calculate the Z statistic as

$$z = \begin{Bmatrix} \frac{s-1}{\sqrt{\mathrm{var}(s)}} if\ s \geq 0 \\ 0 if\ s = 0 \\ \frac{s+1}{\sqrt{\mathrm{var}(s)}} if\ s \leq 0 \end{Bmatrix}, \quad \text{(Eq.5)}$$

After calculating the above statistic, we can compare it with standard normal variate at specified level of significance. The S statistic not only determine the significance of the test but also the direction of the trend. For example, a positive value shows an upward trend while a negative value shows downwards trend in the data. The exact value of slope in the time series could be determined with the help of Sen's estimator, with an assumption that there is a linear trend in the data. It is also a nonparametric method used to find the change per unit time. To find the slope, first we calculate the statistic $Qi\ from\ M\ pairs$ of the given time series as shown below in *Equation 6:*

$$Q_i = \frac{y_j - y_k}{j-k}, \quad \text{(Eq.6)}$$

for i = 1, 2, 3,……..,M; where *"i"* indicates the *ith* pair of the data. The data point at *j*th time should be larger than the data point at *k*th time. The next step is finding the median value of these M values of *Qi*. This median value shows our required Sen's estimator. There are two cases: the first one is that if *M* is odd, the median value is given in *Equation 7:*

$$Q_{median} = Q_{\frac{m+1}{2}} \quad \text{(Eq.7)}$$

Second, if *M* is even, the median value is given in *Equation 8:*

$$Q_{median} = \frac{1}{2}\left[Q_{\frac{M}{2}} + Q_{\frac{M}{2}+1} \right], \quad \text{(Eq.8)}$$

Formation of annual maximum series (AMS) and partial duration series (PDS)

From the basic data of daily rainfall of 25 years we want to formulate two series, such as Partial Duration Series (PDS) and Annual Maximum Series (AMS) for further analysis. The AMS consists of single value, the maximum value in the whole year. It is largest value among 365 values while, PDS consists of all well-defined maximum peaks above a certain threshold level (Beguería, 2005). Selection of threshold is one of the major complexities in the PDS modeling. It turns out that there is, in the state of the art, no universal and unambiguous rule for the selection of the threshold which incorporates as much information as desirable without compromising the independence requirement between occurrences over time. The selection of threshold has direct impact on the analysis. The problem of the selection of threshold is also discussed extensively by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83518367

Rosbjerg and Madsen (1992). They compared different methods to define the threshold level based on certain values of frequency factor *K*. This method presents a predefined frequency factor *K*, can be written as in *Equation 9:*

$$Threshold = E\{1\} + (K).S(1) \quad \text{(Eq.9)}$$

where E {I} and S {I} are, the mean and the standard deviation of the basic data.

To enhance the usage of PDS modeling among the practitioners, it is required to develop a practice-oriented guidelines (Rasmussen et al., 1994). Meeting the independence condition for the set of selected peaks is a prerequisite in frequency analysis of PDS. In terms of computation, PDS modeling is more complicated than the AMS modeling. According to extreme value theory, along with fundamental assumptions of independence and identical distribution, PDS modeling also requires that number of peaks above threshold to follow Poisson process while the peaks themselves follow GPD (Cunnane, 1979). Once the series satisfies the basic assumptions, the next step is to determine the best fit probability distribution. Therefore, we study most commonly used distributions for frequency analysis in this study such as GLO, GEV, GPD, PE3.

Selection of estimation method

Linear moments (LM) estimation technique has been adopted in this study to estimate the parameters of the statistical models. In case of extreme values present in the data series LM method is advantageous over the conventional moments method (Ahmad et al., 2015). Estimates of the conventional moments methods are not robust in quality and do not provide reliable estimates for the probability distributions with three or more parameters. The method of maximum likelihood (MLE) is considered as one of the efficient parameters estimation approach. It gives the least variance of the estimated parameters but it suffers from serious disadvantage of giving biased estimates with small samples especially if the numbers of parameters are large (Ahmad et al., 2016a, b, 2017). The method of LM corresponding to probability weighted moments (PWMs) are variants of the method of moments which provide a different way to summarize the data set. LM are summary statistics for probability distributions and data sample. Measure of location, dispersion, skewness, kurtosis and other descriptive statistics can be obtained through LM. To compute LM, we consider linear combination of ordered statistics. For instance, X_1, X_2, X_3, ... X_r, *be* the random sample of magnitude r, with cumulative distribution function $F(X)$ and quantile function $X(F)$.

Let $X(1:r) \leq X(2:r) \leq \ldots \leq X(r:r)$ be the order statistics of a random sample. For random variable X, the rth population L-moment as explained by (Hosking, 1990) can be written as in *Equation 10:*

$$\lambda_r = \frac{1}{r}\sum_{k=0}^{r-1}(-1)^k \binom{r-1}{k} E(X_{r-k:r}) \quad \text{(Eq.10)}$$
$$r = 1, 2, \ldots\ldots$$

In *Equation 10* λ_r is a linear function of the expected order statistics. The L-moment ratios are also very important. These can be defined as in *Equations 11-13:*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83518367

$$\tau = \frac{\lambda_2}{\lambda_1} \quad \text{(Eq.11)}$$

$$\tau_3 = \frac{\lambda_3}{\lambda_2} \quad \text{(Eq.12)}$$

$$\tau_4 = \frac{\lambda_4}{\lambda_2} \quad \text{(Eq.13)}$$

where τ is a measure of L-coefficient of variation (L-Cv), τ_3 τ_4 are L-skewness and L-Kurtosis, respectively. In general sample linear moments are estimated utilizing the sample obtained from the large set of data. In this study we have also obtained the sample moments using the sample of the large set of daily rainfall records of 25 years of Rawalpindi city. The r_{th} sample L-moments as suggested by Hosking (1990) are given in *Equation 14:*

$$l_r = \frac{1}{r} r \sum_{i=1}^{n} \left[\sum_{j=0}^{r-1} \frac{(-1)^j \binom{r-1}{j} \binom{i-1}{r-1-j} \binom{n-1}{j}}{\binom{n}{r}} \right] X_{i:n} \quad \text{(Eq.14)}$$

$$r = 1, 2, 3, \ldots\ldots$$

The sample L-ratios are defined in *Equation 15:*

$$t = \frac{\ell_2}{\ell_1},\ t_3 = \frac{\ell_3}{\ell_2}\ \ t_4 = \frac{\ell_4}{\ell_2} \quad \text{(Eq.15)}$$

where ℓ1 is sample measure of location, *"t"* is sample measure of CV, t_3 t_4 are the sample skewness and Kurtosis based on LM respectively. These measures are used to identify the distribution from which the sample is drawn. Additionally, these measures are used in the estimation of parameters when distribution is fitted to a sample by equating the sample L-moments to corresponding population L-moments.

Goodness of fit criteria

Another fundamental step in rainfall frequency analysis after selection of efficient robust estimation method is the selection of best fit statistical models. For the selection of best fit statistical model, we have standard criteria, i.e. Akaik Information Criterion (AIC) and Bayesian Information Criterion (BIC), but do not work efficiently in the presence of small sample data. These criteria fail to produce efficient results with asymmetric probability distribution that commonly encountered in extreme events applications. Therefore, in this study we have used Anderson - Darling (A-D) test to verify whether or not a sample belongs to specific population. This test statistics is a modified form of the Kolmogorov Smirknove (K-S) test. This testing criterion is considered to be better than K-S testing criterion as it gives more weight to the tails in the highly skewed distributions. This test also considers specific distribution in the calculation process of critical values. Baldassarre and Montanari (2009) suggested using

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83518367

A-D testing criterion as a goodness of fit test for small sample data. Similar suggestions are found in Onoz and Bayazit (1995). The mathematical form of A-D testing criterion can be defined by the formula given in *Equation 16:*

$$A^2 = -n - \frac{1}{n}\sum_{i=1}^{n}(2i-1) \\ [\ln F(Xi) + \ln(1 - F(1 - F(X_{n-i+1}))) \quad \text{(Eq.16)}$$

In *Equation 16* "n" is the size of the sample, $X_{i,s}$ are the observed data values arranged in an ascending order $F_{(X)_i}$ is the expected distribution function. The larger value of the test statistic will show more discrepancy between expected and empirical distribution function, hence would lead us to reject the null hypothesis. L-moment ratio diagram has also been adopted as an expedient tool for the selection of candidate distribution (Ahmad et al., 2015). These diagrams represent a theoretical relationship between the L-skewness τ_3 and the L-kurtosis τ_4 of different probability distribution. The sample ratio of L-skewness and L-kurtosis goes near to the most appropriate distribution in the diagram.

Basic assumptions of the data

PDS and AMS analysis requires that the data must fulfill the fundamental assumptions of statistical hydrology such as randomness, independence, homogeneity and stationarity. Assumption of randomness uncovers, either the given sample is drawn at random from the population. If the data fulfills the assumption, it implies that the sample values are the realization of a random variable (Naghettini, 2016). NERC (1975) proposed a nonparametric test for checking randomness by considering the number of turning points present in the sample for a given time period. A turning point may be defined as a peak or a trough in a time series plot of the data. Underlying intuitive idea behind the test is that if there are too many or few turning points in the data, then the sample would be declared as possibly non-random. The numbers of turning points "p" is a purely random process of N observations with mean variance mentioned in *Equations 17* and *18:*

$$E(p) = \frac{2(N-2)}{3} \quad \text{(Eq.17)}$$

$$Var(p) = \frac{16N-29}{90} \quad \text{(Eq.18)}$$

This approximation is available in literature for large sample (Yule, 1950). It has been proposed that the resulting variable "t" follows normal distribution for larger size. Therefore, under the null-hypothesis of randomness the standardized test statistic, $(t = \frac{p-E(p)}{\sqrt{var(p)}})$, follows normal distribution.

For fulfillment of independence assumption, we used Wald and Wolfowitz test. The assumption of independence implies that not a single sample value could affect the occurrence or non-occurrence of any other sample value present in the data. Generally, the AMS is expected to follow the assumption of independence, while strong dependence is expected for PDS. In any case, the assumption of independence must be checked before further analysis. Wald and Wolfowitz (1943) suggested a non-parametric test for this purpose. Let $\{x_1, x_2, \ldots, x_n\}$ describe a sample of size N from X,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83518367

while $\{x_1', x_2', \ldots, x_N'\}$ is the sequence of differences of any ith sample value from the sample mean $\bar{x}$.

The test statistic is calculated using R, E (R) $\widehat{Sr}$ given in *Equations 19-21:*

$$R = \sum_{i=1}^{N-1} x_i' x_{i+1}' + x_1' x_N', \quad \text{(Eq.19)}$$

$$E(R) = \frac{s_2}{N-1} \quad Var(R) = \frac{s_2^2 - s_4}{N-1} + \frac{s_2^2 - 2s_4}{(N-1)(N-2)} - \frac{s_2^2}{(N-1)^2} \quad \text{(Eq.20)}$$

where:

$$\widehat{s_r} = \sum_{i=1}^{N} (x_i')^r \quad \text{(Eq.21)}$$

For large sample under true null hypothesis of independence, Wald and Wolfowitz (1943) found that this test statistic follows a normal distribution as mentioned in *Equation 22*.

$$t = \frac{R - E(R)}{\sqrt{var(R)}} \quad \text{(Eq. 22)}$$

The assumption of homogeneity implies that all elements of the sample data belong to a single common population. However, considering mean values or total of values makes easier to detect the heterogeneities. The assumption of homogeneity is generally checked through a non-parametric test developed by Mann-Whitney (1947). For a given sample $\{x_1, x_2, x_3, \ldots\ldots, x_n\}$, of size N, one has to split the data in two sub samples of size N_1 $\{x_1, x_2, x_3, \ldots\ldots, x_{N1}\}$, N_2 $\{x_1, x_2, x_3, \ldots\ldots, x_{N2}\}$ sizes such that $N_1 + N_2 = N$ (with approximately equal subsamples). Once the splitting of the data is done the second step is to rank the entire sample in ascending order by noting the rank order say (m) of each element also from which subsample belongs to. The basic idea behind the test is that if the given sample is not homogenous, the sum of ranking orders of the elements belonging to first subsample would be consistently higher or lower than the sum of ranking orders of elements of the second subsample (Naghettini, 2016).

The Mann–Whitney test statistic can be written in the form mentioned in *Equations 23* and *24*.

$$V_1 = N_1 N_2 + \frac{N_1 (N_1 + 1)}{2} - R_1 \quad \text{(Eq.23)}$$

$$V_2 = N_1 N_2 - V_1 \quad \text{(Eq.24)}$$

where R_1 indicates the sum of ranks of all elements from first subsample. If both of the subsamples are larger than 20, the null hypothesis is true such that the given sample is homogenous, Mann-Whitney (1947) showed that V follows a normal distribution with mean: $E[V] = \frac{N_1 N_2}{2}$; variance: $VAR(V) = \frac{N_1 N_2 (N_1 + N_2 + 1)}{N_2}$; Hence, the require statistic for the Mann–Whitney test will be written as: $t = \frac{V - E(V)}{\sqrt{var(V)}}$, which follows a standard normal distribution.

The notion of stationarity implies that some basic properties of the observed sample as well as relevant functional form of the probability distribution and its parameters do not change with respect to time. Non-stationarity might be in form of monotonic trend

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83518367

as well as abrupt change in the data at some time interval. It is to be noted that a non-stationary series is always non-homogenous but non- homogenous series is not necessarily stationary (Naghettini, 2016).

In order to verify the assumption of stationarity, a non-parametric test named Spearman's rank correlation coefficient is used. It is a statistical dependence between two variables, one is the ordered ranks say (m_t) of the observed sample in ascending order while the other one is the time indices $T_t = 1,2, \ldots . N$. It reveals the monotonic trend which is not restricted to only linear as in case of conventional correlation coefficient. It also depicts the nonlinear correlation between the ranks' orders say (m_t) of the observed sample and the time indices $T_t = 1,2, \ldots . N$. It is written as in the following form given in *Equation 25*.

$$r_s = 1 - \frac{6\sum_{t=1}^{N}(m_t - T_t)^2}{N^3 - N} \quad \text{(Eq.25)}$$

The corresponding test statistic is written in *Equation 26:*

$$t = r_s\sqrt{\frac{N-2}{1-r_s^2}} \quad \text{(Eq.26)}$$

Assumptions of partial duration series analysis

For PDS sample, it is required that it must fulfills the assumption of Poison process. Bogeria (2005) discovered that the original daily rainfall series did not adjust to a Poisson process at lower threshold level, however the study showed that the tendency towards the Poisson process was increased as the level of threshold increases. For at-site frequency analysis, Cunnane (1979) proposed Fisher testing criterion given in *Equation 28* to test Poisson process states that the number of peaks values exceeding certain threshold level must conforms to a Poisson Process with mean such as *Equation 27*.

$$p = \frac{e^{-\mu}\mu^x}{x!} \quad \text{(Eq.27)}$$

A test of Poisson assumption can be piloted on observed series of peaks exceeding the certain threshold level. Fisher test statistics is based on the equation given in *Equation 28*. This statistics is utilized for the verification of PD series.

$$R = \sum\frac{(ni - \lambda)^2}{\lambda} \quad \text{(Eq.28)}$$

In the equation above ni represents the number of peaks above at certain threshold in a year, λ is the mean number of peaks exceeding certain threshold level. In the literature this testing criterion has been used for the verification of Poisson assumption. Under the true null hypothesis, statistics R is distributed as chi-square distribution with the confidence limits as $\chi^2_{\alpha/2}(t-1) < R < \chi^2_{1-\alpha/2}(t-1)$. These confidence limits verify either data series to follow the Poisson distribution. If, test statistics R lies within the upper and lower confidence limits then the PDS will be considered to follow Poisson process. If the classical PDS model comprises the assumption of Poisson process then

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83518367

the exceedances may follow exponential distribution. However, in recent years numerous researches have emphasized that the peaks in PDS modeling follow GPD (see for example Hosking Wallis, 1987; Madsen and Rosbjerg, 1994). Few other research studies have proved that peaks in PDS may also follow distributions other than GPD (for example see Rasmussen et al., 1991).

Results and discussion

Preliminary trend analysis is also very important to know about the nature of the data. In this study, we have carried out the trend analysis using monthly and overall precipitation series of 25 years of data of Rawalpindi city from 1990 to 2014. There are total thirteen variables including one for overall daily rainfall (raw) data and remaining twelve for monthly data. We implemented two non-parametric methods for trend analysis. In other words, Mann-Kendall (MK) test procedure is used to find the significance of the trend while Sen's slope estimator to find change per unit time. The MK test will help to find not only the significance of the trend but also direction of the trend with an assumption of linear trend. Before applying Mann-Kendall's test for significance of the trend, we also implemented lag-1 serial correlation test to determine either we need some prewhitening of the data or not. The data of Rawalpindi station on monthly basis as well as overall data did not show any lag-1 serial correlation among the successive values. This implies that we do not need any prewhitening of given time series. The given series can be used for further trend significance. The bold value in *Table 2* shows the presence of significant trends. All months shows insignificant trends except the month of March. Three months such as Month of January, June and November show negative insignificant trends. Overall data also indicate that the trend is insignificant positive trend. Further, we can also notice that the trend in monsoon season (July to September) is positive insignificant.

Table 2. *Trend analysis in monthly rainfall and daily rainfall data from 1990 to 2014*

Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Overall
-0.01	0.047	**0.127**	0.081	0.05	-0.022	0.014	0.017	0.022	0.018	-0.03	0.005	0.021

Formation of partial duration (PDS) and annual maximum series (AMS)

For AMS frequency analysis, maximum value per year is considered. For the length of 25 years data we have only 25 values, whereas, in PDS, exceedances above certain threshold level are considered. For PDS different samples were selected utilizing different values of *K* (frequency factor) in objective formula.

The size of the sample in PDS is associated with the value of frequency factor (*K*). A slight increase in the value of K reduces the sample to a large extent as shown in *Table 3*. A sample of size 126 was obtained using 3.5 as frequency factor. Similarly, the sample of size 96, 58 were obtained using 4 and 5 as K values in the objective formula. For PDS sample to be used for further analysis is necessary to follow the assumption of Poisson process. Therefore, all the samples of PDS given in *Table 3* were tested for Poisson process. The results are given in *Table 4* based on 99% and 95% confidence interval.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83518367

Table 3. *Frequency factor and number of exceedances using objective formulation*

Frequency factor (K)	PDS sample size
K = 3.5	126
K = 4	96
K = 5	58

Table 4. *The assumption of Poisson distribution for partial duration series*

K	R	C.I (1%)	Decision	C.I (5%)	Decision
3.5	12.49	9.02 < R < 45.559	Accepted	12.401 < R < 39.36	Accepted
4.5	5.82	9.02 < R < 45.559	Rejected	12.401 < R < 39.36	Rejected

Table 4 shows that a sample of size 126 was obtained using value of 3.5 for *K* in the objective formula which fulfills the assumption of Poisson process both at 99% confidence interval 95% confidence interval. The value of the statistic falls in the confidence interval which supports that the PDS sample from this frequency factor is following Poisson process assumption. Whereas, rest of the sample do not fulfills the assumption of Poisson process. For further rainfall frequency analysis we will consider only the sample with frequency factor = 3.5. For AMS analysis we have 25 values while for PDS analysis we have 126 values for further analysis.

Fundamental assumptions are essential before carrying out formal RFA. Therefore, we have tested both samples, i.e. PDS and AMS for randomness, Independence, homogeneity and stationarity. *Table 5* presents that the values of test statistics *t* for different assumptions at 5% level of significance. The calculated values of the said test statistic are less than the critical value of 1.96, therefore it can be suggested that both series are random, independent, homogenous and stationary. Thus it is concluded that both series are suitable for further RFA.

Table 5. *Results of fundamental assumptions for PDS AMS*

Series	Randomness*	Independence*	Homogeneity*	Stationarity*
PDS	$\hat{t} = 1.80$; Since $\lvert\hat{t}\rvert < Z_{1-\frac{\alpha}{2}} = 1.96$ Do not reject H_0	$\hat{t} = 1.48$; Since $\lvert\hat{t}\rvert < Z_{1-\frac{\alpha}{2}} = 1.96$ Do not reject H_0	$\hat{t} = -0.153$; Since $\lvert\hat{t}\rvert < Z_{1-\frac{\alpha}{2}} = 1.96$ Do not reject H_0	$\hat{t} = -0.3279$; Since $\lvert\hat{t}\rvert < t_{1-\alpha/2,(N-2)} = 0.687$ Do not reject H_0
AMS	$\hat{t} = 1.29$; Since $\lvert\hat{t}\rvert < Z_{1-\frac{\alpha}{2}} = 1.96$ Do not reject H_0	$\hat{t} = -0.412$; Since $\lvert\hat{t}\rvert < Z_{1-\frac{\alpha}{2}} = 1.96$ Do not reject H_0	$\hat{t} = -1.22$; Since $\lvert\hat{t}\rvert < Z_{1-\frac{\alpha}{2}} = 1.96$ Do not reject H_0	$\hat{t} = 1.419$; Since $\lvert\hat{t}\rvert < t_{1-\alpha/2,(N-2)} = 1.66$ Do not reject H_0

*5% level of significance

To find the best distribution for both samples, we considered most commonly used distributions for at-site frequency analysis. The goodness of fit of these distributions is evaluated using the most common goodness of fit criteria, i.e., AD and L-moment ratio diagram. Based on the AD testing criterion and the L-moment ratio diagram, the best fitted probability distribution for PDS sample was the GEV while for the AMS sample the GLO distribution. In case of AD testing criterion, the smallest test statistics values

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83518367

would be considered as the best fitted and will be ranked one. As shown in *Table 6,* the best fitted probability distribution is GEV that ranked one in case of PDS sample whereas, GLO in case of AMS. The ratio of sample L-skewness and L-Kurtosis is shown with symbol "+". The closeness of symbol "+" to the curve in the diagram declares the distribution as best fitted for sample at hand. It is apparent from *Figures 1* and *2* that GEV distribution is the best fitted for PDS while GLO for AMS. The outputs of the graphs validated the mathematical results obtained from AD testing criterion.

Table 6. *Determination of best fit probability distribution for PDS AMS*

Distributions	PD Series (n = 126)		AM series (n = 25)	
	AD	Rank	AD	Rank
GEV	0.29438	1st	0.49	2nd
PE-3	5.5266750	4th	6.11	4th
GLO	3.57	2nd	0.47	1st
GPD	3.646	3rd	2.92	3rd

The next step in RFA after declaration of the best fitted probability distribution is the quantiles estimation. Quantile estimation provides estimates to ensure a resilience hydrological structure. Therefore, we constructed a *Table 7* that consists of quantiles estimates for various return periods. These estimates are computed for PDS and AMS samples separately and further their standard errors are given in parenthesis. These standard errors will assure the robustness and efficiency of PDS and AMS samples. The relationship between return periods and occurrence of an extreme event is established through notion of a geometric random variable (waiting time until an extreme event occurs) using mathematical expression: $E(X) = T = 1/p$, which is in fact the mean of the geometric random variable (average time for occurrence of an extreme event, for example exceeding of water flow above certain level of a hydrological structure), where p is the probability of occurrence or exceedance for T year return period. Suppose we have a return period of ten-years, the corresponding probability of exceedance is calculated using above equation as 0.1 and the probability of non-exceedance as 0.9. The corresponding quantile estimates based on the best fitted distribution (GEV for PDS) is 129.64 mm, which implies that in next ten-year, the daily rainfall in the city would exceed 129.64 mm once on the average with a probability of 0.1. These quantiles could be used for planning of water-related emergencies, sustainable water resource management, construction of better flood design estimates in the form of culverts, bridges other hydrological structures in the city. The quantile estimation for AMS series showed significant variation in magnitude as compared to PDS for various return periods. Further, to identify the best technique between AMS and PDS, we calculated the standard errors of these quantiles estimates at different return periods. These standard errors are given in parenthesis as shown in *Table 7*. The standard errors of PDS sample are significantly smaller than AMS sample. It implies that PDS sample outperforms than AMS sample at different return periods which strengthens the use of PDS in the current study. Comparisons of AMS and PDS extreme events have also indicated that for all return periods PDS give more consistent, efficient and robust predictions of extreme rainfall than AMS. The predicted magnitude based on PDS are also more closer to the historical records as compared to AMS. The quantiles estimates

for different return periods are helpful to construct a variety of hydrological infrastructures such as bridges, culverts and others in the city

Conclusions

In this study, we conducted rainfall frequency analysis in the fast growing city Rawalpindi, Pakistan by extracting two series such as PDS and AMS from daily rainfall data measured in millimeters for a period of 25 years (1990-2014). The selection of best sample between PDS and AMS had always been a dilemma in rainfall frequency analysis. This study also provided a comparative analysis of these two techniques. After preliminary trend analysis, for PDS sample extraction we used objective method. The size of the sample for PDS was higher than AMS. After extraction of the required samples, we implemented the most common probability distributions used in statistical hydrology to check the best fit. For this purpose two GOF criteria such as Anderson Darling (A-D) test and L-moment ratio diagram were implemented. The analysis revealed that GEV was best fit for PDS while GLO for AMS. In this study we also found quantiles estimates using the parameters of the best probability distributions for both series. The predicted values based on quantile estimation for AMS series showed significant variation in magnitude as compared to PDS for various return periods. The standard errors of quantile estimates based on these techniques revealed that PDS was better than AMS. PDS would be a more reasonable and effective choice for such type of frequency analysis. Our results are also analogous to the outcomes of earlier studies (e.g., Fischer and Schuman, 2014; Alahmadi et al., 2014; Karim et al., 2017) where PDS technique outperformed than AMS.

Thus we can conclude that the results obtained using PDS sample were generally preferable for at-site quantile estimation. The findings from this study could be implemented in selection of better design criteria for flood management, particularly flood protection measures in the city. This study could also be extended for rainfall frequency analysis in the other areas of Pakistan with similar geomorphologic hydrological characteristics.

Abstract. The egg is a widely consumed food material with the higher nutritional value obtained from poultry. It contains almost all the nutrients needed by metabolism, therefore, the biological value of an egg is high. The aim of this study is to determine the levels of eighteen elements in free-range hen eggs. Eggs (n=217) were collected from February 2017 to September 2017 in the spring, summer and autumn seasons from towns near the Syrian border. The ICP-MS method was used to determine the Na, Mg, K, Ca, Cr, Mn, Fe, Co, Ni, Cu, Zn, Se, Ti, As, Cd, Tl and Pb elements levels in the study. The most abundant elements were Na and K ranging between 248.12-7755 mg/kg and 80.25-4235 mg/kg, respectively. When the element levels of the free-range hen egg samples were examined, it was seen that there was a statistical difference between the seasons while the samples were contaminated with As on an average of 1131.25 µg/kg when the toxic element levels were examined. It was concluded that the element content of free-range hen eggs produced in this region was affected by seasonal changes.
Keywords: *free-range hen eggs, ICP-MS, macro element, micro element, toxic element*

Introduction

Occupation and income status of a society influences nutritional habits and thereby human health. Due to easily accessible, the widely available food source of hen eggs, which are basic food ingredients, consumed a lot in the worldwide. Hen egg has important nutritional value and contributes significantly to a healthy diet with its' high-quality proteins, vitamins, fats, and minerals (Domingo, 2014). A medium-sized egg includes 78 kcal, consisting of 6.5 g of protein, 2.3 g monounsaturated fat on an average. Most of the lipids of the egg are in the form of lipoproteins found in egg yolk as well as proteins located in all parts of the egg (Kovacs-Nolan et al., 2005; Domingo, 2014). It also includes dietary cholesterol, unsaturated fatty acids, and minerals (Fernandez, 2012). In continents surveyed by Food and Agriculture Organization of the United Nations, per capita egg consumption in 2009 varied from 2.3 kg in Africa to 12.7 kg in Europe (FAO, 2012). According to the Central Association of Egg Producers of Turkey (YUM-BIR), Turks consume 200 chicken eggs per person per year (YUM-BIR, 2015).

In recent years consumers began to prefer free-range hen eggs although the yolk color of free-range eggs was lower than that of battery-reared hen eggs (Kucukkoyuncu et al., 2017). Instead of battery-reared system eggs owing to the common wisdom that free-range hen eggs have preferable nutritional quality. In the free-range system, hens

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83698380

have opportunity pasture foraging in around. A close relationship with the environment may cause to be exposed to contaminants (Van Overmeire et al., 2006). And even free-range hen eggs are expected good bio-indicators of the contaminants of the environment in where the hen's pasture (Chang et al., 1989). Despite this well- known view, home-produced foods like free-range hen eggs are not analyzed to any convenience check by a routine program. Monitoring the levels of the macro, trace, and potentially toxic elements are one of the aspects of the food and also environmental quality. Macro and trace elements are found naturally and essential for throughout life (Esposito et al., 2016). But toxic elements such as Pb, Cd, As known to be toxic and have maximum limits by European Commission in some foods but not for eggs (European Commission Regulation, EC No 1881, 2006). The European Food Safety Authority has reported that the environmental pollutants such as toxic element detected in free-range hen eggs that pasture outdoors and more exposed to environmental contamination were higher than those detected in battery-reared hen eggs (EFSA Scientific Report—update of the monitoring of levels of dioxins and PCBs in food and feed, 2012). Actually, a close relationship with the soil identifies higher levels of Co, Zn, Pb in free-range hen eggs (de Freitas et al., 2013).

Şanlıurfa is located along the Syrian border and has four districts on the borderline. These are; Akçakale, Birecik, Harran, and Suruç. In these districts, that they are close of the Syrian war which is ongoing for a long time, the possible transition of toxic element contaminants from the environment to the local consumers and even to the food chain are not existing. The design of this paper focuses on the content of thirteen essential elements (Na, Mg, K, Ca, Cr, Mn, Fe, Co, Cu, Zn, Se, Ni, Ti) and four toxic elements (As, Pb, Tl, Cd) in fresh eggs of free-range hen eggs which should be bio-indicator of pollution. To the best of our knowledge, this study provides the first seasonal variation of elements in free-range hen eggs worldwide. The aims were for (1) an evaluation of concentrations of elements, (2) a vision of seasonal variations, and (3) indication of cautious risk affects.

Material and Methods

Samples

A total of 217 fresh eggs from free ranged hens were used as study material. The samples were separated depending on the seasonal variations as

i) 60 eggs collected in the spring season.
ii) 73 eggs collected in the summer season.
iii)84 eggs collected in the autumn season.

The samples were collected from home producers from Akçakale, Birecik, Harran, Suruç between March to October 2017 as shown in *Figure 1*. They were transported to the laboratory and stored at 4^{o}C until analyses.

Sample preparation and analytical procedures

Egg samples were homogenized by taking into 50 ml sterile falcon tubes. Whole equipment was previously kept for one night in 10% HNO_3 and then washed with ultrapure water to eliminate possible contamination of elements. One g of the homogenized egg samples were mineralized acid digestion with 6 ml HNO_3 65% (v/v) (Merck, Germany) and 2 ml H_2O_2 30% (v/v) (Merck, Germany) in PTFE vessels of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83698380

Mars Xpress (CEM Corporation) microwave system as described in the literature (Esposito et al., 2016). Subsamples were treated as the following procedure; up to 120ºC for 7 min 1600 W and constant 5 min, up to 160ºC for 5 min 1600 W and constant 5 min, up to 210ºC for 20 min 1600 W and constant 5 min. The same procedure was done for every blank sample (1 ml ultrapure water). After the cooling stage to room temperature (22-23ºC), the subsamples were diluted to 50 ml with ultrapure water (MES MP Mini pure, Turkey).

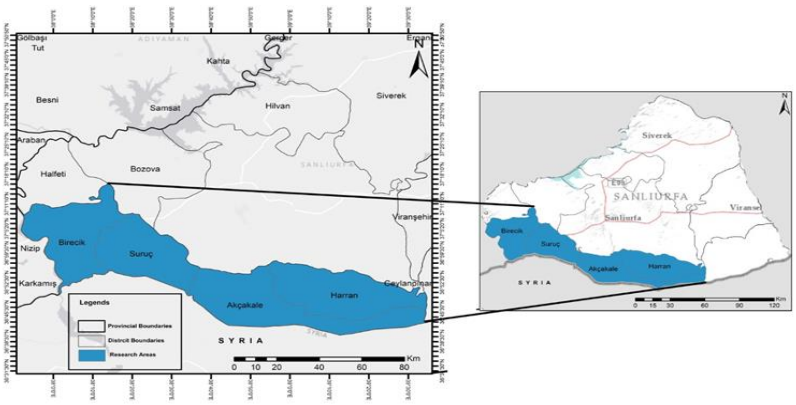

Figure 1. *Map of the study area*

Elemental analyses were done by Inductively Coupled Plasma Mass Spectrometer (ICP-MS) (Agilent 7500ce with an Octopole Reaction System) equipped with a nebulizer (Agilent, Japan), autosampler (Cetac ASX-520), and spray chamber.

All analytical method were performed according to the method of UNI EN 15763: 2010 preferably modified. The following isotopes were measured: $^{23}Na^{+}$, $^{24}Mg^{+}$, $^{39}K^{+}$, $^{44}Ca^{+}$, $^{52}Cr^{+}$, $^{55}Mn^{+}$, $^{56}Fe^{+}$, $^{59}Co^{+}$, $^{63}Cu^{+}$, $^{66}Zn^{+}$, $^{78}Se^{+}$, $^{75}As^{+}$, $^{206}Pb^{+}$, $^{60}Ni^{+}$, $^{48}Ti^{+}$, $^{205}Tl^{+}$, $^{111}Cd^{+}$.

Quality controls were assured to confirm the accuracy of the analytical procedure with the reference materials (NIST SRM 1515 Apple Leaves). The limit of detection and quantification were calculated as three and ten times.

Analyses of certified reference material allowed an assessment of accuracy and precision over a range of element concentrations. Certified values indicated that monitored levels correlated well with certified levels as shown in *Table 1*.

Statistical Analysis

For testing the normality of the data, the Shapiro-Wilk test was performed. In order to compare normal non-dispersive variables in more than two independent groups, Kruskal Wallis and All Pairwise Multiple Comparison tests were used. Spearman Rank Correlation Coefficient was used in testing the relations between numerical variables. For descriptive statistics, mean ± standard deviation values for numerical variables are given. Values of $P<0.05$ was considered as statistically significant. All statistical analyses were performed in order to verify the existence or not of significant differences between the samples. SPSS for Windows version 24.0 package program (SPSS Inc., Chicago, USA) was used for statistical analysis. When the concentration of the element was below the limit of quantification (LOQ) that value did not participate in the statistic.

Results and Discussion

The concentration of Sodium, Magnesium, Potassium, Calcium, Chromium, Manganese, Iron, Cobalt, Copper, Zinc, Selenium, Arsenic, Lead, Nickel, Titanium, Talium, Cadmium in the egg samples are listed in *Table 2*, which reports mean and standard deviation in different seasons and *Table 3* reports median and quartiles of free-range hen eggs. Box plot analyses of groups of data was shown in *Figure 2*.

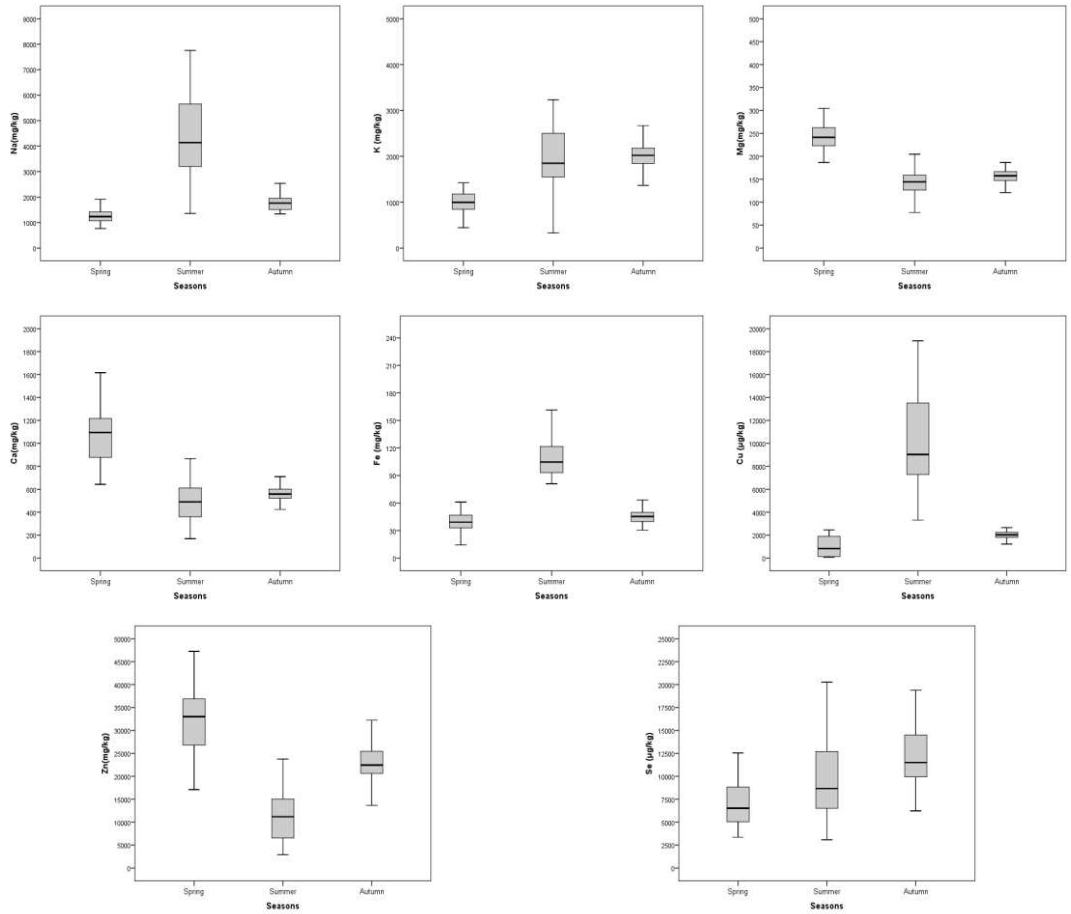

Figure 2. *Box plot of essential elements in free-range hen eggs*

In the present study the sodium content of free-range hen eggs showed an average level of 1278.08 mg/kg in the spring season; this is relatively low when compared with the mean level (1707.73 mg/kg) in the autumn season and also very low when compared with the mean level (4329.86 mg/kg) in the summer season. *Table 4* shows the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83698380

comparison of the levels of elements reported in the different samples of home-grown hen and free-range hen eggs with previous literature. In the literature, the sodium content of eggs showed a mean level of 1149 mg/kg; this is lowly especially compared with the present study (Rubio et al., 2017).

Magnesium concentration of spring, summer, and autumn seasons in free-range hen eggs showed mean levels of 246.15, 143.54, 157.76 mg/kg, respectively. In the literature, a lower value have been reported in Canary Islands (87.5 mg/kg), while value as high as has been found in home-produced eggs from Brazil (674 mg/kg) (de Freitas et al., 2013).

The average levels of potassium detected in free-range hen eggs were 1034.92 mg/kg in spring, 1953.67 mg/kg in summer, and 1964.9 mg/kg in the autumn season. These values are high, especially when compared with the reported data in the literature (Rubio et al., 2017, 2018).

These latter tables report calcium concentrations of 1067.33 mg/kg in spring season while the value is higher than both summer (490.53 mg/kg) and autumn (560.54 mg/kg) seasons. The concentrations in our samples were also comparable to that reported in free-range hens egg from the Island of Tenerife with a mean level of 231 mg/kg (Rubio et al., 2018).

The average level of chromium in the spring season (543.92 μg/kg) is much higher than that detected in both summer (<LOQ) and autumn (<LOQ) season. In the spring, due to the fact that the chromium element is detected in egg samples, agricultural activities in the region are intense and pesticides and foliar fertilizers are generally applied in spring.

The manganese is one of the most abundant elements in the earth crust. The manganese mean content in the spring season (709.41 μg/kg) was higher than the mean content in autumn season (576.16 μg/kg) and in free-range hen eggs in United Kingdom (0.277 mg/kg) (Siddiqui et al., 2011). The iron mean content in the spring season (39.9 mg/kg) was lower than the values found in summer season (112.01 mg/kg) but similar to that analyzed in autumn season (45.65 mg/kg). The mean concentration of iron determined in free-range hen eggs proved to be far higher than the levels reported in eggs in the Island of Tenerife (7.62 mg/kg) (Rubio et al., 2018) and parallel with eggs in Brazil (114 μg/g) (de Freitas et al., 2013).

In the present study, the average level of copper was significantly increased from 974.12 to 9904.66 μg/kg between spring season to summer season afterward in the autumn season the mean copper content was 2012.95 μg/kg. The change rule of the concentration of copper was similar to iron.

The average concentration of Zinc in free-range hen eggs in spring season (32.34 mg/kg) was significantly higher than both summer (11.80 mg/kg) and autumn (22.77 mg/kg) season and was 10-fold higher than reported in fresh cage-reared hens eggs from Canary Islands (Rubio et al., 2017).

The average level of selenium in free-range hens eggs was increased from 7354.92 to 11834.66 between spring to autumn season and marginally higher than found in eggs from residential backyards in Italy (Esposito et al., 2016).

Arsenic is a micropollutant which can be easily detected in the soil, water, fertilizer, and industrial wastes. Long term exposures, arsenic is accumulated in metabolism and should because chronic diseases (Hashemi et al., 2018). The mean concentration of arsenic in free-range hen eggs was 841.66 μg/kg in the spring season, 2545 μg/kg in the summer season, and 990.25 μg/kg in the autumn season.

The reported concentrations of arsenic in egg samples from Italy (Esposito et al., 2016), Australia (Grace and MacFarlane, 2016), Brazil (de Freitas et al., 2013) were 7.0, 30, and 21.5 μg/kg, respectively. The finding of this study is very high than the reported concentrations of arsenic in egg samples from different countries.

The mean value of nickel from Canary Island (Rubio et al., 2018), Italy (Esposito et al., 2016), and Turkey (Uluözlü et al., 2009) were 30, 96, and 90 μg/kg, respectively. These levels are lower than our study (140.25 μg/kg).

Element content in the free-range hen eggs in the spring season

The mean concentration and standard deviation of each element analyzed in the spring season are shown in *Table 5*. Sodium (1278.08 mg/kg) was the most abundant macro-element analyzed in the highest proportion in free-range hen egg samples, followed by Ca>K>Mg.

Table 5. *Descriptive statistics of essential elements for the spring season*

Elements	Akçakale	Birecik	Harran	Suruç
Na (mg/kg)	1280.7±152.97	1440.38±435.26	1244.67±266.59	1146.58±333.55
Mg (mg/kg)	236.3±25.72	254.7±33.09	248.43±39.06	245.17±26.33

The major trace element found in egg samples was selenium (7354.92 μg/kg), followed by Cu>Mn>Ti>Cr>Ni>Fe>Zn>Co. Arsenic (841.66 μg/kg) was the most abundant toxic element found in three free-range hen eggs; Pb, Tl, Cd levels were below the limit of quantification in all samples in the spring season.

Element content in the free-range hen eggs in the summer season

The mean concentration and standard deviation of each element analyzed in the summer season are shown in *Table 6*. The most abundant macroelement in the free-range hen eggs was sodium (4329.86 mg/kg), followed by K>Ca>Mg. As for the trace elements, copper (9904.66 μg/kg) was the most notable in the egg samples, followed by Se>Ti>Fe>Zn. The Cr, Mn, Co and Ni levels were below the limit of quantification in all samples in the summer season. The detected levels of Co and Cd were below the quantification limit. Arsenic (2545 μg/kg) was the most abundant toxic element found in 1 free-range hen egg; Pb, Tl, Cd levels were below the limit of quantification in all samples in the summer season.

Element content in the free-range hen eggs in the autumn season

The mean concentration and standard deviation of each element analyzed in autumn season are shown in *Table 7*. Potassium (1964.90 mg/kg) was the most abundant macro-element analyzed in the highest proportion in egg samples, followed by Na>Ca>Mg. The major trace element found in egg samples was selenium (11834.66 μg/kg),

In spring season, very strong correlations were detected between CaxTi, CaxZn, TixZn, and also strong correlations were detected between NaxZn, NaxCa, KxSe, CaxFe, TixFe, FexZn as shown in *Table 7*. Interestingly there wasn't a correlation between elements with Mg, so further studies required.

In the summer season, very strong correlations were detected between NaxK, NaxCu, CaxZn, KxCu. Strong correlations were found between KxFe, CaxTi, TixZn as shown in *Table 9*. In autumn season, very strong correlations were detected between CaxTi, CaxZn, and strong correlation between NaxCu, TixZn, CuxSe as shown in *Table 10*. A correlation between CaxZn were detected in all seasons thus it means that the season is not influencing this very strong correlation.

Conclusion

In this study, the element levels of eighteen elements in the free-range hen egg samples were examined by means of ICP-MS. Free-range hen eggs are an acceptable source of essential elements, in particular, of Na, Mg, K, Ca, Cu, Fe, Zn, and Se. The presence of Cr in the spring season, Cu in the summer season and Se in all seasons in our samples may be related to a geographic source. Finally, the lack of data on the presence of some Ti in free-range hen eggs does not allow comparisons. It was seen that there was a statistical difference between the seasons so it was concluded that the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83698380

element content of free-range hen eggs produced in this region was affected by seasonal changes.

Compilation of these data may serve to understand the element composition and to define the reference levels of macro, trace and toxic elements to be used in food safety assessments of free-range hen eggs produced in an area near the Syrian border because it was determined that eight samples of free-range hen eggs were contaminated with As on an average of 1131.25 μg/kg when the toxic element levels were examined. It is important to regularly monitoring the levels of toxic elements in free-range hen eggs for assessing the risk of long-term exposure.

(Received 7th Mar 2019; accepted 3rd May 2019)

Abstract. Rapid development of economy has obviously promoted the growth of carbon emission, which causes the ecological environment more fragile. How to calculate the energy carbon footprint and explore tradeoff between energy and environment becomes further significance. This study examines energy carbon footprint in Liaoning Province. The main goal of this study is to calculate the energy carbon footprint using random forest algorithm and verify the performance of random forest algorithm. The study first examines factors of energy carbon emissions and implicates calculating method of energy carbon footprint. Subsequently random forest algorithm is developed in calculating energy carbon footprint. The results show that the calculated results of random forest algorithm is close to the actual value and the trend of change is basically similar to the actual value. Furthermore, the performance of random forest algorithm is compared with Partial Least Squares algorithm. The relative error and average relative error of random forest algorithm are both less than Partial Least Squares algorithm.
Keywords: *carbon footprint, LMDI, energy efficiency, low carbon economy, energy structure, strategies*

Introduction

An ecosystem is an open system, in which many basic substances are continuously cycled. Ecosystem has the capacity to maintain stability via self-regulation. However, when strong pressures on the ecosystem go beyond its threshold level, the ecosystem loses self-regulation ability and the ecosystem structure will be damaged (Ginestet et al., 2013; Tao et al., 2014; Chen et al., 2018). In an age of limited resources and destructive ecology, the idea of ecological civilization should give close attention to build a safe ecological environment (Yasar and Kalfa, 2012).

Carbon footprint which refers to the overall emissions of greenhouse gases can be analyzed by life cycle assessment and comes from the concept of ecological footprint (An and Xue, 2017; Sun, 2017). It is applied to measure the energy using and reveal the trends on climate change and atmospheric environment (Hertzberg and Schreuder, 2016). Current research is focused on the assessment of the carbon footprint model and the approach to reduce carbon footprint (Mancini et al., 2016; Qi et al., 2018; Long et al., 2018). Also many factors are mentioned to reduce the carbon footprint (David et al., 2009; Sovacool and Brown, 2010). Besides, some methods such as input-output model, theoretical modeling, objective program method, profit-maximized carbon cycle model (Dominic et al., 2008; Kenny and Gray, 2009). Studies have shown that carbon accounting standards for the production and consumption-based so that newly industrialized countries face a serious carbon leakage (Sun and Zhou, 2016). The carbon footprint of the developed countries has been seriously underestimated. Therefore, it is recommended to consume carbon footprint accounting system as a benchmark by the rules of regional trade agreements, eliminate carbon leakage and promote equitable global range of carbon emission reduction targets.

DOI: http://dx.doi.org/10.15666/aeer/1704_83818394

The aim of this paper is to develop a random forest algorithm model for calculating the energy carbon footprint in Liaoning Province and identify the main driving factors of carbon emission. The reminder of this paper is structured as follows: after the introduction section, section 2 describes the method of energy carbon footprint, random forest algorithm and model fitting evaluation model. Results are given in Section 3 and discussion is given in Section 4. Finally, the conclusions are summarized in Section 5.

Material and methods

Energy carbon footprint

Based on the actual situation of energy consumption and economic development and taking into account the availability of data, the following categories were chosen for the calculation of carbon footprints: raw coal, coke, crude oil, petrol, diesel oil, black mineral oil and natural gas. Raw coal referred to the coal obtained after the removal of dirt and iron pyrite from the run-of-mine (rom) coal. Coke referred to the solid substance obtained after carbonation of coking coal at a high temperature (Chelgani et al., 2016; Bergthorson, 2018). Crude oil was the mineral oil comprised of the polymer from natural hydrocarbon source. The black mineral oil was the black sticky residue obtained from the distillation of crude oil, or its mixture with lighter components. It was mainly used as the fuel for the steam boiler and other heating furnaces, large slow diesel oil fuel, or other industrial fuels (Romijn, 2011; Pragya et al., 2017; Dalir et al., 2018).

According to the standard coal, the content of carbon emitted from the energy can be calculated clearly. Given the 2006 IPCC Guidelines for National Greenhouse Gas Inventories published by Intergovernmental Panel on Climate Change (IPCC) advice, the carbon footprint of energy consumption in China was computed (Druckman and Jackson, 2009; Ohimain, 2012; Affuso and Hite, 2013). In addition, the coefficient of each fuel conversion, the standard coal identified in China 2015 List of Greenhouse Gases, as well as the way to compute carbon footprint and carbon emission are as follows:

$$f_{CE} = \sum_i \frac{44}{12} \cdot \beta_i \cdot \varepsilon_i \cdot Q_i \cdot V_i \cdot q_i \cdot 10^{-3} \quad \text{(Eq.1)}$$

where

- f_{CE} is carbon footprint emitted from all kinds of energy.
- β_i is the conversion factor of i type of energy which was achieved by transforming the fuel into energy (TJ) in accordance with the net calorific value.
- ε_i is the transforming coefficient for i kind of energy into standard coal Which was the benchmarking for transforming a variety of energies into standard coal.
- Q_i is the consumed amount of i type energy.
- V_i is carbon emission factor of i type energy.
- q_i is the carbon oxidation ratio of i type energy.
- 10^{-3} is the unit conversion coefficient.
- $\frac{44}{12}$ is the conversion coefficient between carbon and CO_2.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83818394

The conversion factor of standard coal was identified in the General Principle for Computing Comprehensive Energy Consumption (GB/T2589-2008). The carbon emission factor, carbon oxidation ratio and energy conversion factor were identified in IPCC National List of Greenhouse Gases (2006). More detailed information of the conversion parameters is shown in *Table 1*.

Table 1. *Parameters of calculating carbon footprint*

Energy	ε_i **(kg kg^{-1})**	V_i **(kg J^{-1})**	q_i **(%)**	β_i **(TJ g^{-1})**
Raw coal	0.7143	25.8	0.90	26.7
Coke	0.9714	29.2	0.90	28.2
Crude oil	1.4286	20.0	0.98	42.3
Petrol	1.4714	20.2	0.98	43.0
Diesel oil	1.4571	20.2	0.98	43.0
Black mineral oil	1.4286	21.1	0.98	40.4
Natural gas	12.1430	15.3	0.99	48.0

Random forest algorithm

Random forest (RF) algorithm is a nonlinear modeling tool which proposed by Leo Breiman (Zhou and Qiu, 2018). It is a useful method to prevent the nonlinear approximation of statistical relationships problems among different variables (Abellán et al., 2018). This method is widely used in cancer analysis, data biology, astronomy, and other fields of discriminate analysis and feature selection (Dalir et al., 2018; Kamińska, 2018). But it is nearly used in calculating energy carbon footprint and few studies reported the use of the RF algorithm in energy carbon footprint applications.

RF algorithm begins with bootstrap sampling method, random vector θ comprise the combined model:

$$h(X,\theta_m), m = 1,2,\text{L},M \quad \text{(Eq.2)}$$

X is the input variable, θ_m is the independent and identically distributed random vector. If the output variable is Y, then the original is (X,Y). The predicted sequence $\{h(\text{X},\theta_1), h(\text{X},\theta_2),\cdots, h(\text{X},\theta_m)\}$ will be obtained by training of m times and this result can be constructed predictive model prediction and eventually results:

$$\overline{h}(X) = (1/M)\cdot\sum_{m=1}^{M} h(\text{X},\theta_m) \quad \text{(Eq.3)}$$

The prediction can be obtained vector $h(\text{X})$ of the extrapolation error mean:

$$EMSE = EX,Y(\text{Y}-h(\text{X})) \quad \text{(Eq.4)}$$

It has its inherent characteristics of random forests. When the number of trees in the forest tends to infinity, there is:

$$E_{X,Y}\left(Y-\alpha v_k h\left(X,\theta_k\right)\right)^2 \to E_{X,Y}\left(Y-E_\theta h\left(X,\theta_k\right)\right)^2 \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83818394

For all θ, then:

$$\mathrm{PE}^{*}\left(forset\right) \le \rho\,\mathrm{PE}^{*}\left(tree\right) \quad \text{(Eq.6)}$$

$$\mathrm{PE}^{*}\left(tree\right) = E_{\theta}E_{X,Y}\left(Y - h(\mathrm{X},\theta)\right)^{2} \quad \text{(Eq.7)}$$

ρ is weight-related between the $Y - h(\mathrm{X},\theta)$ and reaming $Y - h(\mathrm{X},\theta)$, θ is independent.

Realization of random forests is as follows:

Drawn n_{tree} from the original sample by bootstrap. Each sample has not been able to get a sample consisting out-of-bag (OOB) as the test sample.

Set of raw data variables *P*, in each tree each node randomly selects M_{try} feature, and then select the best branches.

In random forest, the choice of the parameters M_{try} is in accordance with $M_{try} = P/3$.

Using the effect of the model to evaluate the residual mean square of OOB prediction. As shown in the following formula:

$$MSE_{OOB} = \frac{\sum_{1}^{m}\left(y_i - \hat{y}_i^{\,OOB^2}\right)}{n} \quad \text{(Eq.8)}$$

$$R_{RF}^{2} = 1 - MSE_{OOB} / \hat{\sigma}_{y}^{2} \quad \text{(Eq.9)}$$

- y_i is the actual value of the output variable of the OOB.
- $\hat{y}_i^{\,OOB^2}$ is the corresponding forecast value.
- $\hat{\sigma}_{y}^{2}$ is the variance of the predictive value of the OOB.

Study area

Liaoning Province is located in the south of Northeast China, bordering on the Huanghai Sea and Bohai Sea in the south, and acrossing the Yangtze River from the North Korea, as shown in *Fig. 1*. It is the gateway to the northeast and the eastern part of Inner Mongolia Autonomous Region of China. Liaoning Province is an important old industrial base in China and is one of the provinces with a relatively complete industrial category. The land area of Liaoning Province is 148,000 square kilometers, the mainland coastline is 2,292 kilometers long and the offshore waters cover an area of 68,000 square kilometers. It is a key area for grain production, animal husbandry, fisheries, high-quality fruits and a variety of special products. At present, there are 39 major categories, 197 medium-sized and 500 small-sized industries in Liaoning Province. With superior location and convenient transportation, Liaoning Province is an important gateway to the northeast area and an important gateway to the Eurasian Continental Bridge. It is an area with relatively developed infrastructure such as transportation and electric power.

DOI: http://dx.doi.org/10.15666/aeer/1704_83818394

Liaoning Province is located in the northern margin of the Pacific Rim. It has excellent geological mineralization conditions and is rich in mineral resources. More than 110 minerals have been discovered, of which 66 have been proved. The magnesite of Liaoning Province is an advantageous mineral in the world, with a reserve of 2.56 billion tons and about 25% of the world. Minerals with advantages in the country include boron, iron, diamond, talc, jade and so on. The minerals with comparative advantages are mainly coal, coalbed methane, natural gas, gold and silver.

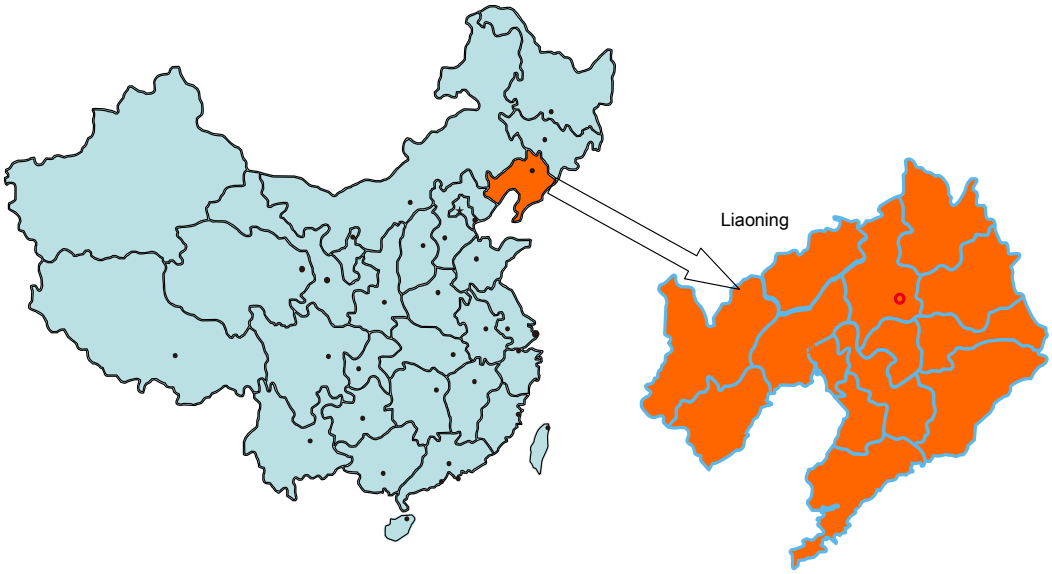

Figure 1. *Location of Liaoning province in China*

In this study, Liaoning Province is chosen to analyze the energy carbon footprint characteristics. First, Laioning Province is listed among the circular economy in 2008. The energy carbon emission should be slowed down dramatically to fulfill the development of circular economy. The circular economy is to reach the harmonious circulation of the economic system and the natural ecosystem through the waste reduction and resource harmlessness in the economic development. The basic principles of circular economy are reduction, reuse, and resource utilization. It is the fundamental change in the traditional growth model of mass production, mass consumption and mass abandonment. Circular economy is a production activity process that comprehensively utilizes energy and waste in accordance with the method of sustainable development under the guidance of sustainable development.

Liaoning Province is a major province of heavy chemical industry with large resource consumption and environmental pollution. Under the traditional economic development mode, the excessive development of resources has increasingly affected economic development and social progress. The depletion of resources is to force transformation to circular economy in Liaoning Province.

Second, as a province depended on nature resources, Liaoning Province is highly similar to other resource-based provinces in industrial transition. Third, because of the vulnerable environments pollution, location and regional characteristics, Liaoning Province deserve to be studied.

DOI: http://dx.doi.org/10.15666/aeer/1704_83818394

Data acquisition

Liaoning is a resource-dependent province, while the most common used are raw coal, coke, crude oil, petrol, diesel oil, black mineral oil and natural gas. In this section, these seven kinds of different energy are chosen to calculate the energy carbon footprint. Raw coal refers to the coal after screening to remove the meteorite, pyrite and so on from the ground or underground. Coke is a kind of solid fuel which is made by high temperature dry distillation of coal, which has high calorific value and is mostly used for iron making. Crude oil is crude oil that is directly extracted from oil wells. It is a dark brown or dark green viscous liquid or semi-solid combustible material composed of various hydrocarbons. Petrol, diesel oil and black mineral oil are liquid oil produced by crude oil.

The energy consumption data used in this section was mainly retrieved from China Statistical Yearbook, China Energy Statistical Yearbook, China Forestry Statistical Yearbook, China Agriculture Statistical Yearbook, and Liaoning Statistical Yearbook published from 1998 to 2016. Part of the data was obtained from the Liaoning provincial government website and Liaoning Statistical Bureau website. The part of the data, which was missing, was compensated by the method of moving averages. Year 1998 was considered as the benchmark, to avoid the influence of price level variations.

Fig. 2 shows energy consumption in Liaoning Province from 1998 to 2016. It is shown that the energy consumption is a increasing trence.

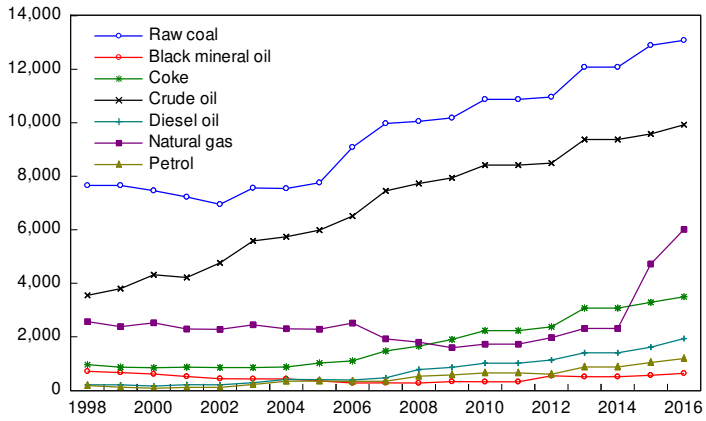

Figure 2. *Energy consumption in Liaoning Province from 1998 to 2016 (unit: million tons)*

Results

Evaluation results of carbon footprint

According to the calculating method of energy carbon footprint mentioned above, the normalized energy carbon footprint and energy carbon capacity as well as energy carbon surplus in Liaoning Province from 1998 to 2016 are figured up. *Fig. 3* shows the carbon footprint (10^4 ton) in Liaoning from1998 to 2016. As shown in *Fig. 3*, the overall carbon footprint in Liaoning Province increased by 236.768% with an annual rate of 13.154% from 410.164 million tons in 1998 to 971.139 million tons in 2016. Energy carbon footprint caused by coal has been the dominant part of energy carbon footprint. Since 2003, the carbon footprint of energy consumption has started a new round of rapid growth. In the period of national economy rapid developing, while

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83818394

accelerating the process of urbanization and a series of external factors driven by the energy consumption continues to rise. The promotion and use of natural gas as well as the rapid growth of private cars has further increased the energy requirements and consumption in Liaoning Province. The carbon footprint of energy consumption in Liaoning Province is mainly influenced by the social and economic factors. To grasp the dynamic change trend of future energy consumption is of great significance to the implementation of sustainable development in Liaoning Province.

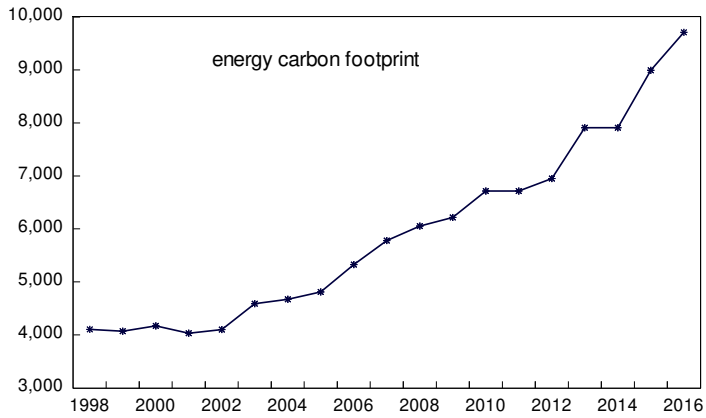

Figure 3. *Carbon footprint in Liaoning from 1998 to 2016 (unit: million tons)*

Fig. 4 shows the each energy carbon footprint in Liaoning from 1998 to 2016.

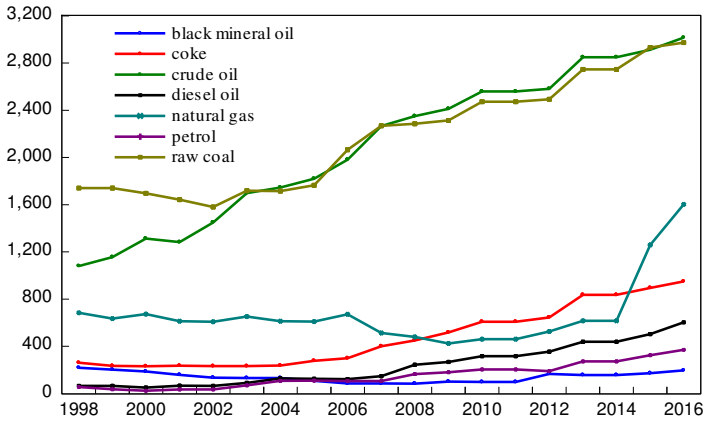

Figure 4. *Carbon footprint of each energy in Liaoning from 1998 to 2016 (unit: million tons)*

It is clear that energy structure of carbon footprint in Liaoning Province is relative stable. The proportions of the raw coal and crude oil have decreased and the proportion of the natural gas increased gradually. The main sources of greenhouse gases on a global approach include consumption of fossil fuels and primary energy. Coal combustion is one of the most important ways of pollution. Primary energy structure dominated by coal, which is impossible to get a complete change in the short term coupled with relatively outdated coal mining technology and refining our processing methods. It has increased the pressure on the government for environmental protection. This will give our global greenhouse gas control and a tremendous challenge.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83818394

Evaluation results of random forest algorithm

The major application of the random forest algorithm in this study was to calculate carbon footprint. Thus, the training dataset was selected from the statistical report from Chinese official bulletin. Then the sampling size and feature number were determined based on the principle of minimal error. And the results were generated with the training dataset with specific sampling size and feature. After a comparison of parameters and multiple simulation experiments, a set of optimal parameters is obtained. Finally, according to the simulation process, the simulation experiment is carried out with this set of parameters: M_{try} is 4 and n_{tree} is 600. The result of random forest algorithm is shown in *Fig. 5.*

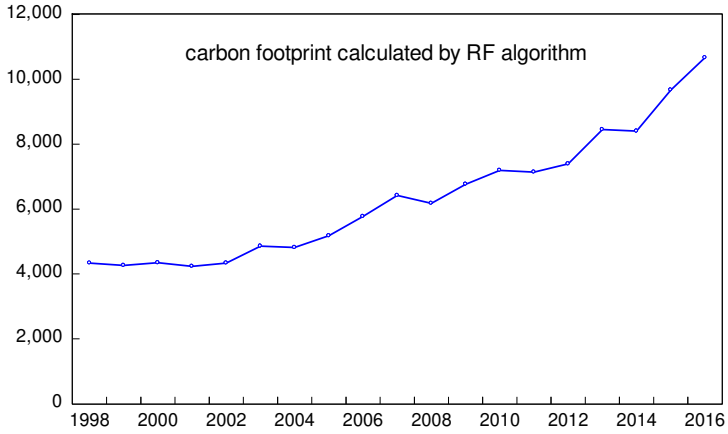

Figure 5. *Carbon footprint calculated by random forest algorithm*

Fig. 6 shows the calculation results of carbon footprint of Liaoning Province by each algorithm.

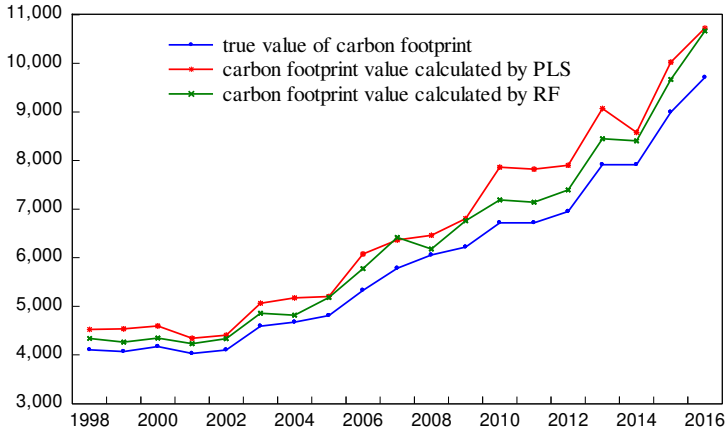

Figure 6. *Comparison of algorithm accuracy*

It can be seen from *Fig. 6* that the calculated results of random forest and PLS are both close to the actual value, and the trend of change is basically similar. However, the value calculated by PLS algorithm is higher than random forest algorithm and the actual

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83818394

value, which indicating that random forest algorithm has higher accuracy. Besides, random forest algorithm has a high accuracy comparing to the linear regression or logistic regression. The main reason of the high accuracy is generated by the random nature in both sampling size and feature. The other reason of the high accuracy is the application of bootstrap method in the algorithm.

Fig. 7 shows the absolute error of each algorithm and *Fig. 8* shows the relative error of each algorithm in calculating the carbon footprint of Liaoning Province.

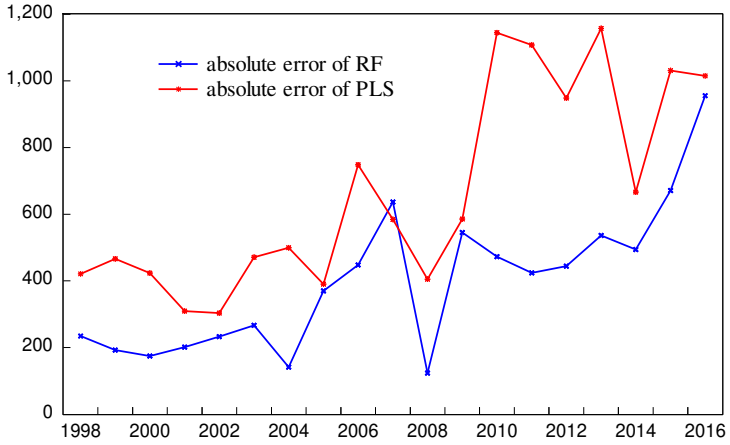

Figure 7. *Absolute error of each algorithm*

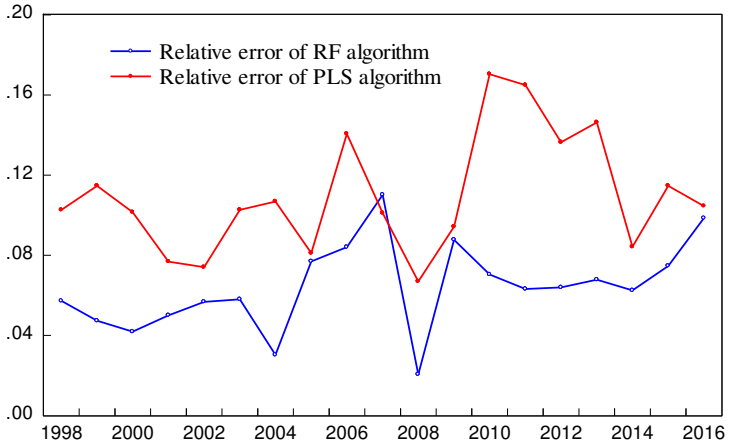

Figure 8. *Relative error rate of each algorithm*

It can be seen from *Fig. 8* that the random forest model has little relative error with the actual value of energy carbon footprint. The relative error of the PLS algorithm is larger and the relative error is at most 0.1704. The relative error of random forest algorithm is less than PLS algorithm, with the largest relative error being 0.1101 and the smallest being only 0.0204. In addition, from the aspect of average relative error, the average relative error of random forest algorithm is 0.0643, while the average relative error of PLS algorithm is 0.1097, which also verifies the superiority of random forest algorithm in reducing the computational error. Thus the results of *Fig. 7* and *Fig. 8* are consistent with the accuracy evaluation of the reflected algorithm.

DOI: http://dx.doi.org/10.15666/aeer/1704_83818394

Sensitive analysis of random forest algorithm

Random forest algorithm is mainly to select the appropriate parameter values by OOB errors. The relationship between M_{try} and OOB error was shown in *Fig. 9*. It is shown that when M_{try} is 2, the OOB error reaches a peak value of 0.000181. When M_{try} value is 7, a minimum of OOB error is 0.000071. With M_{try} increments, OOB error has ups and downs but overall tends to increase.

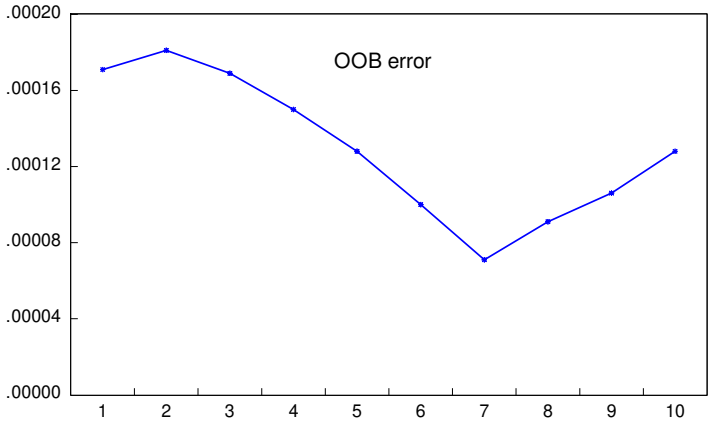

Figure 9. *Relationship between the number of split variables and OOB error*

Discussion

Driving factors of energy carbon footprint

The LMDI (Logarithmic Mean Divisia Index) decomposition method is an empirical research method proposed by Ang et al. in 1998 to decompose and measure energy carbon footprint factors. This method extends the Kaya identity and uses the log-average formula to solve the problem. The elements are decomposed and can effectively eliminate the residuals (Branger and Quirion, 2015). Introducing it into this study, it is conducive to the decomposition of energ carbon footprint driving factors. Considering the complexity of energ carbon footprint systems, the openness and availability of economic data, the influencing factors of energy carbon footprint (Y) is devided into energy structure (X1), energy efficiency (X2), energy intensity (X3) and economic development (X4). The energy carbon footprint factors are decomposed through LMDI, as shown in *Fig. 10*.

The energy structure effect is further exceeded than that of energy effiency, which are the major contributor to the increase in energy carbon footprint. Energy intensity and economic development can curtail the increase in energy carbon footprints. In particular, the energy intensity effect was reduced from -0.1157 to -1.3189. The economic development effect was reduced from -0.0064 to -0.1329. It means that adjusting energy structure can reduce energy carbon footprints and particularly alleviate dependence on primaryenergy. And the use of new energy and the development of green energy can also alleviate thegreenhouse effect.

Based on the accumulative effects of energy carbon footprint factors, the energy structure and energy intensity effects contribute the most to the increase in energy carbon footprint, which is shown in *Fig. 11*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83818394

Duro (2006) provide a methodology for decomposing international inequalities in per capita CO_2 emissions into Kaya (multiplicative) factors which indicated that energy intensity have made a less significant contribution to energy carbon footprint. This paper demonstrate energy intensity effects contribute the most to the increase in energy carbon footprint. In fact, energy intensity is truly affected the energy carbon footprint. This paper is the continuation of energy carbon footprint driving factors.

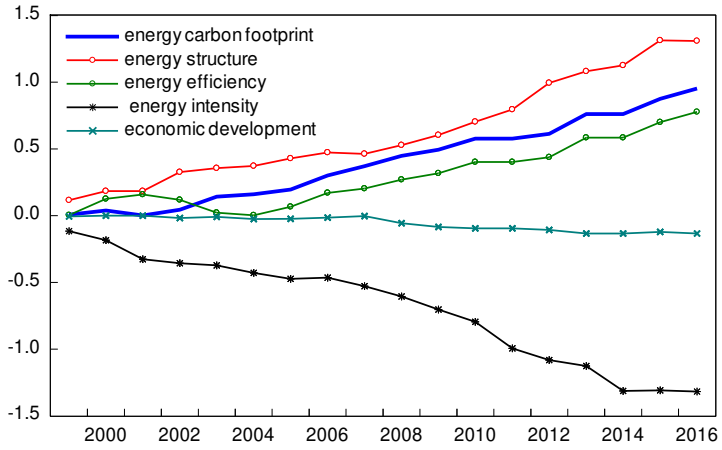

Figure 10. *Factor decomposition of carbon footprint in Liaoning*

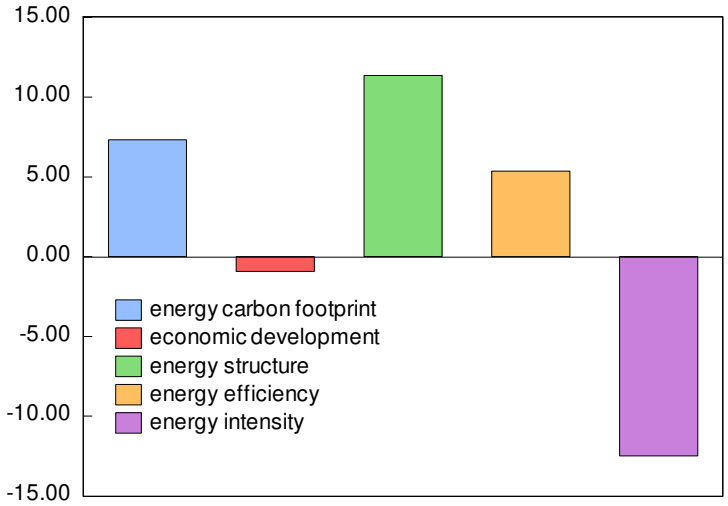

Figure 11. *Cumulative effect of energy carbon footprint*

Besides, Liu (2007) analyzes the change of industrial carbon emissions from 36 industrial sectors in China over the period 1998–2005 and the industrial carbon emissions are decomposed into carbon emissions coefficients of heat and electricity, energy intensity, industrial structural shift, industrial activity and final fuel shift. The overwhelming contributors to the change of China's industrial sectors' carbon emissions in the period 1998–2005 were the industrial activity and energy intensity. This paper also verifed that energy intensity was contribute the most to the increase in energy carbon footprint, which indicated the accuracy of LMDI.

Strategies to decrease carbon footprint

The random forest algorithm used for calculating energy carbon footprint in Liaoning Province reveals the dynamic mechanism and trance of energy carbon footprint. The result of random forest algorithm shows that carbon footprint of energy carbon footprint grow rapidly. This dynamic mechanism also provides a theoretical support and data basis for the growth of carbon footprint and the transformation of economic development model. The conclusion is that the economic development of the rapid increase in carbon footprint played a crucial role. Based on empirical results, combined with the national conditions and development of advanced foreign experience, it proposes relevant measures to mitigate the carbon footprint growth and development of low-carbon economy recommendations. The following recommendations should be taken into consideration so as to decrease the carbon footprint and promote the national economy for sustainable development.

Increase energy efficiency and develop low-carbon economy

Much effort should be made to optimize the energy structures, reduce environmental pollution, develop the green energy, accelerate the modernization of enterprises, increase the quality of economic growth, and finally create a new pattern to develop economy. At the same time, the low-carbon concepts such as green lifestyles, green manufacturers should be advocated and the public awareness of environmental protection should be heightened.

A collaborative reverse logistics network should be established

The reverse logistics can be outsourced to those third-party reverse logistics enterprises for expertise. Thus it can be exploited to increase the management efficiency, decrease resource consumption and reduce the management risks. A prompt product recalling system should be built and the renewable materials should be recommended to achieve the environmental protection.

Design products in an eco-friendly way

The effect on environment and resources should be completely considered in the life cycle of products. And the waste rate of products should be decreased in order to reduce the adverse effect of products on the environment and maximize the resource utilization rates. Meanwhile, renewable resources and secondary energy should be used to slow down exhaustion of resources and ensure sustainable supply of resources.

Conclusions

The goal of this study has been to gain an understanding of the calculation of energy carbon footprint in Liaoning Province. We characterized the energy categories for the calculation of carbon footprints: raw coal, coke, crude oil, petrol, diesel oil, black mineral oil and natural gas. The empirical model subsequently used to calculate the energy carbon footprint in Liaoning Province. In order to evaluate the performance of random forest algorithm, the PLS algorithm is compared with the models proposed in this paper. The results showed that random forest algorithm not only can control parameter deviations, but also it can enhance the precision and accuracy of algorithm.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83818394

The utility of random forest algorithm and results proposed in this paper can be extended by examining the energy carbon footprint of the other regions and countries.

As guidance for the future research, the random forest algorithm addressed in this paper can be enhanced to identify the main environmental and social driving factors of energy carbon footprint in Liaoning Province. It could be highly helpful for public sector to formulate energy policies. Besides, random forest algorithm can be used to deal with the other environmental and social numerical problems.

ANALYSIS OF AGRICULTURAL DEVELOPMENT PLANNING IN LOW HILLY RED SOIL REGION BASED ON PLANTING STRUCTURE

WANG, X.-L.

School of Economics and Management, Zhejiang University of Water Conservancy and Electric Power, Hangzhou, 310018 Zhejiang, China

(Received 8th Mar 2019; accepted 21st May 2019)

Abstract. The main aim of this study is to increase the income of farmers, and to further elaborate the development of low hilly red soil resources and cultivate industries with regionalized agricultural characteristic. By performing principal component analysis of the main agricultural products and determining the influencing factors of the main agricultural products in the low hilly red soil in the region of Jinhua and three key agricultural planting areas, the following conclusion can be drawn: we should expand the scale of land management, improve the basic construction of irrigation and water conservancy, promote the development of agricultural land consolidation projects, and implement the construction of agricultural ecological protection, so as to improve agricultural output and improve agricultural production performance.
Keywords: *the income of farmers, industrial layout, the potential of land resources, Zhejiang Province, agricultural production performance*

Introduction

With the rapid development of Zhejiang's economy, the situation surrounding land resources is becoming increasingly tense (Song, et al., 2012), the contradiction between people and land is becoming more and more prominent, the speed of agricultural development is slowing down, the comparative benefits of agriculture are declining, and the influence of land is growing over the industrial and agricultural production of Zhejiang Province and the sustainable development of the national economy (Zhang, 2011). It leads to some important influencing factors as the foundation of the national economy, agriculture is the basis and precondition for the existence and development of other industries such as commercial trade and crafts. (Gao, 2006). The potential method to accelerate the development of land reserved resources has become an important engine for promoting Zhejiang's economic development (Lü et al., 2000).

In the hilly areas of Zhejiang Province, the low hilly red soil is spread over most of the province's cities. For a long time, due to the long-term unreasonable management of low hilly red soil, single operation, deforestation, unreasonable land reclamation, excessive mining and quarrying (Shen et al., 2013), out-of-control population growth, combined with harsh climatic conditions (serious drought) and the inherent vulnerability of low-valve red soil ecosystems, make the above-mentioned huge advantages and potentials of low hilly red soil not only fully exerted, but also initiate various resources and ecological environment degradation processes (Chen, 2004). On the contrary, it is becoming more and more serious, and the contradiction between people and land is becoming more and more prominent (Zhang, 2013). At present, the development of low hilly red soil agriculture faces the following problems:

First, people increase their land demand, and the contradiction between people and land is prominent (Dai, 2005). The per capita cultivated land and agricultural labor force is extremely limited, the quality is poor, and the development investment is large. With

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83958415

the development of the market economy, it only pays attention to economic opening, but neglects the comprehensive development of resources (Zeng et al., 2006). The phenomenon of arable land abandonment is quite common, and the encroachment and pollution of cultivated land in the development zone is also increasing (Zhang, 2014). The serious slippage of grain production, coupled with the rapid growth of the population, the contradiction between the reverse development of man and land is quite sharp, and agriculture is shrinking.

Second, the agricultural structure is unreasonable and the advantages of the hills have not been realized. In terms of landform and landscape composition, Zhejiang Province has the characteristics of "seven mountains (Deng and Zhang, 2003), one water and two fields", with mountains and hills as the main body, and low hilly red soil areas accounting for about 38% of Zhejiang Province. In the use of land resources, the long-term implementation of the cropping industry as the main food-centred single unreasonable agriculture "model" is only concentrated on the valley plains, mountains and inter-valley valleys (Ni, 1982), basins and low hills. The relatively intensive agricultural operation was carried out in the gently-sloping section of the (Taiwan) area, while the vast mountains and hills in Zhejiang Province were basically idle or insufficient due to extensive management.

Third, the soil resources are degraded and the ecological environment is seriously damaged. The long-term unreasonable development and utilization of resources, combined with harsh climatic conditions, especially severe seasonal rains and droughts, as well as special soil and site characteristics, have led to and exacerbated Zhejiang Province, especially in the densely populated low-lying red soil agricultural areas. Soil erosion and fertility declined, and other processes of soil and agro-ecosystem degradation occurred as well. Therefore, strengthening the management and development of low hilly red soil and improving the agricultural output of low hilly red soil region are effective ways to improve the agricultural benefits of Zhejiang Province.

The low hilly soil region is affected by natural conditions such as topography, climate, parent material and hydrology, and human production activities. It has obvious regional characteristics. Different soil textures and physical and chemical properties determine the development and utilization of land by humans. By understanding the characteristics of various planting types, soil resources development can be rationalised and a stable and virtuous cycle of the soil system can be achieved. Taking the acceleration of agriculture and rural modernization as the starting point focus should be on increasing farmers' income (Jong, 2001), taking market as the guide and relying on science and technology to develop low hilly red soil resources and cultivating industries with regionalized agricultural characteristic. According to the objective needs of social and economic development and regional nature, social, economic, technological and ecological conditions, close focus should be on adapting to the new requirements of agricultural development, facing the needs of the province's internal and external markets, giving play to regional advantages, accelerating the adjustment of agricultural industrial structure, planting agricultural products that can meet market demand, and developing and managing low-lying red soil resources. It is of great practical significance to analyze the planting structure of agricultural products in the low hilly red soil region. This study is based on overall planning, keeping the social economic and ecological benefits unified, adapting to local conditions, maintaining the characteristics of land and agricultural utilization, safe production, efficiency, optimizing resources,

DOI: http://dx.doi.org/10.15666/aeer/1704_83958415

comprehensive development and other principles, in the main distribution area of low hill red soil in Zhejiang Province.

Materials and methods

Literature review

China was one of the first countries to conduct land type research. As early as the 5th century BC, there were records of land type division. According to records, Zhou Li in the Warring States Period divided the land of the country into five categories: Shanlin, Kawasaki, Hill, Wenyan and Yuan. According to the topography, the "People in the Pipeline" divides the national land into three categories: "Putian", "Hill" and "Mountain". The determination of land type is very comprehensive.

(1) About land type division

Since the 1930s, many countries have conducted various investigations and studies on land types and land resource utilization in order to increase grain production and comprehensive development and utilization of land. Former Soviet geographer Berger published his book on "The Soviet Landscape Geography Zone" is a comprehensive exposition of landscape geography, the idea of comprehensive research on land and a systematic theoretical summary of the comprehensive features of land from a geographical perspective.

In the late 1950s, with the full development of China's natural zoning work, some geographers conducted land type surveys and cartographic studies at different scales. For example, Yan Qinshang's research (Yan, 2012; Rawat et al., 2019) on landscape mapping in the Kangding, Jiulong, and Yajiang areas of the Tibetan area, such as Isachinko, etc.; Yang Newzhang's to the west of the Tolahai River in the Qaidam Basin and the Malcommi in western Sichuan Research on the natural landscape of the Yaluolin area.

Since the 1990s, land type research has begun to be combined with practical work, and the scope has gradually focused on small and medium-sized areas. At the same time, significant progress has been made in land cover change and landscape ecology. The main researches of this period were the followings: Zhang (2000), Wang et al. (2000), Junior et al. (2019), Yang (2001), etc. applied remote sensing images, multi-source remote sensing data and other image data to the extraction of land types. Papers by Liu (1990), Shen (1992), Jiao et al. (2005), Liu and Li (2009), Khanchoul and Boubehziz (2019) studied the land types and mappings of the Oasis area in the Hexi Corridor, the agro-pastoral interlaced zone, the hilly area and the Loess Plateau in the arid regions. Liu Wei (2004), Yang et al. (2002), Fu et al. (2001), Liu and Chen (2002), Dali and Kamarudin (2018), proposed corresponding theoretical methods and zoning schemes for China's ecological zoning research. Wang et al. (2001), Cai (2001), Wang and Bao (1999) discussed scales for land use/land cover change, driving force by investment intensity of manpower and physical resources, the social economic output level, the intensity of natural disasters disturbance and educational level of workers.

(2) Indicators on the classification of land types

As early as the early 1960s, some developed countries (Xie et al., 2008) and some international organizations (Huang and Cai, 2005) began to use the relevant indicator

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83958415

system to evaluate economic and social development issues in macroeconomic and social research.

From the perspective of evaluation indicators, after the 1970s, the selection of representative indicator systems (Chen and Tao, 2000) to comprehensively evaluate various issues has become an indispensable and important means in modern management. Yu (2002) and others examined the issue from the point of view of developed agriculture, civilized farmers, affluent rural areas and good environment, Chen et al. (1993), etc. from the status of agriculture in macroeconomics and society, the living standards and quality of farmers, modern technology in agricultural production, application and agricultural production efficiency; Jiang (1997) observed procedures from production efficiency, management level, modern technology application and rural living standards; and other aspects of agricultural modernization, rural industrialization and rural urbanization (Cheng, 1999). The evaluation index system of agricultural modernization has been constructed in terms of output and socio-economic culture (Liang and Wenshun, 2019). Xu and Wu (1994), Tao (2018) and others established five aspects of system structure macro standards, production efficiency, agricultural production technology standards, comprehensive benefits and farmers' living standards (Xia and Li, 2000); Zhang Yuwu et al. established county-level eco-agricultural indicator system from three aspects: resource utilization evaluation, structural evaluation and functional benefit evaluation. Huang et al. (1995), Ma Kangyu, Gu Jianmin and others established an assessment indicator system for high-yield, high-quality and high-efficiency agriculture. Sun et al. (1995) and others have established a comprehensive evaluation index system for ecological agriculture from the aspects of system structure, system function and system efficiency, high yield, high efficiency, benign circulation and sustainable development, resource utilization, ecological function benefit, economic function benefit and social benefit (Ilyas et al., 2019).

From the indicator system, the number of specific indicators range from a few to dozens. Peng (1994) used nine indicators when evaluating the agro-ecological development of the central and sub-tropical agriculture in eastern China and the agro-ecological types of the county; Li et al. (2005) used 34 indicators for the evaluation of the agricultural ecosystem in Fujian Province; Qin Huibao was in the hilly area (Zhou et al., 2017; Asghar et al., 2018). The evaluation of village-level eco-agricultural systems used 26 indicators (Xia, 2013; Wali et al., 2018).

(3) Study on low hilly red soil and classification

The research on the development and utilization of low-hill red soil is firstly the discussion of resource characteristics (Huang et al., 2014; Ogunyele et al., 2018). As a comprehensive low-hill and gentle slope resource of comprehensive natural economic geography complex, the use of low-hill and gentle slope resources varies from vertical to horizontal (Shen et al., 2013). The vertical space difference mainly reflects the characteristics of altitude sunshine hours, temperature, precipitation (Huang and Tang, 2015) and other significant differences in climate resources. From the perspective of horizontal space differences (Wang and He, 2005), it mainly reflects the obvious differences in development costs, significant differences in natural geography and socio-economic conditions (Jia, 2016).

Secondly, the research focuses on the development potential of low hilly red soil resources. From the perspective of environmental analysis, land degradation, vegetation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83958415

cover, soil fertility, soil erosion, and small watershed management are the main problems in the low hilly red soil region (Fang et al., 2010). Geostatistical method was used to study the spatial and temporal variability of soil fertility in the subtropical low hilly red soil region of China (Yin, 2006), and the effects of different utilization methods on soil fertility were analyzed and discussed. The development potential was mainly related to area, aspect, slope and land use. Factors such as status, altitude, and soil texture were also associated (Deng et al., 2017). Taking the typical low hilly red soil region in the Fuyang area of Hunan Province as the research area, the seasonal intercropping of soil moisture content in the long-term experimental plots of different fertilizer ratios in red soil dryland in low hilly areas (Pang, 2015) and its relationship with meteorological factors were studied (Chai, 1997). The variation of soil moisture in typical red soil areas was analyzed.

There is also agricultural planting research in the low hilly red soil region (Shi et al., 2018). The existing low hilly red soil industry development is mainly based on fisheries, forestry, conversion town construction land and ecological agriculture (Wu, and Chen, 2016). There are also test forests in the low hilly red soil area with a number of tree species, and the tree species with good economic and ecological benefits are screened out, which provides a basis for the rational development of low hilly red soil and intensive management of forestry (Wang et al., 2017). Based on the research of the basic characteristics of red soil in Poyang Lake and surrounding economic zones, it is pointed out that the layout of red soil is unreasonable in development and utilization, the production is simple (Bao et al., 2006), the level of forestry production is very low, and the cultivation of cultivated land is lacking, resulting in low yield and instability (Han et al., 2013), soil erosion and other issues.

In summary, for more than a century, domestic and foreign scholars have conducted various researches on land types for different research purposes, with different research techniques and means, so that they gradually mature in theory and method with the development of science and technology. With progress, I began to make extensive use of computer technology (Wang and Tao, 2012). China's research on the quantitative evaluation of agro-ecosystems is mainly focused on the evaluation of the establishment of the indicator system. There is still a lot of room for the understanding of the system as a whole and for the study of multi-level and multi-dimensional systems (Xu et al., 2016). In addition to improving agricultural soil infrastructure, improving agricultural infrastructure, and changing agricultural processing logistics (Chen et al., 2005) and branding, modern agricultural management practices, such as refined agriculture and facility agriculture, are inevitable for low-hill red soil (Ma and Wang, 2010). Regional agricultural development puts forward new requirements. Based on the type of land planting, this paper establishes a more comprehensive and scientific evaluation system of agricultural development, and applies land type planning better in land evaluation research. How to improve the agricultural planting structure in the low hilly regions? The development of the red soil region provides a direction.

Research methods

Since the last century, scientists from all fields have conducted extensive research on land resource changes and cover from their respective disciplines, and have shown a trend of multi-disciplinary cooperation (She, 2014). Principal component research is a core issue in the change of land resource utilization. The main component refers to the main cause of changes in land resource utilization. Since principal component research

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83958415

plays a very important part in the simulation of land resource utilization change (Jia et al., 2001), it has attracted the attention of many scholars at the beginning. Some scholars have analyzed the spatial and temporal changes of land resource utilization in China by establishing mathematical models (Xu, 2017), using principal component analysis models to evaluate the level of cultivated land use in Chongqing, and discovering the inadequacies of land resource utilization in Chongqing and exploiting the land resources of the city. Suggested countermeasures occurred soon. Some scholars have used principal component analysis to evaluate the use of cultivated land in Changsha City, and put forward relevant suggestions on agricultural planting varieties and development directions to promote the effective use of cultivated land in Changsha (Zhu et al., 2018). Based on these studies, this paper intends to use the principal component analysis method to analyze the agricultural development strategy of low hilly red soil region, and provide reference for agricultural planting varieties and categories.

(1) Principle of principal component analysis

Principal component analysis is a common method of data processing. Principal component analysis mainly uses the main factors in a set of data to analyze (Shi and Han, 2013), and transforms many research variables involved in evaluation and analysis into several external variables that have major influences, reducing the complexity of the research. Since 1901, the British mathematician Pearson introduced the principal component and the variables involved in the evaluation (Li and Ye, 2001), this method has been gradually promoted, and after long-term evolution and development, principal component analysis has been applied in data analysis in many fields.

Principal Component Analysis (PCA) (Zhang and Liu, 1995) is a comprehensive method of data dimensionality reduction. Its principle is to transform a series of related index variables into several main principal component index variables by statistical analysis to replace the original complex variables (Liu, 1998). Its mathematical model is a random vector group M = (M1,…,Mr). After orthogonal transformation, the transformed matrix N is obtained. In the matrix N, the components (Lu, 2000) are linearly independent, and the variance of the first component of N is the largest, the second is the next.

(2) Steps of principal component analysis

The steps of principal component analysis are as follows:

The first step is to suppose that there are A research areas, and the original sample matrix X of the B selection index is as follows (*Eq. 1*):

$$X = (Xij)\ A*B,\ i = 1, 2,...\ A,\ j = 1, 2,..., B \quad \text{(Eq.1)}$$

The second step is to compute the correlation matrix Rb*b, its eigenvalue 1 b 0 and the normalized eigenvector ej. The principal component Ti is obtained as follows (*Eq. 2*):

$$Ti = Xej \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83958415

In the third step, the contribution of the j principal component variance is 85%~95%, and the first Q principal component T1, T2,... Tq, then the principal component Q can be used to reflect the information of the original B indicators. The contribution rate formula (*Eq. 3*) is as follows:

$$a = \sum_{i=1}^{q} a_j \quad \text{(Eq.3)}$$

The fourth step is to get the comprehensive score W for agricultural planting in different regions (*Eq. 4*).

$$W = aX_1 + bX_2 + \ldots + xX_x \quad \text{(Eq.4)}$$

where X represents the eigenvector of eigenvalues; a and B are standardized data of original index.

Results

In order to further improve the benefit of comprehensive exploitation and utilization of red soil resources in low hilly areas, and to improve the ecological environment, agricultural productivity and soil and water conservation capacity of red soil areas in low hilly areas, the internal driving factors of red soil management and development in low hilly areas in Zhejiang Province were studied.

Research area

The low hilly red soil defined by the Zhejiang Provincial Reclamation Bureau refers to the hilly red soil area with the lower limit of the slope (Zhang, 2001), 250 m in the north, 300 m in the east and the middle, and 350 m in the south. In addition to Jiaxing City, the remaining 10 cities in the province are distributed.

The scope of this study is Jinhua City, located in the eastern half of the Jinyu Basin in Zhejiang Province. It belongs to the mid-subtropical region and is a key area for the development of low hill red soil in Zhejiang Province, including Wucheng District, Jindong District and Lanxi City under the jurisdiction of Jinhua City. Dongyang City, Yongkang City, Wuyi County, Pujiang County, and Chun'an County have a total of 8 counties and cities.

Low-hill red soil is most widely distributed (Wu and Chen, 1995) and characteristic in the area of Jinhua City in Zhejiang Province. There are a total of 16.3814 million units (mu) of land, including 2,911.3 thousand mu of low hilly red soil, accounting for 17.77% of the total land area. The soil types are roughly divided into three categories: red sand soil, purple sand soil and yellow gluten mud, which are distributed at the bottom of the Jinyu Basin. Low hilly red soil resources, due to its unique natural conditions, have become the main potential of agricultural development in Zhejiang Province. In the low hilly red soil area of Jinhua City, the improved soil methods such as land modification, green manure cultivation and straw returning to the field have been continuously applied. The crops such as tea and fruits have developed rapidly, the income of farmers has increased, the income from agricultural efficiency has increased significantly, and the social economy has continued to develop in general. This study

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83958415

uses the agricultural production resource data of the counties and cities under Jinhua City to analyze and evaluate the development and utilization potential of low hilly red soil, and provide decision-making basis for better utilization of low hilly red soil resources.

Index selection

The establishment of the indicator system in practical application is not necessarily based on a certain theory. It is often necessary to use a variety of theories in combination. The key is to meet certain research purposes and tasks, so that the indicator system can fully reflect the status and substance of the system. The scientific nature of the indicator system ultimately depends on the extent to which the researcher understands the system. In order to improve the functions of the sustainable indicator system, in the construction of the indicator system and the selection of indicators, according to the principles of science, comparability, operability, and simplicity should be selected by the principal component analysis indicators. In the establishment of indicators, the main areas of Jinhua City are considered. The existing agricultural planting structure data, first, the area planted with crops, and the second is the crop yield. Through the data of two types in recent years, the total area of crops, food crops, grains, beans are finally selected. Indicators such as vegetables, potatoes, rapeseed, medicinal herbs, watermelon, mulberry, tea, citrus, peach, and other fruits were selected to explore the laws of agricultural planting in Jinhua City, and better guide agricultural planting and industrial development.

Data collection and audit

The statistical yearbook of Jinhua City in 2014 was selected as the data source (Zhang, 2001), and the data of agricultural planting area in the study area was selected as the research data of affecting the development of low hilly red soil.

In order to ensure the quality of the data and lay a foundation for further analysis, it is necessary to audit the statistical data. The completeness and accuracy of the original data obtained from the direct investigation shall be examined. Audit integrity is mainly to check whether the unit or individual is missing, whether the survey items or indicators are completed and so on. The accuracy of audit is mainly to check the embodiment of the survey data in the objective truth of statistical information.

Sample descriptive statistics

Based on the sown area data of grain (*Table 1*) and main cash crops (*Table 2*) in Jinhua City, this paper analyzes the main driving factors of the development of red soil in hilly area by quantitative method, and summarizes the change law of utilization and quality of red soil in hilly area, so as to guide the management and development of red soil in hilly area better, and realize the cultivated land while increasing the productivity of red soil in hilly area. High efficiency and sustainable utilization provide scientific basis for the sustainable development of regional social economy.

Discussion

According to the local economic and social development needs and the suitability orientation of low hilly red soil, according to local conditions and overall arrangement,

DOI: http://dx.doi.org/10.15666/aeer/1704_83958415

the rational utilization direction is determined, and the principle of "agriculture is suitable, forestry is suitable, garden is suitable" is adhered to, so as to give full play to the comprehensive benefits of low hilly red soil resources.

Table 1. *Agricultural acreage of low hilly red soil region in Jinhua city in 2014 (unit: hectare)*

Index description

All the indicators included factors such as grain, vegetables, fruits and other cash crops, as shown (*Table 3*), for their mean, maximum, minimum and standard deviation.

Index principal component extraction

Taking Wucheng District, Jindong District, Lanxi City, Dongyang City, Yongkang City, Wuyi County, Pujiang County and Pan'an County under the jurisdiction of Jinhua City as the samples, taking the standardized data in the tables as the evaluation data, using SPSS statistical analysis software to process the data, the correlation coefficient matrix of the indices and the characteristics of the matrix are obtained. The information of eigenvalue, variance contribution rate and factor load matrix are extracted by principal component analysis, which contains a lot of information of original variables. After factor analysis of the standardized data in the table, the correlation coefficient matrix, variance of each eigenvalue, cumulative contribution rate and factor load matrix are transformed.

Factor analysis

The total planting area of crops, grain crops, cereals, legumes, potatoes, rapeseed, medicinal materials, vegetables, watermelon, mulberry, tea, fruit trees, citrus, peach and other 14 variables as the analysis indicators have a certain degree of representativeness, the specific situation is shown in *Table 3*. After the above variables are put into SPSS statistical analysis software, the correlation coefficient matrix between the original variables and the correlation analysis results are obtained. From the correlation coefficient matrix, different degrees of correlation were revealed among the 14 influencing factors, and the correlation coefficients among other factors are in different distribution states.

Table 4 shows the common degree of variables of the 14 primitive variables. The index of variable commonality can reflect the degree of dependence of multiple variables on all common factors extracted. From *Table 4*, except for variables X1, X2, X9, X10, X12 greater than 90%, the common degree of all other variables are less than 90%, but higher than 65%, which fully shows that the common factor we extracted can contain most of the information of the original variables, the extraction result will be very satisfactory.

According to the requirements of principal component analysis, as long as the eigenvalue is greater than 1, and the cumulative contribution rate is higher than 80%, it can become the principal component. From the column of the eigenvalues and variance cumulative contribution rate (*Table 5*), we can see that the first three cumulative contribution rates have reached 84.076%. Therefore, the three principal components selected in this study are the first, second and third three common factors. The variance contribution rate of the three principal components after rotation is given in the factor load matrix. From this contribution rate, we can see that although the contribution rate of the three common factors after rotation has changed, the total cumulative variance contribution rate of the three factors has not changed, it is still 84.076%.

4	.898	6.413	90.489			
5	.666	4.758	95.246			
6	.522	3.727	98.974			
7	.144	1.026	100.000			
8	0.0000000000000004488	0.000000000000003206	100.000			
9	0.0000000000000008075	0.0000000000000006218	100.000			
10	0.0000000000000006023	0.0000000000000004302	100.000			
11	0.0000000000000003404	0.0000000000000002431	100.000			
12	-0.0000000000000003773	-0.0000000000000002695	100.000			
13	-0.0000000000000001603	-0.0000000000000001145	100.000			
14	-0.0000000000000004554	-0.0000000000000003253	100.000			

According to the previous results, because the contribution rate of the first common factor is especially large, the common factor (the first principal component) in the index X1 total crop area, X2 grain crop area, X3 grain area, X4 legume area, X8 vegetable area, X9 watermelon area and other indicators, these are mainly planting food crops and vegetables (*Table 6*). Cultivated land, therefore, farmland in Jinhua City plays a larger role, so we need to focus on the management and development of cultivated land.

The second common factor (the second principal component) is evident in the index X5 potato area, X6 rape area, X10 mulberry area, X12 orchard area, X13 citrus area, X14 peach orchard area and other indicators. Among these six indicators, four are mainly reflected in economic forest and fruit products, therefore to strengthen, economic forest and fruit development still needs to be obtained.

The third public factor (the third principal component) is obvious in the index X11 tea garden area, X7 medicinal materials planting area, and has a direct relationship with the characteristic agricultural industry in Jinhua, especially in Pan'an County, the development of Chinese medicinal materials is beneficial and needs to be concerned. To sum up, the factors covered by these three principal components also agree with the previous qualitative analysis.

Analysis

Land use zoning is one of the main basis for determining land use and adopting specific land use measures. Through the use of land division, various agricultural production layouts can be reasonably arranged, that is, rationally planning the production sectors such as plantation, forestry, animal husbandry, and the spatial distribution of various production categories in various industries in order to obtain a certain area. Planting should involve as much quality agricultural products as possible on the land to achieve the best economic benefits and comprehensive social benefits. The layout of agricultural production in a region is inseparable from two conditions: the land type structure of the region and the hydrothermal conditions of the region, that is, the land quality level of the region. On the basis of the regional land quality level, according to the land type structure, reasonable determination of the local production development direction, combined with the appropriate utilization, transformation and protection measures, will greatly promote the production and ecological protection of the region. Therefore, in the basic soil of the above-mentioned evaluation results of land planting structure, to provide scientific theoretical and practical basis for promoting the efficient development of agriculture, combined with the local economic situation, the agricultural development strategy of the low hilly red soil region of Jinhua City is summarized in the followings:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1704_83958415

(1) Traditional agriculture such as grain in the low hilly red soil region

The agricultural land in the low hilly red soil area of Jinhua City plays a relatively large part (Liao et al., 2017), has a long development time, and has many development projects. It is suitable for long-term stable development and enhances the level of low hilly red soil development. As shown in *Figure 1,* Dongyang City, Jinhua City and Lanxi are the county-level administrative units with the largest grain planting area (*Fig. 1*). The low hilly red soil areas in these blocks are relatively flat, the agricultural supporting facilities are more comprehensive, and the agricultural basic conditions are better compared to other areas. More obvious benefits can be generated in the development of cultivated land. In the plain area, the slope is slow, the human activity is the strongest, and the land use diversity is the most abundant. According to the potential of soil resources and crop varieties it is required to optimize production system management, achieve intensive farmland management, develop precise agriculture, and ensure efficient use of resources. Dry land that can be realized by artificial water diversion can be transformed into paddy fields, which can not only obtain higher yield and economic income than dry farming, but also reduce soil erosion, improve soil properties and increase nutrient accumulation. Strengthening the production of food crops is the basis for the development of agriculture, the premise of agricultural industrialization, and the necessary condition for the rapid and stable economic development of Jinhua City.

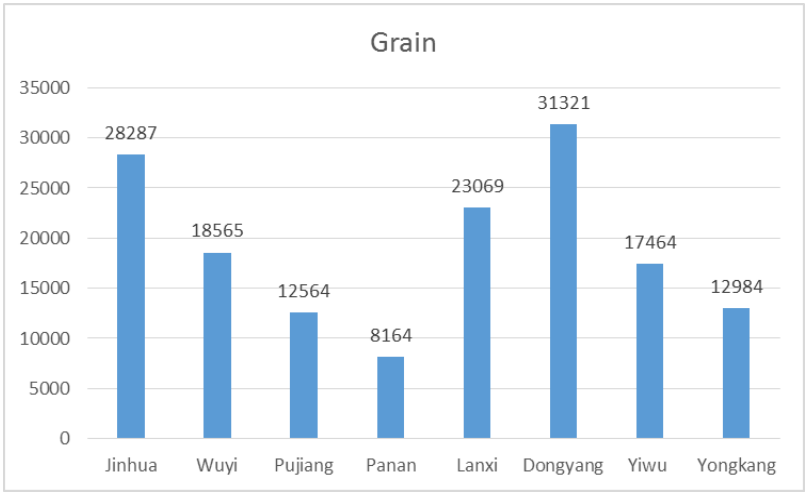

Figure 1. *The grain sown area of each county in Jinhua city (unit: hectare)*

(2) Economic forest fruit production in the low hilly red soil region

It is suggested to focus on and support local specialty products such as tea, camellia oil and citrus. The rapeseed planting area in Lanxi City, Jinhua City and Pujiang County ranks in the top three, and the citrus planting area in Jinhua City, Lanxi City, Yiwu City and Yongkang City is larger compared to other areas (*Figs. 2* and *3*). The economic forestry and fruit industry in Jinhua City has not formed a local regional brand, and there are no local agricultural regional brands such as Changshan Huyou, Yuhuan Wendan and Xianju Yangmei. The quality of citrus, tea and camellia products in Jinhua is not lost to foreign products (Yang et al., 2019). It has a long history and a good industrial foundation. On the basis of analyzing the status quo of land use distribution,
