The first irrigation began on May 25th, 2016 and May 15th, 2017, immediately after the potatoes were planted. Water application intensity in the first was 40 mm for sprinkling irrigation. After the potatoes revived, the sprinkling field was irrigated when the mean soil matric potential (SMP) of the 0–20 cm soil layer decreased to about −24.5 kPa. The distribution of main potato-root zones determined the irrigation duration, which was usually about 1.5 min, with about 10 mm of water each time at a pressure of 0.1 Mpa by automatic control with computer. Sprinkling irrigation was stopped 20 d before harvesting.

The date and water amount of furrow irrigation were implemented based on local irrigation practices. Irrigation was uniformly applied three times throughout the crop growing season: once when potatoes were planted and the second in the tuber set stages and third time during the tuber bulking stages. The amount of water applied at each irrigation event was about 200 mm. The total amounts of water applied for sprinkling and furrow irrigation during the study period were 200.7 and 601.8 mm in 2016, 205 and 593.7 mm in 2017, respectively. Sprinkling irrigation frequency was higher, while total irrigation water was smaller in the sprinkling-irrigated field than in the furrow irrigated field in the experimental seasons. Sprinkling irrigation always characterizes by the higher frequency with a smaller quota for each event respected to furrow irrigation. Total precipitation was less than 200 mm during the crop growing season.

Sampling and analysis of N_2O

The N_2O fluxes were measured in situ simultaneously from each sprinkling irrigation and furrow irrigation plot using a static opaque chamber method (Yang et al., 2018). The chamber headspace was a 125 l cube (50 cm × 50 cm × 50 cm). The outer layer of the chamber was covered with sponge and aluminum foil, which is used to prevent the chamber from being heated by sunlight. The chambers were placed inside the square stainless-steel rings (50 cm × 50 cm) to ensure a good seal without destroying the compactness of the soil. The square stainless-steel rings were inserted into the soil, to a depth of 15 cm. On a day before sampling the gas samples, those rings were taken in order not to disturb the water distribution during irrigation. The chambers were closed for 60 min between 8:00 a.m. and 9:00 a.m. During this time, N_2O concentrations increased linearly. At 0 min, 5 min, 10 min, 15 min, and 20 min, the gas samples (100 ml) were collected in evacuated three-part polypropylene syringes, respectively. They were taken once per week throughout the potato growing season from planting to harvesting. The air temperature inside the chambers was observed during collecting sample. Soil temperature was monitored in the field using a portable digital thermometer (JM 624, JinMing Instrument Co. Ltd., Tianjin, China) inserted into the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1096310976

soil: the monitored data were stored in a data logger. The moisture of soil was measured by the TDR350-indicating instrument (SPECTRUM Inc., ST Petersburg, Florida, USA).

The N_2O in the samples were measured and analyzed within 12 h by gas chromatograph (Agilent 6820D, Agilent Corporation, Shanghai, China) that was used two detectors: an electron capture detector (ECD) and a hydrogen flame ionization detector (FID). Its configurations described by Jiao (2015) were implemented for the N_2O analysis (Jiao et al., 2015).

Soil analysis

After sampling the gas, the soil in each stainless-steel ring was simultaneously collected and soil NO_3^--N and NH_4^+-N were determined by extracting 8 g of fresh soil with 60 ml of deionized water and 50 ml of KCl (0.01 M), respectively. They were measured using a micro-Kjeldahl procedure (Aulakh et al., 2000). SOC was determined by analysing soil extracts using a TOC analyzer (Sievers 5310 C, GE Analytical Instruments, USA) (Lim and Choi, 2014). Precipitation data were collected from the portable weather station located in the potato experimental farm.

Calculation method of N_2O emissions

Fluxes of N_2O was estimated within the closed chamber from the linear increase of gas concentration over sampling time of 0 min, 5 min, 10 min, 15 min, and 20 min based on $r^2 \geq 0.90$ while providing the maximum available flux data in the analysis of gas emissions (Jiao et al., 2015). Gas concentrations were converted to mass per unit volume (μg N_2O/uL) using the Ideal Gas Law at chamber air temperature measured during each sampling event and 0.101 MPa. Fluxes of N_2O were computed as:

$$F = \frac{\Delta C}{\Delta t} \times V/A \times \propto \quad \text{(Eq.1)}$$

where F is the flux rate of N_2O (μg N_2O–N/(m^2 hr)), $\Delta C/\Delta t$ denotes the increase or decrease of gas concentration in the chamber (μg/(L h)), V is the volume of the chamber (L), A is the covered surface area (m^2), and $\propto$ is a conversion coefficient for elemental N (28/44 for N_2O) (*Eq. 1*). Gas fluxes which failed linearity test were not included in the data analysis and accounted for < 2% of the total data set, while gas fluxes that failed significance and detection tests were set to zero flux. A complete discussion of chamber flux method is described in (Adviento-Borbe and Linquist, 2016).

Data statistics and analysis

The N_2O emissions were estimated by successive linear interpolation of N_2O emissions from the soils associated with the different irrigation systems. Statistical analyses were performed using SPSS version 22.0 (SPSS Inc., Chicago, IL, USA). A one-way analysis of variance (ANOVA) was used to evaluate the differences in seasonal and annual cumulative emissions of N_2O between the different irrigation. Tukey's multiple range tests were used to determine whether significant differences occurred between the treatments at a significance level of 0.05. A two-way ANOVA was used to analyze the effects of treatments and their interactions on N_2O emissions. Data drafting was run by SigmaPlot 13 and Excel 2016.

Results

Changes in precipitation and temperatures

The frequency of rainfall in crop growing season in 2016 is higher than that in 2017. There was no significant difference in the total rainfall of the crop growing season in 2016 and 2017 ($p > 0.05$), which were 196.6 mm and 198.8 mm, respectively. The atmospheric temperature showed a consistent trend of change from May to September in 2016 and 2017. The temperature began to increase gradually in April and was higher from July to August than other months (*Fig. 2*).

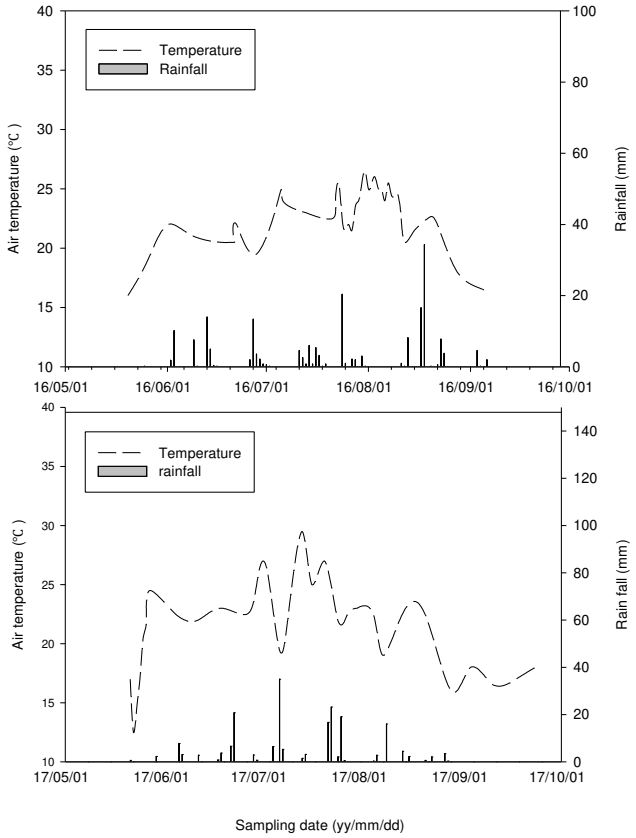

Figure 2. *Variable amount of temperature and precipitation in the potato experimental farm in 2016 and 2017*

Variation relationship between N_2O emission fluxes and the moisture or temperature in the soils of SI and FI

The potato field under four treatments from sprinkling irrigation systems and furrow irrigation systems exhibited a similar trend in N_2O emission fluxes. A significant emission peak of N_2O was detected in July and August throughout the testing stage from 2016 to 2017 (*Fig. 3*). Both the chemical fertilizer applied and the irrigation methods used affected the N_2O emission fluxes (*Fig. 3*). The NF soils from SI exhibited the highest N_2O emission fluxes, with 613.5 μg/(m^2 hr) in July 2017. The highest N_2O emission fluxes were produced with 1047.9 μg/(m^2 hr) from FI in the NF soils in July 2017. For the fertilization treatment and control under furrow irrigation system, the N_2O fluxes observed were higher than that in the sprinkling irrigation system in two crop

DOI: http://dx.doi.org/10.15666/aeer/1705_1096310976

growing seasons, respectively. The N_2O emission fluxes of the fertilization treatment were higher than those of the control treatment in each irrigation system during the experimental period (*Fig. 3*).

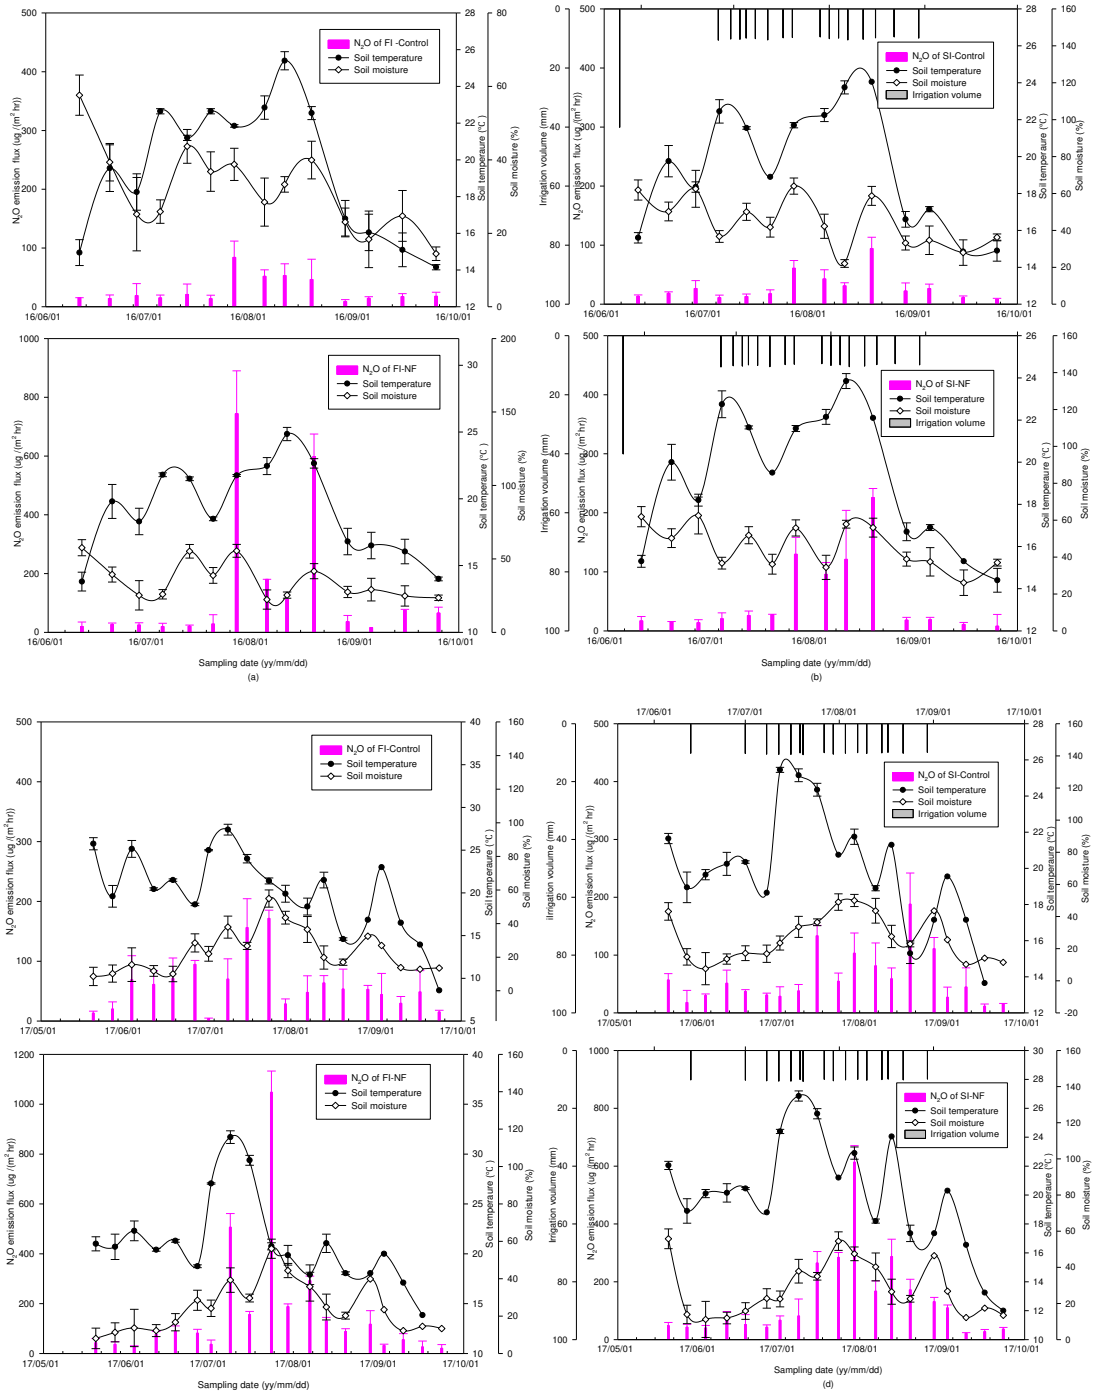

Figure 3. *Variation relationship between N_2O emission fluxes and the soil moisture or soil temperature in Control and NF in 2016 from FI (a) and SI (b), in 2017 from FI (c) and SI (d). DOI: http://dx.doi.org/10.15666/aeer/1705_1096310976

The variables of soil moisture and temperature exhibited generally consistent trends with N_2O emission fluxes from two irrigation systems. The soil moisture and temperature were higher, and N_2O emission fluxes of soils of two irrigation systems were higher in July and August than in May–June and in September (*Fig. 3*). During the irrigation period (from May to September), mean moisture of soil remained 45.9 and 44.5% under the furrow irrigation fertilization (NF) and furrow irrigation control (Control) system, and 39.7 and 34.3% under the sprinkling irrigation fertilization (NF) and sprinkling irrigation control (Control) system in 2016. The mean moisture of soil remained 26.1 and 26.6% under the NF and Control system from FI, and 24.6 and 23.3% under the NF and Control system from SI in 2017 (*Fig. 3*). Mean moisture was generally higher in NF and Control of FI than NF and Control plots of SI. There was no significant effect of two irrigation systems on the average daily soil temperature in the 0–30 cm soil layer from May to September ($p > 0.05$). There was no significant difference in soil temperature and moisture content for fertilized soil and soil without fertilizer of each irrigation system ($p > 0.05$).

Cumulative N_2O emissions in both irrigation systems

A significant difference in cumulative N_2O emissions of soils from the two irrigation systems was measured during the potato growing season in 2016 ($F = 13.84$, $p < 0.001$) and 2017 ($F = 6.49$, $p < 0.001$). The soils in Control of SI ($F = 47.0$, $p < 0.001$), NF of SI ($F = 7.8$, $p < 0.01$), Control of FI ($F = 57.5$, $p < 0.001$), and NF of FI ($F = 3.0$, $p < 0.05$) showed significant differences in the inter-annual cumulative N_2O emissions (*Fig. 4*). The cumulative N_2O emissions were significantly higher for NF and Control from FI than for NF and Control from SI over the annual sunflower growing season. The cumulative N_2O emissions in the fertilized soil were higher than that of the controlled soils each irrigation system. The cumulative N_2O emissions were 373.03 and 425.12 mg/m^2 for the FI with NF in 2016 and 2017. The cumulative N_2O emissions were 150.40 and 252.01 mg/m^2 for SI with NF from 2016 to 2017, respectively. The cumulative N_2O emissions from SI with NF were 59.68% and 40.72% lower than those from FI with NF for 2016 and 2017, respectively. The cumulative N_2O emissions of the Control soil from SI were 74.51 and 177.05 mg/m^2, and were 2.12% (2016) and 2.10% (2017) lower than that of the Control soil from FI in May – September during the annual potato field tested stage (*Fig. 4*). The cumulative N_2O emissions varied significantly with different irrigation systems throughout the potato experimental period. Sprinkling irrigation significantly reduced N_2O emissions.

Emission factor of N_2O

Emission factor of N_2O (EF) denotes the percentage of nitrogen lost in the form of N_2O gas in nitrogenous fertilizer, and can better evaluate the N_2O emission ratio of the fertilizers applied. EF of nitrogen fertilizer has been widely used in estimating regional and global N_2O emission inventories from farmland. The EF increased with N_2O emission due to increasing nitrogen fertilizer applied per unit area. EF from furrow irrigation and sprinkling irrigation in our study was 0.76% and 0.20% in 2016, 0.62% and 0.19% in 2017, respectively (*Fig. 5*). Compared with furrow irrigation, sprinkling irrigation can significantly reduce EF. The EF from sprinkling irrigation was 73.68% and 69.35% lower than that of furrow irrigation in 2016 and 2017. There was no significant difference in the inter-annual EF in furrow irrigation or sprinkling irrigation compared to soil air.

Discussion

Seasonal variation of N_2O emissions in two irrigation systems

The biggest N_2O emission pulses were generated and there are higher emission rate in July and August during the season of vigorous potato growth from 2016 to 2017, in both the sprinkling irrigation and furrow irrigation treatments. Seasonal dynamics of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1096310976

N_2O emissions fluxes were consistent with the changes of moisture and temperature in soil that were greater in July – August than in May–June and September–October (*Fig. 3*). These discoveries are consistent with the results of Kallenbach et al. (2010) in the soils from other arid and semiarid areas (Kallenbach et al., 2010). The production and consumption of N_2O from the soils are affected via the processes of nitrification and denitrification with microorganisms participating. These processes are all related to soil temperature and moisture (Firestone and Davidson, 1989). Soil moisture controls the biotic and abiotic processes, and operates a critical regulation function in the microbial activities of soils, for instance, N mineralization, nitrification and denitrification that are all quantitatively influenced by the applied irrigation methods (Sánchez-Martín et al., 2008). Climate and soil abiotic factors: soil temperature and moisture, can affect the dynamic changes of N_2O, with visible seasonal characteristics, in particular, in water transport.

N_2O emissions fluxes in the fertilized and control soils from sprinkling irrigation and furrow irrigation

Mean emissions fluxes of N_2O was 152.02 μg/(m^2 hr) in furrow irrigation, 36.53 μg/(m^2 hr) in sprinkling irrigation for fertilization treatment from 2016 to 2017. Change of irrigation mode affects N_2O source emission from farmland soil. In furrow irrigation, the peak value of N_2O emissions in the NF was four times higher than in sprinkling irrigation. Sprinkling irrigation compared with traditional furrow irrigation, significantly reduced N_2O emission from potato fields (*Fig. 4*). The amount of applied water in furrow irrigation was more significant than the saturated hydraulic conductivity in the soils, with furrows remaining flooded for several hours. The NH_4^+-N from the NF in the wetting soils was fleetly nitrified, increasing the concentration of NO_3^--N. In FI, the high rate of used water quickly dissolved these fertilizers and produced a great deal of NH_4^+-N and NO_3^--N on the surface layer of the soil profile. Rapidly dissolving a lot of fertilizer would partly illustrate the significantly greater ($P < 0.05$) NO_3^--N and NH_4^+-N concentration found in furrow irrigation system than in sprinkling irrigation system (*Table 1*). The essential differences between the concentration of NO_3^--N and NH_4^+-N of the soil have emerged in the decision on irrigation strategy. The process of soil nitrogen conversion is different from that of N_2O emission between sprinkling irrigation and furrow irrigation. Tensiometers controlled the sprinkling irrigation. The irrigation was triggered when SMP at 0.2 m depth directly under the sprinkling emitters reached –24.5 kPa. The irrigation was stopped when the amount of water applied to each irrigation event was about 10 mm. Values for the soil NO_3^--N and NH_4^+-N concentration in the upper 10 cm layer for the same fertilizer treatment generally remained lower on NF from SI than FI (*Table 1*). The NO_3^--N and NH_4^+-N that will not be leached were concentrated in the root zone of potato under sprinkling irrigation. The NO_3^--N and NH_4^+-N are beneficial to the uptake of potato due to the low amount of water from sprinkling irrigation. The results of Wang et al.'s (2012) research are consistent with our study (Wang et al., 2012). The concentration of NO_3^--N and NH_4^+-N in furrow irrigation soil is significantly higher than that in water-saving irrigation soil. Sprinkling irrigation reduces the concentration of NO_3^--N and NH_4^+-N, inhibits denitrification and reduces N_2O emissions. High concentrations of NO_3^--N and NH_4^+-N trigger higher N_2O emissions during nitrification and denitrification (Sánchez-Martín et al., 2008). In our study, high NO_3^--N and NH_4^+-N contents in furrow irrigation resulted in high N_2O emission.

	SI-Control	1.21 ± 0.01b	53.17 ± 0.38d	6.21 ± 1.20d	30.47 ± 1.97i

SI-NF and FI-NF refer to the treatment of fertilization from sprinkling irrigation and furrow irrigation. SI-Control and FI-Control refer to the treatment of no fertilization from sprinkling irrigation and furrow irrigation. NH_4^+-N and NO_3^--N are seasonal mean. Bulk density and porosity are the value at the end of the growing season

Comparing sprinkling irrigation with furrow irrigation in potato field, soil bulk density under sprinkling irrigation (1.17 g/cm^3) is lower than that under furrow irrigation (1.29 g/cm^3) from 2016 to 2017 (*Table 1*). Sprinkling irrigation compared with furrow irrigation increases soil porosity, improves soil permeability. The topsoil in sprinkling irrigation fields was looser than that in furrow irrigation fields (Sun et al., 2008). Sprinkling irrigation is one of the water-saving irrigation methods widely adopted in agricultural production. The environmental conditions of soils in sprinkling irrigation were similar to that of drip irrigation (Lv et al., 2010), and favored nitrification, contributing to lower emissions of N oxides (Sánchez-Martín et al., 2008). Both the high consumption and frequency of used water in the furrow irrigation strategy produced the high moisture of soil in the plots. The high moisture in the soils resulted in the emergence of a high proportion of anaerobic environment. High soil moisture not only stimulates soil microbial activity, but also reduces the flow of oxygen in soil, leading to nitrification and denitrification. Use of furrow irrigation gave higher N_2O emission losses than drip irrigation (Sánchez-Martín et al., 2008). Different infiltration and redistribution patterns of irrigation water result in different distribution patterns of soil water in time, horizon and vertical depth, which have an important impact on the production and emission of N_2O and its spatial and temporal distribution. Under drip irrigation, as water supply is low, the process of soil N_2O production from denitrification will be limited, and the N_2O emission will be reduced (Kallenbach et al., 2010; Sánchez-Martín et al., 2010). Soil in furrow-irrigated potato fields emits more N_2O than that in sprinkling-irrigated. Sprinkling irrigation can reduce N_2O emission from farmland soil.

The used NF treatment in the potato field also had a significant impact on the results achieved. The concentration of NH_4^+-N and NO_3^--N was significantly ($P < 0.05$) greater in the fertilization treatment than in the Control for sprinkling irrigation and furrow irrigation, respectively (*Table 1*). The N_2O emissions of soils were commonly higher in the fertilization treatment than in the Control in sprinkling irrigation and furrow irrigation throughout the testing stage (*Fig. 3*). In irrigated agriculture, both the availability of water and N fertilizers has an essential effect on N_2O emissions. Higher concentrations of NH_4^+ and NO_3^- were detected in the soils of NF compared with the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1096310976

soil of no fertilizer (Vallejo et al., 2005). The effect of the ions from nitrification and denitrification processes caused higher N_2O emissions in the soils with chemical fertilizer compared with the soils of no fertilizer in drip irrigation and furrow irrigation systems (Sánchez-Martín et al., 2008).

Emission factor of N_2O in two irrigation systems

In our study, mean emission factor of N_2O from nitrogenous fertilizer for two-year growth period in potato fields is 0.20 and 0.69 % in sprinkling irrigation and furrow irrigation, respectively. Statistics such as Xu et al. (2016) show that the N_2O emission factor of nitrogen fertilizer is 0.50%~0.82% during the growth period of summer maize, 0.61%~1.13% in a vegetable field in the arid area (Xu et al., 2016). The EF of N_2O from the potato field of furrow irrigation in our study is in the range of EF from Xu et al. (2016) in the upland field. The EF of N_2O in potato field from sprinkling irrigation was significantly lower than that in the soils of the upland field, and it was 61% lower than the lowest EF (0.61%) of N_2O in vegetable soil and 81% lower than the highest EF (1.13%) of N_2O. Sprinkling irrigation significantly reduces N_2O emissions.

Kang and Eltahir (2018) use the Massachusetts Institute of Technology (MIT) Regional Climate Model (MRCM) to perform simulations for the historical period (1975–2005), as well as future climate (2070–2100) assuming two scenarios of GHG emissions with furrow irrigation which cools surface temperature and moistens surface air, but boosts integrated measures of temperature and humidity, and hence enhances intensity of heatwaves. China is currently one of the largest contributors to the emissions of greenhouse gases, with potentially serious implications to its population (Kang and Eltahir, 2018). Sprinkling irrigation in China is widely used to reduce these greenhouse gas emissions.

The irrigation strategy had an important impact on the pattern of N_2O emissions. The choice of an irrigation system is regarded as a critical way of saving water in arid and semiarid regions and maintaining optimal crop yield. In this experiment, sprinkling irrigation has been demonstrated that it can also be used as a tool for mitigating emissions of N_2O. To date, no results have been published comparing sprinkling and furrow irrigation. Although our results indicate that the N_2O emission pattern of sprinkling irrigation contributed to lower emissions on N_2O, many studies will be essential to assess the effect of some parameters related to sprinkling irrigation. These parameters include soil characteristics, especially hydraulic conductivity of affecting water distribution. Moreover, as sprinkling irrigation is frequently combined with applied chemical fertilizer, further work is needed to assess the influence of frequency, rate and type of N fertilized on N_2O emissions via sprinkling irrigation.

Conclusions

This study demonstrated that the choice of irrigation strategy had a significant effect on N_2O emissions. Sprinkling irrigation saves water and also helps to reduce the production of N_2O. Therefore, it can be regarded as an effective method for mitigating the gas loss in the soils of agroecosystems in arid and semiarid areas. Nevertheless, more field studies are needed to assess the influence of the new irrigation technologies on N_2O emissions and the comprehensive influence of using both water and N.

(Received 26th Mar 2019; accepted 13th Jun 2019)

Abstract. In order to evaluate the drought tolerance and susceptibility of six maize hybrids under water deficit conditions, an investigation was conducted during the growing season of 2016 at the Qlyasan Research station- University of Sulaimani. The field experiment was implemented according to the split plot design with three replications, four different irrigation levels were allocated in main plots, while six maize (*Zea mays* L.) hybrids were cultivated in the sub-plots. The yield response factor (Ky) was estimated through calculating adjusted crop coefficient (Ks) as well as adjusted Crop evapotranspiration (ETc adj.) in growth stages, including initial, rapid growth, mid-season, and the late season, revealing Ks values lower than that obtained by FAO paper No.33, (0.49, 0.6, 0.528, and 0.204) respectively. Four stress tolerance indices, including stress tolerance index (STI), stress tolerance (TOL), mean productivity (MP),) and geometric mean productivity (GMP) were used in this study. Data analysis demonstrated that the indices STI, TOL, MP, and GMP were more effective in defining the high yielding hybrids under different growing conditions. The results of the cluster analysis, yield response factor (Ky) and stress indices corresponded due to tolerance and susceptibility of maize hybrids.
Keywords: *water deficit, resistance, sensibility, maize hybrid*

Introduction

Maize (*Zea mays* L.) is considered as the third most important cereal crop after wheat and rice around the world, it covers 4.8% of the total cropped area and attributes 3.5% of the global agricultural crop output (Ahmad et al., 2011; Deryng et al., 2014). Some of the challenges that influence the productivity and the expansion of the maize cultivation in a semiarid region are caused by water deficit and shortage in water availability, the yield of different crops reaches the maximum value with evapotranspiration (ETm), therefore an actual yield (Ya) matches with an actual evapotranspiration (ETa) (Nacharchi et al., 2011). Drought tolerance consists of ability of crop for growth and production under water deficit conditions. A long-term drought stress effects on plant metabolic reactions associates with, plant growth stage, water storage capacity of the soil and physiological aspects of plant. Crop response to the limited water condition is important for adjusting the relationship between grain yield and efficient irrigation systems to evaluate crop performance under water deficit condition (Carvalho et al., 2016; Irandoust and Bijanzadeh, 2017).

The yield response factor (Ky) is a factor that describes the reduction in relative yield according to the reduction in ETc caused by a soil water shortage, the response of a crop to its soil moisture environment is quantified through Ky (Greaves and Wang, 2017), the values of Ky are crop specific and may vary over the growing season (Steduto et al., 2012). Usually, the decrease in yield due to water deficit during the vegetative and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1097710988

ripening period is relatively small, while during the flowering and yield formation periods it will be large. Values for Ky for individual growth periods and for the complete growing season have been included in the FAO Irrigation and Drainage Paper No 33. The importance of the yield response factor is to determine the efficiency of water use and crop productivity, which is founded on the relative yield loss of any crop to the relative reduction of water requirements, differences in actual evapotranspiration and the crop response factor which usually vary according to crop growing conditions. The average Ky value founded by previous researchers (Najarchi et al., 2011) was higher than the previous reported values, thus, the reductions in yield under effect of deficit irrigation are higher than those reported by FAO (Doorenbos and Kassam, 1979). Enormous distinction of Ky value for maize resulted from variation in environmental effects and growth patterns were represented in the previous research, there was deviation from finding of Doorenbos and Kassam (1979), whom they determined ky value for maize 1.25, while other researchers documented 2.15 for sensitive genotypes and 1.56 for water deficit resistance genotypes, as well the different values of ky 1.58 and 1.50 were showed with stress condition at tasseling or silking and post silking stage, however the ky value for those growing stages were 0.40, 1.50, and 0.50 found by Doorenbos and Kassam (1979).

Drought indices clarify the effect of drought on the yield forfeiture comparing with the yield under no stress condition has been used for drought tolerance checking (Mitra,2001). To evaluate response of plant genotypes to drought stress, some selection indices based on a mathematical relation between stress- and optimum conditions has been proposed. Moghaddam et al. (2002) found Stress Tolerant Index (STI) was more useful in order to select favourable corn cultivars under stressful and stress-free conditions, however the greater TOL value indicate to larger grain yield reduction under stress condition, whereas lowest TOL indicate to lower grain yield reduction under stress condition. Khalili et al. (2004) showed that based on Geometric Mean Productivity (GMP) and STI indices, corn hybrids with high yield in both stress and non-stress environments can be selected. Talebi et al. (2009) concluded that GMP and STI were able to discriminate tolerant genotypes under stress conditions, their results indicated that there was a positive and significant correlation among Yp and (MP, GMP and STI) and Ys and (MP, GMP and STI) and they hence were better predictors of Yp and Ys than TOL. There was indication of significant correlation between MP, STI, and GMP with the yield at both non-stress and stress conditions (Zare, 2012).

Thus, the objective of this study was the evaluation of yield response factor and the efficiency and profitability of different selection indices in the identification of maize hybrids, which are compatible with stressful and optimal conditions, to achieve hybrids that can tolerate water deficit condition especially at sensitive growth stages.

Materials and methods

Six maize hybrids were evaluated in the investigation includes Medium 791, Btaris, Cantabpis, Fajr 260, Es-Solito 655, and Dhqan. All hybrids were produced from College of Agriculture, the University of Kurdistan, Sianandaj-Iran. The study was conducted during the summer season of 2016 at the Qlyasan Research Station, College of Agricultural Sciences, University of Sulaimani/KRG-Iraq (35° 34’ 19” N 45° 22’ 1.6” E with altitude of 754 m.a.s.l). The experiment was laid out in a split plot design in which water deficit levels will be in the main plots and each treatment was replicated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1097710988

three times. Each replication was divided into four main plots with different schedules irrigation. The six hybrids were randomly distributed within the sub-plots. Four irrigation treatments were used as well Irrigation (I_1), deficit irrigation during the vegetative period (I_2), reproductive period (I_3) and both of them (I_4). A net plot size of 4 m × 10.2 m was kept. The crop was sown during the first week of Jully in rows 70 cm apart and 25 cm between plants. In order to prevent the lateral spread of water plots a distance of 2 m between plots was left bare. Phosphorus fertilizer, as triple super phosphate, was applied before sowing time with rate of 150 kg ha^{-1}. The nitrogen fertilizer, as urea 46% N, was applied by two doses, the first one was applied at the seedling stage and the second application was on tasseling stage. All other agricultural practices were behaving as required. The yield response factor (Ky) was calculated, for determining the responses of maize hybrids to the effect of water deficit, a simple, linear crop-water production function was introduced in the FAO Irrigation and Drainage Paper No 33 (Steduto et al., 2012) to predict the reduction in crop yield when crop stress was caused by a shortage of soil water:

$$[1-\frac{Ya}{Ym}]=Ky[1-(\frac{ETc\,adj}{ETc})] \quad \text{(Eq.1)}$$

Where: Ya = actual yield of the crop [ton ha^{-1}], Ym = maximum (expected) yield in the absence of environmental or water stress [ton ha^{-1}], Ky = a yield response factor [-], ETc adj = adjusted (actual) crop evapotranspiration [mm d^{-1}], ETc = crop evapotranspiration for standard conditions (no water stress) [mm d^{-1}].

In the crop coefficient approach the crop evapotranspiration, ETc, is calculated by multiplying the reference crop evapotranspiration, ETo, by a crop coefficient, Kc The adjusted Crop Coefficient, or stress, crop coefficient (Ks) which describes the effect of water stress on crop transpiration was quantified for determining the exact effect of the soil water stress on the crop transpiration in water deficit treatments, the incorporation of the effect of water stress into crop coefficient (Kc) was determined as:

$$ETc\ adj = Ks \times Etc \quad \text{(Eq.2)}$$

Where is the = stress, crop coefficient [dimensionless], Etc = crop evapotranspiration [mm d^{-1}].

$$ETc = Kc \times ETo \quad \text{(Eq.3)}$$

Where Kc = crop coefficient [dimensionless], ETo = reference evapotranspiration [mm^{-1}].

$$ETo = P(0.46 \times Tmean + 8) \quad \text{(Eq.4)}$$

$$Ks = (TAW - Dr) / (TAW - RAW) \quad \text{(Eq.5)}$$

Where TAW = the total available soil water in the root zone [mm], RAW = the readily available soil water in the root zone [mm], Dr = root zone depletion [mm].

$$TAW = 1000\ (\theta F.C - \theta W.P)Zr \quad \text{(Eq.6)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1097710988

Where θF. C = the water content at field capacity [m^3 m^{-3}], θW.P = the water content at wilting point [m^3 m^{-3}], Zr = the rooting depth [m].

$$Dr = 1000\ (\theta F.C - \theta i - 1)Zr \quad \text{(Eq.7)}$$

Where θi – 1 = the average soil, water content for the effective root zone [mm].

$$RAW = p \times TAW \quad \text{(Eq.8)}$$

Where p = average fraction of Total Available Soil Water (TAW) that can be depleted from the root zone before moisture stress.

The studied drought resistance indices were calculated by using the following relationships in *Table 1*:

Table 1. *The computing relations of the parameters studied in the experiment*

Parameters	Formula	Reference
Stress Tolerance Index (STI)	STI = Ypi × YsiYp²	Fernandez, 1992
Tolerance Index (TOL)	TOL = Ypi – Ysi	Rosielle and Hamblin, 1981
Geometric Mean Productivity (GMP)	GMP = Ypi × Ysi	Fernandez, 1992
Mean Productivity (MP)	MP = Ypi + Ysi2	Rosielle and Hamblin, 1981

Ysi = yield of hybrid in stress condition, Ypi = yield of hybrid in normal condition And SI that is stress intensity, where: SI = [1 – YsYp]. Ys = total yield mean in stress condition, Yp = total yield mean in normal condition

The software JMP version 13 and XLSTAT version 16 were used for statistical analysis like one-way analysis of variance and LSD test at the 5% level. The principal component analysis (PCA) Eriksson et al. (1999) was determined to assess the relationship between the variables. Depending on the means of stress indices characters, the dendrogram was produced by using the Euclidean distances and unweighted pair-group method with the arithmetic mean (UPGMA) analysis method.

Results and discussion

Water stress may be induced under the effect of lower water supply and the evapotranspiration will drop below the standard crop evapotranspiration, ETc., The reduction in the value of crop coefficients under water deficit conditions is determined using the stress crop coefficient Ks (calculated with *Eq. 5*). *Table 1* demonstrates the adjusted crop evapotranspiration ETc adj. (Calculated with the *Eq. 2*) For water deficit treatments include I_2, I_3, and I_4 as well adjusted crop coefficient (Ks x Kc), because the modification of vegetation and ground cover mean that the crop coefficient Kc varies during the growing period as well with influence of water deficit levels (Payero et al., 2008; Allen et al., 2017). In order to determining the yield response factor of maize hybrids under influence of well irrigation as well water deficit levels, the adjusted evapotranspiration was used, the stress crop coefficient that calculated for different growth stages of six maize hybrids were declined from 0.7, to 0.49, for irrigation levels, I_2, I_3, and I_4 respectively during initial stage, and from 1.2, to 0.6, for rapid growth stage and from 1.2, to 0.528, for mid season stage and for the late season stage it declined from 0.6 to 0.204. The calculation of adjusted evapotranspiration was done in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1097710988

accordance with adjusted Kc (Kc x Ks). The adjusted crop evapotranspirations were used in calculating the yield response factor Ky of the maize hybrids in different growth stages and demonstrated in *Table 2*, the variation between adjusted evapotranspiration and actual evapotranspiration has created under influence of higher reference evapotranspiration, similar results were documented by (Kuscu et al., 2013).

Yield response factor (Ky)

The effect of water deficit levels represented as I_1, I_2, I_3, and I_4 on the kernel yield of six maize hybrids indicated to decrease in yield with decreasing the water availability, there were variation in the values of yield response factor Ky which indicate to the sensitivity of maize to water stress, and there were differences in the effect of water deficit between the growth stages across the growing season (Dijaman et al., 2013). *Table 3* demonstrate the values of Ky of six maize hybrids in four growth stages include initial stage, rapid growth stage, mid-season stage, and the late season stage, the schedule of the water deficit treatments was varied according to the severity of the water shortage as well the sensitivity of the growth stages, the water deficit treatment during the initial and rapid growth stages were with I_2 and I_4 only, the response of all maize hybrids through Ky values under effect of I_2 were greater than 1 except the hybrids H_3 and H_4 showing (0.843 and 0.616) respectively, demonstrating less sensitivity to water deficit decrease, while Ky of all hybrids were indicated to greater values with the influence of I_4 than that was obtained with the effect of I_2 by (24.226%, 30.8%, 44.5%, 42.6%, 28.8%, and 28.8%) for (H_1, H2, H3, H_4, H_5, and H_6) respectively, demonstrating the greater effect of the water deficit condition created with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1097710988

the effect of I_4 due to decreasing in the kernel yield of six maize hybrids, the most sensitive hybrid in initial and rapid growth stages was shown with response of H_5, showed Ky value of 1.653 and 2.32. The Ky value of all hybrids during the mid season with the influence of the levels I_3 and I_4, the comparative between the Ky value in this stage of tasseling and silking which is sensitive to stress and that obtained by FAO was greater with variation between maize hybrids that expanded from 0.472 of H_3 to 1.306 for H6, Ky values of all hybrids in the late season under the impact of the I_4 level revealed a higher sensitivity of maize hybrids except the hybrid H_4, in the late season the lower values of Ky were taken out for all hybrids with the effect of I_3 and I_4 with specificity to H_3 and H_4 that they manifested Ky values (0.4, 0.65 and 0.469, 0.487) respectively, the results of late season were close to the finding of Doorenbos and Kassam (1979). The higher water potential of the air during the growing season of maize in the region resulted the differences of Ky value in comparison with the finding of previous researchers include that obtained by FAO are in agreement with results of Doorenbos and Kassam (1994), Dagdelen et al. (2005), Mengu and Ozgurel (2008) and Najrachi et al. (2011).

Table 3. *Yield response fractions for six hybrids in four growth stages under stress and non-stress conditions*

Growth stages	Hybrids	I_1	I_2	I_3	I_4
Initial growth stage I_1 & I_3: no stress I_2 & I_4: stress	H_1	-	1.47	-	1.94
	H_2	-	1.323	-	1.913
	H_3	-	0.843	-	1.52
	H_4	-	0.616	-	1.073
	H_5	-	1.653	-	2.32
	H_6	-	1.443	-	2.026
Rapid growth stage I_1 & I_3: no stress I_2 & I_4: stress	H_1	-	0.882	-	1.164
	H_2	-	0.794	-	1.148
	H_3	-	0.506	-	0.912
	H_4	-	0.37	-	0.644
	H_5	-	0.992	-	1.392
	H_6	-	0.866	-	1.216
Mid-season growth stage I_1 & I_2: no stress I_3 & I_4: stress	H_1	-	-	0.896	1.041
	H_2	-	-	0.862	1.026
	H_3	-	-	0.472	0.815
	H_4	-	-	0.767	0.576
	H_5	-	-	1.017	1.245
	H_6	-	-	1.305	1.087
Late-season growth stage I_1 & I_2: no stress I_3 & I_4: stress	H_1	-	-	0.759	0.881
	H_2	-	-	0.73	0.869
	H_3	-	-	0.4	0.69
	H_4	-	-	0.65	0.487
	H_5			0.862	1.054
	H_6			1.106	0.921

According to the irrigation schedule used in the study, the I_1 represented well irrigation in all growth stages, I_3 performed water stress in reproductive stage only (mid and late season), while I_2 caused water stress during the initial and rapid stages, and I_4 exemplified water stress in all growth stages

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1097710988

Stress indices

The results of analyses of variance demonstrated significant differences among maize hybrids for kernel yield under well irrigation and water stress conditions (YPi and Ysi) and for the investigated drought related indices which were presented in *Table 4*. High yield value in non-stress (Ypi) and stress conditions (Ysi) was exhibited by hybrid Medium 791, displaying (7.267 ton ha^{-1}) and (4.058 ton ha^{-1}) respectively. While low yield value in non-stress and stress conditions was exhibited by hybrids Fajr 260 with (2.748 ton ha^{-1}) and Dhqan (1.044 ton ha^{-1}) respectively. The maximum value of STI (1.633), MP (5.662) and GMP (5.370) indices was by hybrid Medium 791. In addition, the highest value for TOL (3.641 ton ha^{-1}) was from hybrid Medium 791. Thus, the hybrid Medium 791 had a desirable yield in all conditions and hence it is recommendable in a semiarid conditions, results are similar to that obtained by previous researchers as Rosielle and Humblin (1981), Fernandez (1992) and Dijaman et al. (2013).

Table 4. *Means and selection indices for grain yield (ton ha^{-1}) of six maize hybrids evaluated under stress and non-stress condition*

Hybrids	Ypi	Ysi1	Ysi2	Ysi3	STI	TOL	MP	GMP
	7.27	4.058			1.633	3.208	5.662	5.37

Ypi: Yield of a given hybrid in optimal conditions. Ysi1: Yield of a given hybrid in stress conditions (in vegetative period). Ysi2: Yield of a given hybrid in stress conditions (in reproductive period). Ysi3: Yield of a given hybrid in stress conditions (in vegetative & reproductive period). STI: stress tolerance index. TOL: tolerance index. MP: mean productivity. GMP: geometric mean productivity

The results of analyses of variance for the investigated drought related indices were presented in *Table 5*. Significant differences were found for all stress indices, The performance of six maize hybrids with stress indices showed significant differences among all hybrids that evaluated under stress and non-stress conditions. The H_1 showed the highest value of STI with 1.426 indicating to high yield potential and higher stress tolerance, and minimum value of H_4 Fajr260 was 0.288, the highest value of TOL was obtained by H_1 (medium 791) revealing 3.694 demonstrating greater reduction in grain yield under water deficit condition, while the minimum value of TOL manifested with

H_3 and H4 (0.935 and 0.859) indicating to a lesser reduction in grain yield. The higher values of MP and GMP showed by H_1 demonstrate high correlation between these indices and the yield. The results were similar to that documented by Papathanasiou et al. (2015).

Table 5. *Mean value for selection indices of six maize hybrids evaluated under stress and non-stress condition*

The biplot analysis (*Fig. 1*) is required to identify the best performance hybrids for both stress and non-stress conditions. The principle component analysis (PCA) converts the variables to the independent combinations. These principle components formed 100% of the total variation among maize hybrids. The two principal components PC1 and PC2 revealed 99.40% of the original phenotypic variation. The value of the contribution of first and second components was 94.29 and 5.11%, respectively. Regarding the distribution of indices and hybrids on PCA plot, the indices or hybrids that were subsisting away from the centre of the plot in the positive trends of distinct traits demonstrated their best performance, whereas; the indices or hybrids that were out most from the centre of the plot in the negative orientation of traits displayed their weak performance (*Fig. 1*). The most important component, PC1, was positively and negatively influenced by indices: STI, MP, GMP, and TOL. The second PCA accounted for 5.11% of all variations. The maize hybrids showed a wide variability in phenotypic traits among them. Four groups of maize hybrids with different genetic constituents were highlighted on scatter plot: the first group composed of H_1. The second group included H_2 and the third group composed H_3 and H_4, whereas the fourth groups contained H_5 and H_6, respectively. On the other hand, the results of some stress indices (STI, GMP, MP, and YI) for H_1 hybrid were opposite to those recorded for H_6 hybrid. As shown in PCA biplot, the highest values of GMP, MP, STI and YI were recorded by H_1 hybrid signalizing that genotypes with larger PCA1 and lower PCA2 scores gave high yields (Darvishzadeh et al., 2010; Khodarahmpour et al., 2011). This result indicates that H_1 hybrid was the most tolerant hybrid, whereas, the hybrids: H_5 and H_6 were the most susceptible hybrids. H_3 and H_4 hybrids shared common indices.

Cluster analysis for the six maize hybrids was behaving to identify a cluster grouping based on kernel yield under effect of water deficit and full irrigation, the results manifested four major groups of maize hybrids with different genetic constituents were highlighted in the scatter plot, the first group was implicated the hybrid (Medium 791), however the second group included Btaris only. The third group composed of (Cantabpis and Fajr 260), whereas the last group composed of two different hybrids (Es-Solito 655 and Dhqan) (*Fig. 2*). The results displayed the existence of variability among the maize hybrids involved in the study, On the other hand, the results of drought resistance indices variation of some traits of Medium 791 hybrid were inversely related

to those recorded for Dhqan hybrid, our results are in agreement with those of Bouslama and Schapaugh (1984), Anwer et al. (2011) and Khalili et al. (2012). The results of the cluster analysis, and yield response factor (Ky) and stress indices of six maize hybrids were corresponded due to maize hybrid performance.

Conclusions

The higher means of seasonal evapotranspiration were imperative to the necessity of determining of the yield response factor (Ky) more accurately in different growth stages, included initial, rapid growth, mid season, and late season stages through calculating of adjusted crop coefficient, as well adjusted crop evapotranspiration. The results of Ky in all growth stages were varied with that was reported by FAO no.33. The results of the correlation coefficient between the yield of maize hybrids and stress indices manifested significant correlation with the water stress conditions created with second and third levels of irrigations, furthermore with indices STI, TOL, MP, and GMP. The results of the cluster analysis displayed the existence of variability among the maize hybrids through four major groups of maize hybrids with different genetic constituents were highlighted in the scatter plot, indicating to the (Medium 791) hybrid as a most tolerant hybrid, whereas, the hybrids Es-Solito 655, and Dhqan were the most susceptible hybrids. Although the hybrid Medium 791 with a desirable yield in all conditions is recommendable in a semiarid conditions, further research may be required to be conducted for evaluating the tolerance and susceptibility of maize hybrids.

(Received 27th Mar 2019; accepted 2nd Jul 2019)

Abstract. This study presents spatiotemporal variability of two important air pollutants, Formaldehyde (HCHO) and Nitrogen dioxide (NO_2), concomitant to underlying anthropogenic, biogenic and pyrogenic emission sources from different landuse/landcovers over South Asia, from 2005-2016, using OMI sensor onboard Aura satellite. Annual and seasonal spatial distributions for both the gases reveal that trends of change are linked with landuse/landcovers of different geographical regions of South Asia. Annual distribution of NO_2 shows a negative trend from 2012-2016, with annual decrease of ~1.06% in comparison to a rise, from 2005-2011 at a rate of ~1.86%/year. Analyzing seven study zones, distinctively identifies higher-emissions for both the gases from anthropogenic sources, in zones, 2,3,4 and 6, highlighting, emissions from megacities of Pakistan (Lahore, Faisalabad), India (Delhi, Kolkata, Lucknow) and Bangladesh (Dhaka), mainly due to urbanization, power-generation plants and mining-activities. Episodes of pyrogenic-emissions dominate seasonally in zones2 and 4, due to crop residue burning from Punjab plains of Pakistan and India and zone5 from Bangladesh and Myanmar. Isoprene, a precursor to HCHO is one of its main biogenic sources and higher emissions of HCHO dominate in zones3 and 7 with deciduous forests of lower Himalayas in northwest and Western Ghats in southwest India. In zones 4,5 HCHO emissions are dictated by isoprene emissions from Sundarbans in Bangladesh and palm-oil-plantations in Myanmar.

Introduction

In the troposphere, Formaldehyde (HCHO) exists everywhere as a short-lived indoor and outdoor pollutant with a lifetime of few hours during the daylight (Sander et al., 2006). It is a carcinogenic pollutant, affecting the tropospheric photochemistry (Hassan

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

et al., 2018) and U.S. Environmental Protection Agency has declared, HCHO as the most important carcinogen in the outdoor air and is identified amongst the 187 hazardous air pollutants (Zhu et al., 2017; Zhang et al., 2018) Main source of tropospheric HCHO is oxidation of methane (CH_4) by Hydroxyl (OH) radicals. Whereas, short lived Non-Methane Volatile Organic Compounds (NMVOC) like alkanes, alkenes, aromatic hydrocarbons, and isoprene as a source of oxidation, dominate Methane in the continental boundary layer and contribute significantly to tropospheric HCHO concentrations. Ecologically, predictable and broadly defined trends for the isoprene dominance have been established as a Biogenic Volatile Organic Compounds (BVOC) over monoterpene. Isoprene as one of the BVOC after oxidation produces HCHO as a major product, and describes the temperature variations as a dominant variable at ecosystem level (Harrison et al., 2013). These temperature variations in the bigger context of climate change also affect the natural emissions of Volatile Organic Compounds (VOCs), like the emission of isoprene from vegetation (US-EPA, 2009). HCHO in the atmosphere is also contributed by vegetation (Lathiere et al., 2006), biomass burning processes and fuel combustion (Lee et al., 1998) in lesser content than oxidation. In midlatitude and forest cover of tropical regions, Isoprene as a VOC is the major precursor of HCHO (Palmer et al., 2003, 2006; Barkley et al., 2008; Curci et al., 2010).

Atmospheric oxidation of VOCs produces HCHO in large amounts, that can be detected through space as a total column by solar UV backscatter (Chance et al., 2000). Monitoring and recording of observations for HCHO columns from space started with the launch of the Global Ozone Monitoring Experiment (GOME) instrument in 1995 (Chance et al., 2000). Detection of HCHO columns using remote sensing data have been successfully used as a proxy for the identification of biogenic repositories and emissions of VOCs from the underlying sources (Palmer et al., 2003; Millet et al., 2008; Stavrakou et al., 2009; Marais et al., 2012; Barkley et al., 2013; Bauwens et al., 2016), pyrogenic sources (Shim et al., 2005; Gonzi et al., 2011) and anthropogenic sources (Fu et al., 2007; Marais et al., 2014; Zhu et al., 2014; Souri et al., 2017). Long term trends of HCHO column data have been analyzed by (De Smedt et al., 2010, 2015) with the help of GOME instrument and with the succeeding satellites like GOME-2, Ozone Monitoring Instrument (OMI) and Scanning Imaging Absorption Spectrometer for Atmospheric Cartography (SCIAMACHY).

In a recent study by (Zhu et al., 2018) using Ozone Monitoring Instrument (OMI) onboard Aura satellite, observing HCHO concentration over china for a period of 2005-2015, have observed strong seasonal pattern existing for high concentrations of HCHO in the summer season. At regional scale, increase has also been observed in the HCHO column for a period of 2005 to 2010 while, a decrease has been observed from 2010-2015. In addition to this, (Zhu et al., 2018) have also found that urban areas exhibit higher concentrations of HCHO column and increase has been observed for the emissions from industrial sources along with the similar emissions from residential sources. In summer times it has been concluded, that, anthropogenic VOCs contribute to high emissions along with the isoprene emissions.

In the atmosphere, nitrogen dioxide (NO_2) is considered as a highly reactive gas (US-EPA, 1998). Nitrogen oxides ($NO_x = NO + NO_2$), especially NO_2 in the atmosphere, has been observed to have adverse impacts on both, the human health and on the natural environment (Case et al., 1979; Barck et al., 2005). Another important aspect of the presence of NO_x in the atmosphere is that these gases and hydrocarbons are correlated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

with the surface level ozone (Varotsos et al., 1992). The tropospheric NO_2 pollution is greatly influenced by the spatial patterns of socio-economic conditions of certain geographical regions as well as it is affected by the changes in meteorological conditions, and also can be attributed to the topographic attributes, defined by the elevation, land use and land cover of the area under investigation (Parra et al., 2009). Emissions of NO_2 along with the other trace gases in Indo-Gangetic Plain (IGP) can be specifically associated with the agricultural landuse/landcover. As, significant emissions of NO_2, CO, CO_2, CH_4, and aerosol have been observed from the crop residue burning of both rice, wheat and from rice paddies as well (Ali et al., 2014; ul-Haq et al., 2014; Tariq and Ali, 2015). Keeping in view the environmental perspective, in South Asia, Pakistan is facing severe environmental problems due to rapid urbanization, with the need for more industrialization and motorization, energy crises and deforestation, leading to raised emissions of NO_2 (ul-Haq et al., 2017, 2018).

Atmospheric NO_2 and HCHO both have spectral absorption signatures in Ultraviolet to Visible (UV-Vis) regions of electromagnetic spectrum and are observed through the satellite sensors like OMI. These two pollutants have become of central importance and core data products, even for the future satellite-based programs for monitoring air quality (Nowlaqn et al., 2018). In a study, by (Zhu et al., 2017), emissions of HCHO produced through the oxidation of biogenically produced isoprene are linked with the concentrations of ($NO_x \equiv NO + NO_2$) in the atmosphere. Another important linkage, observed in the study by (Zhu et al., 2017), is between the absence of anthropogenic emissions of NO_x and a reduction observed in the emissions of HCHO. Presence of these two gases as indoor and outdoor pollutants has also been established as a health risk, and in a study by (Maroziene and Grazuleviciene, 2002), low birth weight and preterm births have been observed to have some linkage with the maternal exposures during first trimester to ambient HCHO and NO_2 exposures respectively. According to a study, controlling the emissions of NO_2 is beneficial to both, environment and human health, as it improves the quality of the air with ozone and also reduces the risks of cancer related to HCHO emissions (Zhu et al., 2017).

The objectives of this study are to analyze spatiotemporal trends of tropospheric HCHO and NO_2 columns over South Asia for a temporal window of 12 years, from 2005-2016, with the help of remote sensing data from Ozone Monitoring Instrument (OMI) aboard the NASA Aura spacecraft. Interannual variability and seasonal trend analyses with spatial landuse/landcover pockets in varying scales and diversity of the landforms, influencing and modeling the local columns of HCHO and NO_2 will be analyzed. Some of the major biogenic activities on the global scale are affecting biogenic emissions of VOCs, as tropical deforestation has resulted in 29% decrease in isoprene emissions (Lathière et al., 2006). Assessment of the emission of the subject trace gases, affected by the underlying landuse/landcover in connection with anthropogenic, biogenic and pyrogenic activities is important to understand the atmospheric processes and photochemistry shaping up the overall atmospheric profile in this part of the world. For an in-depth analysis, to analyze the impact and trends of change on local HCHO and NO_2 columns, seven study zones will be analyzed for the assessment of emissions from different landuse/landcover directly or indirectly impacting tropospheric columns of HCHO and NO_2.

Material and methods

Geography and meteorology of study area

South Asia refers to the Southern region of the Asian continent with the most densely populated countries of the world, comprising of sub-Himalayan member states of South Asian Association for Regional Cooperation (SAARC), including Pakistan, India, Bhutan, Maldives, Sri Lanka, Afghanistan, Bangladesh and Nepal (Joshi, 2015) shown in *Figure 1a*. This region is marked in North by three gigantic mountain ranges of Himalaya, Hindukush and Karakoram, with emanating thickly populated, major river basins of Indus, Ganges, Brahmaputra, and Meghna extending from Pakistan to Bangladesh. The driest and deserted Baluchistan plateau located in Afghanistan and Pakistan, while the Peninsular India, consisting of Deccan plateau and the island countries of Sri Lanka and Maldives (Seligman, 2008; UNEP, 2008).

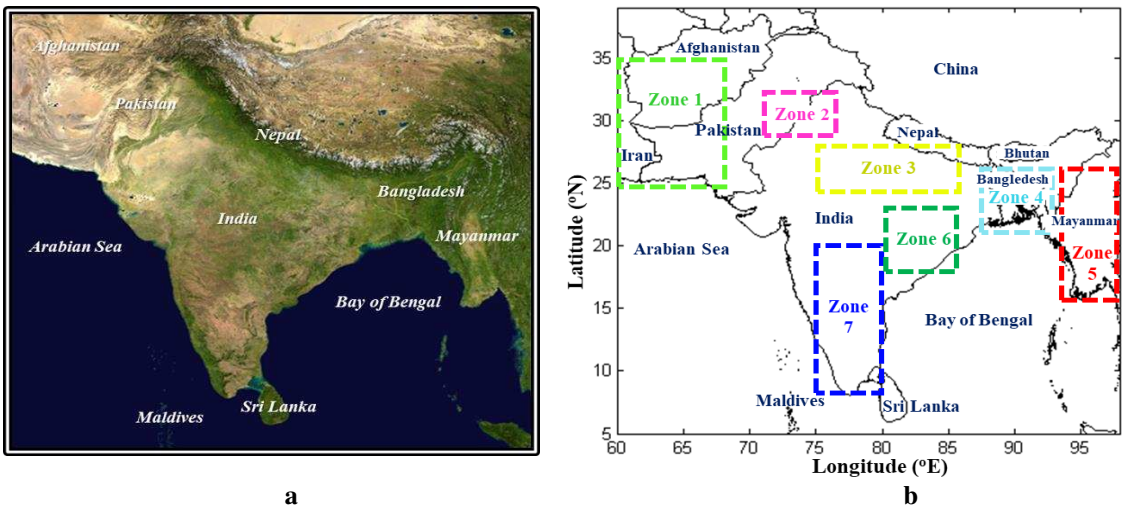

Figure 1. *(a) Satellite image map of South Asia showing landuse/landcover of world's most densely populated region. (Source: https://upload.wikimedia.org/wikipedia/commons/2/2a/Asia_satellite_orthographic.jpg), (b) Map of South Asia showing country boundaries and selected seven study zones shown in different colors*

South Asian climate is quite variant, dictated by highest mountains of the world, exhibiting arctic temperatures, transitioning in temperate regions in lower Himalayas to the tropical scenarios in Deccan plateau in the central India. Alternating wet and dry weather sessions brought by the monsoons control the overall climate of South Asia. Wet monsoons are caused by the moist winds from the sea in summertime, while in winter the dry monsoon is associated with the dry winds blowing out from land areas (UNEP, 2008; Joshi, 2015). For an in-depth analysis and investigation of HCHO and NO_2 along with the processes, South Asian region has been further investigated in seven study zones (*Fig. 1b*), from zone-1 to zone-7, comprising of regions with different landuse/landcovers, representatives of anthropogenic, biogenic and pyrogenic activities and emissions taking place at different scales. These seven study zones with corresponding geographic locations and possible/prominent sources of HCHO and NO_2 emissions from different landuse/landcovers and related activities have been detailed in *Table 1*.

Table 1. *Study zones with geographical locations and prominent landuse/landcover sources of emissions of HCHO and NO_2. (Source: Lathière et al., 2010; Tariq et al., 2015; Sippo et al., 2016)*

Study zones	Geographical bounding	Prominent landuse/landcover sources of NO_2	Prominent landuse/landcover sources of HCHO
Zone-1	25-35 °N, 60-68 °E	Karachi, Gawadar and Chahbhar Ports activities, fossil fuel burning, urban (megacity Karachi)	Karachi, Gawadar and Chahbhar Ports activities, fossil fuel burning, urban (megacity Karachi), Shipping activity and emissions
Zone-2	28-32 °N, 72-77 °E	Large scale crop-residue burning, (post-monsoon and pre-monsoon pyrogenic emissions), Agricultural Landuse/Landcover, urban (megacities Lahore, Delhi, Faisalabad), industries, home heating, brick kilns, power plants	Large scale crop-residue burning (post-monsoon and pre-monsoon), urban (megacities Lahore, Delhi, Faisalabad), industries, home heating, brick kilns, power plants, deciduous forests in lower Himalayas in North Western parts of India (Biogenic emissions)
Zone-3	24-28 °N, 75-87 °E	Crop-residue burning (post-monsoon and pre-monsoon pyrogenic emissions), industries, home heating, brick kilns, power plants	Crop-residue burning (post-monsoon and pre-monsoon pyrogenic emissions), industries, home heating, brick kilns, power plants. Deciduous forests in sub-Himalayan Siwalik ranges in India and Nepal
Zone-4	20-26 °N, 87-92 °E	Large scale crop-residue burning (pre-monsoon pyrogenic emissions), Mining activities, power plants, industries, brick kilns, urban (megacities Dhaka, Kolkata, Anthropogenic emissions)	Large scale crop-residue burning (pre-monsoon), Mining activities, power plants, industries, brick kilns, urban (megacities Dhaka, Kolkata) Biogenic emissions from the mangroves of Sundarbans in Bangladesh
Zone-5	15-26 °N, 93-98 °E	Large scale crop-residue burning (pre-monsoon), fossil fuel burning, home heating	Large scale crop-residue burning (pre-monsoon), fossil fuel burning, home heating, Biogenic emissions from Palm oil plantations in Myanmar
Zone-6	18-23 °N, 80-85°E	Major coal powered energy production plants and the largest coal mining region of India	Major coal powered energy production plants and the largest coal mining region of India
Zone-7	08-20°N, 75-80 °E	South Western Ghats of India, Anthropogenic emissions from the mega city of Bengaluru	South Western Ghats of India with deciduous montane rain forests in Kerala, and Karnataka states of India, Anthropogenic emissions from the mega city of Bengaluru

Maps of relative humidity at 925 mb, surface precipitation, wind vector at 925 mb and surface air temperature for South Asia for study period from 2005 to 2016 have been shown in *Figure 2*. These maps of selected meteorological parameters show the variations captured for four seasons i.e. winter season, comprising of the months of December, January and February, Pre-monsoon, described by March, April and May, Monsoon season, studied for the months of June, July and August, and Post-monsoon season consisting of the months of September, October and November. These

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

parameters have been mapped using records from NCEP–Reanalysis data from NOAA/OAR/ESRL PSD, Boulder, Colorado, USA. *http://www.esrl.noaa.gov/psd/.*

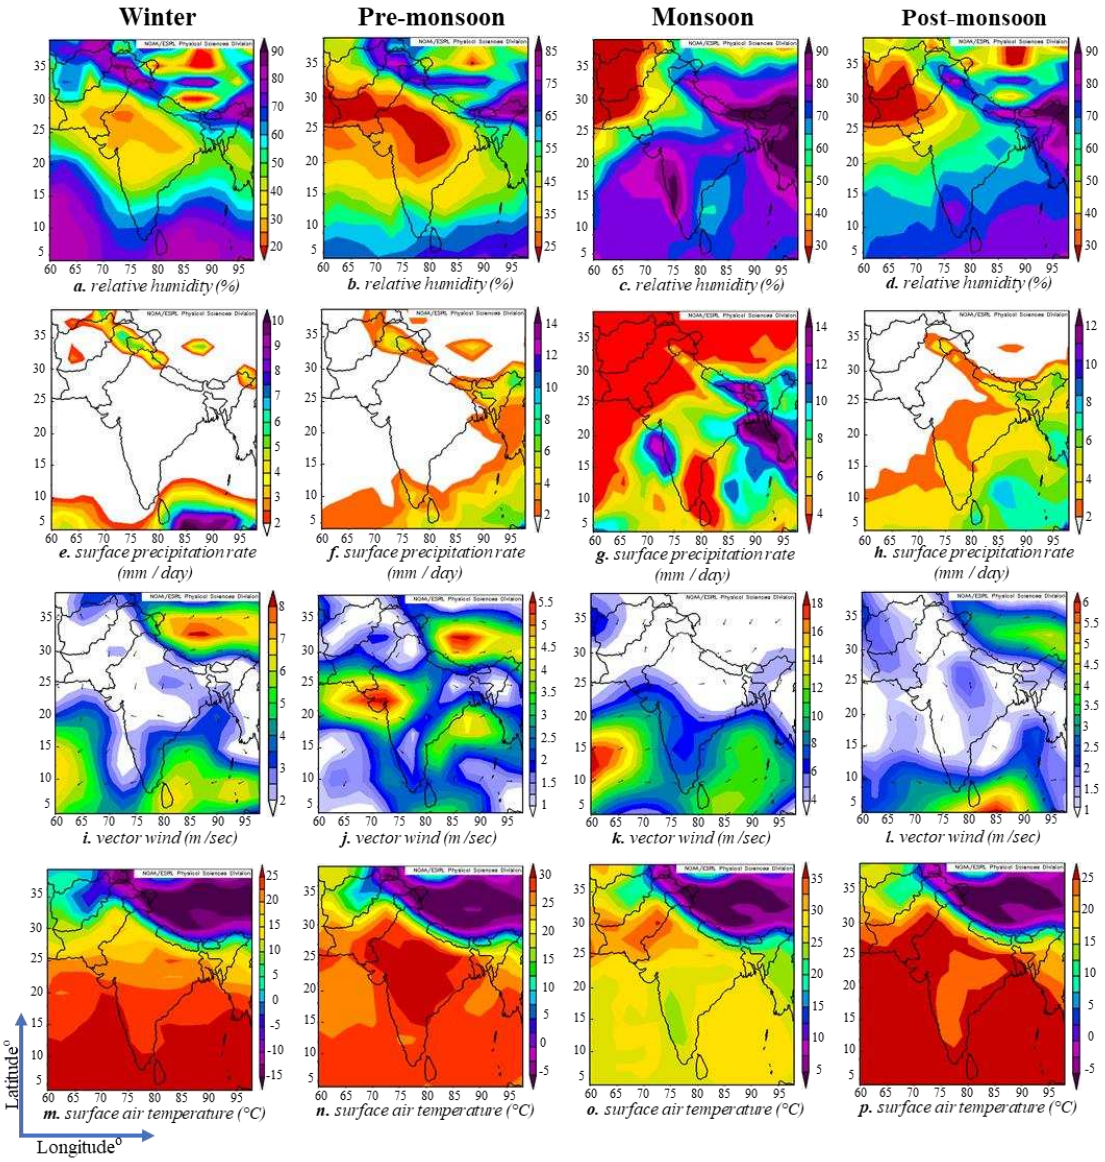

Figure 2. *Maps showing seasonal composite means for the study period (2005-2016) of relative humidity (%) at 925 mb (a–d), surface precipitation rate (mm/day) (e–h), vector wind (m s-1) at 925 mb (i–l), and surface air temperature (°C) (m–p) over South Asia. Source: NOAA/ESRL Physical Sciences Division, Boulder Colorado from their Web site at http://www.esrl.noaa.gov/psd/*

Maps show the highest relative humidity in monsoon season for most of South Asia, especially on the Eastern regions, comprising of Bangladesh, Myanmar and central India along with the coastal belt in the Southeastern parts of India besides the Western Ghats. However, the winter season has been found dry over South Asia for having the minimum relative humidity for the study period. Monsoon season also dominates the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

surface precipitation over South Asia, with few pockets of precipitations observed over the Himalayas in the winter season.

Pre-monsoon season highlights the high content of winds, especially in the mid latitude areas of South Asia, rising from the Runn of Kutch along the India Pakistan coastal border and in the Rajhistan desert. High wind vectors are also observed in Tibetan plateau in the pre-monsoon season. A consistent cold pattern can be observed all along the Himalayas, throughout the year in all four seasons in the maps showing the low surface air temperatures for the study period. Whereas, pre-monsoon and post-monsoon seasons exhibit high temperatures in mid latitudes to the southern parts of South Asia. Changes observed in the concentrations of tropospheric NO_2 column over South Asia could possibly be linked to the shifts in meteorological regimes controlled by the meteorological phenomenon, which result in the changes in the rates of chemical reactions in the troposphere (Voulgarakis et al., 2010).

NCEP/NCAR reanalysis data

In 1991, a reanalysis1 project between National Center for Environmental Prediction (NCEP) and National Center for Atmospheric Research (NCAR) started to expand the National Meteorological Center (NMC)'s Climate Data Assimilation System (CDAS) project capacity. Objective of the CDAS project was to improve the forecasts by NMC operational Global Data Assimilation System (GDAS) over the last decade for the apparent climate change. In this reanalysis project a frozen state-of-the-art analysis and forecast system is used for the assimilation of the past data to perform reanalysis from 1957 to present. For the futuristic development in CDAS, same frozen state-of-the-art analysis/forecast system will be used to assess the anomalies in the current climate in the context of long reanalysis with the same data assimilation system (Kalnay et al., 1996). An improved version of reanalysis 1(R1) has been developed by NCEP/NCAR as Reanalysis 2 (R2). Improvements in R1 include updates in the model with better parameterization, inclusion of additional data and fixing the errors in assorted data assimilation. Data from NCEP/NCAR can be downloaded for more than 80 meteorological variables like, Surface temperature, Relative humidity, geopotential height, u-and v- wind components etc. Data from these sources are gridded and archived at the grid interval of 2.5° × 2.5° providing global data and is available from https://www.esrl.noaa.gov/psd/data/reanalysis/reanalysis.shtml.

OMI data for NO_2 and HCHO

Ozone Monitoring Instrument (OMI) is a joint venture of Dutch-Finnish collaboration (Levelt et al., 2006) onboard NASA's EOS Aura satellite, launched in July 2004. OMI is a push-broom near-UV/Visible spectrometer orbiting in a sun-synchronous orbit with an ascending node, crossing the equator at 13:40 local time. OMI sensor captures data of various trace gases including NO_2 and HCHO. OMI scanner consists of two 2-dimensional Charged Coupled Devices (CCD) detectors (Dobber et al., 2006). To sync the spectral and spatial registration, one of the two CCDs, i.e. CCD1 captures the UV1 (264-311 nm) and UV2 (264-311 nm), while CCD2 captures the VIS (349-504 nm) spectral bands. Spectral features of NO_2 are more prominent in the later channel, while UV2 spectral channel is used for HCHO slant column densities (SCDs) (Zara et al., 2018). OMI sensor captures the global data daily with spatial resolutions of 13 × 24 km^2 to ~25 × 105 km^2 in nadir and to the outermost

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

swath-angle, respectively with a swath of 2600 km at every given exposure in the orbit (De Graaf et al., 2016; Krotkov et al., 2016).

OMI tropospheric HCHO data

OMI sensor has been in orbit for more than a decade, and its long-term observations of tropospheric HCHO column has provided valuable information regarding this important trace gas carcinogen. HCHO column data used in this study has a grid interval of 0.25° latitude by 0.25° longitude, retrieved through Differential Optical Absorption Spectroscopy (DOAS) algorithm and an Intermediate Model of the Global and Annual Evolution of Species (IMAGES) as a priori information (Kaczorowski and Perelli, 2004). OMI sensor also provides a valuable difference in time window, providing a complimentary early afternoon data of tropospheric HCHO column at 13:40 local solar time (Kurosu, 2008; Millet et al., 2008) as compared to the other satellites, like GOME-2 at 9:30 and SCIAMACHY at 10:00 local solar time providing the HCHO column data at mid-morning (Chance et al., 2000; Palmer et al., 2001; De Smedt et al., 2008). The Royal Belgian Institute for Space Aeronomy (BIRA-IASB), in the previous version addressed the instrumental degradation and the striping effect by employing row-dependent background normalization (De Smedt et al., 2015). Several improvements in the product also include accounting for more accurately the absorption of O_2-O_2. For this purpose, interactive DOAS algorithm involving three fitting intervals was used. In order to reduce the degradation, radiances in remote equatorial Pacific were used (De Smedt et al., 2015). In the previous products, some of the main reasons of uncertainty, ranging from 30 to 40% in the tropospheric HCHO column include, errors in retrieval of the SCD and errors in estimation of Air Mass Factor (AMF) (De Smedt et al., 2008), where AMF has been defined as the ratio of SCD and VCD (Millet et al., 2006). Therefore, the HCHO products available on (TEMIS) are highly applicable for the spatial and temporal assessment of HCHO distributions over South Asia in the context of regional landuse/landcover. In this study, daily, global, gridded (OMHCHOd) Level-3 data for tropospheric HCHO Vertical Column Density (VCD) has been used for the study period of twelve years, i.e. 2005-2016, obtained from Tropospheric Emission Monitoring Internet Service (TEMIS) (http://h2co.aeronomie.be/).

OMI tropospheric NO_2 data

NASA's EOS Aura satellite with OMI sensor was launched in July 2004, and provides a daily, global gridded coverage of tropospheric concentrations of NO_2. For retrievals of NO_2 the cloud conditions used, have taken into account the cloud cover to be clear and up to 30% in Air Mass Factor (AMF), that uses the Lambertian Cloud Model with an assumed albedo of 0.8 to develop a simulated profile of NO_2 (Stammes et al., 2008). Radiative transfer models are used to calculate the AMFs, which considers the parameters like, surface albedo, cloud and aerosol properties, optical geometry, vertical distribution of absorbing trace gas and atmospheric scattering by air molecules (Bucsela et al., 2006; Stammes et al., 2008; Boersma et al., 2011). For the estimation of NO_2 Slant Column Densities (SCDs) to retrieve the vertical NO_2 column, Differential Optical Absorption Spectroscopy (DOAS) spectral fitting, with radiance in the range of 405-465 nm has been used. In order to get the Vertical Column Density (VCD) of a gas, SCD, depending upon density of the gas and various other parameters is divided by the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

AMF. Improvement in NO_2 retrievals can be achieved by curtailing the errors introduced in calculating AMF, due to surface albedo, presence of clouds and NO_2 profile as the dominant anomalous factors, affecting the accurate tropospheric NO_2 retrievals over areas with enhanced NO_2 (Boersma et al., 2004). Uncertainties in surface albedo contribute 20-30%, while, for cloud fraction it may contribute as high as 20-50% errors for the estimation of NO_2 column (Boersma et al., 2004). Another factor contributing to the inaccurate estimates of NO_2 are aerosols, that can indirectly affect the calculations for the AMF, as they introduce uncertainties in the cloud fraction calculations (Boersma et al., 2008, 2009). A comparison of ground-based in-situ measurements and the data retrieved from OMI sensor suggests that the data from OMI sensor is 0-30% biased (Lamsal et al., 2010). In this study, OMI sensor product (OMNO2d v003) for tropospheric NO_2 column prepared at level-3, providing the data in gridded form at a grid interval of 0.25° latitude by 0.25° longitude is used and downloaded from Giovanni, https://giovanni.gsfc.nasa.gov/.

MACCity emissions data

MACCity is a joint data product contributed by two projects namely, Monitoring Atmospheric Composition and Climate (MACC) and megaCITY–Zoom for the Environment (CityZEN). MACCity products deliver emission data for various atmospheric gasses for the last about sixty years, from 1960 to 2020 and is provided by Emissions of atmospheric Compounds & Compilation of Ancillary Data (ECCAD). MACCity anthropogenic emission datasets are based on Representative Concentration Pathways (RCPs, 8.5, van Vuuren et al., 2011) and Atmospheric Chemistry and Climate Model Inter-comparison Project ACCMIP, (Lamarque et al., 2010). For the futuristic projections of emissions for different scenarios used in the IPCC AR5 report (van Vuuren et al., 2011), starting point for the development of the RCPs is based on the ACCMIP emissions in year, 2000. Whereas, anthropogenic emissions inventoried through ACCMIP rely on various emission database inventories combined and synchronized together, including RETRO, EDGAR, EMEP, EPA, REAS, GICC and GFEDv2, which are based on emission estimates due to anthropogenic activities, historical emissions databases, modelled studies and satellite observations. Many modelers name the MACCity as A2-ACCMIP for having some minor differences between A2-ACCMIP (AeroCom Phase II-ACCMIP) and MACCity (Diehl et al., 2012). MACCity anthropogenic emission datasets are available for download from Ether/ECCAD databases, provided at *http://www.eccad.sedoo.fr.*

In this study, MACCity data for HCHO and NO_x emissions gridded at 0.5° latitude by 0.5° longitude (Granier et al., 2011) have been analyzed for the study period of 12 years, i.e. from 2005 to 2016, generated through six different anthropogenic emission sectors, including industrial sector (for both non-combustion and combustion), waste burning from agricultural fields, residential emissions, energy production sector, transportation sector and an overall sumsector (Amnuaylojaroen et al., 2014).

Analysis and discussion

MACCity HCHO emissions

Spatial distributions of MACCity HCHO emission data from different emission sectors for South Asia spanning over a period of 12 years, from 2005 to 2016 are shown

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

in *Figure 3*. Spatial representation of sum emissions due to anthropogenic activities contributed by some of the major emission sources are shown in *Figure 3a*. These major contributors to the sum sector include emissions from agricultural waste, residential and commercial practices, from industrial processes, transportation sector and from energy production and distribution sectors as shown in *Figure 3*.

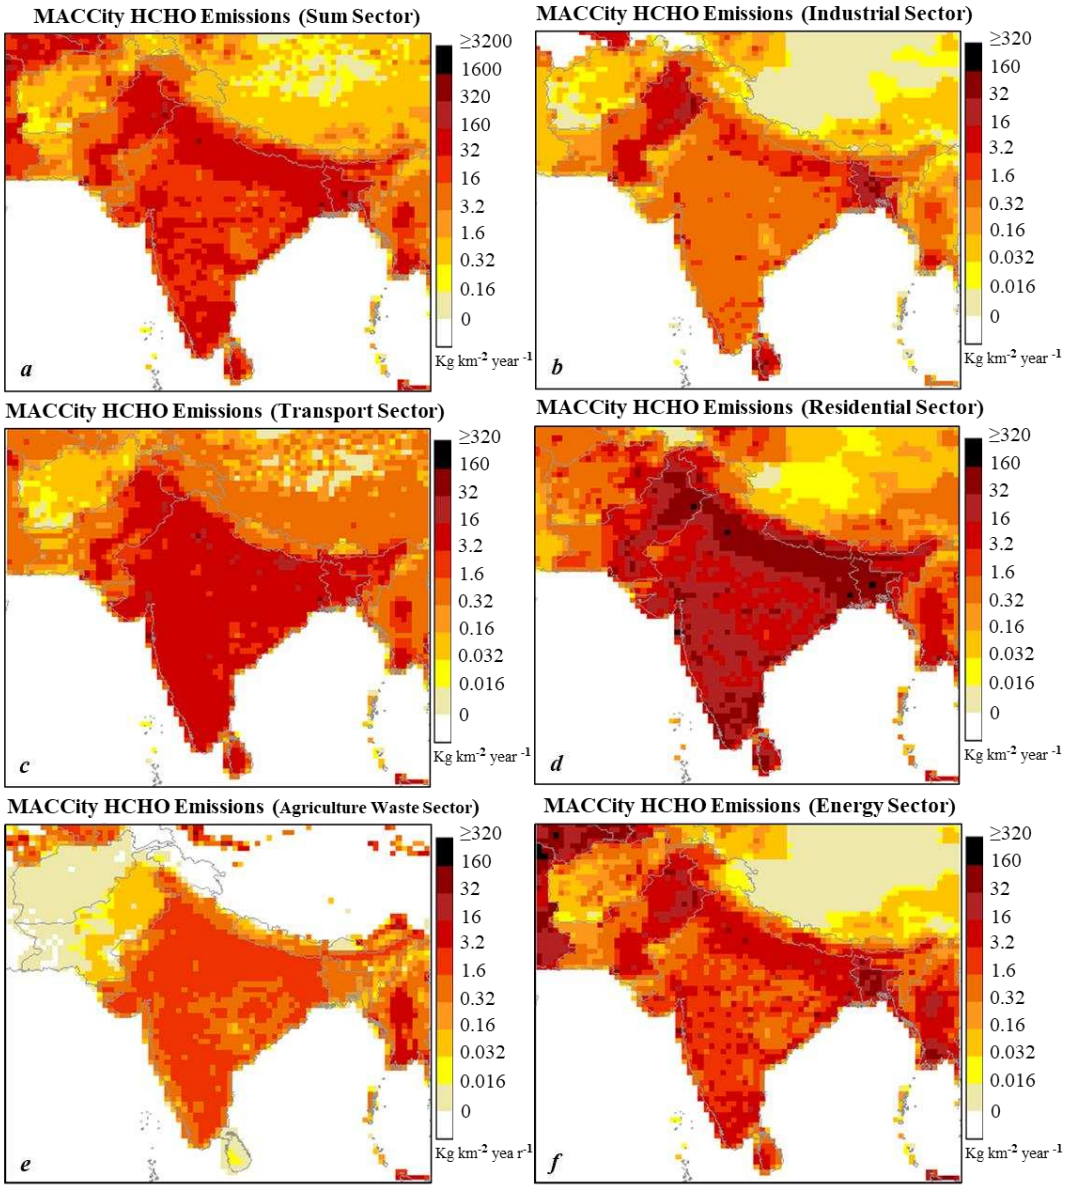

Figure 3. *MACCity based average anthropogenic HCHO emissions (kg km^{-2} year^{-1}) from (a) Sum sector (b) Industrial sector (c) Transport sector (d) Residential sector (e) Agricultural Waste sector and (f) Energy sector over South Asia during 2005-2016*

As shown in *Table 2*, MACCity HCHO anthropogenic emission datasets have shown a considerable rise in emissions from transportation sector in South Asia, raising the emissions from ~8536 kg km^{-2} year^{-1} in 2005 to ~12322 kg km^{-2} year^{-1} in 2016. A

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

statistical linear regression-based change analysis on annual mean data of 12 years (2005-2016), shows, ~51% rise in the emissions from transportation sector with ($R^2 = 0.74$). Like the transportation sector, residential and energy sectors also show significant rises, i.e. 13.8% and 11.5% respectively derived through regression-based trend analysis of 12 years of the study period with corresponding coefficients of determination ($R^2 = 0.72$ and 0.62) respectively. Anthropogenic emissions of HCHO are generally observed to be on a rise during the study period and overall sum sector emissions are raised by 21.6% with coefficient of determination ($R^2 = 0.86$) over South Asia. According to (Surl et al., 2018), these high emissions of HCHO from NMVOCs may be associated with the origination from the stationary combustion sources like, residential areas and also from the transportation sectors. In this study, high percentage changes observed in the transportation and residential sectors during the study period 2005-2016 are also endorsed by the observations in the foresaid study.

Table 2. *MACCity average anthropogenic emissions of HCHO in (kg km^{-2} year^{-1}), percentage change, slope of the regression equation and coefficient of determination R^2 over South Asia from January 2005 to December 2016*

Emission sectors	**Average emissions kg km^{-2} year^{-1} (2005-2016)**	**% Change (2005-2016)**	**(Slope of regression equation); (Coefficient of determination R^2)**
Sum sector	72740	21.6	(1234.2 ± 146.6); (0.86)
Agricultural waste sector	2611	7.5	(17.1 ± 5.1); (0.53)
Energy sector	17207	11.5	(169.9 ± 40.9); (0.62)
Industrial sector	4759	3.5	(14.9 ± 6.2); (0.36)
Residential sector	38909	13.8	(457.3 ± 88.4); (0.72)
Transportation sector	9397	51.1	(347.7 ± 65.2); (0.74)

MACCity NO_x emissions

Spatial distributions of MACCity NO_x emissions from different emission sources for the study region over a period of 12 years, from 2005 to 2016 are shown in *Figure 4*. Spatial representation of sum emissions due to anthropogenic activities contributed by some of the major emission sources in South Asia are shown in *Figure 4a.* Major contributors to the sum sector include emissions from residential and commercial practices, from industrial processes, from agricultural waste, transportation sector and from energy production and distribution sectors as shown in *Figure 4.*

As given in *Table 3*, MACCity NO_x anthropogenic emission datasets have shown a considerable rise in the emissions from the transportation sector in South Asia for the study period of 12 years. Emissions in this sector vary from ~ 573947 kg km^{-2} year^{-1} in year 2005 to ~ 1120025 kg km^{-2} year^{-1} in 2016, making a drastic rise in emissions to about 95.6% with a coefficient of determination ($R^2 = 0.98$), through a linear regression trend analysis. This rise is also consistent with the rise in emissions of HCHO for transportation sector showing the largest change in anthropogenic emissions with an increase of ~51% for the study period. Like the transportation sector, energy and industrial sectors also show significant rises in the emissions of NO_x, i.e. 35.3% and 20.7% respectively with the corresponding coefficient of determination ($R^2 = 0.94$ and 0.97) determined through regression analysis for the entire study period of 12 years.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

Anthropogenic emissions of NO_x are generally on a rise as observed by the overall sum sector emissions raised by 42.7% having a coefficient of determination ($R^2 = 0.99$). In this study, these high emissions of NO_x may be associated with the overall high emissions recorded for the tropospheric HCHO column as well, and as reported by Surl et al. (2018).

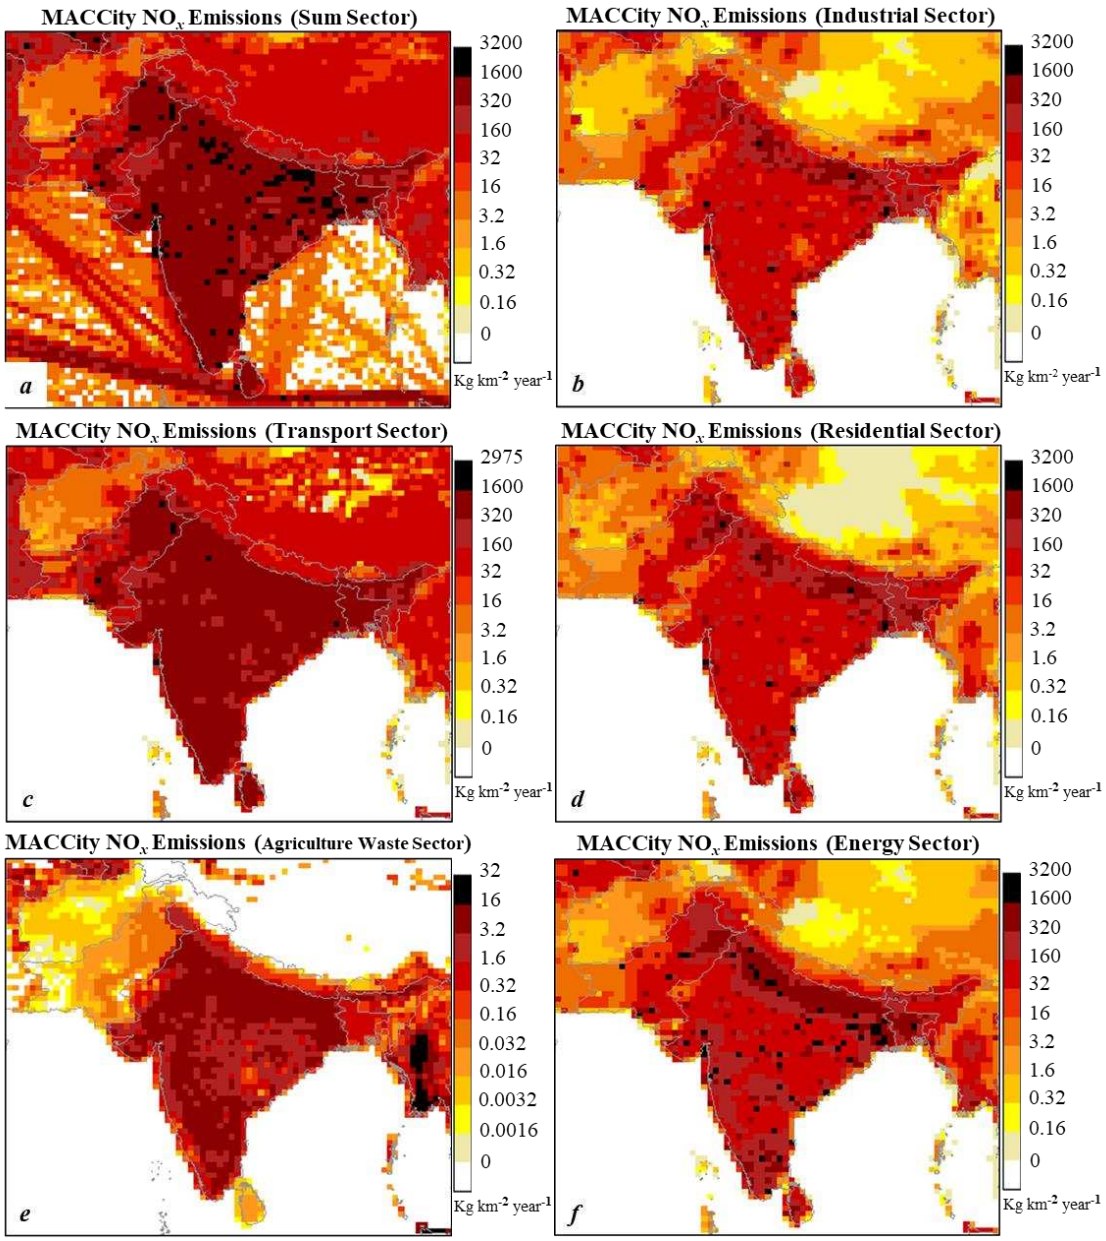

Figure 4. *MACCity based average anthropogenic NO_x emissions (kg km^{-2} $year^{-1}$) from (a) sum sector (b) industrial sector (c) transport sector (d) residential sector (e) agricultural waste sector and (f) energy sector over South Asia during 2005-2016*

Transportation sector	816925	95.6	(48034.7 ± 2017.3); (0.98)

Zonal analyses of HCHO columns

Data products from OMI sensor, for HCHO and NO_2 have been analyzed for spatiotemporal analysis of the tropospheric columns of HCHO and NO_2. Annual means values for both the gases, regression trends and percentage changes for the entire study period of 2005-2016, for South Asia and seven study zones are shown in *Table 4*.

Table 4. *Summary of annual mean OMI-HCHO (× 10^{15} molecules cm^{-2}) and OMI-NO_2 (× 10^{15} molecules cm^{-2}), parameters of linear regression analysis and percentage change over entire South Asia and seven study zones during the period of 2005-2016*

South Asia	0.83 ± 0.05	0.006 ± 0.003	0.34	7.89

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

From *Table 4,* it is clear that the highest annual average value for tropospheric HCHO column, averaged for the entire study period of 12 years has been observed for zone-4, as $(10.20 \pm 0.16) \times 10^{15}$ molecules cm^{-2}. While, the lowest value $(4.22 \pm 0.05) \times 10^{15}$ molecules cm^{-2} for zone-1. The largest positive trend or change (ΔHCHO = 11.50%) has been observed for zone-5, while the lowest trend of change (ΔHCHO = 1.15) has been found for zone-1. This high value of change of HCHO column observed in zone-5, mainly representing the Myanmar region, can be attributed to the high rate of oil palms plantations in southern parts of Myanmar in the last decade. Oil palms have been reported to have a much stronger isoprene emission capacity (Lathière et al., 2010) than the tropical forests of South Asia (Stavrakou et al., 2014). With this plantation activity, associated changes to the landcovers and anthropogenic emissions due to urbanization and changing of natural vegetation with forest plantations have been reported to have significant impacts on the emissions of isoprene (Wiedinmyer et al., 2006) and isoprene being a linchpin for the connection between the satellite observations of tropospheric HCHO column and forested landcover (Wolf et al., 2016). Another high percentage of change in HCHO column, i.e. (ΔHCHO = 11.09%) is observed in zone-7, comprising of the major forest cover on southwestern coast of Indian state Kerala and this region is characterized as a region, where the isoprene has been observed to have the longest lifetime in air (Surl et al., 2018) which also contributes to the high concentrations observed for HCHO column using OMI data. Because of capturing data in early afternoon at 13:40 local time, providing ample time for this longest living isoprene to get converted into HCHO.

Zone-3 also exhibits a considerable change (ΔHCHO = 10.50%) over the study period. Emissions in this study zone are presented with compound influences, i.e., biogenic emissions from forested landcover regions of the states of Uttar Pradesh and Bihar in India and contributions from Nepalis forests. HCHO emissions in this zone are also contributed by the anthropogenic emissions from coal powered thermal electricity generation plants in the states of Uttar Pradesh and Bihar and cities of Jaipur and Lucknow and from the city of Katmandu from neighbouring Nepal. The weak positive trend found in zone-1 with (ΔHCHO = 1.15%) over the span of 12 years can be attributed to the arid and dry landcover, presented mostly by desert landcover, barren rocks and dry sandy soils with weak biogenic sources available for HCHO emissions and the being the least populated region of South Asia, comprising of Baluchistan province of Pakistan and parts of Southwestern Afghanistan for any considerable or noticeable anthropogenic emissions.

Among rest of the zones, i.e. zone-2 with (ΔHCHO = 8.34%) and zone-4 with (ΔHCHO = 8.22%), primarily represent the zones of high anthropogenic emissions through the megacities of Lahore, Faisalabad and Delhi in zone-2, while, Dhaka and Kolkata in zone-4. In zone-2, Pyrogenic emissions contribution comes through crop residue burning activity in the plains of irrigated belts of Punjab, on both, Indian and Pakistani sides. In zone-4, the HCHO contribution is very compound in nature, as all the three, anthropogenic, pyrogenic and biogenic sources are contributing, especially for Bangladesh. Here, contribution to the emissions through pyrogenic sources come from the crop residue burning. While, mangroves of Sundarbans emit significant amounts of isoprene which according to a study, is one of the main biogenic VOC (Barr et al., 2003; Exton et al., 2015) and is a precursor of HCHO. Emissions from zone-6 with (ΔHCHO = 7.58%) represents the regions of Indian states of Orissa and Chhattisgarh, marked with presence of extensive mining and coal powered electricity generation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

power plants and therefore, high emissions through anthropogenic activities. This region is attributed for being the largest coal mining area, along with mega coal powered electricity production plants in eastern India. Mean annual change for South Asia for the study period 2005-2016, ($\Delta HCHO = 9.86\%$) can be understood well with distinct anthropogenic, biogenic and selective pyrogenic sources of emissions of HCHO for different zones of land-use/landcover, contributing to the specific emissions of the tropospheric HCHO column.

Zonal analyses of NO_2 columns

Annual means values of tropospheric NO_2 column, regression trends and percentage changes for the entire study period of 2005-2016, for South Asia and seven study zones are shown in *Table 4*. From *Table 4* tropospheric column of NO_2 for the study period 2005-2016 has been observed with the highest average annual value of $(2.43 \pm 0.15) \times 10^{15}$ molecules cm^{-2} for zone-2, while the lowest value $(0.77 \pm 0.01) \times 10^{15}$ molecules cm^{-2} is observed for zone-1. Emissions captured through OMI sensor of vertical column of NO_2 exhibits the largest positive trend of change with ($\Delta NO_2 = 27.96\%$) in zone-6, and the lowest negative trend of change has been observed for zone-5 being ($\Delta NO_2 = -5.87\%$). It is also interesting to note here, that the annual mean value for the entire study period for zone-5 being $(0.93 \pm 0.02) \times 10^{15}$ molecules cm^{-2} is higher than the annual mean value observed in zone-1 $(0.77 \pm 0.01) \times 10^{15}$ molecules $cm^{-2,}$ but still the overall change for the entire study period of 12 years for zone-5 is less than zone-1. The largest trend of change found in zone-6 can be attributed to the Eastern coal mining zone of Indian states of Chhattisgarh and Orissa, where emissions of NO_2 have increased to $50 \pm 20\%$ from 2005-2015 (Krotkov et al., 2016) and are further complemented by 16 coal fired electricity power plants with a capacity of ~18000 Mega Watts (MW) and ~330 tons of NO*x* emissions annually (Sarath and Puja, 2014).

Zone-2 with a changing trend of ($\Delta NO_2 = 18.91\%$) is characterized with anthropogenic emissions from thickly populated megacities of Delhi, and Lahore, the Industrial city of Faisalabad and also due to pyrogenic emissions from the biomass burning, which also increase the aerosol loading in the region, especially in post-monsoon and winter season (Tariq et al., 2015) from Indian and Pakistani Punjab region. This high aerosol loading may also result in underestimation of NO_2 due to shielding effect of aerosols such as PM2.5 (Jamstec, 2014). Increasing trend in this zone of (~1.58% rise per year) has been found closely consistent with the (Ghude et al., 2009) as of ($1.76 \pm 1.1\%$ per year) for the South Asian countries. This zone-2 has also been found with the highest annual mean concentrations of column of NO_2 value for the entire study period of 2005-2016, i.e. $(2.43 \pm 0.15) \times 10^{15}$ molecules cm^{-2} because of high anthropogenic activity due to rapid urbanization, increasing vehicular activity, more food requirement, high crop residue burning and high biofuel burning for heating purposes. (Azad and Kitada, 1998; Ghose et al., 2004; Badarinath et al., 2006, 2009; Ghude et al., 2008, 2009; Gurjar et al., 2008; Renuka et al., 2014; Ali et al., 2014; ul-Haq et al., 2014; Tariq and Ali, 2015; Tariq et al., 2016). Lowest Observed negative trend ($\Delta NO_2 = -5.87\%$) has been found in zone-5, with annual mean value $(0.93 \pm 0.02) \times 10^{15}$ molecules cm^{-2}, with a consistently decreasing trend after the year 2011, reversing the positively changing trend observed till 2011 to a negative or decreasing trend for zone-5. Data from annual mean values for the vertical column of NO_2 reveal that this negative trend is consistent with the overall South Asian trends observed after the year 2011 to 2016 having ($\Delta NO_2 = -5.29\%$ making it ~-1.05% per year). Similar

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

declining trends have also been observed over China in studies by (Richter et al., 2015; Irie et al., 2016).

Zone-4 has also been observed as one of the positively trending regions with ($\Delta NO_2 = 23.64\%$) and annual mean emissions of NO_2 for the entire study period to be $(1.82 \pm 0.14) \times 10^{15}$ molecules cm^{-2}. This region is attributed with high emissions of NO_2 due to anthropogenic activities from megacities of Kolkata and Dhaka and crop residue burning, especially in pre-monsoon seasons (ul-Haq et al., 2015). Zone-3 has also been reported with high amounts of annual mean NO_2 emissions for the study period, being $(1.91 \pm 0.06) \times 10^{15}$ molecules cm^{-2} representing the changing trend to be ($\Delta NO_2 = 12.11\%$). This region also contributes significantly enough for emissions of NO_2, due to its industrial and anthropogenic activities for having coal mining region and coal-powered electricity generation power plants in the states of Bihar and Uttar Pradesh, emissions from the Indian cities of Jaipur and Lucknow and from neighbouring city of Kathmandu in Nepal. Zone-7 exhibits the similar trend as discussed particularly for zone-5 and generally matches with the changing trends for South Asia. In this zone, a decreasing trend has also been seen for the annual mean values of NO_2 after 2011 up to 2016. This makes the overall spatial average emissions of NO_2 for the study period to be $(1.32 \pm 0.04) \times 10^{15}$ molecules cm^{-2}, with an overall changing trend as ($\Delta NO_2 = 7.66\%$), and is more closely related to what was reported by (Ghude et al., 2008). South Asian mean annual change over the study period 2005-2016, ($\Delta NO_2 = 7.89\%$) can be understood well with distinct anthropogenic, biogenic and pyrogenic sources of emissions of NO_2 for different zones of land-use/landcover, contributing and affecting to the specific emissions of the tropospheric NO_2 column.

Spatial distributions of HCHO and NO_2 columns

Mean Spatial distributions derived from the annual mean values of OMI data for tropospheric columns of HCHO and NO_2 emissions along with the changing trends over South Asia for the entire study period, from 2005 to 2016 are shown in *Figure 5*.

In *row (a), Figure 5,* Spatial distributions of annual-mean area averaged tropospheric HCHO column ($\times 10^{15}$ molecules cm^{-2}), and annual-mean area averaged tropospheric NO_2 column ($\times 10^{15}$ molecules cm^{-2}) over South Asia for the study period of 2005 to 2016 are presented, retrieved through OMI data on left and middle columns respectively. Trends of these area averaged annual mean values, both for, HCHO and NO_2 from 2005 to 2016 over South Asia are also presented in the right column of *row (a)*, *Figure 5*. A linear regression on the annual mean values of NO_2 data shows an increasing trend, with annual increase of ~0.66% and an overall increase of ~7.9% for the entire study period, with a slope of 0.006 (± 0.003), coefficient of determination ($R^2 = 0.35$) and *y*-intercept at 0.830426 (± 0.019072) $\times 10^{15}$ molecules cm^{-2}. These increasing trends of NO_2 for a period of first seven years from 2005-2011, with annual increase of ~1.86% making seven-year increase of ~13.01%, with a slope of 0.0172 ± 0.0029, coefficient of determination ($R^2 = 0.88$) and *y*-intercept at 0.7767 (± 0.013096) $\times 10^{15}$ molecules cm^{-2} have been found well in agreement with the trends presented by (Ghude et al., 2009), i.e. $1.76 \pm 1\%$ per year over south Asia. However, NO_2 retrievals from OMI data, after reaching to a peak value in year 2011 with 0.845567 (± 0.040695) $\times 10^{15}$ molecules cm^{-2} show consistently a negative change, till 2016. This decreasing trend has been observed for every two consecutive succeeding years for tropospheric NO_2 columns, showing the consistency in this declining trend. In the last five years of the study, from 2012 to 2016, the rate of change per year has been

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

observed to be reduced with decreasing values of NO_2 column, having an annual decrease of ~1.06% as compared to the value of change for the first seven years of the study. i.e. ~1.86%, and making an overall decrease for the last five years of ~5.29%, with a slope of -0.012 (± 0.007), coefficient of determination (R^2 = 0.50) and *y*-intercept at 0.907322 (± 0.023287) $\times 10^{15}$ molecules cm^{-2}. Similar decreasing trends of the tropospheric NO_2 column have also been reported in China after the year 2011, where this rate of decline has been reported to be ~6% year $^{-1}$(Richter et al., 2015; Irie et al., 2016). Reasons for lowering the values of the tropospheric column of NO_2 could be linked to the shift in meteorological regions, affecting. e.g., the rates of chemical reactions and air mass visibility for satellite observations in troposphere (Voulgarakis et al., 2010) and due to strategies adopted for lowering NOx emissions through technological improvements like adoption of cleaner technologies and also due to some decline in the economic activity related to NOx emissions (Hilboll et al., 2017).

Linear regression analysis performed on the area averaged annual mean values of HCHO data shows an increasing trend over South Asia, with an annual increase of ~0.74% and an overall increase of ~9.86% for the study period of twelve years, with a slope of 0.050508 (± 0.014932), coefficient of determination (R^2 = 0.53) and *y*-intercept at 6.220404 (± 0.109894) $\times 10^{15}$ molecules cm^{-2}. Such increasing trends of HCHO over countries of South Asia have also been reported in the study by (De Smedt et al., 2010). These increasing trends for HCHO emissions could also be associated with the increasing anthropogenic sources of emission in South Asia as shown by the results from the MACCity emission data sources, which indicate that for the period of 2005-2016 anthropogenic emissions have been increased to about 22% and hence the overall increase in HCHO emissions.

In *Figure 5*, *rows (b), (c), (d)* and *(e)* also represent spatial distributions of area averaged seasonal mean values of HCHO and NO_2 columns averaged from OMI monthly mean data for the entire study period of 12 years from 2005 to 2016 for Pre-Monsoon, Monsoon, Post-Monsoon and Winter seasons respectively. Seasonal spatial distributions of HCHO and NO_2 columns show the variations of emissions with the changing seasonal conditions over different landuse/landcovers. In *Figure 5*, *row (b),* HCHO column exhibits higher concentrations for pre-monsoon season, observed along the Indo-Gangetic Basin (IGB) with the forest cover, especially along the foothills of the Himalayas in northwestern India, industrial landuse and activity in the Eastern mining zone of India, biogenic emissions from the mangrove forests (Barr et al., 2003; Exton et al., 2015; Sippo et al., 2016) of Sundarbans in Bangladesh and the forest cover of western Ghats in the states of Kerala and around. Similar anthropogenic and biogenic emissions have also been observed from Myanmar. In *Figure 5*, *row (b),* the spatial distribution of tropospheric NO_2 column for pre-monsoon season retrieved through OMI also highlights the megacities of Lahore and Delhi representing the major contributions through anthropogenic emissions and from crop residue and biomass burning for heating purposes. These pre-monsoon, spring seasonal high values may be associated with the meteorological conditions as well (ul-Haq et al., 2015). Such highlighted emissions are also observed in the in the Eastern mining zone of India in the states of Chhattisgarh and Orissa, also the pre-monsoon pyrogenic emissions are also highlighted in the Bangladesh region.

DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

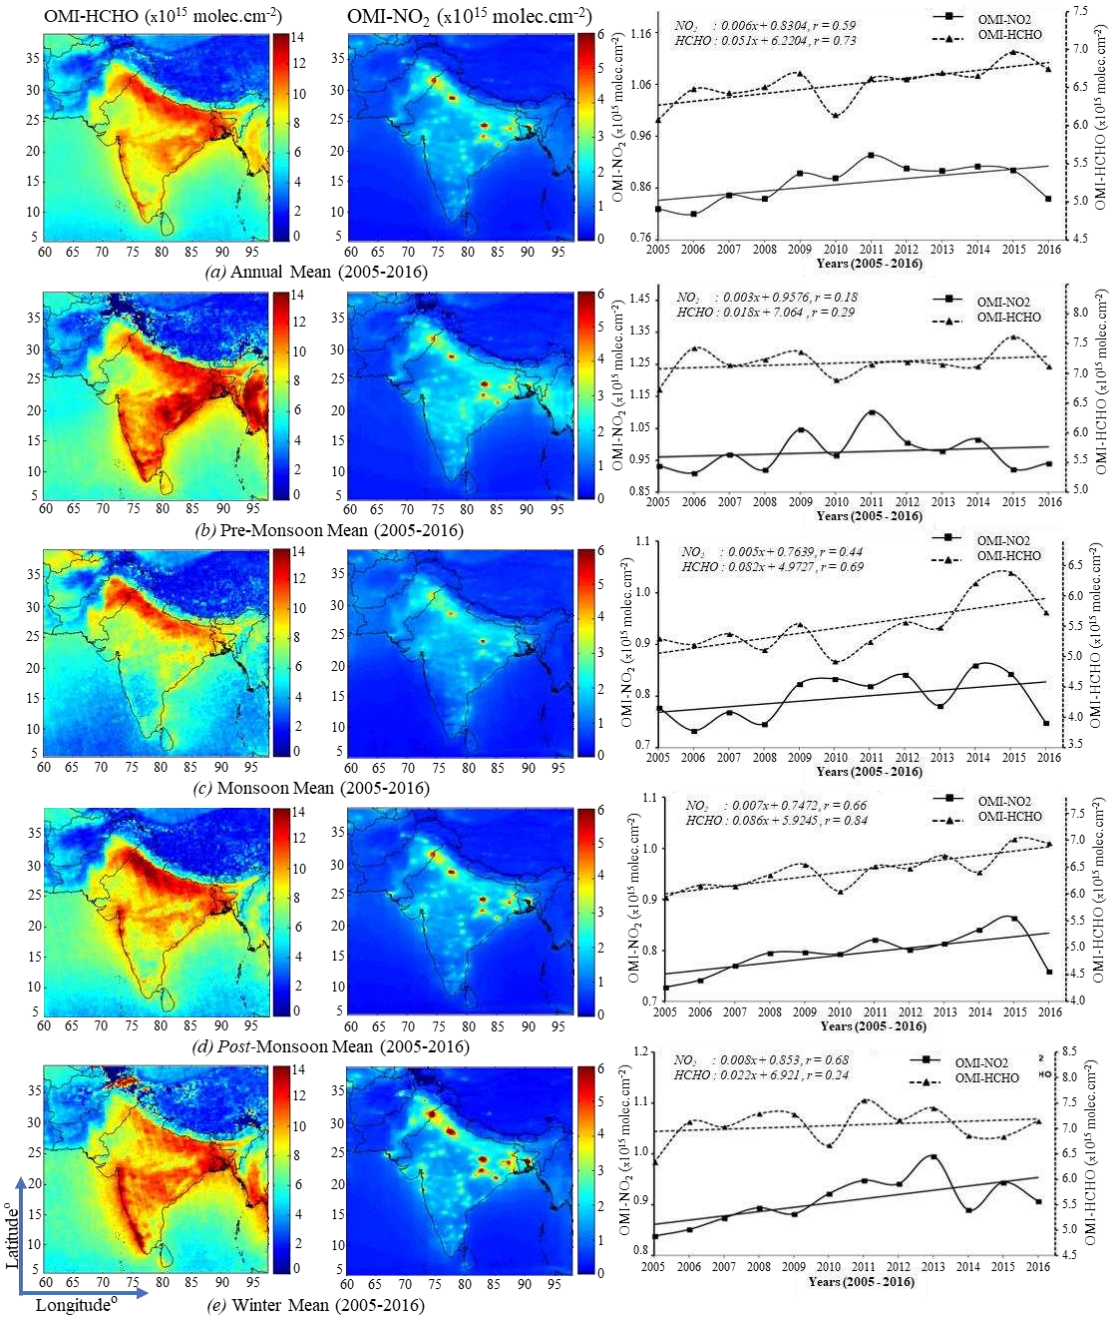

Figure 5. *Annual mean area averaged spatial distributions of tropospheric columns of HCHO and NO_2 (× 10^{15} molecules cm^{-2}) over South Asia for study period of (2005-2016) along with the varying trend for 12 years is shown in row (a), in left and middle columns respectively. Seasonal, mean area averaged spatial distributions of HCHO and NO_2 columns (× 10^{15} molecules cm^{-2}) along with the varying seasonal trend for entire study period for all the four seasons over South Asia from (2005-2016) are shown as, Pre-Monsoon in row (b), monsoon in row (c), post-monsoon in row (d) and winter in row (e), respectively*

Spatial distribution of HCHO and NO_2 columns for the monsoon season (*Fig. 5*, *row c*), exhibits relatively low activity for both NO_2 and HCHO emissions for the underlying landcovers. Lower values of HCHO column in the monsoon conditions could be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

ascribed to low wind speeds, high humidity and rain driven washout of the gaseous air pollutants (Verma et al., 2015). This can also be seen from *Figure 2*, where low wind vectors are observed in monsoon season along with high precipitation resulting in this kind of washout phenomenon of pollutants. Whereas, these seasonal low values observed for NO_2 could be associated with the higher concentration of (Hydroxyl) OH ions, making an increased activity of photo-dissociation of NO_2, advection of clean air mass and due to increased solar radiation for having longer day hours (Ravindra et al., 2003; Ghude et al., 2009; Yoo et al., 2014).

Spatial distribution of HCHO column over South Asia for post monsoon season (*Fig. 5*, *row d*), shows lower concentrations and that can be associated with low biogenic emissions especially from the forested regions due to leaf phenological variations depicted by the low values of NDVI 0.379 ± 0.029, derived by MODIS onboard Terra satellite , as compared to pre-monsoon season with NDVI values to be 0.527 ± 0.018, for the months of March, April and May. These phenological changes in post monsoon season could be one of the reasons for lower values of isoprene emissions and hence the lower concentrations of HCHO column observations (Surl et al., 2018). Post-monsoon relatively higher concentrations of NO_2 column are observed due to the activity of large-scale crop waste burning (ul-Haq et al., 2014).

Spatial distribution of HCHO column over South Asia for winter season (*Fig. 5, row 5*) shows lower concentrations of HCHO, as compared to the summer season. These relatively low emissions may be connected to the lower emissions of Isoprene in winters, as the Isoprene emissions have a clear distinct seasonal cycle, showing high emissions in the summers than in winters (Malik et al., 2018). And as this isoprene is oxidized with air, it gets converted to HCHO (Palmer et al., 2003, 2006), therefore the two associated low emissions could be linked in the winter season. High emissions have been observed for NO_2 in the winter season due to more crop residue burning in the winters in the region of Indian and Pakistani Punjab, especially highlighting the regions near Lahore, and Delhi around, two mega cities with anthropogenic emissions as well. Also, the higher concentrations have been found in the eastern mining zones of India and emissions from the Bangladesh side.

Conclusion

In this study a spatiotemporal assessment of two important atmospheric air pollutants, i.e. HCHO and NO_2 has been carried out over South Asia, being the most thickly populated region of the world, by using satellite remote sensing data from OMI sensor onboard Aura satellite. This study spans over a period of 12 years, from 2005 to 2016. Different analysis on the remote sensing data for these gases, help in identifying three distinct types of sources of emissions for these atmospheric pollutants, i.e. emissions through anthropogenic activities, emissions through pyrogenic activities and emissions through nature or biogenic sources. Further, these three distinct sources have very specific associations with the different landuse/landcovers. These associations are explained and analyzed in seven different study zones, selected at different geographical locations of South Asia, representing different landuse/landcovers ranging from the arid desert like areas, to thickly populated areas, to mountainous forested landcovers, to the mangroves forest cover, to the mining regions and to the agricultural belts defining the main landcovers of the region. Analyses of the annual spatial data for both the gases for a period from 2005 to 2016 show an overall increasing trend for anthropogenic NO_2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1098911015

emissions. A linear regression on the annual mean values of NO_2 data shows this trend with annual increase of ~0.66% and an overall increase of ~7.9% for the entire study period, with a slope of 0.006 (± 0.003), coefficient of determination (R^2 = 0.35) and *y*-intercept at 0.830426 (± 0.019072) $\times 10^{15}$ molecules cm^{-2}. An important finding in this trend analysis is that for the first seven years of the study, i.e. from 2005 to 2011, NO_2 emissions are increasing with a faster rate of about ~1.86% per year but in the last six years, i.e. from 2012 to 2016 this rate has been observed to be reduced to ~1.06% annually, making this rising trend to check. Reasons for lowering the values of the tropospheric column of NO_2 could be linked to the shift in meteorological regions, affecting, e.g., the rates of chemical reactions and air mass visibility for satellite observations in troposphere, and due to strategies adopted for lowering NO_x emissions through technological improvements like adoption of cleaner technologies and also due to some decline in the economic activity related to NOx emissions. Similar increasing trends have been observed for HCHO emissions for South Asia. Linear regression analysis performed on the area averaged annual mean values of HCHO data shows this increasing trend over South Asia, with annual increase of ~0.74% and an overall increase of ~9.86% for the study period of 12 years, with a slope of 0.050508 (± 0.014932), coefficient of determination (R^2 = 0.53) and *y*-intercept at 6.220404 (± 0.109894) $\times 10^{15}$ molecules cm^{-2}. These increasing trends for HCHO emissions could also be associated with the increasing anthropogenic sources of emission in South Asia as shown by the results from the MACCity emission data sources, which indicate that, for the period of 2005-2016 anthropogenic emissions have been increased to about 22% and hence the overall increase in HCHO emissions. Seasonality has been observed in the emission trends of HCHO and NO_2 over South Asia as, the effects of seasonal changes are associated sometimes with anthropogenic activities and sometimes with the biogenic and pyrogenic activities, resulting the corresponding impacts on the emissions of these gases in atmosphere. For further localized analysis, seven study zones have been analyzed, representing some of the available representative variations of landuse and landcovers. These zones have been typically observed in the context of anthropogenic, natural or biogenic and pyrogenic sources of emissions.

Abstract. Highly pathogenic avian influenza viruses (HPAIVs) can cause serious damage to wild birds and poultry. In this study, HPAIVs were administered via intranasal instillation to juvenile and adult domestic ducks, consisting of inoculation and contact groups, for comparative contagiousness. Oropharyngeal (OP) and cloacal (CL) swab analysis showed the overall virus shedding to be higher in OP than in CL. In addition, OP virus titer was higher in adults than in juveniles in the contact group. Our results indicate that adult susceptibility to AIV infection was greater than juvenile susceptibility, in case of samples from inoculated OP swab 2 days past inoculation (dpi) and contact OP swab 7 dpi. AIV distribution in the pancreas in juveniles was higher than that in adults; however, the virus was not detected in the trachea of either adults or juveniles. In conclusion, the results of this study suggest that differences in infectivity and prevalence of viruses in adults and juveniles may be influenced by the species of birds and neuraminidase enzymatic activity of the virus.
Keywords: *highly pathogenic avian influenza virus, contact, inoculation, distribution, birds*

Introduction

Avian Influenza virus (AIV), an influenza virus A of the family Orthomyxoviridae, is a single-stranded RNA virus with sixteen hemagglutinin (HA) subtypes (H1 to H16) and nine neuraminidase (NA) subtypes (N1 to N9) (Woo et al., 2017). Based on its pathogenicity, it is classified as either highly pathogenic AIV (HPAIV) or low pathogenic AIV (LPAIV). HPAIVs include H5 and H7, which are responsible for considerable illness or death in wild birds (Jeong et al., 2014).

In 1997, H5N1 HPAI outbreak occurred in chicken farms and live bird markets in Hong Kong, and the first case of chicken to human direct transmission of H5 was reported. Officially, H5N1 HPAIVs had emerged in 53 countries and human infections had occurred in 15 countries between 2003 and March 2014 (WHO).

In wildlife, the first HPAIV to cause the death of waterfowl was A/tern/South Africa/61 (H5N3) of H5 (Becker, 1966), following which H5N1 HPAIV appeared in many wild birds in Hong Kong (during 2002) and western China (Lake Qinghai; during 2005) (Ellis et al., 2004; Liu et al., 2005). Recently, HPAIVs have occurred throughout Asia, Europe, the Middle East, and several African countries linked to flyways (Olsen et al., 2006). Since wild birds, especially waterfowls, move their breeding site and wintering site, every winter, around 100,000–200,000 mallards arrive in Korea for spending the winter in various environments such as bird sanctuaries, inland small rivers, and lakes. In the spring, the waterfowls migrate for breeding; they pass through the east coast of North Korea after spanning North-eastern China (Kang et al., 2016).

Since 2010, China has reported subtypes of Clade 2.3.4.4 H5 HPAIV in ducks (including H5N2, H5N5, H5N6, and H5N8) (Zhao et al., 2013; Su et al., 2015). The first report of Group C H5N6, clade 2.3.4.4, was from Korea and Japan, in fall 2016. After that, group C of H5N6 had been frequently detected in Korea during 2017 (Jeong et al., 2017; Woo et al., 2017). Despite reports of several types of H5 HPAIVs and comparison across the different subtypes, understanding of infection susceptibility across adults and juveniles is still lacking. Infection susceptibility is important to understand for the prevalence and management of diseases. Especially, comparison between adults and juveniles will be useful for understanding epidemiological consequences. In many wildlife diseases, juveniles have driven the spread of diseases (Ashby and Bruns, 2018). Therefore, in this study, we evaluated the susceptibility of H5N6 as a HPAIV (A/Whooper swan/Korea/Gangjin/W49-1/2016) at both adult and juvenile stages of ducks, and compared the infection sensitivity between the two.

Materials and Methods

Experimental design

The experimental groups consisted of 12 domestic ducks, each including a control group (*Table 1*). Animals confirmed negative for avian influenza virus infection in ELISA test (IDVet, Grabels, France, ID Screen Influenza A antibody Competition Multi-Species) prior to the experiment. Each control group (n = 4) was instilled with 0.2 ml of phosphate-buffered saline (PBS) via the same exposure route. Five ducks were inoculated with H5N6 viruses via the choanal cleft using 0.2 ml of 106.5 50% egg infectious dose (EID50)/100 µl in adult and juvenile, separately. After 8 h, three healthy animals were cohoused with virus-injected animals for infectivity studies. All animal experiments were performed according to the Guidelines for Care and Use of the National Institute of Environmental Research (NIER 18-3) at biosafety level 3 (ABL3, KCDC-15-3-05) and were approved by Institutional Biosafety Committee (NIER-2018-IBC-01).

Table 1. *Group of animals used in the experiments*

Group		**Adult**	**Juvenile**
		Number of Animals	
Control		4	4
Test	Inoculation	5	5
	Contact	5	3

Swab samples from the trachea and cloaca at days 1, 2, 3, 4, 5, 7, 10, and 14 were collected using transport tubes (Universal Viral Transport Standard Kit, BD). Samples were serially diluted 10-fold and titrated using specific pathogens free (SPF) eggs to determine EID50/0.1 ml. After 3 days post inoculation (dpi), two animals each of injection group and control group were euthanized, tissue and organ samples collected (such as trachea, lung, kidney, spleen, caecal tonsil, liver, intestine, pancreas, and proventriculus), and viral replication evaluated by real-time RT-PCR. RNA was isolated from 100 mg of each tissue using a Maxwell RSC simpleRNA Tissue KIT (Promega, Madison) that was discovered using PowerCheck™ Influenza A Real-Time PCR Kit

(Avian Influenza Virus Real-time PCR Kit, JSB-VT-023, JS Biotech, Korea) for nucleoprotein (NP) genes. Statistical analysis was performed using PRISM 5 software and two-way ANOVA (considering mean and standard deviation (SD)).

Results and Discussion

Comparison of infectivity

H5N6 virus from oropharyngeal (OP) and cloacal (CL) swab (A/Whooper swan/Korea/Gangjin/W49-1/2016/[H5N6]) of both adults and juveniles was isolated from 1–5 dpi and 7 dpi, and the overall viral shedding was confirmed to be higher in OP swab samples than in CL ones (*Figure 1*). In inoculated individuals, OP swab samples were also used to compare shedding between adults and juveniles. The first isolated virus at 2 dpi in adult samples showed the highest titer value (105.17 EID50/0.1 ml) of shedding. In addition, OP virus titer was higher in adults than in juveniles in the contact group (*Figure 1*). In inoculation and contact groups, results of OP swab samples at 2 dpi and 7 dpi were statistically significant *($P < 0.01$)*.

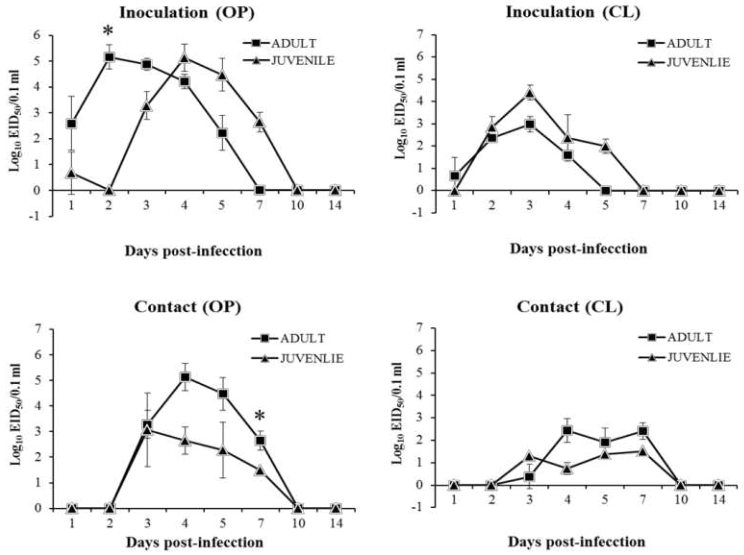

Figure 1. *Comparison between adults and juveniles for the virus isolated from oropharyngeal (OP) and cloacal (CL) swab of animals inoculated with 106.5 EID50/0.1 ml A/Whooper swan/Korea/Gangjin/W49-1/2016/[H5N6], and those non-inoculated but co-housed (Contact) with inoculated ones. Data were analyzed by two-way ANOVA with Bonferroni post-test, using Prism 5 statistics software and calculating the mean and standard deviation (SD) (n = 3, *$P < 0.01$)*

According to previous studies, immunity in juveniles is lower than that in adults, due to which, AIV infection is consistently higher in juveniles than in adults (Ip et al., 2008; Pybus et al., 2012). However, our results showed that adult susceptibility to AIV infection was greater than juvenile susceptibility, in case of samples from inoculated OP swab on 2 dpi and contact OP swab on 7 dpi (*Figure 1*). According to the seroprevalence study on wild waterfowl in Alaska, AIV antibodies in 11 species of wild waterfowls were higher in adults than in juveniles (Wilson et al., 2013), which was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1101711022

probably because the virus susceptibility depends on the exposure of AIV to the species. Same pattern had also been shown in pink-footed geese (*Anser brachyrhynchus*) and Bewick's swans (*Cygnus columbiannus bewickii*) (Hoye et al., 2011a, b).

Moreover, reproduction might also affect influenza host susceptibility (van Dijk et al., 2018). During breeding season, most animals, including birds, use lots of energy in reproduction, hence showing relatively lower immunity than in non-breeding season. Adult individuals in our study were 22-week-old, and since ducks generally breed during May–July, their testicles were found enlarged upon autopsy (Blums et al., 2002; Ashby and Bruns, 2018). Therefore, we suspect that reproduction activity promotes higher infection susceptibility in adult than in juveniles.

The tissue from animals occurred in most of the internal organs of both adult and juvenile from H5N6, except for the trachea, caecal tonsil, intestine, proventriculus, brain, and muscle. AIV distribution in the pancreas from juveniles was higher than that from adults; however, the virus was not detected in the trachea from either adults or juveniles (*Table 2*). Although trachea is one of the main organs for detecting AI virus, almost no virus was detected in our study, which might be explained based on the report by Das et al. (2008), which showed that tracheal swab is less sensitive for detecting AIV in preclinical chickens.

Table 2. *AIV distribution in tissues of infected duck (both adult and juvenile)*

Mucin secretion is an important factor for the prevention of influenza virus infection in the airway (Burnet, 1948; Zanin et al., 2016). Especially, between influenza virus NA enzyme activity and mucus barrier may be affection in infectivity (Cohen et al., 2013; Zanin et al., 2015). Previous study had reported no H5N6 virus infectivity due to aerosol diffusion in ferret model (Sun et al., 2016). In the present study, our results demonstrated that the H5N6 virus is spread by direct contact between individuals and that the infectivity depends on the NA enzyme activity in duck model.

Conclusion

Our results suggest that differences in infectivity and prevalence of virus in adults and juveniles may be influenced by the species of birds, breeding season and NA enzymatic activity of the virus. This information may be helpful in further study to understand age-dependent infection sensitivity of avian species and affection of reproduction and these reasons should be considering when monitoring AIV.

Virucidal activity of

„PMF-concentrate“

against the *Transmissible Gastroenteritis Virus of Swine (TGEV)*

(used as a model virus for the
Middle East Respiratory Syndrome Coronavirus (MERS-CoV)

<u>Short report</u> of the screening test S3

by

PD Dr. Olaf Thraenhart and Dr. Christian Jursch

Study time: in March 2015

Principal: PMF Natural Products company
Arab Republic of Egypt

Product: ***PMF-concentrate***
[Lot-no.: not specified; product sample as arrived; Arrival: 01.08.2014, Storage at 2-8°C]

Parameter of test:

- 0,75 g of PMF-concentrate solved within 2,95 mL of A. bidest (25,42% [w/v])
- T = 37° C and 60 and 240 min. of exposure

Test system:

- Transmissible Gastroenteritis Virus of Swine (TGEV); Strain: Toyama
  (Origin: Virusbank of the Bundesforschungsanstalt f. Viruskrankheiten der Tiere; Friedrich Löffler-Institut, Insel Riems, Germany)
- ST75/2 cells (foetal testis cells of swine)
  (Origin: Robert Koch-Institute, Berlin, Germany)

Test method:

- The testing was performed following the guideline of the DVV and the Robert Koch-Institute (DVV/RKI-guideline [*Bundesgesundhbl. (2008); 51 (8):937-945*]): for the quantitative virucidal suspension test (QST).
- With this testing virus titration of the main samples was performed according to *Lycke's* methodolgy *(Arch Ges Virusforsch (1957); 7:483-493).*

Tab. 1: ***Dosage of product*** *(solvent: A. bidest)*

Set	Product(s)	Conc. in Test *(1x)*	Working sol. *(x 1,25)*	Dosage	pH of working sol.
#1	PMF-concentrate	20,34%	25,42%	0,75 g in 2,95 mL	pH 9,54 *(in test: pH 9,52)*

Tab. 2: Results of virus inactivation

Samples	1a + 1b	2a + 2b
	Virus inactivation	
Exposure time	t = 60 min.	t = 240 min.
Virus input [1] *(per test volume)*	6,11 ± 0,34	5,50 ± 0,32
Detection limit *(cytotoxicity level)*	< 1 ID_{50} *(0,0 lg ID_{50})*	
Residual virus [1] (log ID_{50} ± K [95%])	1,80 ± 0,34 *(43/480 virus positive cell culture units)*	< 1 ID_{50} *(0,0 lg ID_{50})* *(0/480 virus positive cell culture units)*
Reduction [2] (log ID_{50} ± K [95%])	**4,31 ± 0,48**	**> 5,50 ± 0,45**

[1] = Calculation of 95% confidential interval of virus titer as well as virus reduction following DVV/RKI-Guideline.
[2] = Virus reduction: titer of virus control minus titer of sample (lg ID_{50}).

Results: (cf. Tab. 2)

Control tests

- With S3 the amount of input virus at 37° C was estimated to lg ID_{50} = 6,13 ± 0,34 after 60 min.
- After 240 min. of incubation at 37° C virus titer was declined to lg ID_{50} = 5,52 ± 0,32 due to the influence of temperature (Δ virus titer = 0,61 ± 0,46).
- With the *Lycke's* method a sample dilution was done (VF = 1000). With that dilution no cytotoxicity was visible and the susceptibility of the detection cells was given (Δ titer = 0,18 ± 0,47).

Virus inactivation

- With 20,34% of PMF (final test concentration) and after 60 min. the virus reduction factor was estimated to **RF = 4,31 ± 0,48.**
- After the exposure time was prolonged to 240 min. no residual virus could be detected. The corresponding virus reduction factor was estimated to **RF > 5,50 ± 0,45**.

Conclusions:

- Prolongation of the exposure at 37° C from 60 to 240 min. was associated with only a minor reduction of input virus (Δ virus titer = 0,61 ± 0,46). The test virus was sufficiently stable at the test temperature over the observation period.
- After 60 min. at 37° C the tested product PMF-concentrate in its 20,34% dilution (final concentration) inactivated *TGEV* by RF = 4,31 ± 0,48 or by 99,995% under the test conditions. After 240 min. a virus reduction factor of RF > 5,5 ± 0,45 was observed, correspondent to a virus reduction of 99,999%.

Luckenwalde, 18th of March 2015

Dr. Christian Jursch
(Laboratory manager and Managing Director of Eurovir)

Inactivation of *TGEV* (a model virus for MERS-CoV) by *PMF-concentrate*
- testing with the quantitative virucidal supension test at T = 37 °C -

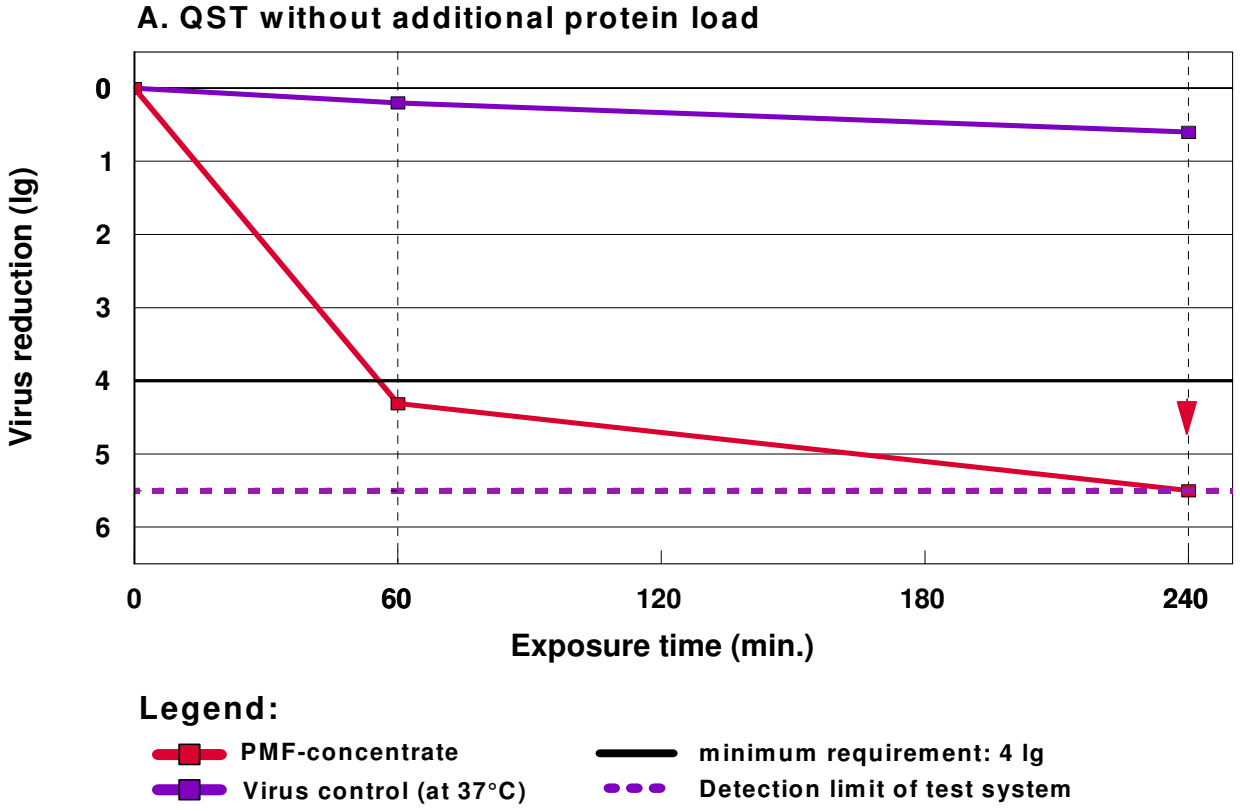

Fig. 1

- Attachment: Experimental protocols -

- Virucidal activity of the product *PMF-concentrate* - Experiment S3 at T = 37° C / testing in the *quantitative suspension test (QST)* using the methodology of *Lycke* for virus titration of the main samples.

  The testing was performed with the *Transmissible Gastroenteritis Virus of Swine (TGEV)* which served as a model virus for the *Middle East Respiratory Syndrome Coronavirus (MERS-CoV).*

Information about the testing

Principal:	PMF Natural Products company	*Test run:*	S3
Product(s):	PMF-concentrate	*Test date:*	12.03.2015
Test system:	TGEV *(Toyama)* + ST75/2-cells	*Analysis:*	18.03.2015 *(6 p.i.)*

Test methodology and test parameters

Test method: quantitative virucidal suspensions test according to DVV/RKI-guideline *(Version 08/08)*
Test mixture: 1 VT protein load + 1 VT virus suspension + 8 VT 1,25fold working solution
Protein load: no additional protein load *(PBS)*
Parameter: test temperature: 37° C with the exposure time(s) of: 60 and 240 min.

Tested product sample(s)

1st product: PMF-concentrate *[Product sample: as received (designation: PMF), Arrival: 01.08.2014, Storage at 2-8° C]*

Tab. 1: Weight of content

Performing of the test

1. Preparation of the product solution: (in the specified sequence)

- ***0,75 g PMF-concentrate*** was solved with agitation and warming to 37°C in 2,95 mL A. bidest.

2. Preparation of the test samples

- Per test point (concentration/exposure time) 2 redundant test samples were prepared.
- Test mixture: 1 vol. PBS + 1 vol. virus suspension + 8 vol. PMF-working solution (1,25-fold)

3. Dilution of the test sample and estimation of virus titer

- ***Termination of virus inactivation:*** after exposure the test samples were diluted with medium *(cf. virus titration).*
- With the ***virus control*** the virus titer was estimated using the methodology of *Spearman & Kärber* with VF = 5 from 113 µL (out of 150 µL of the test sample).
- With the ***virus inactivation samples*** the virus titer was estimated using the methodology of *Lycke.* For each of the test samples (a and b) 48 µL was added to 96 mL Medium, corresponding to a dilution of VF = 1000. All of the 96 mL were then transferred to cell cultures with 200 µL per well (480 wells).

4. Susceptibility control

- Sample 5 (cytotoxicity sample) was diluted 1000fold and was then distributed to cell cultures (cf. virus inactivation). Afterwards a virus dilution serie (VK/E) was transferred to these cells.

5. Judgement of the cells / virus detection

- At day 6 p.i. the cell cultures were examined visually using a microscope (magnification: 100fold). The virus positive cell cultures were identified by the virus induced CPE).

[2] = ratio of virus positive cell culture units to total number of cell cultures.
[3] = Virus reduction: titer of virus control (cf. Tab. 3.1) minus titer of sample (lg ID_{50})

Estimation of virus titer by LYCKE´s method (Arch Ges Virusforsch (1957); 7:483-493)

Calculation of virus titer by using the following formula:

$- ID_{50} = [1{,}4 \times \ln (1-p)]$ p = ratio of positive cell cultures to total number of cell cultures

- ***Example:*** 51 out of 100 cell culture units was virus positive → p = 51/100 = 0,51

p put into formula: $- ID_{50} = [1{,}4 \times \ln (1- 0{,}51)]$

with ln (0,49): $- ID_{50} = 1{,}4 \times -0{,}71$

resulting in: $- ID_{50} = -0{,}998$ or $ID_{50} = 0{,}998$

That means that per single cell culture unit 0,998 or 1 ID_{50} of residual virus was present.

When this content of virus was multiplied with the number of cell culture units (= 100) the complete amount of residual virus was obtained: 1,0 ID_{50} x 100 = 100 ID_{50} or lg ID_{50} = 2,0

Result of the example: the total quantity of residual virus which was present in the examined sample of liquid was estimated to **lg ID_{50} = 2,0**

Materials and reagents used:

- ***Testvirus***

Test virus	Transmissible Gastroenteritis Virus of Swine (TGEV)
Strain	Toyama 36
Origin	Virusbank der BFA f. Viruskrankheiten der Tiere; Friedrich Löffler-Institut, Insel Riems Virus (lyophilisate) v. 05/2003; kindly provided by Dr. M. Dauber (Virus passage FLI +0)

Virucidal activity of

„PMF-concentrate“

against the Influenza A Virus (H1N1)

Short report of the screening tests S1 and S2

by

PD Dr. Olaf Thraenhart and Dr. Christian Jursch

Study time: August - September 2014

Principal: PMF Natural Products company
Arab Republik of Egypt

Product: ***PMF-concentrate***
[Lot-no.: not specified; product sample as arrived; Arrival: 01.08.2014, Storage at 2-8°C]

Parameter of test:

- 0,75 g of PMF-concentrate solved within 2,95 mL of A. bidest (25,42% [w/v])
- T = 37° C and 60 and 240 min. of exposure

Test system:

- Influenza A Virus (H1N1); Strain: New Caledonia
(Origin: Chiron Behring, Marburg/Lahn, Germany)
- Madin Darby Canine Kidney Cells (MDCK)
(Origin: Robert Koch-Institute, Berlin, Germany)

Test method:

- The testing was performed following the guideline of the DVV and the Robert Koch-Institute (DVV/RKI-guideline [*Bundesgesundhbl. (2008); 51 (8):937-945*]): for the quantitative virucidal suspension test (QST).
- With test S1 the *Spearman & Kärber's* method for virus titration of the main samples was used (cf. DVV/RKI-guideline).
- With test S2 virus titration of the main samples was performed according to *Lycke's* methodolgy *(Arch Ges Virusforsch (1957); 7:483-493).*

[1] = Calculation of 95% confidential interval of virus titer as well as virus reduction following DVV/RKI-Guideline.
[2] = Virus reduction: titer of virus control minus titer of sample (lg ID_{50}).

Results: (cf. Tab. 2)

Control tests

Screening test S1:

- The pH of the 1,25fold concentrated working solution were measured to pH 9,54.
- In the test sample this pH changed only slightly to pH 9,52.
- With S1 the amount of input virus at 37° C was estimated to lg ID_{50} = 4,47 ± 0,36 after 60 min. and to lg ID_{50} = 4,38 ± 0,23 after 240 min. (Δ virus titer = 0,10 ± 0,42).
- Using the *Spearman & Kärber's* titration method a cytotoxicity titer of lg TD_{50} = 2,45 was recorded for the test samples. This is equivalent with the detection limit of screening test S1.

Screening test S2:

- With S2 the amount of input virus at 37° C was estimated to lg ID_{50} = 4,88 ± 0,26 after 60 min. and to lg ID_{50} = 4,88 ± 0,39 after 240 min. (Δ virus titer = 0,0 ± 0,47).
- With the *Lycke's* method a sample dilution was done (VF = 1000). With that dilution no cytotoxicity was visible and the susceptibility of the detection cells was given (Δ titer = 0,18 ± 0,53). In addition, the detection limit of screening test S2 could be improved by 2,45 Log.

Virus inactivation

Screening test S1:

- With 20,34% of PMF (final test concentration) and after 60 min. the virus reduction factor was estimated to **RF = 2,28 ± 0,48.** After 240 min. no residual virus could be detected (test virus below detection limit, due to product associated cytotoxicity [lg TD_{50} = 2,45]). The corresponding virus reduction factor was estimated to **RF ≥ 1,93 ± 0,23**.

Screening test S2:

- With 20,34% of PMF (final test concentration) and after 60 min. the virus reduction factor was estimated to **RF = 1,62 ± 0,37.** After 240 min. no residual virus could be detected. The corresponding virus reduction factor was estimated to **RF > 4,88 ± 0,55**.

Conclusions:

- Prolongation of the exposure at 37° C from 60 to 240 min. was not associated with a reduction of input virus. The test virus was stable at the test temperature over the observation period.
- Using the *Lycke's* method of virus titration the results from the first screening test (S1) could be significantly improved.
- After 60 min. at 37° C 20,34% PMF (final concentration) inactivated influenza virus by RF = 1,95 ± 0,30 *(average from S1 and S2)* or by 98,9% under the test conditions. After 240 min. a virus reduction factor of RF > 4,88 ± 0,55 was observed, correspondent to a virus reduction of 99,998%.

Information about the testing

Principal:	PMF Natural Products company	*Test run:*	S2
Product(s):	PMF-concentrate	*Test date:*	19.09.2014
Test system:	Influenza *(H1N1)* + MDCK-cells	*Analysis:*	25.09.2014 *(6 p.i.)*

Test methodology and test parameters

Test method: quantitative virucidal suspensions test according to DVV/RKI-guideline *(Version 08/08)*
Test mixture: 1 VT protein load + 1 VT virus suspension + 8 VT 1,25fold working solution
Protein load: no additional protein load *(PBS)*
Parameter: test temperature: 37° C with the exposure time(s) of: 60 and 240 min.

Tested product sample(s)

1st product: PMF-concentrate *[Product sample: as received (designation: PMF), Arrival: 01.08.2014, Storage at 2-8° C]*

Tab. 1: Weight of content

Set	Product(s)	Conc. in Test *(1x)*	Working sol. *(x 1,25)*	Dosage	pH of working sol.
#1	PMF-concentrate	20,34%	25,42%	0,75 g in 2,95 mL	pH 9,54 *(in test: pH 9,52)*

Performing of the test

1. Preparation of the product solution: (in the specified sequence)

- ***0,75 g PMF-concentrate*** was solved with agitation and warming to 37°C in 2,95 mL A. bidest.

2. Preparation of the test samples

- Per test point (concentration/exposure time) 2 redundant test samples were prepared.
- Test mixture: 1 vol. PBS + 1 vol. virus suspension + 8 vol. PMF-working solution (1,25-fold)

3. Dilution of the test sample and estimation of virus titer

- ***Termination of virus inactivation:*** after exposure the test samples were diluted with medium *(cf. virus titration).*
- With the ***virus control*** the virus titer was estimated using the methodology of *Spearman & Kärber* with VF = 5 from 113 µL (out of 150 µL of the test sample).
- With the ***virus inactivation samples*** the virus titer was estimated using the methodology of *Lycke.* For each of the test samples (a and b) 48 µL was added to 96 mL Medium, corresponding to a dilution of VF = 1000. All of the 96 mL were then transferred to cell cultures with 200 µL per well (480 wells).

4. Susceptibility control

- Sample 5 (cytotoxicity sample) was diluted 1000fold and was then distributed to cell cultures (cf. virus inactivation). Afterwards a virus dilution serie (VK/E) was transferred to these cells.

5. Judgement of the cells / virus detection

- At day 6 p.i. supernatant of the cell cultures were tested with the HA-test (haemagglutination).

[1] = sample volume transferred onto cell cultures: 48 µL from test mix a. plus 48 µL from test mix b. resulting in 2 x 48 = 96 µL
[2] = ratio of virus positive cell culture units to total number of cell cultures.
[3] = Virus reduction: titer of virus control (cf. Tab. 3.1) minus titer of sample (lg ID_{50})

Estimation of virus titer by LYCKE´s method (Arch Ges Virusforsch (1957); 7:483-493)

Calculation of virus titer by using the following formula:

$- ID_{50} = [1,4 \times \ln (1-p)]$ p = ratio of positive cell cultures to total number of cell cultures

- ***Example:*** 51 out of 100 cell culture units was virus positive → p = 51/100 = 0,51

p put into formula: $- ID_{50} = [1,4 \times \ln (1- 0,51)]$

with ln (0,49): $- ID_{50} = 1,4 \times -0,71$

resulting in: $- ID_{50} = -0,998$ or $ID_{50} = 0,998$

That means that per single cell culture unit 0,998 or 1 ID_{50} of residual virus was present.

When this content of virus was multiplied with the number of cell culture units (= 100) the complete amount of residual virus was obtained: 1,0 ID_{50} x 100 = 100 ID_{50} or lg ID_{50} = 2,0

Result of the example: the total quantity of residual virus which was present in the examined sample of liquid was estimated to **lg ID_{50} = 2,0**

(Received 30th Mar 2019; accepted 1st Jul 2019)

Abstract. PMF (a camel urine or PM 701 fraction), is a traditional treatment for many human diseases. Demands for developing clinical treatments against dangerous viruses are increasing. This study aimed to investigate the effects of PMF as a novel pharmaceutical drug *in vitro* in inducing antiviral and/or virostatic activity against MERS-CoV and influenza A (H1N1) viruses. Infectivity assay was determined by end point dilution titration, infective dose was calculated and PMF virucidal activity was evaluated as a reduction factor. Quantitative virucidal suspension test was performed using TGEV virus, as a model for MERS-CoV, and H1N1 virus. The results indicated that PMF concentration of 20.34% inactivated 99.5% of the TGEV virus after 60 min, and 99.9% after 240 min. The results also indicated that the same PMF concentration inactivated H1N1 virus on Madin Darby canine kidney cells (MDCK/63) by 98.90% and 99.99% after 60 and 240 min, respectively. We speculate that copper and zinc elements in PMF might vitally contribute to the antiviral and virostatic activity. In conclusion, PMF was proven to induce antiviral *in vitro* activity against both viruses, hence, is recommended to use as a therapeutic antiviral agent in the future.
Keywords: *PMF, MERS-CoV, TGEV, H1N1, virostatic activity*

Introduction

Corona viruses (CoVs) cause a wide range of respiratory and gastric diseases. Most CoVs are RNA viruses, which replicate in epithelial cells of respiratory and digestive tracts (van der Hoek et al., 2004). These viruses enter the cell by viral spike (S) proteins that bind to cellular receptors and facilitate virus-cell membrane fusions. Du et al. (2017) indicated that spike protein is a key target as antiviral mechanism against CoVs. Lin et al. (2017) were able to induce antiviral activity against the virus by resveratrol treatment. Müller et al. (2017) also indicated the successful usage of binase in inhibiting virus genome replication. The diversity of CoVs is reflected in S protein variability, which is involved in different receptor interactions and respond to different environmental conditions (Belouzard et al., 2012). A new corona virus was identified during summer of 2012 in Saudi Arabia (Zaki et al., 2012) and named Middle East respiratory syndrome corona virus (MERS-CoV) by International Committee on Taxonomy of Viruses (de Groot et al., 2013). The Middle East respiratory syndrome is a pneumonic illness caused by a novel lineage C betacoronavirus (CoV). In 2014, a total of 178 MERS cases were confirmed in humans, which resulted in 76 deaths (WHO, 2014). Infection with MERS-CoV can also cause abdominal pain, diarrhea, fever and renal failure (Assiri et al., 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1102311031

The virus was found mostly in the lower respiratory tract samples, while low concentrations were found in stool, urine, and blood samples (Drosten et al., 2013). Limited human-to-human transmission has resulted in clusters of cases; the remaining sporadic cases in humans are of zoonotic origin (Assiri et al., 2013). Up to date, both reservoir and intermediate hosts remain unidentified, delaying any success on controlling the virus. MERS-CoV had been spread into eleven countries of the Middle East, North Africa, South Korean and Europe. Therefore, there are global concerns over security, but the Economist report announced that "Concern over security must not slow urgent work, studying a deadly virus is risky; not studying it is riskier" (Economist.com, 2014). The demand for developing clinical treatment against MERS-CoV is increasing, but the strict limitations for using strains of new deadly virus is still slowing down and retards scientific investigations. In this study, we used TGEV virus as a model for MERS-CoV, as both are corona viruses. Transmissible Gastroenteritis Virus (TGEV) belongs to corona viridae family, genus *Alphacoronavirus*, species Alphacoronavirus (Frieman, 2014). It is an enveloped virus with a positive single stranded RNA genome. TGEV infects pigs and rarely humans. In pigs, mortality rate is close to 100%. The pathology of TGEV is similar to that of other corona viruses. They enter the host by attaching to cell membrane using spike glycoprotein and multiplies in cell lining of small intestine resulting in loss of absorptive cells and shortening of villi. The infected host then loses the ability for digesting food and dies from dehydration (Frieman, 2014).

H1N1 is the subtype of influenza A virus causing swine and human flu (Lim and Mahmood, 2011; Kong et al., 2015). It is an orthomyxovirus harboring the two glycoproteins haemagglutinin and neuraminidase (Du et al., 2017). Up to 2015, more than 40 million people died due to the infection with H1N1 (Kong et al., 2015). Cloning and sequencing of the eight virus genes revealed that human influenza virus is closely related to avian influenza virus with regard to their coding sequences (Taubenberger et al., 2005; Morens and Fauci, 2007; Taubenberger et al., 2007).

Natural products are important source for novel drug therapies of efficient compounds with diverse biological activities and unique chemical structures. Camel urine is known as a traditional treatment of many diseases in Arabs countries (Alghamdi and Khorshid, 2012; Mahboub et al., 2015). The relative density of mature camel urine ranges from 1.02 to 1.07 g/dL; pH varied between acidic or alkaline; urea level ranged from 18-36 g/dL and creatinine level ranged from 0.2-0.5 g/L (Al-Bashan, 2011). Chemical and microscopic examination showed the presence of phosphorus, calcium oxalate and ammonium urate and some epithelial and granular cells (Al-Bashan, 2011). PMF (a camel urine or PM 701 fraction) is a novel pharmaceutical drug that was extracted from PM 701 (lyophilized camel urine) that is able to selectively inhibit the proliferation of cancer cells significantly without affecting normal cells at human cell culture level and animal models (Khorshid, 2008, 2009; Khorshid et al., 2005, 2009, 2011; El-Shahawy et al., 2010). Prospects of the use of therapeutic nanoparticles, nanobodies and nanorods from this natural product was recently explored for cancer therapy (Getachew Alebie et al., 2017).

New treatments cannot be tested directly on humans because they could be potentially dangerous and experiment can be costly. Alternatively, human cell culture and animal models are used traditionally for testing and developing safe dose and working mechanisms of innovative therapies. In this study, we detected the influence of PMF in terms of antiviral activity on TGEV as a model virus on fetal testis cells of swine (ST75/2) and H1N1 virus utilizing Madin Darby canine kidney cell line (MDCK/63).

Materials and Methods

Extraction of PMF

PMF was extracted at the laboratory of King Fahad Medical Research Center, King Abdulaziz University (KAU) in Jeddah, Saudi Arabia as previously described (Khorshid et al., 2009). Then, PMF was transported in IATA-compliant container from Saudi Arabia to Eurovir Institute in Luckenwalde, Germany. The fraction was stored at 2-8°C prior testing for virucidal activity against TGEV and H1N1 viruses. The PMF product was tested as a working solution of 25.42% (w/v) and pH of 9.71 (0.75 g of PMF-concentrate was solved with agitation and warming to 37ºC in 2.95 mL of aqua bidest). In the test sample, PMF working solution was diluted with a factor of 1:25 due to addition of TGEV or H1N1 suspensions and interfering phosphate-buffered saline substance (PBS).

TGEV and H1N1 virus suspensions

TGEV strain Toyama was obtained from virus bank of the Bundesforschungsanstalt f. Viruskrankheiten der Tiere; Friedrich Löffler-Institut, InselRiems, Germany, as a model virus for MERS-CoV. Influenza A virus subtype (H1N1) the commonest cause of human influenza (flu) and seasonal Influenza, New Caledonia /20/99, IVR-116 Strain was obtained from virus bank of the Chiron Behring, Marburg/Lahn, Germany. Originally obtained viruses were 10-fold diluted with MEM; then stored at -80°C until use.

Experimental cells

ST75/2 cells; fetal testis cells of swine obtained from Robert Koch-Institute, Berlin/ Germany, were used as a target for MERS-CoV virus. They were inspected regularly for morphological alterations and mycoplasmas contamination in which none were detected. For maintenance and growing of the cells, media involved Eagle's minimum essential medium (EMEM), Lot.Nr., glutamine, penicillin/streptomycin, fetal calf serum, PBS and trypsin.

Madin Darby canine kidney reporter cell line MDCK/63; obtained from National reference center for influenza, Robert Koch-Institute, Berlin/Germany, were used as a target for H1N1 virus. Cells survived in living condition with 73th passage of RKI +3/+9/+35 at 09.07.2001 (= RKI +0). These cells are highly permissive for influenza virus replication and provide a highly specific and sensitive approach for simultaneous detection and isolation of influenza viruses.

Infectivity assay

To prepare TGEV or H1N1 test virus suspensions, ST75/2 and MDCK/63 cells, that had been cultured with EMEM and 10% fetal calf serum (FCS), were inoculated with TGEV or H1N1, respectively, in 25 cm^2 cell culture flasks. After 48 hours and after induction of cytopathic effect, freezing and thawing were carried out once. Cell debris was removed by centrifugation at 3000 rpm for 10 min at 4°C and supernatant was recovered as test virus suspension and stored in aliquots at -80°C.

Infectivity was determined by virus titration of end point dilution titration using microliter process. One hundred µl aliquots of samples were serially diluted with cold EMEM and transferred to four wells of polystyrol 24-well microliter plate with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1102311031

performed monolayer of ST75/2 or MDCK cells (placed in each well on the previous day with 100 µl aliquots including approx. $1.5x10^4$ cells). Infective dose ($TCID_{50}$) and their 95% confidence intervals were calculated with Spearman-Karber method (Khorshid et al., 2009). The main samples virus titration was performed and the corresponding virus titer was calculated as previously indicated (Khorshid et al., 2011). The virucidal activity of PMF was evaluated by calculating the decrease in titers in comparison with control untreated titration. The difference is given as a reduction factor (RF). Quantitative virucidal suspension test (QST) was performed following the guideline of DVV and Robert Koch-Institute. Control and virus inactivation screening tests were performed as recently indicated (Al Attas et al., in preparation).

Statistical analysis

Data were expressed as numbers or means +/- standard deviation or numbers as appropriate using SPSS software version 20.0.

Results and Discussion

The results for the influence of PMF on the MERS-CoV virus is shown in *Figure 1* and *Supplementary file S1*. The analysis included one control test in which the amount of input virus at 37°C was estimated to be lg ID50 = 6.13 ± 0.34 after 60 min. After 240 min, virus titer was declined to lg ID50 = 5.52 ± 0.32 due to the influence of temperature (Δ virus titer = 0.61 ± 0.46). With the *Lycke's* method, a sample dilution was done (VF = 1000). With that dilution, no cytotoxicity was visible and the susceptibility of the detection cells was given (Δ titer = 0.18 ± 0.47). With PMF final test concentration of 20.34%, the virus reduction factor (RF) was estimated to be 4.31 ± 0.48 after 60 min. After the exposure time was prolonged to 240 min, no residual virus could be detected. The corresponding virus reduction factor was estimated to be > 5.50 ± 0.45 corresponding to a virus reduction of 99.999% (*Supplementary file S1*).

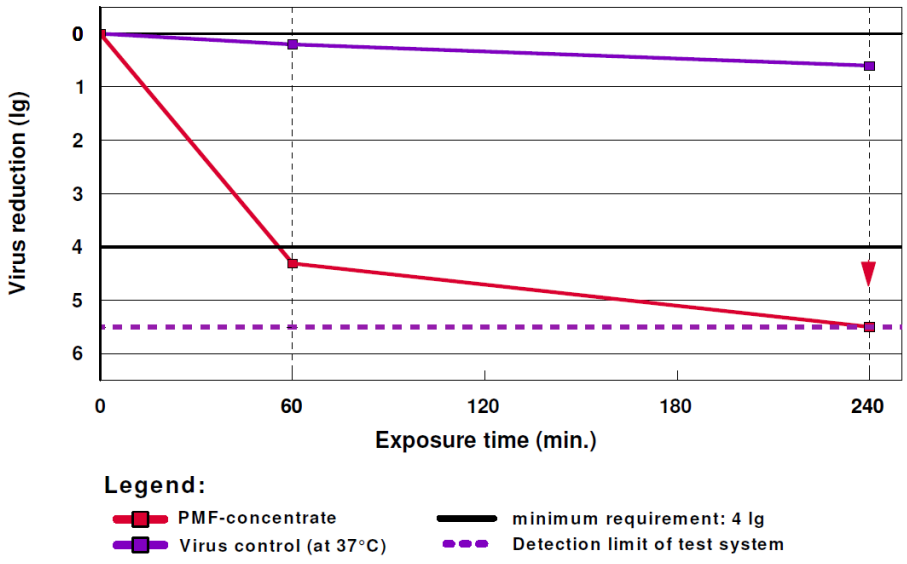

Figure 1. *MERS-CoV virus reduction (lg) as affected by the treatment of camel urine fraction (PMF) and measured after 60 and 240 min. Virus reduction = titer of virus control minus titer of sample (lg ID_{50})*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1102311031

The results for the influence of PMF on the H1N1 virus is shown in *Figure 2* and *Supplementary file S2*. The analysis included two control tests. Screening test S1 indicated that the pH of the 1.25 fold concentrated working solution were measured to pH 9.54, which was changed only slightly to pH 9.52. The amount of input virus at 37°C was estimated to be lg ID50 = 4.47 ± 0.36 after 60 min and to lg ID50 = 4.38 ± 0.23 after 240 min (Δ virus titer = 0.10 ± 0.42). Using the Spearman & Kärber's titration method, a cytotoxicity titer of lg TD50 = 2.45 was recorded for the test samples. This is equivalent with the detection limit of this screening test. Screening test S2 indicated that the amount of input virus at 37°C was estimated to be lg ID50 = 4.88 ± 0.26 after 60 min and to lg ID50 = 4.88 ± 0.39 after 240 min (Δ virus titer = 0). With the *Lycke's* method, a sample dilution was done (VF = 1000). With that dilution, no cytotoxicity was visible and the susceptibility of the detection cells was given (Δ titer = 0.18 ± 0.53). In addition, the detection limit of this screening test could be improved by 2.45 Log. Virus inactivation in this screening test indicated that 20.34% of PMF (final test concentration) resulted in virus reduction factor of 2.28 ± 0.48 after 60 min. After 240 min, no residual virus could be detected (test virus below detection limit, due to product associated cytotoxicity [lg TD50 = 2.45]). The corresponding virus reduction factor was estimated to be 1.93 ± 0.23. For the second screening test, 20.34% of PMF (final test concentration) resulted in the virus reduction factor of 1.62 ± 0.37 after 60 min.

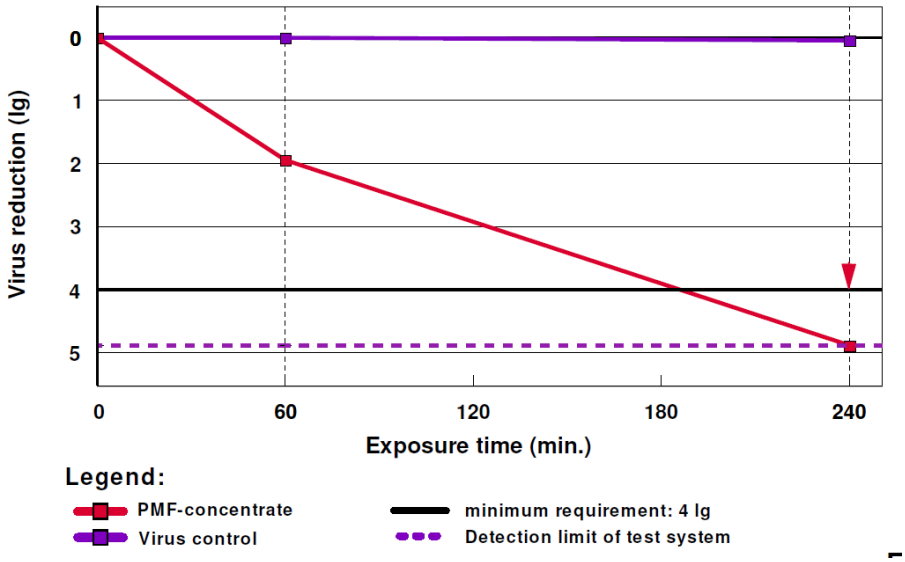

Figure 2. *H1N1 virus reduction (lg) as affected by the treatment of camel urine fraction (PMF) and measured after 60 and 240 min. Virus reduction = titer of virus control minus titer of sample (lg ID_{50})*

After 240 min, no residual virus could be detected. The corresponding virus reduction factor was estimated to be > 4.88 ± 0.55 corresponding to a virus reduction of 99.998% (*Supplementary file S2*).

The overall results indicated that PMF is a promising bio-product derived from camel urine with antiviral potentials. However, the mechanism of action is yet to be deciphered. Many viral diseases have associated with high morbidities and mortalities, and new approaches should be presented to find a cure. Many identified antiviral drugs

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1102311031

have also been used as anticancer agents in which drugs are effective in preventing DNA synthesis. The lyophilized PM701 extracted fraction from camel urine at 150 mg/g inhibited cancer cells proliferation without damaging normal cells at cell culture level (Khorshid et al., 2011; Mahboub et al., 2015). The MDCK reporter cell line established in this study is highly permissive for influenza virus replication and provides a highly specific and sensitive approach for simultaneous detection and isolation of influenza viruses (Hossain et al., 2010). Yao and coworkers (2014) had described that anti-herpes simplex virus drug (acyclovir) is an effective agent for cancer treatment. Camel urine was proven to induce cytotoxic influence in major types of human cancer cell lines (El-Shahawy et al., 2010; Al-Yousef et al., 2012). It was evident that the anticancer properties of camel's urine can be performed as antiviral properties. Anticancer properties were not attributed to a given compound in the camel's urine, such as zinc, copper and amino acids (Khorshid et al., 2009; Raouf et al., 2009; Ahmed et al., 2010; Ali et al., 2011). Jannah and coworkers also described that zinc and copper are the two key elements in PMF that delivers its antimicrobial effect (Jannah et al., 2013). Zinc has been proven to have antiviral activities against TGEV by viral multiplication within cells via inhibiting protein but it has no effect on cell infection (Weia et al., 2012). Sunada and colleagues conducted their study on bacteriophages and concluded that copper ion reduced infectious ability of phages (Sunada et al., 2012). Therefore, both copper and zinc are thought to have a vital role in antiviral and virostatic activity of PMF used in the present study. The high antimicrobial effect of crude extracts of camel urine was speculated to be due to its high osmolarity, high levels of proteins and potassium metallic ions (Stankova et al., 2009; Khorshid et al., 2011). Khorshid and coworkers (El-Shahawy et al., 2010; Khorshid et al., 2011; Mahboub et al., 2015) recorded that camel urine had cytotoxicity only against various human cancer cell lines, with negligible effect on non-tumorigenic epithelial and fibroblast cells (Khorshid et al., 2005, 2015). Several studies have also successfully proven the anticancer, antibacterial and antifungal effects of PMF (Khorshid et al., 2011, 2015; Mahboub et al., 2015).

Up to date, there are no effective treatments against human coronaviruses infections that has high mortality rate of up to 40% (Feikin et al., 2015). The American Academy of Pediatrics (2017-2018) indicated the recommendations for prevention and control of N1H1 by the use of trivalent, rather than the quadrivalent live attenuated influenza vaccine, containing the A/Michigan/45/2015 (H1N1) pdm09-like virus. The report indicated that antiviral medication in children can be important in controlling the disease, but this cannot be a substitute for vaccination. Our results indicate that PMF might be used solely as a potential alternative cure of the disease.

The present study highlighted the virucidal activity of PMF against the two viruses with no observed effects on the control. These results suggested that PMF treatment has an *in vitro* powerful effect on the virus replication process at the cellular level. The antiviral activity mode of action of camel urine fraction PMF has not been identified. Therefore, more investigations are needed concerning gene expression profiling to investigate the apoptotic activity of PMF. The antiviral activity of PMF should be enhanced for fast promising therapy using a wide range of DNA and RNA virus models as well as cancer inducing viruses.

Conclusion

The MERS-CoV and H1N1 viral infections, identified in the Middle East, have global concerns because of their associated high morbidity and mortality. The results of *in-vitro* PMF treatment showed a significant reduction in the titers of the two viruses across time indicating that PMF has potential antiviral activities. More studies are recommended to fractionate and monitor the antiviral activity of PMF compositions and to determine molecular mechanisms of action.

(Received 30th Mar 2019; accepted 13th Jun 2019)

Abstract. The sharp increase in water consumption poses a risk of increasing water scarcity in developing countries. The aim of this study is to the quantify variability of per capita Water Footprint (WF) of consumption of selected crops in Tehran province from 2008–2014. Blue and green WF were computed using WF approach. Besides, per capita WF of crop consumption was evaluated using bottom-up approach. The result illustrated the external water footprint had the largest contribution in total WF of crops consumption in the Tehran province (2008-2014). The total water footprint of crop consumption decreased because the population and per capita WF also decreased. Besides, wheat and rice had the largest per capita WF. This study discloses that it is essential to have appropriate water management to reduce water stress originating from agricultural sector in future. The consumption of wheat in Iran is high, more precisely 2 times larger than global average. It is recommended to reduce the consumption of wheat in Tehran or replace it with other crops. Besides that, decision makers in agricultural sector should reduce water lost, with declining production of cherry, pear, and peach. Furthermore, reducing water footprint of crops and efficient agricultural water management are recommended.
Keywords: *per capita water footprint, water consumption, agricultural water management, CROPWAT model, virtual water*

Introduction

Water footprint is identified as a strong tool to evaluate water consumption through the supply chain of products because it has multidimensional indicator which is able to evaluate direct and indirect water consumption. Besides, water footprint contains information about the types of water used including ground and surface water footprint (blue WF) and irrigation water footprint (green WF) (Hoekstra et al., 2011). The WF method is able to evaluate water consumption in a variety of scale from city (Wu, 2014) to global scale (Hoekstra and Chapagain, 2007). Water footprint of provinces is calculated by summing up the internal and external WFs (Hoekstra and Chapagain, 2007). Virtual water trade plays an important role in mitigating water shortages in water-stressed areas (Qian et al., 2018). However, exporting crops from water-stressed regions can increase water scarcity. Iran is facing severe water scarcity due to population growth, economic growth, inefficiency of agricultural water usage, and inappropriate water management (Madani, 2014). Besides, Iran has the largest blue water consumption and blue water footprint per capita (Hoekstra and Mekonnen, 2011).

In spite of existing vast number of literature, there has been lack of attention to the annual changes of water footprint of crop consumption and the associated water loss and saving at provincial scale. Besides, most of the studies have evaluated water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1103311044

footprint at country scale (Gephart et al., 2016; Ge et al., 2011; Zhuo, Mekonnen, and Hoekstra, 2016; Feng et al., 2015). It is important to know how much water is consumed due to crop use and how human consumption pattern impacts inter-provincial and international water dependencies. Very few studies have been done on the water footprint of Iran's crop consumption (Hoekstra and Mekonnen, 2011; Hoekstra and Chapagain, 2007; Karandish and Hoekstra, 2017); on water footprint of cereal crops throughout different provinces in Iran (Ababaei and Etedali, 2016); on water footprint of the cement industry in western Iran (Hosseinian and Nezamoleslami, 2018) and on the virtual water trade in Iran (Yousefi et al., 2017; Faramarzi et al., 2010). Besides, there has been lack of attention on the provincial water footprint and water saving assessment. Okadera et al. (2015) applied the "top-down" approach to evaluate the WF of energy supplies in one of China's provinces. Besides that, Zhao et al. (2018) and Chen et al. (2017) have assessed water footprints in all the provinces of China.

The objective of this research is to evaluate and analyze water footprint of 14 important crops in Tehran province and to assess water savings and losses from 2007 to 2014.

Materials and methods

Area of study

Tehran province is located in the northern central plateau of Iran with population of more than 13 million people in 2014. It accommodates approximately 18% of Iran population (Statistical Centre of Iran). It is the richest province in Iran which contributes approximately 29% of overall GDP. The area of Tehran province spans 18,909 km^2. The climate in the northern part of Tehran is alpine whereas in the southern part, it is arid and semi-arid. The total average rainfall is around 200 mm annually. The sum of precipitation with minimum and maximum temperature in Tehran in 2008 is illustrated in *Figure 1*.

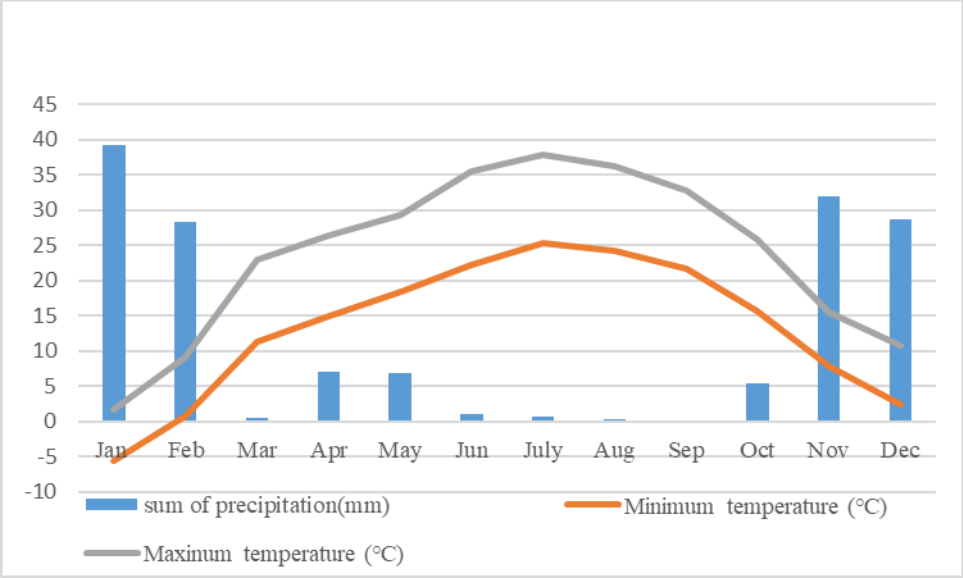

Figure 1. *The plot of minimum and maximum temperature and sum of precipitation (2008)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1103311044

The nation water footprint has two components: internal and external. Internal WF is the water footprint of crops that are produced within the border of Tehran for domestic consumption. On the other hand, external WF refers to WF of crops produced outside of (imported to) Tehran and consumed within Tehran. The WF in Tehran province is evaluated by summing up internal and external WF (*Fig. 2*). Besides, it is important to distinguish between WF of production and WF of consumption. WF of production is defined as the volume of WF that is used from domestic water resources for production of goods and services. However, consumptive WF refers to the volume of WF that is used from domestic and foreign water resources for domestic consumption (Hoekstra and Mekonnen, 2011).

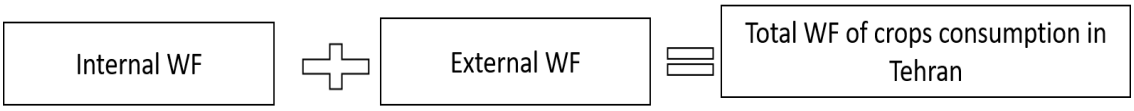

Figure 2. *National water footprint accounting framework based on Hoektra method (Hoekstra and Chapagain, 2007)*

First of all, the water footprint of crop production in Tehran province was evaluated. It was calculated based on Hoekstra method (Hoekstra et al., 2011). Secondly, WF of crops that are produced outside Tehran and consumed within Tehran (Hamedan, Lorestan, Ahvaz, Mazandaran, Qazvin, and Kermanshah provinces); also known as external WF was evaluated. Finally, per capita WF of crops, water saving, and water loss in Tehran were assessed.

Internal and external water footprint of crops in Tehran province

The WF of cultivated crops in Tehran, as well as imported crops from other provinces to Tehran were evaluated. For this research, the most important crops were selected including wheat, barley, maize, peaches, potatoes, rice, onions, tomatoes, grapes, oranges, cherries, peas, and apples. Water footprints of these crops were computed based on Hoekstra approach. The CROPWAT software was used to compute evapotranspiration of each growing crop.

Water footprint assessment methodology

The blue and green WF for each crop and each year were evaluated for each province based on Hoekstra approach. The blue WF was calculated by dividing blue Crop Water Use CWU_{blue} (m^3/ha) by the yield (Y) (ton/ha) – *Equation 1* (Hoekstra et al., 2011). The green water footprint was computed using similar method – *Equation 2* (Hoekstra et al., 2011).

$$WF_{blue} = \frac{CWU_{blue}}{Y} \quad \text{(Eq.1)}$$

$$WF_{green} = \frac{CWU_{green}}{Y} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1103311044

Crop water use (CWU_{blue} and CWU_{green}) were derived by multiplying 10 with ET_{blue} and ET_{green}, respectively – *Equations 3* and *4* (Hoekstra et al., 2011). Ten is used to convert the unit of millimetre, mm to m^3.

$$CWU_{blue} = 10\sum_{d}^{lg\ p} ET_{blue} \quad \text{(Eq.3)}$$

$$CWU_{green} = 10\sum_{d}^{lg\ p} ET_{green} \quad \text{(Eq.4)}$$

Measurement of ET is laborious and time-consuming, hence CROPWAT model was used to simulate ET for each crop by using climate data and crop parameters based on Allen method (Allen, 1998).

Water footprint of crop consumption

The blue and green WF of each crop were evaluated (m^3/year) using bottom-up method (Hoekstra et al., 2011). The water footprint for each crop was estimated by multiplying the volume of crop consumption by water footprint of crops. The WF of crops was calculated using *Equation 5.*

$$WF_{cons,indir} = \sum_{p}^{n} (c[p] \times WF_{P[P]}) \quad \text{(Eq.5)}$$

where $C[P]$ refers to the volume of crop consumption of product p within Tehran (ton/year) and $WF_{pro[p]}$ is WF of crop production from originating region (m^3/ton).

Water saving and loss

Water saving through international crop trade was evaluated based on Champaign et al. method (2006). It was calculated by multiplying the volume of import of crops (ton y^{-1}) by the WF of the crops (m^3 $year^{-1}$) within Tehran. The inter-provincial water saving through inter-provincial trades was assessed using similar method. The water footprints of imported crops from abroad were obtained from Mekommen and Hoekstra (2011). The blue and green water losses were accounted as the water footprints of extra production exported to other regions.

Data

The volume of crop yield and crop production in Tehran and other provinces were obtained from the Ministry of Agriculture, Jahad, in Tehran. The climate data including minimum and maximum temperature, rainfall, sunshine, humidity, and wind speed were obtained from Mehrabad weather station. Rooting depth, critical depletion, yield response, crop height is obtained from OPTIWAT which were local data. Data for the volume of crop consumption and trade were obtained from Tehran's chambers of commerce, industries, mines and agriculture.

Results

Per capita (green and blue) WF of different crop consumption is shown in *Figure 3*. The per capita water footprint of wheat in 2010 had increased due to the increase in the volume of production within the Tehran province which held large volume of WF as compared to the external WF. Besides, WF of wheat consumption showed reduction trend due to the decrease of per capita wheat consumption. WF of rice consumption showed fluctuating trend as it depends on the volume of consumption which was fluctuating too. Besides that, rice consumption per person had decreased from 35 kg/cap in 2008 to 34 kg/cap in 2014.

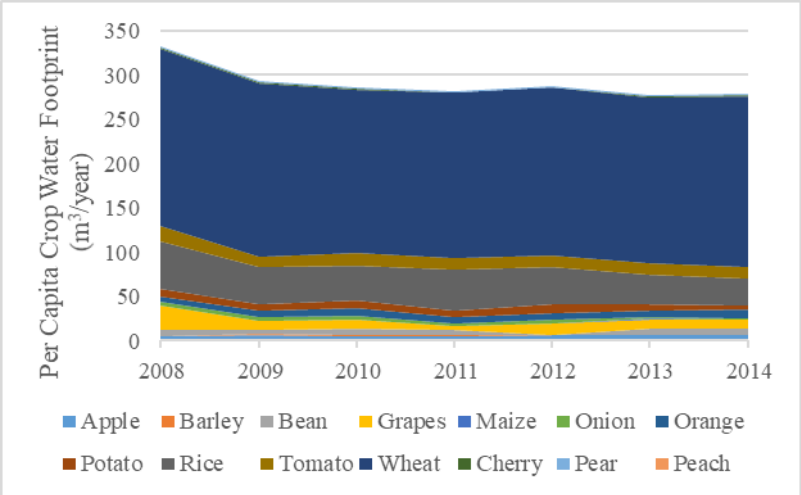

Figure 3. *Per capita water footprint of crop consumption (2008–2014)*

Figure 4 illustrates the total WF of crop consumption in Tehran province (2008–2014). It shows a declining trend in 2010 due to the decrease in the population of Tehran ever since Alborz province was separated from Tehran during the same year. Besides that, the per capita consumption of wheat and rice had also decreased.

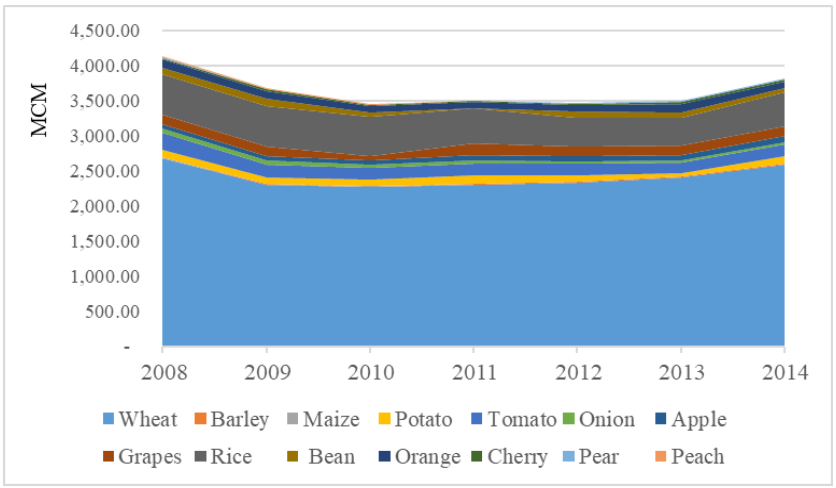

Figure 4. *The total WF of crop consumption in Tehran province (2008–2014)*

DOI: http://dx.doi.org/10.15666/aeer/1705_1103311044

Figure 5 shows the internal and external WF of different crops in the Tehran province. Tehran province is independent of external WF in the production of apples, pears, peaches, and cherries. This means, Tehran province produced and consumed all of the produce. Besides, Tehran imported 2,848 billion m^3 of virtual water and consumed 377 million m^3 of internal water footprint in 2008. Tehran saved water resources by importing crops from other provinces and abroad. For example, most of the wheat consumption within Tehran is imported from the USA. Wheat and rice have the largest WF of consumption in Tehran province since both of them are consumed at a large scale.

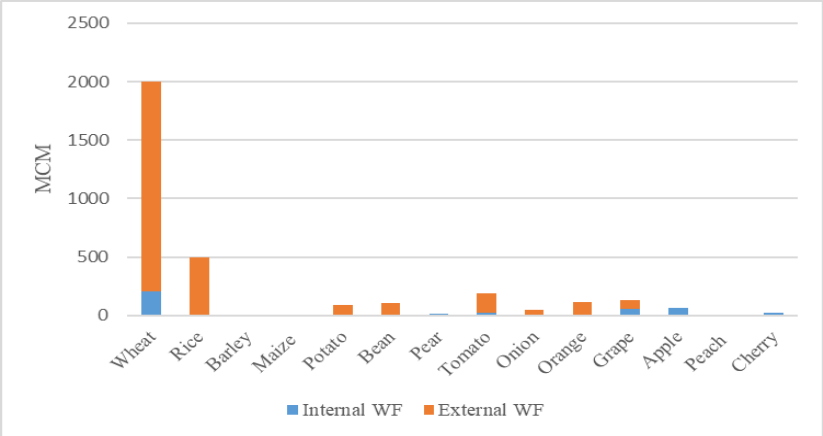

Figure 5. *Internal and external WF of crop consumption in Tehran province*

Figure 6 shows the average per capita WF of crop consumption in Tehran province. Wheat had the largest per capita WF (blue and green) amounting to 189 m^3/cap/year from 2008 to 2014. Next to wheat, rice had the largest per capita WF amounting to 46 m^3/cap/year. These were followed by tomatoes, potatoes, oranges, beans, apples, and grapes respectively. Cherries, pears, barley, peaches, and maize had low per capita WF.

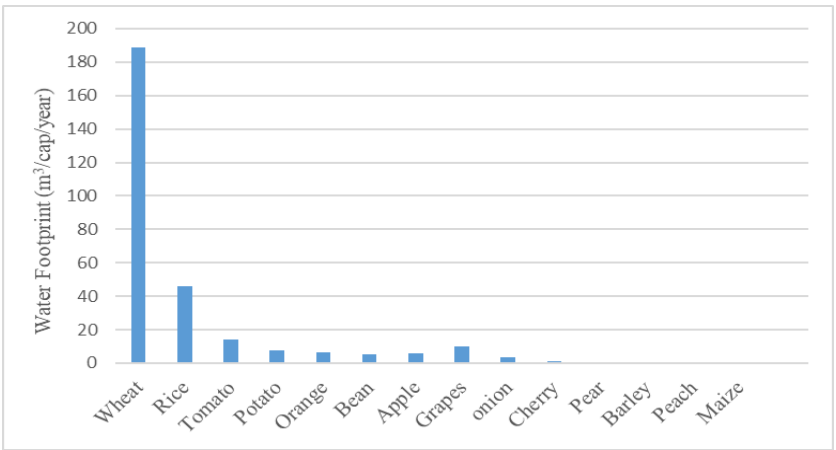

Figure 6. *The average per capita WF of different crops (2008–2014)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1103311044

Internal and external water footprint trend (2008–2014) is illustrated in *Figure 7*. Dependency on external WF had increased in 2010 when Alborz had separated from Tehran. Internal water footprint was a bit higher in 2014 which means water footprint in 2014 had increased. The external water footprint in 2014 was higher than 2008 because consumption of wheat had decreased.

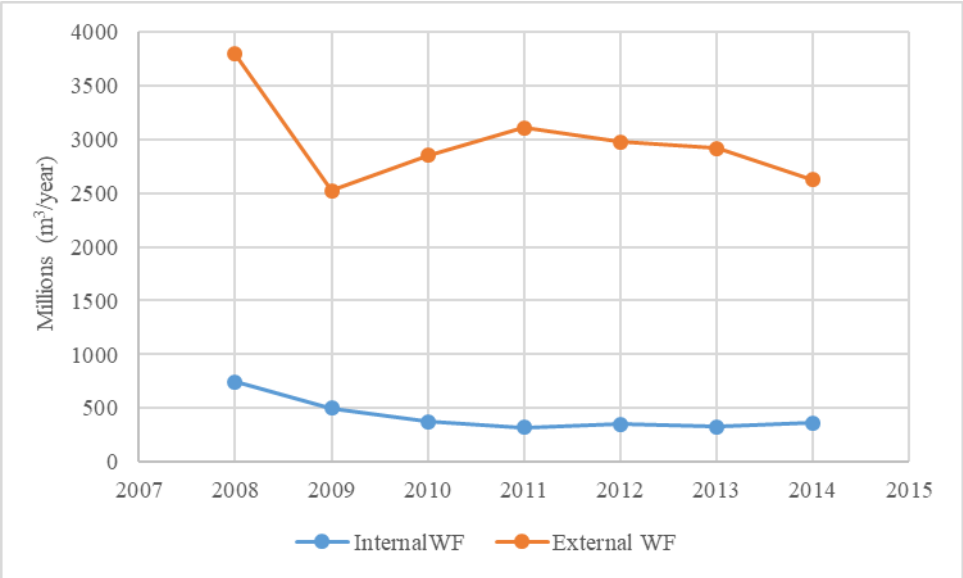

Figure 7. *The internal and external WF trend (2008–2014)*

Figure 8 shows the proportion of internal and external WF in Tehran province. Only 10% of Tehran's WF is attributed to internal WF. Most of the crops are produced outside of Tehran and exported into the Tehran province.

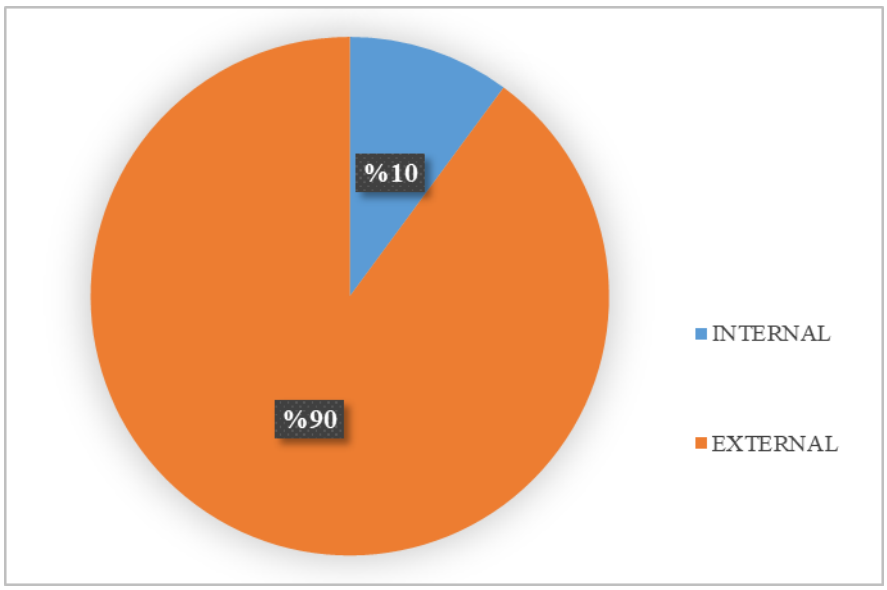

Figure 8. *The contribution of internal and external WF in Tehran's total WF*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1103311044

Figure 9 shows the total water footprint of Tehran province in agricultural sector for selected crops; derived by summing up the internal and external WF. The internal and external WF amounted to 377 million m^3/year, and 2,848 billion m^3/year respectively. The total water consumption was 3,225 billion m^3/year. Blue WF accounted for the largest contribution of internal WF while green WF was the largest shareholder of external WF. By importing crops externally, there will be more saving for Tehran's blue WF.

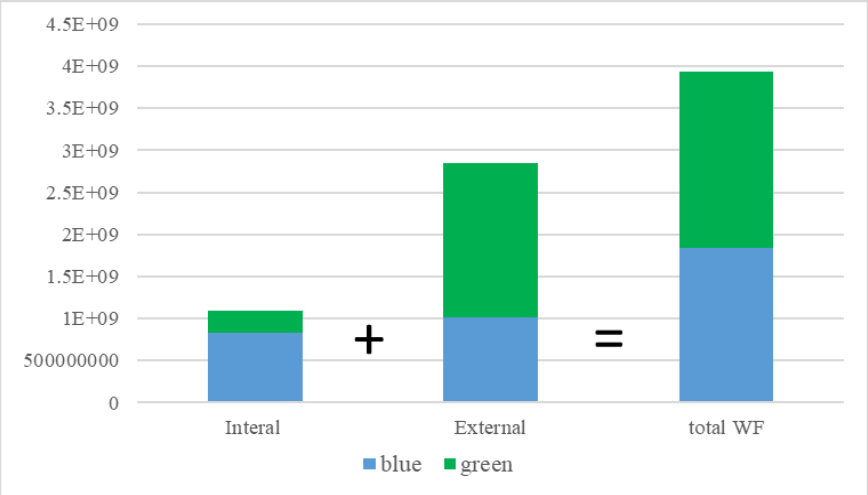

Figure 9. *The total WF in Tehran province*

Figure 10 shows the total blue and green water savings (WS) as a result of international and inter-provincial trades which have fluctuations. The blue water saving resulting from international trade had increased from 1.79 billion m^3 in 2010 to 1.9 billion in 2014 due to the increase in dependency on external WF. The total blue water saving from both international and inter-provincial crops had increased from 3,161 billion in 2008 to 3,234 billion m^3 in 2014.

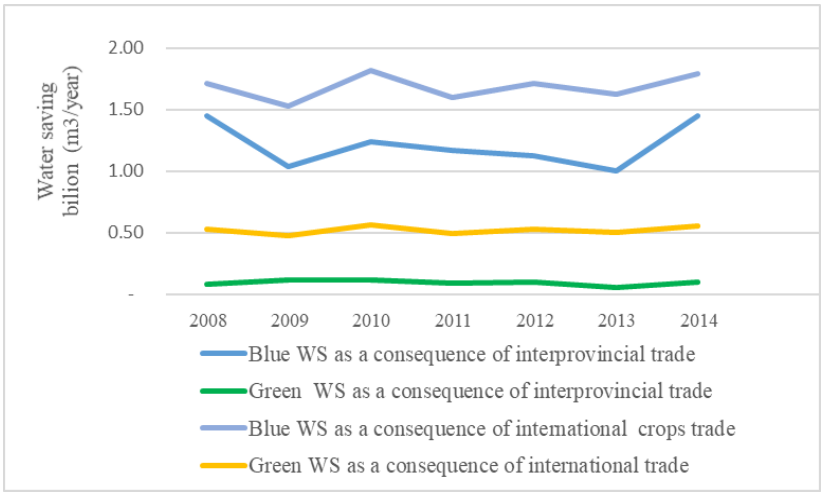

Figure 10. *Blue and green water saving as a result of international and inter provincial trade in Tehran (2008–2014)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1103311044

Blue WF per ton of crops in exporting countries are lower than Tehran as it has arid climate with high evapotranspiration. Blue water saving is increased as a result of international trade. On the other hand, green water saving is low because crop production within Tehran is mostly related to blue water footprint. Besides, green water footprint within the exporting region for all crops is larger than Tehran. Moreover, inter-provincial and international crop trades contribute to overall blue water saving.

Table 1 illustrates water savings from both international and national crop trades in 2008 and 2014. It shows that WS for wheat, potatoes, and onions in 2008 is lower than 2014 as the production of these crops within Tehran had increased. While WS for rice had decreased due to decline in the volume of rice consumption in 2014.

Table 1. *The water saving as a result of crops trade in Tehran Province (2008 and 2014)*

	WS as a result of crops trade (m^3/year)	**WS as a result of crops trade (m^3/year)**
	2008	**2014**
Wheat	2,237,927,587.50	2,343,328,030
Rice	1,111,524,117	993,982,416
Potato	83,311,520	103,726,320
Tomato	108,496,382	91,565,460
Onion	8,120,862	9927648
Grapes	219,463,024	147,818,440

Blue and green water losses in Tehran

Fig. 11 shows total blue water loss in Tehran province from 2008 to 2014. The total blue water loss had declined from 100 million m^3 in 2008 to 28 million m^3 in 2009 due to the reduction in production amount. Total green water loss had also decreased from 9 million m^3 in 2008 to 4 million m^3 in 2009. Moreover, Alborz province had been separated from Tehran during this time and most of the extra production came from pears and peaches of this province (2008). Then, blue water loss showed a fluctuating trend from 2009 to 2014 as it relies on the volume of extra production and the blue WF amount which are not stable. Blue water loss was larger than green water loss as the production of crops in Tehran relies on blue WF.

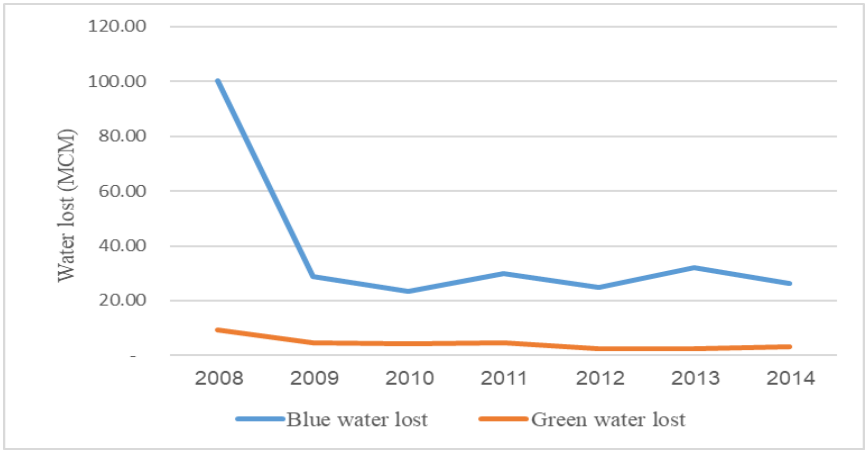

Figure 11. *The blue and green water lost (2008-2014)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1103311044

Discussion

Water footprint accounts for the volume of actual water consumption by humans. It is identified as an appropriate indicator for computing the impact of human activities on water resources. According to current research, there are four major factors impacting water footprint of crop consumption: (1) Population, (2) the volume of crop consumption, (3) the volume of internal production, (4) the external WF per ton of crop production. Besides that, water footprint of crop consumption in Tehran showed a reduction trend due to the increase in external WF. In the current study, per capita WF for wheat in Tehran was larger than evaluated by Hoekstra who has evaluated per capita WF at global scale. However, our result is different because this assessment is done at local scale. Besides, most of the wheat consumed in Tehran are imported from the USA which has low WF. Additionally, other studies have evaluated that water footprint of cereal crops in arid region of Iran was 397 m^3/capita/year which are relatively similar to our result (Karandish and Hoekstra, 2017).

The result indicates that crop production in Tehran has the largest WF compared to other countries, similar to Hoekstra's result who claims that water footprint of Iran is high due to low productivity and high evapotranspiration (Hoekstra and Chapagain, 2007; Fader et al., 2011).

The WF of crop consumption shows a reduction trend which disagrees with the result of Karandish who claims that WF of crop consumption for all provinces of Iran has increased because of population growth and increase in crop consumption (Karandish and Hoekstra, 2017). The WF consumption had decreased from 2008 to 2014 in Tehran province due to the increase in dependency on external WF and decrease in population. The reason for population decrease was Alborz separation from Tehran province in 2010**.**

Conclusion

This study shows Tehran's water self-sufficiency had decreased from 2008 to 2014. Furthermore, per capita WF of crop consumption had decreased due to the increase in dependency on external WF and decrease in population from 2008 to 2014. WF per ton of imported crop production was lower than Tehran because of climate condition. Besides, WF of crop consumption within Tehran is more strongly reliant on external WF. Tehran province has produced only 10 per cent of its crop consumption; it has been under severe water scarcity due to population and climate condition. Moreover, Tehran province can save water resources by importing crops from water-abundant areas. Tehran saved 3.23 billion m^3 of internal water resources through inter-provincial and international crop trade in 2014.

Total blue and green water losses had decreased from 2008 to 2014 due to reduction in the volume of extra production when Alborz was separated from Tehran province. Water loss depends on extra production that is exported to other regions. The decision makers should reduce the production of fruits for export purposes such as pears, peaches, and cherries because Tehran is under high groundwater stress with moderate surface water scarcity (Rezaei Kalvani et al., 2019). Additionally, production of cereal crops should be reduced as these crops consume high volume of blue water in Tehran due to climate condition.

Water footprint assessment can contribute to enhance water use efficiency in agricultural sector by providing useful information for decision makers. Besides, it is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1103311044

crucial to apply developed technology and appropriate water management in order to enhance water use efficiency and lower water footprint per ton of crops to reduce per capita water footprint in Tehran.

The consumption of wheat in Iran is high; two times higher than global average. Change in food consumption habits contributes to increased food security at regional scale. It is recommended to reduce the consumption of wheat in Tehran or replace it with other crops. Besides, changing food consumption habits contributes to increase food security at a regional scale. It would also be helpful to assess the per capita water footprint of different dietary changes in the future water footprint assessment.

Abstract. With the continuous development of society, the agricultural economy has shown a good development trend, but at the same time it has produced more and more carbon emissions, and the greenhouse effect has increased, posing a threat to the ecological environment. Agricultural carbon emissions are important factors. Therefore, studying the temporal and spatial characteristics of agricultural carbon emissions is an urgent task. This paper focused on agricultural carbon emissions from land use and tested and predicted future carbon emissions based on three types of carbon source factors using the auto regressive integrating moving average (ARIMA) model. The spatial and temporal characteristics of agricultural carbon emissions were analyzed from the dimension of time and space. According to the results, the total agricultural carbon emission and intensity of the eastern region ranked the first, followed by the middle region; the total agricultural carbon emission of different regions increased, but slower; the agricultural carbon emission intensity of different regions decreased, and overall decreased faster. This study effectively verifies the deep influence of the development of ecological agriculture on the spatial and temporal characteristics of carbon emission of land use.
Keywords: *ecological environment, carbon source factor, temporal sequence prediction, economic system, temporal and spatial characteristics*

Introduction

In the process of agricultural economic development, the impact of land use change on greenhouse gas emissions has become a core issue in today's carbon cycle research. With the emergence of these phenomena, a series of social and environmental problems have arisen, and the situation of agricultural development is very worrying. Therefore, research on the temporal and spatial characteristics of carbon emissions of land use is extremely urgent (Simmons and Matthews, 2016). In response to this problem, many experts and scholars have put forward their own opinions. Zhang and Fang (2013) effectively assessed and predicted agricultural carbon emissions based on six relevant aspects of agricultural carbon sources, put forward the research method of decomposition factor based on kaya model, and found that the rapid development of agricultural economy increased carbon emission. Liu et al. (2014) proposed a model which was composed of gray model (GM) (1,1) model, auto regressive integrating moving average (ARIMA) model and second order polynomial regression (SOPR) model to predict and analyze the carbon emission intensity of carbon dioxide. Han et al. (2018) believed that there was an inevitable connection between agricultural carbon emissions and agricultural economic growth and put forward the study of the coupling and decoupling effects of agricultural carbon emissions and their driving factors. Chuai et al. (2015) believed that the change of land use type would not only directly affect the carbon stocks in terrestrial ecosystems, but also had an indirect impact on the frequent occurrence of anthropogenic carbon emissions in coastal areas. Therefore, a linear

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1104511053

programming model was proposed to improve the land use structure and achieve the goal of low carbon emissions. Gong and Chen (2011) analyzed the status of carbon emissions and proposed suggestions of land use regulation based on low-carbon emissions: setting up and optimizing land ecological compensation mechanisms, etc., which is conducive to promoting carbon emission reduction and protecting the ecological environment. In this study, the agricultural carbon emission was analyzed and predicted based on the three kinds of carbon source factors of agricultural carbon emission and ARIMA model, and the spatiotemporal distribution characteristics of agricultural carbon emissions were clearly illustrated. This work provides a reference for the development of ecological agriculture in China.

Materials and methods

Development of ecological agriculture

Agriculture is the foundation of a country's foothold, which realizes the basic material data needs of human beings by converting biology into solar energy. While the efficiency of agricultural production is constantly improving, the ecological environment has been sacrificed, which has caused great threats to human beings. In order to slow down the severity of this phenomenon, a scientific and standardized ecological agriculture has been emerged. Ecological agriculture refers to a modern agricultural development mode which combines systematic engineering methods with modern scientific achievements, strictly follows the growth law of ecological economy, is based on the basic principles of ecology, and has the intention of protecting and improving agricultural ecological environment (Wu et al., 2015). It is a project involving multiple aspects, such as economic science and natural science (Onofrei et al., 2016).

The most important feature of eco-agricultural production is ecological character, in which the effect of protecting the ecological environment is significant, but the production efficiency is not very high when the input cost is high. The purpose of eco-agriculture development include protecting the ecological environment and promoting high-productivity and high-ecological double harvest. Therefore, a sustainable, scientific and efficient agricultural development model was developed by combining ecological agriculture with China's national conditions and using modern scientific management tools, and moreover the advantages of every area are taken as the emphatically developed agricultural projects to implement regional eco-agricultural construction, which can effectively protect ecological environment while obtaining large economic benefits and promote the harmonious development of society.

Carbon emissions of land use

Applying land to different application areas, such as planting crops, raising livestock, developing waters, and building high-rise buildings, will result in different types of land use, and changes in land use will have different carbon emission effects. The so-called land-use carbon emissions refers to the carbon dioxide released by changes in the field of land application and people on the land in their production and life (Fu et al., 2017), in a direct or indirect way. Direct carbon emissions represents carbon emissions from changes in land use cover and land management concepts and methods; indirect carbon emissions represents carbon emissions of human activities in different types of land use

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1104511053

(Kato and Yamagata, 2014). Carbon emission of land use is expressed as E *(t)*, the carbon emission of type a land use is expressed as e_a *(t)*, the area of type a land use is expressed as S_a *(hm^2)*, and the carbon emission coefficient of type a land use *(t/hm^2)* is expressed as δ_a. Then the computational formula of carbon emission of different types of land use is:

$$E = \sum e_a = \sum S_a \delta_a \quad \text{(Eq.1)}$$

Agricultural carbon emission is an important part of carbon emission of land use. Therefore, this study investigated carbon emission of land use by focusing on agricultural carbon emission. Agricultural carbon emission is mainly analyzed through three types of carbon source factors, including carbon emission of agricultural land use, carbon emission of paddy fields, and carbon emission of livestock farming (Han et al., 2018). The carbon emission of agricultural land use mainly include carbon emission of chemical products such as pesticides, agricultural film and chemical fertilizers, organic carbon emission produced by the damage of ploughing activities to soil organic carbon pool, and carbon emission produced by electric energy loss and loss of energy such as diesel during farming by agricultural machinery. Specific carbon sources include pesticide inputs and their changes, fertilizer inputs and their changes, agricultural irrigation inputs and their changes, agricultural land cultivation methods and their changes, and agricultural machinery products inputs and changes (Ismael et al., 2018). Carbon emissions from paddy field planting mainly include carbon emission from rice planting in different growth cycles, early rice, late rice and mid-season rice. The main carbon sources in livestock farming are intestinal fermentation of livestock and poultry and livestock manure (Asumadu-Sarkodie and Owusu, 2017).

Spatial distribution

Through the collection and sorting of relevant data on agricultural carbon emissions, the agricultural carbon emission areas are generally divided into four levels, including low agricultural carbon emission areas, medium agricultural carbon emission areas, slightly high agricultural carbon emission areas and high agricultural carbon emission areas. It can be seen from *Fig. 1* that the high agricultural carbon emission areas are mainly distributed in provinces such as Sichuan, Shandong, Jiangsu, Anhui, Hunan and Hubei, the slightly high agricultural carbon emission areas are mainly distributed in provinces such as Inner Mongolia, Heilongjiang, Yunnan, Guangdong and Jiangxi, the medium agricultural carbon emission areas are mainly distributed in provinces such as Gansu, Shaanxi, Zhejiang, Fujian, Jilin and Liaoning, and the low agricultural carbon emission areas are mainly distributed in provinces such as Qinghai, Shanxi and Hainan (Pang and Zhao, 2013). The agricultural carbon emissions of the eastern region account for a large proportion, followed by the central region and western region, which has a great relationship with factors such as climate, economy and environment. The change of every factor will produce different agricultural phenomena and development effects. As the eastern region has good climatic conditions, excellent economic environment and fast agricultural development, the proportion of the agricultural carbon emission of the eastern region is larger than that of the other two regions.

Relevant data on agricultural carbon emissions in the eastern, central and western regions in 2015 were collected and sorted, and experimental results were obtained based

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1104511053

on the algorithm of agricultural carbon emissions. The experimental data mainly consisted of carbon emissions generated by different chemical products in agricultural land use, carbon emissions generated by the rice planting process in different periods, carbon emissions generated by livestock breeding and total agricultural carbon emission. Moreover deep study was carried out to analyze the spatial difference characteristics of different regions in the dimension of space, and corresponding experimental conclusions were obtained.

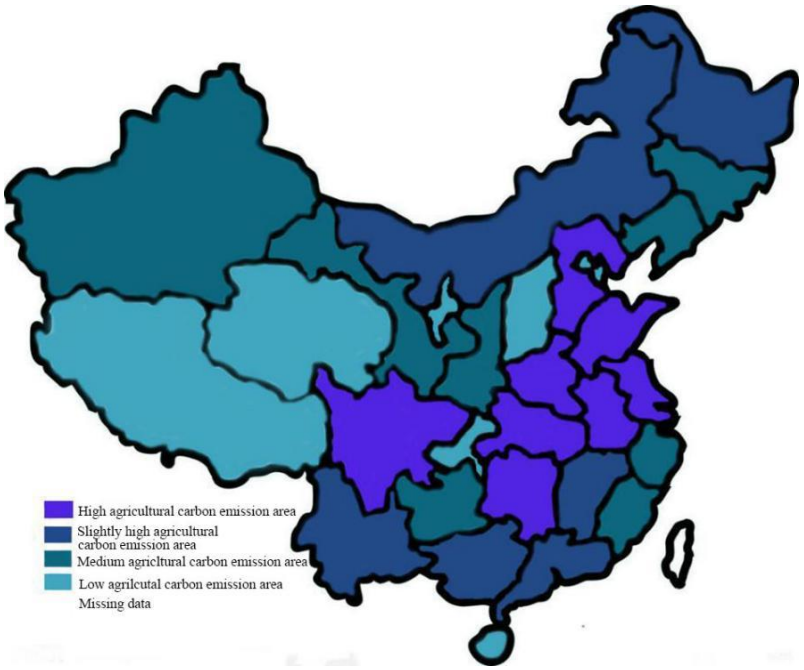

Figure 1. *Spatial distribution characteristics of China's agricultural carbon emissions*

Temporal distribution

Methods for analyzing the temporal sequence characteristics of agricultural carbon emissions

With the rapid development of the agricultural economy, China's agricultural carbon emissions are generally on the rise, and the government's agricultural policy has always placed food security as a top priority to meet China's demand for food. In 2004, the relevant government departments promulgated a number of policies conducive to the agricultural economy and did not forget to promote the development of agriculture while making rapid progress in society. In 2006, the government completely abolished the agricultural tax to promote the enthusiasm of farmers. However, in the environment of rapid development of agriculture and with the continuous improvement of production efficiency, a series of negative phenomena have emerged, such as the sacrifice of the ecological environment; hence the government has paid more and more attention to the protection of the ecological environment. In 2007, the 17th National Congress of the Communist Party of China was fully convened, and the importance of protecting the ecological environment was strongly emphasized. So far, ecological agriculture has continued to develop, and the business philosophy has been moving closer to scientific and normative. The various factors will affect the changes in agricultural carbon

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1104511053

emissions, mainly reflected in the characteristics of time distribution. Therefore, this paper studied the temporal and spatial sequence characteristics of agricultural carbon emissions from the total amount and intensity of agricultural carbon emissions.

Data on agricultural carbon emissions in the eastern, central and western regions from 2012 to 2018 were collected and sorted, and the corresponding calculation was made to obtain experimental results. Moreover, the simulation experiment of prediction was made using EViews9.0. The corresponding ARIMA model was established. A time series was established and tested. Then the relevant parameters of the model were compared, diagnostic test was made, and the total amount and intensity of agricultural carbon emissions from 2019 to 2025 was predicted. The corresponding verification results were obtained, and the temporal distribution characteristics of agricultural carbon emissions in the eastern, central and western regions were analyzed, and the corresponding experimental conclusions were obtained for reference.

Prediction of agricultural carbon emissions

Agricultural carbon emissions in the eastern, central and western regions from 2019 to 2025 were predicted using ARIMA model. The model can be used for time series prediction. It is established by transforming the non-stationary time series into the stationary time series, regressing the lag value, and implementing the regression operation on the present value and the lag value of the random error term. In ARIMA(p,d,q), p is autoregressive item, q is the number of moving average items, d is the number of differences made when the time series is converted to be stationary, ε_t is a stationary time series, and u_t is the residual white noise sequence, and ϕ_m and θ_m $(i = 1,2,\cdots, p, m = 1,2,3,\cdots, q)$ are ε_t and the parameter of ε_t. The calculation formula is:

$$\varepsilon_t = c + \phi\varepsilon_{t-1} + \phi\varepsilon_{t-2} + \cdots + \phi_p\varepsilon_{t-p} + u_t + \theta_1 u_{t-1} + \theta_2 u_{t-2} + \cdots + \theta_q u_{t-q} \qquad \text{(Eq.2)}$$

The prediction steps are as follows. Firstly, the original sequence *ADF* was tested and verified. If there was a unit root, then in order to make it meet the stability conditions, *d*-order differential operation was made on the initial sequence. Then the correlation study was made on the characteristics of sequence after differential operation. Moreover the values of p and q were obtained through the autocorrelation function and partial autocorrelation function graphs of sequence. Dependent variable *AR(p)* and *MA(q)* were estimated by least square estimation or maximum likelihood estimation. Diagnostic test was performed on the residual of the mode. Finally the data of agricultural carbon emission was predicted.

Results

Analysis of spatial characteristics of carbon emission

The spatial characteristics of agricultural carbon emissions in the eastern, central and western regions in 2015 were analyzed, and the results are shown in *Table 1* (unit: tens of tons).

It can be seen from *Table 2* that the carbon emissions of agricultural land use in the eastern and central regions accounted for the largest proportion, followed by the carbon emission of paddy field planting and livestock breeding. The carbon emission of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1104511053

livestock farming in the western region accounted for the largest proportion, followed by the carbon emission of agricultural land use and paddy field planting. In general, there were differences between regions. The eastern and central regions have high land utilization rate because of the large area of plains, and the climatic conditions for rice planting are good; therefore the carbon emissions of agricultural land use and paddy field planting were high. The western region has low land utilization rate because of the high altitude. Moreover the climate conditions for rice planting are bad. But the broad meadow resources are suitable for the breeding of livestock such as cattle and sheep. Therefore the carbon emissions of livestock breeding in the western region was high.

Table 1. *Spatial differences in agricultural carbon emissions in the eastern, central and western regions*

	Carbon emission of agricultural land use	Carbon emission of paddy field planting	Carbon emission of livestock breeding	Total agricultural carbon emission
The eastern region	12078.36	7512.98	3498.35	23089.69
The central region	8102.98	5236.12	3857.26	17196.36
The western region	5423.78	3012.56	7932.84	16369.18

Table 2. *Temporal differences of agricultural carbon emissions in the eastern, central and western regions*

Year	Total of eastern	Total of central	Total of western	Intensity of eastern	Intensity of central	Intensity of western
2012	10023.69	8523.56	7123.89	57.98	53.98	47.26
2013	15756.19	12619.55	12036.25	56.78	52.19	46.96
2014	20523.56	16169.63	15369.36	55.78	51.06	45.02
2015	23089.69	17196.36	16369.18	54.06	50.97	43.46
2016	23965.36	18636.78	16987.16	49.87	47.56	40.12
2017	24579.63	19369.43	17693.98	45.99	43.99	37.98
2018	25969.36	20869.58	18996.78	37.02	36.09	32.13

In 2015, the total amount of agricultural carbon emissions in the eastern region ranked the first, followed by the central region. The total amount of agricultural carbon emission in the western region was the smallest compared with the other two regions, and the differences between the regions were large. The eastern region, compared with the central and western regions, has superior economic environment, larger scale of agriculture and higher modern technology level, which makes agricultural carbon emissions increase; therefore, the total amount of agricultural carbon emissions was the largest. In comparison, the western region had the poorest condition in those aspects; hence the total agricultural carbon emission was the smallest.

Analysis of temporal characteristics of carbon emission

The temporal characteristics of agricultural carbon emissions in the eastern, central and western regions from 2012 to 2018 were analyzed, and the results are shown in *Table 2* (unit of the total carbon emission: ten thousand tons; unit of carbon emission intensity: kg/mu).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1104511053

It can be seen from *Table 2* that the total amount of agricultural carbon emissions in the eastern, central and western regions was generally on the rise from 2012 to 2018, because the scale of agriculture in each region was expanding and the industrial technology was effectively improved. However, the growth rate of the total carbon emissions has slowed down, and the phenomenon of agricultural carbon emission has improved, which is because that China's agricultural policy is constantly adjusted, the popularization rate of ecological agriculture management concept has been greatly improved, and the development mechanism of ecological agriculture has been continuously optimized and improved.

From 2012 to 2018, the carbon emission intensity in the eastern, central and western regions showed a downward trend. Moreover, it can be seen that the decline amplitude in carbon intensity in different regions became larger, which is because that the government tends to pay more attention to environmental protection and release low-carbon agriculture related policies and the mechanism of ecological agriculture becomes more and more scientific.

Prediction of agricultural carbon emissions

A simulation experiment was conducted on the total amount and intensity of agricultural carbon emissions in the eastern, central and western regions from 2019 to 2025, and the results are shown in *Table 3* (unit of the total carbon emission: ten thousand tons; unit of carbon emission intensity: kg/mu).

As can be seen from *Table 3*, from 2019 to 2025, the total amount of agricultural carbon emissions in the eastern, central and western regions increased, but the magnitude tended to be gentle. The gentle increase is because that the continuous development of ecological agriculture has promoted the development of low-carbon economy, and the agricultural management concept is moving closer to the new mode of low input and high production. But the pace of developing the agricultural economy cannot be stopped; therefore, the agricultural carbon emissions has an increase.

Table 3. *Prediction of agricultural carbon emissions in the eastern, central and western regions*

Year	Total of eastern	Total of central	Total of western	Intensity of eastern	Intensity of central	Intensity of western
2019	26001.36	22009.39	20012.96	37.01	35.94	32.06
2020	27098.35	24005.98	22080.45	36.96	35.69	31.96
2021	28809.36	25065.12	23601.78	36.75	35.36	31.65
2022	29500.96	25956.45	24806.95	36.19	35.02	31.08
2023	29769.36	26963.47	25102.69	35.32	34.01	30.56
2024	30002.23	27965.15	25672.63	34.59	33.09	29.56
2025	30400.79	28137.65	26012.73	32.01	31.01	28.46

The intensity of agricultural carbon emissions in the eastern, central and western regions generally declined, and the decline amplitude became larger. The reason is that the change of agricultural policy has made the concept of eco-agriculture economy more and more popular and more and more attention is paid to the protection of the ecological environment during the development of agricultural economy, which makes the intensity of agricultural carbon emission low.

DOI: http://dx.doi.org/10.15666/aeer/1705_1104511053

Generally speaking, with the rapid development of China's eco-agriculture and the high popularity of the concept of protecting the ecological environment, the severe phenomenon of China's agricultural carbon emissions will continue to improve, especially in the aspects of agricultural carbon emission amount and intensity. The improvement of agricultural carbon emissions will affect the carbon emissions of land use, and moreover the ecological agricultural economic system will continue to be optimized to promote the healthy development of agriculture.

Conclusion

With the rapid development of the agricultural economy, the ecological environment has deteriorated and the carbon emissions of agriculture have increased. Therefore, the research on the temporal and spatial characteristics of land use carbon emissions has developed into an important research topic. Studying this topic can grasp the temporal and spatial characteristics of agricultural carbon emissions in various regions and help effectively optimize and improve the relevant mechanisms of agricultural carbon emissions. This paper mainly focused on agricultural carbon emissions among carbon emissions of land use, compared and analyzed the three types of carbon source factors based on agricultural carbon emissions, analyzed the spatial and temporal characteristics of agricultural carbon emissions in the eastern, central and western regions, and established an ARIMA model. The total amount and intensity of agricultural carbon emissions in the western, central and middle regions were predicted and analyzed. It was found that the total carbon emission amount and intensity in the eastern region were the highest, followed by the central region, the total agricultural carbon emissions of all the regions increased, but in a gentle amplitude, and the agricultural carbon emission intensity of all the regions decreased in a fast speed. The study of the spatial and temporal characteristics of carbon emissions of land use is conducive to promoting the efficient development of ecological agriculture in the future.

(Received 1st Apr 2019; accepted 19th Jun 2019)

Abstract. Chinese fir (*Cunninghamia lanceolata*) is a prized timber species, which is grown in China from more than a thousand years. According to 8th national forest inventory data, Chinese fir plantations area expanded over an area of 11 million hectares, which occupies almost 18.2% area of all plantations in China principally in southern China. Successive rotations with clear cutting have become a common practice for Chinese fir plantations. These management practices on continues bases have led to a declining in yield production. Therefore, a serious concern has been raised on the Chinese fir plantations less yield and long-term productivity decline, particularly about the current rotation regime. In this review, we discussed the general causes of Chinese fir productivity decline and their effective solution. In forest conservation, the decline in soil quality is a serious ecological problem and recalcitrant litter, monoculture planting has aggravated the mechanism of soil degradation in Chinese fir plantations. The deteriorated soil properties in Chinese fir plantations were well mirrored in the reduction of plantation growth. Traditional plantation method of successive rotation without the period of fallow and management system of clear cutting, complete ploughing, burning of site and residues removal could be blamed for site degradation resulting in the poor growth and productivity decline of Chinese fir plantations. Complete burning and clear-cutting can lead to soil degradation by the loss of nutrients and organic matter. Therefore, a comprehensive knowledge of Chinese fir in terms of low productivity causes and solutions will allow us better forest management strategies and better development of plantation and afforestation throughout China.
Keywords: *productivity, soil quality, soil degradation, forest conservation, Chinese fir, China*

Introduction

Plantation forests are the significant part of the forest ecosystems of China (*Fig. 1*), and Chinese fir (*Cunninghamia lanceolata* (Lamb) Hook) is one of most planted species in these plantation forests. It is a typical evergreen sub-tropical conifer with high timber yield, excellent timber quality, and fast growth. It is the third most commonly planted species in plantation forests worldwide (State Forestry Administration, 2010). Chinese fir is often used in the provision of the ecosystem as well as inorganic matter storage. It

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1105511067

is characterized by its fast growth rate when grown in a monoculture plantation, producing volumes of up to 450 m^3/ha after 25 years (Wang et al., 2014). Its timber accounts for 24% of China's national commercial timber production (FAO, 2007). Fast growing species, along with the quick economic returns also provide the opportunity to mitigate the climate change by sucking the big carbon emissions, which had a significant impact on global climate (Yang et al., 2005). Since 1949, due to afforestation policies area under Chinese fir plantations increased nearly tripled (Li et al., 2013).

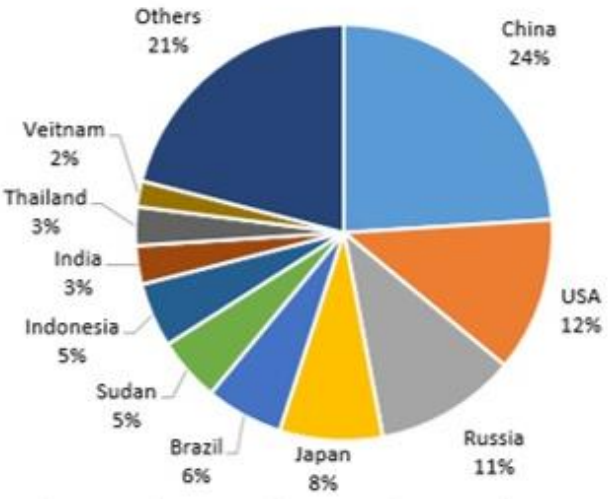

Figure 1. *Distribution of plantations forests worldwide (FAO, 2007)*

As one of the most important subtropical coniferous species, Chinese fir plantations have been using across China for more than one thousand years, especially in southern China (Wu, 1984). China gradually increased its area under plantations since the 1970s (Yu, 1997) and southern China have the highest percentage (54.3%) of forests primarily the plantations (Wang et al., 2014). According to 8th national forest inventory, data indicates that Chinese fir plantations expand over an area of 11 million hectares which occupies almost 18.2% area of all plantations in China and 6% worldwide (FAO, 2015; State Forestry Administration, 2014).

Since the 1980s, the cultivated area under Chinese fir plantations has been expanded from disconnected patches to large plantations (hills to high mountains) to meet the growing need (Ma et al., 2002). Majority of the Chinese fir plantations are monoculture and increasing timber demand resulted in shorter rotations (15 years) without the period of fallow (Bi et al., 2007; Tian et al., 2011). Successive rotations with clear cutting have become a common practice (Hu et al., 2014; Ma et al., 2007). These management practices on continues bases have led to declining in yield production along with soil degradation due to below-ground resources loss (nutrient loss) and accumulation of toxic substances (Chen et al., 2013; Hu et al., 2014). Shorter rotations have led to a high nutrient loss in foliage and biomass per tree component decreased as compare to longer rotations especially in the branches per unit biomass (Fang, 1987; Ma et al., 2007; Zhou et al., 2015). Therefore, a serious concern has been raised on the Chinese fir plantations less yield and long-term productivity decline (Bi et al., 2007; Zhao et al., 2013), particularly about the current rotation regime. Therefore, we have reviewed various aspects of Chinese fir related to short rotations regime, which are directly involved in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1105511067

Chinese fir productivity decline like nutrient availability, nutrient cycling, soil microbes and their biochemical activities etc. We try to uncover the basic problems in the Chinese fir decline over successive rotations and possible effective solutions provided by the various previous studies. This study would provide a reference for future researches.

Chinese fir description

The genus "Cunninghamia" is an evergreen coniferous specie in the cypress family Cupressaceae. Traditionally, it is said that this genus contains two species, Chinese fir (*Cunninghamia lanceolata* Lamb) Hook) and Taiwan fir (*Cunninghamia konishii),* but genetic obedience suggested them as the same species which is usually known as "Chinese fir".

They are native to China, Taiwan, Northern Vietnam, and Laos. Distribution of Chinese fir in China is shown in (*Fig. 2).* They may reach a height of 50 m, generally with the conical shape with tiered and horizontal branches, which often somewhat pendulous toward the tips. Chinese fir has green needle-like leaves, which are softly spun, leathery and stiff (*Fig. 3*). Needles spiral around the stem in an upward arch. Chinese Fir is a valued species in China which is vital because of its fast growth and high-quality timber wood (i.e., straight and decay resistant), along with its historical value and significant culture it is used as an ornamental tree.

Stand development can be the key factors in the nutrient distribution and cycling as well as in biomass production (Li, 1996; Ma et al., 2002, 2007; Zhao et al., 2013). Different factors influence the nutrient absorption of the trees, which include growth rate, nutrient use efficiency and stand nutrient demand (Hobbie, 2015). Climatic as well as physical and chemical factors also affect the nutrient contents and nutrient use efficiency (Piao et al., 2010). According to Ma et al. (2007), annual nutrient uptake and nutrient use efficiency in Chinese fir plantations increased while the nutrient return decreased with stand development. Soil microbes are also the key ingredients in maintaining good soil structure by gas exchange and good drainage, which keeps soil healthy (Bhardwaj et al., 2014).

Data in the *Table 1* showed fungal population firstly increased from 1-year-old plantation to 20-year-old plantation but decreased in 40-year-old plantations. Bacterial population decreased from 1-year-old plantation to 20-year-old but again increase from 20-year-old to the 40-year-old plantation. Overall, microbial population decreased in 20-year-old plantation due to the decrease in bacterial population.

Table 1. *Soil microbial population in different aged Chinese fir (Cunninghamia lanceolata) plantations (10^3.g^{-1} soil)*

Soil microbes	Plantation age		
	1 yr.	20 yr.	40 yr.
Fungi	74	468	199
Bacteria	16900	13660	15760
Total microbes	16974	14218	15959

Nutrient contents and biochemical activity of soil microbes

Chinese fir plantations consume a large number of nutrients because of its fast growth (Farooq et al., 2019a), and due to short rotation periods, nutrient contents availability decreased significantly over the successive rotations. In Chinese fir plantations, soil nutrient contents decreased drastically as the rotation increased (Fang, 1987; Chen et al., 1990). Data in *Table 2* showed that soil humus carbon (SHC) was 37.6 gkg^{-1}, 33.8 $gkg^{-1,}$ and 32.4 gkg^{-1} in first, second and third rotation respectively during Chinese fir plantation. Soil total nitrogen (TN) was 4.28 gkg^{-1}, 3.91 gkg^{-1} and 3.36 gkg^{-1} in first, second and third rotation respectively while total phosphorous (TP) was 0.27 gkg^{-1}, 0.23 gkg^{-1} and 0.14 gkg^{-1}. In first rotation soil total Potassium (TK) was 19.7 gkg^{-1}, moreover, in the second and third rotation, it was 16.5 gkg^{-1} and 14.3 gkg^{-1} (*Table 2*). SHC decreased up to 15.7% in the second rotation while TN, TP, and TK decreased up to 18.4%, 9.6%, and 2.4%, respectively.

In terms of third rotation, SHC decreased up to 32% from the first to third rotation while the TN, TP, and TK decreased up to 36%, 61.2%, and 11.4%, respectively. As the soil depth got deeper, the contents of all the elements declined over successive rotations (Zhang et al., 2004). Plant available contents also decreased from first to the third rotation. When the Chinese fir plantation was regenerated from the site of first rotation, available nitrogen (N_A), available phosphorous (P_A) and available potassium (K_A) decreased significantly by 42.4%, 44.1%, and 37.5% respectively while on the site of second rotation, $N_{A,}$ P_A and K_A decreased by 24.2%, and 47.8% and 5.9% (*Table 2*). When the plantations start getting mature (18-20 years), the nutrient content availability

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1105511067

in the soil surface layer (0-20 cm) was only 50.8%, 14.1% and 36.6% for N, P and K, respectively. In the 20-40 cm and 40-60 cm soil layers' nutrient contents also decreased markedly. Due to the low rate of litter-fall decomposition, this cause imbalance between nutrient uptake and return (Liao et al., 2000). During a study in south China, Yang et al. (2005) described that in surface soil layer (0-20 cm) hydrolysable nitrogen content declined in the second and third rotations by 3% and 18%, respectively, as compared to first rotation while available phosphorus decreased 7% and 20% under Chinese fir stands.

Soil nutrients decline over the successive rotations could be reflected in soil microbial population and in their biochemical activities (Bhardwaj et al., 2014). In Chinese fir plantations, when continuous cropping took place over successive rotations biochemical activity of soil microbes decline significantly (Chen et al., 2015; Wu et al., 2017). Nitrogen fixation was 13.2% in the first rotation while it decreased up to 11.4% and 5.9% in second and third rotation respectively. Ammonification also declined by 82%, ranging from 1.6 mg $N.g^{-1}$ soil to 0.4 mg $N.g^{-1}$ soil from first to third rotation. Fiber decomposition was 3.3 CO_2 mg. g^{-1} soil, 0.8 CO_2 mg. g^{-1} soil and 1.4 CO_2 mg. g^{-1} soil in the first, second and third rotation while respiration was 1.6%, 1.1%, and 0.8% respectively. Nitrogen fixation, fiber decomposition, and respiration decreased by 54.1%, 59.2%, and 39.8% when continuous cropping of Chinese fir plantation took place for twice (*Table 3*).

Table 2. *Variation in the soil total nutrient contents, available nutrient contents, soil microbe's biochemical activity, and productivity over the successive rotations in Cunninghamia lanceolata plantations*

Nutrient contents	1st rotation	2nd rotation	3rd rotation
Total nitrogen (gkg^{-1})	4.28	3.91	3.36
Total phosphorus (gkg^{-1})	0.271	0.238	0.14
Total potassium (gkg^{-1})	19.7	16.5	14.3
Humus carbon (gkg^{-1})	37.6	33.8	32.4
Hydrolysable nitrogen ($mgkg^{-1}$)	105.3	95.3	73.2
Available phosphorus ($mgkg^{-1}$)	58.7	52.3	28.7
Available potassium ($mgkg^{-1}$)	101.5	59.6	53.2

Table 3. *Variation in the biochemical activity of soil microbes over the successive rotations in Cunninghamia lanceolata plantations*

Biochemical activity	1st rotation	2nd rotation	3rd rotation
Nitrogen fixation (%)	13.2	11.4	5.9
Ammonification (mg N. g^{-1}soil)	1.6	0.9	0.4
Fiber decomposition (CO_2 mg.g^{-1} soil)	3.3	0.8	1.4
Respiration (%)	1.6	1.1	0.8

Chinese fir growth and productivity

Chinese fir growth and production decreased over the successive rotations (Selvaraj et al., 2017). In productive Chinese fir stands (25-year-old), 280 t ha^{-1} biomass was reported with about 80% of total biomass allocated to the tree stem, which decreased

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1105511067

over the successive rotations (Zhao and Zhou, 2005). The high soil nutrition consumption due to continuous cropping cause a negative impact on the tree growth of Chinese fir plantations. A decline reported in annual increment in diameter at breast height (DBH) (Farooq et al. (2019b), height and volume in Chinese fir plantations of the same age but with different rotations (Zhou et al., 2016a). Diameter at breast height (DBH) decreased from 14.1 cm to 11.5 cm from first to third rotation (Tang et al., 2016). Plant height also decreased from 15.5 m to 10.8 m from first to the third rotation. Tree volume was 378.5 $m^3.hm^{-2}$, 268.8 $m^3.hm^{-2}$ and 176.4 $m^3.hm^{-2}$ respectively in first, second and third rotation (*Table 4*). The average height, DBH, and volume declined by 14.2%, 12.1%, and 32.3%, respectively in the second rotation and 22.8%, 36.5% and 53.2%, respectively for the third rotation. Higher tree mortality reported in third rotation as compared to the first and second rotation. It was 11.2%, 17.5%, and 21.6% respectively in the first, second and third rotation (*Fig. 5*).

Table 4. *Variation in the growth and productivity over the successive rotations in Cunninghamia lanceolata plantations*

Growth and productivity	1st rotation	2nd rotation	3rd rotation
DBH (cm)	14.1	12.8	11.5
Height (m)	15.4	13.6	10.8
Volume ($m^3.hm^{-2}$)	378.5	268.8	176.4
Tree mortality (%)	11.2	17.5	21.6

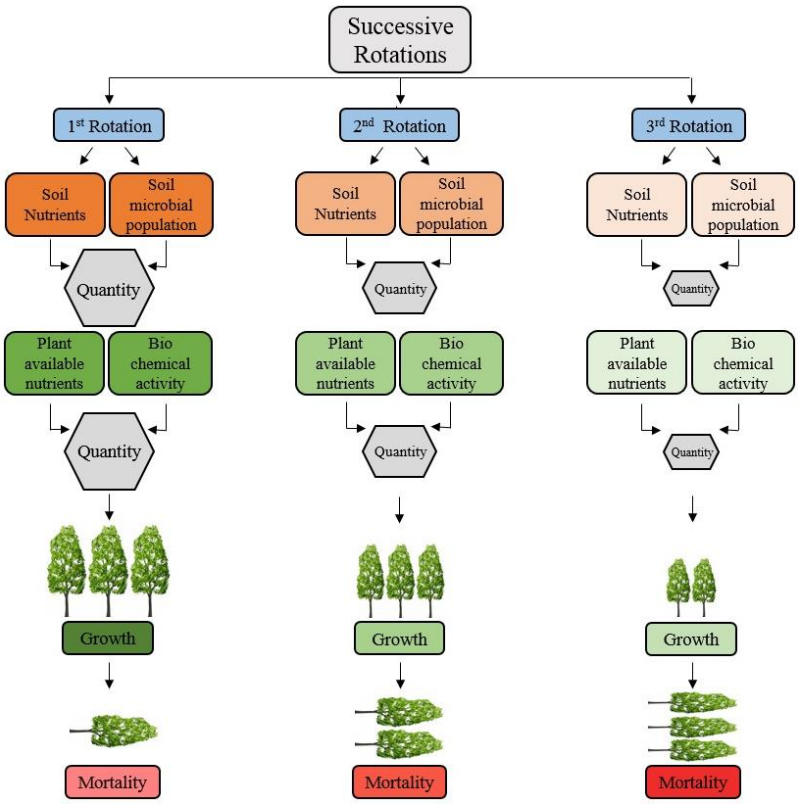

Figure 5. *Graphical summary of soil quality decline affecting the Chinese fir plantations growth and productivity over the successive rotations. (Decrease in the shade of colours of boxes shows decrease in nutrients availability, biochemical activity and growth)*

Discussion

Due to its soft and adorable timber, Chinese fir is an important species of China, which is in use for manufacturing of buildings, temples, furniture, and coffins, as well as an ornamental tree. Additionally, it also used as biomass energy and pulp production (Ma et al., 2002a, b; Wood et al., 2009). Nutrient cycling and biomass production are the important components of forest productivity (Tian et al., 2011; Farooq et al., 2018) which can vary with stand age, development and different silvicultural techniques (Hou et al., 2009; Zhao et al., 2013). Chinese fir productivity decreased over the years, and current management practices and short rotation policy are highly criticized for being a reason for less productivity (Chen et al., 2004). In Chinese fir plantations, these characteristics have been described in various previous studies in different regions of China (Li, 1996; Liao et al., 2000; Chen et al., 2004; Zhang et al., 2004; Zhao and Zhou, 2005; Ma et al., 2007; Wu et al., 2011; Chen et al., 2013; Zhao et al., 2013; Tang et al., 2016; Zhou et al., 2016b; Selvaraj et al., 2017). From the last one thousand years' traditional plantation method and management system of clear-cutting, complete ploughing, burning of the site and residues removal are under-used which is blamed for site degradation resulting in the poor growth and less production of Chinese fir plantations (Zhou et al., 2016c). Complete burning is the cause of organic matter and some nutrient loss; furthermore, minerals are lost due to rainfall (Wenhua, 2004; You et al., 2015). Soil erosion increased significantly due to complete ploughing while clear cutting resulted in soil and water loss (Dias et al., 2015). Conventional management practice effects tree morphology and biomass production. Morphological characteristics such as survival rate, average diameter at breast height, average height and biomass production were lower in stands where plantations were established with clear cutting and complete burning irrespective of rotation time (Bhardwaj et al., 2014).

Monoculture plantations are also the reason for productivity decline as monoculture system has low resistance and more suspected to pest attack due to the less biodiversity and bad stability (Liu et al., 2018). Non-development of understory vegetation and no proper thinning are the critical issues in the less productivity and poor growth because understory vegetation can markedly improve the soil nutrient and enhanced the biochemical activity (Chen et al., 2004; Zhou et al., 2016b). The decline in productivity is also associated with the non-use of fertilizers as in this era fertilizers are vital for crop development especially in the rotations without a period of fellows (Havlin et al., 2016). However, some experiments by different research teams in different areas showed contradictory results regarding the benefits of fertilizers. In a research on the 5-year old plantation, Li et al. (1991) reported that fertilizer applications of P and K could increase stand growth while Liao et al. (2000) found that P application increased stand growth only at the beginning while N fertilizers showed no effect moreover K fertilizer effects negatively.

The conventional Chinese fir plantation management system has to be replaced with the recently science based and rational management system, which is multi-culturing, includes clear cutting but of small area and mild site preparation. Cutting leftovers should be buried rather than burned. Pure plantation should be avoided and gradually replaced with agroforestry (Chinese fir mixed plantation) such as planting different herbs and shrubs. This could enforce higher productivity with the increase of the timber production and improve the soil physical and chemical properties to certain degrees as herbs and shrubs are easy to decompose and are rich in nutrients. Hence, it will enrich the soil resources. In nutrient-poor soils, direct approach of nutrient inputting should be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1105511067

used by applying fertilizers especially the compound fertilizer containing P can have a huge impact on plant growth especially in south china where the sites are mostly P-deficient.

In plantation ecosystem soil microbes are the important decomposers, they are the good indicator of the soil quality and habitat change because they play an important role in nutrient transformations (Chen et al., 2015; Wu et al., 2017). Soil contains a different type of bacteria, algae, fungi, and earthworms. The optimum amount of soil microbial population increases the efficiency of fertilizer and irrigation application (Paul, 2014). Furthermore, it releases essential nutrients N, P, K, and hydrogen back to the soil. On the other hand, excessive soil organic matter can be a problem also as it encourages the growth of unwanted herbs and shrubs, moreover, it also decreases the efficiency of irrigation and fertilizer application (Brevik et al., 2015). These are some of the benefits and disadvantages that soil microbial population can provide to plantation ecosystem (Jacobsen et al., 2014). For soil microbial benefits, an optimum environment that favours soil microbial growth is necessary to build a healthy soil microbial population. Organic based fertilizers can be an excellent way to provide them a healthy environment in which they can thrive in (Hartmann et al., 2015; Hudson, 2015). General causes of productivity decline in Chinese fir plantations and their effective solutions are described in *Table 5*.

Table 5. *Reasons of Chinese fir productivity decline and effective solutions*

General causes of less productivity	Effective solutions	References
Traditional plantation method and management system that creates site degradation	Replacing conventional Chinese fir plantation management system with recently science based multicultural and rational management system	Minghe and Ritchie, 1999; Hu et al., 2006
Short rotation pattern and establishing a plantation on infertile lands	Rotation lengths should be increased and plantation establishment on infertile lands should be discouraged	Ma et al., 2000a; Ma et al. 2007; Slevaraj et al. 2017
Decline in soil fertility due to slash burning and residual removal	Avoid the activities that soil compromise soil fertility. Cutting leftovers should be buried rather than burned	Xiong, 2008; Ma et al., 2000b; Zhijun et al. 2018
Clearcutting and complete plowing before the plantation establishment	Clear cutting but of small area and mild site perpetration	Farooq et al., 2019a; Ma et al., 2002
Introduction of monoculture Chinese fir plantations	Introduction of mixture plantation like agroforestry system should be encouraged and monoculture should be discouraged	Hu et al., 2006; Xiong, 2008; Wang et al., 2008; You et al., 2015
Even aged plantations, non-development of understory vegetation and no proper thinning	Introduction of multi-layering and multi-aged plantations	Lin et al., 2001; Ma et al., 2002; Chen, 2007; Zhou et al., 2015
The decline in the soil microbial population and biochemical activities of soil microbes over the successive rotations	Organic based fertilizers can be an excellent way to provide soil microbes a healthy environment in which they can thrive in	Wang et al., 2008; Zhang et al., 2017
Non-use of fertilizers and organic manure	Essential use of compost and fertilizers	Chen et al., 1990; Liao et al., 2000

(Received 2nd Apr 2019; accepted 11th Jul 2019)

Abstract. With the rapid development of urbanization and industrialization in China, the issue of high-quality economic development and ecological environment has arisen. Taking the Beijing-Tianjin-Hebei region as the research subject, this paper measured the comprehensive scores of economic development and ecological environment, and analyzed the coupling degree of these two systems from 2000 to 2018. According to the four degrees of coupling and coordination, this paper defined the degree of coupling and coordination between the economic development and ecological environment in Beijing-Tianjin-Hebei region, and put forward some policy suggestions. The result shows that, between 2000 and 2018, (1) the coupling degree of economic development and ecological environment in Beijing-Tianjin-Hebei region is $C \in [0.2, 1]$, which is changing with time, and has gone through all stages of coupling; the coordination degree of economic development and ecological environment in Beijing-Tianjin-Hebei region is $D \in [0.1, 0.5]$, which is in the low-middle stage. (2) The coupling degree of economic development and ecological environment in Beijing-Tianjin-Hebei region shows a trend of increasing first and then decreasing, while the coordination degree shows a rising trend, and remains more or less flat compared to the coupling degree.
Keywords: *high-quality development, ecological development, coupling degree, coordination degree, Beijing-Tianjin-Hebei Region*

Introduction

China's economic construction has achieved remarkable results since the reform and opening up, with an average growth rate of 9.78% from 1978 to 2011. Affected by the global economic crisis in 2012, China's economic growth has slowed down, with an average growth rate of 7.2% from 2012 to 2017. It has become a new norm for China's economic growth to shift from high-speed to medium-high speed. A basic feature of the new era for China's economic development is the transition from a phase of rapid growth to a stage of high-quality development, and the promotion of high-quality economic development is an essential requirement for the new normal in economic development (Cheng and Qiu, 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1106911083

In 1978, China's urbanization level was only 17.9%, while by the end of 2018, it was up to 59.58%. According to The Report on Chinese Industrialization issued by the Chinese Academy of Social Sciences, China has entered the second stage of the late-industrialization since 2015, with an overall industrialization level index of 84. What's more, with the industrialization level index of 95, 76 and 71, respectively, all the eastern, central and western regions in China have entered the stage of the late-industrialization (Hu, 2017). The economic growth in the middle and late stages of industrialization mainly depends on the growth of the secondary industry, that is, China's economic development relies heavily on industries with high energy consumption and high pollution. The rapid development of China's economy and the promotion of urbanization and industrialization have caused serious damage to the ecological environment, and the destruction of the ecological environment has also inhibited the economic growth (Liao and Wang, 2019). Since 2016, many cities in China have been affected by haze, especially cities in the Beijing-Tianjin-Hebei Region. Within the Bohai Economic Circle, the Beijing-Tianjin-Hebei Region is not only the largest and most sophisticated economic zone in Northern China, but also an important political and cultural center of China. However, since the economic development in the Beijing-Tianjin-Hebei Region is dependent on high-energy-consumption and high-pollution industries, there have been serious environmental problems in the Beijing-Tianjin-Hebei Region. And the economic development in this region has transformed to the coordination between high-quality economic development and the development of ecological environment. Therefore, this paper analyzed the characteristics of each stage of the economic and environmental development based on the measurement of the coupling degree between the economic development and the ecological environment system in the Beijing-Tianjin-Hebei region, and provided a basis for the high-quality economic development there.

Literature Review

At the 19th National Congress of the Communist Party of China, president Xi Jinping declared that "China's economy has been transitioning from a phase of rapid growth to a stage of high-quality development. This is a pivotal stage for transforming our growth model, improving our economic structure, and fostering new drivers of growth." The transformation of China's economy from a phase of rapid growth to a stage of high-quality development is the essential requirement for the new normal in economic development (Sheng, 2018). In the fundamental economic theories, high-quality development can be expressed as the mode, structure and momentum of economic development living up to its real nature, which is to satisfy people's growing needs for a better life (Jin, 2018). Shi et al. (2018) measured the high-quality economic development index based on the two dimensions of economic growth fundamentals and social achievements. The results show that time span of China's inter-provincial economic growth quality fluctuation cycle has been widening gradually, the distribution of economic growth in the Eastern, central and Western China is unbalanced and difficult to close in short term, and the quality of economy growth of China will enter a long-term uptrend channel. The high-quality economic development refers to the economic development stressing both quantity and quality of economic growth, and lay emphasis on the quality of economic growth. The existing researches on economic development have been mainly conducted from the

DOI: http://dx.doi.org/10.15666/aeer/1705_1106911083

perspectives of sources of economic growth, reasons for slow-speed development of economy and the evaluation of low-carbon or green economy. According to the study of Shen et al. (2011), though the development model oriented by manufacturing and service industries, with urbanization as space carrier and marketization as system, can promote the sustainable and high-speed economic growth in China, the restraints on this model is increasing. Nie et al. (2011) found there has been misallocation of resources in state-owned enterprises, and almost no reallocation of resources within the industries, which contributed to the inefficiency of China's manufacturing industry. Zhuang et al. (2014) evaluated the low-carbon development of several cities in China and made comparisons with that of international cities. Chen et al. (2018) analyzed the relationship between the governance of haze pollution and high-quality economic development, and believed that the improvement of economic development quality is the premise of the transformation of economic development mode, and the governance of haze pollution can help improve the quality of the atmospheric environment and economic development, and promote the high-quality development of economy in return.

"Coupling" is a concept derived from the mechanical nexus between two parts of something. From the perspective of ecology, "coupling" refers to the interaction, transition and development of two or more system elements or subsystems (Zhang et al., 2016). The elements in a coupling system are closely related, and their cooperation can improve the productivity and ecological function of the system. The coupling construction of the ecosystem is actually the development process of the ecosystem from disorder to order (Liu, 2016). Since urbanization involves a series of coupling processes, coupling simulation and optimization are widely applied in solving planning problems and rapid development of regional economy (Li et al., 2011). Using the panel data of Lianyungang, Li et al. (2012) analyzed the challenges of rapid urbanization in coastal cities with a coupling and coordination degree model focusing on the degree of coordination between urbanization and the environment, and found that the dynamic of coordination between urbanization and environment showed a U-shaped curve. Lei et al. (2015) investigated the relationship between urbanization and air environment from the perspective of coupling coordination theory, and found that the degree of coordinated coupling between urbanization and air environment exhibited an S-shaped curve, indicating that the slightly unbalanced development of Wuhan has turned into the barely balanced development, and has entered a period of superiorly balanced development, with the air environment lagging. Wang et al. (2014) conducted a quantitative analysis of the coupling relation between urbanization and ecological environment in Nanchang and Jiujiang urban belts, and the results showed that the coordination degree of Nanchang rises at a faster speed, reaching a moderate balance level, while that of Jiujiang remains at a low level. Therefore, Nanchang and Jiujiang urban belts should further transform its economic growth model, optimize the industrial structure, improve its technology and embark on a new-urbanization path featuring resource-saving, low carbon emission, environmental-friendly and cost effective. You (2016) assessed the coordinated degree of urbanization by quantifying four involved processes (demographic, social, economic and spatial) in Shanghai from 1952 to 2012, and found that the demographic urbanization advanced continuously and roughly presented a U-shaped trend. Guo et al. (2015) examined the coupling relationship between urbanization and environment in the Huaihe River Basin from both exploratory and analytical perspectives. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1106911083

results showed the degree of coupling and the degree of policy coordination appeared to fluctuate over time.

The existing researches on the coupling relationship between high-quality economic development and eco-environmental protection are mainly conducted in the Yangtze River delta, farming-pastoral zones in northern China and mountainous areas, with the coupling coordination degree model and qualitative analysis. Zhang et al. (2015) analyzed the coupling and coordination relationship between economic development and ecological environment system from 1999 to 2003 in the extensive Yangtze River delta with the coupling coordination degree model, and found that the coupling of economic development and ecological environment was in the running-in stage, while the coordination degree of economic development and ecological environment was moderate. Based on the analysis of coupling relationship between regional economy and ecological environment, Jiang et al. (2010) established a dynamic coupling model of coordinated development of the regional economy and ecological environment, and studied the coordinated development of economy and ecological environment in Jiangsu Province. The results showed that, between 1995 and 2007, the economic development index of Jiangsu Province showed a rapid growth trend, while the index of ecological environment system showed a slow growth trend with several fluctuations, the economy and ecological environment of Jiangsu Province were developing harmoniously. Zhang et al. (2010) predicted the coordinated development of economy and ecological environment of farming-pastoral zone in northern China in the future ten years with a variety of methods. Hu et al. (2012) studied the coupling modes and implementation forms of the coordinated development of economy and ecological environment in the lake basins of Yunnan Plateau. Wang et al. (2013) estimated the coupling and coordination degree of tourism economic development and ecological environment of the forest parks in Shanxi Province. Fang et al. (2016) analyzed the theoretical framework and methodology of the interactive coupled effects between urbanization and eco-environment in mega-urban agglomerations with the method of qualitative analysis. In addition, some scholars have studied the response of ecological environment to marine economy development and its influencing factors in Bohai Bay Rim Area (Li et al., 2017; Li and Gao, 2017), explored the coupling relationship between economic development and ecological environment in poverty-stricken areas (Cao et al., 2016; Liu et al., 2007), and analyzed the coupling relationship between the benefit of economic development and ecological environment quality along the Silk Road Economic Belt (Wang, 2018).

It can be seen that, although there are many researches on the relationship between economic development and ecological environment, few of them were conducted in the Beijing-Tianjin-Hebei region, and even fewer from the perspective of high-quality economic development. What's more, the existing researches mainly focus on the economic growth, while this paper tends to take a comprehensive consideration of the scale, level and potential of the economic development, that is, study the coupling relationship between economic development and environmental protection from the perspective of high-quality economic development. The economic growth in China has entered a period of transformation with quality as its first priority, and the economic growth in Beijing-Tianjin-Hebei Region is crucial to China's economic growth. After a long term high-speed economic development in the Beijing-Tianjin-Hebei Region, problems such as the singularization of industrial structure, exhaustion

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1106911083

of resources and deterioration of ecological environment have been emerging, and the "crowding-out effect" of backward production capacity in the core area is getting more and more serious, leading to an outward flow of core industries. Therefore, this paper conducted the research on the coupling relationship between economic growth and ecological environment in the Beijing-Tianjin-Hebei Region from the perspective of high-quality economic development, supplemented the coupling theory of economy and ecological environment with the concept of high-quality development, and provided guidance for coordinating the economic development and eco-environmental protection in the Beijing-Tianjin-Hebei Region.

Materials and Methods

Research Method

Improved entropy method

The entropy method is a method for determining the weight of index according to the amount of information transmitted by each index to the decision maker, which excludes the influence of subjective factors on weighting and the overlap of information brought by multiple index. In order to avoid the shortcomings of the traditional entropy method, it is necessary to process the original data of the index, that is the improved entropy method. It can be calculated as follows:

Standardize

As there is a dimension between the economic system and the ecological environment system, the index should be standardized.

$$u_{ij} = \frac{x_{ij} - \min(x_{ij})}{\max(x_{ij}) - \min(x_{ij})} \quad \text{(Eq.1)}$$

uij is the positive index;

$$u_{ij} = \frac{\max(x_{ij}) - x_{ij}}{\max(x_{ij}) - \min(x_{ij})} \quad \text{(Eq.2)}$$

uij is the negative index;

uij refers to the j-th index in the i-th system, and the value of uij is xij (i=1,2; j=1, 2, …n), with max(xij) refers to the maximum value and min(xij) the minimum value of xij.

Calculate

Calculate the proportion of index uij:

$$\mathrm{R}_{ij} = \frac{u_{ij}}{\sum_{i=1}^{m} u_{ij}} \quad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1106911083

Measure the entropy of each index:

$$e_j = \frac{-1}{\ln m * \sum_{i=1}^{m} R_{ij} \ln R_{ij}} \quad \text{(Eq.4)}$$

Calculate the difference coefficient of each index:

$$g_j = 1 - e_j \quad \text{(Eq.5)}$$

The larger the value of gj is, the more important the index is in the evaluation system.

Calculate the weight of each index:

$$w_{ij} = (1 - e_j) / (n - \sum_{j=1}^{n} e_j) \qquad \text{j=1, 2, …n} \qquad \text{(Eq.6)}$$

Calculate the synthetical value of the system:

$$V_j = \sum_{j=1}^{n} w_j R_{ij} \qquad \text{j=1, 2, …n} \qquad \text{(Eq.7)}$$

The Coupling and Coordination Degree Model

The coupling degree is used to describe the degree of influence among the system or elements (Liu et al., 2011), while the coordination degree is the degree of harmony between systems or elements of the system in the process of development, which reflects the tendency of a system from disorder to order (Wu et al., 1997). It can be seen that, the coupling degree and coordination degree are two different indicators, with the coupling degree reflects the strength of interaction between two parties, regardless of advantages or disadvantages; and the coordination degree is the degree of good coupling in the interaction, reflecting the quality of coordination. Therefore, the research has been conducted from the following two aspects:

Coupling degree function

Construct a coupling degree function of high-quality economic development and eco-environmental protection, that is:

$$C = \sqrt{U_1 U_2} / (U_1 + U_2) \quad \text{(Eq.8)}$$

Among them, the value of C is between 0 and 1. C=0 indicates that there is no coupling relationship between high-quality economic development and eco-environmental protection, and C=1 indicates that there is a good coupling between high-quality economic development and eco-environmental protection.

Coupling and coordination degree function

The coupling and coordination degree function of high-quality economic development and eco-environment protection is:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1106911083

$$D = \sqrt{C \cdot T} \quad \text{(Eq.9)}$$

$$T = \alpha U_1 + \beta U_2 \quad \text{(Eq.10)}$$

where D is the coupling and coordination degree, and T is the comprehensive coordination index of high-quality economic development and eco-environmental protection, representing the coordination index of high-quality economic development and eco-environmental protection at each coupling level. α and β represent the contribution rate of each system, that is, the contribution coefficient of high-quality economic development and eco-environmental protection. Since there is an interaction between high-quality economic development and eco-environmental protection, both α and β are 0.5. Similar to the coupling degree, the coordination degree can also be divided into 4 levels (see *Table 1*).

Table 1. *The level of coupling and coordination degree*

Value of coupling degree	Phase of coupling	Value of coupling and coordination degree	Type of coupling and coordination	Phase of coordination
0<C≤0.3	Separation phase	0<D≤0.3	Low coupling and coordination degree	Separation phase with low coordination
0.3<C≤0.5	Antagonistic phase	0.3<D≤0.5	Medium coupling and coordination degree	Antagonistic phase with medium coordination
0.5<C≤0.8	Running-in phase	0.5<D≤0.8	High coupling and coordination degree	Running-in phase with high coordination
0.8<C≤1	Coupling phase	0.8<D≤1	Extremely high coupling and coordination degree	Coupling phase with extremely high coordination

Index Selection

Due to the wide variety of influencing factors involved in urban economic development and ecological environment, as well as the complex interaction mechanism among them, their development status and impacts cannot be reflected with only one indicator. Therefore, we would like to select indicators and construct an indicator system based on existing researches (see *Table 2*).

Results

With the improved entropy method, we standardized the raw data of the Beijing-Tianjin-Hebei region from 2000 to 2018, and calculated the entropy and weight of each indictor in the economic development and ecological environment system of Beijing, Tianjin and Hebei. The synthesis scores of economic development and ecological environment systems in the Beijing-Tianjin-Hebei Region are shown in *Table 3*.

It can be seen from *Table 3* that:

(1) From the perspective of economic development, there is an uptrend in synthesis scores of the economic development in the Beijing-Tianjin-Hebei region from 2000 to 2018, with Beijing developed the fastest in 2003-2011, followed by Tianjin and Hebei. By the year of 2011, Tianjin ranked the first in economic development, followed by Hebei and Beijing. It can be explained by Beijing's high-speed economic development in the preceding years brought by regulatory policies and convenient transportation.

Data sources: Calculated according to the China City Statistical Yearbook

(2) From the perspective of ecological environment, the low scores of ecological environment system in the Beijing-Tianjin-Hebei Region may be due to the economic development mode and the rapid pace of development, which has caused serious damages to the ecological environment, and the ecological environment destruction, in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1106911083

turn, has restricted the economic development over time. The significant fluctuation in synthesis scores of ecological environment systems after 2010 can be explained by the impact of high-speed of economic development and urbanization on ecological environment, which has led to the energy resources depletion, environmental pollution and ecological imbalance. However, the improvement of synthesis scores of ecological environment systems after 2013 may be related to the economic regulatory policies which laid more emphasis on quality rather than speed of economic development.

(3) Through the comparison of the economic development and ecological environment in the Beijing-Tianjin-Hebei region, we can see that the score of economic development was lower than that of ecological environment from 2000 to 2018. What's more, during the study period, the score of economic development continued to rise, while that of the ecological environment continued to decline, indicating that there is a negative correlation between economic development and ecological environment in Beijing-Tianjin-Hebei region.

Discussion

Characteristics of time variation

The coupling degree (C) and the coordination degree (D) of the Beijing-Tianjin-Hebei region from 2000 to 2018 have been calculated according to the formula (see *Figure 1*).

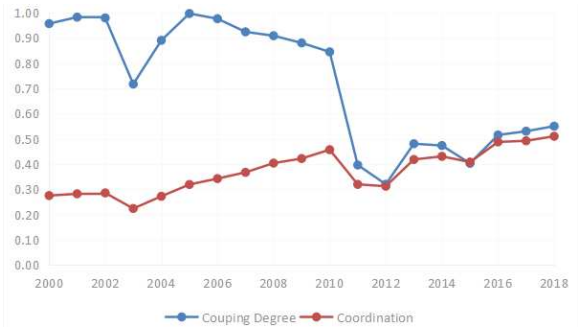

Figure 1. *Mean value of the coupling and coordination degree between economic development and ecological environment system in the Beijing-Tianjin-Hebei Region in 2000-2018*

It can be seen from *Figure 1* that, the coupling and coordination degree between economic development and ecological environment system in Beijing-Tianjin-Hebei Region in 2000-2018 fluctuated greatly. The years from 2000 to 2002 can be seen as the coupling phase and the year of 2003 as the running-in phase, which can ben explained as the lagged effect of China's accession to the WTO in 2001 on the economic development in Beijing-Tianjin-Hebei Region. With the years from 2004 to 2010 as another coupling phase, the years from 2000 to 2010 can be taken as the coupling phase on the whole. During this period, China's economy has been developing rapidly and the environmental problems have not yet emerged, but the coupling degree between economic development and ecological environment in the Beijing-Tianjin-Hebei region has shown a downward trend. In 2011, the coupling degree dropped to 0.4 suddenly and has not exceed 0.5 until 2018. The years of 2011-2018 is the antagonistic phase of the coupling relationship between economic development and ecological environment in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1106911083

Beijing-Tianjin-Hebei region. It is in line with the reality that China's economic development has entered a new normal of medium-to-high-speed growth and is accompanied by the frequent occurrence of environmental pollution problems such as haze. In order to resolve the contradiction between economic development and environmental protection, the coordinated development in the Beijing-Tianjin-Hebei region should be strengthened and the integration of industrial layout should be promoted. What's more, the development of the Circum-Bohai Sea Economic Zone can be promoted by exploring the effective path of ecological civilization construction, strengthening the complementary advantages of Beijing, Tianjin and Hebei, and enhancing the coordination of population, economy, resources and environment in the Beijing-Tianjin-Hebei region.

The analysis of coordination degree shows that, from 2000 to 2018, the coordination degree of Beijing-Tianjin-Hebei Region has been increasing steadily with sight fluctuations, which is at a low-to-moderate level. This can be explained by the high level of urbanization and the continuous optimization of industrial structure, which are not in line with the environmental protection.

From 2000 to 2011, there was a great difference between the coupling degree and coordination degree of economic development and eco-environmental protection. It can be explained by the damage to the ecological environment brought by the rapid development of economy. Since 2011, the gap between coupling degree and coordination degree has been narrowed because of the adjustment of industrial structure and the transformation or upgrading of economy, which has taken the ecological civilization construction and economic development into full consideration.

Characteristics of spatial pattern

The coupling and coordination degrees between economic development and ecological environment of Beijing, Tianjin and Hebei have been calculated by SPSS (see *Table 4*). It can be seen from *Table 4* that, there were large fluctuations in both coupling and coordination degree of Beijing, Tianjin and Hebei after 2010. The coupling relationship between economic development and ecological environment in Beijing has experienced the coupling phase of 2000-2010, the antagonistic phase of 2011-2015, and the running-in phase of 2016-2018. This can be explained by the high-speed economic development and the good environmental condition in 2000-2010. Since 2011, the economic development has slowed down and the problems of environmental pollution has emerged. At present, with the goal of high-quality economic development, Beijing has made more efforts to protect the environment, and the coupling relationship between economic development and ecological environment has been optimizing. The coordination degree between economic development and ecological environment in Beijing has been increasing steadily with slight fluctuations, which is moderate in general. There has been a drastic fluctuation in the coupling degree of Tianjin from 2000 to 2018, with the years of 2004-2008 as the coupling phase. It can be explained by the economic transition and upgrade, or the interaction between various influencing factors of the two systems and the unbalanced economic development. The coupling relationship between economic development and ecological environment of Hebei showed the same trend as that of Beijing, but its coupling degree is lower than that of Beijing, which can be explained by the unbalanced economic and social development, the unreasonable industrial structure, and the serious impact of external factors.

均值	0.75	0.39	0.50	0.31	0.72	0.38

Data sources: Calculated according to the China City Statistical Yearbook

On the whole, the coordination degree of economic development and ecological environment in Beijing-Tianjin-Hebei region shows an upward trend with some slight fluctuations. However, the coordination degrees of economic development and ecological environment in Beijing, Tianjin and Hebei are all at the coupling phase with low and medium coordination, which indicates that, though the advantages in ecological environment have not been fully transformed into advantages in economic development, there has already been a virtuous circle between economic development and ecological environment.

Types of urban development

According to the coupling and coordination degree of urban economic development and ecological environment, the cities can be divided into four types: high coupling & high coordination degree, high coupling & low coordination degree, low coupling & high coordination degree, low coupling & low coordination degree. In cities with high coupling & high coordination degree, the development of economy and ecological environment are promoted together, so that, the emphasis should be laid on the cultivation of talents, transformation of development mode, optimization of industrial structure, protection of ecological environment and improvement of treatment efficiency of municipal waste and pollutants, forming a pattern of synchronous development of economy and ecological environment. The high coupling & low coordination degree indicates that although the economy is developing rapidly, the development of ecological environment is restricted by the local environmental carrying capacity. Therefore, the development mode should be transformed immediately so as to coordinated the development of economy and ecological environment, that is, enhancing the protection of ecological environment, giving full play to the advantages

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1106911083

of local resource endowment, developing the industries with local characteristics, adjusting the industrial structure, replacing the extensive development modes with green and high-efficient ones, and laying a solid foundation for the sustainable development in the future. Cities with low coupling & high coordination degree should be developed in a low energy-consumption, green and low-carbon development mode, which lays more emphasis on publicizing the advantages of local ecological environment, attracting foreign investment, developing industries with local characteristics and accelerating the economic development. Low coupling & low coordination degree may be resulted from the restrictions of historical and natural conditions. With the backward economic development and the crying need for eco-environmental protection, the extensive development mode have to be adjusted, the protection and modification of ecological environment have to be strengthened, the development of economy and ecological environment have to be coordinated through reasonable planning and implementation of various preferential policies for talent introduction.

The distributions of the mean values of coupling and coordination degree between economic development and ecological environment in the Beijing-Tianjin-Hebei Region from 2000 to 2016 are shown in *Figure 2*. It can be seen that, Beijing, Tianjin and Hebei are all regions with high coupling & low coordination degree, which indicates that though the degrees of urbanization and industrialization in these three regions are relatively high, and the economy is developing rapidly as well, the ecological environment has been damaged severely.

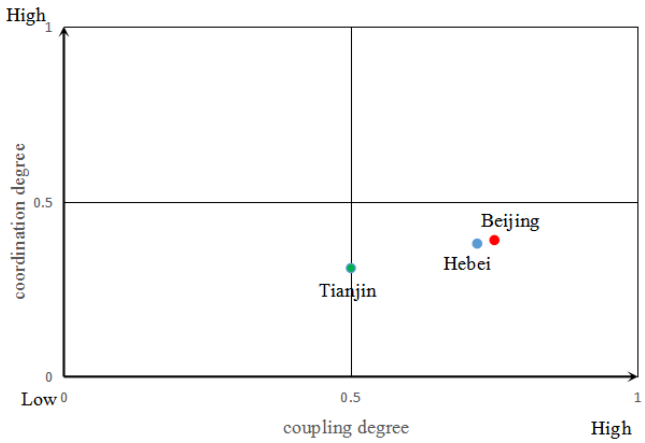

Figure 2. *Distribution of coupling and coordination degree in the Beijing-Tianjin-Hebei Region*

Conclusions and policy recommendations

Conclusions

Taking the Beijing-Tianjin-Hebei region as the research object, this paper measured the comprehensive scores of economic development and ecological environment, and analyzed the coupling degree of these two systems from 2000 to 2018. According to the four degrees of coupling and coordination, this paper defined the the degree of coupling and coordination between the economic development and ecological environment in Beijing-Tianjin-Hebei region, and put forward some policy suggestions. The result shows that, between 2000 and 2018, (1) the coupling degree of economic development and ecological environment in Beijing-Tianjin-Hebei region is C∈[0.2, 1], which is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1106911083

changing with time, and has gone through all stages of coupling; the coordination degree of economic development and ecological environment in Beijing-Tianjin-Hebei region is D∈[0.1, 0.5], which is in the low-middle stage. (2) The coupling degree of economic development and ecological environment in Beijing-Tianjin-Hebei region shows a trend of increasing first and then decreasing, while the coordination degree shows a rising trend, and remains about flat compared with the coupling degree.

Policy recommendations

Since the reform and opening up, with the dependence on the secondary industry, the relationship between economic development and ecological environment in the Beijing-Tianjin-Hebei region is characterized by high coupling and low coordination. In order to build a world-class urban agglomeration with strong international competitiveness and promote the high-quality development driven by national innovation, the relationship between economic growth and environmental protection in the Beijing-Tianjin-Hebei region should be coordinated, and the high-quality development in coordination should be promoted by constructing a sophisticated economic structure.

First of all, the industrial integration in the Beijing-Tianjin-Hebei Region should be promoted to narrow the gap between industrial base and industrial advantages. By giving priority to the development of the tertiary industry, upgrading the structure of manufacturing and service industries, cultivating high-tech industries, and exploring new patterns for industrial development, the quality and efficiency of the economic development in the Beijing-Tianjin-Hebei region will be improved.

Second, the concept of green development should be established. In the process of high-quality economic development in the Beijing-Tianjin-Hebei region, it is necessary to bear the goal of energy conservation and increasing the resource utilization rate in mind, so as to promote the development of green cities continuously and integrate the concept of green development into the economic and social development.

Third, implement the innovation-driven development strategy vigorously. The innovation-driven development strategy is the inevitable requirement for promoting the transformation of economic development mode and the switch of growth momentum in Beijing-Tianjin-Hebei region. It is necessary to build a high-tech and advanced economic structure and give full play to the leading role of Beijing. Promote the organic unity and coordination of the industry chain, value chain, innovation chain and service chain by improving the industry chain, enhancing the value chain, optimizing the innovation chain and expanding the service chain.

Finally, promote the coordinated development of population in Beijing-Tianjin-Hebei region. As the main migration destinations in the Beijing-Tianjin-Hebei region, the pressure on resources and environment carrying capacity in Beijing and Tianjin has been increasing with the growth of population. Therefore, the intellectual and information resources of urban development should be coordinated to promote the high-quality economic development in the Beijing-Tianjin-Hebei region. Taking the opportunity of the construction of the Xiong'an New Area, confine the rapid growth of population in Beijing and transfer the population to Hebei orderly. Promote the rational allocation of human resources and other high-end resources in Beijing-Tianjin-Hebei region, contribute to the coordinated development of industries and promote the industrial upgrading of other regions of the country.

(Received 3rd Apr 2019; accepted 20thAug 2019)

Abstract. Gölhisar Basin which is located in the southern part of Lakes Region, in SW of Turkey contains four main geologic parent materials composed of serpentine-peridotite, Mesozoic limestone, Neogene marl deposit and Quaternary colluvial deposit on which Calabrian pine (*Pinus brutia*) and Anatolian black pine (*Pinus nigra* subsp. *pallasiana*) grow. Tree productivity and/or growth rate is considerably different on these parent materials. This is mainly related to the weathering degree of serpentine-peridotite, stratification and compactness of marl deposit and the crack structure of limestone. For example, the productive Calabrian pine (*Pinus brutia*) trees grow on the deeply weathered serpentine-peridotite parent material in the Gölhisar basin. Draft appearances of Calabrian pines are found on exposed peridotite-serpentine in sloping areas. Besides, tree biomass is low on compact marl deposit due to the fact that taproot development of trees is mostly prevented by the compact marl deposit and horizontal marl layers. The productivity of Calabrian pine and black pine (*Pinus brutia*) trees on the limestone is higher than on the marl deposit and low weathered serpentine in the study area, in general. The aim of this study is to illustrate the importance of parent materials containing serpentine-peridotite, limestone, marl and colluvial deposits on the growth of *Pinus brutia* and *Pinus nigra* trees in the Gölhisar Basin.
Keywords: *tree growth, serpentine weathering, biome classification*

Introduction

Forest trees mostly grow on exposed parent materials occurring most of sloping areas. Here the chemical and physical composition of the parent materials and their weathering degrees play very important roles in the growth of trees. Especially the weathering of the parent materials mostly contributes to the release of the plant nutrients and weathered parent materials form a soft ground to develop of the plant root system, in general. For this reason, there is close relationship between the weathering degree of the parent materials and biomass of trees and/or tree growth rate. According to studies carried out relating to the importance of the tree biomass in Turkey, the good/high site index (site quality class) stands and trees occur on the deeply weathered parent materials; whereas, the poor stands are found on the semi weathered and low weathered parent materials. For example, good site index black pine forests were established on the deep weathered serpentine in the Karsanti locality in east of Mediterranean Taurus Mountains, Dirgine locality and Yenice Basin in NW of Anatolia; while, poor site index forests appear on the low weathered and unweathered serpentine in the Datça Peninsula, Kemer locality, west of Antalya Gulf (Atalay and Efe, (2010a), (2014); Atalay, (2016a).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

In serpentine area of Kemer locality, CEC of soil in the poor stand is 8-10 $cmol_c\ kg^{-1}$, while this figure is about 38 $cmol_c\ kg^{-1}$ in good stand (Atalay, 2014). According to the study made on the parent material and biomass of the forest trees in the western part of Mediterranean Region, the highest productive forests are found on cracked limestone, the lowest one exists on the bare land of serpentine (Tetik and Yeşilkaya, 1997). It can be said that unweathered serpentine in the various parts of Anatolia is generally seen as bare land notably on the sloping area. Herbaceous plants only grow on the stabilized slopes on serpentine with thin soil cover.

On the other hand, different vegetation communities were established on the drift-derived soil and bedrock-derived soil in Keen of Hamar in the Shetland (Carter, 1987). In the study to be made in Central Coastal range of California showed that plant available Mg and Ca in serpentine soils exceed values assessed in chert soils. Magnesium is nearly 3 times more abundant than Ca in the serpentine soils and ion uptake discrimination and ion suppression in the roots are major mechanisms for serpentine vegetation to tolerate the chemistry of serpentine soils (Oze et al., 2008). The vegetation of serpentines presents a wide range of appearances. Biologists have concentrated on the situations where serpentine vegetation is in sharp contrast with that of the surroundings (Proctor et al., 1975). Serpentine soils are extreme habitats for plants. These extreme habitat conditions are rich with floristic diversity, especially endemic and rare taxa. The species which are specialist for serpentine habitats can survive by developing adaptations toward these intense stress conditions (Going et al., 2009). The ecology of serpentine systems has a significant importance for the sustainability of biodiversity and preservation of species (Özdeniz et al., 2017).

As to limestone, cracked limestone having high content of clay on the sloping area contributes a good habitat for the growth of forest trees due to the fact that three roots easily develop toward the deep parts along the cracks of limestone. On the other hand, especially red Mediterranean soil (Alfisol/Luvisol) with clayey in texture and its CEC more than 40 $cmol_c\ kg^{-1}$ that developed along the thin cracks and voids and among the bedding surface of limestones also form suitable conditions for the growth of cedar (*Cedrus libani*), black pine (*Pinus nigra*) and Taurus fir (*Abies cilicica*) trees in the Taurus Mountains (Atalay, 1987, 1997, 2014; Atalay and Efe, 2014).

The stratification situation, particularly the inclination of the layer and compactness of marl deposits forms different environments in terms of the tree growth. Namely, good site index of forests are found on soft marl deposits, while poor site index stand occurs on the compact and horizontal layered marl deposit because tree root development is considerably prevented by compact and horizontal layers (Atalay and Efe, 2014; Gregorich et al., 2001). Vertical cracks and thin soft zone in the marl deposit support taproot development of tree roots in the marl deposit. For this reason, the high growth rate trees and forests are commonly seen in these areas. Marl deposit on the sloping areas is very vulnerable for erosion and sensitive land degradation (Cerda, 1999; Atalay et al., 2019a).

Deep weathered gneiss and micaschist producing sandy soil supports to grow of productive forest; while outcropped gneiss and micaschist appearing as a rocky land on the steep slope is generally absent from the forest. Volcanic sand and tuff deposit, and thick sandy soil developed on the granite and gneiss create a good habitat for the growth scots pine (*Pinus sylvestris*) under cold and subhumid climate and stone pine (*Pinus pinea*) in the Mediterranean climate in Anatolia (Atalay, 2014, 2016b).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

The importance of parent materials on the growth of plants is briefly mentioned some textbooks (Cunningham and Saigo, 1999; Foth, 1990; Smith and Smith, 2003).

The select of Gölhisar Basin as study area is related to display different parent material properties and forests. In this study our aim is to elucidate of the parent material effects on the three growths in the Gölhisar Basin which is located in the Lakes Region of SW Anatolia in Turkey (*Fig. 1*).

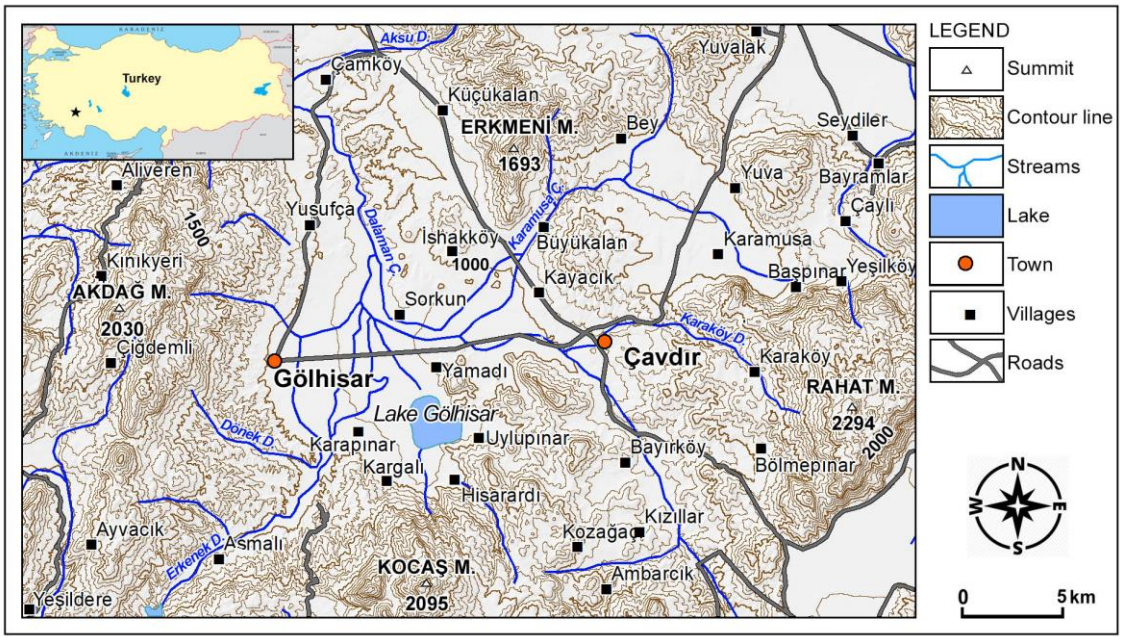

Figure 1. *Location and topographic map of the study area*

Materials and methods

General physical properties like the formation of geologic parent materials, topographic traits, climate, soil and vegetation, notably forest belts of the study area were briefly mentioned. The existence of different parent material and various forest clusters were taken into consideration in the selected experimental sites. Generally, in the selected experimental sites forest cluster and individual tree occurrence change sharply depending on parent material spreading. These areas are clearly seen in the sloping areas of Gölhisar Basin, because they have many parent materials composed of peridotite-serpentine, limestone, marl and colluvial deposit, and two main forest vegetation belts composed of Calabrian pine (*Pinus brutia*) and Anatolian black pine (*Pinus nigra* subsp. *pallasiana*). On the other hand, the main aim of the study is to reveal the growth rate of *Pinus brutia* and *Pinus nigra* on the different parent materials especially serpentine, limestone and marl deposit in the selected sites. Measurements of trees and collecting parent materials and soil samples were carried out in the summer season of 2018 in the study area (*Figs. 1* and *2*).

Pinus brutia experimental sites were selected on the different weathered serpentine-peridotite, limestone; horizontal and inclined layers of marl deposit and colluvial deposit; *Pinus nigra* experiment sites were selected on serpentine and limestone in the Gölhisar Basin. In the selection of trees in the experimental sites the different weathering stages of parent materials were taken into consideration. The figures and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

graphs of trees showing the relationships among the age, diameter and height, and the parent material properties were prepared. Thus, the relationship between weathering situation of parent materials and the tree growth in the selected experimental sites was assessed. Relationship between tree growth and cation exchange capacity of the parent materials mainly indicating the weathering stages and plant nutriment capacity was explained. Special attendance was focused on significance of serpentine weathering on the vegetation growth and relating examples with serpentine were given not only experimental sites but also other places of the study area. Besides water allocation and surface erosion observations were made to explain the relationship between water and weathering properties of parent materials in the field. According to archaeological and historical knowledge human impact on the destruction of vegetation especially forest cover and its effect on the tree growth was mentioned. Lastly, statistical evaluation between tree growth and parent material was made.

On the other hand, to show the distribution of the forest trees and geologic parent material a profile and geologic parent material map were drawn. Topographic maps in the scale of 1/25 000 and modified geologic map in the scale of 1/100 000 were also used. The general geologic, geomorphic evolution and pedogeomorphology of the study area was used from the previous studies (Atalay, 2017; Atalay et al., 2017, 2019b; Altunbas, 2018).

The samples of the soil and semiweathered parent materials of the experimental sites were taken to determine of texture, pH, $CaCO_3$, organic matter and CEC (Cation exchange capacity). Their determinations were made at the Soil Laboratory of Soil Science and Plant Nutriment of Agricultural Faculty, Akdeniz University. Texture of soil samples determined based on Bouyoucos hydrometer method Bouyoucos (1955) and organic material was made Walkley-Black (Black, 1965), $CaCO_3$ determined Jackson (1967), Exchangeable Cations determined according to 1N ammonium acetate method Kacar (1995), Cation Exchange Capacity (CEC) determined According to sodium acetate method USDA (1969) and Kacar (1995), respectively.

Results

Geologic setting and the formation of parent materials

Gölhisar Basin which is located in the southern part of Lake Subregion in the north-western part of the Mediterranean geographical Region of Turkey contains Mesozoic submarine ultramafic volcanic rocks, Mesozoic limestone-marble, neogene sedimentary deposit mostly containing marl and Quaternary fluvio-limnic, alluvial and colluvial deposit (*Figs. 1* and *2*). The basement of the study area is mainly composed of ultramafic rocks especially peridotite-serpentine rocks or parent materials that formed with the eruption of lava erupted from the mid-oceanic ridge and spread on the bottom of the Tethys Ocean occupying the present-day Taurus Mountain belt during the Lower Mesozoic period. The deposited mud composed of carbonates and clay materials on the bottom of Tethys Ocean was converted into limestones with folding and uplifting tectonic movements occurred during the end of Mesozoic Era. Present-day Gölhisar Basin collapsed by the faulting movements was occupied by the Neogene Lake in which clayey and calcareous materials were deposited. Neogene (Pliocene) marly deposits containing marl, sandy clay, calcareous siltstone and sandstone, and clayey layers intercalations are widespread in the southern part of Gölhisar Basin. Thick colluvial and fluvio-limnic deposits are found on the edge of the highlands encircled the Gölhisar

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

Basin (Altunbas, 2018; Atalay, 2017; Atalay et al., 2017, 2019a). Alluvions occur on the bottom land of Gölhisar Basin (*Figs. 2* and *3*).

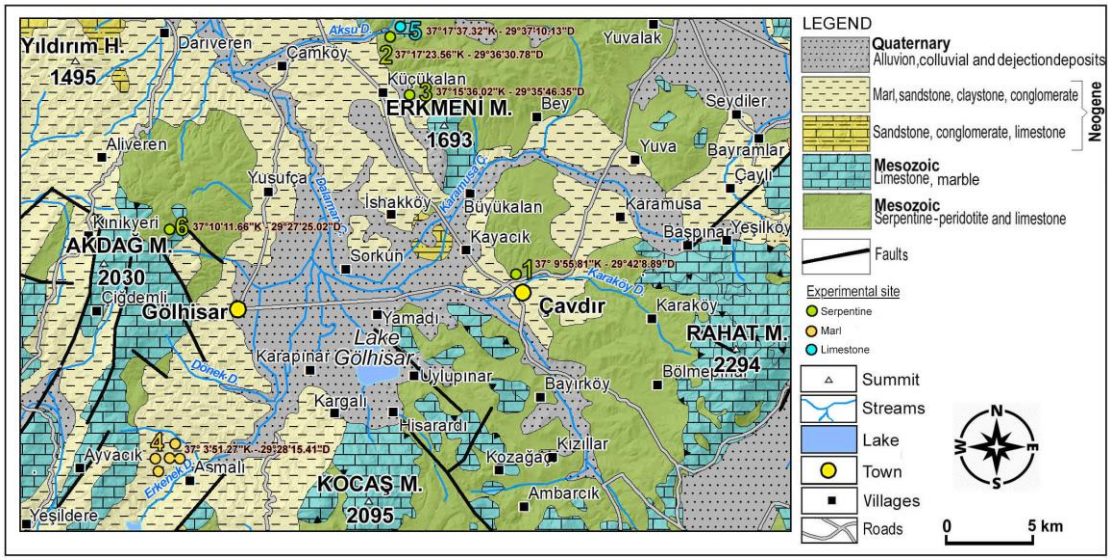

Figure 2. *Geologic parent materials and experimental sites of the study area*

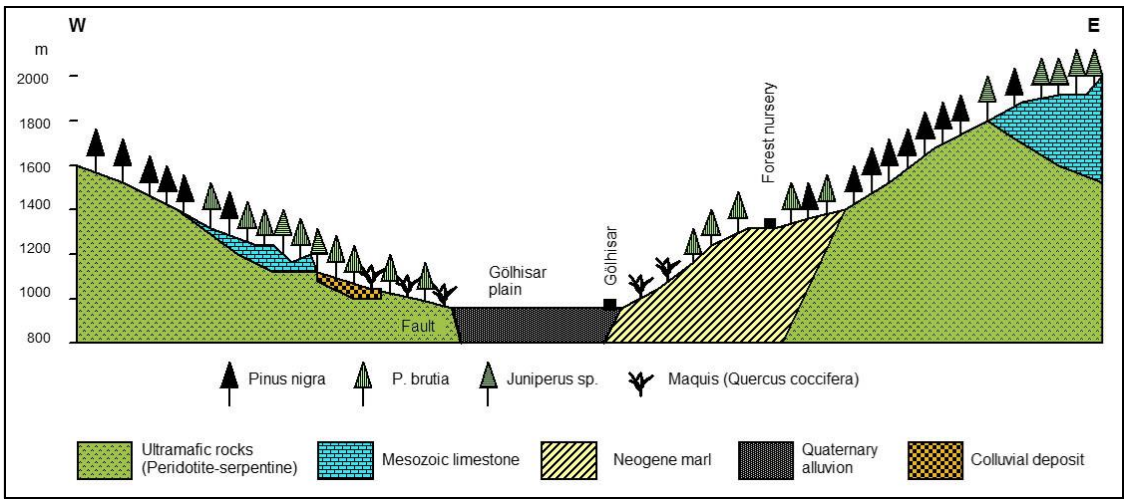

Figure 3. *Geologic cross-section and forest trees distribution in the Gölhisar Basin*

Geomorphic-topographic setting

Present-day topography of Gölhisar Basin was formed by the vertical tectonic movements occurred during the Neogene and Early Quaternary periods (Atalay et al., 2017). Main topographic-geomorphologic units and their formations are shortly explained below:

Mountainous areas

These areas encircling high mountainous areas of the basin were formed by the vertical faulting movements; the relative altitude between the collapsed Gölhisar Basin

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

and its encircling highlands is more than 1000 m. Thus, the highlands have been deeply dissected by the streams flowing into the basin. The slope inclination on fault scarps is over 80% especially on the mountain slopes facing Gölhisar town in the west of study area.

Gully landforms

Neogene Lake occupying the Gölhisar Basin was captured by the Dalaman River flowing in to Mediterranean Sea. Thus, emerging the Neogene Lake deposits have been also incised by the streams that established on the neogene deposit surface. Gully landform resembling bedland topography has been formed. The erosion on the marly deposits is commonly seen on the steep slopes of the valley in the southern part of the basin.

Colluvial deposits

Thick colluvial deposits that formed as the result of accumulation of the eroded materials derived from the upland areas are common on the edge of the mountainous areas. There is some close relationship between the topographic-geomorphological units and the growth rate of the trees in the study area, in general.

Physical geography setting

Climate

The climate of the study area is the transitional climate, characterized with a somewhat mild and rainy winters, a moderate hot and rainless summers, between the Mediterranean climate and continental climate of Central Anatolia according to climatic types of Turkey (Atalay, 2012). According to data obtained from the meteorological stations in the study area, mean annual temperature which is 12 °C at the Gölhisar town decreases continually toward the highlands. The mean annual precipitation which is c. 500 mm rises up to 700-800 m in the highlands. In the spreading areas of Calabrian pine (*Pinus brutia*) clusters the mean annual temperature is about 11-12 °C, mean winter temperature is above freezing point, and mean annual precipitation changes between 300 mm and 600 mm. In the *Pinus nigra* occurrence areas, mean annual temperature is nearly 8-9 °C and mean annual precipitation is over 500 mm.

Soil

In the study area, solum horizon is rarely seen due to the active erosion occurring in the sloping area. Most of soils belong to intrazonal soils reflecting the physical and chemical properties of parent materials in the study area (Atalay et al., 2019b). Indeed, lithosol/entisol containing serpentine particles is common at the all serpentine experimental sites. Clayey and calcareous soil is common on the steep slopes of marl deposit. Only thin A horizon of Rendoll subordo of Mollisol ordo or Rendzic Leptosol with clayey loam in texture and alkaline reaction occurs on the flat land of marl deposit. Red Mediterranean soil/Luvisol which is clayey in texture is found along the cracks of limestone at experimental site 5. Colluvial soil containing sandy and gravelly materials is common on the lower edge of hilly area as is found at experimental site 3. Plant nutriment capacity and texture of the soil/parent material depends on the weathering stage of parent materials, in general.

Vegetation

Two main forest belts are found in the study area: *Pinus brutia* and *Pinus nigra*. The ecological properties of these forests in Mediterranean climatic region of Turkey and the study area are summarized below.

In Turkey, native occurrences areas of Calabrian pine (*Pinus brutia* Ten.) forests beginning seashore climb up to 1500 m on the south facing slopes of Taurus Mountains and cover the lower forest belt of the Mediterranean climatic region of Turkey. Mean annual temperature ranges from 12 to 18 °C and mean January temperature is continually over 0 °C. Mean yearly precipitation changes 400 and 2400 mm most of which fall during the winter season in the optimum growing areas of Calabrian pine forests that are very resistant against drought. It grows all parent materials. The highest productive areas were established summer rainy area and on flysch parent material composed of alternation of sandy, silty, clayey limestone layers in Adana Province (Atalay et al., 1998).

In the study area Calabrian pine (*Pinus brutia*) forest belt generally lies between 1000 and 1200 m and its vertical distribution considerable changes depending on aspect factors (*Fig. 3*). Indeed, the upper limit of the Calabrian pine climb up to 1500 m on the south facing slopes of mountains. Maquis vegetation composed of mainly *Quercus coccifera* which is the lowerstory vegetation of Calabrian pine forest is widespread where Calabrian pine forests have been destroyed.

In Turkey, native occurrence areas of Anatolian *Pinus nigra* subsp. *pallasiana* (Lamb.) Holmboe forests are found between the subhumid-cold climate and subhumid-semiarid continental climate of Turkey and their optimum growing areas cover inland part of the Northern Anatolian Region and oro-Mediterranean forest belt of Taurus Mountains. *P. nigra* forests commence at an elevation of 1000 m in the western inland part of the Northern Anatolia and climb up to 2400 m in the Kahramanmaras Province in the eastern part of Mediterranean Region. In the optimum growing areas the mean annual temperature is about 8 °C, January temperature below the freezing point. The mean annual precipitation is over 600 mm. Good site index of *P. nigra* forests appear backward region of western Black Sea Region, inland part of West Anatolia and oro-regions of Aegean and Mediterranean Mountains (Atalay and Efe, 2010; Atalay, 2014).

In the study area, Anatolian black pine (*Pinus nigra*) forests begin on the upper level of the Calabrian forest belt mostly in the southern highland of the study area and climb up to 2000 m. Some of *Pinus nigra* native occurrence areas are replaced by poor juniper communities composed of *Juniperus oxycedrus, J. foetidissima* and J. *excelsa* in places where *P. nigra* forests have been degenerated and destroyed (*Fig. 3*).

Growth rate of trees at the experimental sites

Experimental sites were selected to determine the growth rate of Calabrian pine (*Pinus brutia*) and Anatolian black pine *P. nigra* on the different parent materials in the Gölhisar Basin. Four experimental sites were selected on the serpentine which is a product of hydrous alternation of ultramafic rocks mostly peridotite in the bottom of ocean covers a large area in the study area (*Figs. 2* and *3*).

The growth of Calabrian pine (Pinus brutia Ten.) experimental sites

To reveal the growth rate of the Calabrian pine (*Pinus brutia*) two experimental sites were selected on the serpentine, one site on the colluvial deposit, and one site on the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

marl deposit; totally four sites belong to the Calabrian pine cluster (*Fig. 2*). General description sites and the measurement of age, height and diameter of *Pinus brutia* at the experimental sites are introduced below.

Experimental site 1

Located near the highway between Burdur-Gölhisar.

General description of the site: Experimental site is located near the Gölhisar-Burdur road, 10 km NE of Gölhisar, at an elevation of 1100 m, 37°9'55.81"N-29°42'8.89"E. Undulating topography is dominant; serpentine is exposed in most part of the area due to the intense erosion. The height and diameter of *Pinus brutia* trees changes frequently depending on weathering degree of the serpentine; the highest height of *P. brutia* is found on the bottom of valley due to the collection of water and weathered serpentine; while, *P. brutia* trees which are in chaparral appearance are found on the exposed unweathered serpentine (*Table 1*; *Fig. 4*). Shirking aspect of this site it to show great changes on the height, diameter and age of *Pinus brutia* trees depending on different weathering stage of serpentine.

Table 1. *The height, diameter and age of Pinus brutia on serpentine experimental site at an elevation of 1110 m in the 10 km NE of Gölhisar town, 37°9'55.81"N-29°42'8.89"E*

Weathering degree of serpentine	Location of trees	Height (m)	Diameter (cm)	Age (year)
Good weathered	1. Bottom of small valley	14	38	45
Exposed serpentine	2. The upper part of hill slope	1.2	4	30
Semi weathered	3. Top of the hill	3.5	37	16
Weathered	4. Top of hill	3.2	14	37
Weathered	5. Top of hill	8	26	36
Semi weathered	6. Top of hill	4	26	36

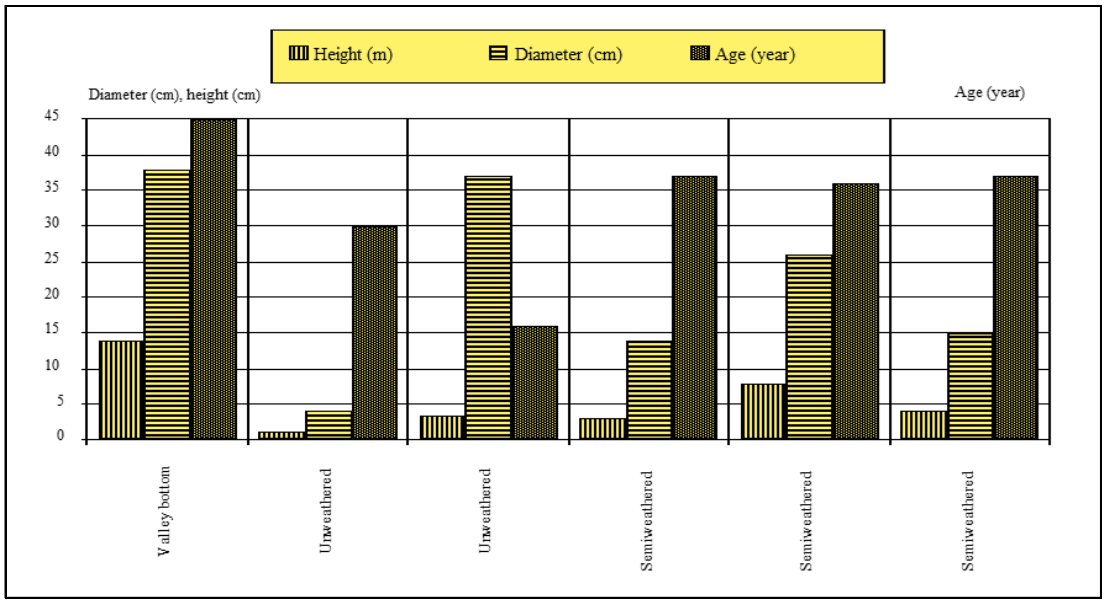

Figure 4. *The graph illustrating the relationships among height, diameter and age of Pinus brutia at the experimental site 1*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

Experimental site 2

Located on the western aspect of the valley in the c. 30 km north of Gölhisar, 37°17'23.56"N-29°36'30.78"E.

General description of the site: Serpentine parent material is common. The weathering degree changes frequently depending of the slope inclination and erosion process. Semi weathered serpentine is widespread on the slightly inclined surface, but unweathered serpentine is exposed on steep slopes of valley. The dissected topography is common; slightly surfaces are found upper parts of the hills.

In this site great differences in the growth of *Pinus brutia* are seen to have depended on weathering of the serpentine. Indeed, the lowest growth rate was established on the active erosion place of steep slopes of valley on which unweathered serpentine was outcropped. There no great differences among the height of *P. brutia* on the slightly inclination area (*Table 2; Fig. 5*).

Table 2. *The height, diameter and age of Pinus brutia on weathered serpentine experimental site at an elevation of 1100 m near road in 25 km NNE of Gölhisar, 37°17'23.56"N-29°36'30.78"E*

Weathering degree of serpentine	Location of tree	Height (m)	Diameter (cm)	Age (year)
Weathered serpentine	The slope inclination low	16	34	85
Weathered serpentine	The slope inclination low	21	42	98
Low weathered serpentine	Inside of valley, active erosion	6	9	50

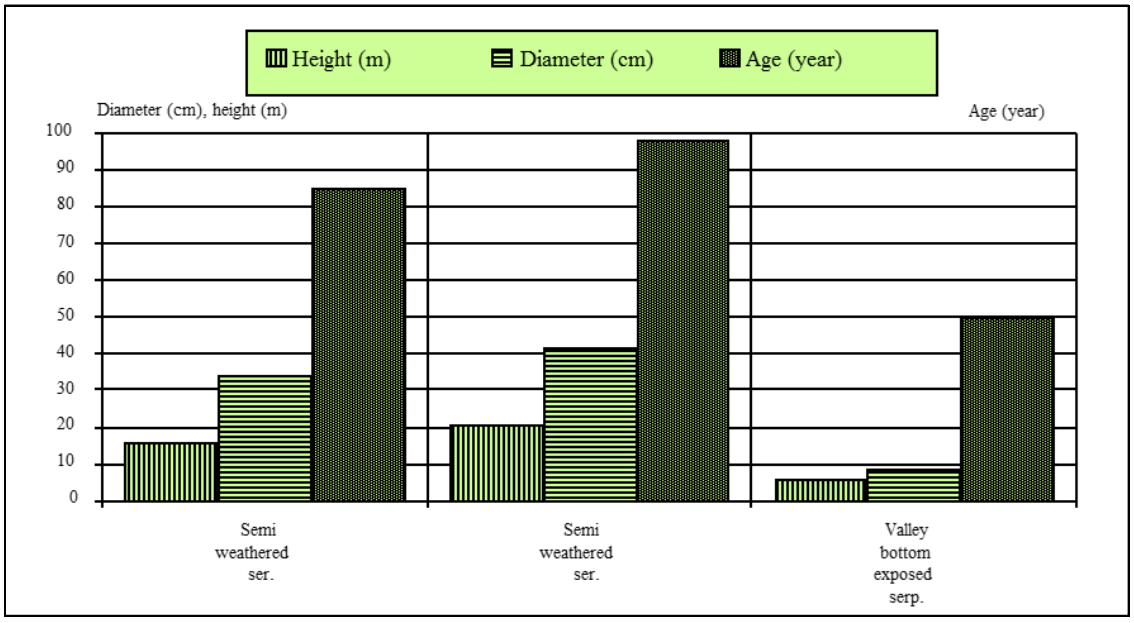

Figure 5. *The graph showing the relationships among height, diameter and age of Pinus brutia at the experimental site 2 on serpentine*

DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

Experimental site 3

Located on the colluvial deposit in the Gölova Forest Directory, near forest fire observation tower, at an elevation of 1150 m, 37°15'36.02"N- 29°35'46.35"E.

General description of the site: Topographically this site is found on slightly inclined area lying on the edge of hilly area. The colluvial deposit has been formed with the accumulation of the small gravels, sands and silts transported by the running water derived from the serpentine area. The reddish colour of the colluvial deposit clearly reflects a good oxidation process.

Thick colluvial deposit creates a good habitat for the growth of *Pinus brutia*. Because both horizontal and taproot development of root structure clearly show the existence of good ecological conditions on colluvial deposit. For this reason, there is no great difference among the height of trees in terms of height, diameter and age (*Table 3; Fig. 6*). The productive *P. brutia* trees are only found on the colluvial deposit when compared to other sites.

Table 3. *Calabrian pine cluster on the colluvial gravelly deposit in Gölova forest directory of Gölhisar, 37°15'36.02"N-29°35'46.35"E*

Parent material	Topography	Height (m)	Diameter (cm)	Age (year)
Very thick gravelly, sandy colluvial deposit	Slightly inclined surface of colluvial deposit	12.5	32	57
Same	Same	16	39	53
Same	Same	17	40	58

DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

Experimental site 4

Located on the neogene marl deposit in the eastern part of the Gölhisar town at an elevation of 1100 m, 37° 3'51.27"N, 29°28'15.41"E.

General description of site: Parent material is composed of marl deposits; it contains both horizontal and inclined calcareous sandstone, siltstone layers and gravelly lenses belonging to fluvial deposit. Marl deposit has been dissected by the tributaries of the main stream flowing into Gölhisar Plain. Small flatlands are seen on the horizontal layer among the upper parts of valleys. The debris flows occur on the steep slopes of valley. Entisol is common on the sloping areas; thin A horizon with rich organic content belonging to rendzina (Rendoll, Rendzic leptosol) is only seen on the flat land. *P. brutia* clusters occur everywhere of the area. But productive *P. brutia* is found on the soft marly deposit and inclined layers. A somewhat productive *P. brutia* trees appear on the marl horizontal layers with soft and crack structure supporting the taproot development, while compact marl creates a poor habitat for the growth of *Pinus brutia*. Besides the high sun radiation somewhat prevents the productivity of *Pinus nigra* on the slopes facing-south due to summer aridity. The growth rate of the Calabrian pine on the marl deposit is generally good as compared with the serpentine parent materials (*Table 4; Fig. 7*).

The growth of Anatolian black pine (Pinus nigra subsp. pallasiana) experimental sites

Anatolian black pine (*P. nigra*) forests appearing upper boundary of the Calabrian pine (*P. brutia*) belt are found only small cluster in the N of Gölhisar and mountainous areas rising 2000 m of elevation in the southern part of the Gölhisar town. To reveal the growth rate of the Anatolian black pine on the limestone and serpentine two experimental sites were selected. General description sites and the measurement results of these experimental sites are introduced below.

Table 4. *Calabrian pine growing on the neogene marl deposit in the north of Gölhisar town*

Properties of neogene deposits	Location	Height (m)	Diameter (cm)	Age (year)
Horizontal hard layers	Almost flat land near road	21.5	40	120
Horizontal layers	Flat and radiation intensity high	14	25	27
Horizontal marl layer	Flat and low radiation intensity	15	17	27
Soft and inclined marly layer	Upper part of the hill near Gölhisar road	23	50	75
Soft and inclined marly layer	Lower part of the hill near Gölhisar road	17	29	63

Experimental site 5

Located near the highway between Burdur-Gölhisar, at an elevation of 1200 m, 37°17'37.32"N-29°37'10.13"E.

General description of site: Located in the 30 km NNW of Gölhisar town. Cracked and crystallized limestone is common on the serpentine. The slope inclination is very low. Most of the *Pinus nigra* trees have been destroyed to obtain timber; thick litter cover appears under the of *Pinus nigra* cluster on the limestone. There is no surface erosion due to the rainfall easily infiltrates along the limestone cracks. There are no notably differences among *P. nigra* trees in terms of the height, diameter and age, in general (*Table 5; Fig. 8*). Cracked limestones containing low content of clay create a suitable condition for the growth of *P. nigra*; because of the roots of *P. nigra* easily develop toward the deeper part along the cracks of limestone.

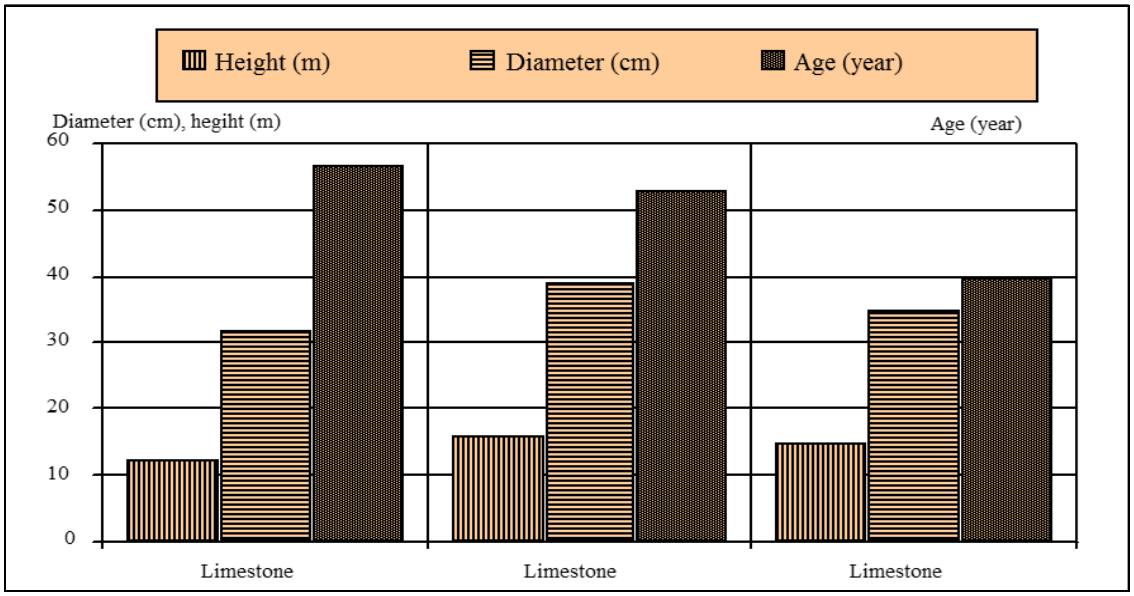

Figure 8. *Relationships among height, diameter and age of Pinus brutia at the experimental site 5 on the limestone*

Experimental site 6

Güdük Hill locality on Ak Mountain, far from 30 km in the west of Gölhisar town, 1600-1700 m, 37°10'11.66"N-29°27'25.02"E.

Description of the site: Güdüktepe locality is found at an elevation of 1600-1700 m on the east facing slopes of the Ak Mountain in the western part of Gölhisar town (*Fig. 1* and *2*). Parent material is composed of cracked and unweathered serpentine. Inclination of the slope is more than 60%, and its elevation is about 1600-1700 m. Güdük Hill is one of the main spreading areas of *P. nigra* forests. Here lithosol/entisol is common due to intense erosion. Lithosol and over grazing activity prevents considerably the regeneration of *P. nigra*. That is why; *P. nigra* seedlings that are rarely seen indicate presence of low native regeneration.

In this experimental site, *P. nigra* grows within the cracks and the partly weathered vertical zone of serpentine. The highest *P. nigra* is found on the cracked serpentine; because the roots of the *P. nigra* easily follow deeply along the cracks of serpentine. Shrinking aspect of this area, weathered serpentine particles have been transported by the runoff due to high inclination of the slope. It can be said that the site index of the *P. nigra* is in poor quality on the exposed serpentine. The growth rate of *P. nigra* is tend to increase from the steep slope to the upper part of the hill and wide bottom of valley, in general. However, there is no direct relationship between the diameter and height of *P. nigra* trees, but considerable differences of *Pinus nigra* age imply the weathering process occurring along the cracks of serpentine, especially in the root zone (*Table 6; Fig. 9*).

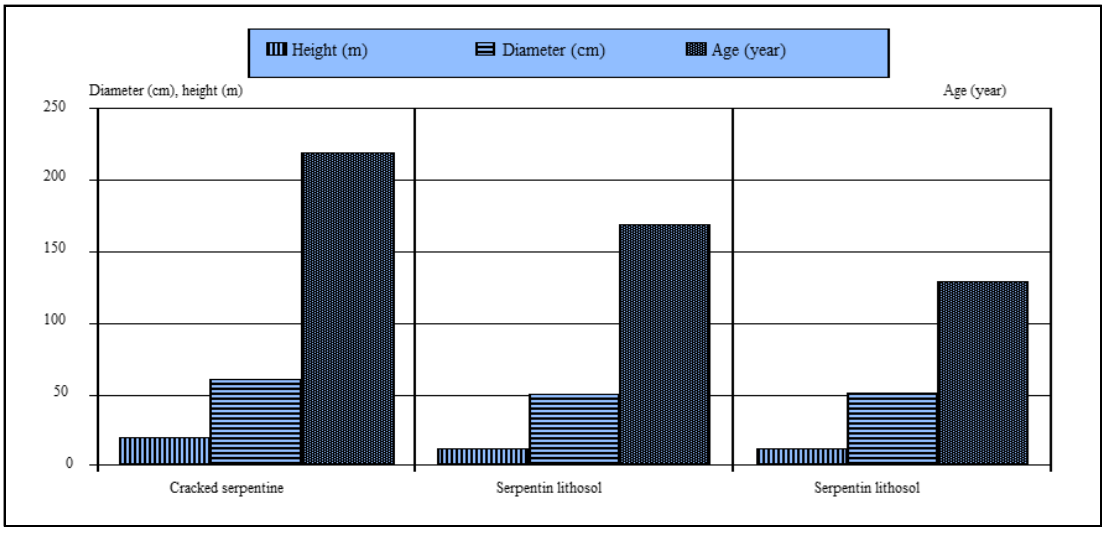

Figure 9. *Relationships among height, diameter and age of Pinus nigra at the experimental site 6 on the serpentine in the Göktepe locality, Ak Mountain*

Lithosol	Near top of hill	13	51	170
Lithosol	Lower slope of valley	13	52	130

Relationship between growth rate of vegetation and physical and chemical properties of parent materials

According to field observations and the data of laboratory analysis of soils and parent materials in the study area there is close relationship between the growth rate of vegetation and weathering degree and/or stage of serpentine. As is seen experimental site 1, the highest height Calabrian pine tree is found on good and deeply weathered serpentine with CEC (Cation exchange capacity) 33 $cmol_c\ kg^{-1}$, this figure is c. 13 $cmol_c\ kg^{-1}$ at the site of the lowest height of Calabrian pine (*Table 7*). Poor stand forest in appearance of dwarf trees and shrubs are common on the low weathered and exposed serpentine which is in green colour. One of these areas notably preventing factor to grow of herbaceous vegetation is found at the Taşpınar locality in the SW of Lake Ak. Here CEC of low weathered and exposed serpentine is about 2 $cmol_c\ kg^{-1}$. In this place other preventing factor is the presence of thin sandy soil with very low field capacity and dissecting with rills that are formed with the transportation of sandy particles by runoff (*Table 8*). The presence of a few *Pinus brutia* trees are not related the low CEC on the sandy soil because the growth of *P. brutia* depends on the weathering process in the root zone. In other words, the release of the plant nutriments on the serpentine surface determine only the growth of seedlings and herbaceous vegetation but the growth rate and/or productivity of trees is mainly related to the weathering degree of the root zone (*Table 7*). Organic material of all sites is less than 1%.

Table 7. *Some physical and chemical properties of serpentine at experimental site 1*

Parent material properties	Sand (%)	Clay (%)	Silt (%)	Texture class	$CaCO_3$ (%)	K ($cmol_c\ kg^{-1}$)	Ca ($cmol_c\ kg^{-1}$)	Mg ($cmol_c\ kg^{-1}$)	Na ($cmol_c\ kg^{-1}$)	CEC ($cmol_c\ kg^{-1}$)
Upper part of weathered serpentine	59	21	20	SCL	13.7	1	51	4.3	0.26	24.3
Lower part of weathered serpentine	79	7	14	LS	5.1	0.2	60	12	0.5	33
Less weathered serpentine	71	13	16	SL	6.7	0.1	39.4	3.4	12	12.9
Sand of serpentine	73	7	20	SL	1.5	0.04	3.2	3.4	12	20

On the other hand, release of the $CaCO_3$, clay contents and cations mainly of Ca^{++} and Mg^{++} are higher on the deeply weathered serpentine than on low weathered serpentine. This is responsible for the increase of CEC in the weathered serpentine (*Tables 8–10; Fig. 10*).

Table 10. *Some physical and chemical analysis of marl deposits in the south of Gölhisar town*

Parent material properties	Sand (%)	Clay (%)	Silt (%)	Texture class	$CaCO_3$ (%)	K ($cmol_c\ kg^{-1}$)	Ca ($cmol_c\ kg^{-1}$)	Mg ($cmol_c\ kg^{-1}$)	Na ($cmol_c\ kg^{-1}$)	CEC ($cmol_c\ kg^{-1}$)
Marl deposit in S of Gölhisar	17	27	56	SiL	53.7	0.8	49.6	15.3	0.29	23.8
Marl deposit	11	47	42	SiC	48	1.3	40.7	18.7	0.28	33.7
Compact marl deposit	21	23	56	SiC	40.5	0.4	34.4	8.7	0.15	10.48

The weathering process in melange area that is composed of the mixture limestone and serpentine frequently changes. In such area, the amounts of CEC of the serpentine depend on the weathering and oxidation process. For instance, in the melange area at the 2 km northwest of the Gölhisar town CEC changes between 12.8 and 43.8 $cmol_c\ kg^{-1}$ (*Table 9*). The fertile agricultural fields are common on the flat land of melange areas of the study area in general. On the other hand, the cracks of serpentine contribute to develop deeply of root system, and chemical and physical weathering processes occurring along the root

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

and crack zones contribute tend to increase the releases of the abundant plant nutriments. This situation produces a good habitat for the growth of trees. In fact, cracked serpentine and deeply developed root system support to increase of the biomass productivity of all trees.

CEC of the soil developed on the serpentine changing between 35 and 50 $cmol_c\ kg^{-1}$ forms fertile agricultural lands in the Gölhisar Basin. Soft marl deposit containing sand particles is generally responsible for the growth of forest due to deeply root development of trees. While compact marl deposit and horizontal compact layers mostly prevent to form good stand of forest because taproot development of trees is very hard and CEC is less than the soft marl deposit (*Table 10*).

General relationships among the height, diameter and age of the trees

There are great differences among the height, diameter and ages of the trees at most of the experimental sites. The highest differences are seen in *P. brutia* sparse cluster on the different weathered serpentine at experimental site 1. Here, the ranges of the height 1.2 m to 8 m, diameter 4 to 37 cm, and age 16 to 45 years. This is mainly related to the weathering stages of serpentine. There is no considerable difference among the *P. brutia* trees on serpentine colluvial deposit at experimental site 3 and *P. nigra* trees at experimental site 5 on the limestone. These last two sites can be regarded as productive forest cluster (*Fig. 10*).

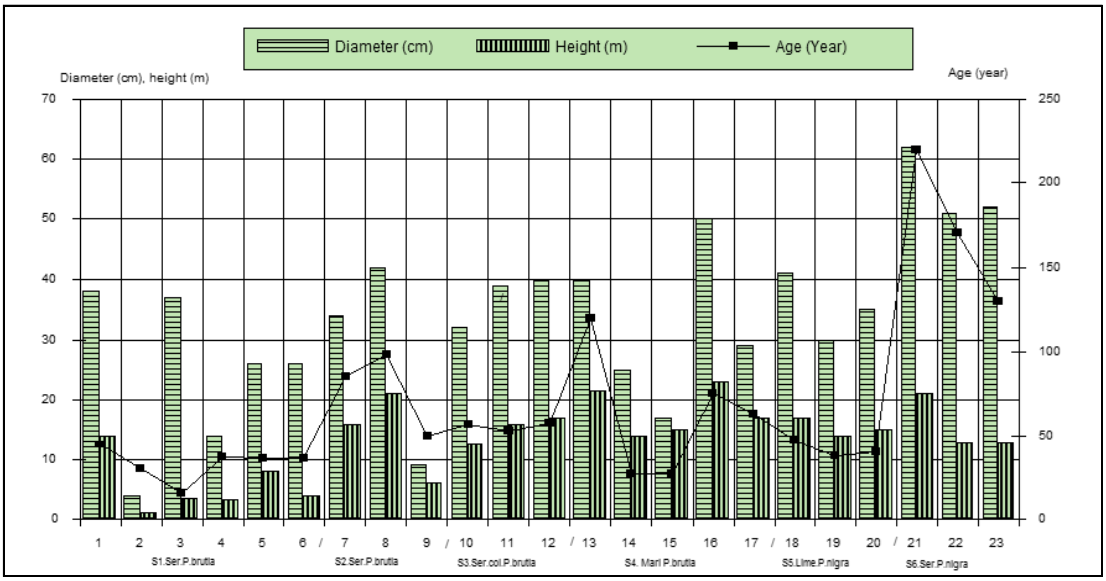

Figure 10. *The graph showing relationships among the age, diameter and height of the individual trees at the experimental sites reveals the importance of the tree growth notably depending on parent materials. "/" indicates between the boundary of experimental sites. (Abbreviations: S1, 2, 3... experimental sites. Ser. serpentine. Ser. col. Serpentine colluvial deposit)*

General relationship between height and age

Relationship between height and age is one of the indicators of the productivity in uniform ecological environment. In the productive habitats there are very little differences between the height and diameter of trees (Saatcioglu, 1976). Very little

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

differences between height and age are found among the *P. nigra* trees growing on the limestone at experimental site 5 and among the *P. brutia* trees growing on the serpentine colluvial deposit at site 3. Here parent materials are in uniform properties. The increase of the differences among the trees indicates clearly the existence of different parent materials and their weathering stages. The existence of great difference between the height and age may relate to the inclination of layer and compactness of marl deposit at the experimental site 5 (*Fig. 11*).

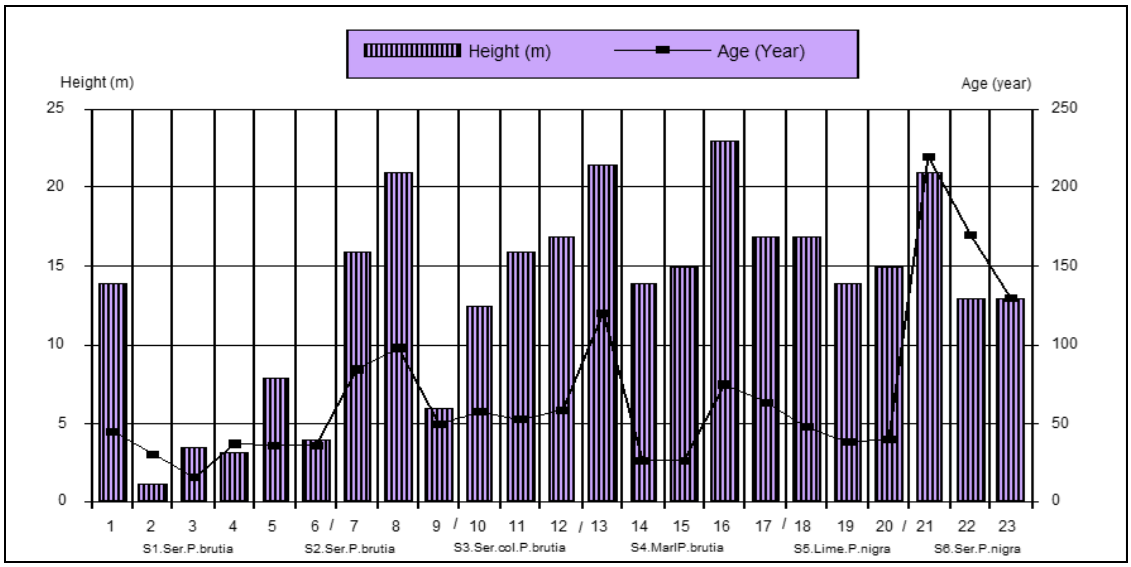

Figure 11. *The relationship between height and age of trees in the experimental sites*

The general relationship between age and diameter

As a general rule, the thickness of diameter continually increases toward the end of felling cycle (rotation, length) of trees and diameter thickness is the best indicator of the annual increment of trees. There is irregular relationship between age and thickness of diameter of most of trees in the study area. Indeed, the great changes are found between the age and diameter at experimental sites 1, 2, 4 and 6; this is related to the different weathering process of the parent materials, while the reasonable relationship between diameter and age is found on the serpentine colluvial deposit at site 3 and on the limestone at site 5 (*Fig. 12*).

Available water effects on the tree growth

Available water capacity of the soil and parent material is generally low due to high inclination surface and sandy and sandy loam texture of soil. Most of the atmospheric water flow as runoff/overland flow on the serpentine and marl deposit occurring on the inclined surface. Here available water of trees depends on the amount of infiltration capacity of water through the cracks and collection of water in the root zone. In the karstic/limestone area almost all atmospheric water easily infiltrates via the cracks of limestone; thus, tree roots take available water from the soil that is developed along the cracks. For this reason, the tree growth rate is higher on the karstic land occurring in the study area, especially at site 5. Meanwhile, that tree productivity is high on colluvial deposit as is the site 3 is related to the accumulation of the water. Individual tree growth also depends on the available water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

content in the root zone. For example, at the experimental site 1 the lowest growth rate of *Pinus brutia* tree is found on the steep slopes, while highest growth rate of *Pinus brutia* is found on the bottom of the small valley due to water collection (*Table 1; Fig. 4*). Field capacity is very low on the sandy material on the serpentine occurring sloping area especially in the vicinity of Taşpınar village. Here the occurrence of the rill erosion and absence of herbaceous vegetation is mainly related to the transportation of mostly sandy particles by runoff and low field capacity of sandy soil.

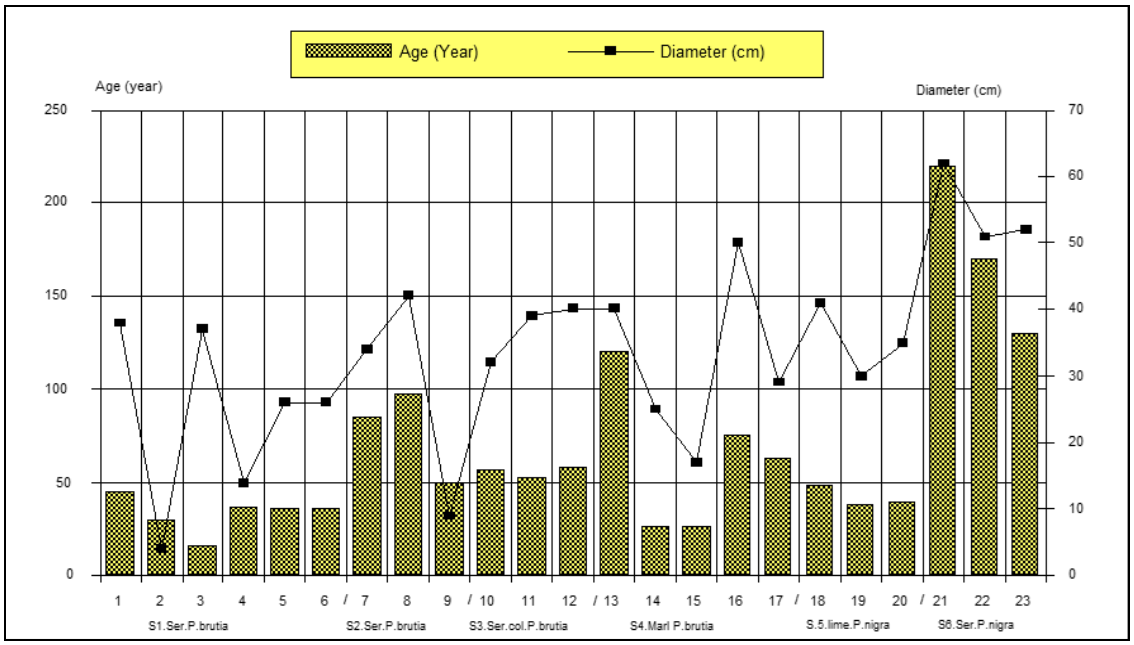

Figure 12. *The relationships between age and diameter at the experimental sites*

Human impact on the growth of trees

The settlement history of Gölhisar basin back to Neolithic period dated at least 7000 year BP (Roberts, 1990; Atalay, 1992). The vegetation especially forest destruction was probably commenced during the Roman period. At that time the famous historical city Kibyra (UNECO heritage city) was located on the crossroads of Phrygian, Carian, Lycian and Pisidian cultures and of commercial routes running east-west and north-south directions on the lower slope of the Ak Mountain in 1 km south of present-day Gölhisar town. Up to present time, most of the forests have been destroyed and degenerate to obtain timber and agricultural land. With the degeneration of the forest, soil and parent material erosion has been started on the sloping area. Thus, parent materials have been outcropped in the various parts of Gölhisar depression. As mentioned before, outcropped parent materials have been led to decrease the growth rate of the trees at most of the experimental sites. It can be said that forest destruction is one of the main reasons of tree growth on parent materials exposed on the degenerated forest area of Gölhisar Basin.

Statistical evaluation

According to statistical evaluation depending on the height, diameter and age of the trees, one-way ANOVA test for *Pinus brutia*, no significant correlation was found in the data range ($P < 0.05$).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

As a result of the independent T-test for Pinus nigra, a significant correlation was found on the age and diameter of the trees ($P < 0.05$) of different parent material. A difference in the tree heights of different parent materials ($P < 0.05$) was not found.

Discussion

Vegetation growth and its productivity depend on not only climatic conditions but also physical and chemical properties of the parent materials. In the flat and slightly undulating areas of same climatic region parent material effects on the tree growth is very little. In these areas site index of forest is found in same category. But growth rate and/or productivity of forest changes considerably depending on the weathering process of the parent materials. In Turkey, the site index of forests shows great difference in terms of timber quality and biomass productivity. For example, the low site index Calabrian pine occurs on the siliceous parent material in north of Foca in the north of Aegean Sea shore, trachyte in south of the Lake Tortum, low weathered serpentine in western coastal belt of Antalya Gulf, Datça peninsula in the south-western part of Anatolia and horizontal marl deposits (Çukur, 1999; Çukur and Atalay, 2004; Atalay, 2014; Atalay and Efe, 2014).

On the other hand, the parent material effects on the tree growth are one of the significant procedures in the silvicultural application and reforestation and afforestation activities. For example, the seedlings to be planted on compact marl deposit have been subjected to dry during one and three year period, because the vertical development of seedlings' roots has been prevented by the horizontal layered and compact marl deposit (Atalay et al., 2014). To make successful reforestation and afforestation marl deposit should be deeply ploughed to plant the seedlings. Unweathered and low weathered serpentine forming hard surface also mostly prevents the natural regeneration. As a matter of fact, the cedar (*Cedrus libani*) plantation to be carried out on the marl deposit and serpentine is not appropriate application since the ecology of the cedar is taken into consideration in the Burdur-Gölhisar Basin. First time, the CEC of the serpentine depending on weathering process and marl deposit on the growth of trees are explained in our study. Stone pine (*Pinus pinea*) reforestation to be carried out on the serpentine is inappropriate application, because this pine only grows on the sand dunes and sandy soil developed on the granite and gneiss under the Mediterranean climatic conditions (Atalay, 2014). In the forest management planning and the classification of forest stand index, the importance of parent material effects have been not sufficiently used in Turkey.

The importance of serpentine, marl and limestone forming lithobiome is detailed explained on the tree growth and the response to the land degradation process. Indeed, in the study area, the exposed unweathered serpentine and marl deposit on the forest destroyed sloping areas can be regarded as vulnerable areas for the formation of land degradation.

To establish the productivity and/or site index and to select the species of trees in the reforestation and afforestation activities it is necessary to classify the natural environment according to lithobiomes and pedobiomes (Bailey, 1995a, b, 1998; Atalay, 2014). These biomes form a distinct habitat on which flora and fauna is different than that other biomes. To classify of given natural environment as biomes can be regarded the one of fundamental principles of sustainable planning of the plant especially forest growth, site index and productivity. On the other hand, these classifications will

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1108511106

contribute the selection of tree species in the reforestation and afforestation activities and silvicultural applications. However, similar studies relating to forestry have not been conducted except for "Ecoregions of Turkey (Atalay, 2014).

Conclusion

The parent material effects on the growth rate and/or productivity of trees in the sloping areas is one of leading issues in the determination of forest products, silvicultural applications and reforestation activities. In the study first time we analyzed the importance of the serpentine, limestone, marl and colluvial deposits on the growth of *Pinus brutia* and *Pinus nigra* trees. In the further studies the lithobiomes and pedobiomes should be used in the assessment of the natural environment and tree growth, and similar studies should be carried out. These studies are necessary to sustainable planning on the forest production and maintain the natural equilibrium.

Acknowledgements. We would like to offer our gratitude to Forest Engineer Oktay Demirci for measurements of the height, diameter and age of the trees and Emrah Ramazanoglu for statistical evaluation of trees. We would like special thanks to Bekir Karacabey, General Director of Forest of the General Forest Directory, Ministry of Agriculture and Forest, Kenan Akduman, Isparta Regional Director of Forest and Celal Korkmaz Burdur Forest Operation Manager for their supports and helps the project named "Ecology, ecosystem and Rehabilitation of Marble Quarries in the Burdur-Gölhisar Basin", prepared by I. Atalay, S. Altunbas and M. Siler.

(Received 4th Apr 2019; accepted 13th Jun 2019)

Abstract. Biochar (BC) is the carbon-rich material, increasingly as a soil additive for carbon sequestration and soil improvement. Various studies have shown that BC have a profound effect on root morphological traits on agricultural systems, however the effect of BC amendments on the root traits of forest species is scant. The current study attempts to evaluate the effects of different BCs as a soil amendment on the growth and root morphological traits of *Fokienia hodginsii.* For that reason, three different types of BCs; bamboo (BB), hardwood (BH), and rice straw (BR) with four levels (0, 5, 20, and 80 g $kg^{-1}$of soil) collectively ten treatment combination including control (Bo) were incorporated to soil and seedlings were allowed to grow in pots in greenhouse for one year. After one year uprooted seedlings roots were scanned and analyzed by using WinRHIZO software for comparison. Bamboo and rice straw BC amendments were found to significantly improve root traits particularly root volume, average diameter, and root length compared to Bo. Additionally, the seedlings treated with BR80, BB80, and BH80 attained 36%, 29%, and 25% biomass, respectively compared to Control (Bo). Soil physiochemical properties particularly soil pH also varied between different BCs types and levels. Consequently, BC alkalinity is an important feature to correct soil acidity and improve soil fertility by altering soil nutrient content. Root establishment in acidic soils can be enhanced by BC amendments but selection of BC and soil is crucial to maximizing soil improvement and seedlings roots traits.
Keywords: *Fokienia hodginsii, root traits, biomass, winRHIZO, alkalinity, soil improvement*

Introduction

Fokenia hodginsii (Fujian cypress) is an important conifer; native to China and Vietnam. Currently, on the basis of its distribution, this conifer is globally threatened, protected species (B2/second degree) in China, and as vulnerable in red list of threatened species; generated by international union for conservation of nature (IUCN) (Luu and Thomas, 2000; Ding et al., 2017; Tarin et al., 2019). Timber of this conifer is valuable because of its straight grain and different aroma and is also being exported to Europe and elsewhere in Asia (Osborn, 2004). Moreover, siam-wood essential oil or pemou oil is extracted from its stumps and roots which contains high sesquiterpene content; which can sanitize and purify the air, kill bacteria, and resist insects. Furthermore, extract oil can be used to improve emotional balance and the mental clarity in aromatherapy (Paluch, 2009). As a result of, certain increase in human

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1110711120

population has put enormous pressure on this conifer community by over logging for utilization of timber wood (Nguyen et al., 2015; Tarin et al., 2017). These anthropogenic (human activities) and pedogenic or natural factors (parent material) has resulted infertile soils (Lal, 2015). Consequently, high rates of deforestation, rise in global temperature (approximately 0.85± 0.20°C) during last 130 years will lead to unfavorable and harsh conditions for plants such as drought and flood etc. globally (Alexander et al., 2006; Tarin et al., 2019) Additionally, intensive forest management for conversion of natural forests into artificial plantations has been shown to deteriorate the soil physical health, like, reducing pH and porosity, and increasing bulk density (Tonks et al., 2017).

Global climate change and intensive forest management both have adversely affected the features of forest soils via decrease in soil organic carbon, acidification, biological properties, and biodiversity (Li et al., 2018). Vast areas of tropical and subtropical regions of Southern China, soils are acidic where; soil fertility is the major constraint to plant growth (Haynes and Mokolobate, 2001; Baquy et al., 2017). However, mineral lime has been conventionally used to raise the soil pH (Adams, 1984) nevertheless, because of its high costs, much attention has been given to replacements like incorporation of crop straw in soil which also can increase soil pH (Xu and Coventry, 2003). Besides, direct addition of such plant residues into the soils do not stay longer because of decomposition (Yuan and Xu, 2011). Recently, biochar (BC) has received much attention as an alternate to these soil organic amendments and is considered as a potential fertilizer due to partial combustion of several organic components. It has mostly alkaline nature subject to pyrolysis temperature over 400°C (Gaskin et al., 2008) and can raise the pH of acidic soils by decreasing exchangeable Al from soil (Chan et al., 2008b). Its amendments into the soil can improve soil fertility (Topoliantz et al., 2005), stimulate the plant growth (Jeffery et al., 2011a) and enhance the sequestration of CO_2 from the atmosphere (Lehmann et al., 2006).

Numerous studies on agriculture and horticulral system have been shown to examine, how BC effects on plant growth and root morphological parameters. Inappropriately, research on effects of BCs amendments on growth of trees particularly on root morphological parameters is rare. BC application into the soil has significant effects on growth and root morphology as plant roots contact directly to its particles for uptake of soil nutrients and water (Prendergast-Miller et al., 2014). Therefore, measurement of roots morphological parameters, such as root length, root diameters etc. are essential to understand plant physiological functions. It is necessary to determine how root morphological traits respond to different BC application under multiple levels for better management of forest species.

In the context of previous studies, responses of root traits like root morphology and biomass (Brennan et al., 2014; Keith et al., 2015), root-associated microbes, and nutrient concentration (Rillig et al., 2010; Vanek and Lehmann, 2015) can be influenced by incorporation of BCs. Moreover, root morphological traits play diversified roles in plant growth and development (Nie et al., 2013). For instance, root length is possibly one of the important parameter, mainly because of general indicator of plant response to environmental factors and also controls the acquisition of nutrients or water (Clothier and Green, 1997; Edwards et al., 2004) whereas for the biomass increase, root diameter is considered as beneficial (Eissenstat and Yanai, 1997). To date, BC effects on root morphological traits are highly variable and controversial. For instance, because of various factors, root biomass remains relatively stable, decrease or increase under BCs

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1110711120

application (Macdonald et al., 2014; Prendergast-Miller et al., 2014; van de Voorde et al., 2014). The BC type (different materials or pyrolysis temperature) is an important factor because it varies significantly in chemical composition and pH (Lehmann et al., 2011). Consequently, the variation in characteristics of BCs and their application rate may also influence the soil physiochemical properties and ultimately alter the root morphological traits (Reibe et al., 2015; Reverchon et al., 2014). For that reason, it is important to know how root traits respond under different BCs application. In the current study, it was hypothesized that addition of BC into the soil may affect the biomass and root traits of the *F. hodginsii* seedlings by improving the soil physiochemical properties. Therefore, one year pot experiment was conducted to examine the effects of three different BCs under four levels (i) to identify the effects of different BCs on the physiochemical properties of soil, (ii) to investigate the effects of different BCs on growth (biomass) of *F. hodginsii* seedlings, and root morphological traits.

Material and methods

Study area and design

The present study was started in March, 2017 at Bamboo Institute of Fujian Agriculture and Forestry University Fuzhou, Fujian Province, P. R. China (lat. 26° 5' N, long. 119° 13' E, elevation 12 m; *Fig. 1*).

Figure 1. *Boundary of Fujian Agriculture and Forestry University (Bamboo Institute), experimental design and order*

The metrological informations of the study site during the entire experiment period are presented in *App. 1*. Three different types of commercial biochars (BCs); bamboo

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1110711120

biochar (BB, produced at 450°C), hardwood biochar (BH, produced at 420°C), and rice straw biochar (BR, produced at 500°C) were used; which were purchased from Nanjing Qinfeng Straw Technology Co. Ltd. China. Before application to soil the physiochemical characteristics of these BCs and basic soil were determined (*Table 1*).

Table 1. *Physiochemical properties of BCs and soil used in the experiment, BB: bamboo biochar*

Characteristics	BB	BH	BR	Basic soil
pH	9.687	5.703	9.833	4.685
EC (m Scm^{-1})	3.140	6.343	4.070	106.667
TC (g Kg^{-1})	311.220	330.530	250.053	3.358
OM (g Kg^{-1})	536.543	569.834	431.092	5.790
TN (g Kg^{-1})	6.243	8.297	5.153	0.497
AP (mg Kg^{-1})	32.381	24.318	29.076	10.245
TP(g Kg^{-1})	0.399	0.296	0.311	0.256
Ext. K (g Kg^{-1})	0.335	0.321	0.371	0.356
C:N Ratio	49.975	39.846	48.641	6.864

BB; Bamboo biochar, BH: hardwood Biochar, BR, rice straw biochar TN: total nitrogen, TC: total carbon, TP: total phosphorus, AP: available phosphorus, OM: organic matter, Ext. K: extractable potassium, C: N: carbon nitrogen ratio

These three BCs were incorporated to soil with four different levels; 0, 5, 20, and 80 g kg^{-1} of soil (Tarin et al., 2019). One-year old seedlings of *F. hodginsii* (uniform size) were collected from forest nursery (Anxi County, Fujian, China), transplanted to poly vinyl pots (height = 18 cm, top circumference = 62 cm, bottom circumference = 52 cm, d = 22 cm), and established in greenhouse in completely randomized design (four replication) for one year till the end of March, 2018. These seedlings were allowed to grow under greenhouse condition (natural light) and usual irrigation practice in order to produce healthy seedlings (Wang et al., 2014; Razaq et al., 2017). Additionally, after 15 days of establishment, all the seedlings were treated 10 g each pot with NPK fertilizer (Tarin et al., 2019). After one year; March 2018, seedlings were uprooted to determine plant fresh/dry weights and morphological parameters of roots.

Determination of physiochemical properties of soil

To determine the soil physiochemical properties, all the analysis were conducted in the Bamboo Institute, College of Forestry, Fujian Agriculture and Forestry University, China. At the start of the experiment (March, 2017), physiochemical properties of soil and all three types of BCs were assessed (*Table 1*). After one year, at the end of experiment (March, 2018), soil samples from 0-15 cm depth from each replicates were collected, mixed to produce composite samples and were sealed in clean, air-tight polythene bags. Four samples from each treatments were air-dried and then passed through a 2-mm/0.149-mm mesh to assess the physiochemical properties of soil. Soil pH (1:2.5 soil/water suspensions) was measured by using glass electrode meter as described by Tarin et al. (2019). Elemental analyzer (Thermo Scientific™, Waltham, MA, USA) was used for determination of soil Total N and C (Carbon) and then calculated as organic matter (OM), whereas for determination of total Phosphorus (TP) and available Phosphorus (AP) alkali fusion-Mo-Sb anti-colorimetry method as described by Sarfraz et al. (2019). Ammonium acetate solution was used for the measurement of extractable Potassium (ext. K) (Pansu and Gautheyrou, 2007).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1110711120

Biomass and morphological parameters

Above ground morphological parameters like plant height and basal diameters of seedlings were measured by using the ordinary measuring tape (cm) and vernier caliper (mm), respectively. Whereas for biomass determination, seedlings were uprooted from pots with intensive care to avoid any damage to the roots, washed with deionized water and similarly, for roots morphological traits, root samples were carefully taken in each treatment, using the procedure described by Guo et al. (2008). The root samples were scanned with Expression 10000XL 1.0 scanner (dpi = 400; Epson Telford, Ltd., Telford, UK). Finally, the seedlings were oven dried to constant mass at 65°C, in order to determine dry mass. Later the images of roots were analyzed by using WinRHIZO (Pro2004b) software (Instruments Regent Co., Ville de Québec, QC, Canada) in order to determine the root surface area, root volume, total root length, and average root diameter.

Statistical analysis

Data was statistically analyzed with SPSS-19 statistical software. All the data were expressed as means and standard errors (SE) with four replications. Comparisons of different means were analyzed by Duncan's multiple range tests; α 0.05 probability level. For tables and figures Origin lab 8.5 and Microsoft excels were used.

Results

Effects of biochar amendments on physiochemical properties of soil

At the final harvest, soil nutrient dynamics under different BCs amended treatments were changed (*Fig. 2*). The change in soil pH after one-year under different BCs (BB, BH, and BR) incorporated samples is shown in *Figure 2a*.

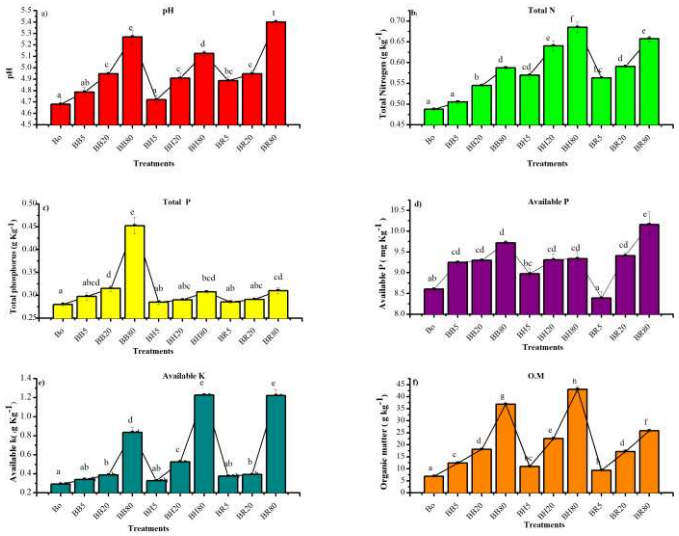

Figure 2. *Comparison of soil physiochemical properties under different biochars amendments. Treatments include; control as Bo, bamboo biochar as (BB; 5, 20 and 80 representing different doses g kg^{-1} of soil), hardwood biochar as (BH; 5, 20 and 80 representing different doses g kg^{-1} of soil), rice straw biochar as (BR; 5, 20 and 80 representing different doses g kg^{-1} of soil). Different letters indicate significant difference (P ≤ 0.05) among different treatments with error bars*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1110711120

The liming effects of BB and BR were significant for rising soil pH ($P \leq 0.05$) as compared to BH. All BCs amended soil presented higher macronutrients (NPK) concentrations compared to Bo. Available P concentrations were significantly higher under BR80 compared to all other treatments, whereas total N concentration was highest in BH80. Overall, the concentrations of macro-nutrients increased under higher doses of BCs depending upon their type. Total N, Total P, available P, extractable K, and organic matter showed significant difference than that of Bo.

Effects of biochar amendments on biomass and morphological parameters of seedling

Application of BC significantly increased the morphological parameters of the seedlings. *Figure 3* shows the complete comparison of treatments combination for above and below ground attributes.

Figure 3. *Complete view of seedlings showing the above and below ground comparison of morphological traits for all the treatments.*
Treatments include; control as Bo, bamboo biochar as (BB; 5, 20 and 80 representing different doses g kg^{-1} of soil), hardwood biochar as (BH; 5, 20 and 80 representing different doses g kg^{-1} of soil), rice straw biochar as (BR; 5, 20 and 80 representing different doses g kg^{-1} of soil)

Our results showed that BCs application increased the plant height, particularly seedlings treated with BB20, BH20 and BR20 were taller and showed significant difference than that of Bo (*Fig. 4a*). Moreover, within different BCs treatments, no significant difference was observed for seedlings basal diameter except BR80 amendments (*Fig. 4b*). Under different BC amendments, biomass of seedlings, treated with BB80, BH20, BH80, BR20, and BR80 were significantly increased than that of Bo (*Fig. 4c*). Likewise, for dry weight, seedlings treated with BB20, BB80, BR20, and BR80 showed significant differences compared to Bo (*Fig. 4d*).

Effects of biochar amendments on root morphological traits

Results from the current study suggested that BC amendment promoted the morphological traits of the roots. Under different BC types and levels, the roots morphological characteristics varied in terms of root volume, surface area, diameter, and length. BC application significantly ($P \leq 0.05$) increased root volume in all the BCs

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1110711120

treated seedlings except BH5 and BR5 as compared to Bo. For all BCs treatment combinations, highest root volume was observed in seedlings treated with BB80 and BR80 (*Fig. 5a*).

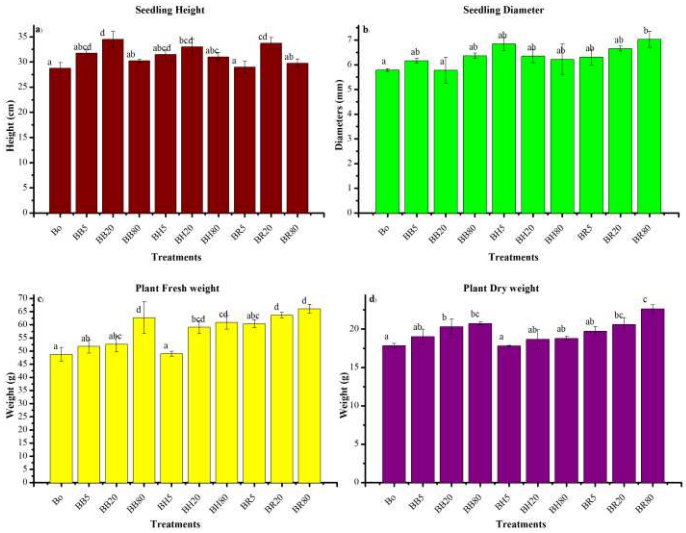

Figure 4. *Comparison of above ground parameters of seedlings treated with different biochars, a) seedling height b) seedling basal diameter, c) plant fresh weight, d) dry weight. Treatments include; control as Bo, bamboo biochar as (BB; 5, 20 and 80 representing different doses g kg^{-1} of soil), hardwood biochar as (BH; 5, 20 and 80 representing different doses g kg^{-1} of soil), rice straw biochar as (BR; 5, 20 and 80 representing different doses g kg^{-1} of soil). Different letters indicate significant difference ($P \leq 0.05$) among different treatments with error bars*

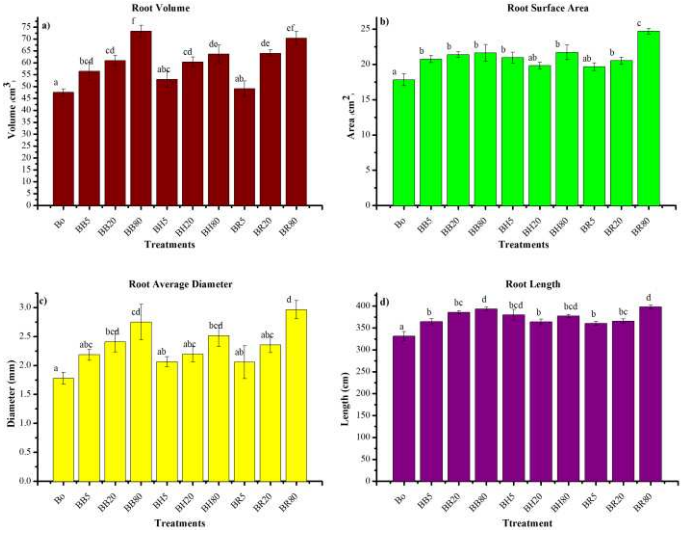

Figure 5. *Comparison of root morphological features among all BC treatments; a) Root volume (cm^3), b) Root surface area (cm^2), c) Root average diameter (mm), d) Root length (cm). Treatments include; control as Bo, bamboo biochar as (BB; 5, 20 and 80 representing different doses g Kg^{-1} of soil), hardwood biochar as (BH; 5, 20 and 80 representing different doses g Kg^{-1} of soil), rice straw biochar as (BR; 5, 20 and 80 representing different doses g Kg^{-1} of soil) Different letters indicate significant difference ($P \leq 0.05$) among different treatments with error bars*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1110711120

Root surface area of the seedlings was not much influenced within the different BC ammendments, although there was significant difference among the seedlings treated with Bo, BH20 and BR5 compared to all other treatment combination with maximum value in BR80 (*Fig. 5b*). For average diameter, seedlings treated with BB5, BH5, BH20, BR5, and BR20 had no significant difference than that of Bo and under BR80 amendments, seedlings had the highest roots diameter followed by BB80 with significant difference compared to Bo (*Fig. 5c*). Similarly, BC treated seedlings significantly increased the root length compared to Bo but between different BCs treatment combinations, there was no significant difference, except BB80 and BR80 (*Fig. 5d*).

Discussion

Effects of biochars amendments on physiochemical properties of soil

Various studies have demonstrated that BC application into the soil can promotes the plant growth by improving physiochemical properties of soil like essential nutrients (NPK), pH and cation exchange capacity (Lehmann et al., 2011). Therefore, the responses of root traits to BC incorporated soil depend on soil type and BC (Macdonald et al., 2014). In addition, BC often applied with fertilizer to the soil has interactively regulated the root growth of the plants (Alburquerque et al., 2015). The incorporation of all three BCs increased soil pH, however the rise in pH was evident under higher dose of BB and BR (*Fig. 2a*) because both of these two BCs have higher pH compared to BH (*Table 1*). Alkaline nature of BCs (BB and BR) to soil has resulted increase in pH. Our results are in the line with the previous findings where incorporation of alkaline BC with higher dose raised the soil pH (Ishii and Kadoya, 1994). Moreover, the liming effect of BR was generally greater than that of other two types of BCs (BB and BH); our findings are in the agreement with the previous study on acidic soil (Wang et al., 2009). Therefore, the pH of BC must be taken into account in order to control liming effects and consequently can be applied to acidic soil to raise the soil pH. In the current study the soil pH of Bo was 4.68, consequently, lower soil pH (highly acidic) always reduces the cation exchange capacity and also the bio-availability of nutrients (Verheijen et al., 2010). The rise in soil pH from 4.68 to 5.27 and 5.40 under BB80 and BR80, respectively altered soil physiochemical properties (*Fig. 2a*) which is the agreement with numerous studies (Vaccari et al., 2011; Yuan and Xu, 2011). Our results were further justified by Yuan and Xu (2011) that incorporation of BC not ameliorates soil acidity and but also improves the soil fertility. The total Nitrogen (TN) contents were highest in BH80 compared to other types of BCs (BB and BR). A potential mechanism for increased Nitrogen retention in soils mixed with BCs is the increased nitrates recycling because of higher availability of C (Verheijen et al., 2010). The increase in SOM and total N following BC application is similar to previous findings where soil C and N were increased because of application of different types of BCs (Stavi and Lal, 2013; Angst et al., 2014). Consequently, under BB80 and BR80 treatments, greater values were observed for available P compared to BH80 (*Fig. 3d*). Nevertheless, evidence suggests that BC can increase the nitrification if applied to acidic soils (Ball et al., 2010; Nelson et al., 2011). On the contrary, as described by few researchers that incorporation of BC to agricultural system, may decrease soil N just after addition, because N demand for agriculture crops has always been higher compared to forests plants (Tammeorg et al., 2012). At the start of our experiment

DOI: http://dx.doi.org/10.15666/aeer/1705_1110711120

(March, 2017) for better effect of BCs, we had applied minimal dose (10 g each pot) of NPK fertilizer to all treatments including Bo. In the view of this, earlier BCs studies have demonstrated that application of BC combined with fertilizers have been more effective for attaining better growth (Sarfraz et al., 2017). Besides, increased N retention under rice straw BC experiment is similar to our findings (Noguera et al., 2010). In our experiment BB80 and BR80 treatments, soil pH was relatively higher than that of other treatment combinations, rise in soil pH resulting availability of P, because pH of BH under three levels (BH5, BH20, and BH80) was not much increased. Our these findings are in the line with the previous findings, because BCs particles not only holds the soil N in the form of nitrates, but also supply P to the soil and plant but their affect varies under different feedstocks (Prendergast-Miller et al., 2014). Additionally BC incorporation increased the extractable potassium (Ext. K) under BC amendments because BC is a soil conditioner which might act like a fertilizer and it contains ash which in return adds nutrients like Potassium (K), Magnesium (Mg), and Calcium (Ca) to soil which in response raises the soil pH and provide essential nutrients to soil for better growth (Agegnehu et al., 2015).

Effects of biochars amendments on morphology and biomass

Various studies have confirmed that BC addition to soil increases the seedlings and roots growth both under natural and nursery conditions (Chan et al., 2008a; Noguera et al., 2010). Growth parameters of *F. hodginsii* seedlings under BC amended soils were improved as compared to Bo (*Fig. 3*) which is consistent with previous findings (Ali et al., 2017; Tayyab et al., 2018). Strong positive responses to BC additions were observed in biomass, resulting increase in plant fresh weight and height of (*Fig. 4a and c*), which is agreement with the previous studies (Caroline et al., 2016; Seehausen et al., 2017). Because BC is a soil conditioner which might act like a fertilizer and provide nutrients to soil for plant growth (Agegnehu et al., 2015). The availability of primary nutrients to soil for plants (Sarfraz et al., 2017) with improved water holding capacity is attributed to the BC structure (Jeffery et al., 2011). Better water retention is the consequence of BC amended soil, which increases the water use efficiency of a plant, thus enhancing plant height and fresh/dry weight (Liang et al., 2006; Uzoma et al., 2011; Younis et al., 2015). In general, seedling growth parameters (seedling height, Biomass, root traits) varied only within the BC types and with the highest doses. The results obtained from the current study suggested that BC application increased the above and below ground morphological attributes (*Figs. 4 and 5*). Although basic soil in this study was strongly acidic (pH 4.68), but the slight increase in pH by applying alkaline BCs (BB and BR) has resulted improvement in nutrient availability (or nutrient use efficiency) with successive growth which is in the line with the findings of Robertson et al. (2012). BCs application particularly under BB and BR (20 and 80 g kg^{-1} of soil) increased the root volume, surface area, total root length, and average root diameter compared to Bo (*Fig. 5*). However, under BH (5, 20, 80 g kg^{-1}) the root morphological traits had greater or no significant difference compared to Bo. Previously for conifers seedling, there is no research data to compare the BC effects on root traits but our findings are attributed to change in the physiochemical properties of soil. Under higher dose of BCs (20 and 80 g kg^{-1} of soil) the improved roots morphological traits are consistent with previous studies (Razaq et al., 2017). Similar to our findings, Guo et al. (2008) reported that BC incorporation to acidic soil has been known to influence the root surface area, length, and volume of the seedlings in acidic red soil. In another study by Ishii and Kadoya

DOI: http://dx.doi.org/10.15666/aeer/1705_1110711120

(1994) who demonstrated that application of BC increases the plant and root biomass. Our these results were further justified by Yang et al. (2015) who confirmed at the seedling stage, incorporation of BC improves the root morphological traits because of improved water holding capacity and soil physiochemical properties ultimately effects the root growth (Piccolo et al., 1996). Even though there are only few other comparable studies like, review by Lehmann et al. (2011) has demonstrated that BC has positive effect on root growth. BC application has significant effects on morphological traits and functioning of roots because its particles contact the roots directly for uptake of nutrients. The increased root length in our experiment (*Fig. 5d*) suggests that BC application increases the plant rhizosphere enabling plants to absorb water and nutrients freely (Prendergast-Miller et al., 2014). BC addition to soil, also enhances the microbe's community, reduces soil pathogen, and boosts plant defenses which consequently improve the seedlings health with minimal damage to the environment (Elad et al., 2010). Overall, these findings demonstrate the potential of BC application for improved seedling growth.

Conclusion

Our results confirmed that positive response of *F. hodginsii* biomass and root growth was attributed to BC amendment at seedling stage because it can serve as a direct nutrient supply through addition of soluble P and biochar-N retention (Prendergast-Miller et al., 2014). But the positive effects varied under different level and BC feedstock used. The seedlings treated with BR80, BB80, and BH80 attained 36%, 29%, and 25% biomass, respectively compared to Bo. Our these findings are in consistent with previous studies suggesting increase in biomass of woody plants summarized by a meta-analysis with an average 41% increase in biomass (Thomas and Gale, 2015). This is the first report on the effect of BC application on *F. hodginsii* morphological traits of root. Biochar application improved the physiochemical properties of soil, biomass and roots morphological attributes at seedling stage in greenhouse experiment. The current experiment was focused on the influence of different BCs application on *F. hodginsii* root traits at the early stage in a pot experiment. It is suggested that further field studies are needed to assess the complete effect of BC application on root system changes, soil microbial and nutrients dynamics.

(Received 4th Apr 2019; accepted 11th Jul 2019)

Abstract. The main aim of this research work is to assess the performance of the various mass transfer-based method with respect to standard FAO56-PM. Daily meteorological data from 1979 to 2018 has been used to compute reference evapotranspiration (ETo). The climatic data from 1979 to 2006 were used for the development of the calibrated equations and data from 2007 to 2018 were applied for validation purpose. The evaluated, calibrated and further validation of calibrated models were compared using statistical tools in order to ranked the models effectiveness using Global Performance Indicator (GPI) where higher GPI value shows better model. The models were then arranged using GPI and it was found that proposed model resulted with best GPI value of 5.02, 2.85 and 5.19 during evaluation, calibration and validation respectively followed by Albrecht model. The results of this study could be used by the water management system, crop cultivators, crop advisors, researchers from research centres. Moreover, it is beneficial for the decision maker in the vast field of agriculture, hydrology and environment**.** The calibration and validation of different ETo equations tend to increase their performance. Thus, the validated evapotranspiration model that used less climatic parameters can predict the ETo condition accurately for Asir region.
Keywords: *water management, calibration, validation, semi-arid condition, reference evapotranspiration model, mass transfer equation*

Introduction

Precise evaluation of reference evapotranspiration (ETo) plays a vital role for water resource management, efficient irrigation management, crop production, environmental assessment (Estevez et al., 2016). The reference evapotranspiration can be measured directly by lysimeter (Xu et al., 2013). However, measurements by lysimeter proved to be tedious work (Irmak et al., 2003). Consequently, Food and Agriculture Organization of the United Nations (FAO) recommends the standard Penman-Monteith FAO-56 PM, which was acknowledged in various parts of the world (Allen et al., 1998). Notwithstanding the aforementioned technique have shortcoming under certain unique conditions (Widmoser, 2009); however, it is still considered the standard technique for computing evapotranspiration for a reference surface (Xystrakis and Matzarakis, 2010;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1112111141

Tabari et al., 2013), i.e., well-watered, actively growing grass of a height of 0.12 m with an albedo of 0.23 that uniformly covers the area and has a surface resistance of 70 s/m (Allen et al., 1998). The only shortcoming in FAO56-PM is that it requires various climatic data which are not easily available or measured. Hence keeping this shortcoming in mind many researchers have developed reference evapotranspiration equation which requires lesser input parameters that are categorized as mass transfer-, radiation-, temperature-, and pan evaporation-based methods (Sentelhas et al., 2010). However, such empirical equations need to be rectified by calibration against lysimetric or standard FAO56-PM technique at different regions. The researchers have performed various studies for simplified evapotranspiration equations against the FAO56-PM technique around the world, including Iran (Tabari et al., 2013), Southern Greece (Xystrakis and Matzarakis, 2010), Canada (Sentelhas et al., 2010), Tunisia (Jabloun and Sahli, 2008), Bulgaria (Popova et al., 2006), the Syria, the USA, Netherlands, the Philippines and Spain (Stockle et al., 2004). The past studies in saudi Arabia were basically assessed different ETo models against the FAO-56 Penman Monteith model based on the Central and Eastern region of Saudi Arabia (Salih and Sendil, 1984; Abo-Ghobar and Mohammad, 1995; Al-Omran et al., 2004; Elnesr et al., 2010; Islam et al.,2019). However very less study have been done in regards with evaluation calibration and validation of mass transfer equation. The mass transfer-based models are based on the principle of Dalton's law and employ eddy motion transfer of water vapor from an evaporating surface to the atmosphere (Singh and Xu, 2002; Tabari et al., 2013), the performance accuracy of these models reduces if aerodynamic effects have lower value as discussed by (Kiefer et al., 2017). These results provide significantly accurate result in many cases (Jensen, 1974). However, air temperature and wind speed have been measured at inconsistent heights, resulting different equations with similar or identical structure. So, the outcome resulting from input climatic condition varies from one location and or height to another and will be difficult to do with certainty (Helfrich, 1982). The mass transfer-based equation as compared to Standard FAO56-PM model have rarely been used in Southern region of Saudi Arabia. Hence, it is utmost important to carry out research based on evaluating the performance of various mass transfer reference evapotranspiration models to determine the best, or a relatively appropriate model for estimating the ETo in Semi-arid region. This can aid in recognizing the suitable method that can be used as an alternative equation to standard FAO56-PM method. The finding of the research work is helpful in reducing the error during the evapotranspiration computation. Moreover, the best-evaluated model equation the for evapotranspiration could assist in computing the evapotranspiration in future in the field of water management system, climate change studies, irrigation and water resource planning.

Study area

Site description

The research work deals with Abha mountainous region of Aseer province, Kingdom of Saudi Arabia having an area of 370 km^2 located between the latitude of 18°10′12.39″N and 18°23′33.05″N and longitude of 42°21′41.58″E and 42°39′36.09″E as shown in *Figure 1*. The zone is prone to heavy rainfall as compared to other parts of Saudi Arabia. The elevation varies from 1951 to 2991 m (msl) with average precipitation of 355 mm which mainly occurs between June and October.

Data availibility

In this research work, weather parameters were collected from Abha meteorological weather station for the period between 1979 and 2018 which includes wind velocity, mean temperature, maximum and minimum temperature, mean relative humidity and solar radiation as well. The data collected were checked (Arnold and Allen, 1996). The weather data are shown in *Table 1*.

Methodology

In this research work ETo were estimated by nine mass transfer reference evapotranspiration model and one proposed model based on available climatic data. Moreover, the reference ETo values were estimated using standardized FAO56-PM. The values evaluated from different mass transfer based equations were compared with the reference value obtained from FAO56-PM for the period between 1979 and 2018. Further, all ten equations were calibrated for the period between 1979 and 2006 then validation of calibrated equation for the period between 2007 and 2018 with respect to FAO56-PM model. The performance of equations was evaluated by utilizing ten statistical finally based on evaluation criteria the global performance index has been computed and the ranking were done in order to get most promising model which can be used alternative to FAO56-PM model. The flowchart (*Fig. 2*) described the stepwise procedure to compute most promising model among nine model to be used as alternate of FAO56-PM model.

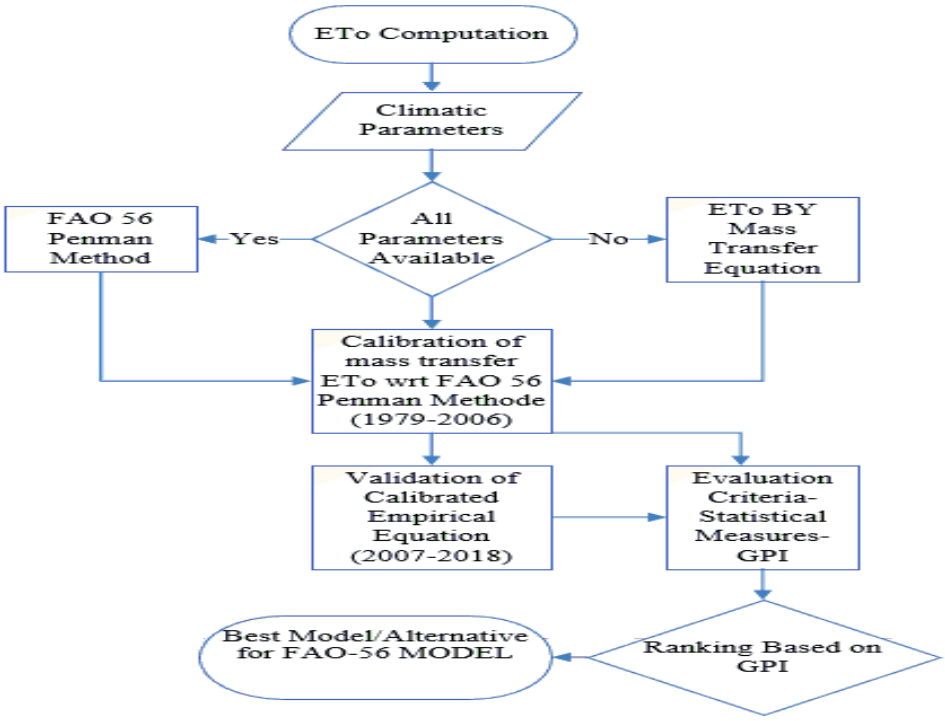

Figure 2. *Flowchart showing stepwise computation of ETo*

Reference evapotranspiration (ETo) model

This study work aims to analyze trends of the monthly ETo calculated by the Standard FAO56-PM model as given by *equation 1* in the Asir region, Kingdom of Saudi Arabia. However, the use of the FAO56-PM is restrained due to limited climatic input parameters; hence, the alternative solution is to use various mass transfer models. In this research work nine-mass transfer and one proposed alternative method for estimating ETo have been chosen for this study. The selection of methods was based on their wide acceptance, simple calculation procedure and applicability in present conditions. The models are described as *equations 2–10*.

FAO Penman-Monteith (Allen et al., 1998)

$$ETo = \frac{0.408\times\Delta\times(Rn-G)+\gamma\times\left(\frac{900}{T+273}\right)\times u_2\times(e_s-e_a)}{\Delta+\gamma\times(1+0.34u_2)} \quad \text{(Eq.1)}$$

Mass transfer based ETo model

Dalton (1802)

$$ETo = (0.3648 + 0.07223u_2) \times (e_s - e_a) \quad \text{(Eq.2)}$$

Trabert (1896)

$$ETo = 0.408 \times 0.3075 \times \sqrt{u_2} \times (e_s - e_a) \quad \text{(Eq.3)}$$

Meyer (1926)

$$ETo = (0.375 + 0.05026u_2) \times (e_s - e_a) \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1112111141

Rohwer (1931)

$$ETo = 0.44(1 + 0.27u_2) \times (e_s - e_a) \quad \text{(Eq.5)}$$

Penman (1948)

$$ETo = 0.35 \times (1 + 0.24u_2) \times (e_s - e_a) \quad \text{(Eq.6)}$$

Albrecht (1950)

$$ETo = (0.1005 + 0.297u_2) \times (e_s - e_a) \quad \text{(Eq.7)}$$

Brockamp (1963)

$$ETo = (0.543u_2^{0.456}) \times (e_s - e_a) \quad \text{(Eq.8)}$$

WMO (1966)

$$ETo = (0.1298 + 0.0934u_2) \times (e_s - e_a) \quad \text{(Eq.9)}$$

Mahringer (1970)

$$ETo = 0.15072 \times \sqrt{3.6u_2} \times (e_s - e_a) \quad \text{(Eq.10)}$$

where ETo = reference evapotranspiration (mm day^{-1}); Rn = net radiation at the crop surface (MJm^{-2} day^{-1}); G = soil heat flux density (MJm^{-2} day^{-1})) that is taken as zero for daily ETo estimation; u_2 = wind speed at 2 m height (m s^{-1}); e_s = saturation vapor pressure (kPa); e_a = actual vapor pressure (kPa); T = temperature at 2 m height (°C); (e_s–e_a) = vapor pressure deficit (kPa); Δ = slope of vapor pressure curve (kPa °C^{-1}); and γ = psychrometric constant (kPa °C^{-1}); T_{max} = Maximum Temperature (°C); T_{min} = Minimum Temperature (°C); T_{mean} = Mean Temperature (°C); RH_{mean} = Mean Relative Humidity (%); RH_{max} = Maximum Relative Humidity (%); RH_{min} = Minimum Relative Humidity (%)

Model development and validation

The fact that leads to model development in study area is that the previously established models for reference evapotranspiration estimation were reliable in the areas for which they were developed. However, when applied in other region it leads to larger errors. To overcome this comparative study of reference evapotranspiration model with standard FAO56-PM or by measuring instrument was performed. The basic idea of comparison was to judge which models gives better result for specific area of interest moreover it allows comparative study of all developed model for same meteorological data and for the same condition and period of time. The main shortcoming of these developed models were they have limited area of reliability as their variables involved in the equation may not be easily available and sometimes it is difficult to compare with one another due to region specific model variables. Recognizing the above concerns, an attempt is made in this research work to analyse various existing mass transfer-based method and to develop new model for Abha Asir region of Saudi Arabia. This is because the mass-transfer approaches generally are easiest to use and often are the only practical method available. The model hence developed must be simple in nature having easily measurable variable comprises of most influencing factors with acceptable accuracy. The proposed mass-transfer (aerodynamic) based methods utilize the concept of eddy motion transfer of water vapour from an evaporating surface to the atmosphere. All such methods are based on Dalton's law. It is evident that evapotranspiration

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1112111141

depends on heat energy and vapour pressure gradient and also depend on other factors, such as geological locations, seasons, etc.

The generalized expression which led to the formulation of proposed equation is as follows (*Eq. 11*):

$$ETo = c(e_s - e_a) = f(u)(e_s - e_a) \quad \text{(Eq.11)}$$

where ETo is reference evapotranspiration, e_s is the saturation vapour pressure, e_a is the vapour pressure in the air and C is aerodynamic conductance. The term e_a is also equal to the saturation vapour pressure at the dew point temperature it is normally assumed to be dependent on wind speed. Therefore, *equation 11* is expressed as the wind function f(u). This function depends on, among other factors, the observational heights of the wind speed and vapour pressure measurements. Although the two heights need not be the same, the same experimental layout must be used for a particular value of the function. Accuracy of the proposed model was measured with statistical indicators as described by Martins et al. (2017) based on regression analysis as given by *Equation 12:*

$$P_i(y) = a0 + b0O_i(x) \quad \text{(Eq.12)}$$

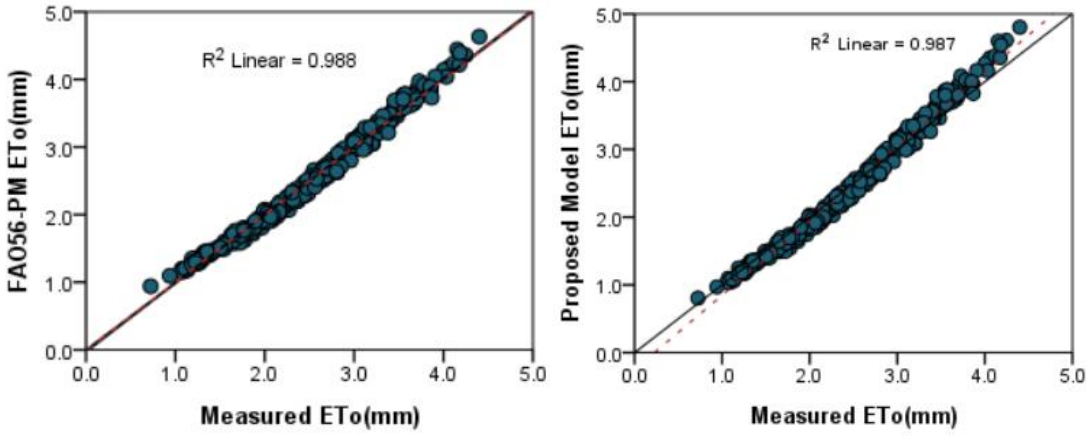
The regression equation (Eq. 12) represents FAO56-PM computed with observed data, Oi (x), and daily ETo computed with estimated variables, Pi (y). A value of b0 = 1.0 indicates that the fitted line is y = x, so that Oi and Pi are similar. A value of b0 > 1.0 suggests over-estimation and b0 < 1.0 under-estimation. The determination coefficient (R^2) regression between Oi and Pi showing value closer to one indicate good fit. Moreover the RMSE Value should also be checked for accuracy of result. Based on regression analysis new proposed equation has been formulated which is expressed as follows:

$$ETo = (0.37 + 0.72u_2) \times (e_s - e_a) \quad \text{(Eq.13)}$$

Although FAO 56 PM, found to work well in numerous locations if the required data are available. However it requires measurements of temperature, relative humidity, wind speed, and solar radiation. This data demand is the main constraint on its use in locations where climate data are limited. In high mountain environments, such as the Abha Asir region, Saudi Arabia, meteorological monitoring is limited and high-quality data are scarce. Moreover measurements of relative humidity by electronic sensors are commonly plagued by hysteresis, nonlinearity and calibration errors (Allen, 1996). In order to make the study more realistic the estimated result of FAO56-PM were compared with reference evapotranspiration value measured from Davis Vantage Pro2 weather stations installed in Abha region. The instrument is affordable, accurate, durable, and easy to use and moreover real-time data for weather conditions can be easily available. It uses air temperature, relative humidity, average wind speed, and solar radiation data to estimate ETo, which is calculated once an hour. ETo requires the optional solar radiation sensor. Also the measured values from instrument were compared with proposed equation. Validation of FAO56-PM and proposed model with measured value as represented by *Figure 3a-b*. After evaluating FAO56-PM with measure ETo the RMSE and MBE value found to be 0.154 and 0.01 mm while coefficient of determination found to be 0.988 with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1112111141

slope and intercept of 1.01 and -0.03, respectively. On the other hand while evaluating proposed model ETo with measure ETo the RMSE and MBE value found to be 0.178 and -0.01 mm while coefficient of determination found to be 0.987 with slope and intercept of 1.09 and -0.249 respectively.



(a) (b)

Figure 3. *Validation of standard FAO56-PM ETo and proposed model ETo with measured ETo*

Calibration and validation of ET_O equations

The linear regression analysis has been performed to calibrate and validate the mass transfer empirical models against the FAO56 PM model (Allen et al., 1998). The specific expression is shown in the below equation:

$$ET_{FA056-PM} = a.ET_{EMP} + b \quad \text{(Eq.14)}$$

where $ET_{FAO56\ PM}$ shows the daily reference evapotranspiration estimated by the standard FAO56-PM model and ET_{EMP} shows the ten mass transfer models respectively. The constant a and b represent calibrated empirical coefficients in the equation. In this research work, the climatic data from 1979 to 2006 were used for the development of the calibrated equations and data from 2007 to 2018 were applied for validation purpose. This partitioning is important as more data is required for the models' training. The main objective of calibrating ETo was to make the slope equally inclined to both x and y axis and intercept reaching zero. For this purpose, a linear regression was done in between Standard PM-ETo and values were obtained through the nine ETo equations. To accomplish this, calibration coefficients need to be determined which can be obtained by applying product operation to the slope of a regression line between the FAO56-PM-ETo and ETo equation by inversing the slope. This will get a new slope so that the new equation will be closer to unity. Moreover, opposite sign value of the intercept was added to get a new intercept close to zero for new regression equation. The calibration and validation of ETo estimates were performed as suggested by (Xu et al., 2013)

Evaluation criteria and global performance index (GPI)

The GPI is computed by using ten statistical measure such as Mean Absolute Error(MAE), Root Mean Square Error (RMSE), Mean Absolute Relative Error (MARE),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1112111141

Uncertainty at 95% (U95), Root mean squared relative error (RMSRE), Relative Root Mean Square Error (RRMSE), Mean Bias Error (MBE), Coefficient of determination (R^2), Maximum Absolute Relative Error (erMax) and t-statistics (Ali et al., 2019). For Coefficient of determination (R^2) the highest value (ideally equal to 1) is preferable, while for all other statistical errors ideally a value of zero is preferred. Despotovic et al. (2015) proposed the GPI by scaling the values of statistical tools in between 0 and 1, followed by subtracting the scaled values of error indicators from the corresponding medians and finally summing up the differences so obtained using the weight factors. Mathematically, for the i^{th} model,

$$GPI_i = \sum_{j=1}^{10} \alpha_j \left(\tilde{y}_j - \tilde{y}_{ij}\right) \quad \text{(Eq.15)}$$

where, α_j have a value of + 1 for statistical errors having a recommended value of 0 and a value of -1 for statistical errors that have a recommended high value of 1 (e.g. R). $\tilde{y}_j$ and $\tilde{y}_{ij}$ are the median and scaled values, respectively.

Willmott and Matsuura (2005) used MAE as statistical measure as shown by Equation 16:

Mean absolute error (MAE)

$$MAE = \frac{1}{n}\sum_{i=1}^{n}\left|ET_{O,Mi} - ET_{o,FAO56-PM}\right| \quad \text{(Eq.16)}$$

Root mean square error

$$RMSE = \left[\frac{1}{n}\sum_{i=1}^{n}\left(ET_{O,Mi} - ET_{o,FAO56-PM}\right)^2\right]^{\frac{1}{2}} \quad \text{(Eq.17)}$$

Mean absolute relative error (MARE)

$$MARE = \frac{1}{n}\sum_{i=1}^{n}\left|\frac{ET_{O,Mi} - ET_{o,FAO56-PM}}{ET_{O,Mi}}\right| \quad \text{(Eq.18)}$$

Behar et al. (2015) and Gueymard (2014) applied U_{95} in modelling of solar radiation as given by *Equation 19:*

Uncertainty at 95%

$$U_{95} = 1.96(SD^2 + RMSE^2)^{\frac{1}{2}} \quad \text{(Eq.19)}$$

Root mean squared relative error

$$RMSRE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(\frac{ET_{O,Mi} - ET_{o,FAO56-PM}}{ET_{O,Mi}}\right)^2} \quad \text{(Eq.20)}$$

Li et al. (2013) applied RRMSE as a statistical performance measure in the modelling of global solar radiation as given by *Equation 21:*

Relative root mean square error

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1112111141

$$RRMSE = 100 \times \frac{\sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(ET_{O,Mi} - ET_{o,FAO56-PM}\right)^2}}{\sum_{i=1}^{n} ET_{O,Mi}} \quad \text{(Eq.21)}$$

Mean bias error

$$MBE = \frac{1}{n}\sum_{i=1}^{n}\left(ET_{O,Mi} - ET_{o,FAO56-PM}\right) \quad \text{(Eq.22)}$$

Correlation coefficient

$$R^2 = 1 - \frac{\sum_{i=1}^{n}\left(ET_{O,Mi} - ET_{o,FAO56-PM}\right)^2}{\sum_{i=1}^{n}\left(ET_{O,Mi} - ET_{O,Mi_{av}}\right)^2} \quad \text{(Eq.23)}$$

Maximum absolute relative error

$$erMAX = max\left(\left|\frac{ET_{O,Mi} - ET_{o,FAO56-PM}}{ET_{O,Mi}}\right|\right) \quad \text{(Eq.24)}$$

Stone (1993) and Mulaudzi et al. (2015) t-statistics in the evaluation of solar radiation t-statistics

$$t = \left[\frac{(n-1)MBE^2}{RMSE^2 - MBE^2}\right]^{\frac{1}{2}} \quad \text{(Eq.25)}$$

$ET_{O,Mi}$ = reference evapotranspiration by ith model; $ET_{o,FAO56-PM}$ = reference evapotranspiration by standard model 1; SD = standard deviation.

Results

The comparative study of all reference evapotranspiration equation with Standard Penman-Monteith equation is shown in *Figure 4a-j.* The plot clearly stated that the reference evapotranspiration value from all the ten equations has a high correlation with the FAO56-PM with the coefficient of determination R^2 range from 0.89 to 0.96 The highest correlation was shown by proposed model while the lowest correlation by Meyer model. The best fit of a model is measured by the linear regression line slope close to unity and the intercept to zero. The variation of slope and intercept for all models is shown in *Table 2*. While evaluating the performance of mass transfer equation against Standard FAO56-PM, the best estimates as shown in *Table 3* were obtained by proposed equation with $R^2 = 0.96$, MAE = 0.2 mm/day; RMSE = 0.23 mm/day; MARE = 0.1; U95 = 1.05%; RMSRE = 0.12; RRMSE = 0.09; MBE = 0.2 mm/day; erMax = 0.23; t-statistic = 18.47 mm/day. Moreover the GPA value shows highest score. Similarly worst outcome was shown by Trabert model. The computed GPI value during evaluation, calibration and validating the calibrated model are shown in *Tables 4–6*. The comparative study of global performance index during evaluation is shown in *Figure 5*.

The main objective of the model calibration is to improve the performance of all equations. The computed result from the year 1979 to 2006 was used to calibrate the evapotranspiration equation. From the result for calibrated model (*Fig. 6a-j*), it can be observed that the coefficient for determination improved substantially with values of R^2 ranges from 0.9 to 0.987 whereby high correlation was shown by proposed model and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1112111141

lower value by Meyer method. While evaluating the performance of mass transfer equation against standard FAO56-PM after calibration the best estimates were obtained by proposed equation with high coefficient of determination $R^2 = 0.987$, MAE = 0.07 mm/day; RMSE = 0.09 mm/day; MARE = 0.03; U95 = 0.85%; RMSRE = 0.04; RRMSE = 0.04; MBE = 0.07 mm/day; erMax = 0.1; t-statistic = 13.48 mm/day as shown by *Table 3*. Moreover, the GPA Value shows that proposed highest score as shown by *Table 5*. Similarly, worst outcome was shown by Meyer model.

Ten calibrated evapotranspiration equations have been validated for the period of 2007–2018 in order to show which calibrated equation perform well and can be further employed as an alternative to Standard FAO Penman Monteith model. From output of validation of calibrated equation (*Fig. 7a-i*), it can be observed that the coefficient of

DOI: http://dx.doi.org/10.15666/aeer/1705_1112111141

determination ranges from 0.87 to 0.92 with high correlation shown by Proposed model and lower value by Meyer model. While evaluating the performance of mass transfer equation against Standard FAO56-PM during validation of calibrated equation, the best estimates were obtained by proposed equation with high determination coefficient (R^2 = 0.92; MAE = 0.19 mm/day; MSE = 0.09 mm/day; MARE = 0.03; U95 = 0.85; RMSRE = 0.04; RRMSE = 0.04; MBE = 0.07 mm/day; erMax = 0.1; t-Statistics = 13.48 mm/day as shown by *Table 3*. Moreover, the GPA Value shows highest score as shown by *Table 6*. Similarly, worst outcome was shown by Meyer model.

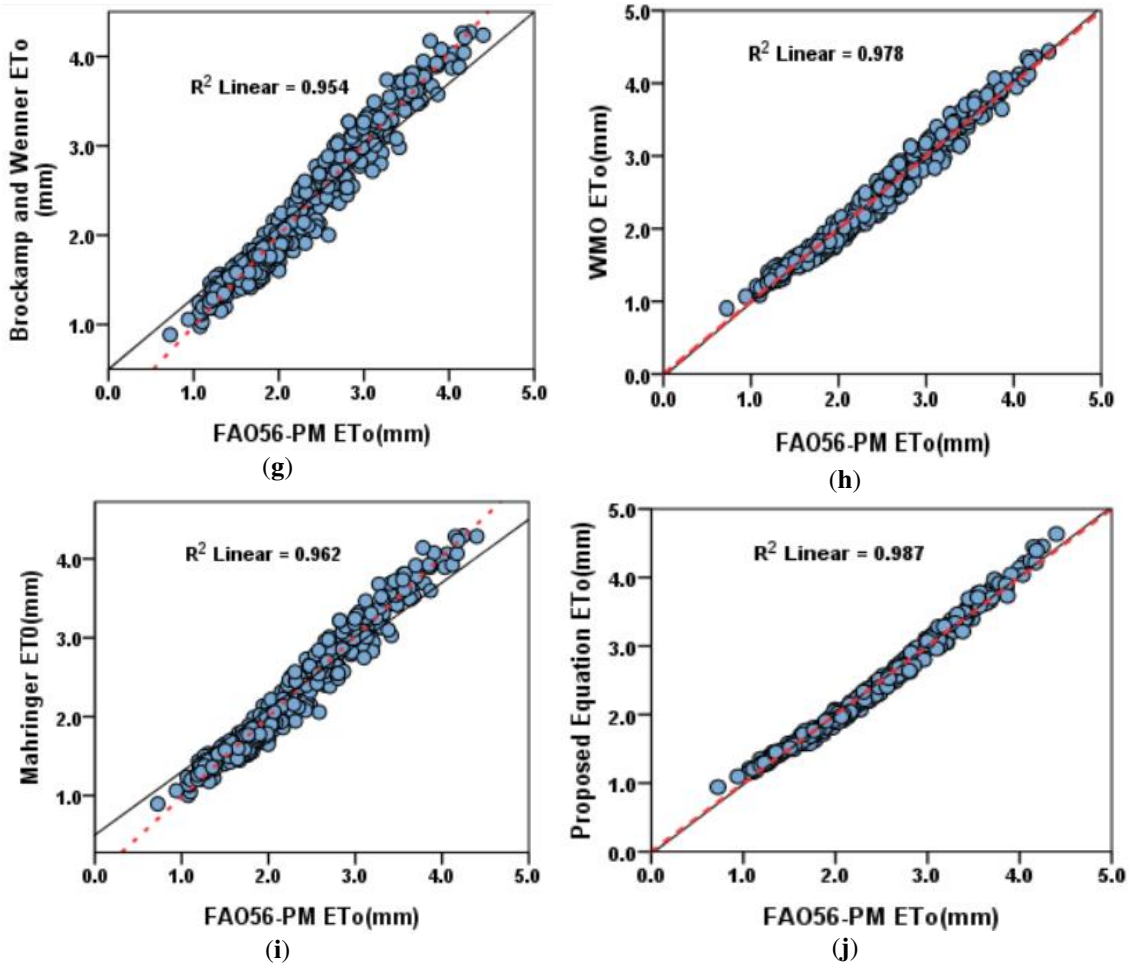

Figure 6. *Relationship between the calibrated daily ETo estimates of each method versus the FAO56-PM at Asir region for the 1979-2006 period*

Discussion

Different ETo models were used around the world to compute the reference evapotranspiration by using various climatic parameters such as mean temperature (Tm), relative humidity (RH) solar radiation (Rs) and wind speed (u)). FAO56-PM model is the most accurate model for estimating the ETo over the past few decades. But due to the constraint of limited climatic parameters, alternative equation has to be found out. Thus, to find an alternative technique of accurate prediction of ETo under climatic condition, the performance of the nine mass models and one proposed model were evaluated against the FAO56-PM model by using the ten common statistical approaches. Additionally, a linear regression model was adopted to calibrate and validate the performance of the empirical models during the 1979–2006 and 2007–2018 time periods respectively. The result evaluated from 1979 to 2018 showed that the proposed mass transfer method performed better without calibration with the highest coefficient of determination ($R^2 = 0.96$). The statistical output showed that the proposed model performed better as compared to the other model. The models are calibrated similar to the studies of Irmak et al. (2003) and Xu and Singh (2001). Valipour (2015) indicated overestimation of ETo by mass transfer-based equations, compared to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1112111141

Penman-Monteith model similar to the results reported by Winter et al. (1995). The Penman equation was the best performing equation among mass transfer equations across 15 provinces in Iran with the least ETo overestimate of 0.03 mm/day as the Papadakis equation (Valipour, 2015). The Trabert and Mahringer equations performed relatively well under the sahelian climatic conditions as reported by Djaman et al. (2015). Tabari et al. (2013) reported that Trabert and Mahringer equations underestimated ETo with average error of 26% and 31%, respectively in Iran while (Djaman et al., 2015) reported average ETo underestimation of 16% and 31% at Ndiaye (coastal area) and at Fanaye (inland area) in the Senegal River Valley and Delta, respectively. Adversely, poor performance of the Mahringer equation was reported in Poland (Bogawski and Bednorz, 2014). Singh and Xu (2002) indicated reasonable performance of the Meyer, Dalton, and Rohwer equation for free water evaporation estimation from four weather stations in north-western Ontario, Canada. The results of this study showed the specificity of each ETo equation and this might have been due to the sensitivity of the models to the climatic variables used in each model (Valipour, 2015). The performance of mass transfer empirical methods was evaluated against FAO56-PM method owing to its, rigorousness, comprehensiveness as from the work of several researchers (e.g. Ali and Shui, 2009; Tabari et al., 2013). After calibrating the empirical equation from (1979-2006), it was observed that there was a remarkable improvement in the performance of these nine equations. Additionally, the findings revealed that the calibration improved the reliability and consistency of different ET_0 equations. The correlation value significantly increased. Moreover, the statistical measures such as RMSE, SEE, MBE and PE significantly reduced for all the models.

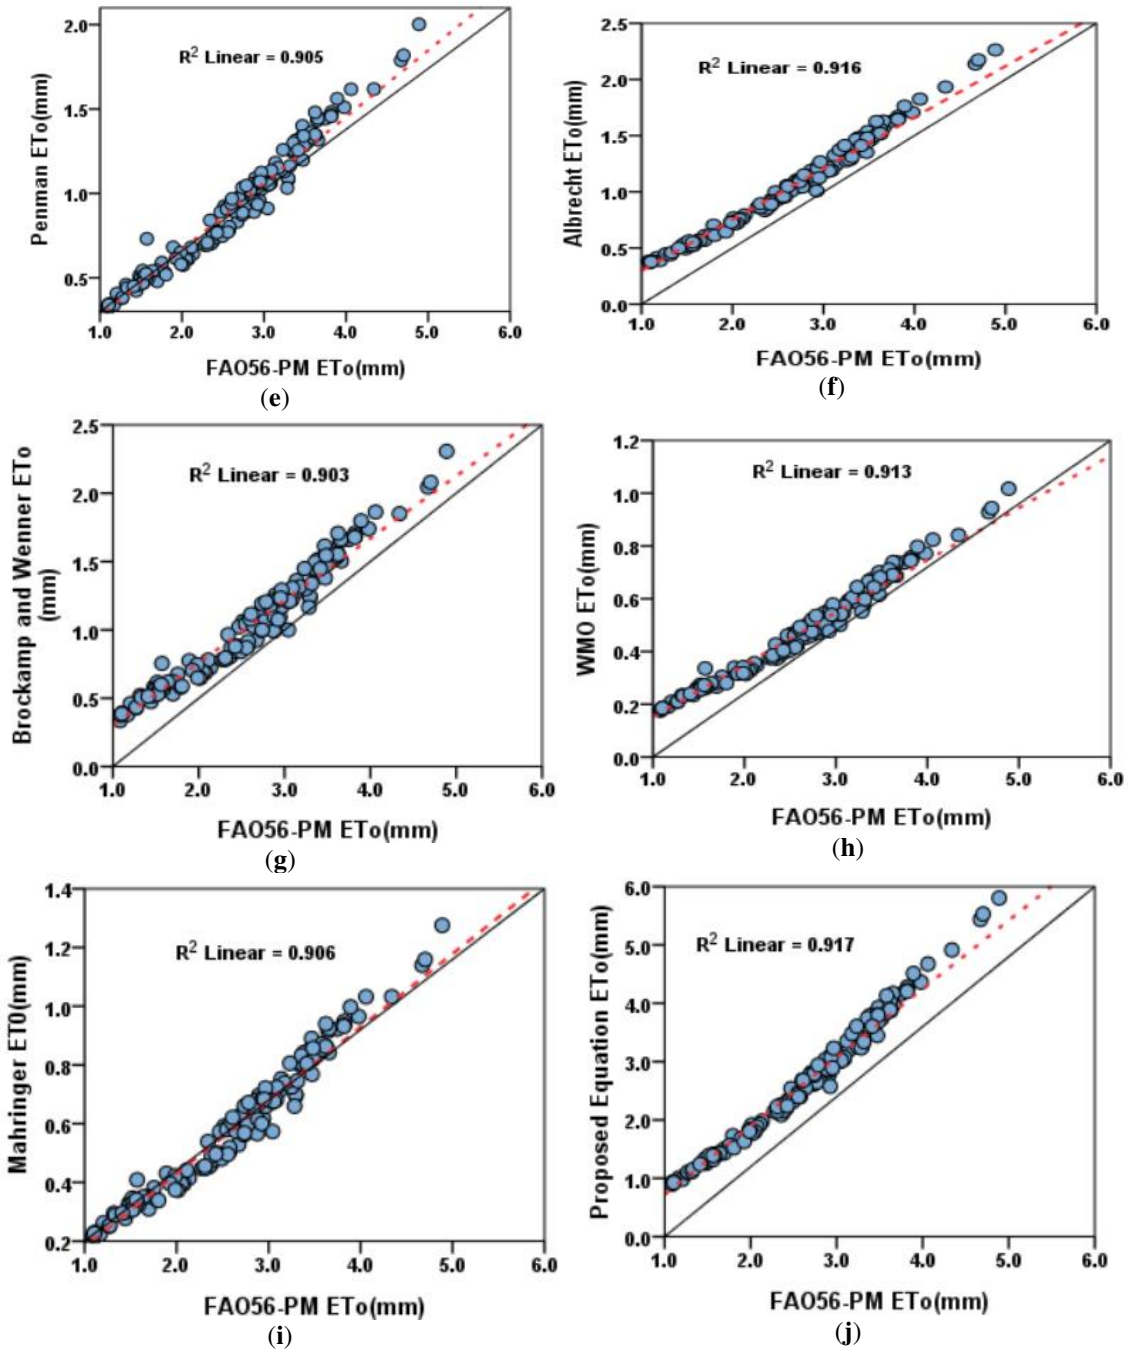

Figure 7. *Relationship between the validation of calibrated daily ETo estimates of each method versus the FAO56-PM at Asir region for the 2007-2018 period*

Valipour (2015) reported that there was an improvement in the calibrated Trabert and Mahringer equations in Iran with MBE as low as 0.02 mm/day. He indicated that the Trabert model can skip the calibration process to generate the best performance in Iran. The dependency of mass transfer equation on the vapor pressure was too small. It was reported that better performance of the Trabert and Mahringer equations were in inland area than at the coastal area in the Senegal River Valley (Djaman et al., 2015). The validation of the nine ETo equations for the 2007–2018 period is presented in *Figure 6*.

The statistical analysis showed a strong correlation between the calibrated equations to the PM estimates (*Table 4*). The findings of the research are in agreement with Kisi and Zounemat Kermani (2014). The outcomes of the study will provide meaningful guidance for agricultural production, hydrological planning and management in the vital region as well as other regions with similar climates.

Conclusions

The current study was performed with an aim to evaluate the ten reference evapotranspiration models (nine mass transfers and one proposed model) with respect to standard FAO56 PM model in the semi-arid region of Kingdom of Saudi Arabia. The ten evapotranspiration models have been successfully evaluated (period: 1979-2018), calibrated (period: 1979-2006) and further validated (period: 2007-2018). Based on the evaluation criteria, the GPI has been computed and the ranking operation was performed in order to observe the performance against the FAO56 PM equation under the available climatic conditions in Asir region. The effectiveness of the evaluated models can be judged based on the regression and statistical evaluation criteria which can be summarized as below:

- There was a remarkable improvement in the performance of calibrated equation. Moreover, the calibration approach improves the reliability and consistency of different evapotranspiration equation.
- The GPI is better to index ranking of equations as it takes into account the integrated approach of all the selected evaluation statistics.
- The ranking based on GPI of evaluated evapotranspiration models shows that the proposed model performed very well without calibration with GPI value of 5.02 and worst performance shown by Trabert.
- The ranking based on GPI of calibrated model reveals the fact that proposed model performed efficiently with the coefficient of determination up to 0.987 with GPI value of 2.85 and the worst performance shown by Meyer model
- Validation of calibrated equation shows that the proposed method was the most promising model and can be used as an alternative approach to Standard FAO-56 Penman Monteith model under the limited climatic condition followed by Albrecht model.
- The results of this study could be used by the water management system, crop cultivators, crop advisors, researchers and students from universities and research centres. Moreover, it is beneficial for the decision maker in the vast field of agriculture, hydrology and environment.

Acknowledgments. The authors would like to acknowledge the Deanship of Scientific Research (King Khalid University, Ministry of Education, Kingdom of Saudi Arabia) for providing administrative and financial support (award number R.G.P.1./74/40). The authors of current work wish to thank Universiti Tecknologi Malaysia, Johor Bahru for their facilities and Lab support. We would also like to thank general authority of the meteorological department, Abha, Asir region, Saudi Arabia for providing the weather data.

Conflict of interests: The authors declare no conflict of interests.

Abstract. This study used the autoregressive distributed lag (ARDL) bounds testing approach to cointegration to examine the dynamic relationship between environmental pollution and life expectancy in Nigeria over the period 1971 to 2014 incorporating the role of the oil sector. The ARDL estimates suggest that while oil export provides the revenue required to improve life expectancy in the country, it also generates economic conditions that accelerate environmental pollution in the country. The results show that the impact of carbon dioxide (CO_2) emissions on life expectancy in Nigeria is negative and stronger in the long run. To further the understanding of the impacts of oil production activities and CO_2 emissions on life expectancy in Nigeria, gender differences in life expectancy were considered. The results highlight the urgent need for health policy measures in Nigeria to incorporate effective mitigation and adaptation strategies to reduce the impact of the increasing role of the oil sector on health condition, wellbeing of the people and the overall goal of improving life expectancy in Nigeria.
Keywords: *export receipts, health policy, carbon dioxide (CO_2) emissions, greenhouse gases (GHG), gas flaring*

Introduction

Life expectancy, a measure of the length of life expected to be lived by an individual at birth is considered an important indicator of a nation's health condition and individual's wellbeing. Since individuals make a nation, improving life expectancy is a very important and necessary condition needed to achieve long-term sustainable economic development (Barlow and Vissandjée, 1999; Alam et al., 2016; Shahbaz et al., 2016). Recent studies show that life expectancy of a nation is reflected in the social, economic, demographic and environmental conditions (see Hertz et al., 1994; Barlow and Vissandjée, 1999; Pautrel, 2009; Bergh and Nilsson, 2010; Mariani et al., 2010; Qureshi et al., 2015; Sede and Ohemeng, 2015; Alam et al., 2016; Kim and Kim, 2016;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1114311162

Shahbaz et al., 2016; Lu et al., 2017; Wu, 2017; Abbas and Awan, 2018; Bader and Ganguli, 2019). Therefore, the impacts of various economic, social and environmental factors on life expectancy for a given country have become a very important issue among policy makers. However, despite the increasing attention of studies on identifying the determinants of life expectancy, there is still no empirical study that examines how oil sector activities and the resultant environmental pollution impact on life expectancy in Nigeria. Hence, this study aims to fill this identified gap in the existing literature by investigating the dynamic relationship between oil sector activities, environmental pollution and life expectancy in Nigeria.

The threat of oil sector activities on environmental quality in Nigeria has been widely recognized and cannot be overlooked (see Ologunorisa, 2001; Ugochukwu and Ertel, 2008; Audu et al., 2016). A deteriorating environment is responsible for many adverse effects on health and well-being (Tai et al., 2015; Chaabouni et al., 2016; Marsh et al., 2016; Perera, 2018). Policymakers in Nigeria are facing pressure in ensuring sustainable health condition and wellbeing of the people. The main reason being that social, economic and environmental conditions that determine the quality of health care services and individual's wellbeing depend significantly on oil sector activities as illustrated in *Figure 1*. On one hand, fiscal spending that determines health care expenditure, quality of education, availability of employment opportunities and sanitation facilities and access to portable drinking water depends solely on the volume of crude oil receipts, which accounts for about 95% of export earnings in Nigeria. Higher volume of crude oil export could therefore be interpreted to suggest more economic resources for better health care services. On the other hand, the exploration and production activities of the oil sector in Nigeria have resulted in environmental pollution, by way of relentless flaring and venting of gas to the environment (Audu et al., 2016). There is a global acceptance that the rising level of greenhouse gases in the atmosphere is the single greatest public health threat of the 21st century. Extreme temperature and weather conditions such as heat wave, storm, drought, and flood caused by the absorption of some of the radiation emitted from the earth by greenhouse gases in the atmosphere are considered by experts as one of the major direct risks to human health (Bezirtzoglou et al., 2011; Franchini and Mannucci, 2015; Wu et al., 2016; Liang and Gong, 2017). For instance, some health issues prevalent in Nigeria including respiratory and cardiovascular diseases, diarrheal diseases in children and mosquito-borne diseases such as malaria are among diseases identified to be most sensitive to temperature and climate conditions (see Bezirtzoglou et al., 2011). With this in mind, the need to understand and control the potential consequences of the activities of the oil sector on health conditions and wellbeing of Nigerians cannot be overemphasized.

Although life expectancy in Nigeria has improved over the years, *Figure 2* shows that it is still below the average life expectancy in Low income countries and Sub-Saharan African economies. Looking at the comparative figures, the life expectancy in South Africa and Ghana is higher with over nine years in 2014. In recognition of the urgent need to improve life expectancy in Nigeria, health policy makers have set policy targets and a number of policy measures have been taken in this direction including the primary health care service intended to enhance access to quality health care, the commercialization policy designed to inject some measures of efficiency into public hospital management and the National Health Insurance Scheme designed to mitigate the cost of access to quality health care (Sede and Ohemeng, 2015). In the light of the above discussion, this study aims at offering some policy measures to the attainment of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1114311162

health policy targets by examining the dynamic relationship between oil sector activities, environmental pollution (as proxied by CO_2 emissions) and life expectancy in Nigeria. This is achieved by employing the auto-regressive distributed lag (ARDL) bounds testing approach for cointegration analysis to uncover the long-run and short-run impacts of the variables including (i) the impact of oil resource as source of revenue on environmental quality and life expectancy in Nigeria (ii) the impact of crude oil production and exploration on life expectancy in Nigeria, and (iii) the impact of CO_2 emissions on life expectancy in Nigeria.

The remainder of this study is structured as follows: Section 2 presents the data and methodology of the study. Section 3 presents the empirical results. In section 4 the empirical results are discussed and some policy implications highlighted. Finally, section 5 offers some concluding remarks.

Materials and methods

Definition of variables and data description

This study uses annual data covering the period from 1971 to 2014 to examine the dynamic relationship between oil sector activities, environmental pollution and life expectancy in Nigeria. The average daily crude oil production is used to capture oil production effect while the value of oil exports is used to capture oil income effect of the activities of the oil sector. Carbon dioxide (CO_2) emissions in metric tons per capita is used to measure environmental pollution. Life expectancy is measured as the average number of years of life of the total population (female and male), male population and female population. List of all the variables and data sources are presented in *Table 1*.

Empirical model and estimation method

This study empirically examines three log-linear models to uncover the relationship between oil sector activities, environmental pollution and life expectancy in Nigeria over the period 1971-2014. Model 1 and Model 2 examine the impact of oil sector activities and CO2 emissions on life expectancy in Nigeria while Model 3 examines the role of oil sector activities in explaining environmental pollution (CO_2 emissions) in Nigeria. In Model 1 specified in *Equation 1* oil sector activity is captured using value of petroleum exports per capita (oil income effect) while in Model 2 specified in *Equation 2* oil sector activity is captured using the average daily crude oil production (oil production effect). *Figure 3* summarises the three causal relationships examined in this empirical study.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1114311162

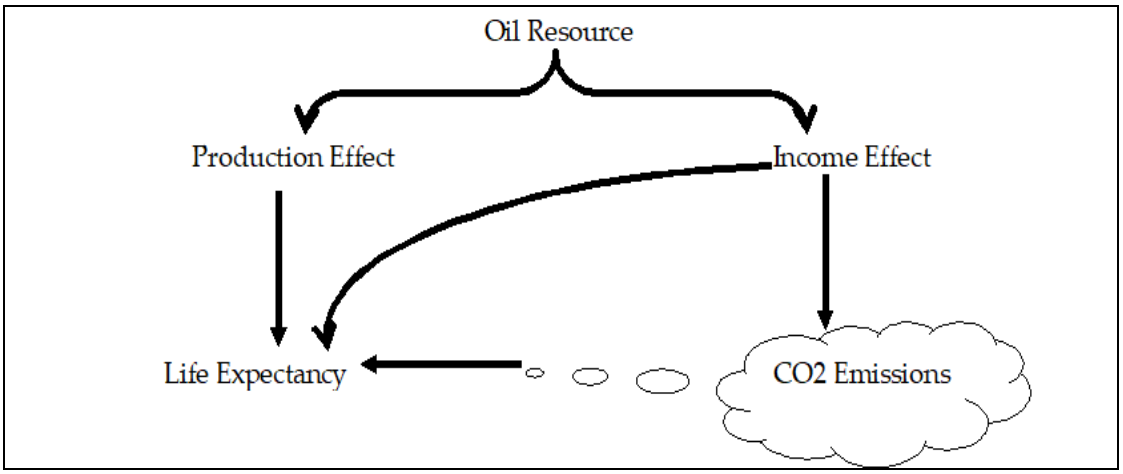

Figure 3. *Hypothesized relationship between oil sector activities, CO_2 emissions and life expectancy in Nigeria*

Model 1

$$lnLif = \alpha_0 + \alpha_1 lnRgdpc + \alpha_2 lnCO2 + \alpha_3 ln\text{Pvet} + \alpha_4 lnContrl1 + \alpha_5 Contrl2 + \alpha_5 Contrl3 + e_t \quad \text{(Eq.1)}$$

Model 2

$$lnlif = \beta_0 + \beta_1 lnRgdpc + \beta_2 lnCO2 + \beta_3 ln\text{Crdoilp} + \beta_4 lnContrl1 + \beta_5 Contrl2 + \beta_6 Contrl3 + e_t \quad \text{(Eq.2)}$$

Model 3

$$lnCO2 = \pi_0 + \pi_1 lnRgdpc + \pi_2 lnlif + \pi_3 ln\text{Pvet} + \pi_4 lnContrl1 + \pi_5 Contrl2 + \pi_5 Contrl3 + e_t \quad \text{(Eq.3)}$$

$lnLif$ represents life expectancy, measured as the average number of years of life of the total population (female and male) $lnLifE$, male population $lnLifEM$ and female population $lnLifEF$. $lnRgdpc, lnCO2, ln\text{Pvet}$ and $ln\text{Crdoilp}$ are as defined in *Table 1*. $lnContrl1, lnContrl2$ and $lnContrl3$ are used to control for the influence of other factors considered important in this empirical analysis. These factors include international trade, financial development and population growth. e_t is the error term.

Following Murthy and Okunade (2016), Shahbaz et al. (2016) and Abbas and Awan (2018) this study employs the autoregressive distributed lag (ARDL) Bounds testing approach to co-integration proposed by Pesaran et al. (2001) to investigate the log-linear empirical model specified in *Equations 1, 2* and *3*. The ARDL approach offers some desirable statistical advantages over other co-integration techniques. While other co-integration techniques require all the variables to be integrated of the same order, ARDL test procedure provides valid results whether the variables are I(0) or I(1) or mutually co-integrated, captures both short-run dynamics and long-run equilibrium adjustment of the studied process and provides very efficient and consistent test results in small and large sample sizes (see Pesaran et al., 2001). The implementation of the ARDL test for *Equations 1, 2* and *3* involves the estimation of the following models:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1114311162

ARDL estimation for Model 1:

$$\Delta lnlif_t = a_0 + \sum_{i=1}^{n} a_{1i}\Delta lnlif_{t-i} + \sum_{i=0}^{n} a_{2i}\Delta lnRgdpc_{1_{t-i}} + \sum_{i=0}^{n} a_{3i}\Delta lnCO2_{2_{t-i}} + \sum_{i=0}^{n} a_{4i}\Delta lnVpet_{3_{t-i}} + \sum_{i=0}^{n} a_{5i}\Delta lnCtrl1_{4_{t-i}} + \sum_{i=0}^{n} a_{6i}\Delta lnCtrl2_{5_{t-i}} + \sum_{i=0}^{n} a_{7i}\Delta lnCtrl3_{6_{t-i}} + a_8 lnlif_{t-1} + a_9 lnRgdpc_{t-1} + a_{10} lnCO2_{t-1} + a_{11} lnVpet_{t-1} + a_{12} lnCtrl1_{t-1} + a_{13} lnCtrl2_{t-1} + a_{14} lnCtrl3_{t-1} + \varepsilon_t \quad (4) \qquad \text{(Eq.4)}$$

ARDL estimation for Model 2:

$$\Delta lnlif_t = \beta_0 + \sum_{i=1}^{n} \beta_{1i}\Delta lnlif_{t-i} + \sum_{i=0}^{n} \beta_{2i}\Delta lnRgdpc_{1_{t-i}} + \sum_{i=0}^{n} \beta_{3i}\Delta lnCO2_{2_{t-i}} + \sum_{i=0}^{n} \beta_{4i}\Delta lnCrdoilp_{3_{t-i}} + \sum_{i=0}^{n} \beta_{5i}\Delta lnCtrl1_{4_{t-i}} + \sum_{i=0}^{n} \beta_{6i}\Delta lnCtrl2_{5_{t-i}} + \sum_{i=0}^{n} \beta\,\Delta lnCtrl3_{6_{t-i}} + \beta_8 lnlif_{t-1} + \beta_9 lnRgdpc_{t-1} + \beta_{10} lnCO2_{t-1} + \beta_{11} lnCrdoilp_{t-1} + \beta_{12} lnCtrl1_{t-1} + \beta_{13} lnCtrl2_{t-1} + \beta_{14} lnCtrl3_{t-1} + \varepsilon_t \quad (5) \qquad \text{(Eq.5)}$$

ARDL estimation for Model 3:

$$\Delta lnCO2_t = \pi_0 + \sum_{i=1}^{n} \pi_{1i}\Delta lnCO2_{t-i} + \sum_{i=0}^{n} \pi_{2i}\Delta lnRgdpc_{1_{t-i}} + \sum_{i=0}^{n} \pi_{3i}\Delta lnlif_{2_{t-i}} + \sum_{i=0}^{n} \pi_{4i}\Delta lnVpet_{3_{t-i}} + \sum_{i=0}^{n} \pi_{5i}\Delta lnCtrl1_{4_{t-i}} + \sum_{i=0}^{n} \pi_{6i}\Delta lnCtrl2_{5_{t-i}} + \sum_{i=0}^{n} \pi_{7i}\Delta lnCtrl3_{6_{t-i}} + \pi_8 lnCO2_{t-1} + \pi_9 lnRgdpc_{t-1} + \pi_{10} lnlif_{t-1} + \pi_{11} lnVpet_{t-1} + \pi_{12} lnCtrl1_{t-1} + \pi_{13} lnCtrl2_{t-1} + \pi_{14} lnCtrl3_{t-1} + \varepsilon_t \quad (6) \qquad \text{(Eq.6)}$$

where Δ is the difference operator while ε_t is white noise error term. The following hypotheses are tested to investigate the existence of co-integration among the variables: the null hypothesis of no cointegration among the variables in *Equation 4* is given as $(H_o: a_8 = a_9 = a_{10} = a_{11} = a_{12} = a_{13} = a_{14} = 0)$ examined against the alternative hypothesis $(H_1: a_8 \neq a_9 \neq a_{10} \neq a_{11} \neq a_{12} \neq a_{13} \neq a_{14} \neq 0)$. In *Equation 5* the null hypothesis of no cointegration among the variables is $(H_o: \beta_8 = \beta_9 = \beta_{10} = \beta_{11} = \beta_{12} = \beta_{13} = \beta_{14} = 0)$ against the alternative hypothesis $(H_1: \beta_8 \neq \beta_9 \neq \beta_{10} \neq \beta_{11} \neq \beta_{12} \neq \beta_{13} \neq \beta_{14} \neq 0)$. In *Equation 6* the null hypothesis of no cointegration among the variables is $(H_o: \pi_8 = \pi_9 = \pi_{10} = \pi_{11} = \pi_{12} = \pi_{13} = \pi_{14} = 0)$ against the alternative hypothesis $(H_1: \pi_8 \neq \pi_9 \neq \pi_{10} \neq \pi_{11} \neq \pi_{12} \neq \pi_{13} \neq \pi_{14} \neq 0)$. The decision to reject or accept H_o (no co-integration among the variables) is based on the following conditions: if the calculated F-statistics is greater than the upper critical bound, then H_o is rejected and the variables are co-integrated, if the calculated F-statistics is less than the lower bound, then H_o is accepted and the variables are not co-integrated, but if the calculated F-statistics remains between the lower and upper critical bounds then the decision is inconclusive (Pesaran et al., 2001).

After testing for cointegration among the variables, the long-run coefficients of the variables are then estimated. The existence of cointegration between the variables implies that causality exist in at least one direction. The error correction model for the estimation of the short run relationships is specified as:

ECM_{t-1} is the error correction term obtained from the cointegration model. The error correction coefficients (λ_1, λ_2 and λ_3) indicate the rate at which the cointegration models correct previous period disequilibrium or speed of adjustment to restore the long-run equilibrium relationship. A negative and significant ECM_{t-1} coefficient implies that any short term movement between the dependent and explanatory variables will converge back to the long-run relationship.

This study implements the following diagnostic tests to ensure the acceptability of the empirical models: Breusch–Godfrey serial correlation LM test, ARCH test for heteroscedasticity, Jarque-Bera normality test and Ramsey RESET test for functional form. The stability of the long-run coefficients together with the short-run dynamics are tested using the cumulative sum of recursive residuals (CUSUM) and the cumulative sum of squares of recursive residuals (CUSUMSQ) tests.

Results

Figure 4 displays plots of the data series of the variables of interest. The figure shows that life expectancy in Nigeria improved from 41.4 years in 1971 to 52.5 years in 2014. CO_2 emissions which increased from 0.56 metric tons per capita in 1971 to 1.01 in 1974 decreased to 0.54 metric tons per capita in 2014. Interestingly daily crude oil production which increased from 1531.20 thousand barrels in 1971 to 2255.0 thousand in 1974 also decreased to 1807.05 thousand barrels in 2014. In the light of the observed movements in these series, it would be of great interest for health policy making to examine the dynamic relationship between oil sector activities, environmental pollution (as proxied by CO_2 emissions) and life expectancy in Nigeria. This is achieved by employing the auto-regressive distributed lag (ARDL) bounds testing approach for cointegration analysis to uncover the long-run and short-run impacts of the variables including the impact of oil resource as source of revenue on environmental quality and life expectancy in Nigeria, the impact of crude oil production and exploration on life expectancy in Nigeria, and the impact of CO_2 emissions on life expectancy in Nigeria.

Unit root tests

The ARDL-bounds cointegration testing approach allows variables to be integrated of different orders [I(0) and I(1)], but does not require any of the variables to be integrated of order 2 [I(2)] (see Pesaran et al., 2001) . It is therefore essential to examine the stationarity of the variables to ensure that none of the variables is integrated of order 2 [I(2)]. To determine the order of integration of the variables, the Augmented Dickey Fuller test for unit root is implemented. The results in *Table 2* show that inflation rate (*ln*Infr) is integrated of order zero, I(0) while other variables are integrated of order one I(1). In the presence of structural breaks however, the Augmented Dickey Fuller test and other conventional unit root tests are known to provide biased results because of their low explanatory strength to reject the null hypothesis of unit root. This is because these unit root tests do not incorporate information about structural break dates emanating from structural changes (Perron, 2006). To overcome this condition, modified augmented Dickey-Fuller test that detects unknown single structural break in a series is employed (see Vogelsang and Perron, 1998). The innovational outlier (IO) model which assumes that the break occurs gradually, with the breaks following the same dynamic path as the innovations is implemented. The results in *Table 2* show a structural break in all the series. For life expectancy (*ln*lifE), a structural break is found in the series in 1997. For CO2 emissions, a structural break exists in 1986. These results give indication that the economy has observed significant policy shocks at the selected break dates. The stationary properties show that none of the variables is integrated at second difference [I(2)]. The integration of the variables at I(0) and I(1) makes ARDL the preferred approach in this empirical analysis.

Results of ARDL co-integration test

In ARDL bounds cointegration analysis, lag length selection test is considered very important as the F-statistic required for the implementation of the model is known to be sensitive to lag order. This first step test involves examining the sequential modified LR test statistic (LR), Final prediction error (FPE), Akaike information criterion (AIC), Schwarz information criterion (SIC) and Hannan-Quinn information criterion (HQ) for the selection of appropriate lag length. The implementation of this first step test shows that 3 is suggested by all the criteria as the appropriate lag length for the implementation of the ARDL bounds cointegration test for all the specifications. Following the suggestion of Lütkepohl (2006) in small sample analysis, this study uses Akaike Information Criterion (AIC) for selecting the optimal lag length.

Given the relatively small sample size of 44 observations (1971-2014) used in this study, the critical values for the evaluation of the null hypothesis are taken from Narayan (2005). Narayan (2005) computed two sets of critical values: lower bounds I(0) and upper bounds critical I(1) for sample sizes ranging from T = 30 to 80. The results of the co-integration test based on the ARDL-bounds testing method are presented in *Table 3*. The results indicate that the F-statistic is greater than the upper critical bound from Narayan (2005) at 1% significant level for all the specifications of the ARDL models examined using restricted intercept and no trend. This study therefore rejects the null hypothesis of no cointegration among the variables. This shows that there is a long-run causal relationship between oil sector activities, environmental pollution, life expectancy at birth and other selected indicators of economic performance in Nigeria.

Long-run and short-run estimates

The estimates for all the specifications of Model 1 are presented in *Table 4*. The long-run coefficients in Panel B show that the coefficient of the oil export revenue *ln*VPet is positive and statistically significant at 1% level in specifications 1 and 3, and at 5% level in specification 2. From the long-run coefficients, a 1% increase in the value

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1114311162

of petroleum exports (oil revenue) significantly increases life expectancy at birth by 0.0714%. Distinguishing between male and female populations, the estimates suggest that a 1% increase in the value of petroleum exports (oil revenue) contributes more to life expectancy of the male population (0.1076%) than the female pollution (0.0457%). The coefficient of CO_2 emissions is negative and statistically significant in all the three specifications of Model 1. For the overall population, the coefficient which is significant at 1% level indicates that a one per cent increase in the level of CO_2 emissions in the Nigerian economy would cause life expectancy at birth to decrease by 0.0438%. Specifications LifEM (male population) and LifEF (female population) shows that a one per cent increase in the level of CO2 emissions in the economy affects the male population more (-0.0596) than the female population (-0.0262). The coefficient of GDP per capita is positive and statistically significant. Panel A of *Table 4* shows that the short-run coefficient of the value of petroleum exports (oil revenue) is positive and statistically significant for the overall population at 5% level. Overall the results in *Table 4* show that the long-run effects of the value of petroleum exports (oil revenue) and CO_2 emissions on life expectancy in Nigeria are stronger in the long run.

The results of Model 2 are presented in *Table 5*. Oil sector activities are captured using the average of daily crude oil production (oil production effect). The long-run estimates in Panel B show that an increase the production activities of the oil sector significantly decreases life expectancy in the country. The coefficient of -0.1276 which is statistically significant at 10% level for the overall population shows that a one per cent increase in crude oil production activities decreases life expectancy in the country by 0.1276%. The results also suggest that the long-run influence of crude oil production activities (oil production effect) on life expectancy of the female population is statistically significant at 1% level. The coefficient of CO_2 emissions is negative and statistically significant in all the specifications of Model 2, confirming the negative impact of an increase in the level of CO_2 emissions on life expectancy in Nigeria as observed from the results of Model 1. It is also observed from the results in Pane A of *Table 5* that the short-run effect of oil sector production activities on life expectancy of the female population in Nigeria is negative and statistically significant at 5% level. The long-run and short-run estimates therefore suggest that oil sector production activities exert more influence on life expectancy of the female population in Nigeria.

The long-run estimates in Panel B show that the coefficient of the oil income *ln*VPet is positive and statistically significant at 5% level in specifications 1, and at 1% level in specification 2. From the long-run coefficients, a one per cent increase in the value of petroleum exports (oil revenue) significantly increases CO_2 emissions in Nigeria by 0.6226% in the long-run. The long-run estimates also suggest that a significant negative relationship exists between life expectancy and CO_2 emissions in Nigeria. The short-run estimates in Panel A show that a one per cent increase in petroleum export (oil revenue) produces over 0.3960% increase in CO_2 emissions in Nigeria in the short-run. It is therefore evident from the results in *Table 6* that oil export revenue contributes significantly to environmental pollution in the long-run as well as in the short-run.
The coefficient of ECM (-1) in all the specifications of Model 1, 2 and 3 is negative and significant at 1% level indicating that the adjustment of variables towards long-run dynamics is achieved. The diagnostic test results in Panel C of *Tables 4, 5* and *6* show that there is no evidence of serial correlation, heteroscedasticity and functional form misspecification in each of the ARDL models specified. *Figures 5–12* show the cumulative sum of recursive residuals (CUSUM) and the cumulative sum of squares (CUSUMSQ) stability test results for each of the ARDL specifications. The CUSUM and CUSUMSQ are all within the critical boundaries for the 5% significance level indicating that the coefficients of the ARDL model in each of the specifications are stable.

Discussion of results and policy implications

The schematic view of the results of this empirical study is presented in *Figure 13*.

The positive relationship between the value of petroleum export and life expectancy in Nigeria suggests the dependence of health care expenditure, quality of education, employment opportunities, access to portable drinking water and other socio-economic drivers of life expectancy on oil income. This result is consistent with the findings of Bader and Ganguli (2019) for the Gulf Cooperation Council (GCC) countries. While oil export provides the income required to improve life expectancy in the country, it also generates conditions that accelerate environmental pollution in the economy. This shows that income from oil export significantly generates economic activities in the energy-intensive sectors and rapid accumulation of energy-using technologies in the economy. It is therefore expected that economic diversification policies in Nigeria would incorporate strategies encouraging firms in energy energy-intensive sectors including oil and gas firms to adopt advanced technologies that minimize environmental pollution. The income from petroleum exports could be used in the development of renewable energy sources in the economy. The development of solar and wind energy sources could increase access to clean forms of energy and lessen the level of CO_2 emissions, which threaten environmental quality and reduce life expectancy of Nigerians.

The significant negative relationship between crude oil production and life expectancy indicates that an increase in the production activities of the oil sector creates environmental conditions considered direct risk to human health (Perera, 2018). While the threat of oil sector activities on environmental quality in Nigeria has been widely recognized (see Ologunorisa, 2001; Ugochukwu and Ertel, 2008; Audu et al., 2016), this study documents that the deteriorating environment is responsible for many adverse effects on health and well-being of Nigerians and therefore suggests that health policies

DOI: http://dx.doi.org/10.15666/aeer/1705_1114311162

targeting improvement in life expectancy will have to incorporate sound environmental measures aimed at reducing CO2 emissions from gas flaring in Nigeria's oil and gas industry. Considering gender differences in life expectancy in Nigeria, the results show that while a one per cent increase in the level of CO_2 emissions in the economy affects the life expectancy of the male population more than the female population, crude oil production activities of the oil sector have significant negative short-run and long-run effects on life expectancy of the female population in Nigeria. This empirical result highlights the complexity of the environmental impact of oil resource on life expectancy in Nigeria.

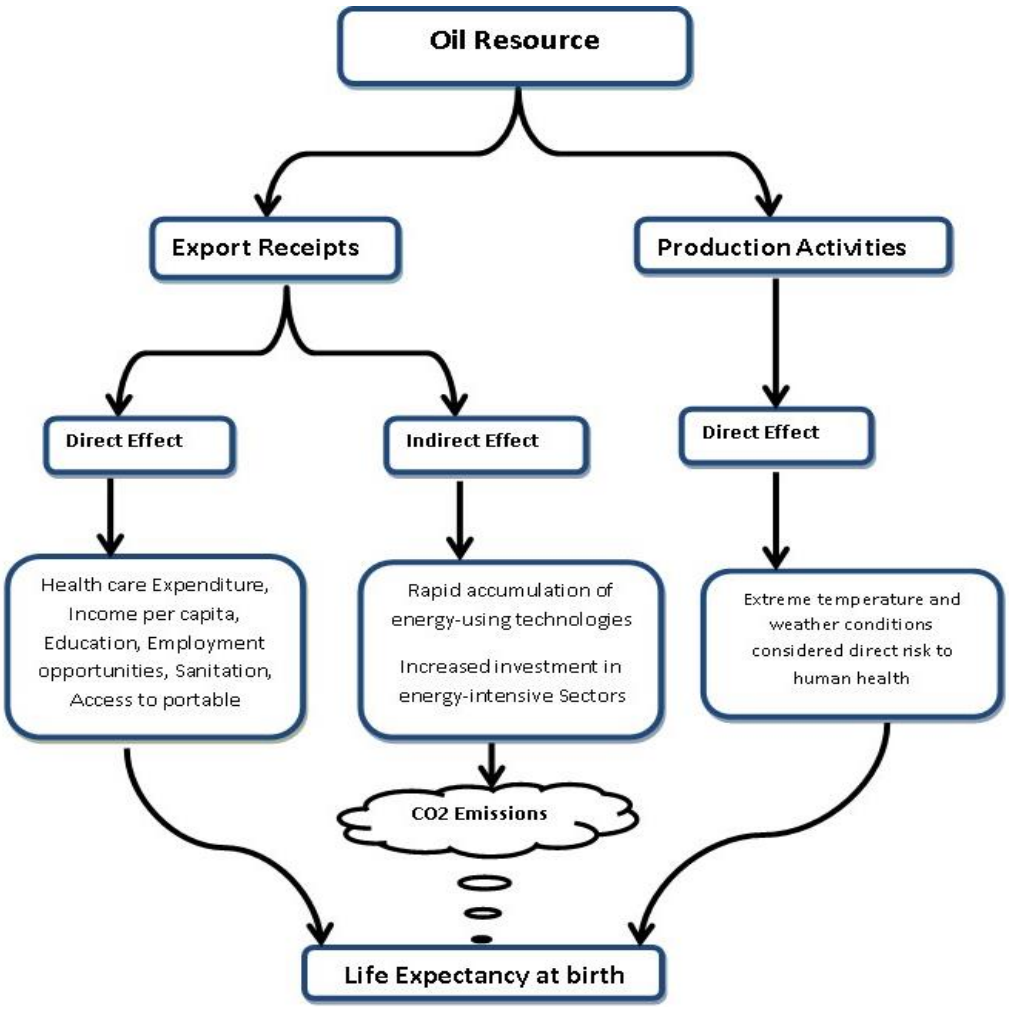

Figure 13. *Relationship between oil resource, CO_2 emissions and life expectancy in Nigeria*

From the above discussion, the health implications of the activities of the oil and gas firms in Nigeria cannot be neglected. The activities of the oil and gas sector in Nigeria generate conditions that harm the health of the people through carbon dioxide (CO_2) emissions. One of these conditions that require urgent attention is the amount of gas flared from oil and gas activities in the country. Nigeria which began the production of crude oil in 1958 still lacked sufficient infrastructure and policy measures to reduce gas

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1114311162

flaring, which is the most significant contributor of CO2 emission from oil and gas activities in Nigeria (Anomohanran, 2012). It may be necessary for the Nigerian government to design policy measures aimed at reducing gas flaring from the activities of oil and gas firms. Oil and gas firms operating in Nigeria have attempted to implement measures aimed at reducing gas flaring in time past. However, it is not certain if any of these efforts yielded significant level of reduction in the amount of gas flared yearly from oil and gas activities as these efforts were either not completed or facilities vandalised (Anomohanran, 2012). The schematic view of the results of this empirical study presented in *Figure 13* therefore highlights the urgent need for policy measures to consider the environmental consequences of the dependence of the economy on oil resource and its implications on health condition, well-being and quality of life of Nigerians, if the country must experience significant improvement in life expectancy.

Conclusion

This study examined the dynamic relationship between oil sector activities, environmental pollution and life expectancy in Nigeria over the period 1971 to 2014. The long-run relationship among the variables is examined using ARDL bounds testing approach to cointegration. The results provide evidence of cointegration between the variables with the incorporation of the presence of a structural break observed in the series. The ARDL estimates suggest (i) a positive relationship between oil export revenue and life expectancy (ii) a positive relationship between oil export revenue and CO_2 emissions (iii) a negative relationship between crude oil production activities and life expectancy, and (iv) a negative relationship between CO_2 emissions and life expectancy. To further the understanding of the impacts of oil production activities and CO_2 emissions on life expectancy in Nigeria, gender differences in life expectancy in Nigeria was considered. The results show that (i) a one per cent increase in the level of CO_2 emissions in the economy affects the life expectancy of the male population more than the female population (ii) a one per cent increase in the value of petroleum exports (oil revenue) contributes more to life expectancy of the male population than the female pollution, and (iii) strong empirical evidence that crude oil production activities of the oil sector have significant short-run and long-run effects on life expectancy of the female population in Nigeria. Overall the results show that the impact of CO_2 emissions on life expectancy in Nigeria is stronger in the long-run.

This study provides empirical evidence to support the urgent need for health policy measures in Nigeria to incorporate effective strategies for mitigation and adaptation meant to reduce the impact of the increasing role of the oil sector on health condition, wellbeing of the people and the overall goal of improving life expectancy in Nigeria.

Abstract. Effect of organic loading rate on the operational performance of reactors and energy conversion efficiency by two-phase anaerobic fermentation was proposed and investigated using molasses wastewater. Hydrogen and methane production rate were determined in the hydrogenic up-flow anaerobic sludge blanket (UASB) reactor and the methanogenic UASB reactor. At analyzed optimum system organic loading rate (OLR) of 20 g COD/L $_{reactor}$·d, hydrogen was efficiently produced from the hydrogenic reactor with the highest production rate of 2.0±0.21 L/L $_{reactor}$·d and in the methanogenic reactor, methane was produced from residual organic matters and volatile fatty acids (VFAs) with a production rate of 1.9±0.3 L/L $_{reactor}$·d. Finally, the energy conversion efficiency was increased from 12.1% (hydrogen only production) to 91.2% (hydrogen and methane coproduction). The results of this study indicated that the hydrogenic reactor presented relatively low energy conversion efficiency while the methanogenic reactor presented a high one.
Keywords: *organic matter, upflow anaerobic sludge blanket, hydrogenic reactor, volatile fatty acids, methanogenic reactor*

Introduction

Hydrogen (H_2) as a renewable energy carrier can replace fossil fuels and address issues of energy shortage and environmental emissions (Lee and Chung, 2010). Hydrogen is being focused on as a promising alternative to fossil fuels because it does not discharge contaminants (Panda et al., 2016). Also, hydrogen is a promising future energy carrier because the sole byproduct of H_2 combustion is pure water that generates 2.75 times more energy (122 kJ/g) than hydrocarbon fuels (Scott, 2004). Furthermore, biological hydrogen production seems to be more attractive because organic waste materials can be used as substrate and the hydrogen-producing system can be operated under low temperature and pressure conditions (Sivagurunathan et al., 2016). The calorific value of hydrogen is three times greater than that of petrol, 3.9 times that of ethanol and 4.5 times that of coal (Fayaz et al., 2012). Among the various hydrogen production methods, hydrogen production from organic wastes by anaerobic fermentation seems to be the most promising and environmentally friendly (Siddiqui et al., 2011). Anaerobic fermentation has unique characteristics like high ecological adaptability, simple reaction conditions and low nutrient requirement

(Puyol et al., 2017) and it can use microbes through manipulating the organic matter in the biomass to extract hydrogen in an anaerobic environment (Han et al., 2012). The advantages of the two-stage fermentation process are high-energy recovery and process stability (Nualsri et al., 2016). Anaerobic digestion entails two-stage processes involving the sequential action of acid-forming and methane-forming bacteria. In the first stage, acid-forming bacteria (facultative and anaerobic bacteria) convert the complex organic compounds into simpler organics (volatile fatty acids-VFAs) and also carbon dioxide and hydrogen gases. In the second stage, the organic acids and hydrogen are converted into methane and carbon dioxide by methanogens. The efficiency of an anaerobic treatment depends on both the acidogenic and methanogenic phases (Shi et al., 2017). Hydrogen is mainly produced in the acidogenic stage of anaerobic digestion during the fermentation of organic wastes. Several factors affect the fermentative hydrogen production, including inoculum, substrate characteristics, reactor type, nitrogen and phosphate contents, temperature and pH, among others (Wang and Wan, 2009). However, the low theoretical energy efficiency of about 33.5% is the main obstacle to hydrogen production by anaerobic fermentation which significantly limits its development and industrial application (Chen et al., 2012). How to increase energy conversion efficiency from organic wastes is a challenging topic. It was found in previous studies (Carucci et al., 2005; Luo et al., 2010) that the effluents of the anaerobic fermentation process including mainly volatile fatty acids (VFAs) and alcohols can be reutilized to recover the thermal enthalpies and further produce methane, thereby dramatically increasing the energy conversion efficiency. Among the various anaerobic wastewater treatment technologies, upflow anaerobic sludge blanket (UASB) reactors have achieved considerable success and these reactors have been applied to treat a wide range of effluents such as sugar, pulp and paper, dairy, chemical, potato starch, bean balancing, soft drinks, fish processing, noodle processing, yeast production, slaughterhouse, and coffee processing industries (Metcalf and Eddy, 2003; Yetilmezsoy and Sakar, 2008; Farghaly and Tawfik, 2017). Therefore, the upfow anaerobic sludge blanket (UASB) reactor has been recognized as an essential wastewater treatment technology among anaerobic treatment methods.

Given these considerations, the present study aimed to evaluate the effect of OLRs on the hydrogen and methane production to achieve the optimum energy conversion efficiency using a two-phase anaerobic process which consisted of two up-flow anaerobic sludge blanket (UASB) reactor.

Materials and methods

Seed sludge and feeding

The seed sludge used in this study was the dewatering sludge obtained from a local municipal wastewater treatment plant (Harbin, China). For the hydrogenic UASB, the sludge was aerated for 30 days to inhibit the methane-producing bacteria activity. For the methanogenic UASB, the raw sludge was acclimatized in the reactor operated at pH 6.5, fed continuously with the molasses substrate at OLR of 4.0 g COD/L·d. After enough enrichment over 30 days, the methanogenic sludge began to be fed with the effluent of the hydrogenic UASB.

Experimental setup

Coproduction of hydrogen and methane from molasses wastewater was carried in a two-phase anaerobic process which consisted of two up-flow anaerobic sludge blanket (UASB) reactor (*Figure 1*) with the same working volume of 10 L.

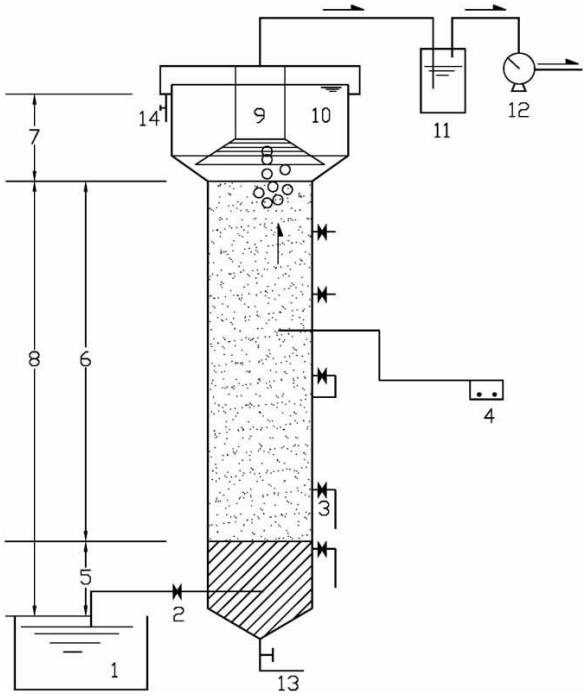

Figure 1. *Structure of the UASB reactor. 1. Raw water tank; 2.Peristaltic pump; 3. Sample connection; 4. Temperature controller; 5. Sludge bed; 6. Superposed layer; 7. Reaction zone; 8. Separating zone; 9. Three phase separation zone; 10. Precipitation area; 11. Water seal; 12. Wet gas flow meter. 13. Mud mouth; 14. Outlet*

The internal diameter was 10 cm and a height of 1.3 m for the two reactors. Operating temperature of the bioreactors was maintained through an electric jacket to 35˚C. The two reactors operated for 60 days, and the operational conditions (OLR and respective HRT) are presented in *Table 1*. The UASB reactor for hydrogen production (hydrogenic) was fed with molasses wastewater using a peristaltic pump while the UASB reactor for methane production was supplied with the effluent collected from the hydrogenic reactor. In this study, the steady-state condition was defined as the condition that the biogas varied within 5% for ten days (*Figure 2*).

Analytical methods

COD, pH, and alkalinity were monitored and measured daily according to Standard methods (Apha, 1995). Hydrogen and methane were analyzed using gas chromatography (SC-7, Shandong Lunan Instrument Factory). The gas chromatograph was equipped with a thermal conductivity detector and a stainless steel column (2 m×5 mm) filled with Porapak Q (50-80 meshes). Nitrogen was used as the carrier gas at a flow rate of 40 mL/ min.

Figure 2. *Physical photo of the UASB reactor*

Conversion efficiency of energy

The conversion efficiency of energy was calculated from hydrogen and methane according to the following equation:

$$R= (V_H \cdot \beta_H + V_M \cdot \beta_M)/ (F \cdot W) \quad \text{(Eq.1)}$$

where R represents the conversion efficiency of energy in the hydrogenic and methanogenic reactor, V_H and V_M represent the volume of hydrogen and methane (L/d), respectively. β_H and β_M represent the COD equivalent of hydrogen and methane, respectively and the hydrogen and methane COD equivalents (g O_2/L H_2 and CH_4) were 0.71 and 2.86, respectively. F represents the influent rate of the hydrogenic reactor (L/d). W represents the COD concentration of molasses wastewater.

Results and discussion

Optimum system OLR for hydrogenic UASB

The UASB reactor for hydrogen production operated during 60 days under different OLR and HRT. Organic loading rate (OLR) is an essential parameter in studying bioreactors (Venetsaneas et al., 2009). To optimize a system for hydrogen production, it is necessary to define either a range of OLRs that the operation can handle effectively or an optimal OLR for a maximum hydrogen production rate. The pH variation at different OLRs and the hydrogen production and COD removal at different OLRs are respectively presented in *Figure 3* and *Figure 4*.

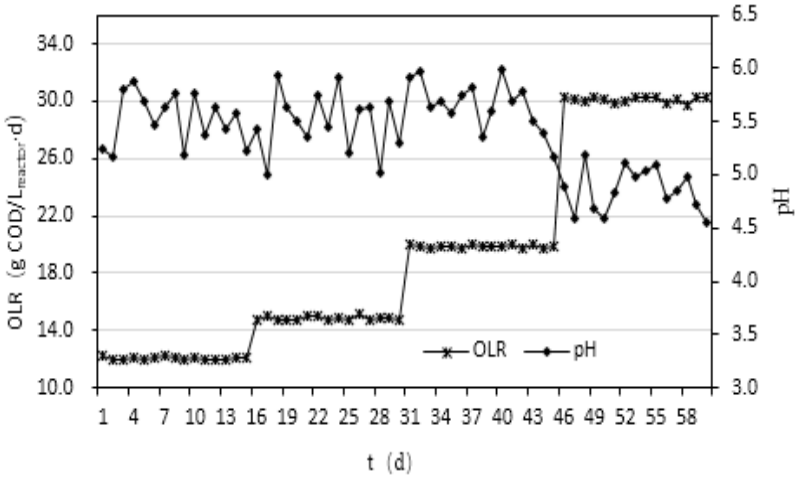

Figure 3. *The pH variation at different OLRs*

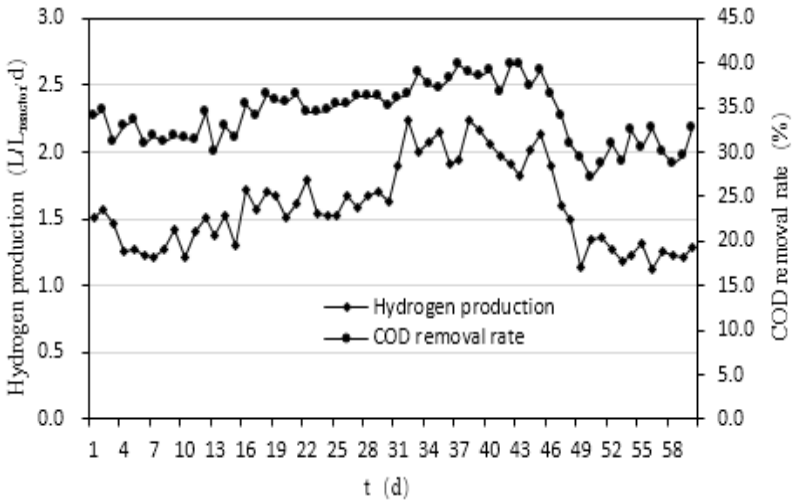

Figure 4. *The hydrogen production and COD removal at different OLRs*

The pH parameter was critical for maintaining the reliability of the hydrogenic fermentation process, and the VAFs (Ethanol, acetic acid, propionic acid and butyric acid) production resulted in a reduction of hydrogenase activity significantly. *Figure 3* shows that the hydrogenic system pH was within 4.5-6.0 range.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1116311174

As indicated in *Figure 4*, the maximum hydrogen production was achieved to be 2.0±0.21 L/L $_{reactor}$·d which stated the most exuberant metabolic activities of hydrogenic microorganisms at the OLR of 20 g COD/L $_{reactor}$·d. At the same time, the COD removal rate presented by hydrogenic reactor was up to the highest level of 38.1±0.55%. The higher OLR showed a negative influence on the hydrogenic microorganisms through decreasing hydrogen production and COD removal efficiency, which was explained by the reduction of pH value caused by VFAs accumulation. These results are similar to those obtained by Krishnan et al. (2017) who observed that increased OLR is considered to indicate vigorous biomass concentration conditions that could bring toxicity to the system. The observed trends were supported by the work of Zhang et al. (2015), they found that the anaerobic digestion of food waste at OLR of 3 gVS/L/d caused VFA accumulation. Therefore, the OLR of 20 g COD/L $_{reactor}$·d was determined to be the suitable operating condition for a hydrogenic reactor with the maximum hydrogen production from molasses wastewater and COD removal efficiency. Zahedi et al. (2018) examined the effect of the increase in organic loading rates (OLRs), by reducing the solids retention time (SRT) from 20 d to 5 d, in single-phase mesophilic anaerobic co-digestion of sewage sludge with glycerine (1% v/v). They confirmed that anaerobic co-digestion of these biowastes under steady-state conditions could achieve an 85 ± 5% reduction in volatile fatty acids (VFA) at SRTs between 20 and 9 d, with a methane production yield of around 0.8 l CH_4/L/d. Decreases in the SRT not only allow the sludge stability and biogas production to be maintained but also lead to an increase in the waste that could be treated and lower operating costs.

Biase et al. (2018) tested the Bench-scale anaerobic moving bed biofilm reactors (AMBBR) at mesophilic conditions and different HRT of 24, 18, 12, 10, 8 and 6 h. They also studied temperatures of 15, 25, and 35˚C at a constant HRT of 18 h. During the HRT study, it was found that AMBBR could be operated with COD removal above 80% at all HRT and therefore OLR below 23 kg-COD $m^{-3}d^{-1}$ at 40% media fill ratio. The highest performance of 92% removal of sCOD was attained at 5.4 kg-COD $m^{-3}d^{-1}$. This corresponded to surface area loading rates (SALR) of 18 g-sCOD $m^{-2}d^{-1}$ with methane yields of 0.34 m^3-CH_4 kg-COD^{-1} removed at 35˚C. At OLR above 23 kg-COD $m^{-3}d^{-1}$, the performance decreased below 80% sCOD removal at 35˚C.

Amorim et al. (2018) evaluated the rapid startup of UASB reactors at 30˚C for the cassava wastewater treatment. The reactor was operated under eight different conditions with a hydraulic retention time (HRT) of 8 or 12 h and organic loading rates (OLR) of 12.0 or 15.5 g $COD.L^{-1}d^{-1}$. The UASB system with the best performance was that with the 8 h HRT and OLR of 12.0 g $COD .L^{-1}d^{-1}$, with COD removal rates ranging from 71 to 80 % and methane production of 0.260 L CH_4 g $^{-1}$ $COD_{removed}$.

Moreover, Corsino et al. (2018) observed that under an OLR lower than 7 kg TCOD $m^{-3}d^{-1}$ the removal efficiency of total chemical oxygen demand (TCOD) was approximately 90% in the two aerobic granular sludge sequencing batch reactors (AGSBR) investigated. In contrast, at higher OLR a significant decrease in the removal efficiency (from 90% to less than 75%) was observed in the reactor R2.

Tritt and Kang (2017) reported that the reactor performance during their investigation showed a maximum 95% COD removal efficiency at an organic loading rate (OLR) of 1 kg COD/ m^3-d with its corresponding hydraulic retention time (HRT) of 7.5 d. At a higher OLR of 4.0 kg COD/ m^3-d, the COD removal efficiency of 75% was achieved with an HRT of 2 d. No significant difference in COD removal efficiencies was found between the reactors operated in both up-flow and down-flow modes.

Methane production from hydrogenic effluent by methanogenic UASB

The UASB reactor for methane production was fed with the acidogenic effluent collected from the CSTR and operated during 60 days under different OLR and HRT. The OLR was gradually augmented by increasing the concentration of the influent and then by decreasing the HRT (*Table 1*). *Figure 5* reveals the profile of the methane production and COD removal rate of the methanogenic reactor during the operation.

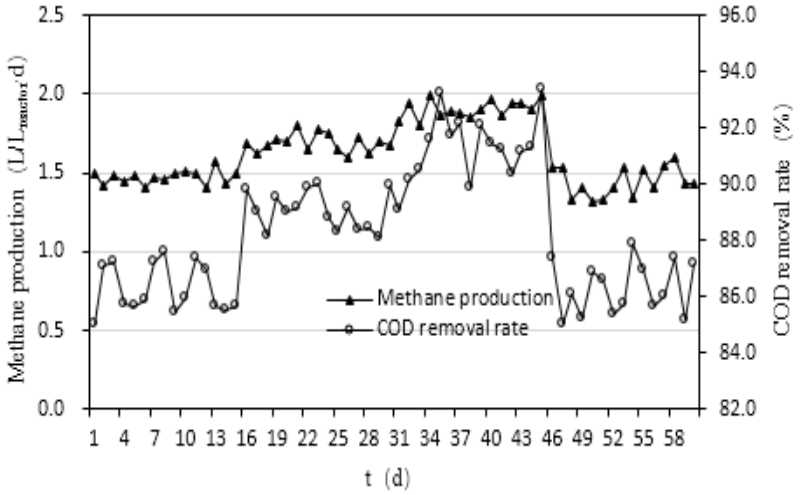

Figure 5. *The methane production and COD removal at different OLRs*

At the HRT 15 h, the OLR of 5.0 g COD/L reactor·d, the methanogenic UASB presented the optimal operation performance with the methane production of 1.9±0.3 L/L reactor·d. At HRT 12 h, the increased existence of activated sludge was detected in the methanogenic effluent caused by excessive flow velocity, so the methane production began to decrease remarkably down to 1.5±0.55 L/L reactor·d which showed that the reactor tends to go to lousy run statement. The COD removal rate has a similar variation curve with methane production, range between 85% and 93.5%, showing its high treatment efficiency and excellent process stability. In another study, Wang et al. (2009) found that increasing the HRT from 6 to 24 h, the COD of the effluent was gradually reduced from 257 to 124.4 mg/L, and the total removal rate of the COD increased from 88.1 to 95.6% in the anaerobic reactor treating starch wastewater. Besides, Colin et al. (2007) observed that the amount of biogas product (L-biogas/L.d) increased with the increase in organic loading rate. At the maximum of OLR of 18.11 g COD/L.d and HRT of 9.5 h, gas productivity of 3.7 L/ (L.d) was achieved in an anaerobic horizontal flow filter packed with bamboo peace treating starch wastewater. Moreover, Wu et al. (2018) reported in their study that the daily CH_4 production from the three treatments increased with the OLR. Results of Begum et al. (2018) disclosed that the range of methane yield in single and two-stage AD fluctuated between 0.21 and 0.34 L CH_4/(g COD removed) and 0.2 to 0.32 L CH4/(g COD removed) respectively with an overall increase of 21% in COD removal efficiencies can be achieved in two-stage AD.

Furthermore, Hu et al. (2018) related that the methane production rate increased with OLR increasing in thermophilic and mesophilic reactors. Their results indicated that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1116311174

thermophilic anaerobic reactors allow higher loading rate and yield higher methane production, substrate degradation, and pathogen destruction.

Shen et al. (2018) reported in their study that the volumetric methane production rate (VMPR) of experimental and control group revealed an increasing tendency with the increment of OLR. They attributed that phenomenon to the accumulation of VFAs in the system, which further inhibited the activity of methanogens and eventually resulted in the acidification of the AD system.

Arreola-Vargas et al. (2018) reported a linear trend between methane production and OLR with the highest volumetric methane production rate of 3.03 L CH_4 $d^{-1}L^{-1}$. Wickham et al. (2018) also reported that the increase in biogas production was proportional to the increase in organic loading rate (OLR) in their study.

Increased energy conversion efficiency by two-phase UASB

During hydrogenic fermentation, the most amounts of organic matters were converted into the VFAs, and the degraded COD was just removed in the form of hydrogen. So, the hydrogenic reactor presented relative low energy conversion efficiency varying between 8.0% and 12.1%, which is shown in *Figure 6*.

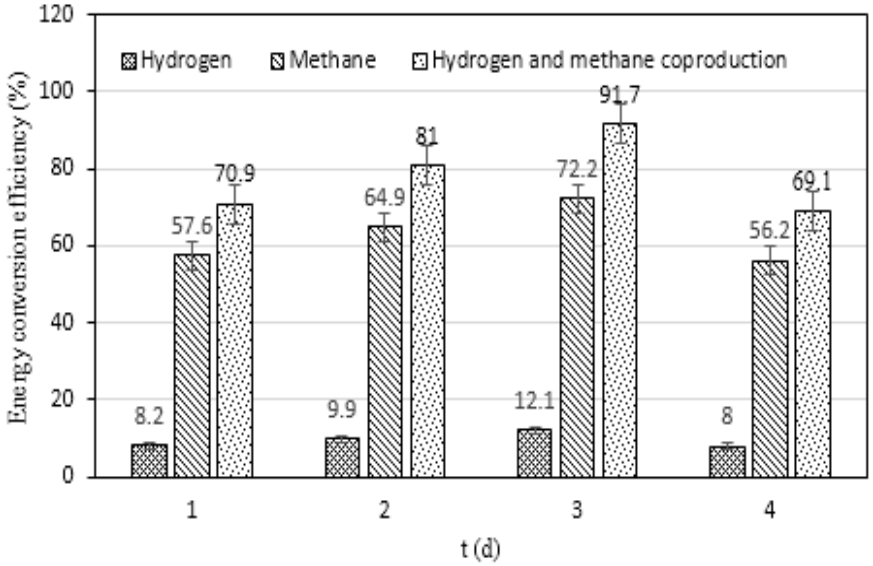

Figure 6. *The energy conversion efficiency for hydrogen and methane production*

At the operation condition of OLR 20 g COD/L $_{reactor}$·d for the hydrogenic reactor, the VFAs existed in hydrogenic effluent could be efficiently utilized by methanogenic microorganisms to produce the methane, which resulted in the high level of COD removal efficiency. The energy conversion efficiency of the methanogenic reactor reached up to the maximum value of 72.2% at OLR 5 g COD/L $_{reactor}$·d. The total energy conversion efficiency was also improved from 12.1% to 91.7% by two-phase anaerobic fermentation system. In the same way, Corona and Razo-Flores (2018) studied continuous H_2 and CH_4 production in a two-stage process to increase energy recovery from agave bagasse enzymatic-hydrolysate. The two-stage ongoing process significantly increased energy conversion efficiency (56%).

Comparison of hydrogen and methane production with other two-stage anaerobic digestion processes

Several researchers have studied the two-stage anaerobic digestion processes as shown in *Table 2*. Among the presented works, the two stages CSTR-UASB achieved the highest maximum hydrogen rate of 6.0 L/L/d and maximum methane rate of 6.4 L/L/d using agave bagasse (Corona and Razo-Flores, 2018).

Table 2. *Comparison of hydrogen and methane production with other two-stage anaerobic digestion processes*

Conclusion

The hydrogen and methane coproduction system containing two UASB reactors in this study were established at optimum OLR of 20 g COD/L reactor·d and 6.2 g COD/L reactor·d, respectively, for maximum biogas production from molasses wastewater. The maximum hydrogen production rate was reached at the OLR of 20 g COD/L reactor·d while the maximum methane production rate was reached at the OLR of 5.0 g COD/L reactor·d. Experimental data illustrated that the two-phase anaerobic fermentation process was a promising mean to recover energy from organic wastewater and provided the essential operation parameters guideline for the future industrial application. The feasibility of the two-phase anaerobic fermentation would need to be further studied.

(Received 22nd Mar 2019; accepted 4th Jul 2019)

Abstract. The dormancy characteristics of oat seed that can germinate after one season or one year are used to build and maintain vegetation to protect soils from desertification in Northern China. The aim of this study was to estimate the effects of endogenous and exogenous GA_3 and ABA on oat seed (*Avena sativa* L. BaiYan 7) germination. The results showed that seed without peel hull had lower endogenous ABA content and the ratio of ABA/GA_3 than seeds with peel hull. The best GA_3 treatment duration for milky ripe, wax ripe, full ripe seeds were 60 min (m) or 120 m, 60 m and 30 m, respectively. Seed germination rate, germination potential and germination index all increased then decreased with the increasing of GA_3 concentrations. The best GA_3 concentration treatment was 100 mg L^{-1}, while the turning point was 200 mg L^{-1}. The dormancy rate of low temperature storage seeds was higher than those stored in room temperature at each storage time, and both decreased with the increase of the storage time. New seeds or stored for 1-2 months, had significantly enhanced germination rate by exogenous GA_3. GA3 treatment had no effect on germination rate for the seeds that had been stored for over 3 months. Germination rate decreased with the increase of ABA concentrations. The most inhibitive effect, which lead to reduction of seed germination by 37.7% and 4.0%, when the concentration of ABA was 500 mg L^{-1} and 1000 mg L^{-1}, respectively. GA_3 could decrease the inhibition effect of ABA on seed germination.
Keywords: *oat, germination rate, gibberellic acid (GA3), abscisic acid (ABA) endogenous, exogenous*

Introduction

China's desertification area is about 1.74 million km^2, accounting for 18% of the total land area, and the area is going to increase in the future (Islam et al., 2011; Cheng et al., 2018). To solve this problem, it is important to build and maintain plant biology to increase surface coverage and restore native vegetation, which is the main reason why Chinese government has set up China Agriculture Research System to support the production and study of oat (Lin et al., 2012; Qian et al., 2018). Oat (*Avena sativa L.*) is a annual herbaceous plant belonging in gramineous precocious subfamily. It has strong ability to resist wind erosion and easy to sow, and easy to build plant (Lin et al., 2012; Zang et al., 2018). Oat can be cultivated in the marginal land with less water and fertilizer requirement so well adapted in desert area (Ren et al., 2007; Rabiei et al., 2012; Zang et al., 2015; Khan et al., 2019). Li et al. (2009) proved the strong anti-erosion ability of oat than corn, sunflower and mung bean, which will help to prevent farmland from desertification. "Baiyan7", breed by Baicheng Academy of Agricultural Sciences, has dormancy characteristics. Some other researches showed the dormancy strength of "Baiyan 7" can affect the vegetation establishment. Now the studies of oat

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1117511189

planting have focused on breeding, cultivation, physiological and biochemical aspects, oat seed science research focuses on the germination optimum temperature, germination substrate, salinity stress and seed storage, but the researches about the effect of phytohormones on germination of dormant oat are quite few. It is an innate property of seed that defines the environmental conditions in which the seed is able to germinate. It is determined by genetics with a substantial environmental influence which is mediated, at least in part, by the plant hormones abscisic acid and gibberellins (Finch-Savage and Leubne, 2006). Many previous studies show that GA_3 is the main regulator on seed germination and it could lift the bud and seed dormancy and promote bud instead of light or low temperature (Mukhtar and Singh, 2006; Ozkaya et al., 2006; Liu et al., 2016). Other study also found that for the germination of brown rice seed, in addition to water and a certain temperature, GA_3 was a promoting substance of seed germination (Damaris et al., 2019). ABA is a phytohormone which has been shown to be involved in a wide range of plant physiology (Wilkinson and Davies, 2010; Zhang et al., 2017). ABA could inhibit seed germination requirement concentration varies.

Therefore, we aims to 1) estimate the best GA3 concentration and treat time for germination of oat seed with different maturity; 2) evaluate the oat seed germination as affected by ABA input; 3) test the combination effect of GA3 and ABA for oat seed germination.

Materials and methods

Study site and materials

The experiment was conducted at Baicheng Academy of Agricultural Sciences, Baicheng, Jilin province, China (45° 37'N, 122° 48'E, 152 m elevation). The detail information of experiment sites could be found in Zang et al., 2018 and Qian et al., 2018. Bai Yan 7 oat (*Avena sativa* L.) seed used in this experiment supplied by the Baicheng Academy of Agricultural Sciences. Part of the seeds collected immediately for germination test, and other stored at room temperature under dry conditions or at 4 °C refrigerator for later use.

Experimental design

a) The effects of GA_3 treat time on germination of oat seed with different maturity

Each different matured oat seed were soaked in 100 mg L^{-1} GA_3 for different times in order to test the germination. The treatments time were T1 = 0 m, T2 = 30 m, T3 = 60 m, T4 = 120 m, and T5 = 240 m, different maturity were S1 = milky ripe, S2 = wax ripe, and S3 = full ripe. So the experiment had 15 treatment combinations, with three biological replications, and each replicates have 200 seeds. First, the seeds soaked and disinfected in 4.0% sodium hypochlorite solution for 30 min, then washed 5-6 times with distilled water. Second, tweezers were used to put the seeds in Petri dishes lined with filter paper, each plate contained 200 seeds and were kept at sufficient distance. Third, the Petri dishes were placed in an incubator maintaining temperature 20 °C, distilled water was used to keep the filter paper moist, sprout numbers in each treatment were recorded every morning, for 10 days, and the whole process were repeated 3 times. (These materials and methods are applicable to the following experiments.)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1117511189

b) The effects of GA3 concentrations on wax ripe seed germination

The wax ripe seeds were soaked in different GA_3 concentrations for 120 min, and then test the germination. Six treatments were established with increasing GA_3 concentrations as 0, 12.5, 25, 50, 100, and 200 mg L^{-1} (i.e. A1, A2, A3, A4, A5, and A6, respectively).

c) The effects of GA3 on germination of oat seed in different maturity with or without peel

Different maturities were cream ripe, wax ripe and full ripe. Each maturity seeds had four treatments: B1 = seeds with peel, B2 = seeds without peel, B3 = unpeeled seeds soaked in GA_3 for 2 h, B4 = peeled seeds soaked in GA_3 for 2 h.

d) The effects of GA_3 on germination of different matured oat seeds under low or room temperature

Oat seeds with different maturity were stored under low or room temperature. Different maturities were cream ripe, wax ripe and full ripe. Each kind of seeds had five storage durations: 0, 1, 2, 3, and 4 months (i.e. C1, C2, C3, C4, and C5).

e) The interaction effect of GA3 and ABA on germination of oat seed

GA_3 and ABA were dissolved in a small amount of ethanol, constant volume with distilled water, GA_3 preparation of 100 mg L^{-1}, the ABA 1000 mg L^{-1} as stock solution, respectively, using the GA_3 liquid and different concentrations of ABA dilution to deal with the sterilized seed, soak 30 min, remove seeds, and dry with filter paper, then do germination test. For GA_3 and ABA application, first the seed soak with different concentrations of ABA solution 30 min, after that soak with GA_3 solution for 30 min, and then start germination test. This experiment has nine treatments: D1 = 1000 mg L^{-1} ABA; D2 = 500 mg L^{-1} ABA; D3 = 250 mg L^{-1} ABA; D4 = 100 mg L^{-1} ABA; D5 = 100 mg L^{-1} GA_3 + 100 mg L^{-1} ABA; D6 = 100 mg L^{-1} GA_3 + 250 mg L^{-1} ABA; D7 = 100 mg L^{-1} GA_3 + 500 mg L^{-1} ABA; D8 = 100 mg L^{-1} GA_3 + 1000 mg L^{-1} ABA; CK use distilled water as control.

The detail experimental design of all experiment in present study also have been summarised as *Table A1* in the *Appendix*.

Determination indexes and methods

a) Seed collection standard

Oat seed development process was divided into three maturity phase. Full ripe: glumes white and open, the appearance of seed is yellowish-white, hard; wax ripe: glumes the sallow semi-open, the appearance of seed is yellow-green, slightly harder, volume reach mature state; milk ripe: glumes green and closed, the appearance of seed is green, tender, the volume does not reach mature state.

b) Determination of germination rate, germination potential, germinating, germination index and T50

Test method reference to the international seed testing and GB/T2930.4-2001.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1117511189

Germinating refers to the ratio of the sum of the maximum number of germination within three days and total number of germination.

T_{50} refers to seed germination rate of the time required in half of the final germination.

$$\text{Germination rate (\%)} = (n / N) \times 100 \quad \text{(Eq.1)}$$

In this equation n refers to the seed within the specified time normal germination accumulated grains, N refers to the total number of tested seeds.

$$\text{Germination potential (\%)} = (A / N) \times 100 \quad \text{(Eq.2)}$$

In *Equation 2,* "A" refers to the cumulative germination rate of 3 d before the test.

$$\text{Germination index} = \Sigma Gt / Dt \quad \text{(Eq.3)}$$

In *Equation 3,* "Gt" refers to the number of germination of the time t, "Dt" refers to the germination days.

Statistical analyses

Experimental raw data use the Excel (2007 version) statistical software to collate, then use both SAS (8.0 version) and Mstate-C statistical software to analyse. A factorial layout within randomized complete block design with 3 replications was used to analysis the variation of GA_3 processing time effect on germination characteristics of seeds in different maturity. Seed maturity were milky ripe seed, wax ripe seed and full ripe seed. GA_3 processing times were included 0, 30, 60, 120 and 240 min. In order to determine the influence of GA_3 concentration on different experimental characteristics, a randomized complete block design with three replications were used. GA_3 concentrations were 0, 12.5, 25, 50, 100 and 200 mg L^{-1}.

Results and discussion

As shown in *Table 1*, fully ripe seeds with or without peel, had significant differences ($p < 0.05$) in endogenous GA_3, ABA and GA_3/ABA at different storage periods. Endogenous GA_3 in fully ripe seeds without peel in each storage period were significantly higher than those with peel ($p < 0.05$). With the extension of storage time, endogenous GA_3 in full ripe seeds without peel were increased by 68.7%, 121.4%, 59.2%, 18.2%, and 29.0%, respectively when compared with seeds with peel. GA_3 contents showed a tremendous increasing trend with the storage time. Endogenous ABA in full ripe seeds with peel in each storage period was significantly higher than that in the seeds without peel ($p < 0.05$), with the extension of storage time, endogenous ABA in full ripe seed with peel than seed without peel were increased by 8.4%, 49.0%, 37.7%, 74.5%, and 36.7%, respectively, which means that it contains a certain amount of ABA within the peel. The ratio of GA_3/ABA in full ripe seeds without peel in each storage period was significantly higher than that in the seeds with peel ($p < 0.05$), with the extension of storage time, the ratio of GA_3/ABA in full ripe seeds without peel than seed with peel were increased by 82.8%, 229.9%, 119.2%, 106.2%, and 76.3%, respectively (*Table 1*).

Table 1. *Full ripe seed phytohormones content at different storage periods with or without peel*

Treatment	Determination index	Storage time (month)				
		0	1	2	3	4
With peel	GA_3 (ng/g.FW)	9.25d	5.24e	11.50c	19.18b	39.95a
Without peel		15.61d	11.60e	18.31c	22.67b	52.52a
With peel	ABA (ng/g.FW)	146.18c	137.41e	148.42b	169.33a	138.01d
Without peel		134.91a	92.23e	107.81b	97.03d	100.94c
With peel	GA_3/ABA	0.06d	0.04e	0.08c	0.11b	0.29a
Without peel		0.12d	0.13d	0.17c	0.23b	0.51a

Different letters within a row indicate significant differences between the mean *($p < 0.05$)*

Table 2 showed that, wax ripe seed with or without peel, have significant differences ($p < 0.05$) in endogenous GA_3, ABA and GA_3/ABA at different storage periods. GA3 content in wax ripe seed which was stored for three months was significantly lower in the seed without peel than seed with peel ($p < 0.05$), the rest are significantly higher than wax ripe seed with peel ($p < 0.05$), with the storage time of 0 m (month), 1 m, 2 m, 4 m, and endogenous GA_3 in wax ripe seed without peel than seed with peel, the increase by 67.7%, 15.5%, 80.1%, and 59.9% was seen. Endogenous ABA in wax ripe seed with peel in each storage period are significantly higher than that without peel ($p < 0.05$), with the extension of storage time, endogenous ABA in wax ripe seed with peel than seed without peel were increased by 55.6%, 152.8%, 165.9%, 270.9%, and 72.9%, respectively; this means that it contains a certain amount of ABA within the peel. The ratio of GA_3/ABA in wax ripe seed without peel in each storage period are significantly higher than seed with peel ($p < 0.05$). Moreover, with the extension of storage time, the ratio of GA_3/ABA in full ripe seed without peel than seed with peel were increased by 161.0%, 191.9%, 378.8%, 209.9%, 176.3% (*Table 2*).

Table 2. *Wax ripe seed phytohormones content of the different storage period with or without peel*

Treatment	Determination index	Storage time (month)				
		0	1	2	3	4
With peel	GA_3 (ng/g.FW)	19.79c	20.10c	16.45d	23.12b	37.09a
Without peel		33.20b	23.20d	29.63c	19.32e	59.29a
With peel	ABA (ng/g.FW)	223.03a	158.33d	169.16c	202.80b	131.84e
Without peel		143.37a	62.63d	63.62c	54.67e	76.27b
With peel	GA_3/ABA	0.09d	0.13b	0.10cd	0.11bc	0.28a
Without peel		0.23d	0.37c	0.47b	0.35c	0.78a

Different letters within a row indicate significant differences between the mean ($p < 0.05$)

Table 3 showed that, milky ripe seed with peel or without peel, the endogenous GA_3, ABA and GA_3/ABA at different storage periods have significant differences ($p < 0.05$). Milky ripe seed without peel GA_3 content in addition to storage for four month had no significant with seed with peel ($p < 0.05$), the rest were significantly higher than seed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1117511189

with peel ($p < 0.05$), with the storage time of 0 m (month), 1 m, 2 m, 3 m, endogenous GA_3 in milky ripe seed without peel than seed with peel were increased by 44.0%, 37.7%, 76.9%, and 25.7%, respectively; the endogenous ABA in milky ripe seed with peel in each storage periods are significantly higher than seed without peel ($p < 0.05$), with the extension of storage time, endogenous ABA in milky ripe seed with peel than seed without peel were increased by 38.9%, 18.8, 162.2, 107.9, 71.3%, this means it contain a certain amount of ABA within the peel. Milky ripe seed without peel the ratio of GA_3/ABA in addition to storage for 0 month had no significant difference with the seed with peel ($p < 0.05$), the rest were significant ($p < 0.05$); with the storage time of 2 m (month), 3 m, 4 m, and the ratio of GA_3/ABA in milky ripe seed without peel than seed with peel were increased by 48.2%, 65.4%, and 73.6%, respectively (*Table 3*).

Table 3. *Milky ripe seed phytohormones content of the different storage period with or without peel*

Treatment	Determination index	Storage time (month)

Different letters within a row indicate significant differences between the mean ($p < 0.05$)

Seed maturity has significant influence on germination potential, germination rate, germination index and T_{50}(d). Uniformity was not significantly influenced by seed maturity. Germination potential, germination rate and germination index were significantly affected by GA_3 processing time; however, this effect on uniformity and T_{50}(d). Like, seed maturity, the interaction between seed maturity and GA_3 processing time has significant effect on all experimental characteristics expect uniformity (*Table 4*).

Table 4. *Analysis variance the effect of GA3 processing time on germination characteristics of seeds in different maturity*

S.O.V	d.f.	Germination potential (%)	Germination rate (%)	Germination index	Uniformity	T_{50} (d)

The highest germination potential was related to full ripe seed and the lowest one was obtained by milky ripe seed, there was no significant difference between wax and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1117511189

full ripe seed, but both of them have significant differences with milky ripe seed. The maximum germination rate and germination index also achieved in full ripe seeds. No significant differences were found in these two experimental traits between milky and ripe seed, but both of them had significant differences with full ripe seed. There were no significant differences among milky ripe seed, wax ripe seed and full ripe seed. Wax ripe seed has obtained the highest T_{50}, but its difference with full ripe seed was not significant. However, not only wax ripe seed, but also full ripe seed had significant difference with milky seed maturity. The maximum germination potential and germination rate was occurred in 120 and 60 min GA_3 processing time, respectively. 120 min GA_3 processing time had obtained the maximum germination index which just had significant differences with control treatment (0 min). There were no significant differences among treatments in uniformity index, furthermore, the maximum one was obtained by control treatment (0 min). On the one hand, the highest T_{50} was related to control treatment; on the other hand, the lowest one was obtained by 60, 120 and 240 min. Moreover, there were no significant differences among treatments. The results show that seeds immersed for 60 m by GA_3 had best effect to promote germination to ripe seeds, and they inhibited germination when immersed for 240 m. The maximum germination potential and germination rate was related to interaction between full ripe seed and 30 min of GA_3 processing time, and the highest germination index was achieved in full ripe seed and 120 min GA_3 processing time interaction. There were no significant differences among interaction traits in uniformity. Both, interaction between milky ripe seed and control treatment in processing time, interaction between milky ripe seed and 30 min of GA_3 processing time had obtained the highest T_{50}, which had significant differences with all other interaction (*Table 5*).

Table 5. *Mean comparison for germination characteristics*

Means with common letters within each column do not differ significantly. The effect of seed maturity, GA_3 processing time, and their interaction were evaluated. The treatments for seed manturity were milky ripe seed (S1), wax ripe seed (S2), and full ripe seed (S3). The treatments for GA_3 processing time were0 (T1), 30 (T2), 60 (T3), 120 (T4), and 240 m (T5)

Germination potential has positive and significant correlation with germination rate and germination index, which means that with increase of germination potential, germination rate increase significantly. However, germination potential has negative and significant correlation with T_{50} and non-significant positive correlation with uniformity. The positive significant correlation was found between germination rate and germination index. T_{50} also had negative and significant correlation with both germination rate and germination index. Furthermore, the correlation between uniformity and T_{50} was positive, but it was not significant (*Table 6*). GA_3 concentration had significant influence on germination potential, germination rate and germination index, but uniformity and T_{50} were not affected by it (*Table 7*).

The highest germination potential and germination rate was related to 100 mg L^{-1} GA_3 concentration, which had significant differences with all treatments, except 200 mg L^{-1} in both experimental traits. The highest and the lowest germination rate were achieved in 100 mg L^{-1} and control treatment (0 mg L^{-1}) GA_3 concentration, which had significant difference with each other. 100 GA_3 concentration had obtained the maximum germination index, which had significant differences with 0 mg L^{-1} and 12.5 mg L^{-1}. There were no significant differences among treatments in uniformity. The highest T_{50} was related to 50 mg L^{-1} and 100 mg L^{-1}, respectively. Like uniformity, no significant difference was found among treatments (*Table 8*).

Influence of different maturity seed germination by dealing with GA3

The results showed that, after manual peel out seed, the immersed with GA_3, seeds in different maturity had significantly improved germination rate, germination energy and germination index, which had significant difference with other treatments. Manual removal treatment (B2) and GA_3 treatment (B3) had significant difference with B1 in germination rate. Milky ripe seeds had significant differences in germination potential by dealing with GA_3; seeds treated by B4 were significantly higher than other treatments in germination rate, there was no significant difference between B2 and B3, but also it was significantly higher than B1; seeds treated by B4 was significantly higher than other treatments in germination index, when others have no significant difference; T_{50} of B4 and B3 is shortened one day than B2 and B1. B4 had no significant difference with B3 in the germination potential of wax ripe seed, but it was significantly higher than B2 and B1; furthermore, there was no significant difference between B3 and B2, but B3 was significantly higher than B1. There was no significant difference between B2 and B1; seed treated by B4 was significantly higher than other treatments in germination rate, there was no significant difference between B2 and B3, but they were significantly higher than B1. Seed treated by B4 was significantly higher than other treatments in germination rate, furthermore, B2 was significantly higher than B3 and B1 in germination index, and there was no significant difference between B3 and B1; T_{50} of B4 and B3 was shortened one day than B2 and B1. Full ripe seed had significant difference in germination potential. Full ripe seed had significant difference in germination rate, there was no significant difference between B4 and B1, but all of them were significantly higher than other treatments; T_{50} of B4 and B3 is shortened one day than B2 and B1 (*Table 9*).

Influence of different maturity seed germination under low temperature and room temperature storage conditions by dealing with GA3

The results showed that using GA_3 treatment to harvest and storage one month cream ripe seed at room temperature, the germination rate were higher than comparison results, the difference reached significant level ($p < 0.05$), increasing 8 and 5.1 percentage points; using GA_3 treatment at room temperature to storage for two months, three months and four months, seed germination rate compared to the comparison was not significant. Storage at room temperature for three and four months, seed germination rate was lower than the comparison, reduced by 2 and 3 percentage points. Germination rate of the new harvest, cold storage for one and two months milk ripe seed treated by GA_3, was higher than the comparison, the difference reached significant level ($p < 0.05$), increasing 8, 6.9 and 5.5 percentage points, respectively; germination rate of cold storage two and three months milky ripe seed treated by GA_3 was lower than the comparison for 4%, the difference was not significant (*Table 10*).

The results of this experiment showed that the GA_3 treatment promote seed storage at room temperature or low temperature seed germination, especially for two months, but not for three or more months or even inhibition.

GA3 and ABA interaction effects on seed germination

The test results showed the significant differences, in the germination rate of each treatment compared with CK, D5, D6, D7 ($p < 0.01$); the D8 germination rate was significantly higher than that of D4, D3, D2, D1, ($p < 0.05$). D1 and D2 were the most important treatment which inhibited seed germination compare to other treatments, seed germination in D3 and D4 were 36.0% and 24.0%, respectively; under the same concentration of ABA, the seed germination rate of ABA and GA_3 interaction treatment was higher than ABA treatment, but it was still lower than CK levels. These results suggest that ABA inhibits seed germination, and inhibition increased with the increase trend of ABA concentration; furthermore GA_3 can alleviate the inhibitory effect of ABA on seed germination and alleviating margin of D1, D2 with GA_3 is larger than the D3, D4 (*Fig. 1*).

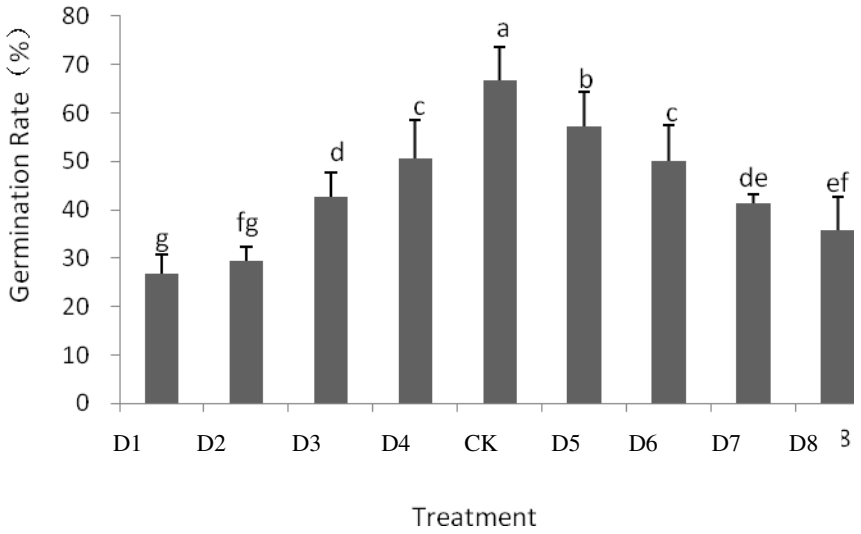

Figure 1. *GA_3 and ABA interaction effects on seed germination*

The results of this experiment showed that the endogenous GA_3 content of each maturity degree oat seed increased with the storage period, while endogenous ABA content decreased with storage time to extend. Different maturity seed GA_3/ABA ratio increase with the storage time, and this result is the same for maturity germination rate. Furthermore, GA_3 content of seed without peel were higher than those with peel at each storage time, while ABA content showed the opposite. Thus, the peel may contain more ABA and conducive to seed dormancy. This was in agree with the observed germination of wild oat with positive relationship between ABA/GA_3 ratio and seed germination, it further strongly affected the dormancy rate (Yu et al., 2016; Esashi, 2017). Zeng and Zhao (2001) indicated that the red string seed showed during seed development, the content of endogenous GA_3 showed a decreasing trend, that GA_3 content in dry seeds in room temperature and low temperature during storage have

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1117511189

shown pre gradually reduce, the latter has an upturn, and the content of endogenous GA_3 and no significant correlation with the seed germination rate. Seed germination rate significantly increased with storage time extended, the role of GA_3 to enhance the seed germination rate weakened. This is similar to the results of Zeng and Zhao (2001) that related to GA_3, a role on a red string seed germination. This experiment showed that when seeds are treated with different concentrations of exogenous ABA, seed germination rate decreased with the increase of ABA concentration, even when at the same time there is application of GA_3, the germination rate of seed was certain upward, but still lower than in CK. So ABA inhibited seed germination, but its inhibitory effect in a certain extent can be remission by GA_3. Wang et al. (2004) also reported the influence of ABA on the inhibition of rice seed germination results.

Conclusions

Seeds without peel had lower endogenous ABA content and the ratio of ABA/GA_3 than seeds with peel. The best GA_3 treatment time for milky ripe, wax ripe, full ripe seed were 60 min (m) or 120 m, 60 m, and 30 m, respectively. Seed germination rate, germination potential and germination index were all first increased and then decreased with increasing GA3 concentrations. The best treatment concentration of GA_3 was 100 mg L^{-1}, the turning point was 200 mg L^{-1}. The dormancy rate of low temperature storage seeds were higher than those stored in room temperature at each storage time, and both were decreased with the storage time. New seeds or stored for 1-2 months, showed significantly enhanced germination rate by exogenous GA_3. GA3 treatment had no effect on germination rate for seeds that had been stored for over 3 months. ABA inhibits the germination rate, which decreases with the increasing concentration of ABA. The most inhibitive effect, which leaded to a seed germination reduction by 37.7% and 4.0%, appeared when the concentration of ABA was 500 and 1000 mg L^{-1}. GA_3 could abate the effect which ABA inhibited seed germination.

Acknowledgements. We are grateful to the study grants from the earmarked fund for China Agriculture Research System (CARS-08-B-1). Thanks to the guidance of Laichun Guo and Chunlong Wang in the experiment, and thanks the workers in Baicheng Academy of Agricultural Sciences for their skilled technical assistant.

(Received 27th Mar 2019; accepted 19th Jun 2019)

Abstract. Recent advancements in biotechnology resulted in rapid adoption of genetically modified (GM) crops in the agriculture systems. At the same time, transgene escape has also been reported and examples reveal global dimension of the problem. Pollen mediated gene flow (PMGF) is the major pathway for transgene escape. Almost all transgenes have been escaped into their Non-GM counterpart and wild relatives. Although gene flow varies between species, crops, and ecological zones/environments but intraspecific gene flow (> 10%) is not uncommon in adjacent populations. Whereas in outcrossing species, 1% gene flow at thousand meters' isolation is not unusual, and magnitude is even higher than the mutation rate. It is well documented that transgene flow is deteriorating different production systems in agriculture and famers choice to cultivate GM, conventional and organic crops. If comprehensive policy is not implemented, then in future it will be difficult to detect and remove transgenes from the environment; if unexpected problems arise.
Keywords: *biosafety, biological containment, coexistence, genetic contamination, out-crossing, pollen dispersal, transgene flow*

Introduction

Gene flow, a natural phenomenon, changes the gene frequency in population due to outcrossing of gametes, movement of individuals across countries or groups from one place to another (Goodman and Newell, 1985; Ellstrand, 2003; Cerdeira and Duke, 2006). In the current scenario of agriculture, where 189.8 million ha of GM crops were planted in 2017 with global market value of US$ 17.2 billion (ISAAA, 2017), coexistence and identity preservation among transgenic and non-transgenic cropping systems at the field level are becoming important issues (Beckie and Hall, 2008). Concerns have been identified and raised about GM plants in new environmental conditions and in response to transgene escape into wild relatives and crop to crop has

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1119111208

gained much attention of plant biologists. It is not uncommon for transgenic plants to mate with their wild relatives. Spontaneous hybridization will occur among transgenic and non-transgenic plants unless the proper distances are maintained, and also the engineered plants are specifically designed to limit gene flow (Gressel, 1999; Daniell, 2002). It is not necessary that gene flow creates problem but it may enhance local genetic diversity and in part it depends on the phenotypes conferred by transgenes (Ellstrand and Hoffman, 1990; Ellstrand, 2003). Outcrossing poses negative impacts in terms of contamination in non-transgenic crops but again problem depends on new allele whether causes an increase in transgene escape or not. According to Kareiva and Marvier (2000), gene flow varies between species, within species of same crop, populations, genotypes and environments. Surprisingly, intraspecific gene flow occurs at high rate. Gene flow of more than 10% is not uncommon in adjacent populations. For outcrossing species, 1% gene flow at thousand meters isolation is not unusual and the magnitude is higher than the rate of mutation (Ellstrand, 2014). Further, adventitious mixing of GM and non-GM crops also raises the question about maintenance of different production systems in agriculture sector and famers choice to grow either GM, conventional or organic crops. Various measures have been proposed to minimize transgene escape, such as the use of refuge surrounding the GM crop in the field with barren zones, genetic methods to handicap the fitness of transgenic hybrid (Gressel, 1999; Daniell, 2002). Monitoring transgene escape has been initiated to measure the adverse impact on environment (NRC, 2002). The impact of gene flow is so high that even single gene can contaminate the population, so it is difficult to establish an effective monitoring programme (Marvier et al., 1999). This review describes the facts and thoughts behind transgene escape, sources and level of contamination in major crops, containment and mitigation strategies, their comparison, conclusion and future prospects.

Transgene escape: facts and speculations

Transgene escape is a fact and usually restricted to within species or closely related species and this is referred to as vertical gene flow. It is very rare that gene flow occurs between species, i.e. horizontal gene flow. In contrary, diagonal gene flow occurs between closely related species (Gressel, 2015). With these concerns, the genetically engineered (GE) crops have been cultivated for commercial and research purposes under some restrictions to avoid transgene escape. But after 22 years of GE crops, we failed to control gene flow in a systematic manner (Ryffel, 2014).

Convincing evidences of transgene escape have been found in cotton, maize, soybean, oilseed rape, rice, and wheat (Baltazar et al., 2015; Dong et al., 2016; Londo et al., 2011; Mizuguti et al., 2010; Ramzan et al., 2014; Serrat et al., 2013), and describes that transgene escape (*Table 1*). Transgene may not only flow in area bordering the GM field but may also happen far away. These findings are not limited to a certain region of the world instead the examples reveals global dimension of the problem. Hybridization of GM plants with their conventional parents and adventitious presence of seed has been observed as expected.

Cotton is an illustrative example, where gene flow both vertical and diagonal has been documented in several studies (*Table 1*). Transgenes in *Gossypium hirsutum* conferring insect and herbicide resistance have been escaped through pollen to conventional counterparts, *G. barbadense,* refugees and wild relatives (Heuberger et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1119111208

2010). Similarly, PMGF has been reported from GE maize. Similar case is reported in Mexico, where GM corn was not allowed for commercial cultivation but transgene escape was found in landraces (Mercer and Wainright, 2008). Initially these findings were controversial but dies, good evidences for the escape of transgenes were found through comprehensive experimentations (Mercer and Wainright, 2008).

Another example is from oilseed rape, in which glyphosate resistance was found in field grown glufosinate resistant oilseed rape. The fact that in several cases stacked events that were not engineered in the laboratory identified in the field. This showed the rapidity of recombining genes between varieties of an outcrossing species (*Table 1*). In case of wheat, many studies on escape of herbicide resistance genes have been documented as a part of literature. This escape is independent off whether the resistance is created by mutagenesis or transgenic. Therefore, the risk assessment should be based on the biology of a field crop, the traits, occurrence of compatible relatives and transformation method, i.e. classical breeding or genetic engineering used for trait integration.

Genetically modified crops and gene flow

Cotton

Cotton is first genetically engineered crop which was commercially introduced in 1996. It is primarily a self-pollinated crop but 5-30% outcrossing may occur due to pollinators (Poehlman, 2013). Its pollen is large and sticky which makes pollinators potentially important in cross pollination (Van Deynze et al., 2005). Due to often cross pollination GM cotton is continuously contaminating its non-GM germplasm which have superior yield and fiber quality traits required for farmer and industrialist. This threatens the use of refugees and complicates the removal of transgene from the environment if unexpected problems arise. Many studies on the level of contamination in cotton are documented. In a recent study, Ramzan et al. (2014) reported highest rate of contamination (22% from Bt samples and 20% from non-Bt) from Faisalabad, the city of Pakistan where previously cotton was the major commercially grown crop. Heuberger et al. (2010) identified the potential sources of Bt contamination and demonstrated that out crossing (due to abundance of honeybees), proximity to Bt fields and human factors contribute to seed contamination in cotton. Therefore, it is necessary for cotton breeders to screen their breeding material thoroughly for the removal of genetic contamination from non-Bt. Cotton germplasm for the development of non-Bt strains in future.

Maize

In maize, gene flow occurs between all sexually compatible plant types, i.e. commercial hybrids, landraces and eventual wild relatives (Baltazar et al., 2015). The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1119111208

driving sources behind transgene flow are pollen transfer between hybrids of different transgene controlling certain traits, cultivator determined seed selection and mixing. But both traits are affected by farmer's practices and agroecological circumstances.

The cultivation of open-pollinated varieties (OPVs) along with commercial hybrids also increase rate of gene flow (Sanvido et al., 2008). The synchronization of flowering in GM maize and its non-GM is important to determine the potential of pollens for gene flow by cross-hybridization (Palaudelmas et al., 2008). The role of seeds as an additional source for gene flow in maize must not be underestimated (Dyer et al., 2009). Farmers share and recycle maize seeds which increases gene flow locally but also increases the distance that transgene travel. Seed saving and sharing need to be analyzed along with PMGF to understand that what happens from local to regional, national and transnational levels, over time.

Soybean

Weeds are the major problem in soybean cultivation. To control plague a foreign gene CP4 was introduced to develop herbicide resistant soybean. Transgene flow becomes a major problem because the farmers prefer to grow conventional soybean. Cultivation of GM soybean has been increased many fold due to the introduction of glyphosate resistant soybean (Yoshimura et al., 2006). Due to more availability of transgenic cultivars, the contamination of conventional cultivars and unintended combination of transgenes through natural crossing is becoming a serious threat. Ray et al. (2003) reported 0.65 to 6.32% natural cross pollination in soybean in different experiments and highlighted the potential for transgene flow. Cross pollination in soybean is more likely facilitated by insects (Rust et al., 1980), since soybeans are predominantly self-pollinating and the flowers have anatomical features of entomophilous plant species (Erickson and Garment, 1979).

Oilseed rape

Oilseed rape (*Brassica napus* L.) has been genetically modified to tolerate broad spectrum herbicides. Due to its ability of producing large amount of pollen, it is an ideal crop to understand the implications of transgene flow. Oilseed rape is known to exhibit different levels of outcrossing. It is partially pollinated by honeybees and bumble bees and is also known to release large amounts of air-borne pollen. Timmons et al. (1995) demonstrated that cross-pollination in oilseed could vary from 5 to 55%. There are number of factors which control PMGF that includes flowering synchrony, mode of pollen dispersal (wind and insect), area density of donor, recipient plants and physical distance (Campbell, 1985).

Wheat

PMGF is main mode of transgene flow in wheat flower for disseminating transferred alien genes (Song et al., 2004). The gene flow in wheat usually occurs over very short distances and at extremely low frequencies, but measures should be taken to avoid contamination of non-GM wheat. In wheat, average cross-pollination rate is 1-2% in close proximity (Gustafson et al., 2005). Loureiro et al. (2007) demonstrated high rates of cross pollination (37 to 56%) by using emasculated wheat as pollen receptor at 0 m distance between two cultivars of *Triticum aestivum*. In another study, Loureiro et al. (2012) investigated that PMGF in transgenic wheat using three conventional wheat

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1119111208

species and found a maximum outcrossing of 3.5%. Currently there are no commercial GM wheat varieties but extensive research is being carried out for the development of herbicide resistance either through genetic engineering or mutagenesis. Therefore, the concern is that once transgenic is commercially released there is potential for gene flow from GM to Non-GM wheats. So, the effective methods like isolation distances or containment and mitigation strategies should be opted for preventing outcrossing and contamination between compatible genotypes.

Rice

Rice is highly self-pollinated crop but pollen mediated outcrossing occurs when flowering period of various cultivars get synchronized and/or grown in close vicinity, but frequency of gene flow is very low (< 1.0%). Previous studies found that GM rice may hybridize with traditional cultivars (Rong et al., 2005; Yuan et al., 2007), weedy rice (Chen et al., 2004; Zhang et al., 2006; Olguin et al., 2009), and wild rice (Chen et al., 2004; Yao et al., 2008). Transgene flow from GM rice to other cultivars and weedy relatives is a major risk associated with commercial release (Messeguer, 2003). Development of GM rice varieties for having various traits like herbicide tolerance (bar and EPSPs), disease resistance (Xa21) and insect resistance (Bt and CpTI genes) are in pipeline for commercialization (Xia et al., 2011; Parisi et al., 2016). These developments warn the researchers to prioritize the studies related to risk associated with transgene flow from GM to non-GM rice.

Transgene containment and mitigation strategies

While dealing with trans-gene flow one should keep in view the situations according to transgenic crops. The research work on risk assessment during gene escape can be a useful aspect while countering gene flow (Chapman and Burke, 2006). In general, there are two approaches; either we can keep the gene in original GMO or can mitigate the effects (Gressel and Al-Ahmad, 2006). The possible containment and mitigation strategies are discussed here and their comparison on the basis of positive and negative aspects is given in *Table 2*.

Transgene containment strategies

Physical containment

Usually gene flow occurs through pollen or seed, so one way to contain transgene can be preventing seeds and pollen dispersal (Linder et al., 1998). This dispersal can be prevented using isolation of GM crop by using various physical barriers in addition to careful processing of seed (Arriola, 1997). Researchers have found effective solution by using pollen barriers, stopping insect flow in crops and physical isolation. Staniland et al. (2000) limited the out-crossing up to 0.015% complimenting the results of Morris et al. (1994) where out-crossing was reduced to 0.94% in two different experiments. All of this sounds very convincing when used in experiments but when we look at ground realities different shocking cases are reported like, scientists have found traces of trans-genes in seeds from non-experimental area. Landraces of maize (*Zea maize*) in Mexico was found with tarns-genes despite of fact that GM corn was not allowed to cultivate in the country (Ortiz-Garcia et al., 2005). Similarly glyphosate resistance was found in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1119111208

cultivars of *B. napus* grown in Canada, a year before cultivation of GM brassica was allowed to plant (Hall et al., 2000). A non-GM crop was found with trans-genes, this crop was cultivated (at long enough distance to reduce pollen contamination) after a GM crop carrying gene for a pharmaceutical product on a field of registered company following all the rules for isolation (Fox, 2003). More alarming situation will be faced when most of world crops will be transgenic and isolation will not be possible (Rieger et al., 2002). These situations can be addressed by more careful processing and transportation of seed from GM crops plants, isolation of cultivars having sophisticated genes with more sensitive markers.

Table 2. *Comparison of different transgene flow countermeasures for their positive and negative aspects*

Countering technique	Positive aspects	Doubts	References
Physical containments	• Easy and simple to use • Economical • Easily useable to all crops	• Not been able to contain transgene completely • It is almost impossible to stop flow through seed based products	Arriola (1997), Linder et al. (1998)
Biological/molecular containments			
Sterility	• Gain great results using complete sterility	• Male sterility fount to be leaky as it can serve as female parent • For complete sterility vegetative propagation is necessary so not possible in all crops • Farmer will not be able to produce own seed causing monopoly of seed companies	Daniell (2002), Schernthaner et al. (2003)
Clistogamy	• Biological control without use of any danger to gene pool	• Can cause inbreeding depression • Difficult to use in all crops • Some leakage has been observed	Husken et al. (2010), Gealy (2005)
Apomixes	• Good for fixing heterosis	• Difficult to attain • Can cause dispersal through pollen if not complemented by sterility	Bicknell and Kultunow (2004), Bhat et al. (2005)
Maternal transformation	• Can effectively hinders the dispersal through pollen • If complemented with female sterility it can be a good option	• Not possible in all crops due to biparental inheritance • Backcrossing of hybrid with GM crop can disperse the trait	Maliga (2004), Haider et al. (2009)
Incompatible genome	• No extra labor is required	• Can only possible in crops having multiple genomes • Compatibility with homologous genomes have been reported	Lu (2003)
Gene splitting	• It can be effective if complimented with other techniques	• Gene splitting alone can cause up to 25% gene flow in segregating generation	Dong et al. (2015), Wang et al. (2014)
Expression in virus	• Alone can contain transgene flow effectively	• Transgene will be good only for single generation	Kelloniemi et al. (2008)
GURTs	• Sound effective technique	• No evaluation yet • Issues regarding monopoly of seed companies	Swanson and Goschl (2000)
Transgenic mitigation	• It disable transgene irrespective of flow • Found good results in evaluating TM	• If transgene is not removed it can restore expression at any stage • Very minute quantity of transgene flow is still there it can slow down the process but cannot completely shut it down • Different blocking genes used can be a novel threat to biosafety	Gressel and Al-Ahmad (2006), Kuvshinov et al. (2001), Saurabh et al. (2014)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1119111208

Biological and molecular containment

This sort of containment utilizes genetic manipulation to create plants with less ability to disperse transgenes usually by interference in pollination and fertilization process (Moon et al., 2011). There are different processes which are implemented to contain transgene biologically. In the following sections it is tried to explain basic principle and examples of different mechanisms.

Sterility

Most of the times transgene flow occurs through pollens so implying the trait of male sterility can cordially reduce the problem (Daniell, 2002). This system is incorporated in cytoplasmic DNA and can be restored by environmental stimuli or restorer genes in nuclear DNA (Schnable and Wise, 1998). This technology is seemed to be less viable as it is reported that in field male sterile plants are not fully sterile. In addition, if male sterile plant is used as female parent it can recover transgenic trait as a result of backcrossing (Daniell, 2002).

Another technique seems more convincing and viable if compared with male sterility, it utilizes sterility of both the sex in plants and they can still produce viable seed (Seed sterility) this process imply the use of different deleterious genes which can only trigger under specific conditions/stimuli, i.e. temporal or site specific promoters (only express in gametes) or any chemical reaction (Ryffel, 2014). Schernthaner et al. (2003) proposed a technique to produce sterile seed; they used lethal genes (lethal for seed fertility) and these are closely linked with gene of interest along with repressing genes on homologous chromosome on same loci. After hybridization the repressor gene will segregate from combo of transgene and lethal gene will cause death of plant due to having trans-gene that will lead to counter trans-gene flow.

Cleistogamy

Cleistogamy is a modification of flower structure to promote self-pollination but it avoids outcrossing in barley, soybean and rice, and is effective mean against transgene flow (Husken et al., 2010). Cleistogamy can be induced by mutations or genetic engineering. In addition, various genes have been identified, i.e. OsMADS 2, OsMADS 1, OsMADS 3 and SUPERWOMAN 1 (SPW 1) in rice (Lee et al., 2003; Xiao et al., 2003; Prasad et al., 2005; Yadav et al., 2007), and Cly1 and Cly2 genes in barley (Wang et al., 2013). But most of these genes cause sterility due to interaction with reproductive parts of flower (Agarwal et al., 2007). Out-crossing was restricted to 2-6% by transformation of these genes but sterility was in question (Gealy, 2005). To restore the fertility, a mutant of SUPERWOMAN 1 named SPW 1^{145T} was discovered (Yoshida et al., 2007).

Apomixes

The use of apomixes is most successful method to stop trans-gene flow and this is also modification in floral structure that can be propagated by asexual means (Gressel, 2015; Kwit et al., 2011). Some of crops like banana, potato and sugarcane are naturally asexually propagated but introduction of this trait in other crop plants is tedious and time consuming work without effecting the seed production and this mechanism has also a property for fixing the hybrid vigor (Bicknell and Kultunow, 2004). Different

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1119111208

techniques can be utilized for this purpose like apomixes, parthenogenesis and manipulating ploidy levels. As study goes on asexual reproduction it is taken that most easy and frequently considered way is using apomictic traits (Gressel, 2015; Ryffel, 2014). Apomictic plants produce seed without undergoing meiosis, but in combination with male sterility can be a more effective method for containment of unwanted gene flow (Bhat et al., 2005). According to an estimate about 400 plant species and 40 families reproduce through apomixes (Carman, 1997). So this trait can be used widely because 40 representative families are available as reference. The over-expression of various genes (*OsLEC1* and *OsLEC2)* enhances production of apomictic embryo. The gene namely *SERK* and *OsAPOSTART* are found responsible for apomixes induction in *P. pratensis* (Albertini et al., 2005). Use of apomixes as a containment strategy has been proven in GM-bahia grass where transgene flow was limited to only 0.2% (Sandhu et al., 2010).

Maternal effects

One of the few techniques for containing unwanted gene flow can be transformation of genes controlling economically important gene in plastids and mitochondria (Maliga, 2004). This method can be useful in decreasing the frequency of transgene flow but cannot be effective in traits where complete leakage is found (Gressel and Al-Ahmad, 2006). As crossing is a two way process so GM crop can also serve as female parent so with backcrossing hybrids can recover the transgene and spread it (Stewart et al., 2003). An additional problem is that some species like brassica share cytoplasm along with nucleus during meiosis (Haider et al., 2009). Some research works revealed that there is 0.4% introgression of transgene occur while using this technique (Avni and Edelman, 1991). Another experiment showed that pollens transmit cytoplasmic traits in 3×10^{-4} hybrids out of 780000 (Wang et al., 2004). Ruf et al. (2007) showed in an experiment that transmission was 1.58×10^{-5}. This small leakage can be further controlled by complimenting this trait with female sterility.

Incompatible genome

One possible option against gene flow is to incorporate the transgene in such a way that its probability to disperse through gamete is at minimum value. Some crops like wheat contain different genomes (Werner et al., 1992). By targeting the genome which is less compatible to wild and weedy relatives to incorporate the transgene will make fairly less chance for gene to escape (Lu, 2003). This technique has some practical problems; firstly it does not work for all the crops, secondly there have been reports for partial compatibility of homologous genomes (Knott et al., 1989; Snow, 2002). This partial compatibility can play role for unintended gene flow.

Gene splitting

Hirata et al. (1990) discovered a genetic structure called as intein which are capable of protein *trans*-splicing, it can combine two different DNA sequences in shape of a single protein and splice out of mature protein. Dong et al. (2015) proposed a containment strategy taking intein as major working agents, they proposed to split the gene of interest into two different sequences and place far away in genome and combine them with inteins, as far away sequences have more chances to segregate during meiosis and named it as gene splitting. Wang et al. (2014) practically perform this phenomenon

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1119111208

to produce GM tobacco. This technique showed no signs of transgenes into F_1 population but backcross population showed 25% plants with trans-gene.

Expression in virus

Another technique can be to use virus mediated expression of beneficial trait using shuttle vector. Successful expression has been observed using this technique (Kelloniemi et al., 2008). By this gene can be limited to virus and danger of dispersal will be minimum but problem with this technique is making transgenic every year will increase cost of seed production as GM will remain good for just a single generation (Gressel, 2015).

Genetic use restriction technology (GURT)

GURT or "terminator technology" is also one way to preventing transgene flow. This technology was developed by multinational companies to protect intellectual property rights (Swanson and Goschl, 2000). GURT can be categorize into variety based (V-GURT) and trait based (T-GURT) (Van-Acker et al., 2007). V-GURT works on principle of seed sterility while T-GURT works on limiting the exposure of a specific trait to other crops. V-GURT was found more effective as compared to T-GURT (Goeschl and Swanson, 2003). Lin et al. (2008) used RNAi mechanism to contain herbicide resistant gene in rice. RNAi gene was closely linked to glyphosate resistance gene (gene of interest) to avoid crossing over during meosis, the RNAi gene was used to silence a gene which confer resistance to another herbicide, bentazone so GM rice was resistant to glyphosate but susceptible to bentazone. By applying bentazone to following generation plants carrying escape genes were effectively abolished. Similar experiment was repeated by Liu et al. (2012) using double transgenic and found complimentary results. GURTS are more effective for transgenic with industrial products (Lee and Natesan, 2006). Major concerns about terminator technology are that it will create the monopoly of seed companies but despite that it is an effective technique (Hills et al., 2007).

Transgene mitigation strategies

Containment techniques pose a major question to counter with the problem as when they are assessed almost every technique allows a little leak (Gressel, 2015). Even a smallest leak cannot make sure the complete containment, it rather slow down the process or direct it to a single direction but ultimate results are similarly harmful even if it appears some time later, just the slightest chance to not spread trans-gene is if it have no selection advantage or unfit for spread (Ryffel, 2014). If somehow expression of transgene is limited or sequence is deleted from offspring/gamete it will be more efficient way to block unintended gene flow. Scientists have tried and still coming up with different methods to fulfill the goal, in general these techniques are termed as "transgenic mitigation (TM) techniques" (Ryffel, 2014). TM was found more efficient to deal with transgene flow for traits more beneficial to agriculture (Lee and Natesan, 2006). Gressel (1999) proposed a technique to decrease the fitness of volunteer plant by incorporation of a deleterious gene closely linked to transgene and causing negative selection pressure on volunteer plants. These genes can be for say breaking dormancy, reduce shattering and dwarfing genes. Some experiments were effectively carried out to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1119111208

show the effectiveness. Al-Ahmad et al. (2004) inserted herbicide resistance gene linked with a dwarfing gene into tobacco plant. Both genes were linked close to avoid later crossing over and confirmed by PCR. Results revealed that volunteer plants and hybrids had only 17% fitness leading fewer chances for them to survive. Using same model on B. *napus* revealed only 12% fitness in the following progeny (Al-Ahmad and Gressel, 2005). Efficiency of this technique is strictly depends upon level of unfitness of trait to volunteer plants and nature of GM crops, this system can be made more effective using two or more TM genes (Gressel and Al-Ahmad, 2006). Some effectively used TM genes are; giberallic acid insensitive conferring dwarfness, abscisic acid insensitive which break seed dormancy and SHATTERPROOF confer less seed shattering (Daniell, 2002). Kuvshinov et al. (2001) described a technique named as "recoverable block of function" (can also categorize under chemical TM). They incorporate a blocking sequence and a recovering sequence along with trans-gene, recovering sequence remains active in normal conditions and stops working under chemical control. Pollen excision also works on similar principals as it excises transgene from pollen or cause complete pollen sterility by triggering RNAi mechanism. Site specific mutagenesis or recombinase is utilized for this purpose (Saurabh et al., 2014). Moon et al. (2011) use a codon optimized serine resolvase recombinase (CinH) with its recognition sites along transgene, CinH was incorporated under influence of a pollen specific promoter LAT 59 to hinder the expression of transgene into pollen and ultimately hybrids. They found less than 1% pollens expressing transgene. In additions zinc finger nucleases, TALEN, CRISPR-Cas and Ecor1 restriction endoneucleases had also found effective to deletion of transgene from pollen (Straus and Lahaye, 2013).

Conclusion

Escape of transgene from GM crop plants to non-GM and wild relatives may pose potential environment risks. Understanding of transgene escape will facilitate the sustainable and safe cultivation of GM varieties of different crops. Further, perceived food safety and identity preservation is necessary for different production systems in agriculture sector and famers choice to cultivate GM, conventional or organic crops. Therefore, to favor the GM technology, we should take into consideration the biosafety measures as well as potential techniques to contain or mitigate the transgene effect.

Abstract. Some researchers believe that organic farming can improving farmer's resilience in dealing with climate change. Livelihood resilience is attributed to buffer capacity, self-organization, and learning capacity. Therefore, this study aims to 1) compare buffer capacity, self-organization, and learning capacity between organic and conventional farmers, 2) compare the level of livelihood resilience between organic and conventional farmers, and 3) know important determinants that influence the livelihood resilience of farmers in the face of climate change. Data were obtained through a survey involving 112 organic farmers and 112 conventional farmers in Java, Indonesia. The t-test was used to find out the buffer capacity, self-organization and learning capacity and livelihood resilience of farmers in the face of climate change. Ordinary least square was used to find out important determinants that influence the livelihood resilience level of farmers. The analysis shows that buffer capacity and learning capacity of organic farmers are better than that of the conventional farmers. Organic farmers have better livelihood resilience than conventional farmers. Important determinants that influence the farmer's level of resilience are cooperation networks, adaptation strategies and accessibility to extension services, and climate information and training. The study recommends that policymakers need to develop organic farming and supporting institutions to increase farmer's resilience in dealing with climate change.
Keywords: *buffer capacity, learning capacity, self-organization, adaptation, vegetable farming*

Introduction

Recent climate change has adversely affected horticultural crops (Haryono and Las, 2011; Rejekiningrum et al., 2011; Surmaini et al., 2011). The various negative impacts of climate change on horticulture crops, especially vegetables, include crop failure, decreased quantity, decreased product quality, increasing number of pest attack and plant disease problems, thus making farmers at risk of unprofitable vegetable cultivation (Ayyogari et al., 2014). Reports have been made on the negative impacts of climate change on vegetable crops in Indonesia that include extreme rainfall damaging vegetable crops and decreasing agricultural production, which may eventually lead to crop failure. In addition, it was reported that extreme rain throughout 2010 caused several vegetable productions in Indonesia to decrease by 20-25% (Rejekiningrum et al., 2011).

On this account, it is noteworthy that organic farming plays a significant role in dealing with climate change. Organic farming will have higher resilience than

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

conventional farming (Jacobi et al., 2015). As a result, farmers with a better level of resilience will be more capable at maintaining and improving their livelihood and welfare opportunities since they are more adjustable to facing climate change disruptions. In the face of climate change, it is necessary to integrate resilience and livelihood because climate change will affect human livelihoods at greater intensity (Tanner et al., 2015). The approach on livelihood focuses on interactions between the livelihood context, livelihood assets, institutions, livelihood strategies, and the impact of livelihoods. Meanwhile, livelihood resilience in the face of climate change is characterized by a strategy carried out by actors to maintain and enhance their assets (Speranza et al., 2014).

Farmer's resilience in dealing with climate change varies between regions. There have been several studies to address the level of farmer's resilience in the face of climate change conducted in developing countries (e.g., Lal, 2014; Marseva et al., 2016; Tambo, 2016). In the face of climate change, most farmers' resilience levels are classified into the weak to moderate categories, such as farmers in Nepal (Lal, 2014) and farmers in northeast Ghana (Tambo, 2016). The research conducted by Marseva et al. (2016), also showed that in Central Java, Indonesia, farmer's resilience in the face of climate change is still relatively low. Low resilience level in dealing with climate change is attributed to the low level of human, social and physical capital owned by farmers.

There are some dimensions of measuring the level of resilience to climate change used by researchers. Some dimension used to measure resilience include: 1) based on asset (e.g., Thulstrup, 2015), 2) based on six dimension of Resilience Index Measure and Analysis (RIMA) of the Food and Agriculture Organization of the United Nations, which include income and food access, access to basic services, assets, social safety nets, stability, and adaptive capacity (e.g., FAO, 2016; Tambo, 2016; Tambo and Wünscher, 2017; Weldegebriel and Amphune, 2017). The measurement of resilience integrated with livelihoods, known as livelihood resilience, was put forward by Speranza et al. (2014). Livelihood resilience in the face of climate change is constituted of buffer capacity, self-organization, and learning capacity (Speranza et al., 2014).

As what the experts have put forward, organic farming is the right solution to increase the farmers' livelihood resilience in the face of climate change. However, there were only few researches to address the livelihood resilience of the farmers' in dealing with climate change despite its relevance to the current situation. Therefore, this study aims to 1) compare buffer capacity, self-organization, and learning capacity between organic and conventional farmers, 2) compare the level of livelihood resilience between organic and conventional farmers in dealing with climate change, and 3) know important determinant that affects the livelihood resilience of organic farmers and conventional in dealing with climate change.

Materials and methods

Research location and sampling

The research location was determined purposively in Java, especially in the Special Region of Yogyakarta and Central Java Province, considering that the two areas greatly develop organic vegetable cultivation. Some regencies of each province were selected for the research location, namely Sleman Regency (Special Region of Yogyakarta) and Magelang Regency, Boyolali Regency and Semarang Regency (Central Java) (*Fig. 1*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

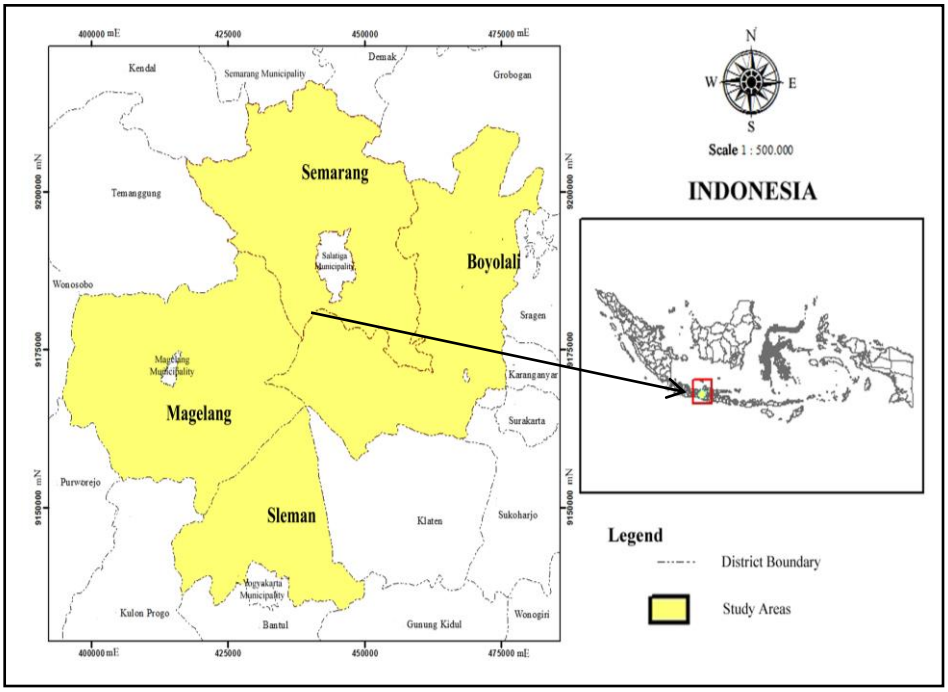

Figure 1. *Study area*

The survey was conducted in February - August 2018, by involving organic farmers and conventional farmers. Organic farmers selected by using proportionate random sampling method (*Table 1*).

Table 1. *Population and sample of organic farmers*

Regency	Population	Sample
Sleman	30	22
Magelang	24	17
Boyolali	25	18
Semarang	77	55
Total	156	112

The sample size based on Slovin's formula, is given as follows: $n = N/(1+(N.e^2)$, where n is the sample size, N is the population size and e is the margin of error (0.05). Therefore based on the formula, the sampling size in this research is 112 organic farmer, and as comparison, there are 112 conventional farmers. Conventional vegetable farmers are living nearby organic vegetable farmers with the consideration that both groups experience the negative impact of climate change and relatively have similar socioeconomic conditions.

The survey was conducted with a structured questionnaire guide. The first part of the questionnaire collects some background information such as age, household size, marketing network in selling crop yields with other parties, and accessibility to various institutions such as credit institutions, extension, access to information and climate training. The second part investigates adaptation strategies adopted by farmers to reduce

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

the negative impact of climate change on vegetable farming. The last section addresses farmers' livelihood resilience in dealing with climate change. This study collected 224 questionnaires for analysis.

Analytical methods

Data analysis

Data were analyzed by t-test and ordinary least square (OLS) regression analysis. The t-test was used to compare buffer capacity, self-organization and learning capacity and the level of livelihood resilience between organic vegetable farmers and conventional vegetable farmers in the face of climate change. OLS was used to find out important determinants affecting the farmers' livelihood resilience index in dealing with climate change. Important determinants that affect farmers' livelihood resilience in dealing with climate change were selected based on the previous studies, such as age (Tesso et al., 2012; Weldegebriel and Amphune, 2017), household size (Weldegebriel and Amphune, 2017), engagement in trade (Weldegebriel and Amphune, 2017), and accessibility to various institutions such as credit institutions (Keil et al., 2008; Tesso et al., 2012), extension institutions (Tesso et al., 2012), information on climate change (Keil et al., 2008), climate training and the amount of adaptation that farmers have applied to deal with climate change (Tambo and Wünscher, 2017; Uy et al., 2011). The description of each variable used in this study is presented in *Table 2.*

Table 2. *Description of variables*

Variable	Description of the variables
Livelihood resilience	Livelihood resilience in the face of climate change (index)
Age	Age of the head of the family in years
Household size	Number of family members in the household
Engagement in trade	Dummy (1 = if farmers have engagement in trade and 0 = if otherwise)
Access to credit	Dummy (1 = if farmers have access to credit institutions and 0 = if otherwise)
Access to extension services	Dummy (1 = if farmers have access to extension services and 0 = if otherwise)
Access to climate information	Dummy (1 = if farmers have access to climate information and 0 = if otherwise)
Access to climate training	Dummy (1 = if farmers have access to climate training and 0 = if otherwise)
Number of adaptation strategies	The number of adaptation strategies applied by farmers in facing climate change

Adaptation strategies adopted by farmers to reduce the negative impacts of climate change were obtained from the previous research and preliminary information, namely implementing implementing mixed cropping (Abid et al., 2016; Fosu-Mensah et al., 2012; Ichdayanti, 2014), using superior varieties (Ali and Erenstein, 2017; Ichdayanti, 2014; Milambo, 2013; Ruminta, 2015; Tambo, 2016), growing non water-intensive vegetable (Ichdayanti, 2014), implementing crop rotation (Kurniawati, 2012), adjusting planting and harvesting dates (Ali and Erenstein, 2017; Deressa et al., 2009; Fosu-Mensah et al., 2012), increasing the dose of organic matter (Irham et al., 2018; Makate et al., 2017), using mulch (Ichdayanti, 2014), using shade (Adiyoga and Lukman, 2018; Kurniawati, 2012), changing irrigation techniques (Abid et al., 2016; Tambo, 2016), using *pranata mangsa* a local technique based on regular natural events (initial information from farmer interviews).

Table 3. *Components, indicators, description and values of livelihood resilience in dealing with climate change*

Component	Indicators	Description	Units
Buffer capacity	Human capital	Duration of education	Years
		Farming experience	Years
		Other skills besides farming	Count
		Number of sick family members	Count
	Financial capital	Annual revenue of vegetable farming	USD/ha
		Livestock saving	USD
		Annual labor income	USD/year
		Dependency ratio: a ratio of members aged below 15 and above 64 to those aged 15-64	Ratio
	Social capital	Asset increase due to organization partnership	USD
		Support of workforce from the group	Man-days
		Use of group equipment	Count
	Physical capital	Machinery, equipment, buildings, farming wells	USD
	Natural capital	Weighted averaged soil fertility of the land owned by farmer	Index
Self-organization	Cooperation and network	Number of group organization followed by farmers	Count
	Trust	Trust between community members in lending and borrowing funds	Percentage
	Reliance on own resources	The closest distance needed to obtain farming inputs	Kilometer
Learning capacity	Knowledge of treat and opportunities	The ability to analyze threats to increase production over the past 12 months	Count
		Ability to analyze opportunities to increase production over the past 12 months	Count
	Shared vision	Frequency of discussion on farming development over the past 12 months	Count
	Commitment to learning	Frequency of regular meetings with counselors	Count
		Discussion frequency on the previous farming performance with counselors and other farmers	Count
		Time allocated per month to find information on technology	Minute per month
	Knowledge identification capability-monitoring	The best time to sell and buy the best product	Count
		Frequency of consultation on planning agricultural products sold	Count
		The number of technological innovations to applied by farmers in the upcoming planting season	Count
		The number of technological innovations tested by farmers in the last 12 months	Count
		Number of technological innovations adopted by farmers in the last 12 months	Count
		Number of technological innovations applied now	Count

DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

		Frequency in discussing the problem of farming production with other actors in the group	Count
	Knowledge sharing capability	Number of farmers given new information or methods by respondent farmers	Count
	Knowledge transfer capability	The number of ideas that farmers learn from other farmers and other actors	Count
	Functioning feedback mechanism	Frequency of interaction with officers related to business production in groups	Count

Measurement of livelihood resilience

The livelihood resilience used in this study was adapted from Speranza et al. (2014), Murphy (2015), Wahyuni (2016) and based on the construction of this study. Components, indicators and measurements of farmers' livelihood resilience in dealing with climate change are presented in *Table 3*. Livelihood resilience consists of three components, namely buffer capacity, self-organization and learning capacity. Each component consists of several indicators that can represent livelihood resilience. The steps taken to measure the livelihood resilience index are:

1. Normalization

It is important to normalize each indicator to make it in the range of 0 to. 1. Normalization was done because indicators of livelihood resilience are measured on a different scale. The normalization methods were based on the Human Development Index method (UNDP, 2006). Some indicators show that if the indicator value increases, the livelihood resilience will decrease. On this basis, we use two normalization methods so that the increasing value of each indicator will increase livelihood resilience:

a) Indicators where higher values, which imply better resilience such as education time, farming experience, farming acceptance, were normalized using the following formula:

$$\tau_{norm} = \frac{\tau_{ij} - \tau_{\min}}{\tau_{\max} - \tau_{\min}} \quad \text{(Eq.1)}$$

b) Indicators with higher values, which imply lower resilience such as sick family members and dependency ratios, were normalized using the following formula:

$$\tau_{norm} = \frac{\tau_{\min} - \tau_{\max}}{\tau_{\max} - \tau_{\min}} \quad \text{(Eq.2)}$$

where:

τ_{norm} = the value of j indicator is for normalized household

τ_{ij} = the value of j indicator is for household i

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

τ_{max} = maximum value of sub-indicators for all households

τ_{min} = minimum value of sub-indicators for all households

2. Measuring livelihood resilience index

After normalization, the researcher calculated the livelihood resilience index using the equal-weight approach. The equal-weight approach assumes that each indicator has the same contribution to the livelihood resilience index. Measurements using this method are based on the average normalized values (Gbetibouo et al., 2010; Tambo and Wünscher, 2017). The value of each indicator was then averaged to obtain the value of each of the three indicators. The compound value was averaged to obtain the overall value of the livelihood resilience index. The farmers' livelihood resilience index in dealing with climate change resulted in the ranges from 0 to 1.

Result

Socioeconomic profile of farmers and adaptation to climate change

The socioeconomic conditions of organic vegetable farmers are better than those of conventional farmers (*Table 4*). Organic vegetable farmers have better accessibility to credit institutions, extension service, and engagement in trade than conventional farmers. Organic farmers are also younger and have more household members than conventional farmers. Young farmers will easily accept the technology, which can be used to adapt to climate change and family members can help farmers in vegetable farming. Organic farmers also implement more adaptation strategies to reduce the impact of climate change on vegetable farmer.

Table 4. *Socioeconomic profile of farmers and adaptation to climate change*

	Organic		Conventional		Difference[a]	
	Mean	Std. Dev	Mean	Std. Dev		
Age	45.214	12.836	45.455	11.527	-0.241	
Household size	4.125	1.330	3.866	1.212	0.259	
Engagement in trade	0.839	0.369	0.179	0.385	0.661	***
Access to credit	0.321	0.469	0.143	0.352	0.179	**

Buffer capacity, self-organization and learning capacity of organic and conventional farmers

Table 5 presents the description and indicator values of the buffer capacity. The three indicators that greatly contribute to the buffer capacity of organic vegetable farmers and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

conventional vegetable farmers are natural capital, human capital and financial capital. This fact indicates that the three capitals play a significant role in increasing the buffer capacity of farmers. The significant difference from the indicators that compose the buffer capacity between organic vegetable farmers and conventional vegetable farmers lies in social capital, physical capital and natural capital. Organic farmers have higher social capital, physical capital and natural capital than conventional vegetable farmers. Organic vegetable farmers have higher social capital than conventional vegetable farmers because organic farmers get an increase in assets from group membership and support of the workforce from the group. Moreover, organic farmers also have better physical capital values as manifested through their ownership of machinery and other equipment. Natural capital such as soil fertility that owned by organic farmer higher than the conventional farmers.

On the other hand, organic vegetable farmers commonly have lower human capital and financial capital than conventional vegetable farmers. *Table 5* shows that the human capital owned by organic vegetable farmers is lower than conventional vegetable farmers because organic farmers have shorter farming experience and have a greater number of dependents and sick families than conventional vegetable farmers, although the difference between organic and conventional is not statistically significant. Organic vegetable farmers also to have lower financial capital than conventional vegetable farmers, although the difference between organic and conventional is not statistically significant. Organic farmers have greater farming and labor income than conventional vegetable farmers, but organic farmers have a lower number of livestock savings and a higher level of dependency than conventional vegetable farmers. A higher level of dependency of organic farmer than conventional vegetable farmers because organic farmers have more family members than conventional farmers.

The indicator values of the self-organization components that make up the livelihood resilience index are presented in *Table 6.* Reliance on own resources owned by organic and conventional vegetable farmers contribute greatly to the value of self-organization, followed by trust and cooperation and network. Organic and conventional vegetable farmers do not have to travel far distance to obtain inputs. In addition, the people surrounding them also trust each other in terms of lending and borrowing. However, cooperation and network of organic vegetable farmers are higher than conventional farmers, since organic vegetable farmers have established a cooperation with other parties and have better participation in organizations than conventional vegetable farmers.

Table 7 presents the indicator values of the learning capacity component of conventional vegetable and organic vegetable farmers. Three indicators, namely knowledge of threat and opportunities, knowledge sharing capability, and knowledge identification capability of monitoring contribute to higher value than other indicators. This indicates that these indicators contribute highly to the learning capacity of organic and conventional vegetable farmers. Other indicators such as shared vision, commitment to learning, capability sharing and functioning feedback mechanism shared by organic and conventional vegetable farmers indicate a low value.

All description and indicator values of learning capacity of organic vegetable farmers are higher than those of conventional vegetable farmers (*Table 7*). Organic vegetable farmers have better knowledge at analyzing threats and opportunities, various visions, commitment to learning and knowledge of identification, knowledge sharing and transfer, as well as better feedback mechanism than conventional vegetable farmers. The significant difference in the indicator of the learning capacity component between organic vegetable farmers and conventional vegetable farmers lies in commitment to learning, knowledge of identification capability of monitoring, knowledge sharing capability, knowledge transfer capability, and feedback mechanism function. This indicates that organic vegetable farmers have more regular meetings with extension workers, and allocated time per month to find information on technology. Organic farmers also know better the best time to sell and buy products that conventional farmers. Furthermore, organic farmers have applied, adopted, and plan to used more technology, better ability in providing and receiving information from other actors, and more frequency of interactions with officers related to business production in groups than conventional vegetable farmers.

The measurement of the resilience indicator values of organic and conventional vegetable farmers' livelihoods are presented in *Figure 2*. The value of buffer capacity of organic vegetable farmers (0.321) is higher than conventional vegetable farmers (0.283), learning capacity of organic farmers (0.229) is higher than conventional vegetable farmers (0.156), and the value of organic farmers' self-organization (0.559) is higher than conventional farmers (0.524). Organic farmers have a better buffer capacity, learning capacity and self-organization in dealing with climate change than conventional vegetable farmers. Self-organizing ability of organic vegetable farmers is slightly different from conventional vegetable farmers, indicating that organic and conventional vegetable farmers are in the trustworthy community and relatively close distance in obtaining the inputs.

Livelihood resilience index of organic and conventional farmers in dealing with climate change

Figure 3 showed that the value of livelihood resilience of organic vegetable farmers (0.375) in dealing with climate change was higher than that of conventional vegetable farmers (0.329). Organic vegetable farmers are more resilient to climate change than conventional vegetable farmers. *Figure 2* shows that the self-organization of organic vegetable farmer and conventional vegetable farmers contribute the most to livelihood resilience index. The second and third indicator that contributes to livelihood resilience index is buffer capacity and learning capacity.

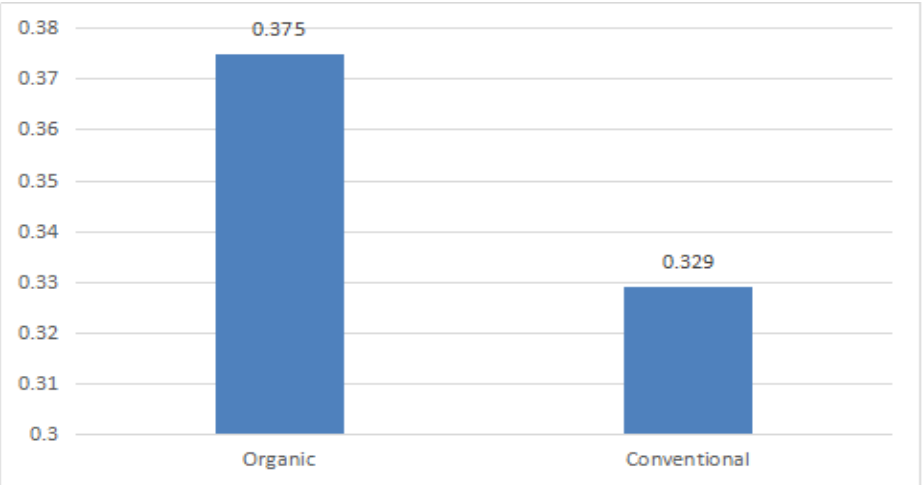

Figure 3. *Livelihood resilience index of organic and conventional vegetable farmers*

Determinants that influence the livelihood resilience of organic and conventional vegetable farmers in dealing with climate change

Important determinants that affect the livelihood resilience index of organic and conventional vegetable farmers in dealing with climate change are presented in *Table 8*. The analysis shows that the livelihood resilience index of organic vegetable farmers in dealing with climate change is influenced by household size, engagement in trade, access to extension service and the number of adaptation strategies adopted by farmers to reduce the impact of climate change. On the other hand, conventional farmers' livelihood resilience index in dealing with climate change is influenced by household size, farmers' access to climate information, access to climate training and the number of strategies adopted by conventional vegetable farmers to reduce the negative impacts of climate change. Each important determinant that influences the level of livelihood resilience of organic and conventional farmers in dealing with climate change are listed as follows:

1. Age

The age of farmers does not affect livelihood resilience index of both organic and conventional farmers in the face of climate change.

2. Household size

Household size affects the level of livelihood resilience of organic and conventional farmers. The negative household size coefficient indicates that the increase in household size of organic and conventional farmers will reduce the level of livelihood resilience of farmers in dealing with climate change. The coefficient of household size for organic and conventional farmers is 0.012 and 0.008 respectively, indicating that any increase in household size of one person will reduce the livelihood resilience index of organic farmers by 0.012 points and conventional farmers by 0.008 points.

3. Engagement in trade

Engagement in trade has a significant effect on the livelihood resilience index of organic farmers. Positive coefficients indicate that farmers who have established trading cooperation in selling farm products with other parties will have higher resilience in dealing with climate change than farmers who do not cooperate with other parties.

4. Access to credit

The access of organic and conventional farmers to credit does not affect the livelihood resilience index of farmers in the face of climate change.

5. Access to extension services

Farmer's access to extension services only has a significant effect on the livelihood resilience of organic farmers in the face of climate change. The coefficient of access to extension services with a positive sign indicates that organic farmers who have access to extension services have a better livelihood resilience in facing climate change than farmers who do not have access to extension services.

6. Access to climate information

Farmer's access to climate information influences the livelihood resilience indexes of conventional farmers in the face of climate change. The access to climate information coefficient of organic farmers having a positive sign indicates that organic farmers who have access to climate information have better livelihood resilience in dealing with climate change than farmers who do not have access to climate information.

7. Access to climate training

Farmers' access to climate training has a positive and significant effect on conventional farmers' livelihood resilience index, meaning that conventional farmers

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

who have access to climate training have higher resilience in dealing with climate change than farmers who do not have access to climate training.

8. Number of adaptation strategies

The number of adaptation strategies will affect the level of livelihood resilience of organic and conventional farmers in the face of climate change. The number of adaptation strategies coefficient shows a positive sign, meaning that each increase in the number of adaptation strategies implemented by organic and conventional farmers can increase the livelihoods resilience index of farmers in dealing with climate change.

Discussion

The study confirms that the buffer capacity, self-organization and learning capacity of organic vegetable farmers is higher than that of conventional vegetable farmers. Social capital, natural capital and physical that make up the buffer capacity of organic vegetable farmers is higher than that of conventional vegetable farmers. Organic vegetable farmers also have more fertile land and equipment to support farming activities. However, financial capital of organic vegetable farmers in the study area is lower than that of conventional farmers, although vegetable farming income received by organic farmers is higher than that received by conventional farmers. Farming income

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

and participation of farmers in groups can increase buffer capacity in dealing with climate change (Jacobi et al., 2015).

Organic vegetable farmers have better self-organization and learning capacity than conventional farmers. The majority of organic vegetable farmers in research locations are incorporated in farmer groups. Farmer groups can also increase learning capacity of organic vegetable farmers to be higher than that of conventional vegetable farmers. Farmers can exchange information related to cultivation, plant disease, pests, harvests, product prices and farming problems due to climate change. Farmer groups also become a key place for farmers to obtain and exchange information and technology between farmers (Bryan et al., 2013). It is noteworthy that organic vegetable farmers and their surrounding communities trust each other very well. Organic farmers can also get their farming inputs in a relatively closer distance than that of conventional farmers. For example, organic farmers can easily find the ingredients for making vegetable pesticides in their surroundings. Organic vegetable farmers receive various information from farmer groups and surrounding communities. The results of this study are in line with those of Jacobi et al. (2015), which states that organic farmers have better networks than conventional farmers.

The second analysis confirms that organic vegetable farmers in the study area are more resilient than conventional vegetable farmers, which is in line with Jacobi et al. (2015). Organic farmers are more resilient because of group membership or cooperation that can increase their adaptive capacity and buffer capacity (Jacobi et al., 2015). Resilience of organic and conventional vegetable farmers in research locations rests on self-organizations. Vegetable farmers in the face of climate change should use this self-organization ability to increase buffer capacity and learning capacity. In many developing countries, organic farming systems have the potential to maintain farmers' livelihoods when farmers are adversely affected by climate change. In addition, organic farming production and income are often the same or higher than those of conventional farmers (Scialabba, 2007). Resilience of organic farming also depends on the ability and experience of farmers in adaptation (Milestad and Darnhofer, 2003).

The third analysis confirms the important determinants that influence the level of resilience of organic and conventional vegetable farmers in the face of climate change. Important determinants affecting the livelihood resilience index of organic farmers in dealing with climate change are household size, engagement in trade, access to extension services, and the number of adaptation strategies implemented by farmers. On the contrary, conventional farmers' livelihood resilience index in dealing with climate change is affected by household size, access to climate information, access to climate training, and the number of adaptation strategies applied by conventional farmers to reduce the impact of climate change.

The household size of vegetable farmers in the study location will influence the livelihood resilience index of organic vegetable farmers and conventional vegetable farmers in the face of climate change. However, this result is not in line with the research conducted by Weldegebriel and Amphune (2017), indicating that household size does not affect the livelihood resilience of farmers in the research area. The household size of organic vegetable farmers and conventional vegetable farmers in the research location indicate the number of family members to be borne by the household. Therefore, an increase of household size would reduce the livelihood resilience of farmers in dealing with climate change. Engagement in trade is positively and significantly affected by the resilience of organic vegetable farmers in the face of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

climate change. The positive relationship between engagement in trade with farmers' resilience in dealing with climate change supports the research of Jacobi et al. (2015). Most of organic vegetable farmers in the research locations have marketing network for agricultural products with other parties. This marketing network ensures certain sales and price, making organic vegetable farmers have a higher income than conventional vegetable farmers. The received income of vegetable farming can increase the buffer capacity of farmers in dealing with climate change.

Organic vegetable farmers in the study area have better access to credit and extension services. Good accessibility can improve the self-organization and learning capacity of farmers in facing climate change. On this account, Jacobi et al. (2015) state that organic farmers are more resilient because they are integrated with farmer organizations that can increase their adaptive capacity and buffer the capacity to deal with climate change. Vegetable farmers at the research location regularly hold farmer group meetings, such as every once a month. At this group meeting, farmers obtain and share information about technology to increase production and efforts made to deal with the negative impacts of climate change. Other factors that influence the livelihood resilience of farmers in dealing with climate change are farmers' access to climate-related information and climate training. The results showed that conventional vegetable farmers' access to climate information and climate training had a positive effect on livelihood resilience, meaning that farmers who had access to climate information and climate training would be more resilient than those without access.

The number of adaptation strategies applied by farmers to reduce the negative impact of climate change also has a positive effect on the level of livelihood resilience of farmers in the face of climate change. In other words, an increase in each number of adaptation strategy can increase the livelihood resilience of farmers in the face of climate change. Adaptation of farmers to climate change will help farmers reduce the adverse effects of climate change. Vegetable farmers at the research site adopted an adaptation strategy in the form of mixed cropping, using superior varieties, planting water-intensive plants, rotating crops, adjusting planting and harvesting times, increasing doses of organic matter, using mulch, using shade, changing irrigation techniques, and using prey institutions. The number of adaptation strategies implemented by farmers to reduce the impact of climate change ranges from one to nine strategies. The combination of adaptation strategies implemented by farmers aims to maintain farming production. Production continuity can increase farmers' income so that the buffer capacity of farmers in facing climate change increases. This result is in line with the research conducted by (Tambo and Wünscher, 2017; Uy et al., 2011) Improved adaptation strategies are required to reduce the negative impacts of climate change, and the government plays a key role in increasing farmers' awareness and knowledge of climate change (Korkmsz, 2018). Farmers should consider the current and future impacts of climate change to establish adaptation strategies to be implemented in the face of climate change (Nhuan et al., 2018).

Conclusions

Overall, organic vegetable farmers have a better buffer capacity, self-organization, and learning capacity than conventional vegetable farmers. These three components contribute to the higher level of livelihood resilience index, so organic vegetable farmers are more resilient in dealing with climate change than conventional vegetable

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

farmers. Self-organization contributes the most to improving livelihood resilience, which increases the livelihood resilience index of farmers in the face of climate change. Therefore, both organic and conventional vegetable farmers should have applied self-organization to increase learning capacity and buffer capacity. It is possible to improve the resilience level of organic vegetable farmers in dealing with climate change through engagement in trade, accessibility of organic vegetable farmers to extension services, and more number of adaptation strategies. Meanwhile, the resilience level of conventional vegetable farmers can be increased through access to climate information, climate training access, and number of farmers' adaptation strategies. This study recommends that policymakers need to develop organic farming and institutions through cooperation and climate training program to increase farmers' resilience in dealing with climate change.

Acknowledgements. We also would like to express our sincere gratitude to Indonesian Agency for Agricultural Research and Development Ministry of Agriculture. This paper is part of a Ph.D. research project at Univeristas Gadjah Mada, Yogyakarta, Indonesia. Our sincere appreciation is also extended to all parties who have provided information to complete this article.

APPENDIX

SURVEY QUESTIONNAIRE

LIVELIHOOD RESILIENCE OF VEGETABLE FARMERS: EFFICACY OF ORGANIC FARMING IN DEALING WITH CLIMATE CHANGE IN JAVA, INDONESIA

This research survey questionnaire is purely for academic purposes with the objective **"Assessing and comparing livelihood resilience between organic and conventional farmers and it determinant".** You are assured of confidentiality of any view expressed in relation to this research. I therefore entreat you to provide information as accurate as possible for true results. Thank you for your kind co-operation.

Questionnaire number	:
Name of interviewer	:
Date of interviewer	:
Name of respondent	:
District	:
Organic/conventional	:

A. FARMERS' CHARACTERISTICS AND ACCESSIBILITY

1. Age : ..... years
2. Household size : ..... person/people

Status in family	Age (years)

3. Do you have access to cooperation in selling crops? ☐ Yes, ☐ No
4. Do you have access to credit institution? ☐ Yes, ☐ No
5. Do you have access to extension services? ☐ Yes, ☐ No
6. Do you have access to climate information? ☐ Yes, ☐ No
7. Do you have access to participate in climate training? ☐ Yes, ☐ No

B. ADAPTATION TO CLIMATE CHANGE

1. Have you made any adjustments in your farming ways in response to climate change ? ☐ Yes, ☐ No
2. What adjustments in your farming ways have you made in response to climate change?

Adjustment in farming	Yes/No
Implementing mixed cropping	
Using superior varieties	
Growing non water-intensive vegetable	
Implementing crop rotation	
Adjusting planting and harvesting dates	
Increasing the does of organic matter	

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

Using mulch	
Using shade	
Changing irrigation techniques	
Using *pranata mangsa*	

C. LIVELIHOOD RESILIENCE

1. BUFFER CAPACITY

a) Human Capital

1. Education : ..... years
2. Farming experience : ..... years
3. Do you have other ability beside farming? ☐ Yes, (specify)....., ☐ No
4. How many family members are permanently ill? …….. person/people

b) Financial Capital

1. Please specify the type, quantity and selling price of the vegetable products that you have produced for the past year.

Type	Quantity	Price (USD/kg)

2. Please specify the type, number of livestock and the price of livestock that you currently have.

Type (cow/goat/others)	Quantity	Price per unit (USD)

3. Please state your work, time and income for you and your family members obtained from work as a laborer in the past year.

Actor (farmer/wife/ others)	Job	Working days a month	Daily earnings	Revenue per month	Period of work per year

c) Social Capital

1. Asset increase due to organization partnership

Please specify the name of group and the income you earn from your participation in a group.

Name of group	Income (USD)

2. Support of workforce from the group

Please state the group name, number of work days and the amount of labor support that you have received from group members in vegetable farming activities during the past year.

Name of group	Farming activities	Number of work days	Amount of labor support

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

3. Use of group equipment

Please specify the type and number of group equipment you have used in the past year.

Name of group	Equitment	Quantity

d) Physical Capital

Do the assets that you currently have, such as machinery, buildings, equipment, water storage, remain productive?

Assets	Quantity	Price per unit (USD)
1. Machinery		
2. Water storage		
3.		
4.		

e) Natural Capital

In your opinion, what is the level of soil fertility on your vegetable farming land? Please fill in 1 if the land is very infertile, 2 if it is not fertile, 3 if it is fertile, 4 if fertile, and 5 if it is very fertile.

Plot	Land area (m^2)	Soil fetility
1		
2		

2. SELF-ORGANIZATION

a) Cooperation and network

Please specify the name of the group or association that you are following.....

.....

b) Trust

What is the level of trust of the people around you in lending and borrowing? ….. %

Questions	Number of People
For example, there are five people around you who need funds for farming, and request a loan without interest. How many people will you give a loan?	
For example, you need a loan for farming. If there are five people around you, how many people will give you a loan?	

c) Reliance on own resources

What is the closest distance between farming land and input resources? …….. meters.

3. LEARNING CAPACITY

a) Knowledge of treat and opportunities

Could you mention the characteristics of the vegetables infected with the primary disease pests such as the following:

Primary disease pests	Yes/No
1. Shrinking leaves, dry shoots curved due to aphids.	
2. The leaves are seen shiny white spots and the become brown which shows	

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

trips.	
3. The leaves are damaged, hollow and the remaining leaf bones are attacked by caterpillars.	
4. For vegetables that have fruit, there are black streaks on the fruit and rot, which indicates fruit flies.	
5. Wilt that occurs in all parts of the plant starting from the leaves and suddenly shows attacked by bacterial wilt.	
6. Rounded spots resembling frog eyes with brownish edges on leaves that show leaf spots.	
7. The fruit is brown and black spotted that indicate an anthracnose attack.	
8. The fruit is brown, rotten, and wet due to fruit rot.	

Do you know the technology below to increase your vegetable farming production? Please give a sign (V) if you know.

Technology	Sign (V)
1. Use of superior seeds without genetic engineering (organic), and superior commercial seeds (conventional).	
2. Seedling and sorting of seeds before moving to the field, especially for small fruiting plants such as mustard greens, tomatoes, and eggplants. Whereas, for large fruiting plants such as cucumber, long beans, and beans, can be planted directly.	
3. Use of mulch for plants such as tomatoes, eggplants, and beans.	
4. Use of roofed shade.	
5. Making beds with a width of 100-120 cm and a height of 30 cm.	
6. The land is cultivated by hoeed or plowed to a depth of 30-40 cm.	
7. The provision of manure is 2-3 tons per 1000 square meters for organic farming, and around 1.5-3 tons per hectare for conventional farming.	
8. Recommended plant spacing according to each type of vegetable crop.	
9. Supplementary fertilization according to recommendation, namely the provision of manure, urine or other organic material (organic), and fertilizer application according to recommendations per plant.	
10. Crop rotation.	
11. Irrigation and watering management.	
12. Mechanical and organic pest and disease control (organic farming), and according to the principle of Integrated Pest Mangement (conventional farming).	
13. Yields are placed in shaded places and treated with care.	

b) Shared vision and commitment to learning

1. How many regular meetings with extension agents in the previous year?.....
2. Did you allocate time to find information on technology? ☐ Yes, that is … minutes/month. ☐No.
3. How many times have you discussed the development and performance of farming with farmers, extension, or other stakeholders during the last 12 months?

Actor	Frequency of farming development discussion	Frequency of farming performance discussion
Farmer		
Extension officer		
District agricultural officer		
Researcher		
Other (specify)		

c) Knowledge identification capability-monitoring

1. In your opinion, when is the right time to sell your agricultural products for the last 12 months to get a good price?.....
2. How many times have you consulted about farming planning forecasting?.....

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1120911232

3. Among the following technologies, give a sign (V) if the technology is used now and in the future, and technology has been tried once and adopted for the past 12 months.

Technology	Sign (V)			
	Tested	Adopted	Applied now	Applied in the upcoming planting season
1. Use of superior seeds without genetic engineering (organic), and superior commercial seeds (conventional).				
2. Seedling and sorting of seeds before moving to the field, especially for small fruiting plants such as mustard greens, tomatoes, and eggplants. Whereas, for large fruiting plants such as cucumber, long beans, and beans, can be planted directly.

(Received 9th Apr 2019; accepted 2nd Jul 2019)

Abstract. Soil erosion is the main cause of the decline in global available land resources, and China is one of the countries suffering from severe soil erosion. In this paper, the RUSLE model and GIS were used to assess the changes in soil erosion in different ecosystems and counties. The results showed that from 2005 to 2017, the highest rate of ecosystem change was in the other ecosystems category, with an increase in mean soil loss to 4.06 $t \cdot ha^{-1} \cdot year^{-1}$. For the counties, the highest soil erosion was recorded in Maoxian County during the study period, because Maoxian County was one of the severely affected counties in the Wenchuan Earthquake. The mean soil loss in Yingjing was relatively small, as the estimates for 2005 and 2017 were 0.08 $t\ ha^{-1} \cdot year^{-1}$ and 0.09 $t \cdot ha^{-1} \cdot year^{-1}$, respectively. The areas with severe soil loss are along rivers, mainly distributed along the Minjiang and Tuojiang River basins and their tributaries. The findings of our study will be helpful for identifying high-risk zones, and developing policies to minimize human, environmental and economic losses in any disastrous event.
Keywords: *soil erosion, revised universal soil loss equation, Landsat, geo-hazards, ecosystem*

Introduction

Soil is a limited natural resource that is vital for human survival (Stefano et al., 2016; Gao and Cao, 2011). Soil erosion is one of the important reasons for the decline in global available land resources. Global soil erosion causes a loss of 2.5 to 4 billion tons of topsoil every year, directly costing $40 billion. Soil erosion also leads to a decline in crop yields, hinders global economic development, and poses a threat to food security and human welfare (FAOUN, 2015; Luca, 2015). China has long suffered from soil erosion (Xiao et al., 2016; Gao and Cao, 2011), and approximately 37.6% of its land resources are affected by soil erosion (Gao et al., 2016; Zhang et al., 2012). Soil erosion is a form of soil degradation, which refers to the process of destruction, separation and sedimentation of soil and its parent material under the external force of hydraulics, wind, freeze-thaw cycles or gravity (Meyer, 1984). Soil erosion has become a focus of global research, because of a series of associated ecological and environmental problems, such as land degradation, and soil fertility loss (Luca, 2015).

The occurrence of soil erosion is determined by natural factors and is influenced by human factors (Guo, 2010). Natural factors determine the occurrence and development of water and soil loss in the region, and human factors have the positive effect of controlling soil loss and have the negative effect of accelerating soil loss, such as land use and land cover (LULC) change (Wischmeier, 1978). Climate change and global warming caused by LULC changes directly or indirectly affect soil erosion at different

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1123311247

scales, accelerating the soil erosion rate (Konukcu et al., 2017; Nojarov et al., 2015). Other human activities disturb the land surfaces of the earth, thus altering the rate of natural erosion and rate of soil degradation (Rompaey et al., 2010; Sharma et al., 2007). The intensities of soil erosion are closely related to land use and are greatly affected by changes in LULC (Wang et al., 2018; Ferreira et al., 2015; Leh et al., 2013). Many previous studies have shown that changes in land use or surface vegetation accelerate soil erosion (Diyabalanage et al., 2017; Ganasri and Ramesh, 2016; Zhang et al., 2017; Balasubraman et al., 2015).

In addition, the occurrence of earthquakes and secondary geological disasters will also aggravate soil erosion (Hovius et al., 2011; Lin et al., 2006). After an earthquake, the surface soil is easily disturbed or buried by secondary geological disasters, destroying the structure of the surface soil. Secondary geological disasters caused by earthquakes, such as landslides, mudslides, and collapses, provide a large amount of loose solid matter for soil erosion under the influence of external forces such as rainfall, runoff, and earthquakes (Vittoz et al., 2001; Peng et al., 2012). The 5.12 Wenchuan Earthquake (Ms 7.9) was one of the most devastating earthquakes in China. Due to the loose soil, steep slope, surface vegetation destruction and additional rainfall after the earthquake, the soil erosion in this area was intensified. After the earthquake, preliminary statistics from the National Bureau of Statistics of China showed that soil erosion occurred in 149.2 km^2 of land, an increase of 11.03% over the previous period (Gan et al., 2018). The area of vegetation damaged by earthquakes in Sichuan Province is 32.867×10^4 ha (FDSP, 2008). After the vegetation is destroyed, the bedrock is exposed, and the "buffering" protective layer that prevents surface erosion by rainfall is lost, which aggravates the erosion rate of the loose material on the surface layer (Cui et al., 2010). Therefore, it is particularly important to quantify the effects of soil erosion and to develop effective soil protection measures (Santillan et al., 2010).

Numerical models are important methods for assessing and predicting soil erosion (Panagos et al., 2017). Various soil erosion models, including the Universal Soil Loss Equation (USLE) (Wischmeier and Smith, 1978), the Modified USLE (MUSLE) (Williams, 1975), the Revised USLE (RUSLE) (Renard et al., 1997), and the Unit Stream Power-based Erosion Deposition (USPED) (Mitasova et al., 1996), or physically-based models, such as the Water Erosion Prediction Project (WEPP) (Nearing, 1997) and the European Soil Erosion Model (EUROSEM) (Morgan et al., 2015), have been developed for estimating, analysing and predicting soil erosion. Among these models, the RUSLE is the most commonly used to estimate the long-term soil erosion rate of hillsides in large-scale studies (Rulli et al., 2013; Panagos et al., 2015; Ganasri et al., 2016; Zhao et al., 2017). This model has been proven effective for estimating soil loss in different parts of the world. An increasing number of studies combine RUSLE and USLE with 3S (GIS, RS, and global positioning system (GPS)) to detect soil erosion rates at different temporal and spatial scales, along with aerospace and computer technology (Alexakis et al., 2014; Anees et al., 2014).

The study area is in the Longmen Shan fault zone, which is the overlying zone of the Qinghai-Tibet Plateau and the Sichuan Basin. It is an important sensitive zone of China's ecological environment because of its complex geological structures and rich biodiversity. During and after the Wenchuan Earthquake (May 12, 2008) the natural environment of the area in the Longmen Shan fault zone deteriorated. Long-term effects and complex aftershocks have caused a series of environmental problems, such as disturbance of ecosystems, vegetation loss and soil degradation. The objective of this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1123311247

study is to use GIS technology to quantitatively evaluate soil erosion in the Longmen Shan area in 2005, 2008, 2010 and 2017 using the RUSLE model to explore the response of soil erosion to LULC changes and the impact of earthquakes on soil erosion. Analysis of the evolution process of soil erosion provides a reference for soil and water conservation in the Longmen Shan area.

Materials and methods

Study area

The Longmen Shan fault covering an area of 55213 km^2 is extended from Luding and Tianquan in the south to Baoxing, Dujiangyan, Jiangyou and Guangyuan Cities in the northeast, and it enters the area of Ningqiang and Jixian in Shaanxi Province. The total length of the Longmen Shan fault is 500 km, and the width is 40-50 km. The peaks are undulating and the river valleys are both vertical and horizontal. The terrain is extremely complicated and is located in the transition zone between the Tibetan Plateau and Sichuan Basin. The terrain forms a natural boundary between the Chengdu Plain and the western Sichuan Plateau. The area has an elevation range of 309~7100 m (*Fig. 1*), and the overall terrain is high in the west and low in the east, with the highest point being 7100 m (Yong, 2006). The landform is mainly in the piedmont alluvial plains, mountains and plateaus (Yong, 2006). The Longmen Shan fault zone consists of four nearly parallel faults, namely, the southeastern boundary of the Longmen Shan fault zone, Guanxian-Anxian fault, central main Yingxiu-Beichuan fault, and the northwestern boundary of the Wenchuan-Maoxian and Qingchuan fault. The temperature in the Longmen Shan area decreases with increasing elevation, showing a geographical distribution of high temperatures in the east and low temperatures in the west, and the three-dimensional climate features are obvious, forming a distinct, unique and diversified vertical climate zone in the region. The mountainous areas with an elevation of 1000-2000 m belong to the humid climate zone, while the polar regions with an elevation of 2000-5000 m belong to the cold alpine climate zone (Li, 2013). The water system in the Longmen Shan fault area is dominated by horizontal rivers. The river and streams flow perpendicular to the Longmen Mountains and discharge into the Yangtze River. The study area has a rich diversity of plants and animal species, such as *Panda*, *Davidia involucrata*, *Cercidiphyllum Japonicum*, and *Ginkgo biloba* (Di et al., 2010).

Data acquisition

The satellite imageries for the years 2005, 2008, 2010 and 2017 were used for this study to see the soil erosion because of LULC changes. Landsat thematic mapping and enhanced thematic mapping (TM and ETM+) for 2005, and SPOT5 and HJ-1 for 2008, 2010, and 2017 were used to classify LULC changes in the study area. TM and ETM + have a 30 m spatial resolution. The important possible drivers of LULC change, including the expansion of farmland, massive resettlement and expansion of mechanized farming in recent years, were captured by selecting the specific periods. In addition, field surveys were carried out from July to September identify to various LULC change classes that prevail in the study area. A digital elevation model (DEM) of the study area with a 30 m resolution was also downloaded from http://www.Gscloud.cn for processing and analysing erosion parameters.

DOI: http://dx.doi.org/10.15666/aeer/1705_1123311247

The rainfall data of Sichuan Province and its surrounding cities were taken from the China Meteorological Science Data Sharing Service Network (http://cdc.Cma.gov.cn), whereas the soil map of the area was obtained from the Nanjing Institute of Soil Science, Chinese Academy of Sciences.

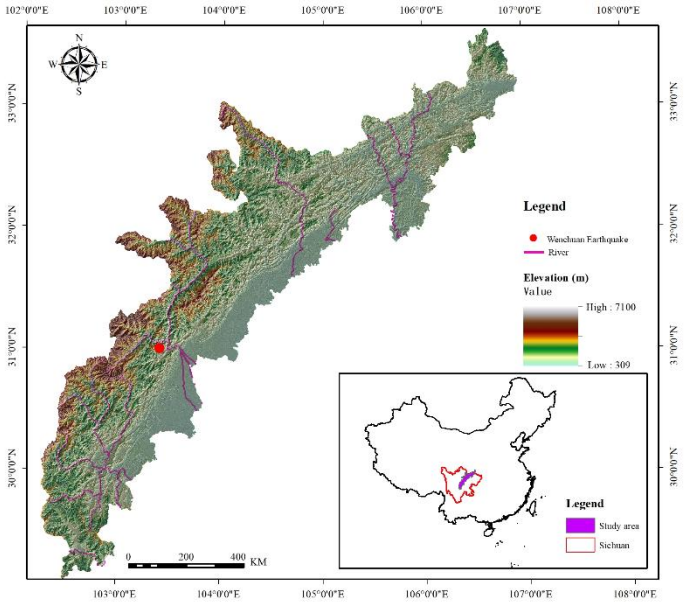

Figure 1. *Location and digital elevation model (DEM) of the study area*

Methodology

We used the RUSLE model, which is an improved version of the USLE developed by Wischmeier and Smith (1978), to estimate annual soil loss. The estimate of soil erosion generated by RUSLE, which has been widely used in soil erosion, is reliable (Anees et al., 2018; Haregeweyn et al., 2017). GIS and RUSLE widely adopted conservation-planning tools throughout the world, which are user-friendly and applicable for a basin with limited data. The RUSLE equation is expressed as follows:

$$A = R \times K \times LS \times C \times P \quad \text{(Eq.1)}$$

where A is the actual soil loss (t ha^{-1} $year^{-1}$), R is the rainfall erosivity factor (m.t.cm/ha.h.y), K is the soil erodibility factor (dimensionless), LS is the slope length and slope steepness factor (dimensionless), C is the cover management factor (dimensionless), and P is the conservation practices factor (dimensionless).

Estimation of rainfall erosivity (R-factor)

The rainfall erosivity factor reflects the erosion potential of rainfall under standard conditions. This factor is a dynamic indicator for evaluating soil stripping and handling erosion, and directly affects the prediction accuracy of the soil erosion model (Özşahin et al., 2018). The annual rainfall erosivity value (R) (Wang and Jiao, 1996) was determined by analysing annual rainfall data from 150 stations in Sichuan and its surrounding cities using *Equation 2:*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1123311247

$$R = 0.207(P \cdot I_{60} / 100)^{1.205} \quad \text{(Eq.2)}$$

where R is the annual erosivity (m.t.cm/ha.h.y), I_{60}-year is the maximum 60 min rainfall (mm), and P-year is the rainfall total (mm). In this study, the R value of the rainfall station in the Longmen Shan area and surrounding provinces was calculated by the above formula (*Eq. 2*), and then, the R-value map of the Longmen Shan area was obtained by interpolation using "Kriging" in the ArcGIS platform (Diodato and Bellocchi, 2007).

Soil erodibility factor estimation (K-factor)

The soil erodibility factor (K) is a quantitative description of the intrinsic erodibility of a particular soil and an indicator of the sensitivity of soil properties to erosion (Zhai et al., 2011). The K-factor represents the relationship among annual average soil loss, hydraulic processes, and sediment transportability under ordinary soil conditions (Özşahin et al., 2018). In this study, the K-factor was estimated by combining the results of the studies (Zhujun et al., 2019; Wang et al., 2018) utilizing *Equation 3:*

$$K = \left\{0.2 + 0.3\exp\left[-0.0256 * SAN(1 - \frac{SIL}{100})\right]\right\}(\frac{SIL}{CLA + SIL})^{0.3} * (1.0 - \frac{0.25C}{C + \exp(3.72 - 2.95C)}) * (1.0 - \frac{0.25SN1}{SN1 + \exp(-5.51 + 22.9SN1)}) \quad \text{(Eq.3)}$$

$$SN1 = 1 - SAN / 100 \quad \text{(Eq.4)}$$

where SAN, SIL, and CLA are the mass fractions (%) of sand, silt and clay, respectively; and C is the mass fraction of soil organic carbon (SOC) (%). The soil type and the SOC data were captured from the soil data.

The K-factor map, obtained using the kriging spatial interpolation method in GIS, is more suitable for soil moisture spatial interpolation in the Longmen Shan region (Yao et al., 2013).

Estimation of the slope length and slope gradient factor (LS-factor)

The LS-factor in RUSLE reflects the ratio of gross soil loss under given conditions with respect to slope length (L-factor) and slope steepness (S-factor) (Renard et al., 1997). The slope length is closely related to soil erosion. On a regional scale, the factors, including the slope length (L) and slope steepness (S), were calculated by using the DEM (30 m×30 m) of the study area. The method developed by Wischmeier and Smith was adopted to calculate L using *Equation 5:*

$$\begin{cases} L = (\lambda / 22.13)^{\alpha} \\ \alpha = \beta(\beta + 1) \\ \beta = (\sin\theta / 0.089) / [3.0 \times (\sin\theta)^{0.8} + 0.56] \end{cases} \quad \text{(Eq.5)}$$

where λ is the slope length (m), 22.13 represents the slope length of the standard district (m), α is the index of the slope length calculated using the method by Renard (1997), β

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1123311247

indicates the ratio of rill to inter rill erosion, and θ represents the slope gradient extracted from the DEM data. The effect of slope gradient on erosion (Zhao et al., 2017) is represented by the steepness factor (S) of the slope, which is calculated using the equation established by Liu et al. (Liu et al., 2000). The greater the slope steepness factor is, the greater the possibility of soil loss and the more severe the soil erosion. The slope steepness factor is calculated as follows:

$$\begin{cases} S = 10.8 \times \sin\theta + 0.03 & \theta < 5^{\circ} \\ S = 16.8 \times \sin\theta - 0.5 & 5^{\circ} \le \theta < 10^{\circ} \\ S = 21.91 \times \sin\theta - 0.96 & \theta \ge 10^{\circ} \end{cases} \quad \text{(Eq.6)}$$

Based on the Map algebra function in ArcGIS (Version 10.2), L was calculated according to the equation. The LS value distribution is calculated by multiplying the spatial distribution of the S and L factors.

Estimation of cover management factor and support practice factor (C and P factor)

The C value reflects the impact of crop and management activities on erosion rate. The protective vegetation layer helps stabilize topsoil, thus preventing soil degradation, and plays an important role in enhancing soil impact resistance. The C value is an important indicator to evaluate the influence of vegetation factors on soil erosion capacity (Rao et al., 2013). The P value is the ratio of the amount of soil loss after soil conservation measures to the amount of soil loss without any soil conservation measures. This value reflects the inhibition of soil erosion by soil conservation measures. The C and P factors are dimensionless numbers between 0 and 1. In this study, by referring to the literature data, the C and the P values corresponding to the land use type are selected (*Table 1*), and the model automatically converts the field into a raster layer (Ran, 2015; Teng et al., 2018).

Results and discussion

The results revealed that significant LULC occurred in the Longmen Shan region (*Fig. 2*) after the Wenchuan Earthquake. The dynamic parameters (rainfall erosivity, cover management and conservation practices) were measured for 2005, 2008, 2010 and 2017. The different input parameters have the capacity to alter the rate of soil erosion (Özşahin et al., 2018). The precipitation data for 2005, 2008 and 2010 were merely used for R-factor values, and the results were 421.86 m.t.cm/ha.h.y, 392.04 m.t.cm/ha.h.y, 451.69 m.t.cm/ha.h.y and 402.37 m.t.cm/ha.h.y, respectively. The R-factor values in 2008 were lower than those in the other years. Vegetation cover is an important component of any prediction model, because it is the erosion risk variable most affected by human manipulation (Sahin and Kurum, 2002). In contrast, the C-factor values spatiotemporally varied due to LULC in the study area, such as the increase in the settlement and bare areas by 317 km^2 and 138 km^2, respectively, from 2005 to 2017. However, the LS and K factors are presented as individual maps because they do not change over time. The K-factor and a higher magnitude of the LS-factor were obtained in the Longmen Shan area.

LULC change

The rate of LULC change was computed from 2005 to 2017 (*Table 2*). The forest ecosystem area decreased by -181 km^2, and the rate of change in the forest ecosystem is relatively stable. The grassland and farmland ecosystem areas decreased by -336 km^2 and -334 km^2, respectively, from 2005 to 2017. The grassland ecosystem and farmland ecosystem have shown a negative rate of change for the study periods. The farmland ecosystem showed the highest rate of changes (-0.16%) in the period (2005-2017). In contrast, settlement, wetland ecosystems and other ecosystems showed a positive rate of change for both periods. Settlements and other ecosystems showed the highest rate of change (2.32% and 4%, respectively) in the period, and the areas of the settlement ecosystem and other ecosystems increased by 317 km^2 and 138 km^2, respectively.

Rapid and massive population growth, the main factor of these LULC changes, leads to overexploitation of natural resources and destruction of the ecological environment caused by the devastating May 12, 2008 Wenchuan Earthquake (Peng et al., 2012). In general, slope steepness, geology and shaking intensity are the main factors that affect the distribution of earthquake-induced landslides (Wang et al., 2007). Furthermore, Di et al. (2010) observed that the combination of elevation and slope may have contributed most to the distribution of mass landslides triggered by the Wenchuan Earthquake.

Soil loss of different ecological types

The soil loss was estimated by integrating the maps of the six RUSLE factors in a GIS environment. An overall increase in soil loss was observed for forest ecosystems,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1123311247

grassland ecosystems, farmland ecosystems and other ecosystems from 2005 to 2010 (*Table 3*), and from 2010 to 2017, the soil loss for forest ecosystems, grassland ecosystems, farmland ecosystems and other ecosystems decreased. The total soil loss of the forest ecosystem in 2005, 2008, 2010 and 2017 was 276.88 × 10^4 t ha^{-1}·$year^{-1}$, 258.26 × 10^4 t ha^{-1}·$year^{-1}$, 295.76 × 10^4 t ha^{-1} $year^{-1}$, 152.62 × 10^4 t ha^{-1}·$year^{-1}$, respectively. The total soil loss of theg rassland ecosystem in 2005, 2008, 2010 and 2017 was 192.77 × 10^4 t ha^{-1}·$year^{-1}$, 176.48 × 10^4 t ha^{-1}·$year^{-1}$, 204.43 × 10^4 t ha^{-1}·$year^{-1}$, 156.34 × 10^4 t ha^{-1}·$year^{-1}$, respectively. The total soil loss of the farmland ecosystem in 2005, 2008, 2010 and 2017 was 129.21 × 10^4 t ha^{-1}·$year^{-1}$, 118.00 × 10^4 t ha^{-1}·$year^{-1}$, 135.34 × 10^4 t ha^{-1}·$year^{-1}$, and 111.52 × 10^4 t ha^{-1}·$year^{-1}$, respectively. The total soil loss of the other ecosystems in 2008, 2010 and 2017 was 3.36 × 10^4 t ha^{-1}·$year^{-1}$, 4.02 × 10^4 t·ha^{-1}·$year^{-1}$, and 10.03 × 10^4 t ha^{-1}·$year^{-1}$, respectively. The amount of soil loss in 2017 was lowest. From 2005 to 2017, the contribution to total soil loss of the forest ecosystem decreased by 35.45%, and that of the grassland ecosystem and farmland ecosystem increased by 36.32% and 25.9%, respectively. The total soil loss of the other ecosystems increased by 2.33%, and in 2008, it increased by 0.60% because of the Wenchuan Earthquake. Geo-hazards induced by the Wenchuan Earthquake resulted in intense surface material movement that led to the removal and destruction of a large area of vegetation. In the upper Minjiang River, forest cover decreased from 28.44% in 2005 to 24.45% in 2008 after the earthquake (Cui et al., 2009; Huang et al., 2009). In Xuanping and Yuli towns, 17.79 × 10^4 m^2 and 1.549 km^2, respectively, of farmlands and forests were submerged along the rising water level of rivers and valleys (Fan et al., 2008).

Table 3. *Soil loss of different ecological types*

Soil loss at the district and county scales

The areas with the highest soil erosion in the Longmen Shan area are mainly distributed in the western part of the Longmen Shan fault zone over a long, narrow area, and are mainly located in Qingchuan, northwest Pingwu, Maoxian, Wenchuan, Baoxing and Hanyuan Counties (*Fig. 3; Table 4*). Soil erosion in Maoxian County was the most devastating, with a mean soil loss value in 2005, 2008, 2010 and 2017 of 2.3 t ha^{-1}·$year^{-1}$, 2.13 t ha^{-1}·$year^{-1}$, 2.45 t ha^{-1}·$year^{-1}$, and 1.55 t·ha^{-1}·$year^{-1}$, respectively, which contributed to total soil losses of 14.77%, 14.74%,14.76%, and 13.87%, respectively. Wenchuan, Baoxing and Hanyuan Counties account for more than 10% of the total area.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1123311247

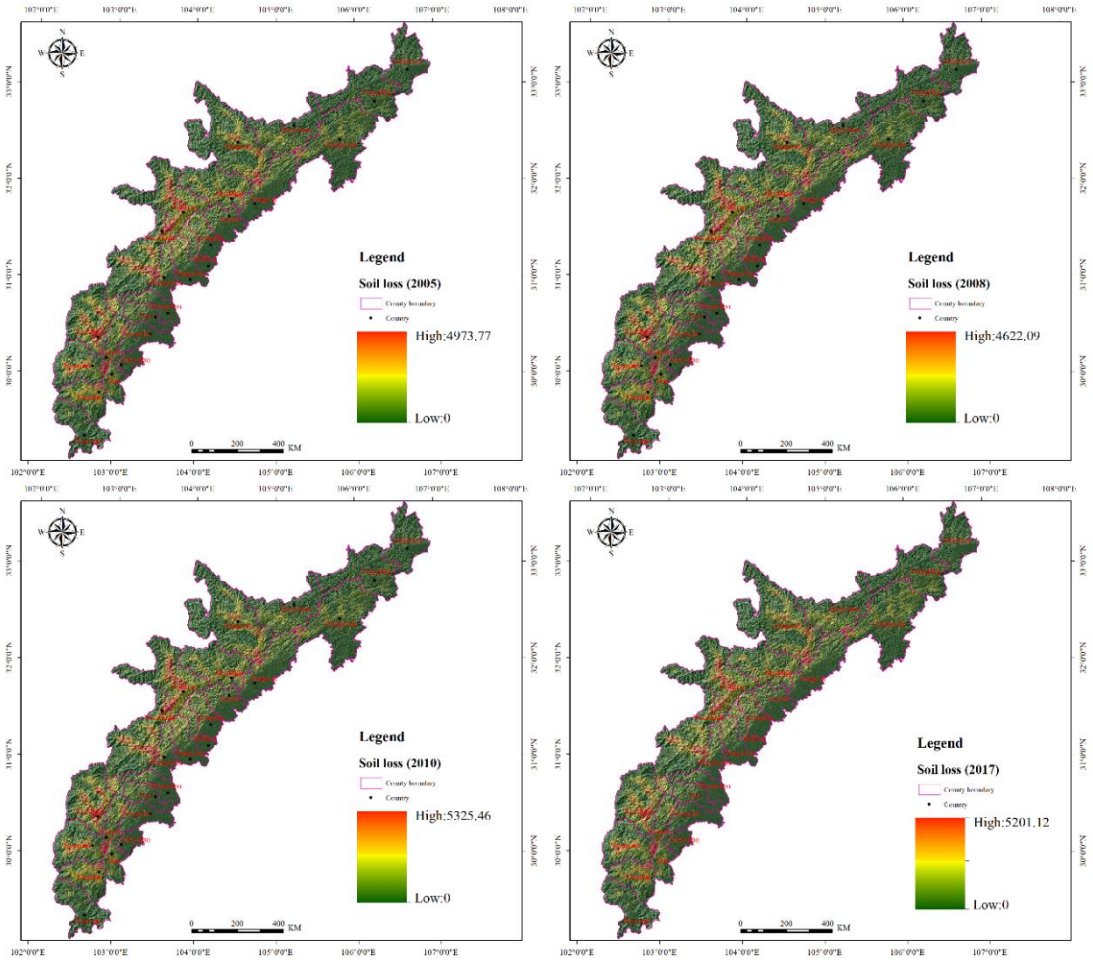

Figure 3. *Soil loss on county scale in 2005, 2008, 2010 and 2017 in the study area*

Less soil erosion was reported at lower elevations. These areas are mainly distributed in the eastern part of the Longmen Shan fault zone: Guanyuan, Jianyou, Anxian, Shifang, Mianzhu, Pengzhou, Dujiangyan, Chongzhou, Dayi, Handan, Mingshan, Yaan, etc. The soil loss of Yingjing was relatively small, with mean soil loss values in 2005, 2008, 2010 and 2017 of 0.08 t ha^{-1}·$year^{-1}$, 0.08 t ha^{-1}·$year^{-1}$, 0.09 t·ha^{-1}·$year^{-1}$, 0.09 t·ha^{-1}·$year^{-1}$, respectively, which contributed to total soil losses of 0.32%, 0.33%, 0.33%, and 0.52%, respectively.

The areas with severe soil loss are mainly distributed along the Minjiang River and its tributaries at higher elevations in the western Longmen. The 2008 Wenchuan Earthquake caused severe damage to the vegetation in the area, increased surface exposure, and caused frequent occurrences of geological disasters such as mudslides and landslides after the earthquake, resulting in an increase in soil loss in 2010. A geological survey in Sichuan Province recorded 3286 landslides and 1218 rock avalanches in the different counties after the earthquake (Li et al., 2011). A massive magnitude of denudation occurs frequently in 3 to 5 years after a strong earthquake e.g., the large debris flow disaster in 2010 after the 2008 Wenchuan Earthquake (Tang et al., 2011). Vegetation along rivers and valleys has been destroyed by debris flows, which also limit potential vegetation restoration (Cui et al., 2009). In the seven years after the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1123311247

Wenchuan Earthquake, there were six large-scale debris flow disasters in the Baisha-Longxi River basin, covering an area of 188.5 km^2 (Peng et al., 2012).

Conclusion

In this study, LULC changes were monitored in Longmen Shan in 2005, 2008, 2010 and 2017 using remote sensing and GIS approach. The map of LULC changes illustrates positive growth in the settlement ecosystem and other ecosystems, which led to a sharp increase in industrialization and geo-hazards induced by the Wenchuan Earthquake. Negative growth has also been observed in the grassland ecosystem and farmland ecosystem due to destruction of the ecological environment. The areas with severe soil loss are mainly distributed along rivers in the high-elevation areas of the western Longmen Mountains and along the Minjiang and Tuojiang River basins and their tributaries.

Risk monitoring of heterogeneous regions in different time series can provide a timely understanding of the status of soil erosion and make reliable predictions. In future research, the erosion model can also be used to predict climate change scenarios, and thus be used for effective erosion management practices. Therefore, the results of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1123311247

this study can adequately show the distribution of soil erosion in the region, and provide an important reference for decision makers to develop appropriate solutions. Finally, the ideas, modelling methods and corresponding policies used in this study are helpful for providing important references for soil erosion analysis in other regions.

(Received 9th Apr 2019; accepted 2nd Jul 2019)

Abstract. Seedlings of six crops including wheat, radish, cucumber, Chinese cabbage, oilseed rape, and lettuce were treated with hexavalent chromium (Cr(VI)) in a hydroponic system. Root surface area, tissue biomass, the activities of superoxide dismutase (SOD) and peroxidase (POD), and chromium contents were determined to evaluate the tolerance and accumulation of Cr(VI) by these crops. The results showed that the biomass reduction of wheat was the lowest, and that of lettuce was the highest. Significant decrease in SOD activity was observed in 1 mg/L Cr(VI) treatment for Chinese cabbage and radish. While significant activation effect on the POD was observed in 1 mg/L or 5 mg/L Cr(VI) treatment for Chinese cabbage and oilseed rape. Moreover, the activities of the two antioxidant enzymes in cucumber leaves did not change significantly at the two levels of Cr(VI) concentrations. The transfer coefficient of Chinese cabbage was the highest, while that of lettuce was the lowest. In conclusion, Chinese cabbage has a certain tolerance to Cr(VI) and exhibits the highest accumulation of Cr in the edible parts. Therefore, when planting crops in low and medium Cr contaminated soil, concerns should be addressed on the food safety issues from leafy vegetables, especially Chinese cabbage.
Keywords: *crop, chromium (VI), physiological and biochemical properties, accumulation*

Introduction

Crops are one of the most important sources of human food, providing the essential energy and nutrients for the human body. There is increasing concern regarding the health risks arising from the absorption and accumulation of heavy metals by the edible parts of crops (Noli and Tsamos, 2016). Among all the heavy metals, chromium (Cr) is considered as a serious environmental contaminant for the biota (Kabata-Pendias, 2011). Consumption of contaminated foods is considered to be the most common pathway of human exposure to Cr compared to inhalation and dermal contact (Wang et al., 2011). Cr(III) and Cr(VI) are the two main forms of chromium, among which Cr(VI) has higher water solubility and thus higher bioavailability. Due to its high redox potential, Cr(VI) can interfere with photosynthesis and respiration processes, uptake of water and minerals, enzyme activity, and leads to damage on the membrane lipid and DNA, resulting in a severe decline in crop yield and quality (Singh et al., 2013). Mutagenic and carcinogenic to humans, Cr(VI) is identified as a class A carcinogen (Prado et al., 2016; Feng et al., 2004). Therefore, studying the biotoxicity of Cr(VI) is essential for the safe production of agricultural products and the protection of the environment and human health.

There are some differences on the stress response and accumulation of Cr by different crops due to the differences in external morphology, internal structure as well as physiological and biochemical mechanisms on the absorption of heavy metals. For example, Bashri et al. (2016) studied the physiological and biochemical characteristics

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1124911260

of two Amaranthus species, in which they found the species with higher antioxidant defense system exhibited higher tolerance to Cr(VI) stress. It was reported that members of the Brassicaceae family can absorb and transfer high concentrations of Cr into the edible parts (Singh et al., 2013; Cervantes et al., 2001). Furthermore, difference in the physiological and biochemical response and accumulation of Cr by different cultivars of the same crop was also reported. For example, Guo et al. (2015) observed that the growth of Lumai 22 (Cr tolerant wheat cultivar) was less inhibited than Zhoumai 9 (Cr sensitive wheat cultivar). Moreover, a greater proportion of Cr was accumulated in the roots and the cell walls of the aerial parts in Lumai 22 compared with those of Zhoumai 9. Gill et al. (2015) found the ultrastructural damage in leaf mesophyll and root tip cells was most pronounced in Zheda 622 cultivar among the four different cultivars of *Brassica napus* L. Plants have specific mechanisms to protect from oxidative damages, such as enzymatic antioxidants and non-enzymatic antioxidants, which scavenge the reactive oxygen species (ROS). Wang et al. (2012) studied the tolerance of three species of grasses to Cr(VI) stress, in which they found Medicago sativa was less tolerant to Cr compared with *Trifolium repens* and *Festuca arundinacea*, which is likely due to the reduced activities of peroxidase (POD) and superoxide dismutase (SOD) of *Medicago sativa* with the increase of chromium concentration. Most of the above researches focused on the comparison of different cultivars of the same crop under the Cr stress. There are still knowledge gaps with regard to the stress response and accumulation of Cr by different crops.

Therefore, in this study, two levels of Cr(VI) were used for hydroponic treatment to study the stress response and accumulation of Cr by six crops including wheat, radish, cucumber, Chinese cabbage, oilseed rape, and lettuce. It can provide theoretical support for the rational and safe cultivation of crops in low and medium Cr-contaminated soil.

Materials and methods

Materials

The seeds of six crops including wheat (Jimai 22), radish (Zheda Chang), cucumber (green cucumber), Chinese cabbage (Jiaoyan 5869), oilseed rape (Shanghai Qing), and lettuce (four seasons lettuce) were purchased from Shandong Academy of Agricultural Sciences (Jinan, China), Ma'anshan Qiutian Seed Industry (Nanjing, China), Nanjing Jinshengda Seed (Nanjing, China), Qingdao Jiaoyan Seedling (Qingdao, China), Nanjing Jinshengda Seed (Nanjing, China), and Nanjing Green Collar Seed Industry Co., Ltd (Nanjing, China), seperately.

Hydroponic experiment

The seeds were firstly sterilized with 10% H_2O_2 for 20 min, then washed thoroughly with distilled water. Subsequently, the seeds were germinated on filter paper saturated with deionized water and placed in the dark at 25 °C for 24 h. The germinated seeds were grown in plastic pots filled with quartz sand, which were placed in an artificial climate chamber with the daylight/night time of 14/10 h, daylight/night temperature of 24 ± 2 °C/18 ± 2 °C, the light intensity of 25000 lux, and the relative humidity of 75%. Wheat, radish, and cucumber were cultured for 2 weeks. Chinese cabbage, oilseed rape, and lettuce were grown to the stage of 4 leaves and 1 core. Then uniform seedlings were selected and transferred to glass containers with 400 mL of modified Hoagland nutrient

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1124911260

solution aerated with an air pump (4 seedlings per container). The nutrient solution (pH = 6.0) consists of 944 mg/L $Ca(NO_3)_2$, 490 mg/L $MgSO_4$, 136 mg/L KH_2PO_4, 510 mg/L KNO_3, 2.86 mg/L H_3BO_3, 1.81 mg/L $MnCl_2$, 0.22 mg/L $ZnSO_4$, 0.09 mg/L $(NH4)_6Mo_7O_{24}$, 0.08 mg/L $CuSO_4$, and 3.67 mg/L NaFe-EDTA. After 3 days of acclimatization, the crops were exposed to 0, 1 mg/L and 5 mg/L of Cr(VI) (K_2CrO_4). Each treatment had three replicates. The nutrient solution was renewed every 3 days.

Measurement of gas exchange parameters

The photosynthetic gas exchange parameters of the crops, including photosynthetic rate, stomatal conductance, and transpiration rate, were measured using a portable photosynthesis instrument (LC pro-SD, ADC, England) after 15 days of treatment.

Measurement of growth and morphological parameters

Crops were harvested and separated into roots and the aerial parts after 15 days of exposure, then washed with deionized water and dried with filter paper to measure the fresh biomass. The aerial parts were placed in an oven at 105 °C for 30 min, then dried at 70 °C. The dry biomass was weighed. The roots were first scanned using a root scanner (ScanMaker i800plus, Shanghai Zhongjing Technology Co., Ltd., China) to measure the surface area, then were dried to measure the dry biomass. The dried crop tissues were pulverized with a stainless steel pulverizer for later use.

Determination of antioxidant enzyme activity

Frozen leaves were homogenized in 6 mL pre-cooled potassium phosphate buffer (50 mM, pH = 7.8) containing 1% (w/v) polyvinylpyrrolidone (PVP) with a chilled mortar and pestle. The homogenate was centrifuged at 10,000 g for 15 min at 4 °C and the supernatant obtained was used for enzymes assay.

SOD (EC 1.15.1.1) activity was determined by the nitroblue tetrazolium (NBT) method (Gonzalez et al., 1998). The assay mixture contained 50 mM phosphate buffer (pH 7.8), 130 mM methionine, 750 μM NBT, 100 μM EDTA-Na_2, and 20 μM riboflavin. A total volume of 3.3 mL assay mixture was placed under a 4000 lx fluorescent lamp for 15-20 min and then determined using an ultraviolet visible spectrophotometer (UV-2550, Shimadzu, Japan) at 560 nm. One unit of SOD activity is the amount of enzyme that is required to cause 50% inhibition in the reduction of NBT. POD (EC 1.11.1.7) activity was determined using the guaiacol method (Zhou and Leul, 1998). The reaction mixture was comprised of 50 mM phosphate buffer (pH = 7.8), 30% H_2O_2, 20 mM guaiacol, and 100 μL enzyme extract. Activities of POD were assayed by measuring the absorbance at 436 nm with 3 mL of the mixture. One unit of POD activity was defined as the amount of enzyme catalyzing the oxidation of 1 μmol of guaiacol in 1 min.

Determination of Cr contents in the crop tissues

For determination of Cr contents, a certain amount of the roots or the aerial parts was weighed into a digestion tube. Ten milliliter digestion solution consisting of HNO_3 and H_2O (1:1, V/V) was added soaking overnight. A graphite digestion instrument (EE, USA) was used to digest the tissues for about 12 h at temperature of 105 °C. Then 1 mL of H_2O_2 was added to the remaining digestion solution and continue to digest to obtain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1124911260

clear solution. The solution was made up to 50 mL using Milli-Q water. Chromium contents were measured by ICP-MS (iCAP Q, Thermo Fisher Scientific, America).

Statistical analysis

Bio-concentration factor (BCF) is the ratio of the concentration of heavy metals in the roots or the aerial parts of plants to that in soil or solution (Ding et al., 2016). The transfer factor (TF) is the percentage of Cr concentration in the aerial parts to that in the roots, indicating the ability of heavy metals to be translocated from the roots to the aerial parts (Ali et al., 2013). The tolerance index (TI) is the percentage of the biomass of crop at Cr stress to that of the control treatment (Wilkins, 1978).

Data processing and analysis were performed using Excel and SPSS 22. One-way ANOVA and the least squares deviation (LSD) test were used to compare the difference among different treatments. Statistical significance was accepted at $p < 0.05$. The figures were graphed using Origin 2017 software. The data results were expressed as mean ± standard error.

Results

Effect of Cr(VI) on the growth traits of crops

The fresh biomass and root area of the six crops showed a decreasing tendency with increasing Cr(VI) concentration (*Table 1*). For the treatments of 1 mg/L of Cr(VI), the root biomasses of wheat and Chinese cabbage were not significantly different from those of the control, while those of radish, cucumber, oilseed rape, and lettuce decreased significantly compared with those of the control, with reduction of 25%, 73%, 30%, and 71%, respectively. Treatments with 5 mg/L of Cr(VI) significantly reduced the root biomasses of all the six crops. The reduction in root biomass was the lowest for wheat (25%), followed by radish (49%), oilseed rape (59%), Chinese cabbage (68%), cucumber (76%), and lettuce (92%). The aerial biomasses of the six crops were reduced significantly under the two levels of Cr(VI) treatments. Similar to those of the roots, wheat showed the lowest reductions in the aerial biomass, which were 27% and 49%, respectively. While lettuce presented the highest reduction, which were 82% and 94%, respectively. Under 5 mg/L of Cr(VI) stress, the root and shoot TI of wheat were 75% and 51%, respectively. While the root and shoot TI of lettuce were 7% and 6%, respectively. The results indicated that wheat has stronger tolerance to Cr(VI) toxicity, while lettuce showed less tolerance compared with other crops.

Under the two levels of Cr(VI) stress, except for cucumber, the TI values for the aerial parts of the other five crops were all lower than those of the roots, indicating the biomasses of the aerial parts other than roots of these five crops are more sensitive to Cr(VI) toxicity and could be used as biomarkers.

Effect of Cr(VI) on the photosynthetic properties of crops

The photosynthetic rate and transpiration rate of the six crops responded differently under the two levels of Cr(VI) treatments (*Table 2*). Under 1 mg/L of Cr(VI) treatment, the stomatal conductance and transpiration rate of wheat, cucumber, and oilseed rape did not change significantly, while those of radish, Chinese cabbage, and lettuce decreased significantly. The stomatal conductance and transpiration rate of the six crops were significantly reduced under 5 mg/L of Cr(VI) treatment. The transpiration rates in

DOI: http://dx.doi.org/10.15666/aeer/1705_1124911260

the leaves of wheat, radish, cucumber, Chinese cabbage, oilseed rape, and lettuce were reduced by 63%, 79%, 56%, 60%, 71%, and 87%, respectively. The stress of Cr(VI) on the transpiration rate in the leaves of wheat, cucumber, and Chinese cabbage is relatively low, which may account for the insignificant change in the leaf water contents of these three crops under Cr(VI) treatment of 1 mg/L (*Fig. 1*). The photosynthetic rates of wheat, radish, and Chinese cabbage did not change significantly, while those of cucumber, oilseed rape, and lettuce were significantly reduced under 1 mg/L of Cr(VI) treatment. Under 5 mg/L of Cr(VI) treatment, the photosynthesis rates of wheat, radish, cucumber, Chinese cabbage, oilseed rape, and lettuce decreased significantly, with reductions of 51%, 61%, 55%, 41%, 79%, and 80%, respectively. The effects of Cr(VI) on the photosynthetic rates of wheat and Chinese cabbage are less than those of other crops, while are higher than those of oilseed rape and lettuce.

Effects of Cr(VI) on the activities of antioxidant enzymes

The effects of Cr(VI) on the SOD and POD activities of the six crops are shown in *Figure 2*.

As can be seen, Cr(VI) treatment of 5 mg/L significantly inhibited the SOD activity of all the crops except that of cucumber. Moreover, for Chinese cabbage and radish, significant decrease in SOD activity was observed at 1 mg/L of Cr(VI) treatment. Especially for radish, SOD activity was not detected at the two levels of Cr(VI) treatments. It is suggested that Chinese cabbage and radish are sensitive to the stress of Cr(VI). Similar to that of SOD, Cr(VI) treatment of 5 mg/L resulted in significant inhabitation on POD activity of all the crops except cucumber and oilseed rape. For Chinese cabbage and oilseed rape, significant activation effect on the POD was observed at 1 mg/L or 5 mg/L of Cr(VI) treatment. Interestingly, the SOD and POD activities of cucumber did not change significantly at the two levels of Cr(VI) treatments. This indicated that cucumber is not sensitive to the stress of Cr(VI).

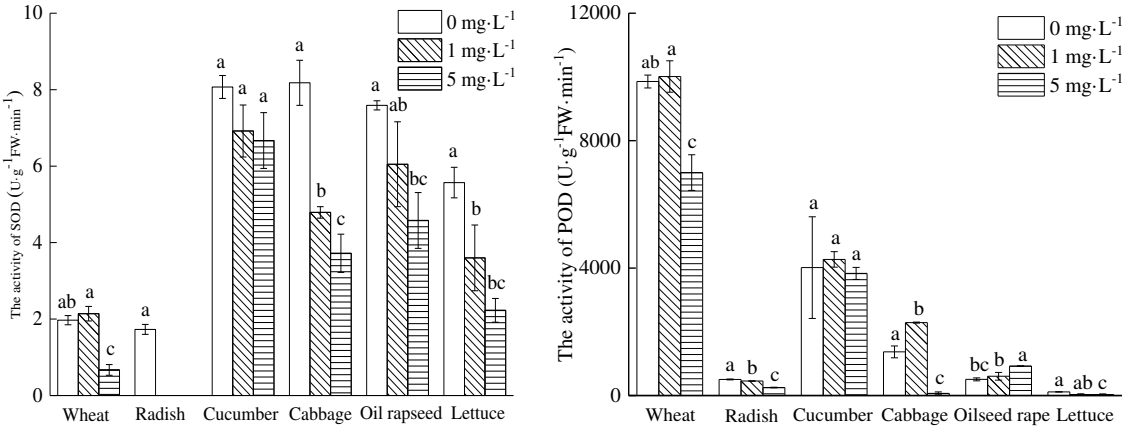

Figure 2. *Effect of Cr (VI) on the activities of antioxidant enzymes in crops. (Bars indicate standard error)*

The accumulation of Cr by crops

With the increase of Cr(VI) concentration in hydroponic solution, the Cr contents in the crop tissues increased significantly except the roots of cucumber and Chinese cabbage (*Table 3*). Under Cr(VI) treatment of 1 mg/L, the Cr content in lettuce roots is the highest (1024 μg/g), followed by oilseed rape (772 μg/g), Chinese cabbage (736 μg/g), cucumber (695 μg/g), radish (651 μg/g), and wheat (246 μg/g). For 5 mg/L of Cr(VI) treatment, the Cr content in lettuce roots is also the highest (2823 μg/g), followed by radish (1453 μg/g), oilseed rape (1161 μg/g), Chinese cabbage (876 μg/g), cucumber (700 μg/g), and wheat (427 μg/g). The Cr contents in the aerial parts of the six crops were far below those of the roots. Under Cr (VI) treatment of 1 mg/L, the Cr content in the aerial parts of Chinese cabbage is the highest (35.9 μg/g), followed by oilseed rape (19.5 μg/g), lettuce (16.2 μg/g), radish (13.4 μg/g), wheat (13.2 μg/g), and cucumber (9.00 μg/g). Under Cr(VI) treatment of 5 mg/L, the Cr contents in the aerial parts of the six crops followed the same order.

Table 3. *The uptake, accumulation, and translocation of Cr by crops*

	Cr(VI) (mg/L)	Wheat	Radish	Cucumber	Chinese cabbage	Oilseed rape	Lettuce
Cr contents in roots (μg/g DW)	1	246±22.3b	611±0.67b	695±38.9ab	736±67.3ab	772±20.9b	1024±105b

Values are presented as means and standard error. Different letters indicate statistically significant difference between different treatments

For the roots, the BCF values of the six crops decreased significantly with the increase of Cr(VI) treatment concentration. Under Cr(VI) treatment of 1 mg/L, the BCF for wheat roots was significantly lower than those of other crops. Under 5 mg/L of Cr(VI) treatment, the root BCF of lettuce was the highest, followed by radish, oilseed rape, Chinese cabbage, cucumber, and wheat. For the aerial parts, the BCF of Chinese cabbage, oilseed rape, lettuce, and radish did not change significantly at the two levels of Cr(VI) treatments, while those of wheat and cucumber decreased significantly with the increase of Cr(VI) treatment concentration. The BCF of the aerial parts of Chinese cabbage is the highest, and that of cucumber is the lowest.

Except for radish, the TF of other crops increased significantly with the increase of Cr(VI) treatment concentration. Under Cr(VI) treatment of 1 mg/L, the TF values of the six crops ranged from 1.16 to 5.12, following the order of wheat > Chinese cabbage > oilseed rape > radish > lettuce > cucumber. Under Cr(VI) treatment of 5 mg/L, the TF values of the six crops ranged from 2.92 to 18.6. Different from that of 1 mg/L

treatment, the order is Chinese cabbage > wheat > oilseed rape > cucumber > radish > lettuce.

Discussion

It has been demonstrated that Cr could inhibit the growth of plant, cause chlorosis in newly budded leaves and the decrease in root surface area. These indicators have been used to assess the responses of crops to the Cr stress (Bashri et al., 2016; Anjum et al., 2017; Liu et al., 2008; Pandey et al., 2005; Tiwari et al., 2009). In the present study, the biomasses of crop tissues decreased with the increase of Cr(VI) concentration in the nutrient solution (*Table 1*). The results are consistent with those of wheat seedlings exposed to Cr(VI) (Guo et al., 2015). All the six crops were stressed by 1 mg/L of Cr(VI), and the aerial parts of the six crops were more sensitive to Cr stress than the roots except for cucumber (*Table 1*). This may be due to the reduced root activity, which inhibits the transport of nutrients from roots to the aerial parts. The growth parameters of the six crops were significantly reduced because the crops could not acquire abundant nutrients to maintain normal physiological activity (Ali et al., 2013). The TI can be used to indicate the tolerance of crops to heavy metals, the greater the value, the stronger the tolerance of plants to heavy metals (Liu and Wang, 2002). In the present study, the growth parameters and the TI values indicated that wheat exhibited strong tolerance to Cr(VI) among the six crops, while lettuce was relatively less tolerant to Cr(VI).

The main parameters affecting crop photosynthesis and transpiration include stomatal conductance, transpiration rate, and photosynthetic rate. In this study, as the Cr(VI) treatment level increased, the stomatal conductance, transpiration rate, and photosynthetic rate of the six crops showed a decreasing tendency. The increase of chlorophyllase activity in crops resulted in the decomposition of chlorophyll under the stress of heavy metals (Hegedus and Erdei, 2001), which led to lower capacity for light-harvesting, thus the decrease in photosynthetic rate. On the other hand, the decrease of the photosynthetic rate under Cr(VI) stress may be attributed to the interference of Cr on nutrient absorption, respiration rate, and cell membrane permeability. In addition, Cr(VI) can induce chloroplast ultrastructural abnormalities, such as the alteration of thylakoid (Luisa Brito et al., 2009). The treatment of 5 mg/L Cr(VI) significantly reduced the stomatal conductance of the crop leaves. This can be explained by the damage to the stomatal guard cells of crop leaves caused by the high oxidation potential of Cr(VI) (Hayat et al., 2012). Former study has found that Cr can reduce the tracheary diameter of bean plants, thereby reducing the longitudinal movement of water (Barceló and Poschenrieder, 1990), which may bring about the reduced transpiration rate of the crops. Similar results have also been reported by Gill et al. (2015), Liu et al. (2008), and Ali et al. (2011), in which they found that high concentrations of Cr can reduce the net photosynthetic rate, stomatal conductance, and transpiration rate of oilseed rape, *Amaranthus viridis L* and barley. Heavy metal stress results in severe dehydration of plant shoots by interfering with the water transport from roots to shoots. In general, heavy metals can affect water contents through water absorption, water transformation of plastids and protoplasts, and stomatal function (Poschenrieder and Barceló, 1999). In this study, under the stress of 5 mg/L of Cr(VI), the water contents of wheat and cucumber did not change significantly, while those of radish, Chinese cabbage, oilseed rape, and lettuce decreased significantly.

Subjected to Cr stress, crops are stimulated to produce reactive oxygen species (ROS), such as H_2O_2, OH^-, O^{2-}, which bring about oxidative damage to biomolecules such as lipids, proteins, and nucleic acids. Therefore, crops control the production of peroxidative radicals by developing a complex enzymatic antioxidant system to prevent plants from being oxidatively damaged (Ashraf et al., 2015). This defense mechanism includes various antioxidant enzymes such as SOD, catalase (CAT), and POD. Crop cells increase the activity of antioxidant enzymes and eliminate excess ROS to maintain ROS balance (Gill and Tuteja, 2010). The differences in antioxidant defense mechanisms induced by heavy metals depend on the species of heavy metal and crops (Hayat et al., 2012). SOD and POD are vital enzymes in crop antioxidant defense mechanisms. SOD is the most critical substance accounting for plant stress tolerance, providing a first line of defense to reduce the toxic effects caused by elevated levels of ROS. In general, the activities of antioxidant enzymes will be promoted under low concentration of heavy metal exposure while be inhibited under high concentrations of heavy metal exposure. Huang et al. (2011) showed that 10^{-6} mol/L of Cr(VI) stress had no significant effect on SOD and POD activities in maize, while 10^{-5} mol/L of Cr(VI) stress showed significant decreases in SOD and POD activities. In this study, under the stress of Cr(VI), the antioxidant enzyme activities of different crops were very different. The SOD and POD activities of wheat, cucumber, and oilseed rape as well as the POD activity of lettuce did not change significantly when treated with 1 mg/L of Cr(VI). The activities of SOD and POD in the leaves of radish and the activity of SOD in the leaves of Chinese cabbage and lettuce significantly decreased, while the activity of POD in the leaves of Chinese cabbage significantly increased. It showed that under 1 mg/L of Cr(VI) stress, wheat was tolerant to the Cr stress, while lettuce presented its sensitivity to the Cr stress. The increase of antioxidant enzyme activity may be attributed to the blockage of electron transport chains in mitochondria induced by Cr(VI), which directly affects the production of superoxide radicals. With the increase of Cr concentration, the enzyme activity decreases, which is due to the inhibition of Cr(VI) to the enzyme system (Hayat et al., 2012). Also, Huang et al. (2011) found that the dramatic changes in antioxidant enzyme activity may be related to the expression of isoenzymes during the transformation of nutritional mode.

The six crops showed considerable differences in the absorption, translocation, and accumulation of Cr. Wang et al. (2012) have found different oil crops showed different tolerance and accumulation of Cr. In this study, Cr was mainly retained in the roots of the six crops, ranging from 2823 μg/g (lettuce) to 426.5 μg/g (wheat). However, due to the difference in the translocation of Cr by different crops, the TF of Chinese cabbage (18.6%) was the highest, which resulted in the highest content of Cr (208.8 μg/g) in the aerial parts of Chinese cabbage. The Cr contents in the aerial parts of oilseed rape and lettuce are significantly higher than those of the other three crops. It has been found that transpiration plays a vital role in the translocation of heavy metals by crops (Ji et al., 2017). In this study, there is a significant positive correlation between the TF of Cr and the transpiration rate of the six crops under Cr(VI) treatment of 1 mg/L ($R^2 = 0.75$), which was not observed under Cr(VI) treatment of 5 mg/L because of the higher toxic effect of Cr(VI) at this level.

Based on the above analysis, it can be found that wheat is more tolerant to Cr(VI) and has a weaker accumulation ability for Cr, while lettuce is more sensitive to Cr(VI) and has a stronger ability to accumulate Cr. Therefore, lettuce will bring more risks than wheat when planted in low and medium concentration Cr(VI)-contaminated soils. This

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1124911260

study is limited to the sensitivity and accumulation of Cr (VI) by six crops under hydroponic conditions. The treatment level of 5 mg/L Cr(VI) may be too high, which resulted in excessive toxicity and high Cr contents in crops. Although the results can reflect the tolerance of crops to Cr(VI), the tolerance, the translocation and accumulation of Cr by these six crops in soil systems remain to be further studied.

Conclusions

Under Cr(VI) stress conditions, the growth traits and photosynthetic characteristics of the six crops were more inhibited with increasing treatment concentration. Among them, wheat showed the strongest tolerance to Cr(VI), with the lowest accumulation of Cr in the shoots. Lettuce presented to be the most sensitive vegetables, with most Cr accumulated in the roots. Chinese cabbage had a certain tolerance to Cr(VI) and showed the highest accumulation of Cr in the edible parts, which may pose a threat to the safety of agricultural products if planted in Cr contaminated soils. In this study, the results on the tolerance and accumulation of Cr were based on the hydroponic conditions, the accumulation of Cr in soil systems by these crops should be further studied in the future.

Abstract. Adaptation to climate change varies according to regions, it could be effective in relation to people and their locations. Adaptation to climate change in sub-Saharan Africa is different from that of developed countries, as resources are limited. This study was conducted in Ngaka Modiri Molema District Municipality in North West Province of South Africa. This study examined the determinants of climate change adaptation strategies among rural farmers' households in the study area. A total number of 346 questionnaires were administered to the farmers in the district using the stratified random sampling technique. Data were captured and analyzed using SPSS and EVIEWS software. Multicollinearity analysis was first performed to remove highly correlated variables from the model followed by the use of Tobit regression analysis. The results of the analysis indicated that farm size ($p < 0.01$), gender ($p < 0.01$), type of farm ($p < 0.05$), farm ownership ($p < 0.05$), land acquisition ($p < 0.01$), source of climate change information ($p < 0.01$), support received on climate change ($p < 0.1$), and adaptation barrier were statistically significant ($p < 0.01$) and influenced climate change adaptation strategies. The study concluded that to support climate change adaptation among the rural farmers in the study area, considerable attention should be paid to understanding the socio-economic characteristics of the rural households, source of information and support received on climate change.
Keywords: *adaptive capacity, Tobit regression model, climate change, Ngaka Modiri Molema District Municipality*

Introduction

Climate change is real, perhaps one of the most serious environmental threats facing agriculture and rural livelihoods in Sub-Saharan Africa (SSA). Year in year out, it has become clearer that change in weather is happening at a rapid pace and it will have a profound severe negative impact on agriculture, management of natural resources and consequently on livelihood and food security. Climate change has significantly affected global agriculture in the 21st century (Ochieng et al., 2016). The effects of climate change on agricultural production and livelihood is expected to intensify over time, and to vary across countries and regions (Food and Agricultural Organization of the United Nations, FAO, 2016). Climate change could impair economic growth and other aspects of human and natural well-being (Butler, 2018).

Climate change is known to be an important challenge facing African countries. The impact is largely due to low income, greater reliance on climate-sensitive sectors such as agriculture, and weak capacity to adapt to the changing climate. Agriculture in sub-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1126111272

Saharan Africa continues to suffer from climate change due to the temperature rising and rainfall frequency and intensity fluctuating (Winifred et al., 2018). Climate change has negatively impacted on SSA countries because of their low human adaptive ability to foresee increases in tremendous events resulting from widespread poverty, heavy reliance on rain-fed agriculture, lack of economic and technological resources, insufficient safety nets and educational progress (Osumanu et al., 2017). According to Adebayor (2012), the effects of climate change, economically, socially and environmentally, have been a bane on sustainable agricultural production and food security in SSA endangering the livelihood of two-thirds of the population who work within the agricultural sector. It is projected that cereal crop may decrease yield in sub-Saharan Africa due to intensifying water stress and frequent incidence of diseases, pests and weeds outbreaks (Niang et al., 2014).

Southern Africa is expected to experience an increase in temperature and disruption in rainfall patterns as well as an increased frequency of extreme climate events such as drought and floods as a result of climate change. South Africa inclusive, is vulnerable to climate change and variability due to a high increase in temperature resulting in the frequent occurrence of drought, shortage of underground water, scarcity and spatial variability of rainfall pattern (Pereira, 2017). South Africa has been experiencing an increase in warmer days and more decrease in the number of cooler days (Davis et al., 2016). According to Linus et al. (2014), it was reported that between 1960 to 2050 the air temperatures in South Africa are expected to increase by 2 °C on average, while atmospheric carbon-dioxide levels are expected to increase by about 235 ppm (from 315 to 550 ppm).

The higher temperature is expected to increase crop heat stress and evapotranspiration demand in the North West Province of South Africa. The impacts are expected to affect natural resources such as air and water, which are considered to be the most critical factor associated with climate change. A report by Kiker (2015), on climate change synthesis on vulnerability and adaptation assessment, revealed that South Africa including North West Province is experiencing climate change which affects the water and air required by crops for survival. According to Blignaut et al. (2009), North West is considerably warmer with evidence that the future temperature will increase than normal which could make the region susceptible to marked reductions in maize production.

Notably, North West Province is one of the largest maize producers in the country (The South African Agricultural Baseline, 2011). The impact of climate change on the production of maize in the study area has resulted in low maize production coupled with a shortage of food and low income. This unpleasant situation in the study area has escalated into maize importation rather than exportation that the country was known of in the past. A report by Sensako (2015), established that South Africa was compelled to import 934,000 metric tons of yellow maize, which was worth about $137 million at current international prices, from countries such as Argentina and Ukraine in 2015 spanning through the end of March 2016 as drought reduced the maize yield. Therefore, there is no gainsaying that the examination of the adaptation measures that farmers need to employ in order to cope with climate change to fully maximize the production of maize which is a staple food in North West Province of South Africa becomes necessary.

Without appropriate responses, climate change is likely to constrain economic development and poverty reduction efforts. Adaptation strategies are needed as a tool to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1126111272

promote livelihood in rural communities. Adaptation is one major policy option for reducing the negative impact of climate change. Since, Sub Saharan Africa is predicted to be among the most vulnerable regions to climate change (IPCC, 2014), and because of the reliance on rainfall and other natural systems, smallholder rural households, who constitute 65% of the total population in SSA are the primary victims of climate change. Some coping mechanisms must be in place to adapt to climate change. In recent years, the determinants to climate change adaptation have been limited, and this has become a key concern to farmers, researchers, and policymakers. The available empirical evidence on the determinants of climate change adaptation among rural household farmers have been on large scale and extremely disintegrated (Osumanu et al., 2017). To ensure a better understanding of smallholder rural households' vulnerability and factors determining climate change adaptation, there is a need to investigate the factors responsible.

The objective of this study is to identify and provide a comprehensive understanding of different factors that determine adaptation to climate change among rural households in the study area. The significance of this study is that the findings will assist in directing specific and appropriate measures in combating the factors that affect climate change adaptation strategies in the study area. This would also help to provide improved supervision on appropriate interventions to enhance the resilience of agriculture-dependent households and communities.

Materials and methodology

The study was carried out in Ngaka Modiri Molema District Municipality of the North-West Province. The province lies in the north of South Africa on the Botswana border, with the Kalahari Desert to the west, Gauteng province to the east and the Free State to the south. North West province is the fourth smallest province in the country. It consists of four district municipal councils (Ngaka Modiri Molema District Municipality, Bojanala Platinum District Municipality, Dr. Ruth Segomotsi Mompati District Municipality, and Dr. Kenneth Kaunda District Municipality) which are in turn divided into 18 local municipalities. The province takes up about 8.7 percent of South Africa's land area (106 512 km²), with mining being the major contributor to the Province economy followed by farming activities in which maize is predominantly planted.

Data were collected from Ngaka Modiri Molema district municipality, which consists of 5 local municipalities as shown in *Figure 1*. The list of small and emerging maize farmers in the district comprising about 575 farmers was obtained from Department of Agriculture, Forestry and Fisheries (DAFF) and also from Grain SA. Raosoft sample size calculator was used to determine the sample size from the population of the small and emerging maize farmers in the study area. The sample size calculator took into account the confidence level, the response distribution and the margin of error as indicated below:

$$x = Z\,(^{c}/_{100})^2\, r(100-r) \quad \text{(Eq.1)}$$

$$n = {}^{N\,x}/_{(N-1)E^2 + x)} \quad \text{(Eq.2)}$$

$$E = \text{Sqrt}\,[{}^{(N\,-\,n)x}/_{n(N-1)}] \quad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1126111272

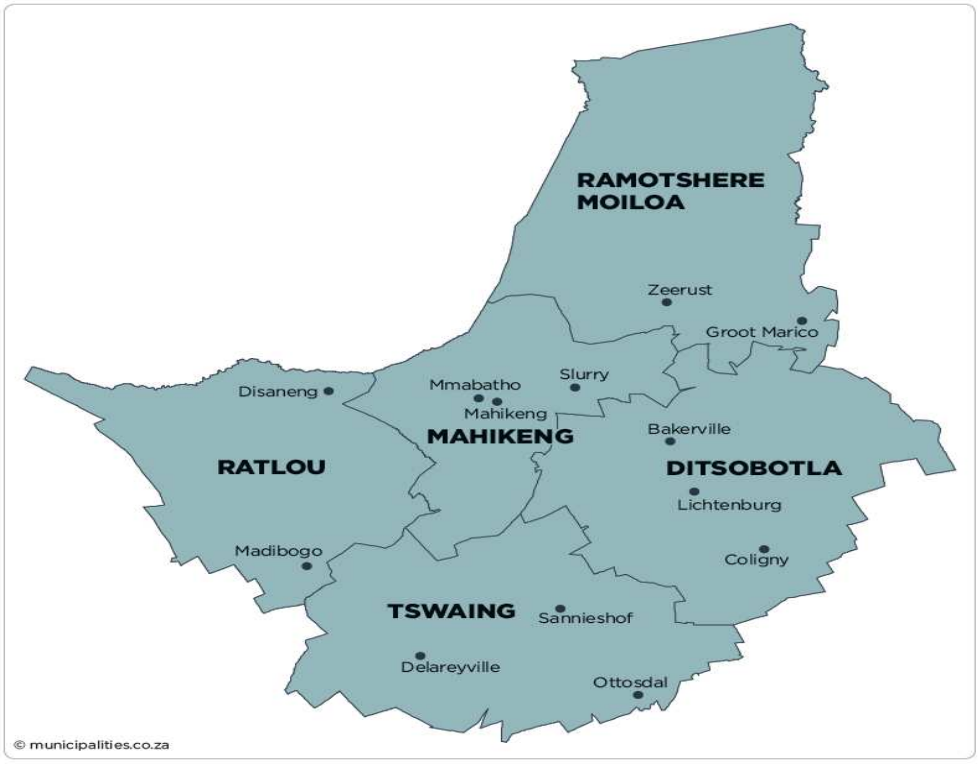

Figure 1. *Map of Ngaka Modiri Molema District Municipality. (Source: Municipal Demarcation Board, 2010)*

A total number of 346 questionnaires were administered to the farmers in the district using the stratified random sampling technique. This technique was employed to group the population of the farmers from the 5 local municipalities in the district into strata. Thereafter, random sampling was used to select from each stratum. A specific number of the sample size was selected from each stratum as shown in *Table 1*.

Table 1. *Data collection according to the selected local municipalities. (Source: author's computation, 2017)*

Stratum (local municipalities in the district)	The population of small scale maize farmers	Selected sample size
Tswaing	200	132
Ditsobotla	150	109
Mahikeng	100	80
Ratlou	15	15
Ramotshere Moiloa	10	10

The questionnaires consisted of a logical flow of questions related to household socio-economic characteristics (demography), climate change adaptation information. The questionnaires were explained to the local extension officers before the survey because they understood the farmers better and could translate the questions into the local language. Face to face interviews and focus group discussions were conducted in each local municipality where each session lasted for about 45 min.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1126111272

The data were captured and analyzed using EVIEWS software. Multicollinearity analysis was employed to remove variables that are correlated to each other from the wide list of variables obtained from the questionnaires as shown in *Table 2*. A Tobit regression model was used to identify the factors that determine adaptation to climate change in the study area.

Table 2. *Multicollinearity analysis. (Source: author's computation, 2017)*

Variables	Collinearity statistics	
	Tolerance	**VIF**
Number of years of farming	0.578	1.731

Channel of information received on climate change	0.658	1.519
Support received on climate change	0.617	1.620
Adaptation barrier	0.685	1.460
Mean VIF		1.422

The Tobit model, also called a censored regression model, was employed to estimate linear relationships among variables when there is either left or right-censoring in the dependent variable as shown in the equation below. In other words, the factors influencing climate change adaptation in the study area were estimated using Tobit regression analysis. The model was developed by Tobin (1958). Following Schwarze (2004), since the dependent variable is bounded between 0 and 1 (i.e., the variables are censored at 0.0 and 1.0), conventional regression methods fail to consider the qualitative difference between zero and continuous observations. However, the Tobit model could combine the properties of multiple regression and Probit/Logit model. Therefore, the Tobit model which was initially established for censored data was applied for the analysis. The model is specified as:

$$Y_i = \beta Xiifi^* = \beta Xi + ui > Ti \quad \text{(Eq.4)}$$

$$Y_i = \beta 0 + \beta iXi + ui \quad \text{(Eq.5)}$$

where: uí = normally distributed with zero mean and constant variance; X_i = vector of explanatory variables; βi = vector of the parameter estimates.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1126111272

The model is fully estimated as follows:

$$yi^* = \beta 0 + \beta 1xi + \varepsilon i = xi'\beta + \varepsilon i,\ \varepsilon i \sim N(0,\sigma 2) \quad \text{(Eq.6)}$$

$$\text{If } yi^* > 0 => yi = \text{climate change} = yi^* = xi'\beta + \varepsilon i \quad \text{(Eq.7)}$$

$$\text{If } yi^* \leq 0 => yi = 0 (y^* \text{ can be negative, but if it is, } y = 0) \quad \text{(Eq.8)}$$

$$\text{Probability Model } --\varepsilon i \sim N(0, \sigma 2) \quad \text{(Eq.9)}$$

$$\text{Prob}(y = 0|x) = \text{Prob}(y^* \leq 0|x) = \text{Prob}\ [(y^* - X\beta)/\sigma \leq (0 - X\beta)/\sigma|x] \quad \text{(Eq.10)}$$

$$\text{Prob}[z \leq - X\beta/\sigma|x] = \Phi(-X\beta/\sigma) = 1 - \Phi(X\beta/\sigma) \quad \text{(Eq.11)}$$

$$\text{Prob}(y > 0|x) = \text{Prob}(y^* > 0|x) = 1 - \Phi(-X\beta/\sigma) = \Phi(X\beta/\sigma) \quad \text{(Eq.12)}$$

Yi = Climate change adaptation strategies index determined by dividing the number of climate change adaptation strategies used by the individual farmers by all the climate change adaptation strategies available in the study area. Thus, the value of the climate change adaptation strategies index ranges between zero (0) and one (1). Thus, the explanatory variables used in the analysis include the socioeconomic variable of the household head and information pertaining to climate change and its adaptation, which are:

X_1 = Number of years of farming (years)
X_2 = Farm size (hectares)
X_3 = Household size (number of persons in the household)
X_4 = Gender of household head (Male = 1; Female = 0)
X_5 = Age of household head (years)
X_6 = Marital status
X_7 = Household head educational level
X_8 = Household head source of income
X_9 = Type of farm
X_{10} = Who manages the farm
X_{11} = Who owns the farm
X_{12} = Land acquisition
X_{13} = Climate change awareness
X_{14} = Information receive on climate change
X_{15} = Source of climate change information
X_{16} = Climate change information through extension services
X_{17} = Channel of information on climate change
X_{18} = Support received on climate change
X_{19} = Climate change adaptation
X_{20} = Adaptation barrier

Results and discussion

The household farm size in *Table 3* was statistically significant ($p < 0.01$) and had a negative association. This suggests that the size of the farm had an influence on climate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1126111272

change adaptation in the study area. Farmers with small farm size tend to ignore adaptation measures as a result low resources, however, farmers with large farm size are likely to have more capacity to try out various adaptation strategies and invest in climate risk coping strategies. This could also mean that farmers reduced their farm size in other to adapt to climate change as they have little resources to cope. The larger the farm size the more the adaptation strategies of changing crop cultivars and crop types. This result is supported by Abid et al. (2015), who reported that farmers with large farm size try more adaptation options. On the contrary, Mohammed et al. (2014) reported a negative result where a large farm size requires greater levels of investment to implement adaptive strategies to climate change. The same result was explained by Acquah and Onumah (2011) that farm size was negatively significant to climate change adaptation and its effects (*Fig. 2*).

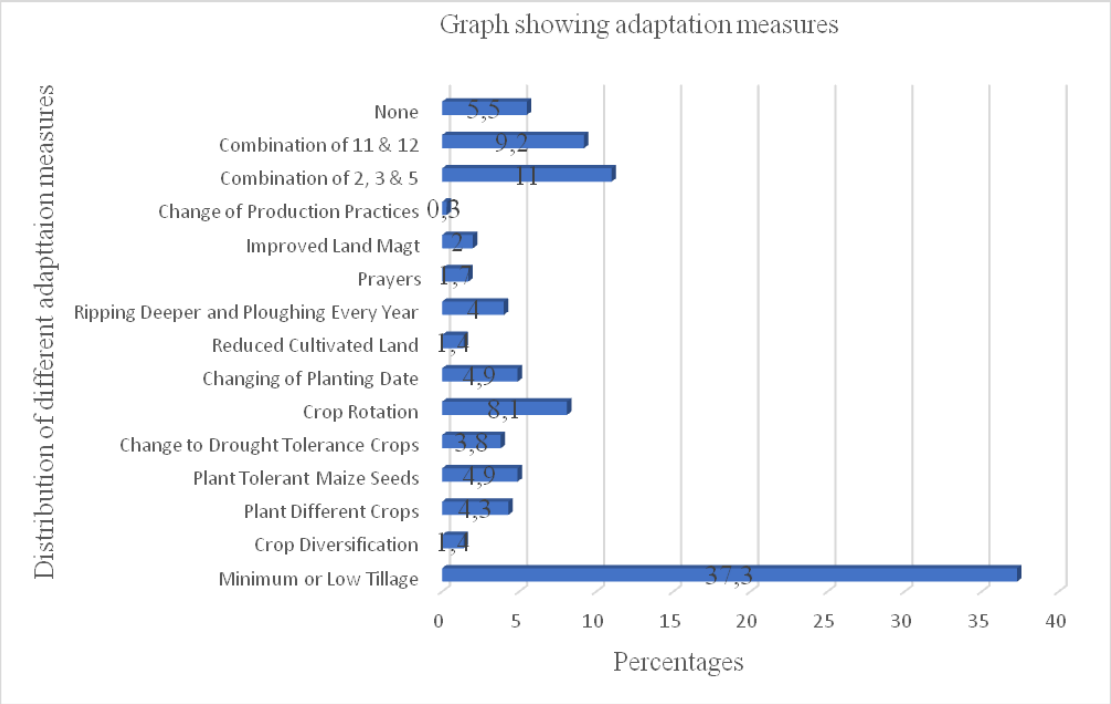

Figure 2. *Distribution of different adaptation measures in the study area*

According to *Table 3,* gender was statistically significant ($p < 0.01$) and influenced climate change adaptation. Various research has revealed that gender is an important factor affecting adoption decision among farmers. The result from the study area revealed that male farmers (84.1%) are more involved in farming and thus, adapting to climate change than women. Male farmers are more likely to perceive a change in the climatic condition unlike female farmer because male-headed households have a higher probability of acquiring information than female-headed households. This finding is supported by Ncube et al. (2016) who reported that male-headed households were more likely to perceive changes in the surrounding than female-headed households. However, Sharaunga et al. (2015) reported that empowering women in smallholder agriculture is very crucial in reducing vulnerability to climate change among rural households.

In *Table 3*, the type of farm a household head engage in has an influence on climate change adaptation. The type of farm in this regard includes individual farm, family

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1126111272

farm, community and tribal farm which was statistically significant ($p < 0.05$) to climate change adaptation. This suggests that individual farms adopt natural resources management and conservation practices better compare to tribal or community farm type as individual can manage information based on his or her household resources and needs.

In the same train of thought, *Table 3* revealed that an individual who owns the farm was statistically significant ($p < 0.05$) and influence climate change adaptation strategies. This result implied that the knowledge and experience of the farm owner determine the adoption of natural resources management and conservation practices to use. Research by Habtemariam et al. (2016) reported that educated and experienced farmers are expected to have more knowledge and information about climate change

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1126111272

and adaptation measures to use in response to climate challenges. Theis et al. (2018) reported that land ownership individually managed, is widely believed to encourage the adoption of technologies linked to physical assets such as land and irrigation system.

The land is a fundamental factor of production. The method of acquiring land or farm by the farmers was statistically significant ($p < 0.01$) and influence climate change adaptation in the study area as shown in *Table 3.* Various methods of land acquisition as identified in the study area include; land redistribution for agricultural development (LRAD), PLAS, land affair, hire, inheritance, own finance. This result implies that adaptation strategies are linked to land acquisition method. Farmers who buy land hire or through land affair tend to adopt adaptation strategies more as they need to produce much in other to pay and make a profit to sustain a livelihood.

The sources of information received on climate change influence adaptation strategies. In *Table 3,* the information source was statistically significant ($p < 0.01$) where the majority of the respondents in the study area obtained information through media (radio). The source of information influence climate change adaptation because the information from non-reputable source might not be the right information needed to adapt in other to transform or increase food production, and different information target different environment and farming systems. In addition, the source from which information is being received determines the effectiveness and farmers' adoption. According to Akinnagbe et al. (2015), it was reported that crop farmers got their information from sources which may not be unconnected with their level of interaction in the communities. Farmers need information in which extension officers play a significant role (Gabriel et al., 2013).

According to *Table 3,* the support received by the farmers was statistically significant ($p < 0.1$). The support received includes; formal credit, insurance, farmer to farmer extension, relatives, subsidies. Adaptation to climate change becomes easier when farmers receive support on climate change. The inability of the farmers to get the necessary support and resources might hinder the farmers from adapting to climate change. According to UNDP (2018), it was emphasized that most farmers in Africa are operating under resource limitation which prevents adaptation measures. Derr (2018) reported that institutional support for climate change adaptation is needed for rural farmers in order to adapt to climate change scenario and events.

In *Table 3,* the adaptation barrier was statistically significant ($p < 0.01$) and influence climate change adaptation in the study area. Barriers to adaptation restrict people's ability to address the negative impacts of climate change. Examples of adaptation barrier in the study area are lack of knowledge and education, lack of structural and infrastructural resources, lack of capital resources and extension officers. Adaptation barriers prevent farmers from adopting various strategies and practices to cope with the impact of climate change variability and events. Farmers need resources and information to be able to adapt without which farm productivity is affected. This result was supported by Brown and Sonwa (2015), who reported that in agricultural communities, lack of financial capital is one barrier to adaptation, such as the adoption of improved crop varieties and diversification of livelihoods.

Conclusion and recommendation

The study reveals that climate change poses several challenges to the livelihoods of rural households in the study area. It also provides a comprehensive understanding of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1126111272

the factors that hinders adaptation to climate change in the study area, which includes; farm size, household gender, type of farms, who owns the farm, land acquisition, source of climate change information, support received on climate change, and adaptation barrier. This study highlights that fostering climate change adaptation does not only entails scientific knowledge especially in the study area (SSA) but also community involvement and development of solutions using local approach and socio-economic characteristics of the rural household. The recommendation drawn from this study is that in attempting to support households' adaptation strategies to climate change, and develop sustainable strategies that will be culturally accepted by rural households and communities, considerable attention should be paid to understanding socio-economic factors such as farm size, household gender, type of farms, who owns the farm, land acquisition, and also information on climate change.

Abstract. Among abiotic stresses, high temperature is an obstructive factor in plant growth and physiological activities for sustainable agriculture, worldwide. Chitosan is a bio-based stimulant and may be helpful in reducing adversative effects of temperature stress. A field experiment was conducted to investigate the role of chitosan as high temperature stress regulator in two eggplant genotypes (Black boy and Sandhya) under arid environment. Temperature stress was maintained by delayed planting of eggplant as compared to its optimum planting time. Results showed that foliar application of chitosan has significantly improved the eggplant growth and yield characteristics. The effect of chitosan was more prominent on the genotype Black boy over Sandhya and recovery of plants improved with the increase in its application rate. The maximum yield was obtained in Black boy that was 42% higher to control and 14% to Sandhya at chitosan application of 175 mg L^{-1}. Application of chitosan also improved the proline content, glycinebetain, total soluble solids and total phenolics accumulation. The late season high temperature stress significantly reduced the linear electron flow and non-photochemical quenching but the application of chitosan significantly improved both these characters. The positive effect of chitosan on plant physiochemical traits was more promising on genotype Black boy over Sandhya. These findings showed that the chitosan can be used as an ecofriendly compound to enhance plants activities under stress conditions.

Introduction

Climate change is expected to continue increasing and poses regionally differing threats to agriculture in this World. South Asia is snowballing in the last few decades and the situation is further becoming severe in global warming scenario (IPCC, 2014). The high concentration of population in this region generally reliance on natural resources and agriculture along the coastal areas to derive their economy and development for their livelihood. Currently, declining soil productivity and extreme weather conditions; rising temperature, salinity, drought as well as deforestation have had sever affects posing a threat to throw the countries back into the poverty trap. The efforts regarding adjustment and mitigation of the source climate change such as green-house gas emissions by burning of fossils fuels, as well as deforestation and urbanization, are needed to combat this issue (Churkina, 2016; Mgbemene et al., 2016; Myers et al., 2017). Agriculture and food security is a fundamental human activity at risk by this global warming. The rising temperature is the key factor controlling the cropping patterns and water availability in coming decades (Rasul, 2016; Teixeira et al., 2013).

Temperature is the primary determinant of crop production, particularly in arid areas (Ihsan et al., 2016). Temperature controls the rate of plant metabolic processes that is ultimate source of biomass, phytonutrients, fruit development and yield of plant. The photosynthetic rates peak at about 30 °C and decreases thereafter 17% for each degree Centigrade in average (Ali et al., 2011; Lobell and Asner, 2003). High temperature affects plant physiology at both cellular and whole plant through stomatal conductance and osmotic pressure. High temperature stress reduces plant growth and development through excessive evapotranspiration effects, may lead to nutritional imbalance such as sulphur, specific ion effects as well as low turgor potential of plant (Ihsan et al., 2016). The adding effect of each of these factors can affect plant processes like lipid peroxidation, photosynthesis, energy and protein formation.

The high temperature in addition with drought spells encourage more `harmful impact on growth parameters such as plant height, the number of leaves per plant, shoot dry weight, shoot length, root length, flower induction, and ultimately the yield attributes (Ainsworth and Ort, 2010; Jiao et al., 2012; Shehata et al., 2012).

Eggplant (*Solanum melongena* L.) is a well-known vegetable, widely cultivated in central, south Asia and some African countries (Hazra et al., 2003; Ranil et al., 2017). The ideal temperature for plant growth and fruit development lies between 22ºC and 30 °C. With an unnatural weather change, temperature in south Asia is often over 35 °C, which is not suitable for growth, flower bud formation, and may cause pollen infertility (Pandit et al., 2010). Such damage is estimated to the reduced harvest and subsequently low yield. Currently, attempts to measure the potential benefits of climate mitigation actions on the agricultural sector, which have been put forward, such as heat-tolerant varieties, improving irrigation systems and certain cultivation measures. However, the use of bio-stimulants, such as chitosan or chitin could be one of the approaches to cope with the negative impact of abiotic stress such as high temperature and heat stress.

Chitosan (CTS) are polysaccharides, a derivative of chitin, obtained from the waste products of sea food is one of the most preferred biopolymers, harmless to plants, animals and, since the last decade, chitosan uses are increasing due to its non-toxicity, biodegradability, biocompatibility, and stimulant to cell activation and plant growth (Elieh-Ali-Komi and Hamblin, 2016). Previous studies reported chitosan use in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1127311287

agriculture to manage abiotic stresses and to improve crop production and quality (Katiyar et al., 2015; Sharif et al., 2018).

Chitosan prevents adverse effects of the abiotic stresses in plants through regulating different mechanisms. Application of chitosan boosted photosynthesis that elicited the scavenging of reactive oxygen species under stress conditions. Chitosan involved in protecting plants from high temperature stress and photo-damage through production of heat shock proteins (Chandra et al., 2015; Landi et al., 2017). The first protein complex (PSII) is more sensitive than PSI (Allakhverdiev et al., 2008; De Ronde et al., 2004; Sonoike, 2011). High temperature stress above 40 °C inhibit PSII activity through denaturation of this protein complex and inhibiting of enzymes activity (Kehoe, 2010; Walters, 2005). The other mechanism damaged through high temperature stress in plants is the thylakoid proton conductance (Baker et al., 2007; Rochaix, 2011). In some plants these mechanisms are more chilling sensitive than high temperature stress (Sonoike, 2011).

The positive role of chitosan in various stresses management is well documented in different crops. Its role in high temperature stress management in eggplant (*Solanum melongena* L.*)* has been never studied and reported. Considering chitosan positive response in different stresses management in agriculture crops, the present study is designed to evaluate its role in PSII regulation and osmoprotectant (proline, soluble carbohydrates, and glycinebetaine) performance under high temperature stress in eggplant (*S. melongena* L.) genotypes. Moreover, the effect of chitosan will be studied on crop agronomic and fruit generative characters.

Material and methods

Experimental site and soil preparation

The field experiment was conducted in the research area of 'The Islamia University of Bahawalpur (29.35˚N, 71.69˚E)., near cholistan desert, Pakistan (*Fig. 1*). The climate of the experimental location is arid with sever hot summer and cool dry winter (*Table 1*). The experimental plots were prepared by deep ploughing, after the harvest of Maize crop. The eggplant (*Solanum melongena*) seedlings were obtained from a vegetable crops nursery near Lahore, Punjab and transplanted on 27th March 2017. In this experiment, a randomized complete block design was used with three replications. The experimental bed size was 1.5 m × 0.6 m, with plant density 7.12 plants m^{-2}. The plantation was made on the both sides of the beds. Plant to plant distance was maintained at 45 cm while row to row distance was maintained at 30 cm apart. The non-experimental area of approximately 1 meter (0.92 m) left fallowed between two blocks.

Treatments application

Two eggplant genotypes (Black boy and Sandhya) were tested against chitosan application for heat stress mitigation on somatic and generative characters. Chitosan was applied at five different levels. Chitosan levels were comprised of T0: 0 mg L^{-1}, T1: 125 mg L^{-1}, T2: 150 mg L^{-1}, T3: 175 mg L^{-1} and T4: 200 mg L^{-1} respectively (*Table 2*). Chitosan application was based into different phases, depending on plant vegetative and developmental stage. The heat stress was maintained by late planting in March that initiated flowering in the hot months of June and July.

Observation in each column are based on monthly data means

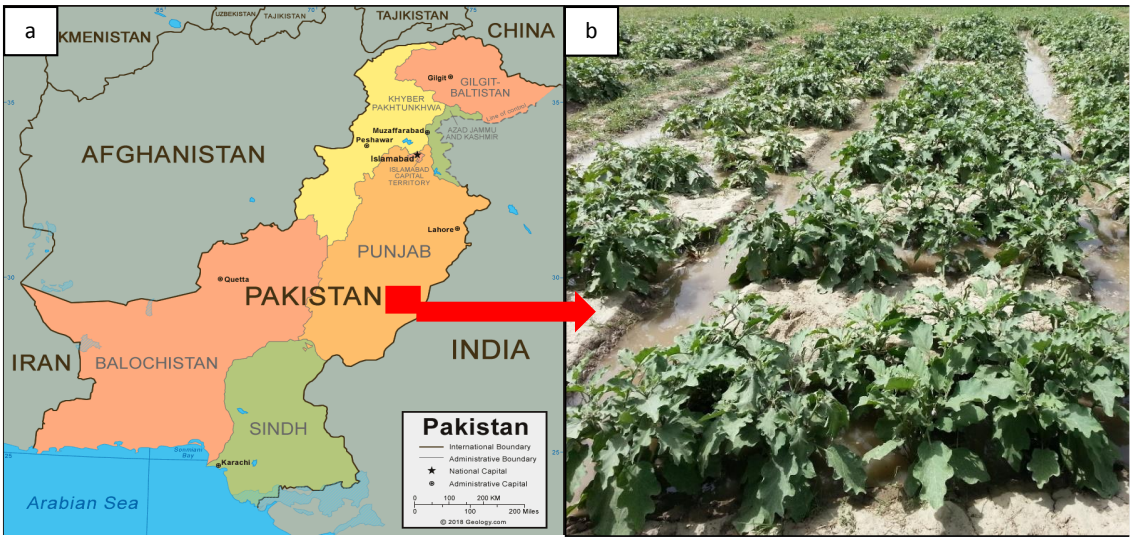

Figure 1. *Location of the experimental region (a = a map of the experimental region, b = a photo of the experimental block)*

Table 2. *Details of different chitosan treatments used in experiment of eggplant (Solanum melongena L.) genotypes under heat and high irradiance*

Parameters		Uses
Treatment	T0	Control (0 mg L^{-1})
	T1	125 mg L^{-1}
	T2	150 mg L^{-1}
	T3	175 mg L^{-1}
	T4	200 mg L^{-1}
Variety	V1	Black boy
	V2	Sandhya

The chitosan was added as fumigant. The growing season was grouped into five phases, and the application of chitosan was based on the requirement and growth of the crop stage

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1127311287

Data collection/sampling

The Data recording was made randomly, 5 plants from each bed, 15 plants from each block and 30 plants from each treatment. The measurements were made for number of leaves, shoot fresh weight, root fresh weight, no of flowers per plant, no of fruits per plant, shoot/root ratio and pant biomass. Chemical analysis of leaf for antioxidant enzymes, i.e., proline, glycinebetaine and total phenolics were also performed at full maturity stage. Measurements were also made for net photosynthesis, linear electron flow and Non-photochemical quenching when plants produced first fruit. Five plants for each treatment were up-rooted and washed to remove debris and soil particles. Shoot length; from hypocotyl to the tip of the shoot was measure in centimeters. Similarly, the root length was calculated from base of hypocotyl to the tip of root. Root/shoot fresh and dry weight and fruit weight were measured in grams with the help of electrical balance. Number of leaves, shoots, flowers and fruits were counted manually at maturity stage. Flower drop were measured by subtracting total number of fruits from total number of flowers.

For the extraction of total soluble sugars, lyophilized leaf samples, 0.05 g was extracted in 5 mL solvent of 80% ethanol for 24 h according to prescribed method of Schortemeyer et al. (1997). Absorbance was measured at 623 nm using a Cary 50 Bio spectrophotometer (Varian, Australia). The total phenolic contents were measured according to the Folin–Ciocalteau method modified to Dewanto et al. (2002). Absorbance was measured at 765 nm using a Cary 50 Bio spectrophotometer (Varian, Australia). Quantification was carried out by comparison against the external standard gallic acid, 3,4,5-trihydroxybenzoic acid (Sigma–Aldrich, Germany). The amount of glycinebetaine was estimated according to the method of Grieve and Grattan (1983). The absorbance for glycinebetaine (GB) was measured at 365 nm using a Varian Cary 50 spectrophotometer (Agilent Technologies Inc., USA). Proline was extracted according to the method of Bates et al. (1973), with some modifications. The absorbance was noted at 520 nm using a double beam spectrophotometer (Hitachi-120, Japan). Proline concentration was determined from a standard curve and calculated on dry weight basis.

To determine whether the tested eggplant (*S. melongena* L) plants are involved in photoinhibition and repair processes, PSII activity was measured. The dissipation of excess light energy as heat was monitored by measuring the development of NPQt. Photosynthesis and energy dissipation was measured on field-grown plants using a PhotosynQ, portable photosynthesis system (Kuhlgert et al., 2016).

Statistics

Five replicate samples were used for each factor. Data for the level of chitosan was evaluated by analysis of variance (ANOVA) followed by Tukey's studentized range test (HSD) ($P < 0.05$) using SPSS version 18.0 (SPSS Inc., Chicago, II., USA). The level of chitosan was taken as independent factor while physiological and biochemical indices as dependent factor. Descriptive analysis (SPSS Inc., Chicago, II., USA were made to reveal the differences between data. Differences were considered to be significant at $p < 0.05$.

DOI: http://dx.doi.org/10.15666/aeer/1705_1127311287

Results

Foliar application of chitosan significantly improved the eggplant growth and yield characteristics except for number of leaves plant^{-1} and number of flowers per plant^{-1}; however, the improvement was dependent on the chitosan dose and the eggplant genotype. Generally, the increase in chitosan level increased the growth and yield of both genotypes (*Tables 3* and *4*). However, the varietal response was variable for different growth parameters to different applied levels of chitosan. The effect of chitosan was significant for, plant height, number of shoots plant^{-1}, root length, root fresh weight and root dry weight for Black boy and plant height, number of shoots plant^{-1}, root length and root dry weight (*Table 5*). Similarly, the effect of chitosan was significant for number of fruits plant^{-1}, weight of each fruit and yield plant^{-1} for Black boy. While the number of fruits per plant^{-1}, flower drop plant^{-1}, weight of each fruit, yield plant^{-1} and flower drop percentage for Sandhya genotype (*Table 6*).

The response of genotypes for above mentioned traits was maximum at 150 mg L^{-1} to 175 mg L^{-1} for most of the traits except for fresh weight of root (125 g) and flower drop % (62%) in Sandhya that was the highest at low concentration (125 mg L^{-1}) of chitosan. During the developmental stages, maximum plant height was recorded with chitosan dose of 175 mg L^{-1} in both of the genotypes; 73.99 cm in Black boy and 64.70

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1127311287

cm in Sandhya (*Table 5*). The maximum number of shoots plant^{-1} was recorded in Sandhya that was 21% higher to control and 3% to Black boy. The root length was significantly varied under chitosan treatments compared to control ($P < 0.05$). The maximum root length was noticed when treated with chitosan at 175 mg L^{-1} in both genotypes of eggplant. The root length was ranged between 17-23 cm in genotype Black boy and 16-22 cm in genotype Sandhya. The mean shoot dry weight was increased up to 22% in Sandhya and 15% in Black boy over control with the increase in chitosan dose from 150 mg L^{-1} to 175 mg L^{-1} respectively.

Both genotypes attained almost similar amount of root fresh weight at medium dose of chitosan and that was only 7% higher to control. The effect of chitosan was non-significant for genotype Sandhya root fresh weight. The maximum root dry matter (26.87 g) was recorded in Black boy that was slightly higher than Sandhya at chitosan dose of 175 mg L^{-1} while Sandhya attained almost similar amount of root dry weight at chitosan dose of 150 mg L^{-1} (*Table 5*).

Chitosan have non-significant influence on number of flowers induced in both genotypes. The values were ranged between 61.38 to 67.88 in Black boy and 61.75 to 65.75 in Sandhya genotype (*Table 4*). At low dose of chitosan, the flower drop was maximum for Sandhya. Genotypes varied significantly in terms of fruit number. A

higher number of fruits were noted in genotype Black boy (36.75) as compared to Sandhya. Exogenous application of chitosan has also a significant influence on yield of eggplant genotypes. The maximum yield was attained at 175 mg L^{-1} in Black boy that was 42% higher to control and 14% to Sandhya at the same level of chitosan. This higher yield was due to a low flower drop and higher fruit setting at 175-200 mg L^{-1} chitosan application.

The effect of chitosan foliar application was also studied on plant physiological characters (*Fig. 2*). The proline content of both the genotypes increased significantly by increasing the chitosan application. There was synergistic stimulation with increased

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1127311287

levels of chitosan. Proline concentration in eggplant leaves were ranged between 8.12 and 10.11 umol/ml DW in Black boy and 8.30 to 9.48 umol/ml DW in Sandhya genotype. However, the highest increase was observed at chitosan concentration of 175 mg L^{-1} in both genotypes. Similarly, the maximum concentration of glycinebetain (8.53 ug/ml DW) was noticed in Black boy at the chitosan rate of 175 mg L^{-1} and that was 45% higher than control. The effect of chitosan application was also prominent on total soluble solids and total phenolics accumulation. As reported in other growth and yield traits, the highest dose of chitosan failed to produce the maximum accumulation of total soluble solids and total phenolics in both genotypes. The total phenolics in Black boy that was maximum (124 mg/g DW) at 175 mg L^{-1} of chitosan. Again, the satisfactory results were obtained at medium dose of chitosan that produced 31% higher total soluble solids and 18% higher total phenolics in Black boy and 33-16% in Sandhya.

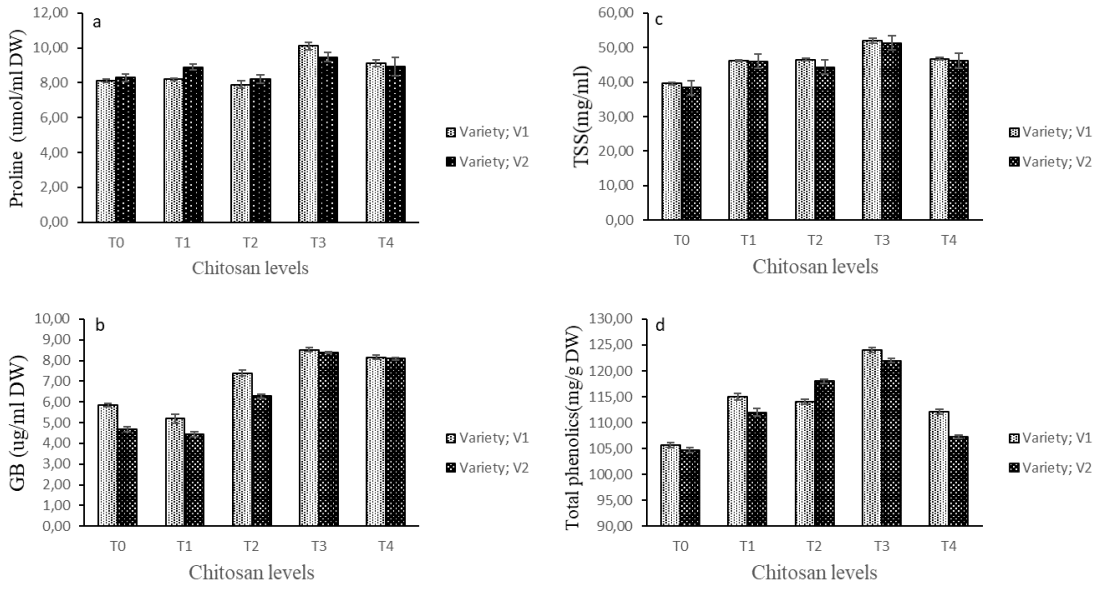

Figure 2. *Mean values for Proline (umol/ml DW ± SD), Glycinebetaine (ug//ml DW ± SD), Total soluble solids (mg/ml DW ± SD and Total phenolics (mg/g DW ± SD) of eggplant (Solanum melongena L.) genotypes subjected to different level of Chitosan (T0, T1, T2, T3, T4) under heat and high irradiance. Treatment (T) 0: control; T1: 125 mg L^{-1}; T2: 150 mg L^{-1}; T3: 175 mg L^{-1}; T4: 200 mg L^{-1}*

The linear electron flow (LEF) was measured from the matured leaves of both varieties. Constant value of LEF was noticed in Black boy for all chitosan treatments except for control that produced the significant lower value for LEF. On contrary, the LEF gradually increased with the increase in chitosan dose in Sandhya genotype (*Fig. 3*). In addition, the non-photochemical quenching (NPQt) was monitored to evaluate the excess heat energy dissipation during high irradiance. The high temperature stress induced more severe NPQt in both genotypes' seedlings. The NPQt was directly influenced to the level of the high temperature and heat stress. Genotype Black boy produced higher NPQt (0.65) as compared the Sandhya that produced slightly lower value for NPQt (0.64). The quantum yield of photosystem II (PSII) has also measured to estimate the efficiency of photosystem II under high temperature stress.

Exogenous chitosan application improved chlorophyll contents in both genotypes. The values were varied between 51.05 and 60.73 (SPAD) in Black boy and 54.75 and 60.83 (SPAD) in Sandhya during late planting high temperature stress. It was the lowest in control, gradually increased with the increase in chitosan dose level up to 175 mg L^{-1} and after that negatively responded to any increase in chitosan dose (*Fig. 3*).

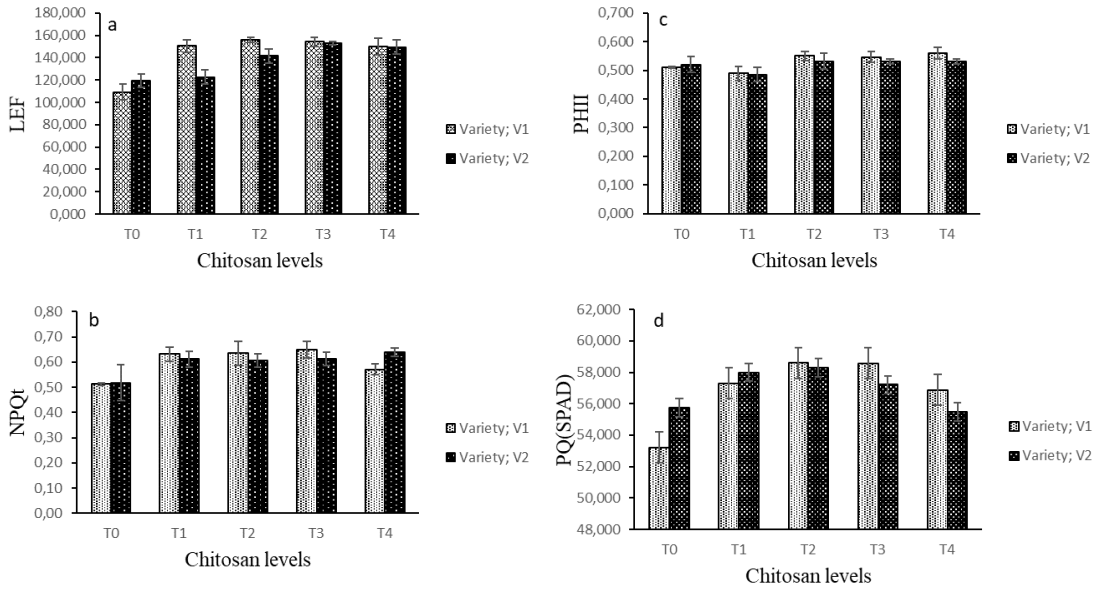

Figure 3. *Mean values (± SD) for Photosystem II, Linear electron flow, Non-photochemical quenching and PQ-spade of eggplant (Solanum melongena L.) genotypes subjected to different level of Chitosan (T0, T1, T2, T3, T4) under heat and high irradiance. Treatment (T) 0: control; T1: 125 mg L^{-1}; T2: 150 mg L^{-1}; T3: 175 mg L^{-1}; T4: 200 mg L^{-1}*

Discussion

Chitosan regulated plant growth, yield and physiological traits studied under high temperature stress. The mechanism of high temperature stress regulation is not still clearly established but however, chitosan application at different growth stages of the plants under stress stimulated the plant growth that has helped plant to withstand the adverse effects of the stress (Katiyar, 2015). The inactivation of enzymes involved in different processes of photosynthesis and the carbon flux are the major effects of high temperature stress.

Similarly, the photo inhibition was due to high light intensity, might be the other reason of plant growth inhibition (Guidi et al., 2019). Chitosan also has stimulated the activity of sucrose hydrolyzing enzymes in seedlings under stressful environment. The additive role of chitosan application has been found to synthesize plant hormones such as auxin and gibberellins by stimulating a signal related to biosynthesis and may help plant to maintain its growth and development under high temperature stress. Some studies have reported its involvement in protecting cell membrane from deterioration under abiotic stresses.

Chitosan application produced the highest shoot dry weight at a concentration of 0.01%. A number of researchers reported similar results related to plant growth and yield improvement with the application of chitosan (Amiri et al., 2015; Safikhan et al., 2018). In this experiment, high temperature stress caused stunted eggplant growth, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1127311287

this might be due to the low availability of nutrients and poor functioning of nutrient uptake mechanism due to impaired photosynthesis. Application of Chitosan improved photosynthesis through increasing leaf chlorophyll content that might has stabilized the cell membrane, detoxify the deleterious effects of antioxidant's, and helped in cell elongation and multiplication (Malerba and Cerana, 2016; Salachna and Zawadzińska, 2014). The improvement in these mechanisms ultimately resulted in significant yield improvement under high temperature stress.

It is concluded that foliar application of chitosan at vegetative stages enhance the plant growth and development (number of leaves, shoots length, pedicel length, plant height) which helped plants to secure fruiting and fruit yield in eggplant.

The physiological and biochemical responses of chitosan has been found to act as stimulator which ultimately encode a gene expression, and thereby plants treated with chitosan may be less prone to stress evoked unfavorable conditions such as high and low temperatures, drought as well as salinity (Zhao et al., 2008). Under high temperature stress, proline content, glycinebetain, total soluble sugars and total phenolics contents in leaves of eggplant genotypes decreased significantly. The application of chitosan improved the total phenolics level in both genotypes. The results are in agreement with previously investigations that reported positive role of chitosan in cell membrane permeability, concentration of soluble sugars and proline (Guan et al., 2009).

Accumulation of total free sugars and phenolic contents serves as adaptive mechanism in plants under high temperature stress. In the same manner osmolytes protect the cell membrane against adverse effects of heat stress. Accumulation of ions such as proline improves the membrane stability in plants and these ions uptake improve with the application of chitosan. Chitosan regulates stomatal closure, ion uptake and transpiration. Moreover, chitosan plays prolific role in many morphological and physiological functions of the plants (Safikhan, 2018).

Exogenous application of chitosan increased eggplant height through improvement in leaf chlorophyll content and number of leaves per plant. The growth stimulatory effects of chitosan on vegetative parts of plants especially number of leaves per plant, plant height and leaf chlorophyll content has previously reported in cucumber (Katiyar et al., 2015; Shehata et al., 2012) and safflower (Amiri et al., 2015). Chitosan foliar spray also helped to control insect pest attack, plant and fruit diseases. Chitosan is a natural, inert and cheap molecule that regulates different biological responses in plants depending upon its concentration, plant species and developmental stage.

We can measure the performance of a plant by its amount of chlorophyll content under stress condition. Chitosan application significantly increased chlorophyll content of both genotypes of eggplant. Foliar application of chitosan increased chlorophyll content of soybean (18%) and peanut (23%) (Dzung, 2005). Plants loss their chlorophyll content as a photo protection mechanism to reduce light absorbance at high temperature stress either by slow synthesis or fast breakdown of chlorophyll contents (Elsheery and Cao, 2008; Wise et al., 2004). Both eggplant genotypes showed positive response to applied chitosan spray through stabilizing the chlorophyll content and maintaining the photosynthetic rate (PSII). Involvement of chitosan has confirmed in modulating the activity of dimers and monomers during the protein synthesis (Sharif et al., 2018).

The NPQT of chlorophyll fluorescence is associated with a decrease in the rate of photosystem II. The NPQT measures the active percentage of PSII reaction center that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1127311287

is capable of photochemistry and changes in PSII (Guidi et al., 2019; Malerba and Cerana, 2016). Similar changes were also noticed in this study where NPQT was slightly increased or stabilized with increased level of chitosan however, this moderate increase was statistically not significant. Consequently, the decreased demand for product of electron transport that was used for assimilation resulted in heat dissipation of light energy.

Previously, it was reported that the abiotic stress may lead to a decrease in the photochemical efficiency and electron transport activity due to the changes in the structure of the photosynthetic apparatus (Guidi, 2019; Mittal, 2012). The results in this study suggest that chitosan can modulate moderately the flow of intercellular ion transport and enhances the activity of antioxidants enzymes which helps in preventing the membrane damage in the granal and stromal thylakoids under stress conditions (Malerba and Cerana, 2016; Salachna and Zawadzińska, 2014). The results in *Figure 2a, b* regarding LEF and NPQT are in agreement with previous studies suggesting the photoinhibition through changes in protective high-energy-state by increase in NPQT (Guidi et al., 2019). Additionally, repair mechanisms such as excision repair, photoreactivation, quenching and free radical scavenging could be activated to prevent and slow down the damage caused by long exposure to high temperature stress by chitosan application (Choi et al., 2013; Zhang et al., 2008).

Conclusion

The exogenous application of chitosan has significant influence on the physiological and biochemical attributes of eggplant genotypes. Major changes were noticed in parameters affecting growth and development such as, flower induction, flower drop, fruits plant^{-1}, weight of each fruit and yield plant^{-1}. The effect was more prominent on Black boy over Sandhya cultivar. The thermostability of reaction center of PSII was also noticed, may possibly due to of less ROS accumulation, an aiding influence due to increased level of chitosan application. The chitosan application especially with concentration 175 mg L^{-1} improved the plant growth and development, increased the content of proline, glycinebetain, total soluble solids and total phenolics. The chitosan has moderated the influence of high temperature and heat stress by accelerating the antioxidant enzymes activities. The yield of the eggplant was positively changed to the level of chitosan application. The increased level of chitosan produced more yield under high temperature and heat stress. It can be concluded that chitosan may be used as an eco-friendly compound to protect and to enhance growth, development and other biochemical parameters under high temperature and heat stress.

Abstract. The purpose of this study was to analyze the effect of biological nitrification inhibitor MHPP on nitrogen fixation and emission reduction for straw and dairy manure composting. During the period from May to September in China, the engineering large-scale composting was performed with dark box sampling was conducted to take composting gas sample which was studied gas chromatography. The result indicated that, in relation to the control, to which no MHPP extract solution was added, the addition of 0.2%, 0.4%, 0.6% and 0.8% MHPP extract solutions reduced the methane emission by 44.52%, 56.56%, 61.93%, 59.59%, the N_2O emission by 36.24%, 39.49%, 62.39 and 55.81%, and the NH_3 emission by 23.72%, 65.61%, 65.40% and 72.61%; after the addition of biological nitrification inhibitor, the composting process slowed down; the ammonium nitrogen content was high while the nitrate nitrogen content was low; all substances thoroughly decomposed in the end. Moreover, the final ammonium nitrogen content was higher in all cases when compared to the control. The results showed that the addition of 0.6% MHPP extract solution worked the best for nitrogen fixation and emission reduction and thus is appropriate to be used extensively in production activities.

Introduction

With the increase of grain output in China, the straw resources grew constantly to more than a billion tons; furthermore, the mushrooming of livestock and poultry feeding industry in China produced a lot of waste. Both are considered environmental difficulties of rural areas and agriculture. As one of the effective approaches of fertilization against non-point source pollution in the planting and breeding industry, high-temperature aerobic composting has aroused wide concern all over the world, and turning into a research focus in the field of eco-friendliness and environmental protection.

High-temperature composting technology that may bring about non-point source pollution is widely recognized in agriculture, but researchers argued that the emission of some harmful gases and greenhouse gases, including NH_3, CH_4 and N_2O, may cause secondary pollution to a certain extent during high-temperature composting. During composting, the degradation and nitrification and denitrification of organic nitrogen produces a certain amount of NH_3 and N_2O; the emission of N-containing gas result in a nitrogen loss that range from 16% to 76%, which not only impairs the quality of compost, but may also lead to environmental pollution (Wu et al., 2012). Moreover, ammonia is not only an important factor affecting acid rain, but is also a key component

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1128911301

of odor substances in composting plants; the Emission Standard for Odor Pollutants (GB14554-93) issued by China in 1993 announces ammonia as the primary odor pollutant. According to the IPPC report 2014, the 100a greenhouse effect produced by N_2O and CH_4 was 25 and 298 times that of CO_2, respectively (IPCC, 2014). From this perspective, the emission of ammonia and greenhouse gases during composting not only adversely reduced the land use value, but also resulted in odor pollution, acid rain, greenhouse effect and other new ecological and environmental problems; in addition, they may harm human and animal health. Hence, along with the growing sophistication of composting technology, how to reduce nitrogen loss and greenhouse gas emission during composting has become a research focus.

Adding chemical additives like peat, calcium superphosphate, ferric chloride, zeolite and clay (Yang et al., 2005) is considered one of the effective ways to emission realize nitrogen fixation and emission reduction. Liu et al. (2015) found that adding 3% bamboo acetic acid to compost materials helped to reduce greenhouse gas emission and improve compost quality. Works of Ren et al. (2008) showed that the nitrogen fixation rate reached 73.1–97% with the addition of phosphate and magnesium hydroxide, etc. during composting; Jiang et al. (2018) found that NH_3 volatilization was significantly reduced during aerobic degradation of pig manure and corn straws by adding calcium phosphate and phosphoric acid.

Through the research on generation and regulation of odor in pig manure composting, Luo et al. (2012) found that the addition of calcium phosphate during pig manure composting not only reduced the compost pH and the concentration of volatile NH_3, but also facilitated the transformation of NH_4^+-N into other forms of nitrogen, thereby improving nitrogen retention. Lin et al. (2008), Weng et al. (2012) and Ren et al. (2009) found that the addition of calcium phosphate helped to reduce NH_3 emission during composting and thus retain nitrogen. Jiang et al. (2016) found in his study that the addition of nitrification inhibitor dicyandiamide (DCD) based on the use of acidic nitrogen fixer reduced the total greenhouse gas emission by 78% and NH_3 emission by 53%. The added nitrification inhibitors (NIs) are a generic term of a class of chemical substances that inhibit nitrification reaction by inhibiting the activity of nitrifying bacteria, thereby reducing nitrogen loss. DCD is widely used in Europe and America as a NI, but it is seldom used for composting. Li et al. (2008) and Ji et al. (2011) found that DCD reduced CH_4 and N_2O emission of rice and wheat by over 20%. Luo et al. (2013) and Jiang et al. (2016) also confirmed that the addition of DCD during composting of pig manure and straws remarkably reduced N_2O emission. Chen et al. (2017) tried to use calcium superphosphate with DCD for sludge composting and achieved remarkable effect: The nitrogen losses were reduced by 13%, and the greenhouse gas emissions by 74.8%.

Although nitrification inhibitors are significantly effective in reducing N_2O emission, they are not extensively used in production due to their high cost and toxicity; hence, some researchers shifted their attention to lower-cost biological nitrification inhibitors. Zakir et al. (2008) identified the MHPP (methyl 3-(4-hydroxyphenyl) propionate) as a biological nitrification inhibitor from sorghum root exudate to inhibit nitrification in soil. Wei et al. and Zhu et al. (2015) studied the molecular mechanism of MHPP, but there are few reports on the application of MHPP in composting. In this study, MHPP was used for composting and is compared with DCD, the most commonly used nitrification inhibitor, to systematically study the effect of this new nitrogen fixation and emission reduction conditioner on the rule of nitrogen gas and greenhouse gas emission during fermentation of straws and dairy manure; its purpose is to provide a theoretical

DOI: http://dx.doi.org/10.15666/aeer/1705_1128911301

basis for the selection of nitrogen fixation and emission reduction conditioner for straw and dairy manure composting.

Materials and methods

Test materials

The wheat straws for the test were taken from the Fengyang Plantation of Anhui Science and Technology University and was smashed to 8-10 cm in size. The fresh dairy manure was taken from the cattle farm of Fucheng Town, Fengyang County, Anhui Province. The initial properties of straws and dung before the test are shown in *Table 1*. The 2nd and 4th row used for calculate C/N ratio. The calcium superphosphate was purchased from Bengbu Tianyi Biological Agents Co., Ltd., and its effective component was defined as P_2O_5 (≥ 18%); the dicyandiamide was analytically pure.

Test design

This test was performed at the plantation test field of Anhui Science and Technology University in China between May and September 2017. It was performed on a cement floor, and the composting treatment design was as follows: Fresh weight of dairy manure: straw = 1.5:1, and the treatment details are shown in *Table 2*. the MHPP leaching liquor was added once every seven days; the calcium superphosphate was added only once, and "blank" indicates no calcium superphosphate was added; refer to *Table 2* for details. 7.5 t of dairy manure and 3t of straws were prepared; the straws were smashed into 8-10 cm in size and mixed with the dairy manure with spray water to a proportion of approx. 65%; the mixture was divided evenly into five piles (4 t per pile); the temperature was raised to above 65 °C, at which manual turning was conducted with the help of weed-grasping machine every 7days. The compost temperature was determined on a daily basis (9:00 am) during composting, and samples were taken d0, d5, d10, d15, d20, d25, d30, d35, d40 and d45, respectively. The composting was ceased when the germination rate of Chinese cabbage seeds reached over 90%.

Test items and methods

Samples of greenhouse gases (CH_4, N_2O, and CO_2) were taken with static dark boxes customized from Fenglu Building Materials Store in Xuanwu District, Nanjing; the sampling case covered with aluminum foil (PVC, L × W × H = 50 cm × 50 cm × 50 cm) was placed over the pile; we measure thecircumference of the pile when we took gas sample. We calculate area by circumference. The pile is protected from disturbance and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1128911301

sealed with water; set it aside for 30 min before the sampling was started, and gas was collected with a 50 ml syringe with a three-phase valve every 10 min (3 cycles in total); the sample test was finished within 24 h; where the test was not finished within 24 h, the gas was collected with a 100 ml sampling bag. CH_4 and N_2O were analyzed with the gas chromatograph (Agilient 4890, the USA) at the same time, and the CH_4 and N_2O concentrations were determined respectively with FID (Flame Ionization Detector) and ECD (Electron Capture Detector). The ammonia sample was taken with dark box through gas collection and ventilation, and the gas was sampled with a sampling pump; 10 ml of sulfuric acid absorbent was put in the bubble sampler, where its flow rate was 1.2 L per minute; the sampling process lasted for 10 min. Determination was performed with Nessler's Reagent. Weed-grasping machine used HTZC-600 (Henan Hengtong Machinery Co., Ltd.) , sampling pump used E-Switch-MRO292-1.2L (Shanghai Shenyuan Scientific Instruments Co., Ltd.) (*Photo 1*).

Table 2. *Addition proportion of materials in each compost treatment*

Treatment	Raw materials (fresh weight)	Percentage of additives to raw materials mass/%	
		Calcium superphosphate	Nitrification inhibitor
CK	Dairy manure: Straws = 1.5:1	0%	0
T1	Dairy manure: Straws = 1.5:1	0%	1%DCD
T2	Dairy manure: Straws = 1.5:1	2%	1%DCD
T3	Dairy manure: Straws = 1.5:1	0%	1% MHPP
T4	Dairy manure: Straws = 1.5:1	2%	1% MHPP

Results

Effect of addition of MHPP addition on the variation of compost temperature

Temperature is an important indicator indicating of whether the organic matters are degraded rapidly during composting of straws and dairy manure. The treatment-specific temperature fluctuations during composting for this test are shown in *Figure 1*. In each

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1128911301

treatment cycle, the mesophilic microorganisms degraded the soluble and easily degradable organic matters in straws and dairy manure at low temperature in the initial phase of composting, where a lot of heat was released, resulting in the quick rise of compost temperature within a short time; with the decrease of available organic matters, the activity intensity of microorganisms decreased progressively, and the compost temperature dropped gradually; in this process, the compost became thoroughly decomposed.

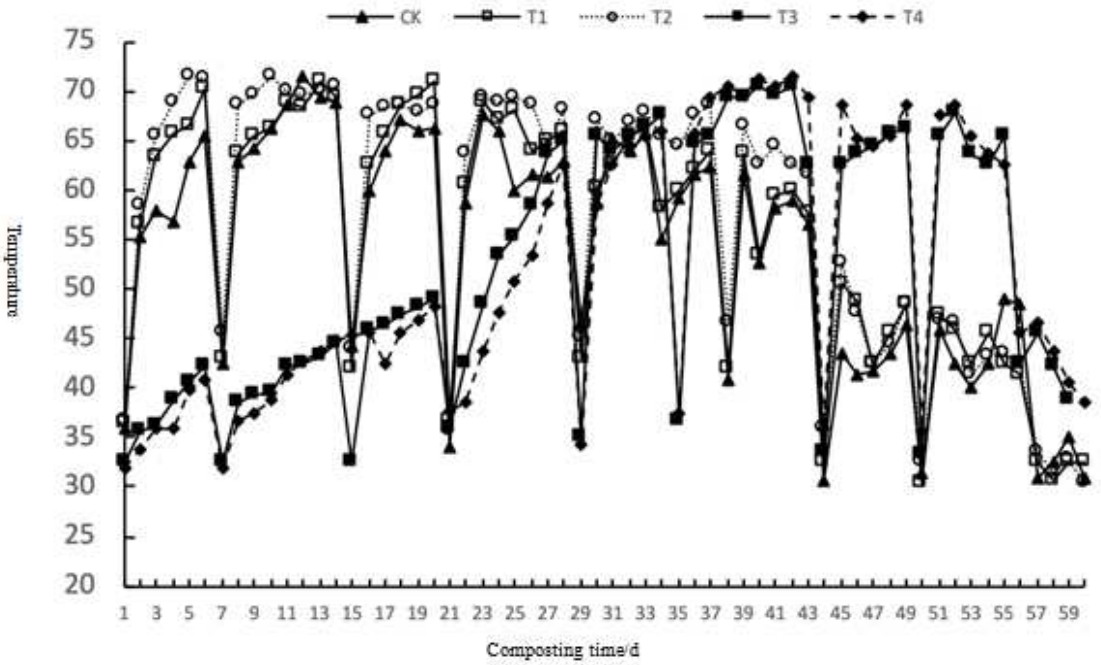

Figure 1. *Change of temperature during composting period*

Control and treatment 1 and 2 got into the high temperature period (> 50 °C) on d2 and went above 70 °C on d5; the heat-up effect was extremely obvious and higher than that of control; the high temperature lasted for approx. one month before the temperature starting to drop. The temperatures of Treatment 3 and Treatment 4 went up slowly at the beginning of composting, and reached 50 °C on d24; this may be because that the microbial activity was probably inhibited with the obvious inhibiting effect of MHPP; despite the slow rise, the high temperature lasted for approx. one month later. The high temperature period (> 50 °C) of each treatment lasted for about one month, which was much longer than 5 days for innocuous treatment according to the national regulations of China; this helps to kill pathogenic microorganisms and pathogenic eggs during composting, thus assuring the innocuous treatment of composting.

Effect of the addition of MHPP addition on emission of methane as a greenhouse gas from compost

CH_4 is a greenhouse gas produced by methane bacteria from the simple organic matters like methylamines, methyl alcohols, methyl acids and other carbon-containing compounds, as well as carbon dioxide and hydrogen in straws and dairy manure in pile. As shown in *Figure 2,* the methane emission peaks of all the four treatments occurred at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1128911301

early stage of composting; the quick rise of temperature in early stage stimulated microorganisms to degrade organic matters efficiently, which consumed a lot of oxygen; as a result, the excessively low locally soluble oxygen content facilitated the production of high content of CH_4. As the composting progressed, the organic carbon available in straws and dairy manure was consumed progressively, and the microbial activity decreased, and the CH_4 emission rate went down gradually; in the end, the degradation of organic matters stopped, so CH_4 emission was hardly detected.

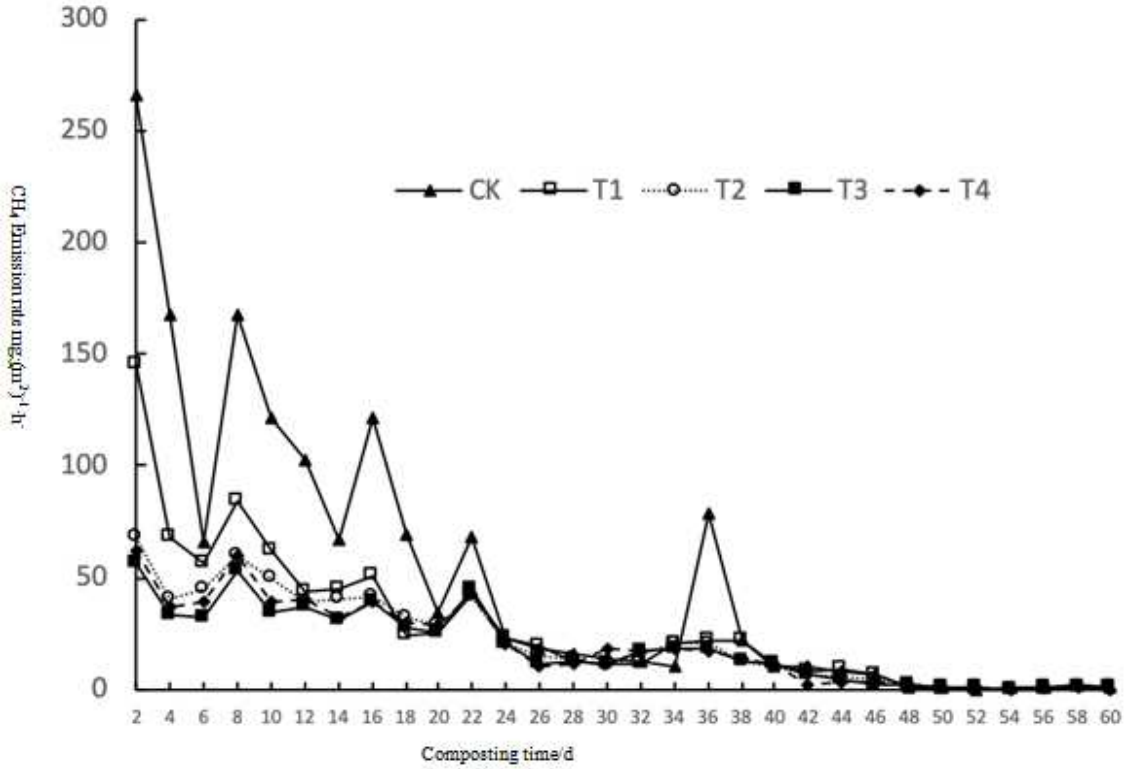

Figure 2. *CH_4 emission rate during composting*

The CH_4 emission peak was detected in CK treatment at the very beginning, where the mean emission rate was 49.52 mg/m^2/h; the T1-T4 drainage rates were lower than that of CK, indicating that the addition of DCD and MHPP played a remarkable role in reducing emission from the composting of dairy manure and straws; measurement and calculation showed that the cumulative emission from CK was approx. 71.30 g/m^2, while the emission from T1-T4 was 39.56 g/m^2, 30.98 g/m^2, 27.15 g/m^2 and 28.81 g/m^2, which indicated the emission was reduced by 44.52%, 56.56%, 61.93% and 59.59%, respectively. It is observed that the effect of DCD to which calcium superphosphate was added was more obvious, while the addition of calcium superphosphate exhibited insignificant effect on MHPP emission reduction.

That the addition of calcium superphosphate and DCD help to reduce methane emission echoed the report of Luo et al.(2012), The main reason for such reduction is because that the sulfate ions in calcium superphosphate help to reduce the pile pH, which further inhibited the activity of methane bacteria, thereby realizing in the reduction of methane emission. In addition, since sulfate reducing bacteria reduce sulfate radicals into S^{2-} with acetic acid, lactic acid and hydrogen ions as electron

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1128911301

donors and with sulfate radicals as electron acceptors during composting, methane bacteria could finish their own biochemical metabolism; a competitive relation existed in between; additionally, S^{2-} had certain toxic effect on methane bacteria. However, the rate of emission reduction was not enhanced after the addition of calcium superphosphate to MHPP; the principal reason may be that the acidic calcium superphosphate brought about no promoter action in the ammonium nitrogen environment of MHPP.

The addition of calcium superphosphate reduced the carbon-nitrogen ratio, indicating that the addition of calcium superphosphate facilitated the ingestion of affecting component in microorganisms during composting, thus facilitating the microbial metabolism and the decomposition of organic matters.

Effect of the addition of MHPP on emission of N_2O as a greenhouse gas from compost

Ammonium nitrogen was continuously transformed into nitrate nitrogen during composting, and N_2O was frequently produced in this nitrification process; in addition, N_2O was generated during the denitrification from nitrate nitrogen to ammonium nitrogen. As can be seen from CK in *Figure 3,* the low temperature and adequate oxygen in early stage of traditional composting promoted the generation of abundant N_2O at compost surface, which was consistent with the studies of Hao et al. (2001) and Sommer et al. (2000). In the thorough decomposition period, the substantive production of nitrate nitrogen brought about denitrification that produced N_2O. The nitrates and nitrites generated in areas where there was plenty of oxygen were carried by pile turning into the anaerobic zone, where denitrification occurred while some N_2O was emitted, which was echoed the studies of Thompson et al. (2004) and Fukumoto et al. (2003); the nitrification process oxidized ammonia into hydroxylamine with the help of catalytic effect of ammonia monooxygenase on ammonia oxidizing bacteria and ammonia-oxidizing archaea; hydroxylamine produced NO_2^- under the action of hydroxylamine oxidoreductase, while NO_2^- was the key source of N_2O, so the major way to reduce N_2O should be the alleviation of nitration and denitrification reaction; there were two key ways of blockage: First, the production of initial NH_3 could be reduced by changing the pile pH; second, the ammonia monooxygenase or hydroxylamine reductase could be inhibited through DCD nitrification inhibitors.

In the present study, calcium superphosphate was used to improve the pile pH by reducing it below 6.5, thereby considerably reducing the emission of NH_3, the precursor of N_2O. As can be seen from *Figure 3,* the addition of DCD, calcium superphosphate and MHPP to T1-T4 caused the N_2O amount to drop significantly; the N_2O emission from T1, T2, T3 and T4 were 36.24%, 39.49%, 62.39% and 55.81% respectively less than the total N_2O emission from CK. The MHPP worked better in emission reduction; the effect of DCD with calcium superphosphate added was more obvious, while the effect of MHPP with calcium superphosphate added in emission reduction was inferior to the effect of MHPP without calcium superphosphate added.

Effect of MHPP addition on emission of harmful gas NH_3 from composting

As shown in *Figure 4,* a lot of ammonia was emitted in early stage of CK during traditional composting because the temperature rise in early stage of composting resulted in constant degradation of nitrogenous organic compounds, which produced

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1128911301

abundant ammonium nitrogen; in the stationary phase, the reduction of degradable nitrogen and the transformation of ammonium nitrogen into nitrate nitrogen or organic nitrogen enabled ammonia to effectively fix nitrogen in the form of ammonium phosphate when calcium superphosphate is added.

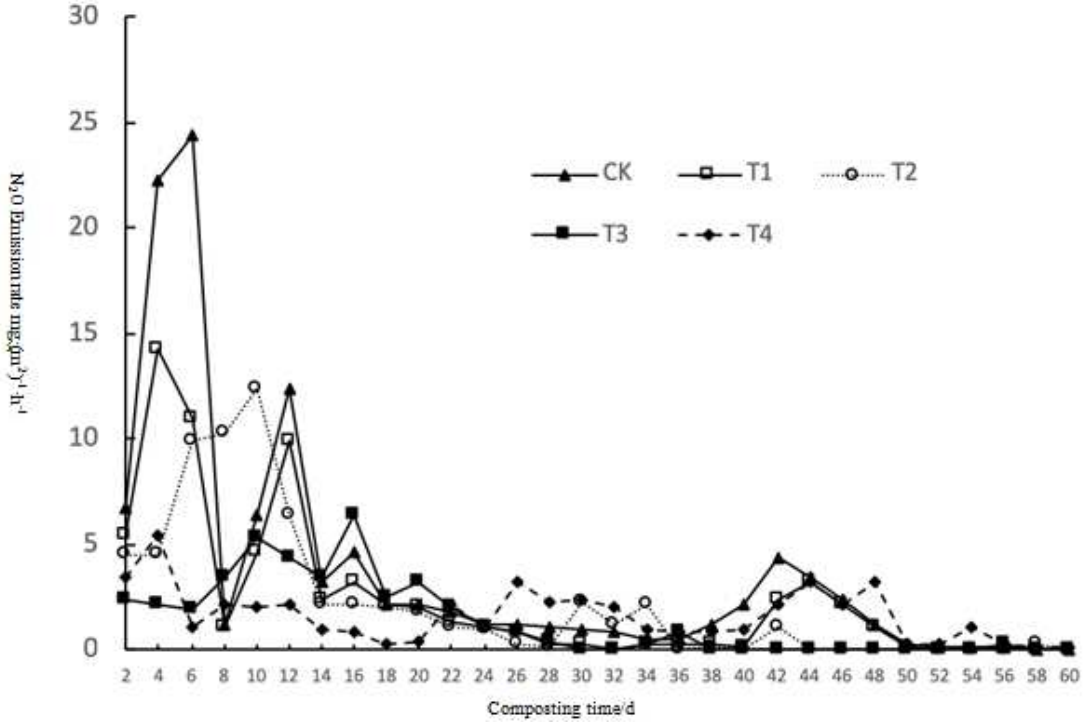

Figure 3. *N_2O emission rate during composting*

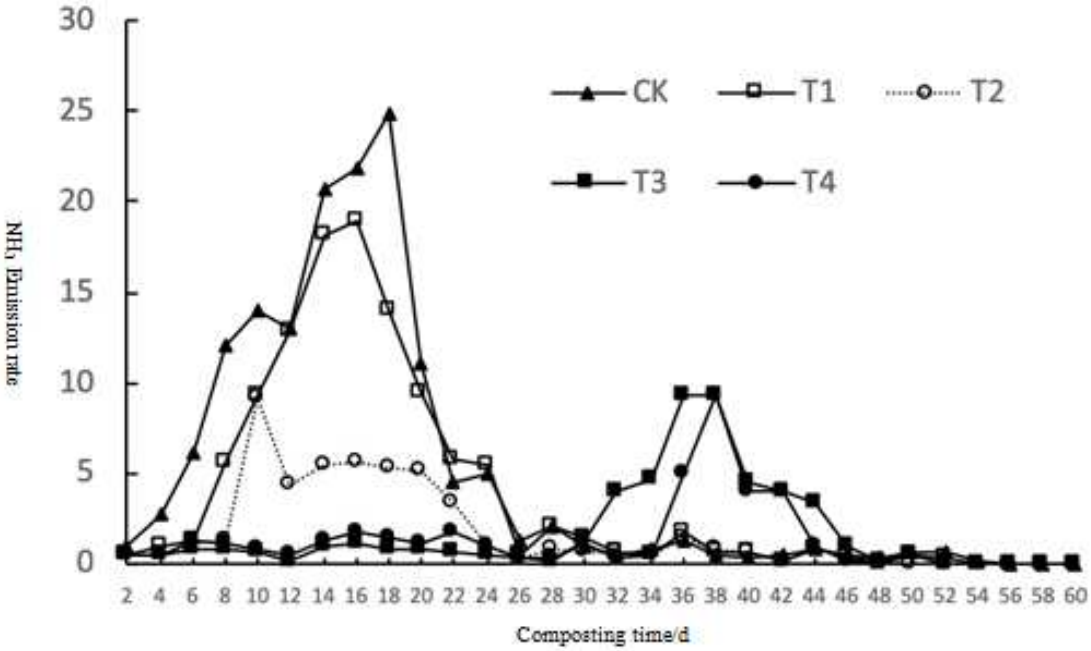

Figure 4. *NH_3 emission rate during composting*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1128911301

The NH_3 emission during composting is shown in *Figure 4,* where the NH_3 emission of all the four treatments peaked during high-temperature period; nitrogenous organic compounds were substantively decomposed during high-temperature period, which produced a lot of ammonia. The ammonia emission was extremely low in the early and late stages of composting when temperatures were relatively low; throughout the stages, the emission of ammonia was reduced by T1-T4 by 23.72%, 65.61%, 65.40% and 72.61% respectively as compared with the control; the dominant mechanism was as follows: The acidic calcium superphosphate regulated the pH during composting below 6.5; as a result, N existed in the form of NH_4+, which went against the release of ammonia; in such a case, it existed in the form of ammonium acid phosphate or ammonium sulfate. The study performed by Li et al. (2008) demonstrated that the addition of calcium superphosphate reduced the ammonia emission from pig manure and rice straws by 39.39%; the value in the present study is greater than in that study, because nitrification inhibitor was added in the present study in addition to calcium superphosphate.

Variation of ammonium nitrogen (NH_4^+-N) content and nitrate nitrogen (NO_3^--N) contents

Ammonium nitrogen (NH_4^+-N) and nitrate nitrogen (NO_3^--N) content variation is considered an important indicator for determination of nitrogen circulation during composting; refer to *Figure 5* for the variation pattern during composting; with the constant degradation of organic matters at early stage of composting, the composting of each treatment reached the high-temperature period, when microbial activity intensified, and the NH_4^+-N content of each treatment rose continually; it is observed that the NH_4^+-N from CK in traditional composting dropped rapidly after 28 days, while the NO_3^--N of CK shot up after the same period, which indicated that the NH_4^+-N of control was turning into NO_3^--N, and that the decrease was greater than the increase; and that the decrease was greater than the increase; this demonstrated that part of the nitrogen was emitted from the pile in the form of gas, namely NH_3 and N_2O. Where calcium superphosphate, DCD and MHPP were added to T1-T4, the NH_4^+-N of T1 slightly decreased in approx. 28 days, while that of T2, T3 and T4 did not went down significantly, which indicated the combination of calcium superphosphate and DCD alleviated the transformation and decomposition of NH_4^+-N; only the NO_3 -N of T1 slightly increased after 28 days while that of T2-T4 exhibited no significant rise, which demonstrated that calcium superphosphate, DCD and MHPP prevented NH_4^+-N turning into NO_3^--N, because DCD and MHPP inhibited the activity of nitrifying bacteria, thereby inhibiting or event preventing the nitrification in compost.

Physico-chemical and material decomposition indicators

Germination percentage is an important indicator for evaluation of compost decomposition; it is generally agreed that thorough decomposition is realized when GI > 80%; “thorough decomposition” means the application of fertilizer to crops bring about no secondary decomposition and lead to no adverse effects. In the present study, the germination percentage was higher than 96%, much higher than 80%; the reason why the germination percentage did not reach 100% may be because that it was impossible for any seeds to realize a germination percentage of 100%. A compost conductivity greater than 4 ms/cm may cause physiological damage to field crops, so

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1128911301

compost conductivity is also known as an important indicator of compost safety; as shown in *Table 3*, the conductivity dropped from 3.19–3.294 ms/cm to 0.96–1.89 ms/cm, which represented the compliance with safety requirements.

Discussion

Chemically synthetic nitrification inhibitors principally include dicyandiamide (DCD), nitrapyrin and DMPP, which have been brought into production; however, these chemically synthetic inhibitors are not extensively used in agricultural production due to their high costs, their instable properties in different climates and soils (Li et al., 2008) and certain problems to be solved.

DCD, as a common nitrification inhibitor, can effectively inhibit the oxidation of ammonia, alleviate the leaching loss of nitrate nitrogen and the nitrogen loss resulting from denitrification, and improve the utilization of nitrogenous fertilizer (Moir et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1128911301

2010); however, there were some drawbacks with the application of DCD: The application rate of DCD had to reach 15–30 kg per Mu (666.7 square meters) so as to achieve inhibiting effect; DCD was extremely mobile in soil since it was easily soluble in water (Jacinthe et al., 1992), and the resulting spatial separation from ammonium nitrogen may impair the inhibiting effect; in the case of intense rainfall or soil with poor water retention capacity, leaching loss of DCD may frequently occur; the repeated application of DCD may cause the degradation rate to increase, thus reducing the half-time. Certain studies reported that the application of DCD may bring about toxic effects on crops (Xmb et al., 2003). The application of nitrapyrin increases the yield by 7%, reduces the nitrogen loss by 16%, and reduces the greenhouse gases emission by 51% (Woil et al., 2004); however, since nitrapyrin is a chlorinated organic matter, its long-term application may adversely affect the environment. Furthermore, nitrapyrin is prone to volatilization and photolysis, which makes it unsuitable for surface fertilization; moreover, the risk of corrosion and explosion makes it difficult to apply and keep this substance. Other studies showed that nitrapyrin exhibited certain toxicity that brought about curved and sallow leaves etc. in some plants (Maftoun et al.1981).

In contrast, the biological nitrification inhibitor MHPP produced through induction in ammonium nitrogen environment is a biological product produced by plants that are not harmful to the environment; since neither toxic nor side effect was detected during the test, MHPP is expected to be extensively generalized in composting and agricultural production. However, this substance is still under study, and the way to turn it into stable powder for extensive popularization is one of the important aspects of next step of research.

Conclusion

1. The combination of calcium superphosphate and MHPP did not cause the composting of straws and dairy manure to slow down, but improved the final compost quality; the ultimate germination percentage of each treatment was 97.5%, 98%, 98% and 97.5%, respectively.
2. The addition of calcium superphosphate and MHPP reduced the nitrogen oxide and ammonia emission during composting; the most appropriate content of MHPP was found to be 0.6%, where the emission of NH_3, N_2O and CH_4 were reduced by 65.40%, 62.39% and 61.93%, respectively.
3. Since the present test was a large engineering test featuring large mass of raw material and fermentation field, it was difficult to perform repeated tests; however, the gas sampling and chemical test indicates were repeatedly tested during the test after adequate mixing of raw materials, so the experimental data are reasonable and rational.
4. Recommendations: The compost will be used in field. We did not research how compost influence gas emission during plant growth. So further researches should be conduct on how compost influences gas emissions during using process.

Abstract. To better assess high-standard farmland development projects, this paper built an evaluation system containing three indices: soil efficiency, infrastructure efficiency as well as economic and social efficiency, which were measured after the development of high-standard farmlands. By combining the matter-element extension theory with the TOPSIS model, the authors built a high-standard farmland development evaluation system to assess the soil efficiency, infrastructure efficiency, economic and social efficiency as well as the overall efficiency after completion of a high-standard farmland development project. the authors found the weight of the index for infrastructure efficiency to be 0.46, with the degree of similarity to the optimal solution reaching 1.0, thus it is rated excellent in terms of its impact on the overall efficiency evaluation; the weight of economic and social efficiency was 0.37, with its degree of similarity being 0.29, thus rated good accordingly; while the weight of soil efficiency was 0.17, with its degree of similarity being 0.00, thus it had the least impact on overall efficiency. The sequencing result by the TOPSIS model showed that the effective depth of soil had the highest impact on soil efficiency, meanwhile the road access rate influenced infrastructure efficiency the most, and public satisfaction mattered most in terms of economic and social efficiency.
Keywords: *land development, land engineering, high-standard farmland, evaluation system, efficiency*

Introduction

High-standard farmland development projects normally involve land development, soil improvement, irrigation and water supply, rural road network building, farmland protection and ecological reservation. These projects aim to reduce or remove major restrictions on farmland development and improve their quality. As proposed in the Chinese government document "*Opinions on Accelerating Modernization of Agriculture and Building a Moderately Prosperous Society by the Central Government and State Council*", the governments at all levels should boost development of high-standard farmlands by increasing investment and integrating financial sponsorship, and governments at all levels should put this endeavour among their top priorities. Thus, development of high-standard farmlands is in fact a land development project in which the scientific evaluation of the project efficiency accounts to be a significant step.

Current Chinese domestic projects (Hwang and Yoon, 1981; Yang et al., 2013; Liu et al., 2012; Zhao and Zhu, 2010; Wu et al., 2008; Li et al., 2010; Xin et al., 2009; Gao et al., 2011) have already studied many topics in this area, including efficiency evaluation of land development projects, evaluation index systems for high-standard farmland development, arable land overall quality evaluation index systems, preliminary location selection of high-standard farmland development, basic farmland demarcation or suitability and timing of high-standard farmland development. For instance, published

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1130311316

studies have used the TOPSIS (Technique for Order of Preference by Similarity to Ideal Solution) model (Tsaur, 2011; Korkmaz, 2008; Jun et al., 2011; Liu et al., 2006) to analyze priorities in high-standard farmland development, and studied the potential quality of arable land based on grading factors and matter-element modeling (Zhao et al., 2017, 2018). Some of these studies have focused on location selection and division of high-standard farmland by combining the TOPSIS model with the local spatial auto-correlation method (Yang et al., 2018, 2017a, 2017b). Some others have expounded on the feasibility and spatial stability of high-standard farmland development via the TOPSIS model and used the four-quadrant method to analyze the spatial and temporal distribution in high-standard farmland development (Xue et al., 2014). Other studies have explored the time series of high-standard farmland development on the basis of land evaluation and site analysis system (Bian et al., 2016). Nevertheless, current research on the high-standard farmland post-development efficiency have been mainly carried out by way of the entropy weight method, the TOPSIS model or the entropy-weight-based matter-element extension model to analyze the efficiency (Xin et al., 2017; Cai and Li, 2014). To enrich the repository of methods for high-standard farmland development evaluation, this research proposed a new evaluation method that combines the matter-element extension model with the TOPSIS model. With the matter element as its basis, the proposed method develops a matter-element model with three post-development indices – soil efficiency, infrastructure efficiency and economic and social efficiency – to evaluate farmland development efficiency through the analysis of the respective weight of the indices in the correlation function. The weights resulting from the function are then introduced into the TOPSIS model to calculate the degree of similarity and evaluate the soil efficiency, infrastructure efficiency, economic and social efficiency as well as the overall efficiency. The result of the weight analysis by way of the correlation function is shown to be in agreement with the result of the efficiency-based similarity analysis.

Materials and methods

Research area description

This research takes the high-standard farmland development project of Shangwei Village in Shannan Town, Feixi County of Hefei in Anhui province of China as the research target to evaluate the post-development efficiency. The study area is situated at about 116° 45’ to 116° 48’ east longitude and 31° 40’ to 31° 42’ north latitude (*Fig. 1*). Located in the northwest part of Shannan Town, Shangwei covers an area of 7.9 km^2, including 260 hm^2 of farmlands and 200 hm^2 of woods. This project area, with its northern part higher than its southern part, mainly consists of hills and is divided into two sections – one in the east and the other in the west – with the County Road No. 042 as the line of demarcation. Subject to the tropical monsoon climate, the area has an average annual temperature that falls between 15 and 16 °C and an average annual precipitation between 900 and 1000. The whole development project lasted from the end of February 2017 to the beginning of August 2017. Given the actual conditions of the project area, three sampling sites were selected for soil efficiency inside a key development region, where farmlands abound.

Research data presented in this study was collected from diverse sources, including the database for land utilization of Feixi, Heifei, in 2013, the land use map of Feixi prepared in September 2016, the (updated) land use database of Feixi, Heifei, in 2016

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1130311316

and the overall land use planning map (2006-2020). Other research materials are also referred to, such as the surveyed landform map of the project area in 2016, the planning report for the high-standard farmland development project in 2016, the project completion landform map, the result of a questionnaire survey carried out in October 2017 and sampling research data obtained in October 2017. In the questionnaire survey, 95 questionnaires were collected from the total of 100 distributed. According to China's high-standard farmland construction standards and evaluation criteria for high-standard farmland construction, the target groups of the questionnaire survey were mainly local farmers, managers and acceptance experts. Among the participants, the ages were mainly between 30 and 60 years old, the education experience of senior high school and college were the main one.

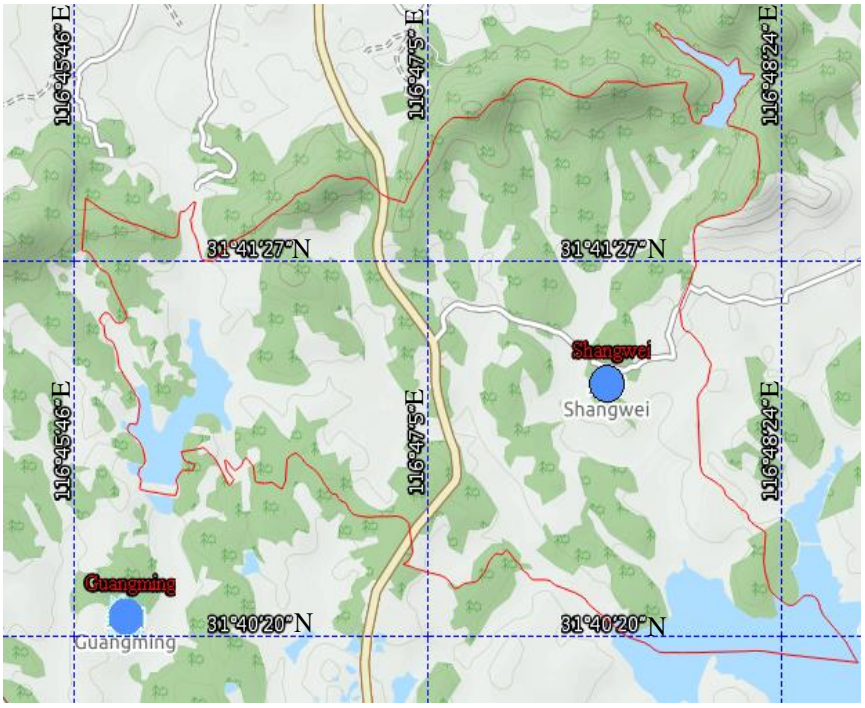

Figure 1. *Location map of research area (Feixi County of Hefei in China)*

Research methodology

The core objective of high-standard farmland development is to maximize economic and social efficiency while ensuring ecological conservation. Extenics is a subject that studies the possibility of extension of matters and explores the law and methods for innovation of the extensibility of matters through formalized models to address problems. There are diverse indicators for evaluation of high-standard farmland efficiency and results from single-index evaluation methods are usually incompatible with each other, therefore, the Extenics theory, which is applicable to such research situations, is applicable to this study. The TOPSIS method works out the degree of similarity between the calculated results and the optimal solution to evaluate the results' quality. The TOPSIS method is based on the Euclidean distance calculated between the positive ideal solution (PIS) and the negative ideal solution (NIS). As presented above, this project presents an evaluation system with three indices (soil efficiency,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1130311316

infrastructure efficiency and economic and social efficiency) according to the high-standard farmland development criteria (Criterion of High Standard Farmland, 2012), establishes a weight model of correlation function index based on matter elements and analyzes the development results. The weights obtained via the correlation function are introduced into the TOPSIS model, which is then optimized to work out the degree of similarity of each index to the ideal solution. In this way, an evaluation can be made on the soil efficiency, infrastructure efficiency, economic and social efficiency as well as the overall efficiency of the high-standard farmland development project.

Evaluation index system

Based on existing studies and the actual conditions of the project area, the model presents an evaluation system of indices, assuming that the indices are representative, comparable, operable and quantitative. The efficiency of high-standard farmland development is taken as the evaluation target, with three indices – soil efficiency, infrastructure efficiency, economic and social efficiency – as the evaluation criteria. Each evaluation index includes multiple criteria with deciding factors, as shown for the index system in *Table 1*. According to domestic research publications, the degree of similarity is divided into four levels to make a qualitative evaluation. The criteria are as follows: when the degree of similarity stands between 0.80 and 1.00, the efficiency is rated "excellent"; when the number falls between 0.60 and 0.80, the efficiency is rated "good"; the efficiency is rated "moderate" when the number is between 0.30 and 0.60; while it is rated "poor" if the number stays between 0.00 and 0.30.

Table 1. *Efficiency evaluation index system*

Target	Criterion and code	Index (deciding factors) and code	Index type	Mean	Suitable value
High-standard farmland development efficiency	Soil efficiency (O_{11})	Effective depth of soil (cm) c_1	Positive	60.0	100
		Organic content of soil (g/kg) c_2	Positive	11.6	20
		pH scale c_3	Suitable	6.8	6.0-7.9
	Infrastructure efficiency (O_{21})	Agricultural mechanization level (%) c_4	Positive	75.0	100
		Irrigation water utilization coefficient c_5	Positive	0.6	1.0
		Rate of guaranteed irrigation (%) c_6	Positive	85.0	100
		Road access rate (%) c_7	Positive	90.0	100
	Economic and social efficiency (O_{31})	Agricultural production cost (10000 rmb/hm^2) c_8	Negative	1.6	0
		Static return on investment (%) c_9	Positive	7.1	100
		Degree of public satisfaction (%) c_{10}	Positive	93.0	100

(1) The indices and suitable values in the table above are identified by referring to relevant regulations for high-standard farmland development (Farmland Construction, 2016; Regulation for Gradation on Agriculture Land Quality, 2012; Cultivated Land Quality Grade, 2016) and related research publications. (2) The average score of soil efficiency is obtained from sampling of the sites, from scores of infrastructure efficiency from scoring results by experts, and from scores of the economic and social efficiency from questionnaire surveys. (3) Agricultural production cost and static return on investment refer to economic efficiency; degree of public satisfaction represents social efficiency

High-standard farmland development efficiency evaluation

The matter-element extension model and TOPSIS model are combined to evaluate the soil efficiency, infrastructure efficiency, economic and social efficiency as well as the overall efficiency of the high-standard farmland development project.

Matter-element model building

According to previous published models (Zhao and Su, 2010; Cai et al., 2008; Yang and Cai, 2008), O_{mj} is set with j levels of evaluation; c_i is the evaluation index for standard levels; V_{mji} is the range of classical field defined by the respective levels of indices; a_{mji} and b_{mji} are the upper limit and lower limit of the classical field, respectively; P is the evaluation standard; x_{pi} is the range of the segment field of P in terms of each evaluation index of c_i; a_{pi} and b_{pi} are the upper limit and lower limit of the segment field, respectively; Q represents the matter element to be evaluated (development efficiency) and x is the efficiency value of Q in terms of the evaluation index c_i. The relation between x_{pi}, the segment field value, and v_{mji}, the classical field value, is $v_{mji} \subset x_{pi}$. The classical matter element model, the segment field matter element model and the to-be-evaluated matter element model that can be built are as follows: $M_{mj} = (O_{mj},\ c_i,\ v_{mji})$, $M_p = (P,\ c_i,\ x_{pi})$, $M_q = (Q,\ c_i,\ x_i)$.

Weight model building

In the evaluation of efficiency (Zhao and Su, 2010; Cai et al., 2008; Yang and Cai, 2008), the weighing method can help measure differences among indices, but in most cases, the scoring method, which involves subjective judgements, dominates and undermines the objectivity of the result. By introducing the average score of each index into the classical field and segment field of the matter-element extension model, our model calculates the weight of each index through the correlation function to decide whether the index meets the standard, so that the result can steer clear of subjective errors and w_i, the normalized weight of c_i, can be calculated. When $x_i \in x_{pi}$ (segment field), the classical field is $v_{mji} = (a_{mji}, b_{mji})$, with $i = 1, 2, \cdots n$ (evaluation index) and $j = 1, 2, \cdots m$ (evaluation standard level), then the correlation function between the evaluation value and the classical field presents as:

$$K_{ji}(x_i, v_{mji}) = \begin{cases} \dfrac{2(x_i - a_{mji})}{b_{mji} - a_{mji}}, \text{when } x_i \le \dfrac{a_{mji} + b_{mji}}{2} \\ \dfrac{2(b_{mji} - x_i)}{b_{mji} - a_{mji}}, when x_i > \dfrac{a_{mji} + b_{mji}}{2} \end{cases} \quad \text{(Eq.1)}$$

In *Equation 1, K_{ji} (x_i, V_{mji})* refers to the simple correlation value between the actual efficiency values and corresponding standard values of evaluation indices; other symbols follow the same pattern in meaning. j stands for the level of evaluation standard. The larger j is, the larger the represented index's influence on the criteria is. The correlative weight calculation model then presents as:

$$q_i = \begin{cases} j \times (1 + \max(K_{ji}(x_i, v_{mji}))), when \max(K_{ji}(x_i, v_{mji})) \ge -\dfrac{1}{2} \\ 0.5 \times j, when \max(K_{ji}(x_i, v_{mji})) < -\dfrac{1}{2} \end{cases} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1130311316

In *Equation 2, j* stands for the highest level of evaluation. On the contrary, the smaller *j* is, the smaller the corresponding index's influence on the criteria is. In this case, the correlation weight calculation model is:

$$q_i = \begin{cases} (m-j+1)\times(1+\max(K_{ji}(x_i, v_{mji}))), \text{when } \max(K_{ji}(x_i, v_{mji})) \geq -\frac{1}{2} \\ 0.5\times(m-j+1), when \max(K_{ji}(x_i, v_{mji})) < -\frac{1}{2} \end{cases} \quad \text{(Eq.3)}$$

In *Equation 3, j* stands for the lowest level of evaluation and *m* is the number of evaluation levels.

TOPSIS model

TOPSIS is a multi-criteria analysis method, which was originally proposed by Hwang and Yoon in 1981 to compare different solutions, and it is also an integrated evaluation method for multi-objective and decision-making solutions. It can not only make the best of the original data and reflect the gap between different decision-making solutions, but also describe the general condition of the objectives or specific targets in an authentic, direct and reliable way, therefore it is widely applicable. The authors assumed that there are a total of *m* objectives, each of which has *n* attributes, and the initial value of the attribute j^{th} of the objective i^{th} is x_{ij}, the initial evaluation matrix *V* is then formed. As the dimensions of indices vary, the initial matrix is normalized into the normalized matrix *V'*. By combining the weight matrix *W* obtained from the correlation function model with the normalized initial evaluation matrix *V'*, the weighted evaluation matrix *Z* is obtained.

(1) We first calculated the positive ideal solution (PIS) and negative ideal solution (NIS) of the evaluated objective through the weighted judgement matrix, then worked out the Euclidean distance that each objective has from PIS and NIS, and last the following model is built:

$$\text{Euclidean distance from PIS: } S_i^+ = \sqrt{\sum_{j=1}^{m}(f_{ij} - f_j^+)^2},\ j = 1,2,...,\ n \quad \text{(Eq.4)}$$

$$\text{Euclidean distance from NIS: } S_i^- = \sqrt{\sum_{j=1}^{m}(f_{ij} - f_j^-)^2},\ j = 1,2,...,\ n \quad \text{(Eq.5)}$$

(2) Next, the authors calculated C_i, the degree of similarity of each objective to the optimal solution (or optimal value):

$$C_i = S_i^- / (S_i^+ + S_i^-),\ \ i = 1,2,...,m \quad \text{(Eq.6)}$$

According to C_i, the scale of the similarity, the objectives can then be sequenced to create the basis for decision-making. In *Equation 6,* the larger C_i is, the closer the efficiency of the item i^{th} is to the optimal value. The values for the degree of similarity fall within the range from 0.00 to 1.00, and the closer the value is to 1.00, the better the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1130311316

corresponding index's efficiency is; on the contrary, similarity closer to 0.00 means poorer efficiency.

Data analysis process

Data processing

Range identification of classical field and segment field

The correlation function in the matter-element extension model plays a pivotal role in determining the weights of indices, and it is related to the classical field and segment field in the model. The conventional methods to identify the range include work experience-based identification by experts, criteria-based identification, sampling data-based identification and others. On the basis of previous reports describing criteria for high-standard farmland development, the research presented here, by referring to data collected from sampling sites of completed projects, statistics from questionnaire surveys and consultation with experts, identifies the ranges of the classical field and the segment field at four evaluation levels for the corresponding indices, as shown in *Table 2*.

Table 2. *Range of the classical fields and the segment fields of evaluation indices*

Index code	Classical field range				Segment field range
	Poor	Moderate	Good	Excellent	
c_1	[30, 50)	[50, 60)	[60, 70)	[70, 100]	[30, 100]
c_2	[0, 5)	[5, 10)	[10, 20)	≥ 20	[0, 20]
c_3	[4.5, 5.5]	(5.5, 6.0]	(6.0, 6.5]	(6.5, 7.9]	[4.5, 7.9]
c_4	[0, 50)	[50, 60)	[60, 70]	[70, 100]	[0, 100]
c_5	[0.1, 0.5)	[0.5, 0.55)	[0.55, 0.6)	[0.6, 1.0]	[0.1, 1.0]
c_6	[10, 50)	[50, 60)	[60, 70]	[70, 100]	[10, 100]
c_7	[30, 50)	(50, 60)	(60, 80)	(80, 100)	[30, 100]
c_8	≥ 2.0	(2.0, 1.5)	(1.5, 1.0)	< 1.0	[0, 2]
c_9	[0, 5]	[5, 8]	[8, 10]	> 10	[0, 10]
c_{10}	[0, 50]	[50, 60]	[60, 75]	[75, 100]	[0, 100]

Index weight in the TOPSIS model

The standard level that an index's evaluation value belongs to is represented by *j*. A larger value of *j* means larger influence of the index on the criteria, hence deserving a larger scale of weight; on the contrary, a smaller *j* means less influence of the corresponding index on the criteria, hence deserving a smaller weight. The results are shown in *Table 3*.

Processing of data on soil efficiency, infrastructure efficiency and economic and social efficiency through the TOPSIS model

The main components of high-standard farmland development evaluation criteria include: construction task evaluation, construction quality evaluation, construction effectiveness evaluation, construction management evaluation, social impact evaluation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1130311316

and comprehensive evaluation (Assessment Standard of Well-Facilitated Farmland Construction, 2016; Criterion of High Standard Farmland, 2012). The high-standard farmland development project, in planning and location selection, aims to improve the infrastructure, increase the level of agricultural automation and achieve agricultural mass production in the selected area. The infrastructure in the selected area is largely poor in quality and suffers from damages, which undermines the land productivity and the level of agricultural mechanization. Besides, irrigation-caused pit ponds and collapses of irrigation canals are rife among alluvial farm fields, casting a blight on agricultural irrigation. When the project is completed, project-acceptance experts select three sampling sites in the project area to assess the soil efficiency. According to the principles of TOPSIS modeling and given the inconsistent quantitative units of indices, the original evaluation matrix is normalized to produce and sequence the degree of similarity of the soil efficiency, infrastructure efficiency as well as economic and social efficiency, as shown in *Table 4*. The statistics for infrastructure efficiency are taken from scores by project-acceptance experts and those for economic and social efficiency are from questionnaire surveys.

Table 3. *Index weight*

Index code	Weight			
	Index correlated	**Index normalized**	**Criterion correlated**	**Criterion normalized**

Processing of data on overall efficiency through the TOPSIS model

Based on data from *Tables 1–4*, our model makes use of the TOPSIS model to calculate and sequence the degree of similarity of three decision-making factors for overall efficiency, as shown in *Table 5*.

Table 5. *Overall efficiency evaluation matrix and similarity degree*

Criterion	Normalized judgement matrix			Distance from PIS	Distance from NIS	Similarity	Ranking

Results analysis

In light of the leveling criteria of efficiency indices and based on the results of *Tables 3–5*, we analyze our results in two different ways: the weights of indices and the TOPSIS modeling results.

Soil efficiency analysis

(1) Analysis of index weight based on the correlation function. The results of normalized weight analysis on the criterion level after completion of the high-standard farmland development project follow the order: effective depth of soil (0.68) > Organic content of soil (0.17) > pH scale (0.15). This means that, among the factors that influence the soil efficiency, the effective depth of soil accounts for the largest indicator, hence it has the largest weight, followed by the organic content of soil and then by the pH scale. According to Jenks natural breaks method, indicators having a weight equaled or above 0.3 are important indicators, those within the range [0.1, 0.3) are secondary indicators and those smaller than 0.1 are boundary indicators. Therefore, among all the indicators for soil efficiency, the effective depth of soil is an important indicator, the organic content of soil a secondary indicator and the pH scale a boundary indicator.

(2) Analysis of the TOPSIS modeling results. The indicator effective depth of soil has the longest distance from the NIS, with a degree of similarity of 0.6177, while its distance from the optimal solution approaches 1.00, hence it is rated excellent in efficiency, which means that this indicator has the largest influence on soil efficiency; the distance of the indicator organic content of soil from PIS is 0.5603, and its distance from NIS is 0.09, so the indicator is rated poor in efficiency and plays a secondary role; the distance of the indicator pH scale from PIS is 0.6177, and its distance from the optimal solution is 0.00, so it is rated poor in efficiency and has the least influence. These indicators are ranked in the model in the following order: effective depth of soil, organic content of soil and pH scale.

Infrastructure efficiency analysis

(1) Analysis of the index weight based on the correlation function. The results of normalized weight analysis of infrastructure efficiency follow the order: road access rate (0.35) > rate of guaranteed irrigation (0.26) > agricultural mechanization level

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1130311316

(0.21) > irrigation water utilization rate (0.18). This means that, among the indicators for infrastructure efficiency, the road access rate plays the most important part, followed by the rate of guaranteed irrigation and then the agricultural mechanization level, with the irrigation water utilization rate having the least impact. According to Jenks natural breaks method, among the decision-making factors for infrastructure efficiency, road access rate is an important indicator, the rate of guaranteed irrigation, agricultural mechanization level and irrigation water utilization rate are secondary indicators, and there are no boundary indicators.

(2) Analysis of the TOPSIS modeling results. The indicator of road access rate has the longest distance from NIS, with a degree of similarity of 0.3273, and its distance from the optimal solution is 1.00, so it is rated excellent and has the largest influence on infrastructure efficiency. The distance of the indicator rate of guaranteed irrigation from NIS is 0.3081, and its degree of similarity to the optimal solution is 0.94, so it is rated excellent and plays a secondary role in infrastructure efficiency. The distance of agricultural mechanization level from PIS is 0.0741, and its degree of similarity to the optimal solution is 0.77, so the indicator is rated good and plays a relatively important role in infrastructure efficiency. The irrigation water utilization rate is most distant from the PIS, with a distance of 0.3273, and its degree of similarity to the optimal solution is 0.00, so it is rated poor in efficiency level and does not have much impact on infrastructure efficiency. These indicators are ranked in the model in the following order: road access rate, rate of guaranteed irrigation, agricultural mechanization level and irrigation water utilization rate.

Economic and social efficiency analysis

(1) Analysis of index weight based on the correlation function. The results of normalized weight analysis of economic and social efficiency follow the order: rate of public satisfaction (0.52) > static return on investment (0.40) > agricultural production cost (0.08). It means that among the indicators affecting economic and social efficiency, the rate of public satisfaction weighs the highest, followed by static return on investment and then by the agricultural productivity cost. According to Jenks natural breaks method, among the decision-making factors for economic and social efficiency, the indicators of rates of public satisfaction and static return on investment are important indicators, and the agricultural production cost is a boundary indicator, as the agricultural production cost is correlated with many unpredictable factors such as the environment and weather (unfavorable weather will increase the cost). The high-standard farmland development project improves the roads, achieves a general mechanization of agricultural production and reduces the workload and extra expenditures. With the cost of fertilization basically unchanged, the agricultural production cost is reduced, moreover, the static return on investment and the rate of public satisfaction would be both increased.

(2) Analysis based on the TOPSIS modeling results. The rate of public satisfaction is the most distant from the NIS, with a distance of 0.6477, and its degree of similarity to the optimal solution is 1.00, so this indicator is rated excellent in efficiency level and has the largest impact on economic and social efficiency; the indicator of static return on investment has a distance of 0.6091 from the NIS, and its degree of similarity to the optimal solution is 0.06, so it is rated poor in efficiency level and plays a secondary role in economic and social efficiency; the agricultural production cost has the longest distance from the PIS, 0.6477, and its degree of similarity to the optimal solution is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1130311316

0.00, so it has the least impact on economic and social efficiency. These indicators are ranked in the model in the following order: rate of public satisfaction, static return on investment and agricultural production cost.

Overall efficiency analysis

(1) Analysis based on index weight and the correlation function. The normalized weight analysis in terms of the criteria in the high-standard farmland development project is presented in the following expression: infrastructure efficiency (0.46) > economic and social efficiency (0.37) > soil efficiency (0.17). This order indicates that, among the indices that influence the project's overall efficiency, infrastructure efficiency has the largest weight, followed by economic and social efficiency, while soil efficiency has the least impact. According to Jenks natural breaks method, the infrastructure efficiency and the economic and social efficiency are thus rated as important indicators, while soil efficiency is a secondary indicator. Infrastructure efficiency consists of one important indicator and three secondary indicators, without boundary indicators; economic and social efficiency includes two important indicators and one boundary indicator; soil efficiency involves one important indicator, one secondary and one boundary. Therefore, it can be concluded that the infrastructure efficiency is positively correlated with the overall efficiency, while soil efficiency, with a lower value, is in negative correlation with the overall efficiency.

(2) Analysis of the TOPSIS modeling results. The infrastructure efficiency is the most distant from NIS, with a distance at 0.1621, and its degree of similarity to the optimal solution is 1.00, so its efficiency level is rated excellent; in the case of economic and social efficiency, its distance from NIS is 0.0469, 0.1152 from PIS and its degree of similarity to the optimal solution is 0.29, so it is rated as poor in the efficiency level and plays a secondary role in the overall efficiency; the degree of similarity of soil efficiency to the optimal solution is 0.00, so soil efficiency is rated poor in the efficiency level and has the least impact on overall efficiency.

To summarize, the index weight analysis results based on correlation functions and those of the TOPSIS modeling are consistent. According to the mean score and suitability score of the project shown in *Table 1*, the key to the overall efficiency of high-standard farmland development is to improve infrastructure efficiency.

Conclusions

(1) The advantage of matter-element modeling is that it extends the actual evaluation indices which are not within the range of the standard values towards the standard values, with the correlation function identifying the positive field, negative field and zero field. The range of the correlation function is $(-\infty, +\infty)$, so it reflects the status of an object in a more accurate way and thus facilitates quantitative evaluation. These advantages are what the traditional fuzzy comprehensive evaluation method and analytic hierarchy process cannot provide. Meanwhile, by sequencing the weights of indices and leveling their respective impacts, the model found that infrastructure efficiency and economic and social efficiency are important indicators in the overall efficiency evaluation, while soil efficiency is a secondary indicator.

(2) The overall efficiency of the high-standard farmland development project is reflected by three indices –soil efficiency, infrastructure efficiency and economic and social efficiency. It is found that infrastructure efficiency is the most distant from the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1130311316

NIS, with a distance of 0.1621, and its degree of similarity to the optimal solution is 1.00, so it is rated excellent in efficiency level while the soil efficiency has the least impact on the overall efficiency, with its degree of similarity to the optimal solution standing at 0.00.

Discussion

(1) The presented research combines matter-element extension modeling with TOPSIS modeling for high-standard farmland development efficiency evaluation. Compared with previous reported methods (Xue et al., 2014; Bian et al., 2016; Xin et al., 2017; Cai and Li, 2014; Tsaur, 2011; Korkmaz, 2008; Jun et al., 2011; Liu et al., 2006), the method used in this work has several advantages. Specifically, by constructing a matter-element model of classical and segment fields, it utilized the extensibility of matter elements to identify the evaluation objectives accurately and comprehensively; and by analyzing the correlation degree among factors in the correlation function, the model calculated the weight of each index, normalized the weight matrix and improved the weight measurement method to avoid the influence of subjective factors on the evaluation result.

(2) It is of great importance to select indices scientifically in evaluating efficiency of high-standard farmland development. The evaluation index system in this paper was built based on analysis of previous published studies, the particular situation of the project area and in consultation with project-acceptance experts. Ecological factors were not taken into account and only one indicator, public satisfaction, was included in the index of social efficiency. In this study, the authors did not compare the results with other results from different research methods, due to limitations on the overall length of the manuscript. In subsequent studies, the authors expect to improve the presented model to increase the accuracy of the research results.

(Received 13th Apr 2019; accepted 16th Jul 2019)

Abstract. *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* has a very restricted spread, and is an endemic black pine variety in Turkey. This plant has a poor generative reproduction performance. It is unclear which factors are responsible for this low reproduction capacity. Therefore, objective of this study was to investigate pollen and seed characteristics of the plant. For this purpose, pollen samples were collected in the pollination period, and seed samples were collected in the cone ripening period in the natural distribution site of this plant in Black Sea Region. Pollen samples were examined whether or not they have normal shape and size. Seed samples were tested for germination percentage and seed size and soundness were also examined. Results showed that pollen samples seemed to have normal shape and size, and seeds have a germination percentage of 71. This study indicated that the conservation of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* through in-situ and ex-situ strategies and the establishment of a seed orchard in a different area by taking grafts are important in terms of ensuring continuity of limited number individuals.
Keywords: *Pinus nigra* subsp. *pallasiana, yaltirikiana, germination, seed, pollen*

Introduction

Pinus nigra J.F.Arnold subsp. *pallasiana* (Lamb.) Holmboe, which spreads across Balkans, Southern Carpathians, Crimea, Cyprus and Syria, constitutes forests in mountainsides of Black Sea, Marmara, Aegean and Central Anatolia regions and Toros Mountains of Turkey, and rarely seen at sea level (Coode and Cullen, 1965; Akkemik et al., 2011; Kandemir and Mataracı, 2018). In accordance with the recent studies, it is accepted that there are three varieties including var. *fastigiata* Businský, var. *yaltirikiana* Alptekin and var. *pallasiana* (f. *pallasiana* and f. *seneriana* (Saatcioglu) Kandemir & Mataraci) in Turkey, and that its taxa except *pallasiana* f. *pallasiana* are endemic (Kandemir and Mataracı, 2018).

Pinus nigra J.F.Arnold subsp. *pallasiana* (Lamb.) Holmboe var. *yaltirikiana* Alptekin is distinguishable from other varieties by the fact that its cones are bigger (at least 8 cm) and leaves are longer (at least 14 cm) (Alptekin, 1987; Yaltırık, 1988; Kandemir and Mataracı, 2018; Oral and Mataraci, 2018). Alptekin (1987), who named the variety, indicated the cone sizes of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* as 7.8 cm (max.11.19) × 3.71 cm (max.4.4).

In Oral and Mataraci (2018)'s article, in which they identified a new epitype (ISTO 37320) instead of a holotype composed of only a cone, the average female cone size was 9.16 (7.69-10.23) x 3.94 (3.55-4.31) cm, male cone size was 1.58 (1.28-2.16) x 0.54 (0.48-0.62) cm; leave size was 17.21 (13.80-20.20) x 0.18 (0.16-0.22) cm and sheath length was 0.95 (0.67-1.16) cm. In addition, it was especially emphasized that the cone and leaf length should be evaluated concomitantly for the diagnosis of taxon.

DOI: http://dx.doi.org/10.15666/aeer/1705_1131711326

It was known that this variety was in 1985 in Karabuk-Yenice and Sinop-Boyabat (Alptekin, 1987). Oral and Mataracı (2018), during a field visit to these locations in 2017, stated that they survived owing to the fact that its individuals in Boyabat were taken under preservation. It is suggested by them that its danger catagory due to fewness of both individuals and seeds was "Critically endangered" (CR) (Ekim et al., 2000). During the field visit to Yenice, it never seen *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* even though all locations given in herbarium records were visited. There were black pines with shorter cones (5.66-8.50 cm) in these locations.

Yaman and Saribas (1999) compared pollen sizes of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* in Karabuk-Yenice, which is its holotype location, with pollens of the other endemic black pines, which were taken from natural areas. As a result of the study, it was stated that it should be compared with the pollen samples in Sinop-Boyabat due to the fact that frequency distribution of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana*'s pollen sizes (length-L and width-l) was not normal.

In this study, it is aimed at determining vitality of the seeds of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* in order to ensure the sustainability of the existence of its in Sinop-Boyabat. Therefore, it has been investigated number of sound seeds and germination percentage, and the morphological characteristics of its pollen to determine whether it has especially a morphological development inhibitive to fertilization.

Materials and methods

Pollen and seed samples were collected from the trees growing only in Sinop-Boyabat, Karageriş Mountain, (41°18′49,91″K, 34°34′41,15″D) at elevation of 1239 m (*Figs.1 and 2*).

Figure 1. *Individuals of Pinus nigra* subsp. *pallasiana* var. *yaltirikiana in Boyabat-Kapaklıpınar*

Only four trees were present in the site with ages of approximately between 80-100 years and height of 10-12 m. Dominant vegetation in the site includes some tree species such as *Pinus nigra* J.F.Arnold subsp. *pallasiana* (Lamb.) Holmboe var. *pallasiana, Pinus sylvestris* L. var. *hamata* Steven f. *hamata*, *Juniperus communis* L. subsp. *saxatilis* Pall. in the overstorey cover, some schrub species such as *Cistus laurifolius* L., *Rubus canescens* DC. var. *canescens*, *Rosa canina* L., *Crataegus monogyna* Jacq. subsp. *monogyna, Mespilus germanica* L. and some herbaceous plants such as *Veronica chamaedrys* L, *Dactylis glomerata* L., *Poa annua* L. in the understorey cover.

Mean annual precipitation is about 620 mm and most of it falls between September and June. The driest month is July, with 30 mm of rainfall. Most of the precipitation here falls in December, averaging 75 mm. Average annual temperature is around 12.9°C and changes between 4°C in January and 21.7°C in July (Climate-Data.org, 2019). The site has a deep soil (>80 cm) with sandy loam texture covered with mull type forest floor with 2 cm depth (GDF, 2011).

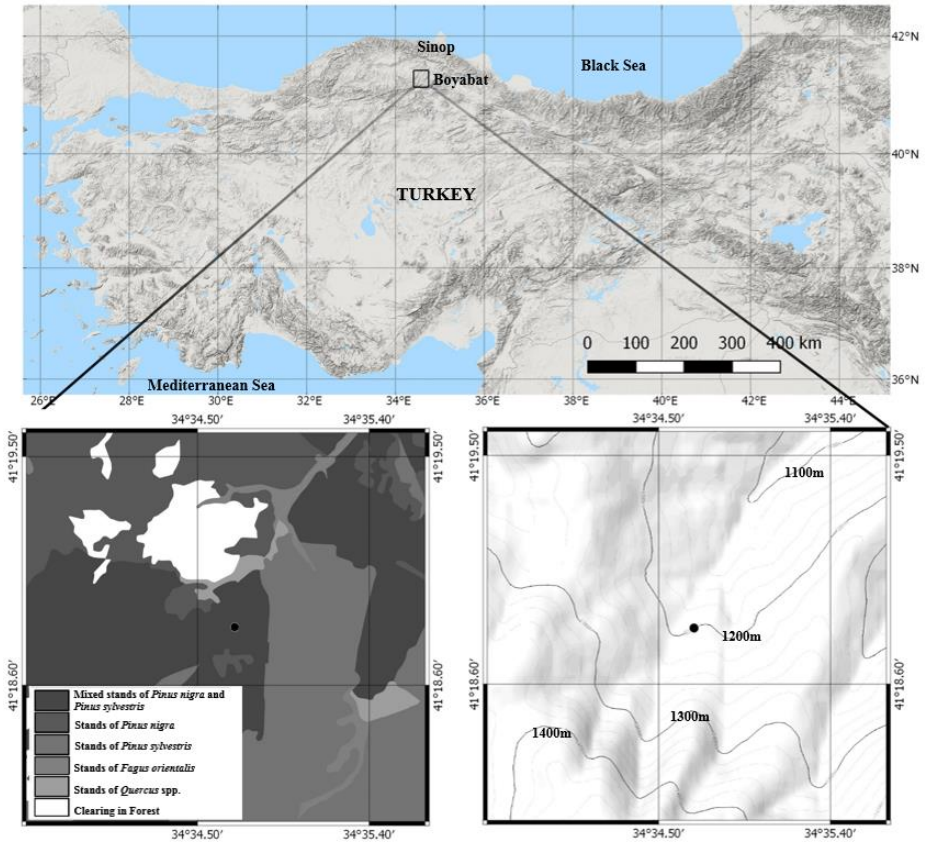

Figure 2. *The location of the sample collection area (●) and the different types of habitats in its surrounding*

Pollen samples were taken from each of four trees at the height of 3 m above soil surface in the pollination period in May 2018 and brought to Palynology Laboratory of Forest Botany Department at Istanbul University Cerrahpasa (I.U.C.) Faculty of Forestry. Then, pollen samples preparations were prepared separately for each individual tree according to the Wodehouse method (Wodehouse, 1959) and the measurements were carried out after waiting for 2 months for pollens in preparations to reach a normal form and sizes (Aytug, 1960). Then, they were examined. The measurements of pollen grains sizes in the preparations were done in the Leica DM750 light microscope (LM) as computer assisted, and 10x ocular, x40, x100 immersion objective were used. Under the light microscope, on equatorial axis of the pollen samples, length (β) and height (P) of saccus, distance from pollen to the outermost end of the saccus (p), height (h) of pollen body; on polar axis of theirs, length (L) and width (l) of pollen, length (B) and width (b) of saccus, distance from pollen to the outermost end of the saccus (be) were measured (*Fig. 3*) (Aytug, 1967).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1131711326

At least 50 measurements were performed for each pollen feature in each of the 4 preparations, then the averages were taken. A part of these pollens was kept in the fridge in +4°C to examine with Scanning Electron Microscope (SEM). The size of the pollen, and ornamentation were studied by taking photos with both SEM and LM.

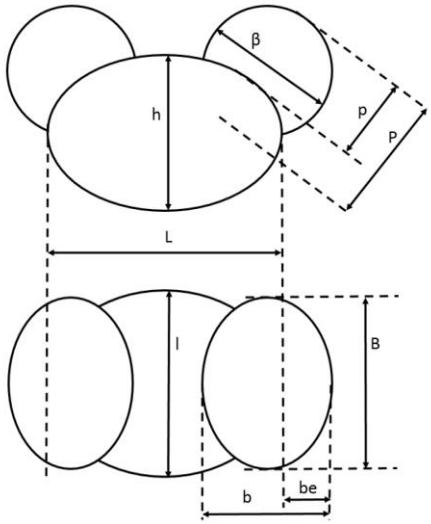

Figure 3. *Pine pollen sizes (upper: polar axis, β: length of saccus, P: height of saccus, p: distance from pollen to the outermost end of the saccus, h: height of pollen body; lower: equatorial axis, L: length of pollen, l: width of pollen, B: length of saccus, b: width of saccus, be: distance from pollen to the outermost end of the saccus)*

On December 20, 2018, cone samples were collected in order to determine the viability of the seeds in 2 years old cones of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana*. A total of 17 cones from four trees were collected from any side of canopy cover at the height of 3-6 m above soil surface. In order not to affect sustainability of its presence in the location, the number of cones was limited by also taking into account the fact that it already has a small number of individuals. The cones, which were brought to I.U.C. Faculty of Forestry, Department of Silviculture, Seed Technology and Silviculture Laboratory, were kept in drying-oven at a temperature of 46°C for 24 hours so that seeds could be taken out (Genc, 2004). Only seeds in 13 cones were counted as there were no seeds in 4 cones; seed length, width and thickness, and wing length and width were measured; and the seeds were weighed to determine their weights.

406 seeds were divided into four groups and placed on filter paper saturated with deionized water in 4 petri dishes at 20°C (±0.5°C) for germination test. The seeds were considered to be germinated when radicles showed geotropism. Seed germinations were monitored for 28 days. As the seeds germinated they removed from the petri dishes. Ungerminated seeds were checked with cutting test for soundness. Germinated seeds were planted into pots (Boydak and Çalışkan, 2014). Besides, it was ensured that they continued development in order to determine the number of cotyledon. The seeds germinated within first week of the study. Planted into pots in the nursery and monitored for seedling survival for 60 days.

In order to determine whether or not a change exists in chromosome number, mitotic chromosomes were prepared from root tips and pre-treated with α-bromo-naphthalene (ABN) at +4°C for 24 h. Roots were fixed for a minimum of 2 h in absolute ethanol:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1131711326

glacial acetic acid, (3:1,v/v), hydrolysed at 60°C in 1 N HCl for 16 min and stained in Feulgen reagent. Finally, root tips were squashed in 1% aceto-orcein. Chromosomes were counted in the groups of in the preparation prepared from the crushed root tips (Altınordu et al., 2014).

Main statistical parameters were estimated and presented in the result section (Akalp, 2016).

Results and Discussion

The results of measurements made for pollen sizes are given in *Table 1* by comparison with the results of literature studies. According to the results of observations and measurements made in pollen preparations showed that pollens of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* were not defective and that there was no obstacle for seed formation by fertilization.

* Yaman and Sarıbaş (1999), ** Aytuğ (1967), ***SD (standard deviation)

Figure 4 shows polar and equatorial view of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* pollens under LM and their exine surfaces under SEM. As in the other varieties (Yaman and Sarıbas, 1999), bisaccate pollens are inaperture; recesses and protrusions are apparent; pollen ornamentation is verrucate, and its structure is tectatae; saccus ornamentation is regular; it consists of small closed islets and canals (*Fig. 4*).

It is seen that sizes of pollens of all varieties of *Pinus nigra* subsp. *pallasiana* (*Table 1*) were similar; however, pollens of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana*, which were collected from both locations, were smaller than the pollens of other varieties. When *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* pollens of two locations (Boyabat and Yenice) were compared, it was found that the width (l), height (h) and saccus sizes (β, P, B, b, be) of pollens in Sinop were lower, while distance from pollen to the outermost end of the saccus (p) was higher. In contrast to pollens of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1131711326

Yenice (Yaman and Sarıbas, 1999), the frequency distributions of pollen dimensions of samples collected from Boyabat were normal. When L/l and L/h ratios were compared, it can be said that pollens in Boyabat is slightly flattened in equatorial view.

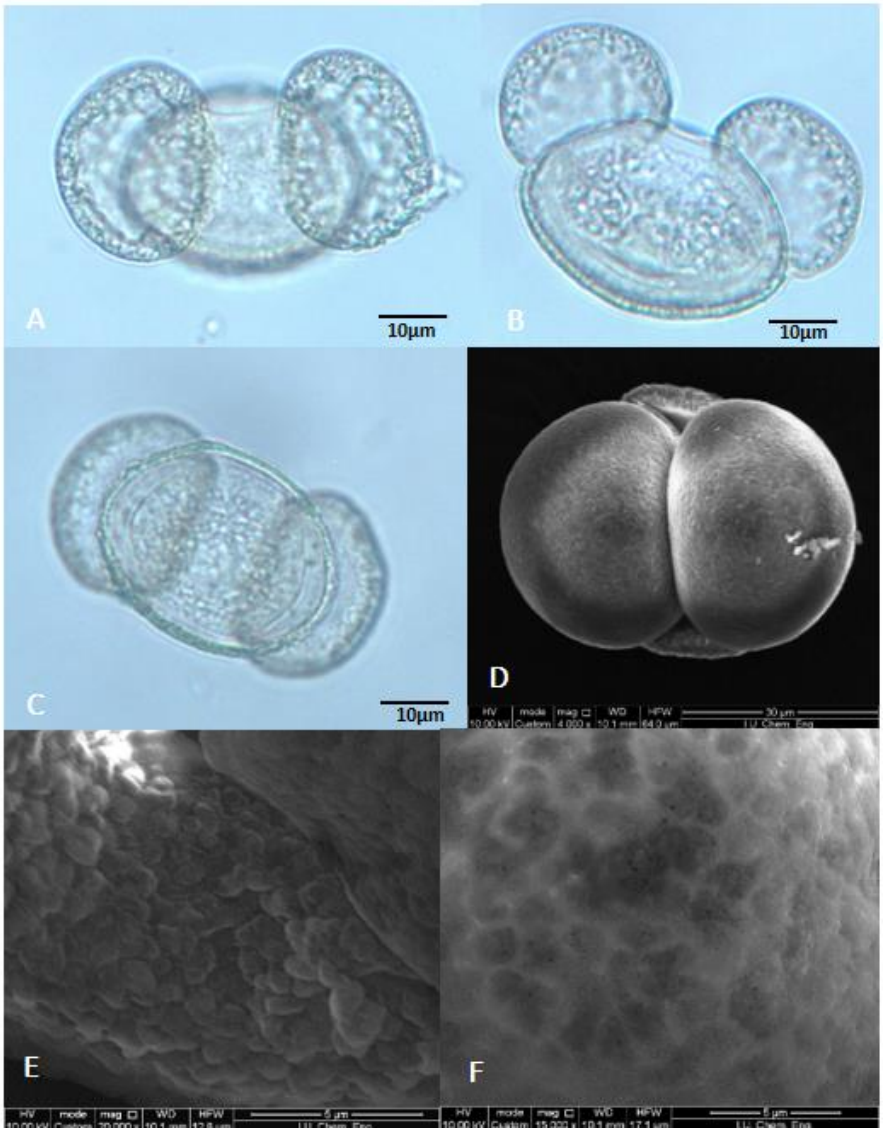

Figure 4. *Pollens of Pinus nigra* subsp. *pallasiana* var. *yaltirikiana. A-C (Light microscope-LM): A-Polar (Distal), B-Equatorial, C-Polar (Proximal) views; D-F (SEM): D-Dry pollen grain, E-Exine surface (proximal pole), F-Exine surface (saccus)*

It is shown that results of the measurements made on 406 seeds and 234 seed wings of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* in *Table 2*. The number of seeds in the first three cones were very low. The sizes of the seeds were 7.10 x 3.83 x 2.40 mm; while the seed-wing sizes were 34.88 x 8.26 mm. In literature, the seed sizes of *Pinus nigra* subsp. *pallasiana* was given as 6.5 (4-9) x 3.71 (3-4) mm; the wing sizes of it as 24.73 x 7.7 mm (Alptekin, 1987; Kandemir and Mataracı, 2018). Accordingly, wing of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* seed is longer.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1131711326

Atay (1959) stated that average germination capability of black pine seeds was 91.3%, average germination energy was 62%, and 1000 seed weight was 22.5 g. As compared to results of previous studies about seeds of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana,* mean germination percentage was 71% on 28th day and the average germination energy was 47%, and 1000 seed weight was around 21.14 g (*Table 3*). Although the germination percentage is considered as the percentage of seeds germinated within the first 7 days, the values at days 4, 7 and 10 can also be used in some cases that require precision (Boydak and Çalışkan, 2014).

Table 2. *Some characteristics of the seeds of Pinus nigra* subsp. *pallasiana* var. *yaltirikiana*

	Number of sound seed in a cone	1000 seed weight (g)	Seed (n=406)			Seed wing (n=234)	
			Length (mm)	Width (mm)	Thickness (mm)	Seed (n=406)	Width (mm)
Mean	18	21.14	7.10	3.83	2.40	34.88	8.26
Range	0-35	11.4-35.1	4.15-8.69	2.59-4.79	0.96-3.42	25.79-41.07	5.29-10.42

Table 3. *Percentages of sound seed, germination, germination rates and number of cotyledon for each cone samples of Pinus nigra* subsp. *pallasiana* var. *yaltirikiana*

	All seeds	Sound seeds	Empty seeds	Germination seeds (for all seeds)	Germination rate (for sound seeds)					Cotyledon
					4	7	10	14	28	
Number	406	198	208	140	70	93	109	126	140	8.3 (6-10)
%	-	49	51	35	35	47	55	63	71	-

As seen from *Table 3*, almost half of the seeds were sound with a germination percentage of 71 (*Fig. 5*).

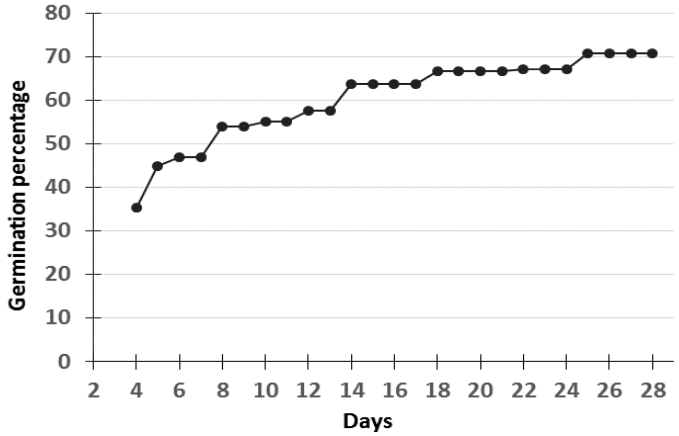

Figure 5. *Germination of Pinus nigra* subsp. *pallasiana* var. *yaltirikiana seeds under 20°C*

As compared to results of previous studies sound seed production and germination of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* was lower when sound seeds were considered. Moreover, if all seeds including unsound ones were considered, germination percentage dropped to 35%, and 49.3% of the germination took place in the four-day period in germination chamber.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1131711326

140 seeds were germinated under laboratory conditions, and germinated seeds were planted into pots. 93 out of 140 germinated seeds were planted into pots seven days after the germination and monitored for seedling survival. As seen from *Figure 6*, more than half of the seedlings (56%) died and 44% survived for 60 days.

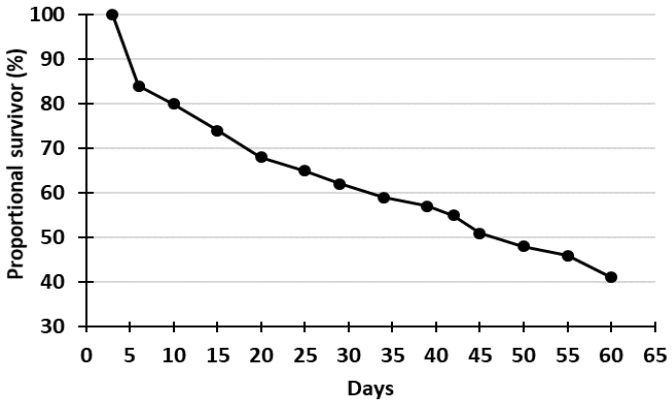

Figure 6. *Proportional survival of Pinus nigra* subsp. *pallasiana* var. *yaltirikiana seedlings*

The number of cotyledons was 8.3 (6-10). Likewise, Kaya and Temerit (1994) stated that the average number of cotyledons for 7 black pine populations they collected from Central Anatolia was 8.25.

In this study, the chromosome number of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* was determined as 2n = 24, as known for black pines (Kaya et al., 1985; Salajova and Salaj, 1992; Hizume et al., 2002; Naydenov et al., 2003).

Ensuring the continuity of the limited number individuals of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* in the natural distribution area is important in terms of genetic diversity and sustainability. These individuals should be taken under conservation by in-situ and ex-situ conservation strategies. As it is determined that seeds with the capacity to produce sound seeds and capability of germination can be obtained through current *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* individuals in the area, seedlings to be grown in the nursery by seeds with these characteristics can be planted around existing individuals to increase the number of theirs in this area.

In addition, seed orchard can be established in a different area by taking grafts from existing individuals, and sound seeds with the capability of germination can be obtained from these individuals. On the other hand, on the long run, observation must be performed in terms of purity of these seeds against the possibility of fertilizing female flowers of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana* individuals of the pollens of *Pinus nigra* subsp. *pallasiana* var. *pallasiana* individuals located in the same spread area.

Conclusions and Suggestions

Pinus nigra subsp. *pallasiana* var. *yaltirikiana* is an endemic variety in Turkey. The chromosome numbers of this taxon was found to be as 2n = 24. Its pollen dimensions were measured and the result showed that pollen seemed healthy with good shape. Therefore, we can conclude that there is nothing wrong with the pollens for reproduction of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana.* On the other hand, it

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1131711326

seemed that this plant taxon has poor cone, germinable seed production with poor seedling survival. Because 49% of the seeds were sound, and 71% of them germinated within 28th days. Additionally, only 44% of seedlings survived and more than half of the seedlings (56%) died within 60 days. These meant that seedling survival of this taxon under nursery conditions was poor. Sound seed production and their germination percentage were lower compared to the results of previous studies. These findings can be considered as an indicator of poor reproduction of *Pinus nigra* subsp. *pallasiana* var. *yaltirikiana.* As it has a limited distribution, it is possible that this taxon which is in danger of survival in the near future, can be removed successfully from the list of danger categories in the future with the protection of the habitat and protection efforts for population growth. Some additional studies are needed for better understanding for seedling survival and growth under field conditions in the second step. It is necessary to maintain the existing stand of this tree firstly to ensure the sustainability of the taxon; and then to increase the presence in the natural distribution area with the individuals to be grown from the seeds.

Acknowledgments. I would like to thank Assoc.Prof.Dr. Ilker Genc for his help in determination of chromosome number; Mr. Mustafa Diktas (Manager) and Mr. Fatih Sahin (Chief) from Sinop-Boyabat Forest Enterprice for their help in field studies.

Abstract. This research studied the six heavy metal contents, their distribution and the level of pollution in sediments at Haizhou Bay in 2009 and 2014. It was found that the content of cadmium (Cd), lead (Pb), zinc (Zn) and copper (Cu) accounted for the major factors in the sediments at Haizhou Bay. The content of major pollutants presented a declining trend from south to north, and the Pb-intensive area moved from the southern waters of the study area in 2009 to the northern waters of Ganyu Port in 2014. Analysis of the pollution load index shows that the study area suffers from medium-level pollution; the most polluted area was the waters around the estuary of Dragon-King River in 2009 and Ganyu Port in 2014, which meant that development of the port had significant impact on the heavy metal contents. Assessment based on the geo-accumulation index shows that Pb pollution deteriorated and Cd pollution abated slightly over the past 5 years. Analysis of comprehensive potential risk index indicates that the ecological risk of the study area from 2009 to 2014 was at the low-medium level, with Cd being the major contributor to the risks.
Keywords: *pollution assessment, spatial distribution, variation characteristics, potential ecological risk*

Introduction

A bay is a recessed area where the ocean stretches into a continent, and as an area that connects a continent with the sea, it provides a space where life and production thrive and where sediments and pollutants from rivers converge (Wang et al., 2008; Reddy et al., 2016). Heavy metal contents are toxic, durable, bio-accumulative, contributive to ecological risks and hard to decompose (Nguyen et al., 2016; Harikrishnan et al., 2017; Jahan and Strezov, 2018; Zhao et al., 2018). Due to these features, heavy metal pollution is a growing concern throughout the world, posing threats to marine ecology and human health (Rahman and Ishiga, 2012; Phillips et al., 2015; Keshavarzi et al., 2018; Wang et al., 2018). In these years, many bays across the world have suffered disproportional heavy metal pollution (Hyun et al., 2007; Qiao et al., 2013; Zhang et al., 2017; Pejman et al., 2017; Celishernandez et al., 2017; Naifar et al., 2018; Qu et al., 2018; Liang et al., 2018). Heavy metals, after finding their way into the water, adhere to and accumulate in suspended sediments before being released into the water again through complicated desorption mechanisms, so marine sediments are the "confluence" and "source" of heavy metal contents (Singh et al., 2005; Guan et al., 2016). Therefore, it is of great significance to record the heavy metal contents in sediments as an environmental indicator.

Located in the northern waters of Lianyungang in Jiangsu province of China, Haizhou Bay is the only bay-styled waters in Jiangsu and is renowned as one of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1132711339

eight largest fishing ports in China for its rich marine resources. As development of coastal regions in Jiangsu was upgraded into a national project in 2009, industrial activities along the coastline boomed and port development projects in the northern waters witnessed a rise. Previous studies on Haizhou Bay have probed into topics like the content, spatial distribution and pollution of heavy metal contents. Li and Xu (2014) researched the distribution and pollution of heavy metal contents in surface sediments; Zhang et al. (2013) researched on pollution of heavy metal contents in intertidal column sediments. At the year end of 2012, Ganyu Port in northern Haizhou Bay was put into operation, which inevitably led to ecological impacts on this area (Dobaradaran et al., 2018; Jahan and Strezov, 2018), but research in the influence of the port on Haizhou Bay is absent. In this study, the heavy metal pollution levels were assessed in surface sediments of Haizhou Bay in 2009 and 2014. The study objectives were to: (1) analyze the content and spatial distribution characteristics of six heavy metal contents in surface sediments in 2009 and 2014 and determine the main pollution factors of Haizhou Bay sediments; (2) Assess the content and distribution of heavy metal contents in sediments over the past five years and analyze the causes; (3) assess the extent of the contamination and ecological risks of the six heavy metal contents in sediments. This study analyzed the changes of sediments in the study area and the influence of human activities on sediments to provide data support and a scientific basis for ecological protection in Haizhou Bay.

Materials and methods

Introduction to the study area

Located in the northeast of Lianyungang city in Jiangsu province, China, Haizhou Bay is a half-open bay that adjoins East-West Tied-island of Lianyungang city on the north and reaches Mount Lan in Shandong province northwards. The seabed slopes to the east and presents a landform of "scouring in the north and silting in the south". Sediments in this area are diverse, with grits being the main sediment in the northern part, silt in the central part and clay in the southern part (Zhang and Feng, 2009; Liu et al., 2010), so the size of sediment particles increases from south to north. On the west of Haizhou Bay are estuaries of over ten rivers including Xiuzhen River and Dragon-King River which bring pollutants from the continent to the bay. Haizhou is a traditional fishing port which, as the port-based industries took off and the Ganyu Port area was put into operation in 2012, has risen to the focus in Jiangsu's initiative to extend the port and boost port-based economy.

Sampling and sample processing

On-site sampling was done in December 2009 and October 2014, and 10 samples of surface sediments were collected each time. The sampling sites are shown in *Figure 1*. The research targets are six types of heavy metal contents – Cd, As, Cu, Pb, Cr and Zn. Sampling and analysis performed in October 2014 were in accordance with technical standards specified in "The Specification for Marine Monitoring – Part 5: Sediment Analysis" (GB17378.5-2007). Using the grab sampler, we collected 3 to 4 sample surface sediments with a grain diameter within 5 cm and placed the samples into wide-mouthed reagent bottles and polyethylene bags for frozen storage. During analysis of the samples, we made use of atomic absorption spectrometry (AAS) to detect Cu, Pb,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1132711339

Zn, Cr and Cd, and used atomic absorption spectrometry to detect As. All reagents used for analysis of heavy metal contents were guaranteed reagents and water used in experiments was ultrapure water. Meanwhile, parallel samples were used to realize quality control and the testing errors between parallel samples of these six heavy metal contents were all below 5%. The heavy metal content detection method performed is detailed in the reference by Li and Xu (2014).

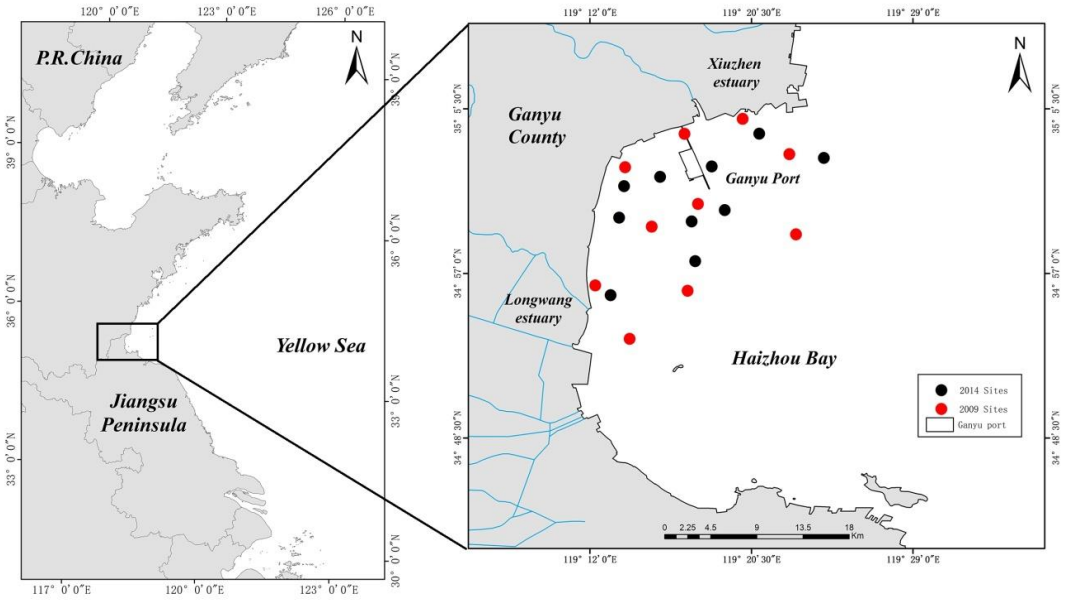

Figure 1. *Location of sample sites*

Methods

Pollution load index (PLI)

The pollution load index was first proposed by Tomlinson in 1980 to assess pollution by different chemical elements at different sites. The equations for calculation are:

$$PLI=\sqrt[n]{C_f^1 \times C_f^2 \times C_f^3 \times \ldots \times C_f^n} \quad \text{(Eq.1)}$$

$$C_f^i = C_n^i / C_0^i \quad \text{(Eq.2)}$$

where PLI refers to the pollution load index of a certain site, C_f^i the pollution index of one element, C_n^i the value obtained through actual measurement, and C_0^i the background value. The grading standard for PLI (Tomlinson et al., 1980; Zhu et al., 2013) is shown in *Table 1*.

Geo-accumulation index

Geo-accumulation Index (Igeo) was first proposed by G. Müller, a German scientist. It is a quantitative index for assessment of heavy metal contents in sediments and can be used to assess pollution caused by heavy metal contents. The calculation equation is:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1132711339

$$I_{\text{geo}} = \log_2 \frac{C_n}{1.5B_n} \quad \text{(Eq.3)}$$

where Cn denotes the content of Element n in actual measurement, and Bn is the background value of this element on earth which, in this research, specifically refers to the background value of the content of the researched element in the tidal marsh of Jiangsu province measured in the 1980s by Chen et al. (1985). 1.5 is a coefficient identified by considering possible changes caused by differences of rocks in different places. The grading standard of geo-accumulation index (Müller, 1969) is also shown in *Table 1*.

Potential ecological risk index

The potential ecological risk index was first proposed by a Swedish environmentalist named Hakanson in 1980 to assess the potential ecological hazards of heavy metal contents in sediments. This method combines the ecological impact, environmental impact and toxicologic research of heavy metal contents to reflect the potential ecological risks of heavy metals. The calculation equations are:

$$C_f^i = C_{\text{n}}^i / C_0^i \quad \text{(Eq.4)}$$

$$E_r^i = T_r^t \times C_f^i \quad \text{(Eq.5)}$$

$$RI = \sum (E_{\text{r}}^i) \quad \text{(Eq.6)}$$

where *RI* is the value of comprehensive potential ecological risks, E_r^i the value of potential risks of one element. T_r^t denotes the toxicological coefficient of an element which, in this research, adopts the standard toxicological coefficients of heavy metal contents proposed by Hakanson (1980): the respective toxicological coefficients of Cd, As, Cu, Pb, Cr and Zn are 30, 10, 5, 5, 2, and 1. C^i_f is the pollution coefficient of a certain element, $C_n{}^i$ the value obtained through actual measurement and $C_0{}^i$ the background value. The grading standard for the potential ecological risk index of a given element and for the comprehensive potential ecological risk index is also presented in *Table 1*.

Results and discussion

Changes in the heavy metal contents

The heavy metal contents in surface sediments in the study area detected in 2009 and 2014 are shown in *Table 2*. The ranges of the heavy metal contents (mg/kg) at different sampling sites in 2009 were: 3.89-8.26 for As (averaged at 5.42), 10.9-29.5 for Cu (averaged at 17.85), 11.8-19.7 for Pb (averaged at 15.875), 37.4-98.8 for Zn (average at 61.96), 38.6-94.9 for Cr (averaged at 63.1) and 0.0964-0.247 for Cd (averaged at 0.144). The ranges of the heavy metal contents (mg/kg) at different sampling sites measured in 2014 were: 6.32-11.31 for As (averaged at 9.16), 11.89-30.69 for Cu (averaged at 20.97), 21.40-43.28 for Pb (averaged at 31.59), 15.6-118.70 for Zn

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1132711339

(averaged at 81.29), 24.74-77.01 for Cr (averaged at 47.38), 0.07-0.15 for Cd (averaged at 0.11). Compared with the data in 2009, the average content of Pb, As, Zn and Cu increased by 98.68%, 68.85% and 17.48% in 2014, while the average content of Cd and Cr declined by 23.83% and 24.90%, respectively. In comparison with the heavy metal contents in sediments obtained by studies in China and other countries (see *Table 2*), the content of Cu, Cd and Pb in sediments in Haizhou Bay exceeded that in other regions, and the content of Zn and Cr stayed at a medium level.

Table 1. *Grading standard for geo-accumulation index and potential ecological risk index of heavy metal contents*

I_{geo}	Pollution Level	*PLI*	Pollution level	E_r^i	Single-factor potential ecological risk	*RI*	Comprehensive potential ecological risk
≤ 0	No pollution	< 1	No pollution	< 40	Low	< 110	Low
0~1	Mild pollution	1~2	Medium pollution	40~80	Medium	110~220	Medium
1~2	Mild-medium pollution	2~3	Heavy pollution	80~160	Medium-high	220~440	High
2~3	Medium pollution	≥ 3	Severe pollution	160~320	High	≥ 440	Extremely high
3~4	Serious pollution			≥ 320	Extremely high		
4~5	Heavy pollution						
> 5	Severe pollution

n.d.: not detected

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1132711339

In 2009, the average content of five heavy metals – Cd, Pb, Zn, Cu and Cr, exceeded the background value of the heavy-metal content in the tidal marsh of Jiangsu province, the detected values of these five heavy metals being 3.42 times, 1.39 times, 1.31 times, 1.19 times and 1.05 times as much as the background values, so Cd, Pb, Zn and Cu are the main factors that exceeded the background value. In 2014, the average content of five heavy metals – Pb, Cd, Zn, Cu and As, exceeded the background value of heavy-metal content in the tidal marsh of Jiangsu province, with the detected values of these five metals being 2.77 times, 2.51 times, 1.72 times, 1.40 times and 1.24 times as much as the background values, so the main factors that exceeded the average value are Cd, Pb, Zn and Cu. The degree to which the content of Pb, Zn and Cu exceeded the background value increased, among which the most salient was that of Pb; though the degree to which the content of Cd exceeded the background value declined, its degree of enrichment remains salient.

Spatial distribution of major factors of high-level content

In light of results of research done in 2009 and 2014 (locations of research sites are shown in *Fig. 1*), we concluded the distribution of major factors of high-level content (Cd, Pb, Zn and Cu) in *Figure 2*.

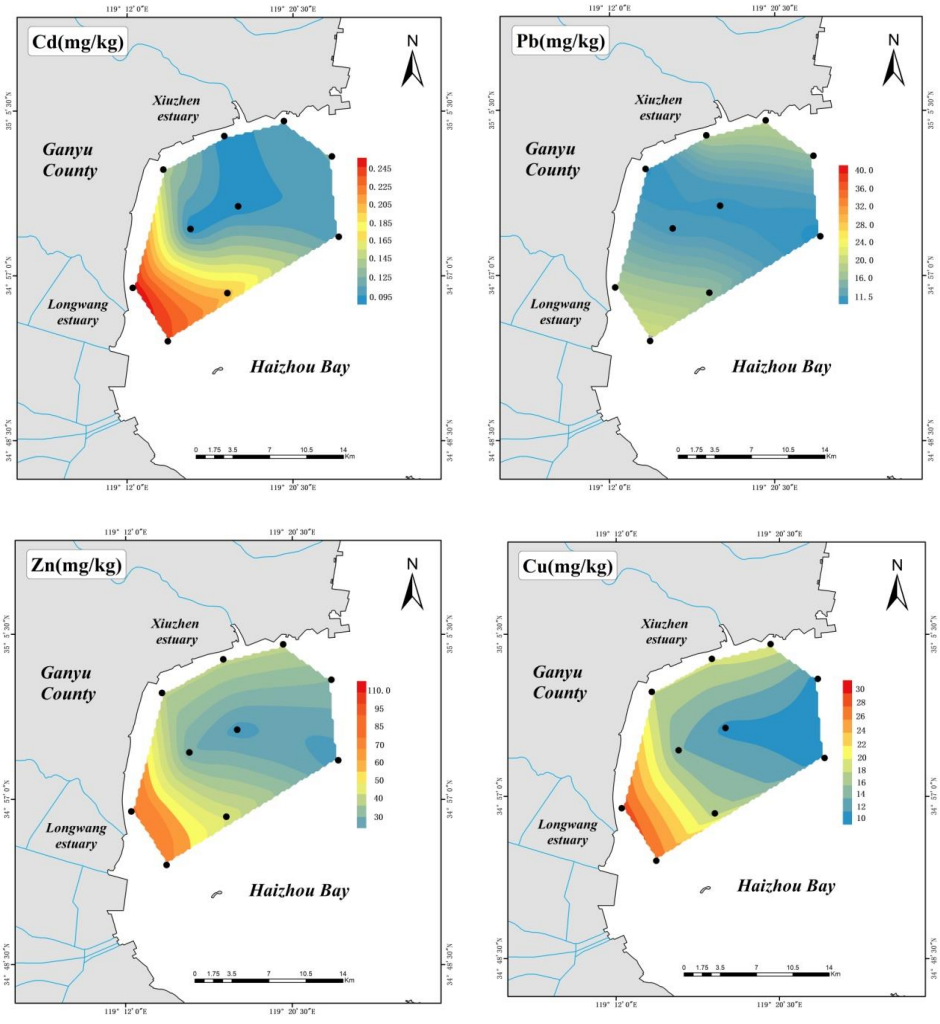

Figure 2. a *Spatial distribution of heavy metal contents in 2009*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1132711339

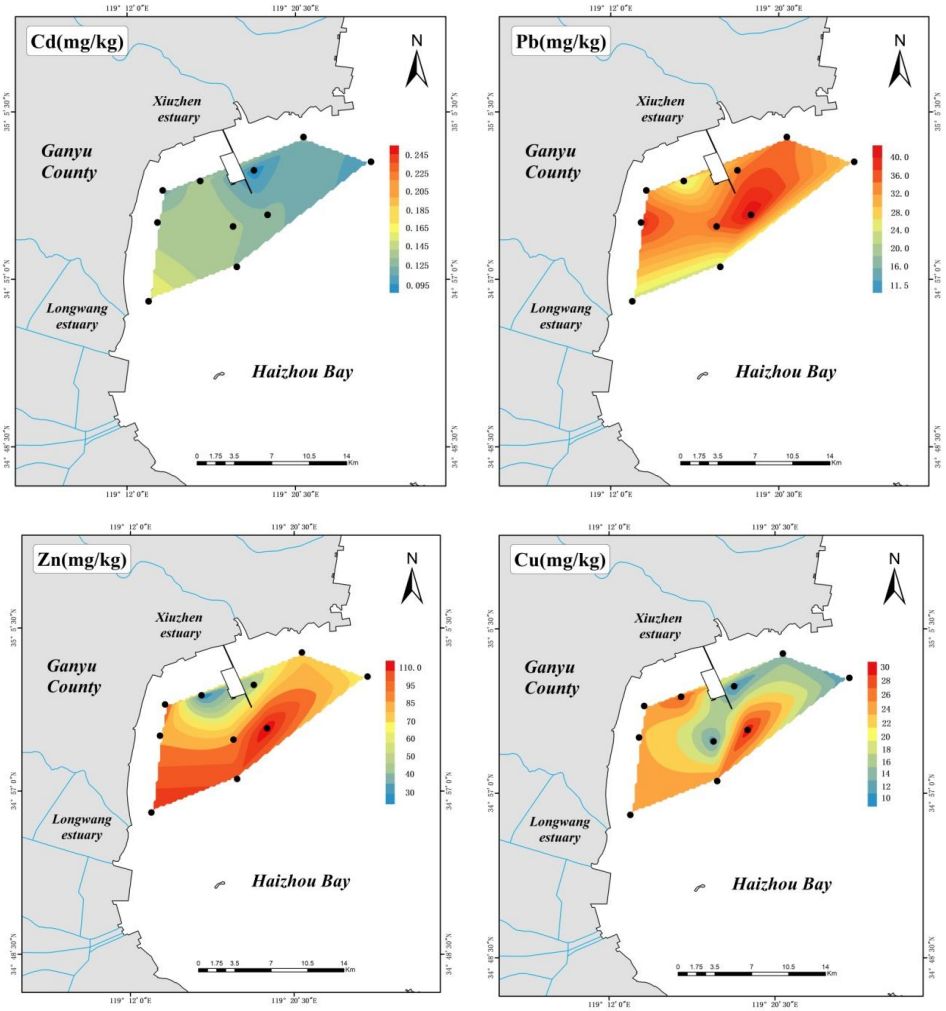

Figure 2. b *Spatial distribution of heavy metal contents in 2014*

In 2009, the content of these four heavy metal contents declined from south to north, and the distribution of Cd, Zn and Cu nearly followed the same pattern as in 2009. Like the heavy metal contents, the size of sediment particles also followed a declining trend from south to north. As proved by many previous studies, the heavy metal contents and the size of sediment particles are interrelated (Li et al., 2015): the larger the surface area of a sediment particle, the more heavy metals it absorbs, and the larger the grain size, the lower the level of enrichment of heavy metals. However, the Pb-intensive area moved from the southern waters in 2009 to the waters around Ganyu Port in 2014, which indicated that the increase of pollutants from ships due to development of Ganyu Port led to a rise of the heavy metal contents.

Characteristics of heavy-metal pollution

Table 3 shows the pollution load index (*Eqs. 1* and *2*) of heavy metal contents in surface sediments in the study area, and *Figure 3* demonstrates the distribution of the pollution load index in sampling sites. In 2009, the pollution load index at the sampling sites changes between 0.92 to 1.96, and the pollution level varies from no pollution to medium pollution. Among all the sampling sites, 80% are rated as medium pollution

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1132711339

and 20% rated as no pollution. In 2014, the pollution load index at the sampling sites changes between 1.12 and 2.12, and the degree of pollution varies from medium pollution to severe pollution; 10% of the sampling sites suffer from severe pollution and 90% from medium pollution. Thus, the pollution load index in 2014 is higher than that in 2009. From the map for distribution of pollution load index, the waters around the estuary of Dragon-King River had the highest pollution load index in 2009, while in 2014, both the estuary of Dragon-King River and the waters around Ganyu Port had a high pollution load index, making Ganyu Port another area of severe pollution. It indicates that development of the bay has led to tangible impacts on the sediments and hence deserves more attention.

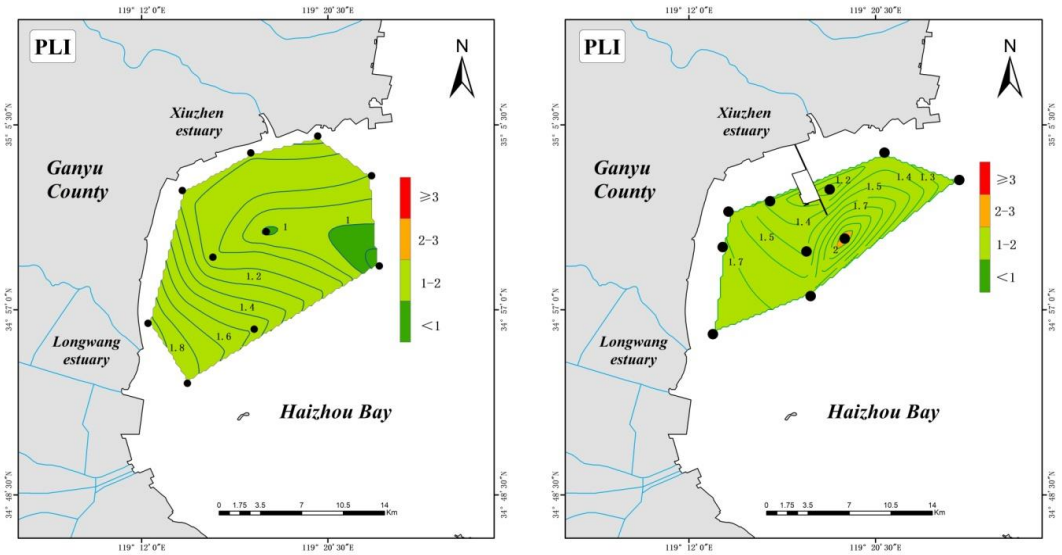

Figure 3. *The distribution of the pollution load index of heavy metals in surface sediments*

DOI: http://dx.doi.org/10.15666/aeer/1705_1132711339

Table 4 demonstrates assessment of the geo-accumulation index (*Eq. 3*). In 2009, the mean of the geo-accumulation index of the six heavy metals in surface sediments in Haizhou Bay is sequenced as Cd > Pb > Zn > Cu > Cr > As, among which Cd shows the highest level of enrichment and is rated as mild-medium pollution in terms of the level of pollution, As is rated as no pollution and the other four metals are rated as clean or mild pollution. In 2014, the mean of geo-accumulation index of the six heavy metal contents in surface sediments in Haizhou Bay is sequenced as Pb > Cd > Zn > Cu > As > Cr, among which Pb has the highest geo-accumulation index and is rated as severe pollution, followed by Cd, and the other four metals are rated as clean or no pollution in terms of the level of pollution. It can be concluded that from 2009 to 2014, the pollution of Pb witnessed a tangible increase while the pollution of Cd has been mitigated. In light of the spatial distribution of Pb in 2014, it can be seen that Pb accumulates in waters around Ganyu Port and its accumulation is closely linked to the number of ships. Relevant studies have proved that consumption of leaded gasoline would increase the content of Pb in the environment (Blake and Goulding, 2002; Wilcke et al., 1998; Lv et al., 2015). The Ganyu Port is teeming with ships and burning of leaded gasoline increases the risks of Pb pollution. Cd is a standard element in fertilizers (Lv et al., 2015). The mitigation of Cd pollution may be attributed to promotion of advanced agricultural technologies, strengthened control over fertilizers and other ecological protection measures.

Table 4. *Geo-accumulation index and potential ecological risk index of heavy metals in surface sediments of the study area*

Assessment of potential ecological risk

According to *Table 1*, we achieved the potential ecological risk of each heavy metal (*Eqs. 4* and *5*) and the comprehensive ecological risk (*Eq. 6*) in 2009 and 2014, as shown in *Table 4*. *Figure 4* shows the distribution of the comprehensive ecological risk index. In 2009, the mean of potential ecological risk of As, Cu, Pb, Zn, Cr and Cd is 7.35, 5.94, 1.39, 6.97, 2.10 and 102.59; and when these metals are sequenced according

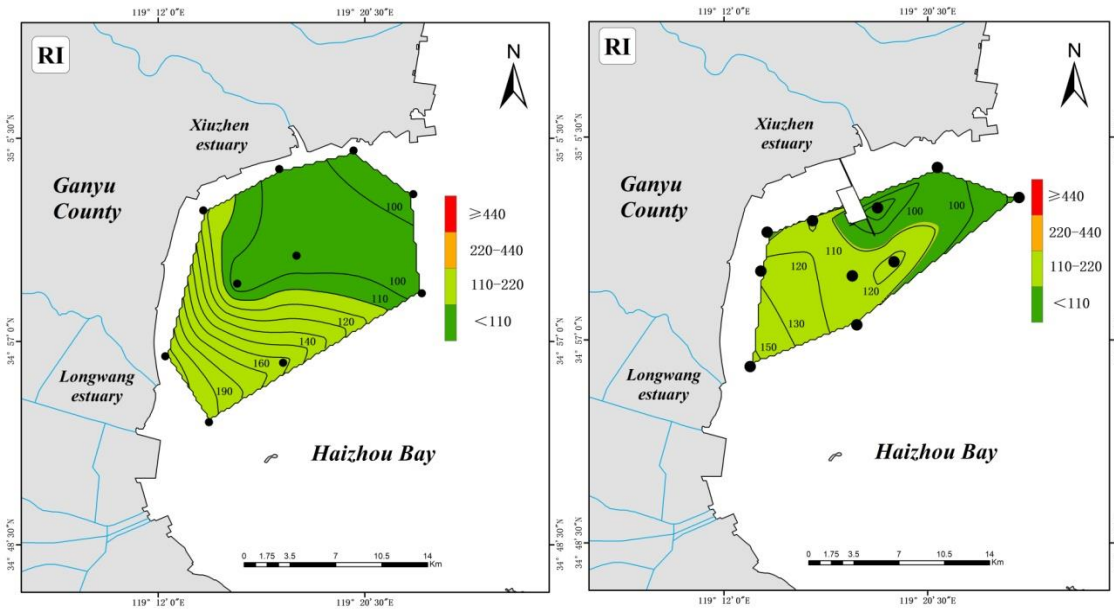
to the size of the mean, it is Cd > As > Zn > Cu > Cr > Pb, and the ecological risk of Cd is rated as medium ~ high. In 2014, the mean of potential ecological risks of As, Cu, Pb, Zn, Cr and Cd is 12.41, 6.98, 2.77, 13.86, 1.58 and 75.43, so the sequence changes into Cd > Zn > As > Cu > Pb > Cr, and the ecological risk of Cd is rated medium ~ relatively high. From 2009 to 2014, Cd remains the main contributor to potential ecological risks in the study area.



2009 **2014**

Figure 4. *The distribution of the comprehensive ecological risk index*

In 2009, the mean of RI (comprehensive potential ecological risk index) of the study area is 126.35, which falls between 90.33 and 208.14, rated low ~ medium in terms of the level of risks. In 2014, the mean of RI is 113.02, which falls between 89.92 and 141.14, rated low ~ medium in terms of the level of risks. According to the map of comprehensive potential ecological risk index distribution (*Fig. 4*), from 2009 to 2014, the comprehensive potential ecological risk index reaches the highest level in the waters around the estuary of Dragon-King River and declines northwards, which is consistent with the spatial distribution of the main pollutant – Cd. Therefore, the waters around the estuary of Dragon-King River remains a region most susceptible to ecological risks in the study area and hence deserves more attention.

Conclusion

As the result shows, in 2009, the average content of As, Cu, Pb, Zn, Cr and Cd is 5.42, 17.85, 15.875, 61.96, 63.1 and 0.144, respectively (unit: mg/kg), while in 2014, the number changes to 9.13, 21.45, 31.99, 84.80, 48.85 and 0.11 (unit: mg/kg). From 2009 to 2014, Cd, Pb and Zn account for the main factors that push the value of heavy-metal content in Haizhou Bay above the soil background value of tidal marshes in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1132711339

Jiangsu province; the content of Pb, Zn and Cu rises, with Pb witnessing the largest increase; the content of Cd decreases slightly but its level of enrichment remains high.

The major pollution factors in 2009 (Cd, Pb, Zn and Cu) and those in 2014 (Cd, Zn and Cu) present a similar trend in spatial distribution, with their content declining from south to north, but the Pb-intensive area moved from the southern waters in 2009 to the waters around Ganyu Port in 2014.

Analysis of the geo-accumulation index shows that from 2009 to 2014, the pollution of Pb witnessed tangible increase while the pollution of Cd was mitigated. Analysis of the pollution load index shows that the study area suffers from medium-level pollution and the pollution increases from 2009 to 2014. In 2009, the estuary of Dragon-King River was the most polluted area, while in 2014, the waters around Ganyu Port accounted for another severely-polluted area, which reflects the obvious influence of port development on the heavy metal contents in sediments in the study area. The pollution of Cd is closely linked to the amount of pollutants brought by Dragon-King River from the continent.

Analysis of the single-factor potential ecological risk shows that the ecological risk of Cd is rated medium ~ high, while that of other heavy metals is rated low. Assessment of the comprehensive potential ecological risk shows that the ecological risk of the study area from 2009 to 2014 is rated low ~ medium, the waters around the estuary of Dragon-King River remains a region most susceptible to ecological risks and is hence worth more attention.

Cd, Pb, Zn and Cu are the main pollution factors in the sediments of the study sea area. Further attention should be paid to the changes trend of these four heavy metal contents and their influencing factors in the sediments of the study sea area in the future. Pollution from rivers and ports has affected the heavy metal contents of sediments in the study area. With the construction and development of Ganyu Port, its impact on heavy metals in sediments needs further investigation and study. In the future, we should strengthen the control of river and port discharge in the study area to reduce the impact on heavy metals in marine sediments.

Abstract. According to the fish checklist of 16 nature reserves in the Wuyi Mountains of China, a total of 126 freshwater fish species belonging to 5 orders and 17 families were present. Cypriniformes (consisting of 101 species and accounting for 69.8% of the total) was the major components of the fish fauna. And species of family Cyprinidae comprised 51.6% of the total and classified into 10 subfamilies. Overall, 72 species (57.1% of the total) were endemic to China. The comparison of species richness, endemic species richness and values of F-index, G-index and G-F index between the west and east slopes of Wuyi Mountains showed that there was a higher fish species diversity in the east slope. And among the three districts (i.e. the north, middle and south sections of Wuyi Mountains), fish species diversity was highest at the north section, good at the middle section and lowest at the south section. We divided 16 nature reserves into two regions according to geographical location and four regions according to river type through cluster analysis. Current threats to conservation of fish species diversity in the Wuyi Mountains were reviewed and management solutions were suggested.
Keywords: *freshwater fish, species diversity, nature reserve, Jiangxi Province, Fujian Province*

Introduction

The Wuyi Mountains is located in the southeast of China, and on the borderline between Jiangxi and Fujian province (*Fig. 1a*). It runs from the northeast to southwest with a length of about 540 km, and the highest peak is up to 2158 m. Therefore, the mountain range had been given "roof of the East China" (Guan, 2016). Streams in the mountain range flow into the Yangtze, Oujiang, Minjiang and Hanjiang rivers which drain into the East and South China seas (*Fig. 1b*). And the mountain range presents a subtropical humid monsoon climate with four distinct seasons. The annual average precipitation of Wuyi mountain is 1600 mm and 2000 mm, and the mean annual temperature range is from 17 to 20 °C, and annual average relative humidity was up to 78% (Guan, 2016).

In addition, the mountain range is a key area for the conservation of biodiversity in Chinese ecosystems. And it preserves the most typical, intact and largest zonal evergreen broad-leaved forest and subtropical forest ecosystems at the same latitudinal band of the world, so the mountain range had been called the "natural botanical garden", "insect world", "avian paradise" and so on (Liu et al., 2012). Fujian Wuyishan Nature Reserve (NR), the first national nature reserve, was created in 1979. By 2015, 45 nature reserves of different grades and types were established including 15 national

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1134111357

NRs, 14 provincial NRs, one city-level NR and 15 county-level NRs. Except for one paleontological relic reserve and seven wildlife reserves, the others are forest ecological reserves (Ministry of Ecology and Environment of the PRC, 2016). Among the 45 NRs, Tongboshan NR, Jiangxi Wuyishan NR, Yangjifeng NR, Matoushan NR, Ganjiangyuan NR, Jinpenshan NR, Lingyunshan NR, Laohunao NR, Fengyangshan NR, Fujian Wuyishan NR, Emeifeng NR, Minjiangyuan NR, Longxishan NR, Junzifeng NR, Tianbaoyan NR, and Guilongshan NR were investigated on fish species diversity. The Wuyi Mountains can be divided into two areas (east slope and west slope), the boundary between east slope and west slope is the ridge of Wuyi Mountains, not only important in physical geography, but also divided Jiangxi Province and Fujian Province. From north to south, the altitude of Wuyi Mountain ranges is getting lower, and can be divided into three regions (north section, middle section and south section) through the geographical division and the description of the location in the investigation report of the nature reserve (Zhong, 2004; Chen et al., 2009).

Figure 1. *Maps showing the locations of Wuyi Mountains (a) and 16 nature reserves (b). In the map b, the Wuyi Mountains (the yellow elliptical region) is divided into two areas (west slope and east slope) by a dotted red line and three districts (north section, middle section and south section) by two blue broken lines*

The 16 NRs are evenly located in the east and west slopes of the Wuyi Mountains, and lie on the north, middle and south sections of the mountain range (*Fig. 1b*). And the basic information of the 16 NRs was given in (*Table 1*).

Almost all of the rivers in those NRs were characterized by shallow water depths, surrounding by mountains, narrow channel widths and relatively fast currents flowing over boulder substrate. The main rivers in NRs are: Shiwudugang River in ToNR; Yanshanhe River in JWNR; Luxihe River, Luotanghe River and Guiganghe River in YNR; Matoushanhe River, Douhuanhe River in MaNR; Guganghe River in LaNR; Linchihe River in LiNR; Shiliaohe River, Pantianhe River in GaNR; Daqiaohe River in JiNR; Haohe River in FNR; Futunxi River, Chongyangxi River in FWNR; Shanxi

At present, many researchers have investigated biodiversity and distribution of the bryophytes, ferns, vascular plants, freshwater crabs and reptiles in the Wuyi Mountains (Guan, 2006; Li et al., 2006; Ye et al., 2007; Zhu, 2010; Cheng et al., 2011; Shi et al., 2012). Although many scholars have studied the biodiversity and composition of fish and published many related articles, the diversity of fish species in mountainous areas has not been comprehensively studied. In order to systematically understand the species diversity of fish in Wuyi Mountain, it is very important to comprehensively analyze the spatial distribution and composition of fish in Wuyi Mountain. The objectives of this study are to: (1) to describe the species composition and diversity of fish in 16 nature reserves; (2) analyse the biodiversity and relationship of fish in 16 nature reserves.

Materials and methods

Many papers have studied on the fish in 16 nature reserves, which is A good compilation opportunity to make a fish species list to research the Wuyi mountain's biodiversity. (Anonymity, 1981, 1997; Lin, 2002, 2004; Lin et al., 2005; Liu and Fu, 2006; Guo et al., 2011; Hu et al., 2011, 2015, 2018; Liu et al., 2012; Zeng et al., 2013; Li et al., 2015; Miao et al., 2016; Zhu et al., 2017). By re-analyze and summarize the research results of fish species diversity in nature reserves, biodiversity information can be obtained.

Nowadays, the G-F index is an important method for studying fish diversity, which is usually used to analyze species diversity of birds and mammals (Jiang and Ji, 1999; Yu et al., 2005; Li and Wu, 2006; Cai et al., 2009; Huang and Liu, 2011). Computing the diversity indexes at the genus level (G-index) and the family level (F-index); then to calculate the ratio of G-index and F-index as G-F index, the values can be either positive or negative.

(1) F-index:

$$D_F = -\sum_{k=1}^{m} D_{Fk} = -\sum_{k=1}^{m}\sum_{i=1}^{n} p_i lnpi \quad \text{(Eq.1)}$$

where n = the number of genera in family k, pi = Ski/Sk, Ski = the number of species in genus i, Sk = the number of species in family k, m = the total number of families in the class.

(2) G-index:

$$D_G = -\sum_{j=1}^{p} q_j lnq_j \quad \text{(Eq.2)}$$

where qj = Sj/S, Sj = the number of species in genus j, S = the total number of species in the class, p = the total number of genus in the class.

(3) G-F index:

$$D_{G\text{-}F} = 1 - D_G / D_F \quad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1134111357

Cluster analysis is often used to study the distribution of fish species and other community ecological problems. (Yin et al., 2016). A dataset containing all species from each site has been established to enable similarity measurements based on the presence (1) or absence (0) of each species from each site. (Huang et al., 2013). Pairwise similarities among all sites were computed in order to create a similarity coefficient matrix. The hierarchical cluster, furthest-neighbour method with pearson correlation was used for cluster analysis based on the matrix. All analyses were performed using SPSS 13.0 software.

Results

Composition of fish species

126 freshwater fish species (see Appendix 1) in the 16 NRs were recorded, belonging to five orders and 17 families. Cypriniformes (comprised of four families and 88 species, 69.8% of total species) was the dominant order followed by Siluriformes (five families and 21 species, 16.7%) and Perciformes (five families and 13 species, 10.3%), while Anguilliformes and Synbranchiformes were represented by two species respectively (*Table 2*). Species of family Cyprinidae comprised 51.6% of the total species richness and classified into 10 subfamilies (i.e. Danioninae, Leuciscinae, Cultrinae, Xenocyprinae, Hypophthalmichthyinae, Acheilognathinae, Gobioninae, Gobiobotinae, Cyprininae and Barbinae).

Table 2. *Fish diversity indices in different districts of the Wuyi Mountains, China*

District	G-index	F-index	G-F index	Species richness
West slope	1.6628	2.3287	0.2860	77
East slope	1.8365	2.9620	0.3800	100
North section	1.6261	2.9232	0.4437	91
Middle section	1.7948	3.0614	0.4137	101
South section	1.3090	1.5061	0.1309	30

Overall, 72 species (57.1% of the total species) are endemic to China, belonging to 11 families. Cyprinidae is the dominant family of endemic species (33 species) and the subdominant family was Balitoridae (16 species), and Bagridae (11 species), while Cobitidae, Amblycipitidae, Percichthyidae, Gobiidae, Sisoridae, Siluridae, Ondontobutidae and Osphronemidae were represented by only one or two species respectively (see *Appendix*).

Spatial variation of fish species diversity

Among the 16 NRs, eight reserves (including ToNR, JWNR, YNR, MaNR, LaNR, LiNR, GaNR and JiNR) are located in the west slope of the Wuyi Mountains, while other reserves (FNR, FWNR, ENR, MiNR, LoNR, JuNR, TiNR and GuNR) lie on the east slope of the mountain range. In addition, four reserves (ToNR, JWNR, FNR and FWNR) are located in the north section of the Wuyi Mountains, nine reserves (YNR, MaNR, LaNR, LiNR, ENR, MiNR, LoNR, JuNR and TiNR) in the middle section of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1134111357

the mountain range, and three reserves (GaNR, JiNR and GuNR) in the south section of the mountain range (*Fig. 1b*).

A greater number of species (average: 42 vs. 21) and endemic species (19 vs. 11) were recorded from the east slope of the Wuyi Mountains compared to the west slope of the mountain range (*Fig. 2*). And the number of species and endemic species from the north section of the Wuyi Mountains was the largest (average: 36 and 20), followed by the middle section of the mountain range (35 and 15), while the average species number and endemic species number in the south section of the mountain range were only 15 and 8, respectively (*Fig. 3*).

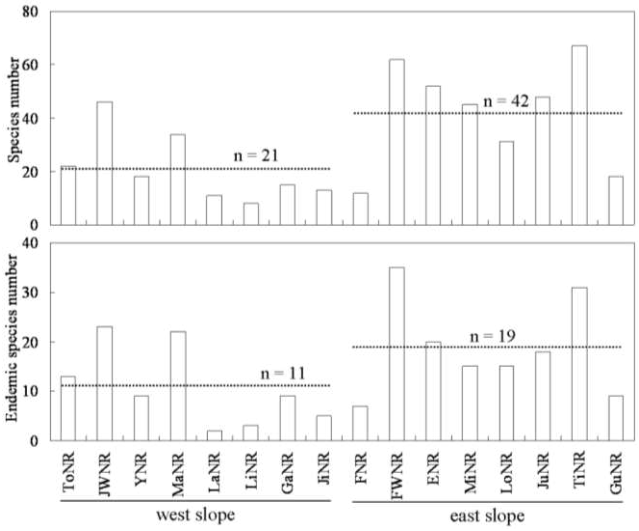

Figure 2. *Species and endemic species richness in the west and east slopes of Wuyi Mountains, China (n = average number of fish species). The nature reserve codes are the same as those in Figure 1*

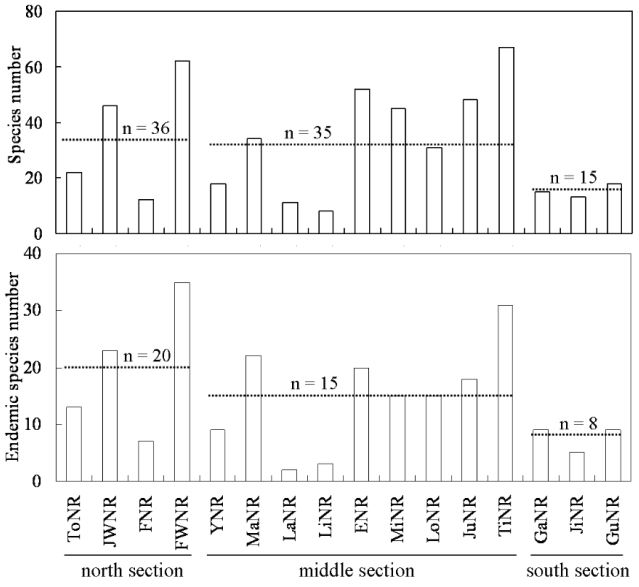

Figure 3. *Species and endemic species richness in the north, middle and south sections of Wuyi Mountains, China (n = average number of fish species). The nature reserve codes are the same as those in Figure 1*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1134111357

In addition, greater values of F-index, G-index and G-F index were also obtained from the east slope of the Wuyi Mountains compared to the west slope of the mountain range. And F-index, G-index and G-F index in the north section and middle section of the mountain range were similar, while the F-index, G-index and G-F index in the south section of the mountain range were the lowest (*Table 2*). The species richness of north section, middle section have similarity. While the species richness of south section were the lowest, and the east slope's richness is higher than west slope.

Clustering analysis

By studying the presence-absence data of fish in each nature reserve in Wuyi Mountains, the fish fauna can be divided into four regions (*Fig. 4*). The first region included MiNR, ENR, JuNR, TiNR, FWNR and LoNR, their mountain streams belong to the Minjiang River Basin. The second and third regions were FNR and GuNR, their mountain streams flow into the Oujiang River or the Hanjiang River respectively. The fourth region included JWNR, LaNR, ToNR, JiNR, YNR, GaNR, LiNR and MaNR, their mountain streams belong to the Poyang Lake Basin which flows into the Yangtze River. In addition, according to the result of cluster analysis, 16 nature reserves can be divided into two faunas, the east slope and west slope of the Wuyi Mountains.

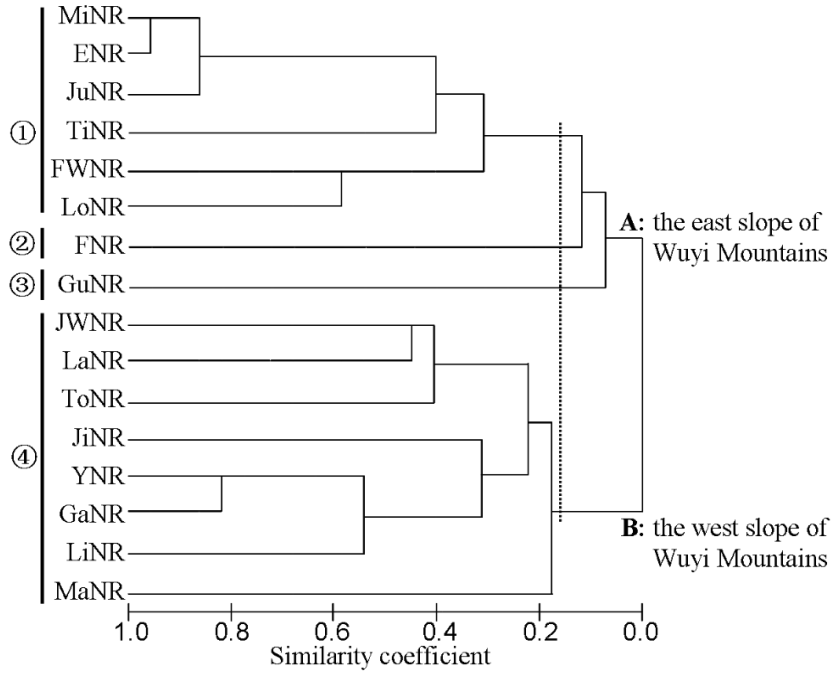

Figure 4. *The classification of 16 nature reserves in the Wuyi Mountains, China. 1: Minjiang River System; 2: Oujiang River System; 3: Hanjiang River System; 4: Yangtze River System. The nature reserve codes are the same as those in Figure 1*

Discussion

Characters of fish species diversity

A total of 1323 species and 877 endemic species of freshwater fish had been reported in China (Xing et al., 2016). The results of the existing studies on the 16 nature reserves in the Wuyi Mountains showed that a total of 126 species (9.5% of all freshwater fish

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1134111357

species in China) and 72 endemic species (8.2% of all freshwater endemic species in China) were found to be distributed in mountain streams. Several endangered (*Anguilla marmorata, Acrossocheilus wenchowensis, Liobagrus marginatus* and *Pseudobagrus medianalis*) and vulnerable species (*Leptobotia elongate, Siniperca obscura* and *Siniperca roulei*) were found in the Wuyi Mountains, and most of them are endemic to China. The coldwater and endemic species (e.g. *Rhynchocypris oxycephalus*) had also been found in the mountain range. In addition, endemic species of families Balitoridae and Gobiidae, the sucker structure under their bodies allows them to attach to the boundary layer matrix created by water flow at the bottom of the water so as to survive in mountain streams, and they were found in most nature reserves within the mountain range. We can conclude that the diversity and conservation of freshwater fish species (especially endemic species) are highly dependent on the mountain stream environment of Wuyi Mountains. The stability and low disturbance of habitats （such as the introduction of less exotic species） may be the reason for the collection of rich species and endemic species in the mountain range. First-third streams are widely distributed in 16 nature reserves in Wuyi Mountains. Temperatures in the mountains also rarely reach 20 °C in summer because of the high forest coverage rates in the riparian areas of the mountain range. And the content of dissolved oxygen is high, which provides suitable living conditions for these fishes (Hu et al., 2011, 2015, 2018; Guo et al., 2011; Huang et al., 2013).

As environments be different, the species composition of fish also change (Cowx, 1994). The comparison of species number, endemic species number and values of F-index, G-index and G-F index between the west and east slopes of Wuyi Mountains showed that there was a higher fish species diversity in the east slope. And among the three districts (i.e. the north, middle and south sections of Wuyi Mountains), fish species diversity was highest at the north section, good at the middle section and lowest at the south section (Fu et al., 2003; Jang et al., 2003; Yin et al., 2016; Song et al., 2017). Existing studies for bryophytes, ferns, vascular plants, freshwater crabs and reptiles in the Wuyi Mountains showed the similar variation tendency (Guan, 2006; Li et al., 2006; Ye et al., 2007; Zhu, 2010; Cheng et al., 2011; Shi et al., 2012).

Current threats

The biodiversity of the Wuyi Mountains is threatened by a wide range of anthropogenic activities, including overexploitation and habitat change. Sedentary species are also affected by hydrological alterations and tend to redistribute along the river gradient (Araújo et al., 2013). Habitat alteration and destruction as the major cause of most extinctions of freshwater fishes (Thomas., 1994). Despite being prohibited by law, unsustainable and short-term fishing practices like electro-fishing are rampant throughout China (Zhao et al., 2015), causing great damage to fish resources in various regions of the country. In the mountain range, some people catch fish for food on streams using electro-fishing, rotenone or other poisons (Guo et al., 2011; Hu et al., 2011, 2015, 2018; Liu et al., 2012; Zeng et al., 2013; Miao et al., 2016). This kind of fishing had led to over-fishing which had also caused a rapid decline in fish biodiversity.

In recent decades, agricultural activity, increased demand for drinking water, and the construction of multi-purpose dams, artificial reservoirs, and levees and weirs have led to major changes in China's streams and rivers (Fu et al., 2003). In the mountain range,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1134111357

dams had been built on streams in most of nature reserves (Guo et al., 2011; Hu et al., 2011, 2015, 2018; Liu et al., 2012; Zeng et al., 2013; Miao et al., 2016). Streams with faster flow rates often slow down and transformed into wide and slow-flowing streams. These factors have impeded the efficient migration of species migrating between different river habitats. This variation means that these organisms will be replaced by species which adapted to slower streams (Hu et al., 2009). Anthropogenic hydrological changes have had a negative affect the biodiversity of fish greatly.

Conservation recommendations

The Chinese government and environmental protection agencies have taken measures to protect the biodiversity of fish in these nature reserves, but these measures have not been effective. Changes brought by human activities and facilities accelerate the deterioration of mountain river environment, so the protection measures for fish biodiversity need to be improved and strengthened.

First, an in-depth understanding of both large-scale species richness patterns and endemism patterns is an essential basis for the conservation of freshwater fish resources (Oberdorff et al., 1999). A more comprehensive assessment of the status of freshwater fish stocks can be achieved using this method. But the data need to be updated in time for the protection agency to formulate the correct protection measures. Therefore, the overall freshwater fish resource assessment of Wuyi Mountains needs to be carried out as soon as possible. In addition, the government should establish a comprehensive database to update the status and information of species.

Second, the development of effective management measures is the first step to protect the species diversity and endemism of Wuyi mountain's fish, which will effectively control and manage the integrity of the fish life cycle and the maintenance of population quantity in the river. The government needs to improve the construction of fish passage facilities so that fish can migrate smoothly between rivers and breeding (Jang et al., 2003).

Third, Penalties for illegal activities should be increased in the mountain area of Wuyi Mountains, so as to better protect fish diversity and resource quantity better. At the same time, fishing must be prohibited in mountainous areas, especially the use of poison such as rotenone. Draft legislation on wildlife buffer zones in the Wuyi Mountains, promoting sustainable agriculture to prevent pollution and limit fishing activities (Jang et al., 2003).

Conclusion

These results indicate that the freshwater fish species diversity is closely related to the environment of Wuyi mountain streams, especially for the endemic species. However, fish biodiversity in the mountain range is facing numerous threats, such as over-exploitation and habitat alteration. Thus, the conservation of fish biodiversity has become urgent, and an integrated management plan should be developed and effectively implemented.

PRELIMINARY STUDY ON BIODIVERSITY OF BUTTERFLIES IN BEYKOZ GROVE OF ISTANBUL, TURKEY

KUCUKOSMANOGLU, A.

Department of Forest Entomology and Protection, Faculty of Forestry, Istanbul University, 34473 Bahcekoy, Sariyer, Istanbul, Turkey
(e-mail: aliko@istanbul.edu.tr)

(Received 17th Apr 2019; accepted 11th Jul 2019)

Abstract. In this study, Lepidoptera species collected by sweep net in Beykoz grove, Istanbul province, Turkey during the years of 2017–2018 was evaluated. A total of 182 specimens were collected in Beykoz. According to identification results, 57 species belonging to 12 families were recorded. The family Noctuidae was represented by the highest number of species (19), followed by Geometridae (16) and Notodontidae (6).
Keywords: *sweep net, butterflies, biodiversity, fauna, Beykoz*

Introduction

Lepidoptera, butterflies and moths, are very common insects and well known because of their very attractive colours and patterns on their wings. This order is recognized as one of the largest order of insects (Romoser and Stoffolana, 1994). Adults of the majority of extant species feed on nectar, the juice of overripe fruit or other liquids. Larvae of almost all species are phytophagous, and no parts of plants remain unexploited. Because of their phytophagus habits and high reproductive rate, many species are important pests (Gillott, 2005). The ecological-faunistic complex situation of butterflies is important for biodiversity.

There are several regional studies to determine the Lepidoptera fauna in Turkey (Akbulut et al., 2003; Akkuzu et al., 2007; Avci, 1997; Beskardes, 2002; Can, 2008; Cebeci, 2003; De Lattin, 1950, 1951; Graves, 1925, 1926; Hakyemez, 1994; Hesselbarth et al., 1995; Kansu, 1963; Kaygin et al., 2009; Kornosor, 1987; Mathew, 1881; Mol, 1977; Okyar and Aktac, 1998, 1999; Rebel, 1903).

With the new records published on butterfly observation sites of Butterfly Turkish (kelebek-turk.com) by butterfly observers, the number of butterfly species in the province of Istanbul is 125. In order to determine the butterfly species diversity of Beykoz grove of Istanbul, a field study was carried out in 2017–2018.

Materials and methods

The study was conducted between the years of 2017 and 2018 in Beykoz grove located within Istanbul region (*Fig. 1*). Beykoz is a small holiday town on the Marmara Sea coasts in the city of Istanbul. Beykoz grove (located at 41° 07’ 59”N, 29° 05’ 54”E) covers in the form of deciduous forests, composed of various tree species and tall shrubs. In the forested area dominant trees are *Platanus* sp., *Quercus* spp., *Alnus glutinosa, Acer campestre, Fraxinus excelsior, Carpinus betulus, Castanea sativa, Tilia tomentosa* and *Poulus tremula.* Having rich flora and suitable climate conditions enabled Beykoz owning rich and divergent Biodiversity.

Specimens were collected using a sweep net. Captured specimens were put into tightly closed killing jars immediately and brought to the laboratory for preparation and identification. Ethyl acetate was used as a killing agent. The collecting dates and locations concerning each specimen were recorded in the field note book. Specimens were pinned using insect pins (mostly, 3 - 4 - 5 sized) and were mounted on spreading boards. For identification, different studies (Fibiger, 1993; Forster and Wohlfahrt, 1971; Marini and Trentini, 1986; NHM, 2009; Savela, 2001; Spuler, 1910) were used. The Lepidoptera collections of Forest Entomology and Protection Department of Istanbul University, Faculty of Forestry were also used.

Results and discussion

A total of 182 specimens were collected from this location in Beykoz region of Istanbul. 57 species belonging to 12 families of the order Lepidoptera were identified and listed as follows. Family names and species in each family were listed as arranged alphabetically:

Order **LEPIDOPTERA** Linnaeus, 1758
Family **COSSIDAE** Leach, [1815]
Cossus cossus (*Linnaeus, 1758*)
Zeuzera pyrina (Linnaeus, 1761)
Family **CRAMBIDAE** Leach, [1815]
Cydalima perspectalis (Walker, 1859)
Family **TORTRICIDAE** Latreille, [1803]
Tortrix viridana (*Linnaeus, 1758*)
Family **PYRALIDAE** Latreille, 1809
Dioryctria abietella (Denis & Schiffermüller, 1775)
Nomophila noctuella (Denis & Schiffermüller, 1775)
Family **LASIOCAMPIDAE** Harris, 1841
Lasiocampa quercus (Linnaeus, 1758)
Family **SATURNIIDAE** Boisduval, 1837
Saturnia pavonia (Linnaeus, 1758)
Family **GEOMETRIDAE** Leach, [1815]

Noctua orbona (Hufnagel, 1766)
Noctua pronuba (Linnaeus, 1758)
Xestia castanea (Esper, 1798)

A total of 182 individuals with 57 species belonging to 12 families were identified in Beykoz grove. Nymphalidae family was dominant, whereas Riodinidae had the least number of individuals. The highest number of species belongs to Noctuidae (19, 33.3%), followed by Geometridae (16, 28.1%) and Notodontidae (6, 10%). The number of species in each family (*Figs. 2* and *3*) and their ratios to the families were given in *Table 1*. In *Table 2,* the data concerning the capturing dates and the collecting locations about each specimen were given.

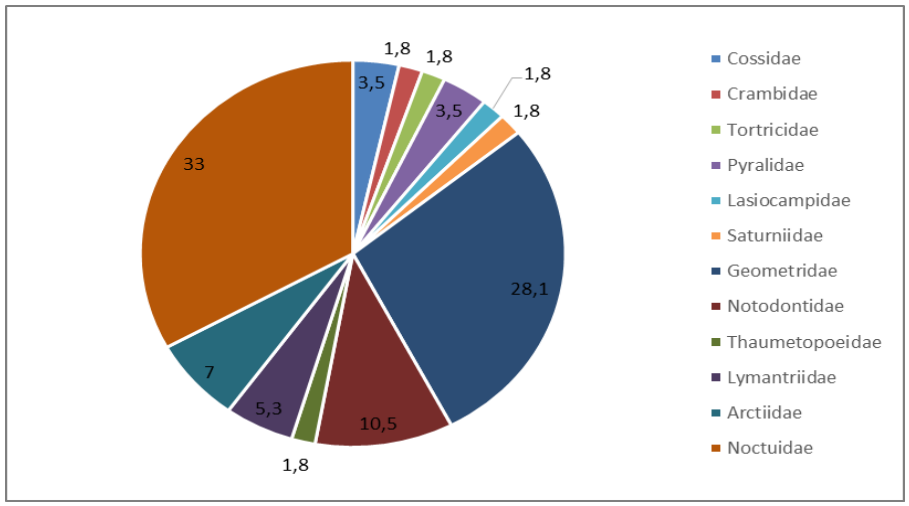

Figure 2. *Percentage of species into each family*

Conclusions

In this research, 57 species belonging to 12 families of suborder Heterocera were captured and identified in Beykoz region of Istanbul. Most of the species were from three families: Noctuidae (19, 33.0%), followed by Geometridae (16, 28.1%) and Notodontidae (6, 10.5%). Among the lepidopteran species collected, 33 were considered pests for forest trees: *C. cossus*, *Z. pyrina, T. viridana, D. abietella, L. quercus, S. pavonia, A. repandata, C. margaritata, G. papilionaria, H. aestivaria, P. dolabraria, S. lunaria, H. pyritoides, D. dodonaea, P. bucephala, P. tremula, P. palpina, S. argentina, S. fagi, T. processionea, C. pudibunda, E. chrysorrhoea, L. dispar, L. monacha*, *P. fuliginosa, S. lubricipeda, A. psi, A. pyramidea, B. bicolorana, C. rubiginea, L. w-latinum, M. lunaris* and *M. alpium* (Kimber, 2009; Savela, 2001). Oak (*Quercus* spp.) is the dominant tree in the region and according to the literature (Kimber, 2009; Savela, 2001), *C. cossus*, *T. viridana, L. quercus, S. pavonia, C. margaritata, H. aestivaria, S. lunaria, D. dodonaea, P. bucephala, S. argentina, T. processionea, C. pudibunda, E. chrysorrhoea, L. dispar, L. monacha, A. psi, A. pyramidea, B. bicolorana, C. rubiginea, L. w-latinum, M. lunaris* and *M. alpium* caterpillars prefer oak leaves as their food plants.

Z. pyrina differs from these species as its larvae food regimes. The adults of *Z. pyrina* fly during June and July were collected in the end of July and in the beginning of August. L. monacha adults are different from L. dispar adults by means of morphological appearances. They often show traces of bright pink colour on the body, especially the abdomen, which however is normally concealed when at rest. L. monacha was regarded as the first record for the region.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1135911366

Most of the species obtained were collected in summer months. This was because summer is the most suitable season for the mating and regeneration activities of Lepidopteran adults.

As Kaygin et al. (2009) said: the habitats, where the butterfly and moth species have been abundantly observed should be protected and these particular locations should be preserved as butterfly protection areas. Beykoz is one of the potential butterfly protection areas.

(Received 18th Apr 2019; accepted 11th Jul 2019)

Abstract. The research aimed to measure the impact of pollution of the aquatic environment of marine fisheries on fish production in Saudi Arabia. This study achieves its objectives based on published secondary data and the estimation of the recursive model by ordinary least squares (OLS) method during the 1995-2017 period. The results of the study show the decline of the productivity of fishing vessels due to overfishing and failure to keep pace with the biological growth rate. The proportion of fish stocks within a biologically sustainable level declined from 87% in 2013 to 54% in 2017. The major factor of the decline of fish stocks and the productivity of fishing vessels is the environmental pollution of marine fisheries such as untreated sewage. The 10% increase of untreated sewage leads to a decrease in marine fish production by 20.9%.
Keywords: *productivity, overfishing, wastewater, recursive model, Red Sea, Arabian Gulf*

Introduction

The coast of Saudi Arabia extends over 2,900 km of the Red Sea and Arabian Gulf. The number of fishermen and fishing workers in the Kingdom is around 28.04 thousand, reaching 0.86% of the total population of 32.55 million in 2017 (Ministry of Environment, Water and Agriculture, 2017). Even with the expansion of the fishing water area and the increase in the number of fishermen and fishing vessels, fish production does not meet the increasing consumption needs. Therefore, there is an increase in the import of fish to the country. The total quantity of fish imports reached 163.85 thousand tons, valued at SR 1315.26 million of the total value of imports of agricultural and animal products which is 27303 million riyals in 2017 (General Authority for Statistics, 2017).

Due to the rapid development of the petrochemical industry in Saudi Arabia, the amount of waste, whether oil, industrial, or carbon ash waste from fuel combustion, in power generation and desalination plants has increased. The Kingdom's solid waste is estimated at about 12 million metric tons annually from the petrochemical, cement and oil refining industries. Heavy materials are thrown into the sea or buried in the soil, desert. Besides the impact of heavy fuel oil waste used in power plants and saltwater desalination on Saudi's marine environment, there is an effect of overfishing of fish stocks in the Red Sea and Arabian Gulf (Alnashwan and Ghanem, 2010). There are several studies have addressed the environmental problems of different fisheries.

Basaham et al. (2009) study showed that although Jeddah's sewage estuary has been moved to the edge of the coral reef towards the open sea, pollution remains widespread, endangering coastal environments and posing a threat to public health. This was evidenced by the heavy growth of algae and the increased concentration of heavy

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1136711374

elements in sediments. Al-Najjar (2015) estimated some heavy elements in the Chirocentrus dorab fish caught from the Iraqi coast. The results showed the total concentration of elements (lead, iron, nickel, cobalt, and copper) was 6590.26 μg/g dry weight for fish. Bouazem and Wennon (2015) estimated the revenues and costs of seawater desalination for Saudi Arabia during the period 2000-2014. In terms of cost, the cost of energy is one of the depleted natural resources, as well as the environmental costs summarized by the volume of emissions and saline solution from the stations. The cost of pollution from desalination plants, especially CO_2, is estimated at 19.4 $ per ton.

Qubartai's (2016) study addressed the environmental impact assessment of desalination technology and its relationship to pre-treatment levels. The saline water desalination results in a brine solution that increases salt content in the water. Additive chemicals also increase pollution. The environmental impact of desalination plants depends on both the physic-chemical properties of the discharged water and the hydrographic and biological properties of the aquatic environment. The other study by Alamin and Guthi (2017) dealt with marine environmental pollution through international law. The study showed that the marine environment is part of the global ecosystem. International law guarantees a set of rules for the protection of the marine environment, the obligations of States and measures that States must apply to their domestic legal systems with a view to protecting the marine environment from pollution.

Qamra et al. (2018) studied the economic effects of Lake Mariout pollution on agricultural production during the period 1990-2015. This study shows the increase of the total quantity of industrial and agricultural waste and the drainage of Alexandria Governorate by 10% leads to a decrease in the production of fish of Mariout Lake by 12.9%. Finally, the Ministry of Environment, Water and Agriculture of the Kingdom of Saudi Arabia (2018) prepared a national strategy for the environment, in view of the increasing pressures on the environment and natural resources in the Kingdom during the past decades. The strategy explained the increasing consumption of non-renewable water and the growing sources of water pollution.

This study aimed to analyze the effect of pollution of the aquatic environment on fish production in Saudi Arabia during the period 1995-2017 by studying the following objectives:

1. The current status of fish production and productivity of vessels operating in Saudi Arabia's marine fisheries.
2. Problems of the aquatic environment of marine fisheries (the Red Sea and the Arabian Gulf).
3. Measuring the impact of pollution of the aquatic environment on the quantity and value of fish production in Saudi Arabia.

Definitions

Through the study there are several research concepts, the most important of which are the following:

Environmental pollution. Pollution is defined as the state of the environment itself or the resultant changes in it and causes the person a direct or indirect disturbance, damage, disease or death. Pollution is also defined as any quantitative or qualitative change in the components of the living or non-living environment, and environmental systems cannot absorb it without changing its balance. Quantitative change results in the addition of toxic substances that are deadly in their natural concentrations such as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1136711374

mercury, carbon oxide, and derived substances, while qualitative variation results from the addition of artificial compounds to natural ecosystems (Alnashwan and Ghanem, 2010).

Modern boats (commercial vessels). Boats with a length of more than nine meters, and contain modern equipment such as the discovery of places of gathering fish, electronic navigation equipment and modern communications devices, in addition to the winch and fishing equipment of high efficiency.

Traditional boats. Boats that are between 5 and 20 meters long and do not contain the equipment included in the modern boats, except for the winch and the bottom trawling of the shrimp fishing in the Arabian Gulf.

Fishermen could be called for traditional fishermen, investors, and fishermen for temporary periods. A traditional fisherman is a citizen who works himself in a fishing craft on a boat he owns. An investor is a citizen who invests part or all of his money in marine fisheries and owns modern fishing boats. The temporary fisherman refers to the children of fishermen who work with their parents in the marine fisheries sector and are under the age of 18 years. In addition, the other citizen fisherman who does the fishing but does not own boats or fishing boats (Ghanem and Al-Obaid, 2002).

Materials and methods

The study based on the secondary data presented in the statistical yearbook issued by the Ministry of Environment, Water, and Agriculture, in addition to the Bulletin of Export and Import Statistics published by the General Authority for Statistics. The proposed model of this study to analyze the impact of pollution of the aquatic environment on fish production during the period 1995-2017 through Recursive model consists of two behavioral equations (*Eq. 1* and *2*) and an indicative equation (*Eq. 3*). These equations are as follows:

$$Y_{1t} = a_0 + a_1 X_{1t} + a_2 X_{2t} + a_3 X_{3t} + e_{1t} \quad \text{(Eq.1)}$$

$$Y_{2t} = b_0 + b_1 \hat{Y}_{1t} + b_2 X_{4t} + e_{2t} \quad \text{(Eq.2)}$$

$$Y_{3t} = \hat{Y}_{2t} \times X_{5t} \quad \text{(Eq.3)}$$

These equations of the model include the following variables: (1) Endogenous Variables: there are three variables which are the fish production of the Red Sea and Arabian Gulf in thousand tons (Y_{1t}), the total fish production of Saudi fisheries per thousand tons (Y_{2t}), and the value of fish production in billion riyals (Y_{3t}); and (2) Exogenous Variables: there are five variables which are the number of fishing boats (X_{1t}), number of licensed fishermen (X_{2t}), total untreated wastewater in million cubic meters (X_{3t}), the total production of the rest of Saudi fisheries in thousand tons (X_{4t}), and the average wholesale price of fish by thousand riyals/ton (X_{5t}). It is clear from the proposed model that the fish production of the Red Sea and Arabian Gulf affects the total fish production of Saudi fisheries and thus affects the value of fish production. Thus, the causality is carried in one direction and not in the other. Models that follow this pattern are called the Recursive Model (Abdelkader, 1990).

Results

Current status of fish production and productivity of vessels

By following the change in fish production and the productivity of vessels operating in Saudi Arabia's marine fisheries during the period 1995-2017 (*Table 1*), it is clear that most of the vessels engaged in marine fisheries (the Red Sea and Arabian Gulf) are traditional. Fishing vessels are concentrated in the Red Sea, whereas 80.22% of the total number of vessels is employed, while only 19.78% in the Arabian Gulf during the study period. Even though the fisheries of Arabian Gulf dominated fish production, with the average production reach to 34.28 thousand tons that represent 45.34% of the average total fish production, followed by Red Sea fisheries by 31.7%, followed by fish farms and international waters by 22.16% and 1.07% respectively.

Modern	1.43	45.78	13.40	13.38	99.85

The average productivity of traditional vessels in Red Sea fisheries decreased from 2.95 tons/vessel in 1995 to 2.58 tons/vessel in 2017. By taking the same period of time, the productivity of modern vessels in Red Sea fisheries also decreased from 63.79 to 33.18 tons/vessel. The average productivity of modern vessels in Arabian Gulf fisheries decreased from 25.33 to 10.0 tons/vessel during the same period of time.

The impact of pollution of the aquatic environment on the quantity and value of fish production

To study the economic effects of the pollution of the aquatic environment on quantity and value of Saudi Arabia's fish production, the equations of the proposed model were estimated by the ordinary least squares (OLS) method during the period 1995-2017. The result from a model analysis in *Table 2* shows the increase of untreated sewage waste in Saudi Arabia by 10% leads to a decrease of 20.9% in fish production of marine fisheries. The increase in the estimated of production of marine fisheries by 10% leads to an increase in total fish production of Saudi Arabia by 0.8%, while an increase of 10% for the production of the rest of Saudi fisheries leads to an increase in total fish production by 9.9%. The significance of this estimation is at 1%. According to the Breusch-GodFrey serial correlation LM Test, there is no autocorrelation in the errors in an estimated regression model. Also, there is no autocorrelation in the squared series, according to the Arch Test. In addition, the estimated equations are well represented in the data used in this estimation according to the efficiency indicators of the model such as U Theil's inequality coefficient, which is close to zero (*Table 3*).

Discussion

In general, it is clear the degradation of the productivity of vessels in Saudi fishery marines during the period of study. This could be caused by different factors such as:

- The continuous increase in the number of fishermen and traditional and modern vessels in the Red Sea and Arabian Gulf regions. Whereas increasing the number of boats in a fishing area means increasing the number of fishing trips on the same fishing area. This phenomenon is known as overfishing, which leads to a failure to keep pace with the rate of biological growth of the fish catch rate, and thus to affect the fish stocks of those.
- The ability of most fishing vessels operating in marine fisheries is less than 100 mechanic horses. Therefore, these vessels cannot sail long distances at sea and approach the continental slope. Since there is a direct relationship between the power of the motor or the engine and sailing long distances in Sea, stand the weather conditions is appropriate, and stay longer in the sea.

Problems of the aquatic environment of Saudi marine fisheries

The marine fisheries of Saudi Arabia have been exposed to several environmental problems, the most important of which is pollution and the phenomenon of overfishing. The pollution of the aquatic environment of Saudi marine fisheries is attributed to several factors: (1) the movement of oil tankers and commercial vessels between East and West, which makes marine fisheries vulnerable to pollution during loading and unloading operations, ship refueling and waste disposal, (2) discharge of untreated sewage and waste of industrial facilities located on the coast of Red Sea and Arabian Gulf, (3) port clearance and ship maintenance and painting, (4) seawater desalination companies, (5) oil and mineral exploration in marine waters, (6) the management of maritime ports and oil companies may have to use chemicals to disperse spots Oily resulting from some accidental accidents and spills, and (7) oil spill resulting from the military operations. Whereas there was an oil spill from Nowruz Field that lasted for eight months during the Iran-Iraq war in 1983. The amount of oil spilled ranged from 200 to 500 thousand tons. Also, the amount of oil leaking was about one million tons during the war of the liberation of Kuwait in 1991. Despite efforts to contain this massive oil spill, it was a major cause of the destruction of at least 300 km from the eastern coast of Saudi Arabia and the deaths of many marine organisms and birds. Because of the pollution of the aquatic environment of marine fisheries and overfishing, the rate of biological growth of the fishing rate has not kept up with a fishing rate. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1136711374

data in *Table 4* show that the percentage of fish stocks within a biologically sustainable level has decreased from 87% in 2013 to 54% in 2017.

Therefore, the pollution of the aquatic environment of marine fisheries is one of the main reasons to decrease the rate of biological growth of the fish that leads to a decrease in the percentage of fish stocks within a biologically sustainable level. This reason confirms by the result of data analysis through this study which there is an inverse relationship between untreated sewage waste and fish production of marine fisheries in Saudi Arabia.

Table 4. *Evolution of the size and proportion of fish stocks within the biologically sustainable level (2010-2017). (Source: Statistical Yearbook, Ministry of Environment, Water and Agriculture, 2017)*

Year	Size of fish stocks within the biologically sustainable level by 1,000 tons	Percentage of fish stocks within a biologically sustainable level %
2010	65.07	71
2011	63.17	79
2012	71.39	80
2013	61.77	87
2014	67.99	74
2015	64.88	62
2016	66.54	62
2017	66.40	54

Conclusion

Pollution sources of marine fisheries (the Red Sea and Arabian Gulf) are abundant in the territorial waters of Saudi Arabia which have negative impacts on fish production, health, and human well-being. Shows the increase of untreated sewage waste in Saudi Arabia by 10% leads to a decrease of 20.9% in fish production of marine fisheries. In order to protect marine fisheries from pollution, the study recommends the following: (1) Raise awareness about the importance of preserving the marine environment through research and regulation of fishing rules such as length of fishhook, number of fishing trips, minimum and maximum size of fish, the amount of fishing, the prohibited fishing seasons and prohibited fishing sites, (2) develop fishing boats and increase their ability to sail long distances in the Red Sea and Arabian Gulf, so the phenomenon of overfishing can be eliminated and the preservation of fish stocks, (3) tighten control over all facilities and plants that discharge their wastes in marine waters, (4) improve the primary treatment of sewage, (5) implement more research to study the effect of pollution to damages the marine natural resources in Saudi Arabia and analysis the effective policy tools to improve aquatic environment, and (6) Cooperation among the Gulf Cooperation Council (GCC) countries on the establishment of a network to monitor and control pollution. This may require aerial and night monitoring and surveillance to detect expected violations.

Abstract. Based on the daily precipitation data of 25 national meteorological stations in the Min River Basin (the MRB), the temporal and spatial variation trends of extreme precipitation events from 1961 to 2016 were analyzed using multiple extreme precipitation indices and the Mann-Kendall trend analysis. The extreme precipitation in different recurrence periods was calculated by using the regional frequency analysis combined with the spatial distribution characteristics of extreme precipitation events. The spatial distribution of the extreme precipitation index in the MRB varies considerably. The average characteristics of extreme precipitation are changing from short-term extreme precipitation to sustained extreme precipitation. The main reasons for this change are the significant increases in wet days and consecutive wet days, particularly the number of heavy precipitation days (R10mm). On this basis, the Min River is divided into four hydro-climatically consistent regions and the maxima of RX1DAY's and RX5DAY's 20-year and 100-year recurrence periods are found. The traditional at-site hydrological frequency analysis averaged the spatial differences within the basin and underestimated the extreme precipitation in the middle reaches. This indicates that the regional frequency analysis has some reference significance for solving the problem of neglecting the uneven spatial distribution of extreme precipitation in precipitation estimation.

Introduction

The IPCC Fifth Assessment Report pointed out that the global average surface temperature increased by 0.85°C between 1880 and 2012 (IPCC, 2013), and global warming has become an indisputable fact. In the context of global warming, extreme events such as floods, droughts, typhoons, high temperatures, low temperatures and freezing rain and snow often occur (Changnon et al., 2000; Zengxin, 2011; Fu et al., 2013; Tian et al., 2016). As an important part of the water cycle, precipitation directly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_113751394

affects the hydrological process of runoff and increases the frequency of flooding disasters (Wang et al., 2004; Kampata et al., 2008; Millett et al., 2009; Chen et al., 2009; Xu et al., 2010; Zhang et al., 2012).

The IPCC report also points out that the land surface temperature in China has risen by 1.38°C in the past 60 years, 0.23°C every 10 years, which is higher than the global average. The climate change is likely to develop further. Many scholars have analyzed the extreme precipitation in different regions of China: the studies have shown that there are obvious regional differences in the extreme precipitation and precipitation frequency in different regions of Qinling-Huaihe River North of Henan (Liet al., 2015), Pearl River Basin (Huang et al., 2014), and Yellow River Basin (He et al., 2014), indicating that there are obvious spatial differences in the distribution of extreme precipitation events.

Though the analysis of the characteristics of extreme precipitation over time in different regions, it is also found that there are spatial differences in the temporal variation of extreme precipitation events (Chu et al., 2012; Li et al., 2012; Bai et al., 2015; Tian et al., 2016). Zhai et al. (2005) found that there was no obvious change trend in annual precipitation and the intensity of precipitation was on the rise. However, the trend of extreme precipitation events showed obvious spatial differences. Influenced by East Asian monsoon activities, China was extremely vulnerable to large-scale flood disasters, especially in the Yangtze River Basin (YRB). Yu et al. (2004) pointed out that while the precipitation in northern China was decreasing, the precipitation in mainland China took the form of "flooding in the South and drought in the North". The probability of flood disasters in the YRB was much greater than that in other regions of China. Zhai (1999) showed that the annual precipitation in the YRB showed a significant upward trend. The extreme precipitation in the middle and lower reaches of the YRB showed a significant upward trend, and the change trend in the upper reaches of the YRB was not obvious. Pan et al. (2017) used the methods of trend and catastrophe analysis, R/S analysis and hydrological frequency analysis to study the temporal and spatial evolution characteristics and future trends of extreme precipitation in the YRB. The results show that the regional extreme precipitation index in the YRB shows an upward trend, and the annual changes of the extreme precipitation index in the middle and lower reaches are greater than in the upper reaches. Wu (2016) used the Mann-Kendall (MK) test to study the changes of extreme precipitation in 11 regions of China, and concluded that the flood disaster in the upper reaches of the YRB had an obvious increasing trend. Bai (2015) used Logistic regression model to study the characteristics of extreme precipitation in the YRB. The results show that the frequency of extreme precipitation in the upper and middle reaches has a significant non-linear increasing trend, but the variation trend of extreme precipitation frequency in the Sichuan Basin located in the upper reaches of the YRB is not obvious. Qian (2005) found that the intensity of extreme precipitation and the frequency of persistent rainy days in the upper reaches of the YRB showed a downward trend. Zhang (2006) simulated extreme precipitation in the YRB through PRECIS climate model simulation and concluded that extreme precipitation events in the middle

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_113751394

and lower reaches had an overall upward trend, but the upstream trend was not obvious. Chen et al. (2017) predicted that extreme precipitation in China would increase significantly in the lower reaches of the YRB in the 21st century by using the IPCC AR4 model and coupling it with the atmospheric circulation model.

From the above conclusions, we can see that the study of the YRB shows that there is an increasing trend in extreme precipitation in the YRB (Zhai et al., 1999; Yu, 2004; Pan et al., 2017), but there are also obvious regional differences there. The consistent conclusion for the middle and lower reaches of the YRB is that the extreme precipitation in the middle and lower reaches shows an upward trend (Zhai et al., 1999; Zhang et al., 2006; Pan et al., 2017; Chen et al., 2017), which is also the main contribution of the overall extreme precipitation in the YRB. At the same time, the conclusions of the upper reaches of the YRB are not entirely unified. Some studies of the upper reaches show an upward trend, but the upward trend is lower than that of the middle and lower reaches of the YRB (Xu et al., 2016; Pan et al., 2017). Other studies show that the extreme precipitation in the upper reaches of the YRB has not changed significantly with time and may even have shown a downward trend (Zhai et al., 1999; Qian et al., 2005; Zhang et al., 2006; Luyao et al., 2015). The conclusion of extreme precipitation variation in the upper reaches of the YRB is not entirely uniform, which may be related to the incomplete data periods, different methods and incomplete definitions of extreme precipitation indices used. When the data period used is not exactly the same, because of the quasi-periodic oscillation of precipitation in the YRB (Chen et al., 2017), the trend of extreme precipitation in the analysis results is related to the length of the time series used in the analysis. When different research methods are used, the results may be different (Qian et al., 2005; Luyao et al., 2015). The methods of extreme precipitation research are mainly divided into two categories. One is statistical analysis of precipitation data, such as using MK trend test, MK mutation analysis, wavelet analysis and other statistical methods (Karl et al., 1998; Bonsal et al., 2001; Pal et al., 2011; Tramblay et al., 2012; Yang et al., 2012; Croitoru et al., 2013). Because statistical methods depend heavily on the length of observation data and the selected site data, the results of different research periods or sites in the same region may vary greatly. The other is to simulate the characteristics of extreme precipitation using models. Because the current climate models cannot accurately simulate the temporal and spatial changes of future extreme climate events, the prediction of future extreme precipitation by multi-model sets also has a series of problems of accuracy and deviation, such as the error of a single model may affect the whole prediction conclusion, and multimodal ensemble forecasting results may smooth some extreme weather events (Li et al., 2012). At the same time, different indicators of extreme precipitation will also affect the results. The indicators of extreme precipitation were proposed by the World Meteorological Organization (WMO) Meteorological Committee (CCL) and Climate Variability and Predictability Research Program (CLLVAR) in 2006. The recommended extreme precipitation indicators can point out the characteristics of extreme precipitation, including intensity, frequency, and duration.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_113751394

Before that, the extreme precipitation indices used were not perfect (Zhai et al., 1999; Qian et al., 2005; Su et al., 2006).

In addition to the above three reasons, which have an impact on the research results of extreme precipitation in the YRB, there is also a reason for the spatial differences of regional changes in the YRB. When the study area is large (for example, dividing the YRB into upper, middle and lower reaches), it will be difficult to reflect the spatial and temporal variations of extreme precipitation in different regions of the basin, because the overall study of the region will smooth out the regional characteristics of extreme precipitation. At the same time, if its trend keeps rising in the future, it will be difficult to reflect the temporal and spatial variation trend by using the entire dataset. The predictions of precipitation estimated by using the whole data will be more uncertain. Moreover, the significance of the trend and changes in the extreme precipitation index in the predictions of precipitation also has not been given sufficient attention. Therefore, the Min River Basin (the MRB), which belongs to the upper reaches of the YRB and is the largest tributary of the upper reaches of the Yangtze River, is selected as the study area for the current study. The MRB is in the transition area from the high-altitude area to the basin on the eastern side of the Qinghai-Tibet Plateau. There are great differences in altitude, topography and climate conditions in this area. The study of extreme precipitation variation in the MRB is of great significance to the analysis of extreme precipitation variation trends in the Yangtze River and the upper reaches of the Yangtze River. Previous research on the precipitation characteristics of the MRB has concentrated on the lower reaches of the MRB, and has mainly focused on the general characteristics of precipitation in the MRB. In the context of global warming, the MRB shows different regional response characteristics, which will have a huge impact on regional environmental ecology. Therefore, on the basis of previous research work, this paper focuses on the MRB, using the daily precipitation data of 26 meteorological stations in the MRB from 1961 to 2016, using MK trend analysis, to analyze the temporal and spatial variation of extreme precipitation in the MRB. Considering the significant changes of extreme precipitation in different regions, the MRB was divided into climatic consistent regions and the estimated precipitation of the basin was calculated by using the regional frequency analysis.

Materials and Methods

The Min River (*Fig. 1*) is the largest tributary of runoff in the Yangtze River. The total drop of the Min River is 3560 meters, and the basin area is 135 881 square kilometers. It is an important area for hydropower development in Southwest China. According to the geographical characteristics of the main river, the upper reaches extend from the source to Dujiangyan City, the middle reaches from Dujiangyan City to Leshan City, and the lower reaches from Leshan City to Yibin City.

Precipitation Data

The daily precipitation data of 25 stations (*Table 1*) from 1961 to 2016 is provided by the China Meteorological Administration. Relevant station data is available at http://data.cma.cn/. The precipitation data have been qualitatively controlled.

Extreme Precipitation Index

Twelve extreme precipitation indices are used in this study. They are recommended by the World Meteorological Organization (WMO) Meteorological Committee (CCL) and Climate Variability and Predictability Research Program (CLLVAR) (Alexander et al., 2006). These indicators have been applied to analyze the characteristics of extreme precipitation (Wu et al., 2016). In this article, three supplementary indices (SPIs) are added to describe the variation trend of precipitation in the MRB. Detailed descriptions of ETIs and SPIs are presented in *Table 2*.

Table 2. *Definitions of extreme precipitation indices employed in the study*

ETIs			
CWD	Consecutive wet days	Maximum number of consecutive days with RR≥1mm	days
R10mm	Number of heavy precipitation days	Annual count of days when RR≥10mm	days
R25mm	Number of very heavy precipitation days	Annual count of days when RR≥25mm	days
RX1DAY	Maximum 1-day precipitation	Annual maximum 1-day precipitation	mm
RX5DAY	Maximum 5-day precipitation	Annual maximum 5-day precipitation	mm
R95T	very wet day precipitation	Annual total precipitation when RR≥95th percentile of 1961-2016 daily precipitation	mm
R99T	Extremely wet day precipitation	Annual total precipitation when RR≥99th percentile of 1961-2016 daily precipitation	mm
PRCPTOT	Annual total wet day precipitation	Annual total precipitation in wet days (RR≥1mm)	mm
SDII	Simple daily intensity index	Annual total precipitation divided by the number of wet days in the year	mm/day
SPIs			
R95PT	Precipitation fraction due to very wet days	Ratio between R95T and PRCPTOT	%
R99PT	Precipitation fraction due to extremely wet days	Ratio between R99T and PRCPTOT	%
WD	Wet days	Annual count of days when RR≥1mm	days

Note: RR denotes daily precipitation

Methods

MK Trend Test

A MK test is a non-parametric test recommended and widely used by the WMO. A MK test does not require samples to follow a certain distribution, nor is it disturbed by a few abnormal values. A MK trend test was used to analyze the trend change of time series of precipitation, runoff, temperature, and water quality (Mann, 1945; Kendall, 1945; Vijay et al., 2010; Wu et al., 2016). It is suitable for non-normal distribution data such as hydrology and meteorology and is easy to calculate (Xu et al., 2007; Burn et al., 2008; Wu et al., 2008; Zhang et al., 2008; Wang, 2009). The calculation formula of the MK test can be found in Reference (Mann, 1945).

Regional Frequency Analysis

The regional frequency analysis combines linear moment with regional analysis method, avoids the limitation of traditional at-site frequency analysis method, improves the unbiasedness and robustness of parameter estimation, improves the accuracy of frequency design value (Lin et al., 2006), and effectively improves the accuracy and reliability of hydrological frequency analysis. At present, it has been widely used in hydrological frequency analysis (Li et al., 2015; Shao et al., 2016; Yang et al., 2009).

Firstly, this study chooses the indicators which can reflect the obvious spatial differences in extreme precipitation. Combining with the longitude, latitude, elevation and linear moment parameters of each station, all stations are preliminarily divided by clustering analysis method, and the discordance detection and heterogeneity detection (Xiong et al., 2004) are used to test whether each zone is a reasonable hydrometeorological consistency region.

On this basis, in view of the divided hydrometeorological consistent region, this study assumes that the stations in the hydrometeorological consistent region conform to Kappa distribution. Monte Carlo simulation is used to simulate the study area N_{sim} times, each time generating the same length of historical rainfall data series corresponding to each site. Furthermore, Monte Carlo simulation test is used to determine the optimal frequency distribution for each hydrometeorological consistency region in the five three-parameter frequency distribution patterns (Chen, 2014): generalized Pareto distribution (GPA), generalized extreme value distribution (GEV), generalized logistic distribution (GLO), generalized normal distribution (GNO) and Pearson III distribution (PE3). Finally, using the index flood method (Cunnane, 1989) and the optimal frequency distribution line, the design values of rainstorm frequencies for different recurrence periods of each station are calculated.

The calculation formula of the discordance detection is as follows:

$$D_i = \frac{1}{3} N (u_i - \bar{u})^T A^{-1} (u_i - \bar{u}) \quad \text{(Eq.1)}$$

In the formula: $u_i = [t^i, t_3^i, t_4^i]^T$ (i = 1, 2, 3... N) is a three-dimensional vector consisting of three linear moment coefficients: linear deviation coefficient L-Cv, linear deviation coefficient L-Cs and linear kurtosis coefficient L-Ck.

$$\bar{u} = N^{-1} \sum_{i=1}^{N} u_i \quad \text{(Eq.2)}$$

$$A = \sum_{i=1}^{N} (u_i - \bar{u})(u_i - \bar{u})^T \quad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_113751394

If the discordance coefficient $D_i \leq \frac{N-1}{3}$, there is no singularity in the region. If $D_i > \frac{N-1}{3}$, it is considered that the site is a discordance point. It is necessary to further check the rationality and reliability of the site data and make a correct trade-off.

The formula of the heterogeneity detection is as follows:

$$H_1 = \frac{(V_1 - \mu_v)}{\sigma_v} \quad \text{(Eq.4)}$$

Among them,

$$V_1 = \left\{ \sum_{i=1}^{N} n_i (t^i - t^R)^2 / \sum_{i=1}^{N} n_i \right\}^{\frac{1}{2}} \quad \text{(Eq.5)}$$

$$t^R = \sum_{i=1}^{N} n_i t^i / \sum_{i=1}^{N} n_i \quad \text{(Eq.6)}$$

where n_i is the length of rainfall data series of the *i-th* station in the consistent area, t^i is the linear potential coefficient L-Cv at the *i-th* station in the consistent area, N is the total number of stations in the consistent area. μ_v and σ_v are the mean and mean square deviation of V_1 calculated by Monte Carlo simulation.

If $H_1 < 1$ the area is acceptably consistent, if $1 \leq H_1 < 2$ the area is possibly heterogeneous, and if $H_1 \geq 2$ the area is heterogeneous. The stations in the area need to be adjusted when $H_1 \geq 1$ is acceptable until they meet the criteria.

Results Analysis

Spatial Distribution

As can be seen from *Figure 2*, the maximum number of consecutive wet days (CWD) in the MRB was relatively uniform. The frequency of extreme precipitation events (R10mm and R25mm) in the lower and middle reaches of the MRB was significantly higher than that in the upper reaches. The spatial distribution of RX1DAY and RX5DAY were similar, showing a gradual increase in the upper and middle reaches of the basin, and a decrease in the lower reaches. The results show that the intensity of extreme

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_113751394

precipitation events in the MRB was largest in the middle reaches, especially in the continuous extreme precipitation, followed by the lower reaches, and lowest in the upper reaches. The percentile index of extreme precipitation events (R95T, R99T, R95PT and R99PT) were larger in the middle and lower reaches than in the upper reaches of the MRB.

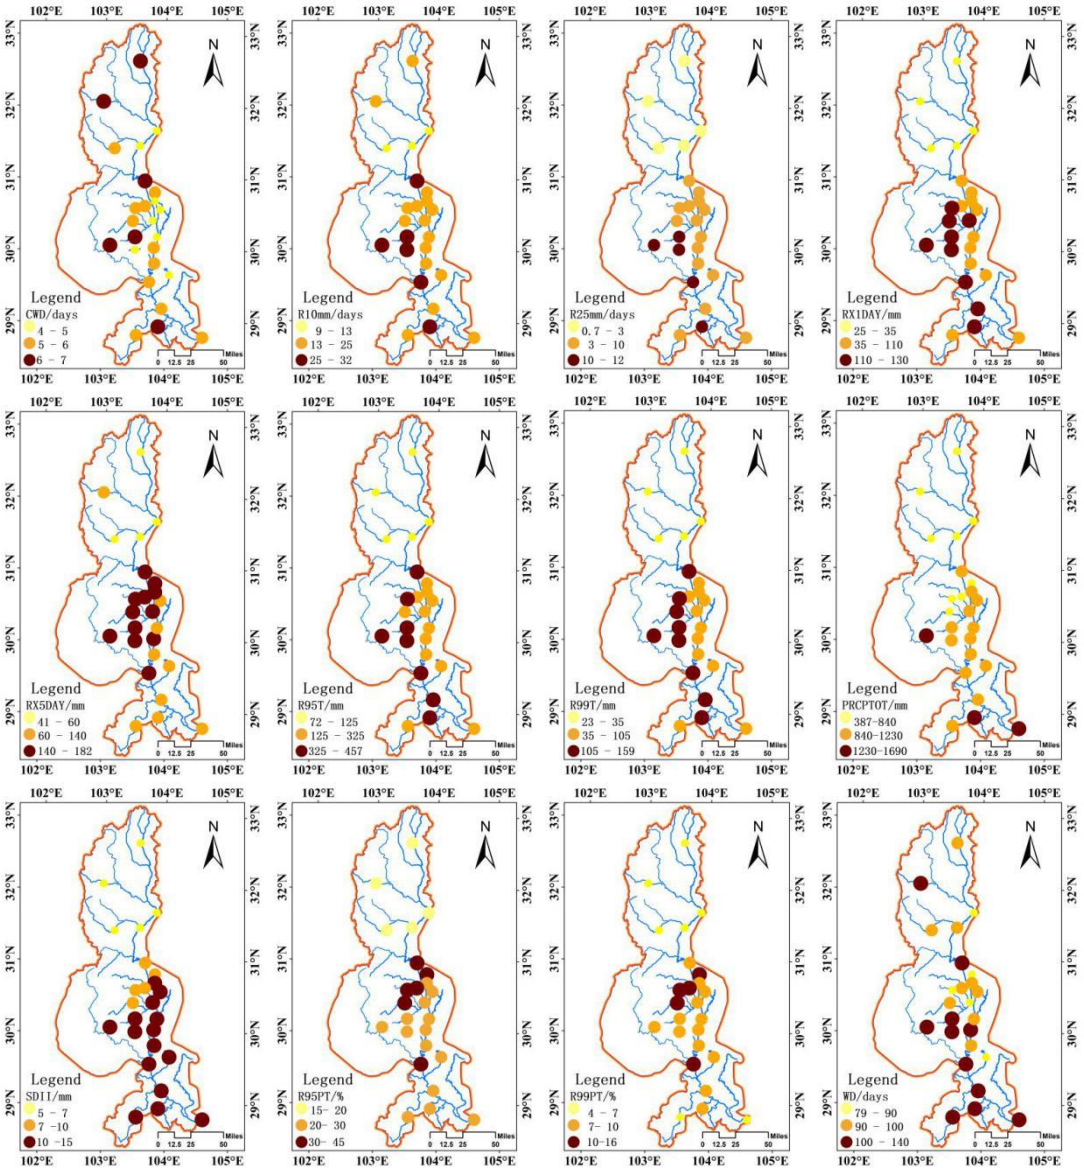

Figure 2. *Spatial Distribution of Extreme Precipitation Index in the MRB*

The PRCPTOT, the WD and the SDII in the MRB were higher in the lower reaches than in the middle reaches, and higher in the middle reaches than in the upper reaches. In a word, the main manifestation is that the high value of extreme precipitation index mainly appears in the middle and lower reaches of the basin, in which there is a high value

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_113751394

center of extreme precipitation intensity in the middle reaches of the basin, while the low value appears in the upper reaches of the basin.

Trends of Spatial Change

As can be seen from *Figure 3*, the CWD shows an upward trend in the whole basin.

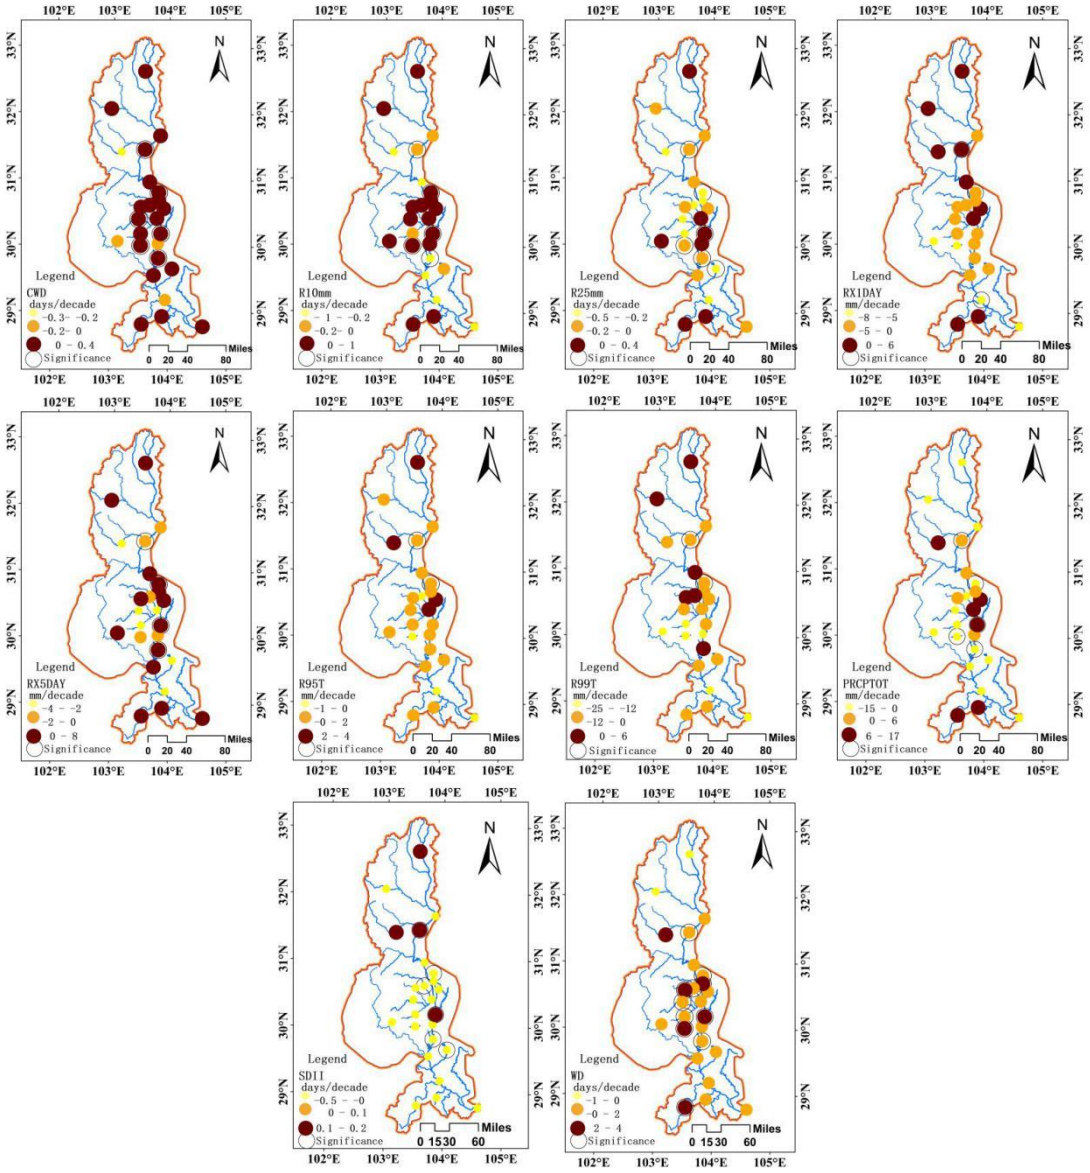

Figure 3. *Spatial distribution of extreme precipitation index in the MRB*

The frequency of R10 mm in the upper reaches of the basin decreases while that in the middle and in the lower reaches increases, while the frequency of R25mm mainly decreases in the whole basin. There are some regional differences in the spatial distribution of the RX1DAY change trend (*Fig. 3*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_113751394

The upper reaches of the basin show a weak growth trend. The weak decrease trend is dominant in the middle and lower reaches. RX5DAY shows a downward trend in the upper reaches of the river basin. The results show that the spatial distribution difference of short-term extreme precipitation decreases and the spatial distribution difference of continuous extreme precipitation increases. The spatial pattern of extreme precipitation ratio (R95T and R99T) shows a decreasing trend. From the PRCPOT of each station in the basin, the middle reaches of the basin show an upward trend, while the upstream and downstream of the basin show a downward trend. The trend of SD II was mainly downward in the basin, and the trend of WD is mainly upward in the basin. In a word, the average characteristics of extreme precipitation in the middle and lower reaches of the MRB are changing from short-term extreme precipitation to sustained extreme precipitation, while the upper reaches of the MRB show the trend of increasing short-term rainfall intensity.

Time Trend

In this paper, the Tyson polygon method was used to assign different weight coefficients to each station in the basin. The temporal variation trend of extreme precipitation index in the basin was calculated using the MK trend test (*Table 3*) and the linear trend method (*Table 3* and *Fig. 4*).

Table 3. *Temporal trends of the ETIs in the MRB*

Index	CWD	R10mm	R25mm	RX1DAY	RX5DAY	R95T	R99T	PRCPTOT	SDII	WD
MK	**2.14**	0.77	0.20	-0.72	1.53	-0.72	-1.37	0.614	-0.67	**1.66**
T	0.15	0.29	0.015	-0.63	2.4	-3.4	-3.8	5.6	-0.021	1.6

Notes: MK denotes MK statistics. T denotes trends (decade^{-1}). Values for the trends at the 0.05 significance level are shown in bold

The CWD of the MRB shows a significant upward trend. The R10mm shows a non-significant upward trend, while the R25mm shows a slightly upward trend. The RX1DAY shows a non-significant downward trend, while RX5DAY shows a non-significant upward trend. It shows that the characteristics of precipitation have changed from short-term heavy precipitation to persistent heavy precipitation. The R95T, R99T, R95PT and R99PT show non-significant downward trends. The results show that the proportion of one-day extreme precipitation to total precipitation has been weakening in recent years. The PRCPTOT showed no significant upward trend, SDII showed non-significant downward trend, WD showed a significant upward trend. In a word, the average characteristics of extreme precipitation in the MRB have changed from short-term extreme precipitation to persistent extreme precipitation. The main reasons for this change are the significant increase of the WD, the CWD and the R10mm, especially the increase of the R10mm.

Estimated Precipitation in the MRB Calculated by Regional Frequency Analysis

According to the analysis above, it is concluded that there are large spatial variations in extreme precipitation in the Min River. Extreme precipitation has the spatial difference of persistent extreme precipitation (RX5DAY), while short-term extreme precipitation (RX1DAY) decreases. On this basis, the regional frequency analysis, which combines the linear moments with the regional analysis method, is used to calculate the estimated precipitation for RX5DAY reflecting persistent extreme precipitation and RX1DAY reflecting short-term extreme precipitation.

Hydrometeorological Consistency Zone

The Cluster analysis is used to classify the precipitation by considering latitude, elevation, and the first order linear distance of the average value of RX1DAY or RX5DAY. The results of the classification are tested for discordance and heterogeneity. *Table 4* shows that the zoning results for RX1DAY and RX5DAY are acceptable according to the discordance test and heterogeneity test.

The Selection of Optimal Frequency Distribution Line

According to the hydrometeorological consistency region of the MRB, the optimal frequency distribution pattern of each hydrometeorological consistency region is determined by the Monte Carlo simulation test. The results (*Table 5*) show that the optimal linear distribution of RX1DAY in the four climate-consistent regions of the MRB was generalized logical distribution (GLO). The optimal linear distribution of RX5DAY in region 1 and region 2 of the MRB was generalized logical distribution (GLO). The optimal linear distribution of RX5DAY in region 3 was generalized extreme value distribution (GEV) and in region 4 was generalized normal distribution (GNO).

Calculation of Estimated Precipitation

According to the distribution function parameters of RX1DAY and RX5DAY precipitation series estimated by L-moments, combined with quantile formula, the precipitation of each station at the level of 1-100a recurrence period was estimated. According to the results of Monte Carlo test, the optimal distribution of RX1DAY and RX5DAY series at different stations in the MRB was selected, and the precipitation extremes at different recurrence periods were calculated by using the optimal distribution.

From the results of regional frequency analysis (*a1-d1 in Figure 5*), it can be seen that the maximum value of the 20-year and the 100-year recurring precipitation was concentrated in the middle reaches of the Min River. The 20-year recurrence period of RX1DAY was 230 mm in Leshan area and the 100-year recurrence period of RX1DAY was 340 mm. The 20-year recurrence period of RX5DAY was 330 mm in Mingshan and the 100-year recurrence period of RX5DAY was 420 mm in Mingshan.

Optimal Distribution Linearity		GLO	GLO	GLO	GLO	GLO	GEV	GLO	GNO

The traditional at-site hydrological frequency analysis (*a2-d2 in Figure 5*) refers to the calculation of all stations using the same frequency function instead of zoning the stations. It can be seen that the 20-year and 100-year maximum distribution of RX1DAY and RX5DAY was mainly distributed in the middle of the Min River, followed by the lower reaches of the basin, and the upper reaches of the basin were relatively small. The spatial distribution was consistent with the results of regional frequency analysis.

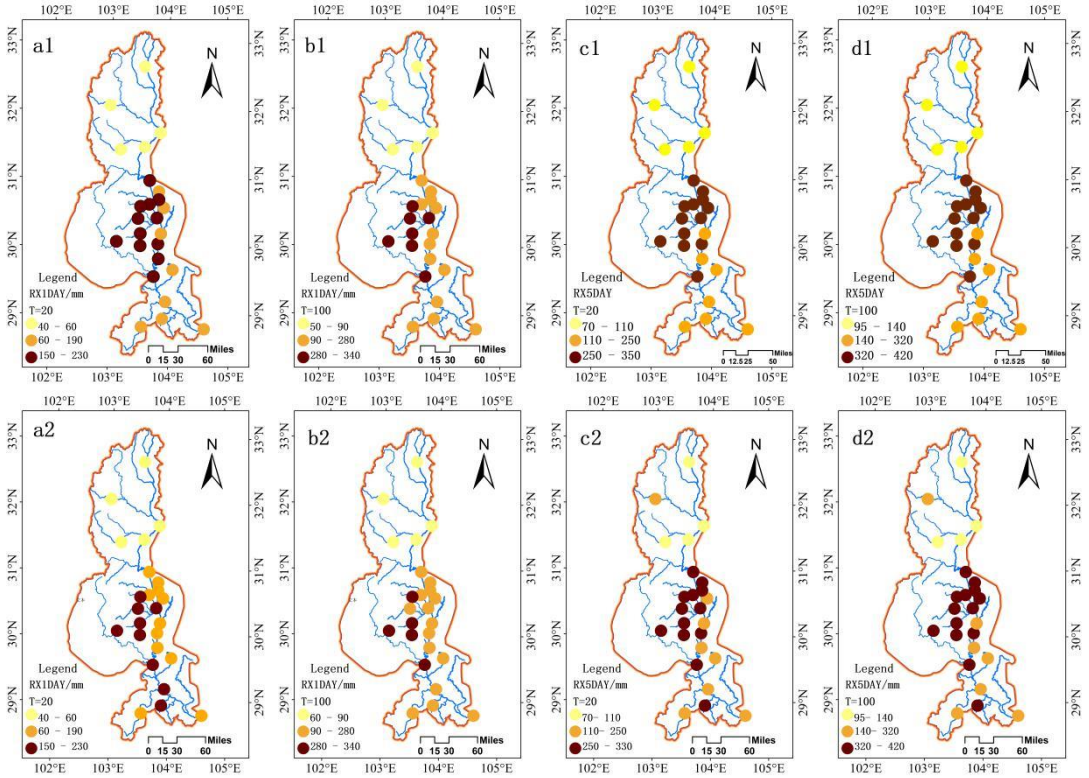

Figure 5. *Spatial distribution of estimated precipitation with RX1DAY and RX5DAY recurrence periods of 20 and 100 years*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_113751394

By comparing the estimated precipitation calculated by the two methods, the extreme precipitation in the middle reaches of the basin by traditional at-site hydrological frequency analysis was lower than that by regional frequency analysis, and slightly higher than that by regional frequency analysis in the lower reaches of the basin. To a certain extent, the difference between the upper, middle, and lower reaches of the basin was reduced, the spatial difference was averaged, and the extreme precipitation in the middle reaches of the basin was underestimated. It is unsafe to estimate the estimated precipitation based on the spatial distribution of extreme precipitation. The regional frequency analysis can effectively avoid the problem that the estimated precipitation estimated by the overall data neglects the spatial distribution of the overall internal changes in the context of climate change.

Discussion

The MRB is located in the transition zone between the Qinghai-Tibet Plateau terrain and the eastern plain of China. The upper reaches of the basin are characterized by low humidity and less external water vapor transport. The middle and lower reaches of the basin are affected by tropical monsoon, subtropical monsoon, and plateau monsoon. The complex climate and special geographical location provide conditions for the uneven spatial distribution of extreme precipitation events. The frequency of extreme precipitation events in the lower and middle reaches of the MRB is significantly higher than that in the upper reaches. This may be related to the fact that the upper reaches of the MRB have low humidity and low water vapor transport due to the high altitude. Meanwhile, the intensity of extreme precipitation events in the MRB is the largest in the middle reaches, especially in the continuous extreme precipitation. The intensity of extreme precipitation events in the lower reaches is larger than that in the upper reaches. This is mainly because the middle reaches of the MRB is located in the rainstorm area in the northwest of the basin, which is affected by the eastern side of the Qinghai-Tibet Plateau and is a rainstorm area far from the ocean in China, resulting in the intensity of extreme precipitation events in the middle reaches of the MRB (Peng et al., 1985; Li et al., 2011).

The spatial distribution of extreme precipitation index in the MRB is quite different. The spatial variation trend of extreme precipitation in the MRB was that the spatial difference of RX5DAY increases, while the spatial difference of RX1DAY decreases. The main factors affecting the spatial variation of extreme precipitation were the spatial variation of R10mm and WD.

According to the trend analysis, the average characteristics of extreme precipitation in the MRB have changed from short-term extreme precipitation to persistent extreme precipitation. The main reasons for this change are the increase of the WD, the CWD and the R10mm, especially the increase of the R10mm.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_113751394

At the same time, with the development of urbanization, Dujiangyan, Meishan and Leshan in the middle reaches of the MRB and Yibin Station in the lower reaches of the MRB are affected by the urban heat island effect, which further makes the distribution of precipitation uneven, thus affecting the distribution of extreme precipitation (Shou et al., 2012; Zhao et al., 2019).

In addition, the analysis methods used in this paper are uncertain, and it is necessary to further study the characteristics of extreme precipitation from different perspectives by various methods. Based on the results of this study, the relationship between extreme precipitation and atmospheric circulation needs to be further verified. At the same time, correlation analysis can be used to find out which factors are related to extreme precipitation.

Abstract. Membrane bioreactor (MBR) is a water treatment system with a combination of the membrane separation unit and the bioreactor. The Activated Sludge Model (ASM) developed by the International Water Association offer a valuable instrument for designing, optimizing, and operation of the MBR. In this research, the MBR process based on the Activated Sludge Model No. 3 (ASM3) was compiled by the use of MATLAB/Simulink platform which can be applied to the water quality analysis of the MBR reactor effluent. The visual ASM3-MBR sewage processing simulation system was developed and had the advantages of an intuitive interface, clear meaning, easy data input, etc. After the model establishment, the division of model components, sensitivity analysis, and model calibration and verification, ASM3-MBR was amended and improved in this study.
Keywords: *activated sludge, MATLAB/Simulink, modelling, water quality, separation unit*

Introduction

The membrane bioreactor (MBR) is a system that combines biological treatment with membrane filtration into a single process. MBR is one of the most tent potent domestic/industrial wastewater treatment and reuse technologies currently (Ng and Kim, 2007). Also, this efficient and reliable technology has become a legitimate alternative to conventional activated sludge processes due to its perfect retention of biomass, pathogens removal, higher process performance and system stability (Castelo-Grande et al., 2010). The membrane bioreactors achieve perfect organics; chemical oxygen demand (COD), biochemical oxygen demand (BOD), and nutrient (nitrogen, phosphorus) removal as well as perfect retention of suspended solids.

Recently, MBR, especially submerged MBR, has been gaining a lot of attention for wastewater treatment in the aspects of high-quality effluent and a small footprint (Braak et al., 2011). The MBR process combines the biodegradation by the activated sludge process and the solid-liquid separation by the membrane filtration (Chang et al., 2006). It is, therefore, reasonable to use Activated Sludge Models to characterize the biomass dynamics in an MBR system. Mathematical modelling of MBR technology may help in providing insight into the factors that play a crucial role in the MBR process (Lee et al., 2002). At the same time, it can provide invaluable data for the design, forecast, and control of MBR technology.

Up to this day, mathematical model simulation of activated sludge processes have been used for the design of structures and control of operations in wastewater plants in most parts of the world. Since the publication of the first Activated Sludge Model (ASM) in 1986 (Liwarska-Bizukojc et al., 2011), the Activated Sludge Model No. 1 (ASM1) and its successors have become increasingly more popular. ASM1 was developed to model BOD and nitrogen removal, but it did not adequately describe all

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1139511407

nutrients removal. Therefore Activated Sludge Model No. 2 (ASM2) was designed to incorporate biological nutrient removal of nitrogen and phosphorus (Gujer et al., 1995). However, ASM2 was far more complex, which created model operational difficulties. Activated Sludge Model No. 3 (ASM3) aimed to correct the defects of ASM1 and presented a new standard for ASM based modelling (Gujer et al., 1999).

The ASM3 model can effectively simulate the operation of the MBR. With the ASM3 model, the dimensions of various structures of the MBR are determined, and the appropriate process flow can be accurately selected. The key operating parameters of the MBR can also be predicted and determined; therefore, using the ASM3 model to simulate the MBR can optimize the operation and management of the MBR. The factors that affect the process of the MBR can be analyzed and evaluated.

Although the ASM series of models have gained widespread recognition from water treatment workers, due to the complexity of the model structure and parameters, it is still difficult to directly use them in reactor design, and many scholars are based on such models. At the expense of the universality of the model, many simplified models have been created, and proper monitoring and control results have been achieved. Using MATLAB/Simulink as the simulation software, the ASM3-based simulation of the MBR process can more intuitively reflect the effect of the reactor operation and can use the program to make a right prediction of the effluent outcome of the MBR (Gao et al., 2018).

Indeed, recently Li et al. (2009) applied a hybrid ASM model and showed the hybrid ASM model was calibrated and validated through a submerged MBR system under the reference condition. Mannina et al. (2011) presented an integrated MBR features and the calibration model protocol was illustrated with a pilot MBR plant in submerged configuration based on ASM1.

The major problem in the simulation of MBR is that the port has not been visualized. Only the programmers who are familiar with the structure can operate it flexible. Hence, through a concise and structured overview of past developments, this paper studied the effects of submerged MBR's wastewater treatment. This paper explored ASM3 based on modelling applied to MBR processes; ASM3 was chosen as the simulator and used the Simulink Toolbox in MATLAB7.0 to build a visual simulated program. The operation was done to predict the variation tendency of the effluent quality under the changing situation of inflow and outflow water quality when the reactor was in operation. This paper searches for the optimal operating parameters and will provide the basis for engineering design.

Materials and methods

Experimental set-up

An integrated MBR was used in the test. The test device diagram is shown in *Figure 1*. The temperature of the reactor 4 was adjusted to 25 °C by the heater 7, 5 is a hollow fiber membrane module, and the membrane material was polyacrylamide, hollow fiber filament. The diameter was about 0.6 mm, the inner diameter was about 0.3 mm, the membrane pore size was 0.05 μm, the length of the membrane module was 0.5 m, the membrane molecular weight cut-off was 10000 Dalton, and the surface area of the membrane was 1 m^2. The device used a micro-porous aerator for aeration, and the amount of aeration can be adjusted by the air flow meter 3. The liquid level of the reactor was controlled by the balance tank. The float valve automatically controls the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1139511407

liquid level with the flow rate of the discharge water. With the change of the flow rate of the discharge water, the float valve was automatically controlled to maintain the balance between the discharge flow and the inflow. The hydrodynamic power was provided by the net head pressure difference. After the new membrane was placed in the reactor, water was pumped out using a glass water injector. The reactor had a sufficient volume of 18 L. The aeration intensity of the device was very large, dissolved oxygen (DO) was maintained at about 8 mg/L. After the commissioning operation was stable, the HRT of the control system was 5 h, during which no sludge was discharged. When the system was operating stably, the concentration of incoming and outgoing water was measured.

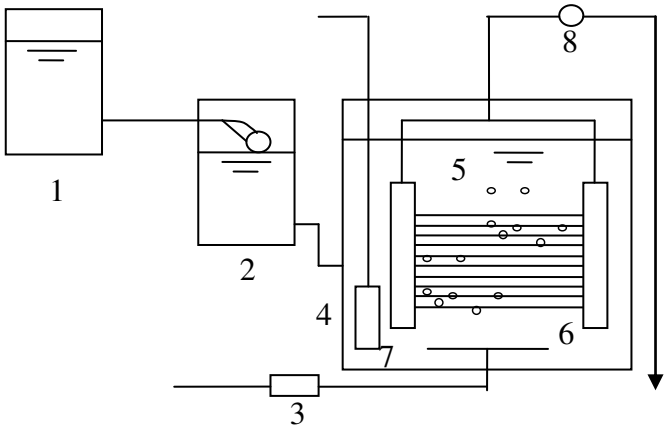

Figure 1. *Schematic diagram of the test. (1 elevated tank, 2 balance tank, 3 air flow meter, 4 reactor, 5 hollow fiber membrane,6 aeration device, 7 heater, 8 vacuum table)*

Mass balance and removal rates

The biological reaction rate of a component (i), at the time (t), r_i was obtained according to the following equation (Mannina et al., 2011):

$$r_i = \sum_j \upsilon_{ij} \rho_j \qquad \text{(Eq.1)}$$

Where υ is the stoichiometric matrix, ρ is the kinetic rate, i and j are respectively the state variables and the biological processes. Meanwhile, the differential equations for all state variables were obtained from *Equations 2, 3* and *4* by the mass balance:

$$\frac{dS_i}{d_t} = \frac{Q_{in}S_{i,0} - Q_o S_i + Q_w S_i}{V} + r_i \qquad \text{(Eq.2)}$$

$$\frac{dX_i}{dt} = \frac{Q_{in}X_{i,0} - Q_w X_i}{V} + r_i \qquad \text{(Eq.3)}$$

$$Q_o = Qf \qquad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1139511407

where Q_{in} is the influent flow-rate, Q_o is the effluent flow-rate, Q_w is the wasted sludge flow-rate, V is the volume of the MBR $S_{i,0}$ and S_i are the concentration of soluble substrates in the influent and supernatant respectively, $X_{i,0}$ and X_i are the concentration of particulate substrate in the influent and reactor, respectively, f is the coefficient of membrane interception.

In consideration of the heterotrophic bacteria and nitrifying bacteria in water in an amount negligible, these two components of this differential equation are simplified:

$$\frac{dX_H}{dt} = r_H \tag{Eq.5}$$

$$\frac{dX_A}{dt} = r_A \tag{Eq.6}$$

The purpose of the sensitivity analysis of the model parameters was to study the influence of the size of the model parameter's error on the system's prediction (Wang et al., 2016). In the simulation, those parameters with higher sensitivity in the model need to be corrected. For parameters with lower sensitivity, the typical default values given by ASM3 can be directly used for simulation.

The sensitivity analysis method was used to analyze the simulated results of the ASM3-MBR model, and the dynamic parameter values and stoichiometric coefficients in the model were increased by 10% based on initial costs (Lee et al., 2002) and changed under the condition of keeping other parameters unchanged. The sensitivity value of a parameter was calculated according to the equation below:

$$\sigma_{j,i} = \frac{\dfrac{C_{i,1} - C_{i,0}}{C_{i,0}}}{\dfrac{\tau_{j,1} - \tau_{j,0}}{\tau_{j,0}}} = \frac{\dfrac{\Delta C_i}{C_{i,0}}}{\dfrac{\Delta \tau_j}{\tau_{j,0}}} \tag{Eq.7}$$

Where $\tau_{j,0}$ is the initial value of the parameter, $\tau_{j,1}$ is the parameter values after the change, $C_{i,0}$ and $C_{i,1}$ are a concentration of effluent indicator before and after the parameter change indicator. After an increase of 10% based on the initial values, the corresponding sensitivity values of parameters are positive and negative points. The positive value indicates that the increase of the parameter makes the effluent concentration of the component rise, and the negative value indicates that the increase of the parameter causes the effluent concentration of the component to decrease.

Modelling

The simulated program establishes its flow chart based on the parameter of the integrated MBR technology and design. ASM3 was chosen as a simulator, and the Simulink Toolbox in MATLAB7.0 was used to build a visual simulated program. The simulation model includes an influent module, the reaction module, and effluent combination module. The reaction module processing corresponding reactions, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1139511407

influent module will feed components distribution in 13 kinds of parts according to specific rules. And effluent combination module is just the opposite; it is a combination of 13 types of component indicators need to detect the effluent, such as COD, Ammonia, total nitrogen (TN), as the basis for process analysis.

The establishment of the model starts with the basic sub-processes rate equation. The other components of the reaction rate equation are built by the mathematical operation. One or several parts of the kinetic equation can be used to describe a sub-process.

In the established model system, all the 13 sub-process can be built with the process. The basic rate equation is multiplied by a sub-process component in a stoichiometric coefficient of the sub-process. The sum of the parts in each sub-process of the reaction rate is the component of the total reaction rate of all sub-processes in which it participates. Such as X_I generated in the sub-process 6, 7, 11, and 12; therefore, X_I's total kinetic equation for the four sub-process reaction rate sums. We have:

$$(dX_I / d_t)_T = f_I[(dX_I / d_t)_6 + (dX_I / d_t)_7 + (dX_I / d_t)_{11} + (dX_I / d_t)_{12}] \quad \text{(Eq.8)}$$

In the MBR, a component of the quality in total rate equation of the ASM3 is the total reaction rate equation and the "one into one out" sum.

To X_I, for example, the total rate equation is:

$$\frac{dX_I}{d_t} = \frac{Q_{in}X_{I,0} - Q_o X_I}{V} \pm \sum \left(\frac{dX_I}{d_t} \right)_R \quad \text{(Eq.9)}$$

According to the method, the 13 component of the ASM3 corresponding model (S_{O2}, S_I, S_S, S_{NH2}, S_{N2}, S_{NOX}, S_{ALK}, X_I, X_S, X_H, X_{STO}, X_A and X_{SS}) is established, and finally the simultaneous integration and then encapsulated.

After the model package, can be entered ASM3 as parameters in the parameter input box, these parameters can be adjusted as needed. In the first time of simulation, the input is the default reference values given by the International Water Association (IWA).

Data conversion is an essential factor in the model simulations. The data conversion floor is the measured data to the component data of ASM3 model transform process. Because the actual test data is not entirely of model constituents and therefore fall under the restriction of various conditions, it is difficult to measure constituents by using experiment. Hence, this concerns the problem of how to transform data into the model. This step is essential, whether the transformation is appropriate or not directly determines the success of the application of the model. In this test, the value influent COD, total nitrogen (TN), and ammonia were measured.

Finally, a visual interface of the ASM3-MBR was established. Simulated program debugs through static data, first carries out a sensitivity analysis for the model parameter and then corrects the parameter, control the error between system prediction's result and the actual measured results of the water within 5%.

Figure 2 shows the simulation program of ASM3-MBR where TCOD represents the total influent COD, V represents the reactor volume, HRT represents hydraulic retention time, Q_w is the wasted sludge flow-rate, SNH4, 0 represents the influent ammonia content, SN2, 0 represents the total influent nitrogen, TN means influent TN content,

SALK, 0 represents influent alkalinity, XSS, 0 indicates influent suspended solids content. After clicking the left of each window to run the input data can be observed on the right side of each window after the simulation of COD, ammonia nitrogen, TN results.

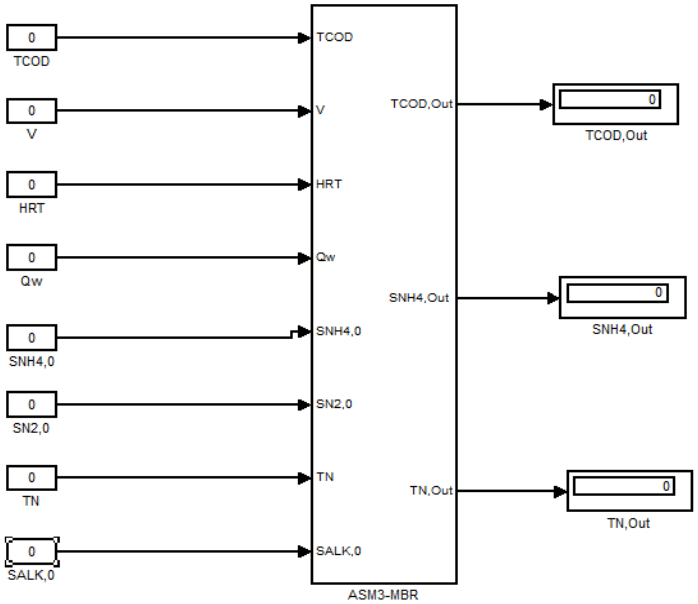

Figure 2. *The simulation program of ASM3-MBR*

The bottom floor of the simulation program is the basic rate equation. The second floor is the encapsulation of the relevant rate equations. The third floor is the encapsulation of a component of the overall reaction rate equation package. The fourth floor is the encapsulation of the integral simultaneous component of the total rate equation. The fifth floor is the input floor of the ASM3 model parameters, is the encapsulation of the entire rate equation integration module, parameter module, initial of points, and influent quality. Enter ASM3 typical kinetic parameter values. The simulation program uses the International Water Association (IWA) recommended default value (20 °C) (Henze et al., 2000).

Results and discussion

Sensitivity analysis

According to *Equation 7, Table 1* shows ASM3 model sensitivity analysis results. From the parameter sensitivity analysis in *Table 1* we can see that:

1. Some parameters have almost no effect on all the simulation results, such as the yield in the endogenous respiration, the rate of hypoxia based respiration, and the significant influence on the simulation results, such as the ratio of the hydrolysates, the maximum rate of growth. For these parameters with high sensitivity, parameter correction must be carried out in the simulation process to meet the precision requirements of the model. For the parameters with low sensitivity, the parameters cannot be corrected in the simulation, and the typical default values of the ASM3 model can be used directly.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1139511407

2. The higher sensitivity of the effluent COD simulation value to the parameter change from high to low is proportion in the hydrolysate, hydrolysis saturation constant, hydrolysis rate constant, aerobic yield per unit stock, aerobic endogenous respiration rate, the aerobic yield of heterotrophic bacteria, maximum specific growth rate.
3. The higher sensitivity of the effluent NH_3-N simulation value to the parameter change from high to low is: the maximum specific growth rate, the ammonia nitrogen saturation coefficient, the aerobic endogenous respiration rate, the aerobic yield of heterotrophic bacteria, the aerobic yield, the maximum specific growth rate, and the saturation constant for the unit stock.
4. The higher sensitivity of the effluent TN simulation value to the parameter change is from the highest to the lowest: the unit nitrate yield, aerobic endogenous respiration rate, heterotrophic aerobic yield, and unit stock aerobic yield, maximum specific growth rate, hydrolysis saturation constant, storage rate regular.

Parameter calibration

The sensitivity analysis method is used to adjust the parameters with high sensitivity, and some settings with low sensitivity are set according to reference or typical values. The model parameter correction is performed on the MATLAB/Simulink platform. The differential equations involved in the model are solved in MATLAB using the established ASM3-MBR model (Song et al., 2012). After studying most of the literature, it was discovered that the process of correcting the model using data from dynamic inflows requires more computational time than static influx, and it has been proved in practice that static influent water is used to simulate the resulting information of the system (Bournazou et al., 2010). It will not be less than that obtained when using dynamic flood simulation (Wang et al., 2016). Therefore, the average value of the actual inlet and outlet water and water quality characteristics of the integrated MBR is used as the steady-state inlet and outlet water values to correct the parameters of the ASM3-MBR model. Because of the average water value, the parameters that make the relative residual difference between the benefits of the simulated values of COD, NH_3-N, TN, and the measured values are minimal.

In the process of model calibration, the following principles need to be followed:

1. Most parameters should not be changed during the calibration process.
2. For each correction, only one parameter is changed. This is because there are usually substantial interactions between parameters in the model, so it is difficult to estimate the combined effects of several parameters, and changing multiple parameters during correction can lead to difficulties in calibration. Therefore, for the two parameters of the interaction, only the one that has a high more significant influence on the simulation result can be changed.
3. If the sensitivity of a parameter is low, this parameter does not need to be modified. However, if for some reason, the parameter must be modified, it must be adjusted according to the logic operation rules.

The model correction mainly adjusts the following four parameters: f_{SI} adjusted to -0.45, μ_A adjusted to 0.8, Y_A adjusted to 0.27, k_H adjusted to 3.1. Other parameters

DOI: http://dx.doi.org/10.15666/aeer/1705_1139511407

were fine-tuned only for those with relatively high sensitivity. Simulation results after adjustment parameters are shown in *Table 2*.

Table 2. *Simulation results after adjustment parameters*

Constituent	COD	Ammonia	TN
The average of influent	460.29	19.71	20.6
Measured value of effluent	17.62	0.31	11.97
Typical simulation results	24.29	0.2465	15.27
Simulation results of parameter correction	17.74	0.3118	11.94
Typical error of simulation results	3.79%	20.48%	37.57%
Correction parameter of simulation results	0.07%	0.06%	0.03%

It can be seen from *Table 2* that the error of the simulated values of the effluent COD, NH_3-N, and TN after correction is 0.07%, 0.06%, and 0.03% respectively. The simulated values are in good agreement with the measured values, and the simulation is ideal. Therefore, the validated ASM3-MBR model can be used to simulate and predict the effluent index of the reactor.

Zhou et al. (2013) in their research reported that the simulated results fitted very well with the experimental data. After 30 days of simulation, the fluctuations in effluent COD concentrations over the intervals were less than 0.3%. The goodness of fit of the COD between the measured and simulated values was 99.7%. The difference between the simulated and measured NH_4-N values was less than 0.8%, implying a right model prediction for ammonia removal. Overall, the modified ASM3 model obtained a right first prediction concerning the long-term behaviour of effluent COD and NH_4-N concentrations. Also, Blomberg et al. (2018) observed that the ammonia oxidation was directly linked to all of the main nitrogen conversion reactions in the activated sludge process (ASP). The model was able to reproduce the measured NH_4 peaks in the effluent of the ASP throughout the simulation. During the calibration period, the modelled peaks were able to reach the measured values throughout the simulation. Consistently, the model was able to reproduce the measured peaks during the validation phase. Elawwad et al. (2017) reported that the ASM3 provided good representation for WWTP performance. The modelled effluent COD was consistent with the measured COD values.

Comparison of simulation results of ASM3 model under different influent water quality

The MBR reactor in this test did not discharge mud during the test. The sludge concentration in the reactor was about 2000 mg/L when the device was started. The temperature of the reactor was maintained at 24 °C and the hydraulic retention time was 5 h during operation, the aeration intensity was maintained at a relatively broad level to ensure the dissolved oxygen concentration in the reactor fully. The DO was maintained at about 8 mg/L.

The measured and simulated values of the integrated MBR effluent COD and the residual analysis diagram are shown in *Figures 3* and *4.*

From *Figures 3* and *4,* it can be seen that the integrated MBR has a good removal effect on the COD, the effluent COD was very low, and the total COD removal rate was high. The overall impact of the ASM3-MBR model on the simulation of COD effluent was good, except for some points, the simulation values and the measured values were in good agreement. After calculation, the simulated relative error of COD was from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1139511407

0.46 to 23.66%, and the average relative error was 3.88%. Wu et al. (2016) observed an average absolute relative error between the measured and simulated values of 16.8% for the COD effluent while simulating and optimizing a practical cooking wastewater treatment plant (CWTP). Their results revealed that the ASM3 model had been successfully established to simulate the biological process of the CWTP.

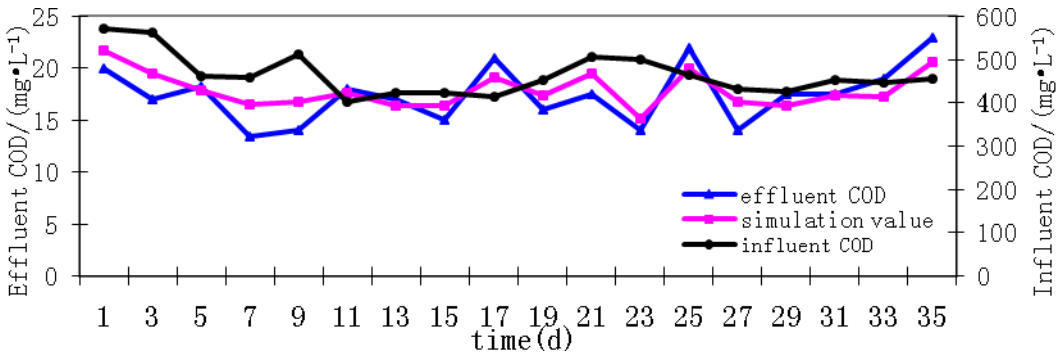

Figure 3. *The measured and simulated values of the integrated MBR effluent COD*

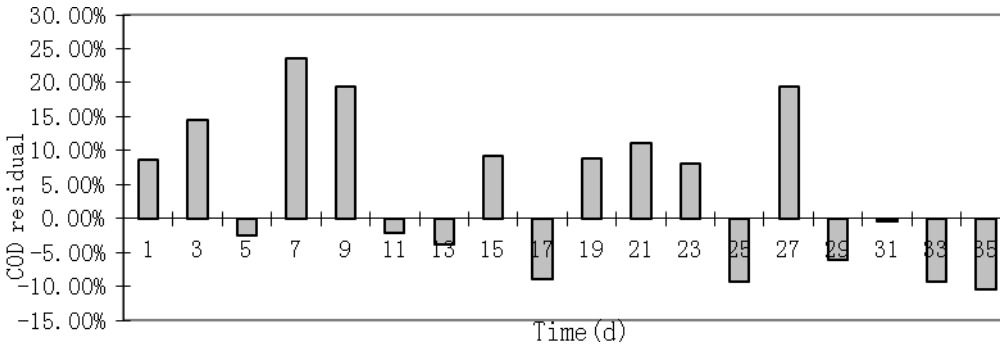

Figure 4. *The residual analysis diagram of the integrated MBR effluent COD.*

The measured and simulated values of the integrated MBR effluent NH_3-N and the residual analysis diagram are shown in *Figures 5* and *6*.

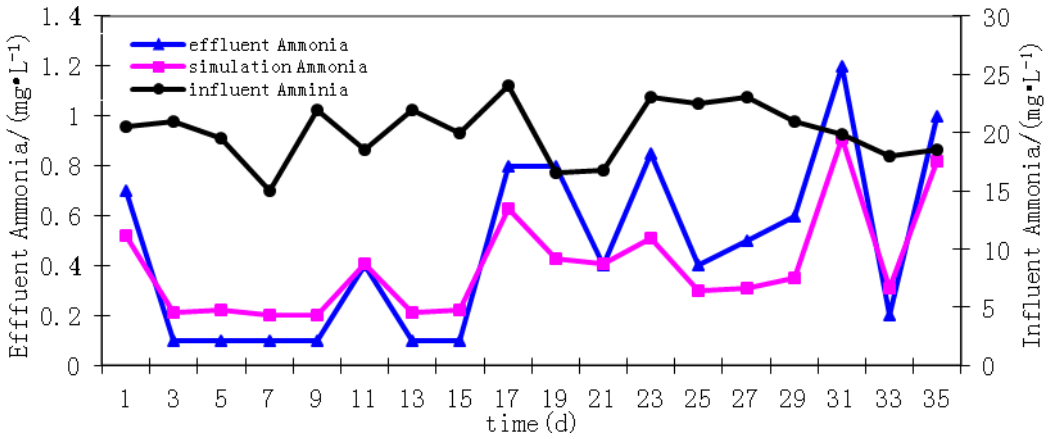

Figure 5. *The measured and simulated values of the integrated MBR effluent NH_3-N*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1139511407

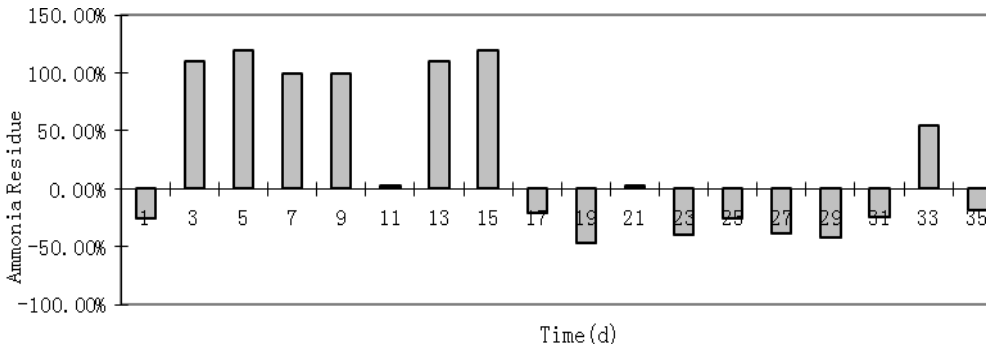

Figure 6. *The residual analysis diagram of the integrated MBR effluent NH_3-N*

As seen in *Figure 5,* the integrated MBR process worked well with NH_3-N. In MBR, since the correlation between the influent NH_3-N value and the effluent NH_3-N value was relatively weak, the simulated value of the effluent NH_3-N during the simulation of the ASM3 model was between the NH_3-N values of the influent. There is a close correlation. Therefore, when using the ASM3-MBR model established based on ASM3 to simulate MBR, there will be some errors between the effluent NH_3-N simulated value and the effluent NH_3-N measured value. However, because the concentration of NH_3-N in the effluent was deficient, and the effluent standard was fully met, and the prediction of total effluent nitrogen was not substantially affected, the prediction could be considered as reasonable. From *Figures 5* and *6,* the relative error of NH_3-N simulation was from 2.5 to 120%, and the average relative error was about 24.44%. However, Wu et al. (2016) observed an average absolute relative error between the measured and simulated values of 15% for NH_4-N effluent and a good agreement in the benefits from the model prediction, and practical measurement was observed.

Figures 7 and *8* show the measured and simulated values of the integrated MBR effluent TN and the residual analysis diagram of the integrated MBR effluent TN.

From *Figures 7* and *8,* the overall effect of the ASM3-MBR model for effluent simulation of TN was good, except for some points, the simulation values and the measured values were in good agreement. After calculation, the relative error of TN simulation was from 0.18 to 27.43%, and the average relative error was 5.39%.

Conclusion

In this research, the established ASM3-MBR model simulation system was used to simulate the steady-state and dynamics of the integrated MBR. The simulation results of the ASM3-MBR model for the effluent COD, NH_3-N, and TN were analyzed. In general, the self-developed simulation system was more consistent with the simulated and measured values of the effluent COD and TN of the MBR system, thus validating the effectiveness and practicality of the ASM3-MBR model. The simulation results also showed that the error between the simulated value and the measured value was unavoidable. The ASM3-MBR model can more accurately simulate the treatment effect of the integrated MBR and the changing rules of various pollutants. This has a significant supporting role in understanding the contaminant removal mechanism of the integrated MBR, optimizing the operational control of the reactor, and predicting the outflow indicators.

It can be concluded that, a precise adjustment and optimization of the simulation program ASM3-MBR can be used to predict the effluent quality of the MBR process sewage treatment plant, and the operation management of the sewage treatment plant can be optimized. More research is, however, required to optimize ASM3-MBR model performance, especially the effluent quality, and reduction of error between the simulated value and the measured value.

This optimization will make ASM3-MBR model more attractive for use as a preferred remediation strategy in wastewater treatment, considering the significant of contaminant removal mechanism of the integrated MBR.

(Received 18th Apr 2019; accepted 1st Jul 2019)

Abstract. COI is the first subunit of the mitochondrial cytochrome C oxidase gene that is commonly used for barcoding via sequencing and molecular identification of insect orders and species. However, fast and cheap data analysis might still be required for the detection of insect orders and species to replace sequencing in large populations. The latter can be emphasized by detecting restriction enzyme site polymorphisms in COI sequences of insect orders and species. In the present study, we have utilized an in silico approach for detecting species- and order-specific molecular markers in insects collected from Saudi Arabia based on the new non-traditional open source tool, namely C*is*SERS. A number of 237 restriction enzymes were checked for the presence of their recognition sites within the *COI* gene sequence of the different insect species. Generated data was displayed in predicted agarose gels as virtual PCR-RFLP patterns. The results indicated the occurrence of 14 species-specific and three order-specific molecular markers representing 10 species and two orders of insect. The highest number of species-specific markers (3 markers) was generated for *Idolus picipennis* (Order: Coleoptera), followed by the two hemipteran *Macrosteles* sp. and *Osbornellus auronitens* (two markers each). Three order-specific markers were generated for orders Lepidoptera (two markers) and Diptera (one marker). The overall results demonstrated that C*is*SERS efficiently allowed for the detection of species- and order-specific markers that can further be utilized in screening large insect populations.
Keywords: *PCR-RFLP, CisSERS, genetic characterization*

Introduction

Subunit I (658 nt) of the mitochondrial cytochrome C oxidase (COX) gene (namely *COI*) started in 2003 to be the most universal marker for species identification in animal (Hebert et al., 2003, 2004). Recent concerns were raised for the insufficiency of insect biodiversity data in Saharo-Arabian region including Saudi Arabia and the lack of conducted traditional surveys (Ashfaq et al., 2018). The latter makes it vital to gain insights on such a virgin area in terms of insect classification and biodiversity.

Our recent study (Ashfaq et al., 2018) proved the feasibility and efficiency of utilizing *COI* gene in barcoding insects collected from Saudi Arabia. In the present study, we further utilized virtual PCR-RFLP based on the barcode sequences targeting the recovery of fast and cheap approach for characterizing insect orders and species in

DOI: http://dx.doi.org/10.15666/aeer/1705_1140911418

large populations. Methods based on restriction enzyme digestion (ex., PCR-RFLP) are easy to perform, reproducible, and cost-effective and require less equipment and expertise (Agarwal et al., 2008). In the past, restriction enzyme-based molecular markers were commonly employed, but with the emergence of high-throughput sequencing technologies, they facilitated more in-depth genomic analysis and characterization. PCR-based restriction fragment length polymorphic markers (or PCR-RFLP) are used for gene mapping and molecular breeding (Shu et al., 2011). To detect the efficacy of re-utilizing PCR-RFLP for molecular characterization, we were required to use efficient in silico tools suitable for analyzing large genomic datasets towards the recovery of a fast and cost-effective approach in characterizing large insect populations in the future.

Access to computational tools that processes massive amounts of DNA sequence information from multiple samples is useful for addressing difficult biological questions. Several current restriction site analysis tools were designed to handle only few sequences for targeted analysis (Neff et al., 2002; Vincze et al., 2003; Ilic et al., 2004; Thiel et al., 2004; Zhang et al., 2005; Taylor and Provart, 2006; Chang et al., 2010). *Cis*SERS (or customizable in silico sequence evaluation for restriction sites) tools were designed specifically for PCR-RFLP marker detection (Sharpe et al., 2016). Such a new graphical user interface helps in detecting enzyme restriction sites in large DNA sequence datasets and enables high-throughput analysis of multiple sequences for restriction sites with a possibly embedded dynamic visualization functionality. It can predict places the enzyme cuts during gel electrophoresis and save time and effort of running unrequired several enzymatically-digested DNA samples. Such information can help in deciding which enzymes to be selected in digesting DNA for restriction-site associated DNA (or RAD) sequencing libraries and further cloning. C*is*SERS can also be utilized in detecting methylated DNAs as the original PCR-RFLP will vary from the virtual pattern for any methylation susceptible restriction enzyme site. C*is*SERS is expected to pave the way between sequence acquisition and implementation of diverse wet-lab approaches to solve biological questions more easily.

In this work, we utilized the COI subunit for specimens of six insect orders collected from Saudi Arabia to detect species- and order-specific molecular markers based on the use of C*is*SERS surface tools in order to generate virtual PCR-RFLP. This information will be useful in the future analysis of large insect populations via PCR-RFLP.

Materials and methods

For sample collection, a Malaise trap (Hutcheson and Jones, 1999; Hill et al., 2005) was installed at Hada Al-Sham station, King Abdulaziz University (KAU) located in the western region (near Makkah) of Saudi Arabia (21.795°N, 39.711°E). Sample collection, morphological classification up to Sanger sequencing were done as indicated in our most recent study (Ashfaq et al., 2018).

C*is*SERS was used to develop fasta files for restriction site analysis and generate predicted gel images as described (Sharpe et al., 2016). Outputs describe the cut counts and locations for each restriction site and dynamically created predicted gel images. The master list of enzymes (237 in the present study) is retrieved from the REbase database (Vincze et al., 2003). A set of formulas used via C*is*SERS is retrieved in order to produce fragment size (Neff et al., 2002; Ilic et al., 2004; Agarwal et al., 2008; Shu et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1140911418

al., 2011). The motif detection feature of C*is*SERS was previously validated using *Nostoc* and *ATPC1* genes (Sharpe et al., 2016).

For validating the in silico datasets, DNAs from the different 30 insect species were isolated and subjected to PCR to recover the *COI* gene fragment (634 bp). Restriction analysis including five selected restriction enzymes was done following standard protocols to validate five species-specific markers of four insect species. The products of restriction analysis were detected using electrophoresis on agarose gels (1.2% in 1x TBE buffer), stained with ethidium bromide (0.3 ug/ml), then visually examined with UV transilluminator and photographed using a CCD camera (UVP, UK).

Results and discussion

Generating a DNA barcode based on the common *COI* gene fragment involves sequencing, then BLAST towards the identification of sequence homology down to the species level. Conventional DNA sequencing is time-consuming and costly, which makes it difficult to be universally utilized. The latter approach generates no particular species- or order-specific markers that can be solely used in preliminary screening of any insect population. In PCR-RFLP, the restriction sites are identified in the target gene fragment (e.g., *COI*), and polymorphism is based on the number and sizes of the cleaved fragment of any given species. This method is simple, cheap and time-saving, thus meets many applications (Liu et al., 2001, 2003; Um et al., 2001; Ding et al., 2003; Wang et al., 2005, 2007; Ying et al., 2007).

In our previous study, *COI* barcodes were analyzed at the DNA level for a number of 560 insect samples collected during four-week time course in Saudi Arabia. Recovered sequences were trimmed to 634 nucleotides and number of samples was narrowed to 175 representing 30 species of six insect orders. Sequences of these species were utilized in generating the virtual PCR-RFLP patterns via C*is*SERS surface tools. A number of 237 restriction enzymes were checked for the presence of recognition sites within the *COI* gene sequence (634 bp) of the different insect species. The consensus sequences of the 30 insect species were fed to the program and restriction sites for enzymes that either uniquely cut DNA of one single species or resulted in the occurrence of a DNA fragment specific to a single insect order are shown in *Figure A1* in the *Appendix*. The figure indicates the positions of the 17 selected enzymes that cut within the COI sequence that meet the above mentioned criterion. Interestingly, no restriction sites were shown in the first 181 nt of the gene (*Fig. A1*; *Table 1*). All selected restriction sites are located downwards. The resulted species- and order-specific markers are shown in the virtual PCR-RFLP patterns shown in *Figures 1* and *2*, respectively, while summarized in *Figure 3*. Species-specific markers were recovered for 10 out of the 30 insect species. The largest number of species-specific markers are shown for *Idolus picipennis* (3 markers) of order Coleoptera, followed by *Macrosteles sp.* and *Osbornellus auronitens* (2 markers each) of order Hemiptera (*Fig. 1*). The single species-specific markers were detected for seven other species, e.g., *Monomorium junodi*, *Camponotus maculatus*, *Balta vilis*, *Belenois aurota*, *Ephysteris subdiminutella*, *Carpomya vesuviana* and *Tabanus striatus*. Numbers of 2, 4, 1, 2, 3 and 1 species-specific markers were shown for orders Hymenoptera, Hemiptera, Blattodae, Lepidoptera, Coleoptera and Diptera, respectively (*Figs. 1* and *A1*). The results at the order level indicate the recovery of three order-specific markers.

Two of which are shown for order Lepidoptera and one is shown for order Diptera (*Fig. 2*). Exact position of each marker is shown in *Figure A1*. Sizes of these markers are 182 and 99 nt for order Lepidoptera and 42 for order Diptera. Enzymes that generated these markers are BclI, DpnI and LpnPI, respectively. Interestingly, DpnI

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1140911418

enzyme has a 4-nt recognition site (GATC) that exists within the 6-nt recognition site (TGATCA) of BclI enzyme. The TGATCA site is located at 453 nt, therefore, the two enzymes cut DNA at this site. DpnI has another site at 552 nt, which is located 99 nt downstream the first, while BclI has no further sites downstream the first (*Fig. A1*). Accordingly, the cut with BclI resulted in the occurrence of 182 nt marker, while the cut with DpnI enzyme resulted in the occurrence of 99 nt marker. The results generated from *Cis*SERS tools were validated via the restriction analysis of PCR products involving five randomly selected species-specific markers and electrophoregram results supported those generated by *Cis*SERS tools (*Fig. A2*). Concerns on the reproducibility of PCR were repeatedly raised. Besides, dry-lab restriction analysis requires validation via wet-lab experimentation. Therefore, we consider the data shown in *Fig. A2* can validate both the PCR approach as such as well as the utility of *Cis*SERS tools. Other universal markers, ex., 16S rRNA gene, were successfully utilized in detecting PCR-RFLP patterns of the causative bacteria of neonatal sepsis, e.g., *Staphylococcus aureus* and *Klebsiella* spp. (Rohit et al., 2016). The results indicated that PCR-RFLP is useful for the early diagnosis of culture negative neonatal sepsis in human.

There are many restriction site analysis tools designed to handle only few/short sequences (Neff et al., 2002; Vincze et al., 2003; Ilic et al., 2004; Thiel et al., 2004; Zhang et al., 2005; Taylor and Provart, 2006; Chang et al., 2010). Of which, NEBcutter handles a less than 300 kb, besides, it is not set up for multiple sequence analysis (Vincze et al., 2003). The other tools are web-server based with limited functionality for high-throughput analysis. However, *Cis*SERS was developed to enable high-throughput analysis of multiple/long sequences for restriction sites. In addition, *Cis*SERS solely allows for custom motif detection to identify conserved sites, e.g., *cis*- and *trans*-acting element binding sites. Sharpe et al. (2016) indicated the effectiveness and multiple distinctive functionalities of *Cis*SERS in analyzing mature sequence data of *cfq* gene. They also indicated that utilizing *Cis*SERS in transcriptomic or genomic analysis enables a guidance during subsequent restriction enzyme-based experimentation. PCR-based approaches could make identification of insect at species level easier, faster and more accurate compared with traditional morphological approaches. We think this work in the first of its kind in detecting species- or order-specific molecular markers in insects as well as in the utility of *Cis*SERS in discriminating insect orders and species. In conclusion, *Cis*SERS is a fast, cost-effective surface tools enable bridging the gap between sequence acquisition and implementation of wet-lab approaches towards addressing important biological clues.

Conclusion

Data generated in the present study from virtual PCR-RFLP via *Cis*SERS provided useful information. Firstly, it narrows the number of restriction enzymes to be used in the future in studying any insect population. Second, it supports the utility of the wet-lab PCR-RFLP as a fast, cheap, requires less equipment and cost-effective approach for characterizing insect populations. Third, it provides species- and order-specific markers that can be used as a first layer of detection at the species or order levels. Such an approach can be adopted for other types of universal markers in prokaryotic as well as eukaryotic organisms.

(Received 18th Apr 2019; accepted 12th Jul 2019)

Abstract. This literature review presents a summary of papers related to the determination of the sources of cobalt compound presence in the environment and the resulting pollution of water and land. Their properties, determining their toxicity to living organisms, have been specified, with sections devoted to their effect on microorganisms and plants. The influence (negative and positive) of cobalt on living organisms in water and soil environments, including the biological balance of the soil (the number of microorganisms, enzymatic activity) and plant growth and development, and the possibilities of their use in the phyto- and bioremediation of areas polluted with cobalt have been described. Particular emphasis has been placed on the presentation of the effect of cobalt on animals and man.
Keywords: *cobalt, contamination, environment, microorganisms, plants, animals, human*

Introduction

Throughout history, human activity has contributed to environmental transformation. Over time, substantial population growth has significantly influenced the introduction of innovations in the world of technology which, in turn, have caused increasing interference of some processes in the environment (Guzmán-Morales et al., 2011). The development of industry, electric appliances, transport and the use of growing amounts of chemicals, mainly in the construction, chemical and agricultural sectors, has led to the appearance of different kinds of pollutants in the environment (Page and Feller, 2005; Murtaza et al., 2008; Dhaneesh et al., 2012; Wyszkowski and Sivitskaya, 2012; Modrzewska and Wyszkowski, 2014).

Heavy metals are the most common group of pollutants reducing the natural regeneration ability of the environment (Malik and Zeb, 2009; Mansouri et al., 2012). Many heavy metals are necessary for the proper functioning of living organisms. Some others, however, exert a negative effect on their development (Wyszkowska and Wyszkowski, 2002, 2003; Ciećko et al., 2005; Wyszkowski and Wyszkowska, 2009; Chmielowska-Bąk et al., 2014) and it should be remembered that the toxicity of a given chemical compound is determined by the dose introduced into the organism in a unit of time (Dhaneesh et al., 2012; Dobrowolski and Otto, 2012; Bezerra et al., 2014).

In environmental protection, the greatest focus is on such heavy metals as cadmium, lead and mercury, although other micronutrients also deserve attention due to the possibility of significant soil loading (Page and Feller, 2005). Among the elements present in amounts exceeding trace values in the soil, water, and air environments, cobalt (not yet fully known as a trace element) has attracted special attention (Fermoso et al., 2010). The diversified use of this metal in different branches of industry has caused growing demand in the world market (Lefebvre et al., 2008; Malik and Zeb,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1141911449

2009; Sytschev et al., 2009; Biswas et al., 2013; Huang et al., 2013). This contributed to the emergence of numerous companies involved in the production of this element. Production of cobalt by major companies worldwide in the recent years has been on a significant increase. The total production of cobalt by major companies in 2008 amounted to 28,901 tonnes (Elliot and Litzinger, 2015), while by 2015, it increased to 220 000 tonnes (Sun et al., 2019).

With the growing demand for this raw material (Liu and Erhan, 2002; Pathak and Choppin, 2009; Fermoso et al., 2010; Banks et al., 2012; Hong et al., 2012; Esther et al., 2013) the problem of its excessive accumulation in the environment began to appear and also started to have a significant effect not only on plants (Akbar et al., 2013) and animal organisms, but also on humans (Balestrazzi et al., 2009; Koigoora et al., 2013; Devi et al., 2014).

The aim of this paper is to present the sources of cobalt occurrence in the natural environment and its effect on the functioning of selected groups of living organisms. The influence of cobalt on environment, living organisms in water and soil environments, including the biological balance of the soil (the number of microorganisms, enzymatic activity) and plant growth and development, animals and man was presented. The possibilities of use of microorganisms and plants in the phyto- and bioremediation of areas polluted with cobalt have been described.

Sources and forms of cobalt presence in the environment

In the periodic table of elements, cobalt is classified as a transition metal (Koch et al., 2007). It has both chalcophile, siderophile and lithophile properties. Its chalcophility manifests itself mainly in the fact that it can occur in the form of sulfides in the lowest parts of the Earth's mantle (Lock et al., 2006), while cobalt siderophility is related to its low affinity to oxygen and sulfur, which makes this metal soluble in liquid nitrogen and able to occur in the Earth's core. Cobalt also occurs in the silicate layer of the Earth's crust, which indicates litophile properties. It is assumed that the natural cobalt content in the Earth's crust does not exceed 12 $mg \cdot kg^{-1}$ (Sheppard et al., 2007). Alkaline igneous rocks are the largest cobalt accumulators. They contain up to 200 $mg \cdot kg^{-1}$ of this element, while the same igneous rocks, but with an acidic character, contain no more than 15 $mg \cdot kg^{-1}$. Small cobalt contents are also found in sedimentary rocks, where its concentration is highest in mudstones (around 20 $mgkg^{-1}$) and lowest in limestones (around 3 $mg \cdot kg^{-1}$). Minerals are also a source of cobalt, which include CoAsS (cobaltite), $CoCO_3$ (spherocobaltite), Co_3S_4 (linnaeite), $Co(Ni)As_3$ (smaltite) and $CoAs_2$ (safflorite) (Luo et al., 2010). The contamination of soil with cobalt have the effect on other trace elements in soil, e.g. they may be increased the content of lead, chromium, nickel and zinc in soil (Kosiorek and Wyszkowski, 2019c).

Cobalt is released during the weathering process in the oxidation state of +2 and is then strongly bound by the mineral and organic-mineral complex in a readily- and slowly- exchangeable form (Swarnalatha et al., 2013). Due to ion exchange and chemical processes, cobalt is adsorbed by clay minerals, which results in the formation of complex compounds on their surface (Li et al., 2009). Special importance in this respect is attributed to montmorillonite, whose sorption capacity (also including for cobalt) is significantly higher than other clay minerals. The adsorption of this element by manganic minerals is also possible. The most frequent form of cobalt presence in the soil is Co^{2+} (ionic form), Co^{3+} (coordination compounds) as well as $CoOH^{+}$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1141911449

and$Co(OH)_3^-$. Moreover, small amounts of readily-soluble cobalt in the form of $Co(OH)_2^0$ occur in the soil solution, whose amount compared to the total content is no higher than 5%. Organic fertilization causes a small increase in the amounts of cobalt in a soluble form in the soil (Faucon et al., 2007). A naturally high soil cobalt level is closely linked to manganese and iron presence as well as organic soils. This is due to the high susceptibility of the oxides of these metals to binding and adsorbing the cations of divalent and trivalent cobalt, as well as easy sorption by organic matter (Dávila-Rangel and Solache-Ríos, 2006). It is assumed that loamy and alluvial soils have naturally high cobalt contents of up to 12 $mg \cdot kg^{-1}$, and podsolic and silty soils have the lowest, with a mean cobalt content of only 5.5 $mg \cdot kg^{-1}$. Compared to the average cobalt content in the world's soils, this value is not much higher than the lowest cobalt content in sandy and silty soils, where it is 8 $mg \cdot kg^{-1}$. However, soils formed from bedrock with a high cobalt content can contain up to 500 $mg \cdot kg^{-1}$ of this element (Tappero et al., 2007).

Cobalt mobility in soils is low (Fujikawa and Fukui, 2001; Edwards et al., 2012). It is assumed that over 95% of cobalt after prior introduction into the soil does not move and it remains in the soil down to a depth of around 5 cm. Increasing the acidity and anaerobic soil conditions causes the cobalt mobility to increase (Narendrula et al., 2012). The main cause of this tendency is the inhibition of valence bonds with Fe and Mn. However, since divalent cobalt and manganese ions do not have strong complex formation abilities, the outer hydration shell is not destroyed during their binding (Lalah et al., 2009). The presence of cobalt in the form of chelates also contributes to increasing the soil mobility of this element. The main causes of increasing the soil cobalt content include improper fertilizer management (Saaltink et al., 2014), use of some pesticides (Defarge et al., 2018) as well as inappropriately-used sludge from municipal sewage treatment plants (Ebrahimi et al., 2009; Ben-Fredj et al., 2014; Li et al., 2014; Zupančič and Skobe, 2014). Application of different substances (e.g. manure, zeolite, calcium oxide) to soil reduced the content of cobalt and other trace elements in soil (Kosiorek and Wyszkowski, 2019c). These materials (especially manure) have a positive effect on the available forms of phosphorus, potassium and magnesium, total nitrogen and other properties of soil (Kosiorek and Wyszkowski, 2019b).

Significant importance is also attributed to cobalt compounds emitted to the air, mainly during the combustion of hard coal and petroleum, which are especially transferred to the soil environment during intensive precipitation (Biswas et al., 2013; Singh and Cameotra, 2013). The extraction of different kinds of raw materials, particularly metallic, also leads to soil pollution with this element (Narendrula et al., 2012; Huang et al., 2013). Transport also causes a rise in cobalt content in the environment (Kuoppamäki et al., 2014; Werkenthin et al., 2014).

In Poland, the soil cobalt content limits are set out in the Regulation of the Polish Minister of the Environment of 1 September (2016) on soil quality standards and land quality standards. For protected areas and land which is part of a protected area and in the surface soil layer (down to 30 cm) of agricultural land, the permissible cobalt content should not be higher than 20-50 $mg \cdot kg^{-1}$ of soil dry matter and in the soil layer in industrial areas, surface mining land in use and communication areas, it may not exceed 200 $mg \cdot kg^{-1}$ of soil dry matter.

Both in surface waters and groundwaters, cobalt occurs in the oxidation state of +2 and +3. Moreover, it can also occur in the form of complex compounds, which it forms with cyanides, ammonia and edetic and nitrilotriacetic acid, most often present in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1141911449

different kinds of detergents (Ghassabzadeh et al., 2010). The natural cobalt concentration in fresh surface waters does not exceed 0.2 $\mu g \cdot dm^{-3}$ and in drinking water it is 0.03 $\mu g \cdot dm^{-3}$. Salt groundwaters, compared to fresh waters, are characterized by its lowest natural content - 0.02 $\mu g \cdot dm^{-3}$ (Qiu and Zheng, 2009). Cobalt solubility mainly depends on the pH of the water environment and on its concentration (Ochieng et al., 2009). The content of cobalt in surface waters is various (*Table 1*).

Due to rapid cobalt binding by organic matter, all kinds of clay minerals and iron and manganese in an oxide form, cobalt in an oxidized form does not persist very long in water. The result is substantial cobalt accumulation in the bottom sediments of both fresh and salt waters (Sukdeo et al., 2012; Ghandour et al., 2014), where its content in the sediments of flowing surface waters is around 13 $mg \cdot kg^{-1}$. According to Jayasiri et al. (2014) the cobalt sedimentation rate is affected by climatic conditions and seasonal fluctuations (Mohiuddin et al., 2012). The mobility and solubility of this element in bottom sediments is determined mainly by its form (Wu et al., 2012) and sorption processes occurring between cobalt ions and negatively-charged sediment molecules (Jayasiri et al., 2014). As a result of changing physicochemical conditions, cobalt in sediments may be re-released to water (Sukdeo et al., 2012; Zamani-Hargalani et al., 2014).

Baltic Sea, Poland	0.45 $\mu g \cdot dm^{-3}$	Kabata-Pendias and Pendias (2001)

The metals and ceramic industries are most responsible for cobalt introduction into surface waters. Due to the wide-ranging application of this metal, particularly in the petrochemical, aviation or power industries, the amount of introduced wastewater with substantial cobalt contents has a negative effect not only on the condition of surface waters, but also on the condition of groundwaters (Wang et al., 2007; Abdel-Razek et al., 2009; Ebrahimi et al., 2009; Abd-Alla et al., 2014; Chanpiwat and Sthiannopkao, 2014). Additionally, pollutants also present in the air, which travel with waste to a given body of water (Mohiuddin et al., 2012; Sandergaard, 2013) and tourist activity (Koigoora et al., 2013) can contribute to this situation. In groundwaters, cobalt content depends mainly on the well location and on the water extraction technique. The main

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1141911449

factors which can cause an increase in its content in groundwaters are: contamination of unconfined groundwaters from bedrocks containing the water-bearing layer (Obiri, 2007) and anthropogenic activities (Upadhyaya et al., 2014).

The permissible cobalt concentration for class I and II of uniform parts of surface waters is set out at ≤ 0.05 mg·dm^{-3} (Regulation of the Polish Minister of the Environment of 21 July, 2016). The permissible cobalt concentration in groundwaters is: class I (very good) - 0.02 mg·dm^{-3}, class II (good) - 0.05 mg·dm^{-3}, class III (satisfactory) - 0.2 mg·dm^{-3}, class IV (unsatisfactory) - 1 mg·dm^{-3}, class V (poor) > 1 mg·dm^{-3} (Regulation of the Polish Minister of the Environment of 21 December, 2015). Cobalt content in surface waters largely depends on the treated wastewater introduced into them. According to the Regulation of the Polish Minister of the Environment of 18 November (2014) the permitted cobalt concentration in treated wastewater from the ceramic industry should not be higher than 0.1 mg·dm^{-3} and less than 1 mg·dm^{-3} in the other wastewater types.

Apart from cobalt presence in soils and waters, this element is also in the air in an oxidized and insoluble form in dust (Pietrodangelo et al., 2014). Its natural content in the air is low. It is assumed that this value ranges from 0.0005 to 0.005 ng·dm^{-3}. Excessive levels of the natural cobalt air content are found only over urbanized areas (Albayrak and Mor, 2011; Canepari et al., 2014; Dos Anjos-Paulino et al., 2014). This relationship is presented in *Table 2* which provides the contents of cobalt in the air in certain parts of the world.

Table 2. *The content of cobalt in the air in selected places in the world*

Place, country	Cobalt content in air	Source
Łódź, Poland	0.31 ng·m^{-3}	Bem et al. (2003)
Cap Ferrat, south-west coast of France	0.10-0.28 ng·m^{-3}	Heimbürger et al. (2010)
South-East Sea of Japan, Japan	0.31-0.41 ng·m^{-3}	Kang et al. (2009)
Milan, Italy	2.10 ng·m^{-3}	Rizzio et al. (2001)
Rio de Janeiro, Brazil	0.40 ng·m^{-3}	Miranda and Tomaz (2008)
Beijing, China	7.90 ng·m^{-3}	Wang et al. (2001)
Frankfurt am Main, Germany	0.08 ng·m^{-3}	Zereini et al. (2005)

The most frequent sources of air pollution with this element are hard coal-fired power plants and road transport (Mahapatra et al., 2013). An increased air cobalt content is caused by: wind erosion (Singh et al., 2013; Canepari et al., 2014), metal industry activity (Sheppard et al., 2007) and the presence of dust rising from storage sites for different kinds of stored waste and hydrothermal particles (Sheppard et al., 2007; Antony et al., 2011; Singh et al., 2013). Seasonal variation of a given area affects the air cobalt concentration (Canepari et al., 2014).

In Polish legislation, the permissible reference values for cobalt are contained in the Regulation of the Polish Minister of the Environment of 26 January (2010) on reference values for various substances in the air. The permissible reference value for cobalt, expressed as the sum of this metal and its compounds in PM_{10} dust, averaged for the time of 1 h, is 5 μg Co·dm^{-3} and for the whole calendar year this value should not exceed 0.4 μg Co·dm^{-3}. EU law sets out the average emission limit values for 10 heavy metals in total, including cobalt and its compounds (expressed as cobalt - Co) at 0.5

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1141911449

$mgN \cdot dm^{-3}$ over a sampling period of a minimum of 30 min and a maximum of 8 h (Directive 2010/75/EU).

Cobalt also occurs in the natural environment in the form of the ^{55}Co, ^{56}Co, ^{57}Co, ^{58}Co, ^{60}Co isotopes, resulting from human activity (Tappero et al., 2007; Antony et al., 2011). They are characterized by radioactive properties, due to which they can emit beta and gamma radiation to the environment. Beta and gamma particles are charged positively or uncharged, respectively. Their formation is the result of numerous nuclear reactions. The radioactive half-life of cobalt ranges from several dozen days to thousands of years (Mollah and Begum, 2001). Cobalt isotopes have very wide application. An example can be ^{60}Co, which serves both for human radiotherapy and also for cold pasteurization of different seasonings and food products. Despite their positive use, cobalt isotopes are also a by-product of nuclear processes (Nagpal, 2004). Their negative environmental impact is associated with their high mobility, which mainly depends on the chelate effect of the radioactive cobalt compound and on its oxidation state. Its decomposition in the soil is a very long process and can be accelerated only by decay if it is organic pollution. In the water environment, radioactive cobalt occurs in the oxidation state of +2 and +3 (Tappero et al., 2007). Cobalt in the oxidation state of +3 is both stable and mobile in the water environment. Cobalt presence in a divalent form allows easier adsorption of free ions of this element on the surface of iron occurring in an oxide form. The cobalt(II) form is not as stable as cobalt(III), which is caused by the absence of ligands responsible for its persistence in water (Hau et al., 2008).

In Polish legislation, there are no set out radioactive cobalt limits and in international law the content limit for this form of cobalt present in surface waters is set out by USEPA (2000 after 56 FR 33121, Appendix B 000), where for ^{57}Co this level is 4870 $pCi \cdot dm^{-3}$, for ^{58}Co - 1590 $pCi \cdot dm^{-3}$ and for ^{60}Co - 218 $pCi \cdot dm^{-3}$.

As it results from the review of the above literature, the main cause for the contamination of the environment with cobalt has become the development of civilisation, and the inextricably linked development of industry. The elevated contents of this element taken up from the soil, water or the air by living organisms have been introduced into the food chain, at the same time creating a risk to their lives and proper functioning (*Fig. 1*).

Cobalt is not biodegradable as after its introduction to the environment, it constantly circulates within it, with only its form being transformed. With the introduction of cobalt into higher and higher links of the food chain, however, the excessive accumulation thereof occurs. Therefore, it creates the greatest risk to the final link of the food chain, namely the human (Biesalski and Grimm, 2012).

Effect of cobalt on microorganisms

The soil is inhabited in the greatest numbers by viruses, bacteria, fungi, algae and protozoa. Due to organic matter decomposition, they expand their biomass and contribute to increasing humus in the soil. Proper microorganism development depends on different kinds of factors, such as: light, humidity, temperature or nutrient availability. Among the many compounds affecting the course of microbiological processes, special importance is attributed to trace elements, which include cobalt (Wang et al., 2007; Abdel-Razek et al., 2009; Hlima et al., 2012). Maintaining its optimal content in microorganism cells can assist metabolic processes or increase their

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1141911449

content of vitamin B_{12} assisting growth processes (Marrero et al., 2007; Kun-Tai et al., 2008; Abskharon et al., 2010). As shown by the results of the study by Hlima et al. (2012), cobalt presence in xylose isomerase ensures the proper course of sugar metabolism in microorganisms. Cobalt is part of the coenzymes of the genus *Rhizobium* bacteria or the free-living *Azotobacter* bacteria responsible for binding nitrogen from the air (Rancelis et al., 2012) because vitamin B_{12} synthesis is necessary for the course of redox processes and nucleoprotein synthesis (Pulgarín et al., 2013; Abd-Alla et al., 2014).

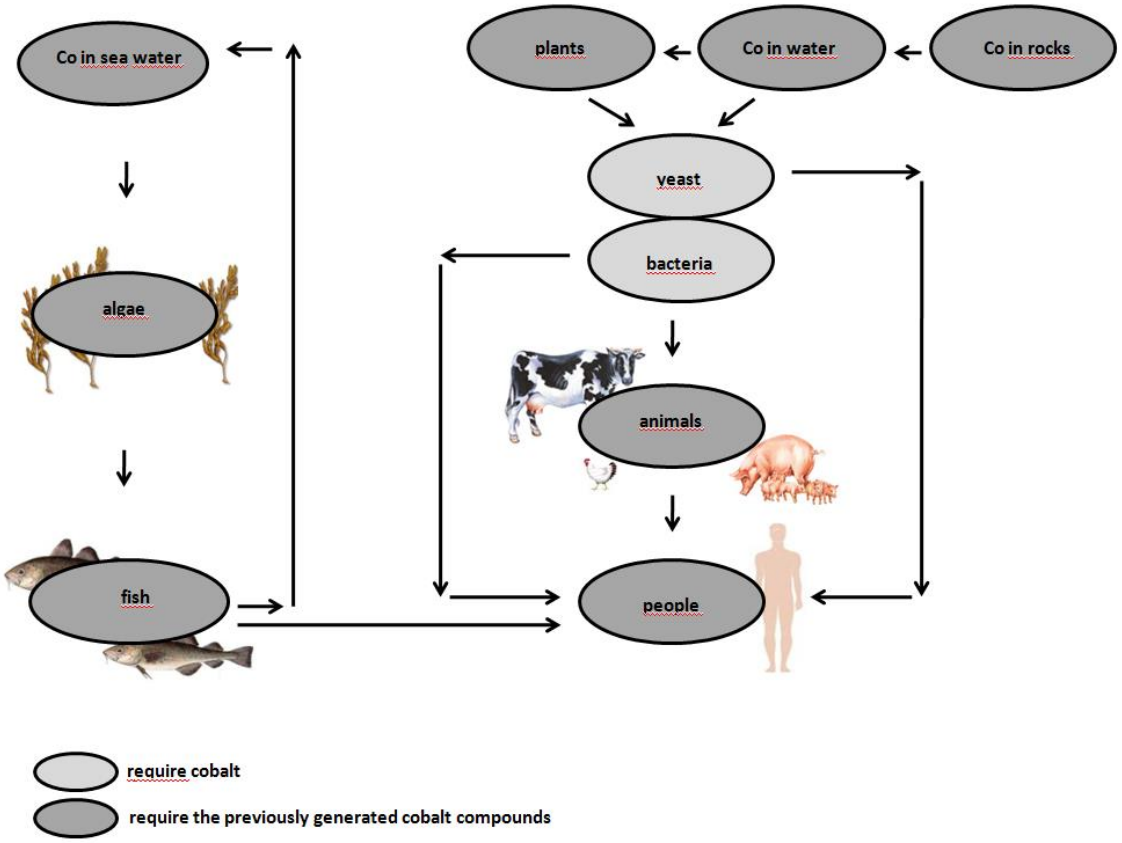

Figure 1. *Cobalt cycle in the environment. (Source: own work based on Biesalski and Grimm, 2012)*

Proper cobalt content in microorganisms is also important due to the initiation of many enzymatic reactions (Minamihata et al., 2012; Elleuche et al., 2014), protein absorption and decomposition (Antony et al., 2011). This is particularly visible for papilionaceous plants, due to their symbiosis with nodule bacteria. In these bacteria, cobalt is the activator of the urease enzyme, which is the catalyst in the urea decomposition reaction (Witte et al., 2002). Apart from carbon dioxide and water, the main product of this reaction is ammonia, which is also the final product of ammonification and enables the initiation of nitrification, where this compound will be oxidized to nitrites and nitrates (Guo et al., 2014). Nitrification is one of the major processes characterizing soil quality. Cobalt has a crucial effect on nitrification rate, but its excessive content in the soil may inhibit the process (Wyszkowska et al., 2006). In a study by Wyszkowska et al. (2006) in soil with a neutral reaction, this process was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1141911449

inhibited to a small degree by cobalt, applied at a lower dose (200 $mg \cdot kg^{-1}$ soil), regardless of the testing date. Under a higher cobalt dose (400 $mg \cdot kg^{-1}$ soil), nitrification decreased twofold-threefold. This adverse effect disappeared completely on the 60th day of soil incubation. An excessive soil cobalt content may cause a decrease in the mineral nitrogen content ($N\text{-}NH_4^+ + N\text{-}NO_3^-$). According to Welp (1999) cobalt acts more weakly in the soil than other heavy metals on the activity of dehydrogenases: $Hg > Cu > Cr^{6+} > Cr^{3+} > Cd^{2+} > Ni^{2+} > Zn^{2+} > As^{3+} > Co^{2+} > Pb^{2+}$ and, in the view of Nowak et al. (2003) also on the activity of acid phosphatase: $Cu^{2+} > Al^{3+} > Cd^{2+} > Zn^{2+} > Fe^{3+} > Ni^{2+} > Pb^{2+} > Sn^{2+} > Fe^{2+} > Co^{2+}$ and alkaline phosphatase: $Cd^{2+} > Al^{3+} > Zn^{2+} > Fe^{3+} > Cu^{2+} > Pb^{2+} > Ni^{2+} > Fe^{2+} > Se^{2+} > Co^{2+}$.

According to Wang et al. (2010) cobalt has an average effect on soil microorganisms in the heavy metal toxicity series (Cr > Pb > As > Co > Zn > Cd > Cu). Exceeding the threshold levels may, however, have a negative effect on the proper course of life processes (Maguire and Collins, 2001). The result may be disturbance of the course of redox reactions, inhibition of biopolymer hydrolysis processes or the slowing of enzymatichydrolysis (Abd-Alla et al., 2014; Hu et al., 2014). Radicals and unstable products of enzymatic reactions, causing cell growth, begin to appear in these organisms. The cell wall bursts as a result of increased osmotic pressure. Another result of an excessive cobalt content in microorganism cells may be the inhibition or acceleration of cell division (Antony et al., 2011).

Apart from microorganisms reacting negatively to high cobalt doses, there are also those which have the ability to remove it. The reduced cobalt harmfulness to these organisms is the result of their having cell systems affecting accumulation, excretion or enzymatic changes, which can reduce its harmfulness (Hoffman et al., 2010). There are also typically specialized groups of microorganisms with specific regenerative abilities enabling the accumulation of excessive cobalt amounts from the soil (Peca et al., 2008; Abskharon et al., 2010).

The analyzed literature shows that a high ability to remove cobalt from the soil characterizes such bacteria as: *Pseudomonas denitrificans* (Rong et al., 2008), *Pectobacterium antrosepticum* (Elleuche et al., 2014), *Escherichia coli* (Freeman et al., 2005), *Cellulosimicrobium cellulans* and yeasts: *Schizosaccharomyces pombe* or *Saccharomyces cerevisiae* (Ruta et al., 2010; Ryuko et al., 2012). Organisms more sensitive to increased cobalt contents include, among others, the bacteria *Rhizobium tibeticum* (Abd-Alla et al., 2014) or *Serratia marcescens* (Marrero et al., 2007). Harmful effects are also visible in fungi, for example, *Aspergillus oryzae* and *Aspergillus niger* (Biswas et al., 2013; Li et al., 2014). Abdel-Razek et al. (2009) also found a high resistance of some fungi from the genera *Paecilomyces, Rhizopus, Penicillium, Trichoderma* and *Pythium* to excessive cobalt contents. Wang et al. (2007) confirmed the negative effects of cobalt on nematodes (*Caenorhabditis elegans*). Earthworms are also at risk due to the accumulation of the part of cobalt which is not excreted (Ashfaq et al., 2009).

Some groups of microorganisms, due to the production of biosurfactants, have the ability to remove cobalt. They mainly include bacteria, fungi and yeasts. One of the many microorganisms able to produce surface active agents in the form of lipopeptides is the bacterium *Bacillus subtilis*. Singh and Cameotra (2013) report that the ability to remove cobalt resulting from the application of this biosurfactant is over 35%.

Maintaining proper growth conditions for a given group of microorganisms to increase pollutant removal efficiency also has a special effect on the initiation of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1141911449

above processes (Abdel-Razek et al., 2009). According to Amir and Pineau (2003) acceleration of cobalt cleanup from the soil by heterotrophic bacteria can be affected by a slightly acid soil reaction. Maintaining the pH at this level creates ideal conditions for faster release of this element in the soil, due to which it becomes more available to these microorganisms. Cobalt biosorption rate is also affected by the ambient temperature at which microorganisms live (Biswas et al., 2013). The higher it is, the more efficient this process is. This relationship was also confirmed by Abdel-Razek et al. (2009) who found raising the temperature by 10 °C led to an increase in cobalt accumulation by around 10%. Soil microorganisms are also able to remove radioactive cobalt, which is confirmed by Sassman et al. (2007).

Cobalt is also present in salt and fresh surface waters and in groundwaters. Its proper amount, not exceeding the limit values, is necessary for the course of growth processes in water microorganisms, as well as for soil microorganisms (Elleuche et al., 2014). Microorganisms present in water are also able to reduce cobalt content under conditions of its excessive accumulation (Amir and Pineau, 2003). These processes include extracellular secretion, biotransformation and intracellular absorption and its precipitation outside the cleaning organism. Apart from naturally-occurring water microorganisms able to absorb cobalt, there are also those which are characterized by a higher biosorptive ability. Bacteria present in sea water can also contribute to cobalt content reduction (Amir and Pineau, 2003; Antony et al., 2011). These organisms include, among others, *Cunninghamella elegans* (Abdel-Razek et al., 2009) as well as *Shewanella*, which reduces the pollution of waters with radioactive cobalt (Hau et al., 2008).

Effect of cobalt on plants

Cobalt is the trace element which have a strong effect on growth and development of plants. The negative effect of soil contamination with cobalt on plants depends on many other factors e.g. soil reaction, content of organic matter, clay and other macronutrients and micronutrients in soil. The result of cobalt presence in the soil is its accumulation in plants, also including in their fruits (Soylak et al., 2013). It is absorbed by plant roots in the form of a cation in the oxidation state of +2 and chelate compounds (Karuppanapandian and Kim, 2013). Cobalt availability to plants largely depends on the soil conditions (Jonnalagadda et al., 2008; Agbenin et al., 2009; Wendling et al., 2009). This was confirmed in a study by Edwards et al. (2012) where the application of drainage in pasture soil accelerated the weathering of minerals and increased cobalt absorption by grasses. The accumulation rate for aquatic plants mainly depends on such factors as temperature, salinity and water oxygen concentration (Chatterjee and Dube, 2005). The necessity of cobalt for marine flora was confirmed by Antony et al. (2011) in a study conducted on marine phytoplankton.

Because of the cobalt presence in the coenzyme of nodule bacteria, it plays a significant role in papilionaceous plants (Tappero et al., 2007; Collins and Kinsela, 2011). Due to flavonoid secretion by plant roots, gene expression by genus *Rhizobium* microorganisms is induced. The genes encoding enzymes in nodules cause the infection of root hairs and then the formation of nitrogen-binding nodules. This is also the reason for the presence of substantial cobalt contents in these plants (Abd-Alla et al., 2014). Cobalt presence in plants also allows the proper course of metabolic and growth processes to be maintained (Page and Feller, 2005; Ashraf and Mian, 2008; Rong et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1141911449

2008; Collins and Kinsela, 2011; Soylak et al., 2012). According to Trejo-Tapia et al. (2001) cobalt content in plants has a positive effect on the production of betalains and secondary metabolites and cobalt is also responsible for leaf pigmentation in leguminous plants (Rancelis et al., 2012). It also plays a significant role during ethylene synthesis inhibition in sunflower, which was confirmed by Benlloch-González et al. (2010). Additionally, it serves as a catalyst in many enzymatic processes (Tappero et al., 2007; Dong Cho et al., 2012; Karuppanapandian and Kim, 2013).

Cobalt content varies depending on plant organ type. Murtaza et al. (2008) found that this content is higher in leaves than in the other parts of vegetables. This was also confirmed in a study by Chatterjee and Dube (2005) where cobalt was accumulated in greater amounts in the aboveground parts of cauliflower and cabbage than in their roots. For cereals, as Page and Feller (2005) reported that a similar tendency was obtained in wheat, but younger leaves have a much higher requirement for this element than older ones.

Cobalt toxicity is closely related with the acidity of the soil. In alkaline soil the toxic effect of cobalt contamination on plant development is smaller than in acid soil. For higher plants, no effect of cobalt on their growth and development has been shown (Tappero et al., 2007; Rancelis et al., 2012; Rognerud et al., 2013). However, to meet the nutritional requirements, cobalt content in their tissues should not be lower than 0.08 mg/kg. Among papilionaceous plants, clovers have the greatest accumulative abilities and among cereals, wheats have the highest. In vegetables, cabbage and lettuce are characterized by the highest cobalt contents (Nirmal-Kumar et al., 2007). Application of different sorbents to soil (e.g. manure, calcium oxide, etc.) is effective in reducing the negative effect of contamination of cobalt on plants (*Figs. 2* and *3*). They reduced the content of cobalt and its bioconcentration and translocation in plants.

As a result of exceeding the limit values for cobalt, iron assimilability is blocked, which causes the appearance of toxic symptoms (Chatterjee and Chatterjee, 2002; Tappero et al., 2007). Increased cobalt contents in plants can cause disturbances of physiological, biochemical and metabolic processes (Wendling et al., 2009). According to Abd-Alla et al. (2014) these contents can also contribute to stopping the growth of nodules on the roots of papilionaceous plants and thus reduce their nitrogen assimilability (Jain and Nainawatee, 2000). The consequence of exceeding the permissible dose in plants is stopping growth processes and the appearance of disease symptoms, such as chlorosis, necrosis or tissue death (Chatterjee and Chatterjee, 2002; Chatterjee and Dube, 2005; Wyszkowski et al., 2009). Photosynthesis is disturbed, the intercellular spaces become smaller and the chloroplast structure disintegrates (Chatterjee and Chatterjee, 2002; Chaudhari et al., 2017).

These disturbances can also delay the maturation of flowers which, in turn, reduces their productivity and decreases plant yield significantly (Keeling et al., 2003; Chatterjee et al., 2006; Wyszkowski and Wyszkowska, 2007; Chaudhari et al., 2017; Muthaura et al., 2017; Jadoon and Malik, 2018). Moreover, much lower amounts of poor quality seeds are produced and the production of sugars, protein or starch deteriorates considerably. Some enzymes, such as peroxidase or acid phosphatase, increase their activity (Chatterjee et al., 2006). The plants growth on soil with the highest contamination of cobalt was halted, because water and nutrients uptake from soil by plants is decreased.

Apart from the above plants, there are also those which do not show symptoms of toxicity associated with excessive cobalt accumulation (McLeod and Ciravolo, 2007). Cobalt content can range in them from 1.000 to even 50.000 $mg \cdot kg^{-1}$ (Faucon et al., 2009). Examples of such plants are: *Alyssum murale, Alyssum corsicum* (Collins and Kinsela, 2011), *Bulbostylis pseudoperennis* (Saad et al., 2012), *Crepidorhopalon perennis, Crepidorhopalon tenuis* (Faucon et al., 2009), *Nyssa sylvatica* (Kukier et al., 2004; Chatterjee et al., 2006; McLeod and Ciravolo, 2007; Tappero et al., 2007; Van der Ent et al., 2013), *Sopubia neptunii, Crotalaria cobalticola* (Saad et al., 2012), *Lemna minor* (Hu et al., 2019).

Both terrestrial and aquatic plants have these abilities (Chatterjee and Dube, 2005). Cobalt presence in the tissues of these plants, called hyperaccumulators, mainly depends on soil, water and air pollution (Guzman-Morales et al., 2011; Saad et al., 2012; Cheruiyot et al., 2013). The soil pH also has a significant effect: the lower it is, the higher the cobalt absorption is by the plants (Tappero et al., 2007; Collins and Kinsela, 2011).

Cobalt accumulation in hyperaccumulators is different in every plant organ. According to Kukier et al. (2004) and Tappero et al. (2007) cobalt contents are much higher in aboveground parts than in roots, but over time this content increases. Such a tendency was confirmed by Tappero et al. (2007) who observed much higher cobalt content in older leaves of *Alyssum murale* than in younger ones. McLeod and Ciravolo (2007) on *Nyssa sylvatica* and *Nyssa aquatica* shows the opposite tendency. The highest cobalt concentration is observed near leaf margins, close to leaf trichomes. Apart from the cobalt presence in leaf tissues, it can also be adsorbed on its surface. The soil contamination with cobalt increased the content of this trace element in plants and the translocation coefficient and decreased the coefficients of the bioconcentration and transfer (Kosiorek and Wyszkowski, 2019d). The stress of cobalt increased the production of some amino and organic acids (Hu et al., 2019). The increased cobalt content in the plants characterized by high abilities for its accumulation usually causes them to have lower amounts of nutrients, such as calcium, potassium or magnesium (Faucon et al., 2009). These plants also have limited water absorption ability (Karuppanapandian and Kim, 2013).

An excessive soil cobalt content, apart from reducing plant growth and development, can affect the absorption of other elements by plants. In a study by Wyszkowski et al. (2009) soil contamination with cobalt caused a decrease content of potassium, phosphorus, sodium, magnesium and especially calcium in the aboveground parts of oats. In another experiment by Wyszkowski and Wyszkowska (2007) low cobalt doses (10-20 mg $Co \cdot kg^{-1}$ soil) had a small effect on macronutrient content in spring barley. Its very high doses (320 mg $Co \cdot kg^{-1}$ soil) caused increased contents of all macronutrients, especially calcium, sodium and nitrogen, in the aboveground parts of this plant. In experiment by Kosiorek and Wyszkowski (2019a) the contamination of soil with cobalt increased the concentration of nitrogen, phosphorus, sodium, calcium in all organs of oat (grain, straw and roots). Chatterjee and Chatterjee (2003) point out a high increase in phosphorus content and Gopal et al. (2003) a decrease in phosphorus and protein and non-protein nitrogen in plants under the influence of cobalt.

Effect of cobalt on animals

Cobalt is included among elements commonly present in the cells of animal organisms. Its content depends on the feed type consumed by a given animal and on the state of environmental pollution at the place where it lives (Söyüt and Beydemir, 2011). Vitamin B_{12} and cyanocobalamin is the most frequent form of cobalt presence inside the body of animals, both terrestrial and aquatic. Cobalt content in these compounds is over 6%. The presence of vitamin B_{12} enables the regulation of erythrocyte production as well as of the metabolism of proteins and nucleic acids (Stangl et al., 2000; Antony et al., 2011). This compound also participates in many enzymatic redox processes as the activator. Only those microorganisms that live in the soil, water environment and in an animal's alimentary tract are capable of its synthesis (Mukherjee and Kaviraj, 2011).

The effect of cobalt on aquatic animals is particularly important due to assisting enzymatic and metabolic processes (Mukherjee and Kaviraj, 2011; Söyüt and Beydemir, 2011). It is absorbed via the respiratory tract, adsorption or as a result of the consumption of vegetable and animal food (Klavins et al., 2009; Malik and Zeb, 2009; Dhaneesh et al., 2012; De Jesus et al., 2014). Cobalt absorption depends on many environmental factors. The state of water environment pollution and the amount of organic matter in a given body of water are included among them most often (Malik and Zeb, 2009). According to Klavins et al. (2009) cobalt accumulation in aquatic animal organs is lower with a higher organic matter content in the water habitat. Numerous studies by researchers (Klavins et al., 2009; Malik and Zeb, 2009; Waheed et al., 2014) also confirm the effect of differences in the age, sex, species and diet of aquatic animals on cobalt assimilation.

Increased cobalt absorption by aquatic animals is also affected by the amount of mobile forms of this element accumulated in the bottom sediments of lakes, rivers and seas (Mohiuddin et al., 2012; Rognerud et al., 2013; Swarnalatha et al., 2013; Jayasiri et al., 2014; Ramani et al., 2014). A particular risk to these animals is posed by sediments near highly populated places or places impacted by different industry branches and on the edge of water bodies (Swarnalatha et al., 2013; Chanpiwat and Sthiannopkao, 2014; Ghandour et al., 2014; Rzymski et al., 2014). A change in physicochemical water conditions is an additional factor causing increased cobalt release to waters (Ochieng et al., 2008; Sukdeo et al., 2012; Wu et al., 2012; Hierro et al., 2014; Zamani-Hargalani et al., 2014). The state of the pollution of coral reefs, which, apart from being a refuge for many animals, accumulate substantial amounts of pollutants, is also included among these factors (Koigoora et al., 2013; Briand et al., 2014). Studies by Malik and Zeb (2009), Chanpiwat and Sthiannopkao (2014) and Jayasiri et al. (2014) also include seasonality, which leads to changes in water parameters.

A high cobalt concentration, both in fresh and salt waters, leads to its excessive accumulation in the internal organs of the animals inhabiting them (Söyüt and Beydemir, 2011; Iqbal et al., 2012). Fish are the most studied aquatic animals in waters polluted with heavy metals, including cobalt. According to De Jesus et al. (2014) and Waheed et al. (2014) cobalt accumulates mainly in the inedible fish parts, which include gills, intestines, kidneys and liver. This was also confirmed by Klavins et al. (2009) and Türkmen et al. (2011). According to Malik and Zeb (2009) among the organs listed above, liver and kidneys stand out for their high abilities for the accumulation and detoxification of this metal. Cobalt also accumulates in the edible parts, such as flesh or skin, with its content much lower than in the above-listed organs (Malik and Zeb, 2009; Schmitt et al., 2009; Tepe, 2009). Waheed et al. (2014) found that cobalt content is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1141911449

higher in the muscles and gills of herbivorous fish than in carnivorous fish. Cobalt accumulation in fish organs leads to changes in the course of genetic, cytological or metabolic processes which are the cause of many diseases (Rzymski et al., 2014). Cobalt also affects the other animals inhabiting aquatic ecosystems, which was confirmed by many studies (Cavet et al., 2003; Türkmen et al., 2011; Lavoie et al., 2012; Abdallah, 2013; Alquezar and Anastasi, 2013; Holland et al., 2013; Sandergaard, 2013) where a high cobalt content was recorded in bivalves, shrimps, blue-green algae and algae inhabiting fresh waters. For salt bodies, excessively high cobalt doses showed a negative effect on scorpions, blue-green algae and sponges (Padovan et al., 2012; Alquezar and Anastasi, 2013; Batista et al., 2014).

High cobalt amounts accumulate in the successive links of the food chain, which are terrestrial and aerial animals (Klavins et al., 2009; Malik and Zeb, 2009; Albayrak and Mor, 2011; Söyüt and Beydemir, 2011; Mansouri et al., 2012; Sandergaard, 2013). In the body of terrestrial animals, cobalt is important due to its participation in the formation of vitamin B_{12} (Stangl et al., 2000). In ruminants, it is produced in the rumen (Agbenin, 2002; Tiffany and Spears, 2005; Bishehsari et al., 2010) and the amount of this vitamin is highest in muscles, liver, kidneys and the heart. Animal products such as eggs, cheeses or milk can also contain substantial amounts of cobalt (Tiffany and Spears, 2005).

Cobalt content within the optimal amount is necessary for the course of proper life processes in every organism living on land. The youngest animals have the highest requirement for this element (Kadim et al., 2006; Ceacero et al., 2009). Older animals have a lower cobalt requirement, but its content rises over time as a result of accumulation. Cobalt also plays an important role as the catalyst of many enzymatic processes (Swarup et al., 2006). Kadim et al. (2006) found that the injection of 350 pg dm^{-3} of cobalt ensures the proper course of growth processes. The appropriate cobalt level in insects inhibits caspase production, due to which the intestinal epithelium is not damaged (Cheruiyot et al., 2013).

Both a deficiency and excess of cobalt can result in the appearance of disease symptoms. Sheep are particularly sensitive to cobalt deficiency, as reported by Bishehsari et al. (2010). An excessively low cobalt dose in the feed of these animals becomes the cause of anemia, reduced plasma homocysteine concentration (Stangl et al., 2000; Taugbol et al., 2010) and decreased weight gain leading to anorexia. Symptoms of reduced body mass and shape in goats resulting from cobalt deficiency are confirmed by Kadim et al. (2006). A higher resistance of goats than sheep to low amounts of cobalt present in their body was also found in their study. Another symptom was discolorations appearing on the wool produced by these animals and a characteristic discharge from the ears and eyes. Reduced absorption of nutrients and necessary trace metals, such as copper, iron or nickel, also leads to a decreased quality of meat from these animals (Stangl et al., 2000). According to Taugbol et al. (2010) an excessively high amount of cobalt present in the blood of dairy cows can lead to a reduced level of fatty acid desaturation products in milk and in blood. Excess cobalt can also cause a reduced flow of divalent metals, such as iron and zinc, to udders and disrupt enzymatic activity in the mammary gland cells. Negative effects of cobalt accumulation have also been observed in the organisms of forest animals, e.g on growth processes in wild boar. Yarsan et al. (2014) found that excessively high doses lead to circulatory and nervous system disorders and bone diseases. According to Ceacero et al.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1141911449

(2009) deer are among the forest mammals which are best able to regulate cobalt absorption.

Other symptoms of the effect of cobalt include lower animal weight gain and a higher mortality of the born progeny. The surviving progeny can inherit the same defects as parental organisms. Due to the carcinogenic effect of cobalt compounds, it can also lead to the inhibition of DNA repair processes, change gene expression patterns or generate oxygen and nitrogen in a reactive form. It can significantly affect the FAS signal and the caspase pathways similar to this signal, thus contributing to the induction of apoptosis (Wang et al., 2007; Cheruiyot et al., 2013).

The presence of different kinds of cobalt compounds in the air and food can significantly contribute to their excessive accumulation in bird organs. Albayrak and Mor (2011) report that these compounds accumulate in similar amounts in the organs of both sparrow sexes. The only exception is female kidneys, where much higher cobalt contents were found than in male kidneys. These differences are the result of the metabolism of cobalt participating in the activity of sex hormones. Females can contain much higher cobalt contents than males due to an increased amount of feed consumed during egg formation. After eggs are laid, cobalt content in female organisms decreases (Norouzi et al., 2012). A study by Mansouri et al. (2012) on cobalt content in the organs of seabirds shows the opposite tendency, which is affected by moulting. It was also found that cobalt content in the organs of migratory birds was higher than in the organs of sedentary birds, which is significantly affected by the quality of the consumed feed.

Increased cobalt contents can also accumulate in bird feathers as a result of interstitial excretion from their internal organs (Norouzi et al., 2012). Determining the cobalt content in young feathers allows its concentration in blood to be determined, while in older feathers it is not possible due to blood flow changes (Malik and Zeb, 2009). Another animal organism sensitive to cobalt contamination are the larvae of the silkworm *Antheraea assama* (Devi et al., 2014). Excessive cobalt concentration in its body prevents it reaching the stage at which it is able to produce silk and may cause death.

Effect of cobalt on the human body

Cobalt in the human body, as in animals, performs an important role in the formation of vitamin B_{12} (Dobrowolski and Otto, 2012). According to ATSDR (2004) 0.1 μmol of cobalt in the form of vitamin B_{12} supplies a necessary amount of cobalt to the human body. The highest cobalt intake which does not cause negative effects is 1800 μmol. Vitamin B_{12} deficiency is supplemented, apart from its supply in plant and animal products to the human body, also by the application of drugs (Ulusoy et al., 2012). Its deficiency in the human body leads to the appearance of anemia, resulting from a low amount of produced vitamin B_{12}. Another manifestation of a cobalt deficiency in the human body is disturbed functioning of the alimentary, nervous and osseous systems (Jonnalagadda et al., 2008; Soylak et al., 2012).

The disease symptoms resulting from exceeding the permissible dose include, among others, allergic reactions, lung and heart diseases (Basu et al., 2010; Díaz-Rizo et al., 2012; Dobrowolski and Otto, 2012; Ryuko et al., 2012; Ulusoy et al., 2012; Devi et al., 2014). Intensification of the above symptoms is most often encountered in industrial plants, where exposure to the harmful effect of this element is much higher than in other places with a human presence (Benderli-Cihan et al., 2011; Pietrodangelo et al., 2014).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1141911449

Basu et al. (2010) and Ryuko et al. (2012) report that the most frequent symptoms of potassium excess are skin inflammations and asthma. Frequent use of tools which contain cobalt admixtures, as well as the presence in industrial plants, significantly affects the induction of allergic reactions, mainly on the skin of the hands. The occupations particularly exposed to such risks are carpenters and metal workers (Thyssen et al., 2011).

The harmful effect of cobalt can also be the result of absorbing its too high dose with food and drinking water (Obiri, 2007; Upadhyaya et al., 2014). This is particularly important for pregnant women who, depending on the type of consumed food, can accumulate substantial amounts of cobalt in their bodies, which also affects the developing fetus. This was confirmed by Chan-Hon-Tong et al. (2013) who found that a group of tested pregnant women eating mainly fish had a higher blood cobalt content than the women consuming sweets, fruit, milk products and soups. A study by Foster et al. (2012) did not find, however, differences in the blood cobalt content of pregnant women depending on consumed food. Due to genotoxic properties, it is important that the cobalt limit is not exceeded (Chan-Hon-Tong et al., 2013). A low cobalt content present in alcoholic beverages can cause the appearance of disease symptoms. This was confirmed in a study by Ulusoy et al. (2012) where it was found that the consumption of beer with a content of cobalt chloride from 1 to 2 $mgdm^{-3}$ caused changes in the nails of palms and feet, called dyshidrosis. Other symptoms include frequent vomiting and diarrhea, blood pressure changes or headaches. High cobalt contents also lead to damage to the immunological system (Bezerra et al., 2014; Valera et al., 2014). Another symptom of exceeding the permissible dose is damage to DNA and disruption of its repair. Cobalt toxicity has a stronger effect in the presence of iron, to which it is linked by similar atomic properties (Ryuko et al., 2012).

Due to its quite high solubility in systemic fluids, it becomes more mobile and also more harmful to all internal organs. Benderli-Cihan et al. (2011) found much higher cobalt contents in the hair of women with breast cancer than in healthy women, as well as the possibility of cobalt accumulation in nails and teeth. The defense reaction of the body to the presence of an excessively high cobalt dose involves physiological processes. Therefore, its amounts are highest in kidneys and liver (Ulusoy et al., 2012). Cobalt harmfulness in the human body is also associated with the radiation of isotopes of this element, which are the cause of many short- and long-term diseases. An excessively high cobalt isotope accumulation also leads to an increased cancer risk (Bezerra et al., 2014).

Summary

Apart from natural cobalt contents in the environment, pollution with this element has begun to increase in recent years. The main cause of this is the growing extraction and manifold application of cobalt in different branches of industry (Biswas et al., 2013). The appearance of cobalt levels exceeding the environmental threshold levels has led, however, to disturbances in the proper functioning of living organisms. Not only animals or plants which are the first component of the food chain are at risk, but also the subsequent trophic levels, where accumulated cobalt contents show signs of toxicity (Maguire and Collins, 2001; Basu et al., 2010). The application of sorbents to soil (especially organic matter and calcium oxide) reduce the effect of cobalt on soil organisms and plants. A very important role in the removal of cobalt from soil plays

DOI: http://dx.doi.org/10.15666/aeer/1705_1141911449

phytoremediation by plant hyperaccumulators. High cobalt doses are not, however, the only cause of its negative influence on living organisms. The presented literature review shows that cobalt is also an indispensable dietary micronutrient for living organisms, from microorganisms to the human body. Cobalt deficiencies cause many diseases, whose treatment is a long-lasting process requiring, in most cases, diet adjustment to the dietary needs of a given organism (Soylak et al., 2013).

Focusing on the elements included in the group of heavy metals is useful in assessing environmental pollution. However, it would also be advisable to systematically monitor cobalt content in the environment (especially the soil environment), which affects the quality of produced feed and food, which consequently directly affects the absorption of optimal cobalt amounts by living organisms.

Abstract. The understanding of the effect of vegetation on the flow and sediment transport is extremely important for modern river management and water ecological restoration. In this study, the laboratory experiments are carried out to study the 3D flow velocity, turbulence and sediment transport affected by 3 types of flexible vegetation. The results show that the submerged and emergent vegetation generates an obvious flow resistance and significantly alters the vertical distributions of the flow velocity, especially in the vegetated and downstream regions. Due to the influence of vegetation, the flow in downstream generates many vortices with different sizes. Compared with the submerged vegetation, the emergent vegetation has a more obvious influence on the vortex flow. Vegetation also results in a nearly constant fine suspended sediment concentration in the water column for all cases, while the large flow resistance has a stronger filtration effect on the coarse sediment, which leads the coarse sediment to be deposited and the total sediment along the vegetated channel to be gradually refined. The experiment also analyzes the influence of the transverse flow on the suspended sediment transport and the interaction mechanism of flow and sediment.

Keywords: *vegetation, flow velocity, turbulence, sediment transport, vortex flow, diffusion coefficient*

Introduction

Vegetation can be found in abundance in the shore and shallow water region of rivers and plays an important role in influencing the turbulent flow field in a river channel. At present, as people pay more and more attention to the ecological protection of rivers, the research on the problems of flow and sediment transport in vegetated rivers has become one of the hottest topics in river dynamics. For a river, the vegetation tends to increase the flow resistance during the flood periods, increase the water level and thus reduce its overcurrent capacity. Besides, with the growth of vegetation and the increasing resistance, it will change the local flow and the distribution of sediment transport. Therefore, it is important to carry out research on the characteristics of flow and sediment transport in vegetated rivers. The open channel flow movement is usually a boundary layer turbulence. Under certain channel profile conditions (e.g. straight and shallow channel), it can be considered as a two-dimensional flow (Wang and Li, 2002). While affected by the physical and distribution characteristics of vegetation, the flow in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

the vegetated open channel has strong properties of three-dimensional motion. The main differences in the characteristics of the two flow motions are the distribution of flow characteristic parameters, such as flow velocity, turbulence intensity, Reynolds stress, etc. (Stephan and Gutknecht, 2002; Carollo, 2002; Tang et al., 2007. The distribution of the vegetated flow has two or three divisions of the zone in the vertical direction, and the whole distribution in vertical direction does not follow the logarithmic distribution any more. Ikeda and Kanazawa (1996) conducted laboratory experiments on the flow characteristics of flexible vegetation and found that eddies and flow velocity changed significantly near the vegetation. Nezu and Onitsuka (2001) studied the turbulent flow structure in the vegetated open channel and found that the horizontal vortex near free surface was caused by the increase of Froude number and vegetation density. In terms of the maximum turbulence intensity of the flow Ikeda and Kanazawa (1996) found that the maximum turbulence intensity appeared at the top of vegetation, which was consistent with some experimental and numerical simulations. However, some researchers demonstrated that the maximum turbulence intensity of the vegetated flow was generated at the junction of the vegetation's top and non-vegetation zone (Su and Li, 2002). Wilson et al. (2003) proposed that the position of maximum turbulence tends to move toward the free surface with the increase of submergence, for the flexible vegetation with leaves. Sediment transported in the vegetated open channel has also drawn the attention of many researchers. Shi and Cao (2000) found that the presence of vegetation led to a decrease of the coefficient of turbulent diffusion and a significant increase of gravitation. In his opinion, the vegetation can not only block the bed-load transport effectively but also intercept the suspended sediment movement. However, experimental studies by Elliott (2000) on the effects of sedimentation rate by vegetation show that compared with non-vegetation, the presence of vegetation reduced sedimentation rate and made sediment more easily suspended. Lu (2008) investigated the suspended sediment transport in the rigid vegetated open channel and analyzed the influence of vegetation factors on the distribution of turbulence and sediment concentration. Jordanova and James (2003) established an empirical formula for the rate of bed-load transport in non-submerged rigid vegetated open channel by using the analogy of the equation of bed-load transport rate in non-vegetated rivers and his experimental data. Li and Shen (1973) found that compared with the parallel arrangement of vegetation in the open channel, the plum blossom staggered arrangement could obstruct the flow more efficiently and the amount of sediment transport was also relatively small. Therefore, when considering flood control and soil conservation of rivers, the vegetation arrangement in the channel should be reasonably designed.

There is plenty of research on the characteristics of flow and sediment transport in the vegetated open channels at present. Due to the complexity of vegetation morphology and the difficulties of using numerical simulation methods, there are relatively more studies using the experimental flumes. However, there are some problems that still need to be further studied: (1) There are many kinds of aquatic vegetation in river ecosystem, but at present, most of the research mainly focuses on specific types of vegetation, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

there are few research results on both submerged and emergent vegetation. Therefore, systematic research needs to be strengthened. (2) The research on the turbulent structure of three-dimensional flow in the vegetated open channel has been very thorough, but it is limited to the problems of sediment sample collections and measurement equipment. There is little research on the characteristics of flow and sediment transport within the upstream and downstream region in the partly vegetated open channel. In this paper, three representative submerged and emergent artificial flexible vegetation is used to carry out experimental studies on the characteristics of flow and sediment transport in a partly vegetated open channel. The three-dimensional distribution of flow movement, suspended sediment transport in the partly vegetated open channel is obtained. Based on these, the mechanism of interaction between flow and sediment transport in the partly vegetated open channel is further discussed. These research results aim at further enriching the understanding of the regularity of flow and sediment transport in the vegetated channel and lay a foundation for further research.

Material and Methods

Experimental equipment

All the experiments are conducted in the Hydraulics Laboratory in Changjiang River Scientific Research Institute, Wuhan, China. The experimental apparatus is mainly composed of three pumps, an inlet section to generate fully developed turbulent flow, a test section with a rectangle flume to operate interaction between flow and vegetation, an automatic control system installed at the inlet of the rectangle flume to control the amount of sediment. The re-circulating flume is 0.5 m wide, 0.5 m high and 28 m long, with glass sidewalls and bottom (*Figure 1*). The range of the flume slope is 0‰-5‰. Thin plastic board is laid on the bottom of the flume, on which the simulated vegetation is planted. In order to decrease the inlet turbulence and maintain the uniform flow, a wave dissipation board is set at the inlet of the flume. An automatic water level control system located at the outlet of the flume is used to accurately control the water level. Preliminary experiments are carried out to ensure there is no flow turbulence effect due to the thin plastic board within the measurement region. It is long enough far from the inlet to ensure that the flow through the vegetation is smooth and the measurement data is accurate. A three dimensional Macro-Acoustic Doppler Velocimetry (ADV) (SonTek, San Diego, CA, USA) is used to measure the flow velocity and turbulence at a frequency of 25 Hz with 30 second (s) sampling time. From the initial control experimental run, it is revealed that the sampling frequency is enough to obtain accurate velocity and turbulence characteristics (Li et al., 2015). Thus, 750 data measurements are collected at every location and with post-processing software (WinADV), and an average velocity value is obtained. Measurements at 5 cm below the free surface can not be taken due to ADV limitations. For more information about the application of ADV on flow measurement in a flume, refer to (Qu, 2014). The measuring equipment used in the experiment include electromagnetic flowmeter, the ADV three-dimensional

Figure 1. *Experimental equipment and instruments*

Experimental program

The experiment investigates the affection of the effects on the flow and sediment transport in the open channel, based on the acquired laboratory data conducted using three artificial flexible vegetation (two kinds of submerged flexible vegetation, and one kind of emergent flexible vegetation). The three kinds of artificial vegetation use the same flexible plastic material (the material proportion is 1.35 g/cm^3, the elastic modulus is 0.03×10^5 Mpa). This kind of plastic vegetation has foliage and flexibility characteristics like true plants, which are representative of the vegetation in the riparian zone of rivers, and can simulate nature vegetation drag force in open channel (*Figure 2, Figure 3*). The three kinds of vegetation are used in the experiments with the same arrangement, and ten measured sections are arranged in the partly vegetated open channel (*Figure 4*). The flow and sediment of experimental conditions are as follows: The inlet discharge of the flume is 30 L/s. The outlet water level of the flume is 35 cm, and the amount of sediment at the inlet of the flume is 5.0 g/s. The sediment using in the experiment is a kind of plastic synthetic sand, its wet and dry density is 1.38 t/m^3, 0.67 t/m^3, respectively (Sun and Wei, 2005). *Figure 5a* shows the grading curves of the artificial sediment used for all cases and they follow a similar composition with a median particle size (D_{50}) of 0.18 mm. The maximum slope of the flume using in this experiment is 5/1000. All the experiments are controlled according to the standard of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

uniform flow (the slopes of flume and water surface are the same). In order to obtain the approximately uniform flow if the slope of the water surface in the vegetated area is always larger than the maximum slope of the flume, then the flume is adjusted according to the maximum slope of 5/1000. The experimental results show that the slope of the water surface in upstream and downstream of the vegetated region is less than that in the vegetated region (*Figure 5b*), so the slope of the water surface in upstream and downstream region is less than the slope of the flume. The flow in the upstream and downstream region is the decelerating flow (Yang and Lee, 2007).

Vegetation P1 Vegetation P2 Vegetation P3

Figure 2. *Image of artificial different vegetation*

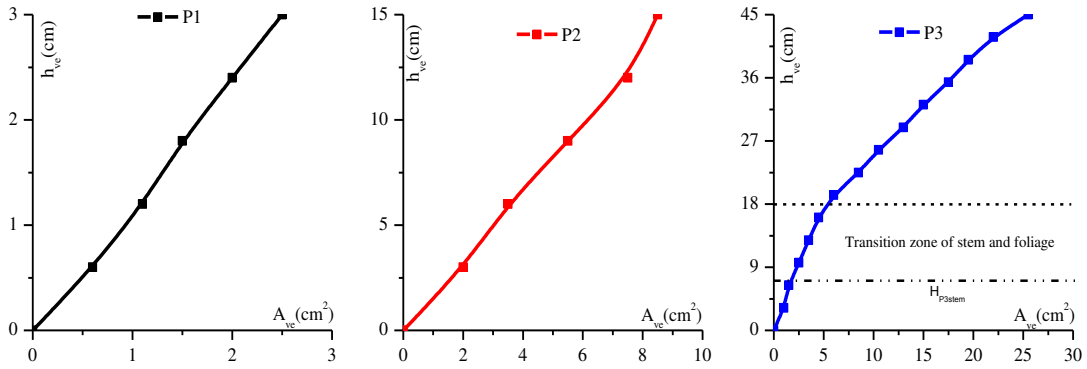

Figure 3. *Profile of the variation of the vegetation cumulative area with respect to the height of vegetation*

There are two points to note in this paper. (1) The flow pattern is different along the stream-wise in the partly vegetated open channel, however, the main research is on the effect of the flow and sediment transport in the partly vegetated channel. (2) The preliminary experiment shows that the sediment transport is basically balanced (the concentration of sediment at inlet and outlet of the open channel is basically the same) in the non-vegetated open channel under the experimental condition of *Table 1* (Case 1). In order to facilitate the comparison with the flow and sediment transport in the open

DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

channel under different types of vegetation, the flow patterns in the upstream and downstream regions are approximately regarded as a uniform flow.

Results

Flow velocity characteristic

Longitudinal flow velocity

(1) Flow velocity along stream-wise

To highlight the effect of artificial vegetation on the flow characteristics along the stream-wise, the longitudinal velocity data has been processed and plotted at different positions in the open channel. *Figure 6* represents the vertical distribution of the u-velocity component normalized by Ua at different longitudinal positions in the midline of the open channel. For P0, the vertical distribution of longitudinal flow velocity from S1 to S10 cross-sections basically complies with the logarithmic distribution.

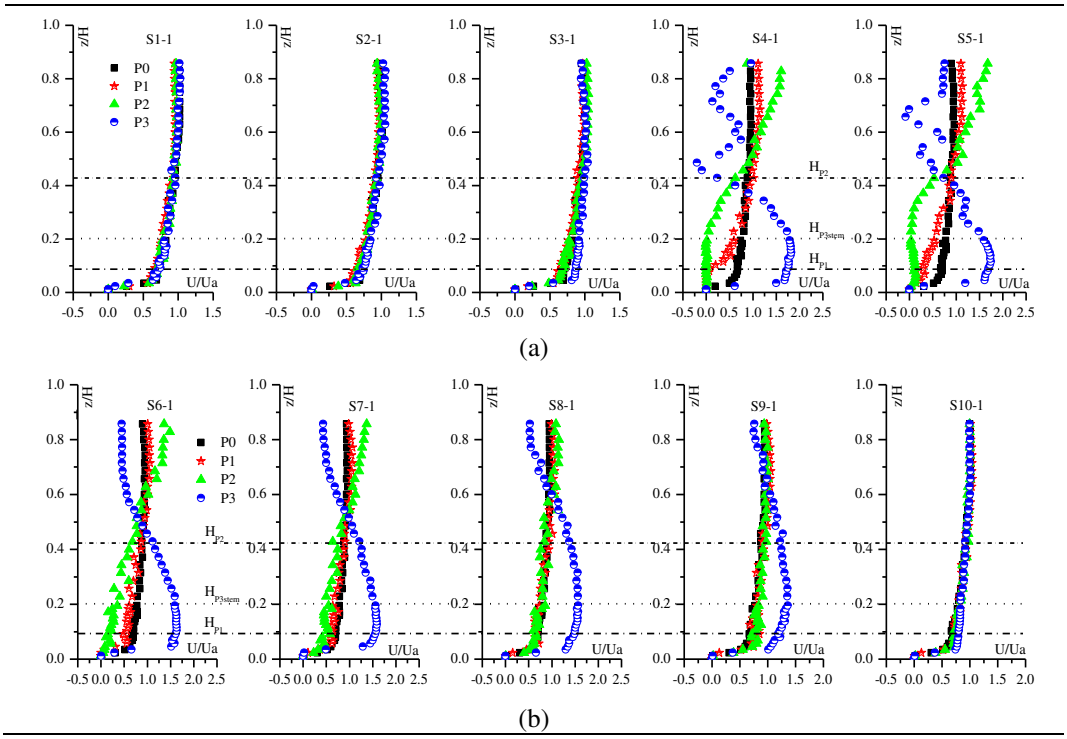

Figure 6. *The vertical distribution of the normalized velocity u/ua changed along the stream-wise in the vegetated open channel (a) from S1-1 to S5-1, (b) from S6-1 to S10-1*

For P1, in upstream region (S1-1 to S3-1), the vertical distribution of longitudinal flow velocity is basically similar to that of P0; in the vegetation region (S4-1), the flow velocity in the zone below the height of 0.2 z/H is smaller than that of P0, however, the flow velocity in the zone above the height of 0.2 z/H is larger than that of P0. The vertical distribution of flow velocity in longitudinal direction basically satisfies the logarithmic distribution from the top of P1 to the free surface (above 0.1 z/H). In the downstream region (at S5-1), the flow velocity in the zone below the height of 0.3 z/H reduces obviously. Since then, the more toward the downstream of the open channel, the flow velocity gradually approaches to that of P0, and is similar to P0 at S7-1. For

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

P2, the change characteristics of longitudinal flow velocity in the open channel are similar to that of P1. Since the height of P2 is significantly larger than that of P1, the change of flow velocity is not only greater than that of P1, but also the recovery distance in downstream region is significantly longer than that of P1. For the emergent vegetation (P3), the longitudinal velocity in the zone below the height of 0.3 z/H along the stream-wise is all increase to some extent compared with that of P0, especially that of at S4-1. Due to different types of vegetation with P1 and P2, the recovery distance of P3 is also significantly longer than that of P1 and P2, and not yet been fully approached to that of P0 at S10-1.

There are different vertical distributions of longitudinal flow velocity along the stream-wise in the different types of vegetated channel. For submerged vegetation, the flow velocity decreases obviously in the zone under the top of vegetation due to its strong flow resistance, while the flow velocity in the zone above the top of vegetation is increased obviously and basically complies with the logarithmic distribution. Affected by the exchange of water fluxes in different vertical zones of the downstream region, the flow is restructured and gradually restored. For emergent vegetation, the whole flow resistance is significantly higher than that of submerged vegetation due to its higher height. However, the emergent vegetation is generally composed of stem and foliage. Because the water blocking area of the stem is significantly smaller than that of the foliage, the flow velocity in the zone below the height of stem in the open channel will increase obviously, Meanwhile, the flow velocity will decrease significantly in zone of foliage, and the more closely to the vegetated region, the greater variation of flow velocity in the two vertical zones will be. The flow will undergo vigorous momentum mixing exchange in the two vertical zones, result in obvious secondary flow, and gradually return to the flow pattern of non-vegetation along the stream-wise in the downstream region.

(2) Flow velocity in transverse direction

In order to study the distribution of flow velocity in transverse direction of the partly vegetated channel, cross-section S1, S3, S4, S6, S8 and S10 are selected. Since the cross-sections and the arrangement of vegetation are strictly symmetrical along the midline of the flume, hence only half of the cross-sections of the open channel are measured. Five vertical measurement lines are arranged on each measured section, and the transverse distance of the measurement lines from the midline of the flume is 0 cm, 4 cm, 8 cm, 15 cm, 21 cm (*Figure 4*). As shown in *Figure 7*, the transverse distribution of flow velocity of every cross-section in the different types of the partly vegetated channel is basically similar. Normally, the flow velocity in transverse direction decreases gradually as approaching from the midline to sidewall of flume, which mainly due to the relatively large flow resistance on the sidewall of the flume. However, for P3, due to its larger flow resistance, near the sidewall, the flow velocity in some vertical zones (0-0.4 z/H) is greater than that of in the middle of the flume. There is no vegetation in the downstream region, where the resistance of the sidewall is the main part of the whole flow resistance, since the flow velocity at different transverse positions is affected differently by the sidewall of the flume, which results in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

significantly different recovery of flow velocity at different transverse positions. For example, when the velocity of vegetated flow is greater than that of non-vegetated flow, the distribution of velocity near the sidewall recovers more rapidly. In contrast, when the velocity of vegetated flow is smaller than that of non-vegetated flow, the distribution of velocity near the sidewall recovers more slowly.

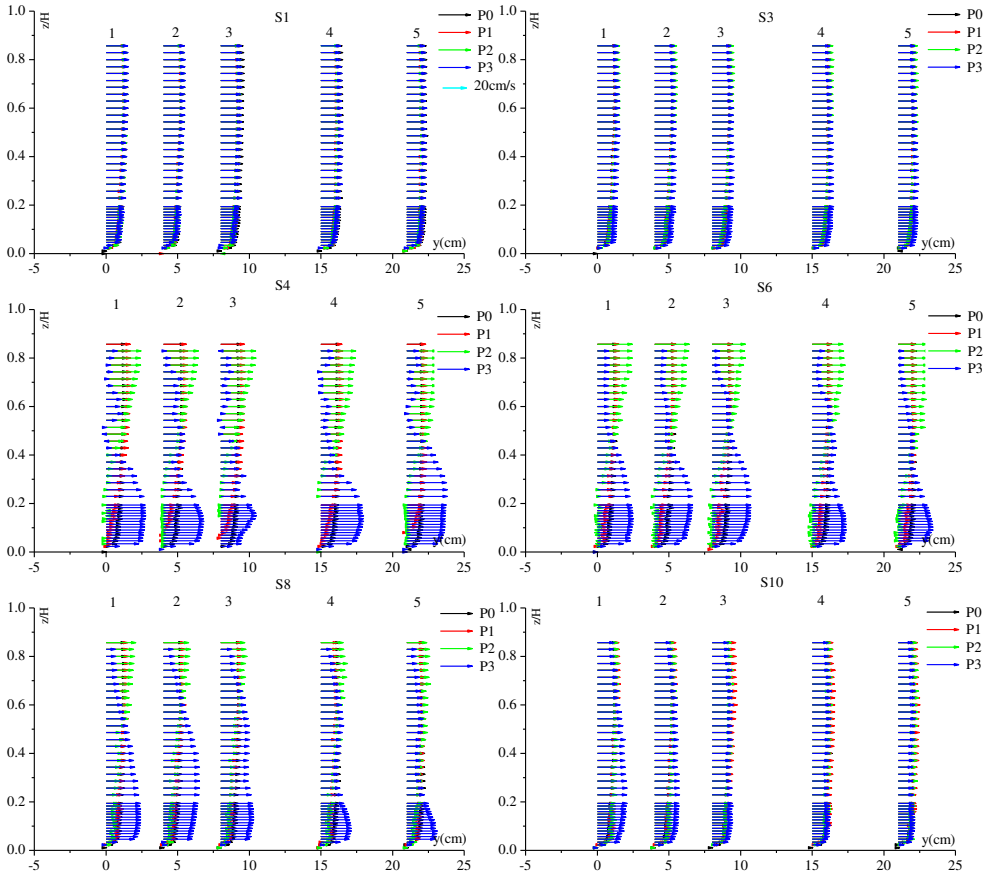

Figure 7. *The distribution of flow velocity at different transverse positions in the vegetated open channel*

(3) The regularity of influence

According to the experimental data of ten measured cross-sections, the regular influence on flow by different types of vegetation is analyzed. Considering that the regular influence of the flow characteristic at different vertical positions maybe not the same, three positions in the vertical direction are selected to be analyzed in this paper, which represent the bottom flow, the middle flow and the surface flow respectively. As shown in *Figure 8*, in terms of the range of influence, the influence on flow by different types of vegetation is greater in the downstream region than that in the upstream region. In terms of the degree of influence, all types of vegetation have great effects on the flow at the bottom position, followed by the surface position, and then the middle position.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

The relative flow velocity of different types of vegetation is (P*-P0) /P0 (*represented the type of vegetation), the variation range of which near bottom, the surface and the middle is -116%-161%, -85%-68% and -73%-56%, respectively. The middle zone is the main place where the flow from bottom and surface mix intensively. Therefore, the distribution of relative flow velocity in the middle zone is more uniform than that in the other two zones. For different types of vegetation, the submerged and emergent vegetation have completely opposite effects on the bottom flow and the surface flow. Relative to submerged vegetation, emergent vegetation has a greater influence on flow and longer influenced distance.

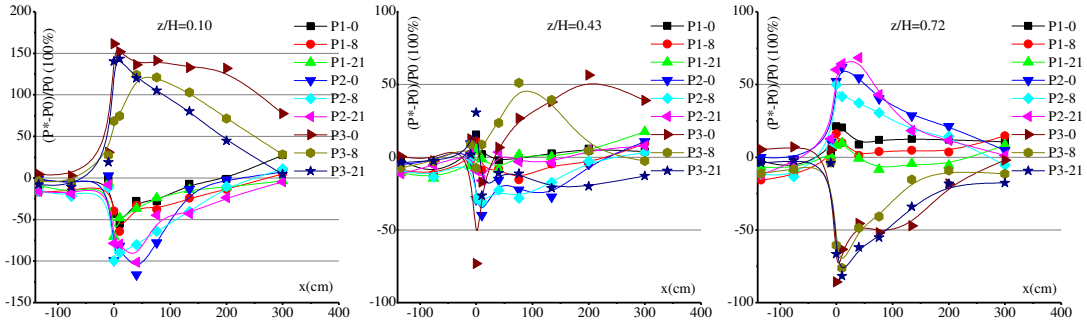

Figure 8. *The regular influence on the flow in the different vegetated open channel*

Secondary flow

The secondary flow is a relatively minor flow superimposed on the primary flow; however, it plays a crucial role in the sediment transport of the open channel. In this section, the secondary flow in the different types of the vegetated open channel is still investigated.

As can be seen from *Figure 9*, the secondary flow propagates from left sidewall to the centre of the flume at section S1 (left half of the flow) under different types of vegetation. Since the flume is strictly symmetrical with respect to the central line, the right half of the flow should propagate from right sidewall to the centre of the flume. The velocity of the secondary flow of section S1 in the vegetated open channel is larger than that of in non-vegetated open channel. Although there is a significant effect of vegetation on the secondary flow in section S1, the movement characteristic of the secondary flow does not change fundamentally.

In section S3, for the submerged vegetation (P1 and P2), because of its large flow resistance in the bottom and middle parts of the section (a place full of vegetation), the vertical distribution of secondary flow obviously propagates from the bottom to the free surface. For the emergent vegetation (P3), the vertical distribution of secondary flow obviously propagates from the free surface to the bottom for its large flow resistance in the middle and upper part of the section (a place full of foliage). However, in the bottom part of the section S3 (a place full of stem), the transverse flow of P3 is clearly shifted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

towards both sides of the plant stems, which is similar to the flow movement of the cylindrical spoiler (*Figure 10*), and the similar phenomenon we still can get from Graf and Yulistiyanto, 1998.

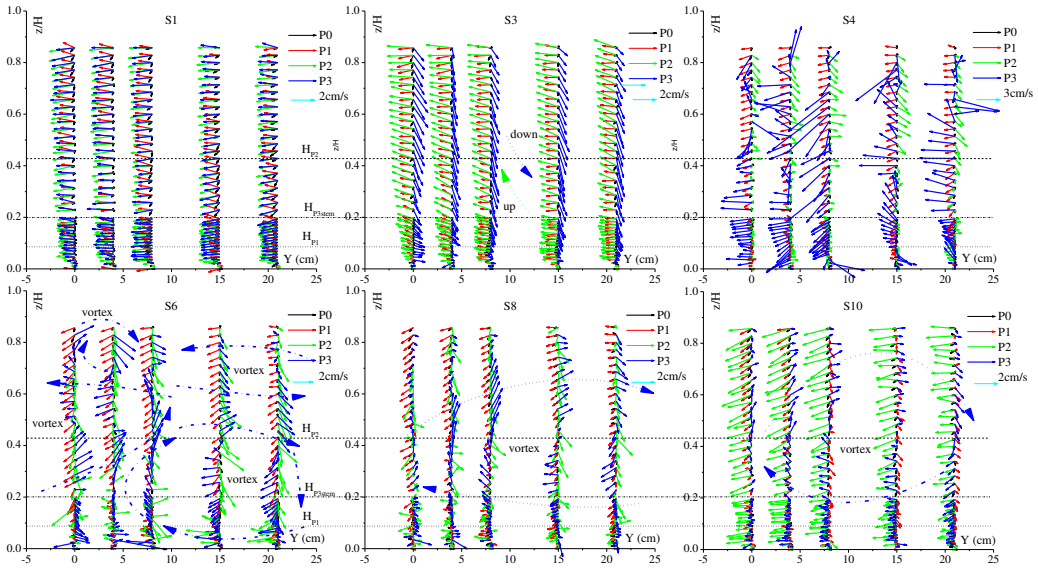

Figure 9. *The vertical distribution of secondary flow in the vegetated open channel*

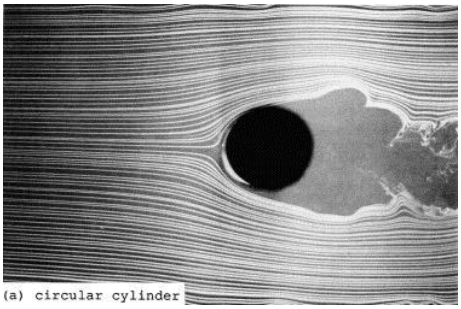

Figure 10. *The flow pattern around circular cylinder at Re=3×10^4, reprinted from Yoon & Ettema (1993)*

In section S4, where the vertical distribution secondary flow becomes more complicated due to the strong influence. For submerged vegetation (P2), the velocity of secondary flow in the zone under the height of 0.8 HP2 is small, whereas the velocity in the zone above the height of 0.8 HP2 is obviously increased. At the same time, the transverse direction of secondary flow in these two zones is not strictly consistent, which may be the result of the exchange of flow momentum and the shear layer near the canopy of submerged vegetation (*Figure 11*). For emergent vegetation (P2), its flow resistance is significantly different in the zones of stems and foliage. In the zone of foliage, the secondary flow is more significant mutations scattered and occurred in some

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

local positions. However, in the zone of stems, the secondary flow is less influenced and has a regular flow pattern. Furthermore, the secondary flow of P3 propagates from left sidewall to centre of the flume at the majority positions in section S4, whose direction is opposite to that in the section S3. The reason for this phenomenon might be related to the vortex flow generated in the vegetation area (see *Figure 12b*).

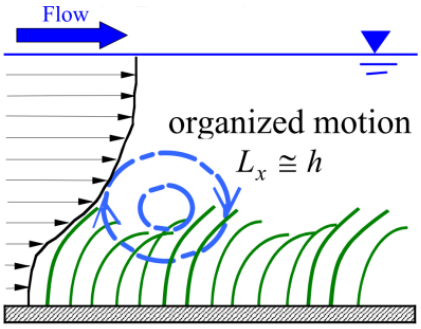

Figure 11. *The flow patterns in dense flexible vegetation (Okamoto & Nezu 2010)*

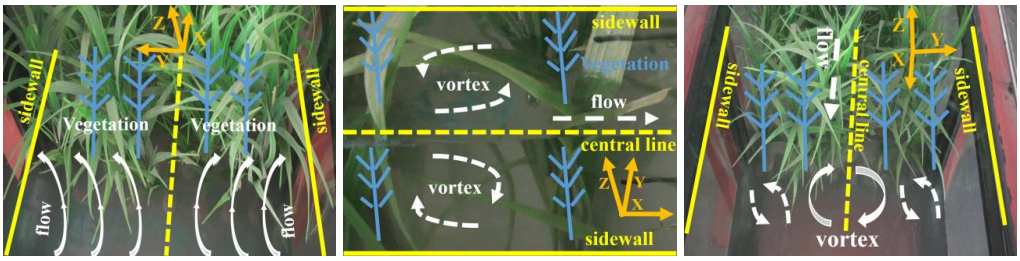

(a) S3 (b) S4 (c) S6

Figure 12. *The characteristic of secondary flow of different region under the condition of P3*

In the downstream region (S5-S10), due to the influence of vegetation, there is a significant momentum exchange among the water masses in different vertical positions and significant vortex flow is generated. In order to further analyze the characteristics of vortex flow in the downstream region, this paper selects three sections (S6, S8 and S10) and calculates the measured data by *Equation (1)*, finally obtains the vertical distribution of vortex flow in the longitudinal direction. For the purpose of making the result clearer and more intuitive, more significant distribution of vorticity is taken as an example (vegetation P3). As shown in *Figure 13*, six vortices are generated in the flow field of section S6, which indicates that there are some strong vertical exchanges of flow momentum. Obviously, in the case of sediment, this condition of flow is conducive to sediment diffusion in the three-dimensional direction and makes sediment concentration consistent in the whole section. With the mix of flow in the downstream region, the energy of flow gradually decreases, and the flow converges and merges into two vortices in section S8. Finally, there is only one large vortex in section S10 and the vorticity intensity is further weakened.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

$$\Omega_x = \frac{\partial w}{\partial y} - \frac{\partial v}{\partial z} \quad \text{(Eq.1)}$$

As previously analyzed, due to the influence of vegetation, the flow in the downstream region generates many significant vortices. Compared to the submerged vegetation, emergent vegetation has more obvious influence on the flow in the downstream region. Therefore, in terms of ecological rivers, the presence of intense vortex flow in downstream of emergent vegetation region will make the substances in rivers fully diffused, which is obviously conducive to the survival and propagation of aquatic organisms.

Figure 13. *The vertical distribution of vortex flow in longitudinal direction under the condition of P3*

Sediment transport

According to the analysis of the data measured by rivers and laboratory experiments, Hu and Hui (1995) considered that the vertical distribution of sediment concentration in open channel usually had three types. Type I distribution is that the sediment concentration increases gradually from the free surface to the riverbed, and when it reaches a maximum value at a certain vertical position, then it will decrease. Type II distribution is that the sediment concentration monotonically increases from the free surface to the riverbed, with the maximum concentration near the riverbed. Type III distribution is that the sediment concentration increases gradually from the free surface to the riverbed, with the maximum concentration still near the riverbed, and yet the sediment gradient will vary significantly at one vertical position. Ni et al. (1991) considered that the vertical pulsating flow velocity was the fundamental reason for the existence of suspended sediment in a turbulent flow. If the sediment concentration is not very large, there will be more opportunity for Type I distribution when the bed is smooth with the uniform particle size of sediment. On the contrary, there will be more opportunity for Type II distribution.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

Hu and Hui (1995) considered that the appearance of Type I distribution could not be explained by only the vertical pulsatile flow velocity distribution. Whether Type I distribution occures in flow with a higher concentration depends on the ratio of particle size to flow depth, and if the ratio exceeds the critical value the flow may appear Type I distribution. The formation condition of Type II distribution is that the suspension index is large and the gravity plays a dominant role, while the formation condition of Type III distribution is that the suspension index is small and the turbulent diffusion plays a dominant role. In order to study the vertical distribution of suspended sediment transport in the different vegetated open channel, laboratory experiments are carried out. The experimental conditions are shown in *Table 1*. The median diameter of experimental sediment ranges from 0.16 mm to 0.18 mm, and the sedimentation velocity is calculated by Zhang Ruijin formula (Qian and Wan, 1986). Experimental samples are obtained by sediment sampler (*Figure 1*). The Samples are taken twice from every measured position by 1000 ml graduated cylinders, filtered and dried, and then are weighed by an electronic balance. Finally, the sediment concentration of the sample is calculated and the average of two results in the same position is taken as the sediment concentration of the measured position.

Suspended sediment concentration

According to the experimental data in three vertical lines of S1-1, S4-1 and S8-1, the vertical distribution of the suspended sediment concentration in the different types of the vegetated open channel is analyzed. As shown in *Figure 14*, the vertical distribution of the suspended sediment concentration under different types of vegetation in the upstream region (at S1-1) is basically satisfies Type I and Type II distribution, which is similar to that of in the middle reaches of Changjiang River (Cross-section JM01, Time 24 June 2016, Discharge 17900 m^3/s, Water depth 14.5 m, Depth-averaged velocity 1.47 m/s). In the vegetated region (H_2-H_3), due to the influence by vegetation, the vertical distribution of the suspended sediment concentration changes greatly relative to that in the upstream region. The value of vertical sediment concentration under conditions of P2 and P3 decreases significantly and vertical change characteristic satisfies Type III distribution. In downstream region (at S8-1), the vertical concentration of suspended sediment under different types of vegetation is distributed more evenly.

The vertical distribution of suspended sediment gradient is an important factor that represents the variation of suspended sediment transport. Since the distribution of suspended sediment concentration is more scattered than that of flow velocity, the vertical distribution of suspended sediment concentration will not be simulated in this paper, instead of being obtained by differentiating the experimental data (*Figure 15*). As shown in *Figure 15*, the sediment gradient in the zone under the height of 0.2 z/H is relatively large under the condition of vegetation, while the value of suspended sediment gradient in the zone above the height of 0.2 z/H gradually decreases and is basically negative. For P1, the vertical distribution of suspended sediment gradient in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

the vegetated open channel is basically the same as that of P0, which indicates that the vegetation (P1) has a relatively slight influence on the suspended sediment transport.

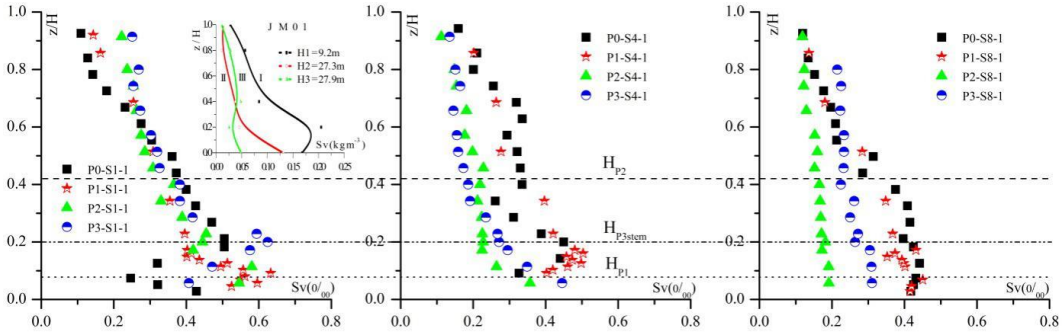

Figure 14. *The vertical distribution of the suspended sediment concentration in the different types of the vegetated open channel*

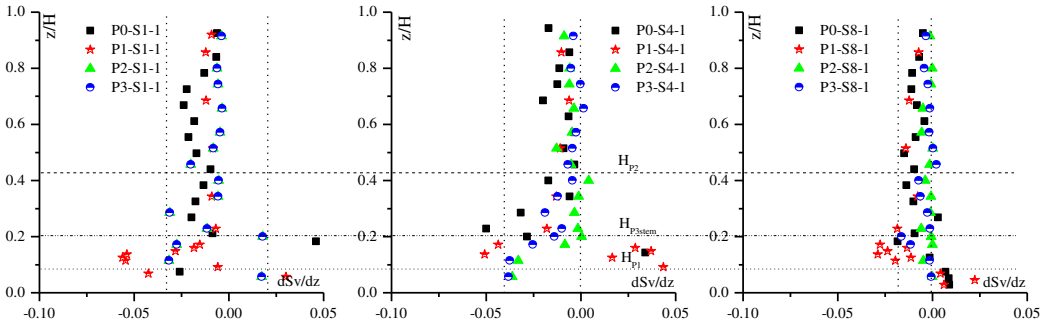

Figure 15. *The vertical distribution of the suspended sediment gradient in the different types of the vegetated open channel*

However, for P2 and P3, the vertical distribution of suspended sediment gradient gradually decreases along the stream-wise, that is to say, the vertical distribution of suspended sediment concentration tends to be consistent at S4-1 and S8-1. There are two possible reasons to explain the significant change of characteristics under conditions of P2 and P3. First, influenced by the water blocking of vegetation (P2 and P3), the large particles of suspended sediment are largely deposited in the upstream and vegetated region and the particle size of suspended sediment along the stream-wise becomes smaller and smaller, which will be conducive to the sediment suspension in the flow. Second, for P2 and P3, the turbulent diffusion of flow at S4-1 and S8-1 is significantly stronger than that of P0, which will be beneficial to the diffusion of suspended sediment in the flow.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

Particle size of sediment

Malvern Mastersizer 2000 particle size analyzer is used to analyze the particle size of suspended sediment, and then the vertical distribution about different particle size of suspended sediment (less than 0.1 mm fine sediment particles and more than 0.1 mm coarse sediment particles) is analyzed. As shown in *Figure 16*, the size of suspended sediment median particles gradually diminishes from bottom to free surface. However, for P2 and P3, the vertical distribution about the size of suspended sediment median particles at S3-1 does not have significant changes, which should be related to their greater turbulence intensity of the flow in the downstream region.

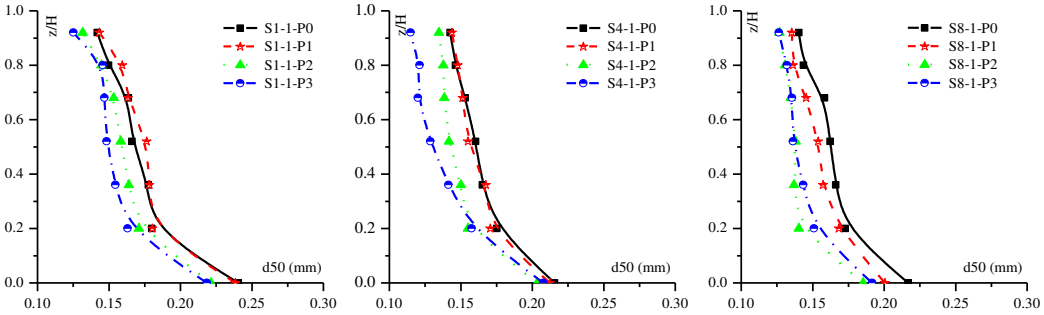

Figure 16. *The vertical distribution of suspended sediment median particles size (d_{50})*

As can be seen from *Figure 17*, the concentration of fine sediment particles does not change obviously along with the water depth. Therefore, the vertical distribution of fine sediment particles is not related to the type of vegetation and the location of the vegetated open channel.

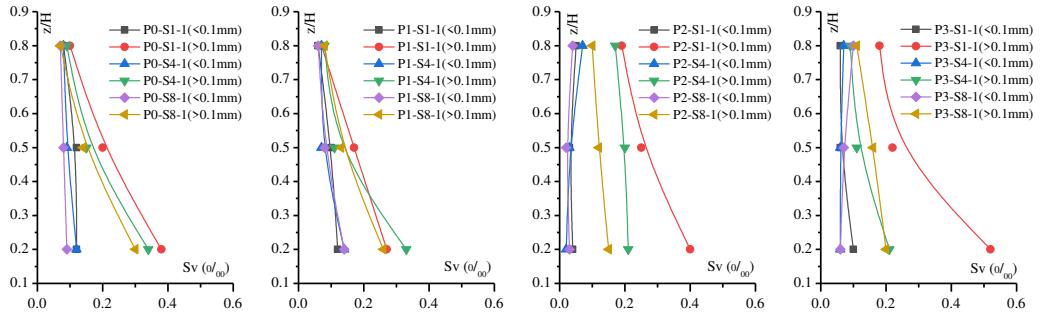

Figure 17. *The vertical distribution about concentration of different suspended sediment particles size*

On the contrary, for coarse sediment particles, the concentration decreases obviously along with the water depth. Taking P2 and P3 for example, the coarse sediment at S1-1 rapidly decreases with the increase of water depth, yet slowly decreases at S2-1 and S3-1. There are two possible reasons to explain the different changes of coarse sediment.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

First, coarse sediment is largely deposited in the upstream and vegetated region due to the water blocking the impact of the vegetation. Second, the turbulence of flow in the two regions is strong and the vertical dispersion of suspended sediment is very significant. Experiments show that vegetation has a weak filtration effect on fine sediment in the open channel, but has a strong filtration effect on the coarse sediment. The proportion of fine sediment in a total load along the stream-wise gradually increases, in contrast, the proportion of coarse sediment in a total load along the stream-wise decreases gradually. As a result, the suspended sediment along the stream-wise in the vegetated open channel is gradually refined.

Discussion

Flow and sediment diffusion coefficient

Due to the turbulent characteristics of the flow, sediment transport is actually bi-directional in the process of turbulent diffusion. Under certain conditions, the total amount of sediment entering the lower concentration zone is equal to the total amount of sediment entering the higher concentration zone, at which time the distribution of sediment concentration reaches equilibrium. The reason for this balance is that the upward turbulence force of sediment is equal to the downward gravity (Ni, 1991). The sediment diffusion coefficient and flow diffusion coefficient are important indicators of flow and sediment diffusion intensity. This paper attempts to study the mechanism of interaction between flow and sediment in the partly vegetated open channel through the analysis of flow diffusion and sediment diffusion coefficient. According to the momentum transfer theory of turbulence (Ni et al., 1991) and diffusion equation of two-dimensional constant uniform flow under equilibrium conditions, formulas for calculating momentum diffusion coefficient (ε_m) and sediment diffusion coefficient can be derived (ε_s).

As shown in *Figure 18*, the vertical distribution of flow momentum diffusion coefficient increases firstly and then decreases in different types of the vegetated open channel. At S1-1, the greater flow resistance of vegetation is, the smaller value of flow momentum diffusion coefficient along the water depth is. For P2 and P3, the value of flow momentum diffusion coefficient is obviously smaller than that of P0 and P1. *Table 2* shows the correlations of flow momentum diffusion coefficient under different types of vegetation. The correlations between P0 and P1, P2, P3 are 0.81, 0.58 and 0.90, respectively. Obviously, the correlation between P0 and P2 is very low, which indicates that vegetation P2 has the greatest influence on the flow momentum diffusion coefficient in the upstream region. In the vegetated region (H_2-H_3), due to the effect of vegetation P2 and P3, the values of flow momentum diffusion coefficient in some vertical zones are significantly larger than those in upstream. The correlation between P0 and P3 also significantly reduces compared with those in upstream (*Table 2*). In the

DOI: http://dx.doi.org/10.15666/aeer/1705_1145111473

downstream region (at S8-1), for P2 and P3, the vertical distribution of flow momentum diffusion coefficient is basically similar to that of P0, however, the maximum value along the water depth is obviously larger than that of P0, and the correlation between P0 and P2 also increases significantly relative to that in the vegetated region, yet the correlation between P0 and P3 is still small. The above change indicates that the influence on flow in the submerged vegetated open channel is mainly in the upstream and vegetated region, while that in the submerged vegetated open channel is mainly in the vegetated and downstream region.

As shown in *Figure 19* and *Table 2*, the vertical distribution of sediment diffusion coefficients is obviously more complex than that of the flow momentum diffusion coefficient in different types of the vegetated open channel. For P1, the vertical distribution of sediment diffusion coefficients along the stream-wise have a high correlation with that of P0. For P2, the vertical distribution of sediment diffusion coefficients has a high correlation with that of P0 in the vegetated region (H_2-H_3). However, the correlation between P2 and P0 in the upstream and downstream regions are significantly low. For P3, the vertical distribution of sediment diffusion coefficients in the whole open channel has a low correlation with that of P0, and all of the correlations are negatively correlated.

Mechanism of interaction between flow and sediment

The reason why suspended sediment can move forward with the flow is mainly due to the contrast between the turbulent diffusion of flow and the gravity of sediment (Hu and Hui, 1995). The process of suspended sediment transport is the process of the interaction between turbulent diffusion and sediment gravity. The experimental analysis also shows that there is a medium to the high degree of correlation between the momentum and sediment diffusion coefficients in the non-vegetated open channel (*Table 2*). The mechanism of the interaction between flow and sediment in open vegetated channel is very complex. When the morphology of vegetation is relatively small, it has little effect on the process of flow and sediment transport in the open channel.

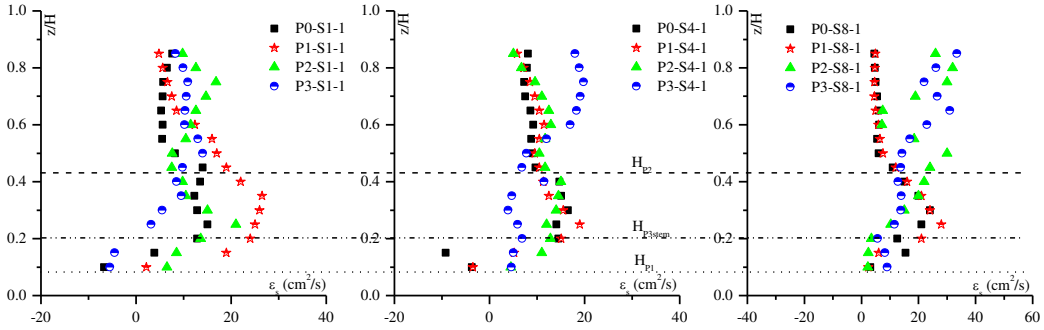

Figure 19. *The vertical distribution of sediment diffusion coefficient along the stream-wise*

However, when the morphology of vegetation is relatively large, its influence on the process of flow and sediment transport in the open channel is greater. At this time, the correlation between the flow and sediment transport is significantly reduced and even negative correlation occurs. With the increased volume of the vegetation, the area of water blocking in the cross-section gradually increases and the turbulence intensity of flow also significantly increases in the open channel, which leads to the obvious three-dimensional vortex flow in some zones. The existence of three-dimensional vortex flow is conducive to the diffusion of sediment in different directions. Since the calculated flow diffusion coefficient in this paper does not consider the influence of transverse flow in the open channel, yet the distribution of sediment concentration in the vegetated open channel is caused by the three-dimensional movement of the flow, so the correlations between the flow momentum diffusion coefficient and the sediment diffusion coefficient in some areas are low or not relevant. All these analyses show that the movement of transverse flow in the partly vegetated open channel has a crucial impact on suspended sediment transport.

Conclusions

Experiments are conducted on characteristics of the flow in the partly vegetated channel. For submerged vegetation, the flow velocity decreases obviously in the zone under the top of vegetation due to its strong flow resistance, while the flow velocity in the zone above the top of vegetation increases obviously and basically complies with the logarithmic distribution. The place slightly below the top of submerged vegetation can be regarded as the "riverbed", and is called "vegetation-equivalent riverbed". For emergent vegetation, the place where the vertical distribution of the longitudinal flow velocity fluctuates strongly is the transition zone between the stem and foliage, therefore, the upper edge of the transition zone can be regarded as the "equivalent riverbed" for the emergent vegetated channel.

The regular influence on flow in the partly vegetated open channel is analyzed. In terms of the range of influence, the influence on the flow of different types of vegetation is greater in the downstream region than that in the upstream region. In terms of the degree of influence, all types of vegetation have a great effect on the flow at the bottom position, followed by the surface position, and then the middle position. For different types of vegetation, the submerged and emergent vegetation has completely opposite effect on the bottom flow and the surface flow. Relative to submerged vegetation, emergent vegetation has a greater influence on flow and longer influenced distance.

Due to the influence of vegetation, the flow in the downstream region generates many significant vortices. Compared with the submerged vegetation, emergent vegetation has a more significant influence on the flow in the downstream region. Therefore, in terms of ecological rivers, the presence of intense vortex flow in the downstream region will make the substances in rivers fully diffused, which is obviously conducive to the survival and propagation of aquatic organisms.

The vertical distribution of suspended sediment in the partly vegetated channel becomes more and more uniform along the stream-wise. Besides, the vertical variation of the suspended sediment gradient decreases gradually along the stream-wise. Vegetation has a weak filtration effect on fine sediment in the open channel but has a strong filtration effect on the coarse sediment. The proportion of fine sediment in a total load along the stream-wise gradually increases; in contrast, the proportion of coarse sediment in a total load along the stream-wise decreases gradually. As a result, the suspended sediment along the stream-wise in the partly vegetated open channel is gradually refined.

The mechanism of the interaction between flow and sediment in the partly vegetated channel is very complex. When the morphology of vegetation is relatively small, it has little effect on the process of flow and sediment transport in the open channel. However, when the morphology of vegetation is relatively large, its influence on the process of flow and sediment transport in the open channel is greater. At this time, the correlation between the flow and sediment movement is significantly reduced and even negative correlation occurs. These show that the movement of transverse flow in the vegetated open channel has a crucial impact on suspended sediment transport.

In this paper, the vegetation is made by flexible plastics. Although the plastic vegetation has some flexibility, it is still different from natural aquatic vegetation in stiffness. To further improve the research, it is necessary to use real aquatic vegetation to carry out future experiments. For future experiments, the aquatic vegetation can be planted in the flume in advance. The effects on the flow and sediment transport can be studied separately according to the different growth stages of aquatic vegetation.

Abstract. Soil organic carbon (SOC) storage in forest ecosystems plays a major role in the global carbon cycle. Soil carbon across an age sequence may vary of Chir pine forest. In this study, based on the silvicultural shelterwood management system, forest area was classified into stands of three different age groups, including young stand, mature stand, and over-mature stand. Soil carbon density was assessed in each stand at three depths (0-20, 20-40, and 40-60 cm) by Walkley Black method. The results showed that SOC was higher in different stand ages at a depth of 0-20 cm as compared to the 20-40, and 40-60 cm depth. Altogether, the average potential of soil carbon density at a depth of 0-60 cm in young, mature and over-mature stand ages of Chir Pine forest was 70.96 (Mg C ha^{-1}), 68.96 (Mg C ha^{-1}) and 61.02 (Mg C ha^{-1}), respectively. The result indicates that soil carbon stock decreases with increasing forest stand ages. The results confirm that-- current management operations such as cutting, thinning, tending, may affect the soil carbon. Moreover, we recommended the regular periodic survey of soil and permanent sample plot establishment is necessary for the accurate soil carbon measurement in different stand ages of Chir pine forest.
Keywords: *shelterwood system, management operation, soil bulk density, soil depths, Murree Hill*

Introduction

Soil carbon storage is one of the most essential and significant carbon sinks in the terrestrial ecosystems, which facilitates carbon sequestration. Monitoring and assessment of soil carbon in forests are critical for the mitigation of climate change. The soil is an important sink for carbon storage (Ahmad et al., 2018; Mannan et al., 2019; Saeed et al., 2019a). Among various forest carbon pools, the estimation of soil organic carbon (SOC) is essential, because the soil is the world's largest terrestrial carbon pools, which plays a vital role in the global carbon budget (Saeed et al., 2019b). Therefore, a slight change in the soil carbon storage can have large impacts on the global carbon cycle (Johnson et al., 2007). The increasing emission of carbon dioxide from the soil is reinforced by the rising of temperature and climate change (Yang et al., 2010). SOC stored in the world's soils is approximately 1100–1600 Pg (petagrams), more than twice the carbon stored in the living vegetation, which is 750 Pg (Sundquist, 1993). Soil releases carbon to the atmosphere through deforestation and other anthropogenic activities may significantly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_114751487

increase the greenhouse gases concentration (Watson et al., 2000). The potential capability and assessment of soil are essential for the mitigation of CO_2 emission, improvement of surface water quality, soil physical properties, enhancement of forest production and stability, as well as decreasing of soil erosion (Lal, 2004; Lal et al., 2007).

Stand age is an essential factor affecting storage of carbon in various forest components such as in upper-story vegetation, understory vegetation, deadwood, and soil (Martin et al., 2005; Zerva et al., 2005; Peichl and Arain, 2006). Moreover, stand age is a reliable predictor of the structure and function of a forest ecosystem which may affect the carbon density among carbon pools (Bradford and Kastendick, 2010). Furthermore, various carbon pools of a forest respond differently to stand age (Zhu et al., 2010). Therefore, it is essential to understand the relationship of stand age with soil carbon and sequestration rate (Cheng et al., 2014). Some studies underlined that the potential of soil carbon sequestration is age-independent (Song et al., 2018). Some studies showed that soil carbon increase with the increase in stand age (Cao et al., 2012; Zhao et al., 2014). The soil carbon inconsistency may be depending on many other factors such as forest types, climate, previous land use and soil properties (Taylor et al., 2007).

In Pakistan, the researchers focused on the forest carbon stock such as temperate forest (Ahmad et al., 2015, 2018; Ahmad and Nizami, 2015), subtropical forest (Nizami, 2012), and in the planted forest (Saeed et al., 2016). However, no up-to-date studies have been conducted on the soil carbon allocation concerning stand age. Therefore, the current study was carried out in subtropical Chir pine (*Pinus roxburghii*) forest. This species is widely distributed in the Murree, Swat, Dir, and Azad Kashmir. The height of *Pinus roxburghii* is 120 ft, and girth is 7 to 8 ft with the whole of the top canopy. The Chir pine canopy tends to be even-aged over a compact area. The heavy needle falls, and burning reduces the growth of shrubs. Only a few of the species of grasses and herbs are noticeable, the fire virtually immune the older trees from damage and seedling show resistant after the first year while rootstock persists and new shoots appears (Champion et al., 1965). A forest fire is a common behavior of Subtropical Chir pine forest. Regularly, the forest fire incidents took place from April to June during the summer season. The falling of dry needle of Chir pine acts as fuel for forest fire (Nafees and Asghar, 2009). This species is easily cultivated and naturally regenerated in the northern area of Punjab and Khyber Pakhtunkhwa province. *Pinus roxburghii* considered as relatively short-lived and fast-growing species. Because of its longevity and fast growth, seems a suitable species for wood production. *Pinus roxburghii* is a valuable species for forestation, afforestation, and reforestation of denuded areas of Pakistan (Sheikh, 1993; Amir et al., 2018).

Under the shelterwood management system, the Chir pine forest is managed. According to this system, the forest area is divided into various blocks on the base of age, following different management operations. Felling and cutting activities are concentrated on over-mature blocks. In the mature block, thinning operations are carried out. In the young stand, cleaning operations are carried out. These different management operations in each stand age block may influence the soil carbon. Therefore, the study was designed to assess soil carbon of *Pinus roxburghii* forest ecosystem in age-sequence and to outline, the effect of management operations practices on carbon stock in different stand age classes. Moreover, to provide necessary information on carbon storage potential for the reporting of the Kyoto protocol to provide future recommendations for suitable forest management and making policy decisions. Here, our objective of the study was to investigate SOC stocks in age-sequence along various soil depths.

Materials and Methods

Study site

The present study was conducted in Murree Hill of Pakistan. The latitude and longitude of the study site were ranged from 33º 47'15" to 33º 54' 47" N and 73º 16' 54" to 73º 29' 18" E. The elevations of the Chir Pine forest from sea level are range from 939 to1873 m. The mean precipitation ranges from 500 to 1200 mm while the temperature of the studied forest varies from -5ºC in winter to 40ºC in summer. The sedimentary rocks are comprised of shales, limestone sandstones, and marls. The soil was loamy with a proportion of silt, clay, and sand (Sheikh, 1993). The study area is the natural zone of Chir Pine forest that is managed under a shelterwood system. The dominant tree species of the study area is Chir Pine. The major associated tree species are *Pinus wallichiana* (kail), *Pyrus pashia* (batangi), and *Quercus incana* (rhin). The associated understory flora consists of *Carissa spinarum* (granda), *Myrsine africana* (khukhal), *Dodonea viscosa* (sanatha), *Berberis lycium* spp. (sumblu), *Capparis decidua* (karir), *Cannabus sativa* (Bang) and *Adhatoda vasica* (Bahekar). The map shows the location of the study area (*Fig. 1*).

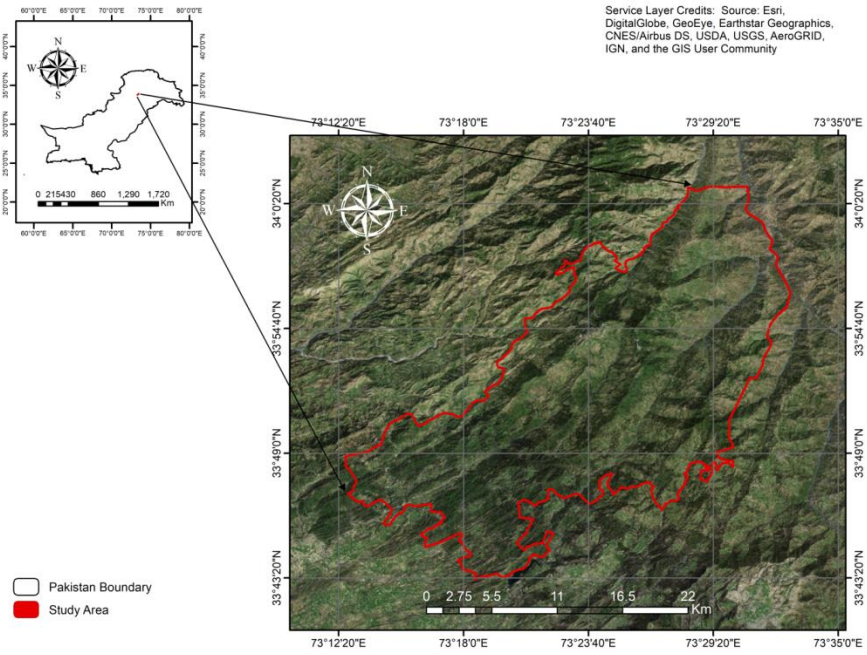

Figure 1. *Range of study area, Murree Hill*

Research design

Pinus roxburghii forest was managed under a shelterwood system. Based on uniform shelterwood silvicultural management system, the Chir Pine forest consists of four periodic blocks (PBI, PBII, PBIII, PBIV) with rotation age (100 years) and regeneration period (25 years), which followed stands of four ages (1-25, 26-50, 51-75 and 76-100 years) (*Table 1*). According to the system, regeneration felling is carried out in PBIV, but some prescribed numbers of trees are retained for seed production. After the establishment of regeneration, then seed bearer is removed for the development of new trees. The duration between regeneration and final felling take 25 years. In PBIII, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_114751487

thinning operations are carried out in PBIII for growth enhancement. The study area was classified into three age classes on the base of current forest structure and accurate measurement, PBI and PBII representing young age class (1-50 years), PBIII representing the mature stand (50-75 years) and PBIV representing over the mature stand (>75 years). Moreover, the comparison of SOC with growing stock and biomass of the *Pinus roxburghii* forest, information has mentioned in *Table 2* (Amir et al., 2018).

Table 1. *Sketch of the uniform shelterwood system*

Periodic Blocks	Age at the time of formation	Age at the end of the regeneration period
PBI	1-25	76-100
PBII	26-50	51-75
PBIII	51-75	26-50
PBIV	76-100	1-25

Table 2. *Characteristics of Chir Pine forest. Superscripts in each column show significant differences at α=0.1 and p= <0.0001)*

Age group	Mean Basal Area (m^2ha^{-1})	Mean Stand Density (trees ha^{-1})	Mean Stand Volume (m^3ha^{-1})	Mean total tree biomass (t ha^{-1})

Mean	32.3	350.4	329.4	338.3

Soil samples collection and treatment

The area maps and topographic sheets were taken from the respective forest department. GPS determined coordinates and elevation (m) of each sample area. The stratified random sampling method was done in each block. The soil samples were collected from the subplot of (1×1 m^2) within quadrate at a depth of 0-20 cm, 20-40 cm, and 40-60 cm. In each stand, eight sample plots were taken with three replicate plots. The soil samples were collected by using the Soil Augur. The volume of the soil core was 198.24 cm^3 with 5.9 cm diameter and 7.25 cm height dimension. After weighing and packing of the labeled soil samples were brought into the laboratory to keep it in the oven for 48 hours at 72ºC for further analysis and the soil bulk density was determined from air-dried soil samples. The air-dried sample was ground with a pestle and passed through 0.5 mm sieve manually for SOC determination, as mentioned by Lu (1999).

Soil bulk density calculation

For the determination of total soil carbon, the soil bulk density of samples in each age group was determined from the weight of soil sample and known volume of soil core according to given *Equation (1).*

$$SBD\ (g/cm^3) = \frac{WS}{VS} \qquad \text{(Eq.1)}$$

where SBD = soil bulk density (g/cm^3), WS = weight of soil sample (g) and VS = volume soil core (cm^3).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_114751487

Soil carbon measurement

Soil carbon density was determined by using the oxidizable organic carbon method (Walkley and Black, 1934; Rayment and Higginson, 1992; Anderson and Ingram, 1994; Ahmad and Nizami, 2015). In this method, the Potassium dichromate solution was prepared by drying in an oven at 105ºC for two hours and cooled it. Then distilled water was added into the 49.09 gm of dried potassium dichromate to dissolve and took one volume of solution from it. 196 gm of distilled water was added into the ferrous ammonium sulfate solution and to dissolve and prepared to one-liter volume. 5 ml sulfuric acid was taken and mixed with it and brought to one volume of solution. One gram of diphenylamine indicator was dissolve and added into the concentrated H_2SO_4. One gram of soil was taken in 500 ml beaker with 10 ml Potassium dichromate solution. 200 ml of concentrated H_2SO_4 was added, and the mixture was kept for 30 minutes, and then 10 ml of H_3PO_4 and 10 ml of water was added to the mixture, then the mixture was kept to cool for ten minutes, and 10-15 drops of Diphenylamine indicator was added to this mixture. When the mixture changes the color from violet-blue to green by the titration of 0.5 ferrous ammonium sulfate solution and then reading was noted. The total organic carbon was calculated by the given *Equation (2)*.

$$Oxidable\ organic\ carbon\ \% = \frac{blank\ volume - actual\ volume \times 0.3 \times M}{Weight\ of\ air-dry\ soil\ (gm)} \quad \text{(Eq.2)}$$

where M = Molarity of ferrous ammonium sulfate, $0.3=31\times0^{-3}\times100$, here 3 shows equivalent to the weight of carbon, Av = volume of Ferrous ammonium sulfate to titrate with sample and Bv = Ferrous ammonium sulfate solution volume to titrate it with the blank solution.

Soil carbon (Mg C ha^{-1}) calculation

Soil carbon (Mg C ha^{-1}) was calculated from the soil organic carbon (SOC %), soil bulk density (g/cm^3) and thickness of horizon (cm). Soil carbon (Mg C ha^{-1}) was calculated from the following equation (Pearson et al., 2007; Nizami, 2012; Ahmad et al., 2015).

$$Soil\ carbon\ (Mg\ C\ ha^{-1}) = SBD\ (g/cm^3) \times SOC\ (\%) \times SHT\ (cm) \times 100 \quad \text{(Eq.3)}$$

where SBD = Soil bulk density (g/cm^3), SOC = Soil organic content (%) and SHT = Soil horizon thickness (cm).

Statistical analysis

Sigmaplot (12.5 version) and Statistics (8.1 version) software were used for statistical analysis. Mean, standard deviation and standard error were calculated. Analysis of variance (One-way ANOVA) along with all pairwise comparison and least significance difference (LSD) test was performed to test the significant difference of the means values of the soil bulk density and soil carbon.

Results

SOC was higher in young stand ages at a depth of 0-20 cm as compared to the 20-40, and 40-60 cm depth (*Fig. 2*). The average SOC in the young stand at a depth of 0-20, 20-40 and 40-60 cm was 36.49, 17.43 and 17.04 Mg C ha^{-1}, respectively. Moreover, the significant differences found between different stand ages at a depth of 0-20 cm, F (2, 14) = 71.70, p = 0.0000. The higher SOC was found at a depth of 0-20 cm in the mature stand age. The mean SOC in the mature stand at a depth of 0-20, 20-40 and 40-60 cm was 37.43, 17.22, and 13.31 Mg C ha^{-1}, respectively.

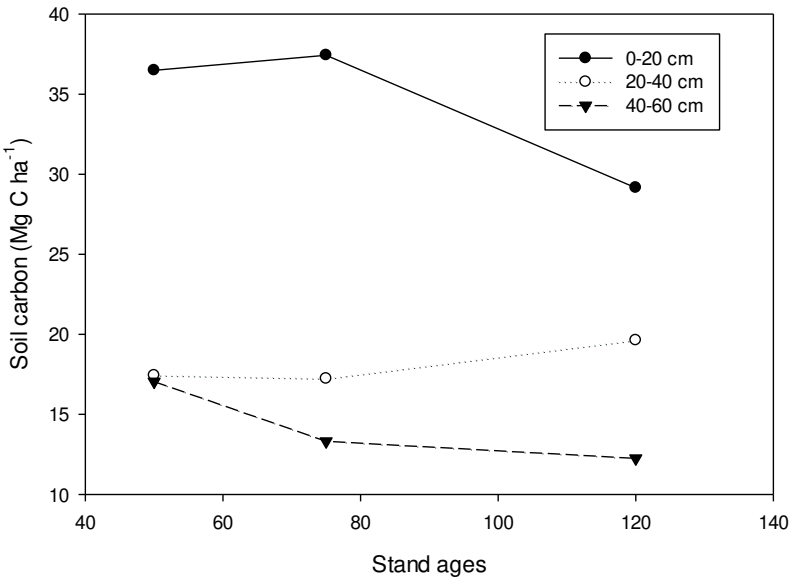

Figure 2. *Soil carbon stock of different stand ages at various soil depths*

The results showed significant differences at the top layer of the mature stand, F (2, 14) = 30.09, p = 0.0000. SOC was higher in over-mature stand ages at a depth of 0-20 cm as compared to 20-40, and 40-60cm depth. The mean SOC in over-mature stand at the depth of 0-20, 20-40 and 40-60 cm was 29.15, 19.62 and 12.25 Mg C ha^{-1}, respectively, with a significant difference, F (2, 14) = 10.14, p = 0.0019 (*Table 3 Table 4*).

Table 3. *SOC in young, mature and over-mature stand at various soil depths*

Soil depths	Young	Mature	Over-mature
0-20 cm	36.49 ± 3.98^{A}	37.43 ± 2.92^{A}	29.154 ± 3.3^{A}
20-40 cm	17.43 ± 4.23^{B}	17.22 ± 7.84^{B}	19.627 ± 6.81^{B}
40-60 cm	17.04 ± 4.06^{B}	13.31 ± 7.81^{B}	12.250 ± 8.11^{B}

Table 4. *Relationship type, equation and R^2 value of the Pinus roxburghii stands*

Soil depths	Parameters	Relationship type	Equation	R^2 Value
0-20 cm	SA & SC	Polynomial, linear	y = -0.1132x + 43.454	0.83
0-40 cm	SA & SC	Polynomial, linear	y = 0.0339x + 15.32	0.81
40-60 cm	SA & SC	Polynomial, linear	y = -0.0631x + 19.351	0.79

SA= Stand ages (<50, 50-75, >120 years old stands) and SC = Soil carbon (Mg C ha^{-1})

SOC was higher in different stand ages at a depth of 0-20 cm as compared to the 20-40, and 40-60 cm depth. The average SOC in young, mature and over-mature stands were 36.493, 37.44 and 29. 15 (Mg C ha^{-1}), respectively. Moreover, the significant differences found between different stand ages at a depth of 0-20 cm, F (2, 21) = 14, $p = 0.0001$. While, the non-significant differences found at the depth of 20-40 cm (F (2, 21) = 0.34, $p = 0.72$), and 40-60 cm (F (2, 21) = 1.04, $p = 0.36$) for different stand ages. The average SOC for young, mature and over-mature stands were 17.43, 17.22, 19.62 Mg C ha^{-1} at a depth of 20-40 cm, while at a depth of 40-60 cm, there were 17.05, 13.31, 12.25 Mg C ha^{-1}, respectively (*Fig. 3*).

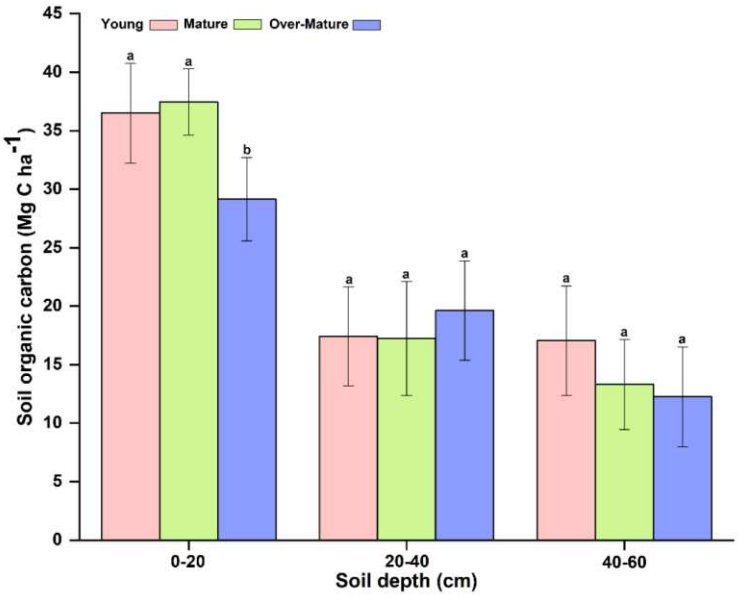

Figure 3. *Soil organic carbon contents. SOC in young, mature, and over-mature stand at various depths. The different letters on the bar are showing significant differences while the same letters are showing the non-significant different between different classes of stand ages. Alphabets on the top of each bar are showing the* $LSD_{0.05}$ *difference*

The soil organic matter (SOM) in the young stand at a depth of 0-20, 20-40 and 40-60 cm was 2.95, 1.68 and 1.38%, respectively. The SOM in the mature stand at a depth of 0-20, 20-40 and 40-40 cm was 2.88, 1.35 and 0.98%, respectively. SOM in the over-mature stand at a depth of 0-20, 20-40 and 40-60 cm was 2.76, 1.68 and 0.96%, respectively. The resulted that higher SOM was found at the 0-20 cm soil depth and following the decreasing trend from upper to lower soil depth in each stand. Soil Bulk density (SBD) results showed almost similar values in different stand ages at each depth. The mean SBD in young, mature and over-mature stands at a depth of 0-20 cm were 1.09, 1.04 and 0.93 (g/cm^3), respectively. Moreover, the significant differences found between different stand ages at a depth of 0-20 cm, F (2, 21) = 9.51, $p = 0.0011$. The average SBD in young, mature and over-mature stands at a depth of 20-40 cm were 1.13, 1.10 and 1.04 (g/cm^3), respectively. The significant difference observed at a depth of 20-40 cm in young stand ages, F (2, 21) = 4.34, $p = 0.0265$. The mean SBD in young, mature and over-mature stands at a depth of 40-60 cm were 1.15, 1.08 and 1.06 (g/cm^3),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_114751487

respectively. Meanwhile, the significant difference found in different stand ages $F(2, 21) = 3.64$, $p = 0.0440$ (*Fig. 4*).

Generally, the results of soil carbon analysis showed a decreasing trend with increasing stand age. Soil carbon showed decreased with increasing at different soil depth in each stand. This decreasing trend in soil may be attributed to the soil disturbance during the felling operations in the over-mature stand and decrease in the natural thinning with the stand age. Additionally, there was an inverse relationship between soil carbon and soil bulk density. Soil bulk density increased with a decrease in soil organic carbon at various depths. The higher degree of soil organic matter (SOM) showed a lower degree of bulk density. The SOM and SBD are inversely proportional to each other, which indicate higher infiltration and, proper aeration and granulation. The soil bulk densities in each stand age showed significant variation.

Discussion

It is quite difficult to compared SOC with forest biomass (Teklay and Chang, 2008; Laganiere et al., 2010), because SOC may be affected by various factors, such as stand age, tree species, forest type, climate, and soil chemical and physical properties (Richter et al., 1999; Guo and Gifford, 2002; Paul et al., 2002; Peichl and Arain, 2006; Mora et al., 2014; Wang et al., 2014). Soil organic carbon across stand age has been widely carried out with different results. In many studies, SOC stock increases with the forest stand age (Smal and Olszewska, 2008; Berthrong et al., 2009) while the opposite result was also found after afforestation (Teklay and Chang, 2008; Mao et al., 2010). Afforestation and reforestation have been considered to be essential to reduce atmospheric CO_2 emission by sequestering carbon in soils (Richter et al., 1999; Smal and Olszewska, 2008). Therefore, SOC in surface soil layer could be affected by the changes of the upperstory, understory, litter, shrub and herb biomass, and soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_114751487

characteristics with stand age sequence (Six et al., 2002; Noh et al., 2010). Many studies found that the SOC content declines firstly and then increases with the increasing of stand age (Chen et al., 2005; Mao et al., 2010). The mean soil carbon showed decreased with respective stand age as well as with soil depth. The soil carbon was recorded higher in the topsoil of each stand as compared to deeper soil. It may be due to producing of SOC by the decomposition of the root system and litter, which entered into topsoil first near the ground as demonstrated by other studies (Peichl and Arain, 2006; Tian et al., 2010; Zhang et al., 2012). The current study showed carbon content of soil layer showed a decreasing trend with stand age while other study showed increasing of soil carbon with stand age due to the availability litter productivity in high older stands (Ming et al., 2014).

Soil carbon depends on the forest stand age, forest types, forest productivity, the chemical and physical properties, and litter decomposition rate of the soil (Gower, 2003; Kang et al., 2006; Jandl et al., 2007; He et al., 2013). Our study showed a decreasing trend with stand age. The proportion of soil carbon stock should need focus during any management activities for the enhancement of future soil carbon sequestration of *Pinus roxburghii* forest ecosystem.

The SOC exists different debates on whether or not SOC potential could change with respect to forest stand ages (Farley et al., 2004; Lemma et al., 2006). Some previous researches showed that soil carbon stock is not increasing with increasing stand ages significantly (Farley et al., 2004; Cheng et al., 2013), while some other researches showed that SOC increasing with increasing forest stand age (Hooker and Compton, 2003; Pregitzer and Euskirchen, 2004; Lemma et al., 2006). The difference may be due to various factors such as soil factor climatic factor and forest type (Peichl and Arain, 2006). However, generally, SOC increases with stand age in conifer forest, due to the accumulation of organic matter in older stages (Zerva et al., 2005; Li et al., 2013). However, in the case of the present study, the soil carbon decreases with increasing stand age, may be due to the result of management operations such as felling and thinning activates. During these operations, the top layer of the soil exposed to rainfall and wind, wash out the soil surface, which may lead to reducing of soil carbon.

Conclusion

The soil carbon density decreased with the increase of forest stand ages and decreased with increasing soil depths in different stand ages. However, the soil carbon showed gradually decreasing trend from young to over-mature stand. Furthermore, our results showed the effects of management operations on soil carbon. The decreasing of soil carbon value with respect to stand ages may be is the result of soil disturbances during management operations. Therefore, we suggest different protection measures such as reduced impact logging, soil conservation through mulching, maintaining understory vegetation and forest cover through regeneration, control grazing and effective management of forest fire should be considered. The appropriate management of forest could allow the importance of forest soil in the regional carbon budget.

Furthermore, the results highlighted that regeneration and afforestation of Chir Pine could promote the potential capability of SOC and provide necessary data for estimating the carbon stocks of Chir Pine forest ecosystem. The present results highlighted the importance of stand age in assessing forest soil carbon measurement for policymakers when modeling climate scenarios.

Abstract. Aspect of forest dynamics is also the formation of forest gaps. Certain plant species typical for understory, still persists in newly formed forest gaps. For such species, environmental conditions change significantly. In research the physiological response of local populations of *Cyclamen purpurascens* Mill. in forest gaps, depending on time of their formation was examined. The physiological response was measured as anthocyanin and quercetin content in cyclamen leaves, depending on forest gap and season. It was found that anthocyanin content in leaves from all gaps was statistically higher in autumn than in spring. A comparison of anthocyanin content between leaves from different gaps has shown that leaves from the youngest gap in the spring contained a statistically lowest quantity of anthocyanin malvidin 3-rutinoside, malvidin 3-glucoside, and peonidin 3-O-neoheseridoside. There were no differences between other locations. For quercetins, it was found that leaves from the youngest gap in the spring contained the highest amount of myricetin-3-rhamnoside. Conclusion is that cyclamen leaves on the youngest gap have not yet completely adapted to increased solar radiation. Quercetins represent first and immediate response to increased UV-B radiation. Leaves on youngest gap in the spring do not yet have sufficient anthocyanin to protect them against radiation.
Keywords: *anthocyanin, forest dynamics, light stress, quercetin, temperature stress*

Introduction

Forests are one of the most common type of vegetation on the Earth. The layers, from top to ground, are as follows: canopy, understory, shrub layer, and herbaceous layer. A consequence of this stratification are also microclimatic conditions in individual layers. Moisture is thus highest by the forest floor due to evaporation from the ground, and the lowest slightly above the canopy, as air circulation is more intensive there (Smith and Smith, 2001). In terms of temperature, the highest is in the canopy layer, where solar radiation is the most intensive. Temperature then drops towards the floor. Another characteristic is the day and night cycle (generally, the temperature is lowest during the night) and the seasonal cycle in deciduous forests of the warm temperate climate. During spring months in such forests, the temperature is higher also in the organic layer, since canopies lack the leaves, allowing sufficient solar radiation to reach the floor. Increased temperature along the floor in the spring thus facilitates quick growth of spring geophytes (Smith and Smith, 2001; Schultze et al., 2005). Like the temperature, light intensity is also decreasing from top to bottom. In deciduous forests, only 5% of total solar light thus reaches the floor (Chazdon and Pearcy, 1991).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1148911508

Considering the lower exposure to light, plants of the herbaceous layer have various adaptations that enable efficient photosynthesis. They are capable of photosynthesis with the lowest solar radiation, utilising the light of longer wave lengths. While investing less energy into growing above-ground segments, they store more reserve food in underground plant organs, which in spring act as an additional source of food for the start of their growth (Whittaker, 1975). In plants that grow in the herbaceous layer while the canopy is leafed, photosynthetic activity mostly depends on sunflecks on the forest floor (Chazdon and Pearcy, 1991). Their leaf surfaces are larger, leaves are thinner, and have a poorly developed mesophyll tissue. They have only one layer of palisade tissue and a lower number of chloroplasts per surface unit, even though the quantity of chlorophyll in chloroplasts is higher than in leaves of plants growing in the sun. Thus, plants growing in the shade utilise to the highest possible degree the light reaching the undergrowth. Furthermore, they capture additional light with hypodermis and epidermis cells (Schultze et al., 2005; Lambers et al., 2008).

A forest gap caused by disturbances can lead tremendous stress as the sudden exposure to solar radiation for understory plants. Forest gaps are otherwise a normal occurrence and are part of the forest dynamic (Peterken, 1996). Compared to surrounding forest, temperature of floor and air, light intensity, and atmospheric humidity change to a greater extend in the area of a forest gap. Maximum light intensity in a gap is reached between 10 AM and 2 PM, and is highest at the centre of the gap. Floor temperature is positively correlated to light intensity, growing from morning to evening in large gaps. In small and medium-sized gaps, floor temperature is the highest between 12 noon and 2 PM (Buajan et al., 2016). Due to the high quantity of sunlight, all plant species that lacked sufficient light for successful growth in the understory under the canopy cannot start to grow in such locations. Generally, the number of herbaceous species is higher on forest gaps than in understorey, and is positively correlated to the size of the gap (Collins and Pickett, 1988; Mihók, 2007). Furthermore, forest gaps represent a chance for forest stand regeneration. Individual trees that only stagnated in the herbaceous layer due to lack of light can accelerate their growth when a forest gap forms (Peterken, 1996).

The larger the forest gap, the greater the effect on local populations of plant species. At the same time, a formation of a forest gaps greatly affects understory plants that are otherwise adapted to weaker sunlight intensity under the canopy. Plants of the understory can respond to the formation of a forest gap, which for them represents stress, either as stress tolerant plants or by avoiding such stress. Shady plants have a lower response plasticity to the stress factor (Middleton, 2001). The adaptation can also manifest in a population reduction of a specific shady species, with only individual specimens thriving in microenvironments, where they are still somewhat protected by the shade of other plants. For instance, when studying the species turnover in forest gap formation, the population of species *Galium odoratum* Scop. was found to be smaller on a gap than in the forest. However, some species (*Viola sylvestris* Lam., *Mercurialis perennis* L.) have adapted to the changed environmental factors (Kelemen et al., 2012).

Substances that protect the plant against permanent damage and death are flavonoids. Their synthesis is induced by UV-B radiation through phytochrome (Caldwell et al., 1983). Flavonoids include anthocyanins, water-soluble pigments present in all plant tissues. Anthocyanins have a key role in protecting tissues against

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1148911508

photo-inhibition and photo-oxidation (Chalker-Scott, 1999; Cooper-Driver, 2001; Gould et al., 2002; Ishizaka et al., 2002; Hughes et al., 2005, 2007; Hughes, 2011). They act as anti-oxidants that bind free radicals. This forms an anthocyanin-peroxidase system that provides protection against oxidation damage (Yamasuki, 1997; Steyn et al., 2002). Anthocyanins are located in or just under the epidermis. Located closer to the upper side of the leaf, they act as a filter, reducing the level of inbound solar radiation. Anthocyanins thus protect the internal parts of the leaf – primarily chloroplasts – against damage (Gould et al., 2000; Timmins et al., 2002). For this reason, they are – in this case – located above the chloroplasts. Plants growing in locations exposed to strong sunlight contain higher quantities of anthocyanins in leaves, stems, and flowers, compared to shady plants (Wheldale, 1916). In shady plants, they also accumulate in the lower epidermis, thus additionally participating in capturing sunlight (Chalker-Scott, 1999; Steyn et al., 2002). Anthocyanin synthesis is also light-induced; however, as opposed to other flavonoids, anthocyanins absorb sunlight in the visible part of the spectrum and less in the UV-B part (Caldwell et al., 1983; Mendez et al., 1999). Low temperatures under 25 °C accelerate anthocyanin biosynthesis, while high temperatures over 35 °C cause their degradation and inhibit their accumulation (He et al., 2010). Furthermore, excessive UV-B radiation inhibits anthocyanin synthesis, likely due to DNA damage (Chalker-Scott, 1999). In addition to anthocyanins, quercetins are also very effective in binding reactive oxygen compounds. Their synthesis increases both in low and high radiation (Agati et al., 2012; Mierziak et al., 2014). The quantity of anthocyanins and quercetins can therefore act as an indicator whether or not a plant experienced light stress (was suddenly exposed to increased solar radiation), or if it has already adapted to increased solar radiation.

In our study, the physiological response of local populations of common cyclamen (*Cyclamen purpurascens* Mill.) in Dinaric fir-beech forest to increased exposure with solar radiation, as a result of forest gap formation, was examined. The common cyclamen as the subject of our study was chosen because it is one of the typical representatives of understory. Furthermore, it is a perennial plant, allowing us to measure the response of specific specimens to forest gaps, depending on the time from the gap formation, when they were exposed to increased solar radiation. By measuring anthocyanin and quercetin quantity in common cyclamen leaves, the response of specimens in local population was determined. A higher anthocyanin content in specimens of populations growing on older forest gaps, where plants have been exposed to a strong solar radiation for a longer period was predicted. Regardless of the location (forest gap), we predicted a lower anthocyanin quantity in leaves of all common cyclamen specimens during the spring, and higher quantity during late summer and autumn. Quercetin content was examined with the same purpose. A higher quercetin quantity in leaves of specimens growing on older forest gaps was predicted.

Material and methods

Experiment design

In the study 6 sampling locations were included, where five represented forest gaps in Dinaric fir-beech forests (*Omphalodo-Fagetum*) that naturally formed at different times and one sampling location that represented juvenile phase of beech forest. All

This biogeographic region is characterised by the contact of Sub-Mediterranean climate and the temperate continental climate of western and southern Slovenia, resulting in large quantities of precipitation in this region (between 1,400 and 3,500 mm) (*Fig. 3*), with a distinct autumn maximum and indistinct spring maximum (Kordiš, 1993). A thick snow cover is also characteristic, and can persist long into spring due to low temperatures. Average annual temperatures in the region are between 5 °C and 8 °C (*Fig. 4*). Temperature decreases with altitude, with characteristic temperature inversion in certain areas. Beside the data for whole area we also made temperature measurements at the biggest sampling location (Goteniška gora) from May to end of December in year 2016 (*Fig. 5*). At the end of July (because of the peak of year radiation) on sunny day measurements of UV-B radiation at all sampling sites between 9:00 and 15:00 were done. Radiation was measured in transect in the middle of localities (forest gaps) and at two opposite edges (on junctures with forest). Measurements were done by Digital Ultraviolet Radiometer Model 6.2. UVB by Solarmeter USA (*Fig. 6*).

Leaf sampling for anthocyanin and quercetin analyses

The common cyclamen is a widespread species in Slovenia (Bavcon, 2009). It is a geophyte representative, as it has an underground tuber that represents a food storage tissue (Grey-Wilson, 2002). Its leaves are evergreen and whither in summer months before flowering. After flowering, new leaves begin growing (Bavcon, 2009). Leaves contain anthocyanins on their abaxial side, which in most cases give leaves a purple

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1148911508

colour (Grey-Wilson, 2002). Common cyclamen specimens that grow in the shade have a more intensely coloured purple leaves (Kerner, 1894). An even more intense purple colour can be found on leaves of specimens growing in locations with strong solar radiation exposure (Grey-Wilson, 1988, 2002; Mathew, 2013).

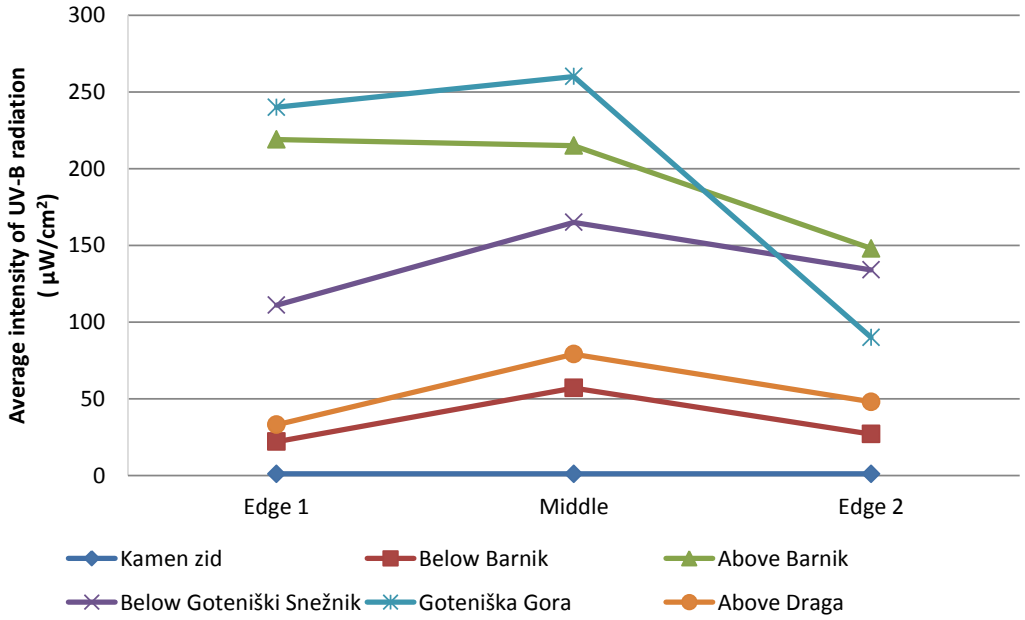

Figure 6. *Average intensity of UV-B radiation at sampling localities, measured at the end of July 2016 (Middle – middle of the gap/locality, Edge 1 – first edge of the gap/locality, Edge 2 – second edge of gap/locality)*

In year 2016 all leaves from three to six plants from all 6 sampling locations (depending on the abundance of specimens in the local populations) were removed, put in plastic bags, and stored in a portable cooling container. During spring, we did not find any common cyclamen leaves in sampling locations Goteniška gora and Below Goteniški Snežnik, because leaves had died of hard conditions during winter. During late summer, only one cyclamen leaf at the sampling location Above Barnik was found, in which we measured the anthocyanin content. This sample was not included in further statistical analysis. The leaves taken in spring were not from the same specimens then leaves taken in late summer. Cyclamen leaves were then frozen until further processing in a freezer at -18 °C. Cyclamen leaves were collected in April and then once again in late August (*Table 2*).

Anthocyanin and quercetin content measurements

Each leaf was ground in liquid nitrogen before the powder was mixed with 2 ml of extraction solution (3% formic acid + % methanol), and the anthocyanins were extracted for 1 h in an ice ultrasonic bath. The samples were then centrifuged for 7 min at 12.000 × g, filtered through Chromafil AO-20/25 polyamide filters into vials, and stored until HPLC-MS analyses in the freezer at -20 °C (Osterc et al., 2014).

Phenolic compounds were analysed on a Thermo Finnigan Surveyor HPLC system (Thermo Scientific, San Jose, USA) with a diode array detector at 350 nm (flavonols) and 530 nm (anthocyanins). Spectra of the compounds were recorded between 200 and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1148911508

600 nm. The column was a Gemini C18 (150 mm×4.6 mm 3 µm; Phenomenex, Torrance, USA) operated at 25 °C. The elution solvents were aqueous 0.1% formic acid in double distilled water (A) and 0.1% formic acid in acetonitrile (B). Samples were eluted according to a linear gradient from 5% to 20% B in the first 15 min, followed by a linear gradient from 20% to 30% B for 5 min, then an isocratic mixture for 5 min, followed by a linear gradient from 30% to 90% B for 5 min, and then an isocratic mixture for 15 min before returning to the initial conditions. The injection amount was 20 µl and flow rate 0.6 mL min^{-1} (Osterc et al., 2014).

Table 2. *Numbers of samples taken per one location in each of two seasons*

Sampling location	No. of samples (spring)	No. of samples (late summer)
SL1 (Kamen Zid)	8	0
SL2 (Below Barnik)	15	13
SL3 (Above Barnik)	9	1
SL4 (Below Goteniški Snežnik)	0	15
SL5 (Goteniška gora)	0	10
SL6 (Above Draga)	18	18

All phenolic compounds were identified by a HPLC-Finnigan MS detector and an LCQ Deca XP MAX (Thermo Finigan, San Jose, CA) instrument with electrospray interface (ESI) operating in positive (for anthocyanins) and negative (other phenolic groups) ion mode. The analyses were carried out using full scan data-dependent MS^n scanning from *m/z* 110 to 1500. Column and chromatographic conditions were identical to those used for the HPLC-DAD analyses. The injection volume was 10 µL and the flow rate maintained at 0.6 mL min^{-1}. The capillary temperature was 250 °C, the sheath gas and auxiliary gas were 60 and 15 units, respectively; the source voltage was 3 kV for negative ionisation and 4 kV for positive ionisation and normalised collision energy was between 20 and 35%. Spectral data were elaborated using the Excalibur software (Thermo Scientific). The identification of compounds was confirmed by comparing retention times and their spectra as well as by adding the standard solution to the sample and by fragmentation.

Content of the following anthocyanins and quercetins was determined:
Anth1 = Malvidin-3, 5-diglucoside, **Anth2** = Cyanidin-3-neohesperidoside, **Anth3** = Malvidin-3-rutinoside, **Anth4** = Malvidin-3-glucoside, **Anth5** = Peonidin-3-O-neoheseridoside
Comp1 = Quercetin di rhamnosyl hexoside1 expressed as Quercetin-3-rutinoside, **Comp2** = Quercetin di rhamnosyl hexoside2 expressed as Quercetin-3-rutinoside, **Comp3** = Myricetin-3-rutinoside expressed as Myricetin-3-rhamnnoside, **Comp4** = Myricetin-hexoside expressed as Myricetin-3-rhamnoside, **Comp5** = Kaempferol dirhamnosyl hexoside expressed as Kaempferol-glucoside, **Comp6** = Quercetin-3-rutinoside, **Comp7** = Laricitin-3-O-rutinoside expressed as Quercetin-galaktoside, **Comp8** = Myricetin-3-rhamnoside, **Comp9** = Quercetin-3-galactoside, **Comp10** = Kaempferol 3-rutinoside expressed as Kaempferol-glucoside, **Comp11** = Isorhamnetin-3-rutinoside expressed as Isorhamnetin-glucoside, **Comp12** = Quercetin-3-rhamnoside, **Comp13** = Neohesperidoside expressed as Quercetin-3-galactoside

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1148911508

Statistical analysis

The effects of location and time were assessed by Two-way ANOVA followed by Duncan's multiple range test with a 95% confidence interval for the comparison of the mean values of anthocyanin and quercetin contents. We used the statistical programme Statgraphics-Plus. Uneven sample size was handled by automatic approximation of statistical program.

Results

Anthocyanins

Higher quantities of all anthocyanins of leaves collected in late summer compared to leaves collected in spring (*Fig. 7*) was found. Of leaves collected in spring, the highest anthocyanin content was measured in those collected at locations Kamen Zid and Above Barnik. In terms of anthocyanin quantity in the spring, leaves from all locations combined had the higher quantities of malvidin-3,5-diglucoside (196.6 ± 122.8 μg g^{-1}) and malvidin 3-rutinoside (69.7 ± 74.5 μg g^{-1}) (*Fig. 7*). When comparing anthocyanin content quantities in cyclamen leaves from different locations, no statistically significant differences were found for malvidin-3,5-diglucoside and cyaniding-3-neohesperidoside. For anthocyanins malvidin-3-rutinoside, malvidin-3-glucoside, and peonidin-3-O-neoheseridoside, there were statistically significant differences in content quantities for all three compounds between locations Above Barnik (*Fig. 8*) and Above Draga, as well as Above Draga and Kamen Zid. In both cases, leaves collected at location Above Draga contained significantly lower quantity of anthocyanins compared to leaves collected at the other two locations (*Fig. 8; Table 3*).

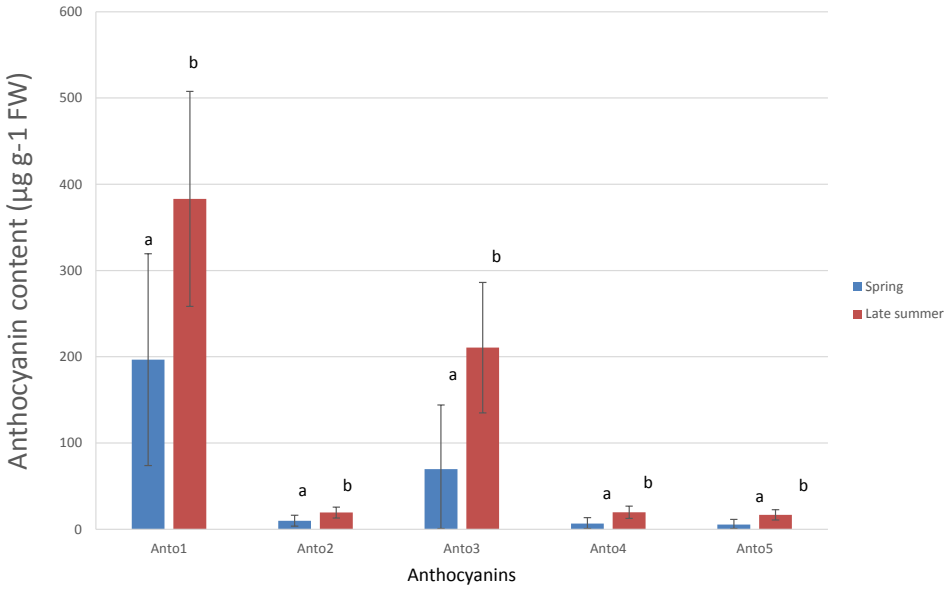

Figure 7. *Mean values, upper and lower anthocyanin content limits in cyclamen leaves collected in spring and late summer. With a 95% confidence interval and $P \leq 0.05$. Characters a and b are used to mark statistically significant differences in content of specific anthocyanins between spring and late summer samples (**Anth1** = Malvidin-3,5-diglucoside, **Anth2** = Cyanidin-3-neohesperidoside, **Anth3** = Malvidin-3-rutinoside, **Anth4** = Malvidin-3-glucoside, **Anth5** = Peonidin-3-O-neoheseridoside)*

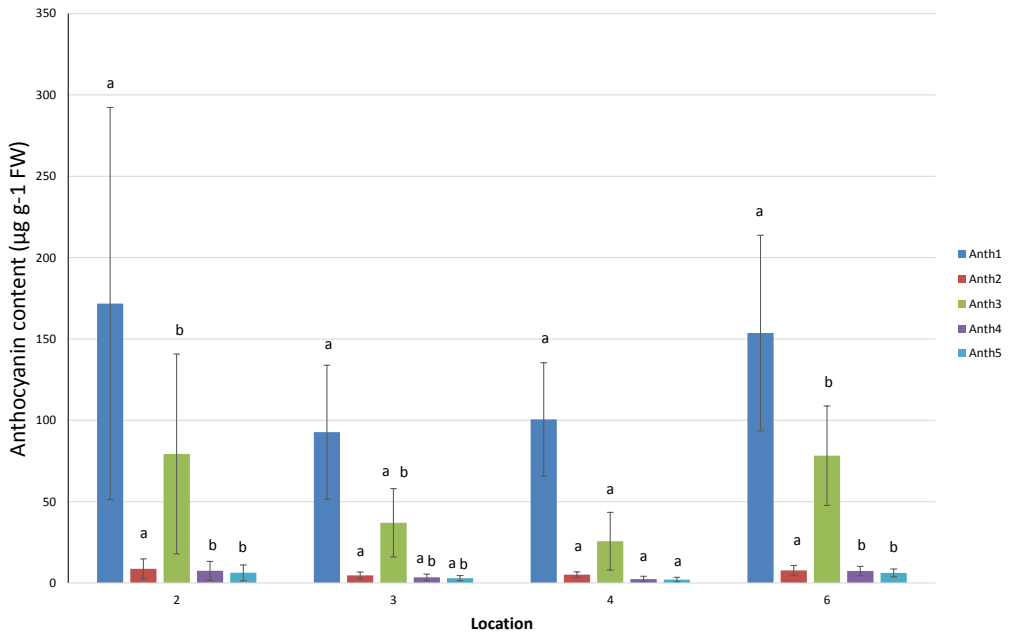

Figure 8. *Mean values, upper and lower anthocyanin content limits in cyclamen leaves collected in spring at various sampling locations (2 = Above Barnik, 3 = Below Barnik, 4 = Above Draga, 6 = Kamen Zid). With a 95% confidence interval and $P \leq 0.05$. Characters a and b are used to mark statistically significant differences in anthocyanin content of between individual locations (**Anth1** = Malvidin 3,5-diglucoside, **Anth2** = Cyanidin 3-neohesperidoside, **Anth3** = Malvidin 3-rutinoside, **Anth4** = Malvidin 3-glucoside, **Anth5** = Peonidin 3-O-neoheseridoside)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1148911508

During late summer, the highest anthocyanin content was of leaves collected at location Goteniška gora and the lowest in those collected at location Below Barnik. Even in late summer, malvidin-3, 5-diglucoside (383.1 ± 124.7 µg g^{-1}) and malvidin-3-rutinoside (210.6 ± 75.6 µg g^{-1}) were predominant for all locations combined *(Fig. 9)*. When comparing anthocyanin content in leaves from various locations, a statistically significant difference in late summer samples for anthocyanins malvidin-3, 5-diglucoside and cyanidin-3-neohesperidoside, specifically only between locations Goteniška gora and Below Barnik (*Fig. 9*) was found. So, statistically significant differences were between Goteniška gora as a oldest and largest forest gap on which temperature fluctuation are the highest (*Fig. 4*), and Below Barnik as smallest forest gap where the effect of forest edge was expressed (shading and slipstream because of trees).

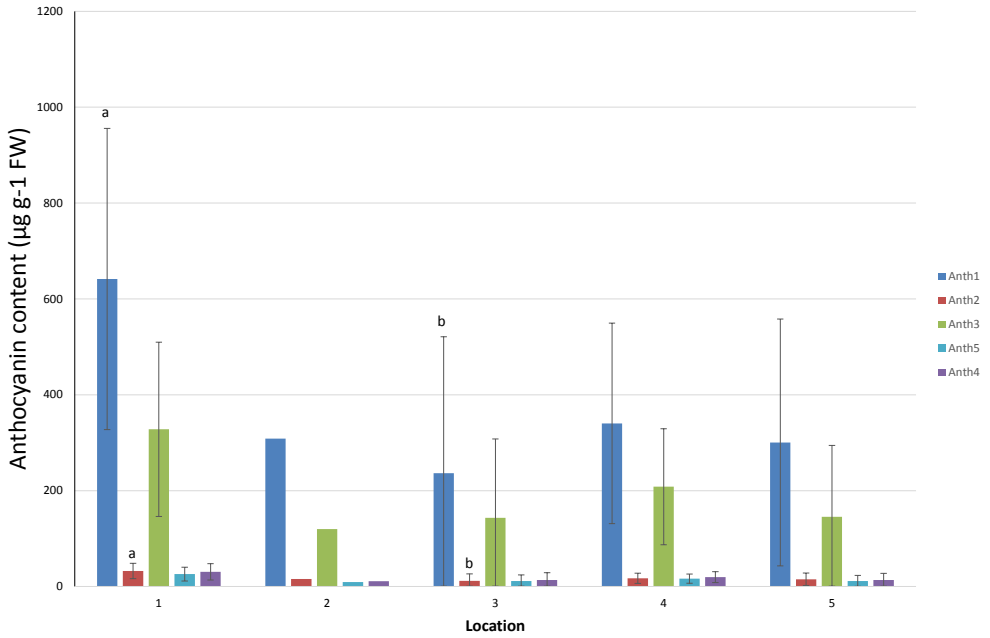

Figure 9. *Mean values, upper and lower anthocyanin content limits in cyclamen leaves collected in late summer at various sampling locations (1 = Goteniška gora, 2 = Above Barnik, 3 = Below Barnik, 4 = Above Draga, 5 = Below Goteniški Snežnik). With a 95% confidence interval and P ≤ 0.05. Character a and b is used to mark statistically significant differences in anthocyanin content between individual locations (**Anth1** = Malvidin 3,5-diglucoside, **Anth2** = Cyanidin 3-neohesperidoside, **Anth3** = Malvidin 3-rutinoside, **Anth4** = Malvidin 3-glucoside, **Anth5** = Peonidin 3-O-neoheseridoside)*

Quercetins

A comparison of quercetin content between spring and late summer cyclamen leaves showed a statistically significant higher content in late summer leaves for the following quercetins: quercetin di rhamnosyl hexoside2, quercetin-3-rutinoside, laricitin-3-O-rutinoside, myricetin-3-rhamnoside, and quercetin-3-galactoside. For quercetin di rhamnosyl hexoside and Myricetin-3-rutinoside content was higher in spring, but there were no statistically significant differences in content between seasons for the rest of the quercetins. When analysing the late summer quercetin content in cyclamen leaves from various locations, we measured the highest content in all leaves for quercetin-di-rhamnosyl hexoside2 (4050.5 ± 2413.9 µg g^{-1}), quercetin-3-rutinoside

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1148911508

(6129.7 ± 2961.2 µg g^{-1}), and myricetin-3-rhamnoside (1721.6 ± 1014.6 µg g^{-1}) (*Figs. 8* and *9*). Statistically significant difference in quercetin content in leaves for as many as eight quercetins between locations Above Barnik and Below Barnik was found. Quercetin quantity in leaves collected Above Barnik most often differed from other locations; in addition to the abovementioned, also from locations Above Draga (yungest gap) and Kamen Zid (juvenile beech forest). Quercetin quantities kaempferol dirhamnosyl hexoside and neohesperidoside most often differed with a statistical significance between locations Above Barnik and Below Barnik, Above Barnik and Above Draga, Above Barnik and Kamen Zid, and Below Barnik and Kamen Zid. While quercentin contents for quercetin-3-galactoside in kaempferol 3-rutinoside differed with a statistical significance between the following locations: Above Barnik and Below Barnik, Above Barnik and Kamen Zid, Below Barnik and Above Draga, and Below Barnik and Kamen Zid, contents of laricitin-3-O-rutinoside and myricetin-3-rhamnoside differed with a statistical significance between locations Above Barnik and Above Draga, Below Barnik and Above Draga, and Above Draga and Kamen Zid. In spring samples, no statistically significant differences based on sampling location for quercetin di rhamnosyl hexoside2 and quercetin-3-rhamnoside (*Figs. 10* and *11; Table 4*) was found.

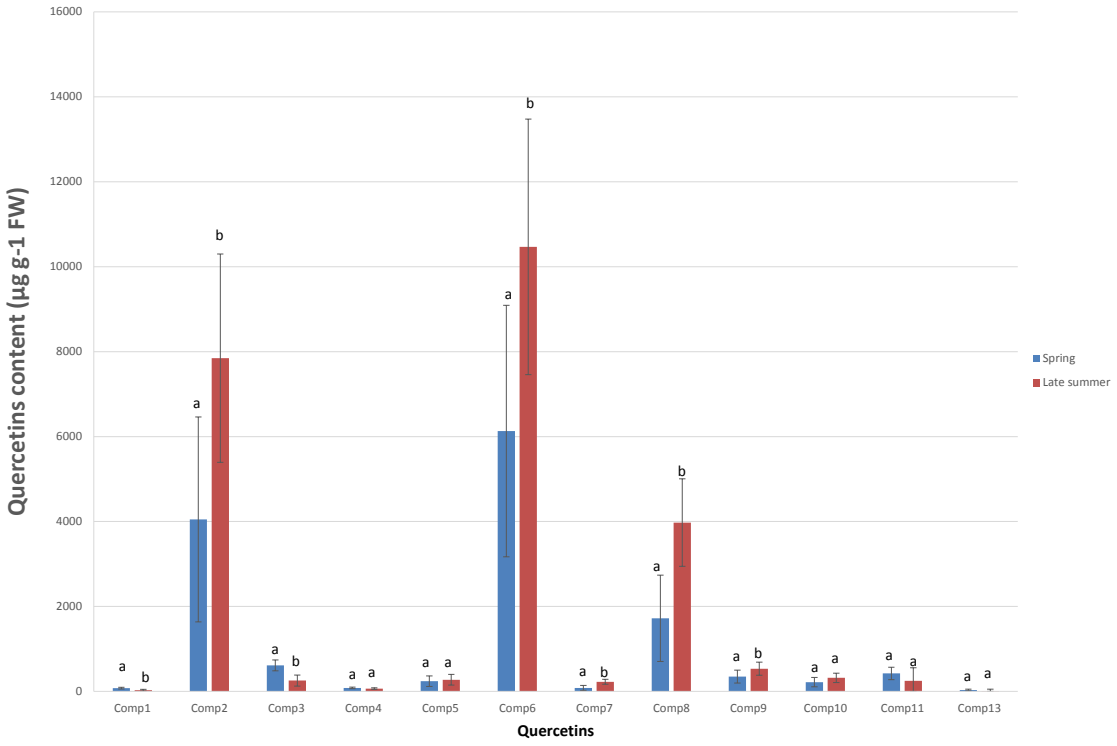

Figure 10. *Mean values, upper and lower quercetin content limits in cyclamen leaves collected in spring and late summer. With a 95% confidence interval and P ≤ 0.05. Figure 11. *Mean values, upper and lower quercetin content limits in cyclamen leaves collected in spring at various sampling locations (2 = Above Barnik, 3 = Below Barnik, 4 = Above Draga, 6 = Kamen zid). With a 95% confidence interval and P ≤ 0.05. Characters a, b and c are used to mark statistically significant differences in quercetin content between individual locations (**Comp1** = Quercetin di rhamnosyl hexoside, **Comp3** = Myricetin-3-rutinoside, **Comp4** = Myricetin-hexoside, **Comp5** = Kaempferol dirhamnosyl hexoside, **Comp6** = Quercetin-3-rutinoside, **Comp7** = Laricitin-3-O-rutinoside, **Comp8** = Myricetin-3-rhamnoside, **Comp9** = Quercetin-3-galactoside, **Comp10** = Kaempferol 3-rutinoside, **Comp11** = Isorhamnetin-3-rutinoside, **Comp13** = Neohesperidoside)*

In late summer cyclamen leaves collected at different locations, the predominant compounds by quantity in all locations were quercetin di rhamnosyl hexoside2 (7846.6 ± 2951.2 µg g^{-1}), quercetin-3-rutinoside (10467.4 ± 3006.9 µg g^{-1}), and myricetin-3-rhamnoside (3974.9 ± 1030.2 µg g^{-1}). A comparison of specific quercetin content based on location of leaf collection showed statistically significant differences only for myricetin-3-rutinoside and quercetin-3-rutinoside, specifically for the former between locations Goteniška gora and Below Barnik, Goteniška gora and Above Draga, and for the later between locations Goteniška gora and Below Barnik, and Goteniška gora and Goteniški Snežnik (*Fig. 12*).

Discussion

Anthocyanin synthesis represents an immediate reaction to increased sunlight intensity, since they act as protection against harmful UV-B radiation (Gould et al., 2002; Steyn et al., 2002; Huges et al., 2007; Huges, 2011). Anthocyanin content can therefore be a good indicator of the level of adaptation or response of originally shady plants to increased radiation intensity, which can be the result of forest gap formation.

In present study, the results confirmed the assumption that spring cyclamen leaves from all sampling locations contain lower anthocyanin quantities than late summer leaves. Plants on forest gaps are not yet exposed to such strong solar radiation during spring than in late summer (Turton, 1991; Brown et al., 1994). Higher anthocyanin

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1148911508

quantity in late summer probably leads to protection against increased radiation in late summer. In terms of specific anthocyanin content, leaves collected on gaps in spring and late summer contained the highest quantity of anthocyanin malvidin-3,5-diglucoside, as confirmed to be the predominant anthocyanin of *C. purpurascens* regardless of season and population (Osterc et al., 2014, 2017). The low anthocyanin content in leaves from Above Draga (youngest gap) could be explained by the fact that this forest gap is youngest, and that plants are not yet completely adapted to the increased radiation intensity, in comparison to plants that have been growing in open surfaces for some time, such as those at location Above Barnik. The latter is also facing SE and therefore distinctly exposed to strong solar radiation for most of the day. The local cyclamen population Above Draga is the most abundant in comparison to other locations. At other locations, populations are smaller, with individual cyclamen specimens growing only occasionally. As early as spring, these rare specimens already have a higher anthocyanin content and are optimally adapted to solar radiation exposure. We can thus suggest that specimens adapted from the time of forest gap formation to the time of sampling by increased anthocyanin synthesis, or that the specimens whose leaves were collected for sampling are in fact offspring of those exposed to increased solar radiation at the time of forest gap formation. Most likely, only the offspring with already higher anthocyanin content, which protect the leaf against excessively strong solar radiation, managed to survive. The latter statement seems more likely, since the study (Osterc et al., 2017) comparing anthocyanin content in wild specimens of common cyclamen, brought and grown further in culture, found unchanged anthocyanin content. Regardless of the changed environmental factors during the move to a new location, with all relocated specimens equal, cyclamen leaves collected at sunny locations contained higher quantities of malvidin-3,5-diglucoside in comparison to cyclamen specimens collected in shady habitats. Therefore, synthesis of specific quantity of anthocyanin persisted for 10 to 12 years after replanting (Osterc et al., 2017). Based on the development and ecology of the common cyclamen, we can suggest that local populations on older forests gaps are in fact not the same specimens that grew there at the time of forest gap formation. Increased anthocyanin quantity thus ensures easier survival with increased solar radiation, which was also proven with two corn genotypes (HOPI and W22) (Pietrini et al., 2002). Genotype HOPI, containing anthocyanins in leaves, could be exposed to higher light intensity with no photo-oxidation processes detected, as opposed to genotype W22.

With much higher anthocyanin quantity compared with other locations, no differences were shown between leaves collected from Kamen Zid (juvenile phase of beech forest) and on gap Above Barnik, despite the environmental differences of the two locations. One of the reason could lie in the fact that in spring, before beech trees grew leaves (beech tree leaves in this location only developed after sampling), cyclamen leaves on location Kamen Zid were exposed to increased solar radiation (comparing to season with developed beech leaves), and had increased anthocyanin synthesis for protection (Huges et al., 2005; Klančnik et al., 2016). Nevertheless, the young trees on this location are quite dense, and probably the solar radiation is still not so strong; the reason for such anthocyanin content could therefore also be lack of light, with anthocyanins additionally absorbing solar radiation (Chalker-Scott, 1999). Anthocyanin synthesis as a result of low solar radiation is common primarily in tropical understory plants, where the lack of light is more prominent and sun flecks are rarer (Wheldale, 1916; Lee et al., 1979). Species *Episcia lilacina* Hanst. was found to contain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1148911508

anthocyanins primarily in the spongy tissue next to palisade tissue, which as such cannot act as protection, but can only contribute to additional light absorption (Rauch, 2009). To confirm thus hypothesis in our samples – leaves of *C. purpurascens* – additional leaves of specimens from location Kamen Zid should be collected. Using microscopic slides, we could precisely determine the location of anthocyanin accumulation in leaves. In the analysis of late summer samples, differences in content quantities of anthocyanins malvidin-3,5-diglucoside and cyaniding-3-neohesperidoside, specifically only between locations Goteniška gora (oldest gap) and Below Barnik were found. There were no differences for these two anthocyanins in spring samples, based on a comparison with the other three anthocyanins, which only showed differences in spring samples. Therefore two groups of anthocyanins could be observed: the first, with statistically significant differences in content during spring between the youngest gap (Above Draga) and the other two (Above Barnik, Below Barnik); and the second group of anthocyanins, with statistically significant differences during late summer, specifically only between the gaps Goteniška gora and Above Barnik. The leaves collected at Goteniška gora contained twice as much anthocyanins malvidin-3,5-diglucoside and cyaniding-3-neohesperidoside. The difference in content between the leaves from these two forests gaps likely is not a results of exposure duration (considering the gap formation) to increased radiation, since the gaps do not differ significantly in terms of formation time. Furthermore, they also do not differ significantly in terms of anthocyanin content during spring. We therefore assume that the late summer differences in contents of malvidin-3,5-diglucoside and cyanidin 3-neohesperidoside are the result of temperature fluctuations and high exposure to UV-B radiation (*Fig. 4*). Anthocyanins in plants also have a protective role against low temperatures and frost (Wheldale, 1916; Mendez et al., 1999). These two anthocyanins could be the ones in *C. purpurascens* leaves that act as protection against low temperatures, since differences in content occurred only in late summer, specifically between locations that differ significantly in size and exposure. The location of Goteniška gora has the largest and most exposed gap, with consequently greater temperature fluctuations (Buajan et al., 2016), which can be noticed there already in late summer, when early mornings can be quite cold (*Fig. 2*). The gap Below Barnik is the smallest, with lower temperature fluctuations due to the surrounding forest stand. At the latter location, cyclamen leaves have not yet been exposed to such low temperatures that would require protection.

Three quercetins, quercetin-di-rhamnosyl hexoside2, quercetin-3-rutinoside, and myricetin-3-rhamnoside, with much higher contents among all quercetins in *C. purpurascens* leaves taken both in spring and late summer were found. Similar results also were reported by Osterc et al. (2014, 2017). Although all five anthocyanin contents were higher in late summer than those in spring, not all quercetin showed differences between spring and late summer. Based on this we can conclude that all quercetins do not have the same function in cyclamen leaves, as was already determined for other plants, where they for example act as a protection against insects and other pathogens (Mierziak et al., 2014). Also in cyclamen leaves probably some of them do not directly participate in the protection of the leaf against increased UV radiation. In spring, statistically significant differences in content for as many as 8 quercetins (quercetin di rhamnosyl hexoside1, myricetin-3-rutinoside, myricetin-hexoside, kaempferol dirhamnosyl hexoside, quercetin-3-rutinoside, quercetin-3-galactoside, kaempferol 3-rutinoside, neohesperidoside) between locations Above Barnik and Below Barnik was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1148911508

found. Based on analyses conducted, there is no explanation what causes such differences. Statistically significant differences between other locations were also found, but were quite varied based on the type of quercetin. In spring the leaves from location Above Draga contained a higher quantity of quercetin myricetin-3-rhamnoside than the leaves from locations Above Barnik, Below Barnik, and Kamen zid. Quercetins represent the immediate response and also the main protection against UV-B radiation (Mierziak et al., 2014). This specific quercetin probably provides specific quercetin provides the first protection against radiation for *C. purpurascens* leaves in spring, since the leaves at this location in spring contain the lowest quantity of anthocyanins, compared to leaves from other locations.

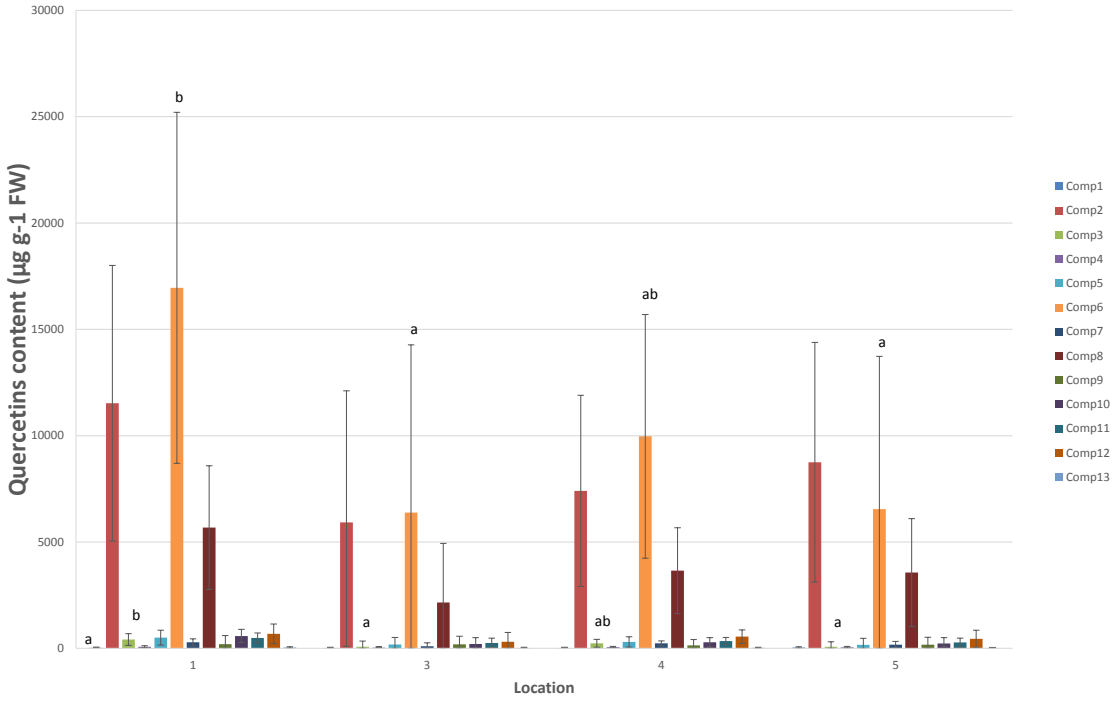

Figure 12. *Mean values, upper and lower quercetin content limits in cyclamen leaves collected in late summer at various sampling locations (1 = Goteniška gora, 3 = Below Barnik, 4 = Above Draga, 5 = Below Goteniški Snežnik). With a 95% confidence interval and $P \leq 0.05$. Character a and b is used to mark statistically significant differences in quercetin content between individual locations (**Comp1** = Quercetin di rhamnosyl hexoside, **Comp2** = Quercetin di rhamnosyl hexoside2, **Comp3** = Myricetin-3-rutinoside, **Comp4** = Myricetin-hexoside, **Comp5** = Kaempferol dirhamnosyl hexoside, **Comp6** = Quercetin-3-rutinoside, **Comp7** = Laricitin-3-O-rutinoside, **Comp8** = Myricetin-3-rhamnoside, **Comp9** = Quercetin-3-galactoside, **Comp10** = Kaempferol 3-rutinoside, **Comp11** = Isorhamnetin-3-rutinoside, **Comp12** = Quercetin-3-rhamnoside, **Comp13** = Neohesperidoside)*

A 60-min exposure to UV-B radiation is enough to activate intensive quercetin synthesis (Shourie et al., 2014). Our results from location Kamen zid confirm this characteristic of quercetins. Leaves from these locations contained a statistically significant lower quantity of eight quercetins, compared to the leaves collected at other locations. Location Kamen zid is characterised as a juvenile phase of beech forest, and is therefore the shadiest location. Because UV-B radiation is lower there (*Fig. 4*), the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1148911508

leaves do not require immediate protection, and the quercetin content is therefore lower. In late summer, results showed an interesting turnaround in statistically significant differences of quercetin content. Only for two quercetins (myricetin-3-rutinoside and quercetin-3-rutinoside) the differences were measured, where the leaves from Goteniška gora contained the highest quantity of the two quercetins, which significantly differed from content in leaves from locations Below Barnik, Above Barnik, and Goteniški Snežnik. The highest content of the two quercetins in leaves from this location could be explained by their synthesis being indirectly dependant on the accumulated UV-B radiation (Sullivan and Teramura, 1988), as this gap is the largest and most exposed to solar radiation (*Fig. 1*). Quercetins therefore additionally protect the leaves on this location against radiation.

Conclusion

The cyclamens from at Above Draga have yet adapted to the increased radiation intensity due to the pretty recent formation of forest gap, as shown from their lower anthocyanin content in spring but not in summer, comparing with other locations. In the study, a wide range of anthocyanin functions was confirmed. In addition to protecting the plant against strong solar radiation, they can assist in additional absorption of light in shady plants. This was established with the statistically significant higher anthocyanin content in spring cyclamen leaves from location Kamen Zid – juvenile phase of beech forest. This is actually the shadiest location (and actually the oldest forest gap). Furthermore, the function of anthocyanins as protection against low temperatures was confirmed, specifically in cyclamen leaves at the largest and most exposed gap Goteniška gora. At this location, leaves in late summer contained a statistically significant higher quantity of anthocyanins than leaves on the smallest, less exposed gap. Higher quercetin content at the youngest gap (Above Draga), with leaves not adapted to permanent sun exposure, indicates that quercetin acts as the first immediate protection against UV-B. In late summer, the quercetin content that stands out is the one in leaves from the largest gap, which is most exposed to solar radiation for the longest duration. The reason for this is increased synthesis of anthocyanin and quercetin due to UV-B radiation accumulation. Based on study results, it is confirmed that local populations of common cyclamen were capable of surviving in forest gaps only because of increased anthocyanin and quercetin content, which protect plants against strong solar radiation. For a more detailed examination of anthocyanin accumulation in common cyclamen leaf tissues, microscopic slides would have to be prepared in the future.

(e-mail: deryasari@artvin.edu.tr; phone: +90-466-215-1092; fax: +90-466-215-1093)

(Received 21st Apr 2019; accepted 4th Jul 2019)

Abstract. Individuals, who struggle due to various stress factors in urban areas, travel to recreation areas to spend their leisure time, to relax, to make contact with nature and to replenish their energy. Rural recreation areas meet these requirements and offer the best natural environment for urban residents. However, the sustainability of recreation areas and recreational activities are important due to the increasing demand and diverse visitor objectives. Thus, sustainable plans for rural recreation areas should include a balance between human preferences and demands and preservation of the nature. The aim of the present study was to determine the qualities that affect the preferences of individuals for rural recreation areas. In this context, the quality preferences of potential visitors in Artvin province (Turkey) were determined based on a survey that investigated 21 qualities in detail. In the study, correlations between participant attributes and preference rates were analyzed with t-test and analysis of variance. The cluster analysis conducted based on the mean preference scores demonstrated that 8 qualities were most effective on preferences. Concurrently, significant differences were determined between occupant attributes and preference scores. The present study was conducted to contribute to future planning strategies for decision makers and further comprehensive studies.
Keywords: *visitor preferences, rural recreation, survey, quality preferences, nature tourism*

Introduction

Most recreational activities are conducted in natural environments (Kraus, 1971), and today, rural recreation areas are among the spaces where individuals predominantly fulfill their recreational needs. Due to their natural integrity and richness, rural recreation areas offer renewal and leisure opportunities for urban dwellers.

Outdoor recreation refers to the activities that individuals conduct in spaces that allow access to nature or green areas as part of their daily or weekend routines. Nature tourism is a term that includes the activities that individuals conduct to have fun during holidays and focus on nature and generally involve overnight accommodations. This usually means traveling to national parks, forests, lakes, seashores or rural areas and participating in activities that are compatible with the natural qualities of these spaces (Bell et al., 2007).

Outdoor recreation, conducted in natural and semi-natural environments, often referred to as green and blue spaces, plays a crucial role in physical and mental health, as well as wellbeing and social outcomes, and contributes significantly to human health (Hartig et al., 2014; Korpela et al., 2014; Triguero-Mas et al., 2015; Cox et al., 2017; Schirpke et al., 2018). Increasing involvement in outdoor recreation activities can be considered as beneficial for both the individual and the society at large (Eriksson and Nordlund, 2013).

The pressures on individuals to live under negative living conditions in residential areas that are not adequate for their mental and physical requirements, technological advances, transportation facilities and the increase in per capita leisure time improved

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1150911523

the interest of individuals living in metropolitan cities and high income areas in rural areas (Guo et al., 2010; Sahbaz and Altinay, 2015; Yang, 2017; Schirpke et al., 2018).

Urban parks and green spaces offer physical activity, entertainment, natural experience and social interaction opportunities for urban residents (McCormack et al., 2010; Andkjær and Arvidsen, 2015). For example, ancient trees in these spaces attract visitors and contribute to the urban ecological, aesthetic and functional quality (Jim and Zhang, 2013). However, the activities that individuals could conduct in these spaces, which are part of the urban everyday landscape, are limited. Thus, rural areas play an important role in active outdoor recreation activities for individuals. For example, the main goal in visiting forests is the increasing interest in relaxation, getting away from the daily routine, to exercise and conduct sports activities in the forest (Hansen-Moller and Oustrup, 2004; Andkjær and Arvidsen, 2015).

Nature-based recreation provides visitors the opportunity to meet their recreational needs, while maintaining the diversity and richness of regional natural, cultural and historical resources. Recreational visitors search for natural spaces to meet their recreational needs and often go to remote areas for recreation. This leads to a high demand for natural areas and resources (Shrestha et al., 2007).

As a result of the increase in recreational activities, individuals started to change their recreational space preferences. Thus, the demand for national parks that are rich in natural and cultural values, has increased. Several countries transformed these trends into an advantage, inviting tourists to preservation areas such as national and nature parks (Şahbaz and Altınay, 2015).

The results of surveys conducted in the United States indicated that more than 206 million people aged 15 and over participate in outdoor recreation activities every year, and several outdoor activity participants preferred forests, parks and preservation areas. Visitors visited natural spaces to participate in nature-based recreational activities such as hiking, having fun with family and friends, picnicking and watching natural landscapes, which are among the most popular outdoor activities conducted in the USA (Cordell et al., 2002; Shrestha et al., 2007).

Participation of individuals in recreational activities may vary based on their lifestyles and how they would like to spend their time. The diversity in participation varies based on the country, the social structure, the cultural level and the modern life habits of the population (Tekin et al., 2012). However, several factors such as age, gender, occupation, income level, etc. could be effective on individual recreational preferences. Today, the participation in leisure and recreational activities became a rapid growth industry and the activities offered to masses became a significant market (Tekin et al., 2012).

The extensive literature on outdoor recreation often targeted special natural areas, that include the following elements (De Valck et al., 2017): Forests, mountains, lakes, rivers, coastal areas, protected areas, and national parks. Furthermore, despite the extensive literature on destination attractions (Lee et al., 2010), there is a gap in the literature about studies on the decision-making processes involved in recreational destination preferences for the use of nature (De Valck et al., 2017).

Thus, determination of the factors that affect the demands for nature-human interaction would guide future planners and managers to identify the adequacy, content and adequacy of future recreational activities. The aim of the present study was to determine the qualities that were effective on the selection of rural recreational areas by individuals.

DOI: http://dx.doi.org/10.15666/aeer/1705_1150911523

Materials and methods

In order to determine the qualities that are effective on rural recreational area preferences, initially, a literature review was conducted. Several studies were found in the literature on nature-based tourism activities. Most accessed research were based on surveys and focused on recreation potential (Plieninger et al., 2013; De Valck et al., 2016) or conducted with proxy-based methods (Paracchini et al., 2014; Grêt-Regamey et al., 2015). Fewer studies emphasized demand based on participant approaches (Beeco et al., 2014; Zoderer et al., 2016) and economic evaluation techniques such as willingness-to-pay (WTP) (Nielsen et al., 2007; Rosenberger et al., 2012) or travel-cost method (Fleming and Cook, 2008; Schirpke et al., 2018). Furthermore, personal interviews with experts and SWOT analysis were also used as an instrument to measure the problems of sustainable tourism in the theoretical framework and to collect qualitative data (e.g. Sanagustin Fons et al., 2011).

The recreational services available in the market were determined based on consumer preferences, that were expressed through demand patterns (Tribe, 2011). Thus, 21 qualities were identified in order to determine the potential visitor expectations from rural recreation areas and the qualities the potential visitors considered more important. The preferences of these qualities were determined with a questionnaire.

The survey was conducted with 448 individuals who were the residents of Artvin province located in northeastern Turkey on the Black Sea coast, Artvin Çoruh University staff and students. In the province of Artvin, there are several rural recreation areas, including 2 National Parks, 3 Nature Preservation Areas, 2 Nature Parks, 2 Natural Monuments, 1 Wildlife Development Area and 1 Biosphere Reserve Area. Furthermore, there are 8 Forest Recreation Areas and 1 Urban Forest (Eminağaoğlu and Beğen, 2015). Due to these characteristics, the survey was conducted in the city of Artvin.

Survey participants were randomly selected and initially, participant demographics such as gender, age, education, profession and income level were determined (Torkildsen, 2005). In the second section of the questionnaire, participants were asked to answer the question "When deciding to visit a rural recreation area, rate your preference for each quality listed below." In the questionnaire, 21 qualities were scored based on a 5-point Likert-type scale. Accordingly, the scoring was as follows: 1 = I do not prefer at all, 2 = I prefer less, 3 = I prefer a little, 4 = I prefer a lot, 5 = I prefer the most. To improve the comprehensibility of the questions, descriptions (explanations) were provided for Recreation and Rural Recreation Activity terms in the questionnaire form.

Participant demographics and classification were determined with frequency analysis. Mean preference score (MPS) and significance (effectiveness) were determined for each question. For the included qualities, the MPS was classified as follows:

- $1 \leq MPS < 2$: the quality is least effective in rural recreation area preference.
- $2 \leq MPS < 3$: the quality has moderate effect.
- $3 \leq MPS < 4$: the quality is effective.
- $4 \leq MPS \leq 5$: the quality is highly effective.

Cluster analysis was conducted for 21 qualities based on the MPS values. Thus, a dendrogram, where the most preferred qualities were categorized based on the similarities, was created. PAST (Paleontological Statistics) software was used in cluster

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1150911523

analysis and the dendrogram. The t-test (for gender) and One-Way ANOVA were conducted to determine the significant differences between participant demographics and preferences. The data are presented as a summary table to facilitate the interpretation of the statistical findings. SPSS 19.0 statistics software was used for the analyzes.

Results

After the survey was conducted, faulty and inconsistent forms were excluded and the answers in the remaining 448 questionnaires were converted into Excel worksheets. Thus, the final 238 participants were male and 210 were female. The distribution and frequencies of the participants based on age (4 categories), education (3 categories), occupation (4 categories) and income (6 categories) are presented in *Table 1*.

Table 1. *Survey participant demographics (n=448)*

Participants		Percentage (%)	Frequency
Gender	Male	53.1	238
	Female	46.9	210
Age	16-25	41.7	187
	26-35	31.7	142
	36-45	19.9	89
	> 45	6.7	30
Education	Middle and High school	14.1	63
	University	63.8	286
	Postgraduate	22.1	99
Occupation (Job)	Student	33.9	152
	Civil servant	29.5	132
	Self-employment/Private sector employee	17.0	76
	Other (unemployed, worker, retired, etc.)	19.6	88

	500-1500	11.6	52
	1600-2500	11.4	51
	2600-3500	11.8	53
	3600-4500	16.5	74
	≥ 4600 and over	15.2	68

*1 Turkish lira (TL)= 0.16 EUR= 0.18 USD, The cross exchange rate is based on the date 18.03. 2019

Based on the survey data, where 21 effective qualities on rural recreational area preferences of individuals were questioned, arithmetic mean of preference scores was determined for each question (*Table 2*). The general study findings demonstrated that the four most preferred qualities were "being in contact with the nature, facilities to rest, relaxation, and to have a peace of mind" (Q3, MPS = 4.68), "Recreation area has beautiful landscapes" (Q4, MPS = 4.58), "The recreational area is clean and natural" (Q11, MPS = 4.58), and "The recreation area is safe" (Q20, MPS = 4.49). The three least preferred qualities were "availability of activities such as festivals, concerts etc. in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1150911523

the recreation area" (Q18, MPS = 3.12), "Presence of various geological formations in the recreation area" (Q15, MPS = 3.60) and "a space I have experienced and enjoyed before" (Q21, MPS = 3.78).

Table 2. *The qualities that were effective on rural recreational area preferences and mean preference scores (MPS)*

Questions/qualities	Qualities that affect rural recreational area preferences	MPS
Q1	Easy access to the recreation area	3.98
Q2	Inexpensive recreational area	3.94
Q3	Being in contact with the nature, facilities to rest, relaxation, and to have a peace of mind	4.68
Q4	Recreation area has beautiful landscapes	4.58
Q5	The area allows the visitors to leave with good memories	4.40
Q6	The area provides entertainment facilities	3.96
Q7	The area makes the visitors feel renewed physically and psychologically	4.43
Q8	Recreation area facilities that allow the visitors to spend time with family and friends	4.42
Q9	Availability of facilities that allow to spend alone time in the recreational area	3.83
Q10	The area provides different landscapes in summer, winter and fall	4.29
Q11	The recreational area is clean and natural	4.58
Q12	The area provides food-beverage and picnic facilities	4.08
Q13	The area provides facilities for sports activities (such as skiing, swimming, trekking, mountain biking, etc.)	3.90
Q14	Availability of moving or still water in the recreation area (such as lake, sea or stream)	4.03
Q15	Presence of various geological formations in the recreation area (such as valleys, canyons, and cliffs)	3.60
Q16	Presence of a forest in the recreation area	4.10
Q17	Calm and non-crowded recreation area	4.05
Q18	Organization of activities such as festivals, festivities, concerts, etc. in the recreational area	3.12
Q19	Facilities to experience adventures and discoveries	3.90
Q20	Safety in the recreation area	4.49
Q21	Previously experienced and satisfactory recreational area	3.78

The groups formed as a result of the cluster analysis, where the preferred qualities were classified based on similarity, are presented in *Figure 1*.

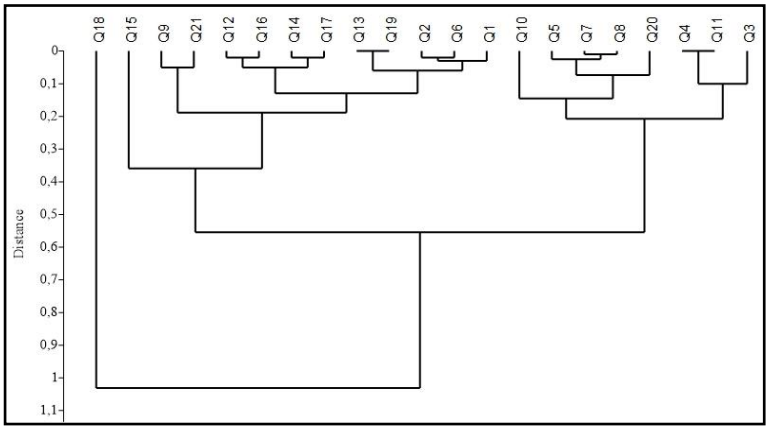

Figure 1. *Cluster analys dendrogram for qualities (Similarity measure: Euclidean)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1150911523

Thus, the most effective qualities about rural recreation area preferences were grouped as follows:

- Q3: "Being in contact with the nature, facilities to rest, relaxation, and to have a peace of mind".
- Q11: "The recreational area is clean and natural".
- Q4: "Recreation area has beautiful landscapes".
- Q20: "The recreation area is safe".
- Q8: "Recreation area facilities that allow the visitors to spend time with family and friends".
- Q7: "The area makes the visitors feel renewed physically and psychologically".
- Q5: "The area allows the visitors to leave with good memories".
- Q10: "The area provides different landscapes in summer, winter and fall".

T-test and analysis of variance were used to determine whether there were significant differences based on gender, age, education, occupation and income. It was determined that there were significant differences between preference scores of Q1, Q3, Q4, Q5, Q6, Q7, Q8, Q9, Q11, Q20 based on gender (*Table 3*), Q2, Q3, Q6, Q9, Q16, Q18, Q19 based on age (*Table 4*), Q2, Q3, Q4, Q6, Q7, Q8, Q9, Q12, Q16, Q18 based on education level (*Table 5*), Q2, Q5, Q9, Q13 based on occupation (*Table 6*), and Q2, Q5, Q6, Q7, Q9, Q12, Q16, Q18, Q21 based on income level (*Table 7*).

Discussion and conclusions

Schirpke et al. (2018) reported that social preferences could be explained by landscaping properties and tourism infrastructure. In fact, the primary aim of the present study was to determine the correlation between individual preferences for rural recreation areas and the landscape qualities. Several studies were conducted on the expectations/preferences of individuals about recreation areas (e.g., Cheung and Jim, 2013; Chiu et al., 2016; Heagney et al., 2018). The present study is not a field study, but it is about the qualities that determined the rural recreational area preferences of the individuals.

The way individuals spend leisure time is, above all, closely associated with certain demographics. Thus, participants' gender, age, occupation, education and income level data were scrutinized in the study.

The rural recreation area satisfaction factors vary based on occupant demographics. In a study conducted by Uzun and Müderrisoğlu (2010), it was partially confirmed that rural recreation area satisfaction factors varied based on user demographics and the user demographics such as age, education level, time spent in the area, visit frequency and group size were effective on rural recreation area satisfaction. In the present study, analysis of participant preference scores for 21 qualities demonstrated that the highest difference (significant difference) was based on differences in gender, education and income levels (for 10 qualities). This was followed by age (7 qualities) and occupation (4 qualities). Participant demographics also affected the preference rankings.

In certain studies conducted with couples, it was found that there was no significant difference between the leisure satisfaction levels based on gender (e.g., Siegenthaller and O'Dell, 2000; Di Bona, 2000; Berg et al., 2001). In the present study, it was determined that there was a significant difference between 10 quality scores.

The most preferred experiences include enjoying the natural scenery, peace and quiet. These qualities are preferred preferably near the home of the visitors; however, these are increasingly found only in rural and suburban areas (Bell et al., 2007). In the present study, it was observed that the most important quality for the potential visitors was "being in contact with the nature, facilities to rest, relaxation, and to have a peace of mind" (Q3).

Previous studies in the literature reported that besides the natural characteristics of rural recreation areas (such as unique landscapes and locations), other factors that affect the visitor demand include weather conditions (Humpel et al., 2002; Suminski et al., 2008; Nasir et al., 2012), accessibility (Humpel et al., 2002; Neuvonen et al., 2007; Bestard and Font, 2009; Paracchini et al., 2014; Ala-Hulkko et al., 2016), facilities, price and quality of services (Sava, 2015), accommodation and periodical lodging facilities (Humpel et al., 2002), peer recommendation, advertising-promotions (Sava, 2015), and security and aesthetic features (Humpel et al., 2002). Furthermore, Folmer et al. (2016) investigated the reasons for attractiveness and participant descriptions for the most attractive green spaces. In conclusion, it was determined that qualities such as large green areas, silence, naturalness, water (attractive water surface, river, lake or sea), panoramic and open views, good recreational opportunities, diversity (diverse plant species, land use and seasons), non-urban characteristics, personal bond, historical characteristics, wildlife and flora, harmony (of the landscape), farming (the landscape used by farmers) were effective on occupant preferences. The qualities scrutinized in the present study are consistent with previous study findings.

Recreational and aesthetic values generally overlap and these are usually discussed together (Van Zanten et al., 2016). For example, a beautiful landscape is an important factor in tourism destination and nature-based recreation preferences (Scolozzi et al., 2014). The high landscape quality and unspoiled nature in rural recreation areas are among the most sought-after qualities by potential visitors, as demonstrated by Q4, Q10 and Q11.

On the other hand, urbanization and high number of visitors negatively affect recreation quality (Scolozzi et al., 2014). The present study findings demonstrated that festivals, festivities, concerts, etc. organized in the recreation area were moderately or relatively effective (Q18, MPS: 3.12) on visitor preferences. However, the calmness of the recreation area, the lack of crowds (Q17, MPS: 4.05) were more effective factors on preference.

Certain studies reported that cultural preferences might affect park occupancy (Tu et al., 2015; Chow et al., 2016). Public spaces and recreation facilities offer a variety of facilities for children, adults and families, however activity preferences in parks depend on the occupant age and gender (Cohen et al., 2007; Kaczynski et al., 2011; Moore et al., 2017). Thus, alternatives should be designed based on different user requirements, or thematic approaches should be preferred in plans.

Accessible infrastructure determines the occupancy of a suitable recreational area and proximity to residential areas is a crucial factor for recreational area occupancy (Weyland and Laterra, 2014; Peña et al., 2015; Ala- Hulkko et al., 2016; Schirpke et al., 2018). Certain studies demonstrated that there was a correlation between the distance to the recreation area and the number of visits to the recreation area; the number of visits decreased with an increase in the distance to the recreation area or the nearest forest (Roovers et al., 2002; Neuvonen et al., 2007). However, it was observed that one of the most significant preference factors was proximity to home parameter (e.g. Sava, 2015). Furthermore, there was a significant correlation between accessibility, facilities, and aesthetic attributes and physical activity (Neuvonen et al., 2007). However, the present study findings demonstrated that "easy access to the recreation area" (Q1, MPS = 3.98) was an effective quality and among the most preferred 8 qualities. This may be due to availability of natural resources in the city of the participants' residence, personal preferences and other factors.

Individuals prefer forests, bodies of water and natural mountain landscapes for wildlife observation, hiking and trekking activities (Bell et al., 2007; Pastorella et al., 2017). Most rural recreation areas include forests. The presence of recreational facilities such as picnic areas, training paths and parking lots could affect the recreational preferences in forests (Tapsuwan et al., 2012; Agimass et al., 2018). Furthermore, the presence of various landscape characteristics in or near the recreation areas (such as different landscapes, water and coastal areas) increases the value of the area for complementary recreational activities. Previous studies demonstrated that the presence of water leads to high landscape preference scores (Kaltenborn and Bjerke, 2002; Dramstad et al., 2006). Kaplan and Kaplan (1989) reported that this preference may be due to the evolutionary adaptation of humankind (De Valck et al., 2017). In fact, it was determined that Q14 was "very effective" (MPS = 4.03) on rural recreation area preference.

In visitor decision-making processes, peer recommendations are more effective when compared to mass media promotion of services (Sava, 2015). It was determined that previous experiences and satisfaction were an effective factor on repeat visits in these

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1150911523

areas (Q21, MPS = 3.78). On the other hand, the fact that the facilities available in the recreation area that allow the visitors to spend time with family and friends (Q8, MPS = 4.42) was preferred more when compared the ability to spend personal time (Q9, MPS = 3.83). This may be due to the personal or cultural traits of the participants.

The present study findings were relatively parallel to the findings of similar studies conducted in various countries. However, the present study findings demonstrated that the 8 qualities were more effective on visitor preferences about a rural recreation area. These qualities were also the most influential qualities for a rural recreation area to attract visitors. On the other hand, it was noted that there were significant differences between the preference scores based on participant demographics.

Unspoiled rural landscape without human intervention and related natural beauties decrease every day and the importance of these areas increase gradually. Thus, sustainability of natural resources is one of the important targets for nature-based tourism destinations. It is important to understand the expectations of the occupants and to take management decisions accordingly (Lime et al., 2004). In order to achieve a broader perspective in the measurement of the demand for recreation areas, it is necessary to investigate the factors that affect the preferences and tendencies of potential visitors with a multidimensional approach (such as social and cultural traits, service providers, local administrations). It was observed that the qualities discussed in the present study had significant effects on rural recreation preferences. Therefore, the present study could contribute to the future planning strategies of the decision-makers and further comprehensive studies.

Acknowledgements. The author would like to thank Artvin Coruh University for their consent and all participants for their contribution to the study. The experimental section of the present study was previously presented in the XI. European Conference on Social and Behavioral Sciences (2016, Rome, Italy).

(Received 22nd Apr 2019; accepted 16th Jul 2019)

Abstract. Sorghum [Sorghum bicolor (L.) Moench] is an important cereal crop with high nitrogen utilization efficiency. In order to analyze the mechanisms of different sorghum genotypes to low-N tolerance and provide the theoretical basis for the breeding of low nitrogen tolerant sorghum varieties, two materials (KZ15 and SZ7) with different tolerance to low-N were treated with nitrogen by hydroponics, the phenotypes were observed, physiological indexes were measured and transcripts were analyzed in this study. Compared to SZ7, KZ15 showed significantly higher capacity of low-N tolerance. The results showed that the change of KZ15 chlorophyll content was lower than that of SZ7 under low-N stress. The activity of nitrate reductase (NR) and glutamine synthetase (GS) had a smaller reduction in KZ15 than SZ7 under low-N stress. High-throughput sequencing revealed several common differentially expressed genes (DEGs) between KZ15 and SZ7, including nitrogen transport and nitrate assimilation genes. In the tolerant genotype KZ15, there were more transcripts related to high affinity nitrate transporters (NRT2.4, NRT3.1 and NRT4.5), suggesting an improved uptake efficiency of inorganic and organic forms of nitrogen. In addition, an abundance of certain transcription factors in the tolerant genotype KZ15 suggests that they may play roles in regulating the response to N-stress. This study will enable us to discover candidate genes potentially useful in improving the resistance to low nitrogen stress by genetic engineering technology and provide theoretical basis for the breeding of low nitrogen tolerant sorghum varieties.
Keywords: *sorghum, N tolerance, chlorophyll, transcriptome, differentially expressed genes, candidate genes*

Introduction

Nitrogen is a necessary major element for the growth and development of higher plants, which takes part in a series of physiological and biochemical reactions,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1152511536

involving various metabolic pathways (Kraiser et al., 2011). There are two mechanisms for obtaining nitrogen in plants: one is to absorb nitrogen nutrition by nodular nitrogenase, which is mainly in leguminous plants. The other is to absorb $NH4^+$, $NO3^-$, and other mineral ions from the soil by root transporters. Sorghum mainly absorbs nitrogen through the second mechanism. Studies of nitrogen stress by quantitative trait loci analysis have mainly focused on maize (Gallais et al., 2004), rice (Obara et al., 2004), Arabidopsis (Loudet et al., 2003a,b) and sorghum (Gelli et al., 2017). At present, the study in low nitrogen tolerance of sorghum has lagged behind other grain crops (Rosa et al., 2014). Few studies of the answers of the molecular response mechanisms of growth and development to nitrogen deficiency of sorghum have been reported.

In this study, the phenotypic and transcriptomic responses of two sorghum varieties, KZ15 and SZ7, under low nitrogen stress and control were investigated. Unraveling mechanisms underlying low nitrogen tolerance of sorghum may provide useful information to genetic engineering and improve the low nitrogen tolerance of sorghum. Such knowledge can also be useful for increasing nitrogen use efficiency for sustainable agriculture.

Materials and methods

Plant materials and growth conditions

Two sorghum varieties, Keza15 (KZ15, tolerant to nitrogen starvation) and Suiza7 (SZ7, sensitive to nitrogen starvation), were used for this study, which were provided by the Keshan branch of the Heilongjiang Academy of Agricultural Sciences.

This experiment was conducted in the greenhouse of Keshan Branch of Heilongjiang Academy of Agricultural Sciences in China. Uniform and plump-eared sorghum seeds were selected and germinated under dark conditions after disinfection, and then sown in vermiculite.

Stress treatments and sample preparations

Trifoliate seedlings were moved into foam boxes wrapped in black plastic film and then cultured with Hoagland nutrient solution. The average temperature and light-dark period were 25°C/20°C and 14 h/10 h. $CaCl_2$ was added to supplement Ca^{2+}. Control plants (in the solution of 4 mmol/L $Ca(NO_3)_2$) were grown in parallel and collected at the same time points. The pH value was adjusted to 5.8 (Ma, 2014). KA, SA, KB and SB indicated the seedlings of KZ15 and SZ7 in low nitrogen treatment and control, respectively. The process was repeated in triplicate. Leaves of seedling which treated for seven days were taken as samples.

The method of the determination of chlorophyll content was referred to the modified method cited by Wang et al. (2006). The following formulas were used to calculate the content of photosynthetic pigments, in which V and W indicated the volume of extracting liquid (ml) and the weight of material (g).

$$\text{Chlorophyll a (Ca) / mg·g-1= (12.21A663-2.81A646) V/ (1000 ×W)} \quad \text{(Eq.1)}$$

$$\text{Chlorophyll b (Cb) / mg·g-1= (20.13A646-5.03A663) V / (1000× W)} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1152511536

The method of nitrate reductase determination was referred to Rajasekhar et al. (1986). The determination of glutamine synthase (GS) was referred to the method of Ding et al. (2006).

The experiment was performed using three biological replicates, and differences were statistically analyzed using Student's t-test ($^{*}P<0.05$, $^{**}P<0.01$). Bars indicate standard error of the mean. Microsoft Excel 2010 and SPSS 18.0 software are employed for data collation and analysis.

RNA seq analysis

Total RNA was isolated from each sample. Quality and quantity evaluation of total RNA, library constructing, and Illumina sequencing were performed in the Beijing Genome Institute (BGI, Shenzhen, China).

Transcript data analysis

TopHat 2 (Kim et al., 2015) was used to compare transcripts with reference genomes. After genome comparison, the StringTie tool was used to identify exonic regions, and then the transcript was reconstructed. The transcript was reconstructed by the DeNovo assembly method. The actual transcripts were screened out, and the low expression transcripts were filtered by the TPM value (filtering criteria: TPM > 0.5 in at least one sample).

Differential expressed genes between samples were defined by DESeq using two separate models (Anders and Huber, 2010), based on fold change >2 and false discovery rate–adjusted P value < 0.05.

According to the result of GO annotation, DEGs were classified to GO terms according to official classification. Phyper was used to perform GO functional enrichment. The p-value calculating formula in hyper geometric test was:

$$P = 1 - \sum_{i=0}^{m-1} \frac{\binom{M}{i}\binom{N-M}{n-i}}{\binom{N}{n}} \quad \text{(Eq.3)}$$

Then, false discovery rate (FDR) was calculated for each p-value. In general, the term FDR <= 0.01 was defined as significantly enriched.

Results

Phenotypic investigation of KZ15 and SZ7 under low-N stress

To evaluate the impact of low-N stress on sorghum, seedlings were planted in an intelligent greenhouse with low-N stress (0 mmol/L) and under control conditions (4 mmol/L). Under low-N stress, the seedlings of SZ7 leaves turned pale yellow, but the seedlings of KZ15 leaves did not significantly change (*Fig. 1A and 1B*). Subsequently, chlorophyll content, activity of nitrate reductase (NR) and glutamine synthetase (GS) were measured in both KZ15 and SZ7 of the low-N treatment and control. The results showed that the seedlings of SZ7 have a 28.77% average decrease in total chlorophyll content, but the seedlings of KZ15 only have 12.39% average decrease (*Fig. 1C*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1152511536

Compared to the control, the content of chlorophyll a and chlorophyll b in SZ7 showed a 27.32% and 33.66% decrease, respectively. But the content of that in KZ15 was 8.86% and 22.71%, respectively (*Fig. 1D, 1E*). These results demonstrate that the change of KZ15 chlorophyll content was lower than that of SZ7 under low-N stress, and chlorophyll b content was more sensitive under low-N stress than the content of chlorophyll a. In addition, the activity of NR and GS was significantly reduced in SZ7 under low-N stress, but the activity of NR and GS exhibited little change in KZ15 under low-N stress (*Fig. 1F, 1G*). These results demonstrate that KZ15 is more N-stress tolerant compared with SZ7.

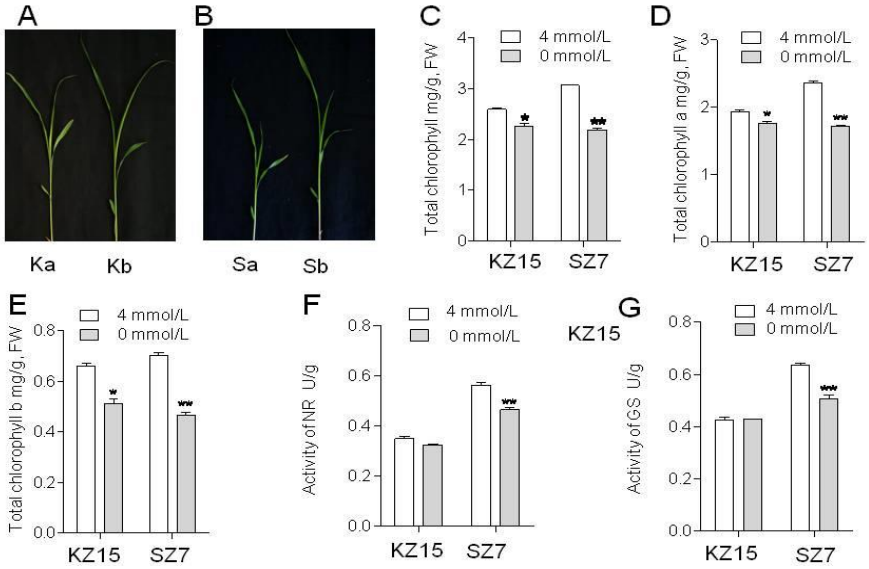

Figure 1. *Morphological performance of KZ15 and SZ7 measured under low-N treatment and non-stress concrol nitrogen concentration treatment. (A, B) Phenotype of KZ15 and SZ7 under low-N treatment. (C) Total chlorophyll content. (D) Chlorophyll a content. (E) Chlorophyll b content. (F) Activity of NR. (G) Activity of GS. (*P <0.05; **P <0.01). The experiment was performed using three biological replicates, and differences were statistically analyzed using Student's t-test (*P<0.05, **P<0.01). Bars indicate standard error of the mean*

Summary of transcriptomic profiling sequencing

Both full-N and low-N treatments were used to analyze the response of sorghum seedlings to nitrogen stress. Twelve libraries were constructed and sequenced. After removing low-quality reads, an average of 24.09 Mb (range of 24.04 to 24.11 Mb) clean reads were obtained in each library, in which more than 86.27% of clean reads per library could be mapped to the reference sorghum genome (*Table 1*). The Q30 values were higher than 90%, which indicated that the sequencing quality was good. The GC content of 12 samples ranged from 52.11% to 55.24%. This result indicated that the sequencing data could be used for further analysis.

Special and common low-N-responsive DEGs between KZ15 and SZ7

To examine the special and common DEGs between KZ15 and SZ7 under low-N treatment, a Venn diagram were constructed. Many common DEGs were identified in KZ15 and SZ7. In total, 793 DEGs were common low-N-responsive genes (*Fig. 2A*),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1152511536

among which 277 were upregulated (*Fig. 2B*) and 486 were downregulated (*Fig. 2C*). Under low-N treatment, 404 DEGs were found specifically upregulated in KZ15 and 762 DEGs were specifically upregulated in SZ7. In addition, 642 and 1132 DEGs were specifically downregulated in KZ15 and SZ7, respectively (*Fig. 2A, 2B*).

GO enrichment of DEGs

The DEGs were categorized into 46 functional groups in KZ15 and SZ7. According to the significance and reliability, GO entries with significant enrichment were screened and simplified. Twenty-six GO entries with the highest enrichment significance were screened out in KZ15 (*Table 2*), and 11 GO items with the highest significance were selected in SZ7 (*Table 3*). In biological process, GO terms related to metabolic process were the most enriched both in tolerant cultivar KZ15 (513) and sensitive cultivar KZ15

In molecular function ontology, catalytic activity was the term which was enriched and most abundant in both KZ15 (633) and SZ7 (951). The terms oxidoreductase activity, cofactor binding, tetrapyrrole binding and heme binding were found in both KZ15 and SZ7. GO terms belonging to molecular functions such as glutathione transferase activity, chlorophyll binding, glucose transferase activity, 3-quercetin

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1152511536

glucosyl transferase activity, and UDP-glucose transferase activity were enriched in KZ15. With respect to cellular component ontology, 64 genes were enriched in the extracellular region, followed by the photosynthetic pathway, suggesting that genes differentially expressed in the photosynthetic system and extracellular region of KZ15 may play an important role in low nitrogen tolerance. In SZ7, the most significant Go term was extracellular domain (87 genes). The other two GO terms (Photosynthetic system I and photosynthetic system) were related to the photosynthetic system.

Functional enrichment of significant genes

In this study, KEGG pathway enrichment analysis of DEGs of KZ15 and SZ7 under nitrogen starvation were carried out. In KZ15, a total of 1526 genes were found to be enriched in 124 pathways, which were divided into five branches: cell process, genetic information processing, environmental information processing, metabolism, and biological system. The results showed that nitrogen starvation had certain effects on the biosynthesis of secondary metabolites, carbohydrates, amino acids, lipids, terpenoids, ketones, cofactors, vitamins, plant signal transduction, membrane transport, protein folding, sorting, degradation, and DNA transcription. In addition, there were 125 DEGs that were related to environmental adaptation. In this study, the top ten pathways with the highest enrichment level were analyzed (*Table 4*). We found that the difference of nitrogen treatments caused changes of genes related to secondary metabolites biosynthesis, porphyrin metabolism, chlorophyll metabolism, photosynthetic antenna protein pathways, and other pathways, suggesting that these substances may be related to the absorption or metabolism of nitrogen in KZ15.

Table 4. *Top 10 KEGG pathway in KZ15 after N-starvation*

No.	Pathway ID	Pathway	DEGs genes	Pvalue	Qvalue

10	ko00908	Zeatin biosynthesis	10	0.000301345	3.67E-03

In SZ7, a total of 1694 genes were found to be enriched in 119 pathways. The results showed that nitrogen treatment had certain effects on the metabolism of carbohydrates, secondary metabolites, amino acids, lipids, terpenoids, ketones, cofactors, microorganisms, plant signal transduction, membrane transport, and DNA transcription and translation. A total of 161 DEGs were related to environmental adaptation. In this study, the top ten pathways with the highest enrichment level were analyzed (*Table 5*). We found that the difference of nitrogen level in SZ7 caused the different expression of genes related to the biosynthesis of secondary metabolites, monoterpenes, carotenoids, content of amino acids, starch, and sucrose, suggesting that these substances might be related to the metabolism of nitrogen uptake of SZ7.

Genes involved in nitrogen metabolism and glutathione metabolism

The results of GO enrichment analysis indicated the common low-N responses on nitrogen metabolism and the processes of glutathione metabolism in both KZ15 and SZ7. Nitrogen metabolism was composed of nitrogen transport and nitrate assimilation. In total, 16 genes participated in nitrogen metabolism, including nitrate reductase, ferredoxin-nitrite reductase, ureide permease 2, chloride channel protein and the NRT1/ PTR FAMILY (NRT2.2, NRT2.3, NRT3.1, NRT4.3, NRT4.4, and NRT6.3), which were all upregulated in both KZ15 and SZ7 under N-starvation. Only five genes (IN2-1, NRT4.3, NRT6.3, NRT8.3, and NRT8.5) encoding nitrate transport proteins were downregulated after N-starvation (*Figure 3A*).

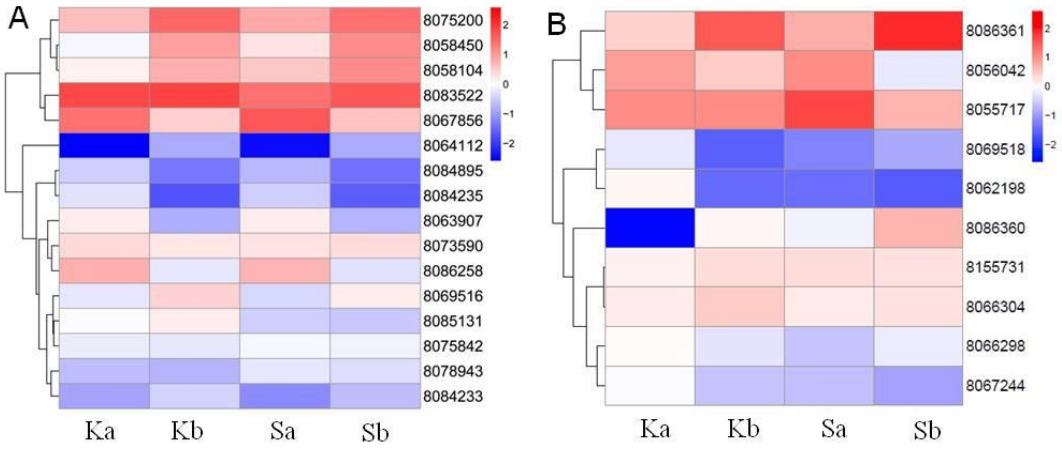

Figure 3. *Heatmap of differentially expressed genes (DEGs) related to Nitrogen metabolism (A) and Glutathione metabolic (B) in KZ15 and SZ7 under N-starvation*

Although similar expression pattern of genes involved in nitrogen metabolism existed in both varieties under N-starvation, the gene expression pattern in cell redox homeostasis was distinct. Among these, eight DEGs mapped to the cell redox homeostasis pathway and glutathione metabolism was found to be upregulated in KZ15 and SZ7 under N-starvation. Only two DEGs had the opposite expression (*Figure 3B*).

DEG transcripts abundant in KZ15 under N-starvation

Genes that are differentially expressed in only one variety should be important for the phenotypic differences between KZ15 and SZ7 under N-starvation. A total of 389 genes that were especially up-regulated in KZ15 were functionally involved in low-N tolerance. The expression of DEGs related to nitrogen metabolism and defense response was identified, which included genes associated with nitrate uptake and assimilation, transcriptional regulation, hormone-signaling, and oxidative stress. The results of RNA-seq for known nitrogen transport and assimilation genes indicated that N-stress may increase the abundance of genes encoding high affinity nitrate transporters in tolerant cultivars KZ15. For example, genes encoding the nitrate transporters NRT2.4, NRT3.1, and NRT4.5 were more abundant in the tolerant genotype KZ15 than SZ7 (*Figure 4A*).

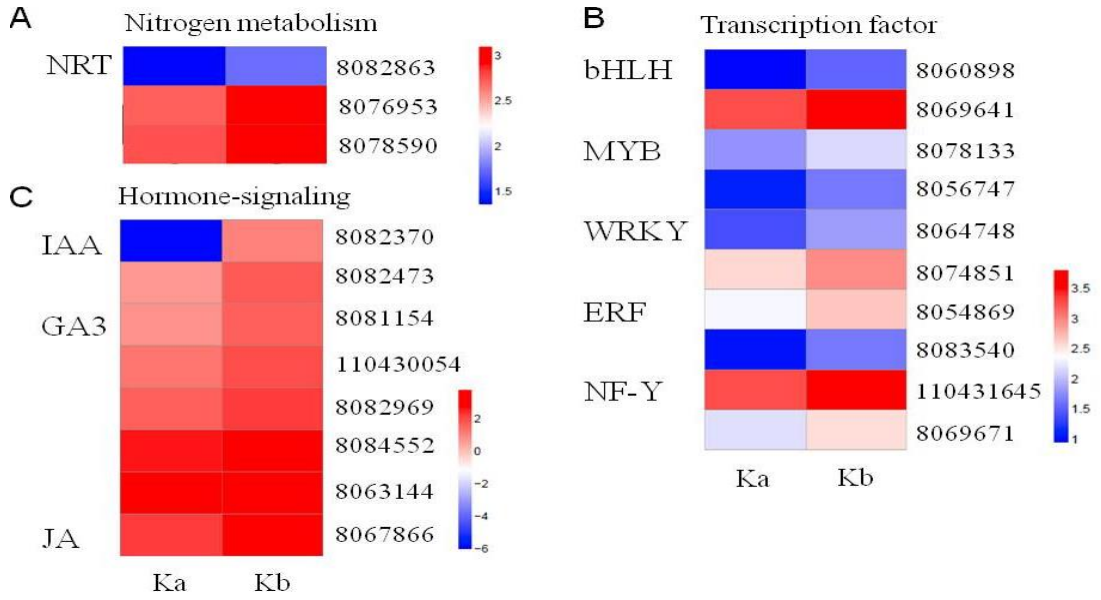

Figure 4. *Heatmap of differentially expressed genes(DEGs) related to low-N tolerance responses in KZ15. (A) Nitrogen metabolism. (B) Transcription factors*

Transcription factors are important in molecular mechanisms regulating growth, developmental processes, and responses to biotic or abiotic stress. In this study, a total of ten transcription factor (TF) encoding genes were especially upregulated in KZ15 under N-starvation. These transcription factors included the WRKY, MYB(myeloblastosis), bHLH(b helix–loop–helix) , ERF (ethylene responsive factor), and NF-Y(nuclear factor-Y) transcription factor families (*Figure 4B*). In addition, several genes associated with hormone-signaling pathways were upregulated in the tolerant genotype KZ15 under N-starvation, such as auxin responsive GH3(Gretchen Hagen 3) gene, auxin-responsive protein IAA30, gibberellin receptor GID1(Gibberellin insensitive dwarf 1), gibberellin 2-oxidase, and jasmonate ZIM (Zinc finger gene) domain-containing protein (*Figure 4C*). DEGs involved in oxidative stress response and flavonoid metabolites were also upregulated in KZ15 under N-stress.

Discussion

Changes of physiology and expressing genes in sorghum under low-N stress

The results of this study showed that the DEGs in chloroplast of SZ7 were significantly more abundant than that of KZ15. When nitrogen was deficient, physiological analysis also showed that the chlorophyll content of SZ7 was significantly lower than that of the normal nitrogen application, while the chlorophyll content of KZ15 did not change significantly under different nitrogen treatments. The activity of NR and GS decreased under low nitrogen, but the decrease of KZ15 was lower than that of SZ7. The decrease of low nitrogen tolerance sorghum was lower than that of low nitrogen sensitivity sorghum. The results of this study are consistent with previous studies on maize (Presterl et al., 2010), wheat (Han et al., 2007; Xiong et al., 2016), and rice (Zeng et al., 2007).

The results of RNA-sequencing revealed a series of DEGs between KZ15 and SZ7. To understand the molecular mechanisms of these two sorghum cultivars with significantly different nitrogen uptake levels, we found that 681 genes and 1039 genes were upregulated in KZ15 and SZ7 without nitrogen application, respectively, and the number of downregulated genes were 1128 and 1618, respectively. As an N^+ starvation sensitive genotype, the results showed that the DEGs of SZ7 were significantly more abundant than those of KZ15 in the process of organic nitrogen biosynthesis and nitrogen metabolism, which is similar to previous studies in maize and Arabidopsis thaliana (Gallais and Hirel, 2004). We also found that both cultivars were involved in photosynthesis and protein differential expression. Similar phenomena have been found in the gene expression profile of Arabidopsis thaliana (Himanen et al., 2004).

Special and common Low-N-responsive DEGs in sorghum under low-N stress

In this study, many DEGs were identified in both sorghum varieties which may be a response to low-N stress. Previous studies have shown that many DEGs associated with high affinity nitrate transporters (NRT2.2, NRT2.3, NRT2.5, and NRT2.6) were identified in low-N tolerant sorghum varieties (Gelli et al., 2014). Consistent with this, we found that the transcript encoding nitrate transporters NRT2.4, NRT3.1, and NRT4.5 were abundant in the tolerant genotype KZ15 compared to SZ7. We also found that the NRT1/ PTR family (NRT2.2, NRT2.3, NRT3.1, NRT4.3, NRT4.4, and NRT6.3) was upregulated in both KZ15 and SZ7 under N-starvation.

It has been reported that SiMYB3 takes part in the growth and development of lateral roots and elongation of main roots mediated by low nutritional stress in millet; it also plays an important regulatory role in the signaling pathways of nitrogen, phosphorus, and potassium (Hu et al., 2015). A total of 235 MYB transcription factors were found in this study. Two MYB transcription factors were especially upregulated in KZ15 under different nitrogen treatments, indicating that MYB transcription factors may play an important role in the process of low-nitrogen stress response in sorghum.

Conclusion

To analyze the molecular mechanism of sorghum response to low nitrogen, the phenotypic and transcript profiling of different resistant varieties were studied. The results showed that the content of chlorophyll and the activity of NR and GS of SZ7

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1152511536

were more sensitive than that of KZ15 under low-N stress. A total of 1809 and 2657 DEGs were identified from KZ15 and SZ7.

We suggest that MYB transcription factors may play an important role in regulating the expression of genes related to nitrogen stress response. The ERF, bHLH, WRKY, and NF-Y families of transcription factors could also be involved in the response to low nitrogen tolerance in sorghum. In the tolerant cultivar KZ15, 389 upregulated genes were found functionally involved in low-N tolerance. These 389 genes are mainly involved in nitrogen metabolism, defense response, oxidative stress response, and flavonoid metabolism. We speculate that three nitrate transporter genes (NRT2.4, NRT3.1, and NRT4.5) and ten transcription factors may play an important role in improving the nitrogen use efficiency of sorghum. Overexpression of these genes may improve the tolerance of sensitive sorghum genotypes to nitrogen starvation. The expression patterns and regulation mechanisms of these genes associated with the tolerance to low nitrogen will be analyzed in future. These genes can also be used as candidate genes for improving sorghum tolerance to low nitrogen by genetic engineering, and lay a foundation for the breeding of new sorghum varieties with low nitrogen tolerance.

Abstract. Enolase is involved in the glycolytic pathway of many organisms and is a key rate-limiting enzyme, which plays an important role in the growth and development of various species. In this study, the enolase gene sequences and amino acid sequences of more than 40 species were first downloaded, and phylogenetic analysis and molecular evolution studies were performed using bioinformatics methods. The phylogenetic tree was constructed to predict the conserved type of enolase evolution and the enolase evolution relationship of each species. It was found that the enolase of each species was very conservative during the evolution process. In addition to studying the evolutionary relationship of enolase of various species, the protein structure was predicted, and the secondary structure of enolase protein was predicted. The results showed that the secondary structure was very similar. The homology modeling method was used to predict the tertiary structure of enolase, and it was found that although there were slight differences, they were similar. In addition, statistical comparison analysis of the introns of each species enolase found that the gap between the number of introns and the locus was small, suggesting their close evolutionary relationship. It is predicted that a variety of plant and animal enolase catalytic kinase-specific phosphorylation sites, the results show that the kinase domain sequence contains three phosphorylation sites: serine (Ser), threonine (Thr) and tyrosine (Tyr). The amount of serine is the highest and the degree of similarity is high. The Ka/Ks ratio of most species is greater than 1. This indicates that enolase is mainly influenced by positive selection in evolution. Our results will help provide insights into the evolution of enolase and provide a theoretical basis for subsequent experiments.

Introduction

Enolase, originally discovered by Lohman and Meyerhof in 1934, is a rate-limiting enzyme in the glycolysis pathway. Enolase not only catalyzes the dehydration reaction from 2-phospho-D-glycerate (2-PGA) to phospho-enolpyruvate (PEP) in glycolysis metabolism, but also catalyzes the phospho-enolpyruvate hydratase reaction to convert PEP to 2-PGA (Lohman and Meyerhof, 1934; Armand et al., 2016) (*Fig. 1*). Further studies have demonstrated some divalent metal ions (Mg^{2+}, Mn^{2+}, Zn^{2+}, Ca^{2+}, Co^{2+} and Ni^{2+}) have activation effect on enolase activity, especially Mg^{2+} which is the strongest natural activator of enolase (Warburg et al., 1942; Mizuno et al., 2007). Enolase has long been considered as an ancient enzyme with only catalytic function. In addition to glycolytic pathways, enolase is also plays an important role in some physiological and pathological processes in organisms, such as ithe regulation of transcription, apoptosis, and cell differentiation (Straeten et al., 1991; Ucker et al., 2016).

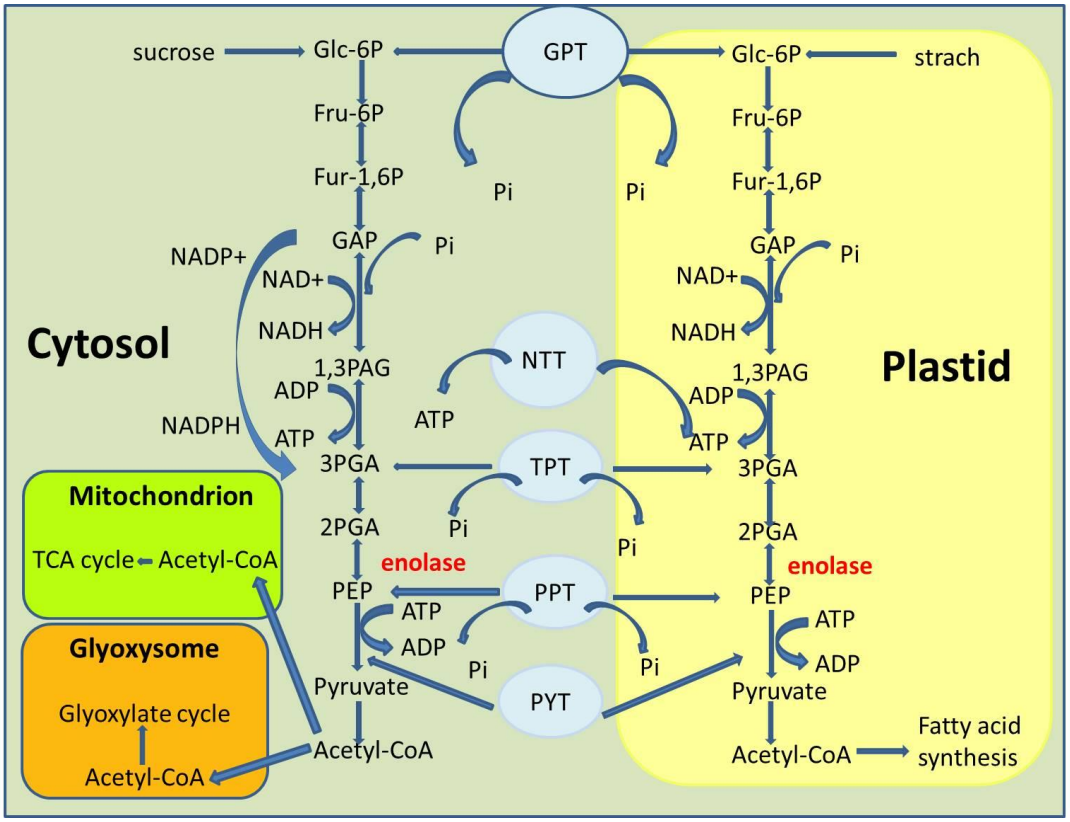

Figure 1. *Glycolysis pathway (PYT: pyruvate translocator; GPT: glucose phosphate/Pi translocator; PPT: phosphoenolpyruvate/Pi translocator; TPT: triose phosphate/Pi translocator; Fru-1, 6P: fructose 1,6 bisphosphate; Fru-6P: fructose 6 phosphate; GAP: glyceraldehyde-3-phosphate; Glc-6P: glucose 6 phosphate; PEP: phosphoenolpyruvate; 1,3-PGA: 1,3-bisphosphoglycerate;2-PGA: 2-phosphoglycerate; 3-PGA: 3-phosphoglycerate)*

Enolase occupies an important position in the fermentation metabolic pathway, especially in the glycolytic pathway. This enzyme is widely present in almost all the species. The gene sequences of enolases are highly conserved. The enolase is evolutionarily affiliated tothe enolase superfamily, which includes the MR (mandelate racemase) family, the MLE (muconate lactonizing enzyme) family, and the enolase family (Gerlt et al., 2012).

The crystal structures of enolase from some prokaryotes and eukaryotes have been resolved. The main structure of the enolase consists of two anti-parallel identical subunits. Each of these subunits contains a relatively long C-terminus and a relatively short N-terminal domain. The former domain is folded into a $\beta_2\alpha_2(\beta\alpha)_6$ topology, and the latter domain is folded into a $\beta_3\alpha_4$ topology (Lebioda et al., 1988). The activity center of enolase is located in the folded cavity of the C-terminal domain. Unlike the high degree of structural conservation and similarity, the aggregation state of enolase varies widely among different species.

Enolase is recognized as a multifunctional protein. In addition to the glycolysis function in metabolic pathway, enolase is also expressed as a receptor for plasminogen on the surface of many types of cells to ensure that plasminogen hydrolyzing activity is concentrated on the cell surface. This causes hydrolase cleavage of plasmin, which leads to the growth of tumor cell invasion and the associated inflammatory response

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1153711550

(Perconti et al., 2017). By removing the function of its plasminogen receptor and its catalytic function in glycolysis, enolase also exhibits other intracellular localization and cellular functions, all of which are well known for its glycolysis function. This suggests that it may play a role in cell recognition and invasion, vacuole formation and development, and transcriptional processes (Pal et al., 2009). In addition, differential expression of enolase is also thought to be associated with some pathophysiological states, such as cancer, Alzheimer's disease, rheumatoid arthritis. For example, a large number of studies have generally shown that the enzymatic enzyme's glycolysis function is significantly enhanced in tumor cells and is used as a marker for cancer progression (Song et al., 2014; Reev et al., 1986). Therefore, enolase is considered as a hallmark of many diseases. In plants studies about enolase have shown that the enolase gene expression and enzyme activity will change under high temperature, anaerobic, high salt, dry early, low temperature and other stress conditions (Barkla et al., 2009; Iida et al., 1985; Grondin et al., 2015). Under stress conditions, plants produce large amounts of free radicals that cause damage to the photosynthetic system. This stress response of enolase can provide energy for its repair. Enolase is a glycolytic enzyme that is consistent with its primary function in the cytoplasm. In the cytoplasm, enolase can be free, and other glycolytic enzymes in the cytoskeleton. Interaction occurs in combination (Subramanian et al., 2000). For example, pyruvate kinase, phosphoglycerate mutase and aldolase. The first two enzymes are closely adjacent to the enolase in the glycolytic pathway, and aldolase interacts with some of the cytoskeletal proteins (Aaronson et al., 1995). Studies have shown that α-enolase has a certain effect on hypoxia tolerance through non-glycolytic pathways. Under hypoxic conditions, the expression of α-enolase may be enhanced in cells. Protection under anaerobic conditions (Straeten et al., 1991).

We will carry out evolutionary cluster analysis of each species enolase, and analyze the protein secondary structure, tertiary structure, phosphorylation site, number of introns, and ka/ks value to prove the conservation of enolase. Through the research results of this paper, we can better analyze the evolutionary relationship between enolase in various species, and provide theoretical basis for subsequent research in molecular biology.

Materials and methods

Identification of enolase genes

In this study, the genes which encode enolase from 50 species were collected from databases and related articles, The relevant enolase sequences were obtained from phytozome database (available) online: (https://phytozome.jgi.doe.gov/pz/portal.html) and NCBI:(https://www.ncbi.nlm.nih.gov) results are merged and the extra sequences are removed. For genes with more than one predicted isotype, we only analyzed the longest peptide sequence for each gene.

Prediction of enolase structure

The amino acid sequences of enolase from 42 species were input into the SOPMA online software (https;//npsaprabi.ibcp.fr/cgi-bin) to predict the secondary structure of the enolase protein. And draw the obtained data into a table. Use SWISS-MODEL

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1153711550

(https://swissmodel.expasy.org/) online software to predict and build a tertiary structural model of enolase

The phylogram and selection of enolase

All enolase amino acid sequences in 50 species including maize, wheat, rice, Arabidopsis, mouse, orangutan were aligned by ClustalX v1.83 (Higgins et al., 1992). Use the default parameters. MEGA 6.0 (Tamura et al., 2011) using the NJ method was used to generate a phylogenetic tree. The enolase gene intron information for maize, wheat, rice, Arabidopsis, mice, orangutans, etc. is from Ensembl Genomes (Available online: http://ensemblgenomes.org/). The value of Ka/Ks was very important since it could estimate the changes of encoded amino acid sequences and gene functions, further estimate gene evolution. Each Ka and Ks value can be calculated by DnaSPv5.0 software (available online: http://www.ub.edu/dnasp/).

Phosphorylation analysis of enolase

KinasePhos (http://kinasephos.mbc.nctu.edu.tw/) was used to predict the kinase specific phosphorylation site in which enolase catalyzes. The software has high sensitivity and specificity, categorizing known phosphorylation sites by substrate sequences and their associated protein kinase classification.

The enolase gene intron information for 30 species including maize, rice, Arabidopsis, orangutan, and mouse is from Ensembl Genomes (available online at http://ensemblgenomes.org/).

Results

Conservative evolution of enolase

To investigate the gene evolutionary relationship, a total of 51 enolases from 50 species were aligned using MEGA software. The clustering analysis result showed that amino acid sequence levels in monkeys, bonobos, Sumatran orangutans, beluga whales, tilapia, rainbow trout, pigeons, ducks, birds, yeast, staphylococcus, staphylococcus, and streptococci. The enolase of 50 species was subjected to cluster analysis at the amino acid sequence level and merged with the system evolution, and the calibration parameters were repeated 1000 times (*Fig. 2*). The gymnosperms Araucaria and Selaginella are clustered together. Monocotyledonous corn, wheat, sorghum, and rice are clustered together, while most dicotyledonous plants such as peanuts, soybeans, pumpkins, and bitter gourds are clustered together, but peppers and tobacco. Gathering together as one, Arabidopsis and mulberry are clustered together. It may be that enolase has some differences in evolution among these species, which is worthy of our subsequent analysis. Enolase generally has the characteristics of closer evolution of the plant within the family. In mammals, mammals such as beluga whales, orangutans, monkeys, and horses are grouped together, rainbow trout in fish, tilapia are grouped together, mosquitoes, fruit flies, and silkworms are grouped together. Staphylococcus, streptococcus, and heatococcus are grouped together. Further analysis found that the similarity of several major crops such as wheat, corn, rice and sorghum was more than 54%, and the sequence similarity of beluga whales, horses, bonobos, red marmosets and Sumatran orangutans reached over 98%. This indicates that the enolase gene is evolutionarily conservative.

Enolase protein structure analysis

The high-order structure formed by folding and winding of amino acid residues by van der Waals force, hydrogen bonding, etc. is called protein secondary structure, and mainly includes α-helix, β-sheet, random coil and extended chain. The secondary structure of 42 species of enolase protein was analyzed online using SOPMA software. The results showed that the enolase protein contained the above secondary structure, α-helix and random. Curl is the most frequently occurring structure, while the elongation chain and β-sheet appear less *(Schedule 1)*. The number of sputum-helix in plants is between 182 and 235, accounting for 39.96% to 46.53%. The number of "random" curls is between 143 and 171, accounting for 32.13% to 35.65%. In animals, the number of sputum-helix is between 184 and 292, accounting for 40.66% to 47%. The number of "random" curls is between 138 and 244, accounting for 31.8% to 40%. In the fungi, the number of α-helix is between 184 and 1945, accounting for 42.99%~44.7%. The number of "random" curls is between 136 and 143, accounting for 31.34% to 33.41%. The SWISS-MODEL uses the online tool SWISS-MODEL to model the tertiary structure of 42 species of enolase protein. After homologous modeling of 42 species of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1153711550

enolase protein, it was found that the proteins are highly similar in spatial structure, and the proteins of each species have highly conserved structural features, so we constructed a tertiary structure of corn, orangutan, and thermococci enolase protein. The figures are representative of plants, animals, and bacteria (*Fig. 3a, b* and *c*). The results show that the tertiary structure of the enolase proteins of the three species is very similar. Both are bilaterally symmetric structures, and the positions of the active centers are also the same. And it can be seen intuitively that the α-helix, β-sheet, "random" curl, the number of extension chains and the sections are similar. However, the number of secondary structures of animal enolase is much higher than that of plants and fungi. Using Swiss-Pdb Viewer to analyze the results of homology modeling, the predicted dihedral angle of the protein residue is located in the yellow core region, indicating that its spatial structure is stable. PyMOL is used to process and analyze the modeling results, and the Ramachandran diagram is obtained. Ramachandran diagrams are mainly divided into permitted areas, maximum allowed areas, and disallowed areas. In general, the ratio of the amino acid of the model to the allowable region and the maximum allowable region is more than 90% of the total protein. The spatial structure conformation of the protein conforms to the rule of stereochemistry. As shown in *Figure 3d, e* and *f*, more than 90% of the dihedral angles of the enolase protein residues were detected in the allowable zone and the maximum allowable zone, indicating that it has a stable spatial conformation. In *Figure 3d, e* and *f* can be intuitively seen that the distribution of the secondary structure of the three representative species in the tertiary structure is concentrated in three main regions, and the representative species of the animal, in addition to the main three regions, are also distributed in other regions. This is different from the representatives of plants and fungi.

Enolase phosphorylation site analysis

Phosphorylation of proteins is one of the important covalent modifications in organisms. About one-third of proteins are hyperphosphorylated during mammalian cell life cycle; 5% of genes in vertebrate genomes The encoded protein is a protein kinase and phosphoenzyme involved in the phosphorylation and dephosphorylation processes. Plants are grown in the soil and cannot move away from biological or abiotic stresses like animals. Therefore, plant cells usually use receptors on the cell surface to sense environmental changes, transmit signals through various signaling pathways in the body, and finally respond appropriately to various external stimuli (Morris and Walker, 2003). The protein phosphorylation sites of eukaryotic cells mainly occur on the hydroxyl groups of the serine (Ser), threonine (Thr) and tyrosine (Tyr) residues, and different protein kinases can recognize and modify the difference of different proteins Site. Kinase Phos (http://kinasephos.mbc.nctu.edu.tw/) was used to predict the kinase-specific phosphorylation sites that 14 plants and 11 animal enolase catalyze. The software is highly sensitive and specific, categorizing known phosphorylation sites by substrate sequences and their associated protein kinase classification. According to the prediction results of phosphorylation sites (*Fig. 4a* and *b*), the amino acid sites with a predicted score of 0.5 or more were recorded. The results showed that the kinase domain sequence contains three phosphorylation sites: serine, serine (Thr) and tyrosine (Tyr). Among them, the potential of serine phosphorylation sites is the highest in animals. Plants have the highest levels of potential serine phosphorylation sites and tyrosine phosphorylation sites. There are 6 phosphorylation sites in rice, wheat and jujube. Maize, citrus, kidney bean, sorghum and peanut contain 5 phosphorylation sites, and corn, rice, wheat, sorghum, jujube and citrus contain Thr47 and Thr59 phosphate. Chemical site. Peanut, kidney bean, soybean, and bitter gourd all contain Thr46 and Thr58 phosphorylation sites, and tobacco contains Thr46 phosphorylation site. Rice, wheat and jujube contain Ser277 phosphorylation sites, citrus, peanuts, and Ser276 phosphorylation sites, and bitter melon and soybean contain Ser275 phosphorylation sites. Kidney beans, soybeans, and bitter gourd contain Ser382 phosphorylation sites, citrus, peanuts, and Ser383 phosphorylation sites, and corn, sorghum, and jujube contain Ser384 phosphorylation sites. Sumatra orangutans, horses, monkeys, and beluga contain Ser289, Ser527, and Thr189 phosphorylation sites.

Enolase intron number analysis

An intron is a non-coding sequence of a break gene that can be transcribed but is cleaved off during mRNA processing, so there is no intron coding sequence on the mature mRNA. In eukaryotes, most genes are interrupted by one or more introns, which may contain “old codes”, which are part of the gene that loses its function during evolution. It may be a key event in the conservative evolution of gene structure. Because the intron is meaningless to the structure of the translation product and is not subject to the pressure of natural selection, it has more mutations than the exon accumulation. In addition, there is growing evidence that loss or increase in introns may be an important factor in the progressive diversity and complexity of genes. We downloaded the enolase genes from 30 species and counted the number of introns. The results are shown in *Figure 5*. Among them, the main crops of maize, rice, sorghum, soybean, and wheat enolase genes had 16 introns. The number of animal introns is mainly concentrated in 11, 13, and 14.

The evolution selection of enolase

In genetics, Ka/Ks or dN/dS represents the ratio between the heterosexual substitution (Ka) and the synonymous substitution (Ks). This ratio can be used to determine if there is a selective pressure on this protein-coding gene. Nucleotide variants that do not result in amino acid changes are referred to as synonymous mutations, and vice versa. It is generally believed that synonymous mutations are not naturally selected, while non-synonymous mutations are naturally selected. Because synonymous substitutions cause amino acid changes that may alter the conformation and function of the protein, and thus cause adaptive changes that result in advantages or disadvantages of natural selection (generally disadvantages). Non-synonymous substitutions do not alter the composition of the protein and are therefore unaffected by natural selection, so Ks can reflect the background base substitution rate of the evolutionary process. The ratio of Ka/Ks can indicate which choice the gene is. In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1153711550

evolutionary analysis, it is meaningful to understand the rate at which synonymous and non-synonymous mutations occur. Commonly used parameters are the following: synonymous mutation frequency (Ks), non-synonymous mutation frequency (Ka), ratio of non-synonymous mutation rate to synonymous mutation rate (Ka/Ks). If Ka/Ks > 1, then a positive selection effect is considered. If Ka / Ks = 1, then a neutral choice is considered to exist. If Ka/Ks < 1, then a purification selection effect is considered (Baumgarten et al., 2003). The frequency of enolase Ka/Ks in plants is mainly between 1.2 and 1.4, and all Ka/Ks are almost > 1 (*Fig. 6a* and *b*). The frequency of enolase Ka/Ks in animals is mainly between 1.0 and 1.2. Although most of the Ka/Ks are > 1, there are certain ratios between 0.8 and 1.0 indicating (*Fig. 6c* and *d*) that the enolase gene is mainly influenced by the positive selection effect in evolution. The enolase in plants is almost always influenced by the positive selection effect in evolution. The enolase in animals is influenced by the positive selection effect in evolution, but some are also affected by negative selection.

Discussion

As one of the key enzymes in the glycolytic pathway, Enolase catalyzes the conversion of 2-phosphoglycerate to phosphoenolpyruvate during glycolysis, which is essential for cell anabolism and energy production (Pancholi et al., 2001). The enolase gene of multiple species was studied, and the genetic evolution relationship, molecular structure and protein function expressed by these genes were analyzed based on bioinformatics methods. It was found that the enolase candidate amino acid sequences of 50 species have high similarity, some even higher than 99%, indicating that they are highly conserved during evolution. From the constructed phylogenetic tree (*Fig. 2*), it can be seen that the gymnosperms are clustered into one, the monocotyledons are clustered into one, and most of the dicotyledons are also clustered into one, but the dicotyledonous plants of pepper and tobacco are gathered together as one. The Arabidopsis and mulberry trees are clustered together and do not cluster with other dicotyledonous plants, probably due to the evolutionary evolution of the enolase genes in these four plants to the rest of the plants. However, in general, enolase has the characteristics of closer evolution of the plant. Animals are divided into two branches, each containing mammals, one of which includes fruit fly, mouse, horse, fish and fungal branches are relatively close, presumably due to the more conservative enolase gene in each species There is little difference within the long process, and only slight changes in the long evolutionary process, so the molecular evolution trend of animal enolase is inconsistent with the evolutionary trend of species. This situation has also appeared in the evolution of other genes. The evolutionary distance of the miR166 gene family is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1153711550

not related to the genetic relationship between the species itself (Xu-Yao et al., 2014) speculate that the gene may evolve in different ways and speeds. The similarity of the enolase amino acid sequence of each species is very high. The similarity between the bean and soybean, sorghum and corn in the plant reaches 100%, the similarity between bitter gourd and pumpkin reaches 99%, and the beluga whale, horse, bonobo, red marmoset in the animal. The sequence similarity of Sumatra orangutans reached over 98%, and the similarity of other animals was above 80%. This indicates that enolase is highly conserved in evolution. Next, we analyze the introns of the enolase gene of each species. Generally, the number of introns is similar, and the intron position and phase between genes with closer evolution are more similar. The number of introns of the enolase gene in most species is concentrated in 11-16 (*Fig. 3*). It shows that the evolutionary relationship of enolase is very close in different species. It is worth noting and discussing that only six of the introns in the Arabidopsis enolase gene are the same as the other species. Enolase is not expressed in the leaves of Arabidopsis, and if silenced, it affects the development of Arabidopsis sporozoites and gametophytes (Prabhakar et al., 2010) and the absence of enolase also affects the root development of Arabidopsis (Prabhakar et al., 2009). The Arabidopsis enolase structure has a pair of disulfide bonds formed by Cys residues, which can undergo redox regulation. The enolase in corn, tomato and ramie does not contain this pair of Cys residues. It seems possible that enolase is redox-regulated by a Cytosolic thioredoxin system in a limited number of plant species including ice plant and Arabidopsis (Anderson et al., 1998). We can later study what kind of particularity the enolase has in its structure and evolution with other plants. The enolase phosphorylation site of each species was predicted to have the highest number of serines and high similarity (*Fig. 4*). The eight phosphorylation sites of Thr46, Thr47, Thr58, Ser275, Ser276, Ser277, Ser382 and Ser383 appeared most frequently in plants. The three phosphorylation sites of Ser289, Ser527 and Thr189 appeared most frequently in animals. The phosphorylation sites of plant enolase are more conservative in evolution than animals, both in number and in location. The similarity of phosphorylation sites in animals is not very high. There are only three phosphorylation sites at high frequencies, and the phosphorylation sites of similar genetically related species are still very similar, such as mammalian orangutans and beluga whales, horse. Most protein interactions are carried out through the activation of phosphating sites, which provides a basis for the subsequent interaction of enolase with its upstream and downstream related proteins. Secondary structure analysis of 42 species of enolase showed that α-helix and “random” crimp were conserved structures, while α-helix and “random” curls were the most numerous, so α-helix and “Random” curl plays an important role in the formation of advanced structures of enolase. The prediction of secondary structure indicates that the secondary structure of protein determines its tertiary structure, which is closely related to the function of protein expression. Based on the similarity of secondary structure of enolase of each species, its functional similarity is predicted. Very conservative, the difference is not big. It can be seen from the (*Fig. 5*) that the tertiary structure of the enolase of each species is also very similar. It is generally accepted that a case where a nucleotide variation does not cause an amino acid change is called a synonymous mutation (Ks), and a phenomenon in which a nucleotide mutation also causes an amino acid change is called a non-synonymous mutation (Ka). Usually, under natural selection, synonymous mutations are not affected, but synonymous mutations are affected by natural selection (Yang et al., 2006). Their ratio Ka/Ks is a molecular evolutionary parameter that weighs

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1153711550

the pressure of selection to determine whether there is a selective pressure on the gene-encoded gene (Shiu et al., 2004). As shown in (*Fig. 6*), it is not that there are positive selection sites for most enolase genes in plants or animals. Some of them have a positive selection site, but their Ka/Ks values are close to 1, indicating positive selection and natural selection for enolase. Genetic evolution affects key roles. Such genes are genes that are rapidly evolving in the near future and are very important for the evolution of species. In summary, we conducted a comparative study on the enolase genes of different species by bioinformatics methods, and found that the enolase gene evolution is very conservative and similar in function. Since enolase is a key rate-limiting enzyme in the glycolytic pathway, the results of this study can provide an analytical basis for subsequent molecular experiments, and are highly versatile in terms of increased yield, resistance to stress, cancer intervention, and treatment in GM crops prospects (Altenberg et al., 2004; Pu et al., 2007).

Abstract. Volatile Solid (VS) parameters are used to study kinetic changes in compost materials. The Michaelis-Menten model is used in determining the volatile kinetics of the process. The composting materials used only are shredded empty fruit bunches (EFB) and palm oil mill effluent (POME) sludges obtained from the palm oil mill plantation. All the composting processes carried out in this study were performed in the rotary drum reactor. This experiment is conducted with 4 different runs. Run A used 10 kg EFB ratio: 1 kg sludge: 5 kg recycle compost, Run B with 5 kg EFB: 0.5 kg sludge: 2.5 kg recycle compost and Run C at 5 kg ratio EFB: 2.0 kg sludge: 0.5 kg recycle compost. The highest temperature achieved is 55°C (Run A), 43 C (Run B) and 53.3°C (Run C). For the final C/N ratios for Run A, B, C and D are 20.61, 17.54, 13.06 and 14.51 respectively. Based on the results of the four Runs that have been done, it is found that the kinetic change in Run has the best mathematical expression $y=103.31^{-0.015x}$ with R-square value of 0.9097 and derived K_1 value of this study is 106.0117 and K_2 is 0.012.
Keywords: *Michaelis-Menten model, shredded EFB, POME sludge, rotary drum reactor*

Introduction

Composting is a biochemical degradation process of organic substances that are converted into a cleaner material and a more stable humus. The main factors in controlling the composting process include the parameters of the environment such as temperature, moisture content, pH and ventilation as well as natural parameters of the substrate material such as C/N ratio, particle size and nutrient content. In determining the degradation and creating useful measurements in the loss of organic matter during the composting process, it is necessary to determine the kinetic process using the data obtained from experimental studies under controlled conditions. According to Levenspiel (1999), kinetics is generally a study of the rate or speed of a reaction. Substrate degradation models play a key role in the mathematical modelling of temperature, moisture and oxygen profiles in the composting process. In relation to temperature prediction, mathematical models have been shown to be mainly successful in simulating the basic shape of composting temperature profiles However, less precise in forecasting peak temperature, and the time required to reach it (Mason, 2009).

Most kinetic parameters are usually used to describe the nature of maturity of compost materials. The nature of maturity of composting materials that is often used is the properties of physico-chemical changes such as C/N ratio, ash and cation capacity change (Planas and Pelaez, 2001). However, there are also studies using enzyme activity measurement as an indicator of composting activity (Pelaez et al., 2004). In general, studies on kinetic changes in composting process are important to obtain a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1155111566

chemical change pattern on the nature of the reaction system, and it is also an important basis for the theory in the combustion and dissolution process which then provides a method for studies involving heat conversion and mass. Knowledge of kinetic reaction changes will also help in the design of a composting system (Manu et al., 2016).

Researchers have studied the determination of decomposition in the composting process. Various parameters have been studied such as the use of oxygen content (Pressel and Bidling Maier, 1981), carbon mineralization rates (Bernal et al., 1998), carbon fractions (Whang and Meenaghan, 1980; Gilmour et al., 1996), biodegradation of lignocellulose (Vikman et al., 2002), biodegradation of polyatic acid (PLA) (Stloukal et al., 2015), biodegradable volatile solid degradation (Mason, 2008; Zhang et al., 2010), organic matter degradation (Kulikowska, 2016; Ge et al., 2015; Manu et al., 2016; Petric et al., 2012; Bustamante et al., 2008), thermal decomposition reaction (Giwa et al., 2018). Tiqua et al. (1996) have studied the changes in microbial characteristics including heterotrophic aerobic population, oxygen consumption rate, dehrogenic activity and C/N microbial mass during pine-stool composting process and wood dust straw. Yamada and Kawase (2006) also reviewed kinetic analysis for microbiological and oxygen use reactions for activated sludge aerobic composting process. In their study, microbiological responses are represented by the Monod equation.

Whang and Meenaghan (1980), Seng (1999) and Tweib et al. (2014) have studied the characteristics of the kinetic composting process. They have measured carbon fractions by using CHN analyzer tools as early as 6-8 days of composting process. They have discovered the characteristics of the composting process using the Michaelis-Menten model. From the study, they have concluded that the constant Michaelis-Menten, K_1 is a constant representing the description of a system used. This study aims to evaluate the rate of kinetic change of volatile substance in the rotary drum reactor. The analysis steps developed in this study can be used to obtain K_1 and K_2 values in a step to increase the composting scale to pilot scale by using Michaelis-Menten model.

Methodology

Raw material and reactor design

The main raw materials used in this study are palm oil mill effluent (POME) sludge and empty fruit bunches (EFB). Shredded fresh empty fruit bunches (EFB) used for compost materials were obtained from Sri Ulu Langat Palm Oil Processing Factory, Dengkil, Selangor, Malaysia. Meanwhile, POME sludge for this study is gathered from conventional aerobic pond treatment from same factory. Recycle compost also used in the mixing of fresh sample for this experiment. The recycle compost is obtained from EFB and POME composting process that is more than 1 year old from previous experiments. *Figures 1* and *2* show the shredded EFB and POME sludge from conventional aerobic pond treatment gathered for this study. While, *Table 1* shows the chemical and physical characteristics of the raw materials and recycle compost that used in this experiment.

Rotary drum reactor system that used in this study facilitated with 3 phase motors. The rotary drum reactor is made from stainless steel measuring 3 m long with a diameter of 0.6 m and an initial active volume of 0.4 m^3. The rotary drum reactor works with the support of a 3-phase motor system with a maximum 2 rotation per minute. There are 8 inner blades with length of 5 cm each in order to enhance the mixing in the

reactor. Mixing of palm oil mill effluents (POME) and empty fruit bunches (EFB) insert through the feeding part. *Figure 3* shows the schematic diagram of the rotary drum reactor used in this study.

C/N	58.9	8.3	10.3

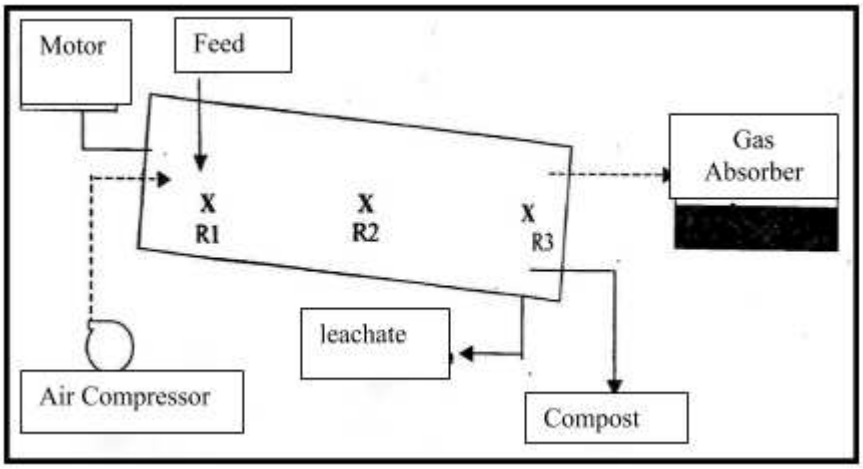

Figure 3. *Schematic diagram of rotary drum reactor*

Temperature profile observation

The temperature of the compost in the reactor is obtained by using the thermometer probe (Digital Thermometer, Thermocouple Thermometer Type K, Nicety® DT804, US). *Figure 4* shows the digital thermometer used to indicate the temperature reading throughout the composting process. The length of this probe thermometer is 1 m. Therefore, temperature readings on composting materials within the reactor can be taken up to 1 meter from the input section (at point R2 referring to *Fig. 3*). The temperature reading of this study is taken twice daily, i.e. in the morning and in the evening. The probe thermometer embedded into the compost heap is left for 5-10 min until the reading on the digital display of the thermometer starts stable.

Preparation of compost mixture

In this experiment, fresh and shredded EFB has been mixed with POME sludge. On average, the length of EFB fiber size taken fresh from the plant used in this phase is within 3-13 cm. In general, smaller particles of organic matter particles will provide sufficient surface area for bacterial and microorganisms reactions. EFB mixtures and POME sludge are mixed manually outside the reactor before being added into a rotary drum. For Run A, as much as 10 kg EFB, 5 kg of recycle compost and 2 kg of POME sludge is manually mixed before being put into a rotary drum reactor every day. For Run B 5 kg EFB, 2.5 kg of recycle compost and 2 kg of POME sludge added daily into

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1155111566

the reactor. Meanwhile for Run C, 5 kg of EFB, 0.5 kg of recycle compost and 2.0 kg of POME sludge added daily. For this experiment runs, only one-time replicate has been carried out of each mixture. *Table 2* shows the mixing ratio of this experimental runs.

Figure 4. *Thermometer digital and thermocouple Type K (Nicety ® DT804)*

The process of adding compost materials of each Runs into a rotary drum is done on daily basis until the content of the drum reactor reaches 90% full. In total, 150 kg of EFB fiber (a mixture of fresh EFB fiber and recycle compost) and 30 kg of POME sludge have been used for each Runs in this study. From the observations on Run A, the compost product reached at the outlet section on the day 11th. Meanwhile, for Run B and Run C the compost product resulted at the outlet section on the day 16th.

The compost products that comes out at the outlet section will then be restored into the rotary drum reactor in the feed section until the composting process is completed. For sampling purposes for pH parameters, moisture content, fiber length, nutrient content and C/N ratio, 200 g of compost was gathered. The sampling process for the above parameters is taken every 3 days. For the temperature parameter, the reading is taken every day in the morning and in the evening. All the compost samples taken were then stored in the frozen room at 4°C before being analyzed.

Table 2. *Weight and mixing ratio between empty fruit bunches (EFB), palm oil mill effluent (POME) sludge and recycle compost on each experimental runs*

Run	EFB (kg)	POME sludge (kg)	Recycle compost (kg)	Mixing ratio	Operational period (days)
A	10	1	5	10:1:5	43
B	5	0.5	2.5	5:0.5:2.5	23
C	5	2.0	0.5	5:2:0.5	29

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1155111566

Volatile solid and carbon content

To analyze the carbon content, the ash method was used is. Sub-samples of dried compost from moisture content analysis were then burned in the furnace for 4 hours at 550°C. Volatile solid computations are shown in *Equation 1* below:

$$\%\ Volatile\ Solid = \frac{X1 - X2}{X1 - M} \times 100 \quad \text{(Eq.1)}$$

where X1 = Initial sample weight and crucible before furnaced, X2 = Final sample weight and crucible after furnaced, M = Crucible weight.

Organic matter is estimated to be equivalent to volatile matter/solid (Hoyos et al., 2002). Therefore, the amount of organic carbon can be determined using the formula as shown in *Equations 2* and *3* according to Hoyos et al. (2002).

$$\%\ Carbon\ C = \frac{\%Organic\ matter}{1.8} \quad \text{(Eq.2)}$$

$$= \frac{\%\ Volatile\ solid}{1.8} \quad \text{(Eq.3)}$$

whereby 1.8 is constant.

Kinetic study

The Michaelis Menten model is a widely used kinetic model in the study of biochemical enzyme reactions that estimate the formation of complex mixtures simultaneously under quasi-equilibrium conditions. Whang and Meenaghan (1980), Seng (1999) and Tweib et al. (2014) have adapted this model in their composting studies. Conceptual reaction mechanisms are interpreted by the following stoichiometric schemes, where the equation rates have been simplified and mathematically manipulated to achieve satisfactory results in the graphic attempts as shown in the following *Equation 4*. *Figure 5* shows how the kinetic study was carried out using the Michaelis-Menten model in this study

$$C + X \leftrightarrow CX \rightarrow X + P \quad \text{(Eq.4)}$$

where C=Substrate, X=Free organism, CX=Activated substrate-organic complex, P=Product from endogenous reaction.

The second estimate made is an endogenous reaction is irreversible based on practical view. Mass stability equations for activated complex substrate microbes, CX can be described as *Equation 5* below:

$$\frac{D(CX)}{D_t} = k_1(C)(X) - (k_{-1} + k_2)(CX) \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1155111566

where K_1=the reaction rate constant of the forward reaction by converting substrate (C) and free organism (X) to the active complex organism substrate (CX), k_{-1}=the reaction rate constant of the inverse reaction by converting substrate (C) and free organism (X) to the active complex organism substrate (CX), k_2=the reaction rate constant of the forward reaction by converting the complex organism substrate (CX) to the free organism (X) and the product (P).

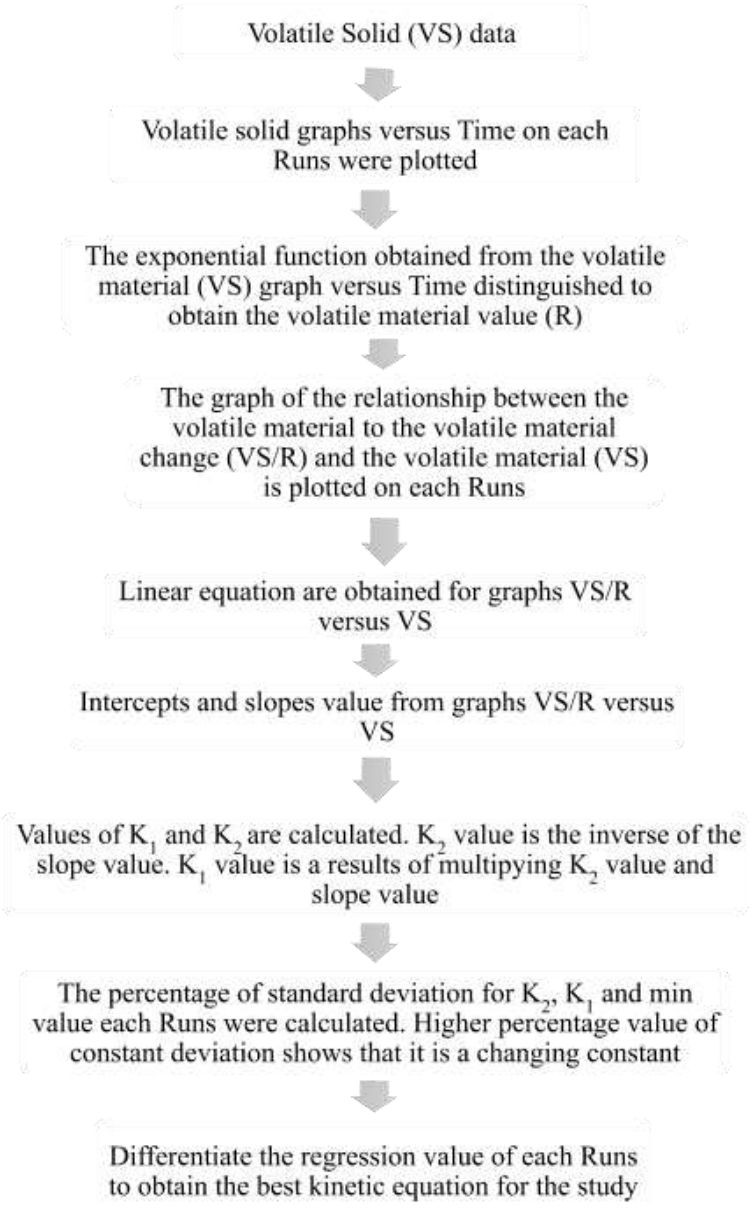

Figure 5. *Michaelis-Menten model kinetic study procedure*

The estimation for an indirect quasi-equilibrium state as *Equation 6:*

$$\frac{D(CX)}{dt} = 0 \qquad \text{(Eq.6)}$$

Therefore, *Equation 5* becomes *Equation 7* as follows:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1155111566

$$(CX) = \frac{(C)(X)}{K_1} \quad \text{(Eq.7)}$$

where k_1 is obtained from *Equation 8,*

$$K_1 = \frac{K - 1 + k_2}{k_1} \quad \text{(Eq.8)}$$

Product production rate (P) is equal to the substrate rate estimate. Therefore *Equation 9* is,

$$\frac{d(P)}{dt} = R = k_2(CX) \quad \text{(Eq.9)}$$

where, R=substrate estimation rate.

In the meantime, the concentration of microorganisms, XT, can be expressed as *Equation 10* as below:

$$X_t = X + CX \quad \text{(Eq.10)}$$

By completing the *Equation 10* and replacing it in *Equation 11:*

$$CX = \frac{(C)(X_T)}{K_1 + C} \quad \text{(Eq.11)}$$

From *Equations 10* and *11,* the R value is obtained by using *Equation 12:*

$$R = \frac{K_2(C)}{K_1 + (C)} \quad \text{(Eq.12)}$$

Where the calculated value of K_2 is obtained from *Equation 13:*

$$K_2 = k_2(X_T) \quad \text{(Eq.13)}$$

Therefore, *Equation 13* is the kinetic equation for the composting process.

Results and discussion

Temperature profile

Temperature gives a huge impact on microbiological processes. Important responses and other elements of composting processes are also affected by temperature changes. Time-temperature relationship affects the rate of decomposition of organic matter and therefore it is important to produce stable and mature compost products for application of plants. In this study, the temperature reading is taken before the compost material is added (morning time), and after the compost material is added (evening time) into the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1155111566

rotary drum reactor. The composting process of Run A is run for 43 days. The initial temperature of the Run A compost mixture is 31.8°C.

At Run A, the highest temperature reached was 55°C on the 10th day of composting process, after composting was added. Temperatures within the range 40–55°C remain for 24 days on the Run A composting process. On day 35 the temperature of the composting process began to show a decrease to the range of 32.1–38.1 C until the end of the composting process. The increase in temperature to the thermophilic phase between 50-70°C during composting is indispensable for the destruction of pathogens and parasites.

Meanwhile, the initial temperature of Run B composting material is 32°C. The increase in temperature on Run B is seen evenly, i.e. from 32°C (initial temperature) to 39.9°C on day 3. On day 4, the temperature starts to reach 40°C range. On Run B, compost temperature remains in the range 40–43°C (the highest temperature reached on the 11^{th} day). The final day of composting, the temperature value before the sample was entered and after the sample was entered has decreased to 37°C and 39.6 C respectively. The compost temperature of this mixture is seen to not achieve optimum temperature of 45°C. This may be due to a 5 kg mix EFB: 2.5 kg recycled compost: 1 kg of POME sludge is not an ideal mix for the optimal development of microbes in compost heap.

The initial temperature of compost material on Run C was 25.5°C. The observed temperature increases gradually in this run. The temperature within the range 30°C lasts for 8 days at the beginning of the composting process. Starting from day 9, the temperature starts to raise into the range 40°C until day 22. On day 23, Run D composting temperature increases to 53.3°C. Temperatures within the range of 50°C to 53°C are seen to last for only 4 days. On 27th day the temperature began to decline again with the final temperature of 36.7°C before the addition of composting material and 45.8 C after composting material was added.

From the three mixtures, the mesophilic phase begins in the first 3-8 days of the composting process. The abundance of organic substances at present has encouraged the activity of microorganisms and subsequently generating heat energy which causes temperature rise to occur. When temperatures rise above 45°C, thermophilic microorganisms will dominate the compost mass. *Figure 6* shows the temperature profile for Run A, B and C.

Volatile solid degradation

In this study, the degradation kinetics of the volatile material were used to study the kinetic changes of compost materials. The Michaelis-Menten model is used in determining the kinetic content of volatile composting samples. All the data from the experiments obtained are appropriate to the exponential function. *Figures 7–9* show graphs of volatile material against time for each Run.

Table 3 shows the exponential function obtained from the experimental runs along with the regression factor for the volatile solids compost material against the time of the study conducted.

The exponential function obtained as described in the table above is then differentiate. The differential equations obtained from the above exponential function represent the volatile solid change (R) in the compost material. The differential equation of the all Runs as shown in *Equations 14–16* below.

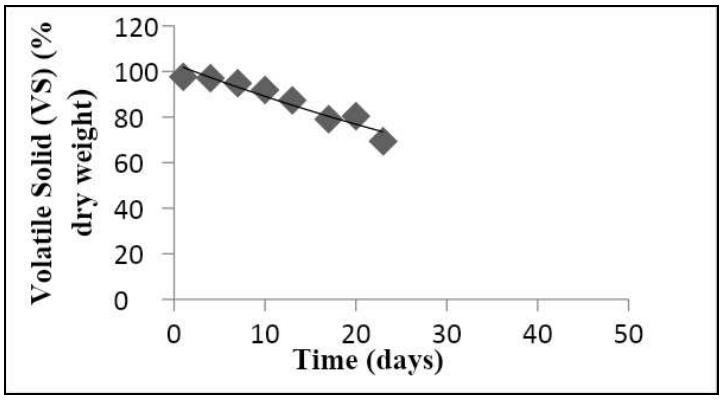

Figure 8. *Volatile solid changes on Run B*

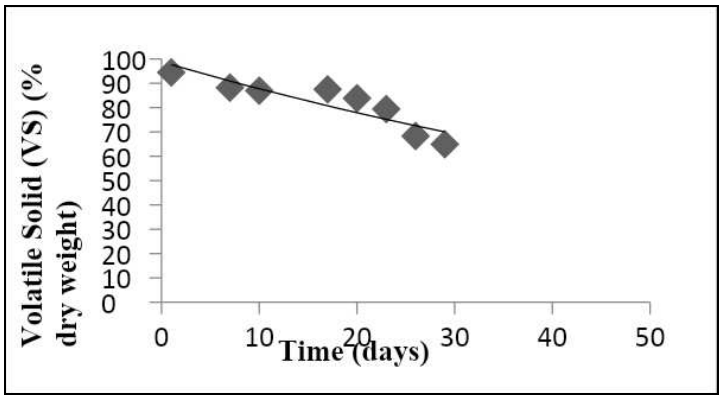

Figure 9. *Volatile solid changes on Run C*

From the volatile solid value (VS) and the volatile solid change value (R), the relationship between the volatile solid to the volatile solid change (VS/R) and volatile solid (VS) can be correlated graphically. The relationship between volatile solid to volatile solid change (VS/R) and volatile solid (VS) is most suitable for linear equations. The VS/R graph against VS on each Runs is shown in *Figures 10–12*.

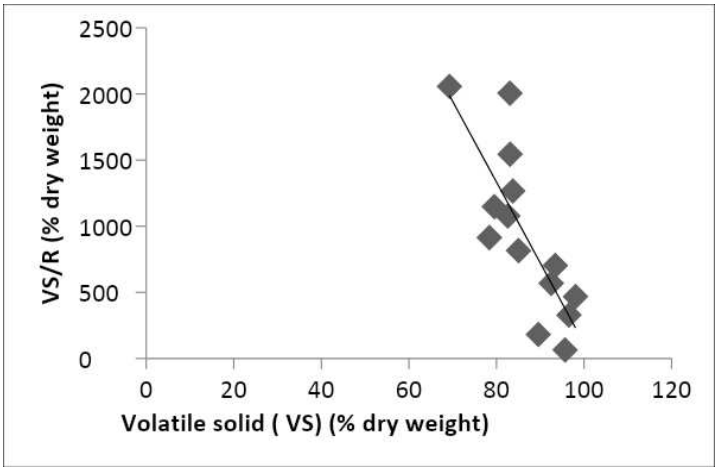

Figure 10. *VS/R against VS for Run A*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1155111566

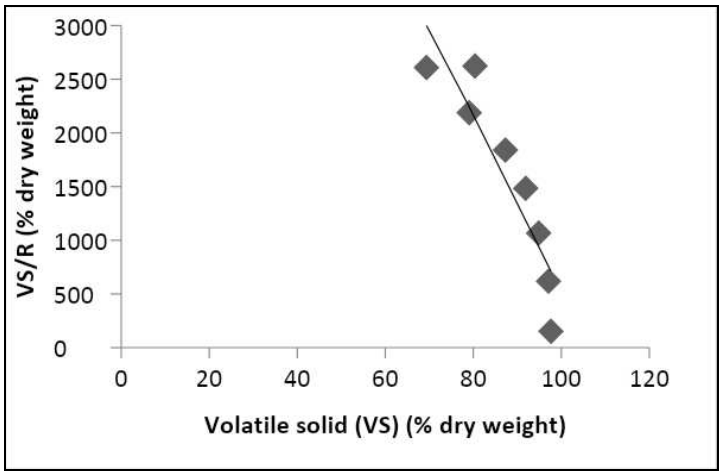

Figure 11. *VS/R against VS for Run B*

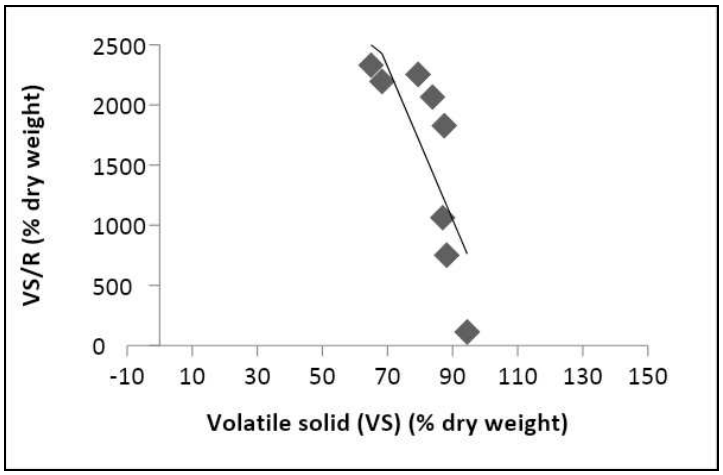

Figure 12. *VS/R against VS for Run C*

The formula for linear equations obtained from the VS/R graph against VS and the regression factor as shown in *Table 4*.

Table 4. *Linear equation for VS/R graph against VS and regression factor*

Run	Liner equation	Regression factor
A	Y = -61.042x + 6216.9	0.6423
B	Y = -82.443x + 8761.3	0.8378
C	Y = - 63.575x + 6769.3	0.6195

Based on regression factor value obtained from exponential function and linear function, it is found that Run B composting process is best in terms of volatile solids degradation process (VS). Therefore, linear function for Run B has been selected as kinetic mode for Phase composting process. The intercept and slope values obtained from the above linear equations are then considered for K_1 and K_2 values. The value of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1155111566

K_2 is calculated by inverting the value of the slope. Whereas the value of K_1 is obtained by multiplying the value of K_2 with the intercept value from the linear equation above. The conclusions on the values of slope, intercept, K_1 and K_2 are shown in *Table 5*.

Table 5. *Slope, intercept and K_1 and K_2 value*

Run	Slope	Intercept	K_1	K_2
A	61.042	6216.9	101.9572	0.0164
B	82.443	8761.3	106.0117	0.0121
C	63.575	6769.3	106.2780	0.0157
Mean			103.7517	0.0142

From *Table 5*, the value of K_1 obtained is within the range 101.957–106.2780, whereas the value of K_2 is in the range of 0.0121–0.0164. The mean values of K_1 and K_2 are 103.7517 and 0.0142 respectively. Then, the percent of error of each constant obtained is also calculated. The result of the percent of error and standard deviation as shown in *Table 6.*

Table 6*. The percent of error, mean and standard deviation of K_1 and K_2 on each run*

Run/mean/standard deviation	K_2	Percent of error K_2 (%)	K_1	Percent of error K_1 (%)
A	0.0164	15.49	101.957	1.73
B	0.0121	14.79	106.0117	2.18
C	0.0157	10.56	106.2780	2.43
Mean	0.0142	13.0275	103.7517	2.305
Standard deviation	0.00216	2.4730	2.8084	0.4805

From the results obtained in *Table 6*, it is found that the percent of error for the K_2 constant is within the range of 10.56 - 15.49% with a mean value of 13.0275%. Whereas, the maximum percent of error for the K_1 constant is 2.43% and the minimum value is 1.73% with a mean value of 2.305%. If compared to the mean values of K_1 and K_2 each recorded at 2.305% and 13.0275% respectively, it is found that the K_2 constant value is higher than K_1 and this indicates that the value of K_2 is a variable independent. This is consistent with the Michaelis Menten model, while the K_1 value is dissociation constant for a system. Meanwhile, K_2 is the variable dependent on composting system towards the microbial population found in the compost material.

The constants obtained from this experiment are also compared with previous earlier study by Whang and Meenaghan (1980), Seng (1999) and Tweib et al. (2014). K_1 and K_2 value obtained from Whang and Meenaghan (1980) study are 1.2243 and 0.0325, resepectively. The value of K_1 and K_2 from Seng (1999) study are 80.515 and 0.9029, respectively. Meanwhile K_1 and K_2 value from Tweib et al. (2014) are 81.64 and 1.0301, respectively. The value of K_1 and K_2 from this study shows a big difference compared to the value obtained from Whang and Meenaghan (1980). This difference is due to the different experiments performed. Whang and Meenaghan (1980) have used carbon fraction as a limitation indicator by using a unit of weight of carbon (gram) per weight of ash (gram) which finally the result found is dimensionless (g/g). While this study uses volatile material (VS) as an indicator parameter, expressed as a percentage unit (%) per dry weight sample. However, the similarities between this study and the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1155111566

studies conducted by Seng (1999) and Tweib et al. (2014) are using volatile material (VS) as indicator parameters, which are expressed in percentages (%) per dry weight sample. In addition, the K_1 constant value is equal to the initial value of the indicator parameter which is the percentage of volatile material. Thus, the magnitude of K_1 values in the results of this study and the study conducted by Seng (1999) and Tweib et al. (2014) is in two digits (in percent value), while the results of the study by Whang and Meenaghan (1980) are in the form of one digit.

The value of K_2 is the system variable as defined in the Michaelis-Menten Model, where this value depends on the number of microbial populations and the second stage constant reaction, k_2. Due to the function of the relationship between the total microbial population and the operating system, the K_2 value indirectly serves as an indicator of the efficiency of a composting system. Found that K_2 constant value for this study and the research done by Whang and Meenaghan (1980) is almost identical. Whang and Meenaghan (1980) have used a mixture of cow and wood dust as a compost material while this study uses EFB and POME as compost materials and carried out on a large scale. Whereas, studies conducted by Seng (1999) and Tweib et al. (1999) were conducted on a small scale, hence the value of K_2 in both studies was greater compared to this study and Whang and Meenaghan (1980) because the composting process on the laboratory scale was easier to control than the large-scale composting/pilot scale

Based on the results of the 3 Runs that have been done, it is found that the kinetic change in this study has the best mathematical expression is in Run B as *Equations 17* and *18* below:

$$y = 103.31^{-0.015x} \qquad r^2 = 0.9097 \qquad \text{(Eq.17)}$$

where y = Volatile solid material, x = time.

After *Equation 17* above is obtained, plot VS/R against VS for model is also done to get linear equations:

$$y = -82.443x + 8761.3 \quad r^2 = 0.8378 \qquad \text{(Eq.18)}$$

The K_1 value for Run B is 106.0117 and K_2 is 0.012. From the volatile kinetic results obtained from this study, two assumptions can be made i.e., the formation of simple complex mixtures and endogenous reactions are irreversible.

Conclusion

The production of sludge and solid materials in the palm oil plant, as well as the need to address the increasingly expensive disposal problems as well as the current disposal methods that potentially create contaminants and their own sludge potential as soil adapters are the contributing factors and the stimulants in the production and use of composting methods. In the composting process, optimization is an important step in obtaining an effective process and good compost quality. On average, 150 kg of EFB fibers have been used in each Runs in this experimental study. The maximum temperature (thermophilic temperature) achieved at Run A, B, C is 55°C, 43°C and 53.3°C, respectively. For the final C/N ratios of Run A, B and C respectively are 20.61, 13.06 and 14.51 respectively. Based on the C/N final value reading at each run, it can be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1155111566

concluded that all runs achieve the optimum C/N ratio. However, the lowest C/N ratio is obtained in Run B. This is compounded by the mixture in Run B using more recycle compost as well as assisting in the process of decomposition of fresh compost. Recycle compost used in this study contains a low C/N ratio of 10.3 and has matured over 1 year. In kinetic studies, volatile changes in Run B experiments are also seen to be more stable. In the determination of volatile solid kinetic for the composting process, it was found that the Michaelis Menten model was appropriate. Overall, it can be concluded that the composting process is one of the alternatives to solving the problem of solid waste dumping in palm oil plantation in an integrated solid waste management system. This method has the potential to conserve and retrieve beneficial ingredients compost with many positive features. The resulting compost is also the final product that can be used as a soil enhancer or plant fertilizer.

(Received 22nd Apr 2019; accepted 11th Jul 2019)

Abstract. In this study, a constitutive model for debris flow erosion of slope soil under the influence of barriers was derived and established based on the Bingham Model theory. The upper reaches of the Laoshan were used as a study case to build an indoor slope model and simulate the debris flow erosion of slopes. Debris flow velocity, soil erosion patterns and extent of accumulation were analyzed. The results indicated that without a barrier, debris flows maintained an accelerated motion, and loose particles moved under the action of shearing strength and subsequent slope surface erosion. Accumulation was observed as overlapping stacked slices. Under the influence of barriers, debris flows were separated and blocked, which resulted in the reduction of the velocity and quality of the moving body with two symmetrical bodies formed in the accumulation area. When the barrier was placed in a high position, debris flows were distributed early and the new velocities and impacts were smaller. Furthermore, the solids carrying capacity decreased and the slope soil depths in the most in-depth sections of the erosion pit were less variable. Therefore, the erosion competency was relatively weak, which provided better protection to the downstream slope soil.
Keywords: *Laoshan area, shearing strength, barrier, soil erosion depths, slope surface*

Introduction

Debris flows are very destructive geological disasters. Due to their shearing strength, loose materials also move, which creates secondary disasters induced by erosion. Construction projects are often destroyed. Moreover, people's lives and property safety are threatened. Therefore, it is necessary to research the mechanisms of rainfall-induced debris flows, which can facilitate a better understanding of these disasters. These models can be used to forecast, prevent, and mitigate disasters. Thus far, research on debris flow processes have focused on numerical simulations and experiments.

International scholars have established a dynamic model for debris flows based on the SH theory. For example, the DAN calculation model was proposed by Hungr and McDougall (Hungr, 2008; Hungr and McDougall, 2009), which assumes that resistance includes internal and slope resistance and considers internal forces and erosion. The model represents different motion states and the simplified model has been verified with multiple inversion analysis. He et al. (2007) studied the initiation mechanisms for corroding to a ditch using numerical simulations. The authors also discussed the influence of factors on initial velocities, such as gravity, falling gradient, and soil strength. Fan et al. (2010) simulated dynamic entrainment processes, and they found that entrainment could increase the volume of debris flow motion, making debris flows more destructive. Based on Bingham rheological theory, Zhang et al. (2012) built a debris flow model and simulated gully bed evolution to explore bed erosion deposition processes. Wang (2001) established an energy theory for debris flow movement. He also derived a theoretical formula to determine average velocity,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

which was verified by experiments. Based on small flume experiments, Liu (2006) found that under specific experimental parameters, the regression equations for velocity and range resulted in both velocity and deposition range ratios. Lin et al. (2013) used experiments to explore debris flow deposition laws over erodible beds with changes in debris flow intensity, the total amount of debris flow, channel slope, and bed material density. Han et al. (2012) examined the Lian Hua-xin and Niujuan gullies to discuss the erosion and development and evolution features of slope and gully debris flows, respectively.

Setting barriers can be an effective measure to control debris flow processes. Based on simulations and experiments, many scholars (Ma et al., 2007; Fan et al., 2010; Huang and Lu, 2013; Prieto et al., 2018) discussed barrier effects on debris flow motion. Zhou et al. (2013) conducted model tests to explore the effect of anchor-slope protection in preventing slope debris flows and macro-meso mechanisms of soil deformation. Zhao et al. (2015) studied slope sliding and debris flow evolution with and without barriers. Those studies suggest that bank erosion increases the mass and density of the debris flow.

Many studies have found that debris flows separate when passing through a barrier (Langhans et al., 2017; Zhang et al., 2018; Lee and Jeong, 2018; Ugelvig and Egholm, 2018). The barrier position and rotation angle could change the deposition areas. When the rotation angle is equal to the critical value or exceeds it, parts of debris flow are blocked, and deposition areas drastically decrease. However, most researchers have focused on the deposition process and have rarely considered the barrier effect on velocity and slope soil erosion depths. Deposition areas are often centralized places where people live in mountainous areas. The deposition range is an important parameter to categorize dangerous areas. However, research that combines deposition range and the characterization of parameters such as velocity and erosion depths in slope soil is limited. Therefore, it is challenging to analyse disaster mechanisms and risks from debris flows systematically.

At present, most experimental studies are strongly empirical, and the applicable scope of the regression formula needs further validation, which is a challenge because of their complexity in composition and variability of dynamical processes. In addition, studies combining constitutive theories on the erosion process with laboratory experiments are few.

This study derived and established a constitutive model for the evolution of debris flows with and without barriers based on the Bingham Model theory. An indoor slope model was built to experimentally simulate debris flow erosion of slope soil. The constitutive model was validated using the experimental results gathered through inversion analysis.

Material and Methods

The model includes the viscous force, turbulence intensity within the slurry, and friction and collision force between the particles during energy transfer. Slurry and slope properties, including the roughness of soil surface, are incorporated. The turbulence power of the debris flow can be ignored because of its significant viscosity. The simplified Bingham model is adopted:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

$$\tau = \tau_B + \eta \frac{dv}{dy} \quad \text{(Eq.1)}$$

where, τ is shearing strength, τ_B is yield shearing strength, η is the coefficient of viscosity, and dv/dy is the velocity gradient in the y direction.

Influencing factors, such as the concentration of debris flow, distribution of particle size, and slope, are considered. The Manning equation is used in the velocity equation; the starting velocity is expressed as follows (Shu and Fei, 2003):

$$v_0 = 1.62\left[\frac{S_v(1-S_v)}{d_{10}}\right]^{\frac{2}{3}} h^{\frac{1}{3}} J^{\frac{1}{6}} = 1.62Bh^{\frac{1}{3}} J^{\frac{1}{6}} \quad \text{(Eq.2)}$$

where, S_v is the volume concentration of debris flow, d_{10} is the lower limit of particle size, h is the depth of mud, and J is the slope. *Eq. (2)* has been verified using measured data from Jiangjia Gully and Hunshui Gully.

Constitutive model of debris flow erosion on soils without barriers

Debris flows are influenced by the friction resistance from the slope surface and internal viscous forces as they start to move. The slope surface resistance and quality of the landslide body from t_{i-1} to t_i can be expressed as:

$$\begin{cases} f_i = \mu_0\left(m_{i-1} + \dfrac{dm}{dt}\Delta t\right) g\cos\beta \\ m_i = m_{i-1} + \dfrac{dm}{dt}\Delta t \\ \Delta t = t_i - t_{i-1} \end{cases} \quad \text{(Eq.3)}$$

where, μ_0 is the friction coefficient of the slope surface, β is the slope of the flowing area, dm/dt is the velocity of the quality change, g is gravitational accelerations, f_i and m_i are resistance from slope surface and quality of debris flow at time ti, respectively. Moreover, Δt is the time that the debris flow is moving, i=1,2,3….

From t_{i-1} to t_i, the laws of conservation of energy are:

$$\begin{cases} \dfrac{1}{2}m_{i-1}v_{i-1}^2 + m_{i-1}g(Y - y_{i-1}) - m_i g(Y - y_i) - \dfrac{1}{2}m_i v_i^2 = W_f(t_{i-1} \sim t_i) + W_S(t_{i-1} \sim t_i) \\ W_f(t_{i-1} \sim t_i) = \mu_0 g\cos\beta \int_{t_{i-1}}^{t_i}\left(m_{i-1} + \dfrac{dm}{dt}t\right)dt \end{cases} \quad \text{(Eq.4)}$$

where, v_i is the velocity at time ti, Y is the initial height of the debris flow, $W_f(t_{i-1} \sim t_i)$ and $W_S(t_{i-1} \sim t_i)$ are energy consumptions to overcome resistance and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

viscous forces from the slope surface, respectively. The formula is the typical expression of the work of cohesion from t_{i-1} to t_i.

According to another expression of energy (Huang and Lu, 2013):

$$E_i = h_{ci} + \frac{v_i^2}{2g} \quad \text{(Eq.5)}$$

The energy consumption of debris flow from t_{i-1} to t_i is:

$$\Delta E = h_{ci-1} - h_{ci} + \frac{v_{i-1}^2 - v_i^2}{2g} \quad \text{(Eq.6)}$$

where, h_{ci} is the height of center of mass of debris flow at time and ΔE is energy consumption.

After combining *Eq. (4)* with *(6), Eq.(7)* is the recursive expression about v_i^2:

$$v_i^2 = \frac{v_{i-1}^2(m_{i-1}g - 1) + Am_{i-1} + B \cdot \frac{dm}{dt}\Delta t + C}{m_{i-1}g + g \cdot \frac{dm}{dt}\Delta t - 1} \quad \text{(Eq.7)}$$

where, A, B, and C are expressed as $2g^2(y_i - y_{i-1})$, $2g^2(y_i - Y)$, and $2g(h_{ci} - c_{i-1})$, respectively.

When i=1, the common expression for v_t^2 can be obtained:

$$v_t^2 = \frac{v_0^2(m_0 g - 1) + 2m_0 g^2 y + 2g^2(y - Y)\frac{dm}{dt} \cdot t + C_1}{m_0 g + g \cdot \frac{dm}{dt} \cdot t - 1} \quad \text{(Eq.8)}$$

where, C_1 is $2g(h_{ct} - h_{c0})$, t is time, and y is the y intercept.

A new equation for shearing strength can be obtained by substituting the derivation of *Eq. (8)* into *Eq. (1)*:

$$\tau = \tau_B + \eta \frac{m_t g^2}{(m_t g - 1)v_t} \quad \text{(Eq.9)}$$

where, m_t and v_t are the quality and velocity of debris flow at time t, respectively.

Similarly, the cohesion power from 0 to t can be obtained from the law of conservation of energy:

$$W_S(0 \sim t) = \frac{1}{2}m_0 v_0^2 + m_0 g Y - m_t g(Y - y) - \frac{1}{2}m_t v_t^2 - \mu_0 g \cos\beta \int_0^t (m_0 + \frac{dm}{dt} \cdot t)dt \quad \text{(Eq.10)}$$

Constitutive model of debris flow erosion on soils with barriers

The barrier is designed as an equilateral triangular prism to simplify the calculation. The length of the waist and bottom sides are l_0 and l_1, respectively. The safety height is H, regardless of the displacement and overflow over the barrier under the impact of the debris flow.

The barrier is fixed on the central axis of the slope (*Figure 1*) to reduce the variables' interference on the constitutive model based on the barrier position. The distance from the barrier to the side of the plat is x_1 (note: the physical quantities without vector symbols are scalars, such as t_1 and x_1). The energy consumption to overcome the friction from the barrier is ignored, because the roles for shunting and obstructing are stronger than the buffering role.

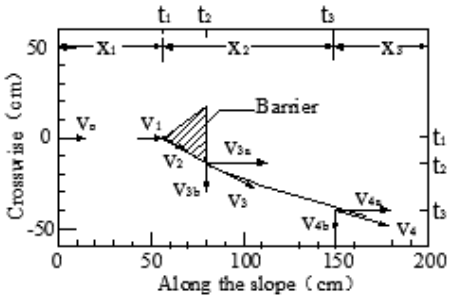

Figure 1. *Velocity diagram for a barrier on the axis of the slope*

The movement before a debris flow contacts the barrier is the first phase, followed successively by movement along the barrier and after separating from it.

According to the decomposition principle for velocity, v_1 is decomposed into two symmetrical components at time t_1 (*Figure 2a*):

$$v_2 = \frac{v_1}{2\cos\frac{\theta}{2}} \tag{Eq.11}$$

where, θ is the apical angle of the triangle.

Similarly, the quality has an equal distribution:

$$m_2 = \frac{1}{2}m_1 \tag{Eq.12}$$

From t_1 to t_2, the law of conservation of energy can be expressed as follows:

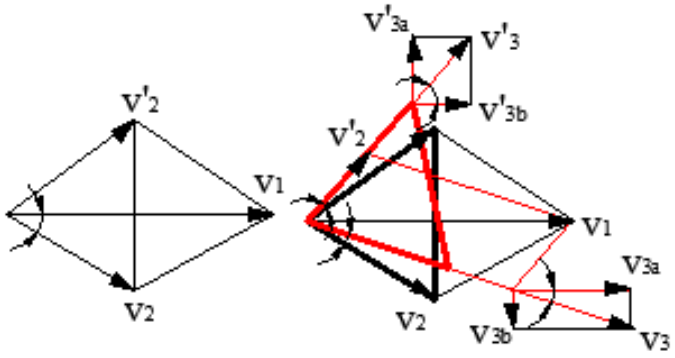
$$\begin{cases} \frac{1}{2}m_2{v_2}^2 + m_2 g(Y - y_2) - \frac{1}{2}m_3{v_3}^2 - m_3 g(Y - y_3) = W_f(t_1 \sim t_2) + W_S(t_1 \sim t_2) \\ m_3 = m_2 + \frac{dm}{dt}(t_2 - t_1) \\ W_f(t_1 \sim t_2) = \mu_0 g \cos\beta \int_{t_1}^{t_2} (m2 + \frac{dm}{dt}t)dt \end{cases} \tag{Eq.13}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

where, v_j, m_j and y_j are velocity, quality and y intercept after separating from the barrier at time t_{j-1}, respectively. Wherein, j=2, 3…..

$$v_3^2 = \frac{v_2^2(m_2 g - 1) + Am_2 + B \cdot \frac{dm}{dt}(t_2 - t_1) + C}{m_2 g + g \cdot \frac{dm}{dt}(t_2 - t_1) - 1} \quad \text{(Eq.14)}$$

where, A, B and C are expressed as $2g^2(y_3 - y_2)$, $2g^2(y_3 - Y)$, and $2g(hc_3 - h_{c2})$, respectively; h_{cj} is the height of the center of mass of debris flow at time t_{j-1}.



(a) (b)

Figure 2. *Velocity diagrams for a barrier on the slope: (a) along the axial; (b) Rotated* ϕ

From t_2 to t_3, the trajectory of the debris flow is approximately a parabola. The slope surface resistance consists of resistance on the slope axis direction and lateral resistance. The law of conservation of energy can be expressed as follows:

$$\begin{cases} \frac{1}{2}m_3 v_3^2 + m_3 g(Y - y_3) - \frac{1}{2}m_4 v_4^2 - m_4 g(Y - y_4) = W_f(t_2 \sim t_3) + W_S(t_2 \sim t_3) \\ m_4 = m_3 + \frac{dm}{dt}(t_3 - t_2) \\ W_f(t_2 \sim t_3) = (\mu_0 + \mu_1) g \cos\beta \int_{t_2}^{t_3} \left(m_3 + \frac{dm}{dt} t \right) dt \end{cases} \quad \text{(Eq.15)}$$

where, μ_1 is coefficient of friction of lateral resistance.

The velocity after separating from the barrier at time t_3 can be obtained by combining *Eq. (14)* with *Eq. (15)*:

$$v_4^2 = \frac{v_3^2(m_3 g - 1) + Am_3 + B \cdot \frac{dm}{dt}(t_3 - t_2) + C}{m_3 g + g \cdot \frac{dm}{dt}(t_3 - t_2) - 1} \quad \text{(Eq.16)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

where, A, B, and C are expressed as $2g^2(y_4-y_3)$, $2g^2(y_4-Y)$, and $2g^2(y_4-Y)$, respectively.

Higher values of θ result in longer lateral distances. Thus, the scope of the 'Not erosion zone' is large, which means that the protected areas in the middle and lower reaches are broad.

A new equation for shearing strength when debris flow passes the barrier can be obtained after substituting the derivation of *Eq. (16)* into *Eq. (1)*:

$$\tau = \tau_B + \eta \frac{m_P g^2}{(m_P g - 1)v} \quad \text{(Eq.17)}$$

where, m_P and v are the quality and velocity of the debris flow at t, respectively; wherein, m_P can be expressed as $m_0/2 + (t3 - t_1/2)\,dm/dt$.

Based on these equations, the change in the barrier position and rotation angle can be quantified (*Figure 3*).

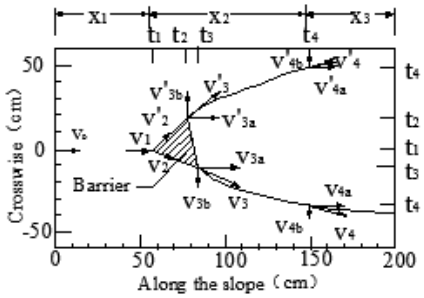


Figure 3. *Velocity diagram for a barrier rotating ϕ degrees*

Assuming that the distance from plat to the vertex of barrier is fixed (x_1), the degrees of counterclockwise rotation that centers the barrier vertex is ϕ. The velocity will be decomposed into v_2 and v'_2 when the debris flow contacts the barrier according to the sine theorem:

$$\frac{v_1}{|\sin(\pi-\theta)|} = \frac{v_2}{\left|\sin(\frac{\theta}{2}+\phi)\right|} = \frac{v'_2}{\left|\sin(\frac{\theta}{2}-\phi)\right|} \quad \text{(Eq.18)}$$

The quality of the moving body on the left is not equal to the right under the influence of rotation. The volume is expressed as $V = \int dV = \iiint da \times db \times dh$, and the qualities of moving body on both sides at time t_1 are:

$$\begin{cases} m_2 = (m_1 - D)/2 \\ m'_2 = (m_1 + D)/2 \end{cases} \quad \text{(Eq.19)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

where, D is $\rho \tan\phi \iiint db \times db \times dh$.

According to the law of conservation of energy, a left moving body from t_1 to t_3 and from t_3 to t_4 can be expressed as follows, respectively:

$$\begin{cases} \frac{1}{2} m_2 v_2^2 + m_2 g(Y - y_2) - \frac{1}{2} m_3 v_3^2 - m_3 g(Y - y_3) = W_f(t_1 \sim t_3) + W_3(t_1 \sim t_3) \\ m_3 = m_2 + \frac{dm}{dt}(t_3 - t_1) \\ W_f(t_1 \sim t_3) = \mu_0 \cos\beta \int_{t_1}^{t_3} \left(m_2 + \frac{dm}{dt} t \right) dt \end{cases} \quad \text{(Eq.20)}$$

$$\begin{cases} \frac{1}{2} m_3 v_3^2 + m_3 g(Y - y_3) - \frac{1}{2} m_4 v_4^2 - m_4 g(Y - y_4) = W_f(t_3 \sim t_4) + W_S(t_3 \sim t_4) \\ m_4 = m_3 + \frac{dm}{dt}(t_4 - t_3) \\ W_f(t_3 \sim t_4) = (\mu_0 + \mu_{1)} \cos\beta \int_{t_3}^{t_4} \left(m_3 + \frac{dm}{dt} t \right) dt \end{cases} \quad \text{(Eq.21)}$$

The velocity of the left body at time t_4 after separation from the barrier can be obtained by combining *Eq. (20)* with *Eq. (21)*.

$$v_4^2 = \frac{v_3^2(m_3 g - 1) + A m_3 + B \frac{dm}{dt}(t_4 - t_3) + C}{m_3 g + g \cdot \frac{dm}{dt}(t_4 - t_3) - 1} \quad \text{(Eq.22)}$$

where, A, B, and C are expressed as $2g^2(y_4 - y_3)$, $2g^2(y_4 - Y)$, and $2g(h_{c4} - h_{c3})$, respectively.

Identically, a new formula for the shearing strength of the left moving body at time t can be expressed as follows:

$$\tau = \tau_B + \eta \frac{m_1 g^2}{(m_1 g - 1) v} \quad \text{(Eq.23)}$$

where, m_l is $(m_0 - D)/2 + (dm/dt)(t - t_1/2)$.

Similarly, the velocity of the right body at the same time is:

$$v'^2_4 = \frac{v'^2_3(m'_3 g - 1) + A m'_3 + B \frac{dm}{dt}(t_4 - t_2) + C}{m'_3 g + g \cdot \frac{dm}{dt}(t_4 - t_2) - 1} \quad \text{(Eq.24)}$$

where, A, B, and C are expressed as $2g^2(y'_4 - y'_3)$, $2g^2(y'_4 - Y)$, and $2g(h'_{c4} - h'_{c3})$, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

The shearing strength of the right moving body at the same time is:

$$\tau = \tau_B + \eta \frac{m_r g^2}{(m_r g - 1)v} \quad \text{(Eq.25)}$$

where, m_r can be expressed as: $(m_1 + D)/2 + (dm/dt)(t - t_1)$

The adjusted rheological model under the influence of a barrier is identical to the condition without it. Therefore, the shearing strength can be expressed as:

$$\tau = \tau_B + \eta \frac{mg^2}{(mg - 1)v} \quad \text{(Eq.26)}$$

The qualities with the three conditions can be deduced as followings:

$$m = \begin{cases} m_0 + \dfrac{dm}{dt} t & (without\ barrier) \\ \dfrac{m_0}{2} + \dfrac{dm}{dt}(t_3 - \dfrac{t_1}{2}) & (barrier\ rotates\ along\ axies) \\ \dfrac{m_0 - D}{2} + \dfrac{dm}{dt}(t - \dfrac{t_1}{2}) & (body\ on\ left\ side) \\ \dfrac{m_0 + D}{2} + \dfrac{dm}{dt}(t - t_1) & (body\ on\ right\ side) \end{cases} \quad \text{(Eq.27)}$$

Without a barrier, debris flows accelerate motion under the resultant force. According to *Eq. (8)*, the impact force increases along with the ever-increasing quality, and the capacity to erode slope soil increases. However, the overall shearing strength decreases as a result of weak liquidity. As a result, the erosion depths shallow. After setting a barrier, debris flows will be separated as they make contact with it. Comparing *Eq. (8)* with *Eq. (22)*, the velocity with a barrier is much smaller than others. The acceleration decreases along with a decrease in quality, and the impact decreases. Eventually, slope soil erosion downstream weakens.

Results

Figure 4 shows a plan view map of the Laoshan area in Nanjing, China, the study area. It locates at 32°07'3.55"N and 118°37'42.30"E. The area of interest trend is from southwest to northeast and the western section is higher and steeper than other areas. As shown in *Figure 5*, the mountain profile consists of bed rock on the bottom, the gravel layer and the soil layer. The layer thickness ration is about 3:2:9. Most area of the slope are steep, from 30 to 60. It has a high incidence of debris flow under rainfall that will clog roads and other construction facilities.

Configuring the indoor soil model

A 2.1 m long, 4 m wide, and 2 m high slope soil model was built inside (*Figure 6*). The reduced scale represents the natural proportions of the soil structure. A 30-cm-thick bevel face with a gradient of 5° was built on the bottom as the bedrock using cement

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

mortar. The model soil slope was composed of a 20-cm-deep sand stratum with an overlying 90-cm-deep soil stratum. There is a flat crest at the top and flat base near the toe of the slope. The flat base is fully open. In addition, a 1.93 m long, 0.5 m wide, and 0.4 m high storage tank was placed on the flat crest. The storage tank had a 30° slope inside which could accommodate 0.386 m^3 slurry that could be released all at once. When the door opened, the slurry flowed along the ramp way.

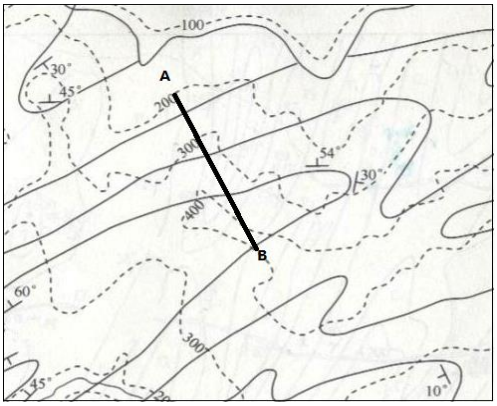

Figure 4. *Plan view map of the study area (1:25000)*

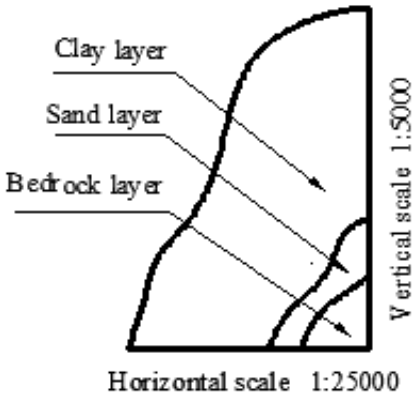

Figure 5. *Exploration section line map*

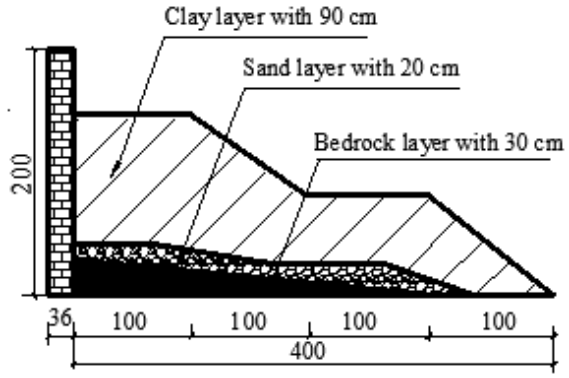

Figure 6. *Cross-section of the model slope indicating the thicknesses of each stratum*

The model slope was fully consolidated under natural conditions in order that the soil was returned to the pre-disturbance state. The soils used in the model experiments were collected from the research area to maintain natural conditions. Before each test, various monitoring indicators were measured. Experiments began once each index indicated essential stability. And embedded probes were placed at eight monitoring locations on the upper and lower layers, as shown in *Figure 7*. Points 1 and 4 were on the middle of the platform; points 2 and 5 were on the side edges; points 3 and 6 were in the middle of the slope; and points 7 and 8 were near the toe.

After scaling, soils from the corresponding locations in the study area were collected to test the mechanical properties. Slope sliding and the debris flow detection system was determined to measure the shearing strength of the experimental and undisturbed soils (*Figure 8*). The shearing strength of the undisturbed soils in the upper layer was higher

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

than that in the lower layer. According to *Figure 8*, the shearing strength at monitoring points 1, 2, 3, and 8 plotted along line. Based on these results, the shearing strengths of experimental soils were close to those of the undisturbed soils. Therefore, the accuracy of the model was guaranteed.

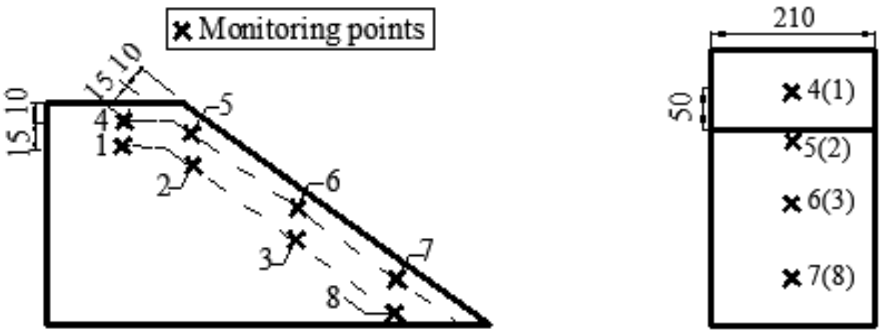

Figure 7. *Locations of monitoring points:(a) side view; (b) top view*

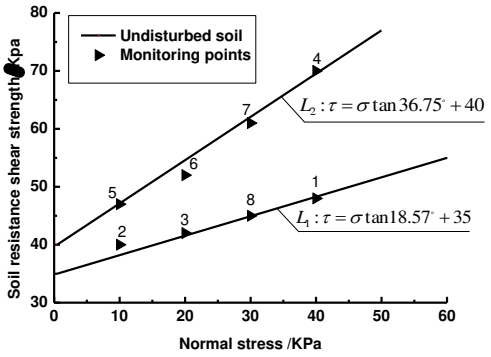

Figure 8. *Lines of shear strength*

Based on soil thickness and the maximum erosion depth without a barrier, a 30-cm-high barrier to form a 'Not erosion zone' was used in the experiments. Along the bottom, each side was 30 cm long and it was buried 10 cm deep in the soils. The barrier positions and rotation angles on the model slope are shown in *Figure 9*.

Figure 10 shows the coordinates used in the experiments. The debris flow process induced by rainfall on a 200-cm-long slope with a 45° slope was studied. The slope was 140 cm high and 140 cm wide (horizontal), with observation points at 7 cm intervals starting at 0 on the Y coordinate axis.

The density of slurry was 20.1 kN/m^3. A 45° slope was used for the movement area. The barriers were placed at L/3 and L/2 (L is the length of slope) along the slope, and barriers' rotation angles of 0° and 15° along axis were considered. Several trials were performed under these four conditions. *Table 1* shows the set of variables for each condition category.

Analysis of debris flow evolution

In the experiment, debris flows began with a nonzero initial velocity, and the velocity along the slope was faster than other directions, as shown in *Figure 11*. The gravity,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

slope friction and internal viscous force changed as the amount of solid material carried along the slope increased. Particle separation was generated during the process due to the incorporation of large particles, which hindered an increase of velocity. This resulted in a nonlinear acceleration curve and overall change in shearing strength of the debris flow.

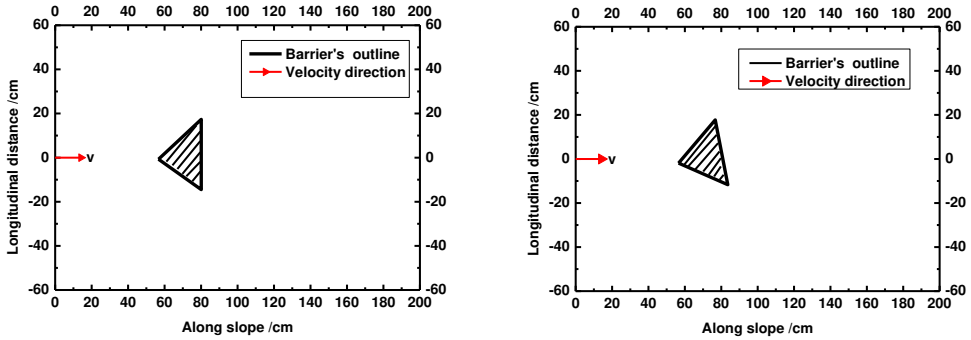

Figure 9. *Schematic diagram of the barrier positions and rotation angles:(a) barrier without rotation; (b) barrier rotated* ϕ

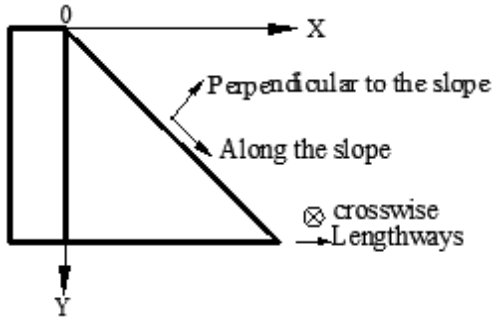

Figure 10. *Schematic diagram showing the coordinate directions*

Table 1. *Variables for each condition*

Conditions	Density (kN/m^3)	Slope (°)	Barrier	
			Position	Angle (°)
Condition Ⅰ	20.1	45	no	no
Condition Ⅱ	20.1	45	L/3	no
Condition Ⅲ	20.1	45	L/3	15
Condition Ⅳ	20.1	45	L/2	0

According to the experimental and calculated results, curves showing the relationships between velocity and time were generated, as shown in *Figure 12*. Conditions (II), (III), and (IV) were used to evaluate the right side of the flow surface. Based on the $v-t$ curve and calculations, the relationship between shearing strength and time is shown in *Figure 13*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

Figure 11. *Debris flow patterns*

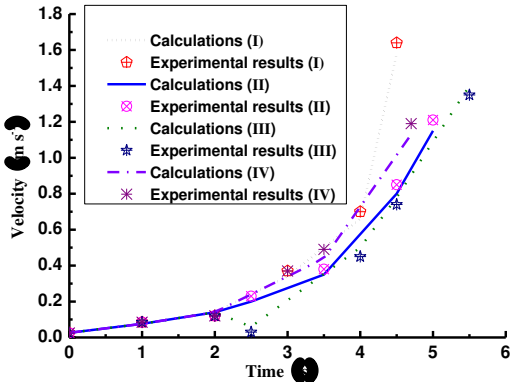

Figure 12. *Velocity-time curves for different conditions*

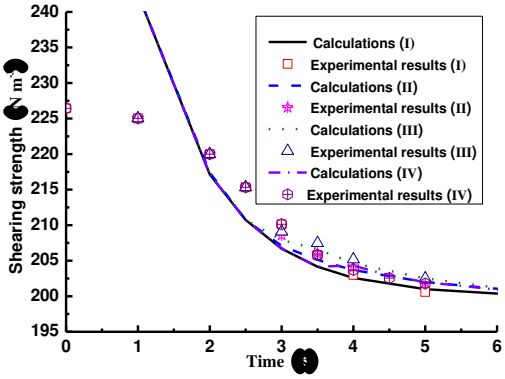

Figure 13. *Shearing strength-time curves for different conditions*

Figure 12 shows that under Condition (I), the debris flows showed accelerated motion with a nonzero initial velocity, with 2 s and 4 s as significant turning points. Loose material was carried by shearing strength along the slope surface, with an increasing impact force. The erosion capacity was enhanced and the velocity reached a peak of 1.6 m/s, when the debris flow arrived at the toe of the slope at 4.5 s. Comparing Conditions (I), (II) and (III) in *Figure 13*, after contacted with the barrier at 2 s, the velocity decreased. The velocity of Condition (II) was almost constant at 2.5 s, because

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

the decomposition generated it under a force equal to the fundamental force. However, the acceleration decreased with a reduction in quality, reaching a lower velocity at the same time as Condition (I). Under Condition (III), the barrier diversion decreased the velocity 0.1 m/s at 2.5 s, and velocity of rotation (right side) was significantly faster than the other side (*Figure 2b*). Simultaneously, the quality also changed so that it was more extensive on the right side. The slower the 'initial velocity', the lower the kinetic energy, and weak soil erosion was confirmed in both the calculations and experimental results.

Comparing Conditions (II) and (IV) in *Figure 12*, when the barrier was close to the toe of slope, the original movement pattern was maintained longer and contact with the barrier was later. Under condition (II), the debris flow began a new accelerated motion when it made contact with the barrier at 2 s. The velocity under Condition (I) was the same as under Condition (IV) and both were greater than the acceleration under Condition (II) from 2 s to 3.5 s. The velocity under Condition (IV) reached 0.5 m/s at 3.5 s. This velocity was unchanged at contact with the barrier, and then accelerated along it. At this point, the maximum numerical difference in velocity between Conditions (II) and (IV) was 0.1 m/s. Subsequently, Condition (IV) was greater than Condition (II). Therefore, the impact force upstream of L/3~L/2 under Condition (IV) was greater than that under condition (II), and soil erosion in the region was significant, indicating that the protective effect of the downstream region was weaker than that in Condition (II). These conclusions were the same in both the calculations and experimental results.

Figure 13 shows a non-linear negative correlation between shearing strength and time. Comparing *Figure 12* with *Figure 13*, four conditions reached a maximum shearing strength at 1 s. As the debris flow process advanced, loose particles increased. In spite of the increasing velocity, the overall shearing strength decreased. The curve under Condition (I) flattened after 4 s and the head of the debris flow was close to the slope toe. As the liquidity worsened, the overall shearing strength weakened and approached the yield stress. Influenced by the barrier position, the velocities at the head both decreased after 2.5 s and 3.5 s under Conditions (II) and (III). The overall shearing strength declined, flattened out after 5 s and 6 s, and consistently approached the yield stress. The curve of the shearing strength under Condition (III) was gentler than that under Condition (II). The overall energy consumption was large and the shearing strength decreased under the influence of the barrier. Both the ability to carry loose particles and erosion weakened. Therefore, variations in velocity and shearing strength under Condition (III) were moderate.

In summary, debris flows slowed after contact with the barrier. With quality deallocation, the impact force weakened and the surface erosion in the downstream area decreased. When the barrier was in the high position, the weakening effect was clear.

Furthermore, a greater rotation angle resulted in the experimental results were in agreement with calculations.

Analysis of soil erosion depths after debris flows

To explore the soil erosion effect on erosion depths, the right side was evaluated under Conditions (IV), (V) and (VI). *Figure 14* shows the cross-sectioned positions. Based on the experimental data, variations in slope surface erosion patterns under different conditions are shown in *Figure 15*, which were similar under all the evaluated conditions. The upper part of the model slope was shallow, while the center at 56 cm

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

appeared deeper than other areas. Erosion depths shallowed in the lower part of the slope. The slopes differed between the upper and lower segments: steep in the upper (49.3°) and more moderate in the lower (36.5°). Debris flows were in a state of accelerated motion in the movement area. Loose material on the pathway surface moved under the influence of shearing strength, which resulted in the surface erosion. The mechanism for erosion was an increase in the capacity of carrying solids at a certain velocity. This erosion was also associated with a reduction in overall moisture content and higher viscosity. Turbulent flow was unusual at high viscosity but could carry more surface materials away. Therefore, the erosion ability would weaken after an increase in density.

Figure 14. *Cutting positions for different conditions: (a) with barrier; (b) without barrier*

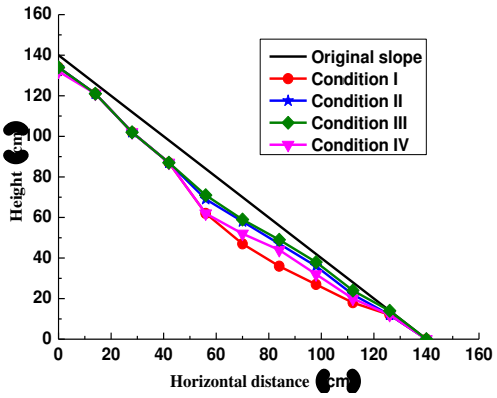

Figure 15. *Variations in slope surface erosion depths for different conditions*

Within the horizontal distance from 0 to 56 cm, the depth variations were consistent for the four conditions. Soils were 5 cm deep from approximately 0 to 40 cm after erosion, and gradually deepened from 40 to 56 cm. Depth variations under Conditions (I) and (II) were consistent and more precise than that under the other conditions. Variations were moderate under Condition (II) and most gentle under Condition (III). At a horizontal distance of 40 cm, debris flows had a resolvable velocity and earlier quality distribution under the influence of the barrier compared to Condition (II).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

Subsequently, on both sides of the moving body, new erosion was initiated with the weak force. The overall shearing strength was small under Condition (II). Therefore erosion depths were significantly less than that under Conditions (I) and (IV). Comparing Conditions (III) and (II), the areas affected on the sides were different, induced by the barrier rotation. As a result, distributions in quality and velocity were also unequal. Although the quality under Condition (III) was greater than that under Condition (II), the overall kinetic energy was smaller. Therefore, the shearing strength was smaller and the ability to carry solid material was weaker under Condition (III). This result is shallower in the curve of erosion depths under Condition (III) than under Condition (II). In the horizontal distance from 56 to 140 cm, the debris flow separated under the influence of the barrier under Condition (IV). Its initial kinetic energy was small and erosion ability was weak, so that the soil depths were shallower than those under Condition (I). The velocity under Condition (IV) was much larger than that under Conditions (II) and (III), hence the curve of the slope surface erosion patterns under Condition (IV) was lower than that under Conditions (II) and (III).

Based on the comparative analysis, the following conclusions were reached: a greater rotation angle resulted in a smaller 'initial kinetic energy' on the side of rotation, weaker overall shearing strength, and capacity for carrying soil. Therefore, appropriate position placement and rotation angle of the barrier will help protect downstream areas. More broadly, the slope line becomes gentle after erosion. A comparison of the experimental results with calculations is provided in *Figure 12*.

Analysis of deposition range after erosion

The head of the debris flow decelerates after arriving at the horizontal plane, while the tail maintains acceleration. However, the tail decelerated rapidly after reaching the ramp exit. *Figure 12* shows the deposition range under different conditions.

When the head of the debris flow reached the slope toe, the velocity peaked. Deposition began when the slope decreased. Influenced by strong friction from the ground, the power components decreased, and longitudinal velocity declined. Because the ground was flat, the boundary constraints in the horizontal direction disappeared and a transverse circulation was generated. The slurry spread and fan bodies fully developed because the flow was unobstructed. In addition, because of complex transverse momentum, the internal resistance of the slurry increased. Eventually, deposition formed under the influence of the viscous force and ground friction.

Figure 16 shows that the depositions all formed lap alluvial fans. Two alluvial fans developed under Conditions (II), (III), and (IV). When the barrier was on the centerline of the slope, this was the point of debris flow contact, which resulted in symmetric split-flows. Moreover, the deposition bodies under Conditions (II) and (IV) were approximately symmetrical.

Discussion

Comparing Conditions (II) and (IV), the single alluvial fan was narrow and long under Condition (IV), but wide and short under Condition (II). The maximum length, width, and thickness of the deposition were 52 cm, 40 cm, and 12 cm under Condition (IV), respectively. The corresponding values were 86.5%, 125%, and 142% of that under Condition (II). The deposition points of the maximum thickness under Conditions (IV) and (II) were located at the leading edge, at 28 cm and 35 cm, respectively. A low

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1156711585

barrier position resulted in a long acceleration time. Therefore, when it reached the horizontal plane, the vertical velocity was large, and the fan could develop fully. Therefore, the position of the maximum deposition thickness was far from the exit ramp.

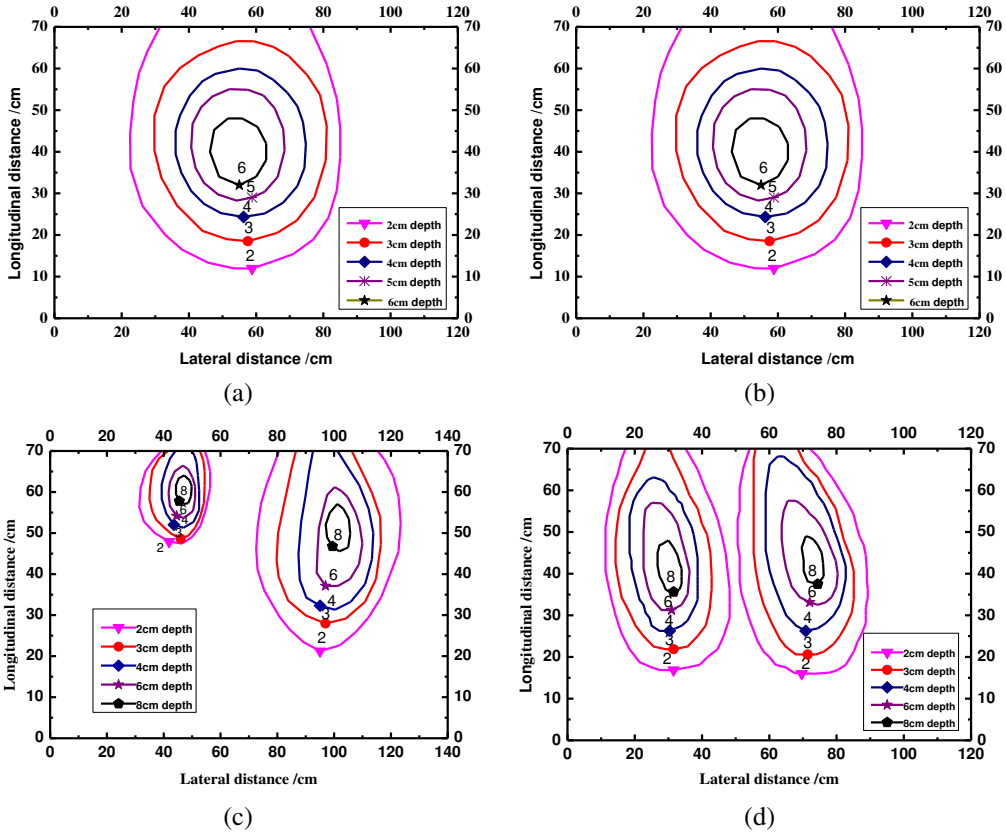

Figure 16. *Accumulation under different conditions: (a) condition (I), (b) condition (II), (c) condition (III), and (d) condition (IV)*

Comparing Conditions (II) and (III), the barrier rotated counterclockwise along the axis was examined. The effective contact area and quality on the right side were larger than that on the left side. The proportional change was approximately 1:2. The maximum length and width of deposition on the left under Condition (III) were 20 cm and 25 cm, respectively. On the right side, the corresponding values were 5/2 and 8/5 times than that on the left. The deposition area was twice as large as that of the left, in agreement with the calculated values. Thus, a greater angle resulted in a more significant quality of the right moving body. The high lateral velocity component resulted in longer movement time in the lateral direction. As a result, the space between the deposition bodies was large and the quality (on the right side) of the deposition body on the rotating direction (reverse) was high. The results also showed that the deposition area ratio was approximately equal to the quality ratio between the left and right for the moving body.

Conclusions

This study derived and established a constitutive model for slope soil erosion due to the debris flow with and without barriers based on the Bingham Model theory. This constitutive model was established based on Bingham Model velocities and equations under Conditions of different barrier positions and rotations. Equations for the modified Bingham Model were provided under three Conditions.

The upper reaches of the Laoshan was used as the study case to build an indoor slope model and simulate debris flow erosion processes. The experimental results were in agreement with calculations. Based on the constitutive equations, predictions of the soil erosion depths and deposition range after erosion were more accurate. Expressions for the shearing strength were also verified through experiments.

The buffering effect improved as the barrier and edge of platform were moved closer. In these Conditions, the shearing strength weakened, and then the damage in the downstream region due to soil erosion also decreased. A greater rotation angle also weakened the damage in the direction of rotation. Therefore, interception facilities should be built on the upstream slope and the rotation angle based on the characteristics of the active region downstream should be considered. These efforts will result in the optimal interception, diversion, and weakening of slope erosion.

In future research, we will focus on the secondary disasters of debris flow because debris flow is a very destructive geological disaster. Loose material moves in response to debris flow's shearing force, thereby creating a secondary disaster induced by erosion. Rainfall is the main reason for slope instability, which leads to large-scale landslides.

Abstract. This study was carried out to evaluate ecological restoration status of restored coal gangue pile in Shanxi Province, China, using ecological restoration status index (ERSI) based on a dynamic plant-soil system. ERSI was a unitless value that indicated the status of ecological restoration in the restored site. Five-year dynamics of the plant-soil system were monitored in the restored coal gangue pile at Sima Coal Mine of Lu'an Group, Changzhi, Shanxi, China, from 2009 to 2013. The fixed plots were established based on the chronosequence (space-for-time). The natural secondary community was selected as the reference site. The parameter system for evaluation of ecological restoration status was established on the basic characteristics of the plant community and soil physicochemical properties. Principal component analysis (PCA) was employed to derive ERSI. The first year was taken as the benchmark year. Except for year 2, the ecological restoration status in years 3 to 5 of the recovery and reference site were better than that in the benchmark year. Overall, the ERSI value increased with recovery age during the early stage of recovery. With recovery age, the uncertainty of ERSI showed decreased trend by Monte Carlo simulation (MCS).
Keywords: *ecological restoration status index, soil property, plant community, Monte Carlo, early stage*

Introduction

Soil properties and plant community characteristics are two critical milestones of any restoration plan (Orozco-Aceves et al., 2017; Li and Liber, 2017). In a plant-soil system, plants and soil are interdependent (Krumins et al., 2015). Soil development is necessary to support plant growth (Orozco-Aceves et al., 2017). In turn, plant growth can improve the soil properties (Ahirwal et al., 2017; Li and Liber, 2017). Therefore, it is essential to evaluate the ecological restoration status through both aspects of plant and soil. How should the parameter system of ecological restoration status evaluation based on a plant-soil system be established for a restored site? How should the restoration status of a restored site in every year of recovery be scientifically evaluated? These questions are still debated by researchers of restoration ecology. Thus, many current situation evaluations of ecological restoration status (Rossini-Oliva et al., 2016) have been reported, but they are insufficient dynamic evaluations of ecological restoration

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1158711604

status base on chronosequence. Moreover, these current situation evaluations have mostly focused on a particular aspect of the plant-soil system, such as plant community characteristics or soil physical or chemical properties (Gomez-Ros et al., 2013) but are insufficient when aiming at the plant-soil system.

Many evaluation parameters including qualitative parameters (e.g., habitat complexity) and quantitative parameters (e.g., vegetation coverage) have been presented. There are some recognized evaluation parameters, such as species diversity, plant biomass, vegetation coverage, soil density, total porosity, field capacity, organic matter content, TN, available nitrogen, total phosphorus, AP, and pH (Ott and Van Aarde, 2014; Licina et al., 2013; Parraga-Aguado et al., 2013; Anawar et al., 2013; Bodlák et al., 2012). However, the parameters of basic plant community characteristics (such as the index of growth and decline of species, community similarity, and community stability) are insufficient for ecological restoration status evaluation. The parameter system of evaluation for ecological restoration status is still not systemic (Liu, 2011).

Evaluation methods are varied. Single evaluation methods and combination evaluation methods are usually used for evaluations. The analytic hierarchy process (AHP), fuzzy comprehensive evaluation method (FCE), principal component analysis (PCA), clustering analysis and gray correlation evaluation, among others (Gomez-Ros et al., 2013), are single evaluation methods. AHP-FCE, PCA-AHP, and PCA-TOPSIS (Hao et al., 2016; Zhao et al., 2014; Bouzon et al., 2016) are combination evaluation methods. Based on the way of determining the weight of parameters, these methods are divided into three categories: subjective assignment value (e.g., experts scoring method, AHP), objective assignment value (e.g., PCA, entropy value method), and comprehensive assignment value (e.g., FCE). These methods include the following three features in selecting recovery goals for ecological restoration status evaluation.

Take existing standards as the recovery goal. Zhang et al. (2007) took the figure of 1/100 land resources in the People's Republic of China as a grading standard. The soil suitability evaluation hierarchy of vegetation restoration in a coal gangue pile was divided into 4 levels: very suitable, suitable, barely suitable, and temporarily not suitable. By referring to the degree of land desertification, soil wind erosion intensity grading and the secondary general survey of soil data, Yao and Yang (2014) divided the degree of mine ecological restoration status into four levels: perfect, fine, average, and low.

Take a certain ideal status as the recovery goal. Zhao et al. (2014) set evaluation grades with a relatively proximity degree between soil quality and the worst state. The closer the value was to 1, the closer to the ideal evaluation object and the higher the evaluation grade were, but the lower the evaluation level was.

Take natural secondary communities or communities without human disturbance as the main recovery goal. Lacking long-term dynamic monitoring and mechanism research of the plant-soil system (Tripathi et al., 2016), these recovery goals are unscientific to some extent (Mark et al., 2012). Whether these recovery goals are optimal is usually questionable.

The evaluation of ecological restoration status based on plant-soil systems is important to estimate the restoration status of restored sites, so establishing a parameter system for the ecological restoration status is essential (Pietrzykowski and Chodak, 2014). In the present research, the parameter system was established on the basic plant community characteristics and soil physicochemical properties. Based on the parameter

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1158711604

system, an integrated 'ecological restoration status index (ERSI)' could be developed by principal component analysis and used to evaluate the ecological restoration status quantitatively based on the chronosequence in a restored coal gangue pile. Moreover, the first year was taken as the benchmark year, the recovery goal was not specifically selected. It will be expected that if the ERSI value in one year is below that of the benchmark year, the ecological restoration status in this year is worse than the benchmark. Conversely, if the ERSI value in another year is above that of the benchmark year, the ecological restoration status in this year is better than the benchmark (Mukhopadhyay et al., 2014). It was predicted that the ERSI value would increase with recovery age in the early stage of recovery (Mukhopadhyay et al., 2014; Orozco-Aceves et al., 2017; Hao et al., 2015). This study was carried out to evaluate ecological restoration status of restored coal gangue pile in Shanxi Province, China, using ERSI based on a dynamic plant-soil system.

Material and methods

Study site

The study site is representative ecological restoration area in north of China. The study was conducted in the restored coal gangue pile at Sima Coal Mine of Lu'an Group, Changzhi, Shanxi, China, from 2009 to 2013 (*Fig. 1a*). The climate is temperate, with a 9 °C mean and a -29 °C minimal annual temperature. The frost-free period is 160 days. The annual rainfall is approximately 340 mm to 833 mm, and the annual evaporation capacity is approximately 1,558 mm. The original soil type was loess-like calcareous soil. The soil erosion modulus was from 500 to 1,000 $t \cdot (km^2 \cdot a)^{-1}$. The original landforms were mainly ravines covered by native secondary plants, such as *Bothriochloa ischaemum*, *Artemisia lavandulaefolia,* and *Melilotus officinalis* (*Fig. 1b*).

The fixed plots were established based on the chronosequence (space-for-time) (Mudrák et al., 2016; Alvey et al., 2003; Elgersma, 1998; Hao et al., 2016). The restored coal gangue pile consisted of three platforms with a stair-step shape established in 2009, 2010 and 2011 (*Fig. 1c*). The area of each platform was 1,500 m^2 (50 m long, 30 m wide). The total area of the three platforms was 4,500 m^2. The altitude difference between adjoining platforms was 10 m. The restoration procedure included forming and leveling the surface of each platform. During the forming process, the coal gangue layer and soil layer were alternated in stacking. Above each coal gangue layer, there was a soil layer. The thickness of each coal gangue layer was 3 m. The thickness of each soil layer was 50 cm. The last layer was the soil layer with a thickness of 80 cm. The soil was taken from the surrounding loess-like calcareous soil. After leveling the surface of each platform, *Populus tomentosa* (no canopy, 3.5 m height) was grown on each platform. The distances between the arbors and rowledges were 1.5 m and 2 m, respectively. Herbs maintained spontaneous recovery after trees were planted.

There were three sample plots. Each sample plot (400 m^2) consisted of 16 tree subsamples (area of each tree subsample = 25 m^2) established at the middle of each platform (*Fig. 1d*). 48 tree subsamples were set. An area of 1 m^2 was set at the left corner of each subsample for the herb sample. Each sample plot consisted of 16 herb samples. 48 herb samples were set. The reference site was a native secondary community with dominate species *Artemisia brachyloba*. The distance between the reference site and the restored coal gangue pile was approximately 1,000 m. Six samples (area of each sample = 25 m^2) were in the reference site on the north of the coal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1158711604

gangue pile using GPS. The contents of investigation including basic plant community characteristics, soil physical properties and soil chemical properties in each sampling unit were repeated each year during the summer (August) from 2011 to 2013.

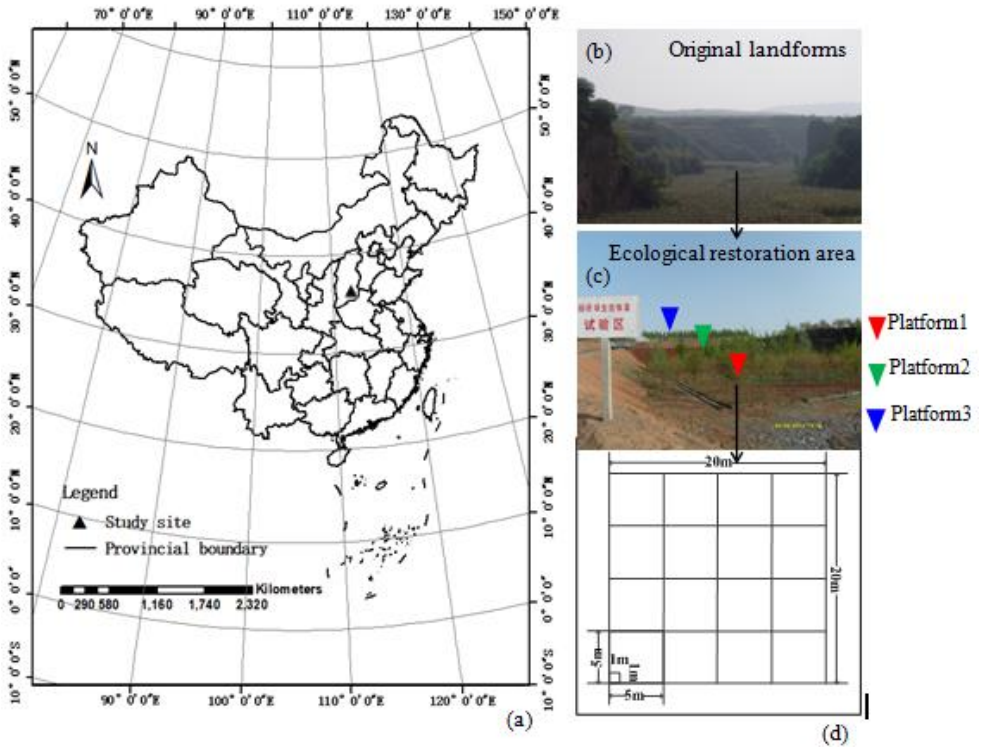

Figure 1. *Locations and design of experimental plots. (a) Location of study site in China. (b) Original landforms of study site. (c) Ecological restoration area. Red triangle: platform1 established in 2009. Green triangle: platform2 established in 2010. Blue triangle: platform3 established in 2011. (d) Design of experimental plots in each platform*

Plant community

The basic characteristics of the plant community, including the diameter at breast height (DBH) of trees, plant species, height, canopy, and coverage, were investigated. Twelve typical sampling units (area of each typical sample = 1 m^2) were set on each platform and the reference site to obtain the herbal biomass. All herbal bodies were harvested, placed in sealed bags, cleaned, and dried to a constant weight at 80 °C in the incubator. The dry weights of the herb were determined by electronic scales (accuracy 0.01).

The integrity of the vertical structure (IVS) was assigned 1, 2 and 3: 1 means the vertical structure has only one layer; 2 means the vertical structure has two layers; and 3 means the vertical structure has three layers.

The species richness index (SRI) was assigned a value according to the species evenness and dominance of a community (*Table 1*).

The index of the growth and decline of species (IGDS) indicates the dynamic of immigration and emigration of plant species in a community. If the index of growth and decline of species is close to 1.00, growth and decline maintain a dynamic balance. In the present study, taking the first year as the benchmark, the index of growth and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1158711604

decline of species was determined by the net immigration rate in year 1 and is set equal to 100 (*Eqs. 1-3*).

$$IGDS_j = I_j/E_j(j = 2,3,4,5)(If\ j = 1, C_1 = 100) \quad \text{(Eq.1)}$$

$$I_j = \frac{N_{Ij}}{N_1} \times 100\%\ (j = 2,3,4,5) \quad \text{(Eq.2)}$$

$$E_j = \frac{N_{Ej}}{N_1} \times 100\%\ (j = 2,3,4,5) \quad \text{(Eq.3)}$$

where j is a plant community, $IGDS_j$ is the index of growth and decline of species for community j, I_j is the net immigration rate of community j compared to the benchmark, E_j is the net emigration rate of community j compared to the benchmark, N_{Ij} is the number of immigration species of community j compared to the benchmark, N_{Ej} is the number of emigration species of community j compared to the benchmark, and N_1 is the number of species of the benchmark year (year 1).

Table 1. *The assignment and implication for index of species richness*

Assignment	Implication
1	Obvious dominant species, worse species evenness
2	Obvious dominant species, better species evenness
3	Unobvious dominant species, worse species evenness
4	Unobvious dominant species, better species evenness

Index of species evenness < 0.95 means worse species evenness; > 0.95 means better species evenness

The value of community similarity (VCS) was determined by the Jaccard similarity index, which means the similarity of species between community *A* and community *B* (*Eq. 4*).

$$VCS = \frac{c}{(a+b-c)} \times 100\% \quad \text{(Eq.4)}$$

where a is the number of species for community *A*, b is the number of species for community *B*, and c is the number of species in common between communities *A* and *B*.

The index of community stability (ICS) was determined by M. Godron's stability determination method (Godron, 1972).

Soil property

In each platform, eight big samples (25 m^2) were selected and located by GPS. Three typical samples of topsoil (0-20 cm) were collected after clearing away the surface litter in each big sample. Each typical sample consisted of three subsamples (area of each subsample = 0.04 m^2). The subsamples were in the typical sample point approximately 20 cm and mixed thoroughly. There were eight replicates in each platform. The sampling was carried out each year from 2011 to 2013 during the summer. Moreover, in the summer of 2011, three typical contrasted sampling units were established in every big sample at the reference site. Each typical sample consisted of three subsamples (area

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1158711604

of each subsample = 0.04 m^2). Eight replicates were carried out in each platform. These typical soil samples were air-dried and used for physical and chemical analysis. Soil moisture (SM) content, soil field capacity (SFC), and soil density (SD) were determined according to Xie et al. (2012). Soil total porosity (STP) was calculated according to Zhang (2006). The contents of soil total organic carbon (STOC), soil organic matter (SOM), readily oxidized organic carbon (ROOC), particulate organic carbon (POC), total nitrogen (TN), available phosphorus (AP), available potassium (AK), and soil pH were determined according to Su (2010).

Ecological restoration status index (ERSI)

In this research, Principal component analysis (PCA) was used to calculate the weight of each parameter and select the major parameters. Principal components (PCs) that had an eigenvalue ≥ 1 and that explained at least 5% of the variation of the data were selected. On each particular principal component (PC), the highly weighted parameters (absolute value) were considered very important and chosen for the ecological restoration status index (ERSI). ERSI was a unitless value (from 0 to 1) that indicated the status of ecological restoration in the coal gangue pile (Mukhopadhyay et al., 2014). It is expected that if the ERSI value is higher, the ecological restoration status is superior (Mukhopadhyay et al., 2014). In this study, the first year of recovery was taken as the benchmark year. By comparing the ERSI value in every year of recovery to that in the benchmark year, the ecological restoration status was evaluated. The final ERSI equation is as follows (*Eq. 5*):

$$ERSI = \sum_{i=1}^{n} W_i S_i \quad \text{(Eq.5)}$$

where i is the number of parameters, W_i is the normalized weight value (w_i) of parameter i, $\sum_{i=1}^{n} W_i = 1$, S_i is the normalized value of parameter i, and $W_i S_i$ is the contribution of parameter i on the calculated ERSI.

The W_i equation is as follows (*Eq. 6*):

$$W_i = w_i / \sum_{i=1}^{n} w_i \quad \text{(Eq.6)}$$

where w_i is the weight value of parameter i by PCA, and $\sum_{i=1}^{n} w_i$ is the total weight value of the major parameters selected by PCA; this W_i equation was used to normalize the weight value of parameter i.

The S_i equation is as follows (*Eq. 7*):

$$S_i = a/[1 + (x_i/x_{i0})^b] \quad \text{(Eq.7)}$$

This S_i equation was used to convert the real values of the ecological restoration status parameters into unitless scores (from 0 to 1), where x_i is the real value of parameter i, x_{io} is the mean value of parameter i with all stages of recovery, and a is the maximal score of the ecological restoration status property and is set equal to 1.00. In the real value range of each parameter (from minimum to maximum of the real value), the lower the value of the parameter, the better the development of the parameter, thus, b was set equal to 2.5. In turn, b was set equal to -2.5 (Mukhopadhyay et al., 2014). The similar method described by Mukhopadhyay et al. (2014) aimed at mine soil quality and derived a mine soil quality index (MSQI). MSQI was derived based on the mine soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1158711604

physical, chemical and biological parameters without the parameters of the plant community. In the process of mine ecological restoration, the interaction between mine soil and plant community always exists. ERSI involves not only the parameters of the mine soil physicochemical properties but also the parameters of basic characteristics of plant communities. The dynamic development of a mine plant-soil system could be expressed by ERSI.

Monte Carlo simulation (MCS)

Monte Carlo simulation (MCS) is a method to estimate uncertainty with the aid of computer software. This methodology provides an uncertainty value without any approximations or shortcuts (Zeng et al., 2018). In this research, MCS was used to analyze the uncertainty of the ERSI. Firstly, the means and standard deviations of parameters in each recovery age were calculated. Based on the current sample data and experiences, the distribution functions of parameters were defined. Then, ERSI was defined by the function of define forecast according to *Equation 5*. Finally, using the function of run preference, the number of simulation and sensitivity analysis were operated. ERSI values of each period were obtained. In this paper, 10000 simulations were conducted. The confidence level was 95%.

Statistical analysis

PCA was completed by using Microsoft Excel and SPSS 11.5. The correlations and differences between variables were calculated according to Pearson's coefficient and Least-significant difference (LSD), respectively (Hao et al., 2015). A probability level of 0.05 was always used as the threshold for significance. MCS and sensitivity analysis were conducted by Crystal Ball software.

Results

Plant community

The dominant species of the herbal community were *Artemisia lavandulaefolia* (years 1 and 2), *Puccinellia distans* (year 3), *Leymus chinensis* (years 4 and 5), and *Artemisia brachyloba* (reference site). The coverage of the community achieved 80% in years 4 and 5. In previous research (Hao et al., 2016), overall, the average DBH of trees (ADT) (from 4.89 to 11.85 cm), coverage of the herb layer (CHL) (from 35 to 80%) and coverage of the community (CC) (from 40 to 80%) increased with recovery age. The average ratio height and canopy of trees fluctuated due to the growth characteristics of *Populus tomentosa.* The average height of the herb layer (AHHL), total biomass of the herb layer (TBHL) and index of species diversity (ISD) also fluctuated due to the differences of dominant species and species components, which were expressed by the dynamics of immigration and emigration of plant species in a community. In years 4 and 5, IGDS maintained a dynamic balance (from 1.0 to 1.1). The community stability was worse. The vertical structure of the community always had two layers (tree and herb) from years 1 to 5. From years 3 to 5, the index of species richness mainly remained 1, and the change of VCS mainly remained within 0.688-0.710. It was indicated that in years 1 to 2, the species component changed significantly. However, in later years, the species component changed slightly with the promoted soil properties.

Soil physicochemical properties

In previous research (Hao et al., 2015), overall, SM (from 4.095 to 2.860%) and SD (1.603 to 1.243 g/cm^3) decreased with recovery age due partly to the worse water retaining capacity of the mine soil. Partly because the weathering of coal gangue strengthened gradually, STP, STOC, SOM, TN, AP, and AK increased (Sena et al., 2015). In addition, SFC deceased (from 21.2% to 20.2%) in years 1 to 3 but increased (21.5%) in later years. POC contents decreased in year 2 and were 0.011-0.012 g/kg in later years. The soil was alkaline due to aluminum ion exchanged through the weathering of coal gangue; pH values ranged from 8.50 to 8.03 and decreased with recovery age due to aluminum ion loss by rainfall. Significant differences of soil properties were shown between year 5 of recovery and the reference site ($P < 0.05$) (Hao et al., 2015).

Correlation between plant and soil

During the early stage of ecological restoration in the coal gangue pile, significantly negative correlation was shown between ADT and SM content ($P < 0.05$) (*Table 2*). CHL was significantly negatively correlated ($P < 0.05$) with SD. ISD was significantly positively correlated with POC ($P < 0.05$). IGDS was significantly negatively correlated with STP ($P < 0.05$).

Table 2. *Correlation between basic plant community characteristics and soil properties*

Parameter	ADT	CHL	CC	ISD	IGDS
SM	-0.921*	-	-	-	-
SD	-	-0.822*	-	-	-
STP	-	-	-	-	-0.812*
STOC	0.940*	0.903*	0.875*	-	-
ROOC	0.938*	0.930**	0.903*	-	-
POC	-	-	-	0.850*	-
pH	-.923*	-0.852*	-0.814*	-	-
AP	0.916*	0.852*	0.832*	-	-
AK	0.951*	0.974**	0.970**	-	-

The average DBH of trees (ADT), coverage of the herb layer (CHL), coverage of the community (CC), index of species diversity (ISD), the index of the growth and decline of species (IGDS), soil moisture (SM), soil density (SD), soil total porosity (STP), soil total organic carbon (STOC), readily oxidized organic carbon (ROOC), particulate organic carbon (POC), soil pH (pH), available phosphorus (AP) and available potassium (AK)
Note:* Correlation is significant at the 0.05 level (2-tailed). ** Correlation is significant at the 0.01 level (2-tailed).

Ecological restoration status index (ERSI)

Through principal component analysis, eigenvalues were above 1.0 in the first four principal components (PCs) (*Table 3*). Significant positive correlations were shown between principal component-1 (PC-1) and STOC, ROOC, TN, and AP (*Fig. 2*). The significant negative correlation was shown between PC-1 and pH. STOC and ROOC, pH and TN were significant positively ($P < 0.01$) and negatively ($P < 0.05$) correlated,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1158711604

respectively. It was indicated that PC-1 represented the soil chemical properties. Under PC-2, ADT was highly weighted. ISD was highly weighted in PC-3. TBHL and SOM were highly weighted in PC-4. Given adequate time, the rich herb biomass can supply SOM. However, in this research, neither parameter showed significant correlation due to the limit of the recovery age (only five years). The percentage of cumulative explanation was 97.6% by nine parameters (ADT, TBHL, ISD, SOM, STOC, ROOC, pH, TN, AP). Thus, the nine parameters would be used to derive ERSI.

The parameters of *Equation 7* are presented in *Table 4*. ERSI in every year is as follows (*Eq. 8*):

$$ERSI = \sum_{i=1}^{n} W_i S_i \ (n = 9) = W_1 \times S_1 + W_2 \times S_2 + W_3 \times S_3 + W_4 \times S_4 + W_5 \times S_5 + W_6 \times S_6 + W_7 \times S_7 + W_8 \times S_8 + W_9 \times S_9 = 0.13270 \times S_1 + 0.13270 \times S_2 + 0.13270 \times S_3 + 0.13270 \times S_4 + 0.26540 \times S_5 + 0.10060 \times S_6 + 0.05379 \times S_7 + 0.02470 \times S_8 + 0.02470 \times S_9 \quad \text{(Eq.8)}$$

Soil total organic carbon (STOC), readily oxidized organic carbon (ROOC), soil pH (pH), total nitrogen (TN), available phosphorus (AP), the average DBH of trees (ADT), index of species diversity (ISD), total biomass of the herb layer (TBHL) and soil organic matter (SOM)
The value range: The value range of each parameter is from the minimum to maximum real values

Using the PCA, the contribution of each ecological restoration status parameter to the calculated ERSI in every year is shown in *Figure 3*. Comparing to other parameters, the contribution of AP was largest in every year and was 0.10, 0.07, 0.14, 0.13 and 0.14, respectively. The contribution of pH ranged from 0.06 to 0.07. The contributions of STOC and ROOC increased with recovery age (from 0.02 in year 2 to 0.08 in year 5).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1158711604

The first year was taken as the benchmark year. The ERSI value (0.25) was lower in year 2 of recovery than that in the benchmark year. ERSI then increased from 0.45 in year 3 to 0.53 in year 5, more than that in the benchmark year. A significant difference was shown between year 5 and the other years ($P < 0.05$). ERSI of the reference site was the highest (0.65) in *Figure 3*. A significant difference was shown between the reference site and other years ($P < 0.05$). It was indicated that the ecological restoration status of the restored site would take more time to reach the level of the reference site. A quadratic curve ($R^2 = 0.7892$) between ERSI and recovery age is shown in *Figure 4*. Overall, ERSI increased with recovery age during the early stage of recovery (the first five years) (*Fig. 5*).

Uncertainty analysis of the ERSI by MCS

To analyze the uncertainty of the ERSI, the study introduced MCS. Based on the distribution function, mean and standard deviation of each parameter in every recovery age in *Table 5*, 10000 simulations were carried out. 10000 random values of each parameter were generated in every stage. Then based on the *Equation 8,* 10000 simulations of ERSI were conducted in every stage (*Table 6*). The uncertainty in 2 year was maximum (± 4.00%), the largest uncertainty contribution came from the SOM (*Table 5*). In later years of recovery, the uncertainty became lower. The uncertainty in 5 year was minimum (± 1.89%). In RS, the uncertainty was ± 3.08%.

Table 5. *Distributions, means and standard deviations of the parameters in the estimation of ERSI using the MCS*

RS	0.65	± 3.08	0.54-0.69

Uncertainty: the standard deviation of ERSI value from MCS divided by the arithmetic mean of it. Reference site (RS)

During the different period, the sensitivity of each parameter to ERSI was different (*Fig. 6*). In years 1 and 2 of recovery, STOC was main influencing factor to ERSI, the sensitivity coefficient of STOC was 0.570 and 0.402, respectively. In years 3 and 4 of recovery, ROOC was main influencing factor to ERSI, the sensitivity coefficient of ROOC was 0.516 and 0.573, respectively. The sensitivity coefficient of TN was highest (0.684) in year 5. SOM (0.449) was the most sensitivity factor in RS. It was indicated that at the early stage of recovery, STOC, ROOC and TN played important roles in improving ecological restoration status in coal gangue pile. With the restored area becoming near-nature in adequate time, SOM will play an important role in ecological restoration. It was suggested reasonably supplying STOC, ROOC and TN content will promote ecological restoration process at early stage of recovery.

Discussion

Correlation between plant and soil

During the early stage of ecological restoration in the coal gangue pile, significantly negative correlation was shown between ADT and SM content because the growth of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1158711604

Populus tomentosa consumed more soil moisture. CHL was significantly negatively correlated with SD because herbal roots and litters improved soil porosity. With increasing ADT, CHL and CC, STOC, ROOC, AP and AK increased significantly due partly to heavy litters falling from trees (*Populus tomentosa*), and herbs decomposed to improve the soil organic carbon, phosphorus and potassium (Sorenson et al., 2011; Mukhopadhyay et al., 2016). It was indicated that *Populus tomentosa* can be the pioneer species to achieve quick recovery in mining areas (Li and Liber, 2017). ISD was significantly positively correlated with POC, which is probably because dead species bodies improved the POC content (Hao et al., 2015). IGDS was significantly negatively correlated with STP. This was probably because in the benchmark year (year 1), the plant species was the net immigration species, the penetration of plant roots was limited, and STP was low. In the later years, immigration and emigration of species maintained the dynamic balance, IGDS was 1.0-1.1, and STP increased with increasing penetration strength of plant roots (Mukhopadhyay et al., 2016). Lower SM content, better gas porosity and permeability, rich STOC, AP and AK were beneficial to the biomass accumulation of *Leymus chinensis* and *Setaria viridis*. Increasing SOM, POC, AP and AK caused an adverse effect on the biomass accumulation of *Artemisia lavandulaefolia* and *Melilotus officinalis*. In turn, the accumulation of herb biomass also supplied SOM content in adequate time. Leguminous plants, such as *Melilotus officinalis,* immigrated and fixed nitrogen to increase TN content (Hao et al., 2015).

Ecological restoration status index (ERSI)

The parameters system of evaluation comprised six parameters of soil chemical properties and three parameters of basic plant community characteristics. It was suggested that soil chemical properties play a very important role in mine ecological restoration status. The growth of a plant community depends on improved soil chemical properties, such as rich soil nitrogen and organic matter. In turn, the nitrogen fixing capacities of leguminous plants increase TN content. The biomass of plants supplies organic matter to the soil. The basic characteristics of plant community in the restored area as the important parameters that should be included in the ecological evaluation of the recovery status. Mukhopadhyay et al. (2014) also determined six soil parameters, but they were soil physical (2, number of parameters), chemical (2) and biological (2) parameters. Only STOC was a common parameter. The difference of initial parameters resulted in the differences of the other five parameters in both experiments.

Although ADT increased, the total declining content of AP, ROOC, STOC, ISD and TBHL were greater than the increasing content. AP, ROOC and STOC supported rich plant species during the first year. In turn, ISD and TBHL decreased due to the number of species decreasing in year 2 of recovery. A lower score also existed in year 2 of restoration in Mukhopadhyay et al. (2014). It was suggested that the ecological restoration status in year 2 was lower than that in the benchmark year. Trees and herbs grew rapidly with recovery age. Species diversity and community stability were enhanced gradually. Nitrogen fixation of leguminous plants, such as *Melilotus officinalis,* increased TN content. The total organic carbon increased with the accumulation of vegetation litter and biomass. Moreover, plant roots enriched SOM in the rhizosphere (Montiel-Rozas et al., 2015). AP content also increased from gradual weathering. In turn, the biomass of the herb layer also increased based on the increasing species diversity and soil nutrition with recovery age (Lv and Zheng, 2009). It was suggested that the ecological restoration status in years 3 to 5 was better than that in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1158711604

benchmark year. In Mukhopadhyay et al. (2014), the mine soil quality index (MSQI) reflected the soil properties. In this research, ERSI reflected the results of the interaction between the mine soil and plant community. Their interaction revealed the internal cause of development in mine ecological restoration status.

This time for disturbed mine soil could be at least 20 years based on proper restoration strategy, as reported by Anderson et al. (2008). Orozco-Aceves et al. (2017) suggested that in 22 years, soil physicochemical and key biological properties after restoration still were not recovered to the conditions of the reference soil. In addition, if the restoration method is unsuitable, the restored mining site may remain polluted even 30 years later (Gomez-Ros et al., 2013). The restoration statuses are different in different study sites, climate and restoration methods, etc. However, the reference site was not the final recovery goal. For example, the reference site (natural secondary community) was not the optimal recovery goal in Li (2010). With increasing recovery age, the ecological restoration status in the coal gangue pile would be better than at the reference site (Hao et al., 2016).

We found that a quadratic curve is showed between ERSI and recovery age. It was reported that a positive liner correlation was shown between the mine soil quality index and recovery age (Mukhopadhyay et al., 2014). The different type of correlation might result from the differences of the parameter system and study site. Overall, ERSI increased with recovery age during the early stage of recovery (the first five years). It was indicated that ecological restoration status had a promoted trend during the early stage of recovery (Orozco-Aceves et al., 2017; Mukhopadhyay et al., 2014). This suggested that the functions of the plant-soil system gradually improved with recovery age. However, Li (2010) found that the evaluation result of the ecological restoration status was as follows: year 5 > year 4 > year 3 > reference site > year 1 > year 2. The conclusion was different from this study. The causes of this difference were the differences of artificial planting species and the parameter system. For example, in Li (2010), the dominant species of the tree layer was *Crataegus pinnatifida*, and the parameter system involved soil heavy metal content. In the present research, the dominant species of the tree layer was *Populus tomentosa*, and soil heavy metal content was uninvolved in the parameter system.

Ecological restoration and natural succession are dynamic processes. At present, artificial vs. natural recovery is controversial for the restoration of coal gangue piles (Woziwoda and Kopec, 2014). This study suggested that artificial recovery (establishing trees) in the first year of recovery, followed by natural herbal recovery in later years, could achieve quick ecological restoration during the early stage of recovery in the mining area. It was suggested that a rapid recovery process could be achieved by reasonable artificial imitation or appropriate interference (Burton et al., 2006; Mudrák et al., 2016). However, it is noteworthy that if invasive alien species are planted in the process of artificial restoration in the mining area, the opposite effect may occur (Holl, 2002). Thus, considering the magnitude of the problem and developing each restoration method are essential steps to evaluate the status of ecological restoration at restored sites (Gomez-Ros et al., 2013).

ERSI was developed based on the plant-soil system of a restored coal gangue pile in the first five years of recovery. The first year was taken as the benchmark year. By comparing the ERSI value in every year of recovery to that in the benchmark year, the ecological restoration status was evaluated. Long-term monitoring the plant-soil system

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1158711604

will be the focus of further research. ERSI could play a positive demonstration and radiation role in the future evaluation of ecological restoration status in mining areas.

Conclusions

The parameter system for evaluation of ecological restoration status in restored coal gangue piles was established on the basic plant community characteristics and soil physicochemical properties. Principal component analysis (PCA) was employed to derive an ecological restoration status index (ERSI). ERSI was developed based on the parameter system of the plant-soil system in a restored coal gangue pile during the early stage of recovery (the first five years of recovery). The first year was taken as the benchmark year. By comparing the ERSI value in every year of recovery to that in the benchmark year, the ecological restoration status was evaluated. Except for year 2, the ecological restoration status in years 3 to 5 of recovery and the reference site were better than that in the benchmark year. ERSI reflected the results of the interaction between the mine soil and plant community. Overall, ERSI increased with recovery age during the early stage of recovery.

With recovery age, the uncertainty of ERSI showed decreased trend by MCS, and the sensitivity of each parameter to ERSI was different. At the early stage of recovery, STOC, ROOC and TN played important roles in improving ecological restoration status in coal gangue pile.

Abstract. Remote sensing of soil moisture can provide important data for monitoring large-scale agricultural drought. Due to differences between the various sensors and inversion methods, remote sensing data from different sources are unsuitable for direct comparison and analysis. Data fusion has become an area of active research regarding the application of remote sensing data. Based on the principle of cumulative distribution function matching, this study proposed a continuous relationship establishment algorithm for multisource remote sensing soil moisture data. Using this new algorithm, soil Moisture and Ocean Salinity (SMOS) and Climate Change Initiative (CCI) satellite data from the Songnen Plain as test data were fused to a long time series product of real-time remote sensing soil moisture data. This application validation of this new method to SMOS and CCI indicated that this Lagrange interpolation continuous fusion algorithm could improve the fusion accuracy of multisource remote sensing soil moisture data significantly. The low-value region of the cumulative probability distribution curve is a crucial data segment for characterization of agricultural drought. Through implementation of the proposed continuous fusion algorithm, fused SMOS and CCI data were found to have high coincidence at each quantile in the low-value region of the curve.
Keywords: *agricultural drought, continuous fusion, Songnen Plain, SMOS, CCI*

Introduction

Remote sensing of soil moisture has been used in simulation, monitoring and analysis of drought characteristics (Atlas, 1993; Su, 2003; Sheffield and Wood, 2007; Bolten et al., 2010). It is effective for quickly detecting change in large-scale agricultural droughts. However, such remote sensing data can have different spatial and temporal resolutions and various time series lengths due to the variety of platforms, sensors and inversion methods available. Satellite data of the same terrestrial object released by different sources cannot be used directly for continuous analysis and the absolute value cannot be compared directly. To overcome this problem, remote sensing data fusion is proposed as an effective means of integrating multisource satellite-derived ground object information (Schmitt and Zhu, 2007, 2016).

Data fusion is defined as a multilevel integration process for detection, association, analysis and a combination of sensors designed to produce a single signal of higher quality and reliability (Waltz and Llinas, 1990; Sportouche et al., 2011; Li et al., 1995). Due to the resource complementarity of multiple sensors, multisource fusion can

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1160511617

provide information that is more comprehensive than obtained from a single sensor (Khaleghi, 2013). The data fusion principle is the cumulative distribution function (CDF) matching method. The CDF principle was first proposed by Calheiros in 1987 (2010), and it has since been used for the correction of radar remote sensing precipitation data (Atlas et al., 1990; Anagnostou et al., 2010). In recent years, this CDF matching principle is widely used to reduce the systematic biases between the original data and the reference data by rescaling the target data to the direction of the reference data (Reichle, 2004; Drusch, 2005; Brocca et al., 2011; Lee and Im, 2015).

In the implementation of the CDF principle based on some reliable data, the fusion of remote sensing data from other sources can be used to improve the spatiotemporal resolution of the data or to extend the length of the data time series. Fused remote sensing data can improve its quality and reliability and enable its maximal utilization (Li et al., 1995). Previous studies that have used this principle to conduct fusion research on different remote sensing data groups have reported reduced remote sensing data bias and improved time series lengths for single data sources (Reichle and Koster, 2004; Liu et al., 2009). Based on this principle, the same basic data can be used to correct the fusion of multiple remote sensing datasets from different sources (Liu et al., 2010). In recent years, this principle has also been applied to the data fusion of multiple remote sensing soil moisture products (Lee et al., 2017). The CDF principle can maintain the original relative change mode of remote sensing data (Liu et al., 2010) and adjust the data scope to be close to the real value, which can improve the accuracy of remote sensing soil moisture data for characterization of surface features. However, the above calculation algorithm of fusion is simplistic and the fusion precision needs to be improved. The piecewise linear regression method is generally used to establish the relationship between the cumulative distribution curves of data from different sources. This method sets the same section for different cumulative distribution curves, and it obtains the linear equation of the two data correlations in that section to realize the fusion of one set of data to the other on the same quantile. The main disadvantage of subsection fusion is that the subsection properties will lead to a certain fitting error of the curve in the subsection, irrespective of the subsection density.

Given the increasing levels of research into remote sensing products and their application, the demands for data in terms of time series length and real-time update speed have increased. Improvement of the accuracy of multisource remote sensing data fusion is one of the most important scientific problems to be overcome in relation to research of remote sensing applications. Based on the CDF matching theory, this study constructed a new continuous fusion algorithm to address the problem of low accuracy in the piecewise linear fusion method, to improve the fusion accuracy in the low-value region of the cumulative probability distribution curve (i.e., this critical stage related to impending or emerging drought). The fusion effect of this proposed algorithm was verified by SMOS and CCI data in the Songnen Plain (Northeast China).

Data and study area

Soil moisture and ocean salinity (SMOS) data

The Soil Moisture and Ocean Salinity (SMOS) satellite designed specifically for monitoring global soil moisture content and ocean salinity. The L-band, which is insensitive to surface roughness and vegetation coverage, is very suitable for soil moisture inversion. The SMOS soil moisture data are obtained using a radiative transfer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1160511617

model using luminance temperature data (Calvet et al., 2011; Ramirez-Beltran et al., 2010). Related study has proven that the SMOS soil moisture data has high inversion accuracy and signification advantage over other remote sensing data in areas with high vegetation coverage (Al-Yaari et al., 2014). The daily SMOS Level-3 volumetric ($m^3 m^{-3}$) soil moisture data (January 2010 to March 2016) used in this study were obtained from the expert center in Barcelona, Spain (http://www.smos-bec.icm.csic.es/smos_products). For SMOS data, radio frequency interference (RFI) is revealed to be an important source of noise (Anterrieu, 2011). This dataset discarded some data which do not meet the quality requirement in the processing of RFI. The Level-3 data in this dataset is remapped to an Equal Area Scalable Earth grid of 25 km × 25 km. According to the data analysis, during the main growth stage of crops from April to October, this dataset still has a high coverage in Northeast China. This daily SMOS dataset is a near real-time soil moisture data (delay one day). In the management of agricultural drought resistance, timeliness is important for the evaluation of agricultural drought. But this data cannot be used to perform frequency and evolution analysis due to the short length of the time series.

Climate change initiative (CCI) data

The European Space Agency (ESA) launched the Climate Change Initiative (CCI) program in 2010 to generate a dataset of global soil moisture based on passive, active and fused products (Dorigo et al., 2017). This program was designed to produce complete and consistent global soil moisture dataset by several active and passive remote sensing data. The long time series CCI dataset, which comprises a variety of integrated multisatellite soil moisture products, provides the possibility for long-term dynamic analysis of global soil moisture (Hollmann et al., 2013). This dataset has been widely adopted since its release, and it has been verified and applied in many regions of the world (González-Zamora et al., 2018; Jian et al., 2018; Wang et al., 2018; Siyu et al., 2017). As reprocessing data, real-time drought evaluation cannot be undertaken using this dataset. This study uses daily CCI (version 02.2) volumetric ($m^3 m^{-3}$) combined data (1978-2014) to carry out the algorithm validation. These daily soil moisture products have a grid resolution of 0.25° (Chakravorty et al., 2016).

The fusion calculation algorithm proposed in this study can extent the time series of remote sensing data. And it will have another significant advantage if the new fusion data has the property of near real-time update at the same time. Therefore, in this study CCI data is the basic data in fusion calculation. Through fusion calculation, the real-time update SMOS data has been rescaled to CCI to produce the new fusion data, which has the property of both long time series and real-time update. Before fusion, both SMOS and CCI data have been rescaled to the same spatial and temporal resolution.

Study area

This study verified the proposed continuous algorithm by application to an area of the Songnen Plain (43°36′–49°45′N, 121°27′–128°12′E), which is one of the main bases for grain production in Northeast China (Wang et al., 2004). The Songnen Plain has a temperate semihumid-semiarid continental monsoon climate (Zheng et al., 2015). Mean annual precipitation is 350–600 mm with 70–80% of precipitation occurring in June–September. The typical zonal soils are black soil and chernozem. The Songnen Plain is within the drainage area of the Songhua River. The Second

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1160511617

Songhua River and the Nen River merge in the center of the area to form the Songhua River. In recent years, mean precipitation on the Songnen Plain has declined and the area has suffered frequent drought disasters, especially in western regions. Due to its flat terrain, simple underlying surface type and wide distribution of farmland, this region is ideal for research on remote sensing evaluation of drought. The elevation of the Songnen Plain is 200– 250 m above sea level. The soil in this region is fertile with vast farmland and few hills. Black soil, meadow soil, dark-brown soil and chernozem are widely distributed in there (Jiang et al., 2016).

Methodology

Data fusion in this study is to rescale one data against another basic data by the relationship obtained from data for the overlapping period. The CDF matching method is the principle of establishing relationship by cumulative distribution curves in data fusion. The calculation error of fusion in the process of establishing the relationship between two curves is very important because it determines the accuracy of the data produced for subsequent application. Currently, the relationship establish algorithm is piecewise linear regression. The relational fitting curve constructed by piecewise might lead to large error in the fusion result. To reduce error and improve fusion accuracy, this study proposed a continuous relationship establish method in fusion of multisource remote sensing soil moisture data based on the CDF principle. By using this new continuous algorithm, the overlapping period (2010-2013) data can be used to establish the relationship between CCI and SMOS in each quantile of the cumulative probability distribution curve. In the absence of CCI soil moisture data, the relationship of each quantile can rescale real-time SMOS to CCI, consequently to produce a new fusion data with the property of long time series and real-time update.

Cumulative distribution function (CDF)

The CDF is the sum of the probabilities that a random variable falls within a certain interval in the sample space, and it is the integral of the probability density function. When plotting the integral distribution function, it is often defined as the integral of the histogram distribution because the real probability distribution function is unknown. The objective of this study is to derive an algorithm by using CDF principle to fuse real-time SMOS data to the benchmark long time series CCI remote sensing soil moisture data. This new algorithm can make the SMOS and CCI data having the similar distribution curves. Subsequently, a set of real-time updated and long-term remote sensing soil moisture data could be synthesized.

The fusion process of soil moisture data can be expressed as follows:

$$cdf_c(x') = cdf_s(x) \quad \text{(Eq.1)}$$

where cdf_c is the CDF of the CCI soil moisture, cdf_s is the CDF of the SMOS soil moisture, x is the soil moisture of the SMOS product and x' is the fused SMOS soil moisture. In fusion computing, the closer the match of the two curves, the better the fusion precision and the effect.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1160511617

Piecewise linear algorithm

Piecewise linear regression is the commonly used correlation calculation method in fusion and its calculation process is shown in *Figure 1*. As an example, the cumulative probability distribution curves of the SMOS and CCI datasets were divided into 10 segments: 0%, 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90% and 100%. The correlation between their respective cumulative probability distribution curves can be obtained based on the linear equation of these two datasets in each segment.

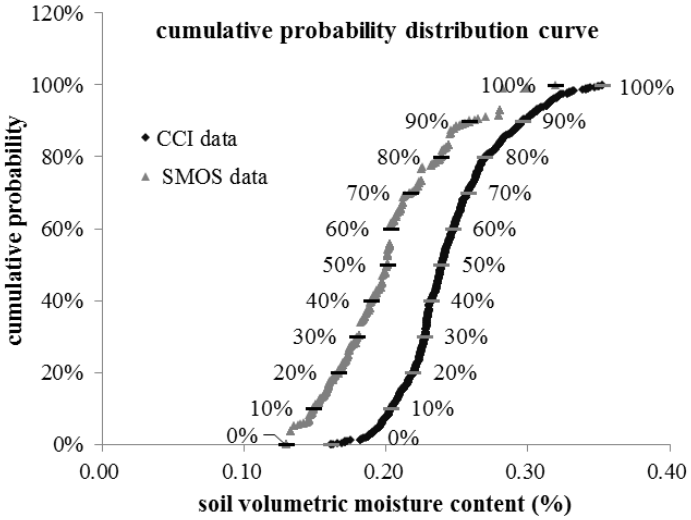

Figure 1. *Schematic of piecewise linear fusion between SMOS and CCI soil moisture*

Lagrange continuous algorithm

To improve fusion accuracy, correlation calculation algorithms of cumulative probability distribution curve between different data need to be further improved. This study proposed a Lagrange continuous algorithm to establish the relationship between the SMOS and CCI cumulative probability distribution curves. Between the cumulative probability distribution curves of the SMOS and CCI datasets, each SMOS value has a corresponding probability distribution value *P*. On the CCI curve, if a CCI value corresponds to this probability value *P*, this CCI value is used as the fused SMOS value. If the probability value *P* has no corresponding CCI value, an appropriate value is calculated using an interpolation method. The Lagrange equidistant interpolation continuous algorithm can realize continuous fusion of the SMOS and CCI data in each quantile on the probability distribution curve.

Interpolation refers to the interpolation of discrete data to the continuous function, such that the continuous function curve passes through all data points. Interpolation can be used to estimate an approximation of the function at other points based on the value of the function at a finite point. Unary interpolation can calculate the approximate value at interpolation point t using the function when given the value at n equidistant nodes. The Lagrange interpolation polynomial was first published by Waring in 1779, rediscovered by Euler, and published by Lagrange in 1795 (Meyer et al., 2008; Jeffreys and Jeffreys, 1988). Lagrange interpolation polynomial can be expressed as follows:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1160511617

$$L(x) = \sum_{j=0}^{k} y_j \ell_j(x) \quad \text{(Eq.2)}$$

where, $l_j(x)$ is the Lagrange basic polynomial (also called the interpolation basis function), which can be expressed as

$$\ell_j(x) = \prod_{i=0, i\neq j}^{k} \frac{x - x_i}{x_j - x_i} = \frac{(x - x_0)}{(x_j - x_0)} \cdots \frac{(x - x_{j-1})}{(x_j - x_{j-1})} \frac{(x - x_{j+1})}{(x_j - x_{j+1})} \cdots \frac{(x - x_k)}{(x_j - x_k)} \quad \text{(Eq.3)}$$

Through Lagrange interpolation, each SMOS data element has a corresponding CCI value, and the CCI value obtained using this interpolation method has minimal deviation on the cumulative probability curve. *Figure 2* shows the cumulative distribution curve schematic of SMOS and CCI, together with the fused SMOS (labeled SMOS' in the figure) obtained using the proposed Lagrange interpolation continuous algorithm. It can be seen that the cumulative distribution curve of the SMOS' data almost overlaps with the curve of CCI data.

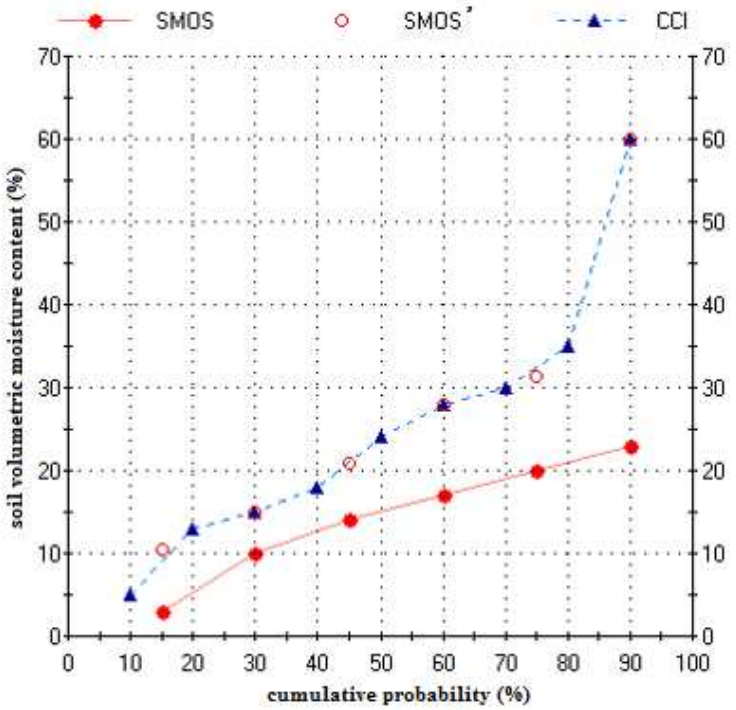

Figure 2. *Schematic of Lagrange continuous fusion between SMOS and CCI soil moisture*

Continuous fusion algorithm results analysis

Analysis of fusion data time series

Comparison of time series of remote sensing soil moisture data before and after fusion can illuminate the change of scope of the remote sensing data manifest by the fusion algorithm. As an example, the comparison of Shuangcheng in Songnen Plain is presented in *Figure 3*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1160511617

Following the fusion process, the fused SMOS data (labeled SMOS' in *Fig. 3*) are clearly closer to the CCI data distribution. The values of the SMOS data time series before fusion are generally lower than the CCI data values. After fusion, the soil water content of the SMOS data is increased, especially in months with low soil water content. The SMOS' data maintain the change characteristics of the original data time series. And the range of data values is adjusted to a certain extent, enhancing the degree of similarity with the CCI data range. In the case of Shuangcheng, the SMOS data range of Shuangcheng changed from 13–30% to 19–35% through fusion.

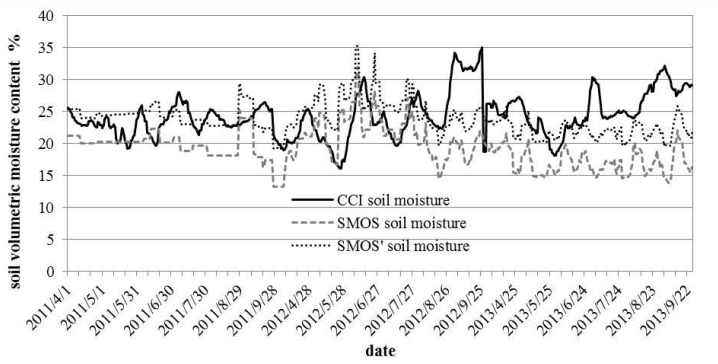

Figure 3. *Soil moisture time series of SMOS, CCI and fusion SMOS data in Shuangcheng*

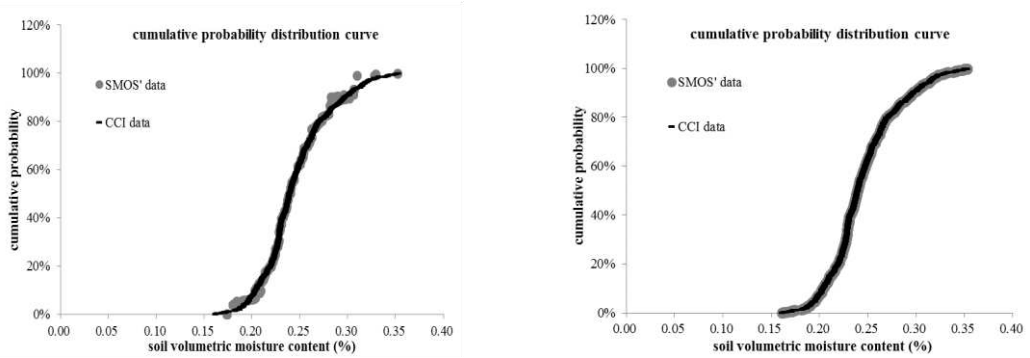
Comparison of cumulative probability distributions between the two fusion methods

According to the CDF matching principle, the closer the curve of the target data to the cumulative probability distribution curve, the higher the fusion accuracy. Here, the result of the fusion of SMOS and CCI data of Shuangcheng (in Songnen Plain) is taken as an example for comparative analysis. The relationship between the cumulative probability distribution curves of the fused SMOS (labeled SMOS' in *Fig. 3*) and CCI data fused by piecewise linear algorithm and the Lagrange continuous algorithm is shown in *Figure 4a* and *b,* respectively.



a. Piecewise linear fusion method **b. Lagrange interpolation fusion method**

Figure 4. *Cumulative probability distributions derived using (a) piecewise linear algorithm and (b) Lagrange continuous algorithm in Shuangcheng*

The result of the piecewise linear fusion shows certain error in SMOS' data, especially in the low-value region that is indicative of drought. This error would cause

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1160511617

loss of accuracy in real-time drought evaluation based on this fused soil moisture. The correlation established using the linear equation in each segment is the cause of this error. The result of the Lagrange continuous fusion shows the cumulative probability distribution curves of the SMOS' data (fused data) and CCI data (target data) coincide almost exactly (*Fig. 4b*). The two curves retain a high degree of coincidence in the low-value region of the curve. In terms of the cumulative probability distribution curve, the Lagrange continuous algorithm has higher fusion accuracy than the piecewise linear algorithm in fusion calculation.

The fusion precision of the two algorithms is also assessed quantitatively assessed by determining the coefficient of correlation (R^2) and the Nash efficiency coefficient (E_{NS}). The Nash efficiency coefficient can be calculated as follows:

$$E_{ns} = 1 - \frac{\sum_{i=1}^{n} (O_i - P_i)^2}{\sum_{i=1}^{n} \left(O_i - \overline{O}\right)^2} \quad \text{(Eq.4)}$$

where O_i and P_i represent the CCI and SMOS' data, respectively, and $\bar{O}$ is the average of the CCI data. The closer the value of E_{NS} to 1, the better the degree of coincidence between the two results.

The values of R^2 and E_{NS} of the two curves obtained using the piecewise linear algorithm were 0.98 and 0.97, respectively. And the R^2 and E_{NS} values in the low-value region were 0.73 and 0.52, respectively. The values of R^2 and E_{NS} of the two curves obtained using the Lagrange continuous algorithm were 0.99 and 0.99, respectively. And the R^2 and E_{NS} values in the low-value region were also 0.99 and 0.99, respectively. Therefore, it is evident that the Lagrange continuous algorithm improves the fusion precision significantly in the low-value region which be used for the characterization of drought.

Verification of remote sensing soil moisture by drought event

The fused SMOS data (SMOS' data), SMOS and CCI data were also evaluated for accuracy of drought expression. Site observation data from six stations within the study area were used as the basis for quantitative evaluation of the degree of consistency between the remote sensing data and the site observation data in the expression of drought events. The in situ data comes from China crop growth and development data set in China meteorological data network. This dataset contains moisture data per ten-day for 7 soil depths at each site. The surface 10 cm data was compared with the remote sensing data for verification. Here, as quantitative evaluation indices, hit rate (*H*), false alarm rate (*F*) and equitable threat score (*ETS*) are used to reflect the level of agreement of remote sensing of soil moisture with drought events (Grayson and Western, 1998). The higher the *ETS* value, higher the *H* value and lower the *F* value, the closer the level of agreement between the remote sensing data and drought events. The cumulative probability distribution of 30% is used as the threshold of the occurrence of drought both for remote sensing data and in situ data.

These evaluation indices define *a* as the number of events when drought is shown to occur in both the in situ observations and the fused SMOS data, *b* is when drought occurs in the fused SMOS data but not in the in situ observations, *c* is when drought occurs in the in situ observations but not in the fused SMOS data and *d* is when drought

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1160511617

does not occur in either the fused SMOS data or the in situ observations. Then, *H* can be expressed as follows:

$$H = \frac{a}{a + b} \quad \text{(Eq.5)}$$

where the range of values of *H* is 0–1(1 being the best); *F* can be written as

$$F = \frac{b}{b + d} \quad \text{(Eq.6)}$$

where the range of values of *F* is 0–1 (0 being the best) and *ETS* can be expressed as

$$ETS = \frac{a - a_{ref}}{a - a_{ref} + b + c} \quad \text{(Eq.7)}$$

where the range of values of *ETS* is -1/3 to 1 (1 being the best). Here, a_{ref} is expressed as

$$a_{ref} = \frac{(a + b)(a + c)}{(a + b + c + d)} \quad \text{(Eq.8)}$$

The drought verification of SMOS, CCI and SMOS' data for the six sites in the study area is shown in *Table 1*. CCI (version 02.2) dataset produced by several active and passive remote sensing data has integrally highest hit rate and equitable threat score. SMOS data as a single data source has integrally lowest hit rate and equitable threat score. SMOS' data is a combination of CCI and SMOS, with real-time update feature as with SMOS, and has significantly more accurate results for drought events verification than SMOS. The fused SMOS data has the characteristics of long time series and real-time update, which achieves the purpose of fusion research in this paper. In terms of drought event validation, SMOS' has a better validation effect than SMOS, indicating that this SMOS' dataset can be applied to drought evaluation research.

Comparison of CCI data between version 02.2 and version 04.2

The latest version of CCI soil moisture product (v04.2) has already included the SMOS soil moisture. *Figure 5* shows the time series comparison of two different version of CCI data in a county in the study area. The new version of CCI data that incorporates SMOS is more similar in scope to SMOS data. The time series of CCI (v04.2) combined dataset is form 1978 to 2016, and the timeliness limited the application in real-time evaluation. The fusion method proposed in this paper can generate near-real-time, long-sequence data products that can reflect real drought events more accurately than SMOS.

Discussion and conclusion

The efficacy of the application of remote sensing soil moisture data to the evaluation of agricultural drought is reflected mainly in the validity and accuracy of the remote sensing data when soil moisture is low (i.e., impending or emerging drought). Remote sensing data fusion technology that uses one dataset to extend a time series or to improve the update speed of another dataset is an important method with which to improve the performance of remote sensing data application. Fusion precision and the fusion algorithm are the primary problems associated with the application of such techniques to remote sensing datasets.

The existing piecewise linear fusion method can produce certain deviation, especially in the low-value region of a soil moisture curve that represents the stage of impending or emerging drought. Such deviation could easily lead to large errors in fused data used in drought forecasting, which could result in the misreporting or omission of agricultural drought events. Adopting the fusion principle of cumulative distribution function matching, this study constructed a continuous fusion algorithm, based on which analysis of the precision of the fusion of Soil Moisture and Ocean Salinity (SMOS) satellite data with Climate Change Initiative (CCI) satellite data was conducted at county level on the Songnen Plain (Northeast China). It was demonstrated that the proposed Lagrange continuous fusion algorithm could improve the fusion precision of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1160511617

multisource remote sensing data and enhance the sensitivity of remote sensing soil moisture data in the characterization of drought.

Through application of the fusion algorithm, a fused CCI–SMOS remote sensing soil water product was generated at the county level for the Songnen Plain area. Through analysis of time series data before and after the fusion process, it was revealed that the fused SMOS data range was closer to the CCI data range than the original data, while the relative change mode of the original data was retained. After the in situ data verification, fused SMOS data has a better validation effect than SMOS. The systematic deviation of the fused remote sensing soil water product was reduced, while displaying the advantages of a long time sequence and near real-time features. The results of this study could provide data support for further real-time evaluation and frequency analysis of large-scale agricultural drought on the regional scale. Validation analysis studies between the other different data sources and in other regions are needed to further verify the availability of this new fusion method.

Abstract. Aerobic manure composting was carried out using raw materials of like fresh manure of cattle, pig and chicken, and 10% corn stalk as a raising agent. The changing trend of the composting parameters in the composting process of different livestock manures including temperature, pH, water content, nutrients and humus were studied mainly. The results showed that the organic carbon content continued to decrease during composting. At the end of the composting, the total carbon content of the composting R2 (pig manure) was highest with a value of 294.7 ± 19.15 $g \cdot kg^{-1}$, whereas the total carbon content of the R3 (chicken manure) was the lowest with the value of 284.57 ± 11.78 $g \cdot kg^{-1}$. The contents of the total nitrogen, phosphorus and potassium showed an increasing trend during livestock manure composting process. The total nitrogen and total phosphorus were found to be highest in the R2, while total potassium was the highest in R3 with values of 2.25 ± 0.18%, 2.41 ± 0.15% and 0.78 ± 0.19%, respectively. The contents of total humic acid and free humic acid demonstrated an initial decreasing trend, and later showed an increasing trend. The contents of the total and free humic acid were found to be highest R3, with values of 29.84 ± 1.98 and 25.84 ± 1.25%.

Introduction

The gradual increase in the number of extensive and intensive livestock and poultry farms satisfied the human needs for the livestock and poultry products. However, the casual stacking and inefficient treatment of the large amounts of livestock manure makes a significant burden on the environment (Liang et al., 2013). Nowadays, the livestock manure, industrial waste water and domestic waste water have been considered as the three paralleling pollution sources. Livestock manure has been an important factor that impedes the healthy development of the breeding industry. Besides, it also wastes the precious nutrient resources in large amounts (Xi et al., 2016). Currently, the livestock manure is increasing in its production with a speed of 10% each year. In 2014, the total amount of livestock manure was 6 billion t, which contained 60 million t of the nutrient resource, and equaled the quantity of the main fertilizer used in China in that year (Wang et al., 2013; Finstein et al., 2016; Guo et al., 2016). On one hand, these solid wastes contribute a certain extent of pollution to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1161911628

the environment. On the other hand, these wastes contain high quantities of organic matter and essential nutrient such as nitrogen, phosphorus, potassium and the biomass which is vital for the plants (Zhou et al., 2014). Thus, the application of the organic fertilizers prepared from the livestock manures on farmlands can not only effectively decrease the quantity of fertilizers and decrease the input cost of fertilizers, but also increase the organic matter content of soil and the soil fertility, thus promoting the sustainable utilization of farmland (Warker, 2001). In 2015, the Chinese government proposed "the activity of zero increase of the pesticide application quantity", thereby providing an unprecedented opportunity for development of organic fertilizers.

The humus produced in the composting process is a lignan derivative produced by the oxidation of the side chain of the lignan by microorganisms, which forms the key core and the skeleton of humus. This is one of the most important formation pathways of the humus (Ktilcia et al., 2014; Smars et al., 2002). In the composting process, the index of humification is related to the water-soluble carbohydrate and phenolic structure. It demonstrates the inverse relationship between the phenolic compounds and the humification index in the composting process, which confirms that the phenolic compounds are the principle materials of humus. The generation of humus with smaller molecular weight, less hydroxyl groups and minimal functional group occurs very rapidly in composting than in soil. There are many enzymes involved in the composting process, mainly including the hydrolase and redoxase. The mineralization extent of composting is mainly affected by the change in the enzyme activity of the hydrolase, while the extent and intensity of humification are affected by the change in the enzyme activity of the redoxase (Gao et al., 2010; Bernal et al., 2010). The species of the inducible enzyme dominates the composing process. Thus, the enzyme activity can demonstrate the change in the organic matter in different stages of the composting reaction (Bolta et al., 2003). Abdennaceur et al. (2011) showed that the transformation in the aromatic organic compounds in composting humus could be characterized by the enzyme activity of polyphenol oxidase, with an inverse relationship to the maturity of composting. Currently, many studies have been conducted on the microflora in aerobic composting with materials of single livestock manure; however, there are scarce reports on the comparison of the change of humus and nutrients in the composting process with raw materials of different livestock manures. In this study, the changes of material composition of heap in the composting with different livestock manures were studied using the raw materials of three livestock manure of cattle, pig and chicken, focus on change rule of TN, TP, TK, humus and free humus content in the composting process, which could provide a theoretical evidence and technical support for local enterprises.

Materials and methods

Experiment materials

Cattle manure, pig manure and chicken manure used in the composting process with livestock manures were procured from the breeding farm near Shenyang Aerospace University in Shenbei New District, Shenyang, Liaoning. Corn stalks were also provided by the same breeding farm. Corn stalks were cut into pieces of 2-4 cm by the knife mill before use. The physicochemical properties of composting materials are shown in *Table 1*.

DOI: http://dx.doi.org/10.15666/aeer/1705_1161911628

Table 1. *Agrochemical characters of different compost materials*

Raw materials	Water content (%)	pH	Total carbon (%)	Total nitrogen (%)	Total potassium (K_2O%)	Total phosphorus (P_2O_5%)	C/N
Cattle manure	68.9	7.64	38.32	1.78	1.48	1.45	21.53
Pig manure	73.4	7.35	39.41	1.80	1.58	1.78	21.89
Chicken manure	70.8	7.28	41.15	2.99	1.52	2.98	13.76
Corn stalk	21.5	7.19	54.82	1.04	0.98	0.46	52.71

Experimental method

An aerobic static composting was conducted using the composting materials of three livestock manures, including cattle manure (R1), pig manure (R2) and chicken manure (R3). The 21 d composting reaction was conducted with 6 self-designed aerobic composting boxes among which 2 composing boxes were considered as a group to contain single type of livestock manure.

The results of every parameter data in the experiments were taken as an average. The porosity and organic matter content of the livestock manure were adjusted by additives of 10% corn stalk. In the whole composting process, different parameters like temperature, oxygen concentration, carbon dioxide concentration, density, etc. was monitored. Besides, the stink gas produced during the composting process was treated using a bio-filter (as shown in *Fig. 1*). The changes in the aforementioned parameters in the composting process were compared and the pile nutrients (the content of C-N-P-K) in the composing process in different livestock manure, humus and free humus were mainly analyzed.

Experiment apparatus

The self-designed composting box was used in the composting experiment. The experiment apparatus of the composting is shown in *Figure 1*.

Results and discussion

Changes in C-N-P-K content in the composting with different livestock manures

Change in total carbon content in the composting with different livestock manures

Figure 2 shows the changes in the total carbon content in the composting process with different livestock manures. It was seen that the total carbon contents in the pile were in the following order at the initial stage of the composting process: R3 (chicken manure) > R1 (cattle manure) > R2 (pig manure), with corresponding values of 378.45 ± 25.45 g·kg^{-1}, 366.28 ± 18.18 g·kg^{-1} and 358.24 ± 24.18 g·kg^{-1}, respectively. With the process of the composting of the livestock manures, the organic carbon source was transformed to carbon dioxide due to the decomposition of the organic carbon by microorganisms. Thus, the organic carbon content in the pile exhibited a decreasing trend. At the end of the composting, total carbon content was in the following order: R2 (pig manure) > R1 (cattle manure) > R3 (chicken manure), with corresponding values of 294.7 ± 19.15 g·kg^{-1}, 290.45 ± 13.14 g·kg^{-1} and 284.57 ± 11.78 g·kg^{-1}, respectively. The decreasing amplitude of the total organic carbon in the composting piles with different livestock manures of R1, R2 and R3 were different with a degradation rate of the organic carbon of 20.7%, 17.7% and 24.8%, respectively. The decreasing amplitude of R3 (chicken manure) was the largest, whereas the decreasing amplitude of R2 (pig manure) was the smallest. In the whole composting process, the change of the total carbon content showed a decreasing trend due to the transformation of the carbon, which was the main component of energy material of microorganisms and cells to yield carbon dioxide and humus by the decomposition and utilization of microorganisms in the composting process. The loss of carbon due to the emission of the carbon dioxide resulted in the gradual decrease of the organic carbon during the composting process. At the end of the composting, the total carbon content of R2 (pig manure) was the highest, whereas the total carbon content of R3 (chicken manure) was the lowest (Khalil, et al., 2011; Guo et al., 2016).

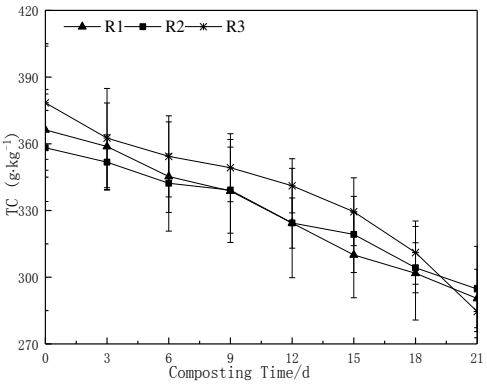

Figure 2. *Change of TC in three kinds of livestock dung composting*

Change in total nitrogen content in the composting with different livestock manure

Figure 3 shows the change in the total nitrogen content in the composting process with different livestock manures. It was seen that the total nitrogen content in the initial composting process was in the order of: R2 (pig manure) > R3 (chicken manure) > R1 (cattle manure), with corresponding values of 1.57 ± 0.11, 1.41 ± 0.08 and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1161911628

1.28 ± 0.18%, respectively. With the process of the composting reaction, the total nitrogen percent content in all the composting piles with livestock manures showed an increasing trend, mainly because both the organic carbon and the organic nitrogen were assimilated and catabolized by microorganisms in the composting process. The need of organic carbon in the microorganisms was higher than the need of organic nitrogen, with the general need ratio of carbon to nitrogen as 25:1. The degradation velocity of organic carbon was higher than that of organic nitrogen in the composting degradation process, resulting in the lower attrition rate of organic nitrogen than that of organic carbon in the composting process. Thus, the percent content of total nitrogen in all the composting piles with livestock manures demonstrated an increasing trend. At the end of the composting, the total nitrogen content in R1, R2 and R3 composting increased, with the corresponding increasing amplitude of 50.78%, 43.33% and 51.77%, respectively, among which the increasing amplitude of R3 (chicken manure) was the largest, while the increasing amplitude of R2 (pig manure) was the smallest.

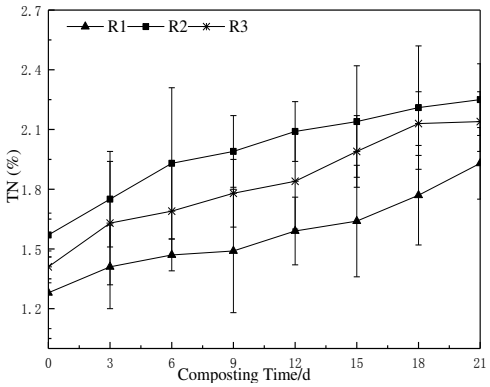

Figure 3. *Change of TN in three kinds of livestock dung composting*

Change in total phosphorus content in the composting with different livestock manure

Figure 4 shows the change of the total phosphorus content in the composting process with different livestock manures. It was observed that the total nitrogen content in the initial composting process in different piles was in the following order: R2 (pig manure) > R3 (chicken manure) > R1 (cattle manure), with corresponding values of 1.80 ± 0.12, 1.64 ± 0.17 and 1.25 ± 0.15%, respectively. The percentage content of total phosphorus in all the composting pile with livestock manures demonstrated an increasing trend with the process of the composting reaction. This was mainly due to the assimilation and catabolism of organic carbon, organic nitrogen and organic phosphorus by microorganisms in the composting process with livestock manures. The need of organic carbon for microorganisms was higher than that of the organic nitrogen and organic phosphorus. And the general need ratio of C:N:P was 100:5:1. The degradation velocity of the organic carbon in the composting degradation process was higher than that of organic phosphorus, resulting in the lower attrition rate of organic phosphorus than that of the organic carbon and organic nitrogen in the composting process. Thus, the percent content of total phosphorus in the composting piles with livestock manures demonstrated an increasing trend. At the end of the composting, the total phosphorus contents of R1, R2 and R3 composting increased by 25.61%, 33.38% and 11.58%, respectively, among which the increasing amplitude of R2 (pig manure) was largest,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1161911628

whereas the increasing amplitude of R3 (chicken manure) was smallest. There was neither any production of leachate nor any loss of phosphorus. Thus, the evaporation loss of the total phosphorus in the composting was relatively small.

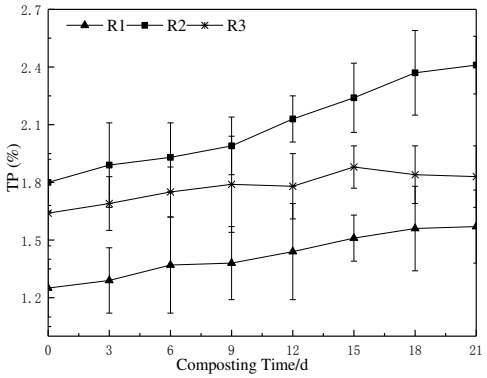

Figure 4. *Change of TP in three kinds of livestock dung composting*

Change in total potassium content in the composting with different livestock manures

Figure 5 shows the change in the total potassium content in composting process with different livestock manures. It was seen that the total potassium content in the initial composting process in the piles was in the following order: R3 (chicken manure) > R1 (cattle manure) > R2 (pig manure), with corresponding vales of 1.21 ± 0.12, 1.14 ± 0.12 and 1.03 ± 0.22%, respectively. The total potassium percentage content in all the composting piles with livestock manures demonstrated an increasing trend with the process of composting reaction due to the low adsorption and utilization rate of potassium. In the composting process with livestock manures, the organic carbon, organic nitrogen and organic phosphorus were all assimilated and catabolized by microorganisms. The need of organic carbon, organic nitrogen and organic phosphorus of microorganisms were higher than that of organic potassium. There was almost no loss of potassium in the composting process. Thus, the total potassium percentage content in the composting pile with all different livestock manures demonstrated an increasing trend. At the end of the composting, the total potassium content of R1, R2 and R3 composting increased by 35.88%, 62.13% and 47.07%, respectively, among which the increasing amplitude of R2 (pig manure) was largest, whereas the increasing amplitude of R1 (cattle manure) was smallest.

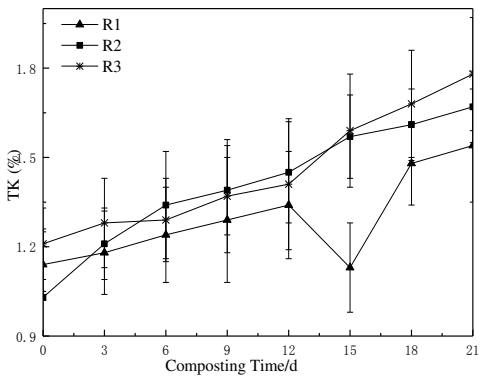

Figure 5. *Change of TK in three kinds of livestock dung composting*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1161911628

Change of humus content in the composting process with livestock manures

The humus content is the key index describing the quality of organic fertilizer, which can enhance the soil fertility, change the formation of aggregate structure, adjust the soil porosity, and increase the ability of ventilation and water-retaining of soil. Furthermore, the growth of crops can be promoted by the changing of metabolism in plants influenced by the changing of enzyme activity.

Change in total humic acid content in the composting process with livestock manures

Figure 6 shows the change in the total humic acid content in the composting process with livestock manures. It was seen that the total humic acid content in the initial composting process in the piles was in following order: R3 (chicken manure) > R1 (cattle manure) > R2 (pig manure), with corresponding values of 37.82 ± 2.45, 36.84 ± 1.25 and 32.18 ± 1.58%, respectively. With the process of the composting reaction, the total humic acid content in the pile demonstrated an initial decrease, followed by an increase in all the piles. In the 0-15 d period of the reaction, the total humic acid in the initial period of R1, R2 and R3 was 36.84 ± 1.25, 32.18 ± 1.58 and 37.82 ± 2.45%, respectively, that decreased after 15 d to 14.87 ± 1.98, 13.64 ± 1.78 and 18.45 ± 2.40, respectively, with a corresponding decreasing amplitude of 59.63, 57.61 and 51.21%, respectively. This was due to the decomposition of the unstable humic acid generated in the degradation of the susceptible organic matters by the thermophilic bacteria in the high temperature period. The content of total humic acid reached the minimum at 15 d, and then increased. At the end of the reaction, the total humic acid content of R1, R2 and R3 were 25.12 ± 1.77, 24.21 ± 1.89 and 29.84 ± 1.98%, respectively. The increase of the total humic acid content in the late stage of the reaction was due to the decrease of the temperature and the enhancement of the microorganism activities, which was beneficial for the stability of humus structure and properties. The organic matter that was difficult to degrade was transformed to humic acid by the microorganisms. Thus, the total humic acid content in the product was found to be increased, thereby enhancing the quality of the composting product.

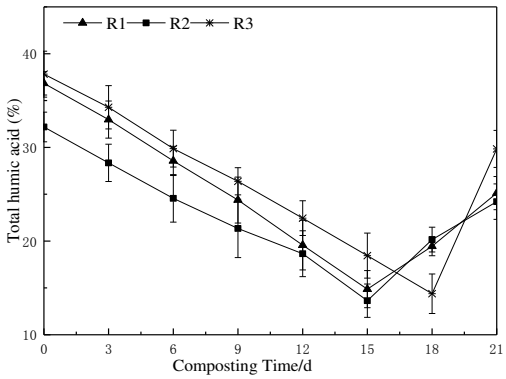

Figure 6. *Change of total humic acid in three kinds of livestock dung composting*

Change in free humic acid content in the composting with different livestock manures

Figure 7 shows the change in the free humic acid content in the composting process with different livestock manures. It was seen that the changing trends of the free and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1161911628

total humic acid were similar. The free humic acid content was in a descending order: R3 (chicken manure) > R1 (cattle manure) > R2 (pig manure) in the initial stage of composting reaction with livestock manures with corresponding values of 26.84 ± 1.87, 19.87 ± 1.23 and 18.53 ± 1.29%, respectively. With the process of the composting reaction, the free humic acid content in the pile demonstrated a trend of initial decrease, with a subsequent increase. In the 0-15 d period of the reaction, the free humic acid content in the initial stage of R1, R2 and R3 piles was 19.87 ± 1.23, 18.53 ± 1.29 and 26.84 ± 1.87, respectively, which decreased to 16.88 ± 1.99, 15.98 ± 1.98 and 20.18 ± 1.27, respectively, at 15 d, with corresponding decreasing amplitudes of 15.04, 13.76 and 24.81%, respectively. This was due to the decomposition of the unstable humic acid and the even more unstable free humic acid by the thermophilic bacteria. The content of free humic acid reached the minimum at 15 d and then increased. At the end of the reaction, the free humic acid content of R1, R2 and R3 was 24.84 ± 1.87, 23.45 ± 1.56 and 25.84 ± 1.25, respectively. The increase of the free humic acid content in the late stage of reaction was due to the decrease in the temperature and the enhancement of microorganism activities, which were beneficial for the stability of humus structure and properties. The organic matter which was difficult to degrade was transformed to total humic acid by the microorganisms. Thus, the total humic acid content in the product was increased, thereby enhancing the quality of the composting product.

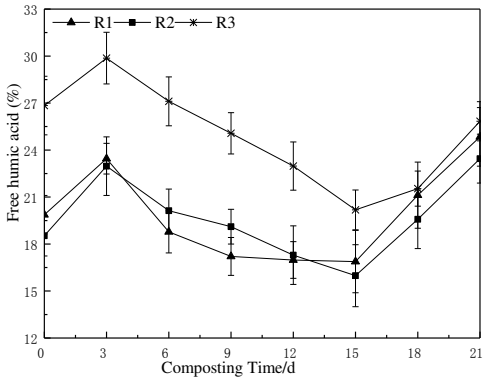

Figure 7. *Change of free humic acid in three kinds of livestock dung composting*

The results of the variance analysis showed that the discrimination of free humic acid content in the composting piles with R1, R2 and R3 livestock manures was not significant with a descending order of R3 (chicken manure) > R1 (cattle manure) > R2 (pig manure).

Humic acid in the composting was transformed from newborn and original humic acid in the materials. The composting time, raw materials, composting technologies, and the environment conditions can be factors limiting the formation of humic acid in composting (Xiao et al., 2011). Besides, microorganisms are also known to greatly influence the formation of humic acid, e.g. mesophilic microorganisms in the composting process can promote the formation of humic acid (Kinney et al., 2012; He et al., 2004; Malifiska et al., 2014).

The experimental results showed that the contents of total and free humic acid in all the composting piles with livestock manures increased dramatically in the late stage of the composting, accompanied by a decrease in temperature. The decrease of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1161911628

temperature and maturity could promote the increase of the content of total humic acid and thus enhance the composting quality. At the end of the composting, the contents of total and free humic acid in the composting with chicken manure were highest.

Conclusions

1) The organic carbon content in the composting with livestock manures gradually decreased. At the end of the composting, the total carbon content of R2 (pig manure) composting was highest with the value of 294.7 ± 19.15 $g \cdot kg^{-1}$, whereas the total carbon content of R3 (chicken manure) composting was lowest with the value of 284.57 ± 11.78 $g \cdot kg^{-1}$.

2) Total nitrogen, total phosphorus and total potassium in all the composing process with livestock manures demonstrated an increasing trend. At the end of the composting, the contents of total nitrogen, total phosphorus and total potassium were highest in R2 (pig manure), R2 (pig manure) and R3 (chicken manure), respectively, with corresponding values of 2.25 ± 0.18, 2.41 ± 0.15 and 1.78 ± 0.19%, respectively.

3) The contents of total and free humic acid in all the composting process with livestock manures demonstrated a trend of an initial decrease, followed by an increasing trend. At the end of the composting, the contents of total and free humic acid in R3 (chicken manure) were highest with corresponding values of 29.84 ± 1.98 and 25.84 ± 1.25%, respectively.

This article mainly writes the use of pig manure, chicken manure and cow dung for composting, to explore the trend of physical and chemical indicators such as temperature and humus during composting. In this experiment, only a single livestock manure is used for composting. Next, I will choose different livestock manures mixed compost, or livestock manure and straw mixed compost will be selected for scientific guidance of agricultural and livestock waste composting quality control.

(Received 22nd Apr 2019; accepted 12th Jul 2019)

Abstract. Biodegradable plastic films, which are alternatives to traditional polyethylene plastic films and have similar functions, are incorporated into the soil after the crop season, and could, therefore, increase grain yield and decrease film-residues. In this study, we investigated the effect of three types of biodegradable films mulched (liquid film (LF), multi-functional paper film (MPF), and powder film (PF)), conventional plastic film mulched (PE) and unmulched (CK) on soil water and temperature in pots without crops. The results showed that cumulative temperature increased markedly under LF, PF, PE, and MPF by 20.3, 19.3, 24.4, and 22.7 °C, respectively, compared to CK. The greatest reduction in total evaporation compared to CK was observed under PE (43.9 mm). Soil evaporation was reduced the most under PE (36.5mm); however, the MPF and PF treatments significantly decreased total soil evaporation by 2.7 mm and 3.1 mm, respectively, compared to CK. Our results indicated that biodegradable films improved the average soil temperature at a depth of 10 cm and reduced soil evaporation, under MPF and PF resulting in the greatest overall improvement. We concluded that multi-functional paper film and powder film can be alternatives to traditional polyethylene plastic film.

Introduction

In recent decades, plastic film mulching has been one of the most important agronomic practices impacting crop yields worldwide (Zhang et al., 2016). Many earlier studies have shown that plastic film mulching offers considerable advantages, such as increasing soil temperature, reducing evaporation, improving crop quality and yield, controlling salinity accumulation, and reducing the leaching of fertilizer (Wang et al., 2016; Xu et al., 2006). For these reasons, the utilization of plastic film has increased substantially; similarly, the area mulched has also increased. Previous studies have shown that the worldwide consumption of plastic film has reached 0.5–1.5 million tons per year (Yang et al., 2015). Consumption of plastic film in China accounts for 60% of the world plastic film demand, making China the largest market in the world for these products (Yang et al., 2015). However, from the environment's perspective, plastic film mulching can cause several environmental issues because of its non-degradable nature. After crop harvesting, the plastic film progressively breaks down into pieces that remain and accumulate in the field (Briassoulis et al., 2013, 2015). Moreover, these residual films have been shown to decrease soil permeability, hinder crop root development, reduce nutrient and moisture absorption by crops, and inevitably result in crop production losses (Yan et al., 2006). Many measures have been undertaken to counter these problems, including burning and recycling of plastic films or disposal in landfills (Kyrikou and Briassoulis, 2007). In China, however, the recovery rate of plastic films from the fields was very low because of high labor costs and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1162911638

poor efficiency of the recovery machinery (Zhang et al., 2016). Thus, an increasing number of studies have been conducted to develop eco-friendly alternative mulch products that satisfy all the desired functional properties of plastic films (Touchaleaume et al., 2016). Alternative mulching products such as biodegradable films, which have properties similar to conventional plastics but are decomposed and catabolized by microorganisms into carbon dioxide and water over time, are being increasingly used for crop production as they represent a sustainable agronomic solution (Costa et al., 2014). Studies have indicated that biodegradable film can theoretically reduce disposal and labor costs markedly by becoming incorporated directly into the soil rather than requiring disposal by burning or landfill use (Kasirajan and Ngouajio, 2013). Additionally, the biodegradable film had considerable beneficial effects on soil temperature and water content by reducing heat loss and evaporation (Ren et al., 2016). However, different biodegradable films have different functional properties. Studies have shown that some biodegradable films do not have a significant influence on soil water content and temperature because of their short lifespan. Moreover, it has also been suggested that the degradation rate of some biodegradable films is low, causing more serious problems than residual films. Taken together, these results suggest that the development of new types of biodegradable films is required to consistently improve their performance in the field.

In this study, three new types of biodegradable films and their effect on soil water content and temperature were investigated. The first film was a liquid mulching film; this is a new kind of agricultural product that is mainly manufactured from organic polymer materials. It is sprayed or poured onto the soil surface and dries to form a durable, permeable film that connects with soil particles to form a special soil membrane structure; this allows the plant to breathe and water to penetrate, thereby aiding moisture retention and prevention of scattering of solid fertilizers (Yin et al., 2013). The second film was a powder mulching film (humic acid-degradable film) that is mainly manufactured from the raw material humic acid. It can also be sprayed onto the fields to form a durable and biodegradable black film that helps retain moisture and improve soil conditions (Tian et al., 2008). The third film was a multi-functional paper film that not only has good mechanical strength, light transmission, water penetration, and water and heat preservation properties, but also can degrade naturally over a certain period of time (Zhou and Zhu, 2002); this film is produced from plant paper pulp and annexing agents such as wet strength and transparent agents.

In this study, these three different types of degradable mulching films were used as soil mulch to compare their effects with common plastic films and a non-mulching control. The effects and characteristics of the different mulch films on soil moisture and temperature were determined. The results of this study will be useful for farmers in selecting more suitable field mulch films, and for smallholders in improving their products and increasing the yield in future.

Materials and methods

The experiments were conducted from 7 September to 15 November 2014 in the rain-protection shed of the Liaoning Province Key Laboratory of Water Saving (Institute of Applied Ecology, Chinese Academy of Sciences) that is located in Shenyang city, Liaoning Province. It is situated at 41°10′N–42°12′N latitude and 123°20′E–123°45′E longitude at a height of 44.7 m above sea level. This area is characterized by temperate semi-humid continental climate, with a daily average of 6 h of sunshine.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1162911638

The soil was collected from Fuxin Mongolian autonomous county of Liaoning province. The type of soil is brown earth and the texture is sandy loam. Prior to the experiment, the soil was dried and ground through a 5-mm sieve.

We used the following films: polyethylene plastic film (width of 200 mm, thickness of 0.01 mm); powder film (fully degradable plastic powder); liquid membrane (fully degradable liquid mulch film); and multi-functional paper film.

In this experiment, five treatments were used: mulching with (a) polyethylene plastic film (PE), (b) liquid film (LF), (c) multi-functional paper film (MPF), or (d) powder film (PF), and (e) an unmulched control (CK) (*Fig. 1*). The experiment was conducted in a randomized complete design and each treatment repeated three times. Each pot was filled with 10 kg of soil to which 3.6 kg of water was added to achieve an average soil moisture content of 28%. The pot height is 30 cm and the upper and lower inner diameters are 26 cm and 18 cm, respectively and the height of soil in pot is 25 cm.

(a) (b) (c) (d) (e)

Figure 1. *The different treatments used in this experiment*

The weight of each pot was measured at 9:00 A.M. on the first day using an electronic balance with an accuracy of 0.005 g. The pots were weighed daily for the first 20 d after the films were mulched, every 2 d from 20 to 40 d, and every 5 d from 40 d to 70 d. The amount of evaporation between two time-points was calculated as the difference between the weight of the pots at those two time-points. For each treatment, the cumulative soil evaporation was the difference between the weight of the first pot and the weight of the last pot and then it was converted to expressed in millimeters.

Soil temperature was measured at depths of 5 and 10 cm using a geothermometer at 9:00 A.M every 3 d from the first day to the last day of the experiment. For each treatment, the cumulative soil temperature was the sum of all recorded temperatures.

The liquid membrane was observed using a Quanta 250 environmental scanning electron microscope at half a month and four months respectively after it was mulched

SPSS software (version 20) was used for statistical analysis of the experimental results. The effects of the treatments on the measured parameters (soil evaporation and soil temperature) were evaluated using one-way analysis of variance (ANOVA). Least significant differences (LSD) were used to analyze the differences between the means of treatments. The differences were considered statistically significant with a threshold of $p \leq 0.05$.

Results and discussion

Effect of different treatments on soil moisture

Differing patterns of soil evaporation (soil water change) were observed under different mulch treatments from 7 September to 15 November 2014. This is consistent with the different materials having different effects on evaporation (*Fig. 2*). *Figure 2* shows that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1162911638

mean soil evaporation of MPF, PF, LF and CK during the experiment period were 1.1, 1.1, 1.2 and 1.2 mm, respectively, which are significantly higher than that of PE (0.2 mm). In addition, soil water evaporation fluctuated more under the biodegradable film treatments (MPF, PF, and LF) and the control (CK), which coefficient of variance were 89%, 83%,87% and 82% respectively, than the PE treatment (47%). These results indicated that the polyethylene plastic film was able to better prevent evaporation than the biodegradable films; this is consistent with previously reported results (Ren et al., 2016). Costa et al. (2014) also reported that the average soil water content under the PE treatment was markedly higher than that under the biodegradable film mulching treatments. Marked variations in soil water evaporation under the biodegradable film mulching treatments and CK were recorded in first twenty days mainly because of the higher air temperature and longer lighting time in September; this seasonal pattern also likely explains that greater fluctuation in evaporation observed in September than after September. *Figure 3* shows that although evaporation under PE was lower than that under the three biodegradable film mulching treatments, the MPF and PF treatments greatly improved moisture retention in comparison with CK. This result is consistent with the results of Ren et al. (2016), who found that the use of biodegradable films considerably reduced soil water evaporation and enhanced the retention of soil moisture, and those of Wang et al. (2016), who reported that the use of biodegradable films resulted in soil water storage values between 90.4%–95.4% of those obtained under the PE treatment. Taken together, these results indicate that biodegradable films are acceptable substitutes for plastic film in terms of moisture retention.

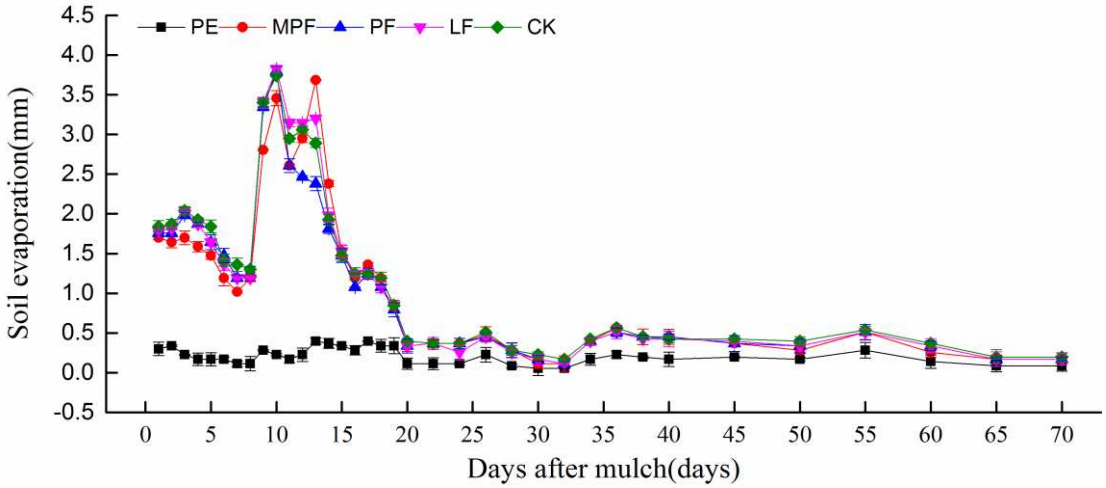

Figure 2. *Changes in soil moisture under different treatments*

The total evaporation for different mulching treatments are illustrated in *Figure 3*. Generally, the total amount of soil evaporation under the mulching treatments was significant less than for CK. Compared to CK, the, LF, PF, PE, and MPF treatments reduced the total evaporation by, 0.7, 3.1, 36.5 and 2.7 mm, representing 1.6%, 7.1%, 83.0%, and 6.0% of the evaporation observed under CK, respectively. Overall, the total soil moisture evaporation was the lowest under PE and higher under PF, MPF, and LF in that order. This was similar to the results of a four-year field study in semi-arid areas, such as the Loess Plateau, conducted by Ren et al. (2016), who found that the PE treatment showed markedly higher soil moisture than the liquid film mulching and non-mulching treatments.

DOI: http://dx.doi.org/10.15666/aeer/1705_1162911638

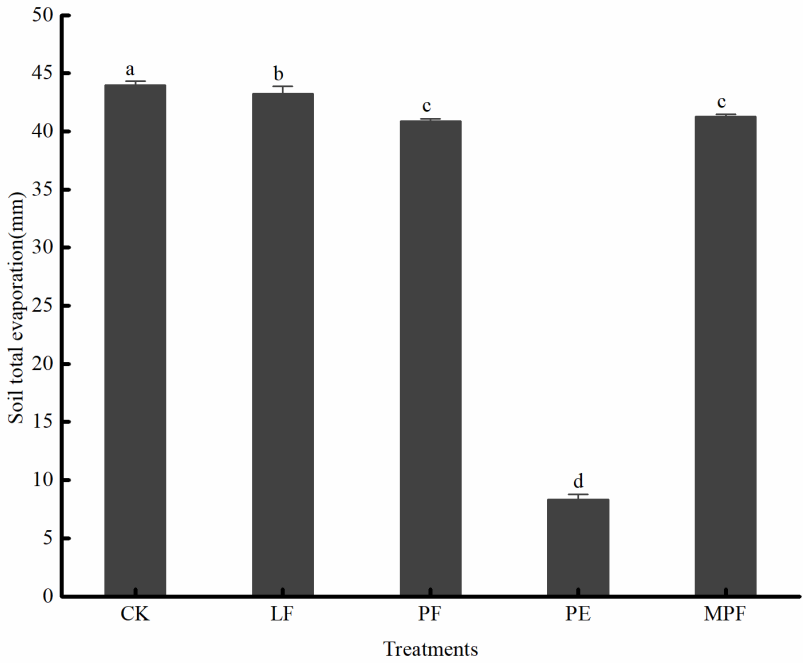

Figure 3. *Total evaporation under different treatments. (Different lowercases in a group indicate significant differences at p = 0.05 level among different treatments)*

Effect of different treatments on soil temperature

The trends in soil temperature were almost identical under the five treatments, likely because of the effects of air temperature. Many previous studies have suggested that topsoil temperature is affected considerably by air temperature (Bai et al., 2015). Consistent with these, we also found that average soil temperature at the depth of 10 cm was generally significantly affected by mulching ($p < 0.05$) (*Fig. 4*). The experimental results showed that mean soil temperature under the four mulching treatments was significantly higher than under CK. This result is consistent with a previous study that showed mean soil temperature was effectively enhanced by mulching with plastic films and biodegradable films (Ren et al., 2016). *Figure 4* also illustrates that at different stages of the experiment, the warming effects of different mulching materials differed. From 25 d to 50 d after the start of the experiment, the soil temperature was the highest under PE, indicating that PE has a stronger effect on soil temperature. This result is in agreement with those of previous studies (Costa et al., 2014; Ren et al., 2016). In the first 25 d of the experiment, however, the soil temperature under LF and MPF was higher that under PE, probably because in the first 25 d of the experiment, stable structures formed under MPF and LF were more useful in early stage. In the last 20 d of the experiment, although the soil temperature increased with air temperature about 55 d after mulching, there were no significant differences in soil temperature between the four mulching treatments. The reason is that in the last mulching period (in November), the air temperature was relative low and had not significant influence on soil.

The cumulative soil temperatures under different treatments are shown in *Figure 5*. For the mulching treatments, all the cumulative mean soil temperatures were markedly higher than for CK. Compared to CK, the cumulative temperatures under LF, PF, PE, and MPF were increased by 20.3, 19.3, 24.4, and 22.6 °C, representing 5.0%, 4.8%,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1162911638

6.0%, and 5.6% of the cumulative temperature of CK. These findings are consistent with the results of other studies (Bai et al., 2015; Li et al., 2012). Liu (2012) reported that there were significant warming effects under biodegradable film treatments compared to CK. Moreover, Hu (2015) demonstrated that the use of biodegradable film in maize cultivation considerably improved the soil temperature at the depth of 10 cm. Notably, *Figure 5* illustrates that the cumulative temperature was the highest under PE, being 4.1, 5.1, and 1.7 °C higher than that under LF, PF, and MPF, respectively. This is consistent with the results of Bai et al. (2015), who found that the mean temperature at the depth of 25 cm was increased by 1.0 °C under PE, compared to biodegradable film. Although the cumulative temperature was lower under LF, PF, and MPF than under PE, these three treatments still had considerably higher cumulative temperatures than CK. A similar result was obtained by Costa et al. (2014) who reported that biodegradable film mulching improved soil warming and provided highly favorable conditions for crop growth. Taken together, these results indicate that biodegradable polymers, because of the warming effects of the biodegradable film, are sustainable alternatives to PE films in some agricultural production systems.

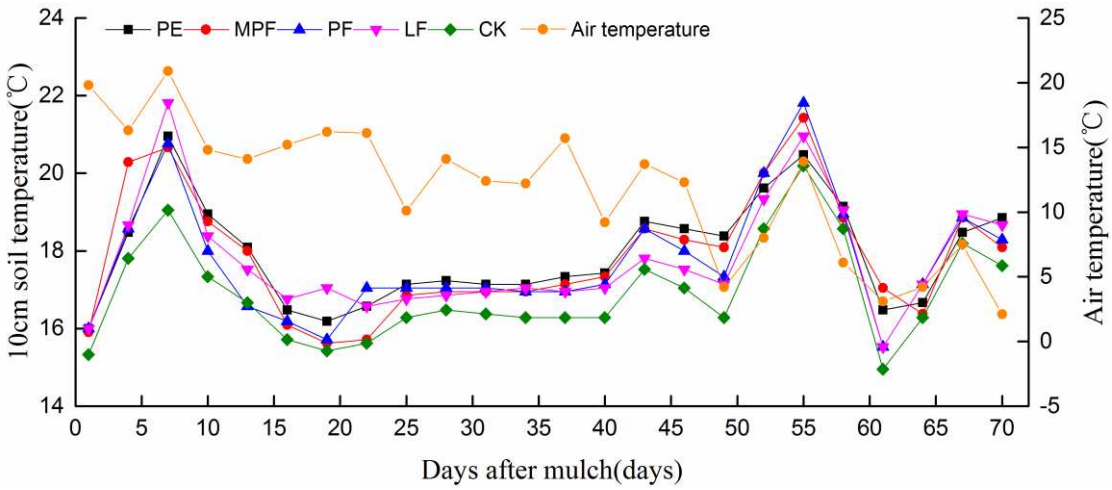

Figure 4. *Soil temperature at the depth of 10 cm under different treatments*

Modelling the effects of time spent mulched by film and soil temperature on total soil evaporation

Soil moisture is an important factor affecting crop growth; film mulching could reduce excessive soil moisture evaporation and improve soil temperature. Therefore, evaluation of the effects of different film mulching treatments on soil evaporation may provide useful information regarding selecting mulching planting technologies. The time spent mulched by a film and the soil temperature were chosen as independent variables that affect changes in soil moisture content, and the total variation in total evaporation under different treatments was chosen as the dependent variable to establish a regression model using SPSS 20.0; this model was used to analyze the effects of film-mulched time and soil temperature on total soil evaporation. The results are shown in *Table 1*.

Table 1 shows that the least adjusted R-square of all treatments was 0.69 at $p < 0.05$; this indicates that the linear equations effectively and adequately represent the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1162911638

relationship between soil evaporation, soil temperature and mulching time. A negative relationship between evaporation and mulching time was obtained from the linear equations of LF, PF, MPF, and PE. This suggests that a long film- mulched time would reduce the total evaporation of soil moisture. In contrast, a higher soil temperature would result in increased evaporation.

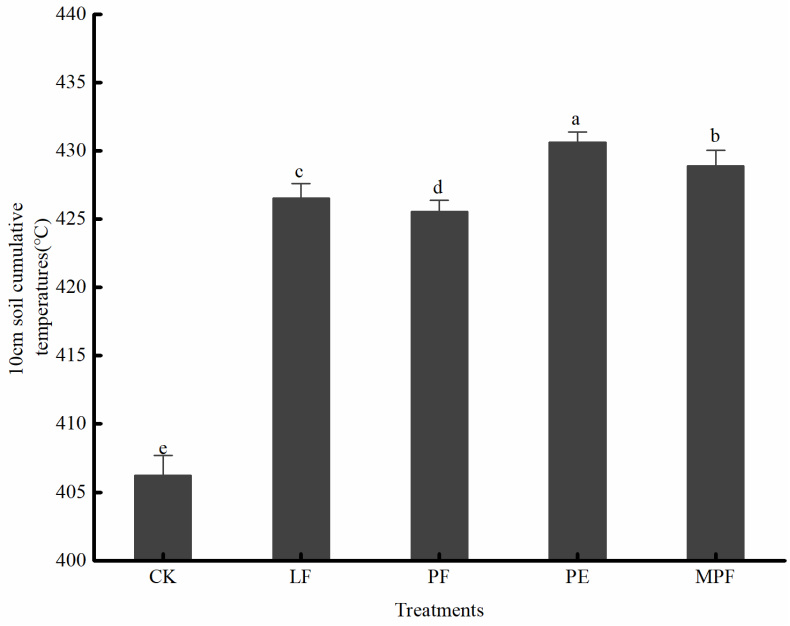

Figure 5. *Cumulative soil temperature under different treatments. (Different lowercases in a group indicate significant differences at p = 0.05 level among different treatments)*

Table 1. *Soil moisture model under different treatments*

Treatment	Linear relationship	Adjusted R Square	Sig.
Liquid film	Evaporation = 0.001-t*0.002 + 0.004*T	0.746	.000[b]
Powder film	Evaporation = 0.007-t*0.002 + 0.003*T	0.826	.000[b]
Paper film	Evaporation = 0.025-t*0.002 + 0.002*T	0.694	.000[b]
Plastic film	Evaporation = 0.008-t*0.002 + 0.04*T	0.718	.000[b]

t: time spent mulched; T: cumulative temperature

Microscopic effects of liquid film on soil structure

Combination of liquid film and soil particles

Microscopic analysis of the effects of liquid film on soil structure is shown in *Figure 6.* The results show that many small particles are combined into large particles on the soil surface by sticky flocculated colloid. Between these large particles, there were many fabric couplings that were similar to the chemical bonding that occurs in molecular structures. These couplings could connect two or more of the soil particles, allowing them to form a stable structure. In addition, these fabric couplings have a strong bonding force that makes soil particles connect in a lattice frame rather than "point to point".

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1162911638

When soil particles were mulched by the liquid film, the physical and chemical properties of soil improved and the accumulation of organic matter contributed to the formation of soil membrane structure that enhanced the stability of the soil surface.

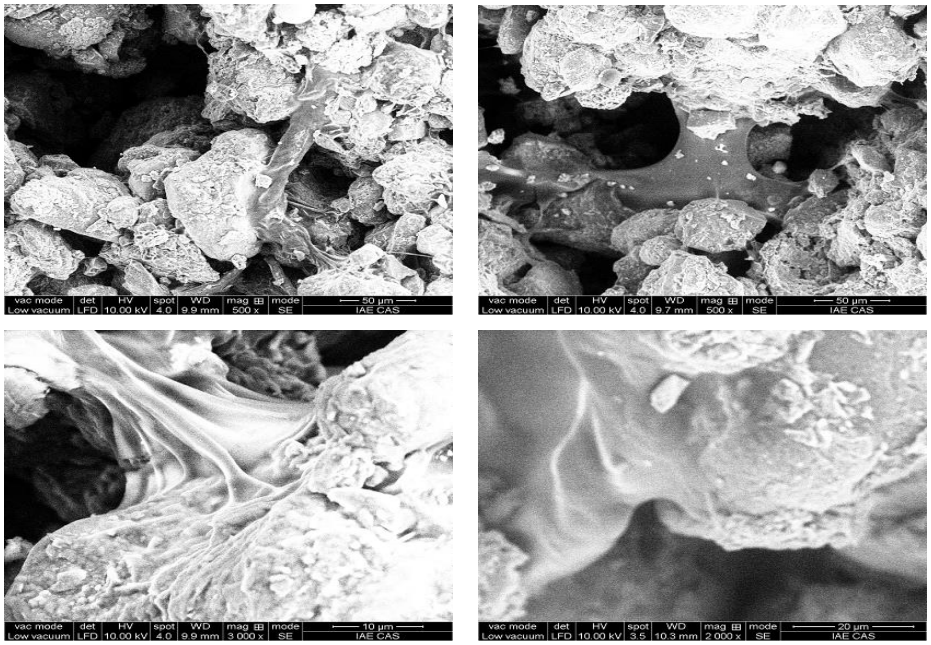

Figure 6. *Connection of the liquid film with soil particles*

Surface tension of the membrane structure

Surface tension of the membrane structure is illustrated in *Figure 7*. These images show that even with the irregular size of soil particles and the irregular size of the pores between particles, the membrane can make a tight connection between rough soil particles through the surface tension of the liquid membrane. Regardless, the surface tension of the liquid membrane on the surface of soil particles was easily broken. As shown in *Figure 7*, the liquid membrane between the soil particles was prone to damage, thereby reducing the films moisture-retaining effects. This likely explains why evaporation was higher under LF than under the other two biodegradable film mulching treatments (*Fig. 3*).

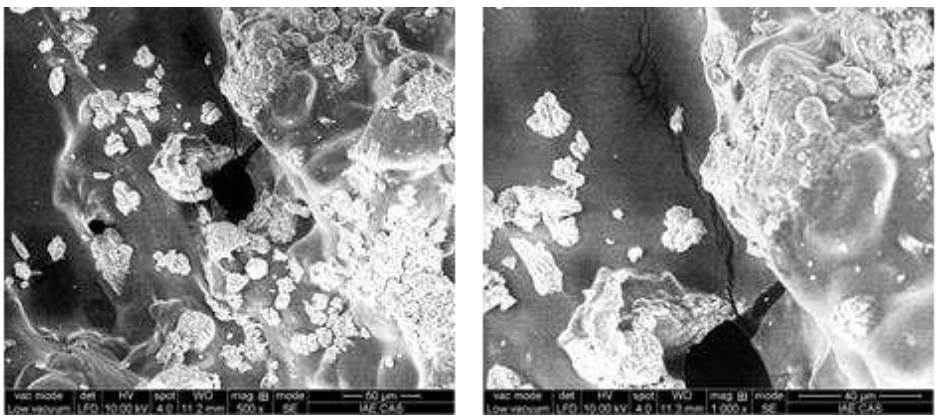

Figure 7. *The surface tension of the membrane structure*

DOI: http://dx.doi.org/10.15666/aeer/1705_1162911638

Conclusion

Three biodegradable mulching films (liquid film, powder film, and multi-functional paper film) were used in this study and compared with the common plastic film and an untreated, unmulched control. Significantly less evaporation was observed under powder film, multi-functional paper film, and polyethylene plastic film treatments relative to CK. In terms of water retention, plastic mulch film was the best, followed by powder film and multi-functional paper film, with the liquid mulch having the lowest water retention of the tested films.

Soil warming was enhanced by mulching with plastic and biodegradable films. Moreover, soil temperature was the highest under the plastic film, followed by multi-functional paper film, powder film, and finally liquid film. The increase in cumulative soil temperature was significantly higher in the early stages of the experiment than in the later stages.

Scanning of the soil microstructure using an electron microscope showed that the correct spraying of liquid membrane could effectively cement soil particles together and reduce moisture evaporation. However, the stable structure formed by the liquid film degraded easily, accounting for the reduced moisture-retaining and warming effects that were observed under the liquid film compared to the other biodegradable film treatments.

The results of this study indicate that, currently, the effects of biodegradable films on water retention and conservation of soil temperature are still inferior to plastic films. Biodegradable film producers should, therefore, further improve their products to meet future agricultural development needs.

Abstract. The green building rating tools can be used to evaluate, and promote the building industry's sustainability, but previous relevant research on the comparative analysis were mainly conducted at the general, category or criteria level, very little research has been done from the indicator level via statistical analysis. Especially, research on the comparison of water efficiency is rare. To this end, this paper will focus on a thorough and comprehensive comparison of the water efficiency between Leadership in Environmental and Energy Design (LEED, US) and Evaluation Standard of Green Building (ESGB, China). The comparison of the specific terms includes six aspects, i.e. macroscopic, building water use, landscape water use, heat and cooling system use water, nontraditional water source utilization and water monitoring system. The similarities and differences of water efficiency standards are described. In the end, the development direction of domestic water efficiency technology is pointed out and meanwhile, a more reasonable water efficiency standard in China is suggested. The LEED is also suggested to use the detailed items of the non-traditional water source utilization from ESGB for reference. The research results would serve as a useful reference for both industry practitioners and academics that are interested in green buildings.
Keywords: *building certification systems, water, sustainability, green rating systems, comparative analysis, research review*

Introduction

The building industry gives great contribution in creating monetary values and jobs, and makes profound influence on the economy and society (Kang et al., 2016; Lin and Liu, 2015; Liu and Lin, 2016; Marjaba and Chidiac, 2016). However, the development of building industry causes more consumption on the natural resources and energy, simultaneously creates more social problems with carbon emissions, environmental degradation and global warming, etc. According to the World Business Council for Sustainable Development, building block production accounts for approximately 40% of total energy consumption (WBCSD, 2008), 30% of greenhouse gas (GHG) emission (UNEP SBCI, 2008), 17% of fresh water consumption, 25% of the harvested wood (Smith, 2005; Say and Wood, 2012), and produces 45%-65% of disposal waste in landfills (Yudelson, 2008). Hence, the industry is controversial. As a consequence, how to reduce the adverse environment impacts of the building industry becomes a hot point issue.

A Green Building Rating System (GBRS), defined by Nguyen and Atlan (2011), is a tool that can be used to evaluate and promote the sustainability of building industry.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1163911653

With the guidance and better insights into sustainability through information analysis, valuation and comparisons, the GBRS can provide the following suggestions on the green buildings:

i. Minimize environment impact of the buildings
ii. Measure buildings' effect on the environment
iii. Objectively evaluate and judge buildings' development (Awadh, 2017)

Many GBRSs have been put into practice in the worldwide (Haapio and Viitaniemi, 2008; Kyvelou and Sinou, 2013; He et al., 2018; Ding et al., 2018), such as Building Research Establishment Environmental Assessment Method (BREEAM, United Kingdom) (BREEAM, 2016), Leadership in Environmental and Energy Design (LEED, the United States) (LEED, 2013), Evaluation Standard for Green Building (ESGB, China) (ESGB, 2014), Green Mark (GM, Singapore) (Green Mark, 2013), Comprehensive Assessment System for Building Environmental Efficiency (CASBEE, Japan) (CASBEE,2014), Green Star (GS, Australia) (Green Star,2015) and ITACA (Italy) (ITACA, 2015). Due to the fact that the GBRSs can promote sustainable practices and play an important role to the development of sustainable buildings, an increasing number of researchers have focused on the comparison the methods and tools used to evaluate the environmental performance of different kinds of buildings (US Green Building Council, 2018).

In the past years, more researchers focused on the development of the assessment standards and the refinement of the existing ones to reduce the environmental impact of the green buildings (Cole, 2006; Ding, 2008; Wang et al., 2012). For example, Mattoni et al. (2018) analyzed the five well known GBRSs (i.e. CASBEE, GS, BREEAM, LEED and ITACA) in detail to find their differences and similarities on six macro-areas (site, water, energy, comfort and safety, materials and outdoor quality), and further explored which issues exhibited more influence on the final performance rate of each systems. Lee (2013) compared the five representative assessment schemes (i.e. BREEAM, LEED, CASBEE, BEAM Plus (Hong Kong) and ESGB) and found that the BREEAM and LEED are the most comprehensive, two-phase certification method is preferable of LEED, CASBEE and BEAM plus, and the weighting coefficients adopted by ESGB were the most representative. Feng and Hewage (2014) took the energy saving performance of green vegetation on LEED certified buildings into consideration and found the green vegetation is not cost-effective in winter months or cold climatic regions due to low energy saving performance, and hence, recommend to improve overall energy performance in green buildings. Li et al. (2017) conducted a systematic review of the existing literature on green building assessment methods through comparative analysis and found the main contributing authors and represented countries, the number of comparative assessment methods, and the current topic is focused on the general comparison and the category comparison. The future research should be developed to the indicator comparison. However, there is no literature that does comprehensive comparisons on water efficiency among GBRSs in detail. Therefore, the objective of this paper is to carry out a comparative analysis on the indicator of water efficiency between LEED and ESGB from six aspects, i.e. macroscopic, building water use, landscape water use, heat and cooling system use water, nontraditional water source utilization and water monitoring system.

This paper begins with the background review of LEED and ESGB, followed by the research methodology for statistical analysis among the paper samples to present the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1163911653

evidence of the basis on the topic selected. Then, the six detailed aspects are compared within the water efficiency indicator. Finally the current research focuses are presented; with future development direction is suggested. The results of the systematic review in this paper will serve as a useful reference for both industry practitioners and academics that are interested in the water efficiency of green buildings.

Overview of LEED and ESGB

LEED

LEED was developed by the US Green Building Council (USGBC) for the US Development of Energy (Wu et al., 2016; Hu et al., 2017; Schwartz and Raslan, 2013), and has become the most widely used GBRS in the world. Available for virtually all buildings, communities and home project types, LEED assessments have been carried out in 41 countries, including Canada, Brazil, Mexico, India and China (Lee, 2013; Gelowitz and McArthurand, 2018; Kern et al., 2016; Chen and Lee, 2013). LEED provides a frame work to create healthy, highly efficient and cost-saving green buildings. LEED certification is a globally recognized symbol of sustainability achievement. Now more than 2.2 million square feet is LEED certified every day with more than 92,000 projects using LEED. LEED buildings can save energy, water, resources, generate less waste and support human health. The LEED 1.0 of new construction was first launched at USGBC in 1998 (Altomonte and Schiavon, 2013; Wu et al., 2017), and LEED 2.0 based on modifications made during the pilot period was released. Then the LEED continued to be modified to respond to the needs of the market, and has been expanded to cover different kinds of buildings types. The detailed development of LEED can be seen in *Figure 1* (Doan et al., 2017).

Figure 1. *LEED development history*

Currently, LEED v4 is the newest version. It focuses on materials to get a better understanding of what is in them, and the effect of those components on human health and the environment. A stronger and performance-based approach is used to indoor environmental quality for better occupant comfort. In addition, it brings the benefits of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1163911653

smart grid thinking to the forefront with a credit that rewards projects for participating in demand response programs and provides a clear picture of water efficiency by evaluating total building water use.

As *Table 1* illustrated, there are seven categories that cover (maximum number of points for each category in parentheses): location and transportation (32), sustainable sites (10), energy and atmosphere (33), water efficiency (11), materials and resources (13), indoor environmental quality (16), regional priority (4) and innovation (6); the maximum possible total score is 125 points. For example, location and transportation category includes eight indicators (maximum number of points for each indicator): neighborhood development location (16), sensible land protection (1), high-priority site (2), surrounding density and diverse uses (5), access to quality transit (5), bicycle facilities (1), reduced parking footprint (1), green vehicles (1). Each category has the prerequisites condition, which means that the criteria must be included before a project can be evaluated and the core credits given for meeting or exceeding the requirements in the categories (Alyami and Rezgui, 2012). As shown in *Table 2*, the LEED buildings awarded points for individual aspects of assessment are summed and compared against a rating scale to yield an overall grade, which may be certified (40-49 points), silver (50-59 points), gold (60-79 points) or platinum (> 80 points).

Table 1. *The comparison of LEED and ESGB on categories*

GBRS (maximum number of the points for each category)	LEED V4 (125)	ESGB 2014 (110)
Category (maximum points)	Location and transportation (32)	Sustainable site and outdoor environment (21)
	Sustainable sites (10)	Energy use (24)
	Energy and atmosphere (33)	Water saving (20)
	Water efficiency (11)	Material use (17)
	Materials and resources (13)	Indoor environmental quality (18)
	Indoor environmental quality (16)	Innovation (10)
	Regional priority (4)	------
	Innovation (6)	------

Table 2. *The comparison of LEED and ESGB on certified grade*

GBRS	**Grade**	**Credits**
LEED	Certified	40~49
	Silver	50~59
	Gold	60~79
	Platinum	> 80
ESGB	1-star	50~60
	2-star	60~80
	3-star	> 80

ESGB

In China, with the rapid increasing for building industry, the green building began to be explored in the early 1980s in response to the increasing energy use of the residential sector, especially for air-conditioning and heating (Lee, 2013). In March 2006, the first

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1163911653

Evaluation Standard of Green Building (GB/T 50378-2006) was promulgated by the Ministry of Construction (Lee, 2012). Then it was updated in 2014 with the second version ESGB (GB/T 50378-2014) (ESGB, 2014). From the beginning of 2008 to the end of 2015, the green building certification review system was implemented in China. There were 4071 certified projects with the total area of 472 million square meters for green building, among which 3859 projects with the area of 444 million square meters were green design, and 212 projects with the area of 28 million square meters were green operation (Ding et al., 2018).

There are six categories that cover (maximum number of points for each category in parentheses): Sustainable site and outdoor environment (21), Energy use (24), Water saving (20), Material use (17), Indoor environmental quality (18) and Innovation (10); the maximum possible total score is 110 points. For example, sustainable site and outdoor environment category includes four indicators (maximum number of points for each indicator): land saving (7.14), outdoor environment (3.78), transportation and public service (5.04), site design and ecology (5.04). The score were evaluated by both prerequisites condition and the core credits system. As is shown in *Table 2,* the overall grade of ESGB buildings is on a scale of 1-star (50 - 60 points), 2-star (60-80 points) and 3-star (above 80 points).

Research methodology

Three stages research methodology

Due to the fact that so many researchers have made fully comparisons between different GBRSs from different directions, the three stages was practiced in this review to find a new direction to conduct the analysis.

In stage 1, a thorough search was implemented in the three major data bases: Science Direct, Engineering Village, and Scopus with the key words: LEED, ESGB, green building, assessment methods, sustainable building, energy efficiency, water efficiency, environment protection, indoor environment quality, sustainable site. These reviews mainly cover papers published from 2001 to 2017. After careful reviews of paper contents and removal of duplicates, a total of 73 articles were identified for the next analysis.

During stage 2, the statistical analysis of these 73 articles was carried out to find and identify the research direction from the following aspects:

(i) The statistical number of papers in each year, as illustrated in *Figure 2*. From 2013, more and more researchers focused on the GBRSs innovation and comparison, because the GBRSs are the principle and tool to promote the development of green buildings. Based on these researches so many countries began to implement their own GBRS according to the local condition.

(ii) The statistical number of papers in each country based on the first author's nationality, as explained by *Figure 3*. Currently, green building development in China is still at its initial stage (Zhu et al., 2017; Borong et al., 2016). The BREEAM and LEED are still occupying the dominant position in the green building evaluation market with their mature experience of the green building development in UK and the US. So the papers from Chinese researchers get the main percentage for nearly about 19%. As a developing country, Chinese researchers still has a long way to explore the green building development in theory and practice.

DOI: http://dx.doi.org/10.15666/aeer/1705_1163911653

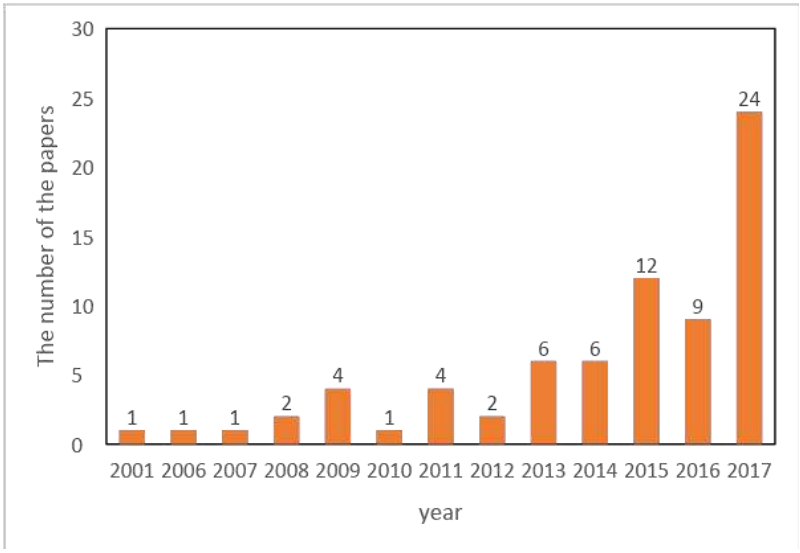

Figure 2. *The number of papers in each year of the selected articles*

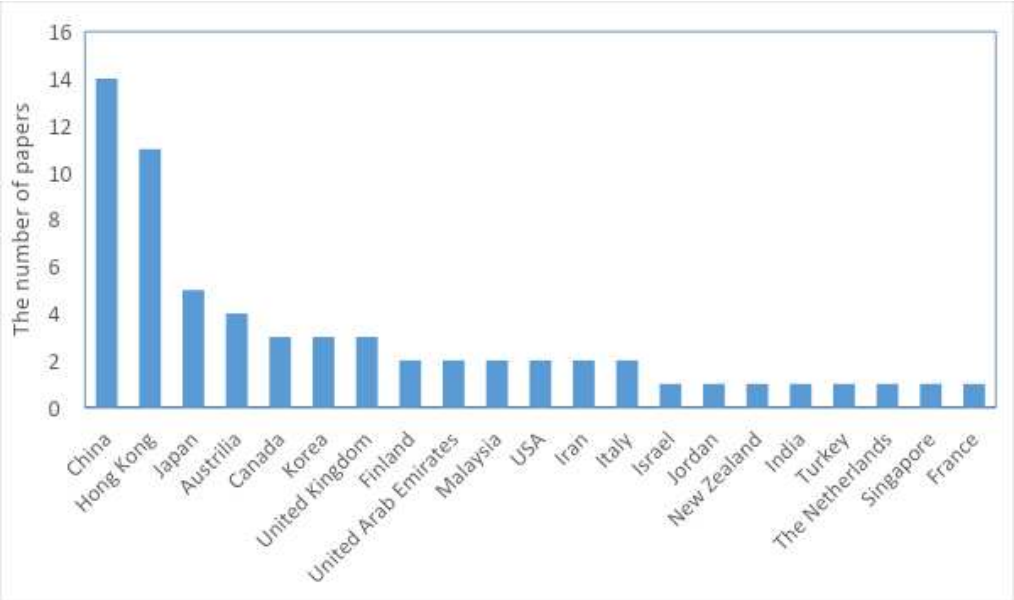

Figure 3. *The number and the percentage of the papers in each country of the selected papers*

(iii) The result to determine the main contributing authors. The formula proposed by Howard for determining the contribution of authors to a multi-authored article was adopted (Howard et al., 1987). The formula is shown in *Equation 1:*

$$\text{Score} = \frac{1.5^{\text{n-1}}}{\sum_{i=1}^{n} 1.5^{\text{n-i}}} \qquad \text{(Eq.1)}$$

where *n* denotes the number of authors of the paper and *i* is the order of each author. As indicated in *Table 3*, Lee from the Hong Kong Polytechnic University is the most active

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1163911653

author by far. The research from Lee focused on the comprehensive comparison of the GBRSs and the indicator of energy use from different assessment methods. Sharifi focused on the topic of the neighborhood sustainability assessment with different GBRSs (Sharifi, 2016; Sharifi and Yamagata, 2016; Sharifi and Murayama, 2013, 2014).

Table 3. *Main contributing authors*

Author	Number of papers	Score point	Affiliation
Lee W. L.	6	3.92	Hong Kong Polytechnic University
Sharifi Ayyoob	4	2.80	Nagoya University
Ann T. W. Yu	4	1.84	Hong Kong Polytechnic University
Haapio Appu	2	1.60	Helsinki University of Technology
Jian Zuo	2	1.39	University of Adelaide
Illankoon I. M. C. S.	2	0.89	Western Sydney University

(iv) Four levels comparison of the GBRSs of the selected articles. A comprehensive analysis of the selected papers is mainly compared at four levels as is shown in *Table 4:* (a) general comparison (80%); (b) category comparison (71%); (c) criterion comparison (51%); (d) indicator comparison (31%). This result is similar with the investigation result from Li et al. (2017). Thus it can be seen that the indicator comparison is still at a low level for their complicated characteristic in a very detailed sector. Among these indicators, the water efficiency comparison gets the lowest percentage (1%). At the same time, more researchers focused on the comparison on the energy use (11%) and environment (11%) etc. This phenomenon can be explained by the following reasons: (a) The experts in the water utilization sector focused on the development of the water treatment process, chemistry and material, and little relevant experts focused on the green buildings' demand. (b) Water efficiency get relatively lower points from the total scheme, which is easy to be ignored by the auditors and the owners. (c) It is difficult for the building to get more points from water efficiency indicator even after doing some improvements, but it is much easier to be optimised from the energy sector etc. So in this paper, the water efficiency indicator in LEED and ESGB is chosen to make a comparison in order to give a useful reference for both industry practitioners and academics that are interested in the GBRSs.

Table 4. *Four levels of the comparison*

Comparison topics	Sub-topics	Percentage of papers
Level 1: general comparison	• History • Certification levels • Schemes available	80%
Level 2: category comparison	• Weighting or points	71%
Level 3: criterion comparison	• Mandatory criteria • Prerequisite • Minimum points	51%
Level 4: indicator comparison	• Energy (11%) • Environment (11%) • Materials and waste (4%) • Project management (4%) • Water efficiency (1%)	31%

In terms of stage 3, the comparison of the water efficiency is analyzed from six aspects, i.e. macroscopic, building water use, landscape water use, heat and cooling system use water, nontraditional water source utilization and water monitoring system. Detailed discussions of these comparisons are shown below.

Methodology roadmap

The methodology roadmap of this review is illustrated in *Figure 4*.

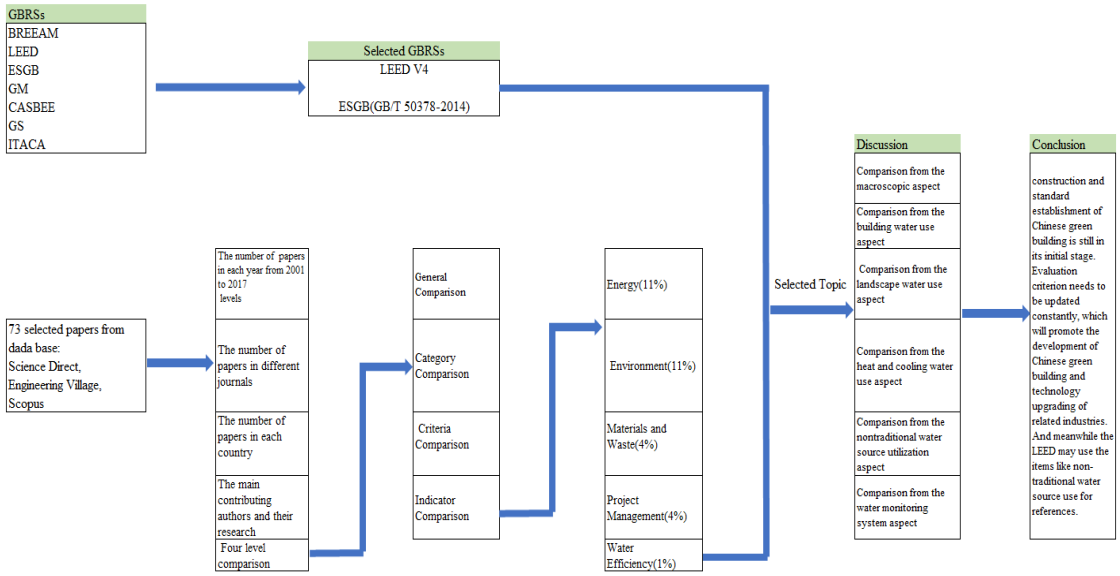

Figure 4. *Methodology roadmap*

Discussion

In this section, comparison analysis results focused on the water efficiency of the LEED and ESGB are carried out from six aspects, i.e. macroscopic, building water use, landscape water use, heat and cooling system water use, nontraditional water source utilization and water monitoring system. The differences between LEED and ESGB are related but not limited to (Awadh, 2017):

i. Considering various and interrelated categories
ii. Prioritizing and weighting concerns

Macroscopic aspect

From the macroscopic point of view, we can clearly find that:

(1) The water efficiency standards of ESGB and LEED are both composed of prerequisites items and credits items (Chen et al., 2015). The differences on prerequisites items are shown as follows:

(i) ESGB prerequisites items mainly focuses on the planning and designing of the whole water system, using water efficiency implements and setting up reasonable and thorough water system, but without any specific quantity indexes. LEED prerequisites items mainly focus on specific and measurable indexes, e.g. reducing the project's landscape water requirement by 30% from the maximum daily water requirement in this region, reducing building water consumption by 20% from the baseline and the basic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1163911653

requirements of water efficiency devices, which are detailed into the energy level as well as adoptive energy-saving and water-saving methods.

(ii) Water meter measurement and installation is regarded as a credit item in ESGB but a prerequisites item in LEED.

(2) The water saving standards of ESGB and LEED both focus on building water saving, landscape water saving and condensate water systems (Joustra and Yeh, 2009). They both suggest non-traditional water resource utilization and landscape plants without irrigation required. But their concerns are obviously different. ESGB concerns about daily water consumption, pipe leakage and safety in the whole contestant area; LEED water-saving percentage concerns about each tool, such as faucet, toilet, urinal, dishwasher and clothes washer, etc.

Building water use aspect

Inclusive contents, prerequisites items indexes, water-saving instruments baseline requirements are compared to analyze the similarities and differences of ESGB and LEED.

(1) Inclusive contents

From *Table 5,* we can see that ESGB covers more comprehensive contents. Besides water meter settings and sanitary devices of water-saving requirements, ESGB also concerns water saving and using quota, pipe network leakage, with or without overpressure outflow and the conditions of public bathroom, of which the water saving and using quota standard is Civil Building Water Saving Design Standard GB50555-2010. Valve devices with tight sealing, grading measuring water meter installation are adopted to reduce pipe network leakage. With less than 0.3 MPa water supply pressures of water use spot, points of without overpressure outflow can be gotten. Showers with thermostatic control and temperature display function, user fees are promoted in public lavatory. Public water-saving consciousness is improved by connecting fees with water use. LEED does not have special requirements to public lavatory, but requires controlling the discharge water temperature and gives concrete measures, such as using back-fire arrangement, adding heat collecting system or recycling steam to boiler.

Table 5. *Comparison table of LEED and ESGB on building water-saving contents*

Items	LEED	ESGB
Water saving and consumption quota	×	√
Pipe network leakage	×	√
With or without overpressure outflow	×	√
Water monitoring system	√	√
Public bathroom	×	√
Water-saving requirements of sanitary instruments	√	√

(2) Prerequisites items indexes

ESGB prerequisites items indexes are mainly about macro-direction, which require setting out water resource utilization program, setting reasonable water supply and drainage system and selecting water-saving instruments. LEED requires specific and quantitative indexes, which includes:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1163911653

(i) Building water use: the total water-saving amount of toilets, urinals, towers, kitchen faucets etc reduces 20% by the baseline.

(ii) Clothes washers, dish washers, ice machine are all qualified of "Energy Star", and water amount of spray valve is no more than 0.082 L/s.

(iii) Regulating limiting value of maximum water amount to dish washers, food steamers and combination stove.

(iv) Water meter statistics can be checked for at least five years. LEED has more concrete prerequisites item indexes and is more difficult than ESGB to get points.

(3) Water-saving instruments baseline requirements

From the basic requirements of water-saving instruments in China and the US in *Table 6,* LEED water-saving instruments have better water-saving effect than ESGB in most cases. LEED has more strict water-saving efficiency requirements. For example, LEED requires 6 L/flush in toilets and ESGB single grade toilets require 6.5 L/flush. Urinal requirement is 3.8 L/flush in LEED and 4 L/flush in ESGB. The faucet flow seems to be the same, but LEED requires higher water flow than ESGB. Consequently, LEED has more strict requirements, which means China has quite a lot to do to improve on instruments using water-saving technology.

Table 6. *Water-saving requirements baseline requirements*

Items	LEED	ESGB
Toilet	6 L/flush	According to the limit value and GB25502-2010 level of toilets water-use efficiency, the minimum requirements of scoring are 3 grades: single grade 6.5 L/flush, double/big grade 6.5 L/flush, small grade 4.2 L/flush and the average value is 5.0 L/flush
Urinal	3.8 L/flush	According to the limit value and GB28377-2012 level of urinals water-use efficiency, the minimum requirements of scoring are 3 grades, namely 4 L/flush
Faucet	Under 0.415 MPa, public lavatory faucets	According to the limit value and GB25501-2010 level of faucets water-use efficiency, the minimum requirements of scoring are 3 grades, namely 0.15 L/s (0.1 ± 0.01 MPa)
	0.03 L/s, private lavatory faucets	
	0.14 L/s, kitchen faucets 0.14 L/s	
Showerhead	Under 0.55 MPa, the flow is 0.16 L/s	Under 0.1 ± 0.01 MPa, the flow is 0.15 L/s

Landscape water use aspect

ESGB and LEED both suggest growing plants without permanent irrigation requirements. LEED requires reducing 30% landscape water by maximum daily water consumption in the prerequisites item. More than 50% water saving percentage equals 1 point, and 100% water saving percentage equals 2 points. ESGB suggests adopting water-saving irritation system, setting up soil humidity sensor, and closing device on rainy days, etc. In a word, ESGB standard concerns whether there is corresponding measures, whereas LEED pays more attention on the ultimate water-saving effect and gives specific quantitative indexes.

ESGB encourages concerning rain utilization facilities. To be specific, during the stage of the landscape design, it is highly suggested that more than 60% of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1163911653

landscape water amount should be derived from rain water. Besides, it requires using non-point source pollution controlling facilities to purify rain in landscape water and encourages using aquatic animals and plants to purify water.

Heat and cooling system water use aspect

LEED prerequisites items have regulations on cooling tower and evaporative condenser: water meter, conductance controller, overflow warning, valid drift canceller (controlling the maximum water drifting to 0.002% of recycling water in counter-current tower and 0.005% of recycling water in disposable water quality) are needed. The requirements in credit item are:

(i) Disposable water quality analysis of cooling tower and evaporative condenser have to include Ca^{2+}, total alkalinity, SiO_2, Cl^- and conductivity.

(ii) 1 point can be gained if the maximum cycle index of cooling tower reaches 10. Whether improving supplementary water quality to 10 minimum cycle index, or using 20% non-drinking water source on the basis of 1 point can get 2 points.

ESGB suggests setting water-treatment facilities to water reuse system, such as enlarging water catching tray, setting balance tube or water tank, requiring more than 80% evaporation water consumption of water supplement in the cooling tower, or using non-evaporating cooling water consumption technology. ESGB approves utilizing non-traditional water source in cooling water supplementary system. The higher the percentage of non-traditional water source use is, the higher the points are.

In terms of similarity, both of LEED and ESGB put forward concrete and quantitative indexes to specific water-saving methods, process controlling and obtained results.

Non-traditional water source utilization aspect

LEED regulates that on the basis of control items 20% water-saving percentage, the additional water-saving percentage can be acquired by the alternative water source: the additional saving of 25% = 1 point, 30% = 2 points, 35% = 3 points, 40% = 4 points, 45% = 5 points, and 50% = 6 points (Alawneh et al., 2018).

ESGB points out that reclaimed water, rainwater and sea water etc. are included in non-traditional water source. Different points come from different building types. Quantitative criteria and non-traditional water source approving use direction are definite. ESGB approves and guides non-traditional water source to flush the indoor toilet, which can gain higher points. ESGB also approves using non-traditional water source as supplementary cooling water and landscape water and gives certain points according to the proportion.

As shown in *Equation 2,* the ratio of non-traditional water source use (NWSU)

$$= \frac{\text{The total quantity of the NWSU}}{\text{The total quantity of the wateruse}} * 100\% \quad \text{(Eq.2)}$$

The NWSU includes the reuse water use, the rain water use, the sea water use and other types of NWSU. For the purpose to get the same score, the NWSU ratio requirement with the municipal reuse system (MRS) is higher than without MRS. For the new construction building, the NWSU is suggested to be used for outdoor greening, road watering and car washing. But if the project wants to get a higher score, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1705_1163911653

NWSU should take the indoor toilet flushing into consideration in order to increase the NWSU ratio. Because the latter need stricter water quality and deeper water treatment process.

From this point of view, the ESGB has a bit more detailed direction to guide the NWSU and help the owner to get more score. This item may be used by LEED for references.

Water monitoring system aspect

LEED and ESGB both approve setting water monitoring system to the kitchen, lavatory, greening, air conditioning system, swimming pool, and landscape, respectively, according to the purpose. LEED regards the water meter monitoring system as a control item and requires 5 years' water quantity record. 80% measurable water quantity of the total quantity is required in the credit item (Kern et al., 2016). While in ESGB, water monitoring system is only a credit item. But additional points can be gained by setting water measurement devices to measure water quantity according to fees and administrative units, respectively. The arrangements will help searching leakage and venting points of the pipe and reducing the leakage of water quantity.

Conclusion

In this review, a statistic analysis from the relevant papers of different GBRSs comparison has been carried out. It is clear that some existing GBRSs from the general, category and criteria levels have been compared in the past research efforts.. But little work has been done on the comparison of water efficiency. A thorough review of comparison on water efficiency between LEED and ESGB is carried out due to their similar structure and international repercussions. Six aspects including macroscopic, building water use, landscape water use, heat and cooling system use water, nontraditional water source utilization and water monitoring system are relatively compared in detail. In terms of their similarities, ESGB and LEED are both composed of control and scoring items. Moreover, both of the two standards concern building water-saving, landscape water-saving and condensate water systems, and approve non-traditional water source utilization and landscape plants without irrigation requirement. As for their differences, ESGB mainly concerns the planning and designing of the whole water system, using water-saving instruments, setting reasonable and thorough water system, without specific and detailed quantity indexes; whereas LEED mainly concerns specific and measurable indexes. Through contrastive analysis, a lot of work still needs to be done to improve the indexes control of instruments on water-saving efficiency for China. Relating to improve non-traditional water source use ratio, more effective and feasible measures, such as cooling water supplement, rainwater utilization in landscape water, indoor toilets flushing of non-traditional water source, are put forward. In conclusion, construction and standard establishment of Chinese green building is still in its initial stage. Evaluation criterion needs to be updated constantly, which will promote the development of Chinese green building and technology upgrading of related industries. And meanwhile the LEED may use the items like non-traditional water source use for references.
