(Received 13th Jun 2019; accepted 16th Oct 2019)

Abstract. This study was carried out in two growing spring seasons 2017 and 2018 at Kanipanka Agricultural Research Station (Lat. 35°13'12", Long. 45°25'48", 550 MASL) in Shahrazoor valley 35 km east of Sulaimani. The aim was to investigate the effect of two irrigation intervals (5 and 10 days) and thirteen biotic and abiotic treatments on yield quantity and quality of potato under field condition. The results showed that the 5 days irrigation intervals gave the maximum values of total yield, Total Soluble Solute percentage, while 10 days of irrigation intervals obtained the highest values of tuber hardness and all of the amino acids in the tuber seasons 2017 and 2018, while the maximum values of total yield were acquired through mycorrhizal inoculation. Total Soluble Solute and tuber hardness were achieved by potassium chloride treatment. Whereas the maximum values of all amino acid in the tuber were given by the mycorrhizal inoculation treatment with (6 g L^{-1}) of *Glycyrrhiza glabra* extract in the first season 2017. Concerning the second season 2018, the maximum total yield gave by treatment of potassium chloride and (6 g L^{-1}) of *Glycyrrhiza glabra* extract, while the potassium chloride treatment gave the maximum values of Total Soluble Solute in the tuber.
Keywords: *watering period, T.S.S and starch percentage, proline, glycine, lucien, lysine*

Introduction

Potato (*Solanum tuberosum* L.), which belonging to the Solanaceae family, is the fourth most important agronomical feed crop worldwide after winter wheat, maize, and rice. The total world production of potatoes was 388 million t in 2017, (FAOSTA, 2019). The potato production in Iraq was more than 190,000 t with a total cultivated area of 7950 ha on average 23.996 t h^{-1} (Central Statistical Organization, 2016). Regarding the Kurdistan Region, the potato production was estimated to be over 150,000 t in 2016 data to the Ministry of Agriculture and Water Resources in the Iraqi Kurdistan region.

Irrigation aimed for supplying water totally or partially for crop requirements, decreasing soil and plant temperature, leach excess salts, increase storage of groundwater, facilitate continuous cropping, and to enhance fertilizer application. Some other benefits of irrigation include the direct cut on water stress, increasing the investment in inputs such as fertilizers and improving cultivars affected by uncertain crop production under rained conditions (Zotarelli et al., 2009).

Muthoni and Kabira (2016) reported that water is the most important limiting factor for potato production and it is possible to increase production levels by well-scheduled irrigation programs throughout the growing season in Tigoni, Kenya. Water stress limits crop productivity by affecting photosynthetic processes at the canopy, or by feedback, inhibition if the transport of photosynthesis to sink organs is limited (Murchie et al., 2009). Moisture stress first causes stomatal closure thus reducing CO_2 uptake for photosynthesis; this leads to reduced plant growth and yield (Mafakheri et al., 2010). Sugar concentration within the leaf tissue increases to increase the osmotic potential of the plant, these clues to response inhibition of photosynthesis (Basu et al., 1999). Finkel and Holbrook (2000) found that the water stresses affected to increased accumulation of reactive oxygen species (ROS) in plants such as (O_2^-, H_2O_2). Overproduction of ROS can disrupt normal plant metabolism through impaired enzyme activity due to oxidative damage, protein degradation.

The natural plant extracted can be achieved easily, safely and cheaply. Furthermore, it is considered as highly eco-friendly compounds. Sarby et al. (2009) reported that licorice root extract contains some compounds, which have similar effect to the growth promoters. Also have a wide range of minerals (P, K Zn, Mg, Fe, and Ca), amino acids (alanine, lysine, arginine), vitamins (B_1, B_2, B_6), with carbohydrate and nitrogen addition, It also contains mevalonic acid that can be used in gibberellins synthesis. Matar et al. (2012) found that the spray (5 g L^{-1}) of licorice extract significantly increased protein percentage in tubers with the maximum values of the total and marketable yield of the potato plant. 5% foliar application with licorice extracts resulted in significant increases total tube, and marketable yields and in addition to decreases in physiological disorders and mechanical injury of tomato plants (Fan et al., 2016). EL-Sagan (2015) reported that the mechanism of action of licorice extract in plants is similar to the gibberellic acid action in stimulating of vegetative growth of plants. Moreover, the licorice extract is available, low cost and effective easy to apply. In addition licorice, foliar applications increase the percentages of N, P, and K in plant's leaves, chlorophyll content in the leaves of cucumber (Khalel and Hado, 2011).

The role of potassium in molecular mechanisms and physiological stress resistance, furthermore, ROS damage would be justifying by K under water stress conditions that resulting in the cell death (Wang et al., 2013). Potassium foliar application is another factor that has been used for improved nutrient management and increasing potato growth and yield (Fageria et al., 2016). Asmaa and Magda (2010) concluded that the total yield of potato tubers significantly with the increases of potassium level in tow season growth. In addition, they concluded that the potassium application significantly affected tubers nutritive values. Maximum tuber yield 36.65 t ha^{-1} was obtained from 600 kg K_2SO_4 ha^{-1} for trickle irrigation and 35.23 t ha^{-1} for furrow irrigation. Interaction between irrigation and potassium fertilization were significantly affected in relation to leaf area, the relative water content in leaves, water potential, stomatal resistance and number of the tiny and marketable tuber of potato (Khosravifar et al., 2008). Zelelew et al. (2016) reported that potato needs different plant nutrients for both growth and developments lacking such nutrients caused the reduction in both qualities and quantities of tubers. AL-Alousi (2013) Studied the effect of potassium fertilizer with three levels (0, 200 and 400 kg potassium ha^{-1}) in form of K_2SO_4, also spray with two levels of potassium sulfate (0 and 5000 mg potassium L^{-1}) and spray with organic extract (0 and 10 ml L^{-1}). The results show the addition and spraying of potassium gave the highest values of vegetative day weight, total tuber yields, number of tuber $plant^{-1}$, tuber weight and percentage of starch

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1478714804

in tuber with 6243.33 kg h^{-1}, 36.07 t h^{-1}, 6.45 tuber $plant^{-1}$,140.33 g $tuber^{-1}$ and 12.41% for treatments K400, F5000 and M10 respectively.

Tuber dry matter is a varietal character; however, growing location, season, climatic conditions and cultural practices greatly affect the accumulation of dry matter in tubers, a dry matter content of more than 20% is considered ideal for making chips (Saran and Chhabra, 2014). As a food, potato ranks second to soybean in protein amount produced per hectare, and second to sugarcane in carbohydrate production (Alavijeh and Yaghmaei, 2016). Chakraborty et al. (2010) showed that potato tuber proteins have been found to be of high nutritional value.

The mycorrhiza's function is enhancing the processes of nutrient absorption from the soil and increase the plant resistance against drought and diseases. Microorganisms are an essential component of the agricultural system. Mycorrhizae are a global soil microbe, can subordinate with the roots of most native crop species (Duc, 2017). Several benefits were observed when arbuscular mycorrhizal (AM) fungi is colonized crops including; increased growth and yield, enhanced plant resistance to environmental adversities, increase the plant resistance to abiotic stress (Birhane et al., 2012). ROS production, and thus antioxidant enzyme activity, is enhanced when plants are exposed to various abiotic stresses, such as drought (Caverzan et al., 2012). Osmosis is a mechanism for maintaining water relations under osmotic pressure. It involves the accumulation of a group of active/osmotic molecules/ions including dissolved sugars, sugar alcohol, proline, glycine betaine, organic acids, calcium, potassium, chloride ions and others under water shortage and due to the dissolved accumulation of the cell, which attracts water to the cell and helps maintain the turgor. Potatoes respond to dehydration and salts accumulated through the accumulation of proline which acts as an endoscopy device (osmoprotector), osmoregulator and ROS scavenger (Vahdati and Lotfi, 2013), they study the effects of different irrigation systems during two stages of growth on total chlorophyll in, total soluble sugars content and antioxidant activity in potato leaves.

The aim of this study was to evaluate the effect of irrigation intervals and some biotic and abiotic treatments on potato yield and quality in two growing spring seasons 2017 and 2018, as well as studding the possibility to reducing water requirements of potato while maintaining the tuber quantities and qualities under the field conditions in Sulaimani – Iraqi Kurdistan region.

Material and methods

This study carried out in two growing spring seasons 2017 and 2018 in Kanipanka Agricultural Research Station which located in North-East of Iraq (Lat. 35°13'12", Long. 45°25'48", 550 MASL) in Shahrazoor valley 35 km east of Sulaimani. GIS software was used to create the study sites shown in *Figure 1*. Generally, the elevation of this region ranges between 5 and 2368 m above sea levels. This study includes the interaction effect of two irrigation intervals (5 and 10 days) and thirteen treatments such as *Glycyrrhiza glabra* extract, potassium chloride (KCl), and mycorrhiza inoculation and their interaction on yield quantity and quality of potato plant under field condition. The climate of the study area is generally characterized by warm, dry summer and cold winters (Najmaddin et al., 2017). Thus, the meteorological data of Kanipanka during both growing seasons are shown in *Table 1*. Some physical and chemical properties of Kanipanka soil are shown in *Table 2*.

Bio inoculation

The fungal inoculants *Glomus mosseae* was obtained from Al-Zaefaraniya Agricultural Research Station/Ministry of Science and Technology/Baghdad. The inoculants were consisting of mycorrhiza spore with 47 spores g^{-1} dry soil and the residual of the infected roots. Potato tubers were inoculated with the mycorrhiza spores by using 20 g from the mixture of the inoculums and the pet moss inside the pores, which specified for inoculation treatment before planting the tubers where the pad method was used to ensure the infection by touching the inoculums during planting.

Bicarbonate (HCO3-)	0.90	meq L^{-1}
Chloride (Cl-)	2.49	meq L^{-1}
Sulfate (SO4=)	2.16	meq L^{-1}

Preparation of Glycyrrhiza glabra extraction

Glycyrrhiza glabra roots powder (3 and 6) g was soaked separately in one litter hot distilled water at 50 °C for 24 h in dark colure bottles with shaking continuously. The solution filtered through several layers of filter papers, to obtained two concentrations of the extraction 3 and 6 g L^{-1} and several drops of Twin20 were added as a spread material to reduce the surface tension. The plants were sprayed two times 45 and 60 days after planting date, after the sun seat in both years 2017 and 2018 (Lazim and Sulaiman, 2012).

Preparation of potassium fertilizer (KCl)

Two half five gram of potassium chloride (KCl) was dissolved in one liter hot distilled water at 40 °C with shaking the potassium completely dissolved and several drops of Twin20 were added as a spreading material to reduce the surface tension. The plants were sprayed at the morning trice 40, 55 and 70 days after planting in both years 2017 and 2018.

Addition of chemical fertilizer

Six hundred kilograms per hectare of Di-Ammonium Phosphate (DAP) 18:18:0 fertilizer was added in two times. The first was during the cultivation of the tubers (spares on the furrows) and the second addition was after one month from the first

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1478714804

addition as recommended for the chemical fertilizer treatment only (Esho et al., 2009), while half of the recommended were added for the rest of the treatments.

Field practices

Potato tubers (Acterice varieties) which produced by the Agro-plant's Company/Nederland, used in the study, each experimental unit (furrow) was 3 m long and 0.8 m apart (2.4 m^2), each furrow consists of 12 plants in one side. Planting dates were 10 March 2017 and 5 March 2018 at the first and the second season respectively, while the harvesting was accomplished after 100 days on 20 June 2017 and 15 June 2018 at the first and the second season respectively. The land was plowed perpendicularly at 30 cm depth by using moldboard plow then the soil was smoothed by disc harrow then leveled the all the divisions were made to furrow according to the experimental layout (*Fig. 2*). Each experimental units (furrows) within the blocks were divided into four groups, each group consists of four furrows the last one was one furrow, each group were conducted with a 10 cm diameter plastic pipes to feeding them with water from the mainstream. Watering timing from the mainstream to the furrows was calculated according to the field design for furrow irrigation system (*Fig. 3*).

The irrigation timing was computed until the water reached the standardized line in each furrow in order to measure the amount of water that entered each furrow through the plastic pipes in the irrigation intervals (5 and 10 days). The amount of water and its operation time were calculated to estimate the discharge of sub main irrigation pipe. Depending on the knowledge discharge, Furrow area, number of furrow, and operation times for irrigation, the depth of irrigation was calculated as well as it can be used to estimate the amount of irrigation (*Eq. 1*). In 2017, the depth and the amount of irrigation were 369 mm and 0.885 m^3 $furrow^{-1}$ respectively for **I_5**, while the values were 228 mm and 0.547 m^3 $furrow^{-1}$ respectively for **I_{10}**. In 2018, the values were 363 mm and 0.871 m^3 $furrow^{-1}$ respectively for **I_5**, and 287 mm and 0.668 m^3 $furrow^{-1}$ respectively for **I_{10}**.

$$Q\,t = n\,A\,d \qquad \text{(Eq.1)}$$

where: Qt: the amount of irrigation (L), Q: discharge of sub main (L s^{-1}), t: operation time (s), n: No. of the furrows, A: area of the furrow (2.4 m^2), d: depth of irrigation water (mm).

Statistical analysis

A factorial experiment was conducted in a split-plot design with three replicates; the first factor (Irrigation intervals) was implemented in the main plots and conducted with Randomized Complete Block Design (RCBD), while the second factor (Treatments) was implemented in the subplots. All possible comparisons among the means were carried out by using Least Significant Difference (L.S.D) test at a significant level of 5% after they show their significance in the general test (AL-Rawi and Khalafallah, 1980). The study included treatments as specified in *Table 3*.

Quantitative and qualitative yield characters

After tubers maturity harvested were performed manually (100 days from planting date), the yield was calculated (*Eq. 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1478714804

$$Total\ Yield\ (t\ ha^{-1}) = \frac{Yield\ of\ the\ Experimental\ Unit\ (t)}{Area\ of\ the\ Experimental\ Unit\ (m^2)} \times 10000\ m^2 \quad \text{(Eq.2)}$$

Total soluble solid (%)

Total soluble solids were measured by Refractometer (LCD DIGITAL BENCH MODEL). In order to measure T.S.S. (%), a drop of the tuber extract was placed on the prism of the digital Refractometer and the total soluble solids were read in Brix (A.O.A.C, 1986).

Tuber starch percentage (%)

The percentage of starch was estimated based on the dry weight of the tuber (A. O. A. C. 1970), according to *Equation 3*.

$$Tuber\ starch\ (\%) = 17.55 + 0.891(Tuber\ dry\ matter\ percentage - 24.18) \quad \text{(Eq.3)}$$

Analysis and estimation of some amino acids in potato tubers

Amino acids in tubers were estimated and analyzed using High-Performance Liquid Chromatography (YL9100 HPLC System, Model: YL9101 Vacuum Degasser, S/N: D2714120911, YL: instrument CO. LTD, made in Korea) device in potato tubers. Five grams from the tubers mixed with the methanol and water in 10:40 ratio respectively. The mixture was filtered using fine Tapestry cloth, then the precipitated leach was stored in a sterile bottle (-20 °C) (Itakura et al., 2001). It is worth to mention that the Orethophthalheide derivative (OPA) was prepared according to (Graser et al., 1985). Approximately 5 mg of the sample was weighed into a 10 ml headspace glass vial with crimp cap and 3 ml hydrochloric acid (6 M with 0.1% w/v phenol) was added. The vial was sealed and placed in a preheated oven at 110 °C for 24 h. After hydrolysis, the samples were allowed to cool to handling temperature then neutralized with 3 ml sodium hydroxide (6 M) mixed thoroughly and left to cool to handling temperature. After cooling, an aliquot was filtered through a 0.45 µm, 13 mm diameter nylon filter (*Figs. 4* and *5*).

Mobile phase = acetonitrile: buffer (30: 70), Flow = 1 ml min^{-1}
Injection: injection program, including derivatization steps with OPA
Injected volume = 100 uL
Column = ZORBAX Eclipse-AAA; 3.5 µm; L × i.d. = 150 × 4.6 mm
Detector: fluorescence (Ex = 360 nm, Em = 450 nm)

Results

Table 4 shows the effects of irrigation intervals on yield quantitative and qualitative characters. The irrigation intervals were significant effects on total yield, total soluble solid (T.S.S%) in the tuber and all amino acids in the tuber with an exception for Lucien in the first season 2017. The **I_5** gave the highest values of total yield and T.S.S% in the tubers with 40.418 t ha^{-1} and 9.536%, while the **I_{10}** gave the minimum values of total yield and T.S.S% in the tuber with 32.205 t ha^{-1} and 5.872%, but the **I_{10}** gave the highest values for Proline, Glycine, and Lysine with 2.707, 2.681 and 2.861 mg g^{-1} respectively, and the **I_5** gave the lowest values with 2.060, 2.091, and 1.882 mg g^{-1} respectively.

Concerning the second season 2018, the irrigation intervals had a significant effect on total yield, Proline, Glycine, and Lysine character. The **I_5** gave the highest values for total yield with 42.886 t ha^{-1}, while the lowest values gave by **I_{10}** with 31.431 t ha^{-1}. The **I_{10}** achieved the highest values for Proline, Glycine, and Lysine with 2.681, 2.988, and 2.951 mg g^{-1} respectively. The lowest values achieved by **I_5** with 2.091, 1.991 and 1.942 mg g^{-1} respectively.

Table 5A illustrates the effects of treatments on yield quantitative and qualitative characters in the first season 2017; data shows the treatments were significant effect for all characters with the exception of starch% in the tuber. The highest values of total yield gave by **T_3** with 44.912 t ha^{-1}. The minimum values obtained by **T_1** with 25.984 t ha^{-1}**.** And the maximum values of T.S.S% in the tube achieved in **T_4** with 8.925%. The minimum values of T.S.S% in tuber were achieved in **T_{10}** with 6.592%. The highest values of Proline, Glycine, Lucien, and Lysine in the tuber gave by **T_9** with 5.906, 5.823, 6.104 and 6.143 mg g^{-1} respectively. The minimum values were recorded by **T_1** with 0.241, 0.211, 0.293 and 0.126 mg g^{-1} respectively.

Table 5A illustrates the effects of treatments on yield quantitative and qualitative characters in the first season 2017; data shows the treatments were significant effect for all characters with the exception of starch% in the tuber. The highest values of total yield gave by **T_3** with 44.912 t ha^{-1}. The minimum values obtained by **T_1** with 25.984 t ha^{-1}**.** And the maximum values of T.S.S% in the tube achieved in **T_4** with 8.925%. The minimum values of T.S.S% in tuber were achieved in **T_{10}** with 6.592%. The highest values of Proline, Glycine, Lucien, and Lysine in the tuber gave by **T_9** with 5.906, 5.823, 6.104 and 6.143 mg g^{-1} respectively. The minimum values were recorded by **T_1** with 0.241, 0.211, 0.293 and 0.126 mg g^{-1} respectively.

Table 5B shows the effect of the treatments on yield quantitative and qualitative characters in the second season 2018, the statistical analysis reveals a significant difference for all of the characters. The highest values of total yield gave by **T_{11}** with 42.106 t/ha. The minimum values obtained by **T_1** with 29.678 t ha^{-1}**.** And the maximum values for T.S.S% were given by **T_4** with 9.083%. The minimum values were given by **T_5** with 6.450%. Regarding the starch% in the tuber, the **T_1** gave the highest values with 26.948%. The lowest values obtained by treatments **T_{13}** with 18.222%. The maximum values of Proline, Lucien and Lysine were obtained by **T_9** with 5.823, 4.971 and 6.096 mg g^{-1} respectively. Whereas the maximum values for Glycine were recorded by **T_8** with 5.596 mg g^{-1}. The minimum values were recorded by **T_1** with 0.211, 0.222, 0.289 and 0.106 mg g^{-1} for Proline, Glycine, Lucien, and Lysine respectively.

Table 6A shows the interaction effects of irrigation intervals and treatments on yield quantitative and qualitative characters at the first season 2017, the statistical analysis reveals significant difference for T.S.S% and amino acid in the tubers (Proline, Glycine, Lucien, and Lysine). The highest values for T.S.S% was obtained in the interaction of **I_5** × **T_{13}** with 11.200%. The lowest values obtained in interaction **I_{10}** × **T_8** with 4.250%, and the highest values of Proline, Glycine, and Lysine gave by interaction **I_{10}** × **T_{13}** with 6.724, 6.912 and 7.525 mg g^{-1} respectively. But the

Data in *Table 6B* illustrates the interaction effects of irrigation intervals and treatments on yield quantitative and qualitative characters at the second season 2018, the interaction had the significant effect on T.S.S, starch and amino acid in the tuber. The highest values of T.S.S were obtained by interaction **I_5 × T_4** with 10.767%. But the lowest values obtained by interaction I_{10} × with 6.167%. Regarding on percentage of starch in the tuber, the highest values were achieved by **I_5 × T_1** with 28.226%, the minimum values achieved by **I_{10} × T_{13}** with 15.964%. The highest values gave by interaction **I_{10} × T_9** Proline, and Lysine with 6.912 and 7.290 mg g^{-1} respectively. And the maximum values for Glycine recorded by interaction with **I_{10} × T_8** with 7.181 mg g^{-1}. The maximum values of Lucien gave by interaction **I_5 × T_9** with 6.094 mg g^{-1}, while the minimum values for all amino acid with exception Glycine were recorded by interaction **I_5 × T_1** with 0.126, 0.252 and 0.079 mg g^{-1} respectively. But the minimum values of Glycine gave by interaction **I_{10} × T_1** with 0.198 mg g^{-1}.

Table 7 shows the effect of seasons on yield quantitative and qualitative characters. The season had no significant effects on yield qualitative characters.

Discussion

Water is one of the most essential elements in growing plants, which constitutes more than 80% of the active cells. Thereby, the amount of applied water during crop irrigation, added time, irrigation methods, quality of added water, and prevailing micro-meteorological conditions have found to play limited roles in yield quality and quantity. In Asia, statistics showed that the yields for most crops have increased 100–400% after

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1478714804

irrigation. In the first season of irrigation intervals (5 and 10 days) were applied after 50 days from sowing and were ended at 96 days after sowing, since, the amount of irrigation water for 5 days interval was cover the most of depleted water at this time. The cumulative depth of irrigation for 5 and 10 days from (10 May 2017 to 15 June 2017) were practically measured and formed to be (369 and 228 mm) respectively. Since the numbers of irrigation were 10 and 6 times for 5 and 10 days of irrigation intervals respectively, while the amount of actual evapotranspiration for 2017 and 2018 was (529, 423, 515 and 440 mm) respectively, while the cumulate depth of irrigation and precipitation were (535 and 394 mm) respectively.

In the season 2018 the irrigation intervals (5 and 10 days) was applied from the sowing date and were ended at 95 days after sowing, the amount of irrigation water for 5 days interval which cover the most of depleted from (5 March 2018 to 10 June 2018) were practically measured (363 and 287 mm) respectively. Since the numbers of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1478714804

irrigation were 9 and 5 times for 5 and 10 days of irrigation intervals respectively, while accumulate depth irrigation and precipitation were (513 and 437 mm) respectively. These results are in agreement with the findings of several other kinds of research (Ati et al., 2013; Ati and Nafaou, 2012). Gander and Tanner (1976) showed that mild water stress of -3 to -5 bars greatly reduce leaf expansion in potatoes, and for best tuber yields, a 120-150 day potato crop requires 508-698.5 mm of the water.

The treatment of mycorrhizae inoculation gave the highest values for water use efficiency; this may be due to its high ability to produce the glomalin compound, which binds the soil minutes to each other and to the aggregation of aggregates. as well as the mycelium hypha played a major role by increasing the soil mass and stability (Fokom et al., 2012) indicates that there are positive correlations of correlations between organic matter and chlorine associated with Glomalin Related Soil Protein (GRSP). Peng et al. (2013) recorded that the fertilized soil with mycorrhizae increases the stability of its aggregates as a result of the action of the mycorrhizae hypha and the result of its production of glomalin, a watery and insoluble molybdenum protein compound that contributes to the formation and increase stability of the soil complexes where it is released to them and reduce their hydration because it is a glue-absorbing composite. (Martin et al., 2012 and Wu et al., 2013) reported that organic matter also plays an important role in improving the properties of physical, chemical and biological soil. The Glycyrrhiza glabra extract contains various elements such as calcium, iron, silicon, aluminum, magnesium, sulfur, potassium, zinc, and phosphorus, which play an important role in growth (Vispute and Khopade, 2011). Licorice extract also contains mevalonic acid, which enters the synthesis of gibberellins (Moses et al., 2002). AL-Hamdani and AL-Zuhairy (2017) nitrogen enter the formation of chlorophyll as well as the formation of amino acids in the formation of Chloroplast, which increases the leaves content of chlorophyll. Myint et al. (2010) showed that chlorophyll was directly related to the plant content of nitrogen.

Potassium is also associated with many other important phylogenetic functions, including activation of enzymes, regulation of opening and closing of stents, as well as its important role in the synthesis of ATP, where the electrostatic charge in the ATP production sites is closely related to the K^+ (Prajapati and Modi, 2012) and sugars (Van Brunt and Sultenfnss, 1998), water and nutrient transport (Thomas and Thomas, 2009) and protein synthesis and starch (Patil, 2011).

The combination of the licorice extract and the inoculation of the mycorrhizae on the composition of amino acids, especially in the case of a lack of irrigation or dehydration, and the interference of the element nitrogen and potassium religions reduce the presence of amino acids in potato tubers.

Conclusion and recommendation

The 5 days irrigation interval had highly effect on the total yield, while 10 days irrigation period had a significant effect on the tuber hardness, and most of the amino acid content in the tubers. The treatments were significantly affected on all of the studied characters with the exception of starch% in the tubers. The interaction of the 10 days irrigation interval with both of the Mycorrhizal inoculation and Spraying with (2.5 g L^{-1}) KCl + Spraying with (6 g L^{-1}) *Glycyrrhiza glabra* extract recorded significant effects on total soluble solid percentage, tuber hardness and all of the amino acid in the tuber.

Carrying out more investigation on different irrigation intervals as well as more biotic and abiotic treatments to determine their effect on the quantitative and qualitative traits in in different locations and for different years in Sulaimani region to generalize the results and to ensure the potato yield stability. Reduce the use of chemical fertilizers and replace them by increasing the use of different plant extracts at different concentrations according to the recommendations of specialists in that field. The use of

fungal, bacterial, bio inoculators, and transpiration compounds and potassium salts on potato is recommended to increase the resistance to abiotic stress.

(Received 13th Jun 2019; accepted 10th Sep 2019)

Abstract. The objective of present study was to investigate sequencing of four genes (AlphaS1-casein, alphaS2-casein, beta lactoglobulin and Major histocompatibility complex) that related to milk traits in Karadi sheep. A total of 300 ewes from three flocks were studied. The results revealed which are include effects of lamb's sex, dam's age and month of lambing were not significant on the milk traits except the ewes flock has significant effect on daily milk yield. The Best Linear Unbiased Prediction value for all ewes concerning daily milk yield, protein and fat percentages ranged from -10.5293 to 10.7504, -2.0546 to 2.0097% and -1.7033 to 1.4067%, respectively. The DNA sequencing results show that there are differences between ewes with high and low milk production in AlphaS1-casein, alphaS2-casein, beta lactoglobulin and Major histocompatibility complex loci sequences these differences reflected by milk performance of ewes in two groups, ewes in high group produced 300% more daily milk than ewes in low group (355.8 vs. 102.8 g/day). In conclusion results showed that there are agreements between Best Linear Unbiased Prediction value with DNA sequencing results in the select best animal and the selection process with molecular technique can play a major positive and rapid role to improvement and increasing milk production in this breed of sheep.

Introduction

In Kurdistan, there are many native sheep breeds with different productive and reproductive performances. One of the most important of them is the Karadi sheep that reared mainly for milk, meat and wool production. Solid content of ewes milk is a higher than other farm animals (cow and goat), which means the sheep milk is particularly suited to produce cheese and yogurt (Bencini and Johnston, 1997; Gutiérrez-Gil *et al*., 2014). After weaning all milk is used for yogurt and cheese production, for that milk content are very important (Carta *et al*., 2009). The total number of sheep in Iraqi-KRG was 7,722,372 heads (Al-Alaq *et al*., 2011).

The research to locate the gene responsible for the prolificacy in this breed, using molecular genetic markers, may help its use commercially to improve other local breeds. The polymorphism of blood genetic markers gives some useful information in studying the relationships among breeds and their evolution. It can also be used for indirect selection if there were some relationships between these markers and some economically important quantitative traits (Anous *et al*., 2009). Molecular methods have also provided new markers for the study of genetic variation and evolutionary relationships of closely related populations (Visser *et al*., 2004; Iamartino *et al*., 2005;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1480514822

Kumar *et al*., 2005). Improvement of livestock has focused on the selection of breeding individuals with superior phenotypes. With the development of increasingly advanced statistical methods that maximize selection for genetic gain, this simple approach has been extremely successful in increasing the quantity of agricultural output and productivity. However, information now available on the organization and functioning of the genome could be used in breeding programmers to improve a range of traits. While genetic markers for QTL that are linked to the trait gene could be used to choose animals for selective breeding programmers, the most effective markers are the functional mutations within the trait genes. Strategies to identify markers for traits and the application of these markers are described by reference to examples of loci that control a range of different traits (Williams, 2005).

Therefore, the objective of the present study is to assess the genetic structure within the Karadi sheep population at the DNA level in order to find molecular genetic markers which can differentiate between females with high and low production and help for the identification of the prolificacy gene in Karadi sheep in Iraqi-KRG.

Materials and methods

Animal and DNA isolated

Experimental done on nearly 300 Karadi ewes (2-5 years old) from three private flocks at different locations of Sulamania governorate Arbat District (Latitude, 35° 25' 14", Longitude, 45° 03' 36", W, elevation 681 m), Sharazoor District (Latitude, 35° 15' 27", Longitude, 45° 42' 21", W, elevation 614 m) and Mawat District (Latitude, 35° 52' 34",45° 24' 35", W, elevation 858 m), Karadi ewes were studied for their milk production with percentage of protein and fat in ewes milk for one season (5 months), milking methods depend on ICARDA (1995). All necessary information was records for each ewe (age of dam, sex of lamb, month of lambing, daily milk production, fat%, and protein %). Protein% and fat% of milk were estimated from the milk sample monthly using milkoscan TM minor machine (P/N 6004 4208, Issue 1 GB, March 2010, FOSS Analytical, 69, Slangerupgade, DK 3400 Hillerod, Denmark).

Whole blood (5 ml) was collected from each ewe from jugular vein into 10 ml Vacutainer tubes containing EDTA for genetic studies. Genomic DNA was extracted from whole blood using Quick-DNATM Miniprep Kit (ZYMO RESEARCH CORP, USA). Following the extraction, the quality and quantity of the extracted DNA samples were assessed using a Nanodrop spectrophotometer 2000 (UK). Laboratory work was done in the postgraduate laboratory at the faculty of agricultural sciences, Sulaimani University, Sulaimani.

PCR amplification and genotyping

Four specific genes were used and the primer sequence and their PCR condition are shown in *Table 1*. PCR reaction was carried out for forward and reverse primers in 50 μL of total volume, containing 10 X PCR buffer (50 mM/L Kcl, 10 mM/L Tris-HCl (pH 8.0), 0.1% Triton X-100), X mM MgCl2, 0.2 mM of each dNTP, 10 pM/L of each primer, 50 ng ewe genomic DNA and 1U Taq DNA polymerase.

The PCR Thermal Cycler (TC9610 /TC9610-230, Applied Bio systems, USA) was done in a final reaction volume of 50 μL. A master mix for all samples for each gene was readied and 40 μL filled in every PCR tube. Ten μL of DNA sample was added to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1480514822

each tube to make the last volume 50 µL to accomplish homogeneity of reagents and decrease the risk of contamination, control reaction was situated up without genomic DNA. A GoTaq® Green Master Mix (ADM7122 00000311719, Promega-USA) incorporates with 25 µL Taq DNA polymerase (25 Units/mL, dNTPs 200 µM, and MgCl2 1.5 mM), 4 µL primer (0.1-1 µM, forward and reveres), 5 µL (100 ng) of DNA template and 16 µL DNase free water.

Ewes genotyped were done by using the PCR and direct sequencing. To confirm results, thirty randomly chosen PCR samples of each groups (High, and low milk yield) were sequenced from both directions. Direct sequencing was performed by commercial services using 3100 ABI PRISM sequencer (Applied Bio-systems, USA). Sequences were obtained with the same primers used for PCR amplification.

Table 1. *The sequences and information of primers used in this study*

Bioinformatics analysis

Sequences were analyzed using the Chromas version 2.6.5 Technelysium Pty Ltd. Sequence analysis and alignments were carried out using NCBI BLAST: Nucleotide sequence. The nucleotide sequences of the four tested genes in Karadi ewes were submitted to GenBank (NCBI, BankIt).

Statistical and genotypic analysis

The PROC GLM (General Linear Model) procedure (SAS, 2002) was used to analyze the data for daily milk production (g), fat and protein %. Fixed effects studies

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1480514822

were flock, age of dam, sex of lamb, and month of lambing were fitted in the following model:

$$Y_{ijklm} = \mu + F_i + A_j + S_k + M_l + \varepsilon_{ijklm} \quad \text{(Eq.1)}$$

where: Y ijklm = milk yield, fat and protein% of m^{th} ewe, of i^{th} ewes flock (Fi, i = 1,2 and3), of j^{th} age of ewes (Aj, j = 2,3,4 and 5 years), of k^{th} sex of lambs (Sk, k = 1, male and k = 2, female) and of l^{st} month of lambing (Ml, l = Nov., 2 = Dec., 3 = Jan., and 4 = Feb.), μ = Population mean, ε_{ijklm} = random error. It was assumed to be normally and independently distributed with mean zero and variance $\delta^2 e$.

For genetics evaluation of ewes (High and low milk production) for various performance traits, Best Linear Unbiased Prediction (BLUP) procedure described by (SAS, 2002) was applied. The model used for this purpose was the Mixed Model (Fixed + Random effects) of (SAS, 2002) software. The individuals of the Karadi breed were assembled in three groups; high (30 ewes), medium (240 ewes) and low (30 ewes) production, according to the BLUP value for DMY: where 10% of ewes for the 1st group (Top milk yield group), 80% for 2nd group and 10% for 3th group (low milk yield group). The above *Equation 1* was used to analyze the difference among ewes group after add the groups effect to the equation.

Results

Phenotypic results

Fixed effect

Least square means of milk traits were 236 ± 10 g/day, 5.33 ± 0.62% and 5.30 ± 12.93% for DMY, protein% and fat%, respectively (*Table 2*). The milk traits curve show that the higher milk yield recorded after one month of ewes lambing was arrived 339 g/ewe/day and lowest at end of lactation, while Fat % curve increase linearly after lambing to end of lactation showed the reverse way with milk production, but the protein % look like milk curve along lactation stage (*Fig. 1*).

As in *Figure 2* the ewes flock have significant effect on DMY and Fat %, ewes in 3rd flock yield more milk compared with other two flocks.

DOI: http://dx.doi.org/10.15666/aeer/1706_1480514822

The milk traits did not affected by age of ewes, but ewes with 3 years old product more milk compared with another ewes age (*Fig. 3*). This may attributed to the biological condition and physiological maturity of three years old ewes. As well as sex of lamb also did not have significant effect on all milk traits in this study (*Fig. 4*).

Genetic merit (BLUP) of milk traits

Best Linear Unbiased Prediction (BLUP) is generally used to predict animal breeding values, given measurements on progeny, or to predict breeding values of animals with repeated records, or to predict breeding values of all animals in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1480514822

pedigree (Cameron, 1997). Best linear unbiased prediction is one of the current methods of choice for genetic evaluation of quantitative traits. BLUP values overall ewes for DMY, protein and fat% were ranged from -10.52 to 10.75, -2.054 kg to 2.009% and -1.703 to 1.406%, respectively (*Table 3*). According to the BLUP values for high and low groups the results show that there are significant deference's between ewes with high and low milk production group for all traits under studies as in *Figures 5–7*.

Genotypic results

In this study, the sequencing analyses for high and low production groups of ewes were done for all genes under study.

AlphaS1-casein (CSN1S1) locus

The results show there are difference between high and low group (*Figs. 8* and *9*) the high group milk production match 100% with NCBI (Sequence ID: JN560175.1) while the low group match 99% with the same NCBI reference which have mutation point at 4298 (T G), this mutation changed the amino acid from cys (UGU) to trp (UGG).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1480514822

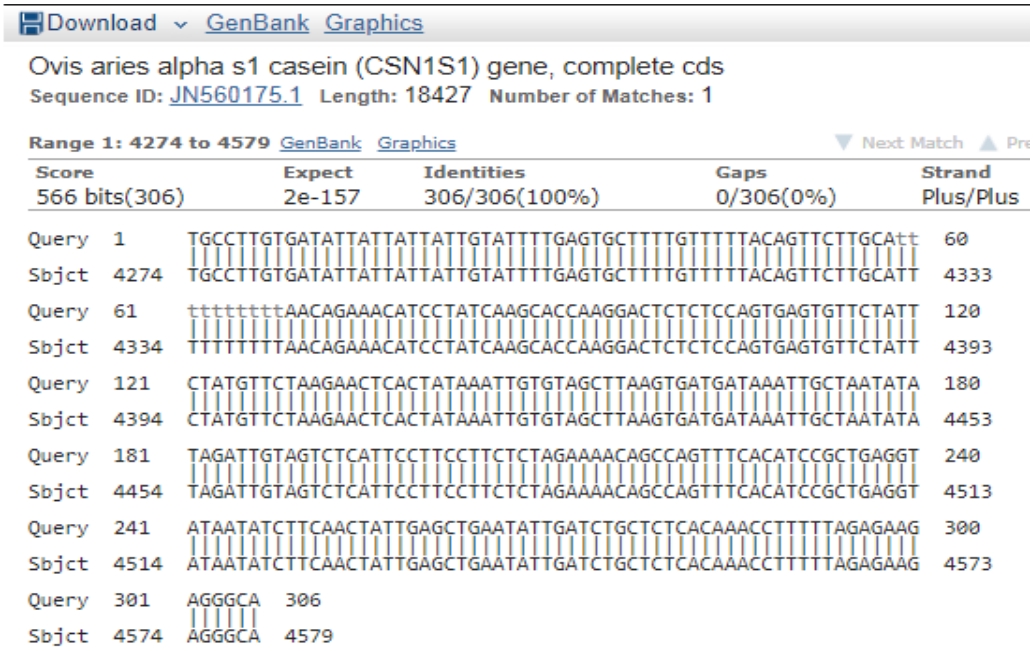

Figure 8. *Sequence alignment of Karadi sheep (high milk production group) CSN1S1with published sequences*

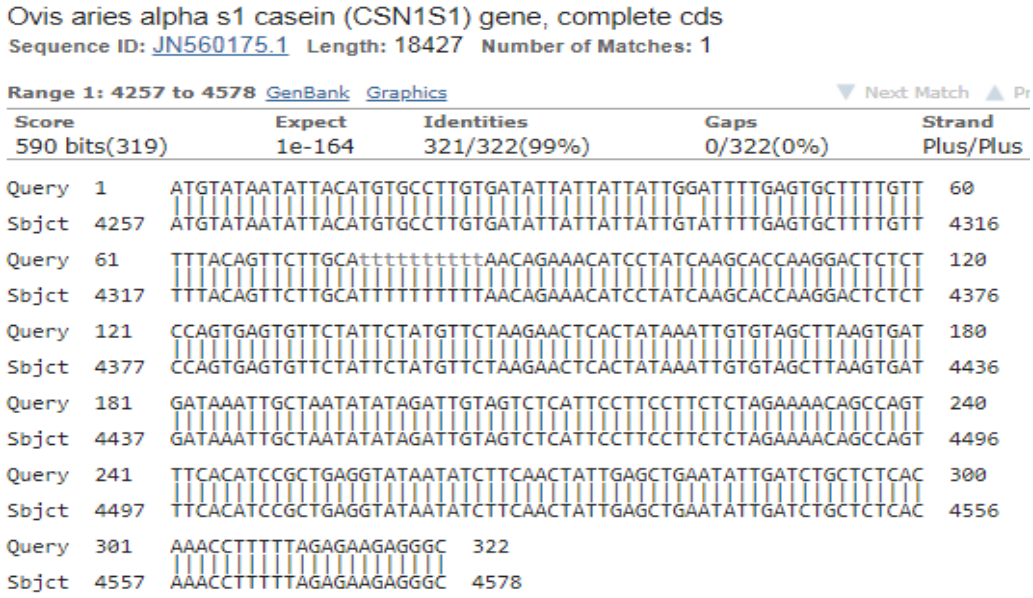

Figure 9. *Sequence alignment of Karadi sheep (low milk production group) CSN1S1with published sequences*

AlphaS2-casein (CSN1S2)

Ewes with low production match 99% with NCBI (Sequence ID: FN601350.1) which have mutation point at 176 (A C) this mutation changed the amino acid from His (CAC) to Pro (CCC), while ewes with high milk production match to the same NCBI 100% (*Figs.10* and *11*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1480514822

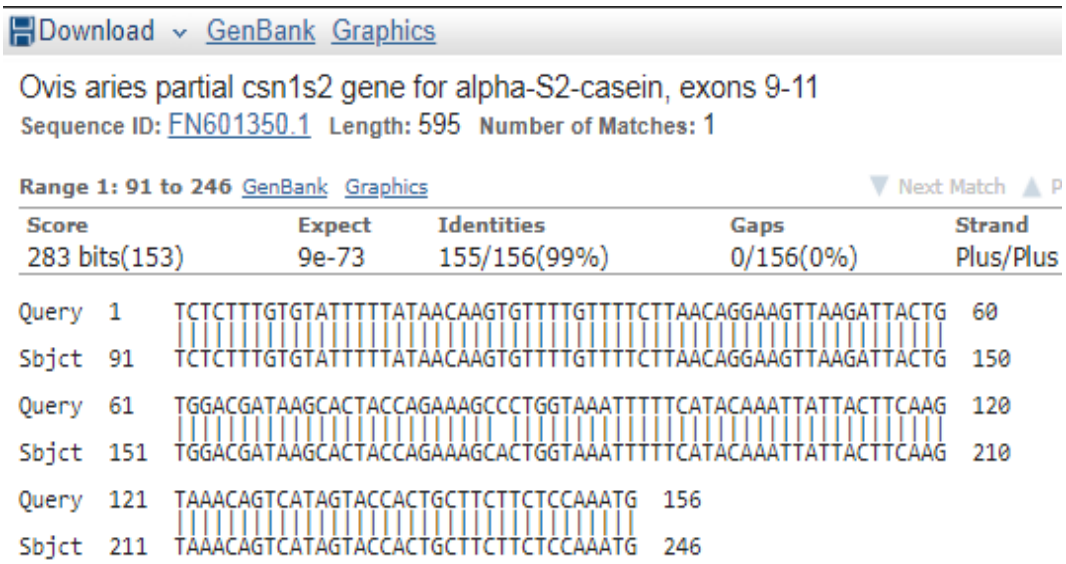

Figure 11. *Sequence alignment of Karadi sheep (low milk production group) CSN1S2with published sequences*

The beta lactoglobulin (β-LG) gene

Both groups was match 100% to the NCBI (Sequence ID: X12817.1) without differences between both groups (*Figs. 12* and *13*).

Major histocompatibility complex (MCH class II DRB)

Ewes in high group milk production match 98% with NCBI (Sequence ID: Z92728.1) for Major histocompatibility complex (MHC- DRB) which have two mutation point, the 1st one found at position 139 (G T) this mutation changed the amino

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1480514822

acid from arg (CGG) to leu (CUG) and the 2nd one at 244 (G -), this mutation changed the amino acid from ser (AUG) to met (AUG), while low group production match 99% to same NCBI sequence with one mutation point at 244 (G C), this mutation changed the amino acid from ser (AGU) to thr (ACU) (*Figs. 14* and *15*).

As in DNA sequencing results for CSN1S1, CSN1S2, β-LG and MHC-DRB loci there are difference between ewes with high and low milk production groups, this differences in DNA sequencing reflected on milk performance of ewes in two groups, ewes in high group produced DMY 355.8 g/day compared with 102.8 g/day in low group.

Discussion

Phenotypic results

The average daily milk yield observed in this study was below the range indicated earlier by several researchers for several sheep breeds (Oramari, 2009; Abd Allah *et al*., 2011). However, protein and fat percentage were similar to other studies reported earlier by several investigators in different breeds of sheep (Bendelja *et al*., 2009; Abd El-Fatah and Awad, 2014). Our results showed that flock has significant effect on DMY and fat%. Similar results were recorded by (Maarof *et al*., 1986; Sanna *et al*., 1998; Ruiz *et al*., 2000; Al-Barzinji, 2003, 2009; Raaof, 2005, 2006; Gardi, 2008; Al-Barzinji and Abdul-Rahman, 2012; Al-Barzinji and Al-Rawi, 2012) on Iraqi sheep breeds. According the effect of ewe age our result is in agreement with many research works (Al-Rawi *et al*., 1997; Mavrogenis, 1996; Fuertes *et al*., 1998; Macciotta *et al*., 2000;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1480514822

Al-Mohammadi, 2002; Al-Barzinji and Hassan, 2005; Raaof, 2005, 2006; Gardi, 2008; Al-Barzinji, 2009; Al-Barzinji and Al-Rawi, 2012). This result is similar to that reported by (Al-Barzinji, 2009; Al-Barzinji and Abdul-Rahman, 2012; Al-Barzinji and Al-Rawi, 2012) in Hamdani sheep breed which showed that sex of lamb had no significant effect on all milk trait in studied in this study.

The BLUP results in present study are similar to reported by Al-Barzinji and Abdul-Rahman (2012) for DMY and fat % in Hamdani sheep breed in Iraq. The BLUP value ranged from -10.5293 in low milk yield group to 10.7504 in high milk yield group. The BLUP value ranged from -2.0546% in low protein yield group to 2.0097% in high yield group and the BLUP value ranged from -1.7033% in low fat yield group to 1.4067% in high yield group. These results show significant differences among ewes groups, these differences return to genotypic effect among ewes group. The breeder can use these wide ranges of ability to produce more milk among ewes and can make selection process to increase the allele frequency of quantitative loci to speed up the improvement of milk yield which have significant effect on lamb's performance in next generation.

Genotypic results

The results of the study Mroczkowski *et al*. (2004) indicate the superiority of sheep with CC αs1–CN genotypes of the milk yield, fat and protein percentage. Similar results are reported by Chianese *et al*. (1996), who analysed Sarda, Comisana and Delle Lanqhe crosses and observed the milk production level to decrease in the following order: BC > CC > CD. Animals with the CC genotypes were characterized by a higher percentage of fat and casein in milk compared to both the CD and BC genotypes. Piwczyński *et al*. (2002) reported that in a population of Polish Merino × prolific sheep, ewes with BC αs1–CN genotypes were highly significantly better in milk production than animals with AC and CC genotypes. However, CC homozygotes were better in percentage of protein and solids than AC and BC heterozygotes. Ovine milk containing CSN1S1 genotype CC showed a higher protein and/or fat content than AC, CD, DD, or CX milk (Chianese *et al*., 1996; Pirisi *et al*., 1999; Mroczkowski *et al*., 2004; Wessels *et al*., 2004). Therefore, CSN1S1 CC milk had better renneting properties, and better cheese-making characteristics than CD and DD milk (Chianese *et al*., 1997; Pirisi *et al*.,1999).

An investigation was carried out to explain characterize the ovine alphaS2-casein (CSN1S2) by Picariello *et al*. (2009) of three Italy sheep breeds showed that B variant differs from the most common form A with two amino acid exchanges: Asp75 Tyr75 and Ile105 Val105.

Investigations in many countries have shown that β-lactoglobulin is polymorphic in various breeds of sheep. Three co-dominant alleles (A, B and C) have been reported in this species differing by one or more amino acid changes. The genetic variant A differs from variant B in the amino acid sequence at position 20 ($Tyr_{20} \rightarrow His_{20}$) (Bell and Mckenzie, 1967; King, 1969; Kolde and Braunitzer, 1983; Ali *et al*., 1990), the rare variant C is a subtype of A with a single amino acid exchange at position 148 (Arg→Gln) as reported by (Erhardt, 1989).

Pietrolà *et al*. (2000) did not find any direct effect or linkage between milk yield and β-lactoglobulin genotype. Ramos *et al*. (2009) observed higher milk yield in AB heterozygotes in Merino and Serra da Estrela sheep. In addition, the Serra da Estrela AA ewes presented lower milk yield when compared with AB animals with no significant difference AB and BB genotypes Ramos *et al*. (2009). Kawecka and Radko

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1480514822

(2011) found no associations between β-lactoglobulin genotypes and milk yield and composition in some Polish sheep breeds. Yousefi *et al*. (2013) revealed significant associations between AB genotypes and higher milk fat percentage in indigenous Zel sheep. Finally, in Portuguese sheep breeds, a study was conducted to investigate the effect of the genetic variants at the β-lactoglobulin and α_{S1}-casein loci and milk yield. The genetic variants of β-Lactoglobulin was identified by using PCR-RFLP, which in Portuguese sheep breeds β-Lactoglobulin genotype AA was associated with lower milk yield in Serra da Estrela and Merino ewes (Ramos *et al*., 2009). This marker also affected milk fat content in Serra da Estrela and protein content in Merino. A suggestive effect of the αS1-casein locus on milk yield was detected in Serra da Estrela, but no associations were found between the variants of this marker with milk fat and protein content (Ramos *et al*., 2009).

Major histocompatibility complex (MHC), an organized cluster of tightly-linked genes, encodes the molecules that bind processed peptide antigens including parasite-derived peptides and presents them to T-lymphocytes, thereby triggering antigen-specific immune responses (Millot, 1978). In sheep, the MHC gene family includes two major subfamilies: class I and class II genes (Klein, 1986). Among sheep MHC class II genes, the expressed DRB1 and DQB1 loci have been found to be highly polymorphic (Woodal *et al*., 1997; Konnai *et al*., 2003b; Sun *et al*., 2004). In particular, a high polymorphism level is present in exon 2, which encodes the antigen-binding site (Outteridge *et al*., 1996; Konnai *et al*., 2003a, b). Variation in these genes may impact immune responses to pathogens, which may lead to variation in disease resistance.

The molecular profiles for ewes in high group milk yield show that there are differences between high group ewes with low group ewes in both DNA profile and phenotypic profile, this point can be used by breeder to make or select the parents in future upon these DNA profiles and mate them altogether to increase the allele frequency for marker assisted selection which have high effect on economical traits to increase animals performance in the next generation as well as the outcome of breeder and sheep breeding in Iraqi Kurdistan region.

Conclusion

The molecular and phenotypic results show that there are differences between ewes groups for milk traits ewes in high group produced 355.8 g/ewe/day milk compared with 102.8 g/ewe/day in low group, these values show the ability to increase the breeder outcome about 300% when breeder select the superior animals according to the animal ranking base on molecular and phenotypic profiles. These results showed that there are agreements between BLUP values with DNA sequencing and the selection process with DNA sequencing technique can speed up the improvement and increase milk production in this breed of sheep in Iraqi Kurdistan. For future the bulk sergeant analysis can be performed on various flocks of sheep in Kurdistan which gives more about molecular markers and verification of the result of the present study through selection (and mating) of rams and ewes using the molecular marker investigated in the present study which related to quantitative traits and follow the performance of their progeny in well defined experiment.

(Received 13th Jun 2019; accepted 25th Oct 2019)

Abstract. Long-lived bird species, such as the Northern Bald Ibis (*Geronticus eremita*), are exposed to heavy metals through air, water and food because they are at the highest point in the food supply chain. Birds accumulate heavy metals in their bodies, organs, and in their feathers. The article aimed to investigate the trace element and heavy metal content of Northern bald ibis feathers using ICP-MS, as an endangered sentinel species, in order to both determine the contamination level of the area and evaluate the risk the species is facing. The study included 34 samples of feathers obtained from bald ibises released into their natural habitat. The results of the study showed that the average values of the trace elements ($^{11}Na^+$, ^{24}Mg, $^{20}Ca^+$, $^{39}K^+$, P, $^{27}Al^+$, $^{56}Fe^+$) which are necessary for the survival of living organisms were above 100 µg g-1, the second group of metals ($^{205}Ti^+$, ^{55}Mn, $^{63}Cu^+$, $^{66}Zn^+$, ^{82} Br) which are toxic to the body in high amounts were between 8.24-22.4 µg g^{-1} and those which are highly toxic at very low doses ($^{51}Sb^+$, ^{60}Ni, As, ^{60}Co, $^{138}Ba^+$, $^{208}Pb^+$, $^{111}Cd^+$, Mo, ^{75} Se) were lower than 1 µg g^{-1}. This study of the Northern Bald Ibis species, animals threatened by extinction due to environmental pollution, investigated their levels of heavy metal pollution in the feathers and indicates that Bald Ibis are possible bioindicators of environmental trace element contamination.
Keywords: *bioindicator, environmental pollution, heavy metal toxication*

Introduction

As a result of human activities, pesticides, industrial products and waste materials containing heavy metals impair the biological integrity of the ecosystem in various ways. Heavy metal pollution of the soil occurs in industrial and mining areas, through the use of fertilizers, drain waters, pesticides, waste products of the coal or oil industry and air pollution. These metals include $^{24}Mg^+$, $^{31}P^+$, $^{39}K^+$, $^{56}Fe^+$, $^{11}Na^+$, $^{20}Ca^+$, $^{63}Cu^+$, $^{66}Zn^+$, ^{75} Se and Ag, which are essential for the human body, but can be toxic in high amounts. Other metals, such as $^{60}Ni^+$, $^{111}Cd^+$, $^{138}Ba^+$, $^{27}Al^+$, $^{52}Cr^+$, ^{55}Mn, $^{208}Pb^+$, ^{82}Br, ^{60}Co, ^{205}Ti and $^{51}Sb^+$ are toxic even at very low amounts.

Animals ingest heavy metals by consuming feedstuffs, grass, and water, or from the application of veterinary drugs, or by licking mineral blocks, or paints containing heavy metals (Kara et al., 2016; Govind and Madhuri, 2014; Das et al., 2009). Due to higher sensitivity levels, birds are usually considered to be bio-indicators for monitoring the effects of environmental pollution (Yohannes et al., 2017).

Since long-living bird species such as the Bald Ibis are at the top of the food chain, they are more exposed to heavy metals through air, water and food. When the metals are digested they are either stored in or excreted from the body. Metals that accumulate in the organs or feathers of the birds may also be passed on to eggs (Dauwe et al., 2000).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1482314834

Feathers contain blood vessels during the growth period and heavy metals in the blood are passed to the feathers and then become isolated there after keratinization. Thus feathers provide valuable information on the level of heavy metals in birds' blood. Since the 1960s, feathers have been used as bio-indicators for monitoring heavy metal exposure of birds, and it has been reported that feathers which are directly exposed to environmental pollution may have higher heavy metal contents due to exogenous contamination (Rutkowska et al., 2018).

Thus, there is a need for studies to determine the toxic effects of environmental pollution in order to maintain biological diversity and protect sentinel species such as the Bald Ibis (Bauerová, 2017; Da Silva et al., 2017; Dolan et al., 2017; Borgesi et al., 2016).

Numerous studies have been conducted on birds of prey to determine the residuals of environmental pollutants such as Pb, Cd, and Hg and pesticides (İnangi et al., 2019; Carneiro et al., 2018; Espín et al., 2016). The ingestion of heavy metals by animals has been reported to cause intoxication, resulting in behavioral disorders, impairment of feathering or decreased breeding and hatchability (Kara et al., 2016).

The Bald Ibis population in Turkey declined to a size near extinction due to the intensive use of pesticides (Dichlorodiphenyltrichloroethane - DDT) against grasshoppers between 1955 and 1960. Survivors did not lay eggs for several years and nestlings hatched were weak. In the offspring of subsequent generations, deformations of the beak and feet were observed (Akyıldız et al., 2005). In the red list published by the International Union for the Conservation of Nature (IUCN), the Bald Ibis was classified as an endangered species. There are three different breeding centers in different locations of the world, including the Birecik district of Turkey, Fas in Morocco and Palmyra in Syria (*Fig. 1*). The life span of the Bald Ibises is about 25-30 years. Bald Ibises in Birecik district are housed in wooden nests or in nests carved into calcite rocks (Tel and Keskin, 2012).

The General Administration of Nature Conservation and National Parks, with the support of the World Wildlife Foundation, established a breeding station in the Birecik district of Sanliurfa province. The Bald Ibises are kept semi-captive, eating pests such as snakes, grasshoppers, insects, scorpions, snails, lizards or snapdragons in the fields near the Euphrates River, when they are out of the breeding station in the summer. They are fed on a diet of raw lean meat, whey, cooked egg, and carrot when they enter the breeding station in winter (Mundan and Cetin, 2012).

There have been few studies on the factors threatening the survival of the Bald Ibis. Tel and Keskin (2012) investigated the prevalence of Yersinia spp. and Aeromonas hydrophyla, while Tel et al. (2013) reported the presence of Salmonella spp. Campylobacter spp. and the absence of Chlamydia psitaci in feces samples of Bald Ibisies. Recently, Spergser et al. (2018) reported the cultivable microbiota isolated from different organs of Northern Bald Ibises. As exposure to heavy metals, even at low concentrations, may negatively affect reproduction of birds by decreasing egg production and hatchability, and increasing the mortality of hatchlings (Malik and Zeb, 2009; Scheuhammer, 1987), it is important to monitor the heavy metal exposure status of endangered species, such as the Bald Ibis. However, to the best of our knowledge, there has been no previous report on the heavy metal exposure status of Bald Ibises.

Therefore, the objective of this study was to determine metal and heavy metal contents of feather samples of Bald Ibises raised in the Birecik District of Sanliurfa, Turkey, in order to estimate predict the risk of heavy metal exposure of this species. In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1482314834

the future, Bald Ibises might be an ecological indicator for trace element exposure in pollinated ecosystems and studies determining the source of exposure might help develop conservation strategies for protecting this important and charismatic wildlife species

Materials and methods

This study was carried out with the permission and support of the Turkish General Directorate of Nature Conservation and National Parks (Approval No: 72784983.04-42845).

Sample collection

Feather samples of 34 individual birds (17 male and 17 female) were obtained from the wings or tails of birds raised semi-captive at the Bald Ibis breeding station in Birecik district of Şanliurfa province, Turkey (37.01.29 N:37.58.38 E). The feather samples were placed in plastic bags and stored at -20 °C until analysis. Whole feather samples were used for chemical analysis after the removal of dust or feces residues with distilled water. (Costa et al., 2013) Collection of the feather samples was approved by the General Directorate of Nature Conservation and National Parks in the framework of the protocol signed by Harran University and the General Directorate of Nature Conservation and National Parks (Protocol No: 26130895-030.03)

Figure 1. *Settlement and habitat of the bald ibis and map image of Birecik (Turkey) and Palmira (Syria)*

Chemicals and standard solutions

Chemicals including 60% hydrogen peroxide (H_2O_2), 37% hydrochloric acid (HCl) and 65% nitric acid (HNO_3) were purchased from Merck (Darmstad, Germany). Stock standard solutions for each element were purchased from Agilent Technologies, Japan (Lot number: 10-160YPYZ). The 99.9980% Argon gas was supplied by Linde Gases (Linde Group, Turkey)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1482314834

Microwave acid digestion

After the feather samples were weighed they were washed with distilled water. The samples were put into a Teflon microwave vessel and 2 ml 60% H_2O_2, 3 ml 37% HCl and 1 ml 65% nitric acid (HNO_3) were added to each sample. The samples were left overnight at room temperature for slow digestion. The samples were treated in a microwave oven (Cem Mars 5) at 180 °C and 800 W for 1 h, then transferred to a 50 mL tube and distilled water was added up to 50 mL.

Analysis of essential element and heavy metal content on ICP-MS

Essential element and heavy metal content of the digest was assessed using an ICP-MS device inductively coupled plasma-mass spectrometer with an Auto Sampler and nebulizer (Agilent, 7500ce Octopole Reaction System, Japan) (Mikoni et al., 2017). Calibration of the method was applied using an internationally validated standard. The accuracy of the device and the method was achieved by measuring a certified reference.

Statistical analyses

Statistical calculations were performed using SPSS 22.0 software (SPSS Inc., Chicago, USA). Conformity of the data to normal distribution was assessed with the Shapiro Wilk test. The Mann-Whitney-U test was applied to variables not showing normal distribution. Correlations between numerical variables were determined using the Spearman rank correlation coefficient. The result of the hierarchical clustering was presented in a dendrogram (*Fig. 2*). A value of $p < 0.05$ was considered statistically significant. The correlations between the elements found in the samples were calculated while the significance value was evaluated.

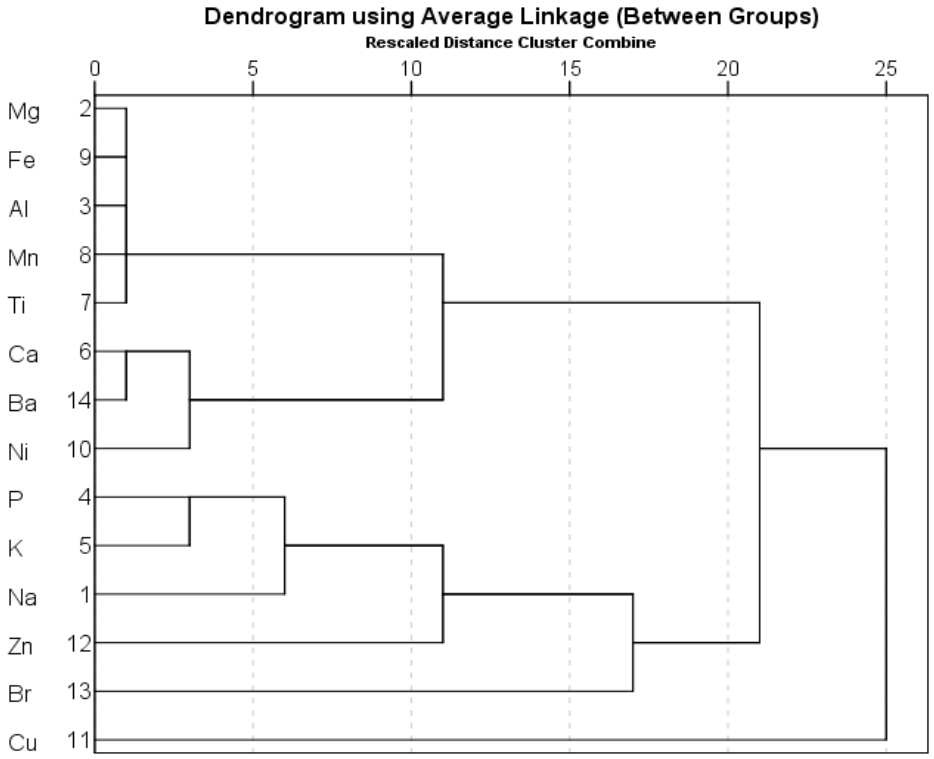

Figure 2. *Hierarchical clustering results of feather samples (dendrogram)*

Concentrations of the essential elements (Na, Mg, Ca, K, P, Al, Fe) were detected to be higher than 100 μg g^{-1} while those of Ti, Mn, Cu, Zn and Br were between 8.24 and 22.4 μg g^{-1}. Of the heavy metals, As was detected in 5 samples with concentrations varying from 44.77 to 2083.05 μg g^{-1} while Co was found in only 2 samples with concentrations of 344.24 and 848.31 μg g^{-1}. Se and Pb were detected in 1 sample each, at concentrations of 447.01 and 119.66 μg g^{-1}, respectively. Detectable concentrations of Sb, Ni, Mo and Pb were not observed. A significant difference in the metal contents between the sexes was observed only for Cu ($p = 0.024$) while no difference was observed in the contents of other metals ($p > 0.05$)

Other toxic elements were found in the values of Co (227-842 μg g^{-1}), As (45-30 836 μg g^{-1}), Se (0-447 μg g^{-1}), and Pb (0-119 μg g^{-1}). The Sb, Cd and Mo values were determined under the measurable value.

The correlation coefficients between individual metal contents of the samples are shown in *Table 2*. High and significant correlations were observed especially among Mg, Al, Ti, Mn, Fe and Ni contents. The hierarchical clustering results among the metal contents are presented in *Figure 2.*

In this study, significant correlations from moderate to high correlation coefficients between essential elements were observed. For example, moderate positive correlations were determined between Na and Br and between Na and P ($r = 0.473$ $p = 0.01$) ($r = 0.566$, $p = 0.001$) and a weak positive correlation was determined between Na and K content (r: 0.388; p: 0.023). In addition, Ca content was moderately correlated with Ni ($r = 0.518$, $p = 0.02$) and Ba ($r = 0.861$, $p = 0.001$) and with Fe ($r = 0.401$, $p = 0.019$) and Mn ($r = 0.412$, $p = 0.016$) and a weak significant negative correlation with Cu ($r = -0.378$ $p = 0.027$).

Fe is a trace element found in complex with other metals. In this study, Fe showed a positively strong correlation with Ni (r = 0.903, p = 0.01), a medium correlation with Ba (r = 0.547; p = 0.01), and weak negative correlation with Cu (r = -374 P: 0.029).

When the correlations of Mg were examined, there was a weak negative correlation with Cu values (r = -0.342; p = 0.049), while there was a moderate positive correlation with Ca values (r = 0.480 p = 0.04), and a strong positive correlation with Al, Ti, Mn, Fe, Ni, and B (r = 0.947 p = 0.01, r = 0.920; 0.881; 0.960; 0.904; 0.571, p = 0.001, respectively).

A strong positive correlation was found between Mn and Fe and Ni (r = 0.939; 0.942 and p = 0.01). There was a moderate positive correlation with Ba (r = 0.55; p = 0.01).

A strong positive correlation was found between Al, Mn, Fe, Ni and Ba (r = 0.971; 0.948; 0.872; 0.582; p = 0.001 respectively). There was a moderate positive correlation with Ca (r = 0.395; p = 0.021).

As all birds were between 1 and 4 years of age, no statistically significant difference was found between age and heavy metal levels (p > 0.05). In addition, gender analyzes in bald ibises can only be performed genetically by Realtime PCR and RFLP-PCR. No statistically significant difference was found between the genders and heavy metal levels in the analyses (p > 0.05).

Discussion

Due to the accumulation of metals in feathers they reflect both the physiological status of the animal and the environmental conditions. Therefore, feathers are valuable materials for monitoring the effect on birds of environmental pollution with heavy metals. This study reports for the first time the metals and heavy metals contents of feather samples from the Bald Ibis.

The natrium (1151-4601, 2048 ± 727 μg g^{-1}) and K (0.13-2178 μg g^{-1}, 168 ± 70.57) content detected in the feather samples of Bald Ibises were similar to those reported for Na (1087-3950 μg g^{-1}) and K (84-285 μg g^{-1}) in the Greater Flamingo (Borgessi et al., 2016).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1482314834

Calcium plays a role in muscle contractions, enzyme activation and cardiac rhythm (Zamberlin et al., 2012). The mean Ca content in the feather samples of Bald Ibises were higher than that reported by Hanson and Jones (1968) for geese (600-2800 μg g^{-1}) from different localities of USA and lower than that (3151.87–4087.67) in red-breasted flycatchers (*Ficedula parva*) as reported by Hanc et al. (2017). The higher level of Ca in the present study could have been due to the higher Ca content of the rocks where the Bald Ibises are housed. Bald Ibises are housed either in wooden nests or in holes carved into limestone rocks within the breeding station. Limestone found around Sanliurfa mostly consists of formations of middle upper Eocene age, comprising limestone (Fonsi Formation) or clayey and chalky limestone (Gaziantep Formation) (Richardson, 1991, cited by Canakci et al., 2007). Turgut et al. (2008) reported that Sanliurfa stone samples contain a high amount of Ca and lower amounts of Al, Fe, Mg, S and Si, while they contain no Na, K and Cl.

Mg plays an important role in protein metabolism, blood pressure regulation and neuromuscular transmission. The Mg content in the feather samples (365.96 ± 28.65 μg g^{-1}) in the present study was lower than that reported by Borghesi et al. (2016) for the Greater Flamingo (463-1843) and higher than that reported by Hanc et al. (2017) in red-breasted flycatchers (*Ficedula parva*) (174.58 μg g^{-1}).

This difference may be related to the feeding patterns of the bird species studied and the environment in which they live. Flamingos feed on small plankton-like animals in wetlands. The Bald Ibises (*Geranticus eremita*) outside of the breeding station feed on insects, snails, etc, and the nesting area includes calcium-rich limestone rocks. This difference might also be related to the age of the bird as the basic elements were expected to be higher because the birds in this study were younger and still in the growth and development period.

Potassium plays an active role in cellular activities, in nerve conduction and bone metabolism. The higher K content of the Bald Ibis feathers associated with environmental pollution, demonstrated that the water, soil and plants in the habitats. Sodium plays a role in the acid-base balance in extracellular fluid. Mean content of Fe in the feather samples in the present study (337.58 ± 48.10) was found to be higher than the reported values of 48.9 ± 5.8, 185.84 ± 18.47 and 52.79 ± 50.69 μg g^{-1} for Common moorhens (*Gallinula chloropus*) (López-Perea et al., 2019), Italian Sparrows (*Passer italiae*) (Innangi et al., 2019) and Anna's humming birds (*Calypte anna*) (Mikoni et al., 2017) respectively. No significant difference in the Fe content between the sexes was observed ($p > 0.05$). The higher Fe content of the Bald Ibis feathers could be attributed to species differences associated with nutritional behavior. For example, moorhens eat plant seeds and invertebrates (Zamani-Ahmadmahmoodi, 2010) while the Bald Ibises in this study consumed both small vertebrates and invertebrates in addition to the diet supplied in the breeding station which contained lean meat. However, the differences may also arise from the geographical distribution of the same species. Innangi et al. (2019) reported that the feathers of Italian Sparrows contained a 9-fold lower level of Fe than those of House Sparrows in Southern Africa.

Based on the observation that Mn together with Zn and Ca is abundant in black-coloured feathers, and that healthier birds have more coloured feathers, Innangi et al. (2019) suggested that higher levels of Mn might indicate a healthier bird. The higher Mn content in the feather samples in this study could therefore be attributed to the black-coloured plumage of Bald Ibises.

The mean Ba content detected in this study (3.48 ± 0.62 μg g^{-1}) was lower than the value reported by Adout et al. (2007) for Feral Pigeons (4.84 ± 1.31-16.7 ± 8.1) and Hooded Crows (*Corvus corone cornix*) in rural (15.6 ± 7.36) or industrial areas (18.3 ± 6.8). This can be thought to be due to industry in the regions close to the study area. Barium can pharmacologically replace Ca (John et al., 2005) ions in the keratin structure of bird feathers and high Ba levels can result in health problems in young birds (Hanc et al., 2011).

The results of this study showed a high correlation between Ba content and Ca content in the feather samples ($r = 0.861$, $p = 0.001$). It has been suggested that environmental pollution with Ba is caused by dust from road aggregate material (Brumbaugh et al., 2006). The lower Ba content in the Bald Ibis feather samples could therefore be explained by the distance of the breeding station from main roads.

The mean Zn content (67.88 ± 7.57 μg g^{-1}) in this study was found to be similar to that reported for birds raised in regions near to industrial areas. López-Perea et al. (2019) reported a mean Zn level of 71.11 μg g^{-1} in the feather samples of common moorhens living in wetlands irrigated with industrial waste water. Dolan et al. (2017) observed the highest levels of Zn (82.1 mg/kg) in the feathers of Northern Goshawks living in regions near to industrial areas in Norway and Spain. Mikoni et al. (2017) found 123.79 mg g^{-1} on the feathers of free-flying Anna's humming birds in California, which was approximately double the values in the current study. The authors attributed the high level of Zn in this species to the pollution of the nectar and flies they eat by Zn contained in dish washing detergents. Innangi et al. (2019) reported Zn content of 106.26 μg g^{-1} in the feather samples of free-flying birds in a region close to an industrial zone in southern Italy. Borghesi et al. (2016) reported levels of 77.44 mg kg^{-1} in bird colonies living near industrial zones in France, Spain and Italy Zinc is an important and necessary element for the keratinization process in birds, and is also used in veterinary medicine as an emetic and antiseptic drug or as an antagonist drug against copper sulphate toxicity. As excessive ingestion of Zn is toxic, environmental pollution with Zn represents a risk for wildlife (Sundaresan et al., 2008; Honda et al., 1986)

The mean value Ni found in the current study (1.86 ± 0.67 μg g^{-1}) was higher than the values found by Borghesi et al. (2016) (1.058 μg g^{-1}) and López-Perea (2019) (0.087 μg g^{-1}) and lower than that reported by Mikoni et al. (2017) (3.28 μg g^{-1}). Thus, the Ni content reported in this study was within the range previously reported in literature. However, Ni is a metal extensively used in industry and industrial activities, and isa major source of environmental pollution. The town of Birecik, where the study was conducted, is close to the industrial city of Gaziantep. The mean concentration of Ni in the sediments at different locations of the Euphrates River has been reported to be 0.16-0.35 μg g^{-1} (Oymak et al., 2009). Therefore, disposal of industrial waste in the Euphrates River may be the cause of Ni exposure of the birds.

Al can be transmitted from the environment to both natural and anthropogenic sources and its toxicity varies according to the target organ. The mean Al content found in the present study (246.52 ± 34.73) was higher than the values found by Borghesi et al. (2016) (3.71 μg g^{-1}) and Dolan et al. (2017) (23 μg g^{-1}). Mn was determined in the range of 20- 491 μg g^{-1} and these values were higher than all other studies [Lopez et al., 2019, (3.93-89 μg g^{-1}), İnnangi et al., 2019, (0.33-23.83 μg g^{-1}) and Mikoni et al., 2019, (0.33-23.83 μg g^{-1}]. Excessive amounts of Mn have been reported to be life-threatening and high amounts of Mn taken by ingesting sediments can cause acute and chronic toxicity (Sánchez-Virosta et al., 2015).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1482314834

In some studies, the Cu content of feather samples gas been found to be 1.97-149.9 μg g^{-1} (Mikoni et al., 2017), 5.04-17.04 μg g^{-1} (López et al., 2019), 6.59 ± 4.72 μg g^{-1} (Bauerová et al., 2017), and 2.68 μg g^{-1} (İnnangi et al., 2019). In this study, the Cu value was determined between 5 -500 μg g^{-1}. This value is higher than those reported by other study groups. Cu is widely used in veterinary medicine as an anthelmintic antiperspirant. Pollution from water, sediment and industrialization affects the amount of Cu in birds. The high Cu concentration determined in this study may reflect the pollution of the habitat in which the animal lives.(Custer et al., 2008) This shows that there is a continuing risk of environmental contamination for the Bald Ibis, which is at risk of extinction.

Arsenic is a toxic element. Acute and chronic intoxication may be seen with excessive intake of this metal (Borghesi et al., 2016; Sanches Virost et al., 2015). In the current study, the mean arsenic levels in the feather samples were 486 ng/g in males and 1451 ng g^{-1} in females although the differences between the sexes were not significant. Bauerová et al. (2017) reported cyanide levels of 1510 ng g^{-1}, Borghesi et al. (2016), 819 ng g^{-1}, and López-Perea et al. (2019) 378 ng g^{-1}. Arsenic is bound to sulphur-rich proteins in feathers (Murphy et al., 1990).

Other toxic elements determined in the current study were Se 447.01 ng g^{-1}, Pb 119.66 ng g^{-1}, and Co 227.96 -848.31 ng g^{-1}. The presence of toxic heavy metals in bird feathers may be due to the contamination of their feathers with external pollution. It has also been reported in other studies that pollution can occur with these metals (Al, Co, Ni, Cu, Fe, Zn, Mn, Ag, Tl, Pb and Cd) during the growth period of feathers (Dauwe et al., 2003). Exposure of birds to Pb, Se, Cd, Zn and As causes reproductive failure, growth disorder, and behavioral changes (Binkowski et al., 2013; Govind and Madhuri, 2014; Alvárez et al., 2013). With the exception of Cu, no significant difference was observed in terms of other elements. Most studies on different bird species have reported no significant difference between the sexes in the metal content of feather samples (Markowski et al., 2013; Squadroneet al., 2016).

The fact that high and significant correlations were observed among Mg, Al, Ti, Mn, Fe and Ni contents might indicate a common physiological or environmental basis. Given that trace elements can move though food chains by a variety of routes.

Conclusion

This is the first study to determine heavy metal pollution in the feathers of the Bald Ibis, which is an endangered bird. In this study, the presence of heavy metals such as Pb, As, Br, Ni, Zn, which are important for the determination of environmental pollution, demonstrated that the water, soil and plants in the habitats of the people are exposed to metal pollution because of industrial, domestic and agricultural activities. The heavy metal limits determined in this study, are at a level that threatens the life of the Bald Ibis and reflects the pollution of the habitat they live in, and that the continued risk of environmental contamination threatens the continuation of the species. This study indicates that Bald Ibis are possible bioindicators of environmental trace element contamination. The only way to ensure the continuity of the species of Bald Ibis and transfer them to future generations is to protect the ecosystem they live in and eliminate or reduce the threats such as the heavy metal elements identified. In order to do this, there is a need for national and international co-operation with local people so that habitat and birds will be protected together in the local community.

DOI: http://dx.doi.org/10.15666/aeer/1706_1482314834

As a result, we recommend further studies to understand the effects of the heavy metals on the population of the species Bald Ibis.

Abstract. Weeds can be a global threat to biodiversity and ecosystems. Understanding the contribution of environmental factors toward weed distribution can vastly improve the effectiveness of the methods adopted for the prevention and control of weed expansion on a large scale. Through multiple studies, we are now aware of the top 10 most dangerous weed species (in terms of endangering biodiversity). However, few studies have paid attention to the contribution of environmental factors toward the distribution of these weed species globally. In this study, we used species distribution modelling to project weed distribution based on occurrence records and environmental factors. We then used the jackknife estimation to assess the contribution of environmental factors toward weed distribution globally. Our results showed that climatic factors coupled with the human ecological footprint significantly contributed toward the distribution of these weed species. However, annual mean temperature made the largest contribution toward the distribution, except in the case of *Sorghum halepense.* Concerning distribution, different weed species respond differently to the annual mean temperature. However, the human ecological footprint can enhance their global distribution. We suggest that climate change and human influence should be analyzed together to realize methods for the prevention and control of the 10 most dangerous weed species globally.
Keywords: *climatic factor, human ecological footprint, risk monitoring, soil, species distribution modelling, weed management, worldwide*

Introduction

Weeds have a high potential to threaten biodiversity and ecosystem functions around the world (Holm, 1969; Tilman et al., 2006; Bajwa et al., 2016; Krak et al., 2019). Owing to their generally broad physiological niches and/or specific traits, weeds can invade human-mediated ecosystems with relative ease (Holm, 1969; Tilman et al., 2006; Shimono and Konuma, 2008; Panetta, 2015). Weed expansion can affect biodiversity across different spatial scales; for example, they can spread widely in disturbed or degraded environments (Shimono and Konuma, 2008). Thus, weed species could be dominant in such habitats and deplete the resources available to native plants, resulting in decreased biodiversity (Holm, 1969; Tilman et al., 2006; Shimono and Konuma, 2008). Furthermore, weed invasion could significantly decrease the ecosystem functions (e.g., nutrient cycling and biomass productivity) (Tilman et al., 2006; Bajwa et al., 2016; Zhang et al., 2018). Such negative effects on biodiversity and ecosystem functions may be due to the wide distribution of weeds as well as the spatial changes observed in environmental factors (Holm, 1969; Tilman et al., 2006; Shimono and Konuma, 2008; Panetta, 2015; Zhang et al., 2018).

DOI: http://dx.doi.org/10.15666/aeer/1706_1483514846

Holm (1969) listed the 10 most dangerous weed species globally. These species have large distribution ranges and can expand widely across different environmental conditions. Ervin and Holly (2011) used species distribution modelling (SDM) to project the distribution of *Imperata cylindrica* in the United States based on pertinent environmental factors. Through further analysis of the results, they made some relevant suggestions on the prevention and control of this particular species (Ervin and Holly, 2011). Goncalves et al. (2014) showed that the climatic niche is conserved across continents for the expansion of *Lantana camara*. Based on a large amount of previous evidence (Holm, 1969; Ervin and Holly, 2011; Goncalves et al., 2014; Ray and Quader, 2014; Wan et al., 2019), we now know that environmental changes affect weed expansion, particularly for these 10 species. Therefore, it is necessary to explore the contribution of environmental factors toward the global distribution of these weed species; this will help us realize more effective methods for their prevention and control.

Here we discuss the following two scientific aspects: 1) which environmental factors could affect the distribution of the 10 most dangerous weed species globally, and 2) how could different environmental factors affect weed distribution. To address these questions, we used SDM to model the global distribution of these weed species. Then, the jackknife estimation was used to assess the contribution of environmental factors toward global weed distribution. Finally, we quantified the changing trends in weed distribution based on the relationship between the distribution probability and environmental factors.

Materials and methods

Species data

The following 10 weed species are termed as the most dangerous, as per Holm's study (1969): *Cynodon dactylon*, *Cyperus rotundus*, *Echinochloa colona*, *Echinochloa crus-galli*, *Eichhornia crassipes*, *Eleusine indica*, *Imperata cylindrica*, *Lantana camara*, *Panicum maximum*, and *Sorghum halepense*. These 10 species are dangerous weeds nowadays (Chandramohan and Charudattan, 2001; Punia et al., 2004; Vila-Aiub et al., 2007; Chauhan and Johnson, 2010; Ervin and Holly, 2011; Patel, 2012; Goncalves et al., 2014; Palma-Ordaz and Delgadillo-Rodríguez, 2014). The global occurrence records of these species were downloaded from the Global Biodiversity Information Facility (GBIF; https://www.gbif.org/; assessed on 19th March, 2019). The cleaning facilities of ModestR were used to minimize the frequently appearing errors in GBIF (García-Roselló et al., 2014). Duplicate occurrence records were removed on a 10.0 arc-minutes (~16.0 km) spatial resolution grid. The number of occurrence records ranged from 1795 to 7931 to support the good performance of SDM in our study.

Environmental data

The environmental data of our study included four climatic factors [annual mean temperature (°C*10); temperature seasonality (standard deviation*100); annual precipitation (mm); and precipitation seasonality], eight soil factors [bulk density (kg/m^3); cation exchange capacity (cmolc/kg); soil texture fraction clay (%); coarse fragments volumetric (%); soil organic carbon stock (tonnes per ha); soil pH; soil texture fraction silt (%); and soil texture fraction sand (%)] (Hengl et al., 2014), and one

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1483514846

human ecological footprint (Sanderson et al., 2002). Non-standard units of temperature were used because this allows for much reduced file sizes, which is important as, for many, downloading large files remains difficult (https://www.worldclim.org). Climate data of 10.0 arc-minutes was downloaded from the WorldClim database (averaged from 1950 to 2000; https://www.worldclim.org), and soil data of 0.5 arc-minutes was downloaded from SoilGrids (https://www.soilgrids.org). The human ecological footprint data was detailed in the study of Sanderson et al. (2002). We chose these environmental factors because they can potentially have a large effect on the distribution of weed species (Holm, 1969; Chicoine et al., 1986; Ervin and Holly, 2011; Goncalves et al., 2014). The four climatic factors, mean and standard deviation temperature and precipitation, were selected because they are widely used in SDMs based on previous studies (Ervin and Holly, 2011; Goncalves et al., 2014; Qin et al., 2014; Wan et al., 2016; Wan and Wang, 2019). Hageer et al. (2017) showed that the eight selected soil factors should be applied to predict distributions of plant species at large spatial scales. The human ecological footprint could explain the the global distribution of plant invaders (Beans et al., 2012; Gallardo et al., 2015). We used ArcGIS 10.6 (https://www.esri.com/software/arcgis/arcgis-for-desktop) to resample the resolution of the soil and human ecological footprint data from 0.5 arc-minutes to 10.0 arc-minutes. Hence, the value ranges of soil and human ecological footprint data were different from the previous studies (i.e., Sanderson et al., 2002; Hengl et al., 2014).

Species distribution modelling and jackknife estimation

We used Maxent modelling to project the global distribution of these weed species based on species data and environmental factors (Phillips et al., 2017). The Maxent modelling sets were as follows: 1) the regularization multiplier (beta) was kept at 2.0 to produce a smooth and general response shape, which represented a biologically realistic behaviour (Radosavljevic and Anderson, 2014); 2) the maximum number of background points was set to 10,000, while maintaining the same bias as the buffer of occurrence records of species on a global scale (Phillips et al., 2017); 3) a four-fold cross-validation approach was used (75% and 25% of occurrence records for training and testing modellings, respectively, in each run) to remove bias with respect to occurrence records (Merow et al., 2013); 4) a complementary log–log (cloglog) transformation was applied for the output of Maxent modelling (Phillips et al., 2017); and 5) the other sets were the same as the study of Merow et al. (2013). The cloglog output format gave each grid cell a value between 0.0 and 1.0, with 0.0 representing the lowest distribution probability of weed species and 1.0 the highest (Phillips et al., 2017). We evaluated the predictive precision of the species distribution models by using the area under the curve (AUC) of the receiver operating characteristic, treating each value of the prediction result as a possible threshold and then obtaining the corresponding sensitivity and specificity values to calculate the curve. Here, the modelling performance was satisfactory for these weed species because the AUC was over 0.7 (Merow et al., 2013).

A jackknife approach was used to assess the percentage contribution (PC) of environmental factors to the distribution probability of weed species using Maxent modelling (Merow et al., 2013; Shcheglovitova and Anderson, 2013; Oke and Thompson, 2015). The output of the jackknife estimation gave each environmental factor a value between 0.0% and 100.0%, representing the increasing PC of environmental factors to the distribution probability (Shcheglovitova and Anderson, 2013; Oke and Thompson, 2015). Response curves of the environmental factors to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1483514846

distribution probability could be quantified using Maxent modelling (Shcheglovitova and Anderson, 2013). We summed up the values of PC based on the groups of climatic and soil factors. In our study, the contribution of environmental factors toward the species distribution was high when the PC was at least 15.00% of the modelling for each weed species (Oke and Thompson, 2015).

Results

Distribution of weed species

The 10 most dangerous weed species were distributed primarily in Europe, Southeast Asia, Australia, southern regions of North America, central and eastern regions of South America, and central and southern regions of Africa (*Fig. 1*). Specifically, *C. dactylon*, *C. rotundus*, and *E. colona* cover most regions of Australia (*Fig. 1*). Compared to other species, *E. crus-galli* and *S. halepense* cover only small areas in the central and southern regions of Africa (*Fig. 1*).

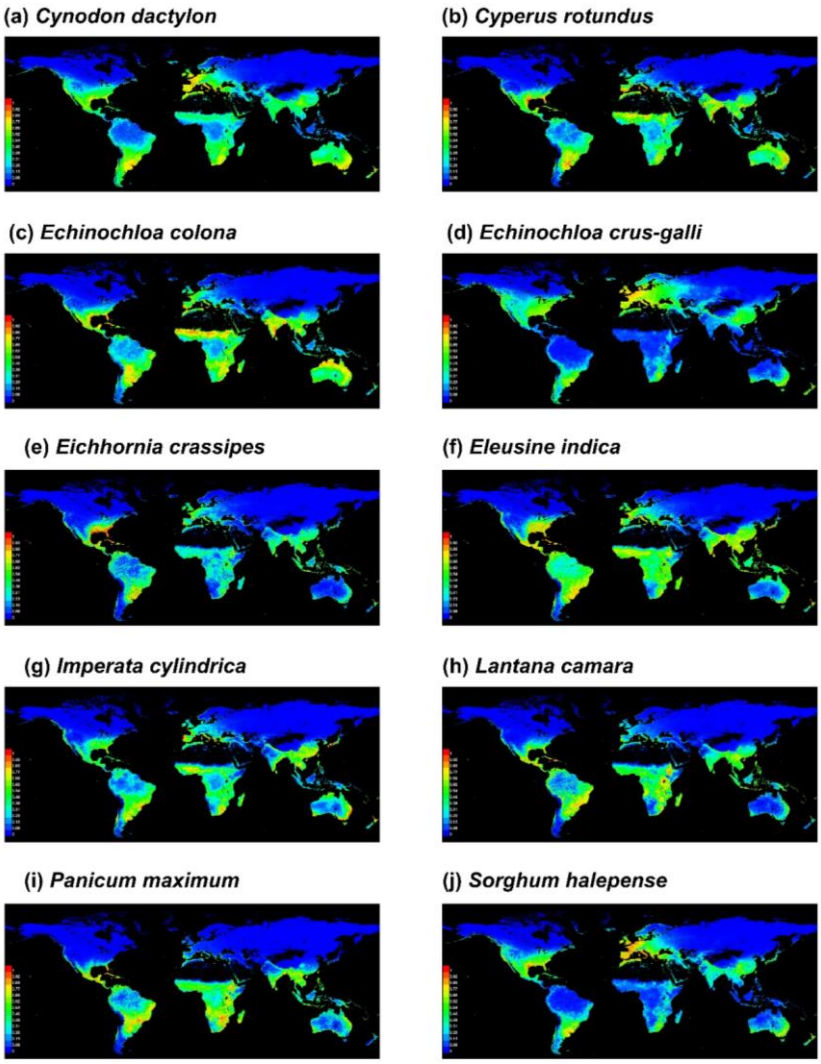

Figure 1. *The distribution of 10 most dangerous weed species on a global scale. The colour of maps from blue to red represents the distribution probability of the 10 most dangerous weed species from low to high levels*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1483514846

Contribution of environmental factors to weed distribution

PCs for all climatic factors were over 50% across all these species, thus indicating that the climatic factor made the largest contribution toward the global distribution (*Table 1*). Among the climatic factors, annual mean temperature made the largest contribution toward the distribution, except for *S. halepense*. Further, temperature seasonality and annual precipitation played an important role in the distribution of seven weed species, i.e., *C. dactylon*, *E. colona*, *E. crus-galli*, *E. crassipes*, *E. indica*, *P. maximum*, and *S. halepense* (PC over 15.00%; *Table 1*). Although the distribution ranges were similar among the species, temperature and precipitation made different contributions toward the distribution, and the response curves of the climatic factors to the distribution varied among different weed species (*Fig. 2*). The response curves of climatic factors to the distribution were simply unimodal for *E. crus-galli*, *E. crassipes*, *L. camara*, *P. maximum*, and *S. halepense*. Also, an obvious increasing trend was observed in the unimodal changes for *C. dactylon*, *C. rotundus*, *E. colona*, *E. indica*, and *I. cylindrica* (*Fig. 2*). We found that soil factors made a small contribution toward the global distribution (*Table 1*). At large spatial scales, climatic factors made a larger contribution toward weed distribution than soil factors (*Table 1*). PC was higher than 15.00% for the human ecological footprint for the global distribution of *E. crus-galli*, *E. crassipes*, *E. indica*, *L. camara*, and *S. halepense* (*Table 1*). Furthermore, the distribution probability enhanced with an increased human ecological footprint (*Fig. 3*).

Discussion

We found that the distribution range of the 10 most dangerous weed species included Europe, Southeast Asia, Australia, southern regions of North America, central and eastern regions of South America, and central and southern regions of Africa, indicating that these weed species have great potential to expand widely around the world. Hence, as per Holm (1969), the threat that these species pose to the ecosystem and biodiversity should be a global issue. It is therefore important to explore the drivers behind the wide distribution of these weeds so that the effectiveness of the preventive and control methods can be improved (Panetta, 2015; Bajwa et al., 2016; Wan and Wang, 2019).

Contribution of climatic factors to weed distribution

We found that PCs for all climatic factors were over 50% across all these species, thus indicating that the climatic factor made the largest contribution toward the global distribution (*Table 1*). Among the climatic factors, annual mean temperature made the largest contribution toward the distribution, except for *S. halepense* (PC over 15.00%; *Table 1*). Although the distribution ranges were similar among the species, temperature and precipitation made different contributions toward the distribution, and the response curves of the climatic factors to the weed distribution varied among different weed species (*Fig. 2*). These results indicated that suitable climatic conditions could drive the global expansion of weed species. Previous studies (e.g., Holm, 1969; Tilman et al., 2006; Shimono and Konuma, 2008; Ervin and Holly, 2011; Panetta, 2015; Wan et al., 2017; Zhang et al., 2018) have shown that weeds can strongly adapt to rapid environmental changes and could grow exponentially in the near future. Weeds have a high level of phenotypic plasticity, and are capable of relatively rapid genetic change to enhance their ability to invade new areas in response to climate change (Clements and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1483514846

Ditommaso, 2011). Hence, it is important to understand the changing trends in weed distribution along with the variation in global climate changes (Ervin and Holly, 2011; Wan et al., 2016; Zhang et al., 2018; Wang et al., 2019). *Figure 2* shows us the importance of monitoring weed expansion under different climatic conditions.

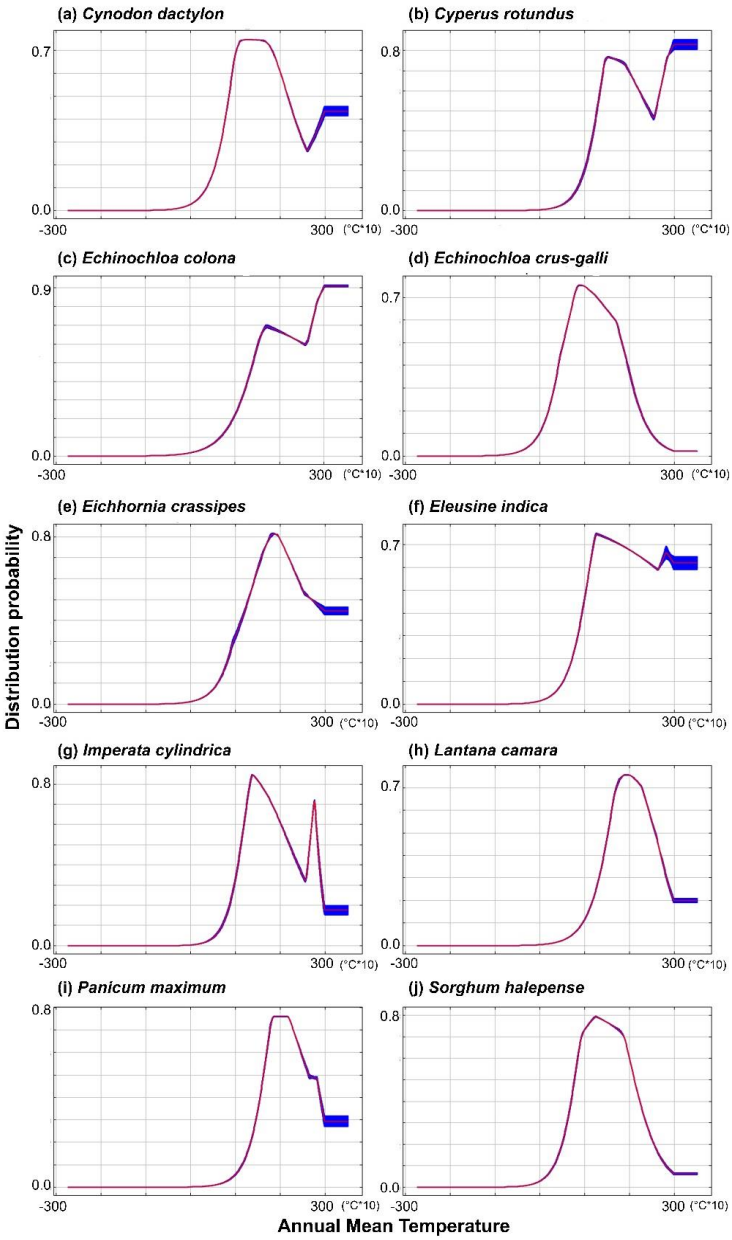

Figure 2. *Response curves of annual mean temperature to weed distribution on a global scale*

Contribution of soil factors toward weed distribution

Our results showed that soil factors made a negligible contribution toward global distribution (PC less than 15.00%; *Table 1*), thus indicating that soil factors solely could not drive weed expansion on a global scale. Numerous experimental studies (Tilman et al., 2006; Ramakrishna et al., 2006; Welch et al., 2016; Zhang et al., 2018) have shown that small-scale soil conditions play an important role in the spatial distribution of weed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1483514846

species. However, based on our results, climatic factors made a larger contribution toward weed distribution than soil factors at large spatial scales. At small spatial scales, biotic factors (e.g., soil microorganisms) make a large contribution to weed physiology and weed seed banks (Kremer, 1993; Kennedy et al., 1999). Attention was paid to abiotic factors in our study. This difference may have been due to the effects of the spatial scale on the relationship between soil factors and weed distribution (Ervin and Holly, 2011; Goncalves et al., 2014). However, we should still pay attention to the effects of soil factors because a weed monitoring strategy should be based on different spatial scales, from something as large as a continent to as small as a micro-habitat (Buhler et al., 1997; Dekker et al., 1999; Gallandt, 1999; Wallace et al., 2018).

Contribution of human ecological footprint toward weed distribution

The human ecological footprint made a large contribution toward the global distribution of *E. crus-galli*, *E. crassipes*, *E. indica*, *L. camara*, and *S. halepense* (PC higher than 15.00%; *Table 1*). Furthermore, the distribution probability enhanced with an increased human ecological footprint (*Fig. 3*). The human ecological footprint is a good indicator of human influence in that it estimates the quantity of nature necessary to support the consumption habits of one individual, population, product, activity, or service (Sanderson et al., 2002; Wan et al., 2018). Our results provide clear evidence that human influence could drive the expansion of the above-mentioned 5 species on a global scale, although previous studies (e.g., Young and Evans, 1976; Treier and Müller-Schärer, 2011; Alvarado-Serrano et al., 2019; Krak et al., 2019) have shown that weeds could expand in lands degraded by human influence. Such influences of the human ecological footprint include global trade and transportation (Sanderson et al., 2002; Wiedmann and Lenzen, 2018). Therefore, we should consider making provisions for better control of global trade and transportation if we are to restrict the global distribution of these five species (Holm, 1969; Panetta, 2015; Zhang et al., 2018).

Climate, soil, and HF denote the total contribution of climate, soil, and human ecological footprint toward weed distribution. The bold values denote the large contribution of environmental variables toward weed distribution. The environmental codes were following: Bio1: annual mean temperature (°C*10); Bio4: temperature seasonality (standard deviation*100); Bio12: annual precipitation (mm); Bio15: precipitation seasonality (coefficient of variation); BLD: bulk density (kg/cubic meter); CEC: cation exchange capacity (cmolc/kg); CLYPPT: soil texture fraction clay (%); CRFVOL: coarse fragments volumetric (%); ORCDRC: soil organic carbon stock (tonnes per ha); PHIHOX: soil pH; SLTPPT: soil texture fraction silt (%); SNDPPT: soil texture fraction sand (%)

Conclusions

We conclude that climatic factors coupled with the human ecological footprint made a significant contribution toward the distribution of the 10 most dangerous weed species globally. The contribution of the annual mean temperature was the largest for all the species, except for *S. halepense*. Various weed species respond differently to the annual mean temperature, but the human ecological footprint could enhance global expansion. Hence, we should analyze climate change and human influence together for the global prevention and control of these 10 most dangerous weed species. The spatial pattern of climates and the human ecological footprint should be closely monitored in Europe, Southeast Asia, Australia, southern regions of North America, central and eastern regions of South America, and central and southern regions of Africa. Future studies should attach importance to the contribution of environmental factors towards more weed species at the global scale. Weed control and management is increasingly becoming a global issue due to global human activities (e.g., global transportation and trade; Beans et al., 2012; Gallardo et al., 2015; Alvarado-Serrano et al., 2019). More and more weed species have a high potential to expand around the world. Furthermore, future studies also should pay attention to the importance of biotic factors (e.g., soil microorganisms) to the distribution of weed species globally. Therefore, studies on more weed species and biotic factors should be conducted for weed species worldwide.

Abstract. Based on the surface meteorological observation data collected by meteorological stations 57687 (Changsha), 57773 (Xiangtan) and 57780 (Zhuzhou) of Hunan province from January 14 to 20, in 2017, and the air monitoring data of Changsha City, Zhuzhou City and Xiangtan City provided by The National Environment Monitoring Station, this paper analyzed the stage characteristics of a continuous haze process in the Chang-Zhu-Tan Region of China and its influencing factors in late January of 2017. The results show that the haze process has stage characteristics with the fog and the haze alternating. Through correlation analysis, it is concluded that PM2.5 concentration, vapor pressure of water, dew point temperature and relative humidity are the four key factors determining visibility. Through analyzing main components, a meteorological factor consisting of vapor pressure of water, dew point temperature and relative humidity is established. A linear model featuring PM2.5 concentrations and visibility and a cubic curve model featuring the meteorological factor and visibility are set up. During the continuous haze process, the average concentration of PM2.5 is greater than 88 ug/m^3 and is inversely related to the visibility. Accumulation of highly concentrated PM2.5 causes low visibility. With the changes of humidity and dew point temperature, fog and haze appear alternatively.
Keywords: *PM2.5 concentration, meteorological factors, visibility, Chang-Zhu-Tan Region*

Introduction

With the rapid development of urban construction, industry and transportation in Changsha, Zhuzhou and Xiangtan (Chang-Zhu-Tan), the increase in the concentration of fine particles such as pollutants and dust in the near-surface layer has led to a decrease in visibility and more severe urban air pollution. Haze weather has become a danger to our living environment and the atmosphere. Major disasters have had serious negative impacts on the environment, health, climate, and economy. Foreign scholars have long been studying the climate characteristics of haze and its impact on regional climate. Elias et al. (2009) studied the effects of particles (smoke and fog) on visible light radiation. Jansen (2014) used the hourly measurement method to explore the role of secondary inorganic aerosols in Particulate Matter 2.5 (PM2.5) in the haze in Hangzhou, China.

Singh and Giri (2011) studied the properties of the interannual changes of fog and smoke and their impact on agricultural production. Domestically, Guo et al. (2015) analyzed the durative heavy fog weather such as aerosols, cloud condensation nuclei (CCN), fog droplets spectrum and micro physical characteristics such as moisture

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1484714858

content, atmospheric visibility and vertical structure characteristics of boundary layer. They explored the characteristics and mechanism of the formation, evolution and transformation of haze weather. Xie et al. (2015) analyzed the meteorological elements, PM2.5 concentration and atmospheric boundary layer characteristics of a large-scale continuous heavy haze process in central and eastern China, and concluded that PM2.5 concentration is inversely related to visibility and relative humidity. Hu et al. (2013) analyzed the characteristics and influencing factors of haze weather in Xi'an area by using the data from Xi'an meteorological station gathered since its establishment. Zhao et al. (2013) studied the characteristics of PM2.5 pollution on Beijing's autumn smoggy days using observation data such as PM2.5 concentration in Beijing's urban and suburban areas in 2011. Li et al. (2017) studied the causes and hazards of urban haze. Sun (2016) and Liu et al. (2013) analyzed the causes of continuous haze weather from the optical perspective. Zhu et al. (2015), Dai and Cheng (2008), Yin et al. (2014) Morones Esquivel et al. (2017) and Hou et al. (2017) all studied the meteorological causes of persistent haze.

At present, the domestic research on smog is mainly concentrated on the weather in the Beijing-Tianjin-Hebei region, Yangtze River delta, the Pearl River delta and other regions, though there are also some researches on the haze weather in Hunan province some other cities. For example, Yuan et al. (2015) and Leura Vicencio et al. (2017) analyzed daily visibility and relative humidity data from 1970 to 2012 of 76 ground meteorological observation stations, and obtained the daily fog and haze conditions in various regions of Hunan, using linear trend to analyze the characteristics of fog and haze years; Zhang et al. (2014) used the meteorological observation data and environmental monitoring data of the Changsha area from 1970 to 2012 to analyze the characteristics and influencing factors of smog in Changsha area over the past 43 years, but an analysis on the cause of the continuous smog process in Chang-Zhu-Tan region has not been reported. In this paper, hourly meteorological and environmental data from January 14 to 20, 2017 are used to study the occurrence and evolution of a persistent haze process in Chang-Zhu-Tan region, and corresponding mathematical models are established based on the influencing factors. The conclusion can provide a strong theoretical basis for optimizing environmental management and preventing haze scientifically in Chang-Zhu-Tan region.

Materials and methods

The research site, Chang-Zhu-Tan region, is located in the central and eastern part of Hunan Province in China, as shown in *Figure 1*. It is an important part of the urban agglomeration in the middle reaches of the Yangtze River, including Changsha, Zhuzhou and Xiangtan cities.

The conventional meteorological data used in this paper comes from the China Meteorological Data Network, which mainly includes ground and high-altitude data from January 14 to January 20, 2017 in Changsha, Zhuzhou and Xiangtan of China. The ground data includes air pressure, visibility, temperature, dew point temperature, and relative Humidity, wind direction and wind speed. Except dew-point temperature, all data is hourly data. Visibility data is obtained by referring to the method of obtaining visibility data in the paper (Cao et al., 2013). The altitude data are from the altitude data of Ma-Po-Ling station once a day (12 o'clock). The air pollutant data are from the environmental quality monitoring station, mainly including Particulate Matter 2.5

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1484714858

(PM2.5) and Air Quality Index (AQI) data of the three cities of Chang-Zhu-Tan region, all of which are hourly average data.

Based on the meteorological and environmental data of Changsha-Zhuzhou-Xiangtan, this paper analyzes the internal relations among the influencing factors by correlation analysis, principal component analysis and regression analysis, and establishes the corresponding mathematical model.

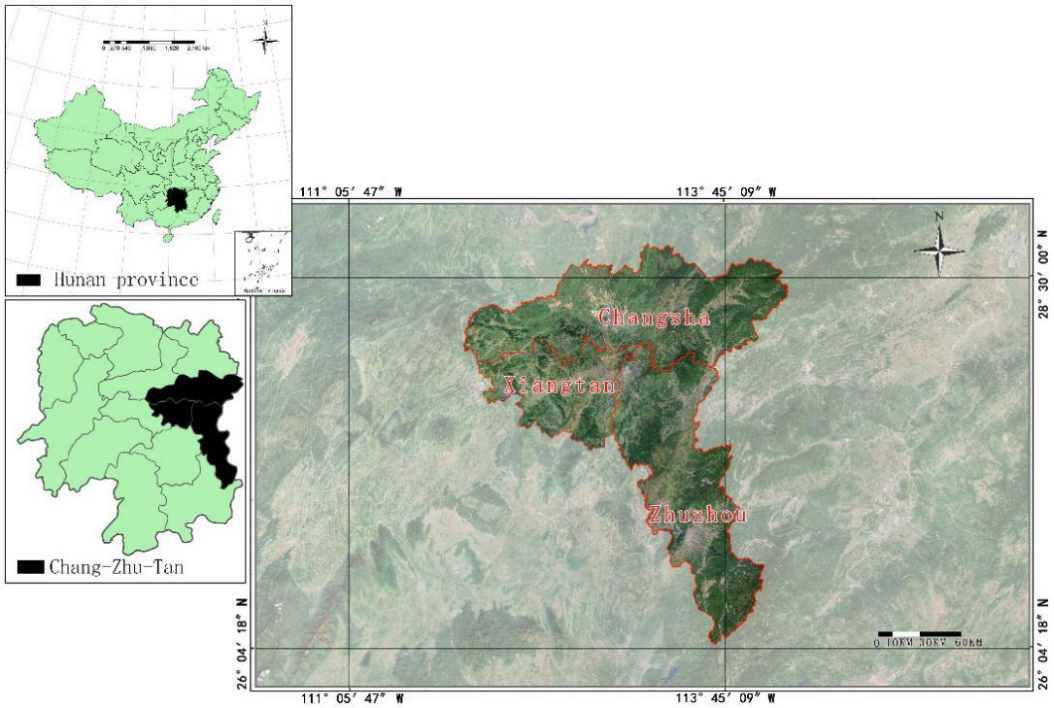

Figure 1. *Location of research site*

Results

Process analysis

Air quality changes in Chang-Zhu-Tan region

Chang-Zhu-Tan metropolitan area is the demonstration zone of the construction of "two-oriented society" and the core growth pole of Hunan province's economic development. Industrialization has accelerated in recent years, and environmental pollution has followed. During this haze, the average AQI and PM2.5 concentrations in Zhuzhou are the highest, respectively, 133 and 101 ug/m^3. The average AQI and PM2.5 concentrations of Changsha are 112 and 87 ug/m^3, respectively. The lowest is Xiangtan city, with average AQI and PM2.5 concentrations of 106 and 80 ug/m^3, respectively. The AQI and PM2.5 concentrations in the three cities all reach peak in the afternoon of the 17th. The changes of AQI and PM2.5 concentration are shown in *Figure 2.*

According to the air quality standards uniformly regulated by the State Environmental Protection Administration, Zhuzhou City has 43 h of moderate pollution and 107 h of light pollution. Changsha has 115 h of light pollution and above. Xiangtan city has 95 h of light pollution and above. The pollution is most serious in Zhuzhou City.

DOI: http://dx.doi.org/10.15666/aeer/1706_1484714858

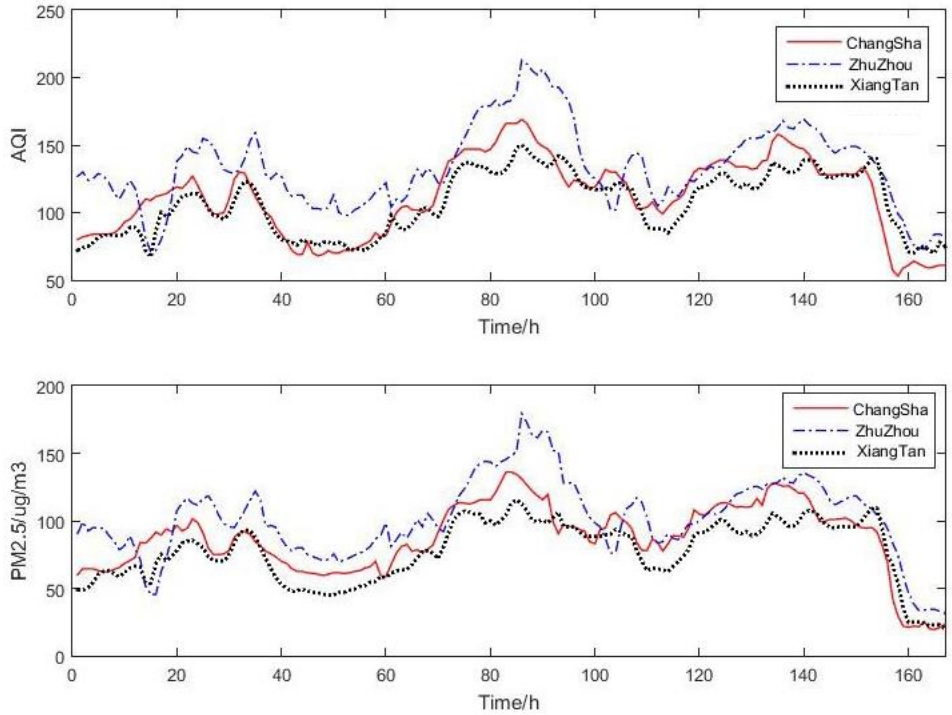

Figure 2. *Variation of AQI and PM2.5 concentration in Chang-Zhu-Tan region*

Evolution of ground visibility

During the smog process from January 14 to 20, 2017, the visibility is less than 1000 m. The visibility is less than 800 m in nearly 136 h, and the visibility is less than 500 m in 20 h. The dense fog process with visibility less than 500 m is 4 h. The minimum visibility of the haze process is 294 m, as shown in *Figure 3*.

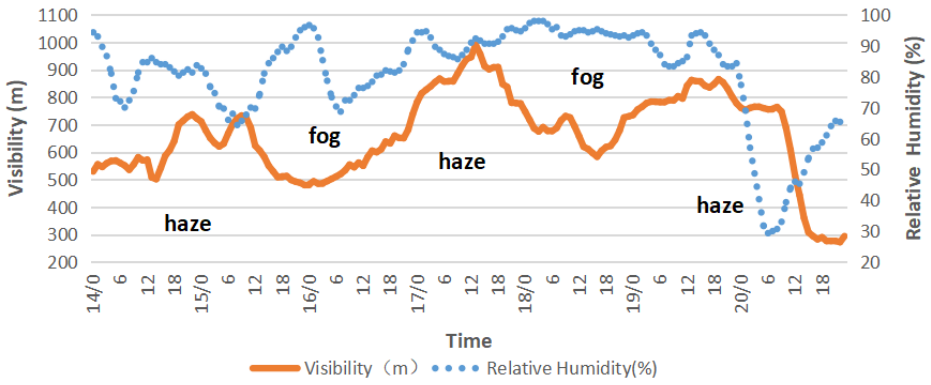

Figure 3. *Variation trend of visibility and relative humidity*

As shown in *Figure 3,* during the haze weather, many transitions and alternations between fog and haze occurred. According to the new haze standards issued by the China Meteorological Administration, atmospheric turbidity with a relative humidity greater than 95% is defined as fog, and atmospheric turbidity with a relative humidity less than 95% is defined as haze. According to the different visibility of haze weather, it is divided into four grades (Xie et al., 2015; *Table 1*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1484714858

Table 1. *Classification of haze levels*

Visibility (km)	[5,10)	[3,5)	[1,3)	[0,1)
Haze levels	Slight haze	Mild haze	Moderate haze	Heavy haze

According to this standard, the haze process in Chang-Zhu-Tan region is divided into five stages. The first, the third and the fifth stages are haze, and the second and fourth stages are fog.

Changes in ground meteorological elements

According to the collected ground meteorological data, the variation trend chart of wind direction, wind speed, maximum temperature, minimum temperature, visibility, relative humidity and dew point temperature is drawn, and the results are shown in *Figure 4.*

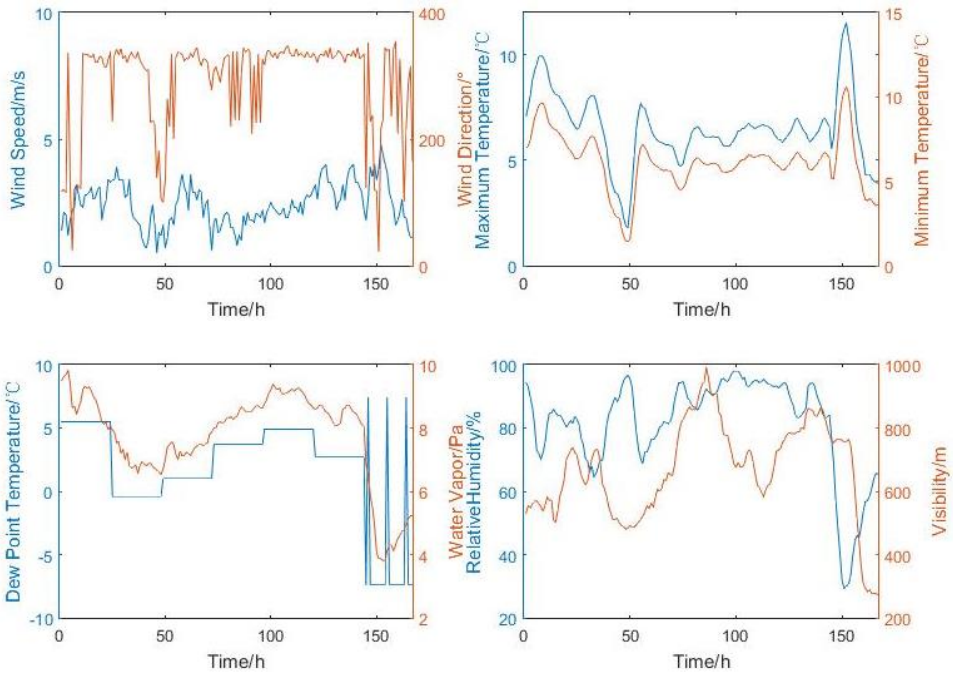

Figure 4. *The trend chart of meteorological factors*

The changes in meteorological elements near the surface of the continuous smog process in Changsha, Zhuzhou and Xiangtan are relatively obvious. The relative humidity increases with the decrease of the dew point and the temperature drop at night, which is conducive for the water vapor to condense to form fog; during the daytime, the opposite is true. In the second and fourth stages, the ground relative humidity increases to more than 95%, corresponding to fog (Torres-Martinez et al., 2017). When relative humidity decreases, fog turns to haze. It can be seen that the increase of relative humidity is conducive to the increase of the hygroscopic growth of aerosol particles suspended in the air. When the air reaches a saturated state, haze will change into fog. As can be seen from the changes in wind speed, the wind speed during the haze is less than 4.8 m/s, and the wind speed during the fog process is mostly between 1.5 m and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1484714858

2.5 m/s. In the process of haze occurrence, the wind speed is larger than that of fog, and the wind speed is between 2 m/s and 4.8 m/s (Bremer Bremer et al., 2016). It can be seen from the change of wind direction that when fog occurs, it is mostly southerly wind. When haze occurs, the wind direction is mainly north wind and northwest wind.

Analysis of factors influencing visibility in haze weather process

Visibility is closely related to ground meteorological elements and aerosol concentration in haze weather. In order to determine the main factors that influence the fog haze weather process at different stages, air pressure, wind direction, wind speed, temperature, dew point temperature, vapor pressure, relative humidity, the visibility and PM2.5 concentrations in this haze process are analyzed by Statistical Product and Service Solutions (SPSS) through Pearson correlation analysis on both sides. Pearson correlation coefficient formulas as shown in *Equation 1*. The correlation results are shown in *Table 2*.

$$r = \frac{\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})}{\sum_{i=1}^{n}(x_i - \bar{x})^2 \sum_{i=1}^{n}(y_i - \bar{y})^2} \quad \text{(Eq.1)}$$

Table 2. *Correlation analysis of visibility and influence factors*

		Air pressure	Wind direction	Wind speed	Temperature	Dew point temperature	Vapor pressure	Relative humidity	PM2.5
vis	Correlation	-0.020	0.274**	0.222**	0.269**	0.352**	0.400**	0.293**	1.000**
	Significance	0.799	0.000	0.004	0.000	0.000	0.000	0.000	0.000

**Significantly correlated at 0.01 level (bilateral)

It can be seen from *Table 2* that in addition to the air pressure, the visibility is strongly correlated with wind direction, wind speed, temperature, dew point temperature, vapor pressure, relative humidity, the visibility and concentrations of PM2.5 are strong correlation, and the correlation is confirmed at 99% by reliability test. Since the average wind speed during the whole haze weather is about 2.4 m/s, the wind speed provides a relatively stable weather background that enables small horizontal transportation, reflecting the consistency of wind speed and visibility on the weather scale. In comparison, PM2.5 concentration, vapor pressure of water, dew point temperature and relative humidity are more closely related to visibility, with correlation coefficients of 1.00, 0.400, 0.352 and 0.293 respectively (Perez-Sicairos et al., 2016). It indicates that PM2.5 concentration, vapor pressure of water, dew point temperature and relative humidity are the four main factors that directly affect the visibility level during the haze.

Establishment of relationship model between visibility and major factors

Correlation analysis is conducted on PM2.5 concentration, vapor pressure of water, dew point temperature and relative humidity, and the results are shown in *Table 2*. It can be seen from the table that dew point temperature, vapor pressure of water, relative humidity and visibility have strong correlation, and passed the 99% confidence interval.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1484714858

In order to study the main factors affecting the visibility and avoid the overlapping effects among the factors, the correlation analysis of the influencing factors is conducted. The results are shown in *Table 3*.

Table 3. *Correlation analysis of influencing factors*

Control variables		The dew point temperature	Vapor pressure	Relative humidity	PM2.5
The dew point temperature	Correlation	1.000	0.834	0.687	0.000
	Significance (bilateral)		0.000	0.000	1.000
Vapor pressure	Correlation	0.834	1.000	0.841	0.000
	Significance (bilateral)	0.000		0.000	1.000
Relative humidity	Correlation	0.687	0.841	1.000	0.000
	Significance (bilateral)	0.000	0.000		1.000
PM2.5	Correlation	0.000	0.000	0.000	1.000
	Significance (bilateral)	1.000	1.000	1.000	

It can be seen from *Table 3* that there is a strong correlation between dew point temperature, vapor pressure of water and relative humidity. Therefore, correlation analysis is conducted again on dew point temperature, vapor pressure of water and relative humidity, and correlation matrix A is obtained. Kaiser-Meyer-Olkin (KMO) and Bartlett tests are carried out, and the results are shown in *Table 4*.

$$A = \begin{bmatrix} 1.000 & 0.856 & 0.718 \\ 0.856 & 1.000 & 0.854 \\ 0.718 & 0.854 & 1.000 \end{bmatrix}$$

Table 4. *KMO and Bartlett inspection*

Sample enough Kaiser-Meyer-Olkin		0.688
Bartlett's sphericity test	Approximate chi-square	434.334
	df	3
	Sig.	0.000

From *Table 4,* the KMO test coefficient is 0.688 > 0.5, and the data have structural validity above 99% confidence interval, so dew point temperature, vapor pressure of water and relative humidity can be used for the principal component analysis. Through principal component analysis, the results are shown in *Table 5*.

As shown in *Table 5,* the cumulative percentage of dew point temperature, vapor pressure of water and relative humidity is 100%. Therefore, dew point temperature, vapor pressure of water and relative humidity can be aggregated into a meteorological factor. As for the component score coefficient matrix, the dew point temperature is 0.350, the vapor pressure is 0.369, the relative humidity is 0.350. Through the score matrix the weight of each factor is calculated, and they are 0.327, 0.345, 0.327, respectively. If the meteorological factor is f, the dew point temperature, vapor pressure of water and relative humidity are x1, x2 and x3 respectively, then *Equation 2* is satisfied.

DOI: http://dx.doi.org/10.15666/aeer/1706_1484714858

$$f = 0.327x_1 + 0.345x_2 + 0.327x_3 \quad \text{(Eq.2)}$$

Table 5. *Principal component analysis of influencing factors*

Component	Initial eigenvalue			Extract the squares and load		
	Summation	Variance's %	Accumulation %	Summation	Variance's %	Accumulation %
1	2.620	87.345	87.345	2.620	87.345	87.345
2	0.282	9.404	96.749			
3	0.098	3.251	100.000			

Model prediction

Meteorological factors and PM2.5 concentration are the main factors affecting visibility. In order to explore the objective relationship between meteorological factors and visibility and that between PM2.5 concentration and visibility, two models are established. First, the model with the highest fitting degree is found through curve fitting. The result is shown in *Figure 5.*

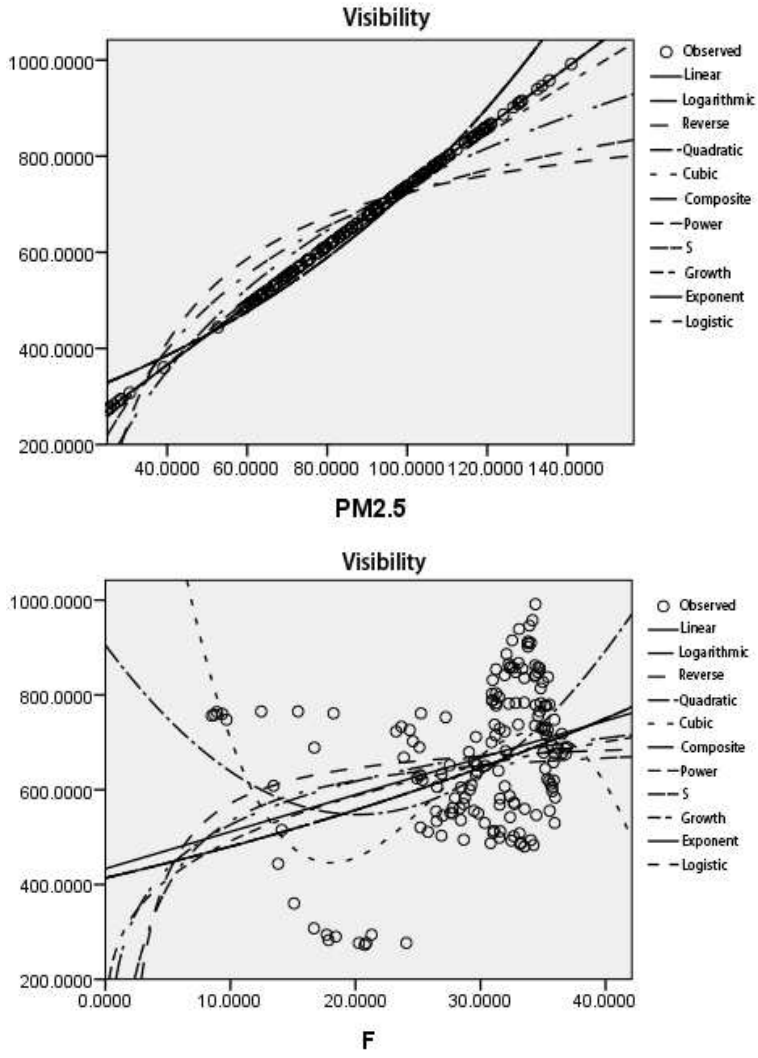

Figure 5. *Model curve estimation*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1484714858

As can be seen from *Figure 5,* the relationship between PM2.5 concentration and visibility fits the linear model best. The relationship between meteorological factor F and visibility fits the three models best. Therefore, visibility is set as V (m), PM2.5 concentration is P (ug/m^3), and meteorological factor is F. The linear model between PM2.5 concentration and visibility, and the cubic model between meteorological factors and visibility are respectively established.

Model establishment

Establishment of a linear model between PM2.5 concentration and visibility

(1) Regression analysis

It can be seen from *Figure 5* that of the relationship between PM2.5 concentration and visibility fits the linear model best, so the linear model is established. The results of linear regression analysis of PM2.5 concentration and visibility are shown in *Table 6*.

Table 6. *PM2.5 concentration and visibility linear regression analysis*

	Coefficient	**Standard error**	**Precision**	**Significance**
(Constant)	117.400	.000	7.974E7	.000
PM2.5	6.200	.000	3.867E8	.000

The linear model between PM2.5 concentration and visibility is established by using the data in the table, as shown in *Equation 3*.

$$v = 6.2p + 117.4 \quad \text{(Eq.3)}$$

(2) Model test

The linear model between PM2.5 concentration and visibility is tested, as shown in *Figures 6* and *7*.

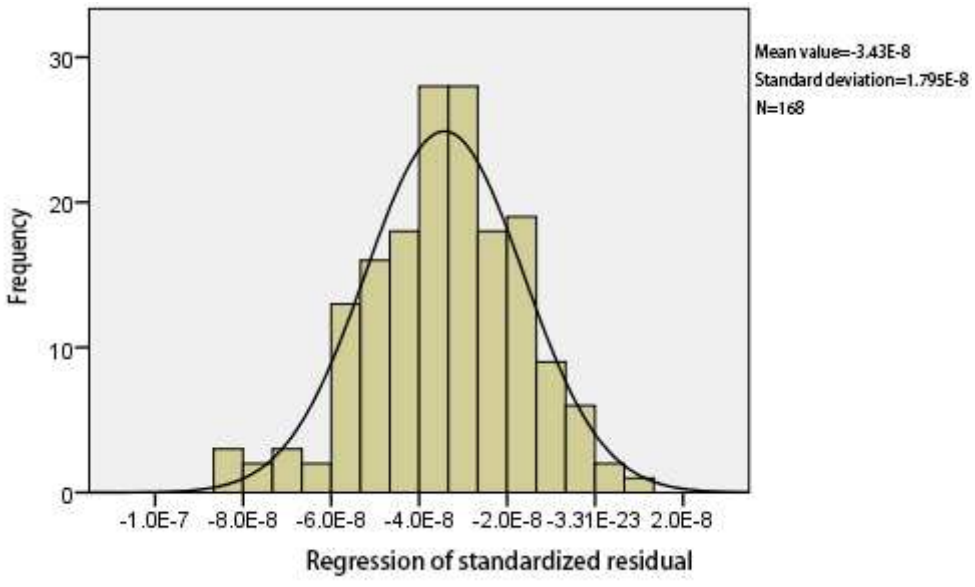

Figure 6. *Visibility standard residual histogram*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1484714858

It can be seen from *Figure 6* that the distribution of standardized residual is basically normal distribution, so the resulting regression equation has practical significance.

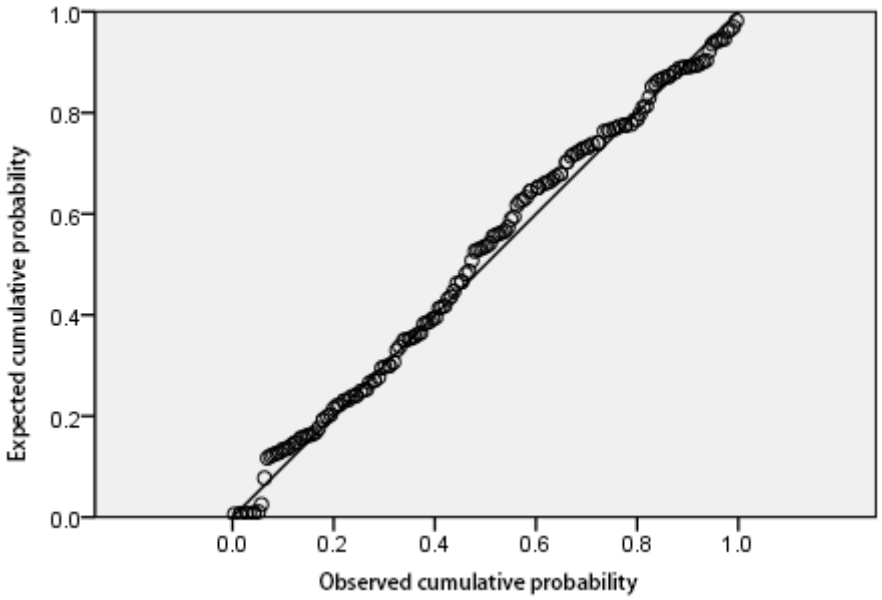

Figure 7. *Visibility standard residual P-P diagram*

It can be seen from *Figure 7* that points in the figure can form approximately a straight line, so the data conforms to the specified distribution after verification.

Establishment of cubic model between meteorological factors and visibility

It can be seen from *Figure 5* that the curve estimation of meteorological factors and visibility has the highest degree of fitting with the third-order model, so the cubic model is established. The results are shown in *Table 7*.

Table 7. *Summary and parameter estimation of meteorological factors and visibility models*

Equation	Model summary					Estimate of parameter			
	R^2	F	df1	df2	Sig.	Constant	b1	b2	b3
Cubic	0.288	22.089	3	164	0.000	2169.164	-231.267	9.755	-0.124

From the data in *Table 6* it can be seen that the fitting degree of the model is 0.288 and the confidence interval of more than 99% passes. Therefore, the three-order curve model between meteorological factors and visibility is established as shown in *Equation 4.*

$$v = -231.267 f^3 + 9.755 f^2 - 0.124 f + 2169.164 \quad \text{(Eq.4)}$$

Description:

$f = 0.327x_1 + 0.345x_2 + 0.327x_3$ and x_1 x_2 x_3 denotes dew point temperature (°C), vapor pressure of water (Bpa) and relative humidity (%), respectively.

Discussion and conclusion

(1) There are stage characteristics in this haze process. Although the time of haze occurrence is relatively short compared with that of haze occurrence, it still presents the phenomenon of haze and fog alternation.

(2) Low ground wind speed, rising PM2.5 concentration and fluctuation of relative humidity provide favorable conditions for the formation and development of haze weather alternation. PM2.5 concentration, vapor pressure of water, dew point temperature and relative humidity are four key factors that determine visibility.

(3) During the haze, PM2.5 concentration is linearly related to visibility, and meteorological factors formed by vapor pressure of water, dew point temperature and relative humidity are correlated with visibility in the cubic curve.

(4) In future studies, more factors such as wind direction and temperature will be considered to establish a more comprehensive mathematical model to predict trends in the ongoing smog process that may occur in the future.

Abstract. Ornamental palms are famous for their patterned leaves, which make them quite suitable for indoor and outdoor decors. Hitherto, palms were identified morphologically resulting in ambiguous identification. Hence, to stitch this loophole in phylogenetic studies, DNA barcoding is a remarkable way for correct identification and evolutionary study of ornamental palms. We investigated phylogenetic relationship of commonly used ornamental palms in Pakistan. We focused on two genetic regions, rbcL and matK, which had been proved as potential DNA barcodes for species identification and phylogenetic studies. In this study, fifteen ornamental palms were investigated for their evolutionary relationship and molecular identification. This study resolved their evolutionary history using Maximum Likelihood method based on Jukes-Cantor evolutionary model. Among them, nine ornamental palm shared evolutionary history, though four showed evolutionary distinctness from the rest. *Chamaedorea seifrizii* and *Chamaedorea costaricana* revealed close residence in the evolutionary tree with 70% bootstrap support. *Syagrus romanzoffiana* resolved as independent lineage with distinct and highly diverse evolutionary history. Furthermore, *Wodyetia bifurcata* and *Dypsis lutescens* nested together with 61% bootstrap though, they belong to different genera. This showed that the genus Wodyetia and Dypsis had very close evolutionary history. The evolutionary forces either geographical isolation or genetic drift could be the reason for the divergence of these palms into two distinct genera, though being the lineages of the same parent.
Keywords: *ornamental palm, DNA barcoding, Bayesian information criterion, maximum likelihood method, Jukes-Cantor evolutionary model*

Introduction

Arecaceae family, also known as Palmae family, is well known for its ornamental palm members. It consists of 240 genera and 27000 species (Lorenzi et al., 2010). It is a monotypic family of Arecales order. Palms are thought to be originated in Australasia and their fossil records reveal their distribution in early Cenzoic era. In present era, palms are mostly distributed in tropical regions and some species are reported in subtropical regions as well (Henderson et al., 1995). Palmae family comprised of commercially and horticulturally famous landscape ornamental palms which are famous for their palmate patterned evergreen leaves and bright, colorful flowers. Palms are noticeably used in outdoor and indoor house decors. Since many decades, the taxonomy of these ornamental palms is poorly understood due to lack of information about their character identification. These problems are caused because of their morphological

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1485914865

similarities with each other and difficulties in hybrid discrimination (Pintaud, 2008). High evolutionary rate has been observed in palm trees and the evaluation of genetic evolution through botanical characters is quite difficult task as morphological traits distinguish the plant at specific life stage. The discrimination based upon such characters results in either ambiguous or wrong identification of palm (Sedra et al., 1996) which made them pseudo palms.

To overcome these problems, botanists have moved towards molecular approach for species identification and discrimination. For this purpose, DNA barcodes are used suggested by CBOL (Consortium of Barcode of Life) in 2009. DNA barcodes consists of conserved short DNA sequences which are unique for every species. In case of animals, well known barcode in COI (Cytochrome oxidase gene) while for plants, many plastid sequences have been studied and confirmed as barcode loci (Kress et al., 2005; Ford et al., 2009). Out of many barcodes, two plastid genes namely maturase K (*matK*) and Ribulose-1,5-bisphosphate carboxylase/oxygenase large subunit (*rbcL*) have been recommended and standardized as potential plant barcodes by PWG (International body of Plant Working Group) of CBOL (2009). The barcodes suggested by CBOL group have great potential for discrimination, authentication and identification for international/foreign as well as native plant species (Maloukh et al., 2017). The discriminatory power of *rbcL* is lower than *matK* but it offers many advantages like its unambiguous and clear alignment power, high sequencing frequency and its universality (Dong et al., 2014). In this study, 15 ornamental palms were investigated for their phylogenetic relationship to unravel their evolutionary history and ancestral inference for assessing their divergence as distinct lineages.

Materials and methods

Sample collection and molecular processing

The leave samples of 15 economically important ornamental palms in Pakistan (*Table 1*) were collected for DNA extraction. Genomic DNA was extracted using Plant DNA extraction kit (Favorgen Biotech Corp.). For the amplification of *matK* and *rbcL* regions, their universal primer pairs suggested by Consortium of Barcode of Life (CBOL, 2009) were used in PCR analysis. The total volume of a reaction mixture for PCR was 25 µl containing 50 ng/µl DNA template, 10 µM each primer in a pair, 2 µl dNTPs, 2.5 µl of HF buffer, 0.25 µl of high fidelity polymerase and nuclease free water for volume makeup. PCR product was resolved on 2% high resolution agarose with gel electrophoresis. The required amplicons were eluted by gel purification mini kit (Favorgen Biotech Corp.) and then sequenced through Eurofins Genomics DNA sequencing services, USA. The sequences were trimmed with BioEdit v7.2.6.1. The success frequency of PCR amplification of each target regions (rbcl and matK) was determined as the proportion of total No. of amplified individuals to the total No. of individuals analyzed in study while successful sequencing was evaluated as the percentage of number of good quality sequences to the total number of sequences of studied individuals.

Data analysis

The good quality trimmed sequences were *in silico* characterized and submitted to NCBI database. The homology search of each sequence was performed using BLASTn

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1485914865

tool. Each sequence was identified based on the 100% identity with the reference sequences of type materials in the NCBI database. The obtained sequences were aligned using ClustalW and then were submitted to NCBI database. For phylogenetic analysis, version 7.0 (Molecular Evolutionary Genetics Analysis) was used to employing Maximum Likelihood (ML) method based on best-fit evolutionary model to generate optimal topology in an evolutionary tree.

Results

Ornamental palms are the pillars of horticultural industry. However, their accurate taxonomic identification is challenging. Hence, in this study, *matK* and *rbcL* regions were targeted to taxonomic investigation of 15 economically important ornamental palm in Pakistan for resolving their phylogenetic topology unequivocally. The universal barcode primers of both genetic regions were used in DNA barcoding analysis.

These two barcode genes *rbcL* and *matK* showed 100% PCR amplification. The sequencing frequency showed that the sequencing success of *rbcL* was comparatively higher than *matK*. The low sequencing rate of *matK* is due to high heterozygosity in the respective regions, which may result in polymerase slippage during Sanger sequencing method. The sequencing rate of *rbcL* was recorded as 86.66% while for *matK* it was recorded as 26.66%. However, the species discriminating power of *matK* is much greater than *rbcL.* The phylogenetic tree for rbcl region of 13 ornamental palm was constructed through Mega 6 software (Tamura et al., 2013) by using maximum likelihood algorithm, which was based upon Jukes-Cantor evolutionary model with Gamma distribution (JC + G) 1 (*Fig. 1*). The best substitution pattern is described the models with lowest Bayesian Information Criterion scores. Akaike Information Criterion (AICc), No. of parameters along with branch lengths and Maximum Likelihood value (lnL) along with estimated values of transversion bias (R), rate of nucleotide substitution (r) and nucleotide frequencies for each nucleotide pair is shown (*Table 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1485914865

The constructed tree showed highest log likelihood of -387.1215 with trees percentage is showed next to the branches. Through neighbor joining method, the pairwise distance matrix was assessed by MCL (Maximum Composite Likelihood) approach. The level of evolutionary differences was estimated by discrete Gamma distribution as + G 0.1000 parameter. The branch lengths of the constructed tree were calculated with the No. of substitutions per sites. The analyses were based upon 13 nucleotide sequences with 1st, 2nd, 3rd and noncoding codon positions. A total of 225 positions were included in final dataset with all missing gaps eliminated (*Table 2*).

Table 2. *Maximum likelihood fits of 24 different nucleotide substitution models on 13 ornamental palms using rbcL barcode*

The phylogenetic topology of the constructed tree revealed the evolutionary history of 13 ornamental palms. Of these thirteen ornamental palms, nine showed evolutionary relatedness. These nine ornamental palms viz., *Chamaedorea seifrizii*, *Chamaedorea costaricana, Roystonea regia, Caryota mitis, Ravenea hildebrandtii Wodyetia bifurcata, Dypsis lutescens, Archontophoenix alexandrae* and *Hyophorbe lagenicaulis* revealed divergence from the same parent in the evolutionary tree (*Fig. 1*) as nested in a clade. This phylogenetic tree showed that they are independent lineages that had been evolutionary diverged. *Chamaedorea seifrizii* and *Chamaedorea costaricana* showed closeness to each other with 70% bootstrap support. They resolved as two different species of the same genus. However, the other ornamental palms resolved as diverse evolutionary history. *Caryota mitis* and Ravenea *hildebrandtii* showed the divergence from the same parent but longer branch length of *Caryota mitis* supported that it is more evolutionary diverse than Ravenea *hildebrandtii* from their parents. Moreover, *Wodyetia bifurcata* and *Dypsis lutescens* nested closely with 61% bootstrap though, they belong to different genera. This showed genus Wodyetia and Dypsis had very close evolutionary history. The geographical isolation and genetic drift during evolution could be the reason of divergence of these palms into two distinct genera, though being lineages of the same parent. Although, *Syagrus romanzoffiana*, *Bismarckia nobilis, Washingtonia robusta* and *Rhapis excelsa* resolved different evolutionary history from nine ornamental palm of a clade. *Washingtonia robusta* and *Rhapis excelsa* showed evolutionary divergence from the same parent by 53% bootstrap support. However, *Bismarckia nobilis* and parent lineage of *Washingtonia robusta* and *Rhapis excelsa* showed close evolutionary history with 44% bootstrap support.

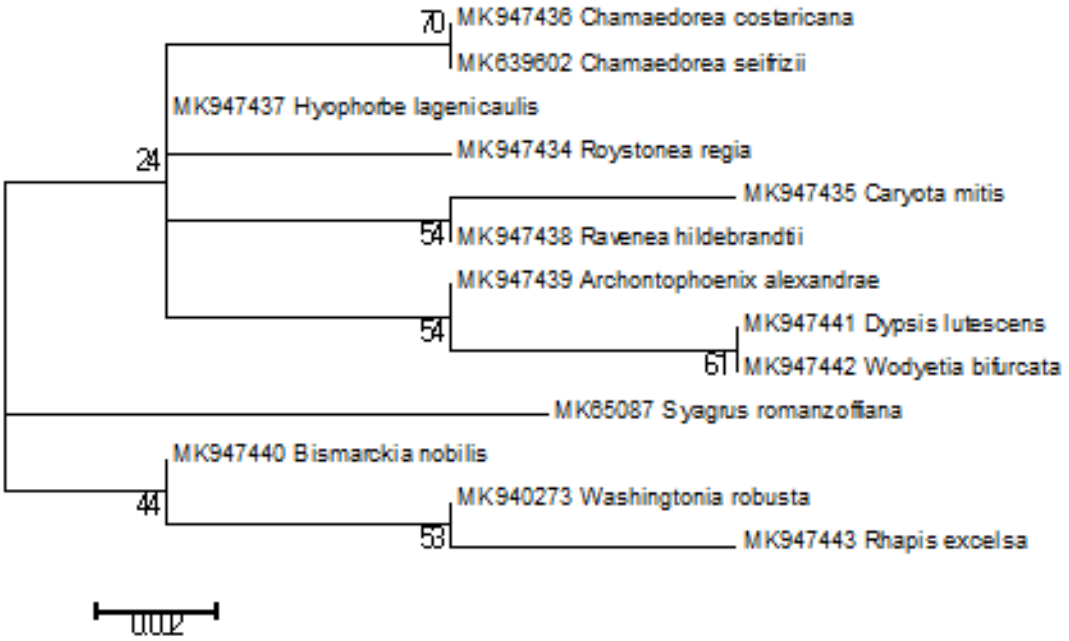

Figure 1. *Chloroplast region, rbcL, based phylogenetic tree of 13 ornamental palms*

Discussion

Ornamental palms, belong to Arecaceae family, are quite important landscape plants of tropical, subtropical and warm climate regions. These are famous for their palmate patterned leaves, and colorful flowers, which makes these plants noticeable in indoor and outdoor decors. High rate of plastid DNA evolution has been observed in palm trees (Asmussen et al., 2000; Dransfield et al., 2008). The determination of genetic evolution and variation through morphological characters is quite tedious in ornamental palm as morphological traits discriminates the plants at particular life stage which results in either wrong or ambiguous identification (Sedra et al., 1996). Taking these problems in account, genetic variability is determined through molecular approaches. DNA barcoding is an efficient molecular approach for efficient species identification based upon the conserved regions as a barcode/marker. For the evaluation of DNA barcode, the success rate of PCR amplification and sequencing are quite important parameters. In the present study, two conserved regions of chloroplast genome, *matK* and *rbcL* were successfully amplified for 15 ornamental palm plant identification. However, the sequencing rate of matK (26.66%) was comparatively lower than rbcL (86.66%) because of its complex heterozygosity nature. The universality of *rbcL* region have been proved by high amplification and sequencing rate as already explained by Huang et al. (2015) and Kang et al. (2017) while studying the Asian tropical trees and tropical cloud forest trees, respectively. The evolutionary tree of thirteen ornamental palms were constructed using Maximum likelihood algorithm whose nodes were supported by bootstrap values. Sequence evolution model, JC + G model, with lowest BIC value (965.423) was selected to generate a tree under maximum likelihood (ML) algorithm. In the respective tree, *Wodyetia bifurcata* and *Dypsis lutescens* are supported by 61%bootstrap, which make them closer to each other although these belong to different genera. This may be due to the less resolving power of *rbcL* genetic region of these two ornamental palm due to less evolution.

Conclusion

The present evolutionary study helped in identifying the ornamental palms of Pakistan through molecular approaches as morphological characterization was not enough for correct identification due their high similarity nature. This phylogenetic study showed that nine ornamental palm shared evolutionary history, though four showed evolutionary distinctness from the rest. *Chamaedorea seifrizii* and *Chamaedorea costaricana* revealed close residence in the evolutionary tree. However, *Syagrus romanzoffiana* resolved as independent lineage with distinct and highly diverse evolutionary history. Furthermore, *Wodyetia bifurcata* and *Dypsis lutescens* showed cladding though they belong to different genera. This showed that the genus Wodyetia and Dypsis had very close evolutionary history.

(Received 18th Jun 2019; accepted 16th Oct 2019)

Abstract. We studied the distribution, pollution characteristics, and ecological risk of heavy metal pollutants in the northern waters of the abandoned Yellow River Delta in Jiangsu Province of China in the surface sediments in May 2018. The results show that the average content of As, Cu, Pb, Zn, and Cd, exceeds their respective background concentration in the tidal marshes of Jiangsu. Analysis of the pollution load index shows that the pollution level is rated as medium pollution; analysis of the composite potential ecological risk index indicates that the level is medium-high, and the waters from the Zhongshan River estuary to the Abandoned Yellow River estuary have the highest level of heavy metal pollution and are most susceptible to ecological risk. Heavy metal content increases from the Guan River estuary to the Abandoned Yellow River estuary, as well as from the shore to the sea with the estuaries and near-shore port areas having the highest content of heavy metals. The content of Cr is mainly derived from natural sources, while other heavy metals primarily originate from the pollutants discharged into the sea from rivers, marine outfalls and marine development activities like port construction and wind-power development.
Keywords: *pollution characteristics, potential ecological risk, spatial distribution, correlation analysis, clustering analysis*

Introduction

As sensitive regions that connect the continent with the sea, estuaries and coasts are areas where both life and production thrive and where pollutants and sediments from rivers accumulate (Li et al., 2007; Wang et al., 2008; Reddy et al., 2016). Heavy metals are toxic, durable, bio-accumulative, contributive to ecological risks, and hard to decompose (Nguyen et al., 2016; Harikrishnan et al., 2017; Jahan and Strezov, 2018; Zhao et al., 2018). Therefore, heavy metal pollution is receiving considerable attention from researchers because it threatens marine ecology and human health (Phillips et al., 2016; Keshavarzi et al., 2018; Wang et al., 2018). Due to the rapid economic development along coastlines in recent years, marine heavy metal pollution has exacerbated, and human activities are primarily responsible for the majority of this pollution in estuaries and coastal areas throughout the world (Begy et al., 2016; Guan et al., 2016; Monferran et al., 2016). Marine sediments act as a repository of heavy metals in the sea. Moreover, because of the absorption and sedimentation of suspended matters, most heavy metals in the sea get deposited in marine sediments; however, when the environment changes, these heavy metals are released into the sea again and cause pollution (Singh et al., 2005; Guan et al., 2016). Compared to sea water and marine

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1486714882

organisms, marine sediments usually contain more heavy metals and can provide more accurate detection results (Liang et al., 2018); therefore, the concentration of heavy metals in sediments is an important environmental indicator.

Located in the central and northern coastal areas of Jiangsu province in China (*Fig. 1*), the abandoned Yellow River Delta has an erosion coast and the –15 m isobath and –10 m isobath on top of the delta are 3.95 km and 2.0 km away from the coastal baseline, respectively, which indicates that the water is deep along the coast. Therefore, this area offers ideal conditions for building a large port. The rivers joining the sea in the study area include the Guan River, Zhongshan River and the abandoned Yellow River, with average discharge of 475 m^3/s, 175 m^3/s and 103 m^3/s respectively. Furthermore, because of the rich resources from the adjacent continent and the strategy of developing coastal areas of Jiangsu province, the development of the northern waters of the Abandoned Yellow River Delta is gaining pace. The primary activities in the area are port development, waste discharge, aquaculture, and wind power development. The Guan River Port is located at the estuary of Guan River, whereas another port is under construction along the coastline from the abandoned Yellow River to Erhongkou. Within the eastern seawall of the Zhongshan River estuary, an industrial park is being developed (occupied primarily by chemical plants). The industrial waste water from this park is discharged into the sea via outfalls that are 6 km away from the Zhongshan River estuary with the daily volume of discharge reaching 20,000 tons. Toward the south of the industrial park is an aquaculture area, and the wastewater from this area is discharged into the sea through gated channels. Furthermore, there are three marine wind-power stations in the study area (A, B and C in *Fig. 1*).

As the coastal economy takes off, the development activities along the coastline will increase, which will lead to additional environmental problems in the delta. Note that the concentration of heavy metals in marine sediments can reflect the level of pollution in the sea. Previous studies on heavy metal concentration in coastal sediments in Jiangsu, such as studies on pollution characteristics, sources, and ecological risks of heavy metals in surface sediments in Haizhou Bay and the radiating shoals, have focused on certain regions. There have been no studies on the sources and ecological risks of heavy metals in sediments of the northern waters of the Abandoned Yellow River delta. In this study, we focused on this region as the study area and used the sediment statistics of 2018 to analyze the concentration of heavy metals in surface sediments in this area. The aims of this study are as follows: i) to analyze the concentration and distribution characteristics of seven heavy metals in surface sediments in the northern waters of the Abandoned Yellow River Delta; ii) to assess the pollution level and ecological risks of seven heavy metals in surface sediments in the study area; and iii), to identify the possible sources of heavy metal pollution in the study area via correlation and clustering analyses. The results revealed heavy metal pollution in the surface sediments of the northern waters of the Abandoned Yellow River Delta, and the effect of human activities on the sediment environment, which would provide a scientific basis for environmental protection and pollution treatment in the study area.

Materials and methods

Study area description

Located in the central and northern waters of Jiangsu province in China, the study area extends from the Zhongshan River estuary to the abandoned Yellow River estuary

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1486714882

and extends 50 km outward into the sea (*Fig. 1*). The study area belongs to the northern waters of the Abandoned Yellow River Delta. With the headland on the north of the Abandoned Yellow River estuary as the point of inflexion, the coastline meanders from northwest to southeast, and then runs from north to south. The coast is a plain erosion silt-muddy coast.

The substrate of the Abandoned Yellow River Delta primarily comprises clayey silt, silt, and sandy silt with a median grain size of 6–8 μm. Clayey silt accounts for 80% of the total fine particles in the study area, whereas silt accounts for 10%–20%; therefore, the study area is the best in Jiangsu in terms of the concentration of fine particles (Hu, 2014). The grain size of sediments in the Abandoned Yellow River Delta decreases from west to east with the major type of sediments changing from sandy silt to clayey silt (Chen, 2014; Hu, 2014). Guan River, which is to the north of the Abandoned Yellow River, is the largest river that joins the sea in Jiangsu, and because of the sediments it carries to the estuary, the grain size of particles in the estuary is relatively big (Hu, 2014; Zhang, 2016). The distribution of sediments is consistent with the change in water depth and landform. From the Guan River estuary to the Zhongshan River estuary, the major particles are sandy silt; however, from the Zhongshan River estuary to the port, the major particles are silt and clayey silt (Hu, 2014).

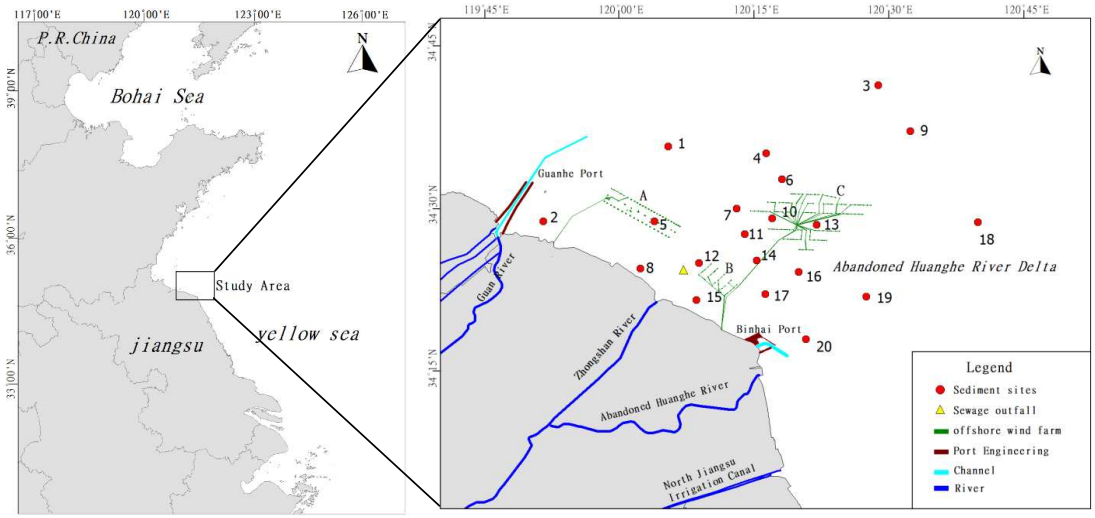

Figure 1. *Location of sample sites*

Sampling and sample processing

We conducted the on-site sampling in May 2018. A total of 20 surface-sediment samples were collected from the sampling sites (*Fig. 1*). The sampling point coordinate range is 34°18′56.34″N–34°42′32.61″N, 119°52′11.18″E–120°40′20.99″E. The test subjects were seven heavy metals, i.e., Hg, As, Cu, Pb, Zn, Cd, and Cr. We conducted the sampling was according to technical regulations established by "Specifications of Marine Monitoring (GB17378-2007)" and "Specifications for Oceanographic Survey (GB/T 12763-2007)". To remove the overlying water, the sediment samples were collected through a grab sampler on the deck. In particular, to test for Cu, Zn, Pb, and Cd, we obtained 500–600 g of wet sample and added it into a clean polyethylene bag, and then sealed the bag. Similarly, to test for petroleum pollutants, organic carbon, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1486714882

total mercury, we obtained 500–600 g of wet sample and added it to a 500 ml wide-mouth bottle, which was then sealed. All wide-mouth bottles were filled with nitrogen, placed in shady areas, and frozen at a low temperature. The frozen samples were wind-dried, and then placed in shady but well-ventilated indoor sites. From these samples, we removed gravels and large debri-like particles (obtained from plants and animals) before they were placed into the agate mortar where these samples were grinded till they were able to pass through a 160-mesh sieve. The mixture was then used for further characterization of chemical elements. We analyzed the test results according to "Specifications of Marine Monitoring – Part 5: Sediment Analysis (GB17378.5-2007)". The atomic fluorescence method was used in order to determine the As and Hg concentrations by AFS-930 Atomic Fluorescence Spectrometer. Flameless atomic absorption spectrophotometry method was used to determine the Cu, Pb and Cr concentration and flame atomic absorption spectrophotometry method was used to determine the Zn and Cd levels and all by VARIAN AA240FS Atomic Absorption Spectrophotometer.

Methods

Pollution load index (PLI)

The pollution load index was first proposed by Tomlinson in 1980 to assess pollution by different chemical elements at different sites. The equations for calculation are:

$$C_f^i = C_{\mathrm{n}}^i / C_0^i \quad \text{(Eq.1)}$$

$$PLI = \sqrt[n]{C_f^1 \times C_f^2 \times C_f^3 \times \ldots \times C_f^{\mathrm{n}}} \quad \text{(Eq.2)}$$

where PLI refers to the pollution load index of a certain site, C_f^i the pollution index of one element, C_{n}^i the value obtained through actual measurement, and C_0^i the background value. The grading standard for PLI (Tomlinson et al., 1980; Zhu et al., 2013) is shown in *Table 1*.

Geo-accumulation index

Geo-accumulation Index (Igeo) was first proposed by G. Müller, a German scientist. It is a quantitative index for assessment of heavy metal contents in sediments and can be used to assess pollution caused by heavy metal contents. The calculation equation is:

$$I_{\mathrm{geo}} = \log_2 \frac{C_n}{1.5B_n} \quad \text{(Eq.3)}$$

where Cn denotes the content of Element n in actual measurement, and Bn is the background value of this element on earth which, in this research, specifically refers to the background value of the content of the researched element in the tidal marsh of Jiangsu province measured in the 1980s by Chen et al. (1985). 1.5 is a coefficient identified by considering possible changes caused by differences of rocks in different places. The grading standard of geo-accumulation index (Müller, 1969) is also shown in *Table 1*.

DOI: http://dx.doi.org/10.15666/aeer/1706_1486714882

Potential ecological risk index

The potential ecological risk index was first proposed by a Swedish environmentalist named Hakanson in 1980 to assess the potential ecological hazards of heavy metal contents in sediments. This method combines the ecological impact, environmental impact and toxicologic research of heavy metal contents to reflect the potential ecological risks of heavy metals. The calculation equations are:

$$E_r^i = T_r^t \times C_f^i \quad \text{(Eq.4)}$$

$$RI = \sum (E_r^i) \quad \text{(Eq.5)}$$

where RI is the value of comprehensive potential ecological risks, E_r^i the value of potential risks of one element. T_r^t denotes the toxicological coefficient of an element which, in this research, adopts the standard toxicological coefficients of heavy metal contents proposed by Hakanson (1980): the respective toxicological coefficients of Cd, As, Cu, Pb, Cr and Zn are 30, 10, 5, 5, 2, and 1. C_f^i is the pollution coefficient of a certain element, $C_n{}^i$ the value obtained through actual measurement and $C_0{}^i$ the background value. The grading standard for the potential ecological risk index of a given element and for the comprehensive potential ecological risk index is also presented in *Table 1*.

Table 1. *Grading standard for geo-accumulation index and potential ecological risk index of heavy metal contents*

Geo-accumulation index (I_{geo}) value	Pollution level	Pollution load index (PLI) value	Pollution level	Single-factor potential ecological risk (E_r^i)	Single-factor potential ecological risk level	Comprehensive potential ecological risk value (RI)	Comprehensive potential ecological risk level
≤ 0	No pollution	< 1	No pollution	< 40	Low	< 110	Low
0~1	Mild pollution	1~2	Medium pollution	40~80	Medium	110~220	Medium
1~2	Mild-medium pollution	2~3	Heavy pollution	80~160	Medium-high	220~440	High
2~3	Medium pollution	≥ 3	Severe pollution	160~320	High	≥ 440	Extremely high
3~4	Serious pollution			≥ 320	Extremely high		
4~5	Heavy pollution						
> 5	Severe pollution						

Statistical and mapping methods

We performed Pearson correlation coefficients between each pair of heavy metals and clustering analysis for the seven heavy metals obtained data from 20 sampling sites by using SPSS. Combining with the spatial information of station location, the data are processed by using Suffer11 software and Kristin interpolation method, and the spatial

DOI: http://dx.doi.org/10.15666/aeer/1706_1486714882

distribution maps of heavy metal contents in surface sediments, pollution load index, and the comprehensive ecological risk index.

Result and discussion

Heavy metal concentration and distribution

Table 2 shows the concentration of different heavy metals in the surface sediments of the study area in May 2018. The concentration range of heavy metals (mg/kg) in the surface sediments of the study area are as follows. The concentration of Hg was 0.0064–0.0287 mg/kg (average of 0.0177 mg/kg); that of As was 5.72–18.1 mg/kg (average of 12.635 mg/kg); that of Cu was 17.9–27.7 mg/kg (average of 22.28 mg/kg); that of Pb was 17.4–25.8 mg/kg (average of 21.77 mg/kg); that of Zn was 60.4–80.2 mg/kg (average of 70.89 mg/kg); that of Cd was 0.137–0.264 mg/kg (average of 0.18 mg/kg); and that of Cr was 35.8–56.7 mg/kg (average of 40.86 mg/kg).

In comparison with the heavy metal contents in sediments obtained by studies in other areas of China (*Table 2*), the average content of Hg, As, Cu, Pb, Zn, Cd, Cr in sediments in the study area stayed at a medium level.

Table 2. *Heavy metal contents of surface sediments in the study area and comparison with other areas (mg/kg)*

In 2018, the average contents of seven heavy metal in sediment did not go beyond the first category standard of "Marine Sediment Quality Standard (GB 18668-2002)". The average concentration of five heavy metals, i.e., As, Cu, Pb, Zn, and Cd, exceeded the background concentration in the tidal marshes in Jiangsu, and the ratios of their

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1486714882

average concentration to the background concentration were 1.71, 1.48, 1.91, 1.50, and 4.29 (*Table 3*), respectively. Among the abovementioned metals, Cd has the highest single-factor pollution index.

Figure 2 shows the distribution of heavy metal in the northern waters of abandoned Yellow River delta. The concentration of Cr is below the background value, which indicates that the presence of this metal is less subject to human activities and its natural level can be maintained. Related studies show that Cr is primarily derived from nature and is subject to properties of the soil form in the parental material, making it a heavy metal of low pollution (Lv et al., 2013; Sun et al., 2013). The concentration of Cr increases from the Guan River estuary to the abandoned Yellow River estuary, and then from the shore towards the sea. The distribution of heavy metal concentration is consistent with the changes in the grain size of sediments. In the study area, the grain size of sediments reduces from the Guan River estuary to the abandoned Yellow River estuary, and then from the shore to the sea (Chen, 2014; Hu, 2014). Many studies have reported that the concentration of heavy metals is closely correlated to the grain size of sediments (Li et al., 2015): if the surface area of the particle sediments is large, more heavy metals will be absorbed, while if the grain size of the particles is large, the concentration of heavy metals will be lesser. Generally, the concentration of the other heavy metals increased from the Guan River estuary to the abandoned Yellow River estuary, and then from the shore to the sea with the estuary and the port area showing the highest values of concentration.

Heavy metal pollution characteristics

Table 4 shows the pollution load indices (*Eqs. 1* and *2*) of heavy metals in sediments in the study area. *Figure 3* shows the distribution of pollution load indices of each sampling site. Note that the pollution load indices in these sampling sites ranged from 1.04 to 1.61 (average of 1.47); hence, according the grading standard for Pollution Load Index shown in *Table 1,* the study area was identified to have medium pollution. However, the pollution load index increased from the Guan River estuary to the abandoned Yellow River estuary with waters from the Zhongshan River estuary to the Abandoned Yellow River estuary showing the largest indices.

Table 5 shows the geo-accumulation index (*Eq. 3*) of heavy metals in the surface sediments in the study area. The I_{geo} for the tested heavy metals are as follows: −2.42 to −0.27 for Hg (average of −1.03); −0.95 to 0.71 for As (average of 0.10); −0.33 to 0.30 for Cu (average of −0.02); 0.03–0.59 for Pb (average of 0.34); −0.23 to 0.18 for Zn (average of 0.00); 1.12–2.07 for Cd (average of 1.50); and −1.33 to −0.67 for Cr (average of –1.15). In terms of I_{geo}, the seven heavy metals are ranked as follows: Cd > Pb > As > Zn > Cu > Hg > Cr. According the grading standard of geo-accumulation index shown in *Table 1,* Cd is marked at the level from mild-medium pollution to medium pollution; Pb is marked as mild pollution; As, Cu, and Zn are marked as clean- mild pollution; and Hg and Cr are marked as clean.

Potential ecological risk assessment

Table 5 shows the potential ecological risk index of each heavy metal (*Eq. 4*) and their composite potential ecological risk index (*Eq. 5*). *Figure 4* shows the distribution of composite ecological risk indices. In May 2018, the ranges of ecological risk indices of the tested heavy metals are as follows. For Hg, the index fluctuates between 11.18 and 49.91 with the mean standing at 30.80; for As, the index fluctuates between 7.75 and 24.53 with the mean standing at 17.12; for Cu, the index fluctuates between 5.96 and 9.22 with the mean standing at 7.42; for Pb, the index fluctuates between 7.63 and 11.32, with the mean standing at 9.55; for Zn, the index fluctuates between 1.28 and 1.70, with the mean standing at 1.50; for Cd, the index fluctuates between 97.86 and 188.57, with the mean standing at 128.82; and for Cr, the index fluctuates between 1.19 and 1.89, with the mean standing at 1.36. In terms of the average potential ecological risk index, the seven heavy metals are ranked as Cd > Hg > As > Pb > Cu > Zn > Cr. According the grading standard of Potential ecological risk index shown in *Table 1,* Cd is marked as at the level of medium high and high ecological risk; Hg is marked as at the level of low and a medium ecological risk; and other heavy metals are marked as at the level of low ecological risks. The composite potential ecological risk index of the study area is between 146.68 and 247.33 (average of 196.57); hence, the study area is under medium-high ecological risks with Cd and Hg being the major contributors.

The composite potential ecological risk index increases from the Guan River estuary to the abandoned Yellow River estuary, with the waters near the latter estuary showing the highest indices. This distribution is similar to the distribution of the heavy metal pollution load index.

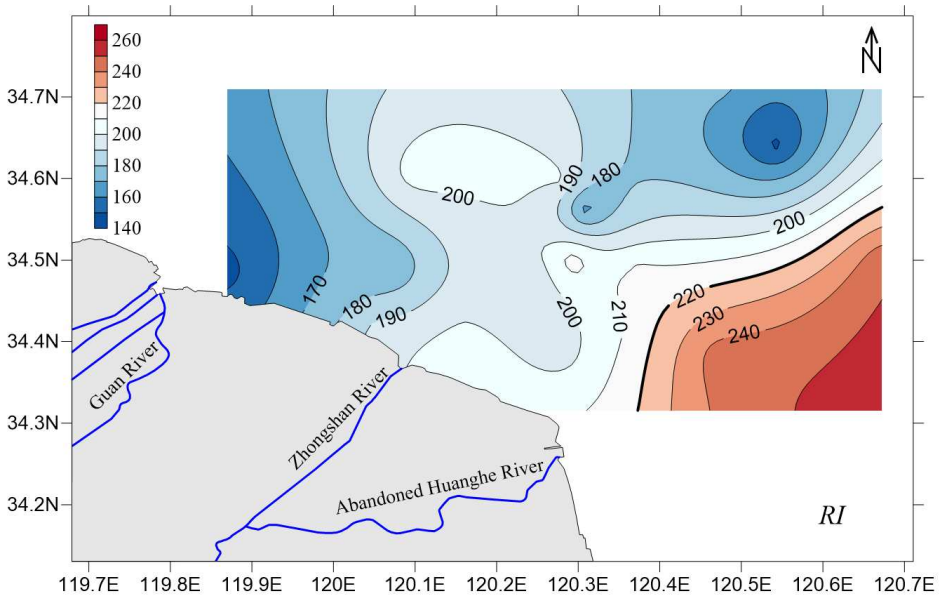

Figure 4. *The distribution of the comprehensive ecological risk index*

Source of heavy metal

Analysis of heavy metals in surface sediments

Correlation among heavy metals reflects the correlation among different elements, which will help recognize the sources of heavy metals (Lv et al., 2015). *Table 6* shows

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1486714882

the Pearson correlation coefficients between each pair of heavy metals. Hg and As (the Pearson coefficient is 0.694), as well as Zn and Cu (the Pearson coefficient of which is 0.681) are positively correlated, which indicates the correlation between Hg and As and that between Zn and Cu is strong and that elements in each pair are highly homogenous.

Table 6. *Correlation coefficient of heavy metal elements*

	Hg	As	Cu	Pb	Zn	Cd	Cr
Hg	1						
As	0.694**	1					
Cu	-0.080	0.000	1				
Pb	0.133	0.263	0.201	1			
Zn	0.170	0.244	0.681**	0.055	1		
Cd	0.104	-0.122	0.439	0.038	0.531*	1	
Cr	0.145	-0.079	0.001	-0.308	0.166	0.197	1

**Significant correlation at 0.01 level (bilateral). *Significant correlation at 0.05 level (bilateral)

Clustering analysis of heavy metals in surface sediments

We performed clustering analysis using SPSS for the seven heavy metals and obtained data from 20 sampling sites, and the analysis of the results is shown in *Figure 5*. The results show that the heavy metals can be divided into three categories. The first category includes Cu, Zn, and Pb; the second category includes Cd and Cr; and the third category includes Hg and As. Hg and As and Cu and Zn fall into the same category, which is consistent with the correlation analysis result. This indicates a high degree of homology between Hg and As and between Cu and Zn.

The 20 monitoring stations can be divided into two clusters. Stations 1, 4, 6, 7, 12, 14, 15, 17, 19, and 20 are located in waters near the shore from the Zhongshan River estuary to the port are part of the first cluster. Stations 2, 3, 5, 8, 9, and 18 are located in the coastal waters from the Guan River estuary to the Zhongshan River estuary, as well as in the distant waters from the shore are part of the second cluster.

Analysis of source of heavy metals in surface sediments

The results from Pearson correlation coefficient and the cluster analysis show a high level of homology between Zn and Cu. Given the distribution of heavy metal concentration, the distribution of Zn and that of Cu is very similar because the high concentration area of both metals occurs at the waters near the Zhongshan River estuary. Therefore, the concentration of Zn and Cu may be subject to the influence of land-sourced pollutants discharged into the sea from Zhongshan River and from outfalls of the chemical industrial parks near the Zhongshan River estuary. The highest concentration of Zn is observed near the wind-power stations; therefore, the wind-power stations along both sides of the Zhongshan River estuary may be contributors to the increase in the concentration of Zn. The sacrificial anode anticorrosion method used by marine wind power stations releases Zn, which will eventually increase the concentration of Zn in sediments.

Zn, Cu, and Pb are chalcophiles and they share similar geochemical processes in terms of the source, transportation, and concentration. Clustering analysis shows that Pb

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1486714882

can be classified into the same category as Zn and Cu. However, the distribution diagram and the Pearson coefficients indicate that Pb differs from these other two metals in terms of the source. A high concentration of Pb is observed near the Guan River port and outer waters of the port, which indicates that port development is the major contributor to the increasing concentration of Pb. Pb gets concentrated in the waters of the port, and related studies have confirmed that engine oil containing Pb increases the concentration of Pb (Blake and Goulding, 2002; Wilcke et al., 1998; Lv et al., 2015). As the port sees a lot of traffic of ships and vessels, the constant combustion of engine oil is very likely to cause Pb pollution.

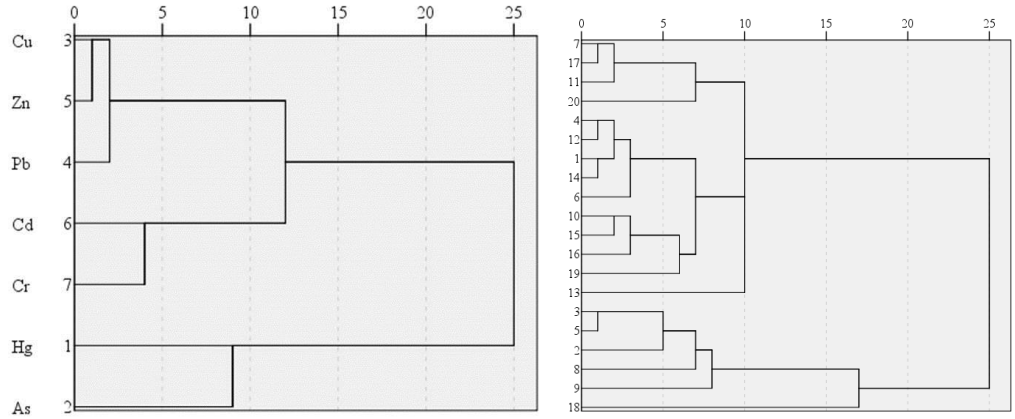

Figure 5. *Heavy metal contents and sample sites location cluster analysis results*

Hg and As share similar distribution characteristics with a high concentration of both metals being observed at the Zhongshan River estuary, the coastal port, and the outer waters of the abandoned Yellow River estuary. In general, Hg and As are obtained from human activities (Liu et al., 2003; Lv et al., 2013); therefore, their concentration is influenced by the discharge of pollutants from rivers, the outfalls of industrial parks, and port development activities.

Based on clustering analysis, we can group Cd and Cr into the same cluster; however, this categorization differs from the correlation analysis results. The Pearson correlation coefficient between Cd and Cr is not high, which indicates that these two metals have no obvious correlation. The concentration of Cr is below the background value and is primarily derived from nature; however, the concentration of Cd is higher than the background value and is primarily derived from human activities. These two metals share similar spatial distribution features as their concentration increases from the Guan River estuary to the Abandoned Yellow River estuary, and then from the shore to the sea. This distribution is consistent with the grain size of surface sediments in the study area. However, it differs in terms of the high-concentration area: the high concentration of Cd occurs in then outer waters from the Zhongshan River estuary to the abandoned Yellow River estuary, particularly in the waters around the abandoned Yellow River estuary. Cd is a standard element in chemical fertilizers (Lv et al., 2015), and the abandoned Yellow River is banked by crop fields; therefore, the high concentration of Cd in the outer waters, a bit far away from the abandoned Yellow River estuary, is possibly caused by the agricultural wastewater discharged from crop fields into the river. However, the high concentration of Cd is not seen in the estuary of the abandoned Yellow River estuary, but in the outer waters far away from the estuary

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1486714882

because the abandoned Yellow River estuary is highly corrosive. Moreover, in the waters with an isobath of –5 m, the shallow waves corrode the seabed, which takes away the fine particles and leaves large-size particles behind; therefore, the surface sediments are large in grain size (Hu, 2014). Note that sediments outside the abandoned Yellow River estuary are large in grain size, which makes it difficult for heavy metals to attach; therefore, there is a high concentration of Cd in the outer waters that are far away from the estuary.

Clustering analysis of the monitoring stations indicates that the distribution of heavy metals is subject to the joint impact of human activities and natural factors. The sources of heavy metals in surface sediments near the shore from the Zhongshan River estuary to the abandoned Yellow River estuary are identical such as pollutants discharged into the sea from rivers, sewage outfalls, and ports and wind-power stations. In the study area, the grain size of sediments is small, which makes it very easy for heavy metals to attach themselves; therefore, the concentration of heavy metals is high. The coastal waters from the Guan River estuary to the Zhongshan River estuary suffer from lesser heavy metal pollution because there are fewer development activities in this area. Moreover, there is a 10-km-long seawall on both sides of Guan River, which directs pollutants from the river to the sea and hence reduces the pollution in waters near the shore. Furthermore, the coastal areas from the Guan River estuary to the Zhongshan River estuary have the largest grain sizes of surface sediments in the study area, so the concentration of heavy metals in this area is low, and the outer waters away from the shore in this area have low concentration of heavy metals because human activities are lesser.

Based on one-tine heavy metal contents in sediments of the Abandoned Yellow River Delta, this study analyzed the status, distribution characteristics and ecological risk of heavy metal pollution, and speculated the sources of pollution. For long-term heavy metal contents changes, distribution rules and characteristics, continuous monitoring and further analysis of the water quality are still needed in the abandoned Yellow River Delta. In the follow-up study, on basis of long-term and multiple monitoring, it is necessary to analyze the risk of heavy metal content and the correlation between water, sediment and organism. In the future, it is necessary to strengthen the accurate study of the sources of heavy metals by more means and methods.

Conclusion

Based on the results, the following conclusions can be drawn.

The average concentration of Hg, As, Cu, Pb, Zn, Cd, and Cr in the surface sediments in the northern waters of the abandoned Yellow River delta in May 2018 is 0.0177, 12.635, 22.28, 21.77, 70.89, 0.18, and 40.86 mg/kg. Among these metals, the average concentration of As, Cu, Pb, Zn, and Cd exceeds the background value of tidal marshes in Jiangsu by a factor of 1.71, 1.48, 1.91, 1.50, and 4.29, respectively.

In terms of spatial distribution, the heavy metal concentration in the study area increases from the Guan River estuary to the abandoned Yellow River estuary, and then from the shore to the sea. Such a distribution pattern is consistent with that of the grain size of sediments in the study area. Except Cr, all other heavy metals show the highest concentration at either the estuaries or the port.

The heavy metal pollution load index of surface sediments in the study area fluctuates within between 1.04 and 1.61 (average of 1.47), and the study area is marked

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1486714882

as medium-level pollution. The index increases from the Guan River estuary to the abandoned Yellow River estuary, with the outer waters from the Zhongshan River estuary to the abandoned Yellow River estuary marking the highest indices. The analysis of the geo-accumulation index shows that Cd has the highest geo-accumulation index and is rated as mild-medium pollution to medium pollution; Pb is rated as mild pollution; As, Cu, and Zn are rated as clean or mild pollution; and Hg and Cr are rated as clean.

The analysis of the single-factor potential ecological risk index shows that Cd is at the level of medium-high and high ecological risks, Hg is at the level of low-medium ecological risks, and other heavy metals are at the level of low ecological risks. The composite ecological risk index shows that the study area is at the level of medium-high ecological risks with Cd and Hg being the primary contributors to ecological risks. The composite ecological risk index increases from the Guan River estuary to the Abandoned Yellow River estuary, and the outer waters of the Abandoned Yellow River estuary marks the largest indices. Waters from the Zhongshan River estuary to the abandoned Yellow River estuary are most susceptible to heavy metal ecological risks.

The distribution of heavy metal concentration in the study area is influenced by both human and natural factors. The concentration of Cr is lower than the background value and is mainly derived from natural sources, while other heavy metals are mainly derived from human activities. Heavy metals in surface sediments in the near-shore waters from the Zhongshan River estuary to the abandoned Yellow River estuary share the same sources such as pollutants discharged into the sea from rivers, sewage outfalls, and ports and wind-power stations. The grain size of sediments in this area is small, which makes it easy for heavy metals to attach themselves, so the concentration of heavy metals in this area is high. The near-shore waters from the Guan River estuary to the Zhongshan River estuary suffer from lesser heavy metal pollution because there are fewer development activities and the grain size of sediments in this area is large. Consequently, the concentration of heavy metals in this area is low, and the concentration of heavy metals in the outer waters of the study area is also relatively low because of fewer human activities.

Abstract. In Amadyia District, Duhok Governorate, Kurdistan Region of Iraq, where there is a high population of people, domestic and stray animals, in addition to the presence of vegetation, grasses and large numbers of pastures. This study was conducted to determine of the soil's contamination with ova of *Toxocara* and other helminths in different areas of Amadyia district. A total of 700 soil samples were collected from different places such as public parks, private gardens, dog shelters, near pastures, parks of schools and around a slaughter house. The soil samples were examined using saturated zinc sulphate with specific gravity 1.2. Helminth ova were found in 593 (84.71%) of the examined soil samples. Ova of *Taenia* were the most frequent helminths and found in 117 (16.71%), followed by ova of *Hymenolepis nana* in 107 (15.28%), *Toxocara* ova in 106 (15.14%), *Ancylostoma* ova in 95 (13.57%), *Ascaris* ova in 71 (10.14%), *Hymenolepis diminuta* ova in 51 (7.28%), and *Trichuris* ova in 46 (6.57%). It is concluded that soils in areas of Amadyia district is contaminated with different helminths. The contamination of soil with *Toxocara* and other helminth ova is relatively high, the population are at a high risk to acquire infection through contact with environment and soil.
Keywords: *environmental contamination, ova, zoonosis, zinc sulphate, Duhok, Iraq*

Introduction

Humans acquire helminth infection by accidental swallowing of infective stages of parasites contaminating the soil (Blaszkowska et al., 2013; Cassenote et al., 2011). Humans are at the highest risk of infection because of outdoor activities and contact with contaminated soils (Al-Megrin, 2010). The poor sanitary condition in developing countries including Iraq leads to the presence of infective stages of parasites in the soils (Mahdi and Ali, 1993). Most often human become infected with helminths by contact with soil, water or food and grasses that contaminated either with ova or other stages of these parasites (Motazeddian et al., 2006; Sadjjadi et al., 2000). Infection rate in certain part of the world is related to poor environmental hygiene such as lack of clean water supply, contamination of the environment by human and animal wastes and bad habits (Anh et al., 2007).

A number of studies in the world have demonstrated the presence of pathogenic parasite in contaminated drinking water (Sprenger et al., 2014), soil (Tavalla et al., 2012), air (Ahmed, 2006) and socio-cultural, such as contact with animals (Thomas and Jeyathilakan, 2014), and lack of public education (Zibaei et al., 2010). In Northern Iraq (Erbil Province), the prevalence of parasitic infections among school aged children have been found to be high (Faraj, 2000). The awareness on the risk of contamination soil is still low (De-Moura et al., 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1488314891

The parasites that cause helminth infections are naturally present in the environment, most often human and animals become infected with helminths by coming in contact with soil, water or food that contains the ova or other stages of these parasites (Soulsby, 1986).

Humans, particularly children are at the highest risk of infection because of their outdoor activities and playing on soils contaminated with animal feces.

The current study aimed to analyze soil samples collected in Amadyia district, Duhok Governorate, Kurdistan Region, Iraq, to determine their rate of infection by *Toxocara* and other helminth ova using saturated zinc sulphate, in order to conclude the infection risk of the local populace.

Materials and methods

Amadyia district (*Fig. 1*) is located in the North of Duhok Governorate – Kurdistan Region of Iraq. The city is situated 4,600 feet (1,400 m) above sea level. Total of human population 11,000. Climate of Amadyia has a hot-summer Mediterranean climate with long, hot summers and cool, wet winters. A total of 700 soil samples were collected from different locations of Amadyia district during the period of the year 2016-2017.

The soil samples were collected from different places of Amadyia district such as private gardens, dogs shelters, public park, parks of schools, near pasture and around slaughter house. During soil samples collection, many children were seen playing in the soil with their hands and not wearing shoes, in addition to that presence of dogs and their puppies around them (*Fig. 2*). The soil samples were collected in plastic bags and examined with some modification according to method of Mandarino-Pereira et al. (2010) and Zibaei et al. (2010). Amount ranging 25-50 g of soil from a depth of 3 cm ground was collected from each place and grinded, dissolved in normal saline, mixed well and filtered by sieving method, then centrifuged in 2000 rpm for 5 min. The supernatant was discarded and the sediment was re-suspended in normal saline. Then, centrifuged again and the supernatant was discarded and saturated zinc sulphate with specific gravity 1.2 was added to the sediment in a test tube and centrifuged in 1500 rpm for 15 min, then few drops of saturated zinc sulphate was added to filling the top of the test tube.

Figure 1. *Map of Duhok Governorate showing Amadyia (Amedi) District*

DOI: http://dx.doi.org/10.15666/aeer/1706_1488314891

Figure 2. *Children playing in the soil and puppy with hands and not wearing shoes (famous in rural areas of Kurdistan Region)*

The cover slip was placed on the upper surface of tube in touch with the solution and was kept in the rack for 45 min, then the coverslip was removed gently in a horizontal position and placed on a glass slide, examined under the light microscope. The ova of parasites were diagnosed according to their morphological features (Soulsby, 1986). The limitations of the current study are not studied the mean number of ova and the association between infection rate and, type of soils, pH of soils and habitats. Analysis of data was carried out using the Chi Square test and Statistical Package for Social Science (SPSS).

Results

Out of 700 soil samples examined, helminth ova were found in 593 (84.71%). *Taenia* eggs 117 (16.71%) were the most frequent helminth, followed by *Hymenolepis nana* ova in 107 (15.28%), *Toxocara* ova in 106 (15.14%), *Ancylostoma* ova in 95 (13.57%), *Ascaris* ova in 71 (10.14%), *Hymenolepis diminuta* ova in 51 (7.28%), and *Trichuris* ova in 46 (6.57%) as shown in *Table 1*.

It was clear from *Table 2,* that the ova of *Taenia* were positive in 17/130 (13.07%) samples of soil obtained from dogs shelters, 20/127 (15.74%) in private gardens, 25/106 (23.58%) in parks of schools, 15/165 (9.09%) near pastures, 29/64 (45.31%) around slaughter houses and 11/108 (10.18%) in public parks. There were statistically non - significant (p = 0. 033) when compared with other helminths.

Ta (Taenia), Hn (Hymenolepis nana), To (Toxocara), An (Ancylostoma), As (Ascaris), Hd (Hymenoleis diminuta), Tr (Trichuris)

Ova of *H. nana* were positive in 5/130 (3.84%) samples of soil examined from dogs shelters, 16/127 (12.59%) in private gardens, 34/106 (22.07%) in parks of schools, 20/165 (12.12%) near pastures, 2/64 (3.12%) around slaughter houses and 30/108 (27.77%) in public parks. There were statistically highly significant differences ($p = 0.00$) when compared with other helminths.

Toxocara ova were positive in 30/130 (23.07%) samples of soil were collected from dogs shelters, 13/127 (10.23%) in private gardens, 15/106 (14.15%) in parks of schools, 28/165 (16.96%) near pastures, 9/64 (14.06%), around slaughter houses and 11/108 (10.18%) in public parks. There were statistically highly significant differences *(*$p = 0.00$*)* when compared with other helminths.

Regarding to *Ancylostoma* ova were positive in 13/130 (10.0%) samples of soil were examined from dogs shelters, 15/127 (11.81%) in private gardens, 28/106 (26.41%) in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1488314891

parks of schools, 7/165 (4.24%) near pastures, 12/64 (18.75%) around slaughter houses and 20/108 (18.51%) in public parks. There were statistically non - significant differences ($p = 0.115$) when compared with other helminths.

Ascaris ova were positive in 4/130 (3.07%) samples of soil were obtained from dogs shelters, 15/127 (11.81%) in private gardens, 21/106 (19.81%) in parks of schools, 11/165 (6.66%) near pastures, 15/64 (23.43%) around slaughter houses and 5/108 (4.62%) in public parks. There were statistically non-significant differences ($p = 0.083$) when compared with other helminths.

The ova of *H. diminuta* were positive in 1/130 (0.76%) samples of soil were collected from dogs shelters, 10/127 (7.87%) in private gardens, 15/106 (14.15%) in parks of schools, 15/165 (9.09%) near pastures, 3/64 (4.68%) around slaughter houses and 7/108 (6.48%) in public parks. There were statistically highly significant differences ($p = 0.002$) when compared with other helminths.

Trichuris ova were positive in 2/130 (1.53%) samples of soil were collected from dogs shelters, 8/127 (6.29%) in private gardens, 21/106 (19.81%) in parks of schools, 3/165 (1.81%) near pastures, 5/64 (7.81%) around slaughter houses and 7/108 (6.48%) in public parks. There were statistically highly significant differences ($p = 0.008$) when compared with other helminths.

Discussion

Out of 700 soil samples examined, 593 (84.7%) were positive for different species of helminth ova. The present study revealed high levels of contamination of soil by parasites. These results concerning the contamination of soil are in agreement with studies in many cities worldwide which also showed that the soils are contaminated with ova of helminth parasites.

In the current study the distribution of *Toxocara* ova was 15.14%, as 23.07% in dogs shelters, 16.96% near pastures, 14.15% in parks of schools, 14.06% around slaughter houses, 10.18% in public park and 10.23% in private gardens. These results agree with the results of Fathailah (1988) which found 16% prevalence of *Toxocara* ova in vegetables collected from different markets in Baghdad city. A study of Molan and Faraj (1989) reported 13.6% prevalence of *Toxocara* ova in Erbil city. A study of Al-Barazanjey (1992) found 14% the prevalence of *Toxocara* ova in Erbil city. In Basra Mahdi and Ali (1993) recorded contamination rate of soil with *Toxocara* ova was 12.2%. A study of Hussein (1997) found 18.1% the prevalence of *Toxocara* ova in Erbil city. A study done by Faraj (2000) reported 16% the prevalence of *Toxocara* ova in Erbil city. A study of Ahmed (2006) found the prevalence of *Toxocara* ova in Erbil city was 13%. In Alnassiriyah city center, southern Iraq, Al-Kassar (2009) found 16.43% prevalence of *Toxocara* ova in public places and children play grounds, A study of Saida and Khder (2014) found that the prevalence of *Toxocara* ova in Erbil city, 12.2% in leafy vegetables. On the other hand, the result of the current study is lower than that observed by Woodruff (1981) in Mosul district Iraq that reported the prevalence of *Toxocara* ova 25%. A study of Nooraldeen (2015) in Erbil city, Iraq found the prevalence of *Toxocara* ova 50% in public squares and parks. In northern and central of Jordan *Toxacara* ova were found in 15.45% of soils collected from school playgrounds and public places (Abo-Shehada, 1989). A study done by Al-Megrin (2010) in Riyadh, Saudi Arabia reported 20% prevalence of *Toxocar*a ova in leafy vegetables. In Turkey,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1488314891

Ge and Ge (2000) reported that 8.25-60.9% of public parks was contaminated with *Toxocara* ova.

In Iran, Motazedian et al. (2006) reported that the contamination rate of public places in Shiraz, Iran was 6.3% with *Toxocara* ova. A study done by Tavassoli et al. (2008) reported that the contamination rate of public places with *Toxocara* ova 7.8% in Urmia, Iran. A study of Zibaei et al. (2010) reported soil contamination with *Toxocara* eggs was 22.2% in Khorram Abad, Iran. A study of Tavalla et al. (2012) found that 79.3% the rate of *Toxocara* ova in public place in Tehran. In Italy, Habluetzel et al. (2003) reported 24% prevalence of soil contamination with *Toxocara* ova. In Brazil, several studies were conducted, and the soil contamination rate with *Toxocara* ova was 22.4% (Mandarino-Pereira et al., 2010), 30.2% (Cassenote et al., 2011) and 36% (Sprenger et al., 2014). A study done by Bojar and Káapeü (2012) in Poland found that 18.6% was prevalence of *Toxocara* ova. Another studies conducted in Brazil by De -Moura et al. (2013) and Marchioro et al. (2013) recorded 44% and 78.6% were prevalence of *Toxocara* ova in soils respectively. In Slovakia, the prevalence of *Toxocara* ova was 79.2% (Rudohradská et al., 2011). In Poland, Blaszkowska et al. (2013) reported that prevalence of *Toxocara* ova was10.6%, while in Portugal 63.3% (Otero et al., 2014). A study done in India, 12.84% (Sudhakar et al., 2013), while Thomas and Jeyathilakan (2014) reported 4.75%, in Philippines 32% (Paller and de Chavez, 2014). In the present study, the rate of soil contamination with *Toxocara* ova was 15.1% and statistical analysis showed the presence of highly significant difference. The differences between the results of all those studies mentioned may be attributed to a wide range of factors, such as climatic conditions, the population of dogs, soil type, number and volume of samples tested, the season in which sampling was performed, the mode of storage of soil samples, and the methods used for examination. In the current study, the public schools included did not keep their areas enclosed and allowing dogs to enter the school grounds.

The presence of ova in the soil samples collected suggests the dogs living around the school may be infected with *Toxocara* ova. During sample collection, children were seen playing in the soil with their bare hands and not wearing shoes or slipper, thus increasing the risk of acquiring *Toxocara* infection. In the current study, parasite ova were identified in almost all places that were not fenced and also in dog shelters. Fenced places specially arranged for dogs recreation were free of helminth ova, this means that the animals which had received anthelmintic drugs. Moreover, in this places have access only dogs with their owners. The explanation is that although the place was initially arranged for recreation of dogs subsequently the fence was broken and the access of stray dogs was free, suggesting a potential route of contamination of places.

In the present study the rate of some other helminth ova was reported as 15.28% of *Hymenolepis nana*, 7.28% *Hymenolepis diminuta*, 6.57% *Trichuris trichuria*, 13.57% was prevalence of *Ancylostoma*, 16.71% for *Taenia* and 10.14% for *Ascaris*. All these types of parasitic ova were recovered from soils in many studies. In Baghdad, Fathailah, (1988) reported the prevalence of ova of some helminths as 22% *Ascaris*, 26% *Hymenolepis nana*, 12.57% *Ancylostoma*, 22% *Toxoplasma gondii*, 14% *Hymenolepis diminuta*. Also in Baghdad Guirges and Al-Mofti (2005) found the prevalence of ova of some helminth eggs as 20% *Hymenolepis nana*, 25% *Ascaris*, 21%, *Hymenolepis diminuta*, 19% of *Ancylostoma* and 15% *Trichuris*. In Erbil city, Saida and Nooraldeen (2014) reported the prevalence of ova of some helminths as follow as: ova of *Echinococcus granulosus* 22.4%, *Ascaris* 18.3%, *Hymenolepis nana* 10.2%,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1488314891

Hymenolepis diminuta 4.0%, *Trichostrongylus* 8.1%, *Enterobius vermicularis* 4.0% and *Dipylidium caninum* 6.1%, the cysts of each of *Entamoeba histolytica* 20.4%, *Entamoeba coli* 22.4%, *Giardia* 16.3% and oocyst of *Toxoplasma gondii* 18.3%. A study done by Nooraldeen (2015) in Erbil city was found ova of *Hymenolepis diminuta* in 75%, *Ascaris* in 33.3%, *Taenia* in 25%, *Ancylostoma* in 25% and 16.7% for *Trichuris*. A study of Anh et al. (2007) reported the prevalence of *Ancylostoma* 19%, *Ascaris* spp 27%, *Hymenolepis nana* 22%, *Hymenolepis diminuta* 20% *Echinococcus granulosus* 23%, in Cambodia. It is not possible to make an accurate comparison between the results of all those studies because the recovery of parasitic ova from different localities was obviously vary depending on environmental conditions, soil types, choice of sampling sites, the number of animals defecating in the sampled area, recovery methods and the increased prevalence of some of those helminth eggs in soil might be due to using of the humans and animals waste for fertilizing the farms in some countries, which is widely used in Iraqi farms.

Contamination of soil may result from poor environmental sanitation specially the presence of large stray dogs population. The cause of that may be return to the preference of these places by stray dogs in addition to that this area was always humid and helminth ova can remain viable at least few months in humid soil. While prolonged exposure to the sun in poor vegetation and dry soil may cause quick disintegration of the eggs. Climate conditions and other factors (temperature, humidity and rain, soil pH and soil type) were important factors for viability and development of ova, therefore, the differences in climate conditions from place to place and from year to year in the same place may lead to differences in contamination rate of soil which recorded along the months of year in different places or even in the same place during different years. In Iraq climatic conditions such as mild temperature, humidity and rain for maintenance and dispersion may be found in winter and spring seasons therefore, highest contamination rate obtained during the months of these seasons.

Sometimes the number of helminth ova per soil sample was not enough to cause infection and there was a positive correlation between the intensity of ova in soil and the prevalence of infection.

Conclusions

This study has shown that there is high level of contamination of soil of different parts of Amadyia district with *Toxocara* and other helminth ova and that examination of soil samples can be used as a strategy to determine the level of contamination of soil with helminth ova. The present study concluded that more consideration is necessary to improve personal and food hygiene particularly in children to avoid transmitting the infective stages of parasites for human through contaminated soils.

It is important that a further study needed to determine the relationship between the infection rate of helminth ova, soil types, soil pH and seasonal climatic variation.

Abstract. Land use in this study of the landscape, the spatial, statistical and comparative analysis is carried out on the tea plantation in Lancangjiang Catchment of Yunnan in China and its other main land use typesin perspective of the elevation gradient by using the GIS and data analysis software. The result shows that the landscape index is invert "V" or invert "U"-shaped, or decreasing linearly along the elevation gradient. The peak appears between 1200 and 1800 m with the highest concentration and spatial heterogeneity. Therefore, the tea plantation area is the largest and the tea planting is most active in this range. On the contrary, the bottom value appears at the elevation below 600 m or above 2600 m. Therefore, it holds the least area of the tea plantation. The four main land use types are weakly correlated with the tea plantation landscape, and the construction land use has the weakest correlation. Except for the grassland, the correlation between the tea plantation and other land use types is mainly reflected in the landscape area, the landscape shape index and the landscape agglomeration index. The research might be helpful for optimizing the land use landscape and improving the ecological conditions in the catchment.
Keywords: *land use, tea plantation, landscape index, development trend, correlation*

Introduction

Land is an important resource and a requisite for our living and development. In recent years, with the rapid increase of the world population and the accelerated urbanization, the land use by human beings is expanding in scope and depth. The socio-economic development is accompanied by the big change of the land cover, and it leads to a series of ecological problems. With the development of the landscape ecology, the landscape pattern analysis has become one of the effective technical ways to study the spatial structure and evolution of the land use (Chen, 2014). Tea is the traditional and main cash crop in Yunnan, and the Lancangjiang Catchment has the longest history of planting tea due to its preferable natural conditions. It also has the largest area of the tea plantation. With the rapid development of Pu'er Tea and increasing tea price, the tea production and the scale of the tea plantation has been expanding. It brings great impact on the ecological environment of the catchment. At the macro level, it disturbs and influences the number, area, shape and distribution of the patches of the land use landscape. Therefore, it is of great significance to carry out the tea plantation landscape research in order to optimize the land use landscape and improve the ecological conditions in the catchment.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

The current land use research in the world covers the relationship of the land use and the climate change (Pavani, 2018; Furlanetto, 2018), the significance of the land use research to the (paleo) environment research (Jaeschke, 2018), the land use scheme (Martyn et al., 2017), and the drivers of the land use (Cattarino, 2014). The tea garden research is more focused on the livelihoods of the tea farmers (Biggs, 2018). There has been a lot of the tea research being done in the Lancangjiang Catchment, but most is about the main ingredients of the tea (Tan, 2012; Gong, 2010), heavy metal pollution (Chen, 2011; Liu, 2008), spectroscopic identification (Ning, 2013, 2010; Zheng, 2013), soil nutrients in the tea plantation (Gao, 2013; Yi, 2011; Li, 2011), and so on. Many of the research are aimed to improve the tea production and quality, so they focus on its quality control, physio-chemical properties of the soil and its impact on the tea. More research has been done on the vegetation cover (Fan, 2012) and land use (Wang, 2008) of the catchment than the spatial distribution and landscape of the tea plantation. For the landscape research, more is done on the land use, the urban area (Chu, 2018), the green park (Fan, 2018), lakes and wetlands (Zhai, 2018; Pu, 2018; Zhang, 2019), much less about the tea plantation. The change with time is more studied than the change with the elevation gradients for the land use and the landscape characteristics.

In this paper, the landscape study is carried out on the tea plantation and other main land use types (farmland, forest land, grassland, construction land) in Lancangjiang Catchment (Yunnan Section), in perspective of the elevation gradient by using the GIS and data analysis software, and by conducting the spatial, statistical and comparative analysis. The research might be helpful for optimizing the land use landscape, adjusting the agricultural structure and improving the ecological conditions in the catchment.

Materials and methodologies

Brief introduction of the study area

Lancang-Mekong River is a famous international river, and the only one river connecting the six countries in Asia. It originates in the northwest of Zaduo County of Yushu Tibetan Autonomous Prefecture of Qinghai Province in China (*Fig. 1*). The Yunnan Section of the river sets between N21°08′41″~29°14′04″ (*Fig. 1*). Lancangjiang River flows 1240 km long in Yunnan Province, with a catchment area of 90,000 km^2, covering Diqing, Lijiang, Dali, Baoshan, Lincang, Pu'er and Xishuangbanna prefectures. The catchment is going from north down to the south, and its water system is shaped as a broom. The difference of the elevation in the Catchment is big, and the temperature and precipitation are increasing from the north to the south. The dry and wet seasons are distinctive, the wet season starting from May to October, and the dry season starts from November to April of the next year. More than 85% of the rainfall concentrates in the wet season. There are various vegetation types in the catchment, including the tropical rainforest, monsoon forest and mountainous grassland. The topographic landform and climate of the catchment provides the preferable natural conditions for the tea production. The increasing tea plantation brings great economic benefits for the local society, but the unplanned expansion of the tea plantation brings many environmental issues as well.

Data source and processing

The current land use data for the research is obtained from the remote sensing images of Landsat8, taken in 2017, with a resolution of 30 m. DEM (Digital Elevation Model)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1489314910

data is the original data from SRTMDEM 90M. The original images come from the Geospatial Data Cloud Platform of Chinese Academy of Science, and the land use and elevation data is drawn out by ENVI5.1 and ArcGIS10.0. The zoning maps of the latitude, elevation and climate are the research outputs of the Land Resources Science, Technology and Engineering Research Center of Yunnan Agricultural University. The downloaded 13 images are calibrated by ENVI5.1 and the Band 5, 4, 3 images are fused with standard false color based on the enhanced processing. The training samples are selected based on the terrain feature in the field to supervise the classification and its accuracy. Except for the main research target – the tea plantation, the other six land use types are interpreted according to the Current Land Use Classification Standard (GB/T 21010-2007) such as farmlands, forest lands, grasslands, construction lands, water and other land uses (including idle land, barren rocky land, garden). The final classification is finished after blurring, mosaic method processing and range-cutting (*Figs. 2* and *3*). Then the land use type and area data are furthermore extracted by ARCGIS10.0 (*Table 1*).

In order to differentiate the tea garden from the forest land, a modified decision tree classification method is applied. The elevation and slope degree which affect the tea garden growth have been used as decision principles, combined with the spectral characteristics of the tea garden and forest land. The ratio index, NDVI value and the texture index are introduced into the decision classification, and the decision tree remote sensing data extraction model is established to improve the accuracy of the remotely sensed image classification.

Research methods

According to the landscape pattern theory, the landscape pattern index is calculated and the pattern of the tea plantation under different elevation gradient and land use is analyzed by spatially overlaying the different map layers. The Fragstats4.2 is applied in this process.

Total	252322	100	8789793.49	100

There are tens of indexes currently used for studying the landscape pattern (Zhao, 2007), out of which, eight indexes are selected. They are landscape type area (CA), proportion of landscape type area (PLAND), average patch area (AREA_MN), patch area standard deviation (AREA_SD), largest patch index (LPI), patch density (PD), landscape shape index (LSI), landscape agglomeration index (AI).

(1) Class area

CA is the total area of a certain landscape patches, with measurement unit of hm^2. In ecological terms, it reflects the energy storage and energy flow of a certain landscape type. The bigger the patch area the more abundant its species, and the faster energy flow. The formula is as follows (*Eq. 1*):

$$CA = \sum_{j=1}^{n} a_{ij} \quad \text{(Eq.1)}$$

in which, a_{ij} is the area of Patch j of Type i, n is the quantity of the patches.

(2) Proportion of landscape type area (PLAND)

PLAND is the proportion of the patch area of certain landscape in the whole landscape area, expressed by "%", showing the dominance or importance of certain landscape type in the whole landscape. The formula is shown as follows (*Eq. 2*):

$$PLAND = \frac{\sum_{j=1}^{n} a_{ij}}{A} \times 100 \quad \text{(Eq.2)}$$

In this equation, "A" is the total area of the landscape; "a_{ij}" is the area of the Patch j of the Landscape Type i; "n" is the number of the patches.

(3) Average patch area (AREA_MN)

AREA_MN is the average area of all the patches of a certain landscape type. The change of its value gives more ecological information of the landscape, and it is a critical index in reflecting the landscape heterogeneity. The formula is shown as follows (*Eq. 3*):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1489314910

$$AREA\_MN = \frac{A_i}{N_i} \quad \text{(Eq.3)}$$

In this equation, "Ai" is the total area of the Landscape Type i; "Ni" is the number of the patches of the Landscape Type i.

(4) Patch area standard deviation (AREA_SD)

AREA_ SD is the standard deviation of all the patch area of a certain landscape type. It reflects the diffusion degree of the patch area of a certain landscape type and the variation degree of the landscape patch scale. The bigger the value, the higher degree of the variation. The formula is as follows (*Eq. 4*):

$$AREA\_SD = \sqrt{\frac{\sum_{j=1}^{n}(a_{ij} - \frac{A_i}{N_i})}{N_i}} \quad \text{(Eq.4)}$$

In this equation, "a_{ij}" is the area of Patch j of the landscape type i; "n" is the number of the patches. "Ai" is the total area of the Landscape type I; "Ni" is the total number of the patches of the Landscape type i.

(5) Largest patch index (LPI)

LPI is the proportion of the largest patch area of a certain landscape type in the whole landscape area. It shows the dominance of a certain landscape type in the whole landscape. Its value reflects the intensity of the human activity. The formula is as follows (*Eq. 5*):

$$LPI = \frac{Max(a_{ij})}{A} \times 100 \quad \text{(Eq.5)}$$

In this equation, "Max(a_{ij})" is the area of the largest patch of the landscape type i; "A" is the total area of the whole landscape.

(6) Patch density (PD)

PD is the ratio of the patch number of a certain landscape type in the whole landscape area, in other words, the patch quantity in each hectare. It shows the fragmentation of the landscape. The bigger the value, the more fragmented the landscape, thus the more complicated spatial structure of the landscape. The formula is as follows (*Eq. 6*):

$$PD = \frac{N_i}{A} \quad \text{(Eq.6)}$$

In this equation, "A" is the total area of the whole landscape, and "N" is the patch quantity of the landscape type i.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1489314910

(7) Landscape shape index (LSI)

LSI is the shape of a certain landscape type, and is generally used to indicate the complexity and stability of the landscape. When the landscape patch shape is close to a square, the value of LSI is close to 1. When the shape is complex or becoming elongated, the value will be increased infinitely. The formula is as follows (*Eq. 7*):

$$LSI = \frac{0.25E}{\sqrt{A}} \quad \text{(Eq.7)}$$

In this equation, "A" is the total area of the whole landscape, and "E" is the total length of all the patch boundaries in the landscape.

(8) Agglomeration index of landscape (AI)

"AI" is the agglomeration degree of the patches in a certain landscape type. Its value ranges from 0 to 100. The bigger the value, the higher degree of agglomeration of the patches. The formula is as follows (*Eq. 8*):

$$AI = \frac{g_{ii}}{Max \rightarrow g_{ii}} \times 100 \quad \text{(Eq.8)}$$

In this equation, "g_{ii}" is the number of similar patches jointing each other of the landscape type i.

When the index values of the landscape pattern are obtained, the correlation between the tea plantation and other land use types is analyzed, in other words, the relative variants are analyzed to find out to which extent they are related to each other. Pearson correlation coefficient is used for the analysis and the formula is shown below (*Eq. 9*) (Zhang, 2014):

$$r = \frac{l_{XY}}{\sqrt{l_{XX} l_{YY}}} = \frac{\sum (X - \overline{X})(Y - \overline{Y})}{\sqrt{\sum (X - \overline{X})^2 \sum (Y - \overline{Y})^2}} \quad \text{(Eq.9)}$$

In which, r is correlation coefficient of variants; $|r|$ is the degree the two variants are related, when $r > 0$ means positive correlation, $r < 0$ for negative, $r = 0$ means zero correlation. The closer the value of $|r|$ to 1, the higher the correlation degree. More specifically, when $|r|$ is 0.8~1, very strong correlation; 0.6～0.8 is strong; 0.4~0.6 is medium; 0.2~0.4 is weak; 0.0~0.2 is very weak or no relation.

The correlation coefficient needs to be tested by the prominence value (P). When $P \leq 0.05$, it has prominent correlation. SPSS 22 is used in this process. In the "r" value results, "*" means at $p \leq 0.05$, and "**" means at $p \leq 0.01$. There exists certain deviation in the correlation results due to the limited amount of the data sample, so the prominence of the correlation is only done for those at $p \leq 0.01$.

Results and analysis

Table 1 shows that as far as the patch quantity is concerned, grassland > farmland > tea plantation > forest land > other land > construction land > water area, and the grassland is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1489314910

the most, holding a proportion of 0.2825; and the water area is the least, holding 0.0089. The tea plantation patches, preceded by the grassland and farmland, is ranked the third, holding 0.1329. In respect of the type area, it is forest land > farmland > grassland > other land use > tea plantation > water area > construction land. The forest land has the largest area in the whole catchment, its proportion is as high as 0.6896. The construction land has the least area with a portion of 0.0094. The tea plantation, with a portion of 0.0244, stands at the fifth place (*Figs. 2* and *3*).

Tea plantation landscape pattern features under different elevation gradients and land use

There is a wide elevation range in Lancangjiang Catchment (Yunnan Section) running from 460 to 6456 m. In order to accurately display the change of the tea plantation landscape pattern under different elevation gradients and land uses, the elevation is graded every 200 m by equal- or non-equal spacing methods to include 14 gradients. They are below 600 m, 600~800 m, 800~1000 m, 1000~1200 m, 1200~1400 m, 1400~1600 m, 1600~1800 m, 1800~2000 m, 2000~2200 m, 2200~2400 m, 2400~2600 m, 2600~2800 m, 2800~3000 m, above 3000 m (*Fig. 4*). The statistical data of the land types is collected after graphic overlaying of the RS image classification map and latitude change map. Then after cutting and transferring to the grid data, they are introduced to Fragstats for the landscape pattern index. It is exhibited in *Table 1* that there is no tea plantation above 2800 m, so it is only needed to analyze the pattern features below 2800 m.

Landscape pattern features of main land use types at different elevation

By overlaying the land use map and elevation map with Arcgis 10.0, each level is converted into ESRI grid format, and the land use landscape pattern index under different elevation is calculated with Fragstats4.2 (*Fig. 5*).

DOI: http://dx.doi.org/10.15666/aeer/1706_1489314910

As far as the landscape area (CA) is concerned, when the elevation is increasing, the farmland, forest land and the grassland is going up and down, and the construction land use is generally decreasing. In respect of landscape area proportion (PLAND), the forest land experiences rapid increase first and then gradual decrease, while the grassland keeps going up mildly, and the farmland and the construction land use experience the slow and then the fast climb-up. For the average area of the patch (AREA_MN), the forest land fluctuates but keeps going up; the grassland is increasing gradually; the farmland and the construction land keep declining from a fast to a slow speed. In respect of the standard deviation of the patch area (AREA_SD), the forest land stays stable after an up-and-down; the farmland is declining with a wave shape; the construction land experiences a steep downward and then keeps stable, and the grassland generally stays constant with little change. In respect of LPI, the forest land fluctuates, the farmland and the construction land experience a steep downward and then keeps stable, and the grassland has little change. In respect of the patch density (PD), the forest land, the farmland and the construction land go from a fast to a gentle downward, the grassland is fluctuating to an upward. The landscape shape index (LSI) shows that the farmland, the forest land, the grassland and the construction land first go up and then down, and the construction land is generally declining. In respect of the agglomeration index (AI), the forest land and the grassland go from upward to a stable status, the farmland goes down mildly, and the construction land fluctuates to a downward.

The landscape pattern index of the tea plantation under different elevation

By overlaying the tea plantation distribution map and the elevation map with Arcgis 10.0, each level is converted into ESRI grid format, and the tea plantation landscape pattern index under different elevation is calculated with Fragstats4.2. The result is shown in *Figure 6*.

(1) In respect of the landscape type area (CA), with the increasing elevation, the area of the tea plantation goes upward and then downward. The tea plantation area is larger between 1000 and 2000 m, and it is 18.93×10^4 hm^2, covering 88% of the tea plantation area under the research. It is a main area for tea planting. Between 1200 and 1400 m, the tea plantation area is the largest, which is 5.48×10^4 hm^2, accounting for 25.71%. The area is reducing below 800 m or above 2200 m, accounting for only 2.03%. The smallest area of 20.97 hm^2 is distributed below 600 m, accounting for only 0.01% of the tea plantation area in the whole catchment.

(2) In respect of the landscape type area proportion (PLAND), with the increasing elevation, the area of the tea plantation goes upward and then downward. The proportion of the tea plantation area is bigger between 1000 and 2000 m, covering 2%~5%. Between 1200 and 1400 m, it is the biggest, accounting for 4.52%, so the tea plantation is dominant in this range. The tea area proportion is decreasing below 800 m or above 2200 m, accounting for less than 0.5%. The smallest tea area proportion is distributed below 600 m, accounting for only 0.04%.

(3) In respect of the mean area of the patch (AREA_MN), with the increasing elevation, the mean patch area of the tea plantation goes upward and then downward, with mild fluctuation. The larger mean patch area occurs between 800-2000 m, nearly all above 4 hm^2. It is decreasing below 800 m, nearly all less than 2 hm^2. The least mean patch area is distributed below 600 m, being only 0.62 hm^2. It goes up between 2400 and 2600 m, mainly because of the less number of the patches.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1489314910

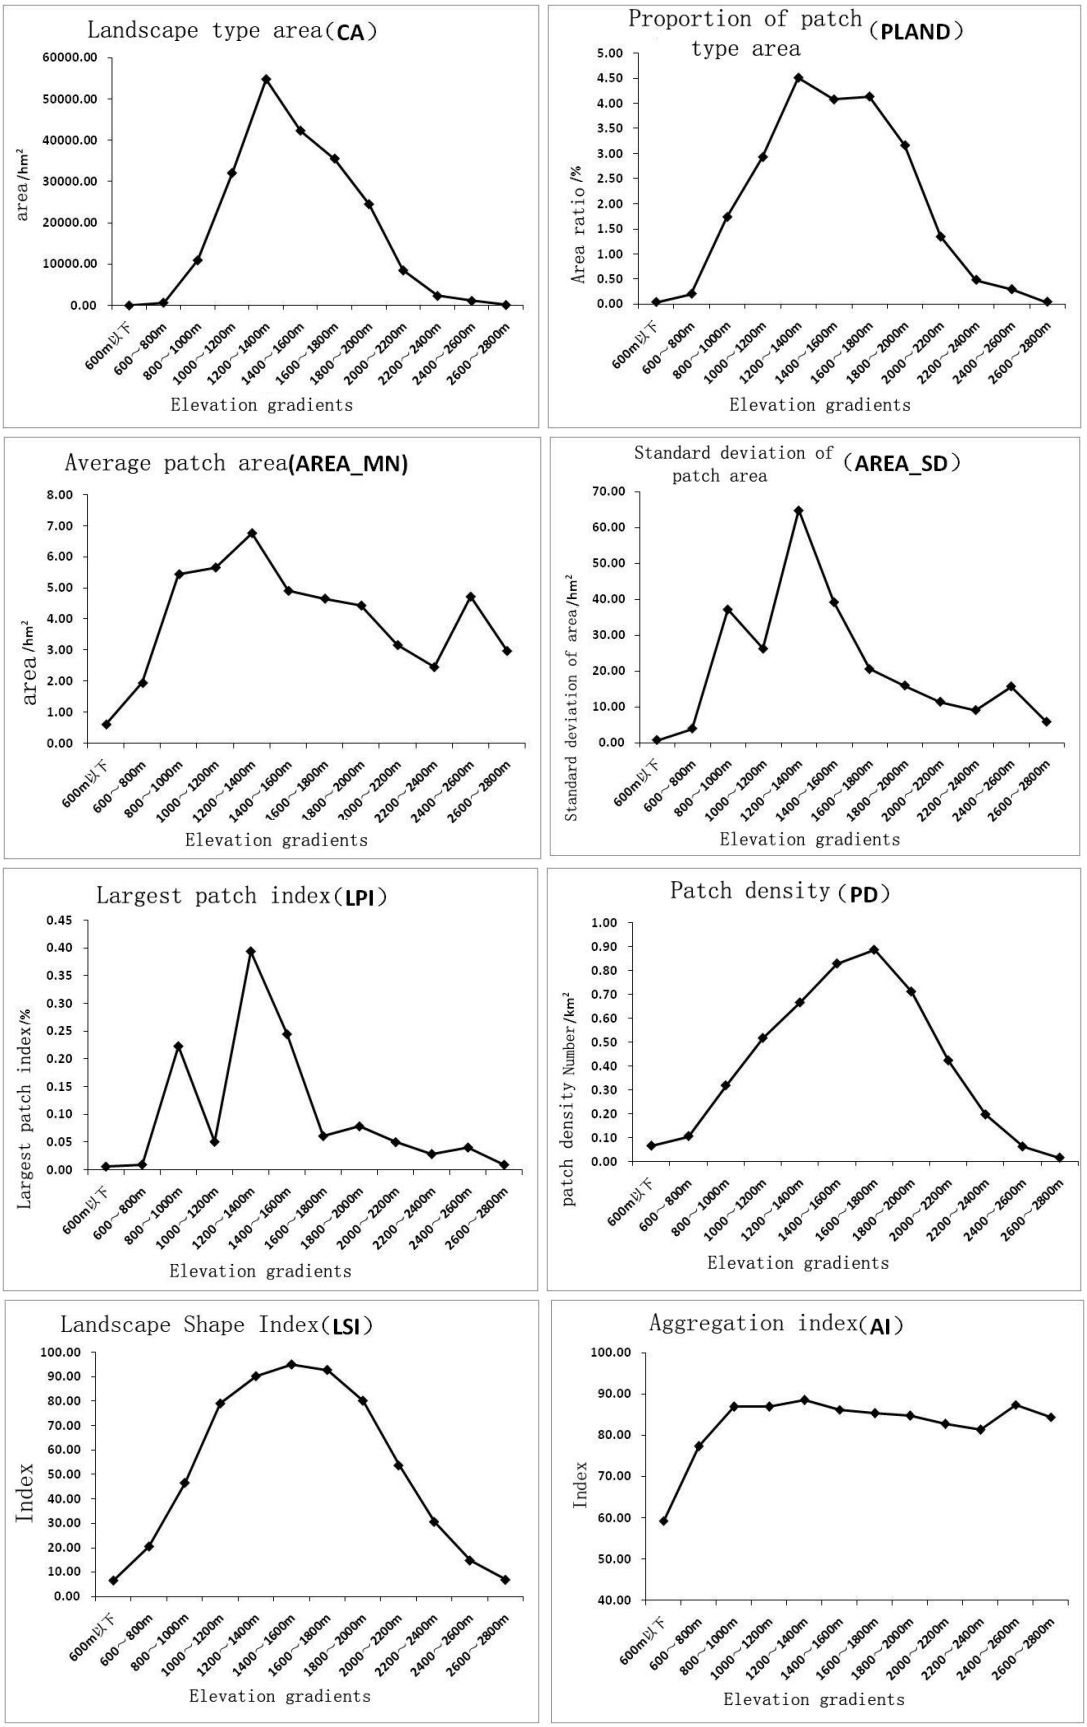

Figure 6. *Landscape pattern index of tea garden in different altitude gradient*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1489314910

4) In respect of the standard deviation of the patch area (AREA_SD), it generally goes from upward to downward with small fluctuation, when the elevation is increasing. The standard deviation is bigger between 800-2000 m, nearly all above 20 hm^2. It means that, in this range, the patch size is with a higher dispersion, the patch scale is more varied with high spatial heterogeneity. It reaches the highest level between 1200 and 1400 m, getting to 64.87 hm^2. Then it goes down below 800 m, nearly all less than 4 hm^2. The least deviation is distributed below 600 m, being only 0.70 hm^2.

(5) In respect of the largest patch index (LPI), with the increasing elevation, the development trend of the proportion of the largest patch is similar to the standard deviation of the patch area. The LPI is bigger between 800-1000 m and 1200-1600 m, all above 0.2%, so in these ranges the scale of the tea plantation is larger and more dominant. The index is less for the other elevation ranges, less than 0.05%. The least is found below 800 m or above 2600 m, being only 0.01%.

(6) In respect of the patch density (PD), the density is going up and then down with the increasing elevation. The patches are most densely distributed between 1000 and 2000 m, all above 0.5. In this range, there are most tea plantation patches with the biggest fragmentation and most complex spatial structure. The density is reducing below 600 m or above 2400 m, all less than 0.1. The least patch density appears above 2600 m, being only 0.02.

(7) The landscape shape index (LSI) is going up and then down with the increasing elevation. The shape index has the highest value between 1000 and 2000 m, all above 50. In this range, the tea plantation patch shape is most complex and irregular. So it is mostly disturbed by est the human activity and has the weakest stability, deviating furthest from the square shape. The lowest index value occurs below 600 m or above 2400 m, being respectively 6.71 and 6.99, mainly because of the smallest area of the tea plantation and more regular shape.

(8) The agglomeration index (AI) is going up and then down with the increasing elevation. Its downward trend is not obvious, and the agglomeration degree is generally high. The agglomeration degree is lower below 800 m, being less than 80. It goes steadily up with little variation above 800 m, with a higher agglomeration degree, being more than 80.

Correlation of land use type and tea plantation landscape pattern under elevation gradient

The correlation analysis of the two variants is conducted when the elevation gradient land use type and the tea plantation landscape pattern index are input in SPSS 22 software.

(1) The correlation of the farmland and tea plantation landscape pattern is shown in *Table 2*. The bolded data with means the variants have closer relation at the layer of $p \leq 0.01$. From *Tables 4* and *5* it is shown that as the elevation changes, the farmland area (CA), the shape index (LSI) and the tea plantation area (CA), the proportion of the tea plantation area (PLAND), the tea patch density (PD) and its shape index (LSI) have strong positive relation, and they have the same relation with the tea average patch area (AM) and the standard deviation of the tea patch area (ASD). So, at the elevation gradient, the farmland area and its shape have similar characteristics of the area, patch density and shape of the tea plantation; they influence each other. The farmland area proportion (PLAND), the farmland patch density (PD) and the average farmland patch area (AM) have strong negative relation with the agglomeration index (AI) of the tea plantation. It means with the increasing farmland area, the patch density is increasing and its average area is bigger, but the agglomeration of the tea plantation is lower and lower.

r: correlation coefficient; p: significance

(2) The correlation of the forest land and the tea plantation landscape pattern is shown in *Table 3*. The bolded data means the variants have obvious relation at the layer of $p \leq 0.01$. From *Table 3,* it is shown that as the elevation changes, the forest land area (CA), the shape index (LSI) and the tea plantation area (CA), the proportion of the tea plantation area (PLAND), the tea patch density (PD) and its shape index (LSI) have strong positive relation, and they have the same relation with the tea average patch area (AM) and the standard deviation of the tea patch area (ASD). So the forest land area and its shape have similar development trends of most tea plantation landscape index. They have strong influence on the landscape pattern of the tea plantation. The forest land area proportion (PLAND) and the agglomeration index (AI) of the tea plantation has strong negative relation, and the largest patch index (LPI) of the forest land is irrelevant with the AI of the tea plantation. Except the two negative relations, the other forest landscape indexes have very strong or strong positive relation with the AI of the tea plantation.

(3) The correlation of the grassland and the tea plantation landscape pattern is shown in *Table 4*. The bolded data means the variants have prominent relation at the layer of $p \leq 0.01$. From *Table 4,* it is shown that as the elevation changes, the grass land area (CA) and the tea patch density (PD) have strong positive relation. It implies that the bigger the grassland area is, the denser and more fragmented the tea garden patches. The shape index and the agglomeration index of the grassland have strong positive relation with the agglomeration index of the tea garden. They influence each other and keep the same development trend.

(4) The correlation of the construction land and the tea plantation landscape pattern is shown in *Table 5*. The bolded data means the variants have more prominent relation at the layer of $p \leq 0.01$. From *Table 5,* it is shown that with the elevation change, the shape index (LSI) of the construction land has a very strong positive relation with the area (CA), the area proportion (PLAND), the patch density (PD) and the shape index (LSI) of the tea garden. The agglomeration index (AI) of the grassland has strong negative relation with most landscape indexes of the construction land.

Table 5. *Correlation analysis results between forest construction tea garden landscape pattern landscape class area (CA), proportion of landscape type area (PLAND), average patch area (AREA_MN), patch area standard deviation (AREA_SD), largest patch index (LPI), patch density (PD), landscape shape index (LSI), landscape agglomeration index (AI)*

Discussion

For the first time, the tea garden landscape pattern change under different land use and altitude gradient is studied for Lancangjiang Catchment (Yunnan Section). It lays a foundation for further research on the ecological environmental effect, and provides scientific basis for optimizing the land use landscape pattern in the catchment and improving the ecological environment of the catchment. However, there is some limitation of this study. Influenced by the resolution of the original remote sensing images, certain interpretation errors exist compared with the actual conditions. The temporal change is not studied due to large research area and time constraints, and only one-year data is studied at the macro level. More field investigation will be done in the future research to collect more information and data to make more accurate research results.

Conclusions

The landscape pattern characteristics of the tea garden under the four main types of the land use (farmland, forest land, grassland and the construction land) is studied from the aspect of the elevation gradient for the Lancangjiang Catchment (Yunnan Section). The study is done through the spatial, statistical and comparative analysis, and by the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1489314910

use of such geographical information and data analysis softwares as ENVI5.1, Arcgis10.0, Fragstats4.2 and Office 2007. The conclusions are made as follows:

(1) The eight landscape pattern indexes of the four main land use types express certain regularity with the altitude change. Their development trend is diverse and different.

(2) The landscape indexes of the tea plantation climb up first and then go down along the elevation gradient, with an invert "V" or invert "U"-shape. The peak appears between 1200 and 1800 m where the tea planting is most active, and it implies that in this range, the tea garden is most extensively distributed, and it has the densest patches, the biggest scale change, the most complicated shapes and the highest spatial heterogeneity. The bottom value occurs below 600 m or above 2600 m, and it implies that in this range, the tea garden is least distributed, and it has the least dense patches, the smallest scale change, the simpler shapes, the lowest agglomeration degree and the weaker spatial heterogeneity.

(3) Along the altitude gradient, there is a relatively strong correlation between the four main land use types and the tea garden landscape pattern, of which, the farmland and the forest land is most strongly correlated to the tea garden landscape, while the grassland is the weakest. Their correlation reflects in the characteristics of the three indexes such as the landscape area (CA), the landscape shape index (LSI) and the landscape agglomeration index (AI).

The next study will combine the temporal and spatial research and discuss the drivers of the change, to better comprehend the temporal change of the tea garden landscape, and its development trend and relationship with the ecological environment, and to provide the scientific basis for the ecological planting of the tea garden and improve the ecological environment of the catchment.

Abstract. In this paper, the numerical simulation of sediment erosion and siltation near the Yellow River estuary is carried out by using wave, tidal current and sediment coupling model. A fine triangular mesh is used in the pattern to improve the spatial resolution of numerical calculations. Comparing the measured water depth data with the simulation results, the result shows that the simulation results are in good agreement with the actual situation. In order to analyze the influence of waves on sediment erosion and siltation, the paper carried out wave influence experiments under four conditions: no wind, north wind, easterly wind and south wind. The experimental results show that the wave has a great influence on the erosion and siltation of the seabed in the study sea area. Under the northward wave condition, an erosion zone is distributed in the SE-NW direction, and the maximum erosion thickness is about 1.9 m. Under the eastward wave condition, the erosion zone is north-south. The maximum scouring thickness is about 1.7 m; the scouring and silting effect under the southward wave condition is relatively weak.
Keywords: *sediment movement, wind wave, tidal current, numerical simulation*

Introduction

The large amount of sediment brought by the Yellow River into the sea has changed the trend of the shoreline of the Yellow River estuary, affected the spatial and temporal distribution of the seabed erosion and siltation in the nearby sea, and affected the protection of land and ecological resources, the exploitation of offshore oil and gas, and the construction of other marine projects. The modern Yellow River delta is formed near the estuary of the Yellow River with the characteristics of short formation time, efficient sedimentation rate and loose structure which make sediments prone to be compacted and consolidate under the geo-static stress and overburden stress. It is one of the areas most susceptible land subsidence disasters in China, bringing a series of safety hazards to production and living (Liu et al., 2018).

Li et al. (2004) calculated the coastal erosion/accumulation rates from 1964 to 1976 using Landsat TM imagery. With the combination of historical data, field observations and satellite remotely sensed images, changes in Yellow River estuary since 1996 when were studied by Fan et al. (2005), mainly including water and sediment discharge from the river, tides, tidal currents, suspended sediment diffusion, coastline changes and seabed development. Liu et al. (2011) analyzed the temporal changes of water discharge and sediment load of the Yellow River into the sea based on hydrological data observed at Lijin gauging station from 1950 to 2008. Huang et al. (2018) investigated the distribution of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1491114926

estuarine salinity and suspended sediment by a three dimensional with numerical simulation under different flow rates. Wang et al. (2019) demonstrated that the shape and length of the Yellow River Delta coastline has changed dramatically since 1976 using the general high-tide line method, which combines remote sensing and geographic information system technology, using multi-spectral scanner, thematic mapper, and enhanced thematic mapper plus images from 1976 to 2014. Yang et al. (2017) investigated water and sediment changes by using coastline and suspended sediment concentration methods, indicate the inter-annual and intra-annual variations of the sediment concentration from 1986 to 2013.

Waves have a vitally important effect on erosion and siltation of shore beach. With the rise of coastal engineering, foreign scholars began to study the sediment movement under the action of waves, and obtained some achievements. Putting forward a variety of sediment starting formulas are mostly limited to the coarser particles of non-cohesive sediment. Because of the complexity of wave motion, the lack of understanding of the oscillating boundary layer flow caused by surface waves and the turbulent mixing mechanism inside the water body, coupled with the randomness of the sediment movement itself, brings a lot of difficulties on theoretical research about sediment movement under wave action. Xu (2003) established a multiple regression equation between the sediment flux to the sea and the influencing factors to estimate the change in the sediment flux to the sea when the influencing variables are further changed. Wang et al. (2005) use a two-dimension numerical model to reveal the tidal and wave dynamics in 2012, and conducts comparative analysis of the changes from 1996 to 2012. Kong et al. (2009) established a numerical model with the application of environmental fluid dynamics code to the Yellow River Delta. The simulation indicates that most of the sediment deposited just out of the Mouth which makes the mouth move forward into the sea 2.5 km per year. Zhan (2017) developed the novel cubic model, which used the ratio of a near-infrared band (740–900 nm) to a visible band (400–600 nm) as factors, for the retrieval of SSSC from Yellow River Estuary. Wang et al. (2019) used a three dimensional current-wave-sediment coupled model to examine the seasonal suspended sediment transport. Yao et al. (2018) developed a new multi-fractional, depth-averaged sediment transport module and embedded into a morph dynamic model for a sand-silt mixed shallow water environment. Comparisons with measurements over two successive tidal cycles indicate that the present model produces very good results on short-time scales.

Due to the complex natural environment, it is a difficult problem to simulate calculation of the sediment erosion and deposition in the sea area of the Yellow River estuary. It is of great significance and practical value to improve the accuracy and precision of sediment numerical simulation by using effective mode. The aim of this paper is to study the impact of surface wave on the sediment erosion and deposition near the Yellow River Mouth by numerical simulation method. The paper is devised into 5 sections. The section 2 is numerical simulation. The section 3 studies the tidal current characteristics and the impact of surface waves is analyzed in section 4. Finally, the conclusion is given in the section 5.

Materials and Method

Measurement data

Research area is near the Yellow River estuary, China, 37.5-38°N, 118.8-119.6°E. The position of the stations is shown in *Figure 1*.

The measured data of tidal level is selected from May 9 to 13, 2004. The measured data of tidal current is taken from May 5 to 6. And the measured data of sediment

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1491114926

concentration is taken from May 1 to 2. Because the various elements are measured separately and the measurement time is dispersed, only the current trend is carried out the measurement of tidal current, tidal level and sediment concentration.

The data of tidal level is measured by RBR in tidal level station, and the data is recorded every 10 min. Tidal currents are measured every 1 hour. The current direction is measured in true north position. The current level of each vertical line is determined by the water depth. The three-point is adopted when the vertical depth is less than 5.0 m that is, the surface layer, the 0.6H layer and the bottom layer are observed. The six-point is adopted when the vertical depth is greater than 5.0 m that is the surface layer, 0.2H layer, 0.4H layer, 0.6H layer, 0.8H layer and the bottom layer are observed.

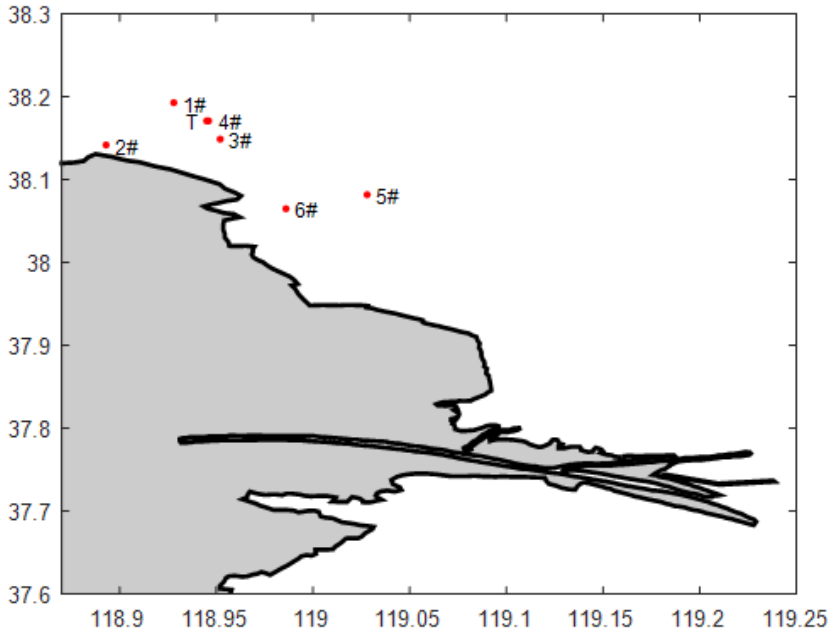

Figure 1. *The Locations of observation stations*

The specific levels are divided as follows:

- Surface layer: 0.5 ~ 1.0 m below the sea surface;
- 0.2H: 0.2×H below the sea surface;
- 0.4H: 0.4×H below the sea surface;
- 0.6H: 0.6×H below the sea surface;
- 0.8H: 0.8×H below the sea surface;

The bottom layer: 0.5 ~ 1.0 meter above the sea floor. Where H is the depth of the vertical water depth during observation, in meters.

Water depth is recorded and water sample are collected for suspended sediment analysis layer by layer when measuring the current.

According to the stratified sediment concentration measured by indoor cup-dry method and weighted by stratified current rate, the average vertical sediment concentration was calculated according to the following formula:

$$\bar{\rho} = \frac{\rho_{surface} \cdot v_{surface} + 2(\rho_{0.2} \cdot v_{0.2} + \rho_{0.4} \cdot v_{0.4} + \rho_{0.6} \cdot v_{0.6} + \rho_{0.8} \cdot v_{0.8}) + \rho_{bottom} \cdot v_{bottom}}{v_{surface} + 2(v_{0.2} + v_{0.4} + v_{0.6} + v_{0.8}) + v_{bottom}} \quad \text{(Eq.1)}$$

Numerical Model

Numerical simulation is an effective method to study the sediment moment and the model in this paper has been also applied and confirmed reliable by Wang et al. (2019). The hydrodynamic model is based on the two-dimensional planar incompressible Reynolds average Navier-Stokes shallow water equation, in which the Boussinesq hypothesis and the hydrostatic pressure hypothesis are used, so that the tide surface can be more accurately Curves and tidal fluxes are simulated. The following two-dimensional depth-average shallow water equations can be obtained by integrating the horizontal momentum equation and the continuous equation in the range:

$$\frac{\partial h}{\partial t}+\frac{\partial h\bar{u}}{\partial x}+\frac{\partial h\bar{v}}{\partial y}=hS \tag{Eq.2}$$

$$\frac{\partial h\bar{u}}{\partial t}+\frac{\partial h\bar{u}^2}{\partial x}+\frac{\partial h\overline{vu}}{\partial y}=f\bar{v}h-gh\frac{\partial \eta}{\partial x}-\frac{h}{\rho_0}\frac{\partial p_a}{\partial x}-\frac{gh^2}{2\rho_0}\frac{\partial \rho}{\partial x}+\frac{\tau_{sx}}{\rho_0}-\frac{\tau_{bx}}{\rho_0}-\frac{1}{\rho_0}\left(\frac{\partial s_{xx}}{\partial x}+\frac{\partial s_{xy}}{\partial y}\right)+\frac{\partial}{\partial x}\left(hT_{xx}\right)+\frac{\partial}{\partial y}\left(hT_{xy}\right)+hu_s s \tag{Eq.3}$$

$$\frac{\partial h\bar{v}}{\partial t}+\frac{\partial h\bar{v}^2}{\partial x}+\frac{\partial h\bar{v}\bar{u}}{\partial y}=f\bar{u}h-gh\frac{\partial \eta}{\partial x}-\frac{h}{\rho_0}\frac{\partial p_a}{\partial y}-\frac{gh^2}{2\rho_0}\frac{\partial \rho}{\partial y}+\frac{\tau_{sy}}{\rho_0}-\frac{\tau_{by}}{\rho_0}-\frac{1}{\rho_0}\left(\frac{\partial s_{yx}}{\partial x}+\frac{\partial s_{yy}}{\partial y}\right)+\frac{\partial}{\partial x}\left(hT_{xy}\right)+\frac{\partial}{\partial y}\left(hT_{yy}\right)+hv_s s \tag{Eq.4}$$

Among them: the first item on the left is the local item, the second and third items are the horizontal convection items, t is the time, x and y are the Cartesian plane coordinates, d is the still water depth, η is the water level, h=η + d is the total water depth, and f is the Coriolis parameters $\bar{u}$ and $\bar{v}$ are respectively the components of the depth average flow velocity in the x and y directions, g is the acceleration of gravity, ρ is the water density.

The equations for sediment transport are following:

$$\frac{\partial \bar{c}}{\partial t}+u\frac{\partial \bar{c}}{\partial x}+v\frac{\partial \bar{c}}{\partial y}=\frac{1}{h}\frac{\partial}{\partial x}\left(hD_x\frac{\partial \bar{c}}{\partial x}\right)+\frac{1}{h}\frac{\partial}{\partial y}\left(hD_y\frac{\partial \bar{c}}{\partial y}\right)+Q_L C_L\frac{1}{h}-S \tag{Eq.5}$$

where $\bar{c}$ is the suspended sediment concentration, D_x and D_y are diffusion coefficient, Q_L is the point source emission per unit level area, C_L is point source emission concentration, S is the source of deposition or erosion.

The sedimentation rate could be expressed as

$$SD=w_s\cdot c_b\cdot p_d \tag{Eq.6}$$

where w_s is the sedimentation velocity; c_b is the bottom sediment concentration; p_d is the settlement probability.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1491114926

In the case of limited water depth, the fluctuation velocity of water quality points can be expressed by the following formula:

$$u = \frac{\pi H}{T} \frac{\cosh[k(z+h)]}{\sinh kh} \cos(kx - \sigma t) \quad \text{(Eq.7)}$$

$$v = \frac{\pi H}{T} \frac{\sinh[k(z+h)]}{\sinh kh} \sin(kx - \sigma t) \quad \text{(Eq.8)}$$

In the formula, k is wave number, σ is angular frequency, t is time, h is water depth, L is wavelength, u and v *r*epresent horizontal and vertical velocity of fluctuating water quality points.

The equation of unbalanced transport of suspended sediment under the combined action of tidal current and wave can be expressed as follows:

$$\frac{\partial(hS)}{\partial t} + \frac{\partial[hS(U_c + U_w)]}{\partial x} + \frac{\partial[hS(V_c + V_w)]}{\partial y} - \varepsilon_S h(\frac{\partial^2 S}{\partial x^2} + \frac{\partial^2 S}{\partial y^2}) + aw(S - S_*) = 0 \quad \text{(Eq.9)}$$

where S is sediment content, S_* *i*s sediment carrying capacity of current, ε_s is sediment diffusion coefficient, σ is recovery saturation coefficient, w is sediment settling velocity.

The reciprocating sediment transport process of waves is generally reflected in a tidal current cycle (half a day or one day). Because the wave period is relatively small (usually only a few seconds, the wave height greater than 10 seconds in the sea area near the Yellow River Estuary is very rare), the tidal current cycle is relatively large. Therefore, as long as the calculated time step is much longer than the wave period (e.g. more than 200 seconds for dt), the transport equation can be averaged in time. When a wave particle rotates elliptically or circularly, its average velocity in the wave period is equal to zero, and it is also zero when the time step is longer than the wave period, so only the current tide velocity is considered. The results of the above equation are as follows:

$$\frac{\partial(hS)}{\partial t} + \frac{\partial(hSU_c)}{\partial x} + \frac{\partial(hSV_c)}{\partial y} - \varepsilon_S h(\frac{\partial^2 S}{\partial x^2} + \frac{\partial^2 S}{\partial y^2}) + aw(S - S_*) = 0 \quad \text{(Eq.10)}$$

Because the imbalanced transport of suspended sediment causes the erosion and siltation of the seabed, the deformation equation can be expressed as follows:

$$\frac{\partial(hS)}{\partial t} + \frac{\partial(hSU_c)}{\partial x} + \frac{\partial(hSV_c)}{\partial y} - \varepsilon_S h(\frac{\partial^2 S}{\partial x^2} + \frac{\partial^2 S}{\partial y^2}) + \gamma \frac{\partial \eta}{\partial t} = 0 \quad \text{(Eq.11)}$$

Among them, γ is the dry density of sediment deposited on the seafloor, η is the change of the thickness of the seafloor, h is the erosion and siltation.

It can be seen from the above that when calculating the sediment erosion and siltation changes in estuaries and coasts on a large time scale, the short-period wave flow field is not needed to be taken into account, and only the effect of tidal current is considered. However, it cannot be concluded that the effect of wave on erosion and siltation can be time-averaged, because the wave will affect the sediment carrying capacity of seawater.

Results

Model validation

The Yellow River Delta locates in the Bohai Sea, which is a shallow semi-enclosed sea that exchanges with the Yellow Sea through the Bohai Strait between Shan Dong and Liao Dong Peninsulas. The topography datasets used in this paper are shown in *Fig. 2*. The modeling range includes the whole of the Bohai Sea (*Fig. 2a*). The triangular mesh is adopted with the resolution 5 km at the open boundary and 700 m at Yellow River Delta nearshore. The model domain is 117.5°E-122.5°E, 37°N-41°N (*Fig. 2b*). On the open boundary the amplitudes and phases of the four main tidal constituents (M_2, S_2, K_1, O_1) are used as the surface elevation forcing on the open boundaries. At the lateral land boundary, a condition of no normal flux is applied to velocity.

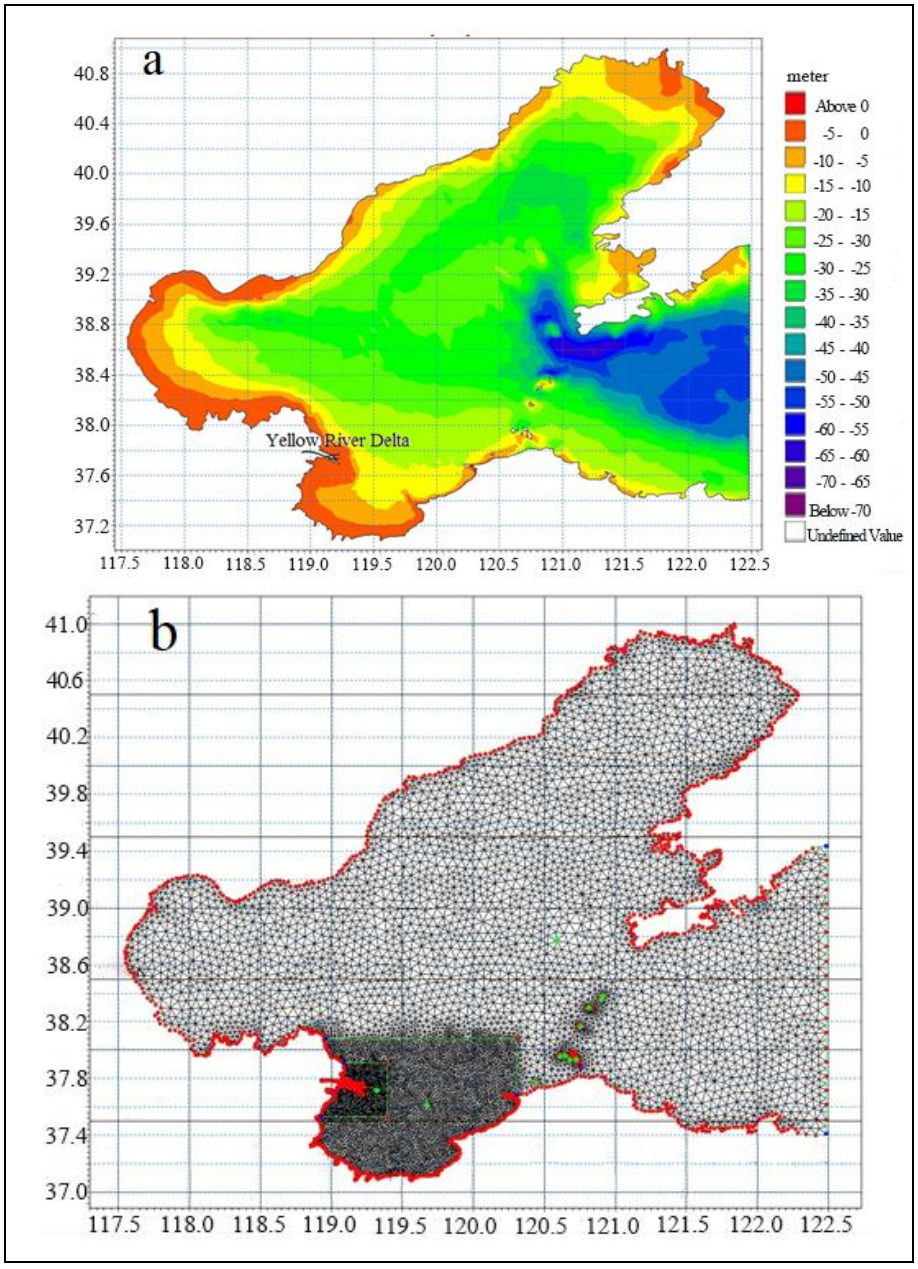

Figure 2. *The topography of Bohai Sea (a) and the model grid (b)*

The measured data of tidal level, tidal current and sediment concentration are collected. The distribution of station positions is shown in *Table 1*. The tidal level, tidal current and sediment concentration in May 2004 were simulated and compared with the measured data. The results are shown from *Figure 3* to *Figure 5*. The comparison shows that it is reasonable to use this model to simulate the hydrodynamic and sediment scouring in the sea near the Yellow River Mouth.

Table 1. *Locations of observation stations*

No.	Longitude	Latitude	Elements

6#	118°59.200′	38°3.920′	Tidal Currents and Sediment

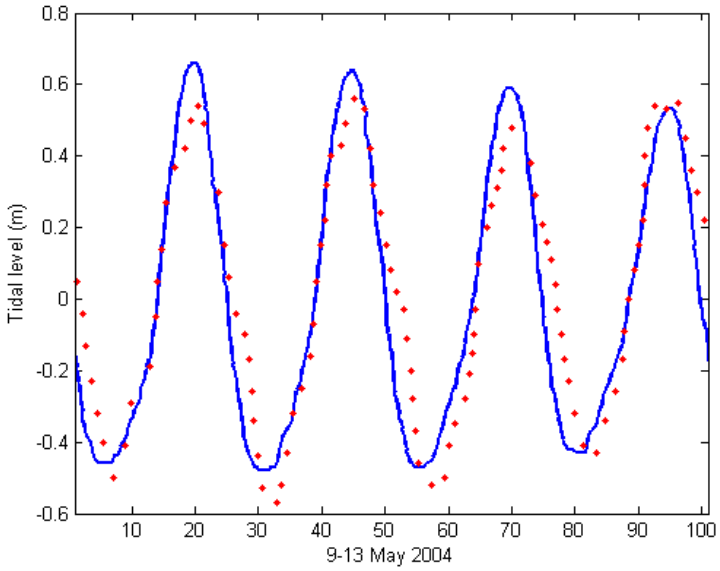

Figure 3. *Comparison of observation tidal level (red dot) and simulation result (blue line)*

The accuracy of the model is estimated by the average absolute error. The average absolute error is calculated as follows:

$$AMEAN = \frac{1}{N}\sum_{i=1}^{N}\left|X_{\text{mod}}^{i} - X_{obs}^{i}\right| \qquad \text{(Eq.12)}$$

Where N is the number of observing stations, X_{mod}^{i} is the value of the mode result interpolated to the i-th station, X_{obs}^{i} is the measured value of the i-th observatory.

The average absolute error of each element of each measurement point is shown in *Table 2*.

Tidal current characteristics

Figure 6 shows the flow field diagram from May 5 to 6, 2004. Overall, the results calculated by the model basically reflect the state of the measured flow rate. The tide of studying the sea area is a regular semidiurnal tide. The tidal waves entering the Bohai Sea are affected by the semi-closed bay form, forming complex rotating tidal waves. During the flood tide, the direction of the tidal current moves from north to south, forming a large clockwise vortex in the east and south sea areas of the old Yellow River estuary and then flowing to the western and central sea areas of Laizhou Bay. During the ebbtide, the sea in the southern part of the old Yellow River estuary (west of Laizhou Bay) was rotated counterclockwise and transported northward. The study of the ebbtide of the sea area lasts longer than the flood tide, and the average flow rate of the ebb tide is greater than the average flow rate of the flood trend, showing an imbalance of fluctuations in the current flow.

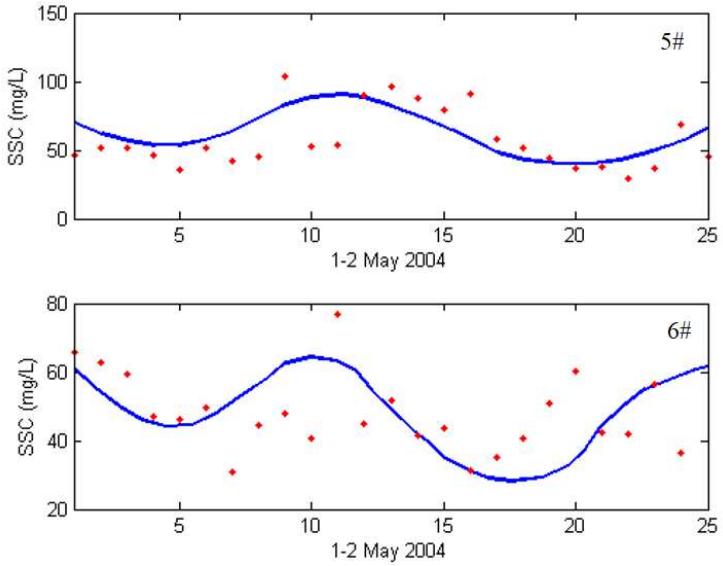

Figure 5. *Comparison of observation sediment concentration (red dot) and simulation result (blue line)*

Figure 7 shows the maximum flow velocity distribution of the study sea area in a full tide in May 2004. The contour of the northern Yellow River estuary is basically parallel to the shoreline. The flow velocity is from 0.5 m/s increased to 1 m/s in the 2-15 m isobath. In the southeast direction of the old Yellow River estuary, the maximum flow velocity

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1491114926

increases rapidly from 0.5 m/s, forming a high value zone with a maximum flow velocity of 1.4 m/s. According to historical data, there are two large flow velocity areas in the Yellow River estuary, one of which is in the southeast of Laohekou. The maximum possible flow velocity is 1.8 m/s.

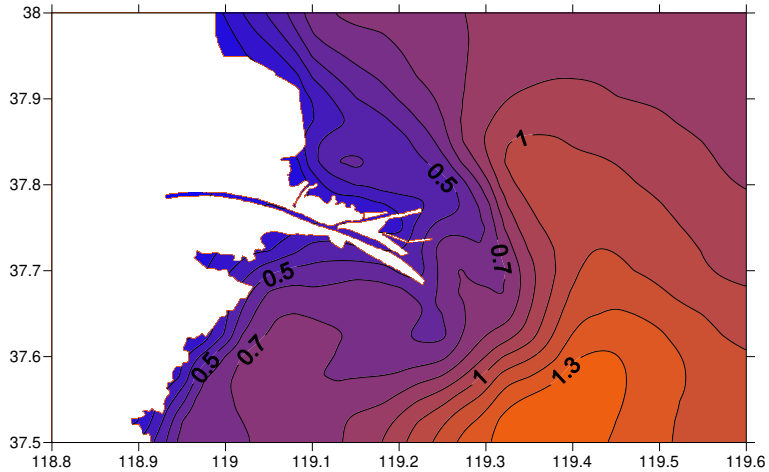

Figure 7. *Maximum velocity distribution (m/s) of the study sea area*

Sediment movement influenced by tidal current

Under the influence of no waves, sediment movement is mainly affected by the trend. The numerical simulation of suspended load concentration and sedimentation and siltation in the absence of wind is shown in *Figure 8*. The northern part of the sea is affected by sediment from the Yellow River and is weakly silted. The concentration of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1491114926

suspended load is generally 0.6 kg/m3, and the southern part is scouring. In the strong tidal zone in the southeast of the old Yellow River estuary, the scouring is the strongest.

Without considering the influence of waves, the stability of the particles is actually mainly controlled by the water pressure of the film and the adhesion between the particles and the performance of gravity is not dominant. From this point of view, in the absence of waves, the finer the sediment particles, the more difficult it is to reach the conditions of suspension. It can be seen that the effect of waves on the sediment, especially the fine sediment, is more obvious. The waves in the Yellow River estuary are basically wind and waves. Although the average wave energy intensity is not large, due to the fine sediment of the Yellow River underwater delta, the levitation force of the waves on the seabed sediment is relatively large.

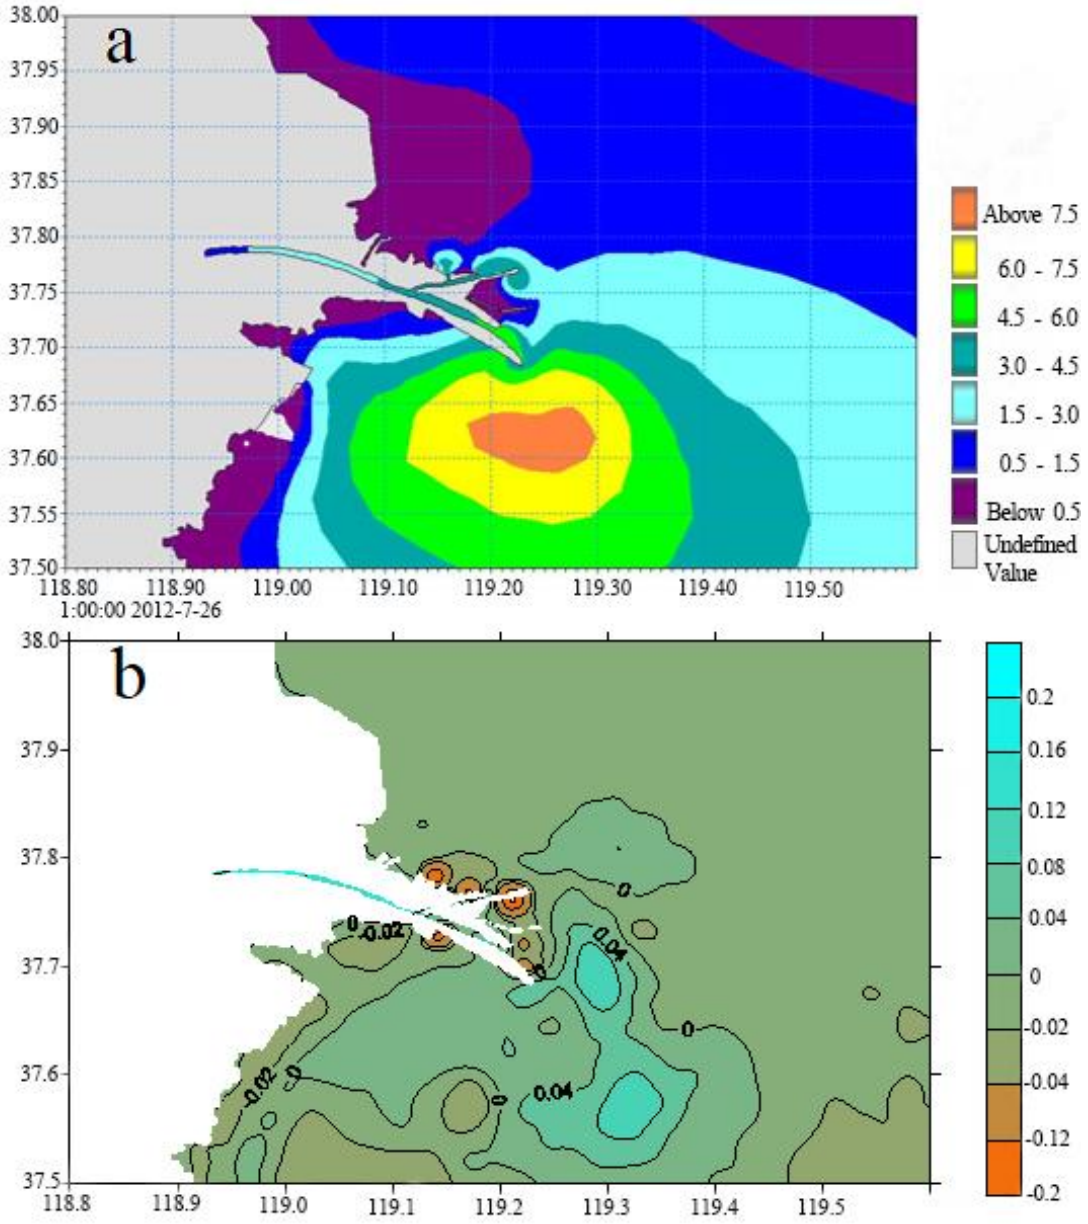

Figure 8. *Distribution of suspended load concentration (a) and distribution of scouring and silting under no-wave action (b, unit: m, positive value is scouring)*

Discussion

Zhang (2011) examined coastline changes in the Modern Yellow River delta in China on the basis of remote sensing and GIS techniques, the Landsat data obtained in 1987, 1996, and 2008. Peng et al. (2010) found that the water discharge and sediment load into the sea were decreasing from 1950 to 2007 with serious fluctuation at Lijin. Cui et al. (2011) extract mean high tide lines of the Yellow River estuary from 1976 to 2005, and explored relationships between the accretion–erosion of land and the runoff and sediment load of the Yellow River. Li et al. (2010) diagnosed the effects of different hydrodynamic factors on the transport of suspended sediment discharged from the Yellow River in the Bohai Sea. Peng et al. (2013) analyzed temporal and spatial evolution of coastline and subaqueous geomorphology in muddy coast of the Yellow River Delta based on measured data of coastline and bathometry.

The coast near the Yellow River estuary is mucky, and the sediment movement is generally dominated by the suspended load. The waves cause the sediment to enter a suspended state, and even if the suspended load is superimposed with the velocity of the smaller water, a large amount of sediment transport will occur. Studies have shown that, without considering the influence of waves, the stability of particles is actually mainly controlled by the water pressure of the film and the adhesion between particles, and the performance of gravity is not dominant. From this point of view, in the absence of waves, the finer the sediment particles, the more difficult it is to reach the conditions of suspension. It can be seen that the effect of waves on the sediment, especially the fine sediment, is more obvious. The waves in the Yellow River estuary are basically wind and waves. Although the average wave energy intensity is not large, due to the fine sediment of the Yellow River underwater delta, the levitation force of the waves on the seabed sediment is relatively large.

Impact of north wave

The north wind in the research area is the strongest, the north wind is the least in summer and the most in spring, autumn, and winter. The average wind speed is 12.3 m/s, and it is stronger at sea. In the cold wave wind on March 3-5, 2007, the average wind speed at sea reached 9-10, and the extreme wind speed is 21.5 m/s. Therefore, in this compromise, the wind speed of the north wind is designed to be 18 m/s and the direction is straight north.

In the process of northbound wind, 2.3 m waves can be formed in the sea near the Yellow River estuary, and the suspended sediment concentration reaches 13 kg/m^3, 20 times higher than that in the case of no waves. Under the influence of northbound waves, the east sea area of Laohekou river presents scour on the whole. There are two high value centers in the northeast and southeast, and the maximum net scour value is up to 1.8m. Inshore waves are small, and the sand-lifting capacity of waves is weak, showing weak deposition of about 0.2 m. The wave action in the new and old Yellow River estuary is mainly reflected by erosion. Erosion in the old Yellow River estuary is caused by both waves and currents.

The distribution of wave field under the action of northbound wind, the distribution of suspended sediment concentration under northbound wave action, the distribution of erosion and deposition under the influence of north waves and the change of scour and silt caused by the north wind waves are shown in *Figure 9*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1491114926

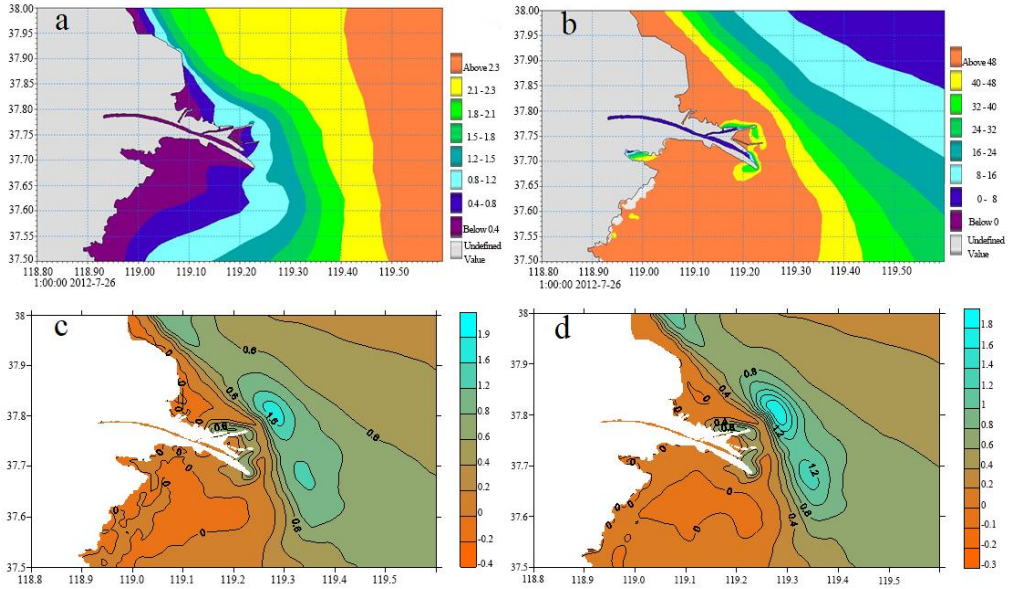

Figure 9. *a Distribution of wave field under the action of northbound wind (significant wave height, m), b Distribution of suspended sediment concentration under northbound wave action, c The distribution of erosion and deposition under the influence of north waves (m, positive for scour) d The change of scour and silt caused by the north wind waves (m, positive for scour)*

Impact of east wave

Under the influence of monsoon climate, the sea area is mainly dominated by south wind and north wind, and the direction is mostly east, forming southeast wind or northeast wind. In a year, 17 out of 33 north wind processes occur in the form of northeast wind, and the average wind is between north wind and south wind. At 21 o 'clock on October 11, 2003, affected by the typhoon, the wind speed of easterly wind increased to 20 m/s and then slowly decreased, and the extreme value is smaller than the maximum value of northerly wind. Therefore, the wind speed of easterly wind is designed to be 15 m/s.

The east wind formed a wave of 2 m in the research area, and the suspended sediment concentration at the depth of 10 m reached 10 kg/m^3, which is 16 times the concentration without waves. The distribution of net scour and silt under the influence of eastbound waves is similar to that of northbound waves, but the scour zone located in the east of the estuary has a smaller scope and intensity, and the net wave erosion depth is 1.7 m, while the direction of scour zone also changes to north-south direction.

The distribution of wave field under the action of eastbound wind, the distribution of suspended sediment concentration under eastbound wave action, the distribution of erosion and deposition under the influence of east waves and the change of scour and silt caused by the east wind waves are shown in *Figure 10*.

Impact of south wave

In the process of the south wind, sea and land breeze wind speed difference is small, the mouth observed port south winds only 3 times a year, with an average of 11.6 m/s, maximum value is 15.6 m/s, appeared in the July 29, 2006, considering the south wind frequency is low, the aerodynamic probability is less, so take the average wind speed for reference, the design wind speed 11.6 m/s, and set this direction due south.

DOI: http://dx.doi.org/10.15666/aeer/1706_1491114926

The south wind process can generate 1 m waves, and the suspended sediment concentration at 10 m reaches 2.7 kg /m^3, which is four times larger than the suspended sediment concentration under no wind condition. Compared with northbound and eastbound waves, southbound waves have weak erosion capacity, with maximum erosion thickness of less than 1 m.

The distribution of wave field under the action of southbound wind, the distribution of suspended sediment concentration under southbound wave action, the distribution of erosion and deposition under the influence of south waves and the change of scour and silt caused by the south wind waves are shown in *Figure 11*.

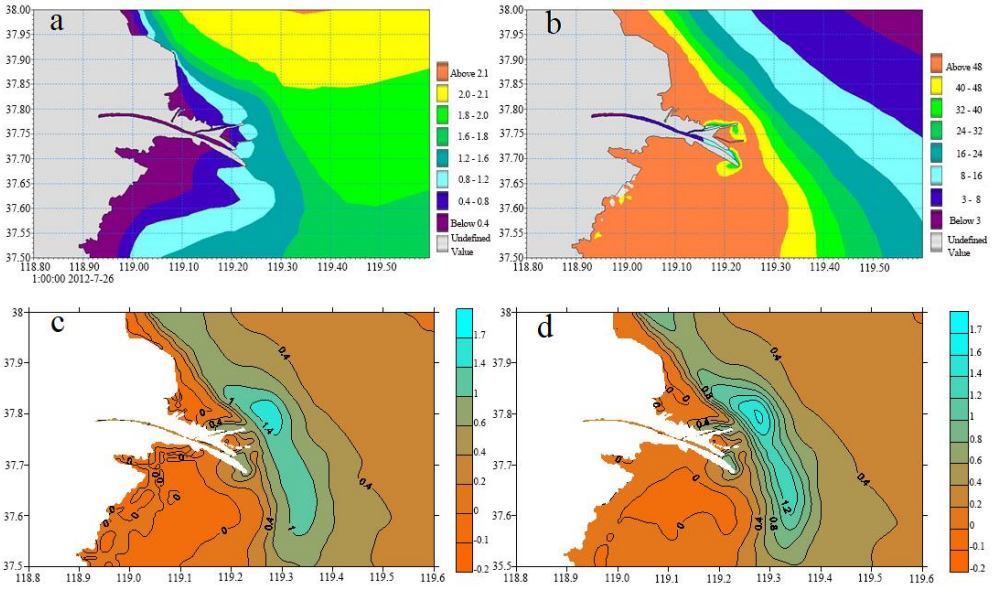

Figure 10. *Same like Fig. 9 but under east wave conditions*

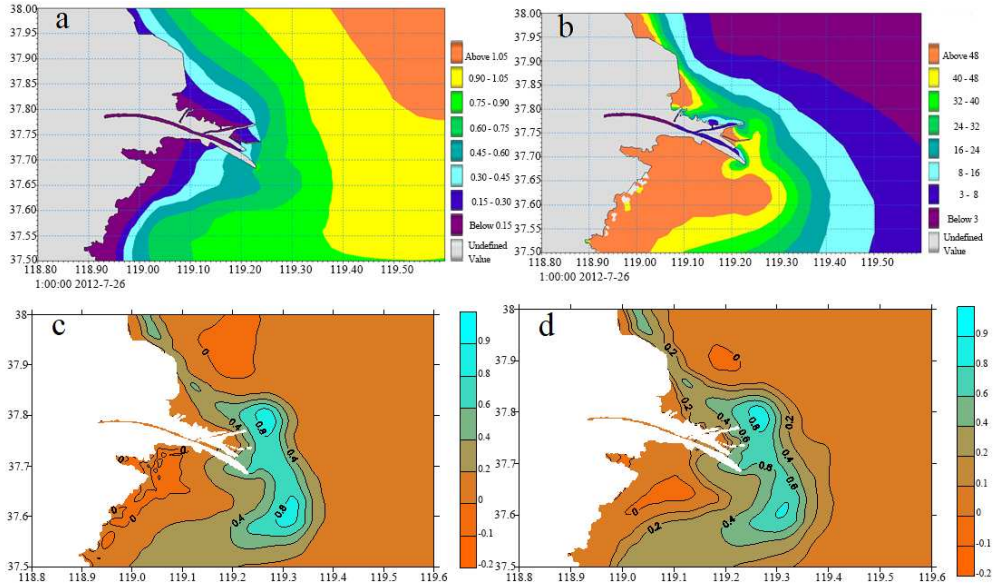

Figure 11. *Same like Fig. 9 but under south wave conditions*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1491114926

Conclusion

Sediment movement is influenced by runoff, tide, wave, sediment particle size, cumulative siltation area and the specific gravity and composition of the sediment. Wave is an important dynamic factor in the process of erosion and deposition of sediment, which plays an important role in the transport of river sediment into the sea, the re-suspension of seabed sediment and the formation of delta coast.

The suspended sediment concentration in the wave action is much higher than the concentration of the tidal current. The sediment concentration is 20, 16 and 4 times of that without wind wave under north, east and south wind condition respectively. The resuspension is strongest under north wind condition and weakest under south wind condition. The erosion is very strong at the north side slope of Yellow River influenced by north and east waves, and the erosion is relative weak at the south side.

The erosion of the shallow sea floor by waves is very obvious. Wind and waves cause strong scour zone to the east of the estuary. Under the condition of northbound waves, the scour zone is distributed in SE-NW direction, with the maximum scour thickness of 1.9 m. Under easterly wave condition, the scour range is more intense, and the scour zone shows a north-south trend, with the maximum scour thickness up to 1.7 m. The scour and silting action of southward wave is weak.

(Received 20th Jun 2019; accepted 16th Oct 2019)

Abstract. Olive knot disease caused by *Pseudomonas savastanoi* pv. *savastanoi* (*Psv*) is one of the major diseases influencing olive (*Oleae europaea* L.) production in Turkey. The disease incidence rate was found to range between 4 and 80% according to the 2015 and 2018 surveys. A total of 67 isolates were recovered from 7 symptomatic Turkish olive cultivars on a semi-selective medium, PVF-1, and then identified as *Psv* by biochemical and molecular tests. The isolates produced characteristic gall symptoms on olive plants and were consistently re-isolated. Fatty acid methyl ester (FAME) analysis indicated that the major fatty acid components were oleic acid (18:1), palmitoleic acid (16:1), and palmitic acid (16:0), and also clustered the olive strains into 2 groups. The repetitive element palindromic PCR (rep-PCR) primer, the BOXA1R primer, produced the discriminatory profile, with amplicon sizes ranging from ~ 200 bp to 2 kb, and categorized the olive strains into 2 separate groups. Pulsed-Field Gel Electrophoresis (PFGE) differentiated the olive *Psv* isolates into 3 discrete haplotype groups after the genomic DNA was digested with *Spe*I. This is the first study using PFGE to determine the genetic diversity of the *Psv* olive population.
Keywords: *FAME, Rep-PCR, olive knot, PFGE, Psv*

Introduction

The olive tree (*Olea europaea* L.) is a standout amongst the most significant and transcendent organic product trees found in western and focal Italy and Spain, southern Morocco and Tunisia, and western Turkey, and Greece (Loumou and Giourga, 2003). It serves as a source of edible fruit and oil for millions of people in various parts of Turkey. At present, global olive oil production exceeds 2,500,000 tons. In 2015, the aggregate production by the member states of the International Olive Oil Council (IOC) was 2,964,500 tons, 94% of the global production. EU production was 2,322,000 tons, whereas the individual IOC member state production showed Spain to be leading with 1,401,600 tons, followed by Italy with 474,600 tons, and then by Greece with 320,000 tons. Turkey produced 143,000 tons, Tunisia 140,000 tons, Morocco 130,000 tons, Algeria 83,500 tons, and Iran 5,000 tons (International Olive Oil Council, 2015). Olive knot disease is perhaps the earliest plant disorder to be specifically reported in ancient times, and is regarded as one of the most critical diseases that affects olive trees.

Olive knot disease is characterised by the production of hyperplastic galls on several plant parts (Nester and Kosuge, 1981). The disease is a serious threat to olive production in the Mediterranean basin, including Turkey, where several climatic conditions including rain, wind, humidity, and temperature favour pathogen

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1492714944

dissemination, growth, development, and infection processes. In Turkey, the disease is known to be infect olive (*Olea* sp.), oleander (*Nerium oleander*), fontanesia (*Fontanesia phillyreoides*), myrtle (*Myrtus communis*), and jasmine (*Jasminium officinale*) in Çanakkale, Muğla, Antalya, Samsun, Şanlıurfa, Bursa, Izmir, Tekirdağ, Adana, Mersin, and Hatay provinces (Basım and Ersoy, 2000; Tatlı and Benlioğlu 2004; Kavak and Üstün 2009; Mirik et al., 2011).

The development of olive knots relies on the ability of *Psv* to synthesise and secrete cytokinins and indolacetic acid (IAA) (Surico et al., 1985; Perez-Martínez et al., 2007; Quesada et al., 2010) as well as the functionality of its Type Three Secretion System (Sisto et al., 2004; Perez-Martinez et al., 2010; Tegli et al., 2011). Moreover, the capacity of *Psv* to actuate olive knot arrangement depends on the quorum sensing intercellular communication system moderated by N-acyl homoserine lactone (Hosni et al., 2011). The disease affects the yield and vegetative parts of the olive plants, and quality of olive oil (Schroth et al., 1973).

Members of *P. syringae,* including *Psv*, have been previously identified based on plasmid fingerprints (King, 1989), fatty acid fingerprinting (Stead, 1992), and analysis of protein (Van Zyl and Steyn, 1990). Recently, DNA profiling techniques such as Restriction Fragment Length Polymorphism (RFLP) (Manceau and Horvais, 1997), Amplified Fragment Length Polymorphism (AFLP), (REP)-REP1-1/REP2-1 (Sharples and Lioyd, 1990), Enterobacterial Repetitive Intergenic Consensus (ERIC)-ERIC1R/ERIC2 (Hulton et al., 1991), and BOXA1R (Louws et al., 1994), Randomly Amplified Polymorphic DNA (Krid et al., 2009), Pulsed-field gel electrophoresis (PFGE) (Chu et al., 1986), Multi Locus Sequence Typing (MLST) analysis of housekeeping genes (Berge et al., 2014), and a set of primers (Guilbaud et al., 2016) have been applied in genotyping and investigating strains and pathovars of *P. syringae*. The whole genome of *Psv* has also been sequenced and annotated (Rodriguez-Palenzuela et al., 2010). Although there are reports of the presence and identification of *Psv* in west Mediterranean region of Turkey (Basım and Ersoy 2000, 2001), few studies have been conducted to characterize this pathogen in detail.

The objective of this study was to evaluate the phenotypic and genotypic features of the *Psv* olive population in west Mediterranean region of Turkey by gas chromatographic analysis of fatty acid methyl esters (GC-FAME), repetitive element palindromic PCR (rep-PCR), and PFGE. To our knowledge, this is the first study of using PFGE to determine the genetic diversity of the *Psv* olive population.

Materials and methods

Sample collection

Samples were collected from olive trees showing symptoms of suspected knot disease by random sampling of different olive orchards in the districts of Antalya Center (7 orchards; 82 olive trees), Serik (3 orchards; 49 olive trees), Aksu (4 orchards; 35 olive trees), Kaş (6 orchards; 96 olive trees) and Döşemealtı (3 orchards; 58 olive trees) in the Western Mediterranean district of Turkey during May–August of 2015 and May–August of 2018. Samples from different local cultivars of olive trees such as Gemlik, Memeli, Ayvalık, Edinciksu, Edremit, Kan, and Memecik were collected for bacterial isolation. Approximately 320 olive trees in 23 orchards in total were surveyed. The samples were packaged and transported to the Department of Plant Protection of Akdeniz University, where the putative pathogen was isolated. *Psv* isolates (*Pss*I2,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1492714944

*Pss*I7, *Pss*I21, *Pss*I24, *Psn*9) obtained from surveys in Antalya province of Turkey in 2000 (Basım and Ersoy, 2000) were also included in this study (*Table 2*). The Myrtus strain, *Pss*I24, and Nerium strain, *Psn*9, were used for clustering. The disease rates within the olive plantations from which the contaminated samples were collected were assessed utilizing the equation as defined by Bansal et al. (1994):

$$\text{Disease incidence } (DI)\ (\%) = (\text{Number of diseased plants / Total number of plants}) \times 100$$

Isolation and identification of bacteria

Bacterial isolation was carried out on olive knots present on two-year-old twigs. Plant surfaces were disinfected using paper towel saturated with 96% ethanol; the decayed sections within the hyperplastic knot tissues were then cut off and grounded in sterile phosphate buffer (0.05 M Na_2HPO_4, 4.26 g; K_2HPO_4, 2.72 g; 1000 ml sterile dH_2O). A loop of bacterial suspension was streaked onto semi-selective PVF-1 medium (glycerol, 10 ml; sucrose, 30 g; casamino acid, 2.5 g; $K_2HPO_4.3H_2O$, 1.96 g; $MgSO_4.7H_2O$, 0.4 g; SDS, 0.4 g; agar, 16 g; 1000 ml dH_2O; pH 7.1) (Surico and Lavermicocca, 1989), King's B medium (KB; protease peptone, 20 g; Bacto agar, 20 g; glycerol, 10 ml; K_2HPO_4, 1.5 g; $MgSO_4$, 1.5 g; 1000 ml dH_2O, pH 7.2) (King et al., 1954) and Nutrient Sucrose Agar (NSA) (Nutrient Broth, 4.8 g; Bacto agar, 9 g; sucrose, 30 g; 600 ml dH_2O) (Surico and Lavermicocca, 1989). The *Psv* isolates utilized in this study are listed in *Table 2*. The bacteria were incubated at 28 °C on PVF-1, KB, and NSA media. Bacterial fluorescent pigment production was examined under UV light at 364 nm. In all, 67 isolates identified as *Psv* were recovered, then freezed in glycerol (30%) at -86 °C for long term storage and further analysis.

Putative *Psv* isolates were identified by several biochemical tests, including LOPAT, according to Schaad et al. (2001). The tests were carried out using flat, greyish-white, irregular margins or semi-translucent colonies grown on PVF-1 medium. The identity of the *Psv* isolates was confirmed by GC-FAME analysis (Stead, 1992) and PCR. The *Psv* isolates were identified directly from bacterial suspension as well as from purified genomic DNA by PCR utilizing primers, IAALN1/IAALN2 (Pelyaver et al., 2000) and PSS1/PSS2; PSS3/PSS4 (Basım and Ersoy, 2001). The polymerase chain reaction (PCR) conditions are given in *Table 1.*

Pathogenicity test

For putative *Psv* isolates, pathogenicity tests were carried out by inoculating the stems of a one-year-old Gemlik olive cultivar. The bark of the stem was wounded with a sterilized needle dipped in bacterial suspension, which contained ~10^8 CFU/ml, and the wounds were then covered with Parafilm for 3 days. The inoculated olive plants were kept in a controlled-room at 25 ± 2 °C and 80-85% RH and monitored for symptom development according to Surico and Lavermicocca (1989). Olive plants similarly treated with reference strains or sterile dH_2O were utilized as positive and negative controls, respectively.

GC-FAME analysis

GC-FAME analyses were performed on each *Psv* isolate as stated in the manufacturer's specifications to determine the phenotypic characteristic of the isolates. The *Psv* isolates were growth on tryptic soy broth agar at 27 °C for 24 h. The each *Psv*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1492714944

isolate (a loopful) was blended within a glass tube containing 1.2 N NaOH in methanol: H_2O. The tubes were shortly vortexed, kept in a bubbling water bath for 5 min. The tubes firmly vortexed once more for 10 s and were exchanged to the bubbling water bath for 30-min warming to finish reaction. Two ml methylation arrangement (325 ml 6.0 N hydrochloric acid, 275 ml methyl solution) was included to the tubes after the tubes were cooled to room temperature. The samples were without further ado vortexed, warmed at 80 °C for 10 min. The samples were cooled quickly on ice, and afterward 1.25 ml the extraction arrangement (N-hexane/methyl tert-butyl ether (1:1; v/v) was included. The samples were tenderly blended utilizing a tube revolver for 10 min. The under aqueous phases of the samples were discarded by a micropipette. Three milliliters of the sample clean up solution (10.8 g NaOH dissolved in 900 ml H_2O) was included into the sample, and tenderly blended for 5 min. And after that ~ 2/3 of natural period of the examples was moved into a dull GC vial. These final extracts were analysed with the HP 6980 GC System (Agilent Technologies, CA, USA), and the MIDI system (Microbial ID Inc., USA) with a 25 m × 0.2 mm silica capillary column was performed. The 67 isolates of *Psv* were identified, and phenotypically characterized based on FAME composition by dendrogram analysis using the MIDI software version 6.0.

DNA extraction

Genomic DNA from *Psv* isolates was extracted based on a modified CTAB method (Doyle and Doyle, 1990), and was dissolved in 50 µl TE buffer. The concentration of DNA was adjusted to 100 ng/µl with TE, using a Nanodrop (Thermo Fisher Scientific, Waltham, MA, USA) and after which the DNA solution was stored at 4 °C.

Rep-PCR

Evaluation of genetic differences among *Psv* was performed by Rep-PCR using primer based on repetitive extragenic palindromic (REP) sequences, BOXA1R (Louws

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1492714944

et al., 1994). The reaction mixture consisted of 4 µl DNA, 27.8 µl ddH_2O, 5 µl 10x *Taq* buffer, 3 µl $MgCl_2$, 8 µl 0.1 mM dNTPs, and 3.5 U *Taq* Pol. The BOX-PCR conditions are given in *Table 2*. PCR products (10 µl) were fractionated by gel electrophoresis (75 V, for 7 h) on 0.5% standard and 0.5% NuSieve agarose. A 1 kb DNA size marker (Fermantas, Vilnius, Lithuania) was used. The agarose gels were stained with ethidium bromide (0.5 µg/ml) for 20 min., and pictured using a imaging system (Vilber Lourmat transilluminator, France). The outcomes were analysed by Bio-gene gel analysing software (VilberLourma, France). UPGMA (Sneath and Sokal, 1973) and Dice coefficient (2a/(2a + b + c) (Dice, 1945) were utilized for the DNA fingerprint matching and dendrogram analyses.

PFGE

The *Psv* isolates were cultured in 5 ml Nutrient Broth at 28 °C at 140 rpm shaking for 24 h. Cell suspensions were adjusted to an OD of 0.3 A (approximately 1×10^8 CFU/ml) at 600 nm by utilizing a spectrophotometer (Eppendorf, Hamburg, Germany). The bacterial suspensions (1.5 ml) were centrifugated at 14,000 rpm for 2 min, pelleted, and resuspended in 1 ml sterile dH_2O. This procedure was repeated twice. After suspension of the cells in 500 µl TE buffer (10 mM Tris-HCl, pH 8.0; 10 mM $MgCl_2$; 25 mM EDTA, pH 8.0),1×10^8 CFU/ml cells were encapsulated in 500 µl 2% (w/v) low melting point agarose (Bio-Rad Laboratories, Hercules, CA, USA), and transferred into sterile fitting-molds (Bio-Rad Laboratories, Hercules, CA, USA). The hardened agarose fittings at 4 °C for 20 min were returned to a 1.5 ml microfuge tube. Agarose fittings with 1 mg/ml Proteinase K in 250 mM EDTA (pH 9.5) and 25% (w/v) N-laurylsarcosine were incubated overnight at 50 °C. The agarose plugs were returned to a sterile tube containing 1.5 ml sterile 250 mM EDTA (pH 8.0) at 4 °C until used. Complete restriction digestion of 1/5 of agarose fittings was performed with 15 U of *Spe* I, *Ase* I, and *Xba* I (Hacıoğlu et al., 1997) at 37 °C for 7 h. The fittings were inserted into 0.9% (w/v) agarose gel in 0.5x TBE buffer [44.5 mM Tris-HCl, 44.5 mM Boric Acid, 1 mM EDTA (pH 8.0)] at 14 °C all through the kept running by utilizing a pulsed field gel electrophoresis unit (CHEF-DR III) (Bio-Rad Laboratories Hercules, CA, USA).

The optimal migration condition was used, depending on DNA size, at 200 V with an angle of 120°, with an underlying switch time of 5 s and a last switch time of 45 s for 22 h. The gel was stained with 0.5x TBE buffer containing 0.5 µg/ml ethidium bromide for 200 min. Low–Range (New England Biolabs, MA, USA) and Yeast Chromosomal PFGE (*Saccharomyces cerevisiae*) markers were utilized as molecular size markers. The gel image was obtained by using a VilberLourma Monochrome ½" IT CCD camera. DNA fingerprint patterns and sizes were analysed by Bio-gene gel imaging programming (Vilber Lourma, France). UPGMA (Sneath and Sokal, 1973) and Dice coefficient (2a/(2a + b + c) (Dice, 1945) were utilized for the DNA fingerprint matching and dendrogram analyses.

Results

Isolation and identification of bacteria

The isolates and their locations are given in *Figure 1* and *Table 2*. The pathogens were characterized after isolation from infected olive trees, thereby establishing their presence across the various districts of Antalya province in Turkey. The incidence of the olive knot disease reported for each district by Bansal et al. (1994) are: 80% in Serik, 20% in Döşemealtı-Kırkgöz, 17% in Aksu-Topallı, 10% in Kaş-Dalyan, and 4% in Antalya-Center.

Psv grew well and produced unique levan-negative colonies on selective PVF-1, KB, and NSA media. The colonies grown on KB medium were flat, with a diameter ranging from 1–3 mm, greyish to white colour, and irregular margins. The bacteria produced fluorescence pigment on both KB and PVF-1 media under UV light. The colonies grown on PVF-1 were greyish white, slightly raised, smooth, and relatively small (2–3 mm). The colonies grown on NSA medium were grey or pale yellow, slightly raised or flat with a diameter of 3–5 mm. LOPAT indicated negative levan, oxidase, potato

soft rot, and arginine dehydrolase tests, but all isolates showed positive hypersensitive reaction in the tobacco plant. In all, 67 isolates were recovered from diseased olive trees in Turkey and identified by PCR. The numbers of groups and strains in each group are presented in *Table 2*.

The pathogenicity of the isolates on the one-year-old Gemlik olive seedlings produced characteristic knot symptoms with variable sizes. The healthy olive seedling treated with sterile dH_2O as a control did not show any symptoms (*Fig. 2a*). The pathogen was reliably re-isolated from the knots in the repeated tests, establishing *Psv* as the causal agent of the knot or gall disease in olive plants, thereby satisfying Koch's postulates (*Fig. 2b* and *c*).

The relationships among the *Psv* strains were established based on FAME analysis. All 67 isolates recovered from the olive plant hosts in Antalya province and the reference strains were analysed. The results show percent similarities of 78.50–100% to the MIS library. The major fatty acids were palmitic acid (16:0), palmitoleic acid (16:1), and oleic acid (18:1) (*Table 3*). The FAME cluster analysis based on the Euclidean distance categorized the Turkish olive strains into 2 groups (*Fig. 3*). Each clade is unique, showing a close relationship among each other.

Rep-PCR

The primer, BOXA1R, which was used to amplify the repetitive DNA sequence of *Psv*, showed various genomic fingerprints. The results obtained by the BOXA1R primer pair showed variability among the *Psv* strains. This primer pair produced different polymorphic patterns among the strains with amplification fragments ranging from ~250 to 2250 bp (*Fig. 4*). BOX PCR cluster analysis categorized all the Turkish olive strains into 2 groups (*Fig. 5*).

PFGE

All 67 isolates and reference strains were evaluated by using PFGE. The results showed various discrete DNA patterns of *Psv* after digesting the total genome with *Spe*I. The restriction digestion of the *Psv* genome yielded fragments which ranged from 9 to 1000 kb (*Fig. 6*). *Ase* I and *Xba* I did not effectively digest genomic DNA in this study. The Turkish olive strains were separated into 3 discrete PFGE groups (*Fig. 7*). Based on the cluster analysis, there was nearly identical linkage between the haplotype

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1492714944

group I and the reference strain. The percentage similarity among the haplotypes as shown by the cluster was 42–100% (*Fig. 7*). Based on the cluster analysis of PFGE, haplotype group I consisted of 38 haplotypes and reference strain NCPPB639; haplotype group II (21 haplotypes): haplotype group III (11 haplotypes), and the myrtus isolate was placed into haplotype group IV as *Figure 7* and *Table 2*.

Discussion

Of the isolates collected from diseased olive plants during the 2015–2018 survey, 67 were found to be heterogenic and divided into 3 haplotype groups by PFGE. From the survey results, the highest percentage of the disease and the olive plant cultivars from which the pathogen were isolated were from the Serik district, and the highest infected (80%) or susceptible cultivar from this district was the Gemlik cultivar. The least infected orchard recorded was from the Antalya-center district. When all the collected samples across the various districts were compared, the Gemlik cultivar showed the highest percentage of infection. Some commercial olive cultivars have been found to be considerably tolerant to olive knot disease (Penyalver et al., 2006). The high rate of infection in the Gemlik cultivar could be due to a high susceptibility to this pathogen. It could also be also be attributed to the exposure of these varieties to powerful winds common in the coastal regions of Antalya-center and Kaş-Dalyan. These strong winds create wounds on the plants which allow entrance for the pathogen. Additionally, the fungus, *Cycloconium oleaginum*, a causal agent of olive leaf spot disease that results in defoliation, creates wounds that can serve as entrance point for *Psv*.

The different groups of *Psv* strains according to PFGE occurred in the same districts because of the large olive plant production as well as different cultivars of olive grown in these areas. There was no association of genetic diversity of Turkish *Psv* population with olive cultivars of isolation. The results of Scortichini et al. (2004) were supported by our findings. On the other hand, Moretti et al. (2008) and Krid et al. (2009) reported an association with geography and olive cultivars.

Understanding the *Psv* population may help to enhance the present control management of olive knot disease. *Psv* isolates obtained from infected olive trees in various geographical region of the world are different. In a few studies, various *Psv* populations were gathered from various parts of the world, including 360 isolates from

Italy (Scortichini et al., 2004), 71 isolates from Italy, USA, Greece, Portugal, former Yugoslavia, UK, the Netherlands, and France (Sisto et al., 2007), 62 isolates from Spain, Italy, Serbia, France, Portugal, USA, Algeria, Greece, Jordan, and Tunusia (Quesada et al., 2008), 58 strains from Tunusia (Krid et al., 2009), 31 isolates from Italy (Cinelli et al., 2014), 124 isolates from various Mediterranean countries (Moretti et al., 2017), and 19 isolates from Japan (Tsuji et al., 2017)

Scortichini et al. (2004) analysed 360 Italian *Psv* isolates and reported the presence of 20 DNA fingerprint patterns by rep-PCR. The 44 Spanish *Psv* isolates were grouped into 3 different groups, and the only 6 Italian isolates were placed into 3 different groups by the presence of IS*53* (Quesada et al., 2008). The 58 Tunisian *Psv* isolates were clustered into 3 different groups by RAPD (Krid et al., 2009). Recently, Moretti et al. (2017) analysed 124 *Psv* isolates from 15 different countries and grouped the isolates into 2 clusters and 4 subclusters by MLST and rep-PCR. The 19 Japanese isolates were differentiated into 5 different groups by rep-PCR (Tsuji et al., 2017).

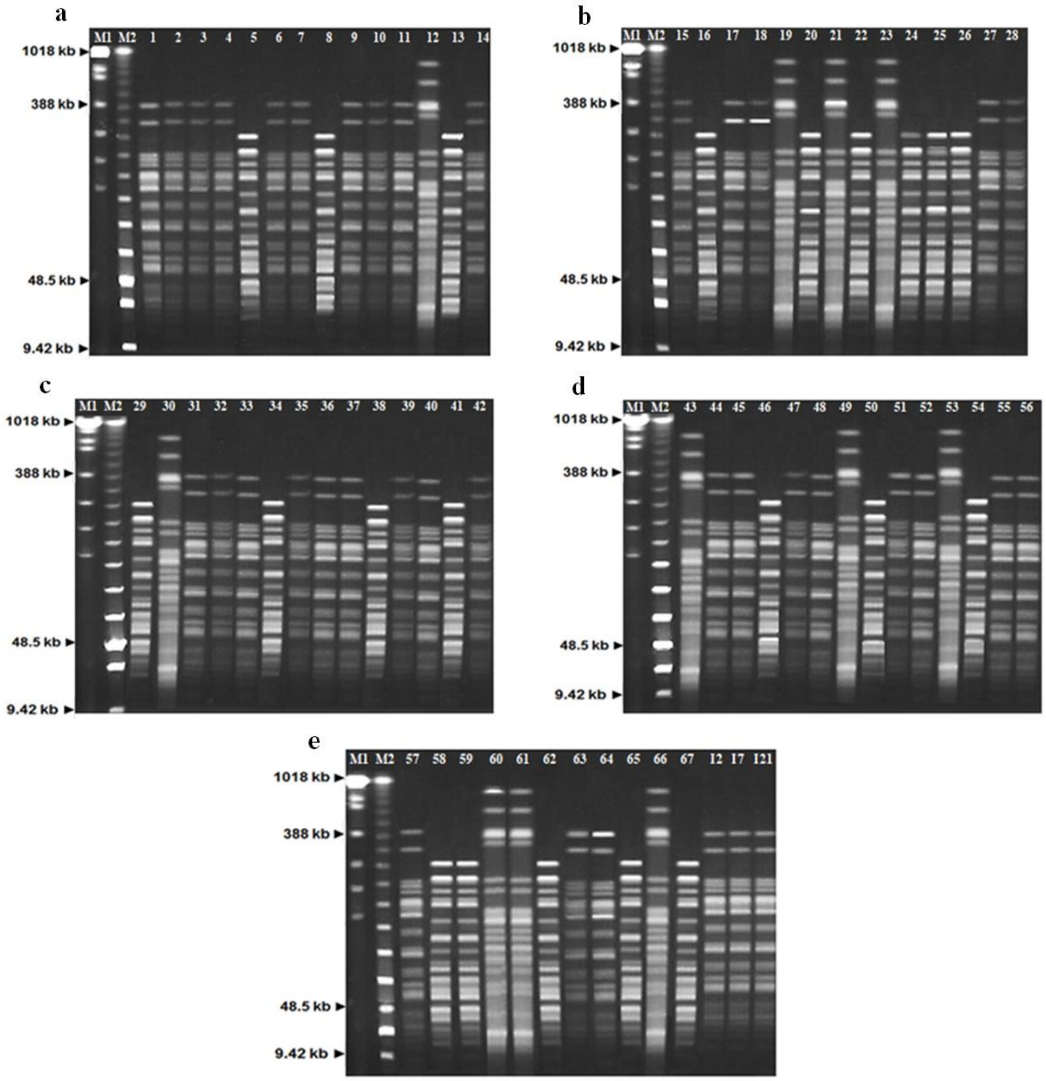

Figure 6. *(a, b, c, d, e) Genomic DNA fingerprints from olive strains of Psv in Turkey by PFGE using Spe I. Lanes: M1 = DNA size standards of Saccharomyces cerevisiae, M2 = Low-range PFGE marker. Lanes: 1–67 = Pss1–Pss67, respectively; Lane: I2, I7, I21 = PssI2, PssI7, PssI21, respectively*

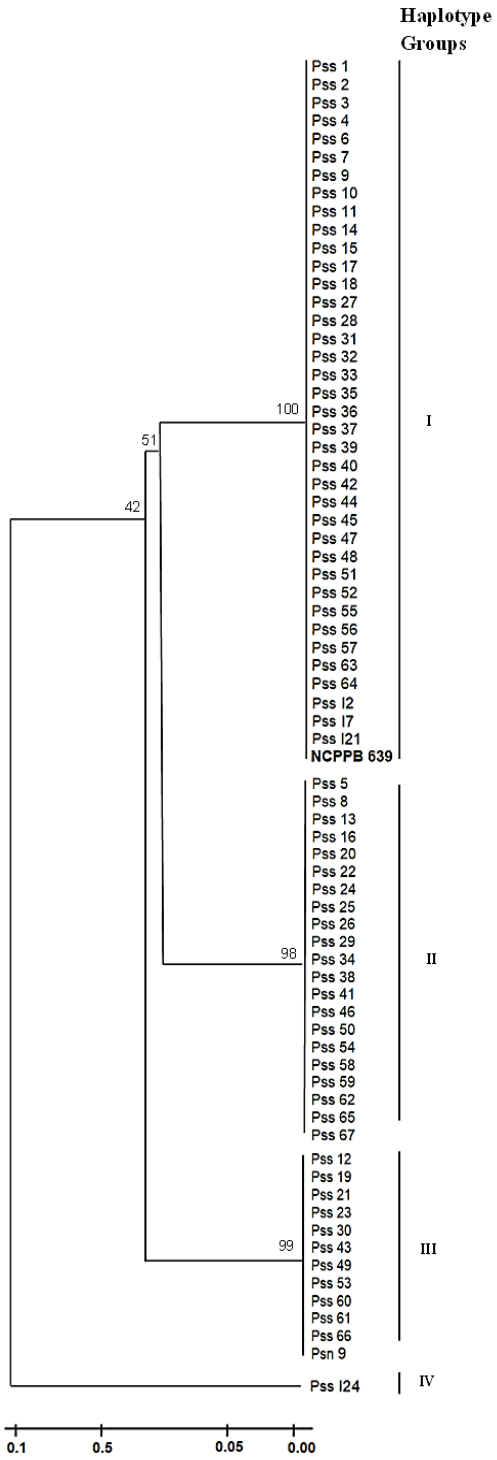

Figure 7. *Unweighted average linkage dendrogram of cluster analysis of Psv (Table 2) haplotype groups generated by PFGE patterns with Spe I. Number of horizontal axes indicates percent similarity as determined by Dice coefficient*

There have been reports of the presence of olive knot disease caused by *Psv* in the Aegean region, which is one of the olive growing provinces of Turkey (Tatlı and Benlioğlu, 2004) and in the western Mediterranean region, specifically in Antalya

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1492714944

province (Basım and Ersoy, 2000), in oleander plants in the South-eastern Anatolia, specifically in Şanlıurfa (Kavak and Üstün, 2009), and from the Adana, Samsun, and Tekirdağ provinces of Turkey (Mirik et al., 2011).

The morphological and biochemical tests indicated that the 3 media used in this study produced colonies typical of *Psv*. Considerable heterogeneity in the colonies established by *Psv* strains isolated from different cultivars of olive in various localities have been reported in Italy (Surico and Marchi 2003). LOPAT showed isolates to be levan negative, and all isolates produced a positive hypersensitive reaction in tobacco plant. The LOPAT profile (Lelliott et al., 1966) and other tests described by Lelliott and Stead (1987) were used to separate a typical *Psv* strain from *P. syringae* subsp. *syringae*. Janse (1981) observed that some *Psv* strains isolated from various host plants had almost similar physiological and biochemical dispositions. All isolates were confirmed to be pathogenic on a one-year-old olive plant, but not on an oleander plant. Our result is in concordance with the findings reported by Perez-Martinez et al. (2007).

Table 3 indicates the relative (percent) total fatty acid methyl esters as found by FAME analysis of the *Psv* isolates, which were entered into the standard MIDI library. The FAME cluster categorized all the strains isolated from olive plants collected from various districts of Antalya province which were clustered into 2 groups based on Euclidean metrics. The FAME analysis provides useful information with regards to the phenotypic identification of the pathogen, but it is not an effective technique for discriminating between strains.

The diversity study was carried out using rep-PCR with primer pair, BOXA1R, which was found to be informative and discriminatory for all the *Psv* isolates tested in this study, and produced polymorphic patterns corresponding to different amplification fragment sizes (*Fig. 4*). All the strains isolated from olive plants formed 2 groups based on the BOX-PCR. Although the BOX-PCR was found to be effective at differentiating *Psv* isolates, its discriminating ability was less than that of PFGE as observed in this study. Interestingly, it could be seen from the cluster tree that strains from different districts of a province or geographical location showed similar genetic homogeneity and were grouped together in one clade by the BOX-PCR cluster analysis (*Fig. 5*).

The genetic variability among the *Psv* strains was further confirmed by using PFGE after restriction digestion with *Spe* I, a rare-cutting enzyme. Three different haplotype groups were produced based on the DNA fragment patterns generated as compared to FAME and BOX-PCR analyses, which categorized the isolates from olive plant hosts into 2 groups each. The results of this study recommend that the FAME and BOX-PCR strategies were not capable as PFGE to separate *Psv* strains. The PFGE utilizing rare-cutting endonuclease *Spe* I given the foremost comprehensive comes about. The effective discriminatory ability and reproducibility of PFGE makes it one of the foremost broadly utilizied method for comparative fingerprinting of most bacterial species (Sails et al., 2003; Lukinmaa et al., 2004; van Belkum et al., 2007). Based on PFGE, most *Psv* strains were placed in haplotype group I with reference strain NCPPB639. The other strains were separated into 2 haplotype groups, resulting in a total 3 different haplotype groups in the olive *Psv* population. This heterogeneity among the *Psv* population can be clarified by even exchange of plasmids and chromosomal genes as seen in *Xanthomonas* and *Pseudomonas* pathovars (Canteros et al., 1995; Basım et al., 1999; Sundin, 2007). Based on PFGE, the isolate *Pss*9 from *Nerium oleander* was placed in haplotype group II, along with several olive strains. However, the same strain was placed in a different haplotype group by rep-PCR analysis.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1492714944

Comparative comes about were found by Moretti et al. (2017). *P. s*. pv. *nerii* and *P. s.* pv. *fraxinii* were plainly isolated from the *Psv* population by utilizing rep-PCR. Based on MLST, isolates of *P. s.* pv. *nerii* and *P. s.* pv. *fraxini* pathovars clearly have a same genetic feature as *Psv*, and may have adjusted to oleander and fraxinus, individually, after *Psv* risen as an olive plant pathogen (Moretti et al., 2017).

Conclusion

Our results show that PFGE using *Spe*I has an effective discriminatory capability for genotypic analysis of *Psv* population. The present study provides important outputs to better comprehension of the genotypic and phenotypic structure of the *Psv* population in Turkey. The results about given an incredible opportunity for following strain shifting in the *Psv* population in future, and for olive breeding programs pointed at the advancement of an olive cultivar safe to the distinctive *Psv* strains.

(Received 21st Jun 2019; accepted 16th Oct 2019)

Abstract. In this study, milk yield from culture, cross-bred, and native cattle breeds in 7 geographical regions of Turkey were investigated by multivariate analysis of variance (MANOVA) in 2015. The values of Pillai's Trace, Wilks' Lambda, Hotelling's Trace and Roy's Largest Root statistics used for the MANOVA test were 0.522, 0.546, 0.711 and 0.490, respectively. The corresponding F values for these statistics were found to be 2.422, 2.518, 2.594 and 5.634, respectively. Mean annual milk yield of cross-bred, culture, and native cattle breeds reached to be 3776.355, 2692.803 and 1311.513 kg, respectively. Therefore, the results of these statistics are very close to each other. As a result of the MANOVA test, the difference within milk yield between the regions was not significant for culture and native cattle breeds, whereas a significant difference was found in hybrid breed cattle ($P < 0.001$). As a result of the Bonferroni test, it was found that the milk yield difference in hybrid cattle was due to the difference in yield between Eastern Anatolia-Aegean, Eastern Anatolia-Marmara, Southeast Anatolia-Aegean and Southeast Anatolia-Marmara regions.

Introduction

Production of animal products and per capita consumption of animal products are among the indicators of the development level of a country (Şapdeniz, 1993). Milk is one of the most important animal products. It is an essential nutrient for a sufficient and balanced human diet and for fulfilling the protein need of the ever-growing world population. Milk consumption is significant in the diets of people of all ages. Although milk has a key role in human diet and per capita consumption of milk has been on the rise in Turkey in recent years, it has not reached to a desired level yet (Akman, 2017).

Turkey has a great potential for increasing animal production due to its geographical position and land structure favorable for animal breeding. While Turkey ranks among the leading countries in terms of animal numbers, the yield per animal is not at a desired level. Therefore, researches performed in Turkey aim to improve the yield obtained per animal rather than to increase the number of animals (Yaylak, 2003). In the republican period, culture breeding cattle were imported from abroad for the improvement of the indigenous breeds. Cattle import activities, which started in the republican period, have continued until today. Currently, 88% of the cattle population consists of culture breeds and cross breeds. While the number of indigenous breeds has continuously reduced in the whole cattle population, the number of cross breeds has shown a significant increase. In researches performed to improve the milk yield obtained from cattle in Turkey, culture cattle breeding has been prioritized since 1958 (Kumlu and Akman, 1999).

In researches on dairy cattle breeding in Turkey, the improvements in milk production, the effects of environmental and genotypic factors and the rate of these factors were emphasized (Alpan and Arpacık, 1998). Milk yield in cattle is affected by two factors, which are; the genotype of the animal and favorable environmental conditions (Tuncel, 1994). Breeding methods and selection are used to improve the milk yield capacity in terms of genetics. On the other hand, environmental factors can lead to long-term and daily changes.

Age, breed, live weight, lactation method, number of daily milking, feeding, ambient temperature, calving season, duration of dry period, diseases and exercises are among the factors that affect milk yield in cows.

In Turkey and in other countries, various researches have been performed on 305-day milk yield of the Holstein Friesian cattle (*Table 1*).

Table 1. *305-day milk yield of the Holstein Friesian cattle in Turkey and in other countries*

Year and authors	Country	Average milk yield	Number of animals

According to the Turkish Statistical Institute (TSI), while the number of cattle in Turkey was the highest in 1981 (15 981 000), the number was 13 994 071 in 2015. This indicates that, whereas Turkey had an important cattle potential in the past, this potential has reduced later. According to the statistics of the year 2015; 16 933 520 (90.77%) tones of the 18.654.682 tones milk annually produced in Turkey, were obtained from cattle (TSI, 2015). In this respect, cattle milk has an increased value as it has the highest share.

5.58% of the milk obtained from cattle was from indigenous breeds, 37.30% of it was from cross breeds and 57.12% of it was from culture breeds. As for the annual milk yield from cattle; around 1307 kg was from indigenous breeds, around 2677 kg was from cross breeds, around 3743 was from culture breeds and it was around 2581 kg in general (TSI, 2015).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1494514959

According to FAO (2017), cattle breeding is most common in Brazil with 214,889,796 animals. India ranks second with 185,103,532 animals and the USA ranks third with 93,704,600 animals. Turkey ranks twenty third in the world with 14 080 155 cattle. FAO (2017) also reported that, the USA ranks first in cattle milk production with 97 734 736 tones, India ranks second with 83,633,570 tones and Brazil ranks third with 33,490,810 tones. Turkey ranks ninth in the world by producing 18 762 319 tones cattle milk. These indicate that Turkey has a key role in cattle milk production.

The aim of the study is to examine the milk yields from indigenous, cross and culture breeds in 7 geographical regions of Turkey and to analyze the region-based variations in yearly milk yield.

Materials and methods

Material

Research material consisted of information obtained from the website of the Turkish Statistical Institute (TSI) with regards to the number of indigenous, cross and culture breeds cattle and the milk yield from these cattle, as presented on provincial-basis for the year 2015. Turkey Statistical Institute (TSI) of the data compiled by the relevant institutions (Ministry of Agriculture and Forestry) were taken from the records.

The amount of milk obtained from the cities of 7 geographical regions in Turkey was divided by the number of cattle milked, in order to calculate the average yearly milk yield. The values obtained were individually identified and analyzed for indigenous, cross and culture breeds. Statistical evaluations were made using IBM SPSS version 23.

Method

Multivariate analysis is performed when there are 2 or more dependent variables in each group with 2 or more members. In other words, mean vectors of more than 2 groups (in k) are compared (Alpar 2011). Comparison of the mean vector of k population for the MANOVA model (*Eq. 1;* Johnson and Wichern 2002):

$$Y_{ijk} = \mu + \alpha_{ij} + \varepsilon_{ijk} \quad \text{(Eq.1)}$$

here, Y_{ijk} : is the k. observed value of the j. variable in i. population, α_{ij}: is the effect of j. variable in i. population, ε_{ijk}: is the error value in observed k. of the j. variable in i. Population.

Error terms (ε_{ijk}) have a normal distribution that are independent of each other, with zero means and $\sum$ covariance matrix (Jeremy 1974). $\bar{x}_i$: is the mean vector of i. group, $\bar{x}$: is the general mean vector, n_i: is the number of observations in i. group, S_i: is the variance-covariance vector in i. group (*Eqs. 2* and *3*):

$$B = \sum_{i=1}^{k} n_i (\bar{x}_i - \bar{x})\,(\bar{x}_i - \bar{x})' \quad \text{(Eq.2)}$$

$$W = \sum_{i=1}^{k} (n_i - 1) S_i \quad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1494514959

Eigenvalues of the BW^{-1} matrix are λ_i. The largest root test statistics of Roy is the highest λ_i value.

Lawley-Hotelling trace test (*Eq. 4*):

$$T_0^2 = \sum_{i=1}^{s} \lambda_i \quad \text{(Eq.4)}$$

Pillai's Trace statistics (*Eq. 5;* Lehmann 1986):

$$T = \sum_{i=1}^{s} \lambda_i/(1+\lambda_i) \quad \text{(Eq.5)}$$

Here, s is the eigenvalue number. Wilks Lambda statistic is developed by Rao (1973) and is shown as (*Eq. 6*):

$$\Lambda = \prod_{i=1}^{s} 1/(1+\lambda_i) \quad \text{(Eq.6)}$$

One of the key hypotheses needed for the implementation of the multivariate analysis (MANOVA) is the homogeneity of the variance-covariance matrices. This is determined by the 'Box's M' test (*Eq. 7*).

$$M = \sum_{i=1}^{k}(n_i - 1)ln|S| - \sum_{i=1}^{k}(n_i - 1)ln|S_i| \quad \text{(Eq.7)}$$

In this Box's M statistic, S is the covariance matrix, S_i is the covariance matrix of each group (Özdamar 2013). For the multiple comparisons, paired comparisons regarding the Bonferroni approach are made in order to form simultaneous confidence intervals (Hsu 1996; Everitt 2001). Multiple test statistics are used in the multivariate analysis in order to test the H_o hypothesis. The Wilks Lambda test statistic presenting F distribution when the number of variables become 1, 2 for the first time, is the most common among these test statistics and calculated as such:

Wilks Lamda test statistic; *Equation 8* used in the calculation of the test variate F statistic is written as:

$$1 + \frac{\text{G.A.K.O}}{\text{G.İ.K.O}} \quad \text{(Eq. 8)}$$

and inverted for the multivariate B and W matrices, to obtain (*Eq. 9*):

$$\frac{1}{1+\frac{G.A.K.O}{G.İ.K.O}} = \frac{1}{1+\frac{B}{W}} = \frac{|W|}{|B+W|} = \Lambda \quad \text{(Eq.9)}$$

The Λ statistic here is called as the Wilks Lambda statistic.

In multivariate analysis, this ratio is used in place of the F statistic used in univariate analysis and takes a value between 0 and 1. If there is no group effect, Λ value is 1 if B = 0. Accordingly, the Ho hypothesis is accepted when Λ gets a value close to 1. If matrix B is bigger than matrix W, Λ value gets closer to zero (0). In this case, the Ho hypothesis is rejected. As in univariate analysis, there is a correlation between Λ and T^2 in multivariate analysis, too.

When k = 2 (*Eq. 10*):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1494514959

$$\Lambda = \frac{1}{1+\frac{T^2}{N-k}} \quad \text{(Eq.10)}$$

When k = 2, Λ and T^2 statistics show p and N-p-1 freedom degree F distribution. When p = 1 (*Eq. 11*):

$$\Lambda = \frac{1}{1+B/W} = \frac{B}{W}\frac{N-k}{k-1} = F \quad \text{(Eq.11)}$$

Results and discussion

Normal distribution of data and covariance matrices homogeneity test were performed based on the hypotheses needed for the covariate analysis (MANOVA). Outlier observations were found in the normality test (*Fig. 1*). Box's Test was performed in the equalities of covariance matrices.

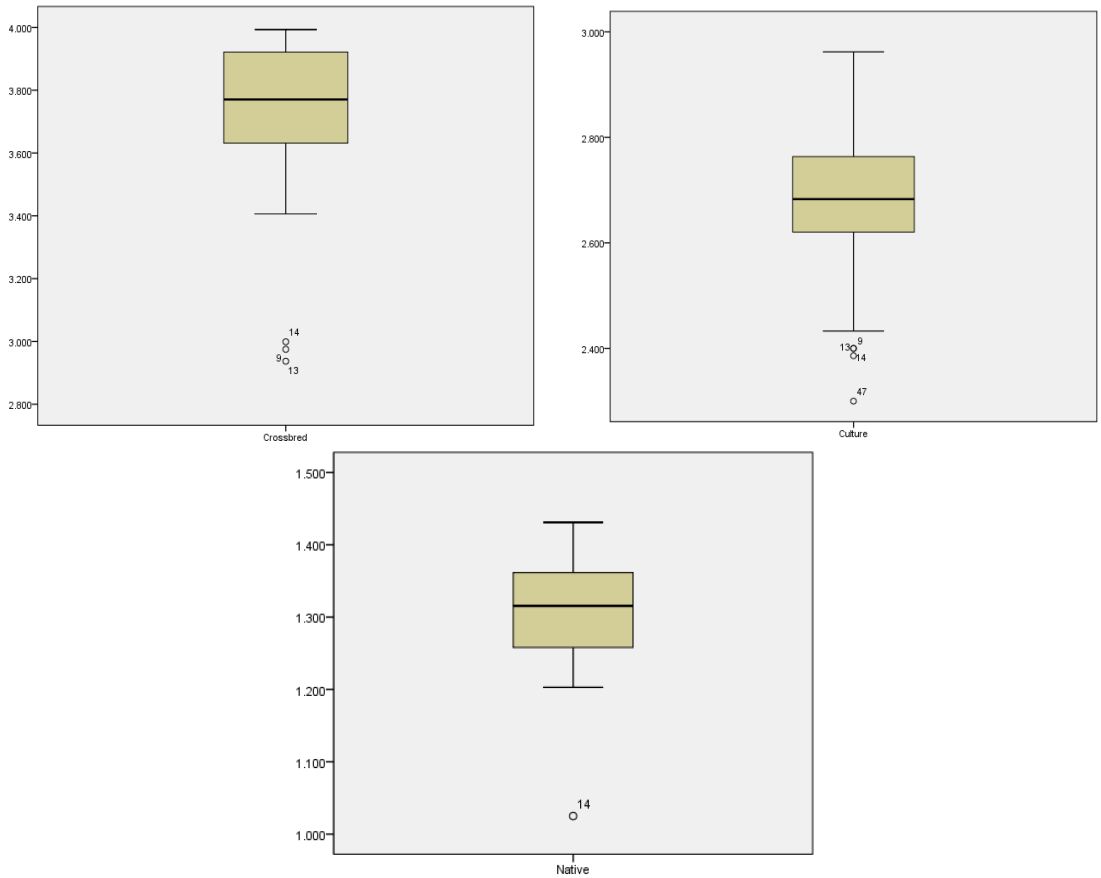

Figure 1. *Outlier observation graph of data (yield-kg)*

As is seen in *Figure 1,* milk yield data of cross, culture and indigenous cattle show a normal distribution. In cross breed group, 9th, 13th and 14th values are the outliers; in culture group, 9th, 13th, 14th and 47th values are the outliers whereas in indigenous group, 14th value is the outlier. As Box's M = 74.391, F = 1.779 and p < 0.01 in Box's M Test as shown in *Table 2*, covariance matrices are not homogenous.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1494514959

Following the obtainment of these results, a reanalysis was performed after the removal of 9th, 13th, 14th and 47th outliers from the observed values since they were interrupting normality. The values belonged to the cities of Bingöl, Bitlis, Hakkari and Bartın. For this reason, Kilis, Bingöl, Bitlis, Hakkari and Bartın were excluded from the research and the research was performed with 76 cities. Q-Q Plot and outlier value graphs obtained from the normality tests performed for the new observations are given in *Figure 2.*

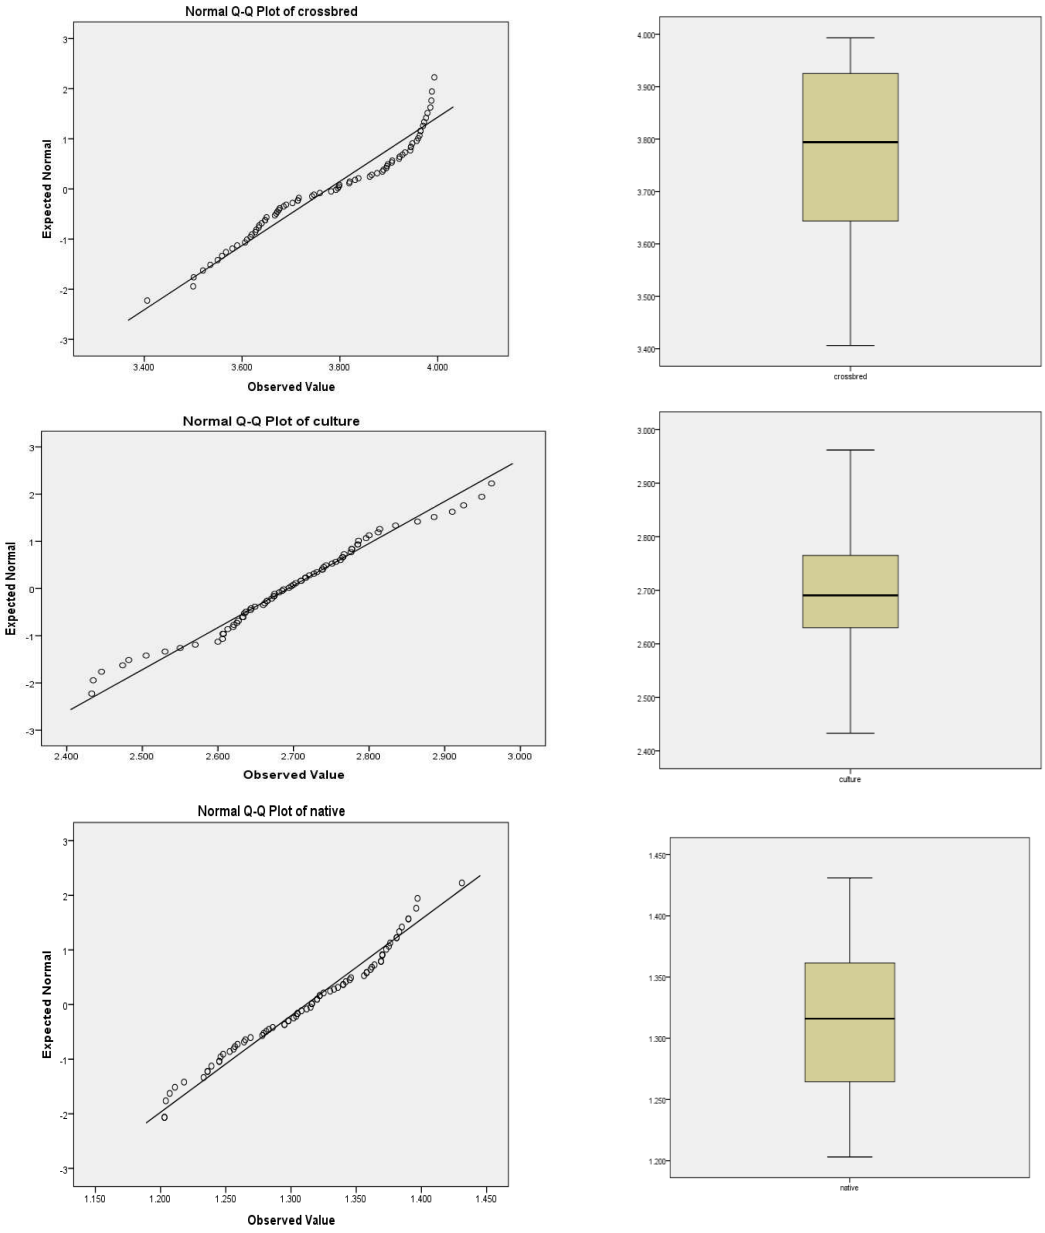

Figure 2. *Normal distribution and outlier observation graph of data*

As is seen in *Figure 2,* milk yield from cross, culture and indigenous cattle breeds show normal distribution according to Q-Q plot graph. This indicates that the outlier value problem has been resolved.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1494514959

At this point, homogeneity test for the covariance matrices of these data is presented in *Table 2* and test for sphericity is presented in *Table 3*.

Table 2. *Box's M Test for the equality of the covariance matrices*

Box's M	74.391
F	1.779
df1	36
df2	5667.462
p	0.003

df: degrees freedom

Table 3. *Box's Test for the equality of covariance matrices of groups*

Box's M	57
F	1.356
df1	36
df2	5677.983
p	0.076

H_0: $\Sigma 1 = \Sigma 2 = \Sigma 3$; H_1: At least one of the group mean values is different from the others. Since $p = 0.076 > \alpha{:}0.05$, H_0 cannot be rejected. Which means; group covariance matrices are equal. Therefore, MANOVA can be performed. In *Table 2*, Box's M = 57, F = 1.356 and $p > 0.05$, indicating that covariance matrices are homogenous. Test for sphericity is checked in *Table 4*.

Table 4. *Bartlett's test for sphericity*

Likelihood Ratio	0.000
Approx. Chi-Square	53.611
df	5
p	0.001

In Barlett's test for sphericity shown in *Table 3*, Approx $\chi^2 = 53.611$ and $p < 0.01$, indicating that MANOVA test can be performed. The assumption of normality is provided when the outlier values are omitted. Non-parametric tests are not necessary since appropriate analyzes can be performed with parametric statistics. Descriptive statistics are presented in *Table 5*. The table presenting representative statistics shows that milk yield from cross, culture and indigenous cattle present inter-regional differences.

The highest milk yield from cross breeds is obtained in the Aegean Region whereas the lowest milk yield is obtained in the Eastern Anatolia Region, the highest milk yield from culture breeds is obtained in the Aegean Region whereas the lowest milk is obtained in the Southeastern Anatolia Region, the highest milk yield from indigenous breeds is obtained in the Eastern Anatolia Regions whereas the lowest milk yield is obtained in the Mediterranean Region. MANOVA test results are presented in *Table 6*.

$\bar{X}$: mean, S_X: standard deviation, $S_{\bar{X}}$: standard error

Table 6. *MANOVA test results*

Effect		Values	F	Hypothesis df	Residual df	p	Power of test
Region	Pillai's Trace	0.522	2.422	18	207	0.001	0.993
	Wilks' Lambda	0.546	2.518	18	190	0.001	0.991
	Hotelling's Trace	0.711	2.594	18	197	0.001	0.996
	Roy's Largest Root	0.490	5.634	6	69	0.001	0.995

df: degrees freedom

H_0: $\mu_1 = \mu_2 = \mu_3$; H_1: At least one of the group mean values is different from the others. Since p = Sig:0.001 < α:0.005, H_0 is rejected.

Within the framework of the results of the MANOVA test, Pillai's Trace, Wilks' Lambda, Hotelling's Trace and Roy's Largest Root test results displayed significant inter-regional differences in milk yields from 3 different breeds (indigenous, cross and culture breeds) ($p < 0.01$). (This indicates that group mean vectors are significantly different.) Which means, according to Pillai's Trace statistic: $F = 2.422$, $P < 0.001$;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1494514959

according to Wilks' Lambda statistic: $F = 2.518$, $P < 0.001$; According to Hotelling's Trace statistic: $F = 2.594$, $P < 0.001$; according to Roy's Largest Root statistic: $F = 5.694$, $P < 0.001$.

Power of test values were very high. Power of test values for Pillai's Trace, Wilks' Lambda, Hotelling's Trace and Roy's Largest Root tests were 99.3%, 99.1%, 99.6% and 99.5%, respectively. Minimum absolute frequency corresponding to a power rating of 80% is generally favorable (Mendeş 2013). In this respect, the findings of these statistical analyses are favorable. As stated above, it is greater than 80% and the power of the test is high. More than 80% of the power of the test indicates that the analysis is appropriate.

Bonferroni and Tukey Multiple Comparison Tests were performed to determine the inter-regional differences regarding milk yield from each breed. Bonferroni and Tukey test results are presented in *Table 7a, b* and *c*.

According to Bonferroni and Tukey test results, there were significant differences between the Eastern Anatolia-Marmara, Eastern Anatolia-Aegean, Southeastern Anatolia-Marmara and Southeastern Anatolia-Aegean regions with regards to average milk yield ($p < 0.05$ and $p < 0.01$). In this respect, milk yield obtained from culture cattle in the Aegean and Marmara regions was much higher than the milk yield obtained from other regions. Milk yield obtained from culture cattle in the Eastern Anatolia and Southeastern Anatolia regions was lower. The highest milk yield was obtained from the Aegean and Marmara regions, respectively. Conditions of Aegean and Marmara regions in Turkey were observed to be favorable for culture cattle. Inter-regional differences regarding average milk yield from crossbreed and indigenous breed cattle were insignificant, indicating that all regions of Turkey are favorable for crossbreed and indigenous breed cattle.

Likewise, when the present situation (2018 year) can be also analyzed, the obtained results are summarized as follows. The effects of breeds and regions on milk yield in cattle are presented in *Table 8*. MANOVA Tests results for region (*Table 8*): Wilk's Lambda: 0.548, Pillai trace: 0.520, Roy's largest root test: 0.487, Hotelling trace: 0.705. Approximate F test: 12.370* on 36 and 5677 d.f. (degrees freedom).

The results presented in *Table 8* show that the highest mean milk yields were experienced in Aegean, Marmara and Central Anatolia (3926.755, 3889.264 and 3796.178 kg respectively), which are greater than the general mean (3779.394 kg) in culture cattle. The lowest mean milk yield was recorded of 3670.258 kg in Eastern Anatolia. The differences in mean yield owing to region are confirmed by the F-ratio for milk yield ($F = 4.923$ and $P < 0.001$).

Aegean and Eastern Anatolia regions had the highest values for milk yield (2735.997 and 2715.171 kg respectively), while Southeastern Anatolia region recorded the least mean milk yield (2624.235) which is less than the general mean (2696.829 g) in crossbreed cattle. The difference between milk yields in crossbreed cattle by geographical regions was insignificant ($F = 0.997$ and $P > 0.05$).

Eastern Anatolia and Central Anatolia regions had the highest mean milk yield of native cattle (1343.499 and 1328.856 kg respectively) which are greater than the general mean (1309.437 kg), while Mediterranean region had a least mean milk yield of native cattle (1278.477 kg), less than the general mean. The difference between milk yields in native cattle by geographical regions was insignificant ($F = 1.952$ and $P > 0.05$).

Bonferroni Multiple Comparison Test was applied to examine the inter-regional differences regarding milk yield from culture cattle. Bonferroni test results are presented in *Table 9*.

Central Anatolia	3796.178	2673.365	1328.856
General mean	3779.394	2696.829	1309.437
S.E.D.	17.632	12.325	6.519
F-ratio region	4.923***	0.997 ns	1.952 ns

***, **, *: significant differences at the 0.001, 0.01 and 0.05 level of significance respectively. ns stands for not significant at 5% level of significance. S.E.D stands for standard error for differences. Power of test values for Pillai's Trace, Wilks' Lambda, Hotelling's Trace and Roy's Largest Root tests were 99.3%, 99.1%, 99.6% and 99.5%, respectively. In short, the results of 2018 data and 2015 data were equal to each other

According to Bonferroni test results, there was significant differences between the Eastern Anatolia-Marmara, Eastern Anatolia-Aegean, Southeastern Anatolia-Marmara and Southeastern Anatolia-Aegean regions with regards to average milk yield ($p < 0.05$ and $p < 0.01$). Inter-regional differences regarding average milk yield from crossbreed and native cattle were insignificant.

Similar results were obtained in the MANOVA test for 2015 and 2018 data. In both data sets, the power of the test gave the same results. Bonferroni test gave the same results for 2015 and 2018 data in determining the difference of milk yield by region.

Çelik (2015) used the MANOVA method to analyze the inter-regional differences with regards to milk yield from small cattle. Research findings presented statistically significant inter-regional differences with regards to milk yield from hair goat and indigenous sheep. As for milk yield from hair goat, there were significant differences between Eastern Anatolia-Southeastern Anatolia, Marmara, Aegean and Mediterranean regions, Southeastern Anatolia-Marmara, Aegean and Mediterranean regions, Marmara-Aegean regions, Middle Eastern Anatolia and Mediterranean regions, Aegean-Mediterranean regions, Middle Eastern Anatolia-Mediterranean regions and Mediterranean-Black Sea regions. As for milk yield from indigenous breed cattle, there were significant differences between Eastern Anatolia-Southeastern Anatolia, Marmara, Aegean, Middle Eastern, Mediterranean and Black Sea regions, Southeastern Anatolia-Marmara, Aegean, Middle Eastern, Mediterranean and Black Sea regions, Marmara-Aegean regions, Middle Eastern Anatolia, Mediterranean and Black Sea regions, Aegean-Middle Eastern, Mediterranean and Black Sea regions and Middle Eastern Anatolia-Black Sea regions.

Indigenous, cross and culture breed animals in Turkey were compared with respect to 11 slaughtering and 18 carcass features and MANOVA analysis was performed. The differences among culture, indigenous and cross breeds were significant with regards to culture breeds (Kızıl and Aydoğan 2014).

In agricultural sciences, MANOVA test has been applied (Engeler and Reyer 2000, Woodward and Bauer 2007, Maposa et al. 2010, Turan 2011).

In this research, studies on other animal breeding data were analyzed using the MANOVA method.

Conclusion

In this research, milk yields from culture, cross and indigenous breed cattle in Turkey were analyzed by multivariate analysis (MANOVA) for 7 geographical regions. In this research, 7 groups (regions) were subjected to MANOVA test on the basis of 3 dependent variables (breeds). The cities of Kilis, Bingöl, Bitlis, Hakkari and Bartın were excluded from the research as they interrupted the observation values of the normality test. Analysis was performed for 76 cities and the observed outlier value was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1494514959

eliminated. After this stage, homogeneity test for the covariance matrices and sphericity test were presented with the aim to apply the MANOVA test. As $p = 0.076 > \alpha = 0.05$ according to the results of the test, group covariance matrices were equal. As Approx $\chi^2 = 53.611$ and $p < 0.01$ according to the result of the Barlett's Test for Sphericity, MANOVA test was determined to be suitable for the analyzed data set. Representative statistical analysis was performed to show that milk yield from cross, culture and indigenous breeds varied on regional basis. While a higher milk yield was reported for cross breed cattle in the Aegean Region, the lowest milk yield was reported for the Eastern Anatolia Region. As for culture breed cattle, the highest milk yield was obtained in the Aegean Region whereas the lowest milk yield was obtained in the Southeastern Anatolia Region. As for indigenous breed cattle, the highest milk yield was obtained in the Eastern Anatolia Region whereas the lowest milk yield was obtained in the Mediterranean Region. According to the results of the Bonferroni test, milk yield differences from cross breed cattle were significant between the Eastern Anatolia-Aegean regions, Eastern Anatolia-Marmara regions, Southeastern Anatolia-Aegean regions and Southeastern Anatolia-Marmara regions. The inter-regional differences observed in milk yield obtained from culture breed and indigenous breeds cattle were insignificant. In general, milk yield from cross and culture breeds cattle was higher in Aegean and Marmara regions whereas milk yield from indigenous breed cattle was higher in the Eastern Anatolia region. Statistical methods proved to be favorable in the research, enabling the essential hypotheses. Consequently, MANOVA test can be considered to be a powerful analysis method in this research. The MANOVA test was determined to be good predictors of the difference of milk yield between regions in agriculture. It can be recommended that the use multivariate statistical methods of such as MANOVA method will be beneficial in future studies in agriculture.

(Received 23rd Jun 2019; accepted 16th Oct 2019)

Abstract. This study aimed to determine the metal (Al, As, Cr, Cu, Fe, Mn, Ni, Pb, and Zn) levels in the gill, liver, and muscle tissues of some fish species, water and sediment samples taken from Tercan Dam Lake (Erzincan, Turkey). Initially, some physico-chemical parameters of the water such as temperature, pH, and dissolved oxygen were measured, and the relationship was determined between these parameters and the metal levels detected in the water. According to the analysis conducted on the water and the sediment, the most frequent metal was determined to be Fe. During the analyses conducted in the water, Pb and Zn metals were not detected, and all metals were detected in the sediment. It was determined that metals accumulated to a higher degree in the liver and gill tissues compared to muscle tissues. The harmfulness of the metal amounts determined in the water, sediment, and fish tissues was evaluated by comparing them to the acceptable values determined by national and international institutions.
Keywords: *accumulation, toxicity, Tercan Dam Lake, water contamination, physico-chemical parameters*

Introduction

The aquatic ecosystem, being part of the biosphere, is a receiver and carrier environment for the waste water and used water in the system, it is more exposed to contamination compared to air and soil (Yarsan et al., 2000). Water, which is in a constant cycle on the earth, loses its environment as a result of mostly human activities. Consequently, the water contamination occurs. Undoubtedly, the leading contaminators are the metals, which are common in today's aquatic ecosystem and which cause high rates of toxicity in aquatic organisms. Metals in general have a particular significance among other chemical contaminators since they can emerge from very different sources, cause a vast amount of contamination, continuously affect the biological systems, and—entering the food chain—can simply accumulate in developed living beings with increasing intensities (Erdoğrul and Ates, 2006).

Metals are carried towards waters by rock fragments through erosion, dust particles carried by the wind, volcanic activities, and forest fires. Metals dissolved in the water merge into the sediment by precipitating to the bottom, and thus, the metals accumulate at the sediment (Fergusson, 1990). The concentration of the metals accumulating at the sediment varies based on the ratio of the sediment particles, the size of the particles, and based on whether there are organic substances in the sediments. Since the sediment is an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1496114972

important accumulation environment for the metals, it is used in determining the metal contamination of the aquatic environments (Salomans et al., 1987).

The fish take the metals through nutrition, water, gills and skin from the external environment. The amount of the metals accumulating at different tissues of the fish vary according to the amount of metal in the environment, the type of the metal, the interaction duration of metal and the fish, the age and metabolic activities of the fish, the phase of its development, the physico-chemical characteristics of the water, tissues, and organs (Köse and Uysal, 2008). The metals received by the fish reach to the tissues and organs via blood path bonded to the carrier protein, and they reach high concentration levels through being bonded by the metal bonding proteins (Sönmez et al., 2016). Metals show their toxic effects on cell membranes, enzymes, and cell organelles in general (Kirici et al., 2017a). The toxicity of metals involves the interaction between the toxicological target and the free metal ions. Additionally, the cells (liver, renal tubular, gastrointestinal), which make metal transfer during their tasks, are the most toxic-effect-sensitive cells (Elbeshti et al., 2018).

Numerous studies have been conducted on the accumulation of metals in water, sediments, and fish (Moiseenko and Kudryavtseva, 2001; Al-Saadi et al., 2002; Özmen et al., 2004; Tekin-Özan et al., 2007; Tao et al., 2011; Tekin-Özan and Aktan, 2012; Başyiğit and Tekin-Özan, 2013; Kirici et al., 2013a, 2016a, 2017b). In this study, it was aimed at determining the metal (Al, As, Cr, Cu, Fe, Mn, Ni, Pb, and Zn) concentrations in the gills, livers, and muscle tissues of Grass carp (*Ctenopharyngodon idella*), Caner fish (*Barbus capito*), Common carp (*Cyprinus carpio*) and Tigris scraper (*Capoeta umbla*), which live in the Tercan Dam Lake—within the borders of Erzincan province—water, sediment, and lake; it was also aimed at determining the relationship between metal levels in the water and the measured certain physico-chemical parameters of the water.

Materials and methods

Research area

Tercan Dam Lake is located 3 km to the Tercan district of Erzincan province (Turkey). The Dam Lake was inaugurated in 1988 for irrigation and energy. The lake has a surface area of 8.85 km^2, a drainage volume of 178 million m^3, and an irrigation area of 29725 ha. It is located between 39°44’2” north latitude and 40°26’40” east longitudes (*Fig. 1*). Tercan Dam Lake is fed by Tuzla Brook, Çirkiz Brook, Bülbül Brook and Pırnaşil Brook.

Field studies

The research study was conducted through samples taken from 3 stations between March 2018 - May 2018. The water (500 mL water samples were taken from each station) and sediment samples (3 g sediment samples were taken from each station) were taken from each station 3 times in different days, which was repeated 3 times per-month. As per the fish samples (grass carp (n = 22), Caner fish (n = 21), Common carp (n = 25) and Tigris scraper (n = 29)), they were obtained by means of fishermen fishing in the area. During the study, the temperature, pH, and dissolved oxygen amount of the water were measured through the Jenco 6010 (Jenco Instruments Co. China) brand portable multi-parameter. The water, sediment, and fish samples taken from the lake

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1496114972

were brought to the laboratories after being contained in sample containers under cold storage conditions. The water samples were treated with HNO_3 with a 2% concentration ratio. The water samples were kept at +4 °C until (24 h) they were analyzed. The sediment samples were taken through ekman spoonnet, being brought to the laboratory within propylene containers.

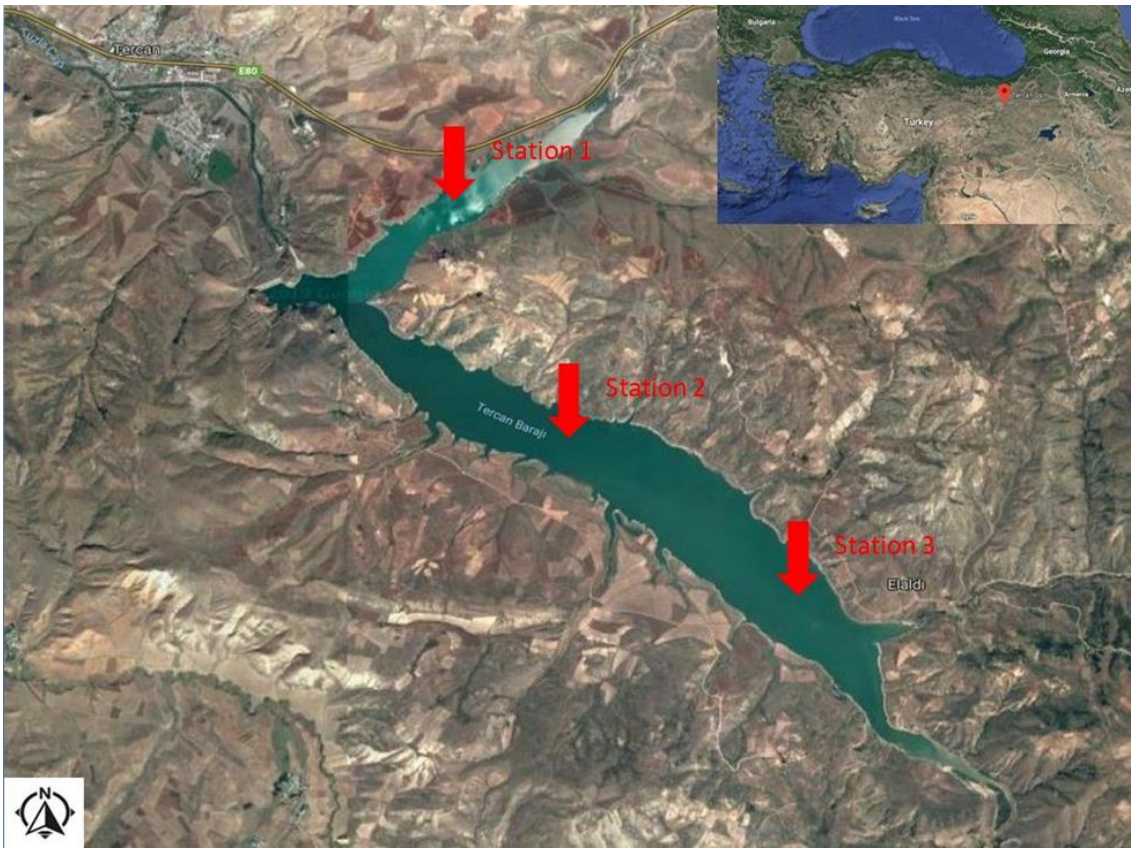

Figure 1. *Tercan Dam Lake*

Laboratory studies

The samples of water, sediment, and fish were brought to the Chemistry Laboratory of Erzincan University Basic Sciences Research and Application Center for laboratory studies. The weights of the fish were measured via scales and their total lengths were measured via measuring board with ± 1 mm precision. Subsequently, muscle, liver, and gill tissue samples of the fish were taken.

In order to determine the Al, As, Cr, Cu, Fe, Mn, Ni, Pb, and Zn accumulation concentrations in the muscle, gill, and liver tissues of the fish, 3-5 g samples were taken from each tissue. The tissue samples were put into heat-proof glass bottles and kept under 105 °C for 24 h in the Drying Oven for drying, and subsequently they were left for cooling down for 24 h. After pulverizing each sample and limiting them to 0.5 g via the precision scale, they were placed into teflon microwave tubes. Adding 7 ml HNO_3 and 1 ml H_2O_2, they were kept at ambient temperature for 24 h. The samples were shaken in the vortex for 10 min, thus, they were mineralized. Placed into microwave tubes, the samples were burnt at 110 °C at 700 W for 45 min. After opening the samples in the fume cupboard, their weights were increased to 200 ml by adding deionized

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1496114972

water. Filtered through a teflon filter, the samples were made ready for the analysis. The metal analyses of the prepared samples were measured through ICP-MS device (Sökmen et al., 2018).

The sediment samples to be analyzed were taken from the lake via ekman spoonnet and placed into containers, and they were kept in deepfreeze until the analysis. For the measurement, 1 g was taken from each sample and placed into microwave solubilization tubes. Adding 5 ml HNO_3 and 1 ml H_2O_2 into each tube, they were exposed to solubilization process in a microwave oven (Milestone Ethos Plus 2000). Taking the tubes out from the oven, they were cooled down at the ambient temperature and the solutions in the tubes were transferred into 25 ml polypropylene volumetric flasks. The solution amounts in the volumetric flasks were completed to 25 ml by adding distilled water. The metal analysis of the samples was conducted in the (Perkin Elmer, 5300 DV model) ICP-OES device. The metal analyses of the water samples were directly conducted. The detection limits of the elements were Cd 0.0012 ppm, Cr 0.0027 ppm, Cu 0.0069 ppm, Fe 0.0381 ppm, Mn 0.001 ppm, Pb 0.0078 ppm, Zn 0.0015 ppm, Al 0.0057 ppm, and Ni 0.0048 ppm (Tekin-Özan and Kır, 2005).

Statistical analyses

The minimum-maximum values, arithmetic means, and standard deviation values of the results obtained in the study were calculated. Pearson Test was applied to determine the relationship between the physico-chemical parameters (temperature, pH, and dissolved oxygen) of the water and metal amounts. All of the statistical calculations were conducted through SPSS 17 package program.

Results and discussion

In this study, the metal (Al, As, Cr, Cu, Fe, Mn, Ni, Pb, and Zn) concentrations were determined in the gill, liver, and muscle tissues of grass carp, Caner fish, common carp and Tigris scraper fish living in the water, sediment, and lake of the Tercan Dam Lake. Additionally, the relationship between the physico-chemical parameters and metal levels in the water was determined.

During the study, the water temperature, pH value, and dissolved oxygen amounts of the Tercan Dam Lake were measured and given in the *Table 1*. According to the *Table 1*, the highest temperature is 14.2 °C, while the lowest is 8.3 °C, and the mean temperature is 11.4 °C.

The results of the metal analyses conducted in the Tercan Dam Lake are given in the *Table 2*. As the conclusion of the metal analyses conducted in the water, it was determined that the highest accumulated metal in the water was Fe metal. Besides, the Pb and Zn metals were under the analysis limitations. The ranking of the mean values of the accumulation in the water was determined as Fe > Al > Ni > As > Cu > Mn > Cr. Reporting that the highest accumulated metal in the Habbaniyah Lake (Iraq) was Zn, Al-Saadi et al. (2002) stated that it was followed, respectively, by Cu, Pb, Ni, Mn and Cd metals. It was also mentioned that the Cd, Co, Hg, Mo, and Pb were under the AAS analysis limitations. In a study conducted in the Texoma Lake by An and Kampbell (2003) it was mentioned that the highest metal concentrations in the water were Na and Ca, and subsequently Mg and K. In a study conducted in the Kovada Lake by Tekin-Özan et al. (2004), Fe, Zn, and Mn were determined in the waters of the lake, and it was also determined that the levels of Cu, Cr, Pb and Cd were under the AAS analysis

DOI: http://dx.doi.org/10.15666/aeer/1706_1496114972

limitations. Similarly, in a study conducted in the Kovada Lake by Kır et al. (2007), it was determined that the most frequent metal encountered in the water was Fe. In a study conducted in the Taihu Lake (China), it was determined that the highest accumulated metal in the water was Zn, while the least accumulated one was Cd (Tao et al., 2012). Similarly, in a study conducted in the Panjkora River (Pakistan), the highest accumulated metal in the water was Zn, while the least accumulated metal was Cd (Ahmad et al., 2014).

Table 1. *Maximum, minimum, mean and standard deviation values of the temperature, pH, and dissolved oxygen values in the Tercan Dam Lake*

	Temperature	**pH**	**Dissolved oxygen (mg/L)**
Minimum	8.3	7.7	8.3
Maximum	14.2	8.1	9.2
Mean	11.4	7.9	8.7
Standard deviation	2.42	0.17	0.39

Table 2. *Maximum values, minimum values, mean values (ppb), and standard deviation values of the metal concentrations measured in the Tercan Dam Lake*

	Al	**As**	**Cr**	**Cu**	**Fe**	**Mn**	**Ni**	**Pb***	**Zn***
Minimum	2.167	1.430	0.003	0.112	4.737	0.045	0.459	-	-
Maximum	4.152	2.219	0.143	0.460	7.016	0.316	4.568	-	-
Mean	3.466	1.811	0.037	0.268	5.703	0.139	1.896	-	-

*Below the analysis limitations

As the conclusion of the metal analyses conducted in the waters of the Tercan Dam Lake and comparing the metal levels of the study to the acceptable heavy metal amounts in the water determined by the World Health Organization (WHO), Turkish Standards Institute (TSI), and Turkish Ministry of Food, Agriculture, and Livestock (MFAL), and United States Environmental Protection Agency (USEPA), it was determined that all metal levels were under the acceptable values.

Using the Pearson Test, the relationships were determined between the temperature, pH, and dissolved oxygen amounts and the metal levels determined in the water, which are all given in the *Table 3*. According to this, there is a negative relationship between the temperature and the Ph, and there is a positive relationship between temperature and dissolved oxygen. In other words, while the temperature increases, pH value decreases, and the dissolved oxygen amounts increase. There is a negative relationship between the pH and dissolved oxygen, in other words, while pH increases, the dissolved oxygen amounts decrease. The pH value has a negative relationship with Cr, Cu, and Ni; while it has a positive relationship with Al, As, Fe, and Mn. While the dissolved oxygen has a negative relationship with Al, Cr, Cu, and Fe, it has a positive relationship with As, Mn, and Ni. Moreover, there are statistically significant differences between dissolved oxygen and As, between dissolved oxygen and Cu, and between Al and Ni (< 0.05).

*0.05 significance level

The metal amounts determined in the sediment samples taken from the Tercan Dam Lake are given in *Table 4*. As the conclusion of the metal analyses on the sediment, it was determined that the highest accumulated metal in the lake waters was Fe, and the lowest one was As. According to the ranking of the mean values of the accumulation in the water, it was determined as Fe > Al > Mn > Cr > Ni > Zn > Cu > Pb > As. In the study conducted in the Texoma Lake (USA), An and Kampbell (2003) determined that the metal accumulation mean values ranking was Ca > Al > Fe > K > Mg > Na. Özmen et al. (2004) conducted a research about some certain heavy metal accumulations in the Caspian Sea (Zn, Fe, Mn, Ni, Cu, Cr, Co and Pb). As the conclusion of the study, it was determined that the ranking of the major elements and heavy metal concentrations in the sediment was Fe > Mg > Ca > Mn > Zn > Ni > Cr > Cu > Co > Pb. In another study conducted in Uluabat Lake, Kurtoğlu (2006) detected that the heavy metals had a ranking such as Pb > Cu > Cr > Ni > Cd > Zn in the sediment samples. In another study conducted in the Cauvery River (India), Venkatesha et al. (2012) examined heavy metals such as Fe, Zn, Ni, Mn, Pb, Cu, Co, Cd and Cr in the sediment samples. As the conclusion of the study, it was determined that the highest accumulated metal in the sediment was Fe. It was followed by, respectively, Mn, Cr, Zn, Ni, Cu, Pb, Co, and Cd metals. In a different study conducted in Odiel River (Spain) by Usero et al. (2003), it was determined that the highest accumulated metal in the sediment was Fe. Usero et al. (2003) explained the reason that the metal that existed in the earth's crust at the highest level was Fe, that was why it was at higher levels in the lake, river, and sea sediment compared to other metals.

When the analysis results of the sediment samples taken from the Tercan Dam Lake were compared to the data of the American National Oceanic and Atmospheric Administration (NOAA), it was determined that all the metals were below the acceptable levels.

The number, total length, and weights of the fish caught by the help of the fishermen fishing in the region are given in *Table 5*. In the study, 22 grass carp fish were used with a length of 29.6 ± 1.02 cm, and weighting 409.4 ± 13.64 g, 21 Caner fish fish were used with a length of 43.2 ± 5.11 cm, and weighting 648.6 ± 15.70 g, while 25 common carp fish were used with a length of 31.2 ± 1.46 cm, and weighting 337.2 ± 10.88 g, and 29 Tigris scraper were used with a length of 32.8 ± 2.48 cm, and weighting 385.1 ± 13.5 g.

It was determined that the metal accumulation in the muscle tissues of Caner fish was Zn > Fe > Cu > Mn > Cr, while the accumulation in the liver tissues of the same species was Fe > Zn > Cu > Mn > Al > Pb > Cr > As > Ni, and the accumulation in its gill tissues was Fe > Zn > Cu > Mn > Al > Cr > Ni > As > Pb. Additionally, it was determined that the accumulation of Al, As, Ni, and Pb metals in the muscle tissues of the Caner fish were lower than the analysis limitations (*Table 6*). It was determined that the metal accumulation in the muscle tissues of Tigris scraper was Al > Zn > Mn > Fe > Pb > Cu > Cr, while the accumulation in the liver tissues of the same species was Fe > Cu > Al > Mn > Zn > Cr > Ni > Pb > As, and the accumulation in its gill tissues was Al > Fe > Zn > Mn > Cr > Ni > Pb > Cu > As. Additionally, it was determined that the accumulation of As and Ni metals in the muscle tissues of the Tigris scraper were lower than the analysis limitations (*Table 7*). It was determined that the metal accumulation in the muscle tissues of grass carp was Fe > Zn > Cu > Al > Pb > , while the accumulation in the liver tissues of the same species was Fe > Zn > Al > Cu > Mn > Cr > Pb, and the accumulation in its gill tissues was Zn > Fe > Al > Mn > Cu > As > Ni > Pb > Cr. Additionally, it was determined that the accumulation of As, Cr, and Ni metals in the muscle tissues of the grass carp, and those of As and Ni metals in the liver tissues of it were lower than the analysis limitations (*Table 8*). It was determined that the metal accumulation in the muscle tissues of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1496114972

common carp was Al > Fe > Mn > Zn > Cr > Ni, while the accumulation in the liver tissues of the same species was Al > Fe > Zn > Cu > Mn > Ni > Cr > Pb > As, and the accumulation in its gill tissues was Fe > Al > Mn > Zn > Cu > Pb > Cr > Ni > As. Additionally, it was determined that the accumulation of As, Cr, and Ni metals in the muscle tissues of the common carp were lower than the analysis limitations (*Table 9*).

There have been numerous research studies conducted in various parts of the world on the accumulation of metals in fish tissues and their detrimental effects on the tissues (Moiseenko and Kudryavtseva, 2001; Uysal et al., 2008; Kirici et al., 2013b, 2016b; El-Moselhy et al., 2014; Baharom and Ishak, 2015; Bosch et al., 2016; La Colla et al., 2017, 2018). For instance, in a study conducted on Avşar Lake (Turkey), Öztürk et al. (2009) examined the metal accumulation concentrations in the muscle, liver, and gill tissues of the Carp, and as the conclusion of the study, it was determined that the Fe metal had the highest accumulation level while Cd had the least. The ranking of metal accumulation in the tissues was determined as Fe > Cu > Pb > Ni > Cr > Cd in the muscle, and Fe > Cu > Ni > Pb > Cr > Cd in the gill and liver. Malik et al. (2010) determined the seasonal changes of some certain heavy metals (Cd, Cr, Cu, Hg, Ni, Pb, Zn) in the muscle, liver, gill, and kidneys of *Labeo rohita* and grass carp species in the Bhopal Lake (India). It was determined that, for the both fish species, the metals accumulated mostly in the livers and at the least levels in the muscles. While the highest accumulated metal in the fish was Zn, it was determined that Hg had the lowest level of accumulation. Taweel et al. (2013), examined the accumulation of Cu, Cd, Ni, Pb, and Zn in the muscle, liver, and gills of Tilapia fish (*Oreochromis niloticus*) living in the Langat River and Engineering Lake. As the conclusion of the study, it was determined that the accumulation ranking of the heavy metals was Cu > Zn > Ni > Pb > Cd in the liver samples, while it was Zn > Ni > Cu > Pb > Cd in the gill and muscle samples. The researchers reported that there was no risk in consumption of Tilapia fish.

The metal amounts determined in the muscle, liver, and gill tissues of the fish were compared to the values determined by the WHO, MFAL, and USEPA. As a result, it was determined that, in the muscle tissue of Caner fish, the Zn amount was higher than the acceptable level determined by the MFAL, the Fe amount in the liver tissue was higher than those of the MFAL and USEPA, the Mn amount was higher than that of the WHO, and the Zn amount was higher than that of the MFAL. Similarly, it was determined that, in the gill tissue of Caner fish, Mn amount was higher than the acceptable level determined by the WHO, and the Zn amount was higher than that of the MFAL. As per the muscle tissue of Tigris scraper, it was determined that the Mn amount was higher compared to the acceptable level determined by the WHO; in the liver tissue of Tigris scraper, it was determined that the Cu amount was higher compared to the acceptable level determined by the WHO, MFAL, and USEPA; as per the gill tissue of Tigris scraper, the Mn amount was higher compared to the level of WHO, and Ni amount was higher compared to the levels determined by the MFAL and WHO.

In the liver tissues of the grass carp, the Mn amount was higher than the acceptable level determined by the WHO, in its gill tissues, the Mn amount was higher than that of the WHO, and Zn amount was higher than those of WHO and MFAL. In the muscle tissues of the common carp, the Mn amount was higher than the acceptable level determined by the WHO for the fish tissues, and the amount of Ni was higher than that of MFAL; in its liver tissues, the Cn amount was higher than that of the WHO, MFAL, and USEPA, and the Mn amount was higher than that of WHO; as per the gill tissues,

DOI: http://dx.doi.org/10.15666/aeer/1706_1496114972

the Zn and Ni amounts were higher than those of WHO and MFAL, Mn amount was higher than that of WHO, and Ni amount than that of MFAL.

Conclusion

As the conclusion of the study, when the metal concentrations determined in the muscle, liver, and gill tissues of fish were compared to the values determined by the WHO, MFAL, and USEPA, it was determined that the metal concentrations determined in the fish tissues were higher than the acceptable levels. It is an important case for the human health, since the muscle, which is consumed by human beings, had a metal concentration over the acceptable levels. Accumulation of metals in tissues directly influences the blood parameters, enzyme activities, growth, and development of the living being. Although numerous factors influence the existence of metals in the waters, undoubtedly the most important factor is the human activities. The water resources are contaminated particularly due to domestic waste, industrial waste, and agricultural activities. At this point, particularly people living around the water resources should be informed by the authorities. Additionally, necessary precautions should be taken against the wastes being released to the water resources from the industrial facilities and these measurements should be supervised by the authorities. Also, a potential danger may exist in the future, depending on the agricultural development in this region. As the Tercan Dam Lake is also used for agricultural irrigation purposes, performance of pollution researches at certain periods is of significance for both environment and public health.

(Received 24th Jun 2019; accepted 16th Oct 2019)

Abstract. Phosphorus (P) is one of the most essential macronutrients for plant growth and development. Most of the soils in the world contain insoluble P that cannot be utilized by the plants. Phosphate solubilizing fungi (PSF) including *Talaromyces pinophilus* possess more potential for providing available P in soil for plant nutrition. There is no report regarding P solubilization potential among the different strains of *T. pinophilus*. The article aimed to compare the Phosphorous solubilization capabilities of 17 *Talaromyces pinophilus* fungal strains, in order to determine the best options for environmentally friendly fertilizers. The P solubilization efficiency of the fungal strains was investigated in broth containing insoluble $Ca_3(PO_4)_2$, $AlPO_4$ and $FePO_4$ compounds. Result showed that $Ca_3(PO_4)_2$ was solubilized the most followed by $AlPO_4$ and $FePO_4$. The strains SI-17URAgr, NBRC 6345 and NBRC 100533 have strong abilities to solubilize $Ca_3(PO_4)_2$, but SI-19URAgr could solubilize both $AlPO_4$ and $FePO_4$. These results also imply that the strains SI-4URAgr and JCM 22801 have the potential to solubilize $AlPO_4$ and $FePO_4$, respectively. Although the P solubilization by different strains were source dependent, the strains SI-17URAgr, NBRC 6345 and NBRC 100533 were proved to be potential for solubilizing P from three sources tested. Solubilized P was negatively correlated with pH of the medium. This study suggested that these strains have a great potential as eco-friendly biofertilizers for sustainable soil management and crop production.
Keywords: *fungal strain, phosphorus, insoluble phosphate, eco-friendly biofertilizers, sustainable soil management, soil pH*

Introduction

Phosphorus (P) is the second most important limiting element required for plant growth and development (Chai et al., 2011; Ram et al., 2015). The soluble soil P concentration varies from 0.05 to 10 ppm, and more than 80% of the P becomes fixed and unavailable for absorption by plants due to adsorption, precipitation or conversion to organic forms (Holford, 1997). The fixed form of P in alkaline soils is tricalcium phosphate, $Ca_3(PO_4)_2$, whereas in acidic soils, it is mainly found as $FePO_4$ and $AlPO_4$ (Subba Rao, 1999).

The application of plant growth promoting microorganisms in agriculture could reduce the use of agrochemicals and support eco-friendly crop production (Herrera et al., 1993; Glick, 1995; Requena et al., 1997). It has been reported that a wide range of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1497314984

microorganisms, especially bacteria, solubilize insoluble phosphate (Badr El-Din et al., 1986; Gaind et al., 1991) although fungi are more efficient than bacteria (Venkateswarlu et al., 1984). A promising biotechnological strategy in the management of P fertilization is the use of phosphate-solubilizing fungi to solubilize rock phosphates and allow the recovery of unavailable P fixed in the soil.

Talaromyces (Trichocomaceae) is an important fungal genus which is derived from the Greek word for 'basket', which capably describes the body in which ascospores are formed. In the past, species producing sexual stages with *Penicillium* anamorphs have been classified in *Eupenicillium* spp. and *Talaromyces* spp. After July 2011, species formally reclassifies as the *Penicillium* subgenus *Biverticillium* were classified in *Talaromyces*. The situation is complicated by the fact that many species now classified in *Talaromyces* will continue to be sought as *Penicillium* species in identifications (Pitt, 2014).

The habitats of *Talaromyces pinophilus* are global in environment, *T. pinophilus* (Samson et al., 2011); anamorph: *Penicillium pinophilum* (Thom, 1910) and *P. allahabadense* (Mehrotra et al., 1962) currently designated by *T. allahabadensis* (Samson et al., 2011) were prevalently isolated from soil, compost (El-Naggar et al., 2015), seeds grains (Ismail et al., 2016), phyllosphere (Lindow et al., 2002), phylloplane (Abdel-Hafez et al., 2015; Abdel-Gawad et al., 2017) and some medicinal plants (Koul et al., 2016; Yao et al., 2017).

T. pinophilus has received increasing attention in mycological research for its ability to act as a fungal antagonist and plant-growth promoter (Nicoletti et al., 2004; Pandey et al., 2008; Wani et al., 2016). A few categorical studies on phosphate solubilizing abilities of *T. pinophilus* were reported previously by others (Abdul Wahid and Mehana, 2000; Sembiring and Fauzi, 2017) but no studies have been made on the in-depth p-solubilization potential and comparative performance of different *T. pinophilus* strains yet. Therefore, the study aimed to compare the phosphorous solubilization capabilities of 17 *T. pinophilus* fungal strains, in order to determine the best options for environmentally friendly fertilizers.

Materials and Methods

Fungal Isolates and Culture Preparation

The study was carried out in the Mycology Laboratory, Faculty of Agriculture, University of the Ryukyus, Okinawa, Japan during September 2017- March 2019 under a class II biohazard cabinet (BHC-1306IIA/3B, AIRTECH, Tokyo, Japan) followed to the biosafety classification by National Institute of Infectious Disease of Japan, because of possibilities including toxic fungal species treated as BSL2 during the working tenure. Seventeen *T. pinophilus* fungal strains were used in this study where 4 strains isolated from subtropical soils in Okinawa, Japan and 13 strains collected from different institutions in Japan (*Table 1*). The isolates were cultured on potato dextrose agar (PDA; Becton, Dickinson and Company, Sparks, MD, USA) slant at room temperature (25^{o}C) for further study.

Morphological Studies

Morphological studies were done according to the method (Watanabe, 2010). Pigment exudation were investigated on PDA slants. High-temperature resistance and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1497314984

pathogenic potential of the isolates were examined. The isolates were cultured on PDA slants in duplicate and incubated at 35^0C, 37^0C and 42^0C for 7 days to evaluate the growth of mycelia. Growth of isolates at 25^0C (room temperature) treated as positive control.

Preparation of Spore Suspension

Sporulated pure fungal cultured slants were selected for preparation of spore suspension followed by standard procedure. A total volume of 5 ml sterile water with 0.02% of tween 80 (Polyoxyethylene sorbitan monooleate, Nacalai Tesque, Inc, Kyoto, Japan) was poured on the culture slants and the fungal colony surface was lightly scraped by a sterile inoculation loop (Thermo Scientific™, Nunc™ Disposable Loops and Needles, Thermo Scientific™ 251586, Fisher Scientific, Tokyo, Japan). The cultures were passing through a syringe with a 4 x 4 cm sheet of a sterile absorbent cotton (Kyualet, Kawamoto Sangyo, Osaka, Japan). Spore count was done by a hemocytometer and the suspension was adjusted to approximately 10^6 spores mL^{-1}.

Determination of TCP Solubilization Index on Solid Medium

All the isolates were tested under *in vitro* condition for their phosphate solubilization activity on Pikovskaya's agar medium containing 0.5% tricalcium phosphate (TSP) as an insoluble phosphorus source. A spot inoculation of each fungal isolate was made onto the plates in triplicate under aseptic condition and incubated at 28°C for 7 days in darkness. At 7^{th} day of incubation, phosphate solubilization index was measured using the following formula (Premono et al., 1996):

Solubilization Index (SI)=[Colony diameter+Halo zone diameter]/Colony diameter

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1497314984

Quantitative Estimation of Phosphate Solubilization

It was carried out using Erlenmeyer flask containing 40 ml Pikovskaya's broth medium supplemented with 0.5% tricalcium phosphate [$Ca_3(PO_4)_2$], aluminium phosphate ($AlPO_4$) and iron phosphate ($FePO_4$). After sterilization, the medium of each flask was inoculated with the 5% (v/v) spore suspension of a particular fungal isolate containing 10^6 spores mL^{-1}. Sterile distilled water inoculated flaks were treated as control. Three replicates were maintained for each test isolate and mean value was recorded. Incubation was done at 25^0C in an incubator shaker (EYELA Multi Shaker MMS-3010) at 120 rpm for 9 days. The samples were autoclaved and centrifuged (TOMY MX-301) at 5000 rpm for 25 minutes to remove any suspended solids and mycelial parts. Then the cultures were filtered through 0.45 µm pore size syringe filter unit (Advantech, Japan). The filtrates were used for analysis of soluble phosphate and pH value. The pH value of the culture supernatants was determined by a pH meter (HORIBA, Japan) equipped with a glass electrode. The amount of soluble phosphorus in culture supernatants was measured by molybdenum blue method (Murphy and Riley, 1962) and expressed as mg/L. Samples cultured for 3, 6 and 9 days were compared. After calculation of mean phosphate degradation ability from 17 isolates of each day, we selected the adequate period for the comparison depending on the substrate.

Data Analysis

All experiments were conducted in triplicate and data were analyzed using Microsoft Excel program. The mean values were compared by Fisher test and significant differences were detected at $p< 0.05$ level. Correlation between solubilized phosphate and pH of the medium was determined by using Pearson correlation studies.

Results

Pigment Exudation

All isolates were reconfirmed based on morphological studies. Morphological studies results are not shown. The isolates produced various colour in PDA slant, such as coffee, orange, yellow and cream (*Fig. 1*). Differential colour formation by *T. pinophilus* isolates might be attributed to the presence of bioactive metabolites.

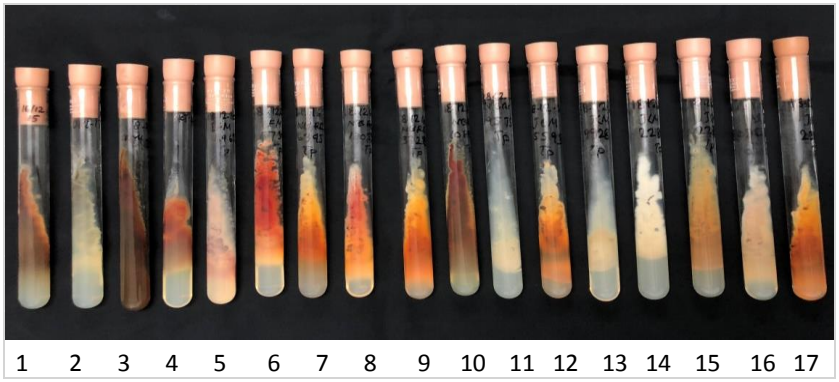

Figure 1. *Talaromyces pinophilus isolates grown on Potato Dextrose Agar (PDA) slant for 7 days at 25^0 C [Coffee: 1, 3, 10; Cream: 2, 5, 11, 13, 14, 16; Orange: 4, 6; Yellow=7, 8, 9, 12, 15, 17]*

Qualitative Phosphate Solubilization

All isolates showed different levels of phosphate solubilization from inconspicuous to a substantial in Pikovskaya's agar medium using tricalcium phosphate as the substrate. Six isolates produced clear zone, 5 developed translucent and the remaining isolates had inconspicuous zones. All isolates also showed significant phosphate solubilization in Pikovskaya's agar medium using tricalcium phosphate as the substrate. The phosphate solubilization index (PSI) ranged from 1.05 to 1.46 (*Table 2*).

Quantitative Phosphate Solubilization

Phosphate solubilization by all isolates were tested in Pikovskaya's broth medium using three substrates of recalcitrant phosphate compounds: tricalcium phosphate $Ca_3(PO_4)_2$, aluminium phosphate ($AlPO_4$) and iron phosphate ($FePO_4$). The phosphate solubilizing ability of fungal isolates varied with incubation period and substrates. The best period of observation was 6 days considering their mean P solubilization for the three substrates (*Table 3*).

All *T. pinophilus* strains were tested for their ability to solubilize hardly soluble phosphate sources [$Ca_3(PO_4)_2$, $AlPO_4$, and $FePO_4$]. All of the *T. pinophilus* strains showed potential P solubilizing in the medium containing $Ca_3(PO_4)_2$ followed by $AlPO_4$ and $FePO_4$ (*Table 4*). The solubilized P ranged between 83.7-574.8 mgL^{-1}, 50.5-192.4 mgL^{-1} and 50.5-192.4 mgL^{-1} from $Ca_3(PO_4)_2$, $AlPO_4$, and $FePO_4$, respectively. Among 17 isolates, 6 isolates (SI-4URAgr, SI-17URAgr, SI-19URAgr, NBRC 6345, NBRC 100533 and JCM 22801) were considered as outstanding isolates because solubilized P was higher than the sum of the mean and standard deviation of P solubilized by 17 isolates. The highest amount of P solubilization from $Ca_3(PO_4)_2$ was shown in NBRC6345 (574.8 mgL^{-1}) followed by NBRC100533 (540.4 mgL^{-1}) and SI-17URAgr (537.2 mgL^{-1}). The highest amount of P solubilization from $AlPO_4$, was

DOI: http://dx.doi.org/10.15666/aeer/1706_1497314984

shown in SI-4URAgr (192.4 mgL^{-1}) followed by SI-19 (153.7 mgL^{-1}). The highest amount of P solubilization from $FePO_4$ was shown in SI-19URAgr (145.2 mgL^{-1}) followed by JCM 22801 (126.1 mgL^{-1}). The strain SI-19URAgr showed outstanding performance in both $AlPO_4$, and $FePO_4$ solubilization (*Table 4*). In case of total solubilized phosphate (mgL^{-1}) from three substrates (TCP, AL-P and Fe-P), the highest amount of P solubilization was shown in NBRC 6345 (829.6 mgL^{-1}) followed by SI-17URAgr (789.2 mgL^{-1}) and NBRC100533 (770.4 mgL^{-1}). The tested isolates produced various colours in broth medium using three P substrates during incubation period (data not shown).

TCP: tricalcium phosphate, Al-P: aluminium phosphate, Fe-P: iron phosphate, Values given are the mean ± standard deviation of P solubilized by 17 fungal isolates, An asterisk (*) indicated outstanding values of solubilized phosphate, It was higher than sum of mean and standard deviation of P solubilized by 17 fungal isolates

Correlation Between pH and Soluble P

The pH of the culture medium exhibited the opposite changes. It decreased with the increased amount of soluble P in the medium. Correlation studies showed a significant inverse relationship between soluble P and pH of the culture medium (*Fig. 2A, 2B, 2C*).

DOI: http://dx.doi.org/10.15666/aeer/1706_1497314984

The negative correlation was observed in all fermented broth culture and correlation coefficient (r) was -0.88, -0.51 and -0.60 in TCP, Al-P and Fe-P, respectively. The strong negative correlation was observed in TCP containing medium.

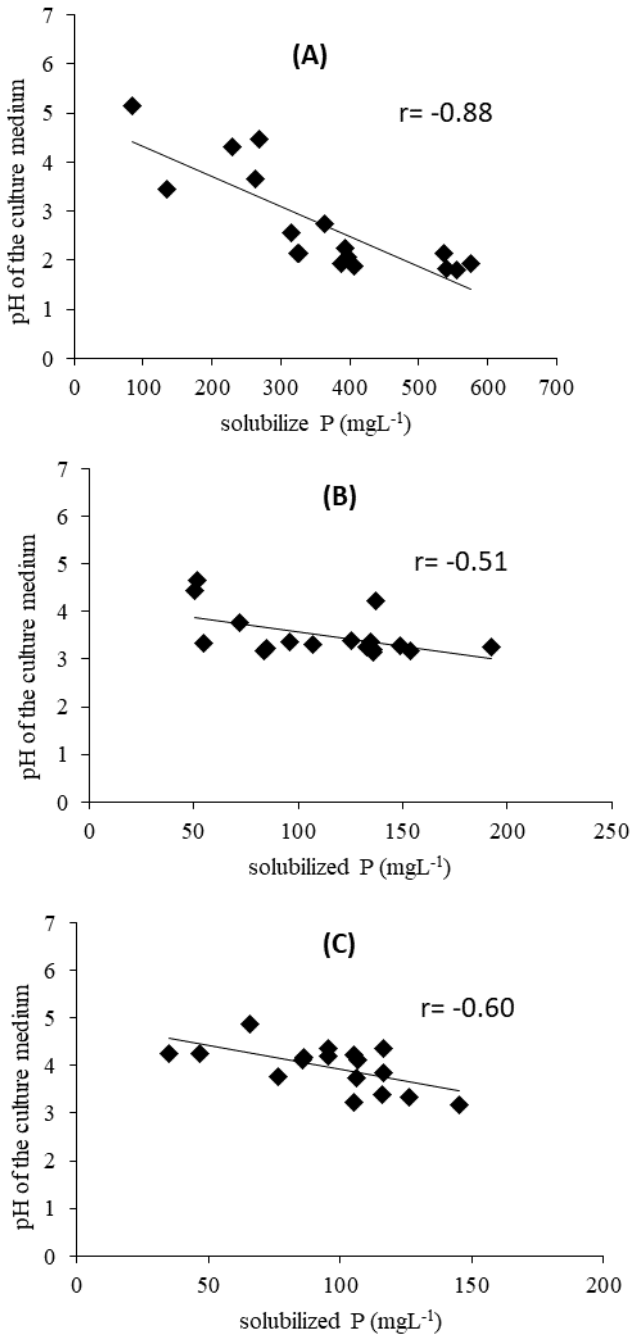

Figure 2. *Pearson's correlation between soluble phosphate and pH of the culture medium supplemented with TCP (2A), $AlPO_4$ (2B) and $FePO_4$ (2C); inoculated by 17 fungal strains. Temperature Effects on Strains

Survival of the strains at different temperature was investigated (*Table 5*). Most of the strains could grow and survive at 25ºC-37ºC. Strain SI-4URAgr, SI-15URAgr, SI-17URAgr, SI-19URAgr and NBRC 106907 could grow at 25ºC-42ºC. These strains are summer tolerant and they could survive both acidic (low pH) and alkaline environment (high pH).

Discussion

Morphological studies reconfirmed that all the 17 strains used in this study belong to *Talaromyces pinophilus.* All fungal isolates produced different colours in the medium regardless of the P substrates, but the colour seemed not to have any relation with P solubilization.

T. pinophilus has various applications based on the production of enzymes (Hansen et al., 2015; Li et al., 2017) as well as a renewable source of pigments, colorants (Caro et al., 2017) and bioactive compounds (Wang et al., 2013; Nicoletti et al., 2016) and degrading ability of agricultural waste (El-Naggar et al., 2015). *T. pinophilus* is able to produce a variety of bioactive metabolites, including alkaloids, peptides, lactones, polyketides and miscellaneous structure type compounds, with different chemical and biological activities. *T. pinophilus* produces biomass-degrading enzymes such as α-amylase (Xian et al., 2015), cellulase (Visser et al., 2013), endoglucanase (Pol et al., 2012), xylanase (Visser et al., 2013), laccase (Dhakar et al., 2014) and α-galactosidase (Visser et al., 2013). *T. pinophilus* produces a variety of medically useful metabolites such as 3-O- methylfunicone, which is used to inhibit mesothelioma cell motility, and talaromycolides 1-3,5 and 11 which inhibit the growth of the human pathogen methicillin resistant *Staphylococcus aureus* (Buommino et al., 2012).

In the present study, all isolates showed better P solubilizing activity in liquid medium compared with solid medium. The possible reason for these anomalous behaviors of isolates on liquid and solid media could be attributed to nutrient availability, varying diffusion rate of different organic acids secreted by fungi, and growth requirement of fungi (Jain et al., 2014).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1497314984

Alam et al. (2002) reported that some isolates having little clear zone on solid agar medium exhibited higher phosphate solubilization efficiency in liquid medium. Some fungal isolates showed larger clear zones on solid agar medium but low phosphate solubilization in liquid medium. This shows that higher PSI on solid agar medium does not necessarily show solubilization efficiency in liquid medium. Thus, the plate technique is insufficient to screen the best P solubilizers and to detect all phosphate solubilizers mentioned by Nautiyal (1999).

The strongest P solubilization was found in $Ca_3(PO_4)_2$ followed by $AlPO_4$ and $FePO_4$ because $AlPO_4$ and $FePO_4$ have complex structure than $Ca_3(PO_4)_2$ while fungi exhibited low P solubilizing ability in media containing $AlPO_4$ and $FePO_4$ (Son et al., 2006; Zhang et al., 2018). The mechanisms of phosphate solubilization by microorganisms are very complex and are not completely known yet. The very common mechanisms are acidification, chelation and exchange reactions (Chai et al., 2011). Organic acids play an important role in phosphate solubilization processes, which can help the release of P by providing protons and complexing anions, or ligand exchange reactions or complexion of metal ions release to solution. Organic acids production depends on the interaction of P source and fungi (Scervino et al., 2013; Zhang et al., 2018).

In the present study, the isolates (SI-4URAgr, SI-17URAgr, SI-19URAgr, NBRC 6345, NBRC 100533, and JCM 22801) showed the highest efficiency in P solubilization by decreasing pH of the culture medium, which indicated higher amount of organic acid production. Solubilization of the different P sources mostly depended on the amount of organic acids production by fungi (Zhang et al., 2018). Tricarboxylic acids and other lower molecular weight organic acids are considered to be the main contributors to phosphate solubilization and a decrease in pH of the medium (Chai et al., 2011).

It was observed that phosphate solubilization was negatively correlated with pH of the medium. There are several reports where such correlation was documented (Pandey et al., 2008; Jain et al., 2012; Wani et al., 2016). The activities in lower pH indicated that the increase of organic acids in the medium (Pradhan and Sukla, 2005; Saxena et al., 2013). However, soluble P was increased without changing pH in some occasion because of other mechanism (Jain et al., 2012, 2017) such as; chelation and exchange reactions (Chai et al., 2011).

Conclusions

The article aimed to compare the phosphorous solubilization capabilities of 17 *Talaromyces pinophilus* fungal strains, in order to determine the best options for environmentally friendly fertilizers. Findings showed that $Ca_3(PO_4)_2$ was solubilized the most followed by $AlPO_4$ and $FePO_4$. Among the strains tested SI-17URAgr, NBRC 6345 and NBRC100533 were potential for $Ca_3(PO_4)_2$ solubilization but SI-19URAgr could solubilize both $AlPO_4$ and $FePO_4$ whereas SI-4URAgr and JCM 22801 were potential for solubilization of Al-P and Fe-P, respectively. Overall findings suggest that the strains SI-17URAgr, NBRC 6345 and NBRC 100533 could be potent for solubilizing P from different sources. Thus these strains might be used as inoculant in the soil containing various inorganic P. However, further trials are needed to determine the capability of these strains for P solubilization in field experiment, sustainable soil management as well as crop production.

Abstract. This study was carried out to determine the impact of different gibberellic acid (GA_3) application times and doses on seed cotton yield and yield components of Stoneville 468 cotton variety in Southeastern Anatolia Region. Experiments were conducted using randomized block design with split plots and with three replications during the 2015 and 2016 growing seasons. Where application times formed the main plots (control, beginning of squaring, beginning of squaring + beginning of flowering and beginning of squaring + beginning of flowering + 14 days after the beginning of flowering one application), application doses formed the sub plots (control, 400, 800, 1200 cc ha^{-1}). Resulting, seed cotton yields varied between 4882.77 kg ha^{-1} and 5557.15 kg ha^{-1}. While the doses of gibberellic acid increased; seed cotton yield, number of bolls per plant, number of sympodia per plant, plant height, seed cotton weight per boll, ginning outturn, seed index, fiber length and fiber uniformity increased, but earliness ratio and fiber fineness decreased. The most suitable GA dose was 1200 cc ha^{-1} and the highest seed cotton yield was obtained from the beginning of squaring + beginning of flowering + 14 days after beginning of flowering administered three times.
Keywords: *plant growth regulator, sympodia, fiber quality, yield, yield components*

Introduction and literature review

Cotton fibers have great economic importance for cotton producing countries with their widely usage areas, added value and created employment opportunities in the textile sector. With the increasing population, increasing interest for natural fibers and living standards increase the demand of cotton fibers. However, because a limited number of countries' ecology allows the cotton farming, about 80% of world production is carried by eight countries including Turkey (Anonymous, 2019a). Cotton farming area in Turkey was 518 000 ha in 2018 and 976 000 tons of cotton fiber were produced from this area. Cotton is grown in Aegean, Mediterranean (Cukurova and Antalya province) and Southeastern Anatolia Regions of Turkey, although 56% of the cotton is produced in Southeastern Anatolia Region, especially 40% of them in the province of Sanliurfa (Anonymous, 2019b). Therefore, Sanliurfa has an important place in the cotton production of Turkey. This ratio is expected to increase with the completion of SAP (Southeastern Anatolian Project) irrigation and energy projects.

Since the cotton is an important industrial product in both export and domestic consumption, many studies are carried out to increase the seed cotton yield and fiber quality characteristics. One of these studies is using and investigating various plant growth regulators in addition to conventional cotton growing techniques. Plant growth

regulators are important in terms of researching the possibilities of improving yield and quality potential gained by breeding, growing techniques and ecology by affecting mostly the growth physiology of the plant. In recent years, usage of plant growth regulators has become widespread in the application of agricultural chemicals. Plant growth regulators; they are chemical substances that are synthesized by plants or synthetically synthesized and given to the plant from the outside, which can affect growth, development and other physiological events of plants even in very small proportions, and can be effective in the tissues they form as well as in other plant tissues and organs in which they are carried. These chemicals are called hormone when it is synthesized in the plant and called plant growth regulator when they are synthesized artificially outside of the plant (Kurt et al., 1994; Çopur et al., 2010 and Parveen et al., 2017).

It is possible to create suitable conditions for plant growth to achieve high yields for cotton. In addition to suitable environmental conditions, good agronomic practices (soil tillage, fertilization, pest and disease control, irrigation, plant growth regulators, etc.) have important effects in order to obtain the highest yields (Mert et al., 2015). Some adverse environmental conditions (excessive vegetative growth, etc.) that come up during the growing period can be mitigated by good agronomical practices. Squaring, flowering and boll formation periods are the most critical periods for cotton plant. In this period, some wrong practices in plant management are directly reflected in the yield and may cause yield losses. Climatic factors such as high temperature, day length and relative humidity may adversely affect the synthesis of certain hormones that form in the plants. Eventually, physiological events happening in the plant are directly affected by this situation and the plants cannot demonstrate its yield potential. Therefore, in order to minimize or completely eliminate the negative effects of environmental conditions on plants, the application of some phyto-hormones to plants with different formation and effect patterns is important for the continuation of physiological events in the normal course and to find out the maximum yield potential (Güllüoğlu, 2004). One of the plant growth regulators commonly used in agricultural production is gibberellic acid. Gibberellic acid is currently not used commercially as licensed for cotton production in Turkey, but it is observed that producers sometimes apply.

Gibberellic acid, called GA_3, is a natural compound used for flowering and for better growth of bolls in plants. Plants produce about 90 pcs of gibberellins (Davies, 1995). Almost no evidence has been found the Gibberellins to harm human health up to now. Gibberellic acid is a plant growth regulator derived from a fungal species called *Gibberella fujikuroi*. Plant pathologists in Japan discovered this fungus in 1926. The fungus used for the first time in rice seedlings was found to cause very tall and thin growth of plants (Davies, 1995). Gibberellic acid is obtained by fermentation of Gibberella fungus in large barrels. It is sold in powder and liquid forms which are soluble in water. Gibberellic acid has vital importance for plants and increases the growth and development of the plant (Bora and Sarma, 2006). It can also be used to increase flowering, boll formation and size. Gibberellic acid forms naturally in plants and regulates plant growth. Low dose of GA_3 promotes seed growth but does not have a permanent effect on the seed.

In studies of GA_3 in plants; it is reported that different doses study on cotton plant was not affect the yield potential (McCarty et al., 2009); applications of 100 mg L^{-1} and at the 6-7 leaves period for onion plant increased seed yield per umbrella (Mustaq et al., 2018); and olive yield per tree increased by the applications (Ülger et al., 2018).

The aim of this study is to determine the effect of different gibberellic acid dosages and application times on the yield and yield components of middle early Stoneville-468 cotton variety under Harran Plain with semi-arid climatic conditions and to provide a source for the studies to be carried out on this subject.

Materials and methods

The experiments were conducted in the Eyyubiye Campus experimental area of Agricultural Faculty of Harran University during 2015 and 2016 growing seasons (*Fig. 1*). The average altitude of the trial area is 465 m and it is located at 37^0 08' N latitude and 38° 46' E longitude and close to the Syrian border. The trial area is clay (62%), organic matter is low (0.5-1.2%) and pH is 7.2 (*Table 1*). The trial area is classified as the Ikizce soil series (Vertic Calciorthid Aridisol) (Anonymous, 2006). Southeastern Anatolia region has semi-arid climatic conditions, summers are hot and dry, and winters are temperate and rainy. In summer the temperature can reach up to 44.1 °C (*Table 2*). Total rainfall in the region in 2015 and 2016 were 312.3 and 440.8 mm respectively. For this purpose, the study was carried out under irrigated conditions. The average temperature for long years was 18.3 °C, the average humidity was 50.3% and the average wind speed was 2.2 m s^{-1} (Anonymous, 2017).

The experiments were carried out in randomized block design with split plots and with 3 replications. Application times formed the main plots (beginning of squaring, beginning of squaring + beginning of flowering and beginning of squaring + beginning of flowering + application after 14 days of flowering) and application doses formed the sub plots (*Table 3*). Stoneville-468 cotton (*Gossypium hirsutum* L.) variety was used as plant material. Cotton seeds were sown with cotton trial driller in 4 rows and 10 m in length with 70 cm inter-row spaces on 01 May in 2015 and 03 May in 2016. After emergence, the plants were thinned with a distance of 15–20 cm (50-60 plants in each row) at the time of 4-5 leaves period.

In the experiments, 70 kg ha^{-1} pure nitrogen and 70 kg ha^{-1} pure phosphorus was applied as a 20.20.0 compound fertilizer. The remaining 90 kg ha^{-1} pure nitrogen was applied as a urea fertilizer (46% pure nitrogen) with the lister machine before the first irrigation. A total of 1050 mm of water was applied during growing season. The first irrigation was applied 4 weeks after sowing, and the other irrigations were practiced 10 times in 10-day intervals. Last irrigation was applied when 10% of the bolls in the plots opened.

Table 3. *Gibberellic acid doses and application times*

Growing stages	Application doses (cc ha^{-1})			
1. PHS (cc ha^{-1})	WA (T1)	400 (T2)	800 (T3)	1200 (T4)
2. PHS + FF	WA	200 + 200	400 + 400	600 + 600
3. PHS + FF + after two weeks	WA	133 + 133 + 134	266 + 267 + 267	400 + 400 + 400

PHS: pin head square, FF: first flower, T: treatment, WA: water application

During the growing season in the experimental years, the plants were hoed two times by hand and three times by tractor. Before the application of GA_3, the pressure regulated back pump was calibrated with water and the required amount of water was determined and then GA_3 was mixed with water and applied to the plots when the air temperature was 28-30 °C before midday. Control plots were sprayed with water only.

Agronomic practices were applied in the experiment based on the studies conducted in the region. First-hand harvests were carried out by hand on 18 and 20 September, and second-hand harvests on 15 and 20 October in 2015 and 2016 respectively. According to Worley et al. (1976), seed cotton yield, plant height, number of sympodia branches, number of bolls, seed cotton weight per boll, ginning outturn and 100 seed weight were examined; fiber length, fiber fineness, fiber strength and fiber uniformity characteristics were examined by HVI Spectrum instrument (Anonymous, 1997). The data determined according to the methods were analyzed separately each year according to the split plots trial design by using the MSTAT-C package program and the means were compared according to LSD test (Anonymous, 1989).

Results and discussion

Seed cotton yield (kg ha^{-1})

Table 4 shows that the average seed cotton yield in terms of GA_3 application doses ranged from 4800 kg ha^{-1} to 5500 kg ha^{-1} in 2015 and 2016 years. It was determined that the seed cotton yield increased with increasing of GA_3 doses and the highest and lowest seed cotton yield were obtained from 1200 cc ha^{-1} and control plot respectively. In terms of application times, the highest seed cotton yield was obtained from PHS + FF + application after two weeks. According to LSD (Least Significant Difference) test, it was determined that different yield groups were formed in terms of application doses and times in both years, while application times × dose interactions were found insignificant in 2015 but were found significant in 2016 (*Table 4*). Seed cotton yield is a complex character affected by genotypic and environmental conditions (Worley et al., 1974). In addition to genotype and environmental conditions, chemicals that are applied artificially by external cultivation techniques can also affect dry matter production per unit area (Kurt et al., 1994). From *Table 4*, it can be observed that the seed cotton yield was positively affected by increasing doses of gibberellic acid and increased seed cotton yield. Gibberellic acid applications contributed to increase the number of squares, but also increased boll fall, hence had no effect on the seed cotton yield is indicated by Emiroglu and Turan (1974) and McCarty et al. (2009). Eid et al. (1986) in the study of the GA_3 applications during squaring and flowering period increased the seed cotton yield. GA_3 positively affects the formation of new cells by accelerating cell division and elongation in meristematic tissues and as a result, it has been reported that GA_3 have a positive effect

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1498514999

on plant growth and flax seed yield (Emongor, 2007 and Rastogi et al., 2013). Our results are compatible with the findings of Eid et al. (1986) but were partially contradictory with the findings of Emiroglu and Turan (1974) and McCarty et al. (2009). As indicated above, different results were published by several researchers. This may be due to cotton genotypes used in the study and changing GA doses and application times. As different locations have different climatic and soil characteristics, variable results can occur.

Earliness ratio (%)

Table 4 shows that the average rate of earliness ratio ranged from 85% to 94% in 2015 and 2016 with an average of 91.29% in 2015 and 89.80% in 2016 in terms of GA_3

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1498514999

application doses. In terms of application doses, the highest average earliness ratio was obtained from control plot; the lowest earliness ratio was obtained from gibberellic acid dose of 1200 cc ha^{-1}. In terms of application times, it can be observed from *Table 4* that the earliness ratio ranged between 88% and 91% respectively. According to LSD test, different earliness groups were formed in terms of application doses and the earliness ratio was decreased with increasing application doses, but there were no significant differences in terms of application times in both years. Among plant growth regulators, GA_3 and auxins are vital for development of plants (Gou et al., 2010). Gibberellins by helping the development of stem, leaves and other organs of the plant can cause extension of the nodes (Bora and Sarma, 2006). For this reason, maturation of plants is delayed and thus can delay the opening of cotton bolls. Therefore, the earliness ratio may decrease. However, this decrease had not affected the harvesting date, so the plants completed their maturation in time.

Plant height (cm)

Table 4 shows that the average plant height obtained from different application doses ranged from 89 cm to 111 cm in 2015 and 2016, the average plant height was 99.14 cm in 2015 and 107 cm in 2016. In terms of application times, the highest plant height was obtained from 1200 cc ha^{-1} and the lowest plant height was obtained from the control plot. In terms of GA_3 application times, it can be observed from *Table 4* that the average plant height varies between 98 cm and 109 cm. According to LSD test, it was found that different plant height groups were formed according to years in terms of application doses and application times, but application time x application dose interaction was not significant in both experimental years (*Table 4*). GA_3 promotes cell proliferation in plant developmental stages due to their own metabolism regulation and promotes the development of cells by increasing turgor pressure (Davies, 2010). In this case, it is thought that it activates different enzymes and has a positive effect on plant growth and thus causes plant heightening. In addition, GA_3 in flax increases plant height was indicated by Rastogi et al. (2013) and Ayala-Silva et al. (2005). Our results are compatible with the findings of Emiroğlu and Turan (1974), Özdemir (1991) and Öncü (1993), and differ from the findings of İncekara and Turan (1977). This case may be derived due to the use of different GA_3 doses, application times and the cotton varieties in the experiments.

Boll number (no. plant^{-1})

Table 5 shows that the average number of bolls per plant obtained from GA_3 application doses ranged from 10.00 no. $plant^{-1}$ to 16.24 no. $plant^{-1}$ with the average of 12.76 no. $plant^{-1}$ in 2015 and 13.47 no. $plant^{-1}$ in 2016. In terms of application times, the lowest number of bolls was obtained from PHS and the highest number of bolls was obtained from PHS + FF + 14 days application. In the application time × GA_3 dose interaction, while the lowest number of bolls was obtained from the control plot and the highest number of bolls was obtained from 1200 cc ha^{-1} and PHS + FF + 14 days application. According to LSD test, it can be observed that there are different groups of number of bolls in terms of application doses and the number of bolls increased with increasing application dose in both years. Cotton yield is the result of the interaction of genetic and environmental conditions and different yield components can affect the cotton yield (Worley et al., 1974). The main feature that contributes to the cotton yield

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1498514999

is the number of bolls formed per unit area or per plant (Wilson et al., 1994). GA_3 positively affects the flowering and boll formation (Mathur and Mittal, 1964; Taiz and Zeiger, 2003). Therefore, it was found that the number of bolls per plant increased and had a positive effect on the seed cotton yield.

Number of sympodia (no. plant^{-1})

Table 5 shows that the average number of sympodia branches changed between 11.76 no. plant^{-1} and 17.82 no. plant^{-1} obtained from GA_3 application doses with the average of 13.40 no. plant^{-1} in 2015 and 16.81 no. plant^{-1} in 2016. The highest numbers of sympodia branches were obtained from 1200 cc ha^{-1} and the lowest number of sympodia branches were obtained from control plot. In terms of application times, the number of sympodia branches per plant was increased by dividing the doses into three times and the highest number of sympodia branches was obtained from PHS + FF + application after two weeks. According to LSD test, it was determined that different sympodia branch number groups were formed in terms of application doses and application times in 2015, application time × GA_3 dose interaction was significant, but only application doses were statistically significant in 2016 (*Table 5*). 80-85% of the bolls formed on the sympodia branches of plant. Increase in the number of sympodia branches increasing the number of bolls per plant, which contributes positively to the increase of seed cotton yield per unit area. Similar findings were determined by Çopur et al. (2010). In addition, GA_3 applications increase the number of branches in flax plant (Rastogi et al., 2013). For this purpose, 1200 cc ha^{-1} GA_3 dose and PHS + FF + after two weeks applications yielded the highest number of sympodia.

Seed cotton boll weight (g boll^{-1})

The most important factor affecting yield is a high-yielding cotton variety, favorable environmental conditions as well as boll weight (Mauney et al., 1978). *Table 5* shows that the seed cotton boll weight increased with increasing of GA_3 doses in both years. While the seed cotton weight per boll was 3.8-3.9 g in control plots, increased to 4.2-4.3 g at a dose of 1200 cc ha^{-1} of GA_3. It was also found that seed cotton weight per boll increased by dividing application doses in terms of application times. According to the LSD test, it was determined that different seed cotton boll weight groups were formed in terms of application doses and application times were statistically significant in 2015 and 2016. Also, application time × GA_3 dose interaction was statistically significant in 2015 but not significant in 2016. GA_3 applications increased the seed cotton boll weight by increasing the number of leaves per unit area to promote more photosynthesis and contributed to increase dry matter per unit area. Similar findings were found by Abro et al. (2004). In addition, Çopur et al. (2010) in his study with different plant growth regulators; GA_3 applications contribute to the formation of heavier bolls than other plant growth regulators. McCarty et al. (1987) reported that the application of GA_3 reduces the seed cotton boll weight. This case may be derived due to the use of cotton varieties and the effect of different climate condition on plant growth in the experiments.

Seed index (g)

Table 6 shows that the average seed index was changed between 8.49-9.01 g with the average of 8.80 g in terms of GA_3 application doses in 2015; ranged from 8.65 to 9.20 g with the average of 8.92 g in 2016. In terms of application doses, the highest seed index

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1498514999

was obtained from 1200 cc ha^{-1} and the lowest seed index was obtained from the control plot. In terms of application times, the average seed index changes between 8.68 and 8.92 g in 2015 and 8.67 and 9.27 g in 2016. When the GA doses and control parcels were compared in terms of application doses according to LSD test, the results obtained from GA_1, GA_2 and GA_3 applications were similar but higher than the control parcel in 2015. In 2016, GA_2 and GA_3 doses were similar but higher than GA_1 and control parcels. It can be seen that seed index was increases with increasing of GA_2 and GA_3 doses. GA_2 and GA_3 applications accelerated the plant growth along with cell division and contributed to the increase of dry matter per unit area and accordingly increased seed weight. Erdemli and Kaya (2015) in the sunflower and Mustaq et al. (2018) in onion reported that an increase in GA_3 doses cause an increase in seed weight. According to these results, it can be said that GA applications had positive effect on seed size.

Ginning outturn (g)

Marketing of cotton in Turkey is done more in ginning enterprises as seed cotton. Ginning enterprises in cotton purchase are taking into account the more ginning outturn as well as the color and the amount of foreign matter for price. For this purpose, ginning outturn is important in the marketing of cotton seed. *Table 6* shows that the average ginning outturn was obtained from the application doses of GA_3 changed between 41-42.36% in 2015 with the average of 41.77%, and between 41-43% with the average of 42.70% in 2016. While the highest ginning outturn was obtained from 1200 cc ha^{-1}, the lowest ginning outturns from the control plot. According to LSD test, it was found that different ginning outturn groups were formed in terms of application doses but there were no significant differences in terms of application times and GA_3 dose x application

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1498514999

time's interaction in both years. In the findings obtained in GA application doses, GA_1, GA_2 and GA_3 applications were similar in both years but higher results were obtained compared to the control parcels. In the studies of Emiroğlu and Turan (1974) and Özdemir (1991) with different plant growth regulators reported that the gibberellic acid had not affected ginning outturn. This situation differs from our findings. Different results may be observed due to the different climatic conditions of the studies, application time and GA_3 dose and different cotton varieties used in the experiments.

Fiber length (mm)

Table 6 shows that the average fiber length obtained from different GA_3 application doses varied between 28.49 and 29.91 mm in 2015 with the average of 29.45 mm were varied between 27 and 28 mm with the average of 27.92 mm in 2016. While the longest fibers were obtained from 1200 cc ha^{-1} the shortest fibers were obtained from the control plot. In terms of application times, the average fiber length varies between 28.82 and 30.00 mm in 2015 and between 27.50 and 28.40 mm in 2016. In 2016, it can be seen that, GA_1, GA_2 and GA_3 applications were similar but they produce higher results than the control parcel. According to LSD test; fiber lengths were affected by GA_3 applications in 2015 but were not affected in 2016. Although fiber length is an inherited character, it can be affected by environmental conditions and cultivation techniques. In the study of Gokani and Thaker (2002); fiber lengths in both in vitro and in vivo were positively affected from GA_3 applications in three cotton varieties used in the experiment; Oral (1986), Jost and Dolar (2004) and Çopur et al. (2010) reported that GA_3 had no significant effect on fiber length. This may be observed due to the fact that the trials were conducted with different GA_3 doses and cotton varieties under different environmental conditions.

Fiber fineness (micronaire)

Table 7 shows that the average fiber fineness value ranged from 4.18 to 4.55 micronaire (mic) with an average of 4.34 mic in terms of GA_3 application doses in 2015, ranged from 4.77 to 4.91 mic with an average of 4.86 mic in 2016. In terms of application times, the average fiber fineness varies between 4.30 and 4.42 mic with the average of 4.34 mic in 2015, varies between 4.83 and 4.96 mic with an average of 4.86 mic in 2016. In terms of GA_3 doses, it can be observed that the coarser fibers were obtained from 800 cc ha^{-1} and the finest fibers were obtained from the control plot in 2015 but there were no significant differences in terms of application times and GA_3 doses in 2016. It can be seen from *Table 7* that the fiber fineness partially decreased with increasing GA_3 doses.

Although the fiber fineness value is an inherited property, it can be affected by environmental conditions. In particular, temperature and consequently photosynthesis and carbohydrate deposition may affect fiber fineness. Thus, with the dose increases, the maturation of the plants is delayed, and the fibers become coarse due to the increase of dry matter in the plants. Although the fiber fineness is partially getting coarser with increasing of GA_3 dose, the values obtained do not pose a problem in terms of its use in textile (expected values are 3.8-4.6 mic). Our results are partially contradicting with the findings of Özdemir (1991), Zibdieh et al. (1998) and Çopur et al. (2010) and this may be observed due to the differences of GA_3 doses and the cotton varieties used in the trials.

Fiber strength (g tex^{-1})

Table 7 shows that the average fiber strength obtained was 31.67 g tex^{-1} according to GA_3 application doses in 2015 and 28.96 g tex^{-1} in 2016, the highest fiber strength was obtained from 1200 cc ha^{-1} and the lowest fiber strength was obtained from the control plot. According to LSD test; different fiber breakage strength groups has not formed in terms of GA_3 doses, application times and interaction of application doses x application times, but fiber breakage strength increased partially with increasing of GA_3 doses, but it was not statistically significant. This shows that GA_3 applications have no significant effect on the fiber breakage strength. Similar findings were determined by Özdemir (1991), Zibdieh et al. (1998) and Çopur et al. (2010).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1498514999

Fiber uniformity (%)

Table 7 shows that the average fiber uniformity ratio obtained from gibberellic acid application doses varies between 83.23% and 85.24% with the average of 84.51% in 2015, and it was varied between 82.97% and 85.27% with the average of 83.81% in 2016. While the highest fiber uniformity was obtained from 1200 cc ha^{-1} and the lowest fiber uniformity was obtained from the control plot. In terms of GA_3 application times, the average fiber uniformity was varied between 84.27 and 84.71% in 2015 and varies between 83.70 and 84.02% in 2016. As a result of the analysis of variance: There were significant differences in all sources of variation in terms of fiber uniformity for 2015, but only a significant difference was found in terms of application times in 2016 (*Table 7*). Fiber uniformity ratio is calculated in the fiber development diagram as 50% fiber length in fiber distribution by comparing to the 2.5% of fiber length. Thus, fiber length is positively affected with increasing doses of GA_3, so that a homogeneous length is obtained with the development of fibers. Increased fiber uniformity is desirable and GA_3 doses have a positive effect on fiber uniformity ratio. Therefore, in GA_3 applications, the dose of 1200 cc ha^{-1} was divided into three as PHS + FF + after two weeks or divided into two as PHS + FF.

Conclusion

In cotton farming, the most important issue that the producers have focused on seed cotton yield. In this study the seed cotton yield varied between 4882.77 kg ha^{-1} and 5557.15 kg ha^{-1}. Cotton yield is the result of interaction of genetic and environmental conditions, and different yield components can affect the seed cotton yield. Therefore, in order to minimize the negative effects of environmental conditions on plants, to maintain normal physiological events in plants and to reach maximum yield potential, it is important to give some phyto hormones to the plant externally. One of the plant growth regulators commonly used in agricultural production is gibberellic acid. Gibberellins promote their growth as they increase the turgor pressure of the cells by promoting cell proliferation during plant developmental stages, thus regulating their own metabolism. Furthermore, GA positively affects flowering, boll formation and number of bolls per plant, thus contributing positively to seed cotton yield. According to our study with different GA doses the most appropriate dose of GA under semi-arid climatic conditions is 1200 cc ha^{-1} and it should be preferred to divide into three doses as beginning of squaring + beginning of flowering + 14 days after beginning of flowering. In addition, it would be useful to carry out more studies related to plant growth regulators at different locations in order to determine the variable dose combinations of GA and the response of different cotton varieties.

(Received 25th Jun 2019; accepted 15th Nov 2019)

Abstract. Soil in riparian zone can alleviate the risk of nitrogen pollution for water by releasing gaseous nitrogen (N) fluxes. As a critically terminal riparian zone in China, the Miyun Reservoir riparian zone is dramatically submerged by water delivered by the South-to-North Water Transfer Project (SNWTP), which is the largest inter-basin water transfer scheme worldwide. However, few studies have proposed a framework to estimate the effect of SNWTP on N removal by soil at the scale of the riparian catchment. Therefore, a framework that integrates the eco-hydrological model, remote sensing technology, and scenario setting was developed in this study to simulate the spatiotemporal variation of N emissions and to estimate the influences of SNWTP on N removal by soil in the Miyun riparian catchment between April and September of 2015. The simulated results indicate that N removal in the whole catchment ranged from 48.83 t to 290.58 t between April and September and the total N removal was 871.97 t in 2015. With water level exceeding 150 m and 160 m, the riparian soil had about 35%-60% of its original N pollution mitigation ability. Changing farmland and grassland into forestland can effectively offset the impacts of SNWTP.
Keywords: *nitrogen pollution, eco-hydrological model, riparian zone, scenario setting, remote sensing, Miyun reservoir*

Introduction

To relieve the emerging crises of water resource shortage, inter-basin water transfer projects are beginning to be used throughout the world. Prominent examples are the Snowy Mountains Scheme in Australia, the California State Water Project in the United States, the West-to-East Water Transfer Project in Pakistan, the Quebec Water Transfer Project in Canada, the Lesotho Highlands Water Project in Lesotho and South Africa, and the Durance-Verdun Water Transfer Project in France (Chen et al., 2013; Wang et al., 2009; Yang et al., 2018a).

A complete water transfer project needs to draw water from a water source, transport this water via conveyance canals, and inject the water into the terminal reservoir (Yang et al., 2018a). Each part of such a water diversion causes different ecological and environmental problems. Specifically, the supply of adequate water without pollution is the most important item to be considered for the water source region (Gu et al., 2012; Tang et al., 2014; Yang et al., 2016; Zhang, 2009; Zeng et al., 2015); the maintenance of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1500115018

adequate water quality and the prevention of disease spread should be the greatest concern in the conveyance canal (Yang et al., 2018a); for the terminal reservoir, protection functions of riparian areas is the main issue due to the drastic increase of the reservoir water level induced by the injection of transferred water (Zhang, 2009; Zhuang, 2016).

So far, the South-to-North Water Transfer Project (SNWTP) that was started to be built in China in 2002 is the largest inter-basin water transfer scheme in the world (Barnett et al., 2015; Li et al., 2016). It includes three independent routines, namely, west, east, and middle routes, where the last two routes have been completed and can deliver about 25 billion m3 of water per year (Liu and Zheng, 2002). At present, a number of studies have reported the ecological and environmental issues related to the SNWTP (Gu et al., 2012; Li et al., 2017; Ma et al., 2014; Tang et al., 2014; Yang et al., 2016, 2012; Zhang et al., 2008, 2018). However, most of these studies focused the water source region and on conveyance canals, while studies on effects of SNWTP on the terminal reservoir are rare.

The riparian zone is the transition region between water and terrace (King et al., 2016). It can intercept non-point source (NPS) pollutants from upland and therefore plays an important role in reducing the pollution risk of the water resource (de Sosa et al., 2018; Shu et al., 2017; Wei et al., 2017). In recent years, NPS N is becoming the key pollutant endangering the water quality safety in the world (Blackburn et al., 2017; Erisman et al., 2013). A number of studies have proposed that the soil in the riparian zone can effectively remove N pollution by releasing gaseous N fluxes (Butterbach-Bahl et al., 2013; de Sosa et al., 2018; Jacinthe and Vidon, 2017; Seitzinger et al., 2006). Furthermore, denitrification, nitrification, and ammonium volatilization have been reported as the three main biochemical processes related to the soil N emission (de Sosa et al., 2018; Groffman et al., 2009; Vymazal, 2007; Wang et al., 2010). In addition, various factors such as soil contents of organic carbon and inorganic nitrogen, moisture, temperature, PH, and microbial activity exert important impacts on soil gaseous N emission fluxes (Brovelli et al., 2012; de Sosa et al., 2018; Figueiredo et al., 2016; Rojas-Oropeza et al., 2010; Si et al., 2018; Wang et al., 2010).

In the past studies, a combination of field sampling and mathematical statistics was usually employed to explore the variance of soil N in the riparian zone (Lind et al., 2013; Shu et al., 2017; de Sosa et al., 2018; Ye et al., 2014; Zhong et al., 2018). This type of method is easy to be conducted; however, it is very difficult to adequately yield an explanation of mechanistic processes and to operate it at the catchment scale (Hoang et al., 2017). In addition, a number of specifically processed models have been developed to simulate the hydrological processes and N dynamics in the riparian, such as the Riparian Soil Model (Brovelli et al., 2012), Wetlands Water Quality Model (Chavan and Dennett, 2008), Soil and Water Assessment Tool-Riparian Ecosystem Management Model (SWAT-REMM, Ryu et al., 2011), Penn State Integrated Hydrological Wetland Model (Zhang et al., 2018), and modified SWAT (SWT-LS, Hoang et al., 2017). In recent years, with the development of remote sensing technology, satellite images with high temporal and spatial resolutions can display the variance of land cover for a large-scale region (Islam and Sado, 2000; Zhao et al., 2018). Moreover, N emissions by the soil at the riparian catchment scale were attempted to be simulated by coupling remotely sensed technology and simple processing models (Wang et al., 2010).

The Miyun reservoir is the terminal reservoir for the middle route of the SNWTP. It is the largest reservoir in North China and its design volume ranges within billion cubic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1500115018

meters. Since 1997, it has become the only surface drinking water supply for Beijing and exerts important impacts on the capital's social stability and economic development. Therefore, it is called the "life water" of the capital. After entering the 21st century, the water volume dramatically decreased due to climatic change and human activities and more and more attention are focused on the water quality. As a crucial terminal reservoir, the water volume of the Miyun Reservoir will increase by 0.8 billion m^3 due to water injected by the SNWT between 2015 and 2020. Furthermore, the water level will increase from currently 136 m to 150 m until 2020 (Yang et al., 2018a). As a result, the rapidly increasing water level will extensively inundate the riparian zone and may result in inevitable ecological risks for the water supply from this reservoir. Furthermore, the abilities of pollutant interception and nutrient degradation in the riparian zone may be weakened and the riparian zone may be rendered from a nutrient sink into a nutrient source (Bettez and Groffman, 2012; Schilling et al., 2006). Zhao et al. (2019) and Yang et al.(2018b) have reported that the plants in Miyun reservoir can effectively remove the N pollution, but the study about the N pollution removed by soil in Miyun reservoir under the SNWTP background has not been reported. Therefore, it is necessary to assess the variance of N emissions by soil induced by the SNWT in the Miyun reservoir. However, few studies have proposed a framework with which to estimate the effect of SNWT project on N removal by soil at the riparian catchment scale.

Consequently, the objective of this paper is to provide a useful framework with which to evaluate the SNWTP on N removal by soil in the Miyun riparian zone. Specifically, this study includes three steps: (1) coupling process-originated model and remotely sensed data to simulate the spatio-temporal varieties of N emissions by soil in the Miyun riparian zone between April and September in 2015; (2) dividing the riparian zone into four contour belts from low elevation to high elevation based on the Digital Elevation Model (DEM); (3) using a scenario setting method to estimate the influences of increasing water level induced by the SNWTP on N removal by soil at the Miyun riparian zone catchment scale. The simulated result is useful for the sustainable management of similar catchments than the Miyun riparian zone.

Materials and methods

Study site

This study was conducted in the riparian zone of the Miyun reservoir, which is located in the northeast of Beijing (40°26'N - 40°35'N, 116°47'E - 117°05'E, *Fig. 1*). The riparian buffer in the Miyun reservoir mainly includes the region surrounded by the road that encircles the reservoir and other adjacent regions schemed by local authority. The Miyun reservoir was constructed in September 1960, and has a total storage capacity of 4.375 billion m^3. The region belongs to the continental monsoon climate. The obvious climatic characteristic is an uneven distribution of precipitation and temperature over four seasons. About 70% of the precipitation falls between June and September (Yang et al., 2018a). In addition, the highest temperature during the year also occurs during this season. *Figure 1* shows that the proportions of Calcareous cinnamon soil and Cambisol soil are the largest and smallest, accounting for about 50% and 0.28% of the study area, respectively. Soil types and soil property datasets in this study, including soil texture, soil nutrients content, bulk density, and pH, were obtained based on the Second National Soil Survey and additional field investigation in the study region.

Framework method

This section introduces the framework (*Fig. 2*) that was developed to assess the impacts of the SNWTP on N removal by soil. This framework integrates an ecological model assessment model and scenario setting method, and the specific parts are introduced in the following. Because the ecological model assessment model in *Figure 2* has been successfully used in a Guanting Reservoir that has a similar geographical conditions and climate with Miyun Reservoir, the model parameters of the Guanting Reservoir are used to apply to the Miyun Reservoir simulation (Yang et al., 2018b). Meanwhile, a field experiment in the nearby (39°40.4'-40°27.6'N, 116°28.2'-117°1') of Miyun Reservoir has been conducted (Geng et al., 2018). In this experiment, two typical drilling profiles were selected to determine the denitrification intensity value of the vadose zone at different sampling depths (0-10 m) and analyze the vertical spatial distribution of denitrification in the vadose zone. The experimental results show that the denitrification rate mainly in the soil layer of 0-0.25 m. So, the soil layer depth between 0 and 25 cm was used to simulate the N emissions in this study.

Model inputs

(1) Remotely sensed data

The DEM data with 30-m resolution was obtained from the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER). Land use types (*Fig. 3*) were interpreted using the man-machine interactive method and the GF-1 multispectral data at a resolution of 8 m. The types and proportions of land use in this riparian zone include forestland (28.72%), grassland (24.52%), farmland (13.45%), bottomland (6.27%), residential land (3.17%), and water (23.88%).

Considering the impacts of satellite observation errors and spatio-temporal resolutions, multispectral Landsat 8 OLI satellite images with 30-m resolution between April and September 2015 were chosen. To eliminate the cloud interference with the spectral response to land surface targets, days 106, 138, 154, 186, 234, and 250 in 2015 for Landsat 8 OLI satellite data were chosen to invert the land surface parameters, e.g. VC, LAI, and land surface albedo. Additionally, to invert land surface parameters, a series of preprocessing steps such as radiometric, atmospheric, and geometric corrections were necessary. All of these preprocesses were operated using the ENVI 5.3 software. Finally, all image data mentioned above were re-projected into Albers with the World Geodetic System-84 datum and resampled into 30 m × 30 m spatial resolutions.

DOI: http://dx.doi.org/10.15666/aeer/1706_1500115018

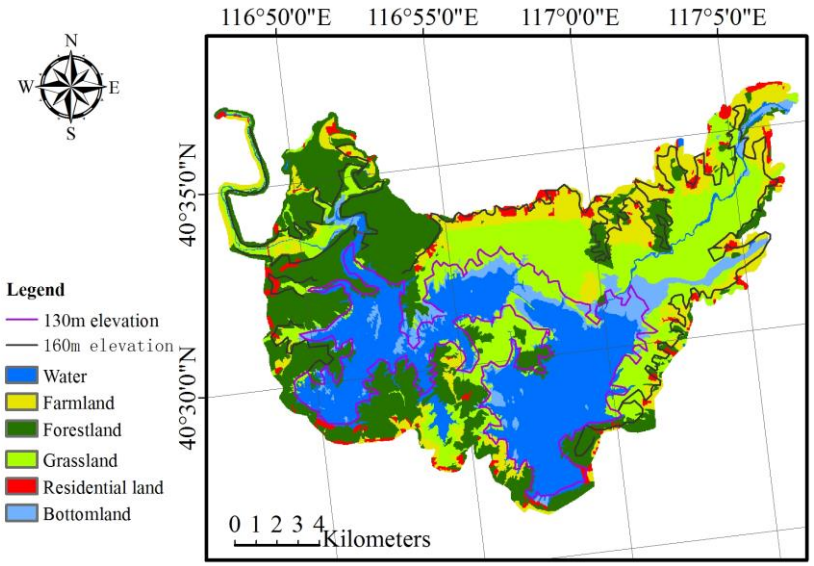

Figure 3. *The land use distribution in Miyun riparian zone*

(2) Meteorological data

The Beijing Meteorological Bureau and National Meteorological Information Center provided the daily observed rainfall data around the Miyun reservoir during the simulated period. Other daily observed climatic data from April to September in 2015 such as wind speed, air temperature, surface temperature, relative humidity, and sunshine duration were downloaded from the National Meteorological Information Center (http://data.cma.cn/site/index.html). The detailed information about the climatic data is listed in *Table A1* in the *Appendix*. All collected site records were generated as raster images using the Inverse Distance to a Power interpolation method using ArcGIS version 9.3.1.

Model descriptions

To simulate nitrogen emissions by the soil of the Miyun riparian zone, an Ecohydrological Assessment Tool (EcoHAT, Liu et al., 2009; Yang et al., 2011) was adopted in this study. EcoHAT was developed based on the mechanism of the ecohydrological processes in the Soil–Plant–Atmosphere Continuum (Dong et al., 2014). It was derived via multi-source data and can simulate hydrological processes, vegetation growth, and nutrient dynamics (Liu et al., 2009). The model used in this study mainly consists of three components: calculations of environmental factors i.e., soil temperature, soil moisture, and soil nitrogen; calculations of soil denitrification; calculations of soil nitrification and ammonia volatilization. *Tables A2* and *A3* (*Appendix*) show the main equations. In addition, model input parameters i.e., NDVI, LAI, and Albedo, were derived from Landsat8 data via remotely sensed inversion. The detailed extraction processes of input parameters and part model principle have been introduced in Zhao et al. (2019) and Yang et al. (2018b). Additionally, Yang et al. (2018b) reported that the EcoHAT has been successfully applied to simulate the N emissions at a region that has similar geographical conditions and climate than the Miyun reservoir; therefore, experimental model parameters in Wang et al. (2010) were chosen for this study.

Estimation of SNWTP influences

This section describes how to estimate the influences of SNWTP on nitrogen removal by soil in the riparian zone based on the simulated results of the EcoHAT model and the scenario setting method. Before estimating the impacts of the SNWTP, the Miyun riparian zone was first divided into four DEM-based contour belts using ArcGIS software. These four contour belts were respectively 130–140 m, 140–150 m, 150–160 m, and 160–170 m. Then, statistics about N emission of each contour were calculated based on the overlay of these four contour belts and the spatial distribution of N emissions by soil from April to September 2015, and for the simulated period. Finally, this study adopted a scenario setting method to suppose that the four contour belts in the Miyun riparian zone were submerged one by one from lower to higher elevations and gaseous N mission in every flooded soil belt was not included in the N removal by soil in the riparian zone.

Model validation in situ

Because the direct measurement of gaseous N emissions in the field is very difficult, a nitrogen mass conservation method was used to validate the gaseous N emissions by soil induced by denitrification, nitrification, and ammonia volatilization. In this method, the total N variances *in situ* are the sum of leaching N, N-uptake by vegetation, and gaseous N emissions. The following equation shows the nitrogen mass balance:

$$TN_{so} - TN_{sn} = N_{se} + N_{pa} + N_{le} \quad \text{(Eq.1)}$$

where TN_{so} and TN_{sn} are respectively the original total nitrogen content and total nitrogen content left in the soil (mg m^{-2} d^{-1}), N_{se} is the total gaseous N emissions (mg m^{-2} d^{-1}), N_{pa} is the N uptake by plant (mg m^{-2} d^{-1}), N_{le} is the leaching N (mg m^{-2} d^{-1}).

In this study, six sample data from three sample plots with 2 m × 1 m in shrub (116.848°E, 40.547°N), grassland (116.947°E, 40.547°N), and farmland (116.968°E, 40.559°N) were measured during April and May 2015. Every sample plot was divided using an iron plate in the middle, the left and right parts were measured at the beginning and end of April and May, respectively. The N uptaken by plants was calculated using the biomass and N uptake ratio coefficients (Yang et al., 2018b).

Results

Validation of N emissions

In this study, considering the precipitation distribution during the year (*Fig. 4a*), sample plots in April and May were used to validate the simulated results to minimize the influences of leaching N induced by precipitation. *Figure 4b* shows the scatter plots between simulated and in situ gaseous N emission data. Moreover, the correlation coefficient was calculated using the software EXCEL 2010. As shown in *Figure 4b,* the coefficient of determination is $R2 = 0.77$ ($P < 0.05$), which implies that the model has a sound simulation effect. However, the validation result indicates that the observed data is smaller than the simulated data, the reasons may be related to the ignorance of N leaching and the scale effect between observed and simulated data.

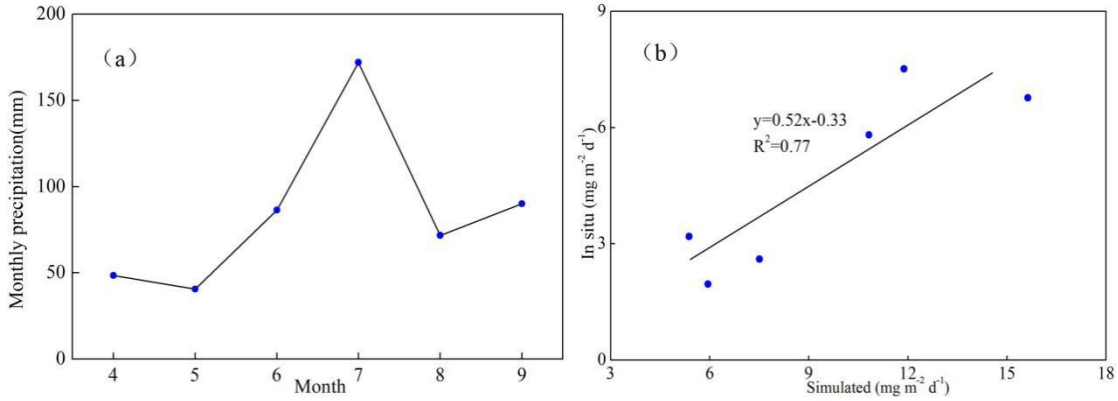

Figure 4. *The monthly precipitation (a) and validation results of N emissions (b)*

Spatio-temporal distribution of N emissions by soil

Figure 5 shows the spatial distributions of the simulated monthly gaseous N emission rate in the Miyun riparian zone from April to September in 2015. *Figure 5* shows that the wetlands distributed near water are nitrogen enrichment regions and have relatively high N emissions by soil. In addition, it is worth mentioning that N emissions by soil in forestland in the north and west clearly exceed those of grassland and farmland in the northeast, especially from June to September. The reasons that explain this phenomenon are related to the soil water content. The soil type in the northeast of this study area is mainly typical cinnamon soil, and the soil type of forestland in this study area is mainly calcareous cinnamon soil (*Fig. 3*). The soil field capacity, soil saturated water content, and soil wilting water content (0.31, 0.45, and 0.11) in typical cinnamon soil are significantly lower than those (0.28, 0.44, and 0.07) of calcareous cinnamon soil based on the experimental analysis. Therefore, for the same rainfall, the calcareous cinnamon regions have higher soil water content, which can further increase the soil dis-anaerobic environment and increase the denitrification rate.

Figure 6 shows the spatial gaseous N emissions in the growing seasons of 2015 for the Miyun riparian zone. The yearly N emission distribution is similar to those of every month. After calculation, the emission distribution in the whole catchment is 871.97 t.

Discrimination of N emission by different soil biochemical processes

Based on the results of model simulation, the contributions of soil N emissions by denitrification, ammonia volatilization, and nitrification were estimated for the simulated period. *Figure 6* shows that the three soil biochemical processes have similar temporal variation trends with a maximum in July and a minimum in April. In addition, *Figure 7* also shows that the proportions of N emissions induced by the three biochemical processes in total gaseous N emissions are significantly different. The soil denitrification process dominated the soil N emissions in this study area; the N emissions ranged from 34.72 t to 260.16 t between April and September and the maximum of 260.16 t of nitrogen occurred in July. In addition, the maximal values for soil nitrification and ammonia volatilization processes were 5.85 t and 24.57 t in July, respectively, and minimal values of 3.18 t and 10.93 t occurred in April. It is worth noting that soil denitrification rates showed dramatic fluctuations during the simulated period in comparison to the other two processes.

N removal by soil in contour belts

After statistical calculation, *Figure A1* (*Appendix*) shows that the N removal load of soil in the four contour belts were 380.38 t, 342.79 t, 302.72 t, and 981.59 t, respectively, from April to September. Furthermore, *Figure A1* shows the maximum N removals (107.77 t, 112.23 t, 107.18 t, and 384.54 t) and the minimum N removals (26.35 t, 20.63 t, 15.67 t, and 34.75 t) for July and April for the four contour belts. For each month, the N removal loads showed minor fluctuations from 130 m to 160 m; where the elevations exceeded 160 m, the N removal loads all steeply increased.

Influences of SNWTP on N removal by soil in the Miyun riparian zone

When the water transferred by the SNWTP was injected into the Miyun reservoir, the water level dramatically increased and extensively submerged the riparian zone. *Figure A2* (*Appendix*) shows the N pollution by the riparian soil when SNWTP submerged the contour belts. Although the N pollution by soil in the riparian zone decreased for all months, the reduction extent was different for each month. When the water level increased to 150 m, the riparian soil had about 50% of the original N absorption ability in April and May and had about 60% between June and September. With the water level exceeding 160 m, the riparian soil only had about 35% of the original N absorption ability in April and May and about 50% from July to September. Furthermore, these results also imply that the submerged riparian zone may develop into a nutrient source from a nutrient sink (Schilling et al., 2006; Ye et al., 2012) when it became ineffective at removing nitrogen.

Discussion

Effects of land use types on gaseous N emissions

The N dynamics in riparian soil follow a close relationship to the plant distribution and types (Wu et al., 2016; Ye et al., 2015); therefore, the distribution of land use plays a key role in influencing the N emissions in the riparian zone (Bedard-Haughn et al., 2006; Wang et al., 2010). *Table A4* (*Appendix*) shows the effect of land use type on the N emissions by soil, showing that the forestland has the most N emissions, accounting for 54.38% of the total gaseous N emissions. This is related to the forestland area distribution and soil moisture retention capacity. Furthermore, this study proves that denitrification is the most important way for the removal of N in three soil biochemical process, which is consistent with the results of previous studies (Bedard-Haughn et al., 2006; Kreiling et al., 2011; Ye et al., 2017; Wang et al., 2010). In this study, forestland showed the highest denitrification of the study period, accounting for 47.08% of total N emission; the grassland, farmland, and bottomland accounted for 11.44%, 12.79%, and 12.11%, respectively. In addition, the forestland and grassland dominated the nitrification and volatilization processes, accounting for 43.93% and 27.95% by soil nitrification and 44.06% and 27.66% by volatilization, respectively. The distribution of forest land on the higher elevation in this study has the most N emissions, which can partly be used to explain N removal by soil in contour belts where the elevations exceeded 160 m.

Adjusting riparian structure to improve the defense for N pollution

The results of this study showed that the increasing water level induced by the SNWTP can weaken N removal by soil in the riparian zone (*Figs. A1* and *A2*). A previous study reported that the vegetation restoration is an effective method for the remediation of degraded ecosystems by influencing soil properties in the riparian zone and by up-taking more nitrogen in the riparian (Zhang et al., 2010; Zhao et al., 2019). Consequently, it is necessary to illustrate the unit area N removal of the Miyun riparian zone. *Figure A3* (*Appendix*) shows the monthly average N emission rate variations for different land use types between April and September. There are typical steep increases from April to July in all land use types. However, different land use categories have important effects on the N emission rates. The ranges of the monthly N emission rates for forestland and bottomland are from 0.15 g m^{-2} to 2.23 g m^{-2} and from 0.51 g m^{-2} to 1.45 g m^{-2}, respectively, which exceed those of other types. The monthly soil emission rates for both forestland and bottomland are 0.94 g m^{-2} and 1.07 g m^{-2}, respectively. The soil emission rates for other land use types were 0.32 g m^{-2} for grassland and 0.58 g m^{-2} for farmland.

According to previous studies (Zhang et al., 2010; Zhao et al., 2019) and the results shown in *Figure A3,* the adjustment of land use types can be used to increase the defense ability for N in the riparian zone. Specifically, the farmland and grassland distributed in the lower elevation area around the open reservoir water and the forestland distributed at higher elevation areas in this study. Therefore, this study suggests to change more grassland and farmland into forestland to effectively offset the impacts of SNWTP on the N removal by soil in the Miyun riparian.

Conclusions

A number of studies reported that the soil in the riparian zones could significantly alleviate the water pollution risk by emitting gaseous N. The SNWTP is the largest inter-basin water transfer scheme in the world, and the Miyun reservoir is the terminal reservoir in the middle route of the SNWTP. With the injection of water since 2015, the riparian zone of the Miyun reservoir was extensively submerged. How to quantitatively assess the effects of increasing water induced by the SNWTP on the N removal in the Miyun riparian has become an important issue.

This study proposed a framework method that integrates the eco-hydrological model, remote sensing technology, and scenario setting to simulate the spatio-temporal varieties of N emissions and to assess influences of SNWTP on N removal by soil in the Miyun riparian zone. The scientificity of the simulated results has been validated by in situ survey data.

The results illustrate that wetlands near the water body are nitrogen enrichment regions and have relatively high N emissions by soil. In addition, the soil N emissions of forestland are higher than those of grassland and farmland, especially from June to September. Moreover, soil denitrification processes dominate soil N emission in this study area. After calculation, N emissions ranged from 48.83 t to 290.58 t between April and September 2015 and the emission distribution in the whole catchment was 871.97 t.

When the water level increased to 150 m, the riparian soil had about 50% of original defense N ability in April and May and had about 60% between June to September. However, the riparian soil had only about 35% of the original defense N ability in April and May and about 50% from July to September with the water level exceeding 160 m. This study demonstrates that changing farmland and grassland to forestland can effectively increase the amount of removed N in this riparian zone.

In summary, the results of this study are helpful for the sustainable management of similar catchment zones than the Miyun riparian zone. However, there are still many follow-up works to be further studied. In this study, the simulation does not consider the effect of groundwater level fluctuation on the removal of non-point pollutants in the Miyun riparian zone. In fact, the depth of groundwater in the riparian zone is shallow, and the water level fluctuates can greatly impact on the soil moisture, and then greatly affects the denitrification and nitrogen release process of the soil. Therefore, it is necessary to increase the simulation module of groundwater level in the future.

Abstract. The membrane-less electrolyzed water (MLEW) has been reported to possess antimicrobial effects against a variety of microorganisms and is considered as an alternative of traditional disinfectants. In the study, the inactivating efficiency was evaluated by using MLEW with free available chlorine (FAC) at concentrations of 50 and 100 mg/L against food-borne related microorganisms, including *Enterohaemorrhagic Escherichia coli* (ECHC), *Salmonella spp.* and *Staphylococcus aureus* individually. D-value (decimal reduction time) was applied for evaluating the antimicrobial ability of MLEW. D-values of ECHC, *Salmonella*, and *S. aureus* were about 120 sec, 5 sec and 5 sec, respectively. Our study demonstrated that MLEW is very effective in reducing the food-borne microbial contamination.
Keywords: *antimicrobial, free available chlorine, food-borne, disinfectants, microbial contamination*

Introduction

Bacteria induced food-borne illness has had serious impacts on public health. People infected with these food-borne bacteria can suffer from gastroenteritis, including inflammation of gut, diarrhea, abdominal pains and cramps, fever, bloody stool, nausea and vomiting. According to the previous study, the top five food categories linked to food-borne illness in the USA from 1990 to 2003 were seafood, dairy products, eggs, beef, and poultry products (CSPI, 2006). Recently, fresh-cut fruit, vegetables, prewashed and pre-cut salads have become popular eating choices. These food categories are generally eaten without processing. Along with this trend and changes in people's eating habits, the study found that microbial infections associated with fresh-cut fruits and vegetable increased (Qadri et al., 2015; Sureshkumar et al., 2016; Mahfuza et al., 2016).

Investigation of fresh-cut fruit and vegetables have indicated that these producing processes was unable to remove bacteria and also food-borne pathogens such as *Salmonella*, *L. monocytogenes*, *Staphylococcus aureus* and *E. coli* O157:H7 (Upadhyay et al., 2016; Sanchís et al., 2016). *Enterohaemorrhagic Escherichia coli* (EHEC) and *salmonella* have been reported as the causal factor of food-borne illness outbreaks (Switaj et al., 2015; Ebel et al., 2016). *Salmonella* and ECHC were estimated to be the leading cause and should be responsible for 30% of food-borne illness hospitalization in United States individually (CDC, 2013; Jadeja and Hung, 2014). *Staphylococcus aureus* is major pathogen in the food industry and listed among the top 5 pathogens causing food-borne illness (Sun et al., 2012; Giaouris et al., 2015).

Therefore, reducing the contamination caused by these pathogenic bacteria is important for protecting consumers from adverse health exposure in food industry. Many

DOI: http://dx.doi.org/10.15666/aeer/1706_1501915027

previous studies have shown that chlorine-related antimicrobial agent is helpful to reduce the bacterial contamination during food-production process (Rahman et al., 2012; Olaimat and Holley, 2012; Waters and Hung, 2014; Petri et al., 2015).

Electrolyzed water is generated from electrolysis of saline solution in a container within anodic and cathodic electrodes with or without ion-selective permeating membrane. The electrolyzed water contains free available chlorine (FAC) compounds such as hypochlorous acid (HOCl), chlorine gas (Cl_2) and hypochlorite ion (OCl^-) yielding its antimicrobial activity. The distribution of fractions of FAC compounds in electrolyzed water is dependent on pH values and affects biochemical characteristics. Acidic electrolyzed water (AEW) is generated in cathode compartment of electrolysis cell within membrane. It has a strong antimicrobial activity on various microorganisms because of its low pH (2-4) and higher proportion of chlorine gas compared to hypochlorous acid. These characteristics of AEW help destroy cell membrane and disrupt metabolism of microorganisms rapidly. AEW has been widely evaluated for antimicrobial application in recent decades.

Neutral electrolyzed water, has near neutral pH value (6-8), giving similar antimicrobial mechanism but result in less metal surface corrosion or skin irritation as AEW (Huang et al., 2008; Cui et al., 2009). This work chose the membrane-less electrolyzed water (MLEW) as the antimicrobial agent. The MLEW is one of the neutral electrolyzed water. Moreover, the membrane-less electrolytsis container is more productive, stable, convenient and economic because of expendable ion-selective membrane is not utilized during electrolysis (Chuang et al., 2013). MLEW becomes more popular in recent years because of above advantages but revealed less information as the alternative of conventional chlorine-related antimicrobial agents.

Neutral electrolyzed water has been extensively used for inactivating food-borne bacteria (Zhang et al., 2016; Machado et al., 2016). However, the MLEW has not yet been applied to inactivate food-borne bacteria. Thus, this study aims to evaluate antimicrobial activity of MLEW against the selected food-borne illness bacterial microorganism including ECHC, *Salmonella spp.* and *S. aureus* strains. In addition, two commercially available chlorine-related antimicrobial agents including bleach and chlorine dioxide (ClO_2), usually used in the food-processing factory, were applied to inactivate the selected bacterial strains for comparison in our study.

Materials and Methods

Preparation of Membrane-less electrolyzed water (MLEW)

The MLEW used in this study was generated by hand-made membrane-less electrolyzing device (Chuang et al., 2013). The schematic diagram of electrolyzing device is shown in *Figure 1*. The device consists of 850 mL cylinder polycarbonate (PP) container (height: 15 cm; diameter: 10.5 cm) filled with saturated NaCl solution (6.15 M). Two Pt/Ti base electrodes module (10×2 cm^2) was installed inside the PP container as cathode and anode with the gap of 0.8 cm between electrodes, giving 12 A electrical current inputs. The FAC concentration of the MLEW solution was measured with N, N-dimethyl-p-phenylenediamine (DPD) colorimetric method, using portable spectrometer (DR 2800, HACH, Loveland, CO, USA). The pH value of the MLEW solution was measured using pH meter (CyberScan pH 510, Eutech Inc., Singapore).

With 30 minutes of electrolyzing process, FAC concentration of NaCl solution would rise up to over 10,000 mg/L. This 850 mL solution with high FAC concentration was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1501915027

subsequently diluted with deionized water (Milli-Q, Millipore, Billerica, MA, USA) to FAC 50 and 100 mg/L as the ready-to-use antimicrobial agent (pH 7.0 ~ 7.2) for further inactivating experiments. In the United States, chlorine-related wash at highest FAC 200 mg/L is allowed to be used sanitizing treatment by the food-production industry (Regulation 21CFR178.1010). Therefore, we applied MLEW with FAC 50 and 100 mg/L in the study for simulate the field application in the factory. Bleaching liquid (NaOCl, Regular-Bleach, Colorox, CA., USA) and chlorine dioxide liquid (ClO_2, CLEAN GOOD, Daisyko Trading Co. Ltd.) were diluted to FAC 50 and 100 mg/L (the same concentrations with MLEW, measured with DPD methos, DR 2800 HACH, Loveland, CO, USA) to inactivate the selected food-borne bacterial strain as the reference antimicrobial agents.

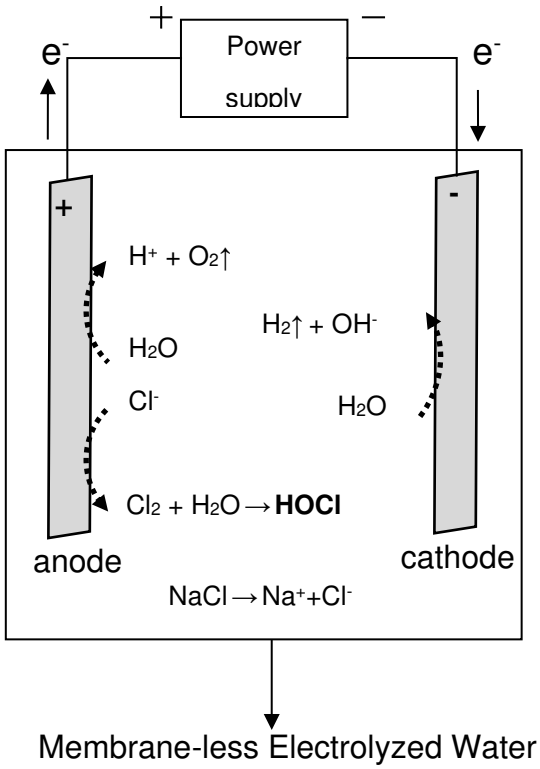

Figure 1. *The schematic diagram of hand-made membrane-less electrolyzing device*

Preparation of test bacterial strains

The bacterial strains used in the study including ECHC, *Salmonella spp.* and *S. aureus* were obtained from Bioresource Collection and Research Center (BCRC, Hsinchu, Taiwan). The preparation and culture of the testing microorganisms based on the previous research (Abadias et al., 2008). ECHC (BCRC 14824), *Salmonella enterica* (BCRC12947) and *S. aureus* (BCRC 10451) pure culture collections were transferred and grown on tryptic soy agar (TSA, BD, N.J., USA) incubating at 37 ± 1℃ for 48 hours. Single bacterial colony was isolated with streaking loop and transferred to tryptic soy broth (TSB, BD, N.J., USA) and incubating at 37 ± 1℃ for 24 hours in order to enrichment. The enriched TSB that respectively contained ECHC, *Salmonella spp.* and *S. aureus* cells were then poured individually into sterile tubes that were then centrifuged

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1501915027

at 2,500 rpm for 15 minutes. Following the centrifugal process, the supernatant of the TSB were removed. The resulting pellet in the tubes were re-suspended with 30 mL sterilized deionized water as testing suspension. The centrifuge and re-suspension processes were repeated twice to totally remove TSB. Culturable bacterial population of the testing suspensions were determined by tenfold serial dilution of 0.1 mL aliquot on TSA by incubation at 37 ± 1°C for 24 hours. The final bacterial population of the testing suspensions were adjusted to 10^6 ~ 10^7 colony forming unit CFU/mL for subsequent inactivating experiments.

MLEW, bleach and ClO_2 inactivating test against 3 bacterial strains

The experimental system and tests were operating in Taiwan, R.O.C. Quantitative inactivating experiments adapted from Robinson et al. (2010) against 3 bacterial suspensions were performed of MLEW, NaOCl and ClO_2 in the study. 1 mL of MLEW, bleach and ClO_2 with FAC 50 and 100 mg/L were added to 99 mL of 3 bacterial suspensions respectively as inactivating treatment samples (1% v/v contacting). After time interval of 10 and 30 seconds, 0.1 mL aliquot of agents-treated bacterial suspensions were extracted for tenfold serial dilution and spread on TSA, followed with incubation at 37 ±1°C for 24 hours. Each test would spread on three TSA plates. The colonies of the plates were counted and convert to original culturable population in the bacterial suspensions for measuring the survival rate at the inactivating time intervals mentioned above. Sodium thiosulfate ($Na_2S_2O_3$, 217263 Sigma-Aldrich, USA) was used to liberate bacterial aliquot from continuously contact of antimicrobial agents while extracted. The experimental limit of the serial dilution and culture method was 10 CFU/mL. On the other hand, as control sample, another group of 3 bacterial suspensions with neither MLEW, ClO_2 nor NaOCl were added were observed by the same aliquot, serial dilution and incubation process. The experiment was repeated triple.

Inactivating efficiency were evaluated by bacterial strains survival population to the extent of being killed in terms of corresponding decimal reduction times (D-value) of antimicrobial agents. The D-value is the time required, at a given condition, to achieve a log reduction, that is, to kill 90% of relevant microorganisms.

Statistical analysis

The inactivating efficiency of testing bacteria after MLEW, NaOCl and ClO_2 were calculated by subtracting the initial mean bacteria concentration (CFU/mL) from the bacteria concentration (CFU/mL) after each treatment. All experimental values showed the means of three different experiments with 3 replicates of the inactivating treatment per experiment. The Statistical Product and Service Solutions (SPSS version 20) program was utilized for statistical evaluation of measurement data. Significant differences between inactivating test with respect to bacterial reduction were analyzed by one-way ANOVA at a significance level of 0.05.

Results and Discussion

The inactivating efficiency of MLEW, bleach and ClO_2 against 3 bacterial strains

Table 1 shows the inactivating efficiency of MLEW, NaOCl and ClO_2 against ECHC with FAC 50 and 100 mg/L. The ECHC in the test suspension was almost totally inactivated by MLEW and bleach with FAC 50 mg/L after 10 second treatment. However,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1501915027

there is still 3.2×10^6 CFU/mL of ECHC remain survival (71%) in test suspension of FAC 50 mg/L ClO_2 after 10 second treatment. It reveals that MLEW and NaOCl performed rapid and effective antimicrobial reaction against ECHC than ClO_2 in the short time contacts ($p<0.05$). It can be expected that longer contact time between antimicrobial agent and bacterial bring better inactivating effect. In our study, 30 seconds treatment of FAC 50 mg/L MLEW and NaOCl did resulted in the same <10 CFU/mL survival population of ECHC. But ClO_2 still could not perform acceptable inactivating efficiency and remain 60% HCHC survival rate (2.7×10^6 CFU/mL) even elongate treatment time to 30 second.

Table 1. *Inactivating efficiency of MLEW, NaOCl and ClO_2 against ECHC*

Time intervals and culturable population of ECHC							
FAC concentration (mg/L)	Control group (CFU/mL)	MLEW		NaOCl		ClO_2	
		10 sec	30 sec	10 sec	30 sec	10 sec	30 sec
50	4.5×10^6	< 10	< 10	< 10	< 10	3.2×10^6	2.7×10^6
100	4.5×10^6	< 10	< 10	< 10	< 10	2.6×10^6	< 10

While treating with FAC 100 mg/L MLEW and bleach, ECHC were also mostly totally inactivated after 10 second contacting. The survival rate of ECHC to FAC 100 mg/L ClO_2 is 58% (2.6×10^6 mg/L) and higher than MLEW and NaOCl ($p<0.05$). In the other way, giving longer treatment time to FAC 100 mg/L ClO_2 cause significant improvement on inactivation. < 10 CFU/mL of ECHC survival was achieved when 30 seconds treatment applied with FAC 100 mg/L ClO_2. Our experimental resulted that ClO_2 does not pose comparable inactivating efficiency to MLEW and bleach in short time contact against ECHC. ClO_2 need longer contact time to present performance the same as MLEW and bleach when treating HCHC.

Table 2 shows the inactivating efficiency of MLEW, bleach and ClO_2 against *Salmonella spp.* with FAC 50 and 100 mg/L. The *Salmonella spp*. in the test suspension was almost totally inactivated by MLEW and ClO_2 with FAC 50 mg/L after 10 second treatment. However, there is still 9.0×10^6 CFU/mL of *Salmonella spp.* remain survived (18%) in test suspension of FAC 50 mg/L NaOCl after 10 second treatment. MLEW and ClO_2 performed rapid and effective antimicrobial reaction against *Salmomnella spp*. than NaOCl in the short time contacts ($p<0.05$). After longer 30 seconds treatment, FAC 100 mg/L of three chlorine-related antimicrobial agents resulted in <10 CFU/mL survival population of *Salmomnella spp*.

Table 2. *Inactivating efficiency of MLEW, bleach and ClO_2 against Salmonella spp.*

Time intervals and culturable population of *Salmonella spp*.							
FAC concentration (mg/L)	Control group (CFU/mL)	MLEW		NaOCl		ClO_2	
		10 sec	30 sec	10 sec	30 sec	10 sec	30 sec
50	5.0×10^7	< 10	< 10	9.0×10^6	< 10	< 10	< 10
100	4.6×10^6	< 10	< 10	< 10	< 10	< 10	< 10

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1501915027

As to FAC 100 mg/L three chlorine-related antimicrobial agents, all *Salmomnella spp*. survival populations were reduced to <10 CFU/mL condition. MLEW, NaOCl and ClO_2 can present comparable inactivation efficiency once enough contact time was set. The result in here indicates MLEW and ClO_2 are better effective antimicrobial agents against *Salmomnella spp*. while rapid treatment is needed.

Table 3 shows the inactivating efficiency of MLEW, NaOCl and ClO_2 against *S. aureus* with FAC 50 and 100 mg/L. Facing to *S. aureus*, FAC 50 mg/L NaOCl and ClO_2 did not give satisfied inactivation efficiency when treating with 10 second. 71% and 46% of S. aureus were still curturable after the 10 second treatment (4.0×10^7 and 2.6×10^7 CFU/ mL survived for NaOCl and ClO_2 treated samples). On the contrary, the MLEW performed <10 CFU/mL survival rate at the same 10 second contacting. MLEW performed rapid and effective antimicrobial reaction against *S. aureus* than NaOCl and ClO_2 in the short time contacts ($p<0.05$).

Table 3. *Inactivating efficiency of MLEW, NaOCl and ClO_2 against S. aureus*

Time intervals and culturable population of *S. aureus*							
FAC concentration (mg/L)	Control group (CFU/mL)	MLEW		NaOCl		ClO_2	
		10 sec	30 sec	10 sec	30 sec	10 sec	30 sec
50	5.6×10^7	< 10	< 10	4.0×10^7	1.7×10^7	2.6×10^7	< 10
100	5.6×10^7	< 10	< 10	3.2×10^7	1.0×10^7	1.4×10^7	< 10

As to longer 30 second contacting samples, only FAC 50 mg/ L NaOCl did not reach significant inactivating efficiency (30% were still survival). Both MLEW and ClO_2 give performed <10 CFU/mL survival rate in the same time of contacting. For FAC 100 mg/L antimicrobial agents experiments against *S. aureus*, NaOCl did not present significant inactivating efficiency no matter 10 second or 30 second treatment (survival rate were 57% and 17%). ClO_2 bought out satisfied inactivating efficiency after 30 second contact rather than 10 second (25% survived). MLEW presented < 10 CFU/mL survival rate against *S. aureus* both 10 second and 30 second treatment in our experiment. Therefore, ClO_2 and MLEW can be selected to inactive *S. aureus* contamination if longer contact time available.

D-values of MLEW, bleach and ClO_2 against 3 bacterial strains

Table 4 presents D-values (decimal reduction time) of chlorine-related antimicrobial agents applied against 3 bacterial strains in the study. According our experimental results, MLEW were the most suitable antimicrobial agents against ECHC, *Salmonells spp*. and *S. aureus* strains. The inactivating efficiency of NaOCl toward to *S. aureus* is limited. ClO_2 also presented limited inactivation against ECHC.

The MLEW reveals comparable even stronger antimicrobial effects with NaOCl in our study. The same trend could also be observed in previous studies of neutral electrolyzed water (Abadias et al., 2008; Machado et al., 2016). The antimicrobial property of MLEW is contributed to multiple factors. Firstly, at the near-neutral pH chlorinated solution, the predominant FAC species is hypochlorous acid. It has stronger biocidal capacity than hypochlorite ion, which is the predominant species in high pH NaOCl liquid (Rahman et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1501915027

al., 2010; Waters and Hung, 2013). Besides, the high oxidation-reduction potential (ORP) in the electrolyzed water is regarded as the primary factor yielding microbial inactivation. ORP can damage the outer and inter membrane of bacterial cell. Then, severely ORP stress can deplete the energy stores and damage the machinery that produced the energy associated with protein structure and cell function. High ORP provides MLEW additional antimicrobial factors apart from FAC species. It may explain the comparative efficacy observed in this study when FAC matched with chlorine dioxide (Thron et al., 2013; Machado et al., 2016). In Thron et al. (2013) study, the 20 minute antimicrobial treatment of electrolyzed water, bleach and ClO_2 against *S. aureus* was conducted. The results showed the order of antimicrobial efficiency was as follows: neutral electrolyzed water > ClO_2 > NaOCl. However, it should be noted there were instances in which no significant difference between agents was observed (Machado et al., 2016). It would going to the same trend if the contact time was elongated to minute level in our experiment. The MLEW did revealed comparable inactivation efficiency against the three common food-borne contagious bacterial strains to ClO_2 and bleach according to our present experimental results.

Table 4. *D-values of MLEW, bleach and ClO_2 against 3 bacterial strains*

D-values and FAC of chlorine-related antimicrobial agents						
Bacterial strains	MLEW		Bleach		ClO_2	
	50 mg/L	100 mg/L	50 mg/L	100 mg/L	50 mg/L	100 mg/L
ECHC	5 sec	5 sec	5 sec	5 sec	144 sec	42 sec
Salmonella spp.	5 sec	5 sec	11 sec	5 sec	5 sec	5 sec
S. aureus	5 sec	5 sec	57 sec	40 sec	5 sec	5 sec

From the standpoint of field usage in food-processing factory and kitchen, MLEW and ClO_2 take the advantages of on-site generation. Since ClO_2 traditionally requires manual mixing of sachets whereas MLEW generation can be automated by device which is simply fabricated and economically maintained. Only water, salt and electrical power are required to generate the MLEW continuously on site. No hazardous matter storage and mixing involved in the MLEW generation (Thorn et al., 2013). Since highly microbial reactive species contained, the disadvantage of MLEW is the rapidly free chlorine loss in the open air. Greatly lost of free chlorine in the electrolyzed water is observed when settled in the open-light environment during several days, following with the significantly decreasing of biocidal efficiency (Han et al., 2018). The generation model comprehend sufficiently supply and using just-in-time is highly demands for the MLEW application in the food-production industry.

Conclusions

Our experimental result indicated that food-borne bacteria inactivation efficiency of MLEW is comparable to conventional chlorine-related agent, including bleach and ClO_2. MLEW even presented more ensuring inactivation to the target strain especially short time treatment set in our study. However, the sanitization in food-production involves

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1501915027

complicated processes and interfering factors, such as various deploying surface (metal plate, fabric surface or wood cutting board), organic matter reaction (blood, feces or tissue residual), co-existence of microbes (viral and bacterial strains). Therefore, further investigations of broad spectrums and various conditions should be fulfilled to clarify the s and applications of MLEW in the food-production industry.

Abstract. Plant polysaccharides exhibit good antioxidant activity and might represent potential novel antioxidants. Chemical composition, characteristics, and biological activity of plant polysaccharides vary between different species. *Chrysanthemum nankingense*, a vegetable in South China, contains many active chemicals which have been used as materials in medicine to treat various conditions. Here, we extracted crude polysaccharides from *Chrysanthemum nankingense* plant using ultrasonic-assisted extraction with a 1:35 (w/v) ratio of leaf powder to water, extraction time of 1h at 60°C. CNP-1 was isolated, using anion-exchange chromatography on a diethylaminoethyl-cellulose column. We determined molecular weight and chemical composition of the fractions using Fourier transform infrared spectroscopy (FT-IR), high-performance liquid chromatography (HPLC), and nuclear magnetic resonance (NMR) spectrometry. Monosaccharide composition analysis indicated that glucuronic acid was the most abundant unit in CNP-1 polysaccharide fractions. Superoxide radical scavenging assessment, 2, 2-diphenyl-1- picrylhydrazyl (DPPH) assay, and a ferric reducing ability of plasma (FRAP) indicated that CNP-1 has significant antioxidant activity in a dose-dependent manner. In summary, *C. nankingense* contains acidic polysaccharides that may represent a promising natural source of antioxidants for healthy food.

Keywords: *Chrysanthemum nankingense, polysaccharide, structure characterize, antioxidant activities, in vitro*

Introduction

Polysaccharides derived from natural sources are associated with a wide range of therapeutic effects and health-improvement properties (Wang et al., 2016). Polysaccharides are effective antioxidants, and may have antitumor, anticancer and antiviral capabilities, and regulate the immune system (Yang et al., 2014). The natural polysaccharides attracted more and more attention for their potential benefits and perceived safety. Polysaccharides extracted from plants have antioxidant effects on free

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1502915040

radicals, which suggests that they may be helpful, for example, in limiting the effects of aging, lowering blood sugar or adjusting lipid metabolism (Qi et al., 2006; Capek and Turjan, 2009; Chen et al., 2012; Lv et al., 2014). Consequently, the study of naturally occurring polysaccharides in plants might lead to the discovery of a novel source of antioxidants beneficial to humans.

Chrysanthemum nankingense is a perennial herb that belongs to the tribe Anthemideae of Asteraceae (*Figure 1*). Its young leaves are used as a vegetable in South China. Moreover, it is used by traditional medicine to treat various conditions, including stomach heat, bitter taste in the mouth, constipation, headache or red eyes (Dai and Wen, 2015; Wu et al., 2015).

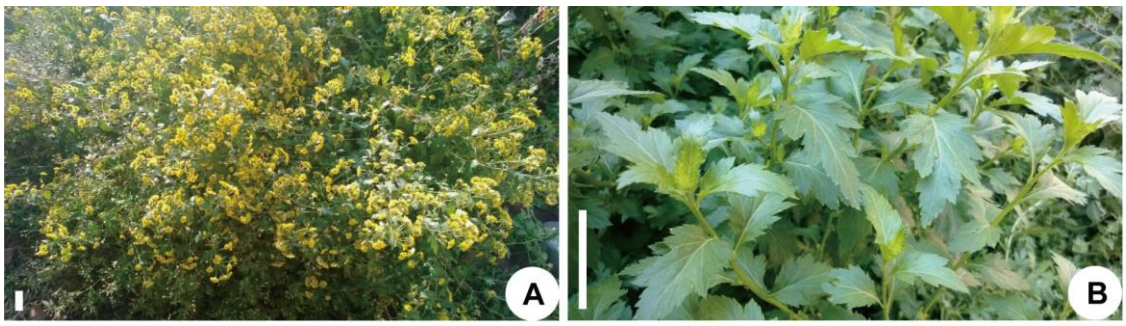

Figure 1. *The Chrysanthemum nankingense plant. A) In flower plant (November). B) Foliage plant (September)*

C. nankingense contains a variety of organic compounds such as flavonoids, polyphenols, alkaloids, organic acids, borneol, and camphor (Yang et al., 2005; Lv et al., 2007; Wu et al., 2015). However, we have little information on the polysaccharides in *C. nankingense*. In this paper, we isolated the polysaccharides present in *C. nankingense* leaves and characterized their properties by Fourier transform infrared (FT-IR) transmission spectroscopy, high performance liquid chromatography (HPLC), and high performance gel permeation chromatography (HPGPC) and nuclear magnetic resonance (NMR) spectrometry. We further explored the polysaccharides antioxidant activity using a variety of in vitro techniques. The objective of this study was to investigate the natural antioxidants fount in *Chrysanthemum nankingense* which may be used as a natural source of antioxidants for healthy food.

Materials and methods

Materials

Chrysanthemum nankingense plants used in this study were collected in the Hubei province, grown in the Nursery Garden of Northeastern University of China. Fresh leaves were collected and washed with distilled water, defatted with two 95% ethanol

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1502915040

washes, and dried in vacuum for 16 h at 60°C. Dry leaves were crushed into powder and filtered with an 80 mesh sieve. The powder was stored in an airtight container at dry place until needed.

All the chemical reagents used were of analytical grade except 2, 2-diphenyl-1-picrylhydrazyl (DPPH), Ascorbic acid (Vc) , 1, 3, 5-tri (2-pyridyl) -2, 4, 6-triazine (TPTZ) and DEAE cellulose DE-52 (DEAE-52) were purchased from the Sinopharm Chemical Reagent Co. (Beijing, China).

Extraction of polysaccharide

About 15 g powder samples were dissolved into deionized water at a 1:35 (w/v) ratio of powder leaves to water, incubated in a water bath at 60°C for 30 min, and subjected to ultrasonic extraction twice for 30 min at a power of 240 W. The mixture was centrifuged at 3000 rpm for 10 min. Then the supernatant was obtained and condensed in a rotating evaporator until a precipitate appeared. The extracts were disposed by activated carbon and Sevag method for decolorizing and removing free proteins. The polysaccharide was precipitate with 80% absolute ethanol overnight at 4°C. The mixture was centrifugated at 3000 rpm for 10 min and lyophilized to obtain raw *C. nankingense* polysaccharides (CNP), which were then stored at −20°C for further use.

Separation and purification of crude CNP

The raw polysaccharides were purified successively by DEAE-52 and Sephadex G-100 chromatography according to the method of Qiao et al. (2009). Five hundred milligrams of crude CNP were dissolved in 10 mL water and applied onto a DEAE-52 column equilibrated with 20 mM phosphate solution (NaH_2PO_4/Na_2HPO_4, pH 6.8). The column was eluted with the 20 mM phosphate solution and sequentially NaCl-phosphate solution gradient (0.05, 0.1, and 0.5 M) with a flow rate of 2 mL/ min. The eluates (5 mL/tube) were collected and monitored by the sulfuric acid anthrone method (Somani et al., 1987). The fraction was collected, concentrated in a rotating evaporator at 50°C, dialyzed in a 21 mm dialysis bag in deionized water for 48 h, and then lyophilized and stored at -20°C till needed.

Characterization of CNPs

FT-IR spectra analysis of CNPs

The infrared spectrum of purified fractions grounded into 1 mm KBr pellets were determined using a FTIR spectrophotometer (Bruker Tensor 27 FT-IR, Bruker Co., Germany) in the frequency range of 4000−400 cm^{-1} (Peng et al., 2012).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1502915040

Nuclear magnetic resonance (NMR) spectrometric analysis of CNPs

About 30 mg CNP1 was dissolved in 500 μL 99.9% D_2O and analysized using Bruker Advance III 600 MHz spectrometer (Bruker Co., Germany) to obtain ^1H NMR spectra. Chemical shifts were determined in ppm.

Monosaccharide composition analysis of CNPs

Ten milligram of purified CNP were complete hydrolyzed by applying 3 mL trifluoroacetic acid (2 M) at 120°C for 6 hours, then centrifuged at 12000 rpm for 5 min after cooling. 0.2 M NaOH was added to the supernatant to adjust the pH to 7.0. The hydrolysate eluted was aadded to 10 mL and stored in sealed container.

The derivatization was determined following the method of Honda et al. (1989) with some modification. Samples (10 mg/mL) and monosaccharide standards arabinose, glucuronic acid, glucose, rhamnose, mannose, galactose, and xylose were mixed with 0.2 M NaOH and 0.5 M 1-phenyl-3-methyl-5-pyrazolone (PMP) solution in 1 mL test tubes. The solutions were thoroughly mixed and incubated at 70°C for 40 min. Then 0.2 M HCl were used to neutralize the NaOH after the samples cooled. One hundred microliters of trichloromethane were added to the mixture and completed mixed, then centrifuged 5000 rpm for 10 min. The supernatant was extracted for three times with chloroform. The final supernatant was filtered with a 0.45 μm membrane and used for high-performance liquid chromatography (HPLC) with a C18 column (250 mm × 4.6 mm, 5 μm). The mobile phase was 19% (V/V) ammonium acetate buffer solution (pH 5.5) and the flow rate was 1.0 mL/ min.

Determining the molecular weight of CNPs

Molecular weights were measured by high performance gel permeation chromatography (HPGPC) using a Waters HPLC system equipped with two serially linked TSK-GEL G3000 PWXL (7.8 mm × 300 mm) columns and RI and connected to a UV detector. The mobile phase was 0.71% Na_2SO_4 and the flow rate was 0.6 mL/min and the temperature of column was kept at 35°C. Molecular weights of the samples were obtained by comparison with a calibration curve created using the Dextran T-series standards with known molecular weights (23800, 80900, 147600 and 273000). The linear equation of the standard curve was: LogM = −0.34974968tR + 9.75252445, with a correlation coefficient of 0.9981.

Determining the antioxidant activity of CNPs in vitro

Determining CNPs' scavenging activity against oxide anions

The measurement of polysaccharide scavenging activity against superoxide anions were conducted as previously described (Marklund and Marklund, 1974). First, 4.5 mL 0.05 M tris-HCl solution (pH 8.0) was incubated in a water bath at 25°C for 20 min. Then 50, 100, 150, or 200 μL of sample (2 g/L) were added and stirred at 25°C for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1502915040

20 min. Finally, the reaction was terminated by adding 100 μL 1, 2, 3-phentriol (3 M). The mixture of tris-HCl and 1, 2, 3-phentriol was used as negative control (A_0). The absorbance of the mixture was measured spectrophotometrically at 325 nm and the scavenging activity against superoxide anions was calculated according to the following equation: scavenging effect (%) = (A_0−Asample)/A_0×100%; rate of oxidation (%) = (A_9−A_1)/3×100%, where A_1 is the absorbance of the first detection and A_9 is the absorbance of the ninth detection.

Scavenging ability of DPPH radical

DPPH radical scavenging activity of CNP was measured following the method reported previously (Jia et al., 2014). Two milliliters of sample at various concentrations (0.3, 0.5, and 0.7 mg/mL) were added to 2 mL DPPH ethanol solution (0.06 mM) in a 5 mL cuvetteand mixed completely. The mixture was kept in the dark for 20 min and the absorbance of the sample was measured at 517 nm using a spectrophotometer (721G, China). Ascorbic acid (Vc) was used as the control. The scavenging rate was obtained according the formula: DPPH radical scavenging activity (%) = (1- As/Ab) × 100%, where As is the absorbance of the sample, and Ab is the absorbance of the blank.

Assessment of iron reducing activity

The ferric reducing activity of plasma (FRAP) was measured following the method reported by Jia et al. (2014), with some modifications. Fresh FRAP reaction solution was prepared by mixing 25 mL acetate buffer (300 mM; pH 3.6) with 2.5 mL 1, 3, 5-tri (2-pyridyl) -2, 4, 6-triazine (TPTZ) solutions (10 mM) and 2.5 mL $FeCl_3$•$6H_2O$ (20 mM). Then, 1000 μL of the sample were put into a cuvette to measure the initial absorbance after the sample was warmed to 37°C. The absorption of the solution was measured at 593 nm while 40 μL sample at different concentration (0.2, 0.4, 0.8 or 1.0 mg/mL) were added to the cuvette. The absorption value was recorded at 10 s intervals until it reached a plateau. Iron reducing activity was calculated referencing to the calibration curve prepared of $FeSO_4$•$7H_2O$ solution with several concentrations (100-1000 M). Three technical replicates were conducted for each analysis mentioned above. Three parallel measurements and technical replicates were conducted for each analysis mentioned above. All the data were processed in Origin 8.5.1.

Results and discussion

Purification and segregation of CNP

We obtained the primary polysaccharides from *C. nankingense* using ultrasonic pretreatment with an isolation time of 5 hours, raw materials to water ratio of 1:35 (w/v), power of 240 W, and a combination of activated carbon decolorization and Sevag method to remove the pigment and proteins. The yield of raw polysaccharide from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1502915040

C. nankingense was about 4.32%. Four elution peaks (CNP-1, CNP-2, CNP-3, and CNP-4) were presented from the crude CNP using a DEAE-52 cellulose anion-exchange chromatogram (*Figure 2*). The major fraction CNP-1 was condensed and lyophilized for next analysis.

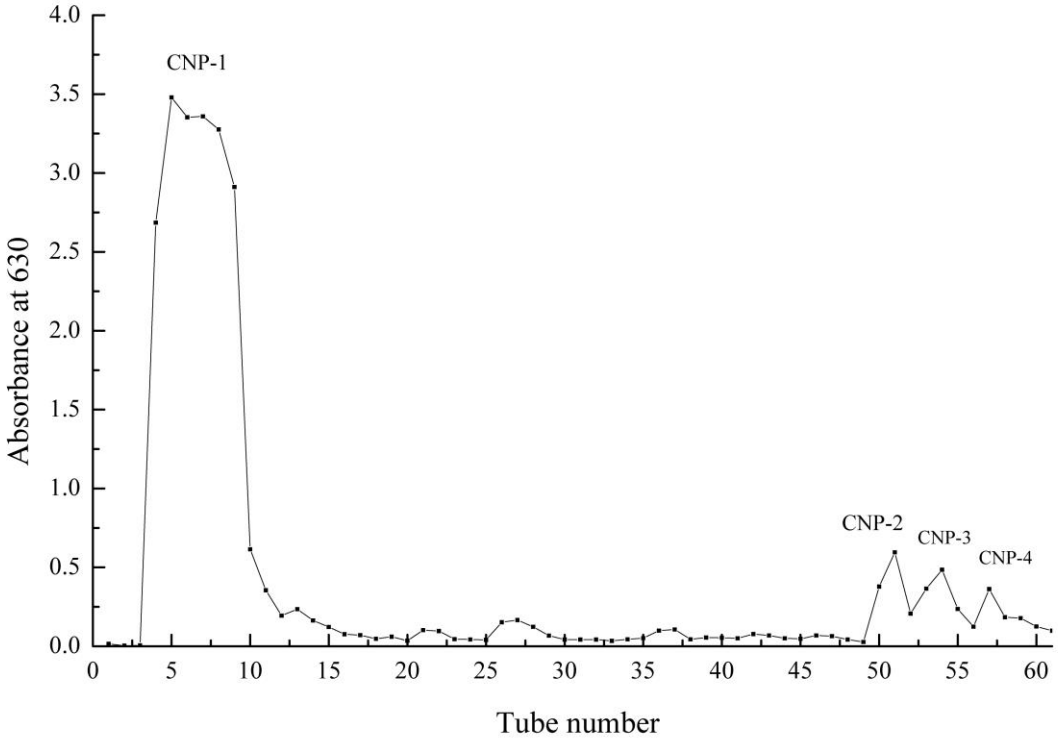

Figure 2. *Elution curve of crude Chrysanthemum nankingense polysaccharide detected by sulfuric acid anthrone method at 490 nm using DEAE52-cellulose column chromatography. CNP-1 was eluted by phosphate solution. CNP-2, CNP-3, and CNP-4 were eluted by 0.5 M NaCl-phosphate solution*

Structure analysis of CNP-1

FT-IR spectra analysis of CNP-1

We characterized the absorption of CNP-1 using FT-IR spectrum (*Figure 3*). This sample showed a wide, intense signals at 3600–3200 cm^{-1}, representing an O-H stretching group, and a weak signal at 3000–2800 cm^{-1}, which we attributed to a C–H stretching vibration (Jia et al., 2014). We also observed peaks in the region of 1630–1510 cm^{-1} and 1420 cm^{-1}, attributed to C=O asymmetric stretching vibration (Cerna et al., 2003), suggesting the carboxyl groups presenting here (Zha et al., 2012). The peaks at 1000–1200 cm^{-1} in the CNP-1 polysaccharide fractions suggests the presence of C–O–C and C–O–H signals, possibly an alduronic acid such as glucuronic acid or mannuronic acid. The CNP-1 fractions presented peaks between 3600 and 3200,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1502915040

3000 and 2800, 1250 and 1000 cm^{-1}, the typical signals for polysaccharides (You et al., 2014). A characteristic signal at 891±7 cm^{-1} was attribute to glycosidic linkages. CNP-1 has a characteristic signal at 937.3 cm^{-1} induced by asymmetric stretching vibration of pyran ring (Coimbra et al., 1998). Thus, we propose that CNP-1 might be pyranose.

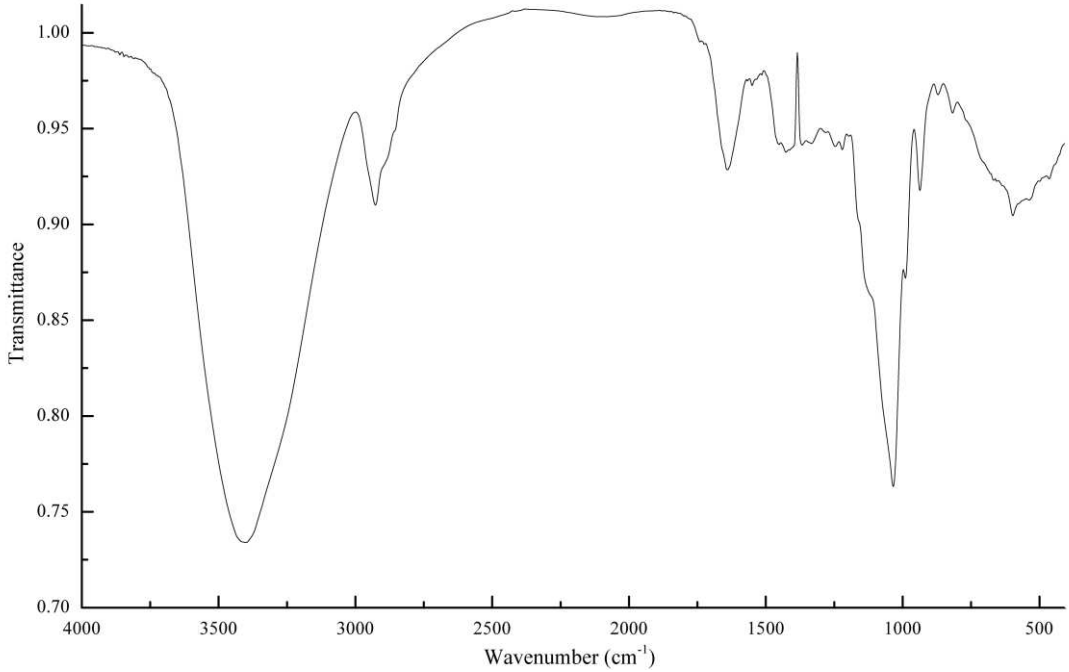

Figure 3. *Fourier transform infrared spectra of CNP-1*

NMR spectra of CNP-1

The structural of CNP-1 was confirmed using ^{1}H-NMR analysis (*Figure 4*). The spectra of CNP was presented between 3.0–5.3 ppm (^{1}H NMR) which were typical signals for polysaccharides (Chen et al., 2016; Wang et al., 2018). The signals induced by protons on sugar rings were present in the region of 3.50–4.50 ppm. We predicted that CNP-1 has a-configuration of saccharide residues for all the resonance signals greater than the shift of 4.8 ppm (Chen et al., 2016). This conclusion further confirmed the results of the infrared spectrum.

Monosaccharide analysis of CNP-1

We characterized the monosaccharide composition of CNP-1 by HPLC (*Figure 5*). Monosaccharide standards of glucuronic acid, mannose, rhamnose, xylose, glucose, galactose, and arabinose produced well separated peaks, with retention times of 16.18, 21.03, 24.47, 26.62, 30.91, 34.12, and 45.69 min. Glucuronic acid was the most abundant monosaccharide in the CNP-1 fraction; mannose and galactose were also

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1502915040

present in trace amounts. These results indicate that CNP-1 is primarily composed of sugar acids, which suggests that it may have deoxidizing activity.

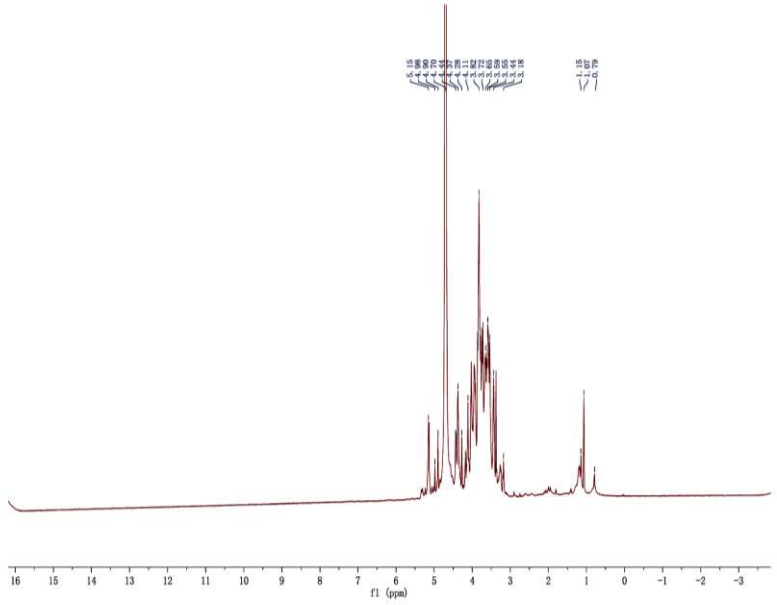

Figure 4. *1H NMR spectra of CNP1*

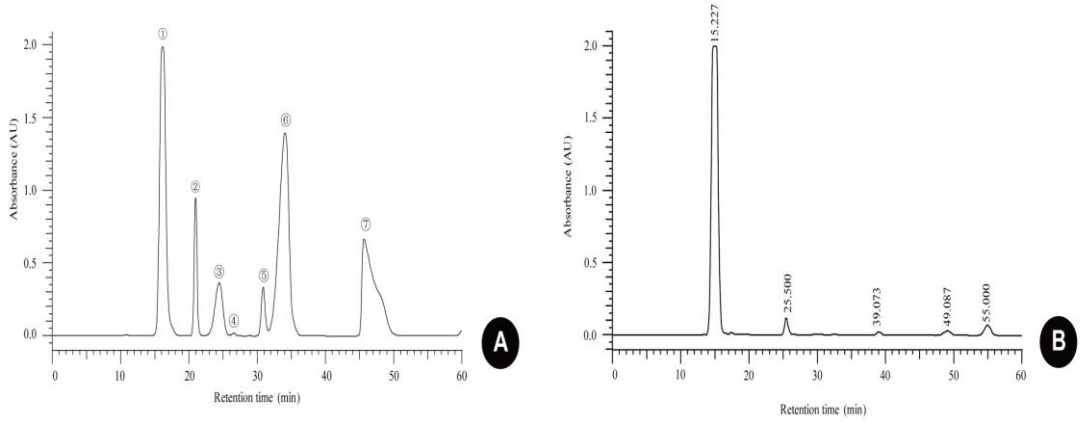

Figure 5. *High-performance liquid chromatograms of three monosaccharide fractions isolated from Chrysanthemum nankingense. Part A shows peaks for the monosaccharide standards glucuronic acid (1), L-mannose (2), D-rhamnose (3), L-xylose (4), L-glucose (5), D-galactose (6), and L-arabinose (7). Parts B shows C. nankingense monosaccharide fractions CNP-1*

Molecular weight of CNP-1

We determined the molecular weight of CNP-1 using the HPGPC method. Based on the reference curve created with dextran standards, we estimated that the average molecular weights of CNP-1 was 4779 Da.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1502915040

Antioxidant activity of CNP-1 in vitro

Using the DPPH assay, we found that the activity to scavenge free radical of CNP-1 at 0.7 mg mL^{-1} was 21.39%, while that of Vc was 89.00% (*Figure 6A*). The results suggested that CNP-1 had a radicals scavenging effect on DPPH. The FRAP value of CNP-1 increased with the concentration of this fraction (*Figure 6B*). At 0.8 mg/mL, the FRAP value of CNP-1 was 2.726 mmol. These results demonstrate that CNP-1 possesses strong ferric reducing activity.

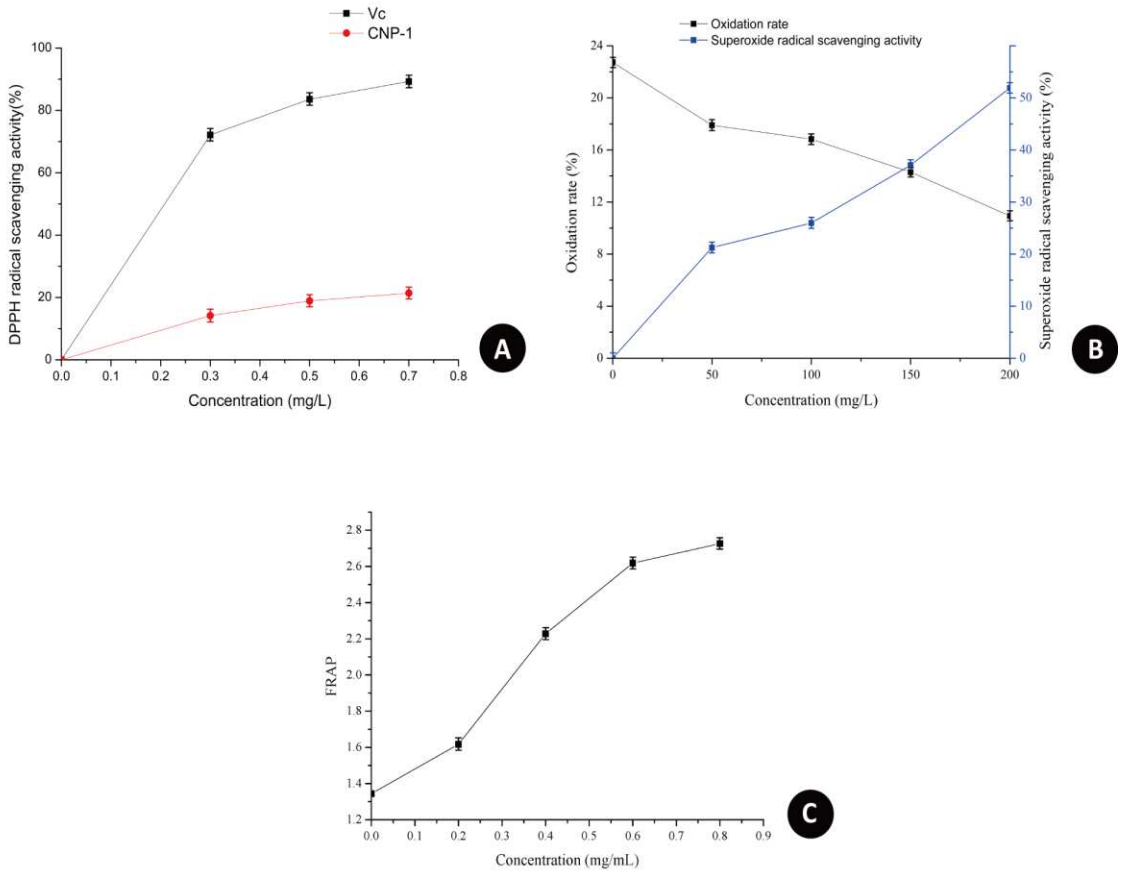

Figure 6. *Antioxidant activity of the purified polysaccharide fraction CNP-1. A. DPPH radical scavenging activity. B. Ferric reducing activity. C. Superoxide radical scavenging activity*

We measured the scavenging activity of CNP-1 on superoxide radical (*Figure 6C*), finding that the oxidation rate of the solution decreased with increases in CNP-1 concentration, while with sample concentration increasing, the scavenging activity of CNP-1 increased also. The scavenging activity of CNP-1 reached 51.91% at the doses of 200 mg L^{-1}. These results demonstrate that CNP-1 is characterized by strong superoxide radical scavenging activity.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1502915040

Conclusion

In this study, we isolated polysaccharides from *C. nankingense*, and characterized its structural features. Glucuronic acid was the main component of the polysaccharides of this plant by monosaccharide composition analysis. Antioxidant activity analysis demonstrated that CNP-1 had high ferric reducing ability and superoxide radical scavenging activity. These findings suggest the polysaccharides from *C. nankingense* leaves might be a potential source of natural antioxidants in functional foods or pharmacological applications. In addition, the studies showed that most of metabolities were associated with the plant phenotypes (Schauer et al., 2006; Sulpice et al., 2009; Chen et al., 2014; Dan et al. 2016). *Chrysanthemum* is complex taxa with different habitat and various ploidy levels. The phylogeny of *Chrysanthemum* is still not clear. Polysaccharide, as a widely existed metabolite in plant, might be a new way to explore the relationship between *Chrysanthemum* species.

Abstract. In Cameroon, climate variability largely controls agriculture related livelihood strategies This variability enhances environmental threats including deforestation, water scarcity and land degradation, which would affect these long and short-term livelihood strategies. This study examined farmers' perceptions of climate variability and the factors that influence various climate adaptation strategies in the highlands of Southwest Cameroon. Using local scale meteorological data from 1974 to 2014 and climate perception data collected from 355 households, in 22 rural villages through household surveys and 12 focus group discussions, descriptive statistics and logit regression model analyses were performed. Results showed 85.1%, 83.9% and 86.2% of the respondents to have observed changes in patterns of temperature, rainfall and number of rainy days. Results further showed household characteristics such as marital status (P-value 0.072) to influence the household decision of increasing in farm size more than gender of household head (P-value 0.221). Also, age of household head (P-value 0.086) influenced adoption of changing planting dates more than gender of household head (P-value 0.207) in a village at the 95% level of significance. This study will help policy makers educate local rural farmers on climate adaptation measures, impacts, and methods for increasing crop yields.
Keywords: *climate variability, perception, adaptation strategies, logit model, smallholder farmers*

Introduction

In Cameroon as in many other sub-Saharan African countries, climate variability exerts varying impacts especially on the agricultural sector. This is probably due to the fact that the majority of the local population mainly relies on rain-fed agriculture for a living (Mukete et al., 2017). Therefore, due to its sensitivity to rainfall and temperature anomalies, the agricultural sector would be adversely affected. These climate effects could likely lead to socioeconomic impacts particularly in the case of farmers whose livelihood (60%-80%) primarily depends on agriculture (Defang et al., 2017). Climate variability is often linked to differential land-maritime interactions which result into various impacts on human lives and livelihoods. Often attributed to changes in rainfall patterns or amount and shifts in thermal and wind regimes, this variation modifies local seasonal and annual water balances. These seasonal and annual water balances in turn influence the periodic distribution for which temperature and moisture conditions permit agricultural crop production (Mongi et al., 2010; Sonwa et al., 2017; Ndiaye et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1504115054

In many developing countries, local farmers continue to perceive climate variability as it exerts varying impacts on crop yields. Farmers have therefore developed various adaptation strategies which permit them adapt to this changing climate. But in order to adopt a particular climate adaptation strategy, farmers must first experience climate change before taking measures to adapt to these perceived changes. According to Oluwatusin (2014) and Mukete et al. (2017), these adaptations are interventions and adjustments which occur in order to take advantage of the opportunities or to manage the losses that take place as a result of any external change. From another perspective, IPCC (2012) refers to climate adaptation as the adjustments in natural or man-made systems in response to actual or expected climatic stimuli or their effects. The assessment of farmer adaptation strategies is necessary if the information required for managing climate risks, adaptation enhancement policy analysis and implementation is to be made available (Mukete et al., 2018a).

In this regard, several studies across Africa have examined climate perceptions, variability and farmer adaptation strategies. For instance, Tsegamariam (2018) showed that majority of farmers around Abeshege Woreda in Ethiopia had perceived a decrease in rainfall with an increase in temperatures during the past two decades. Here, farmers applied soil and water conservation, small scale irrigation, changing planting dates, improved crop and livestock varieties as adaptation strategies to climate variability. Using, the logit regression model, the authors observed farmer educational level, farm size, access to credit schemes, and family size to determine a farmer's decision to adopt climate adaptation strategies. Similarly, Gadédjisso (2015) showed about 85% of farmers in Togo, perceived increase in temperature and 85.58% a decrease in rainfall patterns within the past three decades. Farmer adaptation strategies included crop diversification, off-farm jobs, increase in farm size, change of planting date and planting of cycle crops. A multinomial logit analysis showed education level, farming experience, access to extension services, credit schemes, and climate information enhanced a farmer's adaptive capacity to climate variability.

In another study, Seid (2016) observed 96.3% of farmers in Western Ethiopia, had perceived an increase in temperature and 90.7% a decrease in the amount and timing of annual rainfall patterns between 2000 and 2015. In addition, average annual temperatures were found to have increased by about 0.096 °C while annual rainfall had decreased by about 46.75 mm per year. According to the study, over 49.9% of the farmers have adopted climate adaptation approaches such as crop diversification, irrigation, improved crop varieties, adjusting planting dates and various soil conservation techniques like fallowing. In another study around the Vea Catchment of Ghana, Limantol et al. (2016) found, 90% and 94% of farmers believed that temperatures have increased and rainfall amounts, duration, intensity and number of rainy days have decreased. In this catchment area, farmers who rely on rain-fed agriculture adjusted to climate variability by varying crop types, crop rotation without fertilizer. Meanwhile, farmers who rely on irrigation offset climate variability with a greater use of fertilizer application. According to van der Veen (2013), 78%, 69% and 17% of farmers in the Ethiopian Highlands perceived an increased in temperatures and the level of precipitation was declining over the past 20 years. Farmers employed climate adaptation strategies such as crop diversification, various soil conservation methods like planting of trees, fallowing, irrigation, and changing planting dates. Using a multinomial logit (MNL) model, the farmer's level of education, age, wealth, access

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1504115054

to credit schemes, agricultural extension services and climate change information respectively determined their choice of adaptation strategies.

In Cameroon, agriculture is the main stay of the country's economy, employing over 70% of the population (Kimengsi and Muluh, 2013; Balgah et al., 2016; Tabi et al., 2017). However, agricultural activities have been largely affected by fluctuations in local climate particularly rainfall and temperatures which affect both large scale and subsistence agriculture (Kimengsi and Tosam, 2013; Sonwa et al., 2017). Over the past four decades, lack of reliable quantitative data on agricultural activities and climate variability has been a major challenge for Cameroon's researchers. For instance, and according to Defang et al. (2017), farmers in Southwest Cameroon perceived climate variability as a late start and early cessation of rains, decrease intensity of rainfall, increase temperatures and intensity of the sun. The study also found majority of farmers to have adapted to climate impacts on plantain (*Musa paradisiaca*) and cassava (*Manihot esculenta*) by respectively treating suckers and cuttings with Mocap before and after sowing. MOCAP® is a granular systemic insecticide or nematicide containing 15% w/w ethoprophos which is applied to the soil. It is recommended for the reduction in wireworm damage, potato cyst nematode damage and incidence of Spraing, on all varieties of potatoes. Farmers also changed the cultivated cocoyam variety and planted trees in order to adapt to the impacts of climate change.

Similarly, Darota et al. (2017) observed 92% of the Kaka and 86% of Bulu tribes of Southern Cameroon to have perceived excessive rainfall and which occurs for a short period. Here, 53% of Kaka and 58% Bulu tribes, practiced off-farm activities to compensate for the low income resulting from low harvest due to climate variation. Other adaptation options included, crop diversification, early planting and harvesting as well as cultivating in upland and lowland areas. In another study carried out in the Santa Agrarian Basin of Cameroon's Western Highlands from 2001-2014, Zephania and Bonglam (2016) found farmers to have perceived decreasing rainfall with increasing temperatures and relative humidity trends. The study found over 90% of these local farmers to be aware of climate variability. Meanwhile, about 8.2% were yet to adopt adaptation strategies which would lead to reduced negative impacts, increased crop resilience and integrated animal farming systems. Relatedly, Balgah et al. (2016) found over 97% farmers in North West Cameroon to have demonstrated contextual knowledge of climate variability, as they reported increased rainfall, prolonged dry seasons and changes in rainfall patterns. The study also indicated changing planting dates, and mixed cropping as local farmer adaptation strategies. In another study using primary weather and household livelihood survey data, Mukete et al. (2017) examined the vulnerability and adaptability of women to climate changes in the Rumpi highlands of southwest Cameroon. The study found decreasing amounts of rainfall, receding forests, increasing temperatures, water scarcity, and increasing costs of living. The study also found adjusting sowing dates, adopting petty trading and changing cropping patterns as adaptation strategies applied by these local women.

Although agricultural activity has been largely affected by climate anomalies particularly rainfall and temperature with varying effects on both large and small-scale agriculture, long-term sustainability initiatives and studies are rare. These rare studies such as Defang et al. (2017) and Mukete et al. (2017) have mainly examined farmers' perceptions of climate change and adaptation options without analyzing the various factors that may determine a farmer's choice of climate adaptation measures. Aside farmers' perceptions of climate change and adaptation measures, the present study

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1504115054

analyzes the various factors that may determine a farmer's choice of climate adaptation measures in the highlands of southwest Cameroon.

This study bridges that knowledge-gap as it assesses farmers' perceptions of climate variability and the factors that determine their choice of adaptation strategies. This baseline information may help improve macro-level poverty estimates and serve as an input into agricultural policy. It may also serve as a knowledge platform for effective collaboration between agriculture dependent communities, stakeholders and policy makers to design effective rural community-based agricultural management and rural development programs aimed at reducing climate change impacts and improve crop yields. This will create the possibility of building a broad knowledge base and offer adaptation and mitigation strategies to help farming households cope with climate changes.

Materials and methods

Study area

This study was carried-out in part of the highlands of Southwest Cameroon located along latitude 4°51′26″ N and longitude 9°07′15″ E in Ndian Division (see *Fig. 1*).

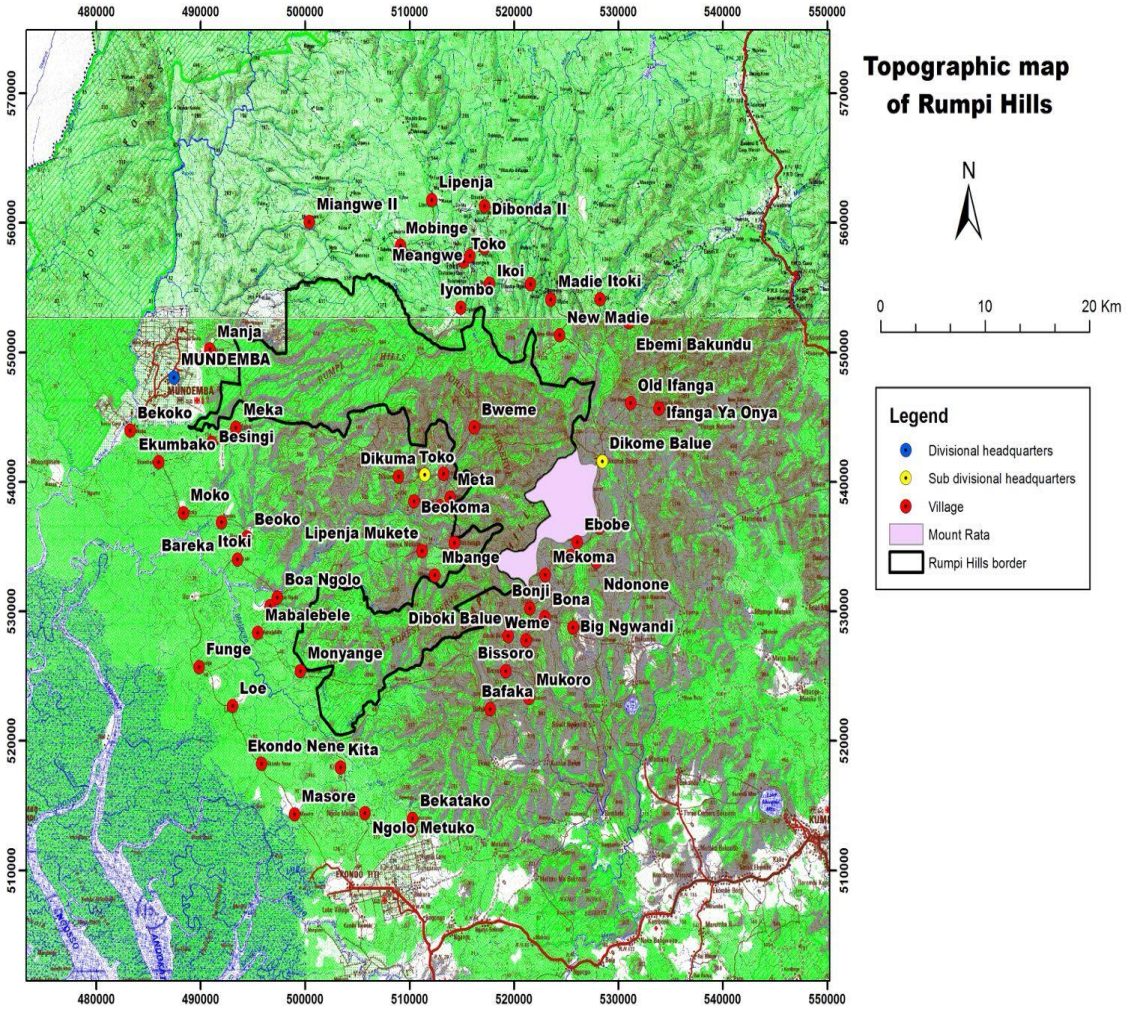

Figure 1. *Map of study area*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1504115054

Majority of the population is rural with over 90% involved in agricultural activities growing food crops (cocoyam, plantains, cassava etc.) and cash crops (oil palm, cocoa and rubber tree etc.). Local communities are also engaged in other livelihood activities such as animal husbandry, petit trading and the harvesting of Non-timber forest products (NTFPs) mostly as off-season jobs. NTFPs are items of biological origin which are not timber and wood, obtained from forests, plantations, woods, fallows and other agroforestry systems. In the highlands of southwest Cameroon, NTFPs are primarily land snails, bitter cola, bush mango, njansang, bush pepper and various edible mushrooms (Ofundem et al., 2017; Mukete et al., 2018c).

Data collection

Data were collected between December 2016 and May 2017 through focus group discussions (FGDs) and individual questionnaires. The number of households in each village was obtained from the local village chiefs because official census data are lacking. In villages with less than 25 households, only semi-structured and open-ended questionnaires through a door to door survey were used. Additionally, villages with more than 25 households were divided into groups for easy implementation of FGDs. The number of participants in an FGD was limited to 10 and included volunteers and or randomly selected farmers of at least 18 years old (according to Cameroon Law). Their national identity cards were verified and in cases where this was unavailable, recommendation was sought from the local village chief or his representative. In instances where potential participants were unable to effectively communicate in English language, "Pidgin English" or Oroko dialect was used by the first author to ensure proper understanding. The interview captured at least 90% of the households per village giving a total of 355 interviews of households across the 22 adjacent villages (Mukete et al., 2018c).

The household was the basic unit for this study and it refers *to a group of people living together in the same house who regularly cook and eat from the same pot*. Here, questions were centered on household head demographic characteristics, socioeconomic activities, perception of climate variability and adaptation methods employed. Meteorological data from 1974-2014 were collected from the Pamol Plantations Plc weather station located in Mundemba, Ndian division of southwest Cameroon. Pamol Plantations Plc is an agro-industrial company specialized in palm oil production and growth of natural rubber. Stata 13.0 was used for the logit regression model analysis to identify the determinants of farmer adaptation strategies. Meanwhile, Microsoft Excel for Windows 10 was used to deduce the meteorological data per parameter. The logit model was employed because it considers the relationship between a binary dependent variable and a set of independent variables, be they binary or continuous (*Eqs. 1* and *2;* Greene, 2018).

$$\text{Log } [P_i/(1 - P_i)] = \log (P_i) = \beta_0 + \beta_1 X_i \quad \text{(Eq.1)}$$

where P_i is the probability of perceiving a variability in climate and X_i an independent variable Therefore, the parameter β_1 gives the log odds of the dependent variable and β_0 is a constant.

The probability of occurrence of an event relative to non-occurrence is called odds ratio and is given by

$$P_i/(1 - P_i) = \exp (\beta_0 + \beta_1 X_i) \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1504115054

The dependent variables are the adaptation strategies which include increase in farm size, use of external inputs (labour, pesticides, fertilizers, and manure), crop diversification, change of planting dates, off-farm activities and NTFPs harvesting. Meanwhile, the independent variables are the household characteristics such as gender, age, educational level, inhabitants, and marital status of farmer.

Results

Household characteristics of respondents

Household characteristics showed 54.4% of the respondents to be males and 45.6% females. About 10.4% of the respondents were aged 21-30 years, 81.4% aged between 31-60 years and 8.2% were over 60 years. Similarly, 79.7% were indigenous while 20.3% were migrants (*Table 1*). Also, 20.8% had no education, 54.4% had only primary education, 21.7% secondary education and only 3.1% had university education.

Table 1. *Household characteristics of respondents*

Variable	Frequency	Percentage
Gender		
Male	193	54.4
Female	162	45.6
Age		
21-30	37	10.4
31-40	113	31.8
41-50	98	27.6
51-60	78	22
Above 61	29	8.2
Inhabitants		
Indigenous	283	79.7
Migrants	72	20.3
Educational level		
No education	74	20.8
Primary	193	54.4
Secondary	77	21.7
University	11	3.1
Marital status		
Married	205	57.7
Single	102	28.7
Divorce	19	5.4
Widowed	29	8.2

Economic activity

Results showed 51% of the respondents were involved in agricultural activities, 19.4% in petty businesses, and 13.2% in forestry resources harvesting (see *Table 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1504115054

Table 2. *Economic activity of respondents*

Sector	Response	Frequency	Percentage
Agricultural	Yes	181	51.0
	No	174	49.0
Public transport	Yes	35	9.9
	No	320	90.1
Petty business	Yes	69	19.4
	No	286	80.6
Forestry	Yes	47	13.2
	No	308	86.8
Other	Yes	23	6.5
	No	332	93.5

Farmer perception of climate variability

About 73.5%, 11.5% and 15% of the respondents had perceived an increase, decrease and no changes in temperature patterns. Similarly, 77.5%, 6.5% and 16% had perceived a decrease, an increase and no change in rainfall patterns respectively. Also, results showed 61.4%, 25.1% and 13.5% thought the number of rainy days had decreased, increased and had not changed (*Table 3*).

Table 3*. Farmers' perception on climate variability*

Climate parameters	Variability	Frequency	Percentage
Temperature patterns	Increase	261	73.5
	Decrease	41	11.5
	No change	53	15
Rainfall patterns	Increase	23	6.5
	Decrease	275	77.5
	No change	57	16
Number of rainy days	Increase	89	25.1
	Decrease	218	61.4
	No change	49	13.5

Variation in mean annual temperature patterns

Mean annual temperature had increased by 0.015 °C per year with 2009 recording the highest mean annual temperatures. The R squared value shows a 16% variation in temperatures (see *Fig. 2*).

Variation in mean annual rainfall

Mean annual rainfall decreases by about 1.7445 mm per year with 1983 having the highest mean annual rainfall and the R squared value shows a 2.5% variation in rainfall indicating that the regression line fits the data as shown in *Figure 3*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1504115054

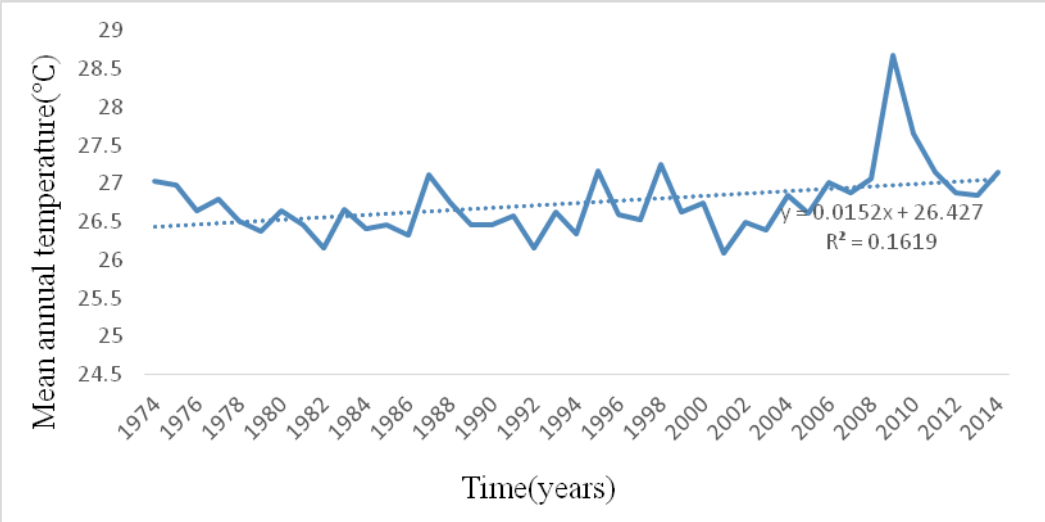

Figure 2. *Mean annual temperature patterns from 1974–2014 (°C)*

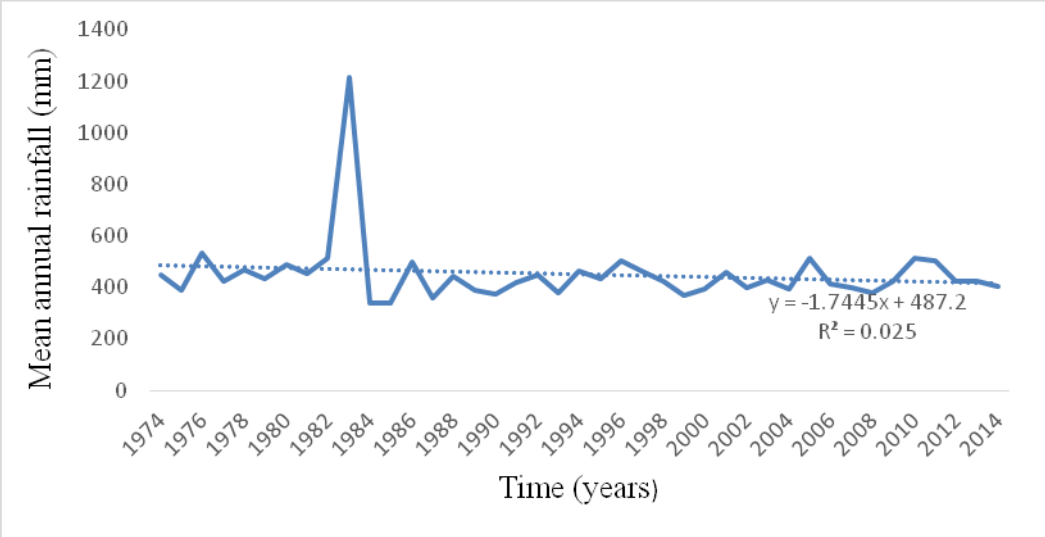

Figure 3. *Trends in mean annual rainfall from 1974–2014*

Variation in mean annual number of rainy days

The number of rainy days from 1974–2014 shows (*Fig. 4*) slight variability and decreases by about 0.0178 days per year with 1993 having the lowest mean annual number of rainy days. The R squared value shows a 2.46% variation in the number of rainy days.

Climate adaptation strategies

The various climate adaptation strategies included increase in farm size (land area under cultivation), use of external inputs (labour, pesticides, fertilizers, and manure), crop diversification, changing of planting dates, off-farm activities such as public transport (commercial motor bikes), and petty businesses (hair beauty salons, barber shops, restaurants), and NTFPs harvesting.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1504115054

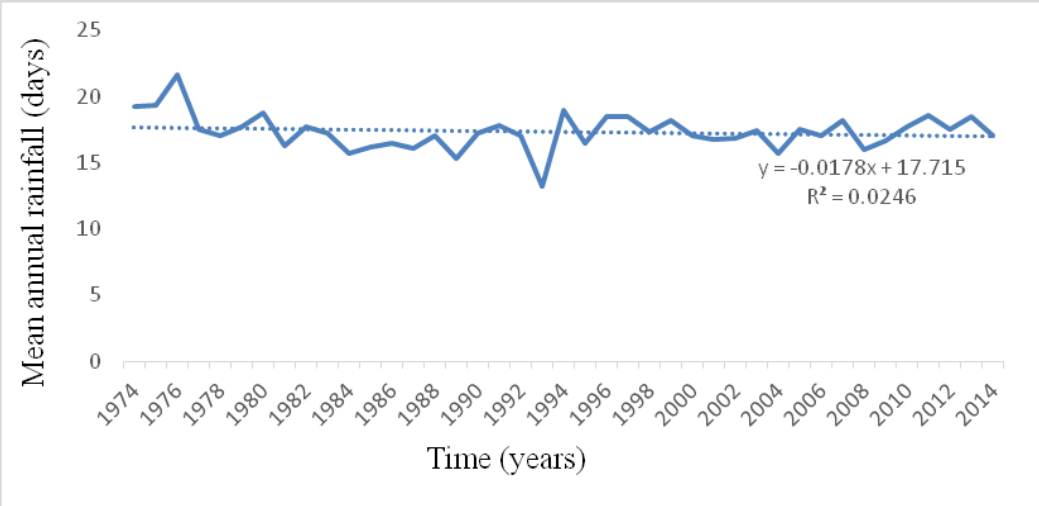

Figure 4. *Mean annual number of rainy days from 1974-2014*

Over 31.8%, 21.7% and 20.6% have adopted crop diversification, off-farm activities and NTFPs harvesting. Meanwhile, 9%, 5.9% and 3.4% had adopted increase in farm size, use of external inputs and changing planting dates as climate adaptation strategies (see *Table 4*).

Determinants of household adaptation strategies

Various determinants of climate adaptation strategies were identified using the logit regression model (*Table 5*). The logit regression model showed marital status (P-value 0.072) to influence a farmer's decision to adopt increase in farm size more than gender of household head (P-value 0.221) in the village at the 95% level of significance. Similarly, age of household head (P-value 0.086) influenced the decision to adopt changing planting dates more than gender (P-value 0.207). Additionally, marital status (P-value 0.128) was more important in the decision to adopt crop diversification than age of household head (P-value 0.187).

Discussion

Household characteristics of respondents

Male headed households were higher than the female headed households due to the tedious nature of farming activity that entails more energy and physical strength. Also, female headed household heads are usually involved in other livelihood activities such as petty businesses and NTFPs harvesting. Majority of the farmers were aged between 31-60 years representing the economically active and working age group. This group has the potential to increase crop productivity by willing to adopt measures aimed at mitigating climate impacts. According to Sofoluwe et al. (2011), individuals in the active working age group have been found to be more knowledgeable about better practices and may be more willing to bear risk and adapt to better farming techniques because of their longer planning horizons. Post primary education was quite low indicating that most youths immediately take up farming after completing primary school. Their choice of selecting climate adaptation practices is usually compromised

DOI: http://dx.doi.org/10.15666/aeer/1706_1504115054

due to lack of access to climate information and knowledge. This is because education increases a farmer's ability and competence in efficient resources use. From another perspective, the allocative effect of education enhances a farmer's ability to obtain, analyze and interpret information (Sofoluwe et al., 2011).

Perception of climate variability

Over time, farmers have observed climate changes usually based on recent climatic events which shape their perceptions and hence adaptive decisions. Perception is thus an essential precondition to undertake adaptation measures such as the existence of long-term changes in temperature, rainfall patterns, and number of rainy days.

Climate variability

Trends in temperature and rainfall between 1974 and 2014 have been changing over time. This is may be due to the inter-annual fluctuations of the intertropical convergence zone which causes a shift in the annual alteration of wet and dry seasons in tropical Africa. This intertropical convergence zone (ITCZ) is an area of low atmospheric pressure that forms where the Northeast Trade Winds meet the Southeast Trade Winds near the earth's equator. Climate variability across Africa is further influenced by the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1504115054

forces and localizations of the African Easterly Jet (AEJ), the Tropical Easterly Jet (TEJ) and sea-surface temperature (SST), in the Gulf of Guinea (UNFCCC, 2007; Mukete et al., 2017; Sonwa et al., 2017)

Climate variability adaptation strategies

Majority of the farmers were aware of climate variability and had undertaken various adaptation options to cope with these negative climate effects. Major adaptation strategies included increase in farm size, use of external inputs, crop diversification, off-farm activities petty businesses and NTFPs harvesting. For instance, crop diversification provides the farmers with a wider choice of growing a variety of crops within a given area. Wondimagegn and Lemma (2016) also observed that this strategy expands production related activities on various crops, reduces the possible risk of climate variations and enables farmers to change crop types which are better suited to the prevailing climate regimes. Off- farm activities which compensated for the climate related low harvest are supplementary or complimentary activities that farmers engage in either offseason or on-season to support themselves. Studies by Ovwigho (2014) and Darota et al. (2017) also found such off-farm activities to include casual labour, transportation business, traditional dancing, palm wine taping, and petty trading. The switch to NTFPs harvesting and collection is frequent due to the mountainous nature of the area and which is surrounded by lowland and sub-montane forests. Mukete et al. (2018b) also observed that aside being a measure to reduce the negative effects of climate, farmers also depend on the NTFPs harvesting and collection to supplement household income, medicines and fodder for their animals.

Determinants of adaptation strategies

Perception of climate variability is directly proportional to the age of the farmers and older respondents are more efficient in perceiving climate variability than the younger respondents. Therefore, as a farmer aged, his or her ability to correctly describe climatic variations increases. A similar study by van der Veen (2013) observed the likelihood of taking up climate adoption measures to be higher among older farmers. She found the coefficient of marital status to positively correlate with the probability of a farmer selecting increase in farm size as an adaptation strategy. Thus, married farming households with large active household sizes would have more available labour force to extend farm sizes. Similarly, farming households could have access to credit schemes to increase their farm size and pay for hired labour. In Kenya, Korir and Ngenoh (2019) found married household heads to exert a significant and positive influence on the adoption of community-based climate adaptation strategies.

Conclusions

In climate change studies, it is necessary to incorporate local farmer perceptions and meteorological data particularly with respect to its influence on agriculture. As such, these perceptions can be used to examine the impact of climate on crop yield or production and various adaptation strategies employed by farmers after perceiving climate variations. As a result of climate variations, farmers have perceived fluctuations in temperature, rainfall and number of rainy days. These fluctuations have been in the form of decreased rainfall, number of rainy days with an increase in mean annual

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1504115054

temperatures. Just as observed in farmer perceptions, meteorological data also showed variations. Mean annual rainfall decreased by 1.7445 mm per year with 1983 having the highest mean annual rainfall. Also, mean annual temperature had increased by 0.015 °C per year with 2009 recording the highest mean annual temperatures while the number of rainy days decreased by about 0. 0178 days per year with 1993 having the lowest mean annual number of rainy days. This study also observed that farmers employed various adaptation measures to mitigate perceived aspects of climate change. These strategies included crop diversification, off-farm activities, NTFPs harvesting, increase in farm size, use of external inputs and changing of planting dates.

In addition, household head's characteristics such as marital status and age affected his or her decision to adopt a particular adaptation strategy. The study has also confirmed the importance of combining and including farmer perceptions with climate and meteorological data in climate studies especially in the context of agricultural resilience to climate change as described by many scientific literatures. It has further provided knowledge of the main adaptation strategies used by farmers in the highlands of southwest Cameroon to adapt to climate change. From these adaptation strategies, effective and appropriate policies can be designed and implemented to reduce the effects of climate variability or changes. Areas for further scientific investigation in the study area could include how creating awareness of climate change and variability can influence farmers' choice of adaptation measures.

Abstract. This study investigates the requirements for creating blue-green infrastructure (BGI) as an instrument of stormwater management, in which nature-based solutions in urban and suburban landscapes are preferred. This case study of stormwater retention ponds (SWRPs) in the suburban landscape surrounding the city of Pilsen (Czechia) evaluates selected qualitative parametres of SRWPs on private land. Evaluated SWRPs have been classified according to the ownership relations and the potential indicators of their involvement within the BGI. Although the drain control as a primary purpose of SRWPs is a main criterion of their design, the ponds' parameters may differ from each other based on how their nature-based elements are used as well as what their amenity functions in a public space are. Based on the analyses of SRWPs' potential, the case study recommends public administration to provide some tools to support the private sector. The economic tools, motivating private sector, must be enhanced. An example of such an instrument could be the establishment of fees for stormwater drainage taking the ecosystem quality of the water management solutions into account.
Keywords: *ecosystem services, hydro-social system, nature-based solutions, private land, rainwater management, landscape planning*

Introduction

Water management in urban agglomerations has been transforming significantly and systematically in the 21st century: it is characterised by its decentralization (Schmidt, 2009; Rygaard et al., 2011; Elemer and Fraker, 2012; Wong, 2013; Yang et al., 2019). Cities all over the world endeavor to react to climate changes, especially to unbalanced rainfall regime and the increasingly frequent deepening occurrence of temperature extremes. These issues are mainly caused by the relatively high number of artificial and watertight surfaces in both urban and suburban landscapes. In spite of the fact that the hydrological cycle's changes are most obvious in urban landscape, it is necessary to remember a sustainable planning of suburban landscape too (Antrop and Entvelde, 2000). Such a landscape has specific ecological characteristics: It is characterized by a connectivity matrix and a high level of landscape heterogeneity. It means that large number of land covers is present (Antrop and Entvelde, 2000). The areas of the suburban landscape are used with different intensity – on the one hand, there are places strongly transformed by humans, such as industrial or commercial grounds (Spilková and Šefrna, 2010). On the other hand, there are nature-based surfaces, such as residual wetlands (Ehrenfeld, 2000). Historical development of catchment area situated next to urban

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1505515072

agglomeration generally enhances the proportion of watertight surfaces and thus changes the hydrological regime (Koronkevich and Mel'nik, 2015).

The functions of a suburban landscape, connected to land use categories could be divided into three groups: i) urban functions (residential housing, transport communication, commercial centres, industrial zones); ii) production functions (agricultural and forestry); iii) specific suburban functions (recreational water areas; parks; background of urban infrastructure, such as waterworks or sewerage; dump; mining areas). Changes of water drainage are influenced especially by a significant increase of built up areas as a direct consequence of residential and commercial suburbanization (Miller and Hess, 2017). That's why it is necessary to pay attention to developing blue-green infrastructure (BGI) in localities of suburban landscape. BGI via nature-close remedies should help to mitigate fast water drainage, increase evapotranspiration and replenish groundwater reserves.

The term "blue-green infrastructure" is used rarely in the Czech environment and when the term is used is mostly referring to foreign sources via inaccurate references. From the terminological point of view, there is a discussion about "green infrastructure" in the Czech Republic, which is based on the European Commission's inputs (EC, 2013; Kopp et al., 2017). Czech planning practice has had quite a solid experience with "ecological networking", in Czech terminology known as "Territorial systems of ecological stability" (ÚKRMP, 2016). Unlike foreign countries, where planning of functionally interlinked infrastructure is often considered in expert studies and plans (e.g. Wagner et al., 2013; Faltermaier et al., 2016; Bozovic et al., 2017), in the Czech Republic, there are only plans to broaden ecological networks from undeveloped landscape to the urban landscape. Thus, for our research purposes, we come from of the conceptions of blue-green infrastructure according to foreign studies (Voskamp and Van de Ven, 2015; van Timmeren et al., 2015; DELWP, 2017).

The authors of this paper understand blue-green infrastructure (BGI) primarily as an instrument for stormwater management, in which ecosystem approaches and water management measures are interlinked with green networks' system (Wagner et al., 2013; Voskamp and Van de Ven, 2015; DELWP, 2017). In this sense, the primarily urban concept of BGI (van Timmeren et al., 2015; Bacchin et al., 2016) builds on the more universal concept of green infrastructure, as it is defined by the European Commission (EC, 2013). Implementation of BGI is significant from the water management's perspective, which could be summarized into three main goals (Faltermaier et al., 2016; Bozovic et al., 2017; DELWP, 2017): (1) to retain rainwater and use it efficiently on places where it falls, (2) to reduce the accelerated runoff from surface into integrated sewerage system and via its overflows into watercourses, (3) to help water bodies, wetlands and verdure to evaporate and thus to decrease the effect of overheated urban and suburban areas.

The objective of the study

In the case study of the Pilsen suburban landscape, we deal with stormwater retention ponds (SRWPs) which have been implemented into individual areas as retention elements for rainwater. The water retained in them is not used in the next operational cycle. The objective of this case study is to assess selective qualitative parameters of selected SRWPs and to evaluate their potential to be engaged into the BGI of the suburban landscape. In a subsequent discussion of the results, we bring recommendations for regional and local administration, how to engage a private sector into a sustainable management of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1505515072

suburban landscape. To be more concrete, our goal is to propose instruments that can motivate the private sector to pay attention to SRWPs not only because of their retention function, but also to support their ecosystem services as well.

Review of literature

Hydro-social context of the BGI implementation

The implementation of BGI could be generally understood as a part of systematic changes in water management of the cities: i) a level of new technology's application (e.g. green roofs, water recycling); ii) a level of organization (e.g. building of decentralized water management zones; integration of the water issue in urban and landscape planning) and iii) a level of thinking (Bozovic et al., 2017). From the sustainable development point of view, the BGI benefits are not primarily related just to water management, but have also ecosystem and social aspects (van Timmeren et al., 2015). The BGI tools are targeted to four key issues (Woods Ballard et al., 2015):

1) Quantity of water: to decrease flood risk; to support and protect the hydrologic cycle;

2) Quality of water: to eliminate sources of pollution of water drainage;

3) Amenities: to create better and more sustainable environment for the life of humans;

4) Biodiversity: to create better and more sustainable environment for organisms.

For example, a British concept Blue-Green City is based on requests for flood protection and simultaneously for quality of life in cities with utilization of ecosystem measures. It pays attention to participatory planning process and evaluation of costs and benefits of blue-green infrastructure elements' implementation (Hoang and Fenner, 2015).

To search BGI tools properly, it is necessary to expand the view on the hydrological system. We have to look at it not only from physical and biochemical perspectives but add to them also a level of hydro-social system, in which human activities have a fundamental link to individual parts of water circulation in landscape (Swyngedouw, 2009; Linton and Budds, 2014). To improve BGI management, it is important to study relations between a regional administration and a private sector that could be both potential barriers and opportunities in water management. There are generally three categories of instruments which a regional administration can use to influence the implementation of new sustainable technologies in private sectors (Retzlaff, 2008; Carter and Fowler, 2008; Ferguson et al., 2013; Kabisch et al., 2016):

a) normative instruments (regulatory): e.g. adaptation strategies, urban and landscape plans, regulatory plans, building regulations, city ordinances, territorial protection, water directives, standards, norms,

b) economic instruments (financial): European/national/municipal subsidies, charging of rainwater discharge, tax allowance to properties with eco-labeling, grant schemes, bonuses in the form of favorable construction conditions,

c) ethical instruments (informational and motivational): programs focused on environmental education, awareness raising campaigns, professional training, environmental marketing of cities or developer projects, good practice examples, participatory planning, eco-labeling of companies, services and buildings.

Ethical instruments have also a significant potential. They can be linked with economic advantages if companies acquire eco-certificate for their operations. Regional administration can provide eco-labeling for companies, which carry out nature-based

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1505515072

solutions beyond compulsory water management measures and thus motivate private sector to enhance their own prestige. In the case of apartment construction, developers use eco-parametres of new residential zones as an instrument for their environmental marketing. Potential of hobby stores as possible epicentres of nature-based promotion of water management on a private land is not used. Despite the fact that they offer their clients artificial ponds for rainwater retention, semi-permeable tiles or a material to build green roofs or green facades, the buildings of these hobby stores unfortunately do not demonstrate any of those solutions.

A more sophisticated level of collaboration between a regional administration and a private sector are partnership projects. The foreign examples show that it is possible to mutually cultivate environmental quality of a territory, if a marketing and conditions for participation are set well. There are several projects that could be examples of joint venture, such as Oeko Business Wien, GreenMoabit Berlin (Pizarro, 2015).

The important instrument to support BGI implementation into practice is Public-Private-Partnership (PPP) (WEF, 2014; Harman et al., 2015; McAllister and Taylor, 2015; Margerum and Robinson, 2015; Koppenjan, 2015). PPP could be drawn up as build-operate-and-transfer (BOTs) arrangements, build-operate-own-transfer (BOOT), design-build-operate (DBO), joint-ventures or voluntary agreements (Hayllar, 2010; Harman et al., 2015). With regard to climate changes, BGI building belongs to PPP projects that are beneficial in terms of both adaptation and mitigation.

Stormwater retention ponds (SWRPs) as a part of BGI

Due to the fact that different instruments are recommended for different areas (e.g. industrial areas, shopping areas, or residential areas), it is necessary to adapt BGI planning in the suburban landscape with regard to land use (Faltermaier et al., 2016). It is appropriate to interconnect suitable elements of BGI with individual types of the landscape in relation to the systems of ecological stability of agricultural areas (Krauze and Wagner, 2019). Stormwater retention ponds (SWRPs) as a frequently used rainwater management instrument is applied in industrial, commercial and residential zones as well as in relation to drainage of roads. (Wong et al., 1998; Scher et al., 2004; USEPA, 2009; Faltermaier et al., 2016).

In spite of the fact that SWRPs are constructed as water management elements, we can sort them to BGI elements too (Hoang and Fenner, 2015). SWRPs, together with wetlands, are classified in methodological manuals about BGI implementation as surface retention elements that are able to clean water and are highly beneficial to the biodiversity of the landscape (Woods Ballard et al., 2015). SWRPs excel in high retention efficiency depending on the retention pond volume. At the same time, both SWRPs and wetlands have the highest initial costs (Hoang and Fenner, 2015). Due to the fact that the hydrological retention function of SWRPs is the top priority, it is also necessary to pay attention to their ecosystem and amenity potentials (Kurilenko and Osmolovskaya, 2007; Chiandet and Xenopoulos, 2011; Noble and Hassall, 2015; Hill et al., 2017).

It is important to deal with a question how to enhance the ecosystem and amenity benefits of SWRPs and how to implement them fully into the BGI of suburban landscape (Moore and Hunt, 2012). Their nature-based qualities determine whether they become a valuable part of the BGI or if they will remain just technical components of a grey infrastructure (Moore and Hunt, 2012; Hoang and Fenner, 2015). There are various types of urban ponds in BGI of urban and suburban landscape. SRWPs, which this paper deals with, are classified as Drainage systems ponds (Hassall, 2014). They differ primarily from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1505515072

other categories, such as Garden ponds or Ornamental lakes and ponds by their retention function and possibly cleaning effect of contaminated water. Industrial ponds differ from them by an engagement into water management operation of the enterprise. Drainage system ponds can be classified as "detention" or "retention" ponds (Hill et al., 2017). With regard to a potential ecosystem benefit, retention ponds (SRWPs) are more important. A stable amount of retained water creates an aquatic environment and a design of a bench zone enables littoral vegetation to occur (USEPA, 2009).

Materials and methods

Study area and study sites

The Pilsen city's suburban landscape is currently an area with clearly obvious features of suburbanization, because of the population size of the Pilsen city (170.000 inhabitants in 2018) and its dominant position in the settlement system of the western part of the Czech Republic (Kopp et al., 2015). A significant share of a suburban landscape is located in the frame of the administrative region of the city. Out of 138 km^2, 27.2% is arable land, 7.2% is grassland and 20.6% is forest area (Kopp et al., 2017). The area of production and storage is also a significant feature of urban and suburban landscapes, with a share of 7.2% of the total extent of the administrative region and 17.2% of the built-up area in the urban and suburban landscape. An important category of land use is also shop and service area that makes 1.7% of the total extent of the region and 4.1% of the built up area (Kopp et al., 2017). New studies point out that those production and storage areas as well as shopping and service zones contribute significantly to making heat islands in the area of the Pilsen agglomeration. Building of those kinds of zones as a part of a commercial suburbanization process at the turn of the century brought extension to typically urban problems of hydrological balance in suburban landscape. Studies from other areas point to similar problems as well (Le Viol et al., 2009; Chiandet and Xenopoulos, 2011; Cizek and Hunt, 2013).

Average annual rainfall in 2006–2015 recorded at the Pilsen-Mikulka station was 514.8 mm. If a cadastral area of the city of Pilsen is 137.67 km^2, the total average annual amount of rainwater falling on the city is 74.6 mil. m^3 (Kopp et al., 2017).

According to the standardized values of the Czech Hydrometeorological Institute for the period 2005–2015 for the station Pilsen-Mikulka, a thirty minute rain with a periodicity of repetition n = 1 year causes a direct specific runoff of 115.6 litres per second per hectare (115.6 $l.s^{-1}.ha^{-2}$). A result of such an extreme rainfall event is overloading of the sewerage network and contaminated water overflowing via a drain directly into local watercourses. For example, two consecutive events 5th July 2018 (22 mm) and 6th July 2018 (10 mm) caused disposable pollution of the river. Due to an oxygen deficit, about 3–5 metric tonnes of fish died (Povodí Vltavy, 2018). That's why it is important to enhance a retention ability of both urban and suburban landscapes connected to sewerage.

The private sector in the city of Pilsen has been obliged, according to state law and city regulation, to deal with rainwater drainage from impervious surfaces (roofs, parking sites or roads) in the last decade. They have been responsible to limit drainage into the sewerage system below 4 $l.s^{-1}.ha^{-2}$. Subsurface or surface retention ponds (SWRPs) are allowed if is impossible for rainwater to infiltrate or to use it in another way inside the area of the enterprise (Vítek et al., 2015).

Dozens of SRWPs of different design have been built in the suburban landscape, most of them are located on private land. Our paper focuses on and evaluates five SRWPs in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1505515072

detail (PP1–PP5, *Fig. 1, Table 1*), which are located on private land. Their parameters are compared with two other SWRPs (PM1–PM2, *Fig. 1, Table 1*), that were designed for the purpose of private construction, but were handed over to the city administration, whose lands they are located on. They were built to runoff rainwater from the zones of the developer construction projects and their property relations could be classified as "combined" (Freie und Hansestadt Hamburg, 2013). Due to the fact that we compare an ecosystem potential of ponds, we included also one retention pond that the city designed and built as a demonstration project to support BGI during reconstruction of a historic park (MM1, *Fig. 1, Table 1*).

Methodology of evaluation of SRWPs'potential

Neither city nor state administrations have systematically recorded SRWPs, which are of interest to this case study. If it is possible to see construction documents (private subjects provide these documents for the research purposes only limited), it is possible to find out technical parameters of the ponds and their planned hydrological functions. When SRWPs are projected and built, the attention toward ecosystem and amenity functions is marginal. No monitoring of their hydrological regime, chemical and hydrobiological status is required, thus it does not exist at all. Some ponds are not accessible due to private property's protection or due to security reasons. The evaluation of SWRPs was primarily based on assessing their spatial parametres using orthophoto maps from different seasons between 2014–2017. We tried to find such pictures, where different levels of replenishment of the pond (and thus different aquatic zone areas) were captured (A_{std}, A_{min}). Another parameter is the detected area of the ponds including safety bench area (USEPA, 2009), which is usually an area of unflooded safety volume (A_{max}). All areas are calculated using orthogonal projection, which was obtained by ortophoto map analysis via geographical information system ArcGIS. The perimeter of a pond is related to a standard area in time, when a pond is normally filled. Out of those parametres, indexes have been calculated:

a) Area amplitude index:

$$I_a = \frac{A_{std}}{A_{min}} \quad \text{(Eq.1)}$$

b) Area unflooded benches index:

$$I_b = \frac{A_{max} - A_{std}}{A_{std}} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1505515072

c) Shape index – ratio of the perimeter area (P_{std}) to the perimeter of a circle with the same area (A_{std}):

$$I_c = \frac{P_{std}}{2\sqrt{\pi} \times \sqrt{A_{std}}} \quad \text{(Eq.3)}$$

These indexes enable us to compare geometrical parameters of the ponds in regard to their ecosystem potential. The ponds with irregular shape with more segmented bench line (*Eq.3*) have a similar quality as natural ponds and have also a potential for higher biodiversity (NJDEP, 2006; Moore and Hunt, 2012). These ponds have also a higher potential of ecological stability in case lower fluctuation of the pond level and area amplitude (*Eq.1, Eq.2*). These features depend on bank's inclination and a set mode of inflow and outflow (Wong et al., 1998; NJDEP, 2006; Blicharska et al., 2016).

Next evaluation of SRWPs has been done according to six criteria that come from recommended features and qualities of ponds included into BGI (Wong et al., 1998; Blicharska et al., 2016). The potential of connection into the BGI network is characterised by a positional feature, which provides a possible link to close elements of green network and water bio-corridors. Ecosystem potential has been distinguished according to the existence and ecological quality of the bench vegetation. A microclimatic significance of ponds has been classified based on a contrast with surrounding areas located nearby, while taking into account the area size. Next two criteria – aesthetic quality and its implementation into a public space – express a social importance of SWRPs as elements of the BGI in a suburban landscape. It is important to distinguish whether a water body is or is not publicly accessible (Li et al., 2019). Even if it is located on a private property, it could be made publicly accessible, as it is obvious in agricultural landscape. The evaluation according to selected criteria has been made via field research and assessment of orthophoto pictures (*Fig. 2*) and documents for city planning. A score for each criterion was made in a scale from 0 to 3 (3 equals the best quality). Rating scales have been derived from particular studies and manuals focusing on the construction of retention ponds according to monitored criteria (Wong et al., 1998; NJDEP, 2006; USEPA, 2009; Moore and Hunt, 2012; Blicharska et al., 2016; Teurlincx et al., 2019) with a request to set the same scale for all parameters. The evaluation of SWRPs was made based on our own assessment in the field. Particular maps and the Master plans' documentation have been used to evaluate certain criteria (potential of connection into the BGI network; microclimatic significance) (ÚKRMP, 2016). Weight for each criterion was not considered, so it was decided that total score equals from 60% ecosystem quality and 40% social quality of SWRPs. Nevertheless, both quality aspects correlate together, for example with an assessment of bank quality or an aesthetic value.

Due to the fact that it was impossible to compare a hydrological regime of ponds using the above-mentioned methodological procedure, our own hydrological monitoring of the water levels in the ponds was used as a material for a follow-up discussion of SWRPs potential. The water level has been realized since mid-2017 on the tank PM2 located in the Nova Valcha site. A primary purpose of this pond is to a course of a runoff from new residential zone's rainwater sewerage. The secondary purpose according to a project documentation is to be a landscaping element in a transitional zone between new buildings and old buildings of the Valcha urban area.

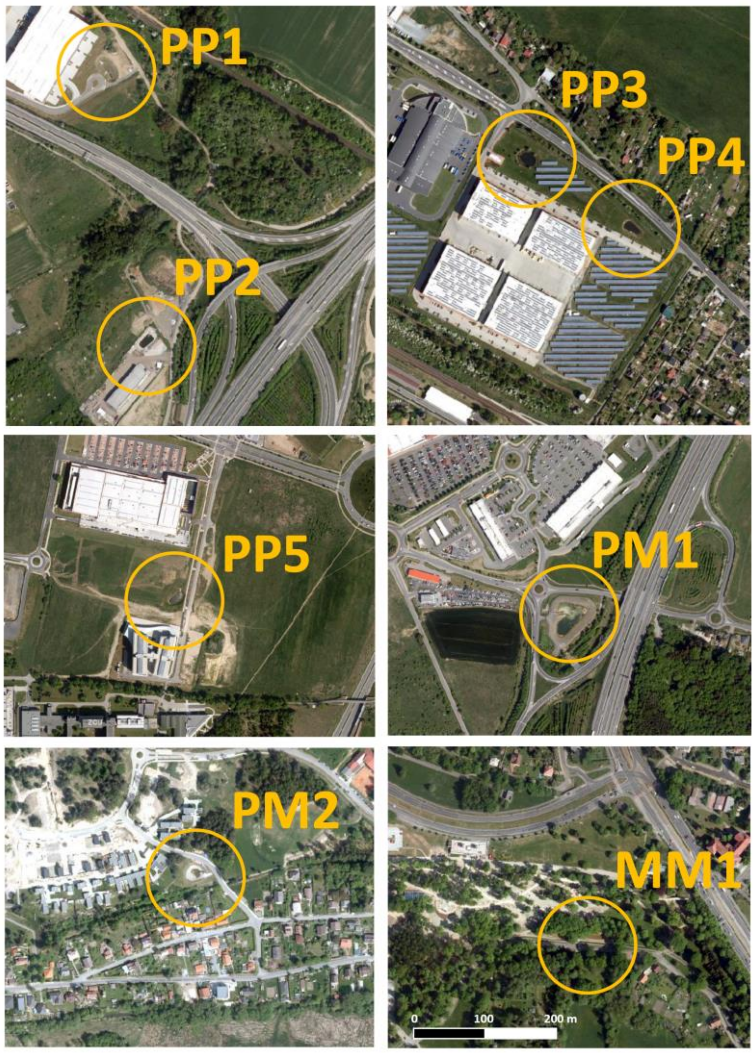

Figure 2. *Location of surface retention ponds in suburban landscape (orthophoto Czech Office for Surveying, Mapping and Cadastre)*

Results

A comparison of area parametres of SWRPs monitored in the suburban landscape proved their different preconditions to be implemented into BGI (*Table 2, Table 3*). Their cubic capacity differs depending on the drainage area. Thus, their sizes differ as well, which directly influences their microclimatic potential. The whole expanse of the tank directly influences the PM1 retention, which drain to a broader zone of a new construction area including impermeable surfaces of surrounding communications (*Table 2*).

A pipeline capacity bringing rainwater corresponds with area and volume of a pond. The pond PP1 has a significant area of unflooded bench slopes, which is in compliance with morphometry and a safety water level of a maximum volume. Consequently, the water level is thus cut deeply under a level of a terrain, which complicates a link of the pond's ecosystem with surrounding areas. From a broader point of view, it also decreases its impact on an aesthetic composition of the landscape. From an aesthetic point of view (*Table 3*), positively influencing aspects are considered not only a quality of vegetation on the benches (PP3) and a morphometry of the bench (MM1), but also adjustment of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1505515072

them. These modifications, however, do not have an ecosystem function's potential (PP2). The essential aspects of ecosystem quality (*Table 3*) are predominantly a segmentation of the pond's shape (MM1) and a quality ecosystem of a bank with its woody plants (PP3). Littoral vegetation is scarce at SRWPs, due to a morphometry of ponds, that are primarily focused on a retention volume. In this way, a potential of SRWP is much lower in comparison with constructed wetlands.

Table 2. *Parametres of surface retention ponds*

Retention pond	A_{min} (m^2)	A_{std} (m^2)	A_{max} (m^2)	P_{std} (m)	I_a – Area amplitude index	I_b – Area unflooded banks index	I_c – Shape index
PP1	120	125	758	57	1.04	5.06	1.44
PP2	223	228	500	59	1.02	1.19	1.10

PM1	1	2	3	1	0	7
PM2	1	0	2	1	2	6
MM1	3	2	1	3	3	12

Note: Score for each criterion in a scale from 0 to 3 (3 equals the best quality)

The implementation of SRWPs into BGI results in their position and various conditions of the surrounding suburban landscape (*Table 3*). We found out that SRWPs that we monitored differ in accessibility. From this point of view, not only ponds located on a private property have been inaccessible (PP2, PP3, PP4), but so have a pond in the city administration' ground (PM1). On the other hand, we discovered a few accessible ponds located on a private property (PP1, PP5). These cases prove there is a potential for social and ecological bindings in a landscape, if there is a will to support these bindings.

We discovered significant area fluctuations during standard filling and during a dry season when we compared a level area of ponds PM2 and partly also PP5. It is related with a morphometry of ponds, bank inclinations and also with a pond level amplitude. A significant fluctuation of water level occurred in the PM2 pond that we confirmed our own continuous monitoring, makes some stable pond ecosystem and potential vegetation on the banks difficult to create (*Fig. 3*). Causal precipitation has been measured at the closest meteorological station Pilsen-Mikulka, provided by the Czech meteorological

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1505515072

institution as a reference station for the territory of the city of Pilsen. Total rainfall for a small new built up area, drained into the pond PM2, have been monitored simultaneously according to other surrounding stations (Stod and University of West Bohemia). After the events have been evaluated, we found out that total rainfalls differed only very little (*Fig. 4*).

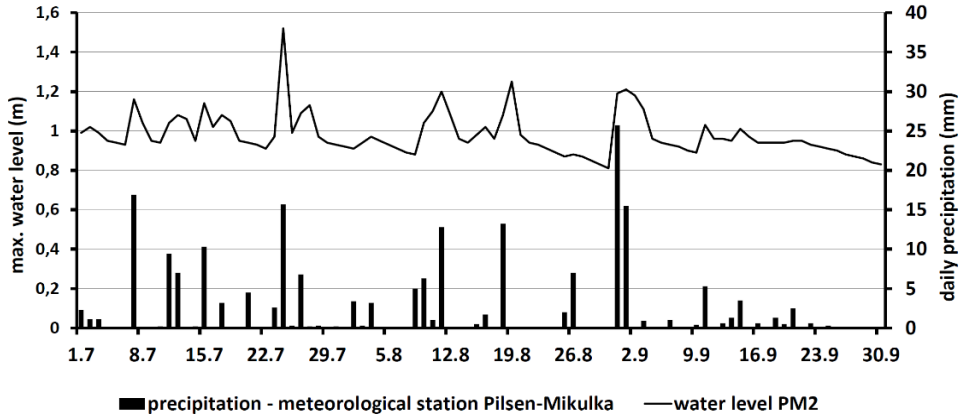

Figure 3. *Maximum daily water levels in the retention pond PM2 (Nova Valcha) and daily precipitation in the weather station Pilsen-Mikulka (July–September 2017). Data of water levels: own monitoring; data for precipitation: Czech Hydrometeorological Institute*

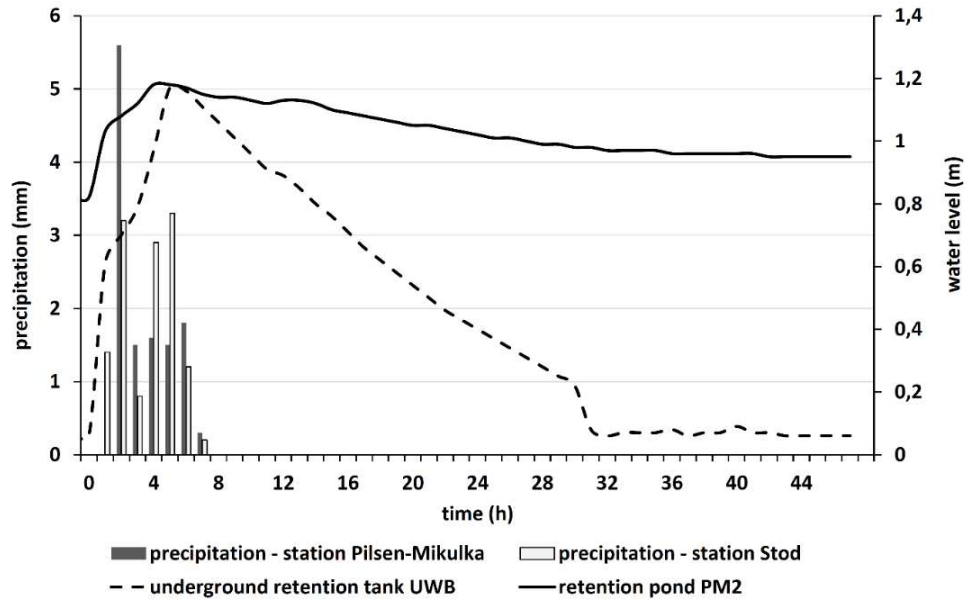

Figure 4. *Development of water levels in retention pond PM2 (Nova Valcha) in comparison with underground retention tank UWB with regulated drain in relation with precipitation event (since 22nd October 2017 at 0:00:00 till 24th October 2017 at 0:00:00)*

According to project documentation, an assumed depth of the PM2 pond during normal regime should be 1.4–0.9 m. However, the water level oscillated between 1.7–0.53 m during the monitoring period (*Table 4*). The lower aggregated average (0.92 m) reflects an especially significantly dry summer in 2018. Based on an analysis of a few

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1505515072

precipitation events, an outlet (a drainage coefficient of the area drained into sewerage) shares 40% out of total rainfall. This figure, however, has to be confirmed with a following monitoring in compliance with a development of neighbouring built-up areas. Our monitoring of water level in the pond PM2 confirmed a huge dispersion of the water level with a negative impact on environmental conditions. As vegetation on the benches does not occur and the pond warms up during low water level, it all creates favourable conditions for algae growth. Follow-up research will have to be focused on monitoring of hydrobiological conditions in SWRPs.

Table 4. *Total amplitude of the water level in the pond PM2 (Nova Valcha) between 1st July, 2017–31st December, 2018*

Minimal water level	0.53 m (23. 10. 2018)
Maximum water level	1.70 m (10. 06. 2018)
Average	0.92 m
Water level amplitude	1.17 m

We monitored the water level of the underground retention tank located in the campus of the University of West Bohemia (UWB), which collects water from the roof of one campus building, to compare changes of the water level of the pond PM2 (Nova Valcha). The underground retention tank has a total volume 34.5 m^3. Its controlled outflow is according to a request to drain water into common sewerage in a maximum value 4 $l.s^{-1}.ha^{-1}$. At the same time, the regulation is set on the allowed upper speed limit of emptying in order to quickly free up the storage space. These types of tanks are legislatively allowed solutions to drain precipitation water, where infiltration is not possible.

Our monitoring proved that the water level of both retention ponds differ in their reaction rate (*Fig. 4*). This documented event shows how both retention systems responded on total rainfall (13 mm), which was recorded during seven night hours on the 22nd September 2017 from surrounding meteorological stations Pilsen-Mikulka and Stod.

The underground retention tank UWB accumulating water from the roof of the building responds faster when filling or emptying. PM2 retention pond on the surface in the residential zone Nova Valcha empties gradually, which is in compliance with its technical function. Surface retention is desirable to limit too fast fluctuation of the water level due to the fact that ecosystem functions of the pond are supported. On the other hand, the underground retention tank has no ecosystem functions.

Discussion

Based on our SRWPs evaluation, it is possible to specify main adjustments for their successful implementation into the BGI system in suburban landscape. A potential of implementation of SRWPs into BGI is summarized in *Table 5*.

This potential is influenced not only by parameters of the ponds and their location in the landscape, but also by a functional typology of the territory according to a spatial plan (ÚKRMP, 2016). It is highly recommended that spatial planning endeavors to build up green network in areas focused on production and storage as well as in the areas where sales and services are cumulated (Berlin Konkret). Thus, we can achieve much better

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1505515072

connectivity of nature-based corridors in a suburban landscape, than it is done when only agriculture and forest lands are interlinked.

Norms and methods prefer surface infiltration over a continuous grassy humus layer. If a drain from hard surface enters into green surfaces with a good infiltration, not a huge retention space is necessary. The case study of the Pilsen-city suburban landscape shows, that wherever a surface has a limited ability to soak up water due to the hydrogeological reasons, private entities can fulfill the rainwater management's duty via SWRPs. *Table 5* shows that it is possible to implement SRWPs into BGI, if suitable design principles are applied (Lawrence and Breen, 1998; NJDEP, 2006; Kurilenko and Osmolovskaya, 2007; Blicharska et al., 2016) and relevant implementations into the BGI territorial systems are made, for example in relation to local water bio-corridors.

Table 5. *The potential of implementation of surface retention ponds to the BGI*

Retention pond	Functional type of the territory according to a spatial plan	Land cover of the surrounding area	Potential of implementation
PP1	industrial and storage areas	lawn and roads	to connect to the blue-green infrastructure network
PP2	industrial and storage areas	semi-permeable surfaces and extensive grass	to make a nature-based ecosystem of the pond banks
PP3	industrial and storage areas	lawn	to connect into the blue-green corridor and into a public space
PP4	industrial and storage areas	lawn	to connect into the blue-green corridor and into a public space
PP5	commercial areas	extensive grass	to make nature-based ecosystem of the pond banks and to connect into a public space
PM1	natural areas	roads and extensive grass	to connect into the blue-green corridor and into a public space
PM2	mixed residential areas – potentially built-up	lawn and roads	to connect into the blue-green corridor and into a public space
MM1	parks areas	forest park and roads	to make a nature-based ecosystem of the pond banks

There is so far limited knowledge related to ecologic functions of SRWPs, because there is neither systematic monitoring nor an effort to plan their hydrobiological qualities. Foreign experiences could not be automatically applied, unless a home comparative research is realized. Researches made abroad show that ponds could be influenced by inflowing water that contains a specific pollution depending on a characteristic of a drained surface (Stoianov et al., 2000; Scher et al., 2004). For example, a study in northern Poland showed that small ponds located in agricultural landscape have a higher load of nutrients, than those in urban landscape (Jarosiewicz et al., 2018). Urban ponds have been classified in terms of nutrients on the border of meso- and eutrophy (Jarosiewicz et al., 2018). On the other hand, retention ponds could become tools for a pollution decrease. According to British methodologies, ponds significantly decrease a load of dissolved substances or a concentration of non-ferrous metals in water (Woods Ballard et al., 2015). Macrovegetation of littoral zone plays an important role in detoxifying of water in urban ponds (Kurilenko and Osmolovskaya, 2007).

Besides quality of inflowing water, many different criteria have to be considered when a pond is designed (Lawrence and Breen, 1998; NJDEP, 2006; Blicharska et al., 2016).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1505515072

Some criteria depends on handling with rainwater (e.g. appropriateness of hydrogeological environment), other ones deal with specifications of their design (e.g. local spatial and slope ratios or implementation into surrounding landscape) or with economic issues, such as operation and maintenance costs in future, ownership, building costs or aspects influencing the economy of water management of the pond itself. There are more specialized methodological publications dealing in detail with selection of measures (WEF, 2014; Woods Ballard et al., 2015; Faltermaier et al., 2016; Perini and Sabbion, 2017).

Ownership relations influence a potential of SRWPs implementation into BGI, especially in terms of legislation for urban and landscape planning as well as the owners' motivation to support nature-based solutions beyond a duty of rainwater retention. There is currently a low motivation in the private sector to voluntarily support BGI in the Czech Republic. It comes out of a lack of political power to pursue new approaches, underestimation and low public awareness about BGI, inappropriately set legislation and a limited scale of opportunities to take over foreign experience from the past (Stránský and Kabelková, 2015; Slach and Ježek, 2015). The situation, however, has been improving in recent years and new methodologies for practical application have been developed (Vítek et al., 2015). A political support for new approaches grows especially in context with a support of adaptation actions of settlements to climate change. Based on an analysis of potential and opportunities in this case study, it is highly recommended to enhance the private sector's motivation to implement SWRPs to BGI.

In the category of normative tools, it is necessary to make BGI one of the requested elements of a landscape. BGI is neither defined nor legislatively anchored in the Czech law yet. BGI could extend current ecological networks (Territorial system of ecological stability) in build-up landscape as a part of planning practice. Ecological networks as part of landscape and regulatory planning are applied predominantly in rural areas, which is not sufficient for suburban areas. The rainwater management obligation (e.g. defining a specific runoff from the land) of municipalities, which legislatively apply for new construction, should be extended by more detailed specification of how they support building of retention elements and nature-based measures. The law about urban planning enables investors to claim a subsidy for infrastructure in the territory. That could be a way to co-finance related BGI elements on public lands.

It is necessary to strengthen economic instruments motivating private sector to apply nature-based measures (Kabisch et al., 2016). Besides decreasing of fees for rainwater drainage, it is possible to take into consideration an ecosystem quality of the measure via e.g. tax land discounts or "green bonuses". The green construction bonuses make regulatory conditions of an investor more favorable, if the investor proves the ecosystem benefits of the measure that has been accomplished (Retzlaff, 2008; Carter and Fowler, 2008; Ferguson et al., 2013).

Conclusion

The evaluation results of SRWPs in the suburban landscape of Pilsen demonstrated their both positive and negative characteristics, which influence their potential for implementation into BGI. Primary water management functions planned during construction are the same – to control the drain from a residential area during intensive precipitation to temper extremely high discharge waves in rain or common sewerage, or during its drain into a recipient. Parameters of SRWPs are different, especially in terms

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1505515072

of how their nature-based elements are used or how their amenity functions in a public space are applied. The results based on a few private SRWPs show that their ecological and aesthetic quality could be comparable with those systems built by the city in the public interest and with taking into account their ecosystem functions. It is rarely used a rugged shape of the plan of the ponds when SRWPs are projected. Solidifying of benches with stones should be combined with bench vegetation that can be more beneficial for suburban landscape. The study shows that bench trees and shrub is possible to use around private ponds.

The continuous research should be focused on monitoring of the water quality in SWRPs depending on the season and how the ponds respond to extreme inflows. This is the way how the ponds could be better projected or handled with the pond level. Moreover, our knowledge about the level of fluctuations of SWRPs in compliance with their morphology is insufficient. Missing information about the SWRPs' ecology does not relate only to our case studies region, but to other Czech cities as well. The foreign experience is, however, limited to a few particular studies.

Initial results of the level monitoring of the pond PM2 showed that outflow settings from the pond can significantly influence fluctuations in flooding of its benches as well as other ecological parameters. Still, the surface SWRPs are much more suitable for general improvement of ecological conditions of the landscape than underground SWRPs. Surface SWRPs, besides their ecological, microclimate and aesthetic potentials, play an important role as a part of the BGI network, that can enhance eco hydrological conditions of the suburban landscape, if a proper spatial planning is made. Thus, a city administration must not only register them, but also actively influence their parameters during the construction process of ponds.

Current SWRPs belong objectively between grey- and blue-green infrastructures. This case study shows that it is possible to implement SWRPs located in a suburban landscape into BGI. Water-management practice of the private sector fulfills only obligatory demands for rainwater drain and they have no reason to take into consideration new requirements of society for BGI as a landscape instrument to adapting to climate change. Ecosystem quality of SRWPs differs a lot and is a result of the non-existence of planning and instruments, which could motivate the private sector to carry out nature-based solutions. It is crucial to focus not only normative, but also economic and ethical instruments and pursue a collaboration between private and municipal sectors.

Acknowledgment. This research has been supported by the Technology Agency of the Czech Republic Grant ÉTA TL01000498 "Revitalization of city centers and other public spaces in the Czech Republic: Problems, foreign inspiration, possible solutions".

Abstract. The influence of pure transgenic wheat strain 1477 and Zhengmai 9023 were used to explore the effect of exogenous *RsRHA2b* gene introduction on the activity of key enzymes for starch synthesis and protein synthesis and the expression of related genes in transgenic wheat during filling period. The results showed that the introduction of exogenous *RsRHA2b* increased the activity of adenosine diphosphate glucose pyrophosphorylase (AGPP), granular starch synthase (GBSS), starch branching enzyme (SBE), soluble starch synthase (SSS) and glutamate synthase (GOGAT), and decreased the activity of glutamyl ammonia synthase (GS). Exogenous *RsRHA2b* promoted the expression of *YTH311, YTH611, YTH1065, YTH2437, YTH2438, YTH2456, YTH2496* and *YTH3049*, and inhibited the expression of *YTH2433*. These results indicated that the change in carbon and nitrogen metabolic key enzyme activity and the effect on related gene expression caused by the introduction of exogenous *RsRHA2b* gene may be the main cause of the increased resistance to ear germination of *RsRHA2b* transgenic wheat.

Keywords: *starch synthase, protein synthase, interacting proteins, gene expression, pre-harvest sprouting*

Introduction

Pre-harvest sprouting (PHS), a problem caused by environmental and genetic factors, affected wheat (*Triticum aestivum* L.*)* production in mature stage. About 85% of the wheat producing areas in China are susceptible to ear germination. After sprouting, the yield and quality of wheat will be reduced, and even food value and processing will be negativly affected, and the number of usable seeds will decrease. Grain traits, including grain maturity and size, seed coat color and thickness, can affect spike germination of wheat to varying degrees.

The main component of wheat grain yield is endosperm starch, followed by endosperm protein. The formation of wheat grain yield is essentially a process of starch and protein synthesis and accumulation in endosperm. Therefore, carbon metabolism and nitrogen metabolism are two main metabolic pathways in wheat grain development. Both of them are interrelated to each other to complete the material accumulation of grains, which determines the quality of grains.

There are many enzymes involved in starch synthesis. It is generally believed that sucrose synthase (SS), ADPG pyrophosphatase (AGPase), starch synthase (SSS and GBSS) and amylopectin branching enzyme (SBE) are key enzymes in the process of starch synthesis and metabolism, and play an important regulatory role in the synthesis

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1507315086

and accumulation of starch in wheat grains (Yang et al., 2004; Baroja-Fernández et al., 2003; Emes et al., 2003). ADPG-PPase and SSS were positively correlated with total starch and amylopectin accumulation rate (Zhao et al., 2004), while GBSS was positively correlated with amylose accumulation rate (Wang et al., 2003; Li et al., 2001). Protein quality of wheat grain is one of the important indexes for evaluating wheat quality (Wang et al., 2001; Pan and Yu, 2002). The main pathway of nitrogen assimilation in plants is directly involved in the synthesis and transformation of amino acids after nitrate reduction to ammonium. Nitrate reductase (NR), glutamine synthase (GS), glutamine synthase (GOGAT), asparagine transaminase (AspAT) and other key enzymes are involved in catalysis and regulation. This study focused on GS and GOGAT enzymes.

AtRHA2b gene of *Arabidopsis thaliana* encodes E3 ubiquitination ligase, which plays an important role in ABA signal transmission and stress. Cloning and characterization of a wheat RING finger gene *TaRHA2b* whose expression is up-regulated (Li et al., 2019). Overexpression of *AtRHA2b* leads to ABA-related phenotypes, such as seed germination and seedling sensitivity to ABA. The genetic distance between radish and *Arabidopsis* is very close, so *RsRHA2b* gene in radish was used for genetic improvement in wheat to avoid the phenomenon of cohomology inhibition in transgenic plants. The transgenic *RsRHA2b* wheat was successfully created by agrobacterium-mediated method at the early stage of seed germination. Compared with the Zhengmai 9023, the resistance of transgenic strains to PHS was significantly enhanced. The proteins interacting with RHA2b were selected by yeast two-hybrid assay. The information of candidate interacting proteins is shown in *Table 1,* including SBE, nitrite reductase, CBL, DDT domain protein, auxin effector factor 1, E3 UFM1 protein ligase 1 homologue, small G protein, AP2/EREBP protein and AGAP. The study of RHA2b interacting proteins is conducive to the study of the mechanism of the *RHA2b* gene.

Table 1. *Summary of related genes at the grain filling period (from NCBI database)*

In order to reveal the regulatory effect and mechanism of RsRHA2b gene on starch and protein formation in wheat grains, the key enzymes and gene expression of starch synthesis, key enzymes of protein synthesis and gene expression in transgenic and control wheat grains at grain filling stage were analyzed. The aim of this study was to provide a basis for further application of genetically modified wheat (GM) resistant to PHS in production.

Materials and methods

The elite Chinese bread wheat cultivar Zhengmai 9023, ahexaploid wheat cultivar with weak resistance to PHS, is widely cultivated in Henan Province. Exogenous *RsRHA2b* gene was introduced into wheat "zhengmai 9023" by agrobacterium-mediated method in the early germination stage. After six successive generations of planting, and combined with basta resistance screening, PCR, RT-PCR and southern-blot analysis, the transgenic strain 1477 with stable inheritance of exogenous *RsRHA2b* gene and strong resistance to ear germination was screened. Transgenic lines and non-transgenic control variety Zhengmai 9023 were planted in the Science and Education Demonstration Park of Henan Agricultural University during the growth season from 2013 to 2014.

Determination of enzyme activity in wheat starch synthesis

The single spike with the same flowering date and the same panicle size was selected. Starting from the 5th day after flowering, samples were taken every 5 d for a total of 6 times. Two grains labeled at the base of spikelet from 4th to 10th spikes were selected. every time take 200 grain, put into liquid nitrogen frozen 30 min, buy –80 °C refrigerator, used for determination of enzyme activity and gene expression. Key enzymes for starch synthesis include ADPG, SSS, GBSS and SBE. Cheng Fangmin's method of extracting crude enzymes from wheat grains was used as reference (Cheng et al., 2001). The activity changes of AGPP, SSS and GBSS were determined by Nakamura's method (Nakamura et al., 1989). The activity of SBE was determined by Li Taigui's method (Li et al., 1997). The steps of these methods are optimized as follows.

Determination of ADPG

Take 20 μL enzyme crude extract, 110 μL reaction solution was added (the final concentration of the reaction solution was 100 mM Hepes-NaOH (pH 7.4), 1.2 mM ADPG, 3 mM PPi, 5 mM MgCl2 and 4 mM DTT); 30 °C, reaction for 20 min, 30 s termination reaction in the boiling water; 10000 × g, 10 min, take 100 μL supernatant, add 5.2 μL supernatant to colorimetric solution (5.76 mM NADP, 0.08 unit P-glucomutase (phosphoglucose mutase), 0.07 unit G6p-dehydrogenase); 30 °C reaction for 10 min, determination $OD_{340\ nm}$ value; The activity of ADPG pyrophosphorylase was calculated based on the increase of $OD_{340\ nm}$ value, and the unit was nmol/1000seeds min.

Determination of SSS and GBSS

Weigh the wheat seeds in the mortar, add liquid nitrogen and grind to powder; transfer to the centrifugal tube, and add appropriate amount of extract, containing 100 mM Tris-HCl (pH 7.5),8 mM MgCl2, 2 mM EDTA, 12.5% (V/V) glycerin, 1% (W/V) PVP-40, 50 mM d-mercapto ethanol; 10000 × g, 4 °C centrifugal 30 min, then collect the clear liquid in an ice bath, as crude enzyme liquid for later use; the precipitate was washed twice with 1 mL extract and then suspended in 2 mL extraction medium for GBSS activity measurement; the 20 μL enzyme crude extract was added to 36 μL reaction solution I (the final concentration of the reaction solution was 50 mM Hepes-NaOH (pH 7.4), 1.6 mM ADPG, 0.7 mg amylopectin, 15 mM DTT); 30 °C, reaction for 20 min, 30 s termination reaction in the boiling water, cooled in the ice bath; add 20 μL reaction solution II, containing 50 mM HEPES-NaOH (pH 7.4), 4 mM PEP, 200 mM

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1507315086

KCl, 10 mM MgCl2, 1.2 unit pyruvate kinase; reaction after 20 min 30 °C, boiling water termination reaction in the 30 s; 10000 × g, 4 °C centrifugal 30 min, the supernatant (60 μL) and 43 μL reaction solution (III), 50 mM HEPES-NaOH (pH 7.4), 10 mM glucose, 20 mM $MgCl_2$, 2 mM NADP, 1.4 unit hexokinase, 0.35 unit G6p-dehydrogenase; 30 °C reaction after 10 min, measuring OD_{340nm} value changes, the unit is nmol 1000 seeds min. The crude enzyme solution boiled at 20 μL was used as the control.

Determination of SBE

The wheat seeds were placed in a mortar, add liquid nitrogen and grind to powder, transfer to centrifugal tube; add 0.05 M citric acid buffer (PH 7.0) (diluted with 0.2 M citric acid buffer by 4 times); 4 °C, 23203 × g under centrifugal 20 min, supernatant is the thick enzyme fluid; take 1 mL crude enzyme solution, add 0.2 M citric acid buffer 1 mL (pH 7.0), 0.1 M EDTA 0.5 mL, 0.75% soluble starch 0.5 mL, according to the same procedure to prepare another as the control; experimental group 40 min in 37 °C water bath heating, control placed on ice, add 4 mL 10% TCA termination reaction; the color was developed with 0.35 mL of iodinated solution (here calculated by adding 0.5 mL of iodinated solution to 10 mL of reaction solution), and the optical density value was measured at $OD_{660\ nm}$ after 10 min, with the non-water bath heating as the control. SBE enzyme activity was expressed as the percentage of decreased $OD_{660\ nm}$.

Determination of the activity of key enzymes for protein synthesis in wheat grains

Key enzymes for protein synthesis include glutamyl ammonia synthase (GS) and glutamate synthase (NADH-GOGAT). Determination of glutamine synthase GS activity by reference to Wang Yuefu's method (Wang et al., 2002). The determination of activity of NADH-GOGAT refers to Wang Xiaochun's method (Wang et al., 2005). The steps of these methods are optimized as follows.

Determination of GS

The wheat seeds were placed in a mortar, liquid nitrogen grinding to powder grinding; transferred to the centrifugal tube, add right amount extraction buffer, 15000 r/min under 4 °C centrifugal 20 min, supernatant fluid is the thick enzyme fluid; in 1.6 mL reaction mixture B, 0.7 mL crude enzyme solution and 0.7 mL ATP solution were added and mixed; 37 °C under thermal insulation 0.5 h, adding chromogenic agent (0.2 M TCA, 0.37 M FeCl3 and 0.6 M HCl mixture) 1 mL, shake and placed after a while; the supernatant was centrifuged at 5000 r/min for 15 min, and the absorbance value at $OD_{540\ nm}$ was determined. 1.6 mL reaction mixture A was added as the control.

Determination of NADH-GOGAT

The wheat seeds were placed in a mortar, ground with liquid nitrogen until the powder, transferred to a centrifuge tube, and an appropriate amount of extract (10 mM Tris-HCl buffer, pH 7.6, containing 1 mM MgCl2, 1 mM EDTA and β-mercaptoethanol l mM); 4 °C under 15000 × g centrifugal 30 min, on a clear night is the enzyme liquid; the total volume of the reaction mixture was 3 mL (containing 0.4 mL 20 mM L-glutamine, 0.05 mL 0.1 mM ketoglutaric acid, 0.1 mL 10 mM KCI, 0.2 mL 3 mM NADH and 0.5 mL enzyme solution, the insufficient volume was supplemented by

1.75 mL 25 mM pH7.6 Tris-HCl buffer; the reaction was initiated by L-glutamine and the extinction value was measured at $OD_{340\ nm}$. 1 min decreased extinction value was as an enzyme activity unit.

Quantitative real time RT-PCR (RT-qPCR)

15 to 20 seeds of uniform size were frozen and extracted from the seeds using Tiangen plus total plant RNA extraction kit. The total RNA was extracted, the quality of RNA was identified by agarose gel electrophoresis, and the RNA concentration and purity were determined at 260 nm/280 nm. Total RNA is used for the synthesis of the first strand of cDNA. The first strand of cDNA was synthesized by FastQuant RT Kit (With gDNase) and ReverTra Ace qPCR RT Master Mix With gDNA Remover (TIANGEN Biotech (Beijing) Co., Ltd., Beijing, China). The above cDNA was detected by wheat internal reference actin gene primers. Specific Primer 5.0 software was used to design the primers for the experiment (*Table 2*).

Results

Effect of exogenous RsRHA2b gene on the activity of key enzymes in starch synthesis in the mature stage

ADPG-PPase is an enzyme that catalyzes the conversion of G-1-P into ADPG (adenosine diphosphate glucose), and ADPG is the direct precondition of starch synthesis. ADPG-PPase is a rate-limiting enzyme for starch synthesis, which plays an important role in regulating starch synthesis and accumulation in grains. The effect of exogenous *RsRHA2b* gene on the key enzyme ADPG of starch synthesis in mature wheat was shown in *Figure 1A,* after 10 d of wheat grouting, the activity of ADPG enzyme in transgenic lines was significantly higher than Zhengmai 9023; within 10-20 d after anthesis, the enzyme activity of ADPG in transgenic lines decreased sharply, but compared with Zhengmai 9023, the enzyme activity of transgenic lines was still higher (10 d, 0.3044/0.0049); from 20 to 30 d after flowering, the trend of transgenic lines and non-transgenic lines was basically the same; in particular, from 25 to 30 d after anthesis, both showed an upward trend, but their activity was very low.

The granule bound starch synthase (GBSS) is directly related with amylose synthesis enzyme. Endosperm lacking GBSS enzyme activity contains only amylopectin. As can be seen from *Figure 1B,* both the transgenic strain wheat and the control group showed only certain activity of GBSS 10 d after flowering. GBSS activity of transgenic lines gradually increased within the range of 10-25 d after anthesis, reached the highest level at 25 d after anthesis, and then gradually decreased. The GBSS activity of Zhengmai 9023 increased gradually from 10 to 20 d after anthesis, and reached the highest level at 20 d after anthesis. Within 10-25 d after anthesis, GBSS activity of transgenic lines was higher than that of Zhengmai 9023 (25 d, 0.05/0.004). At 30 d after anthesis, the GBSS activity of transgenic lines was lower than that of Zhengmai 9023. The GBSS activity of transgenic lines 30 days after anthesis and control group was very low. However, the GBSS activity of Zhengmai 9023 was slightly higher than that of the transgenic lines.

Soluble starch synthetase (SSS) exists in free state in endosperm cells of wheat seeds and mainly catalyzes the synthesis of amylopectin. The results (*Fig. 1C*) showed that the change trend of transgenic lines was basically consistent with that of the control group, and the SSS enzyme activity of transgenic lines was always higher than that of the control group. At 10 d after anthesis, SSS enzyme activity was the highest in transgenic strains, which was about 3 times of that in control group. Within 10-20 d after anthesis, SSS enzyme activity in transgenic lines and the control group decreased sharply (10 d, 0.03/0.009). At 20 d after anthesis, SSS enzyme activity in both transgenic lines and the control group was at the lowest level. In the range of 20-30 d, the SSS enzyme activity in the control group gradually increased, while the SSS enzyme activity in the transgenic lines first increased 20-25 d after anthesis (25 d, 0.02/0.008), and then decreased in the range of 25-30 d.

During the whole grouting process, the SBE enzyme activity of transgenic strains was always higher than that of the control group (*Fig. 1D*). The activity of SBE enzyme in transgenic lines showed a trend of "up-down-up". At 20 d after anthesis, the activity of SBE enzyme in transgenic lines reached the highest peak (20 d, 1.29/0.338), and then showed a "declining-rising" trend, but the range of declining-rising was small (30 d, 1.25/0.265). The SBE enzyme activity in the control group reached the highest peak at 25 d after anthesis (25 d, 1.212/0.748), and then showed a significant decline.

Effect of exogenous RsRHA2b gene introduction on the activity of key enzymes in protein synthesis in wheat maturity stage

The assimilation of ammonia in plants is mainly through GS/GOGAT pathway. GS is a multi-functional enzyme at the center of nitrogen metabolism, which is involved in a variety of nitrogen metabolism regulation. The improvement of GS activity can enhance the operation ability of nitrogen metabolism and promote the synthesis and transformation of amino acids.

The determination result of GS activity in wheat grain was shown in *Figure 2A*. The variation trend of GS content in transgenic lines and the control group was similar, both of which showed a gradually increasing trend with the progress of grouting. However, the activity of GS enzyme in transgenic lines was always lower

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1507315086

than that in the control group within the range of 10-30 d after flowering (30 d, 2.719/3.691).

The determination of GOGAT enzyme activity was shown in *Figure 2B*. The change trend of GOGAT enzyme activity in transgenic lines was similar to that in the control group, and showed a gradually declining trend throughout the grouting period. At 10-25 d after anthesis, the GOGAT enzyme activity of transgenic lines was significantly higher than that of the control group (10 d, 0.2717/0.1574; 20 d, 0.1887/0.0287), while at 30 d after anthesis, the enzyme activity value of both transgenic lines and the control group decreased to a very low level. To sum up, the introduction of exogenous *RsRHA2b* in the mature stage can regulate the activities of GS and NADH-GOGAT, the key enzymes for protein synthesis in wheat grains.

Effect of exogenous RsRHA2b gene introduction on the expression of related genes in the mature stage

In order to further study the regulatory mechanism of *RsRHA2b* gene in wheat grain starch synthesis and protein synthesis, the exogenous radish gene *RsRHA2b* was introduced into the transgenic lines for experiment in *Figure 3*. As can be seen from *Figure 3, RsRHA2b* was almost not expressed in the control group during the whole grain-filling period, since there was no *RsRHA2b* gene in the control group. In transgenic lines, the relative expression of *RsRHA2b* showed a trend of first increasing and then decreasing, and reached the maximum at 10 d after anthurium (10 d, 19.361/1), and then decreased, but was always significantly higher than that of the control group.

The proteins encoded by the 9 genes in this study interacted with RHA2b. The effect of exogenous *RHA2b* gene introduction on the expression of RHA2b interacting protein was studied by using transgenic lines.

YTH311, YTH611 and YTH1065 genes

As can be seen from *Figure 4,* in the process of grain formation, the relative expressions of *YTH311*, *YTH611* and *YTH1065* in the transgenic lines and the control group all showed a trend of increasing first and then decreasing. The relative expression levels of these three genes in transgenic lines were always higher than those in the control group. From 10 to 15 d after anthesis, the relative expressions of these three genes in transgenic lines and the control group showed an increasing trend. At 15 d after anthesis, the relative expression levels of the three genes in the transgenic lines and the control group reached the highest. The highest relative expression of *YTH311* gene (*Fig. 4A*) in transgenic and control groups was 1.2/0.7 (15 d), the highest relative expression of *YTH611* gene (*Fig. 4B*) was 7.5/2.5 (15 d), and the highest relative expression of *YTH1065* gene (*Fig. 4C*) was 10/3 (15 d), respectively. The relative expression levels of the three genes in the transgenic lines decreased about 15-20 d after flowering. The results showed that the introduction of exogenous *RsRHA2b* in the mature stage affected the expression of *YTH311*, *YTH611* and YTH*1065*.

YTH2433 gene

As can be seen from *Figure 4D,* the relative expression of *YTH2433* gene in transgenic lines and the control group both decreased first and then increased during the whole grain filling period (10 d, 1.5/4.46). At 15 d after anthesis, there was no significance between the relative expression level of *YTH2433* gene in both control group and transgenic lines. At 20 d after anthesis, the relative expression level of *YTH2433* gene in the control group was lower than that in the transgenic lines (20 d, 1.07/3.35). The introduction of exogenous *RsRHA2b* in the mature stage affected the expression of *YTH2433*.

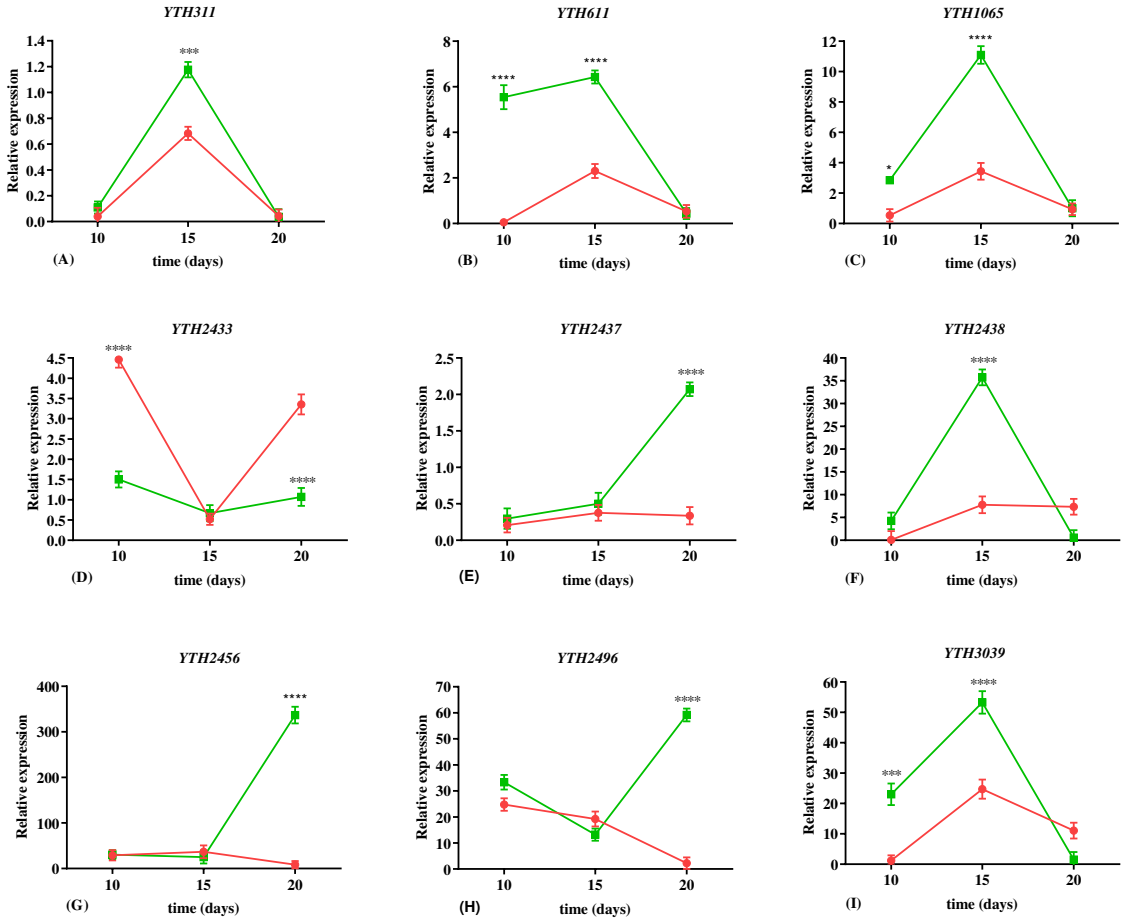

Figure 4. *Expression analysis of candidate genes during grain filling stage. CK, Zhengmai 9023; 1477, transgenic wheat lines. (A) YTH311; (B) YTH611; (C) YTH1065; (D) YTH2433; (E) YTH2437; (F) YTH2438; (G) YTH2456; (H) YTH2496, (I) YTH3039. Data are expressed as mean values ± standard errors from three replicates and error bars represent standard errors. The symbol '*' indicates statistically differences P < 0.05, the symbol '**' indicates statistically differences P < 0.01, the symbol '***' indicates statistically differences P < 0.001, the symbol '****' indicates statistically differences P < 0.0001 (two-way ANOVA, Sidak's multiple comparisons test)*

YTH2437 gene

The relative expression of *YTH2437* gene in transgenic lines and the control group showed an increasing trend during the whole grain filling period (*Fig. 4E*). The expression of *YTH2437* gene in transgenic lines was higher than that in control lines, and reached a significant level at 20 d after anthesis (25 d, 2.071/0.337). The introduction of exogenous *RsRHA2b* in the mature stage affected the expression of *YTH2437*.

YTH2456 and YTH2496 genes

The relative expression levels of *YTH2456* (*Fig. 4G*) and *YTH2496 (Fig. 4H)* in transgenic lines both decreased first and then increased in the process of grain formation, while the relative expression levels of these two genes in the control group

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1507315086

both showed a trend of continuous decrease. However, there was no significance between the relative expression of these two genes in the control group and the transgenic lines at 10 and 15 days after flowering. At 20 d after anthesis, the relative expression levels of these two genes in transgenic lines were higher than those in the control group (20 d, 336.695/8.619, *YTH2456*; 20 d, 59.171/2.217, *YTH2496*). The results showed that the introduction of exogenous *RsRHA2b* in the mature stage affected the expression of *YTH2456* and *YTH2496* genes.

YTH2438 and YTH3039 genes

The relative expressions of *YTH2438* (*Fig. 4F*) and *YTH3039* (*Fig. 4I*) in transgenic lines showed a trend of first rising and then falling in the process of grain formation. However, at 10 d and 15 d after anthesis, the relative expression levels of these two genes in transgenic lines were significantly higher than those in the control group (10 d, 23.022/1.245, *YTH3039*; 15 d, 37.742/7.799, *YTH2438*; 15 d, 53.284/24.743, *YTH3039*). However, there was no significance between the relative expressions of these two genes in the control group and the transgenic lines at 20 d after flowering. The introduction of exogenous *RsRHA2b* in the mature stage affected the expression of *YTH2438* and *YTH3039.*

Discussion

The regulatory network of a series of proteins interacting with RHA2b involves the processes of protein ubiquitination, cell protein metabolism, low temperature tolerance, and response to water loss, ABA, acidic compounds, oxygen-containing compounds and abiotic stress (Jiang et al., 2009; Kurkela and Franck, 1990; Li et al., 2011; Usadel et al., 2008; Nelson et al., 2010; Stone, 2014; Cho et al., 2011; Zheng et al., 2012; Robinson et al., 2010; Sajan et al., 2007; Haynes et al., 2002).

A series of RHA2b interacting proteins were selected by yeast two hybridization. In screening these proteins, the library is ABA treated, so the focus of the study will be on the ABA signaling pathway, or the signaling pathway indirectly mediated by ABA. Bioinformatics analysis showed that the protein encoded by *YTH311* gene may belong to SBE amylase, which is important for starch synthesis in the late endosperm development (Morell et al., 1995). The protein encoded by *YTH2456* gene may belong to RACD protein and participate in different signal transduction pathways through RAC/ROP (Schultheiss et al., 2003). The protein encoded by *YTH2496* gene may belong to AP2/EREBP protein, which is involved in development and abiotic stress (Jofuku et al., 1994; Ohmetakagi and Shinshi, 1995). The properties of these genes confirm the diversity of protein action.

Considering from the view that wheat with exogenous *RsRHA2b* gene can enhance the ability of ear germination, and the ability of ear germination is mainly affected by dormancy. Should be Does this focus on increased seed dormancy in transgenic wheat? How to enhance?

Dormancy of wheat seeds includes two types: embryo dormancy and seed (fruit) skin dormancy. The author speculated that seed coat dormancy caused by exogenous *RsRHA2b* gene can be easily reflected by seed size, maturity and internal restraining substance. If the dormancy is caused by the embryo, it will be affected by the expression of specific genes, as well as the metabolism and activity of specific nutrients. Because embryo dormancy can also be regulated by hormones. Decreased ABA content

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1507315086

promoted germination (King, 1976). Therefore, if the introduction of exogenous genes affects the metabolic pathway of specific hormones, it can also change the ability to resist ear germination.

A large number of studies have shown that the key enzymes in the starch anabolism process, such as AGPP, GBSS, SSS and SBE, play a key role in the synthesis and accumulation of wheat starch (Okita, 1992; Keeling et al., 1988; Nakamura et al., 1993). Protein content, protein components content and proportion not only affect the nutritional quality of wheat, but also have a great influence on the processing quality of wheat (Zhu and Khan, 2001). In addition to ensuring the integration and inheritance of exogenous genes, it is better not to change the biological environment and genetic background of recipient materials in the application of transgenic technology in the improvement of crop varieties. It was found that transgenic materials could not only improve the target traits, but also induce some non-target traits.

In the present study, it was found that the introduction of exogenous *RsRHA2b* could positively regulate the activities of the key enzyme for wheat starch synthesis AGPP, GBSS, SSS, SBE and the key enzyme of protein synthesis NADH-GOGAT in the process of grain filling, and only inhibited the activities of the key enzyme of protein synthesis GS. This indicated that the synthesis of wheat protein was greatly affected by the activity of GOGAT enzyme in the grain, but less by the activity of GS enzyme. This indicates that the complex formed by RHA2b and candidate protein may mediate some important regulatory pathways in the metabolism of carbon and nitrogen, change the metabolism of specific nutrients, and thus improve the resistance to ear germination of transgenic materials.

The results of this experiment showed that the introduction of exogenous RsRHA2b gene did affect the influence of related genes. The introduction of exogenous *RsRHA2b* promoted the expression of *YTH311, YTH611, YTH1065, YTH2437, YTH2438, YTH2456, YTH2496* and *YTH3049,* and inhibited the expression of *YTH2433*. This indicates that the complex formed by RHA and candidate protein may mediate some important regulatory networks of hormone response, play a role on specific pathway sites, and then affect the spike germination characteristics of transgenic materials.

Conclusion

The present research revealed that the introduction of exogenous *RsRHA2b* increased the activity of AGPP, GBSS, SSS, SBE and GOGAT, and decreased the activity of GS. Exogenous *RsRHA2b* promoted the expression of *YTH311, YTH611, YTH1065, YTH2437, YTH2438, YTH2456, YTH2496* and *YTH3049*, and inhibited the expression of *YTH2433*. More work is needed to explore the regulation of *RsRHA2b* gene on transgenic wheat grain quality and its mechanism as follows: (1) α-amylase activity, amylopectin activity and starch content of transgenic lines; (2) sulfhydryl content of stored proteins; (3) determination and analysis of quality related indicators, such as gelatinization properties of starch, flour farinograms and tensile parameters.

AGRARIAN AND WETLAND AREAS UNDER METROPOLITAN THREATS: LEARNING FROM THE CASE OF INCIRALTI, IZMIR (TURKEY)

KARA, B.

Department of Landscape Architecture, Faculty of Agriculture, Aydin Adnan Menderes University, 09970 Cakmar, Aydin, Turkey
(e-mail: bkara@adu.edu.tr; phone: +90-256-772-7022/1401; fax: +90-256-772-7233)

(Received 27th Jun 2019; accepted 25th Oct 2019)

Abstract. The aim of the study is to determine the Land use/land cover (LULC) changes and conversions in Inciralti İzmir (Turkey), and the fragmentation of these land uses between 1996 and 2018. Aerial photographs and Quickbird satellite imagery were used to obtain data. Aerial photographs were georectified using 1: 25,000 scaled topographic maps. The feature (vector) boundary of the study area was used to subset aerial photographs and Quickbird satellite image. LULC classes were defined according to Coordination of Information on the Environment (CORINE) LULC classes. The defined LULCs were digitized. Between 1996 and 2018, the highest conversion rate among agricultural areas occurred in permanently irrigated land with 41.43%, and the highest conversion among wetlands were in inland marshes with 65.19%. Between 1996 and 2018, the LULC with the highest increase in the number of patches was coastal lagoons with 300%. Research data shows that there has been a great change, conversion and fragmentation process in construction sites, wetlands and agricultural areas in Inciralti between 1996 and 2018. Change, conversion, and fragmentation of LULCs have damaged the natural and cultural structure of Inciralti. In order to stop this damage, filling of wetlands and the construction on agricultural areas in Inciralti should be prevented.
Keywords: *agricultural and wetland loss, Cakalburnu Lagoon, CORINE, LULC (land use/land cover) change, landscape fragmentation*

Introduction

Human activities all over the world have been the dominant factor shaping most of the agricultural landscapes (Goudie and Viles, 1997) and wetlands (Moulton and Jacob, 2000). The most important reasons for the loss of agricultural areas and wetlands are population growth (Turner II, 1989; Hobbs et al., 1991) and rapid and unplanned urbanization (Lopez et al., 2001).

Urbanization directly affects fertile agricultural areas by transforming them into residential, commercial areas (Sanders, 2006), and it affects wetlands by transforming them into agricultural (Zhang et al., 2010), industrial and recreational areas and through filling works (Maynard and Wilcox, 1997). This conversion is called as Land use/land cover (LULC) change. One of the most important effects of rapid urbanization is fragmentation, which has a profound impact on urban ecosystems (Fan and Myint, 2014).

Land monitoring enables better using of land. It provides valuable information about the environment (Balado et al., 2018). Analyzing the change characteristics of LULC, revealing the evolution of different time scales are helpful to reveal the process under the influence of human society (Li et al., 2019). There are many ways to monitor or detect LULC change over time (Fonji and Taff, 2014). One of them is LULC mapping. Mapping LULC of large cities is a main component of detecting rapid changes (Rujoiu-Mare and Mihai, 2016; Nuthammachot and Stratoulias, 2019).

DOI: http://dx.doi.org/10.15666/aeer/1706_1508715102

Coordination of Information on the Environment (CORINE) is widely used in LULC mapping. CORINE is the longest available land cover and land cover change database with a consistent class labeling system (Cole et al., 2018). CORINE data sets are useful for describing long term structural changes of ecological complexes (Petrişor et al., 2014). CORINE database is a key for integrated environmental assessment (Dzieszko, 2014).

Urbanization, which has been encouraged by remarkable economic development, has progressed increasingly rapidly in Turkey in the last fifty years. In the industrialization and urbanization processes, it is clearly documented that large agricultural areas have been lost due to non-agricultural uses (Esbah, 2004). Metropolitan areas now cover an important part of Turkey's agriculture. Wetlands are among the most threatened ecosystems of Turkey.

Several studies using Remote Sensing (RS) and Geographical Information Systems (GIS) techniques in Turkey have been conducted to examine the intense pressure of the urbanization on agricultural lands and wetlands and to determine LULC changes.

In a study conducted in Antakya, the Amik plain, one of the most fertile plains of Turkey, was determined to be under the intense pressure of the expansion of urban and industrial areas (Kilic et al., 2005).

LULC changes in the coastal region of the Çandarlı Bay between 1990 and 2005 were examined in terms of the conversion of agricultural areas, olive groves and coastal wetlands into urban areas (Kesgin and Nurlu, 2009).

In the study on the LULC changes in the urban settlement of Kuşadası district between the years 1993 and 2006, it was determined that agricultural areas decreased and were converted into industrial, commercial and residential areas (Kara et al., 2013).

The study area is Inciralti located in the metropolitan area of Izmir, the third largest city of Turkey. The reason for choosing Inciralti as the study area is that it is home to two important ecosystems such as fertile agricultural land and wetlands at the same time in the center of the metropolitan area of Izmir.

The aim of a study is to monitor the changes/conversions and fragmentations in agricultural areas and wetlands in Inciralti in the period of 22 years between 1996 and 2018 by using aerial photographs, satellite image, RS and GIS techniques.

Materials and methods

Study area

Inciralti, which is the study area, is located on the west coast of Turkey, in the Aegean region, in the south of the Izmir bay, and in the metropolitan area of Izmir, the third largest city, within the boundaries of Balcova district (*Fig. 1*). Coordinates of Inciralti are 38°24'42.28"N 27°1'58.47"E and 38°23'55.76"N 27°3'46.64"E. Its surface area is 378.04 ha. Within the boundaries of the study area, there are the Balcova plain and Cakalburnu lagoon, which are among the most fertile agricultural areas and wetlands of the city (*Fig. 2*).

Inciralti is the only area that has been able to maintain its agricultural character despite the intensive urbanization in the metropolitan area of Izmir. In the Balcova plain, there is a very intensive production in greenhouses, open fields, flower, vegetable, citrus gardens and various orchards.

Cakalburnu lagoon, which is one of the most important natural areas of Izmir, is a wetland area integrated with the city, unlike other wetlands. Cakalburnu lagoon is one

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1508715102

of the important wetlands in Izmir with 103 bird species (Sevil, 2010). The world-wide endangered *Pelecanus crispus* (Dalmatian Pelican) and *Hoplopterus spinosus* (Spur-winged Lapwing) that breeds only in Greece also breed only in Cakalburnu lagoon in Turkey. Cakalburnu lagoon is one of the areas where *Tapes decussatus* (Grooved carpet Shell), a mussel species of economic value, is commercially collected in Turkey (Serdar et al., 2010). The predominant vegetation of Cakalburnu lagoon is composed of *Salicornia europaea* L. (Common glasswort).

In addition to its agricultural potential and ecological value, Inciralti is the only green area in Izmir as the "last coast with accessible recreational potential for all.

DOI: http://dx.doi.org/10.15666/aeer/1706_1508715102

Data collection

The main material of the study consists of aerial photographs and satellite image. Aerial photographs and QuickBird satellite image were used to obtain LULC data for the previous years in the study area. The aerial photographs are monochrome monoscopic/stereoscopic with a 1/35.000 scale belonging to the year 1996. High-resolution QuicBird satellite image has a spatial resolution of 0.6-m dated June 25, 2018. ERDAS IMAGINE® 9.2 and Esri® ArcMap 9.3 software were used to process digital data. RS and GIS techniques were used to detect the LULC changes and conversions.

Image pre-processing

The geometric rectification of the aerial photographs was made according to the topographic map with a 1:25,000 scale. Satellite image and digitized aerial photographs were georectified in the Universal Transverse Mercator (UTM) (Zone 35) coordinate system using first-order polynomial transformation and subsetted according to the feature (vector) boundary of the study area.

Interpretation of aerial photographs and satellite image

Visual interpretation and on-screen digitizing method were used to detect the LULC changes and conversions between 1996 and 2018. Aerial photographs and satellite image were visually interpreted on the screen using direct (tone, texture, shape, and pattern) and indirect (location and relationship) identification elements.

Image classification

LULC changes and conversions were detected by using remotely sensed data. The bi-temporal change detection technique (Royer and Charbonneau, 1988) was used to determine LULC changes and conversions from 1996 to 2018. CORINE Land Cover nomenclature was used in change detection.

The cross-tabulation method was used to determine LULC changes. In this way, a change matrix was produced (Wang et al., 2006).

In the study area, 16 CORINE LULC classes were determined at Level 3 (*Table 1*).

Data processing

A comparison between 1996 and 2018 of the field data were generated. Then, the quantitative data of changes, increases, and losses in the LULC of each category were compiled. Thus, the expansion of urban sprawl on agricultural areas and wetlands was determined.

The digitization process not only provided an analysis of the changes in the total area of LULCs but also produced quantitative information on the rate of fragmentation of the parcels and changes in the average parcel size.

Results

Between 1996 and 2018, there were serious changes in LULC in Inciralti (*Figs. 3* and *4; Table 2*). In 1996, coastal lagoons, covering the 19.04% of the area, constituted the largest LULC of Inciralti. In 2018, coastal lagoons became the third largest LULC with a ratio of 13.32%.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1508715102

The second largest area among LULCs in 1996 (17.68% of the total) was the permanently irrigated land, which is the western part of the study area. The majority of permanently irrigated land consists of the areas where vegetables are cultivated. In 2018, the permanently irrigated land occupied less area compared to 1996 but was the second largest area (15.76% of the total).

The LULC with the third largest area in 1996 (15.44%) was the construction sites. A large part of the construction sites consists of fillings (rubble dumping) made in the northern part of the area on Izmir Bay coast and Cakalburnu lagoon. In 2018, the construction sites accounted for 4.11% of the total area and ranked ninth in terms of area size.

The discontinuous urban fabric ranked seventh in terms of area size among LULCs (4.13%) in 1996. The discontinuous urban fabric consists of agricultural enterprises and luxury villas in the central and western part of the area. The area covered by the discontinuous urban fabric increased to 5.52% but remained in the seventh place in 2018.

Between 1996 and 2018, the most significant increase in the LULC in terms of area size was in sport and leisure facilities (100%), green urban areas (83.92%), road and rail networks and associated land (70.58%). The most significant decrease was in dump sites (369.01%), construction sites (275.67%), and inland marshes (167.41%).

Tables 3 and *4* show the changes and conversions between LULCs. The discontinuous urban fabric increased by 25.11% (6.47 ha). Between 1996 and 2018, the city developed on the 8.22% (1.19 ha) of green urban areas, 5.99% (4.95 ha) of permanently irrigated land, 3.16% (2.17 ha) of non-irrigated arable land and 1.07% (0.62 ha) of fruit trees and berry plantations (*Fig. 5*).

Figure 5. *The spread of the discontinuous urban fabric to the non-irrigated arable land and permanently irrigated land*

Green urban areas increased by 83.92% (75.43 ha). The most important reason for the increase in green urban areas is the conversion of 54.32% (2.85 ha) of the dump sites, 50.69% (36.56 ha) of construction sites and 29.14% (25.92 ha) of coastal lagoons into green urban areas.

The non-irrigated arable land (greenhouse cultivation) showed a decrease of -16.84% (9.88 ha). 26.30% (18.04 ha) of the non-irrigated arable land was converted into permanently irrigated land, 3.16% (2.17 ha) into the discontinuous urban fabric, and 1.86% (1.28 ha) into green urban areas.

Inland marshes showed a significant decrease of -167.41% (12.62 ha). Upon looking at the conversion matrix, the main reason for the change in these areas is the conversion of 27.23% (5.49 ha) into construction sites, 24.43% (4.92 ha) into sparsely vegetated areas and 5.34% (1.08 ha) into sclerophyllous vegetation.

Coastal lagoons showed a decrease of -42.99% (26.75 ha). 29.14% (25.92 ha) of coastal lagoons were converted into green urban areas (*Fig. 6*).

Between 1996 and 2018, there were significant changes in the patch numbers and patch areas of the LULC categories (*Table 5*). Between these years, the total patch number of the discontinuous urban fabric increased by 24.12% (from 199 to 247). The highest increase in the patch number was in the area with a 0-0.9 ha patch size (23.86%/from 197 to 244). There was no change in the average patch area size of the discontinuous urban fabric (0.1 ha).

The total patch number of green urban areas increased from 65 to 76 (an increase of 16.92%). The highest increase (300%/from 3 to 9) was observed in the patches of 1-4.9 ha. The average patch area increased by 536.36% from 0.22 ha 1.18 ha.

The total patch number of the non-irrigated arable land increased by 30.77% from 104 to 136. The highest increase in the patch number was in the patch group of 0-0.9 ha with 44.19% (from 86 to 124). The average patch area size of the non-irrigated arable land decreased by 34.85% (from 0.66 to 0.43 ha).

The total patch number of inland marshes decreased by 58.33% from 12 to 5. The highest decrease in the patch number was in the areas with a patch size of 0-0.9 ha (60%/from 10 to 4). The average patch area decreased by 10.12% from 1.68 ha to 1.51 ha.

The total patch number of coastal lagoons increased by 300% (from 1 to 3). The highest increase in the patch number was in the areas with a patch size of 0-0.9 (200%/from 0 to 2). The average patch area decreased by 76.69% (from 88.97 ha to 20.74 ha).

Discussion

The effects of urbanization in Inciralti are observed with the conversion of different LULCs into urban areas. The conversion of agricultural areas (permanently irrigated land, non-irrigated arable land, and fruit trees and berry plantations) into urban areas (discontinuous urban fabric) shows that urbanization in Inciralti creates great pressure on agricultural areas. This result is line with results of a previous survey in Nanping city, China, where the pressure of urban expansion on agricultural areas can be seen as decreases in cultivated land (Fan and Zhao, 2019). An indirect indicator of the continuation of a process leading to the construction of Inciralti is that agricultural areas were left unused. The decrease in the importance given to agriculture has led to the large abandonment of agricultural areas (Price et al., 2015).

Although the impact of human activities is for all natural ecosystems, it particularly affects coastal wetlands (Valdez et al., 2016). The reason for the conversion of wetlands into urban and agricultural areas in Inciralti is the filling of the area with rubble and garbage. As a result of filling Cakalburnu lagoon with rubble, Inciralti has been losing its wetlands characteristics. The reason for such losses in coastal wetlands is tremendous demand for land (Jiang et al., 2015; Kingsford et al., 2016). The major threat to coastal wetlands is the transformation of coastal ecosystems, which is the result of urbanization, which leads to significant loss and change of habitat (Gallant, 2015; Xu et al., 2016). Wetland loss is an important problem in local communities as well as for many wetland species that depend on wetlands (Orimoloye et al., 2018).

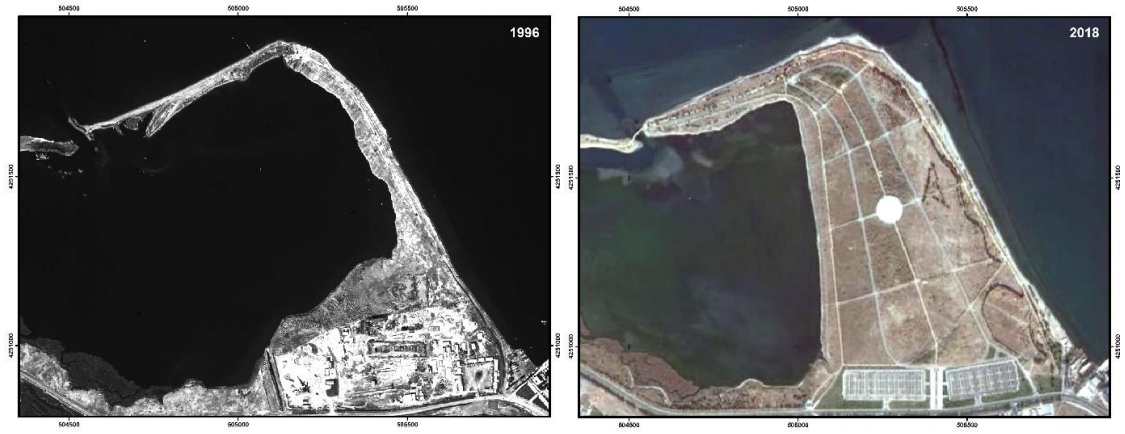

Figure 6. *Conversion of coastal lagoons in Inciralti*

In addition to the change/conversion of the LULC classes, patch numbers and patch area sizes reveal the state of agricultural areas and wetlands in Inciralti. The increase in the patch number with the smallest area size (0-0.9 ha) indicates that the discontinuous urban fabric spread throughout Inciralti (as agricultural enterprises and villas). This result is supported by the view that if the number of small patches increases, fragmentation also increases (Lasanta et al., 2015)

The extension of the discontinuous urban fabric to the west caused fragmentation of the agricultural areas particularly by creating pressure on these areas. The result of this study coincides with the view that the spreading construction areas occupy agricultural areas and divide large agricultural patches into small ones (Liang et al., 2015). A study assessing LULC changes in Romania found that serious fragmentation of agricultural land caused significantly decreasing in the quality and quantity of land use (Popovici et al., 2013).

When the changes in the total patch number, the number of patches with small sizes, the average patch area and total area size of the agricultural areas together, it is observed that these areas were subjected to conversion by severe fragmentation.

The changes in the total area size, total patch number and average patch area and the number of patches with small sizes of wetlands indicates severe fragmentation and rapid conversion. Similarly, on the analysis of LULC changes; it is stated that the total class area, the number of patches, the average patch size and the largest patch size provide information about the fragmentation of the landscape (Grecchi et al., 2014).

The results of the study are important in terms of revealing the LULC changes, conversions and fragmentations in Inciralti in detailed. The results of the study are important to reveal the LULC changes, conversions, and fragmentations in Inciralti in detailed. The results of the study are also important in terms of understanding the agricultural potential and ecological value of the area and contribute to the development of social awareness for the preservation of the agricultural and wetland character of Inciralti.

Conclusion

Changes, conversions, and fragmentations of LULCs in the study area over the years have caused changes in the existing natural and cultural structure of Inciralti. For this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1508715102

reason, ecological importance of coastal areas should be prioritized (Rahman et al., 2017). The wetland characteristics of Inciralti can be protected by preventing the filling works for obtaining green urban areas and making wetland restoration.

Small patches of agricultural areas should be combined in order to reduce the severity of fragmentation.

Planning and management studies for Inciralti should focus on the protection of agricultural lands and wetlands as well as physical and economic development. An ecosystem-based conservation approach can be supported in areas accommodating different uses that meet the needs of multiple bird species/communities (Ma, et al., 2010). Appropriate land management is a way to avoid the negative effects of unplanned development (Rahman et al., 2017). To achieve this, planning and management studies should take into account landscape dynamics and LULC changes/conversions.

In future studies, the effects of temporal changes, conversions and fragmentations of the LULC on the agricultural product model, flora and fauna diversity, and people's mental health can be examined. Future studies provide quantified metrics for their study areas such as percent impervious surfaces, road density, and human population density. The effects of the intense demands of landowners for the development of agricultural land, the most important problem threatening Inciralti, on LULC changes can be analyzed. The pressure of green space demands on agricultural areas and wetlands can also be evaluated.

(Received 28th Jun 2019; accepted 16th Oct 2019)

Abstract. Nutrient limitation constrains the regeneration of *Castanopsis kawakamii* seedlings in subtropical forests. Small Philippine acacia (*Acacia confusa*), a common tree species in mixed forests, is known for its nitrogen fixation capabilities. Therefore, we attempted to intercrop *A. confusa* in a *C. kawakamii* natural forest. However, this forest contained abundant litter, harboring ample tannins and total phenols. Whether the allelopathy of litter could constrain the seed germination of *A. confusa* seed was unknown. Therefore, we aimed to explore the influence of forest litter extracts on the seed germination and radicle growth of *A. confusa*. The results indicate that low concentration litter extracts promote whereas high concentrations inhibit *A. confusa* seeds. The stock solution produced the strongest inhibition, whereas the 1:160 litter extract concentration had promoted the germination rate and radicle growth. The *A. confusa* radicle increase was remarkable in the first eight days, and tended to decrease from day 9 to 15. Overall, the allelopathic effect of litter is not a factor limiting the mixing of *C. kawakamii* and *A. confusa*. This could provide an alternative method to improving soil nutrition, thus promoting the regeneration of *C. kawakamii* seedlings.
Keywords: *germination rate, germination potential, germination index, radicle length, mixed forest*

Introduction

Castanopsis kawakamii is a unique subtropical evergreen broad-leaved species. It has survived as an endangered tertiary relict plant, only found in Fujian, Taiwan, Jiangxi, Guangdong, and Guangxi provinces in China (Buanjan et al., 2018). Currently, natural *C. kawakamii* forests are characterized by limited seed germination and seedling growth due to the low total nitrogen and total phosphorus in the soil (Su et al., 2012). As crucial aspects of a forest ecosystem, the physical and chemical properties and nutrients in the soil are significant to seedling development (Hou et al., 2011). However, previous studies mainly focused on community ecology (He et al., 2019); forest gap regeneration (He et al., 2018); natural forest, its plantation litter, and soil biochemistry cycle (Ma et al., 2015); soil microbes, biochemical characteristics (Ma et al., 2014); and soil-litter

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1510315116

stoichiometry to protect this rare species (Feng et al., 2017). Little research has focused on improving soil nutrition to promote species regeneration in this forest. Thus, in this study, we aimed to replenish soil nutrients to accelerate the regeneration of *C. kawakamii* seedlings.

Consistent with the importance of rhizobia-mediated N partitioning, inclusion of legumes is instrumental for generating positive diversity–productivity relationships (Wang et al., 2019a). With the existence of legumes and rich nitrogen in the litter layers, *Acacia confusa* has powerful fixation ability. Previous reports showed that one hectare of *A. confusa* forest can provide 3500 kg of litter per year, which is equivalent to 500 kg of carbamide after litter decomposition (Hu et al., 2015; Tung et al., 2015; Liu, 2011). As a common tree species in mixed forests, *A. confusa* is cultivated in tropical and subtropical regions in southwestern and southeastern provinces in China. It has a fast growth rate, wide adaptability, high biomass, and good water retention. Mixed with *Castanopsis* plants, such as *C. hainanensis*, *C. carlesii,* and *C. hystrix*, *A. confusa* could help *Castanopsis* plants to grow better. *A. confusa* also does not cause damage to *Castanopsis* plants (Liu, 2011), providing an alternative method for managing *A. confusa* in natural *C. kawakamii* forest to replenish and enrich the nutrient contents and to improve the establishment and regeneration of the target seedlings.

The amount of litter and the contents of tannin and total phenol in the *C. kawakamii* natural forest are relatively high (Feng et al., 2017; Yang et al., 2003). The seed germination and radicle growth of *C. kawakamii* are significantly inhibited under the action of a stock solution of litter (Wang et al., 2019b). The allelochemicals produced by the litter may also affect the germination of *A. confusa* seeds. Therefore, we hypothesized that: (1) different concentrations of litter extracts have different effects on *A. confusa* seeds, and high concentration of litter extracts inhibit the seed germination and radicle growth; (2) under the treatment of litter, *A. confusa* radicles grow considerably in the early period and growth decreases later; and (3) if the litter extract promotes the germination of *A. confusa* seeds, soil N content may be increased to improve the regeneration of *C. kawakamii*'s seedlings; if the litter extract inhibits germination, it indicates that *A. confusa* may not suitable as a mixed tree species in *C. kawakamii* natural forest. Finding other methods to improve the soil N content in this forest is necessary. Therefore, in this study, the extracts of *C. kawakamii* natural forest litter were used as allelopathic substances to explore the allelopathic effects of litter extracts on the germination of *A. confusa* seeds. The objective of our study was to provide a scientific basis for intercropping *A. confusa* species to improve soil nutrition, thereby accelerating the regeneration of *C. kawakamii* seedlings in this forest.

Materials and methods

Study sites and natural history

The *C. kawakamii* Nature Reserve is located in Sanming, Fujian Province, China, at 26°07'–26°12' N and 117°24'–117°29' E. The elevation varies between 180 and 604 m. The climate is medium subtropical monsoon, with an annual average temperature of 19.5 °C, annual precipitation around 1500 mm, and annual relative humidity of 79%. The soil type in this forest is mainly ferric acrisols with abundant humus. The research area has 700 ha of *C. kawakamii*, in which the average age of the population is about 130 years. The arbor layer is dominated by *C. kawakamii, Pinus massoniana,* and *Schima superba*. Accordingly, the population density, average tree height, diameter at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1510315116

breast height, and canopy density are estimated to be 100 individuals/hm^2, 21.5 m, 32.4 cm, and 0.8, respectively. The shrub layer is mainly composed of *Litsea subcoriacea, Vaccinium carlesii*, and *Syzygium buxifolium*; and the herbaceous layers are represented by *Dicranopteris pedata*, *Gahnia tristis*, and *Alpinia oblongifolia* (Liu et al., 2011; Ma et al., 2015).

Experiment design

The litter baskets were arranged in the east, south, west, north, and middle of the fixed plots in the *C. kawakamii* natural forest, and were collected monthly from Sept. 2016 to Sept. 2017. We set up a total of 10 plots and the size of each plot was designed to be about 100 m^2 and the litter baskets were 1.0 ×1.0 m. The litter basket arrangement is shown in *Figure 1*. The collected litter was divided into four types: leaves, nutshells, branches, and bark. Then, we mixed the litter of each of the four types in accordance with their proportion. In the next step, we weighed 1 kg of each type. We collected 5 kg of *A. confusa* seeds from the same family for experimental materials.

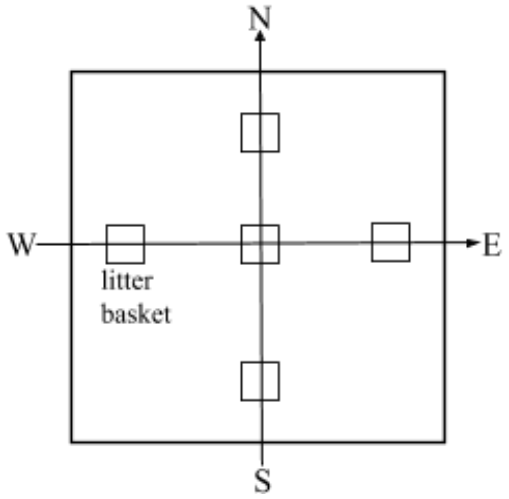

Figure 1. *The location of litter baskets in each plot. The small square box represents the location of the litter basket*

Preparation of litter extracts

Each kilogram of collected litter sample was washed three times with distilled water to remove surface-attached soil and humus. Next, the samples were crushed and sieved after drying in an oven. After sieving, 10 g of litter were placed into a 50 mL centrifuge tube and 15 mL of 70% ethanol was added. The mixture was leached twice at 80 °C for 1 h in a water bath. After free cooling, the samples were placed into a centrifuge at 4 °C for 5 min at a rotation speed at 8000 rpm. To obtain a stock solution (with three replicates), we filtered the extracts twice and then diluted the extracts to 50 mL with distilled water. As the extraction of litter in nature is repetitive and diverse, the range of extract types and contents is relatively wide. Ethanol was applied as an effective extraction agent to ensure polarized allelochemicals could be maximally extracted out of the litter.

The stock solution was then placed on a rotary evaporator to evaporate the ethanol. The average litter quality and annual precipitation of the *C. kawakamii* natural forest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1510315116

fixed plot from 2010 to 2017 were 11,010 kg/hm^2 and 1500 mm/year. Referring to the litter conversion (Yuan et al., 2010), 1:160 is the natural leaching concentration of the litter of natural *C. kawakamii* forest. Considering the rain leaching process, repeated extraction, and microbial decomposition, five concentrations were set as treatments: 1:20, 1:40, 1:80, 1:160, and 1:320. Therefore, the stock solution was diluted again with distilled water with five different concentrations. The dilution rates are listed as follows: 1:20 litter extracts (stock solution was diluted 4 times with distilled water), 1:40 litter extracts (stock solution was diluted 8 times with distilled water), 1:80 litter extracts (stock solution was diluted 16 times with distilled water), 1:160 litter extracts (stock solution was diluted 32 times with distilled water), and 1:320 litter extracts (stock solution was diluted 64 times with distilled water), and then we stored the extracts in a 4 °C refrigerator until use. During the extraction, the ethanol evaporation was incomplete. As a consequence, we also created a blank control group as a contrast that was exempted from the treatment: the same procedure was repeated but without the litter.

Seed germination experiment

The selected and same-sized *A. confusa* seeds were disinfected with 0.5% potassium permanganate for 30 min, then washed with distilled water 3 times before arranging them evenly in a petri dish with *C. kawakamii* forest soil. The *C. kawakamii* forest soil was sterilized in a high temperature sterilization pot at 120 °C for 20 min. The different concentrations of litter extracts were added into each petri dish, with 100 seeds placed uniformly in each petri dish. We set up a total of 6 treatments including stock solution, 1:20 litter extract, 1:40 litter extract, 1:80 litter extract, 1:160 litter extract, and 1:320 litter extract with 3 replications each with distilled water, and a blank control group as the control. The experiment conditions were cultured with a 12 h photoperiod at 25 °C, 12 h dark cycle at 15 °C, light intensity 50 nmol/cm^2/s, and relative humidity 75–80% in the incubators. We added 5 mL litter extract daily into the filter paper of the petri dish to maintain moisture.

We recorded the seed germination 3 days after the experiment. A 2 mm seed radicle was defined as seed germination, and the number of germinated seeds was recorded every day (Aldo et al., 2018). We finished the experiment when no further seed germination occurred for 3 continuous days. The radicle length measurements were recorded when the seed germination reached the peak (Wang et al., 2019b). We measured the radicle length of 20 seeds with a similar radicle length in different petri dishes after recording the seed germination for three days when the seed germination reached the peak. The length of the radicle was also measured daily with an electronic digital caliper with a resolution of 0.01 mm. The radicle daily growth amount was simultaneously calculated by the difference in the value of the radicle length between the current day and the previous day. On the 15th day, we finished the radicle experiment when the radicle growth was generally stable. Finally, the germination rate, germination potential, germination index, allelopathic effect index, and the radicle length of seeds were thereby calculated (Bruce et al., 1988). The formulas are listed below (He et al., 2012; Gabriel et al., 2017).

$$\text{Germination rate} = \frac{\text{number of seeds germinated}}{\text{total number of seeds}} \times 100\% \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1510315116

$$\text{Germination potential} = \frac{\text{number of seeds that were normally germinated to the highest}}{\text{total number of seeds}} \times 100\% \quad \text{(Eq.2)}$$

$$\text{Germination index} = \Sigma \frac{Gt}{Dt} \quad \text{(Eq.3)}$$

where *Dt* refers to the number of germination days, and *Gt* refers to the number of germinated seeds in that *Dt* day.

Allelopathy index:

$$\begin{aligned} I &= 1 - \frac{C}{T} \quad (\text{when } T \geq C) \\ I &= \frac{T}{C} - 1 \quad (\text{when } T < C) \end{aligned} \quad \text{(Eq.4)}$$

where C refers to the control value, T refers to the treatment value, while $I < 0$ represents the inhibition effect, $I > 0$ represents the promotion effect, and $I = 0$ represents the neutral effect.

Data analysis

The experimental data were calculated and plotted using Excel 2016 (Microsoft, Redmond, Washington, USA). The statistical ANOVA was analyzed using SPSS 21.0 (IBM, Almonk, New York, USA). We first calculated the effect of different concentrations of litter extracts on the germination indices, radicle length, radicle growth, and allelopathy index of *A. confusa* seeds. Then, the variance analysis of these data was performed, and Tukey's test was applied in multiple comparisons to determine the significant difference among various treatments. The data were considered to be significantly different at $P < 0.05$.

Results

Effects of different extract concentrations on germination of A. confusa seeds

The effects of various concentrations of litter extracts on seed germination of *A. confusa* is shown in *Tables 1* and *2*. *A. confusa* seeds demonstrated different sensitivities to different concentrations of litter extract, which generally promoted seed germination at low concentrations and inhibited it at high concentrations. We found a negative correlation between litter extract concentration and germination potential, germination rate, and germination index. The germination rate was highest with a litter concentration of 1:160, which promoted the seed germination rate. The seed germination rate was significantly lower than those of the other treatments at a concentration of 1:20, demonstrating the most inhibition of the seed germination rate. The seed germination rates under high concentration treatments (including stock solution, 1:20, and 1:40) were significantly lower than under low concentration treatments (1:160 and 1:320). High concentrations of litter extract inhibited the seed germination rate, whereas low concentrations had a promotion effect. The germination potentials for high concentration (including stock solution and 1:20) flitter extract treatments were significantly lower than for low concentration (1:80 and 1:160) treatments. The germination potential and index were the lowest for the stock solution, which revealed negative effects on the seed germination potential and index. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1510315116

germination indexes for the high concentration (including stock solution and 1:20) treatments were significantly lower than for the low concentration litter extract treatments (including 1:80, 1:160, and 1:320). No significant differences in germination rate, potential, or index were found between distilled water and the control group. We found that when the concentration of litter extracts exceeded the dilution ratio of 1:40, the seed germination was restrained. The 1:80 dilution rate was considered the turning point for seed germination; the optimum dilution for seed germination was found to be 1:160. The 1:160 litter extract was the most appropriate concentration for the germination of *A. confusa* seeds.

Table 1. *Effects of different concentrations of litter extracts on seed germination of A. confusa*

Effects of different concentrations of extracts on radicles of A. confusa seeds

Difference in radicle length between different concentrations of extracts

Figure 2 and *Table 3* show the effects of various concentrations of litter extract on the radicle length of *A. confusa* seeds. Similar to seed germination, the different concentrations of litter extracts tended to promote radicle growth at low concentration and inhibit radicle growth at high concentration. The inhibition effect was aggravated with increasing concentration, among which the most notable effect was observed with the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1510315116

stock solution. The 1:40 to 1:160 litter extracts demonstrated a promotion effect, that was the strongest at 1:160, whereas the facilitation effect gradually weakened when the concentration was 1:320. The growth in radicle length in the early stage was not obvious for the different concentrations of litter extracts. The difference in radicle length between various concentration of litter extracts and distilled water increased with time. Significant differences in radicle length were detected among the stock solution, distilled water, and 1:160 concentration litter extract. At the end of the experiment, the average radicle lengths for 1:160 litter extract, distilled water, and stock solution were 36.09, 30.06, and 19.59 mm, respectively. No significant differences in radicle length were found between the distilled water and control groups.

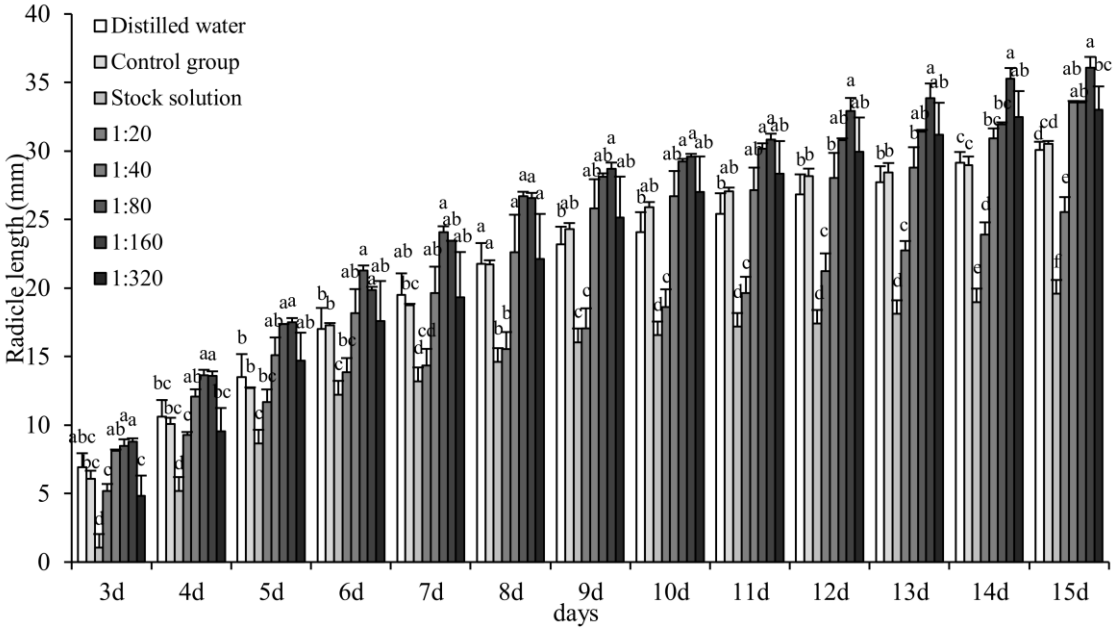

Figure 2. *Effects of different concentrations of litter extracts over time on the radicle length of A. confusa seeds. The different letters (from a to d) represent the difference in radicle length among the different concentrations of the same day. Data (mean ± SD) marked with different letters in plots were significantly different under p level as 0.05 in the same column. Compared with the control group, the treatment group were larger than the control group indicates that the radicle growth is promoted, and vice versa.*

We found that *A. confusa* radicle elongation was inhibited under the stock solution and 1:20 litter extract; at 1:40, 1:80, and 1:160 litter extracts, we observed promotion effects, although it was not conspicuous at the concentration of 1:320 (*Table 3*). The stock solution had the strongest inhibiting effects on seed radicle growth. The best promotion effect was detected for the 1:160 litter extract which showed a relative high promotion effect in the early period, then later decreased. Consequently, the 1:160 litter extract remained the optimum concentration for the growth of *A. confusa* radicle length.

The results of the two-way ANOVA analysis of variance were presented in *Table 4*. There was a significant difference in the length of *A. confusa* radicle treated with time or different concentrations of litter extracts. But the difference in interaction between time and different treatments is not significant.

Differences in radicle growth of A. confusa seeds in different time periods

The effects of litter extracts on the seed radicle growth is shown in *Figure 3*. It shows that the seed radicle growth of *A. confusa* decreased with time, and the growth trends of various concentrations were different. The growth of the seed radicle was greater in the distilled water group at the period from day 4 to 9, and the growth was stable after the 10th day. The radicle growth increased the most on the fifth day and the least on the 11th day. For the stock solution of litter extracts, the seed radicle growth during day 5 to 7 was significantly higher than on other days; the seed radicle grew the most on the fifth day and the least on the 13th day. The 1:20 litter extract group demonstrated the most seed radicle growth on the fifth day and the least on the eighth day; the seed radicle growth during the first eight days was relatively high compared to that on the following days. At the 1:40 concentration, the radicle growth was relatively high during day 4 to 10 (except for the eighth day); the maximum growth occurred on the fourth day, with the least growth on day 11 to 14, and the radicle growth gradually increased in the later stage. At 1:80 and 1:160 concentrations, the seed radicle growth showed a general downward trend, reaching the maximum on the fourth day, and stabilized after decreasing sharply on day 10 to 15. The seed radicle growth at the 1:320 concentration reached a maximum on the sixth day, then declined from day 7 to 16, and the least growth was observed on the 16th day. The different concentrations of litter extracts inhibited the seed radicle growth less in the early period, where the radicle growth was relatively fast, whereas the various concentrations of litter extract had different effects on seed radicle growth in the later stages. Compared with the distilled water group and the control group, the high litter extract concentrations inhibited the radicle growth of *A. confusa*, which was promoted at low concentrations.

DOI: http://dx.doi.org/10.15666/aeer/1706_1510315116

The *A. confusa* seed radicle growth was inhibited on day 7 to 9 and day 12 to 15, and promoted on day 5 to 6 and 10 to 11 in general (*Table 5*). The inhibition effect was obvious in the stock solution and the 1:20 concentration litter extract. The promotion effect appeared in the 1:80, 1:160, and 1:320 litter extract concentrations. The different days and treatments, along with their interaction, significantly affected the radicle growth of *A. confusa* (*Table 6*). Overall, the 1:160 litter extract concentration was the optimum for the increase in *A. confusa* radicle length.

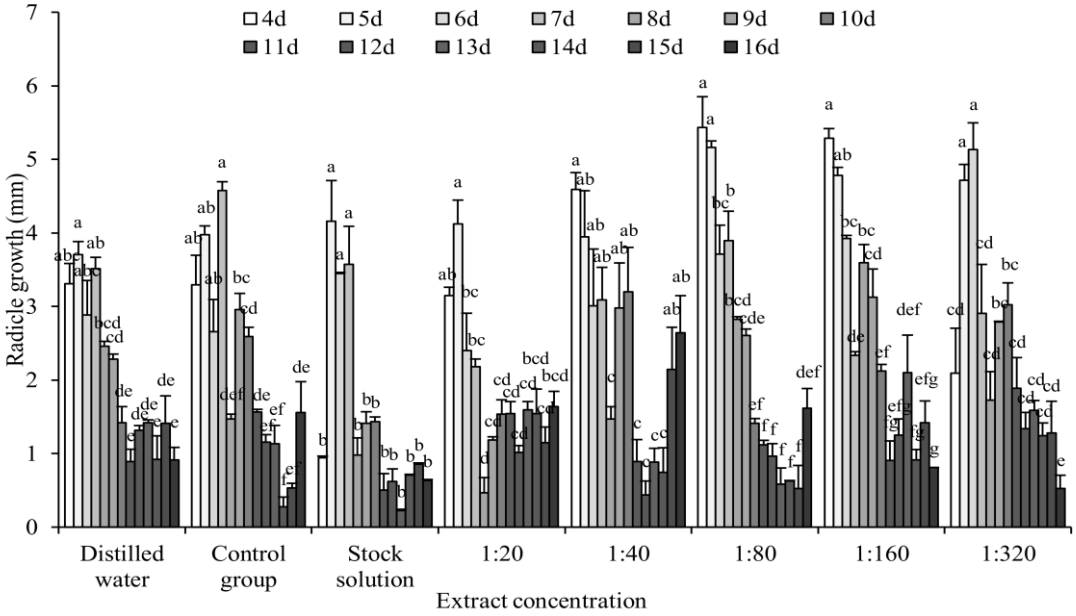

Figure 3. *The seed radicle growth of A. confusa in different time periods. the different letters (from a to g) indicate the difference in radicle growth among different days under the same concentration.The amount of radicle growth refers to the length of the radicle from the next day minus the length of the radicle of the previous day. Data (mean ± SD) marked with different letters in plots were significantly different under p level as 0.05 in the same column*

Discussion

With increasing litter extract concentration, the germination potential, germination rate, and germination index of *A. confusa* decreased. The stock solution and the 1:20 litter extracts concentrations had strongest inhibitory effect on seed germination. The germination potential and germination index of the seeds in the stock solution were the lowest, primarily due to the restraining effect of the allelochemicals in the stock solution on the speed of seed germination. The germination rate in the 1:20 litter extraction concentration group was the lowest and the negative effect of allelochemicals on the seeds were most pronounced. This may be caused by the amount of harmful ingredients in the allelochemicals, which were much more than the amount of beneficial components. Under normal circumstances, the production and elimination of free radicles in plant cells maintains a dynamic equilibrium; under stress conditions, this balance is affected and readily destroyed. When free radicals accumulate to a certain extent, membrane lipid peroxidation occurs, which inhibits seed germination (Shibaeva et al., 2018; Marusa and Ishii-Iwamoto., 2011). At the 1:160 concentration, the three seed germination indices were the highest, and the promotion effect was the most obvious. We speculate that this concentration is the optimum concentration of seed germination, and the beneficial components in the allelochemicals accumulate the most. Within this concentration range, the ion transporters in the cell and various ion channel proteins are involved in cell ion homeostasis, increasing seed germination rate and germination speed (Steven et al., 2003; Zhang et al., 2016; Bachleda et al., 2017; Kilic et al., 2016). The 1:320 litter extract concentration also promoted the germination of seeds, but the overall effect was not significant. The reason for this may be that the concentration was lower and similar to distilled water, and the allelochemicals content was relatively low; thus, the promoting effect was not obvious. In general, compared with the distilled water group, no germination index was significant for the low-concentration litter extracts, whereas high-concentration litter extracts significantly inhibited the germination indices of *A. confusa* seeds. When the allelochemicals content is limited, the plant itself produces stress-resistant immunity. At this time, allelopathic chemicals have little effect on the plant. When the residual allelochemicals increase, accumulate, and increase to a certain amount or exceed the critical content, they are harmful to the plant and thus delay seed germination (Liu et al., 2016; Wei et al., 2018).

With the increase in litter extract concentration, the seed radicle growth of *A. confusa* showed an obvious hysteresis effect. The litter extracts had a significant inhibiting effect on seed radicle growth compared with distilled water, mainly because the seed radicle growth was inhibited by the stock solution and the 1:20 concentration. High litter extract concentrations may have physiologically disturbed the plant, inducing intensive anaerobic respiration, which would therefore weaken the plant's ability to scavenge free radicals, resulting in a decrease in its physiological index (Steven et al., 2003; Zhang et al., 2016; Bachleda et al., 2017; Kilic et al., 2016). The hormone content

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1510315116

and enzyme activity in the seeds of *A. confusa* may have led to the inhibitory effect of litter extracts on seed germination and radicle growth within a certain concentration range (Hunter et al., 2013). When the litter extract concentration was 1:160, the promotion of radicle growth was the most obvious, and the content of beneficial allelochemicals was the highest. We speculate that the concentration of nutrients in this treatment was high, the breathing was strong, the high energy bond in ATP was active, the mitochondria inner membrane activity was strong, the rates of electron transfers and oxidative phosphorylation were fast, and the cell division speed of the apical meristem was accelerated, which effectively promote radicle elongation (Steven et al., 2003; Zhang et al., 2016; Bachleda et al., 2017; Kilic et al., 2016). The 1:320 litter extract also promoted the growth of seed radicle length, but the effect was weakened, which may be due to the litter extract dilution containing less effective allelochemicals. Previous studies have reported low allelopathic effect at low concentration and inhibition at high concentration with: water extracts from corn leaves on the seeds of *Scutellaria baicalensis*, litter extracts on seed germination and seedling growth of *Cunninghamia lanceolate*, and litter leaves and soil extracts on the seed germination and seedling growth of *P. koraiensis* (Chen et al., 2016; Peng et al., 2012; Zhuang et al., 2017). These results are consistent with our findings.

By analyzing the growth in the radicle over time, we discovered that the radicle growth of *A. confusa* treated with litter extract was relatively high in the early stage, and the growth the middle and late stages tended to decline. The reason for this may be that a certain amount of allelopathic substances accumulated in the litter, hindering the water absorption of the seed; inhibiting the respiration, enzyme activity, and radicle growth; and changing the osmotic pressure, thereby constraining the elongation of the radicle (Wei et al., 2018). When the litter extract concentrations were 1:40 and 1:80, the seed radicle growth of *A. confusa* increased gradually in the later stage, which may be due to the increase in peroxidation products in the plant after the stress due to allelopathic substances. When these allelopathic substances reach a certain amount and the stress mechanism is constrained by the plant, its own protective enzyme system could thereby scavenge the free radicals generated. However, this adaptive response is effective, as the degree of damage was relatively low and reversable, whereas the radicle increase was limited at any higher concentration of litter extract (Marusa and Ishii-Iwamoto, 2011).

The low litter extract concentration in nature can promote the germination and radicle growth of *A. confusa* to some extent. So, it is feasible to mix *A. confusa* in *C. kawakamii* forests. However, when mixing *A. confusa*, we should try to select a location where the amount of litter is low and the topography is relatively flat to mitigate the adverse effects of allelopathy. To afforest a successful mixed forest, further studies are required. Firstly, the effects of extracts from *C. kawakamii* natural forest on *A. confusa* should be studied from the perspective of the physiological activity of the radicle. Secondly, the different effects of various types and contents of litter allelochemicals at different forest ages and stages on seeds should be thoroughly considered during the afforestation of mixed forests (Hunter et al., 2013). Allelopathic effect on the plant are complex, having important impacts on the growth of plant seedlings (Kimura et al., 2015; Anne et al., 2019; Chu et al., 2014), thus affecting the colonization and renewal of the population. In the future, research should be continued on the growth response of *C. kawakamii* and *A. confusa* seedlings to litter extract.

Conclusions

In this study, we examined the effects of different concentrations of *C. kawakamii* litter extract on the germination rate, germination potential, germination rate index, and radicle growth of *A. confusa.* Low concentrations promoted growth, whereas higher concentrations inhibited growth. The stock solution had the most obvious inhibiting effect on seed germination and radicle growth, whereas the 1:160 litter extract concentration displayed the strongest promotion. The natural leaching concentration of litter in the wild is about 1:160, which could actually promote the seed germination and radicle growth of *A. confusa*. Therefore, the allelopathic effect of forest litter is not a limiting factor when mixing *C. kawakamii* and *A. confusa* in a forest, providing an alternative method to improve soil nutrition in this forest, and finally promote the regeneration of *C. kawakamii* seedlings in this forest. Further study is needed of the physiological response of *A. confusa* radicle and growth to litter extracts to provide a practical basis to promote *C. kawakamii* regeneration in this forest.

DETERMINATION OF REFERENCE ET_O BY USING DIFFERENT K_P EQUATIONS BASED ON CLASS A PAN EVAPORATION IN SOUTHEASTERN ANATOLIA PROJECT (GAP) REGION

AYDIN, Y.

Department of Biosystem Engineering, Faculty of Agriculture, Siirt University, Siirt, Turkey
(e-mail: yusufaydin@siirt.edu.tr; phone: +90-484-212-1111; fax: +90-484-223-1998)

(Received 28th Jun 2019; accepted 11th Oct 2019)

Abstract. An accurate estimation of ET is very important and the ET estimation method that is suited to the region should be used. Evapotranspiration (ET) is calculated by multiplying reference ET_o with the crop coefficient for the studied plant (K_c) or its pan evaporation coefficient (K_p). The purpose of this study was to use the K_p equations developed based on the Pan evaporation principle for estimating ET_o values and determining the best K_p equation for the GAP region by making comparisons via the standard method. $K_{p\text{-}Pere}$ method (RMSE: 0.48, MAE: 0.30, MR: 0.64 and PE: 3.19) displayed a better performance than $K_{p\text{-}Sny}$ (RMSE: 1.08, MAE: 0.70, MR: 0.80 and PE: 29.35) in the semi-arid climate conditions of the GAP region. It was determined according to the regression analysis results that the $K_{p\text{-}Sny}$ equation is better than $K_{p\text{-}Pere}$ by a margin of 2.1%. Accordingly, $K_{p\text{-}Pere}$ equation based on Pan evaporation can be used as an alternative to the standard method for determining reference ET_o in the semi-arid conditions of the GAP region. Similarly, $K_{p\text{-}Sny}$ equation together with $K_{p\text{-}Pere}$ can be used as substitutes for the standard $ET_{o\text{-}PM}$ method since it requires less climate data.
Keywords: *evapotranspiration, reference ET_o, methods comparisons, FAO-PM equation, pan evaporation coefficient, Snyder and Pereira equations*

Introduction

Evapotranspiration (ET) is a synchronous process during which the water is transferred to the atmosphere by way of transpiration and evaporation from the soil-plant system. Hence, ET is a critical parameter for irrigation planning and operation as well as for climatologic and hydrologic studies. Agricultural yield per unit area should be at a maximum level in order to meet the food demand that is increasing due to rapid urbanization and population increase, industrialization as well as decrease in agricultural areas over time and global warming. This can be accomplished best by applying the amount of irrigation water required by the irrigated plants in order to obtain maximum yield from the agricultural activity while eliminating excessive water use (Ertek, 2011). There are many factors that have an impact on evapotranspiration and these factors should be calculated at different regions for each plant species since they are more closely related to the land and climate conditions. Actual evapotranspiration (ET_c) is generally calculated by multiplying the reference evapotranspiration (ET_o) with a coefficient specific to the plant that can be calculated based on many factors encompassing the water regime and operation. Reference evapotranspiration (ET_o) is the amount of evapotranspiration (FAO-24) from the grass plant covering the soil surface at a height of 8-15 cm under full irrigation conditions and is calculated via mathematical methods based on the evapotranspiration ET_o of other plants (Çobaner et al., 2016). The FAO-56 Penman-Monteith (PMF-56) equation developed by Allen et al. (1998) which is also known as the combination method based on mass transfer is widely used as the standard method for determining the reference evapotranspiration. In addition to the standard method, various other techniques have also been developed for calculations based on climate data such as

DOI: http://dx.doi.org/10.15666/aeer/1706_1511715129

temperature (Thorntwaite, 1948; Doorenbos and Pruitt, 1977), solar radiation (Doorenbos and Pruitt, 1977; Hargreaveas and Samani, 1985; Djaman et al., 2015). Direct and indirect measurement methods used in ET_o estimation vary subject to the region, climate, plant species, current data and the purpose of the calculation (Kanber, 2006). Lysimeter method is generally used for the direct estimation of ET_o. However, the evapotranspiration values acquired using this method are not suited for making comparisons with values calculated from meteorological data. The use of lysimeters in ET_o measurement is not a proper method due not only to its cost and complex operation but also the facts that it is used for measurements at limited areas, does not have sufficient surface area and the acquired data are not sufficiently significant. ET_o estimation in application can be calculated from meteorological data as well as by multiplying the evaporation values obtained from the Pan evaporation cup by a transformation factor (K_{pan}) (Tabari et al., 2013). Trajkovic and Kolakovic (2009) reported that the ET_o estimation method based on Pan evaporation principle can be used successfully as an alternative to the standard method of PMF-56 under Serbia conditions. Similarly, Tabari et al. (2013) carried out a study under the humid climate conditions of Iran comparing the PMF-56 model with a total of 31 reference evapotranspiration calculation models with 8 based on Class A Pan, 7 on temperature, 10 on mass transfer, 4 on radiation and 2 again on radiation. According to the comparisons carried out, the methods based on evaporation and temperature and the K_p equation based on evaporation developed by Snyder (1992) displayed the best performance for ET_o estimation. Castaneda and Rao (2005) used the FAO-56 PM method as standard for comparing the Thorntwaite, Blaney-Criddle, Turc and Makkink methods used for estimating reference ET_o in Southern California conditions. Djaman et al. (2015) compared the 16 ET_o estimation method with the ASCE-PM equation for developing an equation that can be used for ET_o estimation under Senegal conditions with less data. Similarly, Shahidian et al. (2012) compared models based on temperature and radiation with the PMF-56 model developed by Allen et al. (1998) published in FAO Irrigation and Drainage Paper, No: 56 which can be operated based on 4 basic data such as temperature, wind speed, radiation and relative humidity. Aydınşakir et al. (2003) indicate that Class A Pan evaporation method is the best ET_o estimation method for use in estimating grass reference evapotranspiration via empirical models.

The purpose of this study was to compare the reference ET_o values estimated via different methods with the standard PMF-56 standard method and determine the performance of the K_p equations based on pan evaporation method in the GAP region with arid and semi-arid climate conditions. For this purpose, 4 year climate data for the Gaziantep province in Southeastern Anatolia Region acquired from Turkish State Meteorological Service (TSMS) records for the years 1999-2002 were used. The ET_o values calculated using the standard reference evapotranspiration method of FAO-PM and the pan coefficients (K_p) developed by Snyder and Pereira calculated based on Class A Pan were compared. The $ET_{o\text{-}PM}$ values calculated at a daily level under Gaziantep climate conditions by Aydın (2004) and Ünlü (2005) were used as the standard FAO-PM method. The same climate data were used for calculating the compared K_p equations.

Materials and method

Description of study area and weather data

Southeastern Anatolia Region, one of the 7 geographical regions of Turkey is known as the GAP region due to the project comprised of 13 project packages on the Fırat-Dicle

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1511715129

basin for improving soil and water resources and covers a total of 9 provinces including Gaziantep, Kilis, Şanlıurfa, Adıyaman, Diyarbakır, Batman, Mardin, Siirt and Şırnak (*Fig. 1*) (Anonymous, 2019). The GAP region displays continental climate characteristics. Summers are quite hot, whereas winters are rarely cold. Annual average temperatures are 16.4 °C with July averages of 29.8 °C. Annual average rainfall in the region is 565 mm and majority of the rainfall takes place during the winter and spring due to the irregularity in the rain regime. The intensity of aridness increases during the summer months since the annual relative humidity value reaches 53.6% on average. The province of Gaziantep where the study has been carried out is located between eastern longitudes of 36° 28' and 38° 0' and between the northern latitudes of 36° 38' and 37° 32'. It has a climate structure with transition characteristics between the Mediterranean and continental climates. Summers are quite hot and arid, whereas winters are cold and rainy. Average annual temperature is 14.9 °C, with a maximum temperature of 44 °C and minimum temperature of -17.5 °C. The hottest month is July with 27.7 and the coldest month is January with 3.4 whereas the average annual rainfall amount is 544.3 mm. Rains generally take place during the winter months and rarely during the summer months when crops need water and when evapotranspiration is high (Aydın, 2004).

Figure 1. *Locational view of study area*

ET_o estimation methods

Food and Agriculture Organization (FAO), together with the International Commission on Irrigation and Drainage and the World Meteorological Organization (WMO) put forth in 1990 that the FAO-PM (Allen et al., 1998) method can be taken as reference since it yields more consistent and reliable results in comparison with other methods (Castaneda and Rao, 2005; Çobaner et al., 2016). Therefore, FAO-56-PM method was taken as reference in this study for comparing the other methods. Different methods that can be operated with less data have been developed for the difficulties experienced while using the standard method for reference ET_o estimation as well as conditions when sufficient amount of data cannot be acquired. The ET_o estimation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1511715129

developed by Snyder (1992) and Pereira et al. (1995) via K_p equations is one of the widely used methods. Hence, various empirical equations used for determining reference evapotranspiration have been evaluated comparatively. However, since these methods are equations operated based on Class A Pan evaporation values and since evaporation is not measured in Turkey during the winter season, ET_o calculations were made only for the April-November period when evaporation measurement is made. In graphical representations, it is shown only as DOY in order to make the number of days between the mentioned periods high and the graphs easy to understand The climate data used for this purpose have been obtained from the Turkish State Meteorological Service (TSMS) (Anonymous, 2018).

FAO-56 Penman Monteith method

The FAO-56 Penman Monteith method used for determining reference evapotranspiration can be used with daily meteorological data such as temperature, wind speed, evaporation, relative humidity. This equation can be expressed as below (Fisher et al., 2013).

$$ET_o = \frac{0.408x(R_n - G) + \gamma \frac{900}{T+278} u_2 (e_s - e_a)}{\Delta + \gamma\ 1 + 0.34u_2} \quad \text{(Eq.1)}$$

where ET_o: reference evapotranspiration (mm/day); R_n: net radiation (MJ m^{-2}), G: soil heat flux (MJ m^{-2}), T_{mean}: average air temperature (°C), U_2: wind speed at 2 m height ($m.s^{-1}$), e_s: saturation vapor pressure (kPa), e_a: actual vapor pressure (kPa), Δ: slope of vapor pressure curve (kPa $°C^{-1}$), γ: psycrometric constant (kPa $°C^{-1}$).

The ET_o software developed by FAO-56 was used for determining reference evapotranspiration. All parameters used in this software are data measured daily and acquired from the meteorological station.

Snyder equation

The equation developed by Snyder (1992) was used for calculating the K_p values based on Class A Pan. This equation can be expressed as follows:

$$K_p = 0.482 + 0.0424xLn(F) - 0.000376xW_s + 0.0045xRH \quad \text{(Eq.2)}$$

where F: fetch distance (meter) has been assumed as 1 m. W_s: daily average wind speed (m sec^{-1} day^{-1}) and RH: daily relative humidity (%).

Pereira equation

The equation developed by Pereira et al. (1995) for calculating reference ET_o based on Class A Pan which is the second method used for comparisons can be expressed as follows (Tabari et al., 2013).

$$K_p = \frac{0.85x(\Delta + \gamma)}{[\Delta + \gamma x(1 + 0.33x U_2)]} \quad \text{(Eq.3)}$$

$$\Delta = \frac{4098\,[0.6108 \exp\,(\frac{17.27T}{T+237.3})]}{(T+237.3)^2} \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1511715129

where Δ: slope of the saturated vapour pressure versus temperature curve (kPa °C $^{-1}$) and γ: the psicrometric coefficient (kPa °C $^{-1}$), T: mean air temperature (°C), exp (…) 2.7183 base of natural logarithm) raised to the power (…).

$$T_{mean} = \frac{T_{max} + T_{min}}{2}; \quad \gamma = 0.665.10^{-3} x\ P; \quad P = 101.3\left(\frac{293 - 0.0065z}{293}\right)^{5.26} \qquad \text{(Eq.5)}$$

Parameters such as slope (Δ), average temperature (T), psychrometric constant (γ), elevation above sea level (z) and pressure (P) included in the above equations were calculated in accordance with FAO-56.

The K_p coefficients obtained from the equations were used in reference ET_o calculation, (Doorenbos et al., 1977) and the following equation suggested by Tabari et al. (2013).

$$ET_o = E_{pan} x K_{pan} \qquad \text{(Eq.6)}$$

ET_o: Reference evapotranspiration, mm day^{-1}; K_{pan}: Coefficient based on Class A Pan evaporation cup, E_{pan}: Class A Pan evaporation value, mm day^{-1}

The ET_o values for the studied years related with the FAO-56 PM method taken as the standard method were first calculated in the study. Climate parameters such as temperature, relative humidity, wind speed, solar radiation, rain and evaporation for the years between 1999 and 2002 were acquired from meteorological records after which reference ET_o values were estimated using both the standard method for ET_o estimation and the compared K_p equations. Since the climatic data used in the estimation of ET_o for the last years could not be obtained from the meteorological records, the data of 1999-2002 were used in FAO-56 PM calculations. Fetch distance was taken as 1 m while calculating the $K_{p\text{-}Sny}$ equation since the meteorological station is covered with irrigated green plants. The calculations were made separately for each study year, after which 4 year averages were calculated for the ET_o values of the same day thereby obtaining the long term averages for the daily ET_o values. Annual average ET_o values were calculated using the average daily ET_o values. However, since evaporation measurements are not made during the rainy winter months at the meteorological station, ET_o estimation was made by calculating the K_p values with the E_{pan} values for the months during which measurements were made (April-November).

Statistical analysis

$ET_{o\text{-}Sny}$ and $ET_{o\text{-}Pere}$ obtained by using the standard FAO-PM ET_o values calculated daily and the K_p values calculated using Snyder (1992) and Pereira et al. (1995) equations were compared statistically. Paired comparisons were made between R^2 values and ET_o values which were then subject to linear regression analysis and the R^2 equation was determined for the obtained curve. The equations in *Table 1* suggested by Djaman (2015) and Diouf (2016) were used for a more advanced evaluation of the compared equations.

Result and discussion

Figure 2 shows monthly average and cumulative ET_o values. The reference ET_o values calculated via the pre-determined methods. While the references ET_o values

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1511715129

calculated using K_p equations based on Pan evaporation were determined to be higher in comparison with the values obtained using the standard method for the months of May-October (overestimated), $ET_{o\text{-}Pere}$ value for the months of April and November were calculated as below the values obtained using the standard method (underestimated).

Table 1. *Statistical analysis equations*

Source	Equation	
Root mean square error (RMSE)	$RMSE = \sqrt{\sum_{k=0}^{n} \frac{(P_i - O_i)^2}{n}}$	(Eq.7)
Mean absolute error (MAE)	$MAE = n^{-1}\sum_{1}^{n}(P_i - O_i)$	(Eq.8)
Percentage error (PE)	$PE = \left\lvert \frac{P_{ave} - O_{ave}}{O_{ave}} \right\rvert 100\%$	(Eq.9)
Mean ratio (MR)	$MR = n^{-1}\sum_{1}^{n} \frac{P_i}{O_i}$	(Eq.10)
Determination coefficient (R^2) (Todorovic et al., 2013)	$R^2 = \left\{ \frac{\sum_{i=1}^{n}(O_i - \bar{O}).(P_i - \bar{P})}{\sqrt{\sum_{i=1}^{n}(O_i - \bar{O})^2}.\sqrt{\sum_{i=1}^{n}(P_i - \bar{P})^2}} \right\}^2$	(Eq.11)

RMSE: root mean square error; MAE: mean absolute error; MR: mean ratio; PE: percentage error of estimate; n: number of observations, P_i: estimated ET_o by other equations, O_i: PM-estimated ET_o (actual), P_{ave}: mean of the estimated ET_o, O_{ave}: mean of the O_i. In order to determine R^2 the pair wise comparisons were made by using linear regression

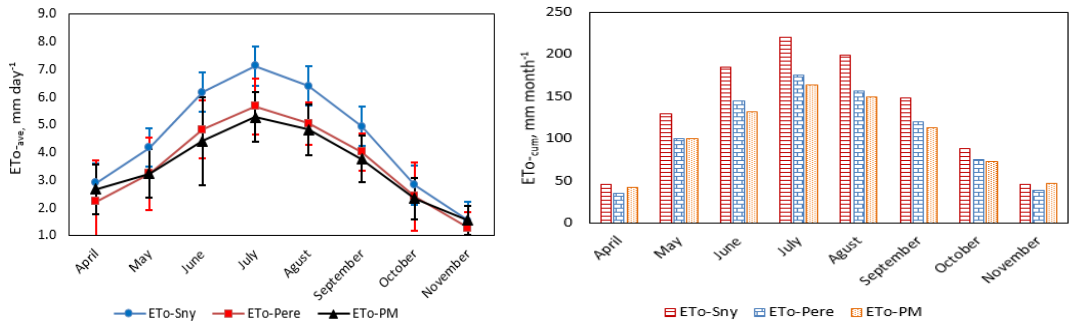

Figure 2. *Temporal variation of four years monthly average and cumulative ET_o values (vertical bars show the standard errors)*

The ET_o values calculated via K_p equations were subject to comparisons between themselves as well as with the standard method. It was observed when the study years were evaluated separately (*Fig. 3*) that the $ET_{o\text{-}Sny}$/$ET_{o\text{-}Pere}$ values calculated via K_p equations and the standard $ET_{o\text{-}PM}$ values put forth tendencies similar to the changes in the monthly averages. The values closest to the standard $ET_{o\text{-}PM}$ method were calculated using the ET_o values obtained by $K_{p\text{-}Pere}$ equation which displayed a better performance than the $ET_{o\text{-}Sny}$ values. This relationship was observed for all study years.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1511715129

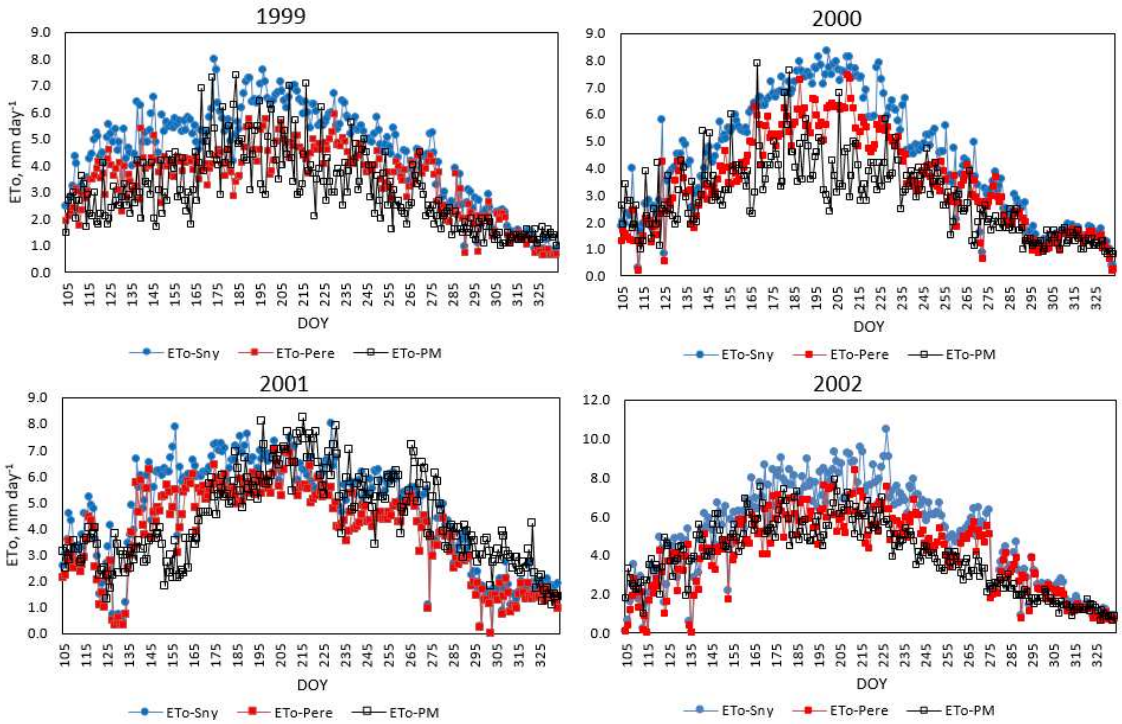

Figure 3. *Comparison of daily average ET_o values obtained from equations and standard method during study years*

Long term daily average ET_o values calculated daily during the study years via K_p equations were subject to paired comparisons separately with the standard FAO-56 PM method (*Fig. 4*). As can be seen from the figure, the ET_o values calculated via the $K_{p\text{-}Pere}$ equation were determined to be closer to the values calculated with the standard method with lower rate of change and change % for the comparison. When compared with the standard method, the $K_{p\text{-}Pere}$ equation displayed a better performance in comparison with the $K_{p\text{-}Sny}$ equation. While both equations yielded overestimated values compared with the standard method, the performances vary with regard to the rates of change and change %. When the changes of the curves in *Figure 2* and the rates of change and change percentage (%) in *Table 2* are evaluated, it can be observed that the $K_{p\text{-}Pere}$ equation put forth a better performance in comparison with $K_{p\text{-}Sny}$ at both the monthly averages level and the hottest months and long term averages levels.

The regression analysis carried out for determining the relationship between the ET_o values obtained via the equations and the standard method along with the R^2 values have been given in *Figure 5* and *Table 3*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1511715129

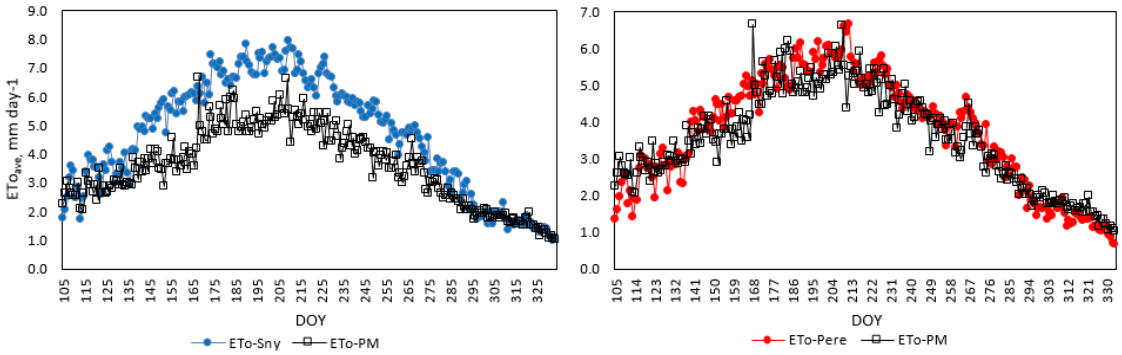

Figure 4. *Comparison of long term daily average ET_o values obtained by K_p equations with standard method*

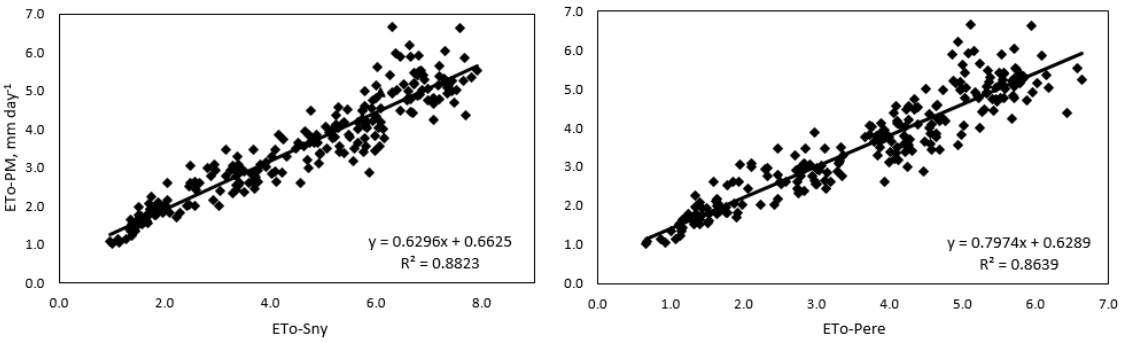

Figure 5. *Determination of regression coefficients between long term daily average $ET_{o\text{-}equations}$ values and standard $ET_{o\text{-}PM}$ method*

The ET_o values calculated via $K_{p\text{-}Sny}$ and $K_{p\text{-}Pere}$ equations used for calculating reference ET_o value were subject to comparisons among themselves for determining their performances and changes throughout the study years (*Fig. 6*). As can be seen from the figure, long term average $ET_{o\text{-}Pere}$ values were lower than $ET_{o\text{-}Sny}$ which can be observed more clearly during the evaporation period, especially during the hot summer months. This distinction can be seen in *Figure 4* where the ET_o values calculated via equations are compared with the standard method. It was observed as a result of the comparison made between ET_o values calculated via equations and the standard method that the $ET_{o\text{-}Pere}$ values provided results that are closer to the standard method than $ET_{o\text{-}Sny}$ thereby displaying a better performance and that the rate of change and change % between the $ET_{o\text{-}Sny}$ and $ET_{o\text{-}PM}$ values are higher in comparison with $ET_{o\text{-}Pere}$.

As can be seen from the comparison between the K_p equations (in *Fig. 6; Table 2*), the $ET_{o\text{-}Sny}/ET_{o\text{-}Pere}$ rate of change varied between 1.30 and 1.17 throughout the calculation period with an average of 1.25 which was calculated as 1.27 for the month of August. The similarities or differences in the rates of change of the equations can also be monitored here when the change %'s are examined. The highest rate of change % was calculated for the month of April (30.3%) while the lowest rate of change was calculated for the month of October and the long term average rate of change was calculated as 24.82%.

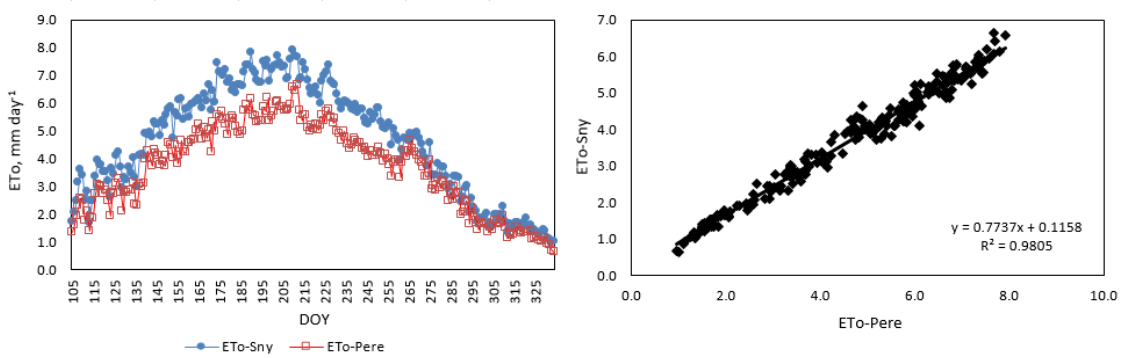

Figure 6. *Comparison of ET_o values obtained by K_p equations with each other and regression coefficient*

Table 2 summarizes the comparisons made between the ET_o values obtained from K_p equations based on Pan evaporation principle used for reference ET_o estimation and Standard FAO-56 PM method. Long term monthly averages were calculated for the ET_o values calculated via the equations and FAO-56 PM values. Afterwards, paired comparisons were carried out for both these values with each other and with the standard method and the relations between the ET_o values and their rates of changes were calculated on a monthly basis.

Table 2. *Monthly average ET_o values obtained from equations and comparison by standard methods*

Methods	Monthly average ET_o values of methods								
	Apr.	**May**	**June**	**July**	**Aug.**	**Sep.**	**Oct.**	**Nov.**	**Mean**
$ET_{o\text{-}Sny}$	2.9	4.2	6.2	7.1	6.4	4.9	2.8	1.5	4.5
$ET_{o\text{-}Pere}$	2.2	3.3	4.8	5.7	5.1	4.0	2.4	1.3	3.6
$ET_{o\text{-}PM}$	2.7	3.3	4.4	5.3	4.8	3.8	2.4	1.6	3.5
Comparisons of equations between them and the standard method as change percentage (%)									
$ET_{o\text{-}Sny}/ET_{o\text{-}PM}$	1.09	1.29	1.40	1.35	1.33	1.31	1.21	0.99	1.24
$ET_{o\text{-}Pere}/ET_{o\text{-}PM}$	0.83	1.00	1.09	1.07	1.05	1.07	1.03	0.83	1.00
$ET_{o\text{-}Sny}/ET_{o\text{-}Pere}$	1.30	1.29	1.28	1.26	1.27	1.23	1.17	1.19	1.25
Variation rates of ET_o values obtained by equations according to standard method (%)									
$ET_{o\text{-}Sny}/ET_{o\text{-}PM}$	8.7	28.8	39.8	35.0	32.8	31.0	20.5	-1.2	24.42
$ET_{o\text{-}Pere}/ET_{o\text{-}PM}$	-16.6	0.1	9.3	7.4	4.9	6.6	2.9	-17.2	-0.33
$ET_{o\text{-}Sny}/ET_{o\text{-}Pere}$	30.3	28.7	27.9	25.8	26.6	22.9	17.2	19.3	24.82

As can be seen from the table, the change in $ET_{o\text{-}Pere}$ values was observed to be lower (underestimated) ($0.83 < 1.09$ and $0.83 < 0.99$) in comparison with $ET_{o\text{-}Sny}$ as a result of the comparison between the ET_o values obtained from equations and the standard method during the months when the evaporation measurement started and ended and the rate of change was calculated as -16.6 and -17.2. The same values were determined as 8.7 and -1.2 respectively for the $ET_{o\text{-}Sny}$ equation. When the compared long term averages are examined, the rate of change for $ET_{o\text{-}Pere}$-$ET_{o\text{-}PM}$ was determined as 1.00 whereas, the rate of change for $ET_{o\text{-}Sny}/ET_{o\text{-}PM}$ was calculated as 1.24. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1511715129

underestimated values observed for $ET_{o\text{-}Pere}$ were at about the same level throughout al the months and were lower than $ET_{o\text{-}Sny}$ during the hottest month of July with a value of 1.07. Similarly, it was also observed as a result of the comparison between $ET_{o\text{-}Pere}$ and $ET_{o\text{-}Sny}$ values with the standard method of $ET_{o\text{-}PM}$ that $ET_{o\text{-}Pere}$ displayed a better performance with regard to the comparison between each other as well as the % rate of change. Trajkovic and Stojnic (2008) carried out a study on reference ET_o determination methods during which Cristiansen and FAO-24 Pan evaporation methods were compared with the standard FAO-PM method. It was reported in the study that the Cristiansen method put forth a better performance in comparison with the standard FAO-PM and the FAO-24 Pan method which is due to the fact that the Cristiansen method makes use of more climate parameters than FAO-24 Pan. Moreover, it was also indicated that the Pan evaporation values can be used as a substitute for the FAO-56 PM method.

Statistical evaluations were carried out in order to define the relationships between the compared K_p equations and the standard FAO-56 PM methods accurately and to determine the levels of relationships (*Table 3*).

Table 3. *Result of statistical analysis among ET_o methods*

	RMSE (mm/day)	**MAE (mm)**	**MR**	**PE (%)**	**R^2**
$ET_{o\text{-}Sny}$-$ET_{o\text{-}PM}$	1.08	0.70	0.80	29.35	0.8823
$ET_{o\text{-}Pere}$-$ET_{o\text{-}PM}$	0.48	0.30	0.64	3.19	0.8639
$K_{p\text{-}Sny}$-$K_{p\text{-}Pere}$	---	---	---	---	0.9805

As can be seen from the table, the ET_o values calculated via $K_{p\text{-}Pere}$ equation yielded values closer to the standard method during the comparisons of the ET_o values obtained using K_p equations with the standard method. The root mean square error (RMSE) values for the $ET_{o\text{-}Pere}$-$ET_{o\text{-}PM}$ comparison were observed to be lower than $ET_{o\text{-}Sny}$ with regard to error statistics (0.48 < 1.08). Similarly, $ET_{o\text{-}Pere}$ put forth values lower in comparison with those of $ET_{o\text{-}Sny}$ with regard to the other error statistics of mean absolute error, mean ratio and percentage error values thereby displaying a higher accordance with the standard method. Contrary to the aforementioned comparisons, a smaller difference is observed only between the R^2 values with $ET_{o\text{-}Sny}$ having an R^2 value of 2.1 times higher than that of $ET_{o\text{-}Pere}$. The K_p equations used in the study were subject to regression analyses as a result of which the R^2 value was calculated as 0.9805 (*Table 3; Fig. 6*). This is an indication that both methods can be used together for ET_o prediction. Tabari et al.(2013) carried out a study during which a total of 31 different models used for determining reference ET_o under the humid climate conditions of northern Iran. A total of 8 methods based on Pan evaporation were evaluated and while the $K_{p\text{-}Sny}$ method was ranked number 4 under humid region conditions (R^2: 0.86, RMSE: 0.53, PE: 4.91), the $K_{p\text{-}Pere}$ method (R^2:0.88, RMSE:0.82, PE:30.16) was ranked number 6. Another study with similar results under conditions of Brazil was carried out by Conceiçâo (2002) regarding the usability of Class A Pan evaporation based equations for determining reference ET_o. In this study, Pan evaporation based $K_{p\text{-}Sny}$, $K_{p\text{-}Pere}$ equations were compared with the standard FAO-PM methods. As a result of the study, the best estimation was obtained with the $K_{p\text{-}Sny}$ equation. It is considered that the better performance of $K_{p\text{-}Pere}$ equation is due to the climate conditions of the region. The consistency and reliability of the method should be re-evaluated for methods based on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1511715129

Pan evaporation in case they are used for different regions and climate conditions since they yield reliable results for the environmental conditions for which they have been developed (Kaya et al., 2016). Sentelhas and Folegatti (2003) carried out a study under Brazil-Sao Paulo conditions for the determination of K_p coefficients while determining daily reference ET_o. It was determined in this study during which six equations based on Class A Pan were tested that the $K_{p\text{-}Pere}$ (Pereira et al., 1995) and Cuenca (1989) equations displayed the best performance for ET_o estimation. However, the researcher suggested the calibration of the equations used for different climates and regions.

Conclusion

Even though the standard ET_o estimation method suggested in FAO-56 and developed by Allen et al. (1998) is widely used, its usage is still limited due to its complex structure and its requirement of climate data such as temperature, relative humidity, wind speed, soil heat flux and radiation. It is not always possible to obtain these data in many developing countries due to the required technological infrastructure and the high costs involved. Hence, equations that can be operated with less climate data which can easily be obtained have been developed for use in ET_o estimation. The K_p equations based on Pan evaporation principle for ET_o estimation developed by Snyder (1992) and Pereira (1995) have been used in the present study which were compared with the standard method.

In conclusion, it was determined that methods based on evaporation can be used as alternative or substitute methods to the standard methods for reference evapotranspiration estimation under the hot and semi-arid conditions of the GAP region and that the $K_{p\text{-}Pere}$ equation displayed a better performance under these conditions in comparison with $K_{p\text{-}Sny}$. However, it is expected that changes will take place in the climate of the region over time due to the developing structure of the region, the expansion of drainage basins as well as the increase in evaporation surface areas. Hence, reference evapotranspiration studies should be evaluated in detail for the region including the standard methods as well and further studies should be carried out for determining high performance methods which can adapt to the continental climate conditions of the region. Accurate estimation of reference evapotranspirations will enable the effective use of the irrigation sources for the ongoing projects in the GAP region in addition to the execution of the correct irrigation programs, thereby paving the way for obtaining maximum yield as well as water savings with the efficient use of irrigation water.

Abstract. Urban ecosystem health assessment helps ensure sustainable urban development. As the provincial capital of Shanxi in China, Taiyuan's development also affects Shanxi, an area rich in coal resources, and its urbanization is closely related to the coal energy structure, which has led to ecological deterioration. This study aims to apply emergy synthesis and information entropy to estimate the urban ecosystem health of Taiyuan during the 2001-2017 period, to provide insight into the policy implications. The results indicated that the urban ecological health of Taiyuan has ameliorated during the 17-year period, mainly due to the resilience and ecological service capacity of Taiyuan urban ecosystem improved over the past 17 years. The continuous reduction of industrial waste emissions leads to ecosystem, which have resilience improving. However, we should be cautious since there are still a lot of problems with the organizational structure. And Taiyuan government still needs to adjust the current energy structure, optimize industrial structure, and reduce the dependence on the resources.

Keywords: *city ecosystem, health evaluation, emergy analysis, information entropy, coal-based city*

Introduction

"*For better or For Worse, For Richer or For Poorer*", the words are often part of a traditional Western wedding ceremony, but they also seem to define dilemma city development may bring. Cities always play an important role in local region economic and population agglomerations, politics, social services, and human culture (Pan et al., 2019), and make human life productive and colorful. Consider our polluted environment

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

and our increased greenhouse gas emissions and municipal solid wastes along with urban expansion and economic development. It is no doubt that without control, urbanization will not only affect living standard and region social economic development, but also result in the collapse of urban ecosystem itself (Liu et al., 2009a). Since the middle of the 20th century, countries all over the world have experienced tremendous changes from rural to urban areas, especially in developing countries, like China which is the largest developing country in the world (Pan et al., 2019). The urbanization of China was 17.92% in 1978, surge to 59.58% in 2018, at the same time, the volume of wastewater discharge has surged more than two times, the final energy consumption has surged about six times, and SO_2 emission has increased almost two times, compared with the values in 1985 (Zhang et al., 2016). In view of these increasing serious environmental problems, the Chinese government has formulated many policies and regulations aimed at achieving sustainable development (Chen et al., 2018). Therefore, it makes sense to evaluate the urban ecosystem health, and offer a better understanding of energy and materials metabolism, which is essential for future decision makers at various levels to address urban ecosystem equilibrium and sustainable economic and social development.

Urban ecosystems exist in the form of open, thermodynamic and far-from equilibrium (Odum, 1979), which rely on the continual input of high quality, low-entropy energy and waste emission to the ecosystem (Liu et al., 2009b). Given that a healthy urban natural ecosystem is equally important for economic and social sustainability (Liu et al., 2009b), subsequently, increasing efforts have been made to protect ecosystem health as a new goal in the environmental management processes. Particularly, urban ecosystem, as a network of multiple interactive relationships (Xiao et al., 2019), and it is usually evaluated by building assessment model. To date, Material Flow Analysis (MFA) (Huang et al., 2006; Barles, 2009; Kovanda et al., 2009; Browne et al., 2011), Ecological Footprint (Bagliani et al., 2008; Graymore et al., 2008; Zhou and Imura, 2011), Life Cycle Assessment(Perkins et al., 2009; Zhang et al., 2010b) are widely used methods for accounting for inputs, outputs, throughputs and storages in urban area (Ricardo et al., 2013). Exergy (Xu, 1997; Gommans and Dobbelsteen, 2007), and Emergy synthesis (Zhang et al., 2011; Viglia et al., 2018) have been proposed and applied to evaluate urban ecosystem health. However, material flow analysis and ecological footprint methods cannot fairly reveal the characteristics of environmental integrity and resource utilization of socio-economic systems (Chen et al., 2018). Also, those methods can hardly accurately judge the real contribution of local ecosystem to local economic development (Chen et al., 2018). Compare to other methods, emergy promotes the environmental support for resource flows and related support for ecosystem services maintaining the economy of the region under study, rather than other aspects, such as thermodynamic and utilization efficiencies (Ricardo et al., 2013). The emergy theory put forward by Odom in the late 1980s provides a method to combine environment and social and economic flows (such as energy, material,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

information, currency, resources and labor), measured by a common unit (the solar emergy joule abbreviated to sej). Besides, taking into account the 'free of charge' of environmental work and the quality of the resources (Ricardo et al., 2013). Emergy synthesis has been widely used to assess the sustainability of countries, regions and cities (Zhang et al., 2011; Yu et al., 2016; Chen et al., 2018; Viglia et al., 2018). The remarkable advantage of emergy synthesis is that it can reveal the quantity and quality of the input flow and track the interactions among the components of the urban ecosystem (Liu et al., 2019).

China is rich in coal resources which account for 13% of the global recoverable reserves (Xu et al., 2015). Given this reason, the rapid urbanization of China is highly correlated with its coal energy structure. And Shanxi Province, the most important energy bases in China, only cover 1/60 territory but its coal production accounts for over 1/4 of the entire quantity in China (Guo et al., 2018). Taiyuan, as the capital city of Shanxi, its development is also a microcosm of Shanxi, that coal related industry contributed to more than half of its GDP in the past decades. It is no doubt that the key to the problem lies in the metabolic imbalance of resource-based cities and the high proportion of urban heavy industry, so it is necessary to adjust the industry. Local government try to support the tertiary industry and new environmental protection non-resource industries from the aspects of government policy, science and technology, funds, talents and so on. At the same time, the government push on the heavy industry enterprises and resource enterprises upgrade the technology, increase the added value of products, and reduce product pollution. The scientific basis of all this is to find out the existing state of urban ecosystem, the health evaluation of ecosystem and the main problems. Only in this way can the government take targeted measures. In this study, we take the typical coal-based Taiyuan City as the research target, aims to construct a framework and propose the index system for evaluating the health status of urban ecosystem based on emergy theory. Particularly, this research provides an empirical evidence for the evolution of the characteristics of urban ecosystem and ecological efficiency based on emergy synthesis of Taiyuan over the period 2001–2017.

Materials and Methods

The process of emergy analysis is based on the energy symbol language, and this research builds a framework to emergy diagram of social, economic and environmental interactions in a given urban ecosystems (*Fig. 1*). With a view to the dynamic simulation, emergy synthesis was propitious to assesses the input/output flows, and calculate efficiency and environmental loading (Liu et al., 2009b). The emergy system diagram of each renewable and unrenewable resource can be figured out by multiplying its energy with its transformity (Wang et al., 2019). The renewable resource emergy (R) of the urban ecosystem was obtained by taking the sum of the solar, geothermal inputs, the secondary and tertiary inputs (such as wind, rain, runoff). Besides, Non-renewable

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

resource emergy (N) is also one of the basic inputs to the urban ecosystem. At the same time, the urban ecosystem receives the input of capital, material and manpower flow, and finally through economic activities exports products and services, also produce waste (W).

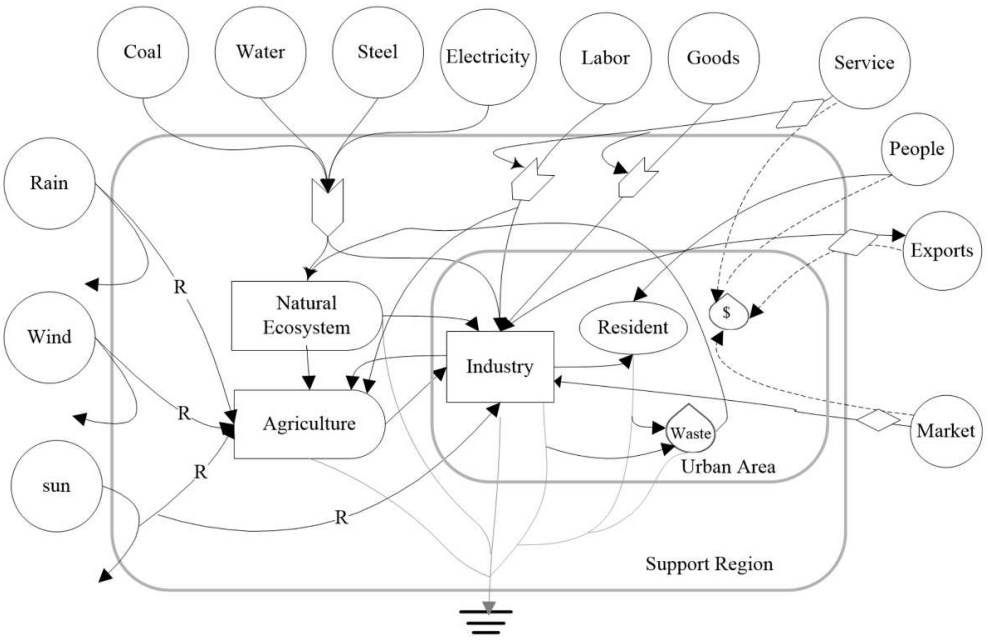

Figure 1. *Emergy system diagram of Taiyuan urban ecosystems*

In this paper, derived from emergy synthesis theory, the comprehensive indicator system of emergy value (*Table 1*) is built to synthetically analyze the material flow, energy flow, money flow and population flow, a set of index and ratios appropriate to policymaking were calculated, and make a unified quantitative analysis of urban ecosystems, finally reveals the evolution trend and characteristics of urban ecosystem.

• Emdollaratio (EDR) = U / GDP. It means that how much emergy would be put into generating an average unit of money in a given year (Viglia et al., 2018). Generally, this ratio is higher in less developed regions because most of the environmental resources are used free of charge. On the contrary, this ratio is usually lower in developed countries because of rapid currency repayments and the huge import of resources.

• Emergy self-sufficiency rate (ESR) = (R + N - Em_O)/U, this rate means that renewable and nonrenewable use of research area to the total emergy use of the research area, was used to evaluate the contribution of local ecosystem to Taiyuan urban ecosystem. The higher the value of ESR, the less reliance on imported resources and the higher economic security (Chen et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

• Emergy exchange rate (EER) = Em_I/Em_O. This rate explains the emergy exchanged in a trade or purchase, equal to the ratio of emergy imput to emergy export) (Lei et al., 2010).

• Emergy density (ED) = U/Area, this index reflects resource available for economic utilization intensity per unit territory, equal to the ratio of total used natural resources to the total regional area (Yu et al., 2016).

Table 1. *The index system of the urban ecosystem health assessment*

Factor	Indicator	Expression	unit
Emergy Flow	Renewable resource emergy	R	sej/yr
	Non-renewable resource emergy	N	sej/yr
	Input emergy	Em_I	sej/yr
	Output emergy	Em_O	sej/yr
	Waste emergy	W	sej/yr
	Total emergy	$U=R+N+Em_I$	sej/yr
	Population	–	–
	GDP	–	$
Vigor (w_i NEYR +w_j ED +w_k REE+w_l EIR)	Net emergy yield ratio (NEYR)	$(N+R+Em_I)/Em_I$	–
	Emergy density (ED)	ED=U/Area	sej/m^2
	ratio of electricity emergy used (REE)	elec/U	–
	emergy investment ratio (EIR)	Em_I / (R + N)	–
organization (w_i NER +w_j EPC +w_k EER)	Non-renewable emergy ratio (NER)	N/U	–
	Emergy per capita (EPC)	U/Population	sej/person
	Emergy exchange rate (EER)	Em_I / Em_O	–
Resilience (w_i ELR +w_j WPR)	Environmental load rate (ELR)	(U-R) / R	–
	Waste produce ratio (WPR)	W/U	–
Ecosystem service (w_i EDR +w_j ESR +w_k ESI)	emdollaratio (EDR)	U/GDP	sej/US $
	Emergy self-sufficiency rate (ESR)	$(N + R - Em_O)/ U$	–
	Emergy Sustainability Index (ESI)	NEYR/ELR	–

• Emergy investment ratio (EIR) = Em_I / (R + N). It mainly measures the energy input required from the local resources of the development unit. In order to make the production process more economical, the rate of stakeholder should be similar to the other competitors. The size of the index is often constrained by political or socio-economic factors.

• Net emergy yield ratio (NEYR) = $(R+N+ Em_I)/Em_I$. This index represents the satisfaction of economic processes in providing basic emergy for economic activity. By comparing the net emergy yield ratio, we can better understand whether a resource is competitive or not, and the economic benefit large or small. If NYER is small, it shows

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

that the competitiveness of the resources is weak and the return benefit is lower. On the contrary, the competitiveness is stronger and the development benefit is higher.

• Environmental load rate (ELR) = (U - R) / R. This index is equal to the ratio between the purchased and non-updated local energy values and the free environmental energy values (renewable resource energy values). Odum claims that this ratio is similar to the load on the circuit. A large ratio value indicates that the higher intensity of energy utilization in the social economic system, which leads to the greater pressure on the urban environmental system (Dong et al., 2011). ELR is a warning to the social economic system, once the urban social economic system is always in a high ELR, will result in irreversible degradation or loss of ecological service function. From the perspective of emergy analysis, a large amount of energy derived from outside world and over-exploitation of local non-renewable resources are the mainspring of the environmental deterioration.

• Emergy Sustainability Index (ESI) = NEYR / ELR, this index was often used to evaluate the sustainable development status of local ecosystem combining both environmental impaction and social economic yield (Liu et al., 2009a). It is obvious that if the economic system of a country or region has a high energy output rate and with a relatively low environmental load rate, the local economic system is sustainable and, conversely, unsustainable. However, it is not absolutely that a higher ESI value represents a higher sustainability. In general, the ESI value between 1 and 10 indicates the vitality and development potential of economic system, and ESI > 10 is a symbol of economic underdevelopment. Viglia et al. (2018) believes that when ESI < 1, it is a consumer economic system.

• ratio of electricity emergy used (REE) = elec / U, this index was often used to evaluate the vigor of the urban ecosystem, because electricity can reflect the extent of development in the area and further measure the efficiency, competitiveness and viability of the system.

• Non-renewable emergy ratio (NER) = N / U, this indicator reflects the structure of energy use, especially the proportion of non-renewable resources used. The larger the specific value, the greater the system relies on fossil energy, and the unsustainable risk is high.

• Emergy per capita (EPC) = U / Population, usually reflected economic influence to environment and the people life level.

• Waste produce ratio (WPR) = W/U, this indicator implys the impact of economic development model on the environment.

Based on Vigor-Organization-Resilience model (VOR) proposed by Costanza, was a widely used Ecosystem health Assessment model, and then complementing an important ecosystem service index, therefore the improved VOR model termed the VORS model (Yan et al., 2016). Based on the systematic understanding of urban ecosystem healthy and its feature (Liu et al., 2009a; Jiang et al., 2009; Yan et al., 2016) and combining the emergy based indicators (Huang et al., 2007; Su et al., 2009, 2010),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

thereby the framework of emergy-based urban ecosystem health index is built including vigor (V), organization (O), Resilience (R) and ecosystem service (S) four factors (Su et al., 2009), and reveal the biophysical foundation of environmental impaction to the urban ecosystem health (*Table 1*). Finally, the index system is represented by 14 emergy based indicators expressing different aspects of the urban ecosystem health.

Vigor manifests the ecosystem activities, including material and energy metabolism, as well as primary productivity (Yan et al., 2016). Efficiency and flux of the urban ecosystem states, reflect the vigor of the urban ecosystem (Liu et al., 2009a). This research selected the Net Emergy Yield Raito (NEYR) index, because it directly reflected the satisfaction of economic processes and provided a basic emergy for economic activities (Yan et al., 2016). The ratio of electricity emergy used (REE) was chosen, because electricity can reflect the extent of development in the area and further measure the efficiency, competitiveness and viability of the system (Huang, 2004; Su et al., 2010). The emergy investment ratio reflected the energy input required from the local resources of the development unit. The Emergy density (ED) reflecting resource gradient available for economic utilization (Su et al., 2009, 2010).

Organization demonstrates the composition and diversity of ecosystems (Yan et al., 2016), which refers to the interconnection relationship between the components, and which is proportional to the number and interaction of components of the ecosystem. The more complicated the organization structure, the much healthier the ecosystem. The present research chooses Non-renewable emergy ratio (NER), Emergy per capita (EPC), and Emergy exchange rate (EER) to present the composition and diversity of ecosystems.

The ability of the ecosystem to resist stress, that is, when the external stress has been eliminated that the ability of the ecosystems to return to their original state, is termed as resilience (Yan et al., 2016). The resilience of ecosystem depends on its own condition in a certain region and period, without changes of the composition of ecosystem, and correspondingly the type of the complex ecosystem and ecosystem elasticity also remained stable without change. Due to some emergy-based index, such as renewable resource emergy ratio and environmental load rate (ELR), are relevant (Liu et al., 2009a), we choose Waste produce ratio (WPR) and Environmental load rate (ELR) to express the resilience factor (Liu et al., 2009a; Su et al., 2009). It is true that critical ecosystem services at different scales are different, but for the regional ecosystem health assessment, the indicators should be selected based on regional characteristics and spatial scales to effectively represent the fundamental ecosystem services (Yan et al., 2016). The focus of urban ecosystem health is sustainable ecosystem services that supports the human with material, goods and services (Liu et al., 2009a). Therefore, the maintenance of urban ecosystem services determines the possible supply of the urban ecosystem resource for urban residents, which can be expressed by the Emdollaratio (EDR) (Liu et al., 2009b), Emergy self-sufficiency rate (ESR) and the Emergy Sustainability Index (ESI).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

Based on the built framework, the assessment method of ecosystem health in the study area is divided into three steps.

(1) Calculating the emergy flow and related emergy indicator. The calculation equation is organized on the basis of emergy concept in order to aggregate input flows according to their characteristics and to convert traditional units (such as J, g, $) into emergy units (sej) (Yu et al., 2016). The *equation (1)* represents the solar emergy of all input flows as showed:

$$U = \sum (T_{r_i} E_i) \;\; i = 1,2,3,\cdots,n \tag{Eq.1}$$

Here, U is the total emergy of input flows, with a unit of *sej* (Yu et al., 2016); E_i is *i*th input flow of material or energy; and *Tri* is the unit emergy value (UEV) of the *i*th input flow.

(2) Standardizing the emergy index, and calculating the weight of index on the basis of information entropy. Because these indicators that vary greatly with different evaluating objectives have more significant impaction on the final evaluation results. Therefore, information entropy is applied to calculated the weights of each index of the EHI (Su et al., 2009). In this paper, $M=\{m_r\}$ is indicator set, usually with different types, here M_1 is positive and M_2 is negative (ratio of electricity emergy used, Waste produce ratio and emdollaratio are negative, the other are positive).

$$\mathrm{W}_r = \frac{(1+\frac{1}{lnp}\sum_{k=1}^{p}\frac{q_{kr}}{q_r}ln\frac{q_{kr}}{q_r})}{(n+\frac{1}{lnp}\sum_{r=1}^{n}\sum_{k=1}^{p}\frac{q_{kr}}{q_r}ln\frac{q_{kr}}{q_r})} \quad (\sum_{r=1}^{n}\mathrm{W}_r = 1, 0 \le \mathrm{W}_r \le 1) \tag{Eq.2}$$

$$\mathrm{q}_r = \sum_{k=1}^{p}\mathrm{q}_{kr} \tag{Eq.3}$$

$$\mathrm{q}_{kr} = \begin{cases} \frac{I_{kr}}{I^*_{kr}}, & I^*_{kr} = \max(I_{kr}), m_r \in M_1 \\ \frac{I^*_{kr}}{I_{kr}}, & I^*_{kr} = \min(I_{kr}), m_r \in M_2 \end{cases} \tag{Eq.4}$$

Here W_r is the weight of the index m_r, and q_r is the integrated value of the indicator m_r, and q_{kr} is the standardized value which derived from the raw data of indicator m_r.

(3) The formula for calculating urban ecosystem health index (EHI):

$$EHI = \sum(W_i\, m_i)\ \ i = 1,2,3,\cdots,n \qquad \text{(Eq.5)}$$

EHI presents ecosystem health score, m_i is the *i*th standardized emergy indicator, W_i is weight of *i*th ecosystem emergy indicator, and *n* is the number of ecosystems emergy indicators.

Taiyuan City, the capital of China's Shanxi Province with the 3 million population, is universally acknowledged as one of the most polluted cities in the world (Mestl et al., 2005). Located at the eastern margin of the Loess Plateau, in the central part of Shanxi, and in the north part of Jinzhong Basin (Zhang et al., 2010a), between the east longitudes 111° 30′ –113° 09′, and north latitudes 37° 27′ – 38° 25′ (see *Figure 2*).

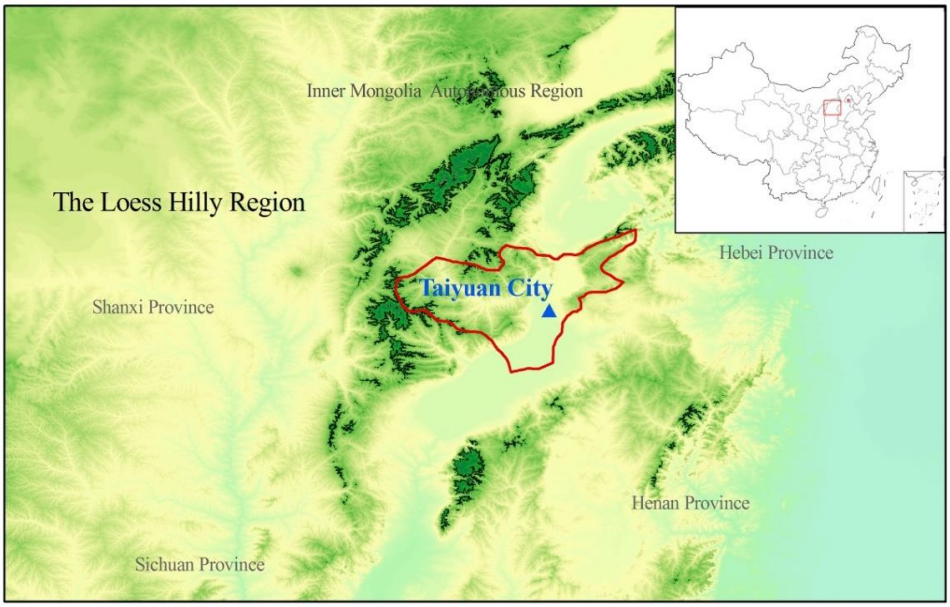

Figure 2. *Location of the study area*

As the important energy and heavy chemical industry bases of China, Taiyuan's economy high relies on the heavy industry, which contributed to more than 75% of its GDP. The urbanization rate in Taiyuan has increased from 54.38% to 84.70% from 2001 to 2017, far higher than the national average of 58.52%. Rapid urban sprawl has promoted the social and economic development, but meanwhile have caused a series of environmental issues, such as the shortage of water resources, serious environmental pollution, fragile ecological environment and so on. Owing to special topography, which surrounded by hills and mountains, thus results in periods of countercurrent and stagnant air masses in the winter, accordingly strengthening the concentration of air

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

pollutants (Zhang et al., 2010a). In summary, Taiyuan was chosen as a suitable case study for evaluating the ecosystem health.

The data used in this paper are derived from Shanxi Statistical Yearbook 2002–2018, Taiyuan Statistical Yearbook 2002–2018, and the achievement of the 30-years "Reform and Opening-up" of Shanxi (Shanxi Province Statistical Bureau, 1983-2015, 2009). And, unit emergy value (UEV) of materials and energy flows were drawled on the experience of related references (Jiang et al., 2009; Su et al., 2010; Pan et al., 2019).

Results

The dynamic emergy flow information on Taiyuan urban ecosystem during the 17-years period was calculated using the *equation (1)*. Using information entropy, in light of the expression of indicator system (*Table 1*) and the *equations (2) ~ (5)*, we can calculate the emergy efficiency index and the weight of each indexes, with weight we can finally obtain the Vigor, Organization, Resilience, Ecosystem service and EHI. Using this method, we obtained the urban ecosystem health evaluation table of Taiyuan (*Table 2*).

Table 2. *The urban ecosystem health evaluation table of Taiyuan (2001–2017)*

DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

The vigor of Taiyuan City changed little, first slowly climbed up and began to decline in recent years, and its trend line like an elongated *S* curve (*Fig. 3*). Among the vigor's indicates, the environmental investment ratio (EIR) accounted for the largest contribution, with a trend trajectory similar to that of vigor changes during the period 2001-2017. During 2001-2009, although EIS increased slowly, the value was always less than 0.3, probably because the economic system is mainly dependent on local coal resource, more coal is obtained from the environment free of charge than other competitors. However, too low the rate of emergy investment will not be conducive to attracting extra-territorial funds, which in turn will affect the development of local resources. From 2010 to 2015, this ratio become large fast, that means inputs are need to pay, prices are rising, and the system is more competitive than past. But in recent years, the index has also declined, possibly due to the government optimizing industrial structure, and the dependence on the resources has not been as serious as past. For example, the industrial added value of the traditional heavy industries accounts for more than 80% of total industrial added value in 2001, but this proportion has decreased to 39.3% in 2017.

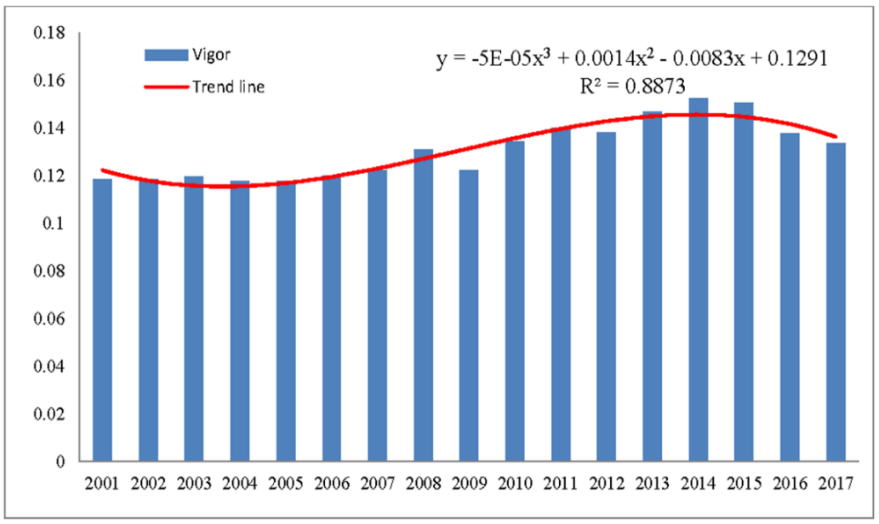

Figure 3. *The vigor and its trend of Taiyuan urban ecosystem*

According to *Figure 4*, we can find that the organization of Taiyuan has fluctuating declined during the 2001-2017 period. The trend line obeys polynomial regression, the equation is y = 2E-05x2 - 0.0007x + 0.034 (R^2 = 0.8406), which reflects the trend line fit the organization well. The contribution of non-renewable emergy ratio (NER), emergy exchange rate (EER) and emergy per capita (EPC) to organization is almost the same level, which is 0.014, 0.010 and 0.011, respectively. But in the recent two years, emergy exchange rate (EER) has slightly picked up.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

The resilience of Taiyuan urban ecosystem fluctuates greatly during the past 17-year period, but overall express rise trend (*Fig. 5*). Here, waste produce ratio (WPR) and Environmental load rate (ELR) were chosen to express the resilience factor. The contribution of waste produce ratio (WPR) and Environmental load rate (ELR)to resilience is 0.388 and 0.022, respectively. Obviously, the continuous reduction of industrial waste emissions leads to ecosystem resilience improving.

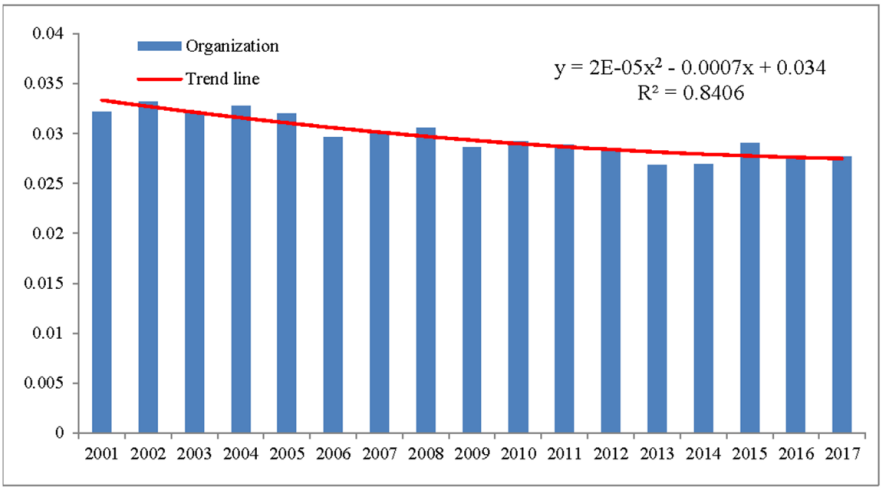

Figure 4. *The organization and its trend of Taiyuan urban ecosystem*

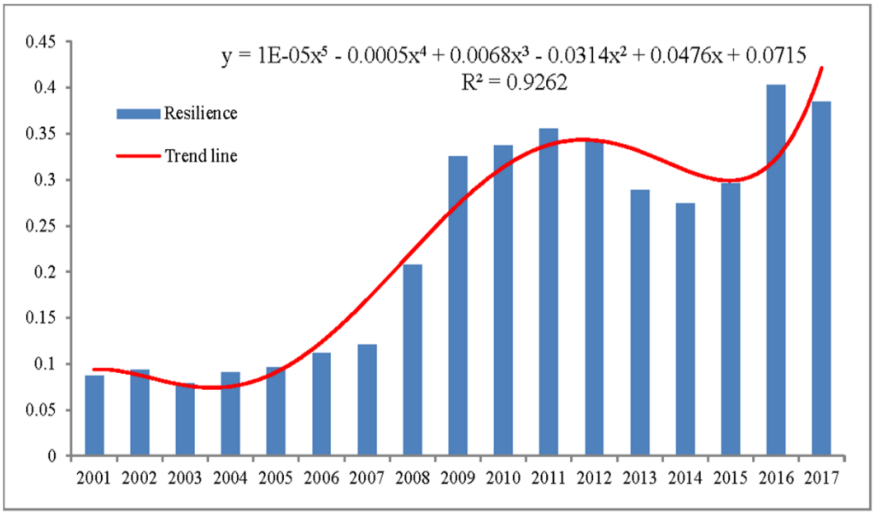

Figure 5. *The resilience and its trend of Taiyuan urban ecosystem*

Figure 6 shows that the urban ecosystem service of Taiyuan was exponential growth during the past 17-years period. The trend line obeys exponential regression, the equation is $y = 0.0899e^{0.088x}$ ($R^2 = 0.9921$), which reflects the trend line better fit the ecosystem service. The contribution of emdollaratio (EDR), emergy self-sufficiency

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

rate (ESR) and emergy sustainability index (ESI) to ecosystem service is 0.312, 0.007 and 0.052, respectively. To a great extent, the ecosystem service keeps climbing result from continuous decline of emdollaratio (EDR). In General, this rate is higher in the less developed regions, because natural resources are basis for its economic development and GDP growth (Yu et al., 2016), and most of the environmental resources are used free of charge. On the contrary, this ratio become lower means that the local economy developed because of rapid currency repayments, a large GDP base and the huge import of resources.

As showed in *Figure 7*, the trend of ecological health index and resilience of Taiyuan is very similar during the 2011-2017 period, but it is a little smoother. From the previous analysis, we know that this is mainly due to the resilience and ecological service capacity of Taiyuan urban ecosystem improved over the past 17 years.

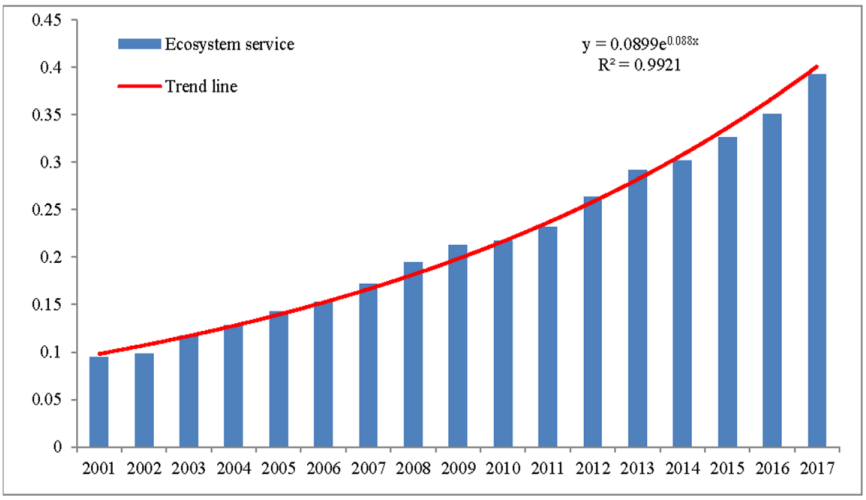

Figure 6. *The urban eco-system service and its trend of Taiyuan*

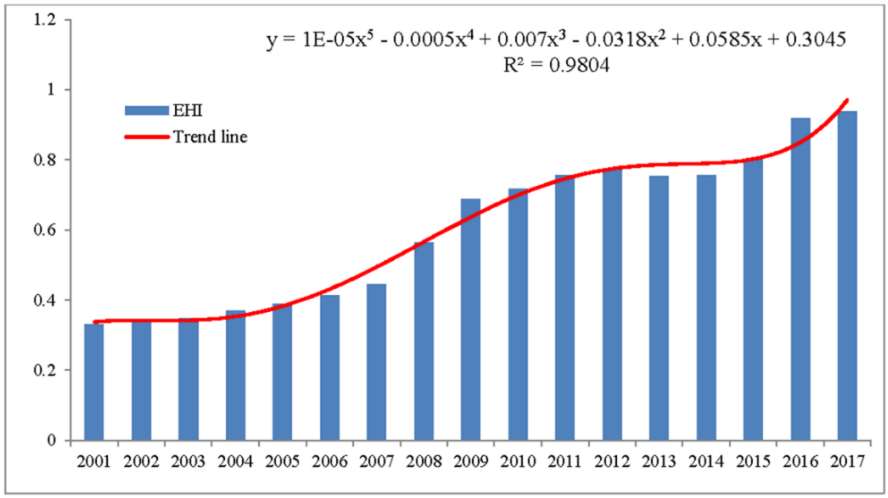

Figure 7. *The EHI and its trend of Taiyuan urban ecosystem*

DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

However, the vigor of Taiyuan urban ecosystem changed little, and even more cautiously since that there are still a lot of problems with the organizational structure. From *Figure 8*, we can also find that correlation coefficient of the ecological health index and were significant positive except for organization. Mostly because the organization of Taiyuan has fluctuating declined during the 17-years period.

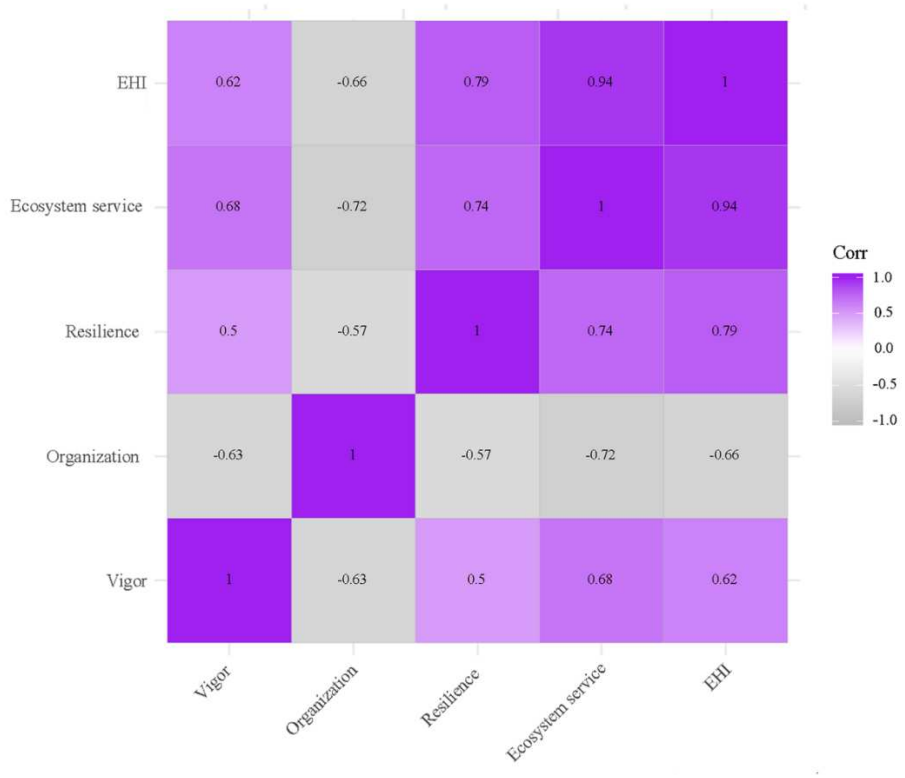

Figure 8. *The correlation coefficient of EHI and VORS4. Discussion*

Discussion

Recently, the relationship between economic growth and environmental performance is worth studying. As Silvio affirmed, cities are the engine of economic development and human wellbeing, however, their dynamics need to be supported by the convergence of a large number of material and energy resources (Viglia et al, 2018). Due to the contradiction between urban economic expansion and environmental protection becomes more and more serious, it is worth investigating the relationship between economic growth and environmental performance (Liu et al., 2009). Basically, the framework definition and application of metrics and models capable of accounting for natural capital value are much needed (Vassallo, 2017). It is necessary to formulate methods and indicators of ecosystem health and apply them to typical coal regional ecosystems (Jiang et al., 2009). This paper tries to construct a framework of assessment model and choose relevant index based on emergy, finally, combining information

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

entropy method to evaluate the urban ecosystem health status from the perspective of the energy and materials metabolism. Nevertheless, there are still many problems that need to be studied in depth. What are the most key factors affecting the health of urban ecosystems, whether there is a causal relationship between them, whether they are short-term or long-term impaction, and so on.

As the provincial capital of Shanxi, Taiyuan's development is also a microcosm of Shanxi. Shanxi Province's coal yield accounts for 1/4 of the total coal production in the whole country, whilst coke production accounts for 2/5 (Guo et al., 2018). The energy intensity of Shanxi province is the highest all over the whole country, 2.4 times compared to the national average in 2006 (Tang et al., 2014). Although air pollution has improved since the early 1990s, the air pollution in the city is still very serious compared to other cities in the country. It is possible because the energy structure of Shanxi Province is mainly dependent on coal for a long time. That's also why the organization of Taiyuan has fluctuating declined. In order to reduce the coal consumption, Taiyuan municipal government intends to improve the current energy structure (Guo et al., 2018), optimize industrial structure, and the dependence on the resources has not been as serious as past. For example, Taiyuan municipal government invested 1.5 billion Yuan (180 million USD) to implement its cleaner production program for the purpose of improving the environmental condition, and in 1999 Taiyuan became China's first cleaner production pilot city (Mestl et al., 2005). According to relevant government reports, 12 industrial pollution sources were closed in 2005, and a total of 121 were shut down by 2012 (Tang et al., 2014). But considering the structure of the coal industry lasting almost 100 years, there is still a long way to go. It is necessary to find clean renewable resources to Offset the consumption of coal resources. The empower that is derived from solar, geothermal and tidal sources drives the productive processes, and make it possible to come true (Brown et al., 2016). Under such circumstances, government should take strong actions to reduce coal consumption and related emissions. In particular, the local government should play a leading role in promoting technological innovation among enterprises through carefully designed policies to improve product sustainability, and to regulate public behavior (such as green public transport travel, garbage classification, purchase of energy-saving products, etc.), thereby achieving a 'win-win' environment and economy.

Conclusions

This study applies emergy synthesis and information entropy to assess the urban ecosystem health of Taiyuan during the period 2001–2017, to provide suggestions for local government formulating the policy and regulation. Result shows that the ecological health of Taiyuan has improved during the 2011-2017 period, mainly due to the resilience and ecological service capacity of Taiyuan urban ecosystem improved over the past 17 years. The continuous reduction of industrial waste emissions leads to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1513115149

ecosystem resilience improving. However, we should be cautious since that there are still a lot of problems with the organizational structure. And in order to reduce the dependence on the resources, Taiyuan government still needs to improve the current energy structure and optimize industrial structure. In the future study, how to take into account the space-time dimension, compare and analyze the resource-based cities' ecological health in China and predict the trend of ecological health development will be the core work of the next step. At the same time, how to improve the accuracy of its measurement, and then identify the key factors that affect the health of urban ecosystem, and provide a clearer basis for urban development, is also the important research direction.

Acknowledgments. We thank Rong Zhou for her great assistance in this study. We would also like to thank the Science and Technology Basic Resources Survey Project of China (2017FY101304), Major R&D Project of Chinese Academy of Sciences (ZDRW-ZS-2016-6-5), National Natural Science Foundation of China (41701062,41471116,41701142), Shanxi Scholarship Council of China (2016–078), Shanxi Normal University Natural Science Foundation (ZR1714), and the Youth Innovation Promotion Association CAS (2016181). We are also grateful to the anonymous reviewers and all the editors in the process of revision.

Abstract. The main objective of this paper is to evaluate the energetic potential and the environmental impacts of different kinds of wastes derived from different sources, namely olive Kernels (OK), sewage sludge (SS), chicken residues (CR), animal meal (AM) and fluffy RDF (F-RDF) and to figure out their feasibility as alternative fuels for cement plants. Decisive parameters promoting the use of wastes as secondary fuels such as: Calorific value, moisture, volatile matter, ash, chlorine, sulfur contents and trace elements were determined. A brief comparison of these fuels has been summarized. A model of fossil fuel savings is estimated using different scenarios with several substitution rates. The results show that chicken residues, fluffy RDF and olive kernels have the highest caloric values, which are 25.02 MJ/kg, 24.79 MJ/kg and 21.68 MJ/kg respectively. Moreover, fluffy RDF can help mitigate carbon dioxide (CO_2) emissions due to its lower carbon content than coal, and its similar caloric power. In addition to their favorable calorific values, chicken residues and olive kernels allow for a significant reduction of fossil-derived CO_2 due to their biogenic origin. Generally nitrogen oxide (NOx), sulfur dioxide (SO_2) emissions decrease while Co-firing waste with coal.
Keywords: *co-processing, organic waste, calorific value, pollutants emissions, fossil fuel saving*

Introduction

Developing countries face a huge challenge in the management and treatment of solid waste (Abdel-Shaf and Mansour, 2018): growing population and urbanization cause rising amounts of waste, landfill capacities are lacking. However, in the case of non-hazardous municipal solid waste, another option has shown its feasibility: Co-processing of pretreated waste as an alternative fuel in cement production is widely applied in industrialized countries. It helps to reduce the volume of waste, conserve natural resources of primary energy, it contributes to reducing landfill emissions and has a positive effect on energy costs for the cement industry.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1515115168

Several studies analysed the feasibility of using waste in cement plants: Materials like waste oils (Kääntee et al., 2004), plastics (Feng et al., 1996), waste tires (Karell and Blumenthal, 2001; Hashem et al., 2019) and sewage sludge (Ninomiya et al., 2004) are often used as alternative fuels (AF) in the cement industry. Furthermore animal meal produced from the slaughterhouse residues can also be used as alternative fuel for cement co-combustion (Denafas et al., 2004; Bhatty, 2006). Apart from this, industrial waste such as non-recycled plastics and paper waste studied by Bourtsalas et al. (2018) and wood wastes investigated by Hossain et al. (2019), agricultural biomass and spent pot linings (Lechtenberg, 2009; Al-Salem et al., 2010; Ghenai et al., 2019) have been also used as alternative fuels in the cement industry for many years. Advances and challenges for the co-processing of waste were also studied by Stafford et al. (2015) in Latin American cement industry. The robustness of the co-processing as waste disposal technique was also revealed by the economic and environmental statistical analysis (Rahul et al., 2016).

Consequently, the use of non-hazardous solid waste could be an option to tackle waste management for developing countries, providing the double benefit of environmental protection and energy recovery. However, in developing countries there is generally a lack of data about the characteristics and quantities of non-hazardous municipal solid waste, the real calorific potential of wastes is little known. In addition no accurate data exists about the real environmental benefit that could be gained when using agricultural or biogenic wastes and their environmental impact as well. On real scale we can notice some modest experiences of co-processing of alternative fuels by local and international groups of cement companies which have been using tire chips and olive kernels as alternative fuels (GIZ, 2013) since a couple of years.

Cement is one of the most significant manufactured materials in the world. Global 2015 cement production is estimated at 4.6 billion tons (CEMBUREAU, 2015). Cement is the most important constituent of concrete, and every year, approximately 1 t of concrete is expected to be produced for each human being in the world (Lippiatt and Ahmad, 2004) due to current developmental trends. Cement is a fine powder obtained from grinding clinker together with gypsum. Other additions like limestone, ashes, blast furnace slugs, and chemical additives may be added according to pertinent standards, (EN 197 2000). The most important ingredient of cement is clinker which is obtained by sintering a mixture of limestone, clay and iron ore at approximately 1450 °C by using flame temperatures of around 2000 °C.

The main environmental impacts of cement production are associated with energy intensive processes (Madlool et al., 2011) and air emissions (Davidovits, 1994) where carbon dioxide (CO_2) is relevant because it accounts for approximately 6% of the total stationary source emissions worldwide (Metz, 2005). Emission in term of CO, NO_X and SO_2 generated from cement process contributes to greenhouse and acid rain effects (Zhang et al., 2011).

The cement industry is considered energy-intensive, because it needs to achieve high temperatures. Traditionally, it used fossil fuels such as coal, fuel oil, and petroleum coke. Their co-combustion in cement kilns is contributing to a rapid increase in the average temperature of the planet through the pollutants emitted to air (Harjanne and Korhonen, 2019).

In recent years utilization of alternative fuels in cement manufacturing has gained a wide attention due to its effectiveness in substituting the thermal energy requirement from fossil fuels and reducing the pollutant emission. Alkaline environment, high temperature and long residence time allow rotary kiln to burn a wide range of waste and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1515115168

hazardous material via co-processing (Rahman et al., 2015). In this process, waste is added to raw materials by replacing, in part, fuels or virgin raw material itself (Porto and Fernandes, 2006).

Studies on the impact of alternative fuels on environmental emission with regard to CO, NOx, SO_2 and CO_2 emissions have also been discussed (Rahman et al., 2015). The effect of various MBM parameters on the process of co-processing with coal, was determined through many experiments with different MBM/coal ratios carried by Gulyurtlu et al. (2005), these experiments demonstrate when the ratio of MBM is increased a minor impacts on emissions of CO and sulphur dioxide (SO_2) were noticed. Moreover, it was found while increasing MBM portion that NOx emissions decreases despite its high nitrogen content.

In addition to the studies that investigate the environmental impact of using waste in the cement industry, another research line focuses on the practical substitution rate for each type of alternative fuels.

This paper investigates chemical and physical characteristics of a diversity of alternative fuels, to evaluate their energetic potential and their environmental impact according to cement plants requirements. We highlight the potentials of a range of alternative fuels regarding the question of how much coal could be substituted and what impact on emissions one can expect. A calculation model of fossil fuels quantity that can be saved while using such waste is also estimated.

Materials and methods

Samples description

The present study was performed in Cadi Ayyad University, Marrakesh-Morocco in collaboration with Technical university of Darmstadt-Germany.

Different kinds of wastes were taken from different sources (*Table 1*). The target samples undergo a series of pretreatment including drying cutting and grinding to produce a fine powder in order to make their structure homogenous enough for the following analysis:

- Proximate analysis parameters: moisture, volatile, ash, and calorific value
- Ultimate analysis parameters: chlorine, sulphur as well as trace elements

The values obtained are results of three replicates. The results regarding moisture and calorific values could change over time, since the moisture affects the CV of the studied AF a continuous control of such parameters need to be performed before their use.

Analytical method

Moisture content: according to DIN51718

The working principle consists of drying samples at 105 °C for 90 min in a Memmert oven**.** The sample (1 g) is spread evenly on a drying bowl crucible, weighed with 0,1 g accuracy and dried in an oven at 105 ± 2 °C until mass constancy.

Volatiles according to DIN 51720

The working principle consists of treating the samples at 900 °C for 7 min using a Nabertherm oven. Approximately 1.0 g of the pre-dried and ground sample is weighed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1515115168

into a crucible which is placed in the oven preheated at 900 ± 5 °C. After 7 min (±5 s), the crucible is removed and reweighed after cooling in a vacuum desiccator. The volatile matter content is calculated from the mass loss of the sample.

Table 1. *Overview of solid waste tested and their origin*

Samples	Description	Sources
Olive mill wastewaters "continuous system" (water-solid mixture) (OMWC)	Since olive production is done by many processes (traditional and continuous), different kinds of OK were collected and other by-product (OMW = water + solid waste mixture)	Olive Oil Factory, Marrakesh, Morocco
Olive kernel "continuous system" (OKC)		Olive Oil Factory, Marrakesh, Morocco
Olive kernel "traditional system" (OKT)		Olive Oil Factory, Marrakesh, Morocco
Olive kernel "canning industry" (OKCa)	OK generated from the process that preserves olives in cans or jars for future uses	Canning Industry, Marrakesh, Morocco
Sewage sludge "M"	The residual, semi-solid material that is produced as a by-product during sewage treatment of industrial or municipal wastewater	Wastewater Treatment Plant, Marrakesh, Morocco
Sewage sludge "G"		Wastewater Treatment Plant, Ennigerloh, Germany (Heidelberg Cement)
Chicken waste	Mixture of chicken heads, intestines, feather and wings	Dajajji Factory, Marrakesh, Morocco
Animal meal	Waste derived from the slaughtering of animals	MVW Lechtenberg and Partner, Duisburg, Germany
Fluffy RDF	Shredded plastic and small parts of paper	MVW Lechtenberg and Partner, Duisburg, Germany

Ash on the basis of DIN 51719

The working principle consists of treating the samples at 815 °C for 5 h.

The ash content is determined by rising the temperature from 550 °C with 5 K/min to 815 °C and holding until constant weight (mass difference ±0.05%) is reached. The ash content is calculated from the mass loss of the sample.

Chlorine and sulphur

Sulphur and chlorine according to DIN51724-3/DIN 51727: The pre-dried and crushed sample is weighted in a porcelain crucible which contains a small quantity of $FePO_4$ powder to help burning. With the aid of a catalyst layer of quartz powder and at high temperatures (>1300 °C) the sulphur/chlorine is oxidized in an oxygen stream. In the resulting solutions, chlorine and sulphur are detected by means of volumetric analysis.

Sulfur titration: Metrohm titrator; standard solution $Ba(ClO_4)_2$, (0.005 mol/l)

The entire solution from the combustion step is transferred into a 250 ml volumetric flask. 50 ml are pipeted off and added with same volume of acetone (for better

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1515115168

precipitation of $BaSO_4$). A few drops of indicator sulfonazo III are added. Under constant stirring barium perchlorate $Ba(ClO_4)_2$ solution is added until the color changes from violet to blue.

Chlorine titration: with $AgNO_3$ (0.02 M)

The remaining 200 ml of the solution above is transferred into a 400 ml beaker. 10 ml of HNO_3 are added, the titration is done by means of silver nitrate $AgNO_3$.

Calorific value according to DIN 51900

For the determination of the calorific values a bomb calorimeter (IKA calorimeter C 7000 duo IKA C 5000) is used. Around 0.3 to 0.8 g of pre-dried and ground sample is weighed into a combustion capsule. The sample is mounted in the combustion bomb with an ignition. The bomb is placed into the calorimeter after been filled with 30 bar of oxygen.

The ignition and the measurement are done automatically. After the combustion the bomb must be checked for signs of incomplete combustion. Only gross calorific values (GCV) have been determined.

Trace elements on the basis of DIN EN 13657:2003-01

About 3 g of pre-dried and crushed sample is weighed into the reaction vessel. 21 ml of HCl and 7 ml of HNO_3 are added. The digestion vessel is sealed and placed in the heating system. The samples can oxidize slowly with acids to ovoid explosion by the direct heating. It is recommended to increase the temperatures of the digestion mixture from 60 °C in modest steps each 20 min to an end temperature of 160 °C (60 - 80- 120 - 160 °C), the digestion lasts for 2 h. After complete cooling, the reaction vessels are opened and the digestion solution is transferred into a 50 ml plastic volumetric flask and filled with deionized water, then adjusted with HNO_3.

The measurements were performed using Inductively Coupled Plasma ICP and Atomic Absorption Spectrometry. To determine mercury a cold vapor AAS (DIN EN 1483) was used.

Elemental analysis (C, N, O, P, Fe)

The elemental analyses were done by means of, a scanning electron microscope (SEM) (TESCAN VEGA3 Centre d'Analyse et de Caractérisation CAC- Cadi ayyad University).

CO_2 and SO_2 emission calculation

CO_2 and SO_2 emissions prevision are calculated by the following formulas (Madlool et al., 2011; Lechtenberg and Diller, 2012):

$$CO_{2\,[m^3/kg\ fuel]} = \frac{1.854 * C_{[\%]}}{100} \quad \text{(Eq.1)}$$

$$SO_{2\,[m^3/kg\ fuel]} = \frac{0.68 * S_{[\%]}}{100} \quad \text{(Eq.2)}$$

Note: [m³kg-1 fuel] are referred to STP.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1515115168

Net CO_2 mitigation calculation

The CO_2 mitigation calculation is done through the following equations: first we calculate the equivalent amount of coal (W) that could substitute 1 t of AF used based on their corresponding calorific values (CV) according to *Equation 3,* then we estimate its corresponding CO_2 emitted amount (X) based on *Equation 4:*

$$W_{[t]}\ of\ coal\ =\ \frac{CV\ (AF)\ (kcal/kg)}{CV\ (Coal)\ (kcal/kg)} \quad \text{(Eq.3)}$$

$$X_{[t]}\ CO_{2\ (coal)} = W * 2.45_{[t]}\ CO_2 \quad \text{(Eq.4)}$$

The calculation of CO_2 emissions from 1 t of alternative fuels (Y) is done by using the carbon content (%C) determined by analysis (*Table 5*) and the molar mass (M) of CO_2 according to *Equation 5*.

$$Y_{[t]}\ CO_2(AF)\ =\ \frac{(C_{[\%]} * (M(C)+2M(O))/M(C))}{100} \quad \text{(Eq.5)}$$

The amount of CO_2 (Z) that could be saved by using AF instead of the equivalent amount of coal is calculated based on *Equation 6:*

$$Z_{[t]}\ CO_2\ =\ 2.45_{[t]}\ -\ Y_{[t]} \quad \text{(Eq.6)}$$

W, X, Y and Z are variables.

Results and discussion

Energetic potential

Proximate and ultimate analysis of the studied alternative fuels: The results regarding calorific value (CV), moisture content, ash, volatiles, carbon, oxygen, nitrogen, sulphur and chlorine of different kinds of waste and of coal as fossil fuel reference are summarized in *Table 2*.

Substitution rate calculation: *Table 3* shows the substitution factor of each alternative fuel referring to calorific value of 1 t of coal or petcoke commonly used in cement facilities.

Olive residues sampled from different industrial units have lower heating values than coal between 18 and 21 MJ kg^{-1}, with carbon content above 50%. The moisture content ranges from 0.33 to 17%, and ash content is between 2 and 30%. The results show that olive kernels produced by means of traditional olive mills systems have the highest calorific value which is close to that of coal due to their higher oily as well as low ash contents compared to OK originated from continuous system (*Table 2*). Hence even that olive kernels are commonly used as alternative fuel it seems very interesting to compare OK from different sources and to highlight the impact of the source on their CV.

As mentioned in *Table 3*, olive residues have calorific values ranging between 4000 and 5000 kcal kg^{-1} (16.75 – 20.93 MJ kg^{-1}); therefore, 1.17 t and 1.58 t are needed to substitute 1 t of coal or 1 t of petcoke respectively, with olive kernels produced by means of traditional system. To maintain a good quality of the final product and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1515115168

convenient conditions of the combustion process while using agricultural biomass as alternative fuels, a substitution rate of 20% is recommended. In comparison to other wastes, the capital investment for their pretreatment is considered to be low (Demirbaş, 2003; Murray and Price, 2008). Some limitations of using biomass are their unavailability all around the year (Al-Hamamrea et al., 2017) and the high fluctuation of their heating value (Chinyama, 2011).

Table 3. *Fuel substitution calculation*

Fuel substitution calculation				
	Gross calorific value (kcal kg^{-1})	Substitution factor CV coal (ton)	Substitution factor CV petcoke (ton)	Saved fossil-derived CO_2 (ton)
Olive mill wastewaters	4319	1.41	1.89	1.73
Olive kernels continuous system	4459	1.36	1.83	1.80
Olive kernels traditional system	5179	1.17	1.58	2.09
Olive kernels canning	5071	1.20	1.61	2.04
Sewage sludge M	4232	1.44	1.93	1.70
Sewage sludge G	3568	1.70	2.29	1.44
Chicken residues	5922	1.03	1.38	2.38
Animal meal	4200	1.45	1.95	1.69
Fluffy RDF	5975	1.02	1.37	-
Coal	6100	1	-	-
Petcoke	8200	-	1	-

For sewage sludge the results show that the calorific value of sewage sludge "M" is 17.718 MJ kg^{-1}, the moisture content is 2.46%, and the ash content is 28.34%, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1515115168

carbon level of 44.97%. For sewage sludge "G" the calorific value, moisture, ash, carbon, and sulphur are 14.938 MJ/kg, 1.37%, 34.61%, 33.03%, and 1.30%, respectively (*Table 2*). The ranges of different contents of elements and calorific values depend on the characteristics of the source and the treatment process of the sewage sludges. We can conclude that the sewage sludge "M" has the highest caloric value along with carbon content of 44.97% and ash content higher than 11.1%. Sewage sludge "M" and sewage sludge "G" have calorific values of 4232 and 3568 kcal kg^{-1} (17.71 – 14.94 MJ kg^{-1}), respectively. To replace 1 t of coal/petcoke with sewage sludge "M", 1.44 t/1.93 t are needed respectively (*Table 3*). To ovoid the possibility of an increased infeed of trace elements, Werther and Ogada (1999) suggested a maximum sewage sludge feeding rate of 5% of the clinker production capacity.

Compared to animal meal, chicken residues have the highest calorific value which is about 24.79 MJ kg^{-1} due to its oily texture and low moisture content of 1.05%. Animal meal has a calorific value of 17.58 MJ kg^{-1} and moisture content of 5.75% (*Table 2*). Therefore 1.03 t and 1.38 t are needed to substitute 1 t of coal or 1 t of petcoke with chicken residues. Around 1.45 t and 1.95 t are needed to replace 1 t of coal or 1 t of petcoke with animal meal (*Table 3*). Animal meal is considered to be available compared to other alternative fuels and their feeding rate is variable from country to another, it is about 15% of the energy needed in Spain cement kilns (Conesa et al., 2005), 40% for Australia (Rahman et al., 2015) and there is no limit in Switzerland.

Owing to its high calorific value of 25.01 MJ kg^{-1} which is similar to that of coal (*Table 2*), and with a low moisture of 1.14% and low ash content, fluffy RDF represents a very suitable alternative fuel for clinker burning. Fluffy RDF represents a perfect candidate for energetic recovery in these industries (Lechtenberg and Diller, 2012). In addition, only1.02 t to 1.37 t of fluffy can substitute 1 t of coal and 1 t of petcoke, respectively. Among all tested alternative fuels**,** chicken residues and fluffy RDF as well as olive kernels produced by means of traditional olive mill system have the highest caloric power along with most favourable substitution factors for the replacement of 1 t of coal/petcoke.

Emissions

CO_2 emissions

CO_2 emitted during co-processing such fuels in cement plant does not exceed the emission resulted from coal [1.30 CO_2 m^3 kg^{-1} fuel] (*Table 4*). However the emitted quantity of CO_2 in case of chicken residues co-firing is higher due to its high carbon level [1.44 CO_2 m^3 kg^{-1} fuel]**.**

The studied products account for pure biogenic material and therefore the co-incineration of such materials contributes to global fossil-derived carbon dioxide mitigation. The extent of the mitigation can be appraised by the following simple calculation: Taking into account the IPCC default emission factor for coal 96 kg CO_2/GJ (IPCC, 1996), 1 t of coal emits approximately 2.45 t of CO_2. Hence, for each ton of coal substituted by 1.45 t of MBM around 2.45 t of fossil-derived carbon dioxide is saved. Or, vice versa, 1 t of MBM can save around 1.69 t of fossil-derived CO_2 from coal (*Table 3*).

Plastics in general cannot be taken into account for fossil CO_2 reduction calculation, this is owing to the fact that their origin is crude oil. Only bio-plastics made of renewable feedstocks (e.g. starch from cereals, corn, sugar cane) can be valuable for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1515115168

this. Mathematical modeling revealed a significant reduction of CO_2 emissions, which is approximately 1.0 t of CO_2 per ton of coal replacement in case of the use of pure polyethylene and polystyrene plastics as alternative fuel (Murray and Price, 2008; Ariyaratne et al., 2011).

We can presume that 1 t of chicken residues can save 2.38 t of fossil-derived CO_2 from coal, which allows a significant reduction in terms of fossil-derived CO_2 emissions (*Table 3*). The saving of fossil-derived CO_2 is not only a matter of biogenic carbon. If a fuel material has lower carbon than coal, but similar caloric power, as it is the case of fluffy RDF, then some net CO_2 mitigation could be obtained.

Based on the *Equations 3, 4, 5* and *6,* 1 t of Fluffy RDF can substitute 0.96 t of coal, this quantity emits 2.4 t of CO_2 compared to 1.94 t CO_2 emitted while using 1 t of fluffy RDF which means 0.51 t CO_2 could be saved by using 1 t of fluffy RDF instead of the equivalent amount of coal.

SO_2, NOx emission

As evident in *Table 2* the sulphur content in olive residues is lower than the one in coal and therefore, co-firing biomass fuels with coal show a significant reduction of SO_2 levels (Demirbaş, 2003; Sami et al., 2001) however, the nitrogen content is higher than 1.2%. Experiments show, that using biomass implies low SO_2 and NOx emissions due to lower sulphur and nitrogen contents compared to traditional fuels. Moreover, taking into account that the most of the nitrogen in biomass is converted to ammonia, which promotes the conversion of NOx to gaseous nitrogen, the emissions of NOx are also reduced (Demirbaş, 2003).

The sulfur content in sewage sludge varies between 1.05 and 1.3%. It is similar to coal, which means that SO_2 emissions will be the same in case of sewage sludge co-processing together with coal. High nitrogen levels have been detected (*Table 2*). However, a study by the U.S. Environmental Agency (2008) showed that the use of sewage sludge reduces NOx emissions.

In animal meal the sulphur content is lower than that in coal (*Table 2*), therefore co-processing such alternative fuels with coal has the capability of reducing SO_2 levels. Chinyama (2011) showed that SO_2 reduction depends mainly to the Ca content in MBM which has the capability to capture sulphur in solid phase. It was observed that NO_X decreases with increasing MBM content in a coal-MBM blend, even if the nitrogen content in animal meal is 8 times higher than that in coal (Gulyurtlu et al., 2005; Ferreira et al., 2018). In contrast, a study launched by Denafas et al. (2004) mentioned that during incineration of MBM using heavy fuel oil, the emission of nitrogen oxides increases.

In fluffy RDF the sulphur content is about 0.2% (*Table 2*) which can decrease the level of SO_2 emitted to air. The nitrogen content of the plastic, and the kiln operating conditions such as the flame temperature, air quantity, and oxygen level in the kiln are the main reasons for NOx emissions (Al-Salem et al., 2010).

Theoretically, all tested fuels can generate SO_2, owing to their sulphur contents. The calculated specific SO_2 quantities are displayed in *Table 4*. However, as explained by other studies, the specific conditions in clinker rotary kilns are very suitable to capture SO_2 from fuels, which ultimately ends up in the clinker minerals (Torsten, 2005; Prakash et al., nd).

All samples present high content of nitrogen in comparison with coal, one would expect that NOx emissions would increase. However, the prediction of NOx emission from nitrogen content is not possible because its generation depends on the combustion

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1515115168

temperature, although the fuel nitrogen contributes to some extent to the formation of NOx. NOx emissions from cement kilns mainly arise from oxidation of fuel-bound nitrogen and nitrogen in the combustion air. Clinker production is a high temperature process with flame temperatures up to some 2.000 °C in the sinter zone and material temperatures up to some 1.450 °C. Due to the quality of the product the process must be operated with excess oxygen. Under these process conditions NOx is inevitably formed from the chemical reaction of the air components, i.e. nitrogen and oxygen. This NOx is called "thermal NOx" (BAT, 2010).

Table 4. *CO_2 and SO_2 emissions calculation according to Equations 1 and 2*

Description	OKC	OKT	OKCa	OMWC	SS "M"	SS "G"	CR	AM	F-RDF	Coal
Carbon (%)	53.80	50.91	58.42	58.04	44.97	33.03	77.89	47	53	70.6

Sulphur (%)	0.14%	0.08%	0.06%	0.13%	1.05%	1.30%	0.52%	0.7%	0.2%	1.3%
SO_2 (m^3kg^{-1} fuel)	0.95210^3	0.54410^{-3}	0.40810^{-3}	0.88410^{-3}	0.71410^{-2}	0.88410^{-2}	0.35410^{-2}	0.47610^{-2}	0.13610^{-2}	0.88410^{-2}

Chlorine

Compared with coal, olive, animal residues, sewage sludge and fluffy RDF have higher chlorine levels (*Table 2*), thus increasing inner salt circulation of volatile elements inside the kiln. These give rise to increased coatings, build-ups and blockages in the colder parts of the preheater (Sami et al., 2001), hence reducing the efficiency of the plant.

A study revealed that biomass can contain considerable alkali and alkaline earth elements and chlorine, which, when mixed with other gas components derived from coal such as sulfur compounds, promotes a different array of vapor and fine particulate deposition in coal fired boilers (Lippiatt and Ahmad, 2004).

Chlorine may have an influence on clinker quality and therefore needs to be limited, as mentioned in the report from U.S. Environmental Protection Agency (2008), which refers to information from US-based Lehigh Cement. However, limitation of chlorine infeed to the kiln in general is advised (according to a rule of thumb, less than 300 g of total chlorine by raw materials and fuels per ton of clinker, which is valid for preheater kilns without bypass (Reference Guide, 2004). Chlorine-based salts are highly volatile under the kiln conditions, thus being the major driver for formation off coatings and cloggings in the preheater. Emission of HCl, dioxins and furans can be increased by the presence of chlorine under specific conditions (Karstensen, 2008; BAT, 2010).

Trace elements

Table 5 shows a detailed characterization of different trace elements as well as a comparison between the hole results obtained regarding ultimate, proximate and chemical analysis with the guideline of requirement of cement plants (average, maximum).

With regard to trace elements like Sb, As, Pb, Cd, Cu, Ni… the results revealed that for olive residues and chicken residues the majority of the elements metals are below the limits mentioned in the Guideline for the Energetic Recovery of Waste in Cement (GERWC) - Lime and Power plants in North Rhine Westphalia (GERWC, 2005; *Table 5*).

MBM contains some 3.4-5.9% P (Lechtenberg and Diller, 2012). Phosphorus is the most limiting factor for MBM firing, because it affects setting time and compressive strength development of cement as well.

The same considerations apply when dried sewage sludge is co-fired. As a rule, sewage sludge contains plenty of phosphorus, as it could be also shown by the examined sample "G" in particular, but also by sample "M".

P is absorbed by the clinker minerals to form C3P-C2S mixed crystals which decrease the C3S content, whilst increasing free lime. Altogether, the early strength of cement would be reduced when level of P_2O_5 in clinker is above 0.8% (Lechtenberg and Diller, 2012).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1515115168

Heavy metals are also present in sludge and are the major problem in terms of sludge management. However, positive results have been achieved in the case of SS additions in cement manufacturing.

As shown in *Table 5* sewage sludge "M" contains higher levels of Cr and V, while sewage sludge "G" contains high level of Co. The level of mercury (Hg) is high in both sewage sludge samples when compared to the other materials (*Table 5*) which comes from the cleaning process at the sewage plant and from the source of the wastewater (ICON IC Consultants Ltd, 2001). To use sewage sludge in cement industry, the suggested maximum mercury content is 0.5 mg kg^{-1} (Karstensen, 2008; Ninomiya et al., 2004). Conesa et al. (2005) affirmed that there was no correlation between sewage sludge feeding rate and heavy metal emissions. But Cartmell et al. (2006) reported earlier that sewage sludge causes an increase in heavy metal emissions compared to fossil fuels.

It were demonstrated that the content of some heavy metals such as Cr, Zn, and Ni have no influence on the formation of the clinker phases, the final compressive strength, and the initial setting time or hydration level when their concentrations are below 0.1% in the raw mixture. The concentrations of heavy metals in the clinker are related to their volatility during the burning process. More studies are needed to establish the reliability of these findings (Chen et al., 2010).

As it is the case of natural materials, also waste-derived fuels contain environmentally relevant elements. Our examinations show that the samples contain fairly low amounts of heavy metals and metalloids. When co-processed, most of the elements are captured by the clinker minerals. But mercury in particular, and also thallium are volatile elements, which are hardly bound in the clinker. Thus, such elements leave the kiln system via the stack. Sewage sludge may have the potential of containing increased amounts of mercury. This tendency has also been observed in our examinations, for sewage sludge M and G contain around 0.8 mg kg^{-1} of Hg (*Table 5*). Mercury emissions of clinker kilns can be mitigated by an array of specific measures, e.g. dust shuttling, the use of activated carbon as sorbent, or wet scrubbers (CSI, 2016).

When using alternative fuels, a thorough sampling and analysis regime should be implemented for monitoring environmentally relevant elements in those materials.

Saving fuels estimation

Based of the calculation models used by MVW Lechtenberg and partners which is one of the world's leading consulting firms for the implementation of alternative fuels from biomass and useable wastes in the cement industry, we were able to calculate the quantity of coal that can be saved using different substitution rate 5%, 10% and 20% respectively of the studied alternative fuels with coal (*Table 7*).

The Kiln operation (hours and days), clinker production rate, specific heat consumption, heat consumption and the calorific value of each fuel (Fossil or AF) are the most important data that allow the calculation of the saved fossil fuel quantity (*Table 6*):

Scenario 1: 100% coal

The dosage of coal is obtained according to its corresponding calorific value and the heat consumption mentioned in *Table 6*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1515115168

Scenario 2: co-processing of coal and AF

First we defined the substitution rate which is the ratio between heat portion and heat consumption, the heat portion of AF is calculated according to its calorific value and its dosed value which is the added quantity of AF that satisfy the choosing substitution rate. While the heat portion of the remaining coal is the subtraction between the heat consumption and the heat portion of AF, the dosed quantity of the remaining coal in this scenario is the ratio between its CV and its heat portion. Savings of fossil fuels value is the ration of subtraction between the dosed remaining coal quantity in scenario 2 and the dosed quantity of coal in scenario 1.

Table 6. *Kiln data*

Kiln operation hours	[h d^{-1}]	24
Kiln operation days	[d a^{-1}]	330
Current clinker production rate	[t d^{-1}]	65 000
	[t h^{-1}]	2 708
	[t a^{-1}]	21 450 000
Specific heat consumption	[kJ kg^{-1} clinker]	3500
Heat consumption	[kJ h^{-1}]	9 479 166 667

We can notice that the quantity of fossil fuels that can be saved is related directly to the substitution rate, calorific value and the dosing quantity of AF used for each scenario.

For a substitution rate of 5% and 10%, we presume that SS with a calorific value of 17 706 kj kg^{-1} and dosing quantity of 27 t h^{-1} and 53.8 t h^{-1} revealed the highest saving quantity of coal which is about 148 352 t a^{-1} and 295 606 t a^{-1} respectively (*Table 7*).

For the substitution rate of 20% versus 80% of coal, chicken residues revealed the highest saving fuels of 592 038 t a^{-1}.

Table 7. *The saved quantity of coal using different substitution rate of 5%, 10% and 20% respectively of the studied alternative fuels*

The amount of fossil fuels that can be saved is directly influenced by the calorific value and the dosing quantity of the alternative fuel used. Higher substitution rate demands higher dosing quantity of alternative fuels and allow higher saving quantities of fossil fuels. The result connected with sewage sludge and olive kernels are based on the averages of the different sewage and olive kernel sources since the calorific value is not the same.

In this paper several alternative fuels that are being currently used in cement manufacturing, have been tested. These fuels have been critically analysed with regard to their gross calorific values, their levels of chlorine, sulphur, nitrogen and trace elements. Greenhouse gas emissions and environmental impact have been discussed as well.

In regards to calorific values fluffy RDF is the best option. It contributes to some net CO_2 mitigation due to its lower carbon content than coal, while the calorific value is on a similar level. Nowadays the use of plastics as alternative fuel is standard in numerous cement plants. Depending on the feeding point, kiln or calciner burners, plastics have to be crushed into appropriate grain size, furthermore chlorine always comes along with mixed plastics. The depletion of chlorine in the treatment process of plastics is of utmost importance.

Chicken residues followed by olive kernels (traditional olive mill system, canning) also have high calorific value and it reduces the green house gas emission due to their biogenic origin. From the emission point of view agricultural biomass could be the best option but due to the unavailability of a particular agricultural biomass all around the year restrict their usage.

Despite the low calorific value of animal meal it can replace coal to some extent and it offers the advantage of fossil derived CO_2 reduction. The environmental impacts are comparatively low. Still the processing costs are very high in the case of MBM.

Among the studied alternative fuel sewage sludge presents the lowest calorific value but the ash derived from the sludge can substitute raw material which is an additional advantage. In case of sewage sludge co-processing with coal a special attention need to be paid for trace elements, especially Cr, Co, V and Hg.

The generation of nitrogen oxides is inherent to the high-temperature process of clinker production. It is normally not influenced by the use of alternative materials. Moreover, depending on the respective locations, the raw material situation can effect the emissions of sulfur dioxide, the content of heavy metal compounds in the exhaust gas is additionally determined by the input situation in the kiln (VDZ CONGRESS, 2002).

In spite of numerous researches to identify the potential benefits and barriers of using different alternative fuel, none of those studies indicate which fuel is better than the others. This is only because there are lots of criteria which need to be considered from different perspectives. *Table 5* shows various criteria of the alternative fuels that have been discussed in this paper.

Conclusion

Based on the results obtained regarding the energetic potential and the environmental assessment: among all studied alternative fuels chicken residues, fluffy RDF and olive residues could be the best option as alternative fuels. The main advantages of using such fuels in cement industry are economic and environmental:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1515115168

These fuels could reduce the carbon footprint and the main atmospheric pollutants (NOx, SO_2…) that result from using fossil fuels and therefore the overall environmental impact of cement manufacturing operations. We presume also from our results that the replacement of coal with such fuels extends the supply of fossil fuels and is a safe way of absorbing waste which otherwise would present disposal problem especially in developing countries. In economic point of view and based on the estimated quantity of coal that can be saved we notice, the use of these waste as fuels saved huge amounts of fossil fuels which is considered to be economically viable.

Heavy metal emissions from the cement industry are a significant environmental concern and need to be controlled through appropriate measures, hence it is necessary that future studies consider the environmental impact from heavy metal emitted after adaptation and implementation of any alternative fuel, through an assessment of these metals released into the environment surrounding (air, soil water and plant from) the cement kilns co-burning waste. A life cycle assessment (LCA) methodology is recommended as well to quantify the potential environmental impacts of each scenario and to figure out the most environmentally friendly ones.

(Received 30th Jun 2019; accepted 16th Oct 2019)

Abstract. The urban agglomeration in the middle reaches of the Yangtze River is within a typical ecologically sensitive area as well as it is a key development area in China. Scientific assessment of urban ecosystem carrying capacity has important scientific value and practical significance. In this study, we established a new assessment framework for urban ecosystem carrying capacity, and then based on the components and structural characteristics of urban ecosystems, we constructed an extended evaluation index system for urban ecosystem carrying capacity. Spatial analysis and a coupling coordination degree model were used to analyze spatial patterns and coupling coordination degree of urban ecosystem carrying capacity in urban agglomeration in the middle reaches of the Yangtze River in 2015. The results indicated that: (1) The urban ecosystem carrying capacity of the study area was spatially differentiated and clearly clustered. (2) Comprehensive coupling coordination in spatial distribution had a significant north-south differentiation pattern of study area. Highly coordinated cities were mainly distributed in the Poyang Lake urban agglomeration and the area around the Dongting Lake, while the less coordinated cities were mainly distributed in the Wuhan urban agglomeration and south of the urban agglomeration around Changsha-Zhuzhou-Xiangtan. (3) In the surrounding area of Wuhan City and southwest of the urban agglomeration around Changsha-Zhuzhou-Xiangtan of coupling coordination degree is low, mainly due to the backward industrial foundation, low economic development efficiency, and heavy load on resource consumption and the environment.
Keywords: *urban ecosystem carrying capacity, moderate indicator, state-space model, coupling coordination degree model*

Introduction

Since the 1990s, continuous promotion of reform and open policy and the gradual improvement of the market economy system have ushered, China's economy into a period of rapid growth (Qi et al., 2015). However, due to the rapid growth of urban population and built-up area, the overexploitation of natural resources, and environmental pollution had significant negative impacts on land cover, biodiversity, the hydrological system, and local climate at different regional scales. In turn, the natural environment has limited regional social and economic development, causing people to gradually realize that regional sustainable development is closely related to regional ecosystem health (Pei et al., 2019). Therefore, to guide the regional

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

sustainable development, it is necessary to evaluate the urban ecosystem carrying capacity according to development status. Ecological carrying capacity is an important indicator, which is used for measuring the utilization degree of natural resources and interference intensity of ecological environment caused by human activities. Meanwhile, it is also an important tool for evaluating the level of regional sustainable development (Xiong et al., 2013). In recent years, it has attracted the attention of global scholars and has been widely used to evaluate urban ecosystem carrying capacity and sustainable development (Wackernagel and Galli, 2007; Zhang et al., 2016; Rudolph and Figge, 2017).

In 1922, Hawden and Palmerzai first proposed the concept of ecological carrying capacity when studying the impact of reindeer population on regional ecosystems. The concept was subsequently developed and improved, transforming from research focused on a single ecological element, to the early stage carrying capacity of an ecosystem (Cui and Yang, 1997; Hudak, 1999; Zhu et al., 2005), and finally to the carrying capacity of a composite ecosystem composed of integrated ecological elements such as nature, society and the economy (Wang et al., 2000; Yang and Sui, 2005; Xiong et al., 2014). The study of ecological carrying capacity based on comprehensive ecological factors has gradually enriched the theory and connotations of ecological carrying capacity, enhancing people's understanding of complex ecosystems. Evaluation methods and index systems for ecological carrying capacity, with the continuous development of the concept and connotation of ecological carrying capacity has also gradually improved with applications in different issues and research focuses. The main methods include human appropriation of net primary production (HANPP) (O'Neill et al., 2007; Sjafrie et al., 2018;), ecological footprint method (Jiao et al., 2011; Xiang et al., 2016; Peng et al., 2019), state-space method (Xiong et al., 2014; Ji et al., 2017), system model (Lein, 2010; He et al., 2011; Mondino et al., 2014; Ge et al., 2016), comprehensive evaluation method (Jin et al., 2015; Wang et al., 2017), ecosystem service consumption evaluation method (Rong et al., 2019), and more. Evaluation methods have the characteristics of diversification and synthesis (Ji et al., 2017).

Current research still has the following problems: in terms of the research on the evaluation index system of ecological carrying capacity, the selection of evaluation indicators has primarily focused on natural elements, and seldom considers the impacts of social development and progress, resource consumption, treatments for environmental pollution and other factors on the overall carrying capacity of a complex urban ecosystem, and the selection scope of indicators needs to be further expanded. From the perspective of the application of the state-space method, its calculation formula can be divided into two types: the first is represented by Xiong et al. (2014), Peng et al. (2016), Ji et al. (2017) and Pei et al. (2019), in which the state-space formula is used to calculate the urban ecosystem carrying capacity index a year or a time series. The advantages of this formula are well known and widely used, but it is unable to evaluate the state of the urban ecosystem carrying. The second type is represented by Li and Ma (2013) and Song and Yu (2014), and is used to calculate current and ideal values for urban ecosystem carrying capacity in a cross-section of a year, and then evaluates carrying status of urban ecosystem based on the difference between current and ideal values. The advantage of this formula is that it can quantitatively evaluate the carrying status of an urban ecosystem. In summary, two issues remain in the application of the state-space method: first, moderate indices are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

seldom mentioned and the forward processing formulas for them have not been clearly described; Secondly, selecting ideal values for each index need to update. In addition, research on urban ecosystem carrying capacity based on the state space method has focused more on the analysis of spatial and temporal patterns, and less on an in-depth analysis of the coupling and coordination among the dimensions of the state-space axis and their causes.

The middle reaches of china's Yangtze River is an ecologically sensitive region that shoulders the important responsibility of ecological protection in the Yangtze river basin of China. At the same time, it is also one of the regions with the densest population, the highest intensity of water and soil resources development and utilization, and the most severe environmental pollution problems in China. At present, there has not been in-depth research on spatial pattern of the carrying state of the urban ecosystem and the level of coupling coordination between dimensions of urban agglomeration in the middle reaches of the Yangtze River. In light of deficiencies in the current research on the evaluation index system for urban ecosystem carrying capacity and applications of state-space method, firstly, our research established a new assessment framework for urban ecosystem carrying capacity and used multi-source data to construct a comprehensive evaluation index system composed by 25 key indicators. Meanwhile, these indicators are selected to depict urban ecosystem carrying capacity in terms of three aspects: the social-economic coordination force, resource-environment supporting force, and ecological resilience. Secondly, we improved the forward processing formula of moderate indicators and determined the ideal value of all indicators. Thirdly, we used the state-space method and coupling coordination degree model to analysis the spital pattern and coupling coordination of urban ecosystem carrying capacity in urban agglomeration in the middle reaches of the Yangtze River in 2015. This study complemented the theoretical and methodological studies of urban ecological carrying capacity, and this paper also has important practical significance and scientific value in guiding the sustainable development of the urban agglomerations in the middle reaches of the Yangtze river.

Study area and data source

Study area

The Urban agglomeration in the middle reach of the Yangtze River is a super urban agglomeration formed by the Wuhan urban agglomeration, the Poyang lake urban agglomeration, and the Changsha-Zhuzhou-Xiangtan urban agglomeration. It is located in the middle of China’s Yangtze River basin, including a total of 31 prefecture-level cities and some counties (districts) in Hubei, Hunan, and Jiangxi Provinces. Lying at 26°03'~ 32°38' N, 110°45 '~ 118°21'E and with a total area of about 326000 square kilometers, the region has a subtropical monsoon climate with annual average rainfall of about 800-1943 mm. The Urban agglomeration in the middle reaches of the Yangtze river is dominated by plains (*Fig. 1*), with fertile soil and abundant water resources. It is home to Poyang and Dongting Lake, the Han and Qingjiang Rivers, and many other rivers and lakes, with a good combination of water, temperature, and abundant agricultural resources that makes it one of the major grain-producing areas in China. However, the urban agglomeration in the middle reaches of the Yangtze river in this densely populated area and important development zone for Jiangxi, Hubei, and Hunan Provinces has been experienced

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

prominent problems in recent years, such as carrying pressure of water resource, ecological security, and land pollution (Li et al., 2017; Chen et al., 2018).

Data source

The socio-economic statistical data used in this paper were obtained from 《China urban statistical yearbook of 2016》, 《Jiangxi statistical yearbook of 2016》, 《Hubei statistical yearbook of 2016》, 《Hunan statistical yearbook of 2016》, and 《China urban construction statistical yearbook of 2016》. Land use/cover data (for Jiangxi, Hubei, and Hunan provinces) were downloaded from the national science and technology infrastructure platform -- national earth system science data sharing platform (http://www.geodata.cn). A Python script was used for batch segmentation, transformation and extraction of 2015 land use/cover data, and then the forest and wetland data from each research unit was subdivided and counted (land cover data was available in five year intervals, the year 2015 with relatively complete data was selected as the study period). In addition, data on missing indicators such as total water resources were obtained from the water resources bulletin, total arable land area and urban and rural residential income were obtained from the statistics bulletin of prefecture-level cities.

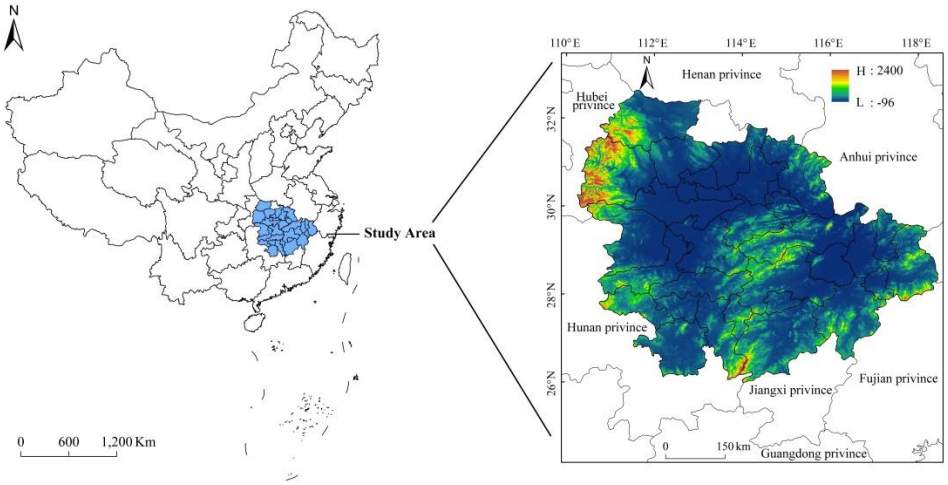

Figure 1. *Location of the study area*

Methodology

Framework of urban ecosystem carrying capacity assessment

There is no uniform concept of urban ecosystem carrying capacity, but by integrating existing research in this paper (Yin et al., 2011; Xiong et al., 2016; Wang et al., 2017; Pan et al., 2017), the concept was defined as: In a certain period and under a certain level of pressure, the urban ecosystem can maintain its own healthy and coordinated development carrying capacity. It is mainly manifested in three parts: the coordination ability generated by the socio-economic subsystem, the supporting ability provided by the resource-environment subsystem to maintain the healthy operation of the system, and the regulating ability and development potential of the ecological resilience subsystem to achieve an appropriate goal.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

We referred to existing studies on urban ecosystem carrying capacity and established a new framework for urban ecosystem carrying capacity assessment, we call it "pressure and driving force - supporting force - regulating force" model. As indicated in *Fig. 2*, the framework of urban ecosystem carrying capacity assessment includes the state plane (plane XY) and development potential axis (axis Z), which together constitute the overall development state of urban ecosystem carrying capacity. The evaluation framework also includes three dimensions: social-economic coordination force, resource-environment support force, and ecological resilience. These take into account the pressure and driving forces behind the social and economic subsystem, the supporting forces of resources and environment subsystem, and the regulating forces and development potential of the ecological subsystem.

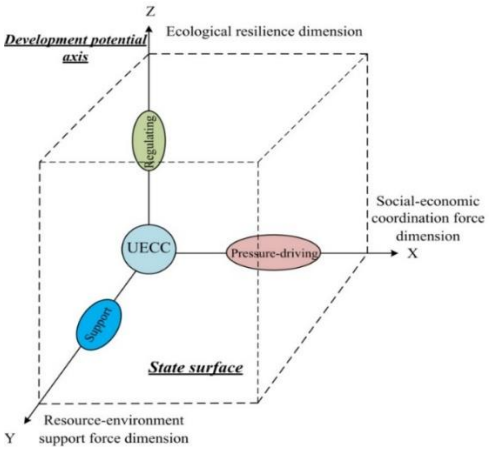

Figure 2. *Framework of urban ecosystem carrying capacity (UECC) assessment*

The composition and functions of the three dimensions of urban ecosystem carrying capacity can be further explained as follows: (1) Social-economic coordination force is the "pressure-driving" part of urban ecosystem carrying capacity. Social and economic coordination force not only reflects unbalanced social development pressure, population bearing pressure, and economic development pressure faced by urban ecosystem, but also reflects driving forces behind social progress, economic improvement, and industrial structure optimization for the overall development of urban ecosystem. (2) Resource-environment supporting force is the supporting and guaranteeing part of urban ecosystem, which reflects the degree of coordination between the supply of regional resource-environment and the demand of social-economic development. (3) Ecological resilience is the regulating part of urban ecosystem, which reflects the regulating power of regional ecological environment, and the development potential generated by human factors acting on the ecological environment.

Index system for urban ecosystem carrying capacity assessment

The purpose of establishing a comprehensive evaluation index system of urban ecosystem carrying capacity is to represent the degree of coordination between the regional socio-economic system and resource-environmental system, and to reflect the carrying capacity of urban complex ecosystem. This paper first considers the component and the structure characteristics of urban ecosystem, takes the impact of human activities as the context, on the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

basis of fully considering the characteristics of the study area, the comprehensive evaluation index system of urban ecosystem carrying capacity is established (*Table 1*). An extensive literature review was instrumental in selecting evaluation indicators. On the one hand, we selected indicators that are generally recognized and widely used by scholars in related fields (Xiong et al., 2013; Jin et al., 2015; Rudolph and Figge, 2017; Ji et al., 2017; Wang et al., 2017; Pei et al., 2019; Rong et al., 2019). On the other hand, we fully considered the impacts of social development and progress, resource consumption and environmental pollution control on urban ecosystem carrying capacity, making this paper somewhat innovative in the construction of index system.

Table 1. *Indicators for urban ecosystem carrying capacity assessment*

System layer	Subsystem layer	Criterion layer	Basic index layer	Properties of index
Urban ecosystem carrying capacity	Social-economic coordination force	Social progress factor	X1: Ratio of annual disposable urban household income to rural household income	Negative
			X2: Ratio of annual urban household comsumption to rural household comsumption	Negative
			X3: Highway passenger volume per capita	Positive
			X4: Hospital beds amount of every 10^4 people	Positive
			X5: Buses and trams amount of every 10^4 people	Positive
		Population development factor	X6: Population density	Moderate
			X7: Natural rate of population growth	Moderate
			X8: Population urbanization rate	Moderate
		Economic development factor	X9: Growth rate of per capita GDP	Moderate
			X10: Energy consumption per 10^4 GDP	Negative
			X11: Per capita GDP	Positive
		Industrial structure factor	X12: The percentage of the primary industry output value	Moderate
			X13: The percentage of the tertiary industry output value	Positive
	Resource-environment supporting force	Resource support factor	X14: Water resources per capita	Positive
			X15: Cultivated area per capita	Positive
		Environmental management factor	X16: Comprehensive utilization rate of industrial solid waste	Positive
			X17: Treatment rate of industrial smoke (powder) dust	Positive
			X18: Standard discharge rate of industrial wastewater	Positive
			X19: Domestic sewage treatment rate	Positive
			X20: Domestic waste treatment rate	Positive
	Ecological resilience	Ecological resilience factor	X21: Forest coverage rate	Positive
			X22: The percentage of wetland area to total area	Positive
			X23: Green coverage rate in built-up area	Positive
			X24: Per capita public green area	Positive
		Ecological potential factor	X25: Per capita investment in science and technology	Positive

Note: data of indicators X3 ~ X13 and X23 ~ X25 are from Jiangxi statistical yearbook of 2016, Hubei statistical yearbook of 2016, and Hunan statistical yearbook of 2016. Data of indicators X16 ~ X20 are from China urban statistical yearbook of 2016 and China urban construction statistical yearbook of 2016. Data of indicators X21 ~ X22 are derived from the data of land use/cover in 2015. Data of indicators X1, X2 , and X15 data are from the prefecture level statistical bulletin. Data of indicator X14 is from the prefecture level water resources bulletin

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

Preprocessing of index data and weight determination

In the process of index data processing, in order to eliminate the possible differences in dimension and magnitude between indices, it was necessary to carry out forward processing and standardized processing of the index data. First, we selected negative indicator for forward processing, referenced the relevant research (Hu et al., 1992), and improved the existing formula, make the value compression after forward processing as $(0,1]$, there will be no height anomalies of $x_{ij}^z = 0$ and avoided the subsequent difficulty of logarithmic operations. The forward processing formula for the negative indicator is:

$$x_{ij}^z = \frac{MAX(x_{ij}) - x_{ij}}{MAX(x_{ij}) - MIN(x_{ij})} + 0.001 \quad \text{(Eq.1)}$$

The forward processing formula for the moderate indicator had not been derived out by existing studies. This study attempts to derive the formula, after verifying several different types of sample data, and found that the dimensionality of the data after the forward calculation by this formula was eliminated. The forward processing formula is as follows:

$$x_{ij}^z = \begin{cases} \frac{1}{\left(1+\left|1-\frac{x_{ij}}{A_i}\right|\right)} & , x_{ij} < A_i \\ \frac{1}{\left(1+\left|\frac{x_{ij}}{A_i}-1\right|\right)} & , \ x_{ij} \geq A_i \end{cases} \quad \text{(Eq.2)}$$

In the above equation (1) and (2): x_{ij} is the original index value, x_{ij}^z is the forward value of the original index, $MAX(x_{ij})$ is the maximum value of the j year and the ith index, $MIN(x_{ij})$ is the minimum value of the j year and the ith index, and A_i is the optimal threshold of the moderate index. By referring to relevant literature (Zhou and Zhao, 2012; Xiao et al., 2013) and consulting experts in relevant fields, the optimal thresholds for GDP growth rate index and the proportion of primary industry in GDP indices were set as 7% and 12.4%, respectively. GDP growth rate and the proportion of the primary industry in GDP were defined as moderate indicators based on the following considerations: (1) Zhou and Zhao (2012) have shown that the GDP growth rate is 7% or lower, which will lead to employment pressure, inflation, and other problems. Therefore, there is an optimal threshold for GDP growth rate. (2) The primary industry usually includes agriculture, forestry, animal husbandry, fishery and other agricultural industries, which provide the basic energy supply for the urban ecosystem. A low proportion of the primary industry affects urban ecosystem stability, while a high proportion is not conducive to the improvement of social and economic coordination. Xiao et al. (2013) pointed out that there is an optimal proportion in the primary industry. In addition, the optimal thresholds for population density, natural population growth rate, and population urbanization rate were set as 600 people /km^2, 5‰ and 60%, respectively, based to relevant research (Li and Li, 2014; Su et al., 2019).

After the forward processing of the negative and moderate indicator, the positive and moderate indicator values were standardized after the forward processing are standardized. In this paper, the maximum and minimum value standardization method was adopted to standardize the data. Considering that the index data in this paper were resources, environment and socio-economic indicators based on the statistics of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

administrative units, the weights of evaluation indicators were determined by the entropy weight method (Ji et al., 2017; Wang et al., 2017). The entropy weight method is an objective weighting method, it can avoid the interference of human subjective factors and make the result have objectivity and higher credibility (Shen et al., 2017).

State-space method

The state space method is an effective method for quantitative describing system state in Euclidean geometry space. It is usually composed of three-dimensional state space axes representing the state vectors of each element of the system. In the three dimensional state space, each point represents the spatial combination of resource-environment and human social-economic activities over a certain period of time, and a specific carrying state of the system can be judged by the position of the points (Ji et al., 2017). The formula for calculating the ideal value (ECC) and the current value (ECS) of urban ecosystem carrying capacity are as follows:

$$ECC = \sqrt{\sum_{i=1}^{n} {w_i}^2} \quad \text{(Eq.3)}$$

$$ECS = \sqrt{\sum_{i=1}^{n} (w_i * x_{ij}^b)^2} \quad \text{(Eq.4)}$$

In *Equations (3) and (4)*, w_i is the index weight, and x_{ij}^b is the ratio coefficient between the original value of each city index and its ideal value (*Table 2*) based on the ratio method according to the differences in the three types of indices. The specific calculation process is shown in *Equation (5)*. The main considerations for determining ideal value of all indices are the sustainability and internal coordination of the urban ecosystem, and experts in related fields were consulted for revision.

$$\begin{cases} x_{ij}^b = \frac{x_{ij}}{I_i}, & \text{Positive indicator} \\ x_{ij}^b = \frac{I_i}{x_{ij}}, & \text{Negative indicator} \\ x_{ij}^b = \begin{cases} \frac{x_{ij}}{A_i}, & x_{ij} \le A_i \\ \frac{A_i}{x_{ij}}, & x_{ij} > A_i \end{cases}, & \text{Moderate indicator} \end{cases} \quad \text{(Eq.5)}$$

Coupling coordination degree model

Referring to the coupling model for capacity in physics, the coupling model for two systems (*Equation (6)*) and three systems (*Equation (7)*) were generalized to explore the coupling coordination relationship between the three dimensions: "social-economy, resource-environment, and ecological resilience" (Xing et al., 2019). The model formula is as follows:

$$C = \left\{ \frac{f(x) \cdot g(y)}{\left[\frac{f(x) + g(y)}{2} \right]^2} \right\}^{\frac{1}{2}} \quad \text{(Eq.6)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

$$C = \left\{ \frac{f(x) \cdot g(y) \cdot h(z)}{\left[\frac{f(x) + g(y) + h(z)}{3} \right]^3} \right\}^{\frac{1}{3}} \quad \text{(Eq.7)}$$

In the formula, *f(x)*, *g(y)* and *h(z)* are respective standardized values of carrying capacity for the three dimensions. *C* is the coupling degree, which ranges from 0-1. Since the coupling degree can only measure the degree of correlation among dimensions, but cannot reflect the coordination level among dimensions, this paper further introduced a coupling coordination degree model, so as to better measure the coupling coordination level among dimensions. The formula is as follows:

$$D = \sqrt{C \cdot T} \quad \text{(Eq.8)}$$

$$T = \alpha f(x) + \beta g(y) + \gamma h(z) \quad \text{(Eq.9)}$$

In *Equations (8) and (9)*, D is the coupling coordination degree ranging from 0-1 and *T* is used to measure the overall synergy between dimensions. α, β, γ are undetermined coefficients representing the contribution of each dimension. We assumed that the three dimensions were equally important to urban ecosystem carrying capacity, so $\alpha = \beta = \gamma = ⅓$.

Results

Evaluation of the urban ecosystem carrying capacity in urban agglomeration in the middle reaches of the Yangtze River

According to the state-space method, the ideal value for urban ecosystem carrying capacity was ECC=0.216, and the ideal value of social-economic coordination force dimension, resource-environment support force dimension and ecological elastic force are 0.154, 0.133 and 0.07, respectively. In order to judge the carrying state of urban ecosystem, the carrying state index is introduced as CSI. According to the principle of state-space method, CSI= ECS-ECC, and when CSI > 0, the system is in a loadable state. When CSI=0, the system is in a fully loaded state. When CSI < 0, the system is overloaded. Based on urban ecosystem carrying capacity, the ideal value of the three dimensions, and the CSI, 28 cities were divided into six state types8: highly loadable area (CSI > 0.05), moderately loadable area (0.02<CSI≤0.05), mildly loadable area (0<CSI≤0.02), fully loaded area (CSI= 0), mildly overloaded area (-0.02≤CSI <0), moderately overloaded area (-0.05< CSI≤ -0.02).

By virtue of the spatial visualization function of ArcGIS10.3 software was used to visualize, the CSI of the urban ecosystem and three dimensions in 2015 was visualized in accordance with the carrying state classification criteria above (*Fig. 3*).

The social-economic coordination force dimension is the "pressure-driven" part of urban ecological carrying capacity. It not only reflects unbalanced social development pressure, population pressure and economic development pressures faced by an urban ecosystem, but also the development ability provided by social progress, economic strength, and industrial optimization. From the perspective of spatial distribution characteristics (*Fig. 3a*), the dimension had a circling spatial structure extending outward from the provincial capitals of Hubei, Hunan, and Jiangxi Provinces.

X25: Per capita investment in science and technology	200	Expert consultation method

As shown in *Figure 3*, the proportion of each carrying state grade in the social-economic coordination force dimension is relatively balanced, but the spatial differentiation was obvious. In detail, light and moderately overload areas were mainly distributed around provincial capitals in Hubei, Hunan and Jiangxi Provinces. This is because the surrounding areas of provincial capitals are in a stage of rapid urbanization, social infrastructure is not perfect, and the urban-rural dual structure is still prominent. In addition, due to poor industrial foundation and undertake capital of core city "three highs" (high pollution, high energy consumption, high emissions) industrial transfer and other reasons, led to a higher proportion of the primary and secondary industries and low economic development efficiency. Low loadable areas were scattered in the central and southeastern parts of the urban agglomeration. Moderately loadable and highly loadable areas were mainly distributed in Xiangyang-Jingmen-Yichang urban belt and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

the provincial capital city. The high carrying capacity of provincial capital city has benefited from good infrastructure, strong economic power, and reasonable industrial structure, which resulted in strong ability of coordination. To some extent, this has also limited the negative impacts due to the large urban population.

The resource-environment supporting force dimension is the supporting and guaranteeing component of urban ecosystem carrying capacity, which reflects the degree of coordination between the supply of regional resource and the demands of social-economic development. From the perspective of spatial distribution characteristics (*Fig. 3b*), the resource-environment support force dimension presents a pattern of north-south differentiation, and it had obvious spatial characteristics of homogeneous agglomeration.

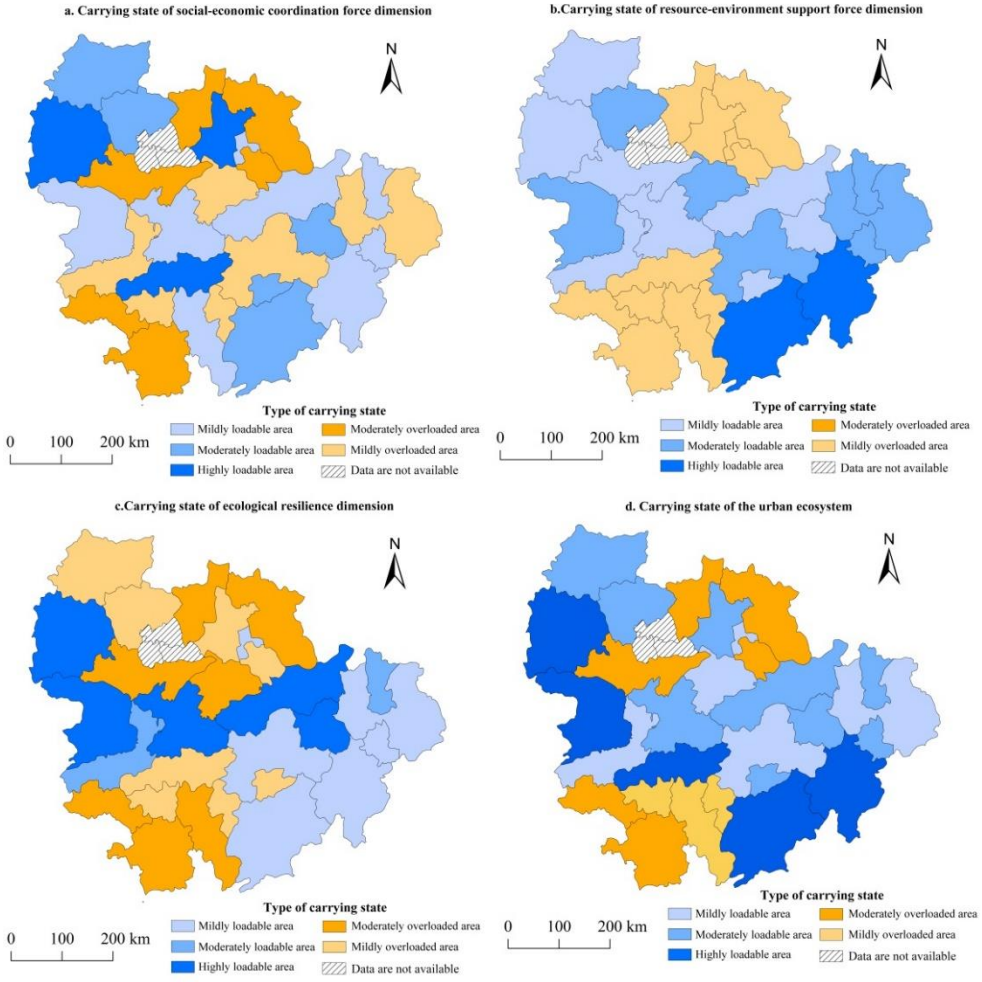

Figure 3. *The spatial pattern of urban ecosystem carrying capacity in the middle reaches of the Yangtze River in 2015*

As shown in *Figure 3*, the proportion of each carrying state grade in the resource-environment supporting force dimension is extremely unequal, and low, medium, and high loadable areas accounted for nearly 65% of the total. In detail, the mildly overload area was mainly distributed in the core area of Wuhan urban agglomeration, and the urban agglomeration around Changsha-Zhuzhou-Xiangtan. The reasons for this are as follows: On

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

the one hand, population clustering and industrial development in these two areas created great resource supply pressure. On the other hand, regional environmental pollution has not attracted enough attention, resulting in serious environmental pollution. The conflicts between accelerated industrialization and resource-environment constraints were prominent. Light and moderately loadable areas were mainly distributed in the Xiangyang-Jingmen-Yichang urban belt, Poyang Lake urban agglomeration, and the area around Dongting Lake. Poyang Lake urban agglomeration and the area around Dongting Lake are rich in natural resources, so the regional resource supply pressure is small. In addition, recent implementation of ecological and environmental protection policies in the region (《Dongting Lake ecological economic zone planning》, 《Poyang Lake ecological urban agglomeration planning (2015-2030)》, and 《Yangtze River economic zone ecological environmental protection planning》) has further improved the control of regional environmental pollution. Xiangyang and Yichang cities have also recently made efforts to build themselves into two major sub-central cities in Hubei Province. The resource and environmental protection in Xiangyang-Jingmen-Yichang urban belt has received great attention, and the regional resource and environmental support level has been continuously improved.

The ecological resilience dimension is the regulating part of urban ecosystem carrying capacity, which reflects the regulating ability of the regional environment and the ecological potential of human acting on the ecological environment. From the perspective of spatial distribution characteristics (*Fig. 3c*), this dimension had a spatial the pattern of north-south differentiation, and it had obvious spatial characteristics of homogeneous agglomeration. As shown in *Figure 3*, the proportion of each carrying status grade was relatively balanced. In detail, light and moderately overload areas were mainly distributed in the core areas of the Wuhan urban agglomeration and the urban agglomeration around Changsha-Zhuzhou-Xiangtan. Light, moderately, and highly loadable areas were mainly distributed around Dongting and Poyang Lakes, and Yichang city in Hubei province. Investigate its reason, the ecological environment conditions of the core region of the Wuhan urban agglomeration and the urban agglomeration around Changsha-Zhuzhou-Xiangtan were worse than the region of Dongting Lake and Poyang Lake, and in recent years, the Wuhan urban agglomeration and the urban agglomeration around Changsha-Zhuzhou-Xiangtan of the rapid advance of urbanization are in the stage of rapid urbanization. The rapid expansion of urban construction area has gradually nibbled away natural elements such as vegetation and wetlands, lowering ecological resilience. Yichang City on the Yangtze River is a national garden, health, and forest city, and the only national model city for environmental protection in Hubei Province. It therefore has great environment background conditions. In addition, Yichang city's economic strength and scientific-technological level are among the highest in Hubei Province with great ecological potential.

Urban ecosystem carrying capacity is a functional status formed by the structural action of the three dimensions, which reflects the comprehensive carrying capacity of urban ecosystem. From the perspective of spatial distribution characteristics (*Fig. 3d*), the carrying capacity of urban ecosystem presents a significant north-south spatial differentiation pattern, and it had obvious spatial characteristics of homogeneous agglomeration. As shown in *Figure 4*, the proportion of each urban ecosystem carrying status grade was extremely unequal, the types of low, moderately and highly loadable areas accounted for nearly 70% of the total, so the overall carrying state of the urban ecosystem in study area was relatively good. In detail, the light and moderately overloaded areas were mainly distributed in the surrounding areas of Wuhan and Changsha. Light, moderately and highly loadable areas

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

were mainly distributed in the Xiangyang-Jingmen-Yichang urban belt, and around Dongting and Poyang Lakes. Investigate its reason, although the resource-environment and ecological resilience dimensions in Wuhan and Changsha were slightly overloaded, the overall urban ecosystem were in a loadable state due to their strong social-economic coordination. In their surrounding areas, all dimensions were mostly in the overload state. Low efficiency economic development, urban-rural dual development structure, ecological destruction, and environmental pollution caused by urban population growth and industrial development are the main causes. Rings of Dongting and Poyang Lakes region, as well as the Xiangyang-Jingmen-Yichang urban belt, benefited from strong resources-environment support force and ecological resilience dimensions. In the future, on the premise of maintaining green economic development and protecting environment, we should focus on optimizing regional social infrastructure, improving economic development efficiency and optimizing industrial structure, so as to improve social-economic coordination force in the region.

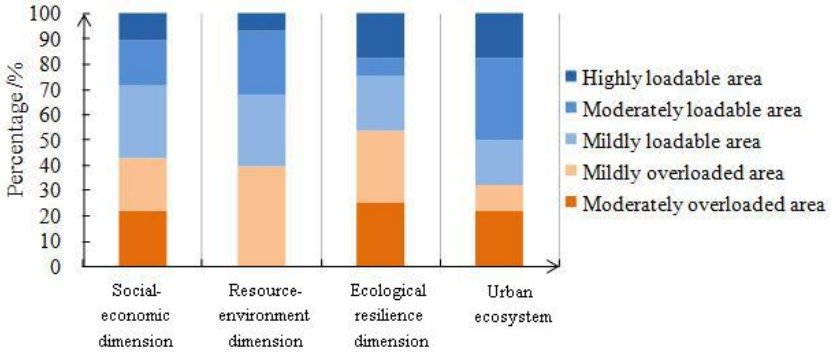

Figure 4. *The percentage of each carrying status in each dimension*

Analysis of coupling coordination among dimensions of urban ecosystem

Evaluating the coupling coordination level between dimensions can reveal the advantages and disadvantages of urban ecological carrying capacity in different regions, and to clarify the direction of development, which are of great significance for regional sustainable development. Because there has been less research on coupling coordination between dimensions, this study adopted a two system model and a three system model to assess coordination between the various dimension, which was visualized using ArcGIS10.3 software (*Fig. 5*).

From the perspective of coupling coordination between socio-economic dimension and resource-environment dimension (*Fig. 5a*), cities with high coupling coordination between socio-economic and resource-environment dimensions were mainly distributed in Xiangyang-Jingmen-Yichang urban belt, southern Jiangxi Province, Wuhan and Changsha. Xiangyang and Yichang in central Hubei Province had strong social development and economic coordination. In addition, as a national garden, health, and ecologically livable city, the area is rich in natural resources and fine environment, so the level of coupling coordination between these two dimensions was relatively high. Wuhan and Changsha, the provincial capitals faced higher population pressure, but had higher society development level, economic strength, and high economic development efficiency. In 2015, for example, tertiary industry proportions in Wuhan, Changsha, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

Nanchang were as high as 51.02%, 45.06%, 41.22%, but average proportions in their surrounding areas were only 33.09%, 35.66%, and 35.77%, so the green economy was prominent. Therefore, the level of coupling coordination between dimensions is high. Low coupling coordination was mainly distributed in the surrounding areas of Wuhan City and southwest of the urban agglomeration around Changsha-Zhuzhou-Xiangtan. The region's social development level and economic strength has largely improved in recent years, but due to poor industrial foundation and undertake "three highs" (high pollution, high energy consumption, high emissions) industrial transfer and so on, it have led to a higher proportion of secondary industries, low economic development efficiency, and weak natural resources and environmental support. Therefore, the level of coupling coordination between dimensions was low. In 2015, for example, the average of primary and secondary industry proportions in the low-value areas around Wuhan and Changsha were as high as 66.91% and 64.34%, respectively.

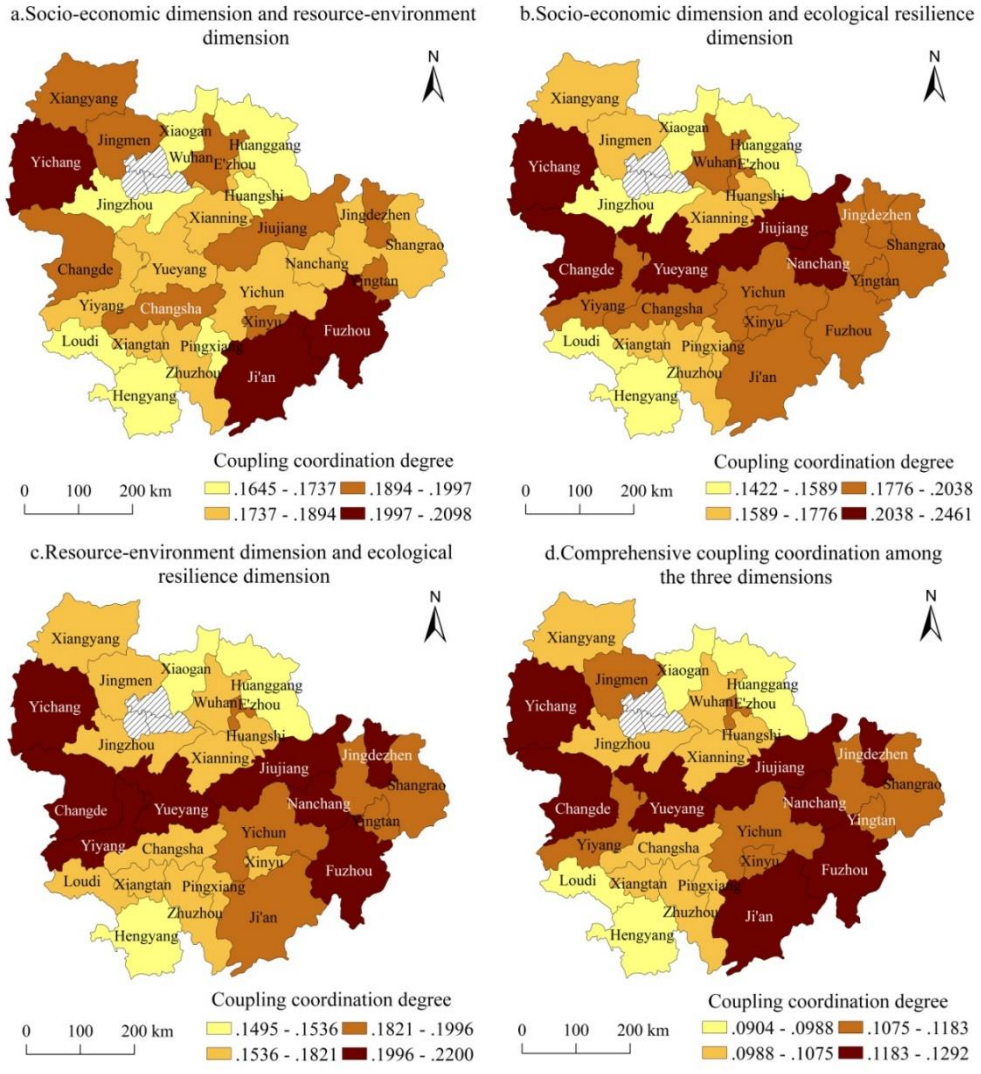

Figure 5. *Spatial distribution of coupling coordination between dimensions in the urban agglomeration in the middle reaches of the Yangtze River in 2015*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

Cities with high coupling coordination between social-economic dimension and ecological resilience dimensions were mainly distributed in the Poyang Lake urban agglomeration, the area around Dongting Lake, and Yichang City (*Fig. 5b*). In recent years, the implementation of environmental protection policies around Poyang and Dongting Lake (《planning of Dongting Lake ecological economic zone》, 《planning of Poyang Lake ecological urban agglomeration (2015-2030)》, 《eco-environmental protection planning of Yangtze River economic zone》), and under the promotion of the new urbanization development planning(《National new urbanization plan of China (2014-2020)》), the region gradually transitioned from previous extensive economic development mode to sustainable development with comprehensive attention to environmental protection and social security. Therefore, coupling coordination between the dimensions of social-economy and ecological resilience dimensions in this region was relatively high. As a sub-central city of Hubei Province, Yichang had strong social-economic coordination force. In addition, as a national garden and ecologically livable city, it also had a high ecological resilience, so there was high coupling coordination between socio-economic and ecological resilience dimensions. Cities with Low coupling coordination were mainly distributed in the surrounding area of Wuhan and southwest of the urban agglomeration around Changsha-Zhuzhou-Xiangtan. The loss of natural elements and environmental pollution caused by human activities in such areas are prominent. In the future, social security, social services, and economic development efficiency should be further improved on the basis of improving the regional ecological resilience and ecological potential, so as to improve urban ecosystem carrying capacity.

Cities with high coupling coordination between resource-environment and ecological resilience dimensions were mainly distributed in the Poyang Lake urban agglomeration and around Dongting Lake (*Fig. 5c*). These regions have strong resource and environmental supporting force. On the other hand, as important ecological protection areas in the Yangtze River Basin, Dongting and Poyang Lake areas have abundant forests, wetlands, and other natural elements, and the region has strong ecological regulating force when facing the interference of external natural and human factors. Therefore, the coupling coordination level between resources-environment and ecological resilience dimensions was relatively high. Areas with low coupling coordination levels were mainly distributed in the Wuhan urban agglomeration and southwest of the urban agglomeration around Changsha-Zhuzhou-Xiangtan. This was because rapid urbanization and extensive economic development in this region had significant impact on land use/cover, biodiversity, the hydrological system, local climate, and other factors at different regional scales that resulted in lower resource-environmental support and ecological resilience than other regions.

From the perspective of comprehensive coupling coordination among the three dimensions (*Fig. 5d*), the level of comprehensive coupling coordination between the three dimensions was generally lower than between any two dimensions. Cities with high coupling coordination were mainly distributed around Dongting Lake and the urban agglomeration around Poyang Lake, while cities with lower levels were mainly distributed in the Wuhan urban agglomeration and southwest of the urban agglomeration around Changsha-Zhuzhou-Xiangtan. Their spatial distributions were similar to the patterns observed between the social-economic and ecological elasticity, and between the social-economic and ecological resilience dimensions, and the resources- environment and ecological resilience dimensions. Investigate its reason, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

three-dimensional carrying capacity levels in the area around Dongting Lake, the urban agglomeration around Poyang Lake, and Yichang City were higher than elsewhere and these areas also had the highest coordination levels. Areas around Wuhan and the southern cities of the urban agglomeration around Changsha-Zhuzhou-Xiangtan have undergone recent improves in the resources-environment dimension, but unbalanced development between urban and rural areas, extensive economic development mode, and the loss of natural elements caused by broad problems, such as low social-economic coordination and ecological resilience, still is the most important reason to resulted in a low level of overall coupling coordination.

Discussion

Index system for urban ecosystem carrying capacity assessment

Urban ecosystem is an on-limits, comprehensive "natural - social - economic" compound ecosystem. On the basis of a deep understanding of the concept and connotation of urban ecosystem carrying capacity, we have established a new assessment framework for urban ecosystem carrying capacity, and constructed a multi-dimensional, multi-index and expanded comprehensive index system of urban ecosystem carrying capacity from macro-scale based on multi-metadata such as earth observation data and socio-economic statistics, it makes up for the lack of comprehensiveness of evaluation system in medium and micro scale research. However, the use of various indicators to represent the urban ecosystem carrying capacity has certain limitations due to the accessibility, representativeness and objectivity of data. For example, urban ecosystem is always in a state of dynamic positive and negative feedback, within the system, system and external environment are continuously carrying on the material flow, energy flow, information flow, and population flow. But in the process of calculating urban ecosystem carrying capacity without considering the interaction of elements and the flow of elements between spatial units, also ignores the transmission effect of urban ecosystem structure, process, and function on urban ecosystem carrying capacity, which is a deficiency in the research (Ji et al., 2017). In future research, we should include more data sources and indicators to improve the accuracy of urban ecosystem carrying capacity assessment. Undoubtedly, although the index system in this paper is not ideal, but it can be easily applied to the rapid urbanization areas of developing countries such as China.

Methodology

The most important step before the evaluation of urban ecosystem carrying capacity is the preprocessing of index data, including forward processing and standardized processing of the index data. Existing studies mainly divided the types of indicators into forward indicator and reverse indicator (Song et al., 2014; Xiong et al., 2016; Ji et al., 2017), but rarely mentioned the moderate type indicator, and the positive treatment formula of the moderate type indicator has not been clearly explained. The contribution of this study is to attempt to deduce a forward processing formula for the moderate type index and scientifically determined the ideal value for each index, which was helpful in using the state-space method to quantitatively evaluate urban ecosystem carrying capacity. However, the forward processing formula for the moderate-type index still needs further improvement in future studies. Determining the ideal value for the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

individual index requires further discussion. In addition, the ideal indicator value was the standard set in a specific year. As time goes by, the ideal value standard will change and should therefore be constantly updated in subsequent research.

In addition to the preprocessing of index data, the determination of index weight is also an important part in the evaluation of urban ecosystem carrying capacity. In the PDSR model of this paper, the determination of multiple index weights is involved. There is no doubt that the weight of indicators will have an important impact on the final results, so its setting is extremely important. Existing studies (Xiong et al., 2016; Peng et al., 2019) mostly adopt objective weighting methods such as entropy weight method, which eliminates the interference of human factors and makes the determination of index weight objective. Therefore, entropy weight method is selected to determine the index weight in this study. In addition, existing studies have shown that spatial interaction between adjacent research units (Shen et al., 2017) should be considered in studies of large regions or urban agglomerations, but some studies pay less attention to spatial effect in the determination of index weight, which needs to be improved in future studies.

Study scale

Spatial extent and spatial resolution are collectively described as the spatial scale (Turner et al., 1989; Xiao et al., 2019). In the study of urban ecological carrying capacity, some research areas are administrative districts and some are natural borders. However, with urban ecosystem carrying capacity plays a more and more importance part in macro ecological decision-making, administrative districts as research unit has become the mainstream (Zeng et al., 2016; Xiao et al., 2019; Su et al., 2019).

In terms of spatial resolution, some researches take remote sensing image pixel as the basic research unit, and then carry out micro-scale researches with the help of remote sensing data. Some studies take county-level or prefecture-level administrative districts as basic research units, and then carry out macro-scale studies with the help of statistical data or multivariate data such as statistical data and remote sensing data. Dialectically, studies at different scales all have their own emphases. Macroscopic scale studies based on macroscopic data or multivariate data are suitable for assessing the carrying capacity of composite urban ecosystem, which is helpful for macro ecological decision-making, but accompanied by the loss of micro-information. The micro-scale research based on remote sensing data is suitable for the assessment of the carrying capacity of a single ecosystem. It can perfectly display the detailed information inside the research area and contribute to the detailed planning of the region. However, the type of ecosystem studied is limited. Therefore, there is no perfect scale for the selection of spatial resolution of ecological carrying capacity, only the most suitable scale. According to the research trend, with the continuous development of the concept and connotation of urban ecosystem carrying capacity, the evaluation index of urban ecosystem carrying capacity has been involved in many fields, such as society, economy, ecological environment, pollution control, environmental protection idea, etc., and the single remote sensing data has long been unable to meet the needs of the latest research. Therefore, it has become the choice of more and more scholars to combine statistical data and remote sensing data to carry out research on urban ecosystem carrying capacity at macro scale.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

Future research direction

At present, the research on ecological carrying capacity has been relatively mature, but the research on urban ecosystem carrying capacity based on complex urban ecosystem is still weak, and many problems need to be further discussed. For example, in this study, the evaluation of urban ecosystem carrying capacity based on state-space method only evaluates the carrying state of urban ecosystem in cross-sectional years. This is because it is very difficult to determine the ideal value of each index in all years, it is unscientific to determine the carrying state of urban ecosystem in all years only by the ideal value of each index in a single year. At present, the evaluation of urban ecological carrying capacity is divided into two categories. Some scholars (Xiong et al., 2014; Ji et al., 2017; Pei et al., 2019) adopted a more flexible method, that is, to compare the change trend of ecological carrying capacity in the same area, in different years or in different regions and in different years through the study of long time series. This method does not determine the carrying state. Another part of scholars (Li and Ma, 2013; Song and Yu, 2014) analyzed the bearing state of urban ecosystem in cross-section years according to the second formula of state-space method. In recent years, many scholars have emphasized that it is of great practical significance to carry out spatio-temporal dynamic analysis and simulation prediction of urban ecosystem carrying capacity from long time series (Zeng et al., 2016; Xiao et al., 2019). Based on this, in future research, we should find a suitable method to determine the ideal value of each index in all years, so as to analyze the changing trend of urban ecosystem carrying state in long time series years, so that we may find more interesting and valuable discoveries.

This study is limited by space and fails to make further analysis on the influencing factors of urban ecosystem carrying capacity, but the research on the influencing factors of urban ecosystem carrying capacity is extremely important, and the results play an important role in guiding the improvement of urban ecosystem carrying capacity in different regions by classification. From the existing research results, future research on the influencing factors of urban ecosystem carrying capacity should focus on the following two aspects. First, in the selection of influencing factors, we should expand the scope of influencing factors and quantify regional policies, environmental protection idea and other factors by questionnaire. Secondly, the interaction between influencing factors and the mechanism of influencing factors should be analyzed in detail.

Conclusion

Multi-source data was used to construct a comprehensive evaluation index system for urban ecosystem carrying capacity. The entropy weight method and state-space method were used to quantitatively evaluate urban ecosystem carrying capacity in the urban agglomeration in the middle reaches of the Yangtze River in 2015. A coupling coordination degree model was then used to analyze the spatial distribution characteristics of coupling coordination degree between dimensions and the reasons for spatial heterogeneity. The conclusions are as follows:

(1) Urban ecosystem carrying capacity in the urban agglomeration in the middle reaches of the Yangtze river presents a significant north-south spatial differentiation pattern, and it had obvious spatial characteristics of homogeneous agglomeration. The social-economic coordination force dimension had a circling spatial structure extending outward from the provincial capitals of Hubei, Hunan, and Jiangxi Provinces. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1516915190

resource-environment supporting force and ecological resilience dimensions had similar spatial patterns. Overloaded area was mainly distributed in core area of the Wuhan urban agglomeration and the urban agglomeration around Changsha-Zhuzhou-Xiangtan, which was mainly caused by large resource supply pressures and environmental loads, as well as the massive loss of natural elements.

(2) Wuhan and Changsha have greater population pressure, but thanks to a higher level of social development, economic strength, and economic development efficiency, so the coupling coordination between the socio-economic and resource-environment dimensions was high. In the surrounding area of Wuhan City and southwest of the urban agglomeration around Changsha-Zhuzhou-Xiangtan had low coupling coordination due to the poor industrial foundation, low economic development efficiency, and heavy resource consumption and environmental load. The spatial distribution characteristics of the coupling coordination between the socio-economic and ecological resilience dimensions were similar to those of the resource-environment and ecological resilience dimensions. The area around Dongting Lake, the urban agglomeration around Poyang lake, and Yichang City all had high levels of coupling coordination.

(3) The cities with higher coordination levels were mainly distributed around Dongting Lake and the urban agglomeration around Poyang Lake, while the cities with lower coordination levels were mainly distributed in the Wuhan urban agglomeration and southwest of the urban agglomeration around Changsha-Zhuzhou-Xiangtan. In these areas, weak social-economic coordination and ecological resilience were caused by the imbalance between urban and rural development, extensive economic development, and the loss of natural elements, which need to be paid more attention in the future.

Acknowledgements. We are very grateful to Yushi Zhou for his great assistance in data processing. We are also very grateful to professor Yaochen Qin and professor Fengxian Lu for their professional advice in this study, Zhixiang Xie for his help in research methods. We would also like to thank the National Natural Science Foundation of China (No. 41671536; No. 41501588) for providing the funding for this research.

Abstract. Deficiency of available phosphorous (P) in soil is one of the major factors that limit plant growth and yield. Microorganisms play an important role to improving available P status in soil by solubilization. Although phosphate solubilizing mechanism is not clearly understood, organic acid production seems to be the main mechanism of P solubilizing. Therefore, present study evaluated the organic acid production potentials of 16 P solubilizing fungal strains (2 *Aspergillus floccosus,* 3 *Aspergillus niger,* 2 *Aspergillus niveus*, 2 *Penicillium oxalicum*, 5 *Penicillium* spp. and 2 *Talaromyces pinophilus* isolates) isolated from soils in Okinawa, Japan to select outstanding strains that could facilitate the P solubilization process. Results revealed that both type and quantity of microbial organic acids production depend on the P sources and fungal strains. The highest quantity of organic acids was found when $Ca_3(PO_4)_2$ was used as substrate followed by $FePO_4$ and $AlPO_4$. Based on the organic acids production potential, *A. niger* (SI-12URAgr) considered as outstanding P solubilizing fungi regardless of substrates followed *P. oxalicum* (SI-6URAgr, SI-16URAgr) and *A. niger* (SI-10URAgr). These strains could have great potential as promising bioresource for efficient P utilization in agricultural production.
Keywords: *phosphorous, organic acids, Aspergillus niger, Penicillium oxalicum, agricultaral production*

Introduction

Phosphorous is the second major nutrient after nitrogen that limits plant growth and yield (Gyaneshwar et al., 2002). This nutrient exists in nature in a variety of organic and inorganic forms. The majority of soils contain insoluble inorganic phosphates, which are of no use to plants unless they are solubilized (Singh et al., 2011). Acidic environment can enhance the solubility of P minerals significantly (Zhen, 2016). This is a feasible pathway to improve the P release from phosphate minerals. Although phosphate solubilizing mechanism is still now not fully understood, the production of organic acids seems to be the main mechanism of P solubilizing (Alam et al., 2002; Siddique and Robinson, 2003). Organic acids also have multiple industrial applications as food additives, pharmaceutical and cosmetic excipients (Sauer et al., 2008). They are fully

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1519115201

degradable molecules and can be used as chemical intermediates or as for the production of biodegradable polymers replacing synthetic chemicals (Sauer et al., 2008).

Many phosphate solubilizing microbes (PSM), including bacteria and fungi have the ability to produce organic acids (Kavanagh, 2011) and they contributes to dissolving insoluble P through the process of acidification, chelation and exchange reaction, thus promotes plant growth (Gerresten, 1948; Singh et al., 2011). Compared to bacteria, phosphate solubilizing fungi (PSF) have ten times higher ability to secrete organic acid (Kavanagh, 2011). Among these, *Aspergillus* spp., *Penicilium* spp., *Talaromyces* spp. and *Eupenicilium* spp. are considered "key organisms" in the P cycle (Jose et al., 2010).

The ability of organic acids production by fungi is basically determined by genes, but it can also be affected by environmental condition (Zhen, 2016). For example, type of phosphate compounds could affect both phosphate solubilization and organic acid production. Previously we isolated phosphate solubilizing fungi from subtropical soils in Okinawa, Japan and studied their potentiality to solubilize different insoluble phosphate compounds. However, organic acid production ability of the fungal strains for different P sources were not documented. Therefore the study evaluated the organic acid production potential of 16 phosphate solubilizing fungal strains isolated from soils in subtropical Okinawa, Japan to select outstanding strains that could facilitate the P solubilization process.

Materials and Methods

Description of the Soil sampling area

The sampling area located at 26.5000°N and 128.0000°E. Its climate is subtropical, temperatures range from 10 to 32°C. Low temperature (10 to 26°C) exists in winter season and higher temperature (27 to 32°C) exists in summer with a humidity level near 100%. The major soil types are dark-red, red and grey soils in this area.

Isolation of phosphate solubilizing fungi

This study was carried out in the Mycology Laboratory, Faculty of Agriculture, University of the Ryukyus, Okinawa, during 2017–2018 under a class II biohazard cabinet (BHC-1306IIA/3B, AIRTECH, Tokyo, Japan) followed to the biosafety classification by National Institute of Infectious Disease of Japan, because of possibilities of including toxic fungal species treated as BSL2 during the isolation. Zero to fifty cm depth soil samples were collected from ten different locations of each soil type in Okinawa using sterile auger. One-hundred-gram soil was taken from each sampling point and it makes a total of 500 g composite sample (five points from each location make one composite sample). The samples were transferred to laboratory in sterile sealed polythene bag under aseptic condition and isolation was done by serial dilution method (Rao, 1982).

Identification of phosphate solubilizing fungi

Morphological identification

The genera of phosphate solubilizing fungal isolates were identified based on the taxonomic keys based on morphologies (Watanabe, 2010). The keys were the colour and tint in colony overs and revers, presence of aerial hyphae, colony surface texture, colony margin and pattern of pigment exudations. Wet mounts prepared from micro culture were mounted in lacto phenol and lacto phenol cotton blue. Microscopic examination and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1519115201

photomicrography were performed with an OLYMPUS BX50 microscopy equipped with image Analysis system (Olympus Corporation, Tokyo, Japan).

Molecular identification

DNA was extracted from one piece of fungal mycelia from a culture incubated at 25°C for 48 h on Sabrouraud medium containing 2% glucose and 1% peptone using a DEXPAT kit (TaKaRa, Japan) to identify the isolates at genetic level (Yamaguchi et al., 2014). Beta- tubulin gene sequences amplified with primers bt2a and bt2b and calmodulin genes amplified with primers CMD5 and CMD6 were determined (Samson et al., 2014). Sequences were analysed by the NCBI BLAST tool to classify and identify closely related fungal sequences. We identified the isolates to the certain species if the BLAST results showed similarity values of 98% or higher. Nucleotide sequences were deposited into DNA data bank of Japan under accession number (*Table 1*).

Table 1. *List of fungal strains with gene bank accession number isolated from different soils in Okinawa, Japan used in this study*

Medium preparation for organic acid production study

Pikoveskaya's (PKV) broth medium consisted of 10.0 g glucose, 5.0 g $Ca_3(PO_4)_2$, 0.5 g $(NH_4)_2SO_4$,0.1 g $MgSO_4 \cdot 7H_2O$, 0.02 g NaCl, 0.02 g KCl, 0.003 g $FeSO_4 \cdot 7H_2O$, 0.003 g $MnSO_4 \cdot H_2O$ 0.5 g yeast extract and 1000 mL distilled water (Pikovskaya, 1948). In this medium $Ca_3(PO_4)_2$ was used as source of insoluble phosphate that was replaced by insoluble $FePO_4$ and $AlPO_4$. The medium was autoclaved at 121^0C for 15 minutes.

DOI: http://dx.doi.org/10.15666/aeer/1706_1519115201

Chloramphenicol (Wako Pure Chemical Corporation, Osaka, Japan) was also used to avoid bacterial growth.

Culturing and preparation of spore suspension

For conducting organic acid production experiment, fungal cultures were made from the re-slanting of pure culture slants that preserved at 4^0C. Sporulated culture slants were selected for preparation of spore suspension. A total volume of 5 ml sterile water with tween 80 (Wako Pure Chemical Corporation, Osaka, Japan) was added in culture slants and the fungal colony surface was lightly scraped by a sterile inoculation loop (Thermo Scientific™, Nunc™ Disposable Loops and Needles, Thermo Scientific™ 251586, Fisher Scientific, Tokyo, Japan).Then cultures were passing through a syringe with a 4×4 cm sheet of a sterile absorbant cotton (Kyualet, Kawamoto Sangyo, Osaka,Japan). Spore count was done by a hemocytometer and the suspension was adjusted to approximately10^6 spores mL^{-1}.

Incubation

The experiments were carried out using Erlenmeyer flask containing 40 ml Pikoveskaya's (PKV) broth medium supplemented with 0.5% tricalcium phosphate [$Ca_3(PO_4)_2$], aluminium phosphate ($AlPO_4$) and iron phosphate ($FePO_4$). After sterilization, the medium of each flask was inoculated with the 5% (v/v) spore suspension of a particular fungal strain containing 10^6 spore mL^{-1}. Sterile distilled water inoculated flaks was treated as control (*Fig. 1.*).

Figure 1. *Farmented Pikovskaya broth culture for organic acid determination by HPLC inoculated with 16 phosphate solubilizing fungal strains*

Three replicates were maintained for each test isolate. Incubation was done at 25^0C in an incubator shaker at 120 rpm up to 7 days. The samples were autoclaved and centrifuged at 5000 rpm for 25 minutes to remove any suspended solids and mycelial parts. The culture supernatants were filtered through 0.22 µm pore size syringe filter unit (Merck KGaA, Darmstadt, Germany).

Detection and quantification of organic acids

Detection and quantification of organic acids were done by High Performance Liquid chromatography (Prominence HPLC system, Shimadzu-CBM-20A, Japan) equipped with diode array detector (SPD-M20A), refractive index detector (RID-10A), column ICE-ION-300 (300 mmX7.8 mm), auto sampler (LC-20AD) and fraction collector (FRC-10A). The injection volume, temperature and flow rate was 50 µl, 50°C and 0.5 ml/min, respectively. Sulfuric acid of 0.01N was used as solvent of mobile phase. Peaks were identified against a set of standards from known organic acids (oxalic, citric, tartaric, malic, lactic, formic and acetic acid).

DOI: http://dx.doi.org/10.15666/aeer/1706_1519115201

Statistical analysis

All experiments were conducted in triplicate and data were analyzed using Microsoft Excel program (version 2016). The mean values were compared by Dancan`s Multiple Range Test and significant differences were detected at $p<0.05$ level.

Results

We detected and quantified seven different organic acids from medium containing insoluble tricalcium phosphate (TCP), aluminium phosphate (Al-P) and iron phosphate (Fe-P). Acids were oxalic, citric, tartaric, malic, lactic, formic and acetic acid. Fungal strains showed significant variation to organic acid production based on phosphate substrates. Detail results presented below under specific headlines.

Organic acid production by fungal strains in TCP [$Ca_3(PO_4)_2$] supplemented medium

All the strains produced oxalic acids and lactic acids. The amount ranged from 2.3-342.0 and 26.3-320.7 µg/ml, respectively. Except SI-3URAgr and SI-5URAgr, other strains produced malic acid ranged from 22.7-139.7 µg/ml, whereas both citric acid and tartaric acid were released by the strains SI-6URAgr, SI-7URAgr, SI-8URAgr, SI-9URAgr, SI-10URAgr, SI-11URAgr, SI-12URAgr, SI-14URAgr and SI-16URAgr. The produced citric acid ranged from 3.0-566.7 and tartaric acid was 1.7-27.3 µg/ml. SI-5URAgr produced citric acid and SI-2URAgr, SI-3URAgr and SI-13URAgr produced tartaric acids. Most of the strains produced formic acid except SI-4URAgr, SI-7URAgr, SI-8URAgr, SI-9URAgr, SI-15URAgr, and most of the strains produced acetic acid except SI-2URAgr, SI-3URAgr, SI-5URAgr and SI-8URAgr. It was ranged from 16.7-1102.7 µg/ml and 9.7-2812.3 µg/ml, respectively. The highest amount of oxalic (342.0 µg/ml), citric (566.7 µg/ml), tartaric (173.3 µg/ml), malic (139.7 µg/ml), lactic (320.7 µg/ml), formic (1102.7 µg/ml) and acetic (2812.3 µg/ml) acids were produced from TCP containing broth by the strain SI-11URAgr, SI-7URAgr, SI-16URAgr, SI-2URAgr, SI-12URAgr, SI-13URAgr and SI-12URAgr, respectively (*Table 2*).

Organic acid production by fungal strains in Al-P ($AlPO_4$) supplimented medium

In aluminium phosphate (Al-P) supplimented medium, most of the strains produced oxalic acid, tartaric acid, malic acid and lactic acid ranged from 3.0-461.3 µg/ml, 3.0-461.3 µg/ml, 16.0-198.0 µg/ml and 5.7-119.0 µg/ml, respectively. The strain SI-2URAgr and SI-8URAgr could not produce oxalic acid and SI-2URAgr, SI-4URAgr and SI-15URAgr could not produce tartaric acids. Only SI-5URAgr could not produce both tartaric and malic acids. The citric acid was produced by most of the fungal strain ranged from 3.7-367.7 µg/ml except the strains SI-2URAgr, SI-3URAgr, SI-4URAgr, SI-5URAgr, SI-14URAgr and SI-15URAgr. Both formic and acetic acids were not detected from the culture filtrate of SI-2URAgr, SI-4URAgr, SI-8URAgr and SI-9URAgr. SI-7URAgr. SI-15URAgr could not produce formic acid. The highest amount of oxalic (461.3 µg/ml), citric (367.7 µg/ml), tartaric (61.0 µg/ml), malic (198.0 µg/ml), lactic (119.0 µg/ml), formic (1313.7 µg/ml) and acetic (1556.0 µg/ml) acids were produced from Al-P containing broth by the strain SI-12URAgr, SI-9URAgr, SI-12URAgr, SI-7URAgr, SI-11URAgr, SI-13 URAgr and SI-6URAgr, respectively (*Table 3*).

Organic acid production by fungal strains in Fe-P ($FePO_4$) supplemented medium

In iron phosphate (Fe-P) supplimented medium, all strains showed the production of tartaric acid (11.3-408.3 µg/ml), malic acid (12.0-383.0 µg/ml), lactic acid (2.7-88 µg/ml) and formic acid (8.3-1082.0 µg/ml), whereas SI-5URAgr did not produce lactic acid. The oxalic acid was produced (1.5-811.0 µg/ml) by the strain SI-4URAgr, SI-9URAgr, SI-11URAgr and SI-12URAgr. Strains SI-3URAgr, SI-5URAgr, SI-7URAgr, SI-10URAgr, SI-11URAgr, SI-12URAgr SI-15URAgr and SI-16URAgr produced both citric and acetic acids, whereas SI-2URAgr, SI-13URAgr produced citric acid, SI-9URAgr and SI-14URAgr produced acetic acid. The highest amount of oxalic (811.0 µg/ml), citric (955.7 µg/ml), tartaric (408.3 µg/ml), malic (383.3.0 µg/ml), lactic (88.0 µg/ml), formic (1082.7 µg/ml) and acetic (342.3 µg/ml) acids were produced from Fe-P containing medium by the strain SI-10URAgr, SI-12URAgr, SI-13URAgr, SI-10URAgr, SI-4URAgr, SI-13 and SI-12URAgr, respectively (*Table 4*).

Comparison of quantities of organic acids produced by 16 fungal strains in different P substrates

In this study, the strongest organic acid production ability of fungal strains was found in medium containing tri-calcium phosphate (TCP) followed by iron phosphate (Fe-P) and aluminium phosphate (Al-P). The produced organic acid ranged between

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1519115201

102.0-3630.0 µg/ml, 22.3-2486.9 µg/ml and 118.7-1803.3 µg/ml in the medium supplemented with TCP, Al-P and Fe-P, respectively. Among the fungal strains, the highest amount of organic acids was produced by *Aspergillus niger* strain SI-12URAgr (3630.7 µg/ml) in the medium supplemented with TCP followed by *Penicillium oxalicum* strain SI-6URAgr (2492.3 µg/ml) and SI-16URAgr (2346.7 µg/ml) in Al-P medium and *Aspergillus niger* strain SI-10URAgr (1803.0 µg/ml) in Fe-P medium. These strains were considered as outstanding because this quantity of organic acids was higher than sum of the mean and standard deviation of the total quantities of organic acids produced by 16 fungal strains in this study (*Table 5*). HPLC chromatograms of outstanding fungal strains shown in (*Fig. 2*).

Discussion

The sixteen P solubilizing fungal strains used in this study were isolated from different soils in Okinawa, Japan under subtropical environment. The isolates were identified as the genera of *Aspergillus, Penicilium* and *Talaromyces* (Islam et al., 2019). Both type and the quantity of organic acids produced by fugal strains varied with the nature of phosphate substrates and fungal strains. In this study, acetic, lactic and formic acids were the major acids in TCP medium, oxalic, citric, malic, tartaric and acetic acids in Fe-P medium, and formic, lactic, malic and citric acids in Al-P medium. Fungal strains produced the highest amount of organic acids in TCP supplimented medium

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1519115201

followed by Fe-P and Al-P. It might be the result of interaction between fungal strains and the P sources. Zang et al. (2018) and Scervino et al. (2013) reported that the quantity of organic acid produce by fungi differed with the nature of phosphate substrates. Another point is that organic acid production by microorganism depends on their genetic variation and each strain has specific ability of producing organic acid during the P solubilization (Protiva et al., 2009).

Organic acid calculated as micrograms per milliliter

Present study showed that *A. niger,* strain SI-12URAgr have the strongest organic acid production ability regardless of P substrates. Isolates *P. oxalicum* (SI-6URAgr and SI-16URAgr) produced higher amount of organic acids in the medium supplemented with TCP and Al-P. Whereas, *A. niger* SI-10URAgr and *A. flucossus* SI-14URAgr were capable to produce organic acids in the medium supplemented with Fe-P. In our previous study *A. niger* (strain SI-10URAgr, SI-11URAgr and SI-12URAgr) considered as the outstanding P solubilizing fungi due to their high capabilities to solubilized three insoluble phosphate compounds by decreasing pH of the culture medium (Islam et al., 2019). It suggested that higher amount of microbial organic acids were produced during P solubilization that accelarate the solubilization process by providing protons and complexing anions, or ligand exchange reactions or complexion of metal ions release to solution (Zang et al., 2018). The solubilization of P mostly depended on the amount of organic acids production by fungi (Bo et al., 2011). They also reported that tricarboxylic acids such as citric acid, oxalic acid, malic acid, formic acids and other lower molecular

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1519115201

weight organic acids are the main contributors to solubilization of phosphate and decrease pH in the medium.

Among the filamentous fungi, *Aspergillus* are prominent for higher concentrations of a variety of organic acid production (Liaud, 2014). The fungi of genus *Aspergillus* are widely used for the industrial production of bio-based products, including enzymes and organic acids (Yang et al., 2017). In fact, *A. niger* has been regarded as the workhorse microorganism for the industrial production of organic acids (Show et al., 2015). These acids contributed to P solubilization (Silva et al., 2014; Li et al., 2016). Besides *A. niger* species, *P. oxalicum* also showed an excellent organic acid production ability in the medium supplemented with TCP and Al-P. This fungal species is important in food and drug production (https://en.wikipedia.org/wiki/Penicillium_ oxalicum). Some members of the genus produce penicillin (https://en.wikipedia.org/ wiki/Penicillium). The molecule penicilin is used as an antibiotic.

TCP: tricalcium phosphate; Al-P: aluminium phosphate and Fe-P: iron phosphate.
An asterisk (*) indicated outstanding values of produced organic acid. It was higher than sum of the mean and standard deviation of organic acid produced by 16 fungal strains. It also indicated the best substrate for organic acid production

Conclusions

From the above discussion it can be concluded that both type and quantity of microbial organic acid production depended on the P sources and fungal species/strains. All the fungi produced more organic acids in TCP medium compared to $FePO_4$ and $AlPO_4$ supplemented medium, which contributed to P solubilization. Among the isolates, *A. niger* (SI-12URAgr) considered as outstanding P solubilizer based on

organic acids production potential regardless of substrates followed *P. oxalicum* (SI-6URAgr, SI-16URAgr) and *A. niger* (SI-10URAgr). These strains could have great potential as promising bioresource for efficient P utilization in agricultural production. Future experiment is necessary to evaluate the performance of the outstanding strains on growth and yield of plant in the soils contain insoluble phosphates.

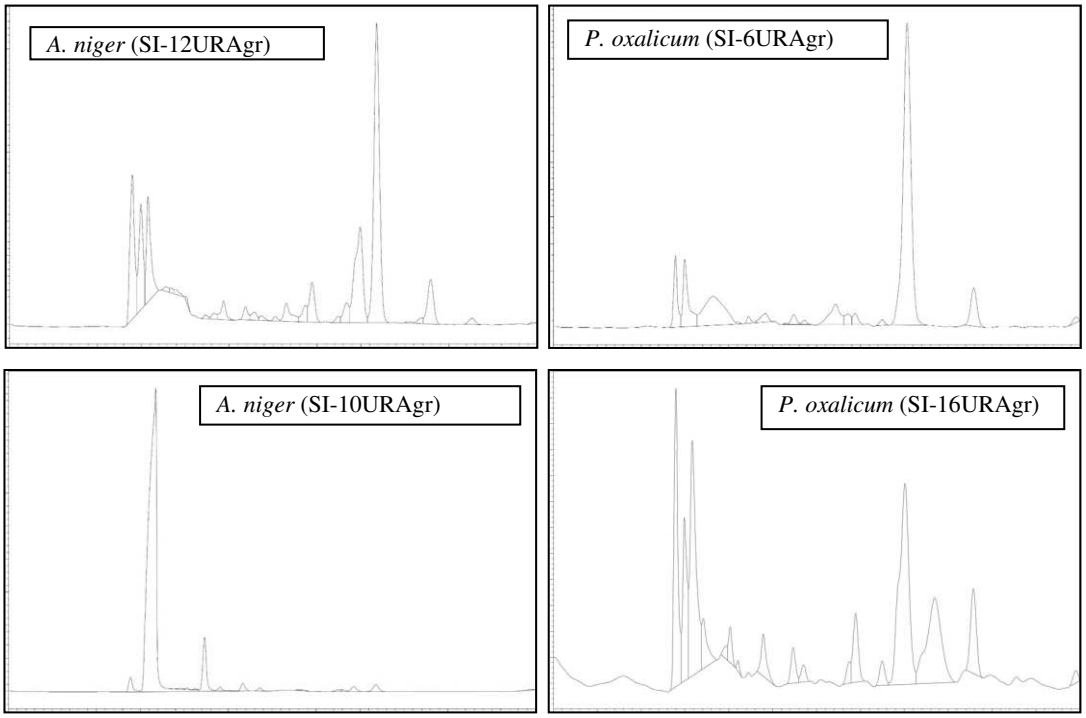

Figure 2. *Chromatograms of organic acids analyzed by HPLC. The acids were produced by outstanding P solubilizing fungal strains [A. niger (SI-12URAgr), P. oxalicum (SI-6URAgr, SI-16URAgr) and A. niger (SI-10URAgr)]*

(Received 1st Jul 2019; accepted 25th Oct 2019)

Abstract. This study was carried out under the ecological conditions of three locations in Turkey (Bilecik, Sivas and Bingol) during 2016 aiming to investigate the variations in yield and yield components of common vetch and to evaluate in different environmental conditions the best performing genotypes using the GGE Biplot analysis. 5 lines and 8 commercial cultivars were used as plant material. GGE biplot analysis concluded that plant height, forage yield, biological yield and straw yield were included in component 1. Dicle genotype was found superior in terms of forage yield and dry matter yield, while Kralkizi genotype reflected its potential for biological and straw yield. Findings of this study are suggesting that the common vetch, plant height, forage yield, biologic yield, straw yield are important traits and can be used as selection criteria for the evaluation of best performing common vetch genotypes.
Keywords: *common vetch, Vicia sativa, genotype, yields, environment, genotype x environment interactions*

Introduction

Turkey is one of the world's biodiversity centre and considered origin and domestication center for various crops, thanks to its geographic (Arystanbekkyzy et al., 2019; Nadeem et al., 2018), containing 20.5 million hectares of processed agricultural land and forage crops are cultivated on an area of 1.8 million ha (TUIK, 2013). Among the various cultivated forage crops in Turkey, common vetch is considered to be the 2nd most cultivated forage crop after clovers covering 499 thousand ha of (629 thousand ha) plantation area. However, it is observed that this increase in the area of forage crops is not sufficient to meet the demands for roughage of Turkish farm animals (Acar et al., 2015). Besides this, low average meat and milk yields and quality of animal products is low here in Turkey (Yucel et al., 2008). However, according to Gokkus and Koc (1996), field residues are not enough to meet with roughage needs for the whole country. In order to reduce feed gap and decrease fallow fields, it is necessary to increase the cultivation area of forage crops.

In order to feed our animals with high quality feed, and to prevent excessive and early grazing of meadows and pastures, the production of forage crops should be given

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1520315217

great importance. Therefore, it is necessary to increase the cultivation area of forage crops, to explain the benefits and importance of these crops, to encourage cultivation, initiate breeding activities for these crops to develop new improved varieties superior in quality and yield (Ozkose and Ekiz, 2005; Ayasan, 2010).

Common vetch (*Vicia sativa* L.), which is one of the most important forage crops and serving a source of feed for animals all around the world, is an important species of *Vicia* genus containing a total of 150 species (Tosun, 1974). According to Elci and Acikgoz (1993), Turkey is rich with the flora of this genus and a total of 59 *Vicia* species can be found in Turkey. However, less efforts has been done for the breeding of this important forage crop and only 14 commercial cultivars have been released in Turkey. One of the most important goals in agriculture is to obtain more products or yield from the unit area. In order to achieve this, it is necessary to develop new lines or varieties with superior efficiency or to determine the performance of those developed in other regions in the region (Kokten, 2011).

Vetch plant, which can be used in both grass and grain, has a short period of vegetation, can grow in almost all types of soils and climatic conditions. Vetch grains with protein content of more than 20% are broken into animals as concentrated feed. In addition, the remaining straw from the harvested plants for grain yield is a good animal feed (Acikgoz, 2001).

Genotype x environment interactions (GEI) is considered one of the main area of study for the plant breeders working on for many years. A variety of methods have been developed to characterize the behaviour of varieties under different environmental conditions. Yield trials under different environments give information about the GEI when analyzed by traditional methods, while they do not give any information about the stability measurements of genotypes. Therefore, various methods have been developed to determine the performance of the genotypes under these environments. The most important of these methods is to determine the stable genotype by stability analysis (Kilic et al., 2003).

Yield is a complex trait that depends on many other features and is largely influenced by environmental factors. However, farming community demands stable varieties with higher yield, but a little fluctuation in the performance of such varieties have been also observed when they grow in various environments. Therefore information resulted by GEI can be very beneficial in the introduction of new plant varieties in plant breeding programs (Sayar et al., 2013; Kendal and Dogan, 2015).

Understanding the relationship between plant performance and environment has been an important topic for plant breeders and geneticists (Yan, 2001). Product performance is a function of genotype (G), environment (E) and an interaction of both, which occur when different phenotypes, different varieties or genotypes react differently to different environments. However, the main effect of environment is not related to the evaluation of varieties. Only genotypes and GEI are important and therefore environmental impacts should be removed from data and focused on genotypes and GEI (Gauch and Zobel, 1996). GGE is the contraction of genotype + GE; The GGE of a MET dataset can be displayed in a GGE pair that allows the researcher to concentrate on the part of the MET data most useful in the evaluation of varieties. Various statistical methods have been proposed to investigate the impact of GE interaction and to use the positive part of the variety development process (Flores et al., 1998). However, not all of these methods are always effective in the analysis of GEI of multi environment/years data sets in plant breeding programs (Sabaghnia et al., 2006). This procedure enables plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1520315217

breeders to investigate the performance of genotypes under different environments and helped to evaluate the most stable genotypes as well.

The aim of this study is to evaluate the yield and yield components of common vetch genotypes in Bilecik, Sivas and Bingol ecological conditions by using GGE Biplot analysis method and to determine the performance of these common vetch genotypes in different environments.

Materials and methods

This study was conducted in three different ecological conditions of Turkey: Bilecik, Sivas and Bingol during 2016. The GPS coordinates of these locations are Bilecik: 40° 0' 57.7728" and 30° 10' 52.6692", Sivas: 39° 42' 20.9592" and 37° 1' 56.1108", Bingol: 38° 53' 47.5620" and 40° 29' 25.9836". The research was established in randomized complete blocks design combined over location with three replications. In this study, locations were random factor and genotype were considered as fixed factor. During this study 5 lines named Hat-1, Hat-7, Hat-8, Hat-13, and Hat-17 developed by Bingol University Faculty of Agriculture Field Crops Department and 8 commercial cultivary mainly used in Turkey named Kralkizi, Dicle, Gorkem, Ozveren, Cumhuriyet-99, Yucel, Alinoglu, and Kubilay common vetch cultivar were used as plant materials. Simultaneous field experiments were conducted at the Bingol University Faculty of Agriculture, Research and Application Department, Cumhuriyet University, Sivas Vocational High School Herbal and Animal Program Research Area and Bilecik Şeyh Edebali University Agricultural and Natural Sciences Research and Application Field in October. In the experiment, the parcel dimensions were set as 3 replications according to the randomized block trial design with a row length of 5 m, row between 30 cm row and 4-5 cm. Fertilized with 3 kg N da^{-1} and 5 kg P_2O_5 da^{-1} with sowing.

The soil properties of the environments where the research was conducted are given in *Table 1*.

Table 1. *Some physical and chemical properties of soils*

Environment 1 (Bilecik)

When *Table 1* is examined, the trial area of Bilecik location is sandy, loamy, moderate alkaline (8.11) and medium salted (0.26%). Moreover, the amount of lime (7.3%) and the amount of organic matter (1.5%) is moderate and the amount of phosphorus (3.5 kg da^{-1}) and potassium (1.1 kg da^{-1}) is low and the micro element content is sufficient. The soil of the trial site of the Sivas location is low phosphorus (3.4 kg da^{-1}), slightly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1520315217

alkaline (7.28), low in organic matter content (1.7%), salty (19.6%) and silty (19.6%). The contents of potassium (K_2O) are high (93.59 kg da^{-1}), micro element contents are generally sufficient. The soil of the trial area of Bingol location is slightly acidic (6.37) without salt (0.0006%), organic matter is less (1.26%), less calcareous, potassium is less (24.45 kg da^{-1}) phosphorus medium (7.9 kg da^{-1}) level is seen.

The climate data of the environments in which the experiment was conducted are given in *Figures 1, 2* and *3*. When the figures are analyzed, it is seen that the average temperature, total precipitation and relative humidity are quite different from each other.

When the sub-fruits of the plants began to mature (about 120-150 days after sowing), the morphological and phenological observations of the plant were taken and the half of the parcel was cut to calculate the green grass yield (according to the Technical Instructions established on the basis of UPOV criteria of the Seed Registration and Certification Directorate). During the harvesting of green grass, 500 g samples of each parcel were taken and dried in a drying oven at 70 °C for 48 h at a constant weight and weighed and dry matter weight was calculated.

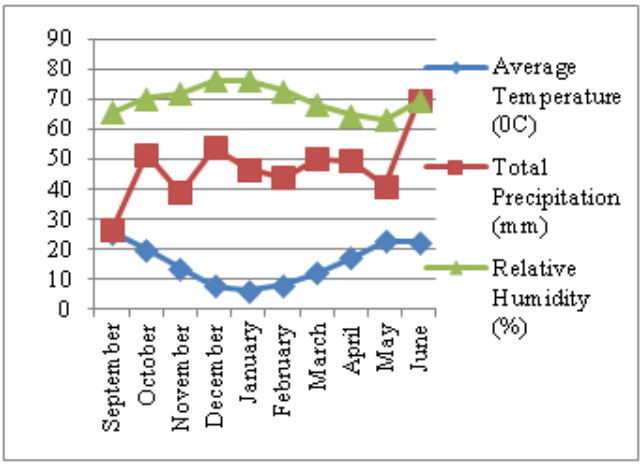

Figure 1. *Climate data of 2016-17 period for the first environment (Bilecik) where the experiment was conducted*

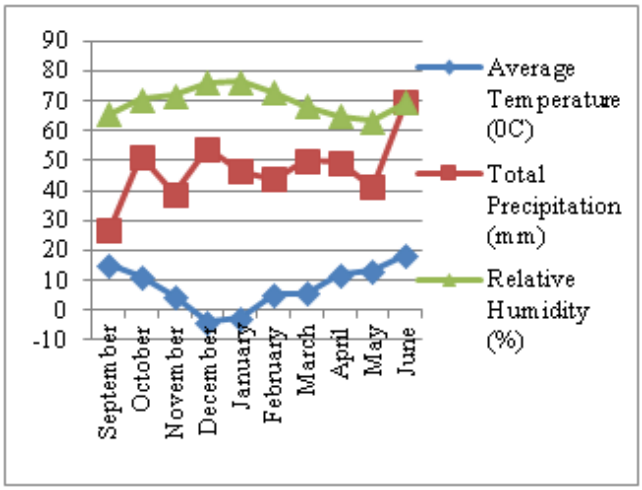

Figure 2. *Climate data of 2016-17 period for the second environment (Sivas) where the experiment was conducted*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1520315217

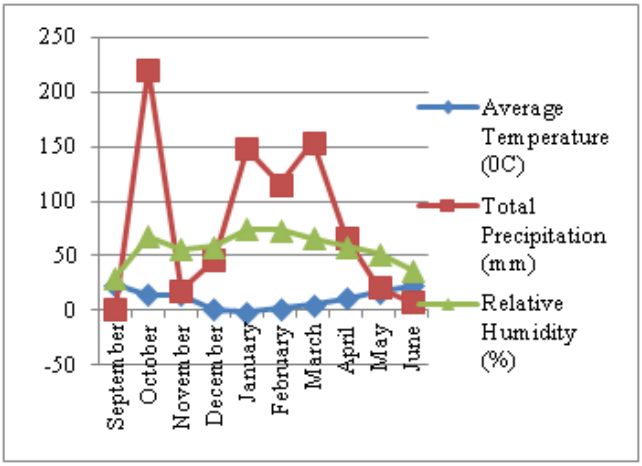

Figure 3. *Climate data of 2016-17 period for the 3 rd environment (Bingöl) where the experiment was conducted*

Seed yield and yield components were made during the period when the plants were completely yellow (about 180-200 days after sowing). The number of pods per plant (pieces/plant), the number of pods in this plant, the seeds of these beans were divided and counted, and the number of seeds (pieces) in pods was found. Then the whole of the parcels was weighed and the biological yield (kg da^{-1}) was calculated, the grains were blended and weighed and the seed yield (kg da^{-1}) was found. Straw yield (kg da-1) was calculated by removing seed yield from biological yield. However, harvest index (%): seed yield × 100/biological yield as calculated. By multiplying the weights of 100 seeds taken from each repetition 4 by 10, the seeds of each species were determined with a weight of 1000 grains.

Data processing

The findings obtained from the study were subjected to variance analysis by using MstatC program. Duncan test was used to determine whether the difference between the averages is significant. Biplot (Genotype + GxE interaction) model analysis was performed using SPSS-16 packet program.

Results and discussion

In this study; values for various observed traits are presented in *Table 2* and statistically significant differences between the lines and varieties in terms of natural plant height in all three locations were observed. Maximum plant height at Bilecik location was obtained from Kralkizi genotype with a value of 49.10 cm, and the shortest plant height was obtained from Kubilay genotype with a value of 22.67 cm. At the Bingol and Sivas locations, maximum plant height was resulted by Dicle genotype with the values of 52.47 and 54.13 cm, respectively, while the minimum plant height was obtained from the Hat-7 genotype with 38.33 and 39.77 cm respectively. In Sivas, high rainfall (154.8 mm) and high relative humidity (66.0%), especially in May, increased the plant height, so the plant height in Sivas was higher than other locations. The average plant height of the common vetch lines and varieties were not found to be statistically significant. Mean plant height ranged between 35.46 and 50.42 cm during

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1520315217

this study. The study conducted by Kokten (2011) in Bingol dry conditions showed that the average plant height of the common vetch lines and varieties was 22.4 cm. Although these results are different from our study, however results of this study made a strong agreement with the findings of Seydosoglu (2014) using the vetch genotypes and conducted experiment in same province and resulted plant height 33.9-62.6 cm.

In the same column, the averages indicated by similar group of letters are not different from Duncan (5%)

In terms of the numbers of pods per plant, statistically significant differences were observed between the lines and varieties at all three locations. In Bilecik, Bingol and Sivas locations, the highest numbers of pods per plant was obtained from Hat-7 genotype with 34.30, 29.73 and 35.00 values respectively, while the lowest numbers of pods per plant was found at Bilecik location; 10.53 value byHat-17 genotype, Bingol location; It was obtained from the Kralkizi genotype with 10.47 and the Ozveren genotype with 6.67 in Sivas location. The average of numbers of pods per plant by common vetch lines and varieties was found to be statistically significant, while the numbers of pods per plant was obtained from the genus Hat-7 with a value of 33.01, while the lowest numbers of pods per plant was obtained from Ozveren genotype with a value of 11.51. In addition, the interaction of locations and location x genotype was found to be statistically significant. The highest numbers of pods per plant in Bilecik (17.87 units) was obtained, followed by Bingol location (15.05 units) and the lowest numbers of pods per plant were obtained from Sivas (13.90 units).

Statistically significant differences for number of seed per pod between the lines and varieties were observed in Bingol location. However, there were no statistically significant differences between the lines and varieties in the locations of Bilecik and Sivas. In the location of Bilecik; number of seed per pod ranged from 4.53 to 6.43. In Sivas, number of seed per pod varied between 3.33 and 6.40. In Bingol location, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1520315217

highest number of seed per pod was obtained from Selcuk genotype with a value of 5.37, while the number of seed per pod was obtained from the Cumhuriyet-99 genotype with a value of 2.97. In addition, while the averages of the locations were statistically insignificant, the interaction of locations and location x genotype was found to be statistically significant. The highest number of seed per pod was obtained in Bilecik (5.70), followed by Sivas (4.88) and the lowest seed number per pod were obtained from Bingol (4.15).

Higher temperature with greater relative humidity at the Bilecik location during the period of study resulted in maximum number of pods and the number of seeds in the pods to be higher than the other locations. In addition, as Fehr (1987) stated, it is natural for the study to be different because of the opinion that the environment can have different effects on the same species and variety and differences in their performances can be observed.

Albayrak et al. (2004) used various vetch varieties and lines by conducting multi location experiments and resulted number of seeds per pod for varieties 6.11-8.44 and 5.44 to 7.22 for lines. Seydosoglu, in his study in 2014 founded seed number per pod in a range of 13.5-21.2, the seed number per pod varies between 4.7-5.6 units (Seydosoglu, 2014). These studies seem to be in harmony with our work.

The average value of forage yield and dry matter yield obtained from common vetch lines and varieties used in Bilecik, Bingol and Sivas locations are presented in *Table 3*.

Table 3. *Bilecik, Sivas and Bingol ecological conditions obtained from different common vetch genotypes, environment, and those interactions of average values of forage yield and dry matter yield*

Genotypes	Forage yield (kg da^{-1})				Dry matter yield (kg da^{-1})

In the same column, the averages indicated by similar group of letters are not different from Duncan (5%)

As seen in *Table 3,* there are statistically significant differences between genotypes in all three locations in terms of forage yield, and it is also observable that there are no statistical differences in the averages where the locations are combined. In addition, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1520315217

interaction of locations and GEI was found to be statistically significant. The highest forage yield was obtained from the Kralkizi genotype with a value of 3733.30 kg da^{-1}, while the lowest forage yield was obtained from the Kubilay genotype with a value of 2630.00 kg da^{-1}. In Bingol and Sivas, respectively, it was obtained from Dicle genotype with 932.53 and 1172.87 kg da^{-1} values, and the lowest forage yield was obtained from Kralkizi genotype with 412.67 and 653.10 kg da^{-1} values. On average, the forage yield varied between 1487.28 and 1835.14 kg da^{-1}. In addition, the highest forage yield was obtained from Bilecik (3200.26 kg da^{-1}), while the lowest forage yield was obtained from Bingol location (714.00 kg da^{-1}).

High temperature with greater relative humidity during the study periods at Bilecik location resulted in higher forage yield as compared to rest of locations. It can be seen that environmental differences such as temperature, relative humidity and precipitation have caused the efficiency of common vetch genotypes to be different in the locations where the study was conducted. According to Gramsh (1982), performance of vetch varieties for forage yield is largely dependent upon the region and its climatic conditions.

In terms of dry matter yield; statistically significant differences between genotypes in all three locations were observed, and it was found that there were no statistical differences in the averages of all the locations when combined. In addition, genotypes and GEI was found to be statistically significant. The highest dry matter yield was obtained from the Dicle genotype with the values of 1107.13, 217.83 and 355.57 kg da^{-1} in Bilecik, Bingol and Sivas locations, respectively, the lowest dry matter yield in the Bilecik location, the Kubilay genotype with 528.77 kg da^{-1} value, Bingol and Sivas and 92.32 and 230.37 kg da^{-1} respectively. On average, the dry matter yields varied between 325.18 and 560.18 kg da^{-1}. In addition, the highest dry matter yield was obtained from the Bilecik location (820.50 kg da^{-1}), while the lowest dry matter yield was obtained from Bingol location (173.29 kg da^{-1}). Similarly to this study, Seydosoglu, in his study in 2014 in the Diyarbakır; stated that forage yield can be vary between 1522.0-3232.3 kg da^{-1} and dry matter yield between 308.0-919.5 kg da^{-1}. Mikic et al. (2014) found 8.8 t ha^{-1} as 2 years averaged DM yield which varied between 8.0 t DM ha^{-1} (cvs. Armantes and Labari) and 10.2 t ha^{-1} (cv. Slavej). These findings are consistent with our findings.

The average value of biological yield and straw yield obtained from common vetch lines and varieties used in Bilecik, Bingol and Sivas locations are presented in *Table 4*.

As it can be seen in *Table 4,* there are statistically significant differences between genotypes in all three locations where the study is conducted and there is no statistically significant difference between the averages where the locations are combined. In addition, the interaction of locations and location x genotype was found to be statistically significant. The highest biological yield was obtained from Kralkizi genotype with 1288.67 kg da^{-1} value at Bilecik location, while the lowest biological yield was obtained from Kubilay genotype with 335.67 kg da^{-1} value. At the Bingol and Sivas locations, the highest biological yield was obtained from the Cumhuriyet-99 genotype with the values of 335.60 and 356.13 kg da^{-1} respectively, while the lowest biological yield was obtained from the Kralkizi genotype with 153.63 and 174.50 kg da^{-1} values respectively. Biological yields ranged between 320.30 and 538.93 kg da^{-1} in the averages of locations. In addition, the highest biological yield was obtained from the Bilecik location (706.95 kg da^{-1}), while the lowest biological yield was obtained from the Bingol location (268.51 kg da^{-1}).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1520315217

In terms of straw yield efficiency, statistically significant differences between genotypes in all three locations were observed, and it was also observed that there were no statistical differences in the averages where the locations were combined. Additionally, genotypes and GEI was also found to be statistically significant. Maximum straw yield was obtained from Kralkizi genotype (1154.00 kg da^{-1}) at Bilecik location, the lowest straw yield was obtained from Kubilay genotype with 204.00 kg da^{-1} values. In Bingol and Sivas locations, respectively, it is obtained from Gorkem genotype with 271.87 and 348.73 kg da^{-1} values, the lowest straw yield is in Bingol location, with 106-180 kg da^{-1} Kralkizi genotype and in Sivas location with 198.87 kg da^{-1} values genotype. The straw yields for all locations combined ranged from 255.27 to 486.84 kg da^{-1}. In addition, the maximum straw yield was obtained from Bilecik location (552.33 kg da^{-1}), while the lowest straw yield was obtained from Bingol location (211.84 kg da^{-1}).

In the same column, the averages indicated by similar group of letters are not different from Duncan (5%)

According to Unal et al. (2016) differences in the performance of genotypes at different locations may be due to abiotic (climatic features, soil properties and topography) and biotic factors (weed, pest and diseases) at the specific location. During this study, temperature and precipitation were found highly variable over all three locations and highly influenced the plant growth, yield and production potentials of vetch plant. Results of this study made a strong agreement with the findings of Albayrak et al. (2004) resulting biological yield between 584 to 729 kg da^{-1} under multilocations.

In the same column, the averages indicated by similar group of letters are not different from Duncan (5%)

As seen in *Table 5,* there are statistically significant differences between genotypes in terms of seed yield in Bingol and Sivas locations, but there are no statistically significant differences between genotypes in Bilecik location. The seed yields of the genotypes at the location of Bilecik ranged between 131.67 and 203.67 kg da^{-1}. In the Bingol and Sivas locations, maximum seed yield was obtained from Alinoglu genotype with values of 74.17 and 82.67 kg da^{-1}, respectively, while the lowest seed yield was obtained from the genotype Hat-13 with the values of 41.50 and 50.00 kg da^{-1}. The differences between the common vetch lines were caused by variations in their genetic makeup. The averages of the common vetch genotypes were not found statistically significant and the seed yields varied between 76.43 and 106.69 kg da^{-1}. In addition, the location and genotype interaction were found to be statistically significant. However, the highest seed yield was obtained from Bilecik location (154.62 kg da^{-1}) while the lowest seed yield was obtained from Bingol location (56.67 kg da^{1}). In the Bilecik location, numbers of pods per plant and numbers of seeds per pod were higher than those of Bingol and Sivas locations. Albayrak et al. (2004) conducted multi locations experiments and stated that seed yield of common vetch can be varied between 98-160 kg da^{-1} and the one thousand grains weight ranged from 57.7 to 63.4 g and these results were found in line with the findings of this study. Similarly, our results were further supported by the findings of Gurmani et al. (2006) resulting seed yields in a range of 643.0 to 1620.0 kg ha^{-1}. In terms of one thousand seed weight, statistically significant differences between genotypes in all three locations were observed, and it is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1520315217

seen that there are no statistical differences in the averages where the locations are combined. In addition, the interaction of locations and location x genotype was found to be statistically significant. In Bilecik, Bingol and Sivas locations, the maximum thousand seed weight was obtained from Ozveren genotype with 69.87, 53.80 and 69.13 g, respectively, while the lowest thousand seed weight was at Bilecik location; it was obtained from the Gorkem genotype with 50.60 g and from the Hat-13 genotype with 37.63 and 44.87 g values in Bingol and Sivas locations, respectively. In terms of one thousand seed weight, the average of the locations of common vetch genotypes ranged from 47.91 to 64.27 g. In addition, a maximum of thousand seed weight was obtained from Bilecik location (61.01 g), followed by Sivas location (60.17 g), the lowest thousand seed weight from Bingol location (48.18 g). Possible reason behind these variations may be due to differences in the ecological conditions of studied locations. Orak and Nizam (2004) measured data of TSW were between 31.92 and 63.52 g and their findings clearly supported the results of this study.

There are statistically significant differences between genotypes in Bingol and Sivas locations in terms of harvest index, but there are no statistically significant differences between genotypes in Bilecik location. Harvest index of the genotypes at Bilecik location varied between 15.23% and 39.13%. Maximum harvest index was obtained from the Kralkizi genotype with a value of 30.53%, while the lowest harvest index was obtained from Selcuk and Kubilay genotypes with a value of 14.73% at the Bilecik location. In Sivas, the highest harvest index was obtained from Hat-1 genotype with a value of 56.30%, while the lowest harvest index was obtained from the Dicle genotype with a value of 35.00%. The average of the locations where common vetch genotypes were combined was not statistically significant, and the harvest index changed between 27.26% and 36.43%. In addition, the location and genotype interactions were found to be statistically significant in terms of harvest index. However, the highest harvest index was obtained from Sivas location (44.56%) while the lowest harvest index was obtained from Bingol location (21.78%). Hereby, the high seed yield naturally results in greater HI. Unal et al. (2016) found that the harvest index for common vetch can vary between 39.23 and 42.54% and their findings made strong agreement with the results of this study.

Determination of ideal properties with biplot method in Bilecik, Bingol and Sivas locations are given in *Figure 4.*

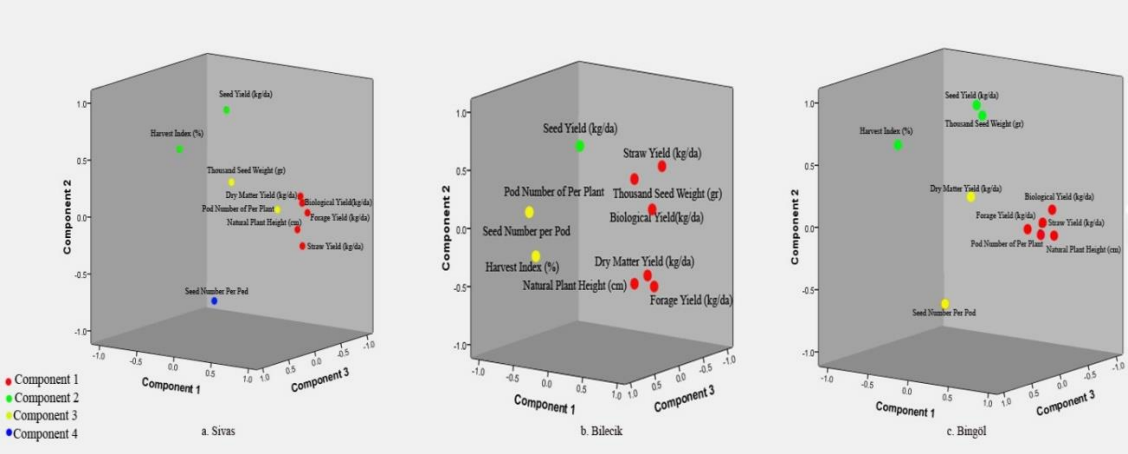

Figure 4. *Determination of ideal properties with biplot method in different locations*

DOI: http://dx.doi.org/10.15666/aeer/1706_1520315217

Biplot analysis is considered one of the most easiest and effective way to select genotypes reflecting superior performance for various traits of interest under multi environments/locations. In this study, biplot analysis was evaluated for each location to evaluate differences for studied traits. It was observable that biological yield, forage yield and straw yield were found main variations contributing factors in component 1 at all three studied locations. However, some differences were present in each location for component two and three for few traits. It is observable that harvest index, seed number per pod and thousand seed weight are changing among the location. Therefore, it can be suggested that good understanding about the behaviour of these traits under multi environmental condition will be helpful in breeding activities. Seed yield is most important trait for any crop and can be used as selection criteria to evaluate genotypes having superior performance. Seed yield was found main contributor in component two in all three locations. Therefore, this trait can be suggested for the selection of genotypes.

Principal component analysis (PCA) was performed to understand the level of variations and importance was given to 1st four components because they accounted maximum variations at the first location (*Fig. 4a*). In the first component, 5 important variables are Forage Yield (0.963), Straw Yield (0.949), Biological Yield (0.909), Dry Matter Yield (0.836) and Natural Plant Height (0.818), respectively, and the second component is Seed Yield (0.934) and Harvest Index (0.454). The third component included Thousand Seed Weight (0.627) and Seed Number per Pod (0.592) and the fourth component included Pod Number of Per Plant (0.651).

Three components were identified at the second location (*Fig. 4b*). In the first component, Dry Matter Yield (0.802), Biological Yield (0.787), Straw Yield (0.771), Forage Yield (0.768), Natural Plant Height (0.692) and Thousand Seed Weight (0.451), respectively were found main variation contributor. In 2nd component Seed Yield (0.738) and number of pods per Plant (0.060) were chief variations contributor. In the third component, maximum variations were due to Seed Number per Pod (0.527) and Harvest Index (0.415).

The third location (*Fig. 4c*) consists of three components. In the first component, Forage Yield (0.958), Straw Yield (0.953), Biological Yield (0.929), Natural Plant Height (0.909) and Pod Number of Per Plant (0.114), respectively. In the second component, Seed Yield (0.935), Thousand Seed Weight (0.868), Harvest Index (0.555), and Seed Number per Pod (0.622) and Dry Matter Yield (0.452) were found.

Analysis of genetic and phenotypic correlations may provide additional benefits to the fundamental analysis of economically important features, as it is used to make indirect choices and predict genetic gain in various annual breeding programs, including soybeans and other annual legumes (Burton, 2011). The cluster analysis of the common vetch inputs tested also confirms that groups may sometimes involve initiatives with close geographical origins, in particular local land areas or varieties used to develop (Potokina et al., 2002).

In this study, biological yield, straw yield, forage yield and natural plant height were included in component 1 at three locations. For this reason, the selection of the genotypes used in the study in the future can be better if the selection is done with these properties. Similar to this study, Mikic et al. (2014) stated that significant differences in the number of common vetch participation and results on the varieties with different geographical origin, feed yield components and related characteristics. Here, information on the relationship between the economically important properties of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1520315217

individual feed yield components, together with the results of the cluster analysis, can help in future reproductive efforts and the selection of parental components for hybridization.

Conclusions

This study was carried out simultaneously at three (Bilecik, Sivas and Bingol) ecological conditions of Turkey during 2016. It can be concluded that various yield components like biological yield, straw yield, forage yield and natural plant height resulted highly significant variations and can be effectively utilized as selection criteria to start the breeding activities for the common vetch. Average plant height of the genotypes in the locations are between 35.46 and 50.42 cm, the pod numbers of per plant is between 11.51 and 33.01, the seed numbers per pod is between 3.61 and 5.60, the seed yield is between 1487.28 and 1835.14 kg da^{-1}, the dry matter yield between 325.18- 560.18 kg da^{-1}, biological yield between 320.30 and 538.93 kg da^{-1}, straw yield between 255.27 and 486.84 kg da^{-1}, seed yield between 76.43 and 106.69 kg da^{-1}, thousand seed weight between 47.91 and 64.27 gr, harvested index was between 27.26% and 36.43%.

Among the common vetch genotypes in the locations, the highest forage yield and dry matter yield were obtained from the Dicle common vetch genotype, the biological and straw yield were from Kralkizi genotype, and the seed yield was from Ozveren genotype. These results suggested that some previously selected genotypes and superior cultivars can be successfully grown and make a significantly positive contribution. Their introduction into crop-rotation will greatly increase dry matter yield and seed yield and overall sustainability by acting as a disease break and contributing immensely to soil fertility.

(Received 2nd Jul 2019; accepted 16th Oct 2019)

Abstract. A total of 22 surface soil samples beside three different types of roads (trunk road, sub-trunk road and branch road) collected in Ma'anshan City, Anhui Province, China, were analyzed by inductively coupled plasma-atomic emission spectrometry (ICP-AES) and multivariate statistics. Besides, spatial distribution characteristics analysis was employed to identify the possible sources. The results indicate that the average concentrations of heavy metals following in the order of Mn > Pb > Co > Cr > As > Cd, and Cr content in the sub-trunk road are much lower than that in the trunk road and branch road. Geo-accumulation index shows that heavy metal pollution exists beside urban roads. Moreover, Cd pollution is the most serious, while Co and Pb are at a high pollution level. Potential ecological risk index shows that Cd poses a severe ecological risk; Pb and Co reach the medium ecological risk degree. Furthermore, two principal components (PC1 and PC2) of the heavy metal elements have been extracted by factor analysis, and the cluster analysis was consistent with the factor analysis. Based on spatial distribution characteristics, two sources have been identified: PC1 (Pb, Mn, Co) are contributed mainly by industrial pollution, and PC2 (Cd, As, Cr) are primarily influenced by traffic pollution.
Keywords: *trunk road, sub-trunk road, branch road, pollution assessment, spatial distribution characteristics, multivariate statistical*

Introduction

With the development of the automobile industry and transportation in China, the motorized travel mode of the public has experienced transformation from motorcycle to automobile, and the transportation structure has also undergone fundamental changes, making urban life increasingly convenient. According to statistics from the traffic management bureau of China's ministry of public security, by the end of the 2015 year, there were 279 million vehicles in the country, including 172 million automobiles. In 2015, the number of newly registered cars reached 23.85 million, and the net increase possessions was 17.81 million. However, the rapid development of roads and traffic also brings about a series of environmental pollution problems. For example, particulate matter containing heavy metals discharged by motor vehicles directly deposited in the road dust, or through wet and dry sedimentation deposited in the soil on both sides of the road, resulting in the accumulation of heavy metals in the soil and dust on both sides of the road. Especially in the current situation of poor vehicle emission performance and poor maintenance, heavy metal pollution problem is more prominent (Guo et al., 2008). Moreover, heavy metal is highly toxic and easy to accumulate in the soil, yet challenging to migrate and degrade. If the concentrations exceed a certain level, there will be higher biological toxicity. Once the soil is contaminated by heavy metals, it is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1521915232

challenging to recover, causing serious damage to human body, environment, and even the whole food chain (Reza, et al., 2015; Hafeez, et al., 2019).

It is significant to clean the environment so as to avoid their entrance into the food chain because it is essential for protecting the health of animals and human beings. However, it is more realistic to understand the pollution status first, and then the sources of heavy metals, because not all of the heavy metals are released by anthropogenic activities, but they can also be produced by natural weathering processes of crust materials (Hashim, et al., 2011).

Pollution of soil in the current world is a major concern of the government and environment scientists, because of the importance of the soil for the survival and development of human society. Therefore, it is of great significance to analyze the pollution status of heavy metal elements in the soil along the traffic lines. Previous studies on heavy metals in soils on both sides of urban roads mainly focused on elements content, distribution characteristics, pollution status and ecological risk assessment (Afanasyeva, et al., 2019; Komendova, et al., 2018; Billah, et al., 2018; Sun, et al., 2015). However, there are few reports on the comparative study of soil heavy metal pollution besides different urban roads, especially in industrial cities. In this investigation, we selected trunk roads, sub-trunk roads and branch roads for systematic sampling and testing analysis in Ma'anshan city, a typical industrial city. In order to provide a scientific basis for the prevention and treatment of heavy metal pollution caused by highway traffic.

Materials and methods

Study area

Ma'anshan City is a steel industrial city that has risen since the late 1950s. It is located on the south bank of the lower Yangtze River and in the eastern part of Anhui Province, China. The longitude is from 118°21′38″ to 118°52′44″, and the latitude is from 31°46′42″ to 31°17′26″. Influenced by the humid climate of the northern subtropical monsoon, the city has an annual average precipitation of 1100 mm, and an annual average temperature of 15.7 degrees (centigrade). In 2015, the city's registered population was 2.277 million, and the urban resident population was 880,000. Ma'anshan City is located in the middle and lower reaches of the Yangtze River polymetallic metallogenic belt. This area is rich in mineral resources, and the main metal minerals are iron, vanadium, copper, gold, cobalt, which provide guarantee the development of local steel industry. The local manufacturers are mainly dominated iron and steel, special-purpose vehicles, high-grade cardboard, new process carbon black, electronic materials, biomedical, textile clothing, green food. Ma'anshan Iron & Steel Group is a large-scale steel joint enterprise and an important steel production base, as well as one of the largest industrial enterprises in Anhui Province. Geographical location of the study area is shown in *Figure 1*.

Sampling sites and sample collection

According to the urban road planning of the study area, the vehicle design speed of the trunk roads is 60 km/h, the number of vehicle lanes is 5~8, and the width of the road is 45~55 m. The design speed of motor vehicles on the sub-trunk roads is 40 km/h, the number of motor vehicle lanes is 4~6, and the width of the road is 40~50 m. As for the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1521915232

branch roads, the design speed of motor vehicles is 30 km/h, the number of motor vehicle lanes is 3~4, and the width of the road is 15~30 m. Before sampling, the trunk roads, sub-trunk roads and branch roads in Ma'anshan city are divided according to the geographical location and the flow of motor vehicles. The trunk road is the main road connecting the main urban districts, mainly including Huolishan Avenue, Jiangdong Avenue, Cihuher Road, Jiuhua Road, Yinshan Road, Yushan Road and the railway line crossing the city. The sub-trunk road is a large number of general traffic roads in the city, which coordinates with the trunk road to form the urban trunk roads network, and plays the role of connecting various parts and distributing traffic, mainly including Hongqi Road, Jiashan Road, Huayu Road, Pingshan Road, Kangle Road. The branch road is an important part of the road system, mainly undertaking short-distance traffic, including Hunan West Road, Jiuhua West Road, Park Road, Xiyuan Road, Pinghu Road, Yucai Road and so on.

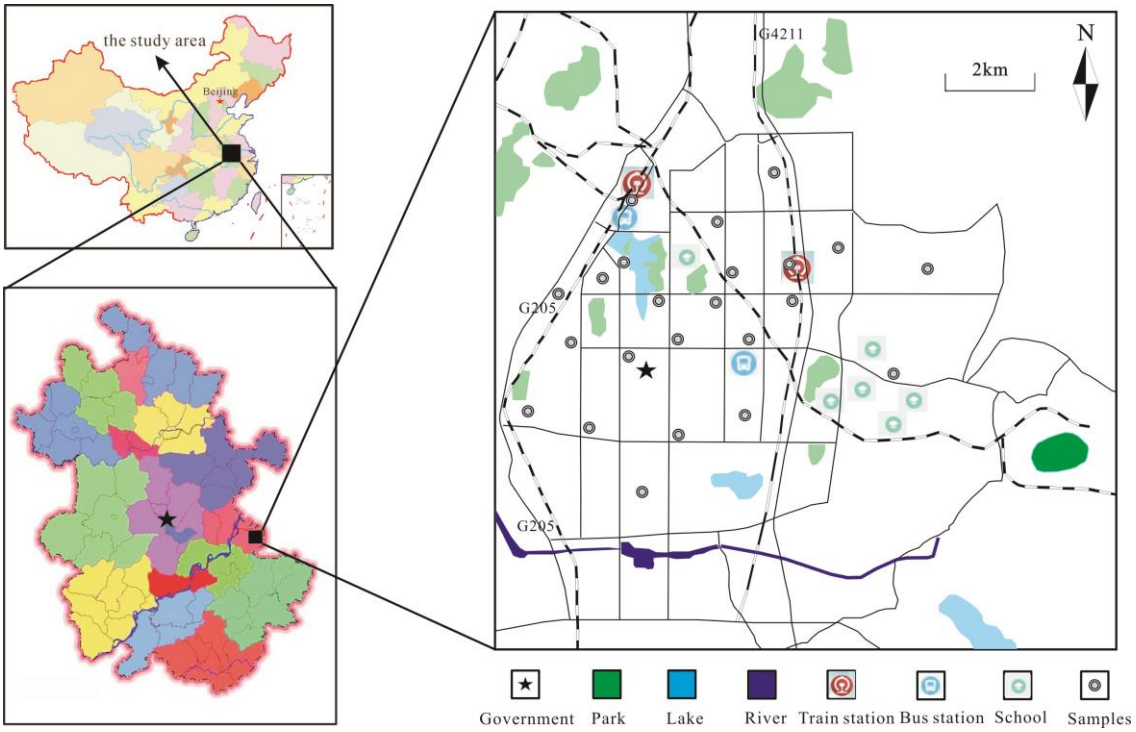

Figure 1. *Geographical location and sampling distribution of the study area*

In this study, samples collection was performed in December, 2015. Plant mulch and topsoil were removed before sample collection, and the sampling depth is 15 cm. For each soil sample, five sub-samples were collected from different cells within a grid of approximately 5 m^2 to form a composite sample to enhance the representativeness of the sample for each sampling site. The samples were stored in polyethylene packages that were transported back to the lab for chemical analysis. The samples were numbered sequentially on the bag. At the same time, GPS was used to determine the location of each sample point. A total of 22 surface soil samples were collected, including 11 trunk roads, 6 sub-trunk roads and 5 branch roads. Soil samples were firstly air-dried in the natural condition, sifted to remove stone and plant root debris, then ground to pass through a 200-mesh sieve.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1521915232

Experimental method

(1) The authors weighed 0.1 g soil powder by electronic balance scale and put the soil into a tetrafluoroethylene digestion tank. Besides, 1 mL concentrated nitric acid, and 1 mL hydrofluoric acid is subsequently added. The authors put the sealed digestion tank in the steel sleeve, tightened the lid, and put it into the oven (190 °C) to heat for 20 h. Then take the steel sleeve out of the oven for cooling, take out the digestion tank, heat it on a hot plate (140 °C) to near dry, add 4 mL concentrated nitric acid and 4 mL of deionized water. Then put the digestion tank into the steel sleeve, tighten the lid, put it in the oven at 150 °C for 2 h, take out the steel can for cooling. After cooling, remove the digestion tank, transfer the liquid from the digestion tank into a 100 mL volumetric bottle, and wash the polytetrafluoroethylene with a certain amount of deionized water for 2 to 3 times. All the washing liquid is poured into the volumetric flask. Finally, the nitric acid solution was prepared, in which concentrated nitric acid 2 mL and deionized water 98 mL were used to titrate the volumetric flask.

(2) Using ICP-AES to determine the volume of solution in a volumetric flask, the internal standard of the element was selected, and the calibration curve was drawn. The concentration in the sample solution was calculated by regression equation to determine the heavy metal element content of the soil.

The above analysis and test were carried out at the Engineering Research Center of Coal Exploration, Anhui Province, China.

Analysis methods

Geoaccumulation index

The geoaccumulation index, also known as the Muller index, was proposed by German scientist Muller and developed in Europe as a quantitative index to study heavy metal pollution in sediments and other substances. The index of geoaccumulation (I_{geo}) ensures the assessment of contamination degrees by comparing the current and pre-industrial concentrations (Muller, 1969), and is calculated as follows.

$$I = log_2[C_n/KB_n] \quad \text{(Eq.1)}$$

In *Equation 1,* C_n means the measured content of the element in the sediment; B_n represents the geochemical background value; and K is the coefficient obtained by considering the variation of the background value that may be caused by the rocks differences in different places (in general, the K value is 1.5). Moreover, the geoaccumulation index is classified as *Table 1*. This method takes into account not only human-made pollution factors and environmental geochemical background values but also takes into account the factors that may change background values due to natural diagenesis, which makes up for the shortcomings of other evaluation methods effectively (Jia, et al., 2009; Chai, et al., 2006)

Potential ecological risk index

Potential ecological risk index is a method for evaluating the pollution degree of heavy metals in soil or sediments and their potential ecological hazards. The potential ecological risk index can calculate as follows.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1521915232

$$C_f^i = C_s^i / C_n^i \quad \text{(Eq.2)}$$

$$E_r^i = T_r^i \times C_f^i \quad \text{(Eq.3)}$$

$$RI = \sum_{i=1}^{n} E_r^i \quad \text{(Eq.4)}$$

In *Equation 2,* C_f^i means the enrichment coefficient of heavy metal; C_s^i means the concentration of heavy metal in the sample; C_n^i means the reference value, generally taking the national or local environmental standard value in soil as the reference value (Fan et al., 2010); In *Equation 3,* E_r^i means the potential ecological hazard coefficient of individual; T_r^i means the toxicity response coefficient of heavy metal, the toxicity response coefficients were Cd = 30 > As = 10 > Pb = Co = 5 > Cr = 2 > Mn = 1 (Aiuppa, et al., 2003; Armagan, et al., 2008), respectively; In *Equation 4,* RI means the potential of ecological risk of multiple metals. The classification criteria of heavy metals potential ecological risk index are listed in *Table 2*.

Table 1. *Classification of index of geoaccumulation*

I_{geo}	Classification	Degree of pollution
$5 < I_{geo} \leq 10$	6	Extremely serious pollution
$4 < I_{geo} \leq 5$	5	Strong-extreme pollution
$3 < I_{geo} \leq 4$	4	Strong pollution
$2 < I_{geo} \leq 3$	3	Medium-strong pollution
$1 < I_{geo} \leq 2$	2	Medium pollution
$0 < I_{geo} \leq 1$	1	Light pollution
$I_{geo} \leq 0$	0	No pollution

Table 2. *Ranking standard of potential ecological risk hazards*

E_r^i	Single ecological hazard	RI	Overall ecological hazard
< 40	Low	<150	Low
40~80	Moderate	150~300	Moderate
80~160	Heavier	300~600	Heavy
160~320	Heavy	>600	Serious
> 320	Serious		

This method not only considers the content of heavy metals in soil, but also considers the migration rule of toxicity of heavy metals in soil, the sensitivity to heavy metal pollution, and the difference of background value of heavy metals, eliminating the influence of regional differences. The degree of potential ecological risk of heavy metals classified reflects the characteristics of bioavailability, relative contribution, spatial differences and so on. Generally, potential ecological risk index is a comprehensive indicator reflecting the potential impact of heavy metals on the ecological environment (Fan et al., 2010).

Multivariate statistical analysis

Multivariate statistical analysis is a method of using mathematical statistics to study multivariate problems. It includes regression analysis, discriminant analysis, cluster analysis, principal component analysis, factor analysis, correspondence analysis and so on. It has been widely applied in education, medicine, economics, environmental science and other disciplines. Multivariable statistical analysis provides an alternative method to identify pollution sources, and many scholars use this method to identify the pollution sources of soil or sediment (Aiuppa, et al., 2003; Armagan, et al., 2008; Reisenhofer, et al., 1996; Sun, et al., 2012).

Factor analysis uses a few factors to describe the relationship between multiple indicators, several same-class variables with relatively close correlations with each type of variable becoming a factor, and fewer factors reflecting most of the original information (Zhang, 2004). The general steps are summarized as follows: (1) standardizing raw data, which does not change the correlation coefficients between variables, and eliminate the influence of different variables dimension; which not change the correlation coefficient between variables, on the contrary, it can eliminate the influence of the dimension of different variables. (2) calculating the correlation coefficient matrix of the normalized data and its corresponding eigenvalues and eigenvectors; (3) using the maximum variance method for orthogonal rotation. This process can make the factor load polarized, which easy to find the information represented by the factor; (4) determining the number of factors, calculating the score of factors, and making corresponding statistical analysis.

Cluster analysis is a simple multivariate analysis method that classifies the research objects according to their characteristics (Zhang, 2004). The basic idea of cluster analysis is to use quantitative statistical analysis method to find some statistics that can measure the degree of affinity between samples or variables. Subsequently, based on these statistics, some samples (or variables) with greater similarity are aggregated into one group and others (or variables) are aggregated into another group.

The multivariate statistical analysis methods mentioned above are all completed by International Business Machines Corporation (IBM) SPSS software. IBM SPSS is a software product and related service program developed by IBM for statistical analysis, data mining, predictive analysis, and decision support tasks. It has been applied to various fields of natural science, technological science, and social science.

Visualization analysis

SigmaPlot is an advanced statistical analysis and scientific drawing software developed by Systat Software Company. The software integrates graphics drawing and data analysis. It has been applied to medicine, life sciences, engineering and environmental sciences due to its simple operation and high efficiency. In this study, SigmaPlot software (version 12.5) was used to construct a three-dimensional model of the spatial distribution of heavy metals in the soil of Ma'anshan city of Anhui Province, China.

Results

Content characteristics of heavy metals

The statistical analysis results of heavy metals in both sides along the road in Ma'anshan city of China are shown in *Table 3,* and the statistical analysis of the data was performed by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1521915232

IBM SPSS statistic software (version 19). According to *Table 1,* the contents of soil heavy metals in this area varied in a certain range. Among them, Pb content ranged from 193 to 711 ug/g (average 463 ug/g); Cd content ranged from 6.8 to 22.25 ug/g (average 12.55 ug/g); Co content ranged from 284 to 395 ug/g (average 349 ug/g); As content ranged from 2.25 to 63.85 ug/g (average 49.21 ug/g); Mn content ranged from 298 to 717 ug/g (average 467 ug/g); and Cr content ranged from 3.05 to 253 ug/g (average 85.19 ug/g), respectively. The contents following the order of Mn > Pb > Co > Cr > As > Cd.

Table 3. *Statistical analysis of heavy metals in soils (ug/g)*

	Pb	**Cd**	**Co**	**As**	**Mn**	**Cr**
Minimum value	193	6.8	284	2.25	298	3.05
Maximum value	711	22.25	395	63.85	717	253
Mean value	463	12.55	349	49.21	467	85.19
Standard deviation	168	4.94	34.11	15.55	119	84.31
Variance	28285	24.44	1164	241.75	14126	7108
Coefficient of variation (CV)	0.36	0.39	0.1	0.32	0.25	0.99
Skewness	-0.013	0.986	-0.615	-2.189	1.141	0.825
Kurtosis	-1.266	1.13	-0.593	5.77	0.413	0.433
Soil background value Ma'anshan (Liu, 2012)	24.43	0.264	—	10.553	—	86.4
Soil background value in Anhui (Environmental Monitoring of China, 1990)	26.6	0.07	16.3	9	530	66.5
Nationals soil background value (Environmental Monitoring of China, 1990)	26	0.08	12.7	11.2	583	61

Coefficient of variation (CV, represents the ratio of the standard deviation to the mean) is an index that can be used for identifying the anthropogenic contribution degree for pollution in environmental studies (Sarkar, et al., 2010; Sun, et al., 2017), previous studies revealed that when CV < 0.10 and > 0.90 mean low and high anthropogenic contributions, respectively. In this study, the CV of the elements in the study area are following in the turn: Cr > Cd > Pb > As > Mn > Co, and Cr reached 0.99, which was a strong variation, while Mn, Pb, Co, Cr, As and Cd were relatively low (<0.40). The results indicate that anthropogenic activities have probably influenced the soil to a certain degree.

Figure 2 shows the distribution of heavy metal elements in different types of road. The contents of Pb, Co and Mn in the soils on both sides of trunk roads, sub-trunk roads and branch roads are higher and its differences are smaller, while the contents of Cd, As and Cr are relatively lower. The contents of Cr in sub-trunks road are much lower than those in trunks road and branch road.

Pollution assessment

In this study, Ma'anshan City soil background value, Anhui Province soil background value and Chinese national soil background value were selected value for reference (*Table 3*). Geo-accumulation index analysis on both sides of different roads in Ma'anshan urban area was conducted, and the results show in *Table 4* and *Figure 3,* I_{geo-1}, I_{geo-2} and I_{geo-3} represent the geoaccumulation indexes calculated by the soil background values of Ma'anshan city, Anhui Province and Chinese, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1521915232

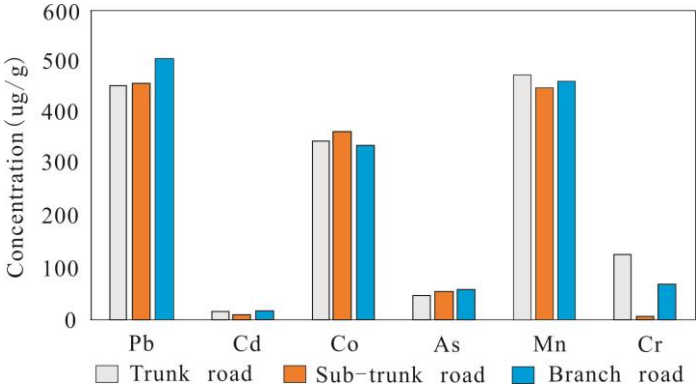

Figure 2. *Distribution of heavy metal elements in different types of road*

Table 4. *Soil heavy metals in different roads on both sides of the geo-accumulation index*

	Trunk roads	**Sub-trunk roads**	**Branch roads**	**Trunk roads**	**Sub-trunk roads**	**Branch roads**	**Trunk roads**	**Sub-trunk roads**	**Branch roads**
	I_{geo-1}			I_{geo-2}			I_{geo-3}		
Pb	3.63	3.64	3.78	3.51	3.52	3.66	3.54	3.55	3.69
Cd	5.23	4.45	5.23	7.15	6.36	7.14	6.96	6.17	6.95
Co	-	-	-	3.82	3.90	3.79	4.18	4.26	4.15
As	1.53	1.76	1.81	1.76	1.99	2.04	1.45	1.67	1.72
Mn	-	-	-	-0.74	-0.83	-0.79	-0.88	-0.96	-0.92
Cr	-0.06	-4.54	-0.97	0.32	-4.16	-0.59	0.45	-4.04	-0.47

According to *Table 4,* no matter which soil background value is taken as reference, soil heavy metals on both sides of urban trunk roads, sub-trunk roads and branch roads have a certain degree of pollution. The Cr and Mn element are non-polluting in the branch roads and the secondary trunk roads. For the trunk roads, if we refer to the soil background value of Ma'anshan City, Cr is non-polluting, if we compare with Anhui Province soil background value and the national soil background value, Cr belongs to mildly polluted. It indicates that the Mn element has not been polluted, Cr element has not been polluted or intensively polluted, and the overall condition is good. Co and Pb were strong pollutions, and Cd was a strong-extremely pollution level in the soil samples on both sides of the urban road in Ma'anshan City.

Risk assessment

The potential ecological risk index of heavy metals pollution in soils on both sides of different roads in Ma'anshan urban area is shown in *Table 5*. According to *Table 5,* the potential ecological hazard coefficients of each element follow the order of Cd > Co > Pb > As > Cr > Mn, which is consistent with the results of the geo-accumulation index method. Among them, Cd reached a severe degree of ecological risk, Pb, Co was a relatively severe degree of ecological risk, As was a moderate degree of ecological risk, Mn, Cr was a low degree of ecological risk. Besides, for the overall potential ecological hazard index (RI), the ecological risk of the sub-trunk road is lower than that of the trunk road and the branch road, but they also have reached the level of potential severe ecological risk. Therefore, the soil heavy metal pollution on both sides

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1521915232

of the road in Ma'anshan city is a potential severe ecological hazard, and even Pb, Co has reached a relatively severe ecological risk. Therefore, in the process of soil environmental treatment in the future, we should strengthen the management of Cd, Pb and Co.

Table 5. *Potential ecological risk index of heavy metals on both sides of the road*

	E_r^i						RI
	Pb	**Cd**	**Co**	**As**	**Mn**	**Cr**	
Trunk roads	87.51	5592	136	40.94	0.82	4.09	5861
Sub-trunk roads	88.02	3238	143.4	47.87	0.77	0.18	3518
Branch roads	97.11	5569	133.3	49.53	0.79	2.17	5852

Discussion

From the previous analysis, we can find that there is an interesting phenomenon here, that is, in the soil on both sides of the road in the study area, the concentration of heavy metals in the branch road is higher than that in the sub-trunk road, or even similar to that in the trunk road. The main reason we consider is that the traffic conditions of the branch roads are not as good as those of the main and secondary roads. According to China Urban Road Engineering Design Code (Ministry of Housing and Urban-Rural Construction of the People's Republic of China, 2016), the width of branches is generally 15-20 m, while the width of sub-trunk and trunk roads can reach 40-55 m, which directly determines the speed of motor vehicles on the road. Generally speaking, the speed of branches is lower than 30 km/h or even lower. However, the sub-trunk road can reach 30-50 km/h and the trunk road can reach 60 km/h. Therefore, in the process of driving on the branch road, automobiles are bound to brake frequently and even start their cars. Brake, brake and tire wear will inevitably lead to the increase of heavy metal content, which makes the heavy metal content of branch road higher than that of sub-trunk road.

In addition, soil heavy metals are not only related to the background value of bedrock (or parent material), but also influenced by the mode and intensity of human activities. According to the analysis above, soil heavy metals in this area are polluted to some extent. In order to identify pollution sources effectively, factor analysis was carried out for heavy metals. According to the eigenvalue and cumulative variance contribution rate, two factors were extracted (*Table 6*). The explanations of variance were 49.512%, 36.764%, respectively, and the complete explanations of cumulative variance were 86.277%. For the sake of understanding the information represented by each principal component, the factors are rotated using the maximum variance method (*Table 6*). According to *Table 6* and *Figure 3,* PC1 is controlled by Cd, As, and Cr, and PC2 is controlled by Co, Mn and Pb.

Xie (2010) holds that Cd mainly originates from industrial activities, such as smelting, electroplating, batteries, metal processing and so on. The sources of Cd in soil are mainly attributed to natural and human activities. The former mainly comes from the background values of rocks and soils, while the latter mainly comes from industrial "three wastes" (waste water, waste gas, and waste residue) and large amounts of Cd-containing fertilizers. Industrial waste gas is the main source of air Cd pollution. The content of Cd in the air of remote areas is generally lower than 1.0 pg/mL, but the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1521915232

concentration of Cd in the atmosphere around industrial areas is higher (Zeng, et al., 2005). Dry and wet deposition of Cd contaminants in the atmosphere is also a significant import cause of soil Cd pollution. Higher concentrations of Cd can enter the soil through rainfall or sedimentation. Plants absorb some of Cd and cause pollution, and the remained Cd accumulates in the soil. Combining the actual situation of iron and steel industry in Ma'anshan city and the spatial characteristics of Cd, As and Cr (*Fig. 4*), it can be concluded that factor 1 is affected by industry. Lead is a tracer element of automobile exhaust emissions (Lv, et al., 2013). In general, The background value of a lead in the environment is very low, and lead is mainly derived from tetraethyl lead anti-explosive agent in gasoline. However, the gasoline combustion process can be decomposed to produce inorganic lead and lead-containing oxides. After being discharged from the vehicle exhaust, it settles in the soil on both sides of roads through the atmosphere. According to this, PC2 can be expressed as the impact of road traffic. So far, it can be concluded that the primary sources of Cd, As and Cr in soils on both sides of urban roads are industrial "three wastes", while the emission of urban traffic exhaust and the wear of urban tires are the essential sources of Pb, Mn and Co pollution in soil samples.

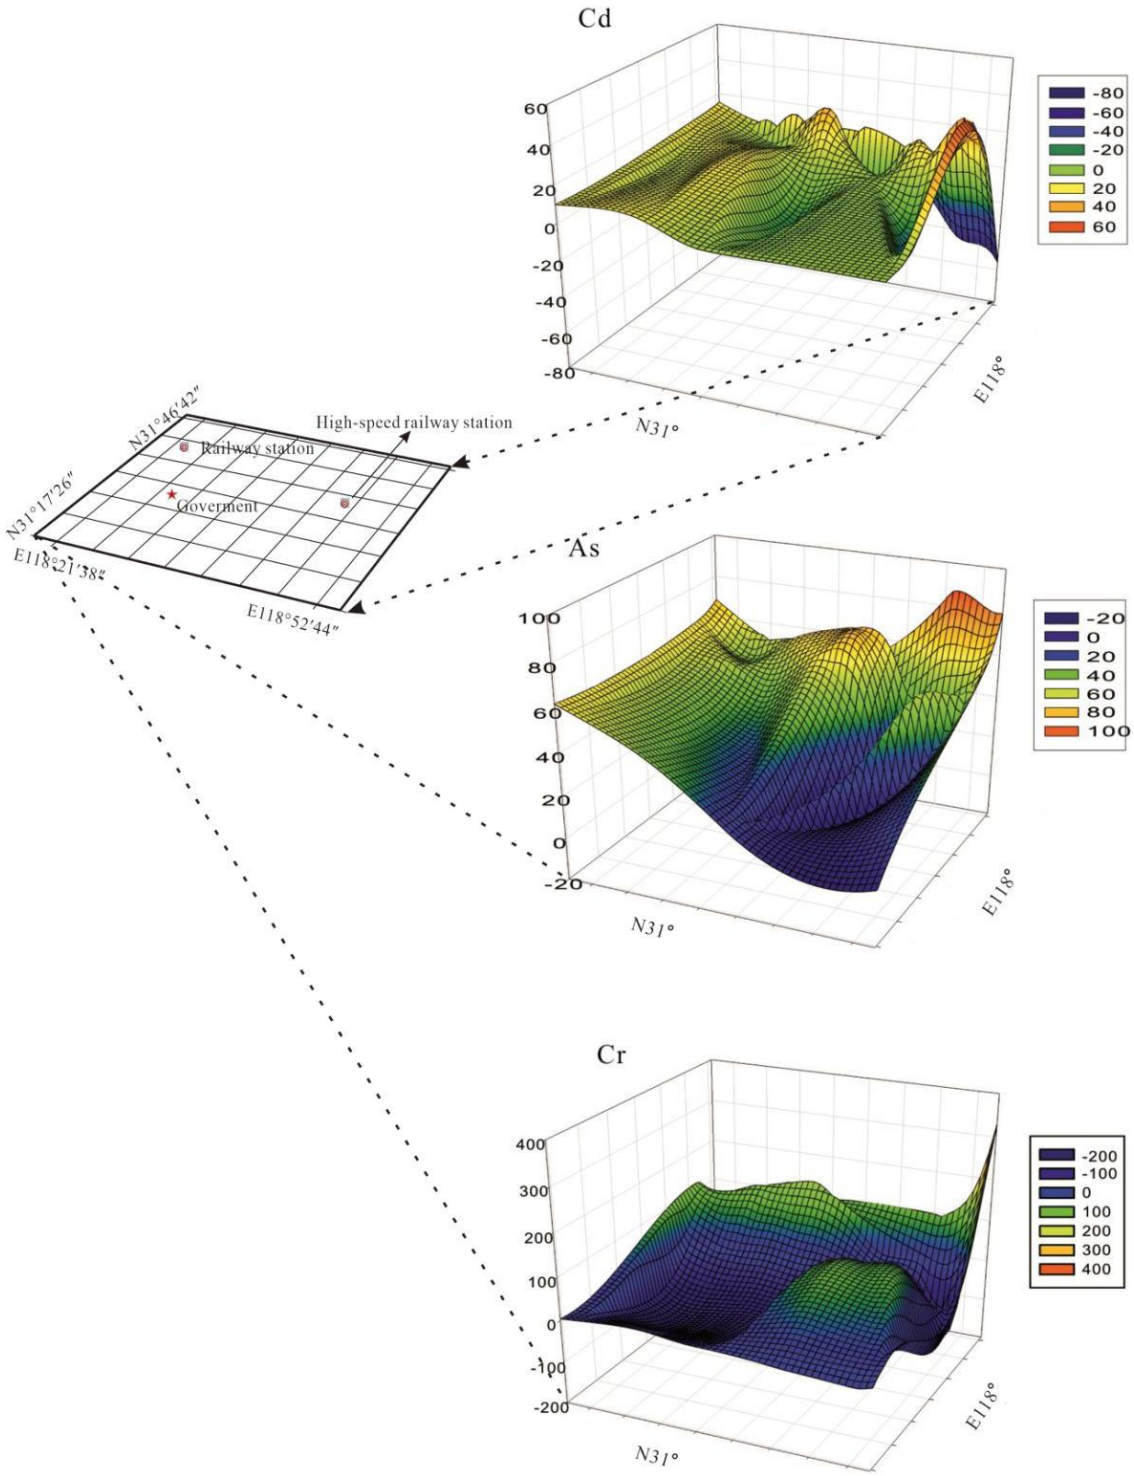

Figure 4. *Spatial distribution characteristics of Cd, As and Cr*

In order to verify the accuracy of the factor analysis method, the soil heavy metal elements were clustered (*Fig. 5*). Clustering results are ideal, and can be divided into three categories: Cd-Cr-As, Co-Mn, Pb clustered into a single group, consistent with the results of factor analysis.

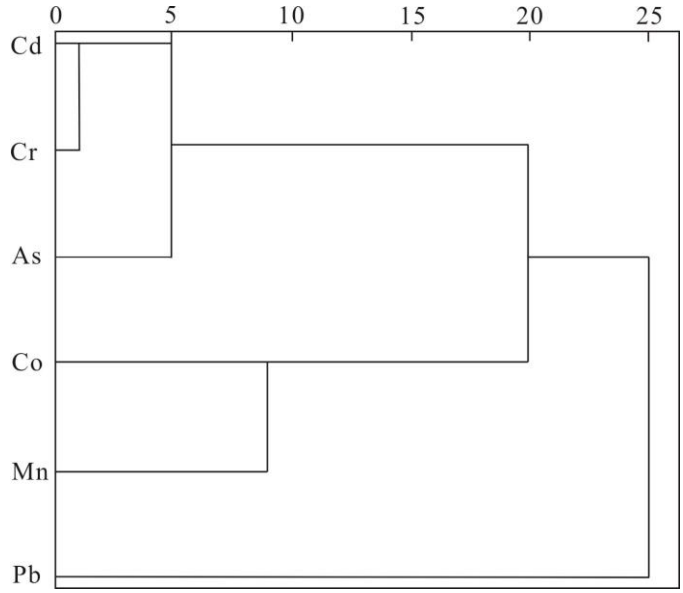

Figure 5. *Cluster analysis of soil heavy metals*

Conclusion

The contents of heavy metals in soils on both sides of roads in Ma'anshan city changed within a certain range, and the average contents were following in the order of Mn > Pb > Co > Cr > As > Cd from large to small. For the soils on both sides of different types of roads, the content of Pb, Co and Mn is higher than that of Cd, As and Cr, and the concentrations of Cr in sub-trunk roads is lower than that of trunk roads and branch roads.

Pollution assessment showed that heavy metals in the soil on both sides of urban trunk roads, sub-trunk roads and branch roads were polluted to a certain extent. Mn is no pollution; Cr element had not been polluted or intensity pollution, the overall situation was good; Co, Pb belonged to strong pollution level; Cd belonged to the severe pollution level.

The risk assessment showed that Cd was a severe ecological risk, Pb and Co was a severe ecological risk, As was a moderate ecological risk, Mn and Cr was a low ecological risk. According to the total potential ecological hazard index, the ecological risk of the sub-trunk road is lower than that of the main road and the sub-trunk road, which has reached a severe potential ecological risk degree. In the future soil quality management process, it is particularly necessary to strengthen the management of cadmium, lead and cobalt pollution.

Two principal components of the six heavy metal elements have been extracted by factor analysis. Combining with the spatial distribution characteristics of heavy metals, two sources have been identified, PC1 (Pb, Mn, Co) and PC2 (Cd, As, Cr). The former are contributed mainly by industrial pollution, while the latter are primarily influenced by traffic pollution.

Recommendations

Taking Ma'anshan City, Anhui Province as an example, this paper discussed the pollution status and sources of heavy metals in soil along the trunk roads, sub-trunk

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1521915232

roads and branch roads of the city, which has a certain practical significance for the prevention and control of heavy metals pollution in urban soil. In the future research, we need to pay more attention to the study of heavy metal pollution level and occurrence in road ash layer, rainfall and other media. We can even make a comparative study of the heavy metal pollution in the soil on both sides of different roads in industrial and non-industrial cities, so as to explore the impact of different types of cities and different specifications of road traffic activities on the distribution of heavy metals, and evaluate their pollution, so as to provide theoretical support for the prevention and control of heavy metal pollution.

Abstract. *Miscanthus* energy grass, being one of the renewable energy sources, has suitable soil-climatic conditions for growth in the regions of Slovakia. The lifespan of a *Miscanthus* plantation is 15-20 years. In the specific conditions of southwestern Slovakia, the plantation productivity was studied under the application of NPK fertilizer after one third of the plantation's lifespan. The measurement interval was 14 days throughout the growing period of the monitored years (2016-2018). Morphometric and selected ecophysiological and production parameters were analysed under three fertilization variants (C – control, V1 – variant with the application of 50 g NPK per individual and V2 – variant with the application of 100 g NPK per individual). Variant V2 had the highest values of the studied parameters in all monitored years and out of all fertilization variants. The statistical significance of differences in growth indicators between the years of cultivation and total biomass production between variants and years was confirmed. Dynamics of stomatal density per mm^2 were determined by microrelief method in three randomly selected clumps of *Miscanthus* × *giganteus* in control and in each variant of fertilization in 2016. There are significant differences in the density stomatal density and width between the control and variants of fertilization in 2016.
Keywords: *NPK fertilizer, energy grass, growth parameters, production, stomata*

Introduction

The use of biomass as a renewable energy source is rapidly increasing worldwide. Further increases in the use of these resources can be achieved through technological development, long-term planning, implementation of integration strategies and appropriate investment. Biomass as an energy source is an easily accessible that is both technologically and ecologically acceptable. The focus on biofuels is increasing due to the reduction of dependence on fossil fuels and the stimulation of rural development and agriculture.

Miscanthus × *giganteus* is a perennial, warm-season Asian grass with the C_4 photosynthetic pathway. In the search for ideal bioenergy crops following the oil crisis of the 1970s, evaluations to determine the biomass yield potential of giant miscanthus began across Europe. *Miscanthus* × *giganteus* grows to a height of 4 m, produces shoots with a length of up to 4 m and a diameter of approx. 10 mm, and can be grown in one location for up to 15–20 years (Dubis et al., 2017).

Miscanthus plantations have several environmental benefits compared to annual crops. These plantations can use water and nutrients more efficiently, they are resistant to pests and diseases and do not require annual soil cultivation (Cadoux et al., 2012). *Miscanthus* × *giganteus* grows very rapidly and produces a high yield of aboveground biomass at relatively low input costs (Clifton-Brown et al., 2015; Roncucci et al., 2015).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1523315244

The cultivation and high yield of *Miscanthus* × *giganteus* are characterized in various climatic and environmental conditions. Higher productivity has also been identified on less productive and marginal soils (Stavridou et al., 2017). *Miscanthus* × *giganteus* has low soil fertility requirements, tolerates cultivation on light soils and has no high nitrogen requirements (Kołodziej et al., 2016).

Several authors have observed the impact of *Miscanthus* plantation fertilization on its production (Maughan et al., 2012; Dierking et al., 2016). Larsen et al. (2014) reported that fertilization of the *Miscanthus* × *giganteus* did not increase the yield. Other authors suggest that yields can be increased by applying annual fertilizers to older stands (Arundale et al., 2014).

To predict the production potential of energy plant species in a particular region, it is necessary to identify the basic morphometric and ecophysiological parameters and their changes due to environmental factors. The shape of organs, especially leaves, often shows the ability to adapt to environmental conditions. These include irradiation density, drought, and extreme temperatures, change anatomy and leaf morphology, skin thickness, stomata density, size, and degree of stomata openness. The stomata density is a relatively plastic feature that is potentially adaptable to environmental changes (Killi et al., 2018; Mwendia et al., 2019).

This article presents the results of the influence of various fertilization variants applied after the sixth growing period of the stand on the morphometric, selected ecophysiological and production parameters of the *Miscanthus* × *giganteus* plantation in the conditions of southwestern Slovakia.

Materials and Methods

Plant materials

Perennial grass *Miscanthus* × *giganteus* is a vital triploid hybrid (57 chromosomes) often used in the field trials. The planting material consisted of rhizomes from Hannes Stelzhammer Austria. The fresh weight of the rhizomes was different (on average 2.61 g), the length of the rhizomes was on average 67.5 mm.

Model locality of the research area

The model area of experimental research of growing fast-growing plants on agricultural soils is located in Slovakia in Nitra region in the cadastral area of Kolíňany (48°21'21" N 18°12'25" E). The area has an altitude of 80 m above sea level. The soil is moderate (loam), pH values range from 7.18 to 7.35, humus content is 1.16 to 2.50% (Demo et al., 2013). In terms of exposure, it is a plane without manifestation of areal erosion. According to climatic conditions the research area belongs to the warm, very dry, lowland climate region. The basic climatic parameters (*Table 1*) were evaluated based on the measurements of the Meteorological station located near the research area. The values were compared with the long-term average values of the 50-year period of 1951-2000 in the Nitra region, according to Slovak Hydrometeorological Institute (*Fig. 1*). The average annual air temperature for the period 2015 to 2018 was 10.99°C (the deviation from the long-term average was higher by 1.13°C) and the average annual precipitation was 483.67 mm (the deviation from the long-term annual total was lower by 63.93 mm). The average length of the main growing period during the monitored years in the research area is 186 days.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1523315244

The research plot was established in 2010. The plant material was planted in a 1 m × 1 m planting distance on an area of 100 m^2. The optimum *Miscanthus* stand density is 10,000 plants per hectare, depending on the abiotic conditions of the habitat – temperature and water. In the research area, *Miscanthus* × *giganteus* rhizomes were planted in wet soil at the beginning of the growing period at a depth of up to 10 cm.

Application of different fertilization regimes

The mineral granular fertilizer N P K (15-10-10), type designation B.1, was applied before to the beginning of the growing period (beginning of April in 2016 – after the sixth growing year since the plantation was established). The fertilizer contained 15% of total nitrogen [N], 10% of total phosphorus [P_2O_5] and 10% of water-soluble potassium [K_2O]. The fertilizer was applied at the centre of the tillering circle of each individual before the growth of new shoots (*Fig. 2*).

In the V1 variant, 50 g of fertilizer per individual (500 kg per hectare of which 75 kg of nitrogen, 50 kg of phosphorus and 50 kg of potassium per ha) was applied. In the V2 variant, 100 g per individual (1000 kg per hectare of which 150 kg of nitrogen, 100 kg of phosphorus and 100 kg of potassium per ha) was applied and variant C (control) remained without fertilization. A schematic representation of the research area with variants of fertilization is shown in *Fig. 3*.

Monitored the growth parameters and production yield

Basic morphometric characteristics of *Miscanthus* × *giganteus* were studied for all three variants. The interval of measurement of morphometric parameters was every 14 days during the whole growing period of the monitored years (2016–2018) at 14 selected individuals. The height of the individuals was determined as the distance from the soil surface to the top of the longest shoot. The number of shoots on individual plants

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1523315244

was determined by counting the shoots in the clump. The shoot thickness was measured on the selected shoot of the studied individuals. The number of leaves on the shoot and the number of leaves in the clump were monitored. Accordingly, the senescence of the leaves on the shoot was determined. In the case of energy plants, a destructive determination of the biomass weight is carried out outside the growing period. After cutting, the total weight of the selected individuals (seven clumps from each variant) was determined. The biomass sample was oven-dried at 105°C and the dry weight was determined. The moisture content of *Miscanthus* × *giganteus* ranges from 19 to 22%. The total weight of the above-ground biomass was calculated (t/ha).

Figure 2. *The tillering circle of Miscanthus × giganteus before the application of the fertilizer in the beginning of the seventh growing period*

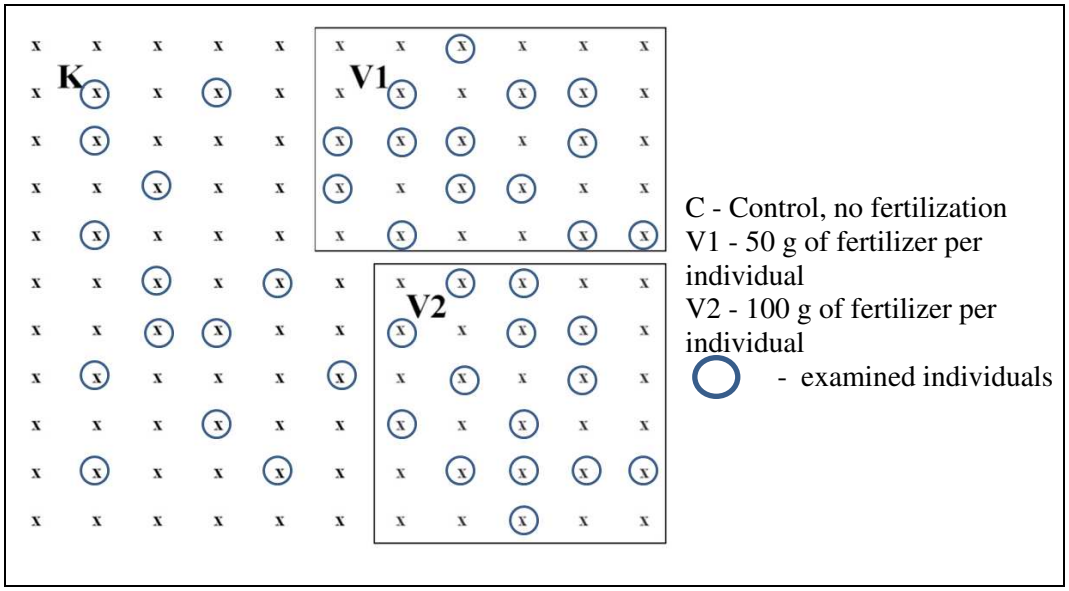

Figure 3. *The schema of application of different fertilization regimes in the research area of Miscanthus × giganteus*

The stomatal density per mm^2 in the leaves was determined non-destructively in three selected clumps in each fertilization variant in 2016. The indicated number of the stomata refers to one treatment. The analysis was performed on the designated stem on the senescence leaf located in the middle of the stand (approximately fifth leaf from the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1523315244

bottom) exposed to western direction by a micro-relief method. Samples were collected in the middle part of the leaf outside the main vein on the adaxial (top) and abaxial (bottom) skin surface in August 2016. The evaluation of preparations was carried out by optical microscope Axiostar plus, Carl Zeiss lens, CP-Achromat 40 × / 0.65, 10 × eyepiece PI / 18, Canon Utilities software Zoom Browser EX 4.6 and hardware Acer Travel Mate 4600, Canon Power Shot A 95. In total, 144 microscopic view-fields were considered in the counting. Stomata length and width were measured on 162 randomly selected stomata.

Statistical analysis of morphometric and production data was performed using STATISTICA 12 by StatSoft. Inc. ANOVA analysis was used to analyse the statistical significance of morphometric and production indicators between years and variants. The result is statistically significant if $p < 0.05$ or statistically highly significant if $p < 0.001$. Statistical significance of stomatal differences was evaluated by LSD-test.

Results and Discussion

The basic prerequisite for the efficiency of growing plants for energy purposes is the ability of the species to adapt to the region's climate. Without fertilization, *Miscanthus × giganteus* has produced an economically efficient above-ground biomass every year since planting in 2010 (Kotrla et al., 2017; Kotrla and Prčík, 2018). In 2016, fertilization was applied to identify the need for fertilization in relation to the growth and production of biomass of the energy grass.

Morphometric analysis of Miscanthus × giganteus

Production of usable biomass for energy use is realized through the formation of above-ground organs. The growth of above-ground organs is limited by the length of the growing period. In 2016 and 2017, the growing period was 176 days and in 2018 it was 219 days. In 2018, average daily temperatures above 10°C began at the beginning of April and ended at the beginning of November compared to previous years.

Fig. 4 represents the course of growth of selected parameters between 2016 and 2018 in the different fertilization variants. The V2 variant had the highest values of the growth parameters in all studied years and fertilization variants. The comparison of the monitored growth parameter values at the end of the growing period 2016 to 2018 is shown in *Table 2*.

The number of shoots in the clump increases at the beginning of the growing season culminates in the second half of June and subsequently decreases (*Fig. 4a*). The shoots continue with intense growth and higher production of green leaves in June, resulting in the drying of shoots in the middle of the clump. The reason for reducing the number of shoots is the competitive struggle of shoots for space, especially light.

In each year, V2 variant has reached the highest height of the clump. When comparing the variants, V1 variant was on average lower by 3.5% and the C variant was on average lower by 6.5% than V2 variant at the end of the growing period. Based on the analysis of the shoot thickness, it can be stated that the shoots in the V1 and C variants were on average thinner by 1.8% and 2.7%, respectively compared to the variant V2. The number of leaves is closely related to the height of the shoots. The dynamics of the number of green leaves on the shoots is shown in *Fig. 4d and e*. Senescence of the leaves (yellowing and drying) begins in the second half of June and continues until the end of the growing period. The ratio of green and dry leaves on the shoot intensely changes in early October

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1523315244

in favour of dry leaves. This trend continues until the end of the growing period when the photosynthetic activity of the leaves ends. The average number of leaves in the variant V2 was 3.3% higher than in the variant V1 and 15.2% higher compared to the variant C. Drazić et al. (2017) examined the impact of fertilization on *Miscanthus* stand in Serbia. They confirmed the increase in morphometric characteristics of fertilized variants. Pogrzeba et al. (2017) also monitored plant growth parameters for fertilized and non-fertilized varieties in Poland. They found no significant differences between these variants.

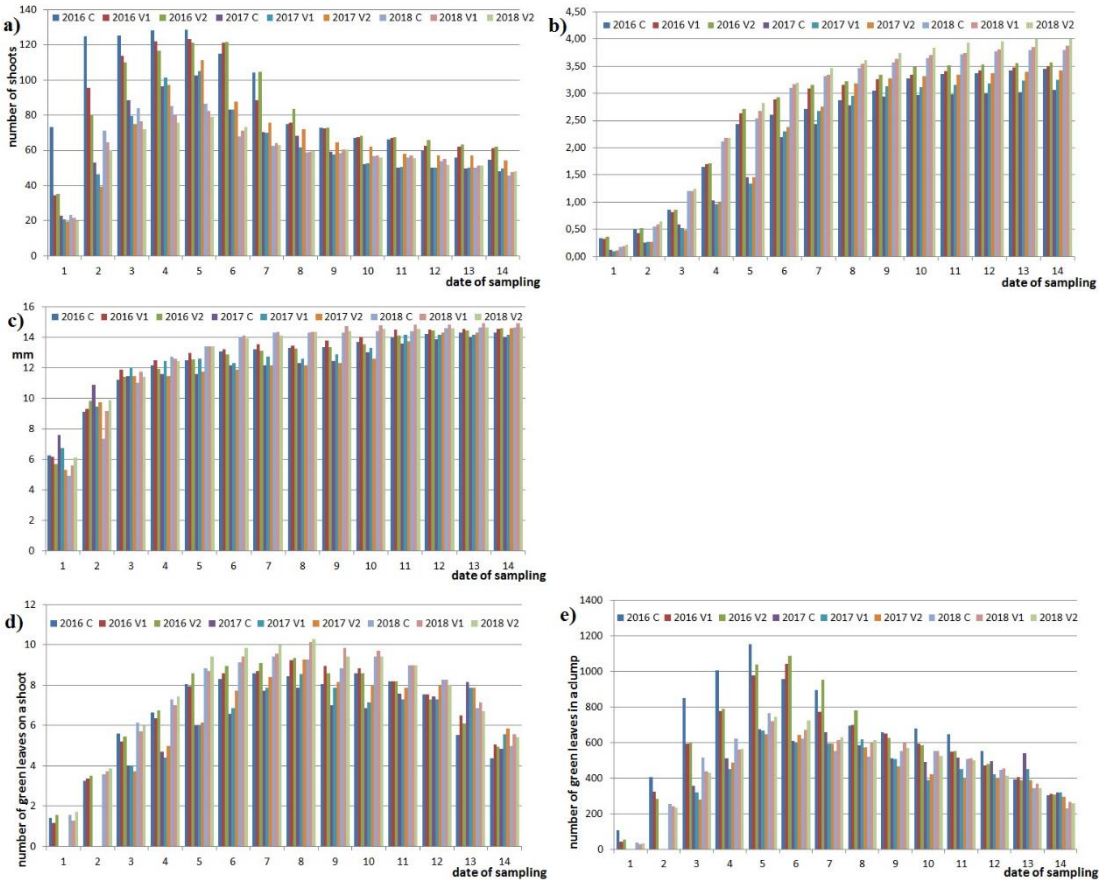

Figure 4. *Morphometric analysis of Miscanthus × giganteus stand in monitored years and fertilization variants [a) number of shoots in a clump, b) height of shoots in a clump, c) shoot diameter, d) number of green leaves on a shoot, e) number of green leaves in a clump]*

The analysis confirmed the statistical significance of the growth parameters between the variants and years. The statistical significance of the growth rate values over the growing period is statistically highly significant only between the monitored years. The reason is the different climatic conditions during the growing period of these years. In each year, the values of the growth parameter between variants C, V1 and V2 are statistically non-significant (*Table 3*).

Production potential of Miscanthus × giganteus

Annual production of the shoots of *Miscanthus × giganteus* represents an amount of biomass usable as an alternative energy source. *Fig. 5* shows the variability of the biomass

DOI: http://dx.doi.org/10.15666/aeer/1706_1523315244

samples collected at the end of February in the following year. Differences in the above-ground biomass weight between years and variants are statistically highly significant (*Fig. 6*). The statistical significance between years (p = 0.00029) and also between variants (p = 0.00019) was confirmed at the significance level of 0.001.

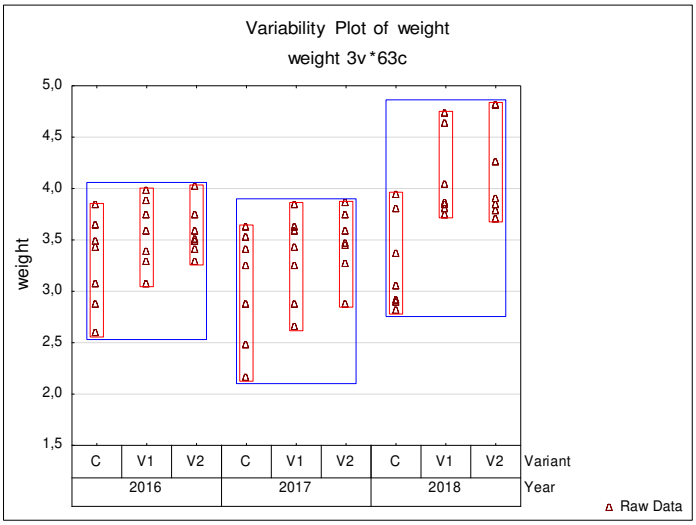

Figure 5. *Variability of biomass samples of the above-ground organs of Miscanthus × giganteus in the studied years and variants of fertilization*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1523315244

Biomass production increased every year in the research area. Since 2015, slight fluctuations in total biomass production have been monitored (*Table 4*). In 2015, the summer was characterized by low precipitation compared to the long-term average. After the application of fertilizer at the beginning of the 2016 growing period, an increase in biomass was observed in fertilized variants compared to the control variant. The variant without fertilization also produced 8.5% more biomass than in the previous year (2015). The difference between the yield in 2015 and biomass yield without fertilization in 2016 is statistically significant ($p = 0.01560$). When comparing the produced biomass between the non-fertilized and fertilized variants, it is possible to state the average increase in fertilized variants by 7.6% in 2016, 10.1% in 2017 and 13.5% in 2018.

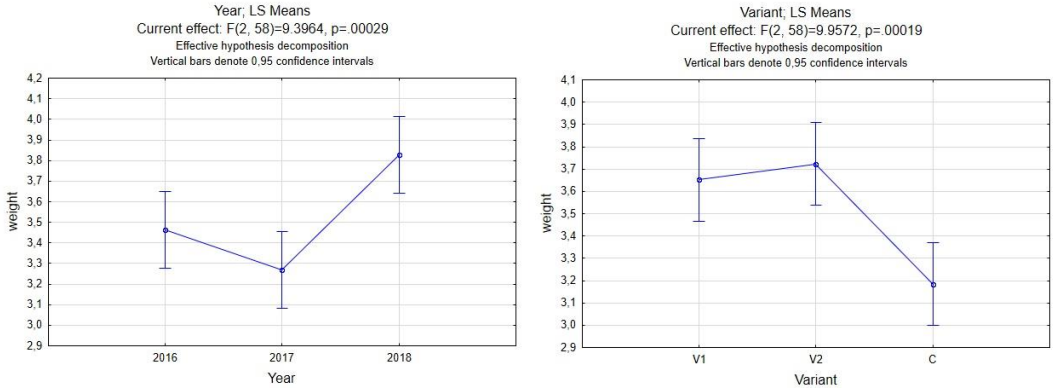

Figure 6. *Statistical analysis of the above-ground biomass weights in the studied years and fertilization variants*

Table 4. *The production of biomass of Miscanthus × giganteus in the fertilization variants since 2016 and compared with 2015 in the research plot in Kolíňany*

Year /Variant	2015	2016	2017	2018
Variant C (without fertilization)	30.1	32.69	30.39	32.97
Variant V1		35.03	33.13	37.17
Variant V2		35.74	34.51	39.1

Lower levels of the biomass produced in 2017 are the result of the climatic situation, especially low temperatures at the beginning of the growing period and spring frosts in late April and early May. The night frost, as a negative phenomenon in 2017, was recorded in the first decade of May (the minimum temperature of -0.196°C was on the 10th of May). These spring frosts negatively affected the growth of the shoots in 2017.

Iqbal et al. (2015) analyzed the stands of energy grasses in a period of ten years. They confirmed that the application of fertilizers did not significantly increase the yield of *Miscanthus*. On the contrary, Dubis et al. (2017) monitored the effect of different fertilization methods on *Miscanthus* productivity. The application of NPK fertilizer increased the biomass yield by 7.7% compared to the non-fertilized variant. Arundale et al. (2014) applied fertilization to older energy grass stand in Illinois, USA. They confirmed an increase in the yield of the fertilized variant compared to the non-fertilized variant by 25%. In the Midwest of the USA, Lee et al. (2017) confirmed a statistically highly significant increase in *Miscanthus* yield compared to the non-fertilized variant, but they did not confirm the differences in the total production between higher and lower

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1523315244

fertilizer doses. Several authors have done fertilization experiments in the first years after planting. However, in the conditions of southwestern Slovakia, it was not necessary to apply fertilizer in the first years, as the energy grass had been reaching an economically profitable yield. The *Miscanthus* stand had shown the culmination of the yield after the sixth year since the establishment, so the fertilization was applied at the beginning of the seventh growing period (which is about a third of the plant's lifespan). Maksimović et al. (2018) observed the effect of fertilization in the first years of the establishment of the *Miscanthus* plantation in Serbia, but they did not find significant differences in biomass production. They confirmed that the profitability of the plantation is affected also by climatic conditions in individual years.

Analysis of the stomata of Miscanthus × giganteus leaves

Photosynthetic performance of *Miscanthus* leaves and their production ability is also influenced by the anatomical structure of assimilation organs. The density and the size of stomata are critical. The stomata play an irreplaceable role in venting the gases between the plant and the atmosphere and they are the place of regulated water discharge in the transpiration process. Their development and movements are indicated by environmental factors.

The number of stomata in leaves was statistically highly significantly affected by adaxial and abaxial leaf surface of the epidermis of *Miscanthus* × *giganteus* (LSD0,05 test ± 12.87). The ratio of stomata was 32:68 on the adaxial and abaxial leaf surface, respectively. The number of stomata per mm^2 of area varied from 97.8 ± 15.0 to 223.6 ± 28.2. Between control and variants of fertilization are significant differences in the density of stomata (LSD $_{0,05\ test}$ ± 7.19 on the adaxial skin, 11.24 on the abaxial skin) (*Fig. 7a*). On the contrary, Weng and Hsu (2001) found that the N treatment could increase the stomatal frequency on the adaxial surface in most tested *Miscanthus* clones in Taiwan, however, no significant effect was observed on that of the abaxial surface.

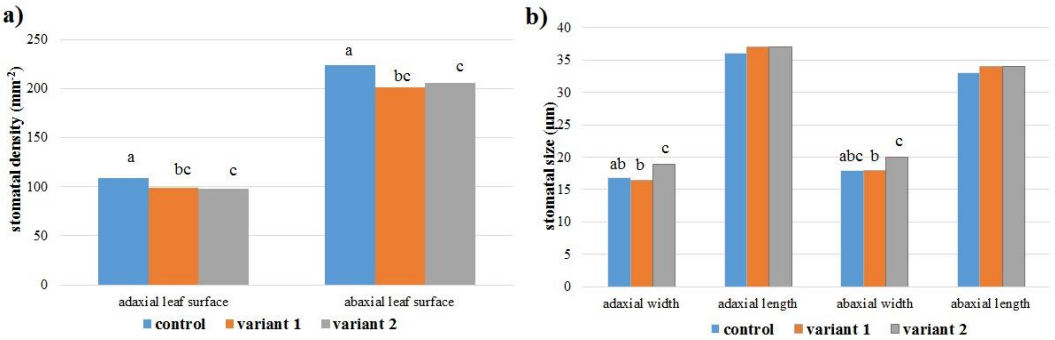

Figure 7. *a) The number of stomata per mm^2 of the adaxial and abaxial surface depending on the variants of fertilization. b) Statistical evaluation of significant differences in the size of stomata (µm) depending on fertilization. Values with different letters (a, b, c) in columns indicate statistically significant difference according to LSD test (P <0.05)*

The stomatal length ranged from 33.5 ± 2.1 µm to 37.4 ± 4.0 µm, and stomatal width from 16.6 ± 1.8 µm to 19.8 ± 2.6 µm (*Fig. 7b*). Rayburn et al. (2009) also compared the size of stomata of two *Miscanthus* genotypes in the USA and confirmed genotypic conditionality of the monitored indicator expressed by the average length of stomata of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1523315244

Miscanthus × *giganteus* 24.4 μm. Moon et al. (2018) recorded the average length of stomata of *Miscanthus* × *giganteus* ranging from 21 to 28.5 μm. In our observations, the average length of stomata of *Miscanthus* × *giganteus* was higher 35.6 μm.

Differences in stomatal width of leaves between control and variants of fertilization on the adaxial surface and between variants V of fertilization on the abaxial surface and V2 were highly significant (LSD 0,05 test ± 1.07 on the adaxial skin, 1.49 on the abaxial skin), while no significant differences were observed in stomatal lengths (*Fig. 7b*).

Conclusion

The plantation of *Miscanthus* × *giganteus* grown in soil-climatic conditions in south-western Slovakia produced an effective yield (more than 30 t/ha) of the above-ground biomass every year. At the beginning of the seventh growing period, NPK mineral granular fertilizer was applied in order to determine the effect of fertilization on crop yield after the first third of the plantation lifespan. The *Miscanthus* stand was divided into three variants, two with different fertilizer doses and one without fertilization. In the growing periods of 2016-2018, morphometric, selected ecophysiological and production parameters were measured. The morphometric analysis confirmed higher growth performance of the fertilized variants. The statistical analysis of the growth parameters is highly statistically significant only between the monitored years. In each year, the values of the growth parameters between the variants C, V1 and V2 were statistically non-significant. Differences between variants and years were statistically highly significant in total biomass production. Statistical significance between the years ($p = 0.00029$) and also between the variants ($p = 0.00019$) in the biomass production was confirmed at the significance level of 0.001.

As a factor affecting the production ability of the *Miscanthus* plantation, the density and size stomata of the *Miscanthus* leaves were analysed. Significant differences in the density of stomata (LSD 0,05 test ± 7.19, 11.24) and stomatal width (LSD 0,05 test ± 1.07, 1.49) were found between the control and variants of fertilization.

Miscanthus cultivated in southwestern Slovakia produced economically efficient yield despite fertilization. The difference in fertilized and non-fertilized variations ranges from 7.6 to 13.5%. The positive effect of fertilization on above-ground biomass production has been demonstrated. A possible negative phenomenon for the *Miscanthus* plantations production is the climatic conditions in each year of cultivation. However, fertilization at certain stages of the energy grass lifespan can maintain plantation production performance even in the later years of cultivation. The aim of further studies will be to find out the period of culmination and decrease in biomass production of *Miscanthus* × *giganteus* in the conditions of southwestern Slovakia and subsequently to apply another dose of fertilization.

(Received 4th Jul 2019; accepted 16th Oct 2019)

Abstract. Purple carrots (*Daucus carota* ssp. *Sativus* var. *Atrorubens* Alef) have received much attention as a natural source of antioxidants, which is confirmed to reduce risk of cancer when consumed frequently. In this study, six purple carrot genotypes (DC17, DC28, DC33, DC34, DC36, and DC37) collected from Anatolia, produced under two distant and very different ecological conditions. Field trials have been planned according to the randomized complete blocks design with three replications. After the harvest, antioxidant activity, total phenolic, total flavonoid, anthocyanin, total soluble solid, titratable acidity and invert sugar values of stored and non-stored roots were assessed. Anthocyanin, total flavonoid and total phenolic content of the six genotypes ranked between 11.3-1,692.4 mg/l. 412.7-3,242.4 mg KE/100 g and 491.4-5,772.3 mg GAE/100 g respectively. Antioxidant activity was determined to be between 9,848.46-3,274.62 µmol TE 100 g^{-1}, 4,676.9-235.6 µmol TE 100 g^{-1} according to 1.1-diphenyl-2-picrylhydrazyl (DPPH) and ferric reducing ability of plasma (FRAP) assays respectively. According to the results, the studied parameters of the genotypes were significantly affected. Different ecological conditions affected the phytochemical composition of the purple carrot roots. The effect of storage on all parameters except total flavonoid content was found significant.
Keywords: *anthocyanin, antioxidant activity, flavonoids, phenolic, titratable acidity*

Introduction

Carrot (*Daucus carota* L.) is a biennial, cool-season vegetable, belonging to *Apiaceae* family. In terms of both production areas and market value, it is amongst the top-ten most important vegetable crop in the world (Simon et al., 2008). Cultivated carrot is divided into two main varieties; the western carrot with orange, yellow or white roots and the oriental carrot with black, purple, red or rarely yellowish roots (Esatbeyoglu et al., 2016).

Production of orange carrot has increased initially in large areas and this led to the gradual disappearance of the other colored varieties, today a new trend is being noticed which is named conservation of biodiversity. In addition to this, improved understanding of the importance of healthy nutrition in human dietary and preventive medicine increased the consumption of vitamin-rich vegetables such as carrot. Obviously, different colors are caused by different chemical compositions namely anthocyanin in purple or black ones (Arscott and Tanumihardjo, 2010). Nowadays, consumption of black or purple carrots is increasing steadily due to their definition as an important source of natural antioxidants (Sharma et al., 2012). Purple or black carrot is useful source of minerals and vitamins and it contains high amount of anthocyanin, which is known as natural dye used in the food industry. Because of their healthful

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1524515254

properties, the development of food colorants from the natural sources has increased interest as alternatives to synthetic dyes (Smeriglio et al., 2018).

Additionally, purple carrot roots have 9 times more phenolic than roots of other colored carrots also they have high antiradical activity which is caused from high anthocyanin content (Leja et al., 2013). As well as the availability of common antioxidants such as vitamins C and E, purple carrots have much more interest with their phenolic (Alasalvar et al., 2001; Kırca et al., 2006; Singh et al., 2011), which contributed to the antioxidant capacity positively (Algarra et al., 2014). In particular, purple carrots have higher antioxidant capacity in comparison with other colors (Sun et al., 2009). Nicolle et al. (2004) tried to understand the influences of genetic variability on carotenoid, vitamin, phenolic and mineral content of the different carrot roots to assist the breeding programs. Purple carrots are often consumed processed (Alasalvar et al., 2001). Limited fresh consumption of them has been maintained in Turkey for years. Mostly it has been used to produce of local drink called 'salgam'. In recent years, production has been increasing dramatically due to the use for anthocyanin extraction by the pigment industry; more than 90% of the purple carrots produced in Turkey are being used by this industry (Ipek et al., 2016).

Because of favorable climate and soil conditions, purple carrot production is mostly spread in Turkey's Konya province. It is considered that quality of the purple carrot roots harvested from this area higher than the other production areas. This makes Konya's purple carrot locally called "Black Carrot" to be well known by the world and makes it an important export product. In this study, the effects of different ecologies on root quality were compared. It is thought that at the end of the project, obtained results could be contributed to spread the production out of the certain growth areas thus; production of purple carrot, also consumption of the vegetable with obvious benefits could be increased. Purple carrot roots, generally consumed by processing, before fabricated they may have to be stored for several months. During the storage, some visible deteriorations occur in the carrot roots and the effects of storage on root quality are not clear. With this study the effects of storage on the quality of the purple carrot roots was determined. Briefly, this study aims to compare the effects of different ecological conditions and long-term cooled storage on the quality characteristics of six local purple carrot genotypes. In this research "quality characteristics" means, determination of antioxidant activity (AA), contents of anthocyanin (AC), total phenolic (TP), total flavonoids (TF), titratable acidity (TA), total soluble solids (TSS), invert sugar (IS) values of the purple carrot root samples.

Materials and methods

Plant material

In the current study, six black carrot genotypes (DC17, DC28, DC33, DC34, DC36, and DC37) collected from the general production areas of Konya province were used as a plant material. These genotypes have been maintained in a limited area (nearly 20 000 da in Eregli and Karapınar regions) by local farmers who act as a seed saver for many years. Before this study, root samples were collected by visits to the local carrot growing fields in Kuzukuyu, Pınarozu, Akoren villages and Basin plateau in Ereğli District within another project. Collected roots brought to the institutes which are located in Yalova (40° 39′N, 29° 17′E) and Konya (Karapinar region; 37° 42' N, 33° 33' E) for planting and selfing. Selfed purple carrot seeds were planted separately when

DOI: http://dx.doi.org/10.15666/aeer/1706_1524515254

the season was appropriate. After a successful vegetation period harvested root samples were divided in two parts and non-stored roots were directly taken to the laboratory. The other part was stored for two months in the cold storage, temperature ranged from 2 to 3 °C and relative humidity (RH) was 85 to 90%. Followed to the storing stage, these samples were taken to the laboratory likewise. Extraction and the laboratory analyzes were done three times at the Ataturk Central Horticultural Research Institute, Yalova.

Field trials

Field trials planned according to the randomized complete blocks design with three replications. Each trial areas' soil conditions are listed in *Table 1.* Because of the climatic conditions (*Table 2*) seed sowing was done on May 15 in Konya and on August 15 in Yalova, harvest was started November 15 in Konya and February 15 in Yalova between the years of 2016-2017.

Physicochemical analysis

After sowing, cultural practices have been done properly throughout the season in two trial areas. Following the harvest, AA, TP, TF, AC, TSS, TA, and IS values of stored and non-stored roots were investigated in 2017. The amount of TF in extracts was determined spectrophotometrically according to the Folin-Ciocalteu method (Thaipong et al., 2006). Total flavonoid content of extracts was measured according to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1524515254

the modified method of Zhisnen et al. (1999). Anthocyanin quantitation was performed by the pH differential method (Moyer et al., 2002). Antioxidant activity was determined by two methods which were 1,1-diphenyl-2-picrylhydrazyl (DPPH) (Thaipong et al., 2006) and ferric reducing ability of plasma (FRAP) (Benzie and Strain, 1996) because of no single method represents AA well. TSS values, were determined by the Abbe refractometer, TA and IS values determined according to Cemeroglu (2007).

Statistical analysis

Study was completed between the years of 2015-2017. Field trials planned according to the randomized complete blocks design with three replications and laboratory tests were done 3 times. All data were analysed using analysis of variance (ANOVA). Analysis of variance was employed to compare the means of genotypes, location, storage and their interactions. The significance of differences between results was determined by DUNCAN multiple comparison technique. The statistical significance is indicated within the *Table 3* ($p < 1\%$).

Results and discussion

Trial areas' soil conditions are listed in *Table 1.* According to the analyzes, Konya's soil is loamy and poor in organic matter, Yalova's soil is clay-loam and richer in organic matter compared to the Konya. According to *Table 2,* climatic conditions of the trial sites are quite different from each other, such as while Yalova was temperate and rainy Konya was arid and hot throughout the growing period. Because of this, different periods of the year were selected for root production. After the harvest it was observed that, the differences between the areas weather and soil conditions affect the roots visible quality, which means harvested roots from Konya looked smoother and marketable compared to the Yalova's mostly shapeless and rough roots. It is thought that, Yalova's different day and night temperature regimes and high air and soil humidity could lead to, undesired lateral root branching and woody root growth. In addition to this it was understood from the researchers' previous studies that, production of purple carrot during spring and summer time cause the undesired early flowering in Yalova conditions. Therefore, cultivation was started in late August for Yalova. Seljasen et al. (2013) reported that quality characteristics of carrots are very sensitive to the influences of biotic and abiotic stresses.

The results of variance analyses for the investigated characters were showed in *Table 3*. All characters were significant for the interaction of three factors (genotype, location and storage) except TF content and TA values ($P < 0.01$). The content of TF and TA were significant for interaction of genotype × storage, and genotype × location (*Table 3*).

According to variance analysis, there was not individual effect of each factor on the content of IS, so all the results about IS, TSS, AC, TP, FRAP and DPPH were compared to each other (totally 24 values) and all the results were summarized in *Table 4*. The lowest IS content measured in genotype-DC28 harvested from Yalova (YL) location, and in non-storage (NS) treatment (3.00 g 100 ml^{-1}), while the highest value obtained from genotype-DC33 harvested from same location and storage (S) treatment (69.25 g 100 ml^{-1}). In a study conducted by Ersus and Yurdagel (2007) IS determined as 3.80 g 100 g^{-1} that was very similar to our non-stored genotype-DC28 harvested from Yalova.

*Means within a column that have a different small letter are significantly different from each other ($P < 0.01$). Lettering was made according to results of variance analyses. Abbrevations as in *Table 3*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1524515254

According to *Table 4,* AC content of the six purple carrot genotypes ranked between 1,692.43 - 11.34 mg l^{-1}, obtained from non-stored roots of genotype DC36 and genotype DC33 respectively, grown in Konya location. With respect to the results, AC content of genotype DC36 found higher than the other genotypes in all locations whether stored or not. Leja et al. (2013) compared the contents of carrots in different colours and reported that purple or black carrots contain more AC than the other coloured varieties.

In a study conducted in Spain, researchers found that two commercial varieties (Antonina, Purple haze) have AC 93-126 mg/100 g in fresh weight respectively (Algarra et al., 2014). In another study, researchers stated that analyses of TP and AC showed significant genotype × environment interactions also in blueberry cultivars (Connor et al., 2002). Recently, newly developed carrot varieties with an extremely high content of anthocyanin (nearly 1,750.00 mg/kg in fresh weight) is cultivated in the fields (Mazza and Miniati, 1993).

The difference between the TP contents of genotypes was found statistically significant ($p < 0.01$). The fresh roots of genotype DC36 cultivated in Konya and Yalova received the highest value (5.772,38 - 5.486,67 mg GAE 100 g^{-1}). In this study, the lowest TP values obtained from stored roots of genotype DC33 harvested from Yalova and Konya (538.86- 491.42 mg GAE 100 g^{-1}). When the results considered location and location × storage interactions were non-significant on TP content. Kramer et al. (2012) reported that total phenolic content varied in a wide range among different coloured carrot roots but purple cultivars significantly exceeded other coloured roots and also influence of growing location was found to be weak in that study. In a trial, 35 carrot accessions, 15 of them orange, 8 yellow, 5 white, 5 red and 2 purple roots were investigated and purple and red ones were determined as rich in phenols (19.8 to 342.2 mg 100 g^{-1} in fresh weight). Also researchers stated that, carrots developing purple roots possessed on average 9 times more phenolic than roots of other colours (Leja et al., 2013). Obtained results showed that used genotypes of the current study, have higher TP content than the previous results. In addition to this, in a research on Guava fruit, TP contents of four genotypes were found 170-344 mg 100 g^{-1} in fresh weight (Thaipong et al., 2006). It can be understood that studied carrot roots have much TP content even from the guava genotypes.

It is evident from the *Table 4* that used genotypes were significantly influenced all of the studied parameters. So the genotypes were grown in Konya or Yalova even if they stored or not, when the studied parameters considered, the differences between the used purple carrot genotypes found significant. Like these findings, Nicolle et al. (2004) and Kramer et al. (2012) found significant differences on mineral compound and total phenolic content of the different carrot cultivars used in their study even if they were in same color.

With the current experiment, functional properties of the selected six genotypes were identified, so it is possible to choose the appropriate genotype before start the any study. Such as, it was clear from the experiment, genotype DC36 was found superior to the other genotypes in all applications for all parameters except IS. On the other hand, when the results of genotype DC33 considered, according to AC, TF, TP content and AA values, it was ranked last on the list but its TSS and IS values ranked top compared to the other genotypes.

In the present work used two (Konya, Yalova) locations did not find significant in terms of the total phenolic and flavonoid content of the purple carrot roots (*Table 5*). However, the other examined parameters like those of AC, AA, TSS and TA were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1524515254

affected from the different environmental conditions. When the TSS values were examined, it was determined that the effect of the location was significant and the genotypes DC36, DC33, DC17, DC28 and DC37 from the carrots grown in Konya were higher TSS values than the ones in Yalova. It has been found that genotype DC34 received 8.9 TSS from the fresh roots of Konya and the other DC34 numbered applications were below this value. It is possible to have different TSS contents because of the effects of different climate conditions (Ersus and Yurdagel, 2007). In a study researchers deal with the detect of the AC profile and AA features of two different black carrots cultivars. While material collecting, researchers took into account growing region and they picked roots from the same location of Southern Spain. As could be understood that, the field conditions could be affect the characteristic of the roots (Algarra, 2014).

The contents of TF was significant for interaction of genotype × storage, and genotype × location (*Table 5*). According to this study, although the genotypes differ in their TF content, chill storage for two months did not affect the TF content of carrot roots (*Table 5*). Moreover, chill storage did not affect the AA according to FRAP values but with respect to DPPH results, storage effect was found statistically important on AA. Alasalvar et al. (2005) studied chill storage effects on AA, AC and TP contents. While total AA remained comparatively constant in orange ones, there was significant decrease was observed in purples. In addition, the content of AC in purples decreased slightly but TP increased at a much higher rate during storage than orange carrots. In our research the effect of chill storage for two months found statistically important when the other applications considered. Klaiber et al. (2005) reported that the content of TP increased throughout the storage of carrots under aerobic conditions.

Table 5. *The effects of location and storage on flavonoid and titratable acid contents of purple carrot genotypes*

Conclusion

Because of its nutritional features, purple carrot is a valuable product and it is exported to the many countries around the world from Turkey. With this study, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1524515254

effects of different environmental conditions and storage on the characteristics of the purple carrot roots were determined. The studies were carried out under natural environmental conditions. It has been understood that the used purple carrot genotypes could be grown outside the current cultivation area. However, with the effect of ecological conditions, the differences in both quality characteristics and external appearance of the roots have been detected. It was observed that the roots harvested from Yalova unsuitable for the fresh market. Moreover, the effect of storage on all applications except total flavonoid content was found significant. These results should be taken into consideration by the producers, plant breeders and processing industry members. In future studies, detailed physiological analysis under fully controlled conditions (such as growth chamber) can be great benefit to plant breeders and food scientists. Furthermore, associations between dietary patterns and gene expression profiles of healthy men and women and additionally investigating the relationship between nutritional values and gene expression profiles of genotypes can be great benefit to plant breeders. With the further studies, the production and consumption of purple carrot, a beneficial, highly nutritional and inexpensive food, can be expanded.

Acknowledgements. The authors would like to thank to Dr. S. Secil Erdogan for the technical advices in laboratory studies and Necati Simsekli for the field experiments in Konya location. (Received 4th Jul 2019; accepted 25th Oct 2019)

Abstract. Carnation (*Dianthus caryophyllus* L.) is one of the most important cut flowers in the world. Some fungi, bacteria and viruses lead to diseases that affect carnation plants, and most of these severe diseases are caused by Fungi. It is considered that *Fusarium oxysporum f. sp. dianthi (Fod)* has induced one of the most serious and detrimental diseases that impair carnation. In this study, the effect of some biological preparations [*Trichoderma harzianum Pseudomonas fluorescens; Bacillus subtilis* QST 713 (SERENADE), *Mycorrhiza* spp., *Trichoderma* spp., *Bacillus* spp. (PANORAMIX), *Lactobacillus acidophilus* + *Lactobacillus paracasei* (VITANAL), tea tree oil extract (TIMOREX GOLD), orange oil extract (PREV-AM), plant extracts of Reynoutria spp. (REGALIA) against *Fod* were investigated. Experiments were performed using a randomized plots design with five replications (five pots and one plant per pot) in a growth chamber. After 30 days, carnation plants were evaluated with a scale of 0-5 values. The effect of biological preparations was calculated based on root size, root number, plant height and number of nodes, then the acquired data were evaluated. The best results were obtained with *T. harzianum* (96%), SERENADE (96%) and PANORAMIX (88%) against *Fusarium oxysporum* f. sp. *dianthi*. All of the control plants (+) were completely dead due to the disease. In conclusion, the biological control improves the Fusarium wilt suppression capabilities of carnation.
Keywords: *Pseudomonas fluorescens, Bacillus subtilis, Trichoderma harzianum, plant extract, orange oil extract*

Introduction

Carnation (*Dianthus caryophyllus* L.) belongs to the Caryophyllaceae family and has been extremely popular amongst cut flowers since the 18th century. Carnation is one of the most demanded cut flower in the world. Netherlands is a leading country which has the biggest market share of carnations in 2015 with around 47% of all imports in the European Union followed by The United Kingdom, Spain, Poland, Bulgaria, Slovenia, Romania and the Baltic states (https://www.cbi.eu/market-information). Turkey also has a substantial place among producers of carnation plant, which is the major horticultural product of that country. Turkey has introduced a variety of popular standards and spray for carnations to marketplace for a long time. Sixty percent of the cut flower production has comprised of carnation plant in Turkey..In addition, most of the grown cut flowers are chrysanthemums, gerberas, solidange, gladiolus and freesia. The lion's share of ornamental plant production in Turkey has been churning out between the cities of Antalya, İzmir and Yalova, and Isparta (TSI, 2016).

Some diseases and pests lead to economic damage during the process of carnation cultivation. The most important disease is Fusarium wilt, caused by *Fusarium oxysporum* Schlechtend: Fr. f. sp. *dianthi* (Prill & Delacr.) W. C. Snyd. & H. N. Hans., which is a soil-borne fungus disease. Fusarium wilt disease is common in 79% of carnation production areas and affects 45% of total production (Anonymous, 2006). The most important phytopathological problem affecting carnation in most areas of the world is Fusarium wilt, caused by *Fusarium oxysporum* f. sp. *dianthi*. (*Fod*). Fusarium wilt is prevalent in 79% of the national production areas of carnation and affects 45% of its total production (Anonymous, 2006). The symptom of *Fod* is characterised by wilting of shoots, discolouration of leaves, and brown streaks on vascular tissue in stem. The infected leaves turn out chlorotic and finally wilt (Sohi, 1992). *F. oxysporum* f. sp. *dianthi* has various biological races and occurs in different carnation cultivars due to their selective virulence. Race 2 of *Fod* is the most prevalent in carnation cultivars (Denmik et al., 1989; Sarrocco et al., 2007). Fusarium wilting disease is controlled by systemic fungicides. This situation has a negative impact on human health, causes pollution and toxicity and also reduces the population of beneficial microorganisms in the soil. Therefore, alternative methods must be found to reduce the use of chemical fungicides. For this reason, biological control studies are of great importance. Mahalakshmi et al. (2015) investigated the effect of different organic inputs viz., neem cake, mauha cake, coipith and vermicompost against the wilt disease in carnation. As a result, Neemcake (10%) effectively prevented the growth of Fod. Hanudin et al. (2017) reported that *Bacillus subtilis* and *Pseudomonas fluorescens* suspended in the vermicompost extract and molases on the concentration level of 0.5% were consistenly effective in suppressing Fusarium wilt on carnation. In addition, fungicides adversely affect human and environmental health. Hence, alternative control methods as biological control which are more environmentally friendly are necessary.

The aim of this study was to evaluate the effectiveness of some biological methods against Fusarium carnation wilt disease using a randomized plots design with five replications over a 30 day period, in order to find the best biological practice to combat the disease.

Material and methods

Fusarium oxysporum f. sp. *dianthi* (*Fod*) was used as a pathogen. *Fod* was isolated from Isparta carnation greenhouses in Turkey and tested for pathogenicity). Some biological organisms and plant extracts were utilised as a biological control. Microorganisms and plant extracts used in the experiment are given in *Table 1*. All treatments were applied on the carnation cuttings by root-dipping.

Isolation and identification of Fusarium oxysporum f. sp. dianthi

Samples exhibiting wilt disease of carnation were collected from the 5 different greenhouses of Isparta, Turkey during 2017-2018 and brought to the laboratory. From these samples five isolates of *Fod* were isolated and identified (Nelson et al., 1983; Burgess et al., 1994). Pathogenicity of isolates was assessed. As a result of the pathogenicity test, ISP-3 isolate, which caused the most diseases in commercial carnation cultivar was used in the experiments.

Tea tree oil extract (TIMOREX GOLD)	5
Orange oil extract (PREV-AM)	5
Plant extracts of *Reynoutria* spp. (REGALIA)	5

Isolation of Trichoderma harzianum, Pseudomonas fluorescens

Trichoderma harzianum and *Pseudomonas fluorescens* were isolated by dilution plate technique from the soil samples collected from Isparta and Aydın, in Turkey (Johanson, 1957). The fungal isolate was grown on PDA plates, the bacteria isolate was grown on Nutrient Agar (HIMEDIA, 13 g/L) media at 25 °C. The isolated species were identified by Rhodes (1959), Whipps (2001) and Chin et al. (2003). The isolates of *T. harzianum* and *Pseudomonas fluorescens* were kept on the PDA/NA medium in the Biotechnology and Plant Pathology Research Laboratory, Isparta University of Applied Sciences, Isparta.

Plant material

The commercial carnation cultivar of Picasso was used for its potential antagonistic capacity to Fusarium carnation wilt disease reaction in a growth chamber condition.

Treatment and assessment

Pseudomonas fluorescens were grown in Nutrient Agar (HIMEDIA, 13 g/L) medium and placed at 90 rpm on a rotary shaker for 48 h at room temperature. The cells were harvested by centrifugation for 15 min at 5000 rpm and the pellet was suspended in distilled water. Suspension of bacteria was adjusted to 1×10^7 cfu/ml. The isolates of *T. harzianum* and *F. oxysporum* f. sp. *dianthii* were cultured in PDA plates and incubated at 25 °C for 10 days. Sterile distilled water was poured on the mycelium of fungi and mycelia were collected with a scalpel and the liquid was taken out. Suspensions were then filtered through sterilized cotton filters to obtain pure conidial suspensions and the spores were counted by using a hemocytometer. The spore suspensions of both fungi were adjusted to 1×10^6 conida/mL concentration with sterile distilled water. When plants had 6-8 true-leaf stages, all treatments (REGULAR-200 ml/100 L, TIMOREX-200 ml/100 L, PREW-AM 200 ml/100 L, VITANOL-300 ml/100 L, PANORAMIX-600 ml/100 L, SERENADE-1000 ml/100 L, *T. harzianum*-1×10^6 conida/mL), *P. fluorescens* -1×10^7 cfu/ml.) were applied on the carnation cuttings by root-dipping for 30 min using 20 mL per plant. Treated plants were separately planted in pots with 2 torf:1 perlit: substrate and the remainder suspensions were added to the pots. After 48 h, inoculum suspension of *F. oxysporum* f. sp. *dianthii* were added using 20 ml per plant. The plants were transferred to growth chambers at 24 °C and 12-h day/12-h night for 30 days (*Fig. 1*). Experiments were performed using a randomized plots design with five

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1525515265

replications (five pots and one plant per pot) in a growth chamber. The experiment was repeated twice. Diseases severity was evaluated 30 days after inoculation with a 0-5 scale values as follows: 0 = no symptoms (0% disease); 1 = weakly affected plant (5%); 2 = local base-stem symptoms (20%); 3 = one-sided and well-developed symptoms (50%); 4 = severe disease symptoms throughout the plant (80%); 5 = dead plant (100%) (Baayen and van der Plas, 1992).

Figure 1. *Different treatment against Fod on carnation cv Picasso in a growth chamber*

The disease severity was monitored every week throughout experimental procedure. The disease severity was evaluated using Townsend-Heuberger's formula (Towsend and Heuberger, 1943). The percentage effect of the applications was calculated using the Abbott formula (Abbott, 1925). The effect of biological preparations (%) was calculated, root size (cm), root number, plant height (cm), number of nodes were measured. Control plant groups were used in the experiment, and control positive plants groups were applied only to Fod and control negative plants only water was applied.

All data were analyzed by analysis of variance (ANOVA) to detect differences between treatments. Mean comparisons were made by using Duncan's tests; all statistical tests were conducted at a probability level of $P \leq 0.05$. All analyses were performed using the SPSS 21 software.

Results

Trichoderma harzianum, *P. fluorescens*, *B. subtilis* QST 713 (SERENADE), *Bacillus* spp + *Trichoderma* spp. + *Endomycorrhiza* (PANORAMIX), *L. acidophilus* + *L. paracasei* (VITANAL), and plant extracts of Tea tree oil extract (TIMOREX GOLD), Orange oil extract (PREV-AM), *Reynoutria* spp. (REGALIA) were applied to carnation wilt disease caused by *F. oxysporum* f. sp. *dianthi*. All applications reduce disease symptoms significantly (*Fig. 2*).

The lowest disease severity (%) was obtained from *P. fluorescens* (4%), SERENADE (6%), and *T. harzianum* (10%) to Fod. Disease severity (%) was determined in the application of PANORAMIX (12%). The percentage of disease severity in control plants was observed as 96% (*Fig. 3*). In the experiment, it was determined that the highest percentage of efficacy values of the biological preparations were for *P. fluorescens* (96%), SERENADE (94%), and *T. harzianum* (90%) to Fod.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1525515265

Control plant groups (+) were completely dead due to the disease. The lowest percentage of efficacy values of the biological preparations were determined with the application of TIMOREX (76%), VİTANAL and REGALIA (72%). In conclusion, the biological control method improves the suppressive capacity against Fusarium wilt disease in carnation (*Table 2*).

Figure 2. *Effects of different treatments on Fod incidence on pot assay in a growth chamber*

Figure 3. *Effects of SERENADE, TIMOREX GOLD and T. harzianum on plant growth*

The effect of different treatments on plant parameters of carnation was presented in *Table 3.* Statistical analysis of figure showed significant differences in treatments at $P \leq 0.05$ levels. Application of different treatments have improved carnation growth statistically. Plant height was showed significant variation with TIMOREX GOLD application. The longest plant height was found in TIMOREX GOLD application (31.60 cm) followed by PANORAMIX (26.46 cm), REGALIA (26.44 cm) and SERENADE (25.98 cm)) applications. The shortest plant height were in *P. Fluorescens*

(21.25 cm) application. Significant variation was observed in the case of the number of roots with different treatments. The maximum root number was in TIMOREX GOLD application with 23.20, the minimum number of root was determined in PREV-AM with 11.60. The root length was showed significant variation with different treatments. The maximum root length was determined on REGALIA application (4.28 cm). Significant variation was determined in the case of the number of nodes. It was indicated that the maximum number of node (9.00) was found VITANAL and REGALIA, the minimum number of node (5.60) was in *P. fluorescens*. Results showed that TIMOREX GOLD, REGALIA and SERENADE in generally were found effective to enhance the plant growth percentage compared to control.

Discussion

In this study, *F. oxysporum* f. sp. *dianthi* was significantly reduced by several microorganisms and plant extracts. In the experiment, it was determined that the highest percentage of efficacy values of the biological preparations were for *P. fluorescens*, SERENADE and *T. harzianum* to Fod. In addition, the application of SERENADE, TIMOREX GOLD and REGALIA increased plant height. SERENADE, *T. harzianum* and *P. fluorescens* are very common biocontrol agents against the pathogen. Biocontrol

DOI: http://dx.doi.org/10.15666/aeer/1706_1525515265

bacteria and fungi produce multiple antibiotics that eliminate plant pathogen bacteria and fungi (Strange, 2007; Wang et al., 2016). *Trichoderma* spp. produce various antibiotics, such as viridin, gliotoxin, polyketides and pyrones, against fungal phytopathogens (Howell, 2003; Harman et al., 2004; Naher et al., 2014). *Bacillus* spp. include bacitracin, mycosubtilin polymyxin, bacillomycins and gramicidin and they inhibit fungal germination, suppress of some plant pathogen. One of the most important antibiotics compound produced by *P. fluorescens* is pyrollnitrin, which inhibited growth of some plant fungal pathogens (Karimi et al., 2012; Santoya et al., 2012; Chapelle et al., 2016).

Competition for nutrients and plant surface is another mechanism for plant pathogens. Competitive exception of pathogens as the result of fast colonization of the rhizosphere or plant surface by biological fungus and bacteria may also be an important factor in the control of plant pathogens. Biocontrol species have a higher affinity for nutrients especially iron, phosphorus, nitrogen and can stimulate plant growth directly by or indirectly. They can suppress a broad spectrum of bacterial, fungal and nematode diseases (Jan et al., 2011).

Many biocontrol bacteria and fungi induced systemic resistance which is characterised by a broad spectrum of resistance against pathogens (Conrath et al., 2006; Pieterse et al., 2014; O'Brien, 2017). Beneficial microbes elicite the signalling pathways, and stimulate the host's immune system. Biocontrol bacteria and fungus induced systemic resistance (ISR), may also contribute to disease suppressiveness (Beredsen et al., 2018).

Plant extracts and essential oils appeared to be efficient to control *F. oxysporum* f. sp. *dianthi*. Some research studies reported the efficacy of REGALIA in controlling bacterial spot of tomatoes and peppers (*Botrytis* spp. of grapes and strawberries, powdery mildew of cucurbits, downy mildew of lettuce (*Bremia lactucae*), Cercospora on soybeans (*Cercospora kikuchii*), *Cercospora zeae-maydis; Podospheria leucotricha*, *Venturia inaequalis,* bacterial canker on citrus (*Xanthomonas axonopodis* pv. *citri*), *Xanthomonas campestris* pv. *vesicatoria* and *Xanthomonas euvesicatoria* (Su, 2012; Worthington et al., 2012; Harbou and Jaksen Ziems, 2015; Delong et al., 2018). Many beneficial bacteria and fungi have a general plant growth promoting effect, and produce analogues of plant growth regulatory hormones, volatile compounds to stimulate plant growth. (Harman et al., 2004; Taghavi et al., 2009; Hermosa et al., 2012; Rashid et al., 2012; Truyens et al., 2014). Some beneficial microorganism is able to establish a symbiotic relationship with plants and they increase the availability of these nutrients to plants (Gutiérrez-Luna et al., 2010; Saharan and Nehra, 2011). Its beneficial effects of *Trichoderma* sp. on beside abiotic stress have been well documented (Donoso et al., 2008; Mastouri et al., 2010, Roatti et al., 2013).

In our experiment, the application of TIMOREX GOLD significantly reduced the Fod. TIMOREX GOLD components include cineole cymene, linalool and terpinen-4-ol (Carson et al., 2006; Goni et al., 2014; Wei et al., 2018). The plant oil and plant extracts include secondary chemical compounds such as terpenes, alcohols, aldehydes and phenols, and these materials exhibit fungicidal potential (Zanellato et al., 2009). Essential oil from tea tree oil extract has shown promising results in reducing disease occurrence and severity induced by *Cercospore beticola* in sugar beets, and *Alternari solani* in potato (Caolotanski et al., 2002). It was also reported that tea tree oil was effective against Fusarium head blight in wheat, barley and oats, barley leaf stripe and powdery mildew Terzi et al., 2007). The application of tea tree oil at 2.0% inhibited the

DOI: http://dx.doi.org/10.15666/aeer/1706_1525515265

mycelium growth of *Botrytis oryzae, Alternaria brassicicola, Fusarium moniliforme, Aspergillus flavus, Fusarium proliferatum* (Thobunluepop et al., 2009).

Conclusion

It has been observed that the treatments had a positive effect against the *F. oxysporum* f. sp. *dianthi* and the plant growth of carnation. Biological control method seems to be safe and environmentally friendly and an alternative method with respect to fungicides. Utilization of beneficial microorganisms could be a common agricultural practice in the near future. In addition, biological control methods might be combined with other control methods, but additional research is needed to develop methods of incorporation of biological organisms into other control strategies for the carnation wilt disease management. It is helpful to conduct an extended study that identifies the microorganisms and plant extracts used in the experiment under greenhouse conditions against Fod and carnation plant growth.

Acknowledgements. We would like to thank Assoc. Prof. Dr. Özgür KOŞKAN for his helps in statistical analysis.

Conflict of interests. The authors declare that they have no conflict of interests.

Funding. This study was not supported by any Research Fund.

Abstract. The paper presents the results of multivariate analysis assessing variation in quantitative traits after the application of various cover crops and tillage methods in cultivation of spring wheat in three years of study. The purpose of this study was to assess the multivariate phenotypic variation of spring wheat under 27 different combinations of three cover crops, three tillage methods and three years of study. 13 quantitative traits were monitored through the course of three years (2011-2013) in Poland. The result was statistically analyzed using the multivariate methods. Analysis of canonical variables proved to be a reliable tool providing a comprehensive assessment of variation in the effect of cover crop and method of tillage combinations on many traits simultaneously. The most diverse treatments were Z-A-1 (cover crop: zero, method of tillage: aggregate, in 2011) and N-P-2 (cover crop: no tillage, method of tillage: plowing, in 2012). The most similar treatments (in terms of 13 traits assessed) included Z-A-1 (cover crop: zero, method of tillage: aggregate, in 2011) and N-A-1 (cover crop: N – no tillage, method of tillage: aggregate, in 2011).
Keywords: *canonical variate analysis, grain yield, biomass of spring wheat, white mustard, Mahalanobis' distances, quantitative traits*

Introduction

In the area of integrated production, it seems necessary to develop a technology for the production of spring wheat, while also taking into account the inclusion of stubble. Crop rotation with a large share of cereals, will improve soil efficiency and create better phytosanitary conditions for the development of spring wheat (Majchrzak, 2015). Catch crops deliver environmental benefits, and they are widely recommended by programs which promote environmentally friendly agricultural practices (Wanic et al., 2019). Simplification of the tillage system can cause an increase in weeds and consequently, a decrease the yield of cultivated plants. Changes in weeds can affect also stubble catch crops and fertilization used as regeneration factors. Regenerating and yielding effect of catch crops cultivation depends, among from habitat conditions, as well as on the type of catch crop and species of the cultivated plant.

Numerous authors have proposed statistical methods for estimation the manner of factors reaction to diverse environmental condition (Wricke and Weber, 1986). Multivariate analysis tools, such as principal component analysis, canonical variables

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1526715276

analysis, canonical correlation analysis, additive main effects and multiplicative interaction and multiple regression, are powerful in dealing with intercorrelated data, such as agroclimatic and other factors limiting crop yields (Qian et al., 2009; Hussain et al., 2014; Nowosad et al., 2017; Nowosad et al., 2018; Bocianowski et al., 2018).

The aim of this study was to conduct a multivariate characteristic of phenotypic variability in 27 treatments being combinations of cover crop, method of tillage and years. The canonical variables analysis was applied, based on the model of multivariate analysis of variance (MANOVA), for observations of 13 quantitative traits in an experiment established in the split-plot design.

Material and methods

Experimental field

The field experiment was performed at the Brody Research and Education Station of the Poznań University of Life Sciences, Poland (52° 26' N; 16° 17' E) on soil classified (WRB 2007) as *Albic Luvisols* develop on loamy sands overlying loamy material (12% clay, 19% silt and 69% sand) in the years 2011-2013 (*Figure 1*).

Figure 1. *The experimental design of spring wheat (Triticum aestivum L.) at the Brody Research and Education Station of the Poznań University of Life Sciences, Poland (52° 26' N; 16° 17' E)*

They were performed in the random block (split-plot) design with three experimental factors in four field replications resulting in a total of 9 plots. The experiment was designed to analyses the effect of cover crop (white mustard cultivar Nakielska) sowing: (control: zero – Z, no sowing of cover crop, sowing of cover crop following skiming – S and no tillage – N direct sowing of cover crop), three tillage methods for spring cultivation (direct sowing – D, simplified tillage (cultivation aggregate to a depth of 12-15 cm) – A, spring ploughing to a depth of 25 cm – P) on 13 quantitative traits (grain

yield, [t ha^{-1}], protein grain yield of spring wheat [kg ha^{-1}], test weight of spring wheat grain [kg ha^{-1}], plants number of spring wheat after emergence [no m^{-2}], leaf greenness index SPAD, height plants [cm], leaf area index [LAI], biomass yield of spring wheat in BBCH 23 [t ha^{-1} DM], biomass yield of spring wheat in BBCH 32 [t ha^{-1} DM], biomass yield of spring wheat in BBCH 55 [t ha^{-1} DM], biomass yield of spring wheat in BBCH 75 [t ha^{-1} DM], number of weeds [no m^{-2}] and the fresh weight of weeds [g m^{-2}]).

Spring wheat cultivar, Vinjett, was sown at the rate of 400 seeds per 1 m^2 across all tillage systems. The size of each tillage plots was 10 m long and 4.5 m wide (45 m^2).

Sowing dates of spring depended of soil water conditions and occurred between 23rd of March 2012 and 17th of April 2013 and sowing depth in all tillage systems were 3-4 cm.

Fertilization was uniform for all tillage systems and each experimental year (90 kg N ha^{-1}, 26 kg P ha^{-1}, 50 kg K ha^{-1}). The herbicide program for tillage systems consisted of pre-plant and post-emergence applications. Before sowing 1.5 L ha^{-1} of Gliphosate herbicide + 1.5 L ha^{-1} adjuvant As 500 SL was applied to all plots with no-tillage to control perennial weed and volunteer plants. For weed control, during the growing season post-emergence BBCH 22 Lintur 70 WG (dicamba 65.9%+triasulfuron 4.1%)+Chwastox Extra 300 SL (MCPA 300 g L^{-1}) herbicide were applied at the rate of 150 g ha^{-1}+1.0 L ha^{-1}. For disease control, Falcon 460 EC fungicide (spiroksamine 250 g L^{-1}+tebuconazole 167 g L^{-1}+triadimenol 43 g L^{-1}) at the rate of 0.6 L ha^{-1} was applied in all plots at BBCH 32 growth stage and Fury 100 EW insecticide (zeta-cypermetryne 100 g L^{-1}) at the rate of 0.1 L ha^{-1} and at last year Karate Zeon 050 CS (lambda – cyhalotryne) at the rate 0.1 L ha^{-1} at BBCH 61 growth stage.

Sampling and Measurements

Plants number of spring wheat after emergence [no m^{-2}] – frame method (2 × 0.25 m^{-2}). Biomass yield of spring wheat in BBCH 23, BBCH 32, BBCH 55, BBCH 75 [t ha^{-1} DM] (2 × 0.25 m^{-2}). Mesurements of leaf area index [LAI] was made in BBCH 51-53 phase, using SunScan Canopy Analysis System type SSI – Delta-T Devices Ltd. Great Britain. Chlopchlorophyll content indicator (SPAD) was determined in BBCH 39 phase using Chlorophyll Hydro N-Tester. Number [no m^{-2}] and the fresh weight of weeds [g m^{-2}] were carried out annually on randomly determined parts of experimental plots covered with foil covers during the application of herbicides. In the development phase (BBCH 31–32) spring wheat was determined on an area of 1 m^2.

Meteorological conditions

In the first year of research, only in July the amount of precipitation exceeded by 86.4 mm the precipitation needs of spring wheat (*Table 1*). For optimal wheat development this year there was no rain: in April 31.1 mm. in May 32.0 mm and June 67.6 mm. Such water shortages adversely affected the emergence, development of plants, tillering and the formation of ears. In year 2012, rainfall deficiencies occurred in April (22.1 mm) and in June (13.2 mm), May precipitation exceeded the demand for water by 11.2 mm, and in July by as much as 108.6 mm. In the last year of research, water was lacking in April (deficit by 29.6 mm), which was partly complemented by May (excess in relation to optimum 97 mm) and June (42.3 above optimal). The rainfall deficit also occurred in July (21.7 mm below needs) for this period. Comparing the multiannual average with precipitation needs, it should be stated that the sums of precipitation occurring in the analyzed region are usually lower than the demand for

DOI: http://dx.doi.org/10.15666/aeer/1706_1526715276

water necessary for the optimal development of spring wheat. To sum up the course of weather conditions, it can be said that the first year of research was the least favorable for the growth and development of spring wheat, while the most favorable was year 2013.

Table 1. *Rainfall sums and rainfall requirements (Dzieżyc, 1989)*

Years	Rainfall sums [mm]			
	April	May	June	July
2011	13.9	34.0	15.4	175.4

Means 1961-2010	38.0	57.4	61.8	77.5
Demand volume in month [mm]				
Rainfall requirements	45	66	83	89

Statistical analysis

Firstly, the normality of the distributions of the studied traits were tested using Shapiro-Wilk's normality test (Shapiro and Wilk, 1965). Multivariate analysis of variance (MANOVA) was performed on the basis of following model using a procedure MANOVA in GenStat 18th edition: **Y=XT+E**, where: **Y** is ($n\times p$)-dimensional matrix of observations, n is number of all observations, p is number of traits (in this study p=13), **X** is ($n\times k$)-dimensional matrix of design, **T** is ($k\times p$)-dimensional matrix of unknown effects, **E** – ($n\times p$)-dimensional matrix of residuals. Nextly, the effects of the main factors under study (cover crop, method of tillage and years), as well as the all interactions between them were estimated using a linear model for three-way analysis of variance (ANOVA) for particular traits. The relationships between observed traits were assessed on the basis of Pearson's correlation coefficients and tested by the t-test. Results were also analysed using multivariate methods. The canonical variate analysis was applied in order to present multitrait assessment of similarity of the investigated treatments in a lower number of dimensions with the least possible loss of information (Rencher, 1992). This makes it possible to illustrate variation in investigated treatments in terms of all observed traits in the graphic form. Mahalanobis' distance was suggested as a measure of "polytrait" treatments similarity (Seidler-Łożykowska and Bocianowski, 2012), whose significance was verified by means of critical value D_α called "the least significant distance" (Mahalanobis, 1936). Mahalanobis' distances were calculated for investigated treatments. In order to determine the relative share of each original trait in the multivariate variation of analysed treatments Pearson's simple correlation coefficients were estimated between values of the first two canonical variables and values of individual original traits. All the analyses were conducted using the GenStat v. 18 statistical software package.

Results and Discussion

All studied quantitative traits have a normal distribution as well as a multivariate normality. Results of MANOVA indicate that the all factors (years: Wilk's λ=0.00127, $F_{2;81}$=143.60, P<0.0001; cover crop: Wilk's λ=0.16470, $F_{2;81}$=7.77, P<0.0001; method of tillage for spring wheat: Wilk's λ=0.07879, $F_{2;81}$=13.60, P<0.0001) and their

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1526715276

interactions (years × cover crop: Wilk's λ=0.06601, $F_{4;81}$=5.27, P<0.0001; year × method of tillage for spring wheat: Wilk's λ=0.07601, $F_{4;81}$=4.90, P<0.0001; cover crop × method of tillage for spring wheat: Wilk's λ=0.15555, $F_{4;81}$=3.19, P<0.0001; years × cover crop × method of tillage for spring wheat: Wilk's λ=0.07820, $F_{8;81}$=2.09, P<0.0001) were significant different for all 13 traits. The ANOVA indicated statistically significant influence of years for all observed traits (*Table 2*). Cover crop was significant for all traits except leaf greenness index, biomass yield in BBCH 23, biomass yield in BBCH 32, biomass yield in BBCH 75 and number of weeds, however method of tillage for all traits except leaf greenness index, height plants, LAI and weight of weeds. In research by Kulig et al. (2010) there was not significant correlation between SPAD values and grain yield but a strong link with the protein content and with the values of grain yield. Lepiarczyk et al. (2005) showed that the method of cultivation and use of fore crop significantly influenced the size of leaf surface. They showed that the value of LAI and the conopy of wheat grain yield is significant and has a high correlation. The year × cover crop × method of tillage for spring wheat interaction was significant for plants number after emergence, biomass yield in BBCH 55 and weight of weeds (*Table 2*).

GY - grain yield, PGY - protein grain yield, TW - test weight, PNE - plants number after emergence, SPAD - leaf greenness index, HP - height plants, LAI - leaf area index, BY23 - biomass yield in BBCH 23, BY32 - biomass yield in BBCH 32, BY55 - biomass yield in BBCH 55, BY75 - biomass yield in BBCH 75, NW - number of weeds, WW - weight of weeds

Kraska (2012) found that with regard to the yield, more reliable were undersown catch crops, compared with stubble crops. Kwiatkowski (2009) think that degree to which catch crops affect regulation of weed infestation is diversified and depends on habitat conditions, cereal species, type of catch crop and plant selection as well as method of its management. According to Wozniak (2011) compared to plough tillage ploughless tillage significantly increased air-dry weight of weeds in the spring wheat crop. The tillage system under comparison did not differentiate the number of weeds per 1 m^2.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)

Testing of Pearson's correlation coefficients made it possible to observe several statistically significant interdependencies between observed traits of spring wheat. Grain yield was significantly positively correlated with protein grain yield, test weight of spring wheat grain, plants number after emergence, LAI, biomass yield in BBCH 23, biomass yield in BBCH 55 and biomass yield in BBCH 75 (*Table 3*). Faber and Nieróbca (1999) found a strong correlation between the maximum LAI and above ground dry mass and slightly less with the grain yield. Lepiarczyk et al. (2005) showed that the values of LAI and the conopy of wheat grain yield is significant and has a high correlation. In our research generally, was observed 42 pairs of significant correlation coefficient: 36 positive and six negative (*Table 3*).

Individual traits are of different importance and have a different share in the joint multivariate variation. A study on the multivariate variation for treatments includes also identification of the most important traits in the multivariate variation of treatments. Canonical variables analysis (CVA) is a statistical tool making it possible to solve this problem (Bocianowski et al., 2016; Lahuta et al., 2018). Results of the CVA for investigated treatments are presented in *Table 4*. The first two canonical variables explained jointly 87.03% total variation between treatments (*Table 4*, *Figure 2*). *Figure 2* presents variation in traits of investigated treatments in the system of the first two canonical variables. In the graph the coordinates of a point of a given treatment are values of the first and second canonical variables, respectively. The greatest, significant linear relationship with the first canonical variables was found for the grain yield, test weight of spring wheat grain, plants number after emergence, height plants, biomass yield in BBCH 32, biomass yield in BBCH 55, and biomass yield in BBCH 75 (positive dependencies), and SPAD (negative) (*Table 4*). The second canonical variable was significantly positively correlated with grain yield, protein grain yield, LAI, biomass yield in BBCH 23, biomass yield in BBCH 75 and number of weeds (*Table 4*). The greatest diverse in terms of all the 13 traits jointly (measured Mahalanobis distances) was found for treatments denoted with symbols Z-A-1 (cover crop: zero, method of tillage: aggregate, in 2011) and N-P-2 (cover crop: no tillage, method of tillage:

plowing, in 2012) (the Mahalanobis distance between them amounted to 24.49). The greatest similarity was found for treatments Z-A-1 (cover crop: zero, method of tillage: aggregate, in 2011) and N-A-1 (cover crop: N – no tillage, method of tillage: aggregate, in 2011) (2.27). Values of Mahalanobis distances for all pairs of treatments are presented in *Table 5*.

cover crop: Z – zero, S – skiming, N – no tillage.
method of tillage for spring wheat: D – direct sowing, A – simplified tillage, P – spring ploughing; years: 11 – 2011, 12 – 2012, 13 – 2013

Conclusion

The presented multivariate characteristic of the behaviour of analysed treatments is a convincing illustration of this aspect. In this way efficiency of the canonical variables analysis was shown. This results from the fact that these variables explained a considerable part of total variation (87.03%). Additionally, we obtained three groups of treatments, classified by the years of study (*Figure 2*). Thus this is a reliable method, which may be confirmed by its extensive application by breeders and geneticists

(Shamsuddin, 1985; Seidler-Łożykowska et al., 2013; Nowosad et al., 2016; Bocianowski et al., 2018, 2019; Wrońska-Pilarek et al., 2018). In our study, the greatest diverse in terms of all the 13 traits jointly (measured Mahalanobis distances) was found for cover crop: zero, method of tillage: aggregate (in 2011) and cover crop: no tillage, method of tillage: plowing (in 2012). However, the greatest similarity was found for cover crop: zero, method of tillage: aggregate (in 2011) and cover crop: N – no tillage, method of tillage: aggregate (in 2011).

Abstract. A total of 48 weaned male rabbits were randomly arrangement to evaluate the effects of the Testosterone Enanthate (TE) for four treatments: negative control-without injection, positive control-Phosphate-buffered saline PBS, (TE) 4 IU and 8 IU injected intramuscularly (B1 and B2, respectively). Body weight traits measured by weekly weighing for 72 days (slaughter weight) their body weight and average daily gains (ADG) were calculated, and were then slaughtered to assess the TE residues of meat. Blood samples were collected for measuring phosphate-buffered saline (CBC) count, ALT, AST, ALP, Growth Hormone (GH) and Testosterone concentration The present study observed a significant increase in total BW gain for group B2 (8 IU), compared to negative control, positive control, and B1 group. The blood Testosterone concentration in the B2 group, significantly increased were higher than other treatment groups, at 2.73±0.26 ng/dL. The TE residue in meat there was no significant difference after 30 days end of treatment. In conclusion, TE injection improves BW traits in male growing rabbits when injected with a double dose of TE, with the exception of some CBC counts and has a significant mitigating effect on stress parameters, and increasing effect on serum GH and Testosterone concentration, with no significant changes in the TE residue in the meat.

Keywords: *buck rabbits, TE injection, body weight gain, CBC, testosterone concentration, TE residues*

Introduction

Domestic rabbits, in recent years, have been identified as economy livestock of meat shortage in high human population developing countries. Animals Meat, including rabbit's meat, supply a valuable and palatable source of protein. Rabbit meat has a very good nutritive value, being comparatively high in protein, low in fat, calories and sodium, and so could bridge the wide gap in dietary protein intake (Adeyinka et al., 2007). Anabolic androgenic steroids (AAS) are synthetic derivatives of testosterone hormone in the male that have been adjusting to improve their anabolic rather than androgenic activity (Shahidi, 2001). The AAS effects promote protein synthesis, muscle growth and erythropoiesis (Mottram and George, 2000). Anabolic steroids are a class of steroid hormones based on the androgen testosterone and are recognized for their effects on building up muscle and are used as an enhancing drug (Thienpont et al., 1998). Anabolic steroids increase muscle size by the promotion of positive nitrogen balance by stimulating protein production and decreasing destruction (Guan et al., 2010). However, there is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1527715287

insufficient available information for their use in these animals. Recently, boldenone undecylenate (androgenic steroid) has been used in the growth improvement and conversion of food in food-producing animals. It is also well known for increasing vascularity in preparation for bodybuilding contests. It might also play an important role not only in controlling normal testicular development, but also in maintaining spermatogenesis and normal testicular function (Tousson et al., 2012). The use of the anabolic steroid (BOL) resulted in obvious improvement in the growth rate (Tousson et al., 2012). This effect could be attributed to the promotion of the body tissue building process by protein synthesis indirectly via stimulation of growth hormone, insulin-like growth factor secretion, and animal appetite (Ferreira et al., 1998) or reduction of glucocorticoid receptor levels and sensitivity to endogenous glucocorticoids; therefore, the strong growth promoting potency is based not only on its anabolic activity as an antiglucocorticoid (Melloni et al., 1997; Thienpont et al., 1998). However, there were some reports reviewed that the rabbits' growth performance was not affected by testosterone injection (Tawfeek et al., 1994). Administration of BOL to male rabbits at a dose of (5 mg/kg body weight) had a positive and significant benefit on growth performance (feed efficiency, total and daily weight gain) and a significant increase in dressing percent (Mohammed et al., 2016). Nahed et al. (2010) reported that using of BOL in rabbit was not sufficient to confirm its use in rabbits although a considerable improvement of total weight gain, feed efficiency and feed conversion ratio were attained after application of BOL in the male rabbit. However, there is no reported in detail study on the effect of BOL on all carcass traits and blood parameters (Abdel-Hamid and Farahat, 2015). The double and the normal recommended dose positively increase serum total protein and globulin, while normal recommended dose apparently increases serum cholesterol and decrease plasma corticosterone level. The European Economic Community (EEC) banned the use of anabolic compounds as growth accelerators in food animals. While the United States Food and Drug Administration (USFDA) permitted the limited use of some hormones with natural origins (such as estradiol and testosterone) and some synthetic hormones (such as Zeranol and trenbolone) in animal husbandry (MacVinish and Galbraith, 1988; Sadek et al., 1998). Little work has been conducted in Iraq regarding the use of testosterone enanthate TE injection as a growth promoter and their residue in edible tissue. A report of Omar (2012), there were no significant differences among the three experimental groups in the TE residue of the cooked meat at 8 months of age, but their values were significantly lower than the fresh meat of Karadi lambs at the same period. A number of authors and official international committees proved that residues of natural steroidal hormones are not dangerous on the health of the consumer (JECFA, 1988; Lone and Van Ginkel, 1997; Galbraith, 2002). Testosterone is usually given in an injection vehicle with oestradiol, and as same with other steroid hormones, the testosterone injection do not differ than the natural hormone inside the body of the organism, and this hormone focused in the liver tissue and kidney, but in fat are the highest concentration of this hormone, When comparing the residues in treated animals and the natural ratios in animals without treatment, they have to be equal or close to it (Omar, 2012). As well as the content of the natural hormone and the testosterone in male sheep and goats is higher than females, although the consumer is preferred the meat of males on other meats. Hence, this study was performed to determine the effects of Two-doses administration of TE on body weight (BW), some blood biochemical parameters and testosterone residual effect of mature local male rabbits.

Materials and Methods

Location and duration of the study: The present study was carried out at the Experimental farm of the University of Sulaimani Polytechnic, Halabja Technical Agriculture College, Halabja-Iraq, during spring (April to June) of 2017. A total of (48 bucks) weaned male rabbits (14 weeks old) of Local breed were randomly assigned to a completely randomized design arrangement of treatments (Four treat 12 bucks /treat: negative control-without injection, positive control injected intramuscularly by Phosphate-buffered saline PBS, Testosterone Enanthate (4 IU) injected intramuscularly (B1) and Testosterone Enanthate (8 IU) injected intramuscularly (B2). All rabbits were injected after 14 days of adaptation and repeated once after 30 days of the first injection. Bucks were housed in a semi-closed rabbitry housing system with does and kept in batteries of individual cages (60 x 50 x 35 cm) supplied with feeding hoppers made of galvanized steel sheet and nipples for an automatic drinker. A commercial concentrate pellets ration is introduced to bucks throughout the experiment (*Table 1*), containing (16.91%) crude protein and (2703 Kcal/Kg DM) ration metabolizable energy (ME) (NRC, 1977). Fresh and clean drinking water was supplied *ad-libitum*. The feed and the water were offered *ad-libitum*. All the bucks were grown under identical environmental and feeding conditions as well as the same stocking density. A photoperiod (12L:12D) from 0900 to 2100 h was used throughout the experimental period. The temperature was maintained at a range of 28-32ºC inside the house.

Table 1. *Ingredient Composition Of The Diet During The Experiment Period*

Ingredient	%

Metabolizable Energy Kcal/Kg Dm	2703

Traits Measurements: Traits measured were; body weights: fryer rabbits were weighed weekly until 72 (slaughter weight) days and weights were recorded in grams. Body weight gain: calculated as differences between two successive different weights. Average daily gains ADG: calculated as the differences between two successive different weights at two different periods divided by the number of days between the two weights.

Blood parameters: Blood samples were collected twice in the experiment, before treatment and after one month after the first injection. The samples were taken in two test tubes, one with an anticoagulant for measuring CBC count levels and the other one without using anticoagulant to separate the serum for measuring ALT, AST, ALP, Growth Hormone (GH) and Testosterone concentration. Plasma and serum samples were stored at -20ºC until assayed. ALT, AST, ALP, Growth Hormone (GH) and Testosterone concentration were measured using commercial kits. For CBC levels we used Hematology analyzer (URIT 2900z, Vet Z plus, China), and for enzymes activity, we

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1527715287

used Biochemical Analyser (Floxer pro. S, China), and Hormone concentration by (MINI VIDAS®, France). For each treatment, five samples were assayed.

TE residue in meat: After slaughtering the bucks, 30 days after the last injection of the experiment. 500 gm of muscle were taken and placed in polyethylene bags and stored at -18ºC. Semimembranosus (SM) from pelvic limb leg was dissected according to the procedure of Butterfield et al. (1983). The surfaces of the muscles were cleaned from all fat and connective tissue. Quantitative determination of testosterone concentration (µg/kg = ng/mL) was carried out by using Radioimmunoassay (RIA) by using (cobas e 411 analyzer, made in Germany). The analytic sensitivity of the assay was 0.025 ng/mL.

Statistical analysis: Complete Randomized Design (CRD) procedures of XLstat. (7.5.2, 2010) in one-way ANOVA were used to determine the effects of Testosterone Enanthate TE and injection effect on the body weight characteristics, blood parameters, and TE residue. Group differences were determined using Duncan's multiple range tests at ($p \leq 0.05$) (Duncan, 1955).

Results

The effect of Testosterone Enanthate-TE hormone on growth performance parameters of local male rabbits was showed in *Table 2*. The results revealed that TE injection in male rabbits resulted not significant ($p>0.05$) different among groups, in initial BW, final BW gain, average daily gain ADG, and the high weight record were seen in B2 group for final BW and ADG (1593.3±41.5 and 6.292±0.384) gm, respectively. But there were a significant ($p<0.05$) different in total BW gain for group B2 (8 IU), which recorded (377.5±23.0) gm compared to negative control, positive control and B1 group, which were recorded (281.2± 60.8) gm, (271.2± 32.5) gm and (284.1± 37.1) gm, respectively. The best results were for the group (B2) in total BW and ADG increased in the ADG for groups (B1) and (B2) compared with the control.

Effects of dose of TE and the injection effect on complete blood picture levels parameters were summarized in *Table 3*. Statistically, no significant differences ($p>0.05$) were recorded before treatment for complete blood picture levels parameters. While, there were significant differences ($p<0.05$) were observed for control groups (negative and positive) compared to TE hormone injection groups after treatment for Hb (g/dL), RBC (10^6xUL) and HCT (%). The hormone injection groups (TE injection) significantly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

($p<0.05$) decrease the Hb concentration, which was (13.0±0.4 g/dL and 13.0±0.4 g/dL) for B1 and B2 respectively, compared to positive control (14.8±0.8 g/dL). Furthermore, the B2 group (8 IU) significantly ($p<0.05$) decrease in RBC and HCT, when compared to positive control (6.97±0.34)10^6xUL and (46.1±2.4) %, respectively. While MCV of the negative control was significant ($p<0.05$) overpowered (69.4±0.1) µL on other injection groups. But, there was no significant ($p>0.05$) difference between control and all injected groups for platelet count PLT (10^3x cells/mcL) count.

The results of *Table 4* demonstrated that changes in Leukocytes levels changed significantly ($p<0.05$) after TE hormone treated. Before treatment there were no significant differences ($p>0.05$) in the leukocytes levels, on the other hand, we recorded significant differences ($p<0.05$) in WBC count, Lymphocyte %, Monocytes %, Neutrophil%, Mean platelet volume (MPV%) and platelet distribution width (PDW). The TE injection increased the WBC count significantly ($p<0.05$), which high count recorded in B1 (4 IU, TE), and the highly significant value for lymphocyte and monocyte percent were recorded in B2 (8 IU) (61.0±1.0 % and 0.75±0.02 %, respectively). Conversely, the neutrophils count significantly ($p<0.05$) higher in BPS injection (Positive Control) (59.6±3.0 %). Also, the significant level was seen in MPV and PDW for B2 injection, which was 6.05±0.02 % and 9.10 ±0.44 %, respectively. As well, B1 injection significantly differenced too in PDW (8.60±0.01 %), when they compared to negative and positive control (7.50 ±0.01 and 7.63 ±0.02, respectively).

The comparison between the injection groups and negative control in the concentration of ALT, AST, ALP, Growth Hormone GH and Testosterone levels in the local rabbit are summarized in *Table 5*. Indeed, no significant differences were seen before treatment in all parameters, except in B1 treatment for AST and ALP levels. The AST recorded high level in B1 (39.0±1.6 IU/L). And ALP recorded less level in B1 (79.0±1.2 IU/L) when they compared to other treatments. After treatment, the parameters level change, the significant record seen in ALT, GH and testosterone concentration for B2 (8 IU) TE injection. The significant level for ALT recorded (69.5±9.4 IU/L), as compared to negative control, positive control and B1 injection. The GH concentration recorded significantly ($p<0.05$) higher level (0.32±0.01 ng/dL) at B2 (8 IU) TE injection when it compared to negative control and positive control (0.24±0.01 and 0.28±0.01 ng/dL, respectively). As well as, the Testosterone concentration in the B2 group, significantly ($p<0.05$) increased and higher than other treatments groups, which recorded (2.73±0.26 ng/dL). And the other groups recorded significant differences for negative control, positive control and B1(4 IU) TE injection, which were (0.60±0.06, 0.83±0.10 and 1.28±0.15 ng/dL).

Discussions

The growth performance improved in treated groups (B1 and B2) proportional to the control groups (*Table 2*), which is consistent with antecedent reports (Thabet et al., 2010). The same observation was described by Tousson et al. (2012) and Mohammed et al. (2016) when they use anabolic steroid (BOL, boldenone undecylenate), who stated that the use of the (BOL) give rise to an obvious improvement in the growth rate. This effect could be imputed to the promotion of the body tissue building process by protein synthesis

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1527715287

indirectly via stimulation of growth hormone, insulin-like growth factor secretion, and animal appetite (Ferreira et al., 1998) or reduction of glucocorticoid receptor levels and sensitivity to endogenous glucocorticoids; therefore, the strong growth promoting potency is based not only on its anabolic activity as an antiglucocorticoid (Melloni et al., 1997; Thienpont et al., 1998). However, Tawfeek et al. (1994) reported that the rabbits' growth performance was not affected by testosterone injection.

The obtained findings in *Table 3* agree with the results of Battista et al. (2003) and Liewellyn (2006) who founded that, testosterone dosage and its entrance to the body caused an increase in hematocrit %. Moreover, Gagnon et al. (1994) founded that, the raised hematocrit and hemoglobin persist for extended periods after the cessation of androgenic steroids use. Similarly, Ahmed (2014) recorded significant increase RBCs, Hb, and PCV in boldenone administered groups as compared to the control one. These results may be imputed to that; anabolic steroids could stimulate erythropoiesis (Gabr et al., 2009) through the direct positive effect of androgenic steroids on erythropoietin production in renal tissues (Liewellyn, 2006). This reaction is mainly driven by the androgen receptor stimulation in renal tissue, leading to the stimulation of erythropoietin production directly. Androgens may also influence the stem cells directly, perhaps by enhancing the stem cell's responsiveness to erythropoietin (Snyder, 2008).

Anabolic steroids could spur erythropoiesis, a mechanism that may occur by stimulating erythropoietic-stimulating factor (Gabr et al., 2009). These results (*Table 4*) are in agreement with Urhausen et al. (2003) and Gabr et al. (2009) who adduced that the liver and kidney functions increased significantly after intramuscular BOL undecylenate injection on weaned male lambs. Similarly, current results are in conformity with Dickerman et al. (1999) and Tousson et al. (2011a, 2011b) who noticed that the anabolic steroid-induced hepatotoxicity. Following the same opinions, Istasse et al. (1988) reported that 17b-estradiol increased nitrogen retention and decreased blood urea nitrogen concentrations. Injection of the anabolic steroid BOL induced changes in oxidative stress biomarker levels and antioxidant defense systems in rabbit liver and kidney (El-Moghazy et al., 2012).

In agreement with our findings (*Table 5*), in treated groups with anabolic androgenic steroid, the serum testosterone levels were significantly higher than that in the control group (Urhausen et al., 2003; Takahashi et al., 2004; Gabr and Shaker, 2006; Gabr et al., 2009; Ishak and Omer, 2014). Simontacchi et al. (2004) reported that administration of testosterone derivatives alone did not induce plasma testosterone levels. Also, Shimomura et al. (2005) showed that the treatment of rats with ethinyloestradiol alone the testosterone levels decreased significantly in serum and the testis. Our results are in agreement with Omar (2012) who studied the effects of Testosterone Enanthate injection on testis function, live weight gain and carcass traits of Karadi lamb rams. The significant increase in testosterone observed in (B1 and B2) of mature rabbits treated by boldenone may be in accordance with the findings of Urhausen et al. (2003), Takahashi et al. (2004) and Gabr and Shaker (2006) who founded that, serum testosterone levels in treated groups with androgenic steroids were significantly higher than that in the control group. These results shore up former reports (Gabr et al., 2009; Tousson et al., 2012) who mentioned that an increase of testosterone may be attributed to the synthesis of a substrate related to the primary male sex hormone.

In the present study, results of TE residue in the fresh meat after 30 days stopped injection, showed no significant difference between the groups (*Figure 1*), these results are in contrast with the finding of Paris et al. (2006), when they found a significant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1527715287

difference between the treated and non-treated lambs of the same age group, for example, the anabolic steroids in the muscle, liver, kidneys and adipose tissue. While there was an increase of TE residue in the fresh meat of the male rabbit treated with 4IU TE and those treated with 8IU TE as compared to control groups. The main possible mechanism for these results could be the testicular hormone especially testosterone which let the male be superior in TE residue than the control groups (Omar, 2012). The exogenous testosterone has also been considered as the other reason for elevating TE residue in fresh meat of the intact animal as compared to the castrated. To our knowledge detained from available literature, no other previous study dealt with TE injection on rabbit male and their residue in meat. These differences may be related to exogenous testosterone in addition to testicular hormone especially testosterone which produce mainly by leydig cells. As well as increasing TE residue in fresh meat, which could be reduced in the cooking process (Omar, 2012).

Conclusion

From the obtained results it could be concluded that, although intramuscular injection of Testosterone Enanthate espesioly B2 (8IU) to male local rabbits enhances body gain and increased some hematological parameters, it increased oxidative stresses biomarkers levels, pro-inflammatory cytokines and creatinine indicating side effects on the liver and kidneys. And a no significant deferences in TE residue was seen in the fresh meat after 30 days of injection.

Abstract. Endophytic fungi (EFs) are one of the important and quantifiable components of fungal biodiversity. In the study, 171 endophytic fungi were isolated from the roots of *Aconitum carmichaelii*, a traditional Chinese medicine, collected from six production sites of Yunnan Province in southwestern China. These EFs were categorized to belong to 28 taxa by molecular identification, and *Chaetomium* and *Fusarium* were the dominant genera with a relative frequency of 16.96% and 16.37% respectively. *Cladosporium* and *Pochonia* were found to be unique dominant genera from the roots of *A. carmichaelii* in Huize and Yulong counties, respectively. The Shannon index ranged from 1.68 to 2.05 and the Simpson's diversity index ranged from 0.81 to 0.92 for the EFs of *A. carmichaeli*, indicating the rich diversity of EFs in *A. carmichaelii*. Preliminary screening of the growth inhibition of three severe fungal pathogens by the isolated EFs was conducted and 17 genera of EFs were found to inhibit the growth of the tested pathogens. For example, *Acrostalagmus luteoalbus, Phoma* sp., and *Thielavia* sp. each displayed good anti-fungal activity against *Alternaria alternate*, *Fusarium oxysporum* f. sp. *cucumerinum,* and *Phytophthora drechleri.* The investigation of the root-EFs diversity of *A. carmichaelii* provides additional fungal resources with the potential to biologically control pathogenic fungi.
Keywords: *traditional Chinese medicine, fungal biodiversity, community composition, ITS sequence, antagonism against fungal pathogens*

Introduction

Endophytic fungi (EFs), well-studied to be potential resources for producing bioactive natural products (Aly et al., 2008), asymptomatically infect healthy plant tissues for all, or at least a significant part of their life cycles (Hyde and Soytong, 2008). The diversity of endophytes has been fully investigated in the case of many plant taxa (Sun et al., 2011; Silva et al., 2012; Kohout et al., 2013; Fernandes et al., 2015; Nascimento et al., 2015), and endophytes were shown to increase ecological adaption by protecting plants against biotic and abiotic stresses (Liu et al., 2009; Morsy et al., 2010; Bittleston et al., 2011).

Nowadays, drug-resistance among bacteria and fungi is spreading significantly, and therefore further search is urgently needed for new and effective antimicrobial agents. Endophytes have the potential to produce bioactive compounds, such as alkaloids, resulting in the improvement of the evolutionary fitness of their host by providing resistance against micro-pathogens (Strobel et al., 2004; Kusari and Spiteller, 2012; Newman, 2015). EFs can produce the antimicrobial compounds with inhibitory activity toward pathogenic fungi (Li et al., 2005), and therefore can be helpful in fungal biocontrol in agricultural production (Mishra et al., 2012).

Aconitum L. is a large genus of more than 400 species, mainly distributed in the temperate regions of the northern hemisphere (Xiao et al., 2006). *Aconitum carmichaelii,* a perennial plant of the Ranunculaceae family, is one of the famous traditional Chinese medicines (TCM) fuzi (附子). As one of the most important TCMs, it has been used extensively by humans as a cardiotonic, to protect cardiomyocytes, as an analgesic and to treat arrhythmia (Zhou et al., 2015). However, there has been only one preliminary study about the EFs in *Aconitum* (Li et al., 2009). We aimed to isolate and identify naturally-occurring EFs in *A. carmichaelii* roots collected from the main production area of Yunnan Province, China, and explore their potential inhibitory activity against three primary fungal pathogens, *Alternaria alternate, Fusarium oxysporum* f. sp. *cucumerinum*, and *Phytophthora drechsleri.*

Materials and methods

Plant materials

The roots of *A. carmichaelii* were sampled in September 2014 across six selected counties including Heqing, Huize, Luquan, Malong, Panlong, and Yulong in Yunnan Province, southwestern China (*Fig. 1*), in order to maximize the endophytic fungal diversity. These *A. carmichaelii* were cultivated by local people. Five plants were randomly selected from each site, from which 3-5 lateral roots were collected. The roots and associated soil were packaged separately in sealable plastic bags, immediately transported to the laboratory, and then stored at 4 °C for isolating of endophytic fungi.

Endophyte isolation and primary classification based on morphological traits

The collected roots were washed under running tap water for 5 min, sterilized in 75% ethanol for 1 min, rinsed once in sterile water, 2% NaOCl for 5 min, and then rinsed three times in sterile water. After drying the roots on sterile paper, they were cut into segments, each about 1cm long. From each of the six collections, we randomly selected 45 segments, and divided into them into three groups with 15 segments each to comprise a replicate sample. The samples were placed in Petri dish containing potato

DOI: http://dx.doi.org/10.15666/aeer/1706_1528915300

dextrose agar (PDA) medium amended with 0.5 g/L streptomycin sulfate, with one segment per plate. The plates were incubated at 28 °C and checked every other day for 3 weeks; and the fungi growing out of the roots were transferred to fresh PDA plates. Primary classification was carried out based on mycelia and colony morphological traits and secretion. After that, at least 50% isolates in each group were randomly selected for the molecular identification.

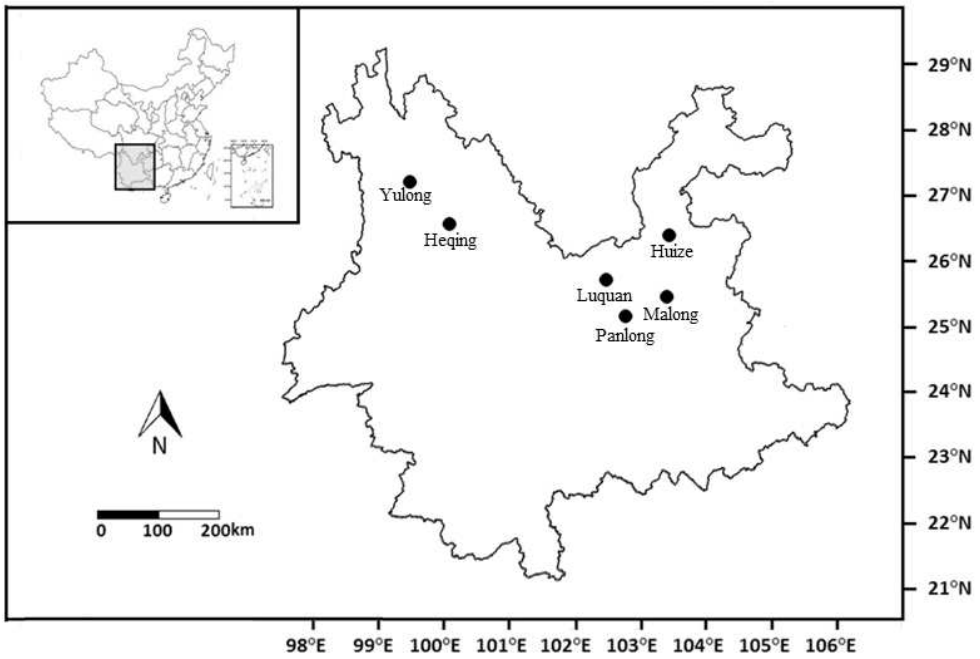

Figure 1. *The geographical locations from left to right represent Yulong, Heqing, Luquan, Panlong, Malong, and Huize counties*

Fungal identification by DNA analysis

Fungal DNA was extracted from pure culture mycelia using a 1 × cetyltrimethylammonium bromide (CTAB) method (Niu et al., 2010). The internal transcribed spacer (ITS) region of nuclear rDNA was amplified with the universal eukaryotic primer pair ITS1 (5'-CTTGGTCATTTAGAGGAAGTAA-3') and ITS4 (5'-TCCTCCGCTTATTGATATGC-3'). PCR amplifications were performed in a reaction mixture containing 2 × PCR EasyTaq PCR SuperMix, DNA extracts, and the primer pair. Thermocycler settings were 5 min initial denaturation at 94 °C, followed by 35 cycles of 30 s at 94 °C, 50 s at 53 °C, 1 min at 72 °C, with a 10 min final extension at 72 °C. Sequences were manually inspected and edited using Chromas 2.4.1. Putative identification of sequences was carried out by comparing consensus sequences to the National Center for Biotechnology Information (NCBI) DNA database using the Basic Alignment Search Tool (BLAST). The following parameters were used to determine significance of BLAST results: alignment score > 500, E < 0.0001, and over 97 % sequence similarity were identified as the same species. The ITS sequences of those isolates were deposited in NCBI (MF962929-MF963015). Through sequences analysis in comparison with each other, phylogenetic tree figure of the isolated EFs was constructed using neighbor-joining (NJ) methods with 1000 boot-strap replications using MEGA 6.0.

Analyses of relative frequency and diversity index

The colonization rate was calculated as follows (*Eq. 1*) (Su et al., 2010), where N_i is the total number of segments colonized by endophytes, and N_t is the total number of segments.

$$\text{colonization rate } (\%) = \frac{N_i}{N_t} \times 100 \quad \text{(Eq.1)}$$

The relative frequency (RF %) (Yuan et al., 2010) was calculated according to the following formula (*Eq. 2*), where n_i is the number of isolates of one species divided, and the N is the total number of isolates.

$$RF(\%) = \frac{n_i}{N} \times 100 \quad \text{(Eq.2)}$$

The Shannon index (H') (Shannon and Weiner, 1963) was calculated according to the following formula (*Eq. 3*), where k is the total species number of one plot and P_i is the relative abundance of endophytic fungal species in the community.

$$H' = -\sum_{i=1}^{k} (P_i \times \ln P_i) \quad \text{(Eq.3)}$$

The fungal dominance was determined by Camargo's index (*Eq. 4*) (Hunter and Gaston, 1988), where S was species richness = the number of species present in any given sample. A species was defined as dominant if $P_i >$ Camargo's index.

$$\text{Camargo's index} = \frac{1}{S} \quad \text{(Eq.4)}$$

Simpson's index (D) and Simpson's diversity index (1-D) (Camargo, 1993), where D was calculated as (*Eq. 5*). D could range between 0 (infinite diversity) and 1 (no diversity).

$$D = \sum_{i=1}^{k} \left(\frac{n_i \times (n_i - 1)}{N \times (N - 1)} \right) \quad \text{(Eq.5)}$$

Anti-fungal activity assays

The anti-fungal activity of the EFs was evaluated against three fungal pathogens: *Alternaria alternate*, *Fusarium oxysporum* f. sp. *cucumerinum*, and *Phytophthora drechsleri* (all provided by Professor Zhiwei Zhao of the State Key Laboratory for Conservation and Utilization of Bio-Resources, Yunnan University). A dual-culture technique was modified to study antagonism (Gao et al., 2002). The pathogen was inoculated on PDA medium center and four different isolated fungi were inoculated around pathogen, incubated at 28 °C for a week, and the anti-fungal zone were measured by ruler (mm).

Results

Colonization rates and diversity of EFs

Colonization rate is an indication of the number of EFs in host plants and varies with the altitude, humidity, precipitation, temperature and plant community (Hashizume et al., 2010). In the present study, the colonization rate of the EFs from six sites ranged from 46.7% to 73.3%, and the highest colonization rate appeared in Malong, while the lowest was appeared in Panlong (*Table 1*). To further investigate the biodiversity of the EFs, we calculated the Shannon diversity index (H'), Simpson's index (D) and Simpson's diversity index (1-D). The Shannon diversity indexes (H') of the endophytic community in the six different sites were 1.98, 1.88, 1.82, 1.76, 2.05 and 1.68, respectively. The Simpson's diversity index is between 1 and 0, with 1 representing infinite variety of diversity, and 0 representing no diversity. The Simpson's diversity index showed a similar pattern for the six sites, which were 0.92, 0.85, 0.88, 0.89, 0.88 and 0.81, respectively.

Table 1. *Number, colonization rate, Shannon-Weiner index (H') and Simpson's diversity index (1-D) of the root- endophytic fungi (EF) of A. carmichaelii from the six regions of Yunnan, China*

Collection site	No. of EFs isolated	Colonization rate (%)	H′	1-D
Heqing	26	48.9	1.98	0.92
Huize	44	60.0	1.88	0.85
Luquan	38	64.4	1.82	0.88

Panlong	26	46.7	2.05	0.88
Yulong	39	53.3	1.68	0.81
Total	171	57.8		

Community composition of EFs

A total of 171 isolates were obtained from collected roots, and identified into 28 taxa by molecular identification based on rDNA ITS sequence analysis (*Table 2*). A total of 10 endophytic taxa from Heqing; 12 taxa were identified from Huize; 10 taxa from Luquan; 12 taxa from Malong; 11 taxa from Panlong; and 10 taxa from Yulong (*Table 2*). The dominant taxa determined by the Camargo's index and P_i were *Chaetomidium arxii*, *Chaetomium* sp., and *Phoma* sp. in Heqing; *Chaetomium* sp., *Cladosporium* sp., and *Fusarium* sp. in Huize; *Chaetomidium arxii*, *Plectosphaerella* sp., and *Pochonia* sp. in Luquan; *Chaetomium* sp. and *Plectosphaerella* sp. in Malong; *Chaetomidium arxii*, *Chaetomium globosum, Ilyonectria* sp., *Phoma* sp., and *Plectosphaerella* sp. in Panlong; and *Fusarium oxysporum* and *Ilyonectria* sp. in Yulong. Only *Chaetomidium arxii* and *Plectosphaerella* sp. were identified in all six sites (*Table 2*). The rates of colonization for *Chaetomium* sp. in Huize and *Fusarium oxysporum* in Yulong were higher than in other sites (*Table 2*). Endemic endogenous fungi were isolated from five habitats of *A. carmichaelii*, including: Huize (*Cladosporium* sp., *Cylindrocarpon* sp., *Mucor racemosus*, and *Verticillium tricorpus*,); Luquan (*Bjerkandera* sp., *Pochonia* sp., and *Thielavia* sp.); Malong (*Acrostalagmus luteoalbus* and *Trametes versicolor*); Panlong (*Daldiniafissa* sp.); and Yulong (*Clonostachys rosea* and *Paraphaeosphaeria sporulosa*). The phylogenetic tree indicated that *Chaetomium* sp., *Fusarium* sp. and *Plectosphaerella* sp. were the

DOI: http://dx.doi.org/10.15666/aeer/1706_1528915300

dominant EFs in this medicinal plant. In this study, phylogenetic analysis revealed that all sequences clustered in at least 18 discrete sequence groups (*Fig. 2*). The majority of clones (73.08%) fell into the G 1 (Group 1), G 2 (Group 2) and G 4 (Group 4), which were distributed across most root samples.

Anti-fungal activity assays

The diversity and antimicrobial potential of EFs from a number of medicinal plants have been studied (Qin et al., 2009; Egamberdieva et al., 2017; Xiang et al., 2017). Our screening of anti-fungal activity of the isolated EFs identified 17 genera which are resistant to the three fungal pathogens (*Alternaria alternate, Fusarium oxysporum* f. sp. *cucumerinum*, and *Phytophthora drechsleri*) in agricultural production (*Table 3*). A*crostalagmus luteoalbus* (LD34), *Phoma* sp. (MC6), and *Thielavia* sp. (LQ14) displayed good anti-fungal effects, and the anti-fungal zone for *Alternaria alternate*, *Fusarium oxysporum* f. sp. *cucumerinum*, and *Phytophthora drechsleri* were 4, 3, and 2 mm; 5, 3, and 3 mm; and 4, 3, and 3 mm, respectively, although they accounted for the small proportion of the colonization (*Table 3*). In addition, *Chaetomium* sp. and *Fusarium* sp., two dominant strains obtained in this experiment, also showed some anti-fungal activity (*Table 3*).

The values of the anti-fungal zone in the table are the average of the three experiments. HQ, HZ, LQ, ML, PL, and YL are indicative of Heqing, Huize, Luquan, Malong, Panlong, and Yulong, respectively and the number after abbreviations showed the isolation order of the endophytic fungi

Discussion

Endophytic fungi were isolated from *Aconitum carmichaelii*, one of the most important TCMs, which laid the foundation for future biological control research. In this study, roots of *A. carmichaelii* were collected from six sites in Yunnan Province, the People's Republic of China for the isolation, identification and antibacterial analysis of EFs. Colonization rate and Shannon diversity index (H') of the EFs in different areas (*Table 1*) indicated that there were rich root-fungal endophytes existing in *A. carmichaelii* in Yunnan. In all isolates, only *Chaetomidium arxii* and *Plectosphaerella* sp. were identified in all six sites (*Table 2*), suggesting that these two endophytic fungi

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1528915300

are host-generalists. The rates of colonization for *Chaetomium* sp. in Huize and *Fusarium oxysporum* in Yulong were higher than in other sites (*Table 2*). This may be due to the fact that the roots are persistent, and can form unique endophytic fungal community. In addition, Huize has been documented heavy metal contamination (Lu et al., 2014), and *Chaetomium* sp. is known as a soil and contaminant fungi (Abdel-Lateff, 2008). Endemic EFs were isolated from five habitats, and the population structure of endophytic fungi normally represents a certain degree of regional specificity (Jia et al., 2016). In contrast to the endemic EFs, dominate endophytic fungi lived in a wide variety of plants such as *Phoma* sp. (Nisa et al., 2015), which was also isolated from *A. carmichaelii* with a RF as 6.43%.

Screening of anti-fungal activity of the isolated EFs identified 29 isolates, such as *Chaetomium* sp. (*Table 3*), with wide-spectrum antibacterial activity (Li et al., 2009). Previous research showed that *Chaetomium* sp. suppressed the growth of bacteria and fungi through direct competition, mycoparasitism, and antibiosis (Rodríguez et al., 2002). Two antibacterial furano-polyenes, (-) - musanahol and 3-epi-aureonitol, were isolated from cultures of *Chaetomium* sp. (Marwah et al., 2007). Dutch elm disease, caused by the fungal pathogen *Ceratocystis ulmi*, can be controlled by the endophytic fungus *Phomopsis oblonga* (Webber, 1981). Leutou et al. (2016) concluded that the microbial transformation of anthranilic acid by the marine-mudflat-derived fungus *Thielavia* sp. produced an antibacterial polycyclic quinazoline alkaloid, thielaviazoline. *Fusarium oxysporum* is well represented in the rhizosphere microflora (Lecomte et al., 2016). Some isolates can induce wilt or root rots while others are considered as nonpathogenic taxa. For example, nonpathogenic *F. oxysporum* in soil can suppress *Fusarium* wilts (Fravel et al., 2003), and the strain has also attracted interest for soil bioremediation and water purification due to its capability to detoxify and colonize polluted environments (Steinberg et al., 2016). Ratnaweera et al. (2015) found that equisetin, isolated from endophytic *Fusarium* sp., exhibited antibacterial activities against the Gram-positive bacteria.

Some recent studies have shown that *Lentzea* sp., *Nigrospora* sp. and *Streptomyces* sp. isolated from *A. carmichaelii* have antibiotic activity (Qiu et al., 2015; Zhang et al., 2016). EFs isolated from medicinal plants sometimes produce similar compounds as their hosts (Newman, 2015). Diterpene alkaloids are the dominant secondary metabolites of *Aconitum* species (Zhou et al., 2015), and other diterpene alkaloids have been reported to be produced by endophytic fungi of the genus *Epichloë* in perennial ryegrass (Philippe, 2016). Based on the anti-fungi activity of diterpene alkaloids (Kobayashi et al., 1998), we hypothesize that certain EFs from *A. carmichaelii* could produce aconitum alkaloids that inhibit these three fungal pathogens. We plan to examine the chemistry of these EFs in the future.

In this study, 171 strains of EFs were isolated and identified from six parts of *A. carmichaelii* roots, of which 29 isolates in 17 genera showed some level of anti-fungal activity. This study helps to lay a foundation for the potential association of EFs and disease resistance in *A. carmichaelii*.

Conclusion

Isolated from the roots of *A. carmichaelii* from six different production sites in Yunnan province, China, the root-endophytic fungi are assigned to 28 taxa. Among these identified taxa, *Chaetomium* and *Fusarium* were the dominant genera in all six

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1528915300

sites while *Cladosporium* and *Pochonia* were unique dominant genera in Huize and Yulong counties. *Acrostalagmus luteoalbus*, *Phoma* sp., and *Thielavia* sp. displayed good anti-fungal activity against *Alternaria alternate*, *Fusarium oxysporum* f. sp. *cucumerinum* and *Phytophthora drechsleri*, providing new biological control clues for these pathogenic fungi. In subsequent experiments, further investigation on whether the endophytic fungi have the same fungal pathogen resistance *in vivo* was necessary. In addition, exploring the chemical composition against these fungal pathogens of endophytic fungi would be helpful for identifying the active leading chemical compounds for fungal disease control.

(Received 8th Jul 2019; accepted 16th Oct 2019)

Abstract. Four groups of one-year-old Yinghong No. 9 tea plants were studied under with different gradients of water. The correlation test and analysis of soil moisture and tea root coefficient, root length, root area and root volume were carried out. The number, length, area and the volume of tea roots were collected by CI600 plant root growth monitoring equipment, and the correlation between the parameters and water was analyzed to determine the suitable range of soil moisture for tea plant growth. The results showed that the soil moisture suitable for tea tree growth in the case of red loam soil was 35%. During the 90-day test period, 13 young roots were newly born for tea trees with 35% soil moisture, the root length increased by 299.02 mm, the root area increased by 1285.207 mm^2, and the volume increased by 1169.063 mm^3. The number, length, area and volume of roots were positively correlated with the growth time at soil moisture of 35%, and the R^2 values were 0.9887, 0.9907, 0.9801 and 0.9919, which were higher than those under difference soil moisture. At the end of the experiment, the root coefficient of tea roots under 35% soil moisture increased by 2.16 times; the length of roots increased by 1.0068 times; the area increased by 0.515 times and the volume increased by 0.64 times. The performance of each index of tea planted under 25% soil moisture was slightly worse than for those tea planted under 35% soil moisture. The performance of each index of tea planted under 15% and 45% soil moisture was average. So the number, length, area and volume of tea roots are positively correlated with growth time at soil moisture of 35%. The tea tree under other moisture conditions does not exhibit this relationship.
Keywords: *CI600, tea tree, root monitoring, soil moisture, situ root measurements*

Introduction

Root system is an important way of material exchange between plants and their environment, and the primary means of water intake. Root system can absorb a large amount of water from soil and provide life activities (Hu, 2013; Guo, 2018). The growth and development of plants are reflected by root growth state, which is mainly concentrated in the development and distribution of roots and physiological characteristics (Wang, 2007; Wang, 2015; Niu, 2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1530115309

Different morphology of root growth is showed under different water stress conditions. Studies have shown that plants subjected to water stress will adapt to water deficit by changing root structure and morphology, which had higher plasticity (Zhanyang, 2017). Zhu (2012) and Lai (2018) presented that the morphological structure and root biomass of the root system may change accordingly to the change of soil moisture, which affected the physiological characteristics of root system and the growth and development of the whole plant. Zhou (2008) pointed out that the root growth index of citrus increased with the increase of water, and Liu (2014) pointed out that the activity and osmotic adjustment ability of various enzymes in roots of drought-resistant peanut varieties were higher than those of weak drought-resistant varieties. Wei (2011) concluded that there is a significant correlation between root volume and water in jujube trees in horizontal and vertical directions. Meng et al. (2017) said that the development of root hair is regulated by a variety of nutrient elements.

The analysis and research methods of root system have made great progress and development from the initial soil-removing research to the later digital analysis, but there are still some limitations, such as inconvenience monitoring methods and complexity of real-time analysis (Liu, 2013; Qin, 2019). The root growth state under water stress was monitored by CI600 plant root growth. The number, length, area and volume of tea roots were collected. The data were analyzed by least squares method to obtain the correlation between root related parameters and soil moisture. Relationships provide a reference for the scientific planting of tea trees.

The article aimed to use CI600 plant root growth monitoring equipment to analyze the roots of four years old Yinghong No. 9 tea plants under varying soil moisture, in order to find the optimal value.

Materials and Method

Test environment

Experiment location: The experimental site is located in the campus of South China Agricultural University, Guangzhou City, Guangdong Province (113°34'N, 23°14'E). The region is warm and rainy, with humid climate and abundant sunshine. It belongs to the subtropical monsoon climate. The annual average temperature is around 20 to 22°C; the annual rainfall is 1720 mm, and the annual relative humidity is 77%. Good climatic conditions are suitable for most plants. The experiment lasted from Feb.10 to May 11, 2019; the daily average maximum temperature was 25°C; the daily average minimum temperature was 17°C, and the daily average relative humidity was 53%, which is suitable for plant growth and control of experimental variables.

Plant culture

Four groups of one-year-old Yinghong No. 9 tea trees with the same growth potential and smaller root differences were selected for experiment. The tea roots need to be properly trimmed to make the whole suitable for the test requirements, and the treated tea trees are planted in a soil box containing red loam for 20 days. Only 2 one-year-old tea trees are planted for each of soil moisture content.

Experiment equipment

(1) DECAGON Em50 Data Logger (DECAGON, USA), including sensors and collectors, is used to collect soil moisture.

(2) CI600 root parameters monitoring system (CID-Bioscience, USA), includes CI600 Root Scanne (Hardware Scanner), CI600 In-Situ Root Imager (Scanning Software) and CI690 Root Snap (Image Analysis Software).

(3) SHT11 air temperature and humidity sensor is used to measure the temperature and humidity of the air.

Experimental design

Four kinds of soil moisture were designed, which were 15%, 25%, 35% and 45%. The red loam soil was mixed, stirred evenly, and sand and gravel were removed before being packed. The weight was evenly distributed into four soil tanks and compacted. The average weight of red loam in each soil box was 20 kg. The experimental tea tree is shown in *Figure 1*.

Figure 1. *The experimental tea tree*

Experiment results and analysis

The root coefficient, root length, root area and root volume of the tea tree roots are measured by CI600 Root Scanne and CI600 In-Situ Root Imager. Date will be automatically calculated by CI690 RootSnap. Resultes is processed by averaging its data.

The root coefficient is defined as the number of tea roots that grow during the test period.

Root coefficient, root length, root area and root volume of tea trees will be tested to find out the effect and relationship of soil water content between them.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1530115309

The growth rate is defined as the ratio of the current root coefficient to the previous root coefficient.

The growth rate is given by *Equation (1)*.

$$\text{Growth rate} = \frac{N_2 - N_1}{N_1} * 100\% \quad \text{(Eq.1)}$$

where N_2 represents the parameter measured at the moment, and N_1 represents the parameter measured at the previous moment. These parameters can be root coefficient, root length, root area and root volume of tea trees.

Effect of Soil Moisture on Root Coefficient of Tea Trees

The variation of the root coefficient of tea tree under different soil moisture is shown by CI600 Root Scanne and CI600 In-Situ Root Imager, and the corresponding curve is shown in *Figure 2*.

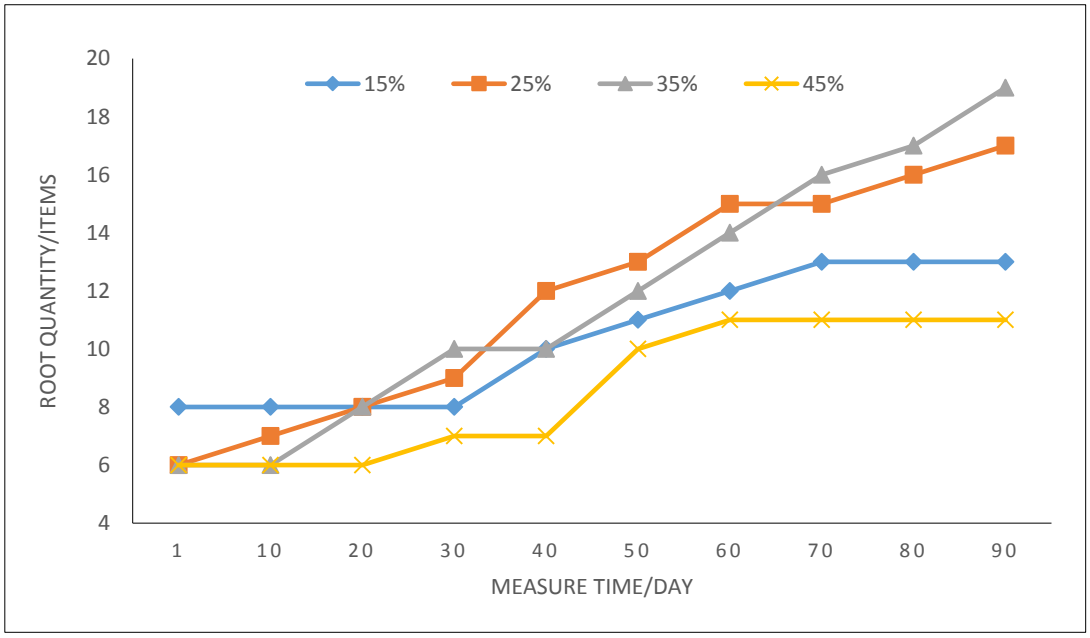

Figure 2. *Curve of the variation of tea root coefficient under different soil moisture*

Experiments show that the coefficient of tea root system under four soil moisture conditions increased by 5, 11, 13 and 5, and increased by 0.625, 1.83, 2.16 and 0.83 times. *Figure 2* shows that the rate of increase of root coefficient of tea tree planted under 35% soil moisture was relatively stable, and had a good performance but slowed in the later stage under 25% soil moisture. Compared with 35% soil moisture, root coefficient growth rate fluctuates too much throughout during the experiment period. However, the root coefficient of tea trees planted under 15% and 45% soil moisture has almost no change. It can be speculated that this humidity is not suitable for tea tree growth. The relationship between the four root coefficient quantities and the growth time was curve-fitted, and the determination coefficients R^2 were 0.9108, 0.9773, 0.9887 and 0.8685.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1530115309

Effects of Soil Moisture on Root Length of Tea Trees

The root length of tea tree under different soil moisture is measured by CI600 Root Scanne and CI600 In-Situ Root Imager., and the corresponding curve is shown in *Figure 3*.

Experiments show that the initial root length of tea planted with 15% soil moisture is significantly longer than that of the other three groups. It can be seen from *Figure 3* that the root lengths of tea trees planted under 15% and 45% soil moisture have similar trends, while the root lengths of tea trees planted under 25% and 35% soil moisture are similar, but the growth rate of root length is significantly larger than that. 15% and 45% soil moisture in two groups of tea trees. Compared with the beginning of the experiment, the root length of tea planted under four soil moisture conditions increased by 31%, 83.5%, 100.68% and 37.75% at the end of the experiment. It can be speculated that it is more suitable for tea tree root growth under the 35% soil moisture. The relationship between the four root coefficient quantities and the growth time was curve-fitted, and the determination coefficients R^2 were 0.9711, 0.9938, 0.9907 and 0.9763.

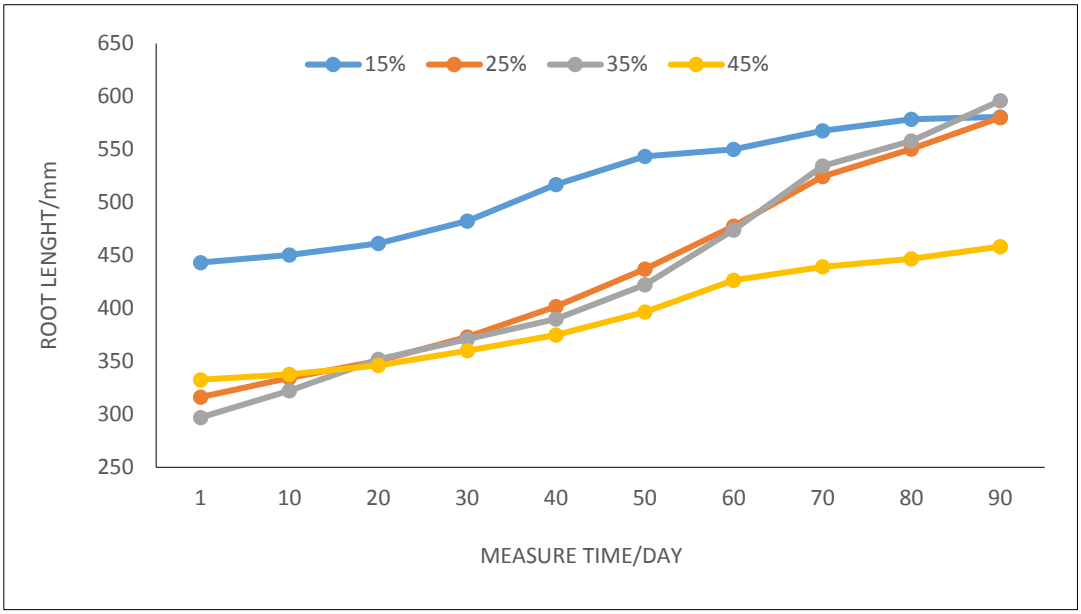

Figure 3. *Curve of the variation of tea root length under different soil moisture*

Effect of Soil Moisture on Root Area of Tea Trees

The changes of root area of tea planted under different soil moisture were obtained from experimental calculations and the corresponding curves were shown in *Figure 4*.

Experiments show that the root area of tea tree planted under four soil moisture conditions increased by 259.509 mm2, 879.491 mm2, 1285.207 mm2 and 369.107 mm2, with corresponding growth rates of 7.56%, 33.4%, 51.5% and 13.6%. *Figure 4* shows that the root area of tea trees planted under 15% and 45% soil moisture is relatively flat, which may be caused by more serious water stress. The root area of tea trees planted under 25% soil moisture increased rapidly, and the tea trees planted at 35% soil moisture increased fastest, indicating that root growth was the fastest. The determination coefficients R^2 were 0.9867, 0.9938, 0.9801 and 0.9946.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1530115309

Effects of Soil Moisture on Root Volume of Tea Trees

The change of tea root area under different soil moisture was obtained from experimental calculations and the corresponding curve was shown in *Figure 5*.

Experiments show that the initial value of root volume of tea tree planted under 15% soil moisture is larger. During the experimental period, the root area of tea planted under 4 kinds of soil moisture increased by 214.458 mm^3, 766.661 mm^3, 1169.063 mm^3 and 316.605 mm^3, with corresponding growth rates of 8.8%, 40.2%, 64.0% and 15.8%. *Figure 5* shows that the root volume of tea trees planted under 15% and 45% soil moisture increased more slowly, while the root volume of tea planted under 25% and 35% soil moisture increased more rapidly. The tea tree planted under 35% soil moisture increased the fastest, reaching 64%, indicating that the root growth was the fastest. The determination coefficients R^2 were 0.9957, 0.9957, 0.9919 and 0.9869, respectively.

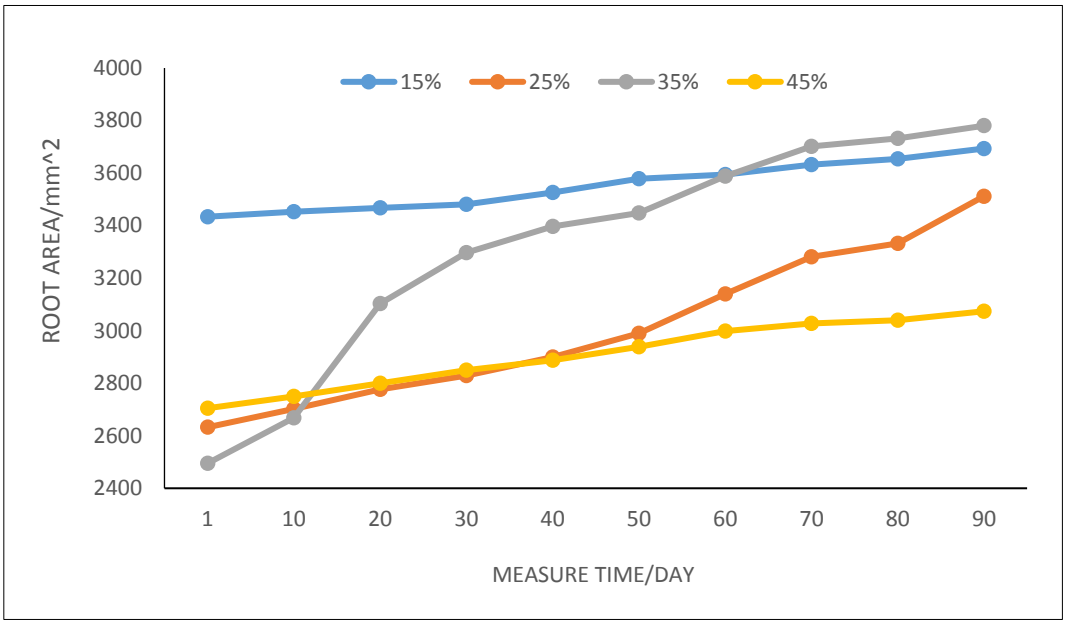

Figure 4. *Curve of the variation of tea root area under different soil moisture*

The comparison of various indicators of tea roots planted under four kinds of soil moisture is shown in *Figure 6*.

Figure 6 shows that the growth rate of various roots of tea trees planted under the condition of soil moisture of 35% is higher than that of other tea trees, and the growth rate of 25% is slightly worse. Soil moisture of 15% and 45% soil moisture is not conducive to the roots growth of tea trees.

Conclusions

First, the relationship between the root development of tea plants and soil moisture was studied. The changes of the number, length, area and volume of tea roots under different soil moisture were studied. Experiments were studied out with 4 groups of one-year-old Yinghong 9 tea trees. The soil moisture was collected by DECAGON

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)

Em50 Data Logger, and the related indicators of tea roots were monitored by CI600 root growth monitoring system.

Second, the results show that the growth rate of various roots of tea trees planted under the condition of soil moisture of 35% is higher than that of other tea trees, and the growth rate of 25% is slightly worse. Soil moisture of 15% and 45% soil moisture is not conducive to the roots growth of tea trees. The number, length, area and volume of tea roots are positively correlated with growth time at soil moisture of 35%. The tea tree under other moisture conditions does not exhibit this relationship. This conclusion can be seen in the experiment and analysis in the second chapter of the paper.

Discussion

The root surface and root volume are derived measures therefore analysing both of those is needed further discussion. The preliminary tests were not considered adequately, and subsequent tests will focus on the parameters that the instrument can directly measure.

The container capacity has been taken into account during the test. The roots of adult tea trees are more developed, and the 20 L container obviously does not meet the requirements. However, the root system of one-year old tea tree is relatively small. According to the experimental observation, the 20 L container does not affect the root development. In the later experiments, the tea tree has been transplanted to cuboid container with a length, width and height of 60 cm * 60 cm * 55 cm.

The test period is only 90 days, and it is carried out in the spring. The growth period is too short and the weather conditions are relatively simple. Subsequent repeated tests will prolong the test time and improve the credibility of the measured data.

The red loam soil was mixed, stirred evenly, and sand and gravel were removed before being packed. However, the nutrient and porosity characteristics of the soil were not analyzed. The experiment only considered the influence of soil moisture on root development. The factors such as nutrient, illumination, air temperature and humidity were not taken into consideration, and subsequent multi-factor tests were carried out. The analysis had significant effects on the root development.

Only four kinds of soil moisture were designed. It was roughly concluded that tea root system developed better when soil moisture was 35%. However, but no further subdivision and tracking test were carried out. The subsequent research will be carried out between soil moisture of 25%-35%.

Abstract. In this study, Fe-modified biochar (Fe-R-BC) was made from rice straw by modified with $FeCl_3$ through pyrolysis, and used to adsorb Cr(VI) from aqueous solution. The properties of Fe-R-BC and rice straw biochar (R-BC) were characterized by Fe content, Brunauer-Emmett-Teller (BET) analysis, Boehm titration, and Fourier-transform infrared (FT-IR) spectroscopy. The Cr(VI) adsorption removal mechanism and regenerative property of Fe-R-BC were explored with batch adsorption experiment. Compared to those of R-BC, the Fe content, specific surface area (BET), total pore volume, and amount of hydroxyl group of Fe-R-BC increased, while the average pore size and amount of methenyl group decreased. For Fe-R-BC, the maximum Cr(VI) adsorption removal capacity was 94.95 $mg \cdot g^{-1}$ at 313 K. The Cr(VI) adsorption kinetics and isotherms can be well described by the pseudo second order model and the Langmuir-Freundlich model, respectively. The Cr(VI) adsorption removal was spontaneous and endothermic. Low pH was beneficial for the Cr(VI) adsorption removal. SO_4^{2-} showed the largest influence on the Cr(VI) adsorption removal, followed by NO_3^- and Cl^-. After 4 sorption-desorption cycles, the regenerated Fe-R-BC still maintained 76.27% of adsorption removal ability compared to that of Fe-R-BC in the initial use. Overall, Fe-R-BC can be applied to treat wastewater containing Cr(VI).
Keywords: *rice straw biochar, modification, property, hexavalent chromium, adsorption removal mechanism*

Introduction

Chromium and its alloys are widely used in daily life and industrial production. With the development of economy, the demanded quantity of chromium and its alloys grows with each passing day. As a result, a large amount of wastewater containing chromium (Cr) was produced in recent decades. Two valence states, i.e., Cr(III) (trivalent chromium) and Cr(VI) (hexavalent chromium), were the main occurrence forms of Cr in these wastewaters. Compared with Cr(III), Cr(VI) has higher carcinogenicity and mutagenicity (Liu et al., 2010). In view of this, many countries and organizations listed Cr(VI) as one of the strictly controlled heavy metals in industrial wastewater (Ma et al., 2014). That is to say, before discharging the industrial wastewater containing Cr(VI), its concentration should be strictly controlled.

There are various methods to remove heavy metals from wastewater such as electrochemical treatment (Golder et al., 2011; Mella et al., 2015), ionic exchange (Rafati et al., 2010), membrane filtration (Soylak et al., 2007), adsorption (Liu et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1531115327

2010). Among these methods, adsorption was regarded as a valid and dependable method to remove heavy metals, which could avoid some disadvantages of other methods, such as the high cost of equipment, production of toxic sludge and other wastes (Baran et al., 2007; Liu et al., 2010). For adsorption method, the treatment effectiveness depends primarily on the adsorbent used (Gu et al., 2005). At present, activated carbon (Kaveeshwar et al., 2018), bioadsorbents (Gupta et al., 2015), zeolite (Wang and Peng, 2010), clay minerals (Uddin, 2017), biochar (Dong et al., 2011; Xu et al., 2013; Inyang et al., 2016), etc. are commonly used as adsorbents. Among these adsorbents, biochar was considered as an emerging and promising adsorbent in view of its low cost and sustainability (Chun et al., 2004; Ahmad et al., 2014; Park et al., 2016a). However, the original biochar has a low adsorption capacity for heavy metals (Zhou et al., 2013; Ma et al., 2014). In recent years, many physical and chemical modification methods have been used to improve the adsorption capacity of biochar (Rajapaksha et al., 2016). For example, Park et al. (2016b) reported that steam activation significantly enhanced the adsorption capacity of red macroalga *Porphyra tenera* biochar for Cu. Ding et al. (2016) found alkali modification promoted the adsorption capacity of hickory wood biochar for Pb, Cu, Cd, Zn, and Ni. Zhou et al. (2017) indicated that introduction of nano-MnO_2 on corn stalk biochar improved its adsorption capacity for Cu.

Rice straw is a kind of common agricultural waste. In China, about 201.0-301.5 million tons of rice straw was generated per year (Jiang et al., 2015). To realize the sustainable development of agriculture, the Chinese government has been sparing no effort to encourage and promote resource utilization technology of rice straw in recent years. Converting rice straw to biochar not only can achieve reutilization of rice straw, but also can benefit carbon-emission reduction. Thus, biochar technology was considered as an effective resource technology for rice straw. At present, rice straw biochar (R-BC) was successfully applied to remove different heavy metals from wastewater (Han et al., 2013; Pan et al., 2013; Xu et al., 2014; Park et al., 2017; Dong et al., 2018). Nevertheless, modification of R-BC could further enhance its utilization efficiency considering the advantage of modification technology for heavy metal adsorption. In the previous studies, Fe oxides were found to have the good selectivity and affinity to Cr(VI) (Tzou et al., 2003). In recent years, Agrafioti et al. (2014) also found that the sewage sludge biochar with high Fe content had higher adsorption rate of Cr(VI) compared with the other two biomass-based biochars. Thus, the Cr(VI) adsorption capacity of R-BC is expected to be promoted by introducing Fe/Fe oxides onto it.

In this study, R-BC and Fe-modified R-BC (Fe-R-BC) were prepared firstly. Then, the properties of R-BC and Fe-R-BC (i.e., the yield, Fe content, specific surface area (BET), total pore volume, average pore size, number of acidic and basic surface functional groups, and category of surface functional group) were compared. After that, a series of batch experiments including adsorption kinetic, adsorption isotherms, initial solution pH, and coexisting ions influence were performed. Moreover, the regenerative property of Fe-R-BC was evaluated by several cycles of adsorption-desorption experiment. The purposes of this study are to (1) characterize the properties of Fe-R-BC, (2) explore the Cr(VI) adsorption removal mechanism of Fe-R-BC, and (3) evaluate the regenerative performance of Fe-R-BC.

Materials and methods

Preparation of R-BC and Fe-R-BC

Rice straw was gathered from Shuangliu County, Sichuan province, China. The gathered rice straw was washed several times with tap water and dried in the air. Then the rice straw was smashed and sieved through a screen (10-mesh). The sieved rice straw was divided into two parts. One part was soaked in the $FeCl_3$ solution (1 M, m/v (g/mL)=1/10) for 48 h at room temperature. After that, the Fe-soaked rice straw was separated by filtration and dried at 333 K to constant weight. The Fe-soaked rice straw and the other part of pristine rice straw were respectively putted into the different crucibles with covers and pyrolyzed for 2 h in a muffle furnace (SX2-4-10, Shenyang Energy Saving Electric Furnace Factory, Shenyang, China) at 673 K. After pyrolyzed, the carbonized pristine rice straw was smashed again and sieved through a screen (60-mesh). The sieved carbon material was R-BC. For the carbonized Fe-soaked rice straw, it was rinsed several times with 3 M HCl to remove excessive iron. And then, the carbonized Fe-soaked rice straw was washed several times with deionized water (18.25 MΩ). After that, the carbonized Fe-soaked rice straw was dried at 333 K to constant weight. At last, the carbonized Fe-soaked rice straw was ground and sieved through a screen (60-mesh). The sieved powder was Fe-R-BC.

Property detection

The yield was determined by the following *Equation 1*:

$$\text{Yield}(\%)=\left(\frac{m_a}{m_b}\right)\times 100\% \quad \text{(Eq.1)}$$

where m_a refers to the acquired R-BC or Fe-R-BC mass (g), m_b denotes the rice straw mass (g).

The specific surface area (BET), total pore volume, and average pore size were measured using a specific surface area analyzer (NOVA-1200, Quantachrome Corp., Boynton Beach, Florida, USA) with N_2 adsorption method (Dong et al., 2011). The quantities of acidic and basic surface functional groups were quantified using Boehm titration (Giannakoudakis et al., 2016). The category of surface functional group was determined by FT-IR spectrometer (Spectrum II, Perkin-Elmer Crop., Norwalk, OH, USA). For the Fe content in R-BC or Fe-R-BC, 0.10 g R-BC or Fe-R-BC was digested with HNO_3 using microwave digestion method, and the Fe concentration in the digestion solutions was detected using a flame atomic absorption spectrometer (PinAAcle 900T, PerkinElmer Management (Shanghai) Co., Ltd., Shanghai, China) to calculate its content. Furthermore, the zeta potential of Fe-R-BC was determined using a zeta potentiometer (JS94H2M, Shanghai Zhongcheng Digital Technology Equipment Co., Ltd., Shanghai, China) to explain the influence of initial solution pH on Cr(VI) adsorption removal.

Batch adsorption experiments

Adsorption kinetics: 0.10 g R-BC or Fe-R-BC was added into 50 mL Cr(VI) solution (100 $mg \cdot L^{-1}$, prepared with $K_2Cr_2O_7$). Then, the initial pH value of the mixed solution was adjusted to 2.0. After that, the mixed solution was placed in a constant temperature oscillation box (TS-2012C, Shanghai Xiren Scientific Instruments Co., Ltd., Shanghai,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1531115327

China) to experience a predefined time period (0.5, 1, 2, 4, 6, 8, 10, 12, 16, 20, and 24 h, respectively) at 120 rpm and 298 K.

Adsorption isotherms: 0.10 g Fe-R-BC was added into 50 mL Cr(VI) solution with a certain concentration (75, 100, 200, 300, 400, 500, 600, and 800 $mg \cdot L^{-1}$, respectively). Then, the initial pH value of the mixed solution was adjusted to 2.0. After that, the mixed solution was placed in the constant temperature oscillation box for 24 h at 120 rpm and a fixed temperature (283 K, 298 K, and 313 K, respectively).

Initial solution pH: 0.10 g Fe-R-BC was added into 50 mL Cr(VI) solution (100 $mg \cdot L^{-1}$). Then, the initial pH value of the mixture solution was adjusted to a predesigned value (2.0, 3.0, 4.0, 5.0, 6.0, 7.0, and 8.0, respectively). After that, the mixed solution was placed in the constant temperature oscillation box for 24 h at 120 rpm and 298 K.

Coexisting ions influence: 0.10 g Fe-R-BC was added into 50 mL Cr(VI) solution (100 $mg \cdot L^{-1}$). Then, the coexisting ion concentration (Cl^- or NO_3^- or SO_4^{2-}) in the mixture was adjusted to a predetermined value (0.005, 0.01, 0.02, 0.05, 0.10, 0.20, 0.50, 1.0, and 2.0 M, respectively). After that, the initial pH value of the mixed solution was adjusted to 2.0. At last, the mixed solution was placed in the constant temperature oscillation box for 24 h at 120 rpm and 298 K.

Adsorption-desorption experiment: Four cycles of adsorption-desorption were conducted in this experiment to evaluate the regenerative property of Fe-R-BC. A cycle of adsorption-desorption was described as follows: 0.10 g Fe-R-BC was added into 50 mL Cr(VI) solution (100 $mg \cdot L^{-1}$). Then, the initial pH value of the mixed solution was adjusted to 2.0. After that, the mixed solution was placed in the constant temperature oscillation box for 24 h at 120 rpm and 298 K. Afterwards the mixture was separated by filtering. The separated adsorbent was added into 50 mL NaOH solution (0.1 M), and shaken at 298 K for 24 h. After that was done, the adsorbent was separated and washed several times with deionized water. The washed adsorbent was used to the next cycle of adsorption-desorption.

After each treatment was completed, the residual Cr(VI) concentration in the solution was analyzed using a UV-vis spectrophotometer (UV-1800, Shanghai Mapada Instruments Co., Ltd., Shanghai, China) with 1,5-diphenylcarbohydrazide spectrophotometric method. The Cr(VI) adsorption removal rate (AR, %) and the Cr(VI) adsorption removal amount at equilibrium (q_e, $mg \cdot g^{-1}$) were calculated by the following *Equations 2-3*, respectively.

$$AR=\left(\frac{C_0-C_i}{C_0}\right)\times 100\% \quad \text{(Eq.2)}$$

$$q_e=\frac{(C_0-C_i)\times 0.05}{0.10} \quad \text{(Eq.3)}$$

where C_0 and C_i denotes the initial and residual Cr(VI) concentration in each treatment, respectively.

Modeling

In this study, the pseudo first order model, the pseudo second order model, and the intraparticle diffusion model were used to fit the adsorption kinetics data. The following

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1531115327

Equations 4-6 gives the function expression of the above three models, respectively (Wu et al., 2017).

The pseudo first order model:

$$q_t=q_e\left(1-\exp^{-k_1,t}\right) \quad \text{(Eq.4)}$$

The pseudo second order model:

$$q_t=\frac{tq_e^2k_2}{1+tq_ek_2} \quad \text{(Eq.5)}$$

The intraparticle diffusion model:

$$q_t=k_3t^{0.5}+C \quad \text{(Eq.6)}$$

where q_t represents the Cr(VI) adsorption removal amount at time t ($mg\cdot g^{-1}$). k_1 (h^{-1}), k_2 ($g\cdot mg^{-1}\cdot h^{-1}$), and k_3 ($mg\cdot g^{-1}\cdot h^{-1/2}$) are the reaction rate constants. C is a constant ($mg\cdot g^{-1}$).

The Freundlich isotherm model, the Langmuir isotherm model, and the Langmuir-Freundlich isotherm model were used to simulate adsorption isotherms. The following *Equations 7-9* gives the function expression of the above three models, respectively (Jung et al., 2015).

The Freundlich isotherm model:

$$q_e=K_F\times C_e^{1/n} \quad \text{(Eq.7)}$$

The Langmuir isotherm model:

$$q_e=\frac{q_mK_LC_e}{1+K_LC_e} \quad \text{(Eq.8)}$$

The Langmuir-Freundlich isotherm model:

$$q_e=\frac{q_mKC_e^{1/n}}{1+KC_e^{1/n}} \quad \text{(Eq.9)}$$

where q_m represents the Cr(VI) maximum adsorption removal capacity ($mg\cdot g^{-1}$), C_e is the equilibrium concentration ($mg\cdot L^{-1}$), K_F ($(mg\cdot g^{-1})\cdot(L\cdot mg^{-1})^{1/n}$), K_L ($L\cdot mg^{-1}$) and K ($L\cdot mg^{-1}$) are the constants, and 1/n is the heterogeneity factor.

The thermodynamics of the adsorption processes were estimated by three important thermodynamic parameters (i.e., ΔG^0 (Gibbs free energy, $kJ\cdot mol^{-1}$), ΔH^0 (enthalpy, $kJ\cdot mol^{-1}$), and ΔS^0 (entropy, $kJ\cdot mol^{-1}\cdot K^{-1}$)). And they were calculated based on the results of adsorption isotherms by using the following *Equations 10,11*.

$$\ln K_c=-\frac{\Delta H^0}{RT}+\frac{\Delta S^0}{R} \quad \text{(Eq.10)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1531115327

$$\Delta G^0 = -RT\ln K_c \quad \text{(Eq.11)}$$

where K_c denotes the adsorption equilibrium constant ($L \cdot g^{-1}$), which can be acquired by plotting $\ln(q_e/C_e)$ vs. C_e (Gan et al., 2015). T is the absolute temperature (K). R represents the universal gas constant.

Data processing

All treatments were conducted in triplicate, and the average value of three replicates was taken as the experimental result. Excel 2007 and Origin 2018 were used for data management, processing, and drawing. Moreover, one-way ANOVA analysis was used to analyze the significant differences of the experimental data with IBM SPSS Statistics 22.

Results and discussion

Properties of R-BC and Fe-R-BC

Table 1 shows the yield, Fe content, specific surface area (BET), total pore volume, average pore size, and numbers of acidic and basic surface functional groups of R-BC and Fe-R-BC. The yield of R-BC and Fe-R-BC was 40.30% and 36.20%, respectively ($p<0.05$). As a result of modification with $FeCl_3$, Fe-R-BC had a higher Fe content than R-BC ($p<0.05$). Compared to those of R-BC, the specific surface area (BET) and total pore volume of Fe-R-BC increased by 24.16 $m^2 \cdot g^{-1}$ and 0.91 $cm^3 \cdot g^{-1}$, respectively, while the average pore size decreased by 2.63 nm. The number of basic groups of Fe-R-BC was 0.23 $mmol \cdot g^{-1}$, which significantly lower than that of R-BC (0.62 $mmol \cdot g^{-1}$) ($p<0.05$). On the contrary, the number of acid groups of Fe-R-BC (0.56 $mmol \cdot g^{-1}$) increased compared to that of R-BC (0.53 $mmol \cdot g^{-1}$) ($p<0.05$).

Table 1. *Yield, Fe content, specific surface area (BET), total pore volume, average pore size, and numbers of acidic and basic surface functional groups of R-BC and Fe-R-BC*

Designation	Yield (%)	Fe ($mg \cdot g^{-1}$)	SSA ($m^2 \cdot g^{-1}$)	TPV ($cm^3 \cdot g^{-1}$)	APS (nm)	BG ($mmol \cdot g^{-1}$)	AG ($mmol \cdot g^{-1}$)
Fe-R- BC	36.20±2.96	17.61±0.69	27.92	1.10	8.54	0.23±0.03	0.56±0.13
R-BC	40.30±1.55	1.31±0.08	3.76	0.19	11.17	0.62±0.10	0.53±0.13

SSA represents specific surface area (BET), TPV denotes total pore volume, APS refers to average pore size, BG is basic groups, and AG is acidic groups

Figure 1 shows the FT-IR spectra of R-BC and Fe-R-BC. The peaks around 3409 cm^{-1} and 3430 cm^{-1} were caused by the -OH (Dong et al., 2011; Samsuri et al., 2013; Xu et al., 2013; Zhang et al., 2015). The peaks at 2922 cm^{-1} to 2928 cm^{-1} can be attributed to the stretching vibration of –CH (Dong et al., 2011; Samsuri et al., 2013; Zhang et al., 2015). The peaks at 1612 cm^{-1} to 1616 cm^{-1} were caused by the C=O (Garg et al., 2007; Yang et al., 2009; Tang et al., 2014; Zhang et al., 2015). The peaks at 1103 cm^{-1} to 1107 cm^{-1} were related to C-O (Dong et al., 2011; Samsuri et al., 2013; Zhang et al., 2015). The absorption peaks at 800 cm^{-1} to 809 cm^{-1} can be assigned to the aromatic compounds =C-H (Pan et al., 2013; Samsuri et al., 2013). Compared the spectra of Fe-R-BC with that of R-BC, it can be found that the peaks of the two materials were roughly the same. The results

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1531115327

indicated that the category of surface functional group of Fe-R-BC did not change. For Fe-R-BC, although the category of surface functional groups did not change, the intensity of the peak around 3409 cm^{-1} to 3430 cm^{-1} obviously increased, and the intensity of peak around 2922 cm^{-1} to 2928 cm^{-1} decreased (*Figure 1*). The results indicated that the hydroxyl group and methenyl group respectively increased and decreased for Fe-R-BC. The results were consistent with the changes of the number of basic and acid groups (*Table 1*).

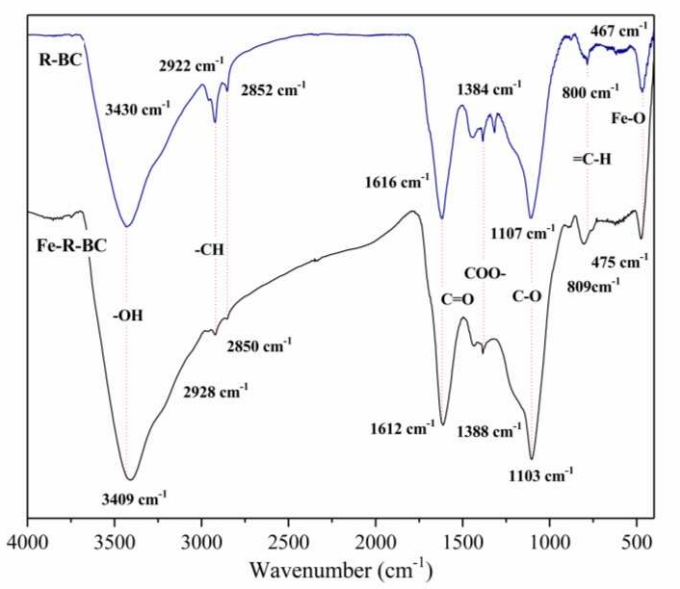

Figure 1. *FT-IR spectra of R-BC and Fe-R-BC*

In summary, some physicochemical properties of R-BC (i.e., specific surface area (BET), total pore volume, average pore size, and numbers of surface functional groups) were changed after modification with $FeCl_3$. The attachment of Fe-oxides particles on the surface of R-BC and the increase of the pore structure of R-BC by the Fe-oxide particles entered the original pores of R-BC led to the changes of basic physical properties (i.e., specific surface area and total pore volume increased, and average pore size decreased) (Wang et al., 2017). The decrease of basic groups and the increase of acidic groups indicate the acidity was increased for Fe-R-BC, which may be due to the protonation-deprotonation reaction on the surface of Fe (hydro) oxide (Sun et al., 2019). In general, the above changes of physicochemical properties of R-BC are beneficial for the Cr(VI) adsorption.

Comparation of the Cr(VI) adsorption removal capacity between R-BC and Fe-R-BC

Figure 2 shows the Cr(VI) adsorption removal rates of R-BC and Fe-R-BC with increasing contact time. For R-BC, the Cr(VI) adsorption removal rate gradually increased and tended to equilibrium after 20 h ($p<0.05$). For Fe-R-BC, the Cr(VI) adsorption removal rate rapidly increased to 93.59% at 6 h ($p<0.05$), and then slowly increased ($p<0.05$) to a stable value ($p>0.05$). The maximum Cr(VI) adsorption removal rate of Fe-R-BC (97.13%, at 24 h) was 1.73 times than that of R-BC (56.01% at 24 h). In general, the results indicated that the Cr(VI) adsorption removal capacity of Fe-R-BC was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1531115327

higher than that of R-BC. The results can be attributed to the following reasons: (1) Fe-R-BC had higher specific surface area (BET) and total pore volume. (2) The surface of Fe-R-BC had the more adsorption sites for Cr(VI), owing to the more acidic groups on the surface of Fe-R-BC (Liu et al., 2010). (3) The Fe oxides formed on the surface of Fe-R-BC had the good selectivity and affinity to Cr(VI) (Tzou et al., 2003).

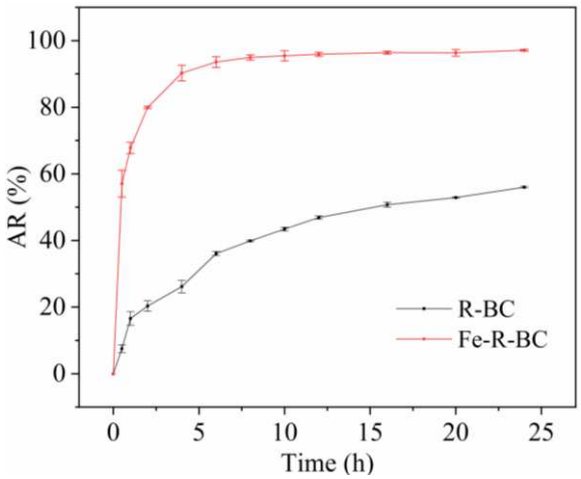

Figure 2. *Cr(VI) adsorption removal rates of R-BC and Fe-R-BC with increasing contact time*

Adsorption kinetics

Figure 3 displays the Cr(VI) adsorption kinetics data of Fe-R-BC. There were three different adsorption removal stages in *Figure 3*, i.e., the rapid increasing stage (0-6 h) ($p<0.05$), the slow increasing stage (6-16 h) ($p<0.05$), and the equilibrium stage (16-24 h) ($p>0.05$). The rapid increasing stage was due to the abundant adsorption sites on the surface of Fe-R-BC in the beginning of experiment, and the slow increasing stage was owing to the decrease of the available surface adsorption sites with the prolongation of experimental time, while the equilibrium stage was related to the adsorption saturation of the surface adsorption sites (Deveci and Kar, 2013; Kaveeshwar et al., 2018).

The fitting results of the adsorption kinetic data by the pseudo first order model, the pseudo second order model, and the intraparticle diffusion model are also displayed in *Figure 3*. The corresponding fitting parameters are listed in *Table 2*. *Figure 3* shows that the pseudo first order model and intraparticle diffusion model could not fit the Cr(VI) adsorption kinetics data of Fe-R-BC very well. The results were also verified by the R^2 values (square of correlation coefficient) in *Table 2*. Compared with the above two models, the pseudo second order model acquired a higher R^2 value (0.997). Moreover, the q_e value (adsorption removal amount at equilibrium) acquired by fitting with the pseudo second order model was 49.46 $mg \cdot g^{-1}$ (*Table 2*), which was consistent with the experimental result (48.57 $mg \cdot g^{-1}$) (*Figure 3)*. The results indicated that the Cr(VI) adsorption kinetics process of Fe-R-BC can be well described by the pseudo second order model. For the pseudo second order model, adsorption process is controlled by chemical adsorption (Mohan et al., 2011). Thus, the rate-limiting step of Cr(VI) adsorption removal by Fe-R-BC was the chemical adsorption process. For the Cr(VI) adsorption removal, the most dominant mechanism is the reduction of Cr(VI) to Cr(III) on the surface of adsorbent (Saha et al., 2010). *Figure 3* also gives the Cr(III) concentration in the experiment. It can be found that the Cr(III) concentration gradually increased ($p<0.05$) and finally

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1531115327

maintained equilibrium after 6 h ($p>0.05$), and the change trend of Cr(III) concentration was consistent with that of Cr(VI) adsorption removal amount (q_t). The results verified that the reduction of Cr(VI) to Cr(III) did happened during the Cr(VI) adsorption removal process. According to the results, it can be deduced that the reduction of Cr(VI) to Cr(III) is maybe a main chemical reaction which controlled the Cr(VI) adsorption removal process of Fe-R-BC.

Adsorption isotherms

The Cr(VI) adsorption isotherms of Fe-R-BC at three different temperatures (283 K, 298 K, and 313 K) are displayed in *Figure 4*. Generally speaking, for the all three adsorption isotherms, the Cr(VI) equilibrium adsorption removal amount (q_e) rapidly increased at first ($p<0.05$), and then gradually approached to the maximum equilibrium adsorption removal amount ($p>0.05$) with the increase of equilibrium concentration (C_e).

The fitted results of adsorption isotherms by the Freundlich isotherm model, the Langmuir isotherm model, and the Langmuir-Freundlich isotherm model are presented in *Figure 4*. *Table 3* lists the corresponding model parameters. At all temperatures, the adsorption isotherms fitted with the Langmuir-Freundlich isotherm model were closer to the experimental data (*Figure 4*). Furthermore, compared to those of other two isotherm models, the R^2 values (square of correlation coefficient) of Langmuir-Freundlich isotherm model (R^2=0.998, 0.999, and 0.990 at 283 K, 298 K, and 313 K, respectively) (*Table 3*) were the largest. The results illuminated that the Cr(VI) adsorption isotherms of Fe-R-BC can be better explained by the Langmuir-Freundlich isotherm model. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1531115327

conclusion means that the Cr(VI) adsorption removal by Fe-R-BC belongs to the multi-molecular layer adsorption, which is regulated by multiple processes due to the heterogeneity of Fe-R-BC (Liu et al., 2010; Jung et al., 2015).

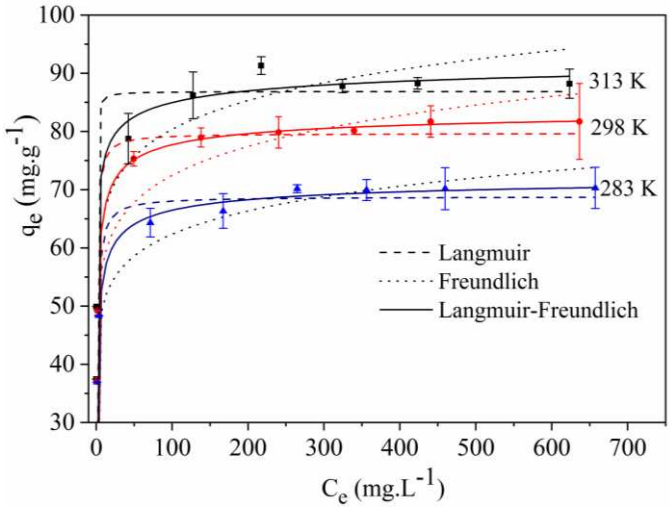

Figure 4. *Isotherms and fitted models of Cr(VI) adsorption removal by Fe-R-BC at three different temperatures*

Table 3. *Fitting parameters for the Freundlich isotherm model, the Langmuir isotherm model and the Langmuir-Freundlich isotherm model*

T (K)	Langmuir model			Freundlich model			Langmuir-Freundlich model			
	q_m (mg·g^{-1})	K_L (L·mg^{-1})	R^2	K_F (mg·g^{-1})·(L·mg^{-1})$^{1/n}$	1/n	R^2	q_m (mg·g^{-1})	K (L·mg^{-1})	1/n	R^2

According to the previous report (Tseng and Wu, 2008), the favorable degree of an adsorption reaction can be divided to five levels based on the value of heterogeneity factor (1/n), namely, 1/n < 0.01: the pseudo-irreversible level, 0.01 < 1/n <0.1: the strong favorable level, 0.1 < 1/n <0.5: the favorable level, 0.5 < 1/n <1: the pseudo-linear level, and 1/n >1: the unfavorable level. According to the values of 1/n (*Table 3*), the favorable degree of Cr(VI) adsorption removal by Fe-R-BC at 283 K belonged to the pseudo-linear level, whereas the favorable degree of Cr(VI) adsorption removal by Fe-R-BC at 298 K and 313 K can be classified as the favorable level. For the constant K (*Table 3*), the value was positively correlated with temperature, which indicated that the adsorption removal capacity of Fe-R-BC for Cr(VI) is enhanced with increasing temperature (Jung et al., 2015). For q_m (*Table 3*), the value calculated from the Langmuir-Freundlich model was respectively 73.04 mg·g^{-1}, 84.68 mg·g^{-1}, and 94.95 mg·g^{-1} at 283 K, 298 K, and 313 K, which was unanimous with our experiment results (71.29 mg·g^{-1}, 81.73 mg·g^{-1}, 88.19 mg·g^{-1} at 283 K, 298 K, and 313 K, respectively).

Compared with some previous reported carbon materials for the Cr(VI) adsorption removal (*Table 4*), Fe-R-BC had a relatively high Cr(VI) adsorption removal capacity. Furthermore, as the raw materials (i.e., rice straw and $FeCl_3$) have the properties of low cost and extensive sources, Fe-R-BC is economical. Moreover, the pyrolysis temperature was 673 K, which was much lower than that of activated carbon (Giri et al., 2012; Nethaji et al., 2013). Therefore the preparation of Fe-R-BC had low energy consumption advantage. In addition, for the modification, only one-time immersion is used. Thereform, the preparation process was relatively simple. In view of the above advantages, Fe-R-BC has the great potential of application for Cr(VI) adsorption removal.

Table 4. *Comparison of the maximum Cr(VI) adsorption removal capacity with those of some previous reported carbon materials*

Adsorbents	q_m ($mg \cdot g^{-1}$)	Temperature (K)
Fe-modified activated carbon prepared from *Trapanatans* husk (Liu et al., 2010)	18.66	313
Polyethylenimine modified biochar (Ma et al., 2014)	435.7	/
Chitosan modification of magnetic biochar produced from Eichhorniacrassipes (Zhang et al., 2015)	167.31	313
Biochar from the blends of oily seeds of *P. terebinthus L.* with alumina (Deveci and Kar, 2013)	6.08	/

Fe-R-BC	94.95	313

Thermodynamic analysis

To better understand the Cr(VI) adsorption removal process of Fe-R-BC, the thermodynamic analysis was performed. *Table 5* lists the calculated values of ΔG^0, ΔH^0, and ΔS^0 for the Cr(VI) adsorption removal by Fe-R-BC. The value of ΔG^0 was -2.05 $kJ \cdot mol^{-1}$, -2.76 $kJ \cdot mol^{-1}$, -3.54 $kJ \cdot mol^{-1}$ at 283 K, 298 K, 313 K, respectively. On the one hand, the values of ΔG^0 were always negative at different temperatures, which manifested that the Cr(VI) adsorption removal process of Fe-R-BC was spontaneous (Tan et al., 2015). On the other hand, the value of ΔG^0 presented a negative correlation with temperature (i.e., the ΔG^0 value decreased as the temperature increased), which indicated that high temperature is favorable for Cr(VI) adsorption removal by Fe-R-BC. The ΔH^0 and ΔS^0 value was 0.0058 $kJ \cdot mol^{-1}$ and 0.034 $kJ \cdot mol^{-1} \cdot K^{-1}$, respectively. The positive value of ΔH^0 and ΔS^0 implied that the Cr(VI) adsorption removal by Fe-R-BC is an endothermic process and the randomness at Fe-R-BC-solution interface has the increasing trend during the adsorption process (Siddiqui et al., 2016).

Effect of initial solution pH on the Cr(VI) adsorption removal

The effect of initial solution pH on the Cr(VI) adsorption removal by Fe-R-BC is shown in *Figure 5*. It can be found that the initial solution pH obviously influenced the Cr(VI) adsorption removal by Fe-R-BC ($p<0.05$). The maximum and minimum Cr(VI) adsorption removal rate was 97.13% and 7.81%, respectively. With decreasing pH, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1531115327

Cr(VI) adsorption removal rate presented an increasing tendency in *Figure 5*. The result was in accordance with the previous studies (Liu et al., 2010; Ma et al., 2014; Wu et al., 2017). For Cr(VI), it can present as the forms of $HCrO_4^-$, CrO_4^{2-} and $Cr_2O_7^{2-}$ in aqueous solutions. At low pH (2<pH< 3), $HCrO_4^-$ is the primary form of Cr(VI). However, the primary form gradually shifts to CrO_4^{2-} and $Cr_2O_7^{2-}$ as pH increases. Compared with CrO_4^{2-} and $Cr_2O_7^{2-}$, the adsorption of $HCrO_4^-$ is easier and more rapid due to its requirement of only one adsorption site (Kuppusamy et al., 2016). Thus, the Cr(VI) adsorption removal efficiency of Fe-R-BC increased as pH decreased. Furthermore, the surface charge of adsorbent significantly influences the Cr(VI) adsorption removal efficiency (Zhao et al., 2017). For Fe-R-BC, *Figure 5* also displays the change of zeta potential with the variation of pH. The point of zero charge (pH_{zpc}) of Fe-R-BC was obtained from the change of zeta potential. For Fe-R-BC, the pH_{zpc} was 2.79. That is to say, the surface charge of Fe-R-BC was positive when the solution pH < 2.79, whereas the surface charge of Fe-R-BC was negative when the solution pH > 2.79. The positive surface charge of Fe-R-BC in the solution pH < 2.79 could promote the positive-negative charge attraction, thus it is beneficial for the Cr(VI) adsorption (Zhao et al., 2017). This may be the other reason for the high Cr(VI) adsorption efficiency of Fe-R-BC under the low pH conditions, especially at pH=2.

Table 5. *Values of Gibbs free energy, enthalpy, and entropy*

ΔG^0 (kJ·mol^{-1})			ΔH^0 (kJ·mol^{-1})	ΔS^0 (kJ·mol^{-1}·K^{-1})
283 K	298 K	313 K	0.0058	0.034
-2.05	-2.76	-3.54		

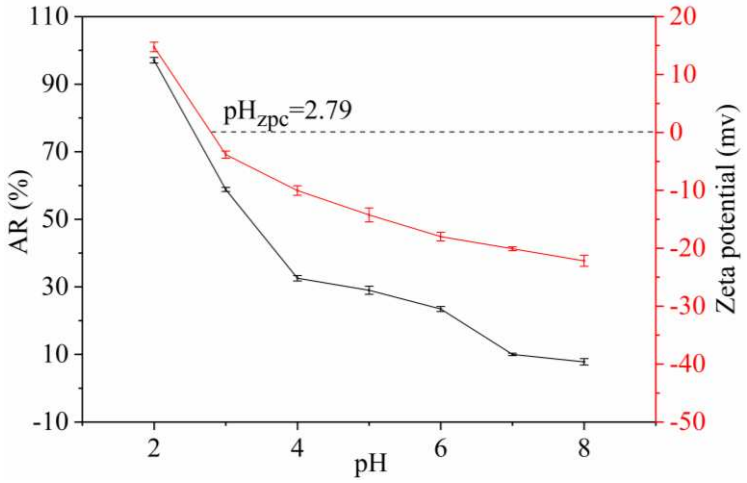

Figure 5. *Effect of initial solution pH on the Cr(VI) adsorption removal by Fe-R-BC and Zeta potentials of Fe-R-BC at different pH*

Effect of coexisting ions on Cr(VI) adsorption removal

Figure 6 shows the effects of three coexisting ions (i.e., Cl^-, NO_3^-, and SO_4^{2-}) on the Cr(VI) adsorption removal by Fe-R-BC. The Cr(VI) adsorption removal rate of Fe-R-BC decreased with increasing the concentrations of three coexisting ions ($p<0.05$). Cl^-, NO_3^- and SO_4^{2-} respectively resulted in 20.65%, 28.82%, and 35.89% reduction of the Cr(VI)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1531115327

adsorption removal rate with the increase of their concentrations from 0 M to 2.0 M. The results showed that the three coexisting ions can affect the Cr(VI) adsorption removal by Fe-R-BC, but the influence degrees of the three coexisting ions were different. Under the same condition of ion concentration, SO_4^{2-} had the strongest effect on the Cr(VI) adsorption removal by Fe-R-BC, followed by NO_3^- and Cl^-. For the three coexisting ions, the reduction of Cr(VI) adsorption removal rate with the increase of ion concentration could be attribute to the decreasing activity of Cr(VI) in solution with increasing the ion concentration (Zhang et al., 2013). However, the different influence degrees on the Cr(VI) adsorption removal might be related to the different adsorption competitiveness of the three coexisting ions with Cr(VI). For SO_4^{2-}, it was a polyvalent anion with semblable structure and size to $HCrO_4^-$, CrO_7^{2-}, and CrO_4^{2-}, thus it had the strong adsorption competitiveness with $HCrO_4^-$, CrO_7^{2-}, and CrO_4^{2-} compared with NO_3^- and Cl^- (Wang et al., 2017). The strong adsorption competitiveness of SO_4^{2-} led to its greatest influence on the Cr(VI) adsorption removal. Based on the above results, for the practical application of Fe-R-BC to remove Cr(VI) from high salt wastewater (especially sulfate and nitrate wastewater), the wastewater should be desalinated firstly.

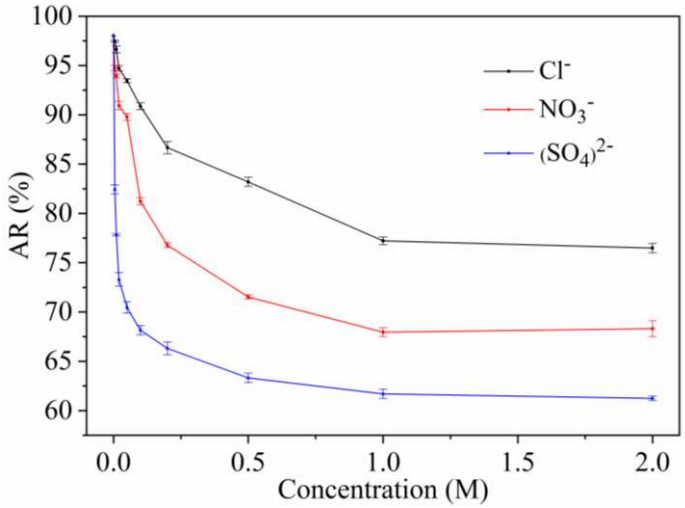

Figure 6. *Influence of coexisting ions on Cr(VI) adsorption removal by Fe-R-BC*

Regeneration of Fe-R-BC

For the application of an adsorbent, the regenerative property of adsorbent should be considered because it determines the economic efficiency of an adsorbent. In this study, the regenerative property of Fe-R-BC was evaluated through 4 cycles of adsorption-desorption experiment. *Figure 7* shows the Cr(VI) adsorption removal rates of Fe-R-BC after experiencing different cycles of adsorption-desorption. With increasing the cycle, the Cr(VI) adsorption removal rate gradually decreased ($p<0.05$). This is a common problem for adsorbents in the cyclic utilization process. It might be owing to the quantity loss of adsorbent and the continuous damage of adsorbent structure during regeneration (Salvador et al., 2015). However, in the fourth cycle, the Cr(VI) adsorption removal rate was 75.12%, which was equal to 76.27% of that of the pristine Fe-R-BC (0 cycle). The results indicated that Fe-R-BC had the good regenerative property, and 0.1 M NaOH solution can be used as an eluent for its regeneration. Generally speaking, the good regenerative property of Fe-R-BC is beneficial to decrease the cost of use.

Conclusions

Fe-R-BC was prepared from rice straw with $FeCl_3$ modification by pyrolyzing in this study. Compared to those of R-BC, the Fe content, specific surface area (BET), total pore volume, and number of hydroxyl group of Fe-R-BC increased, while the average pore size and number of methenyl group decreased. For the Cr(VI) adsorption removal by Fe-R-BC, the adsorption kinetics data can be well described by the pseudo second order model, while the adsorption isotherms data can be well described by the Langmuir-Freundlich isotherm model. For Fe-R-BC, the maximum Cr(VI) adsorption removal capacity was 94.95 $mg \cdot g^{-1}$, which exceed those of some previous reported carbon materials. The initial solution pH had a significant effect on the Cr(VI) adsorption removal capacity of Fe-R-BC, which increased with decreasing the initial solution pH. The Cr(VI) adsorption removal by Fe-R-BC was a spontaneous and endothermic process. The Cr(VI) adsorption removal capacity of Fe-R-BC decreased with increasing coexistence ion (Cl^-, NO_3^-, and SO_4^{2-}) concentration in solution. In addition, the influence degree of Cl^-, NO_3^-, and SO_4^{2-} was ordered as follows: $SO_4^{2-} > NO_3^- > Cl^-$. Fe-R-BC had the good regenerative property, and 0.1 M NaOH solution can be used as an eluent for the regeneration. Overall, Fe-R-BC can be applied to the treatment of wastewater containing Cr(VI). In the future, the treatment effect of Fe-R-BC for other anions needs to be further explored.

Abstract. The preservation and rearing of insect natural enemies is the key for biological control. The biological (survival, longevity and the fecundity) and biochemical (low-molecular-weight carbohydrates, glycerol and fatty acids contents) indexes of *Arma chinensis* fed by *Antherea pernyi* (diet AP) or *Tenebrio molitor* (diet TM) were measured after cold storage treatments. The results showed that the diet affected several biological and biochemical parameters, but varied with the length of cold storage. The survival rate and longevity after 30-day cold storage, and the fecundity after 40-day cold storage were significantly higher for adults reared on TM compared to AP. The super-cooling points and the freezing points were significantly lower for adults reared on TM than AP. Low-molecular-weight carbohydrates, glycerol and unsaturated fatty acids were significantly higher for TM than for AP. The structural equation model showed that diet influenced survival, fertility and SCPs of *A. chinensis* indirectly through the enzyme activity, and the content of carbohydrates, glycerol and unsaturated fatty acids. These results suggested that the nutrient content of diets affects the accumulation of cold-resistant substances, metabolism level and activities of related enzymes in *A. chinensis* in a manner that enhances tolerance to cold storage.
Keywords: *natural enemies, cold tolerance, rearing, development, low-molecular-weight carbohydrates, fatty acids*

Introduction

The preservation and transportation of living insects and the rearing of these insects in sufficient numbers and quality for fluctuating markets is one of the obstacles to the use of insect natural enemies for biological control (Coudron et al., 2007). According to the principle of insect cryogenics, cold storage (cryopreservation technology) may be a useful technique to store and ship insects for extended periods, and accumulate sufficient numbers of insects for the undulating and unpredictable demands, and provide the protection of some endangered insect species (Coudron et al., 2007; Leopold, 2007). Cold storage tolerance in insects has significant plasticity (Gotthard and Nylin, 1995), which can be affected by multiple endogenous and exogenous factors. The effect of temperature, photoperiod, age/stadium on the cold tolerance of insects have been researched extensively (Hodkova and Socha, 1995), whereas the effects of the nutrient quality (diet) are less known (Tzanakakis et al., 1992; Ruberson et al., 1998). Previous studies showed that cold storage tolerance of predators improved by selecting

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1532915347

appropriate developmental stages, temperatures and feeding parameters (Coudron et al., 2007). For example, the survival rate and the reproductive rate of *Podisus Maculiventris* and *Chrysopa Carnea* enhanced by the nutrient quality of diets after the cold storage and pre-processed in cold storage (Chang et al., 1995; Thorpe and Aldrich, 2004). The low temperature survival of *Nasonia vitripennis* significantly improved when parasitism occurred in a host that of those contained more cryoprotectants (glycerol and alanine) (Rivers et al., 2000). The cold storage capacity of *Cotesia marginiventris* adults enhanced with feeding honey or sucrose (Ergin and Uckan, 2003). Egg viability of the *P. maculiventris* adults fed artificial diets was significantly higher than that fed by natural prey (Coudron et al., 2009), which may result from the high protein content and low lipid content contained in the artificial diets (Coudron et al., 2007). Those studies focused on the effect of diet on growth and fecundity indexes after cold storage. However, we know less about how diet influences biochemical indexes of insects after cold storage. Consequently, the physiological mechanisms linking dietary nutrition and cold storage tolerance of a predatory insect are still not known.

Arma chinensis is a predatory insect that is widely distributed in more than 10 provinces in northern China. They prey on several lepidopteran, coleopteran and hemipteran insect pests of agricultural and forestry ecosystems (Chai et al., 2000; Chen et al., 2007; Wang et al., 2012; Zou, 2012), and can use to control the density of pest populations with artificial releases. Since *A. chinensis* plays a vital role in the biocontrol of pests, researchers have investigated environmental (Song et al., 2010) and dietary (Zou et al., 2015; Li et al., 2016, 2018) conditions to optimize the mass production of *A. chinensis*. Some researchers found no distinct difference in developmental duration, survival rate, fecundity, and egg viability of *A. chinensis* reared on diets with different nutrient composition (Li et al., 2016). However, many insect herbivores have evolved counter-adaptations to overcome the plant defence. These adaptations include host plant choice, non-disruptive feeding guilds and various physiological adaptations as well as metabolic enzymatic strategies of the insect's digestive system (Pentzold et al., 2014). There may be an adaptation to the cold tolerance for the various food to the polyphagous *A. chinensis*.

Unlike rearing at normal temperature, consequences of cold storage may result from a combination of both chill-injuries and exhaustion of energy reserves (Colinet et al., 2006). Substances such as glycogen, lipids, glycerol and cell membrane construction maybe activated in response to cold exposure as a method to help insects survive in the adverse environments (Feng et al., 2014). Therefore, the accumulation and the metabolic rate of these substances in insects affect their cold storage tolerance. In this study, we focus on the effects of different diets on the response of *A. chinensis* to cold storage treatments, including its physiological and biochemical responses. We hope to advance diet formulation as a way to improve the use of cold storage for mass production of *A. chinensis*.

Materials and methods

Experimental insects and diet

Rearing A. chinensis

A. chinensis used for these studies originated from over-wintering adults collected from *Ulmus pumila* plantation (farmland shelterbelts) located in Linzi Town, Qian'an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1532915347

County, Jilin Province, China (N123°22'16"-124°22′E, 44°38'47"N) in April 2016. After diapause termination, colonies *A. chinensis* were continuously fed (*ad libitum*) either pupae of *Antherea pernyi* (diet AP) or pupae of *Tenebrio molitor* (diet TM) for 12 generations in insect rearing cages at the ambient temperature of 25 ± 1 °C, humidity of 65 ± 5%, and lighting of 16L: 8D (*Figs. 1* and *2*). For these studies, 3- to 7-day-old adults were collected after 12 generations of rearing on either *A. pernyi* (diet AP; 2,154 adults collected) or on *T. molitor* (diet TM; 2,436 adults collected).

Figure 1. *Morphological of A. chinensis (Fallou). a, Egg mass; b, First instar Nymph; c, third instar Nymph; d, Female adult*

Figure 2. *The nymph of A. chinensis feeding Antherea pernyi (a) and Tenebrio molitor (b)*

Nutrient component and content of two natural diets

The pupae of *A. pernyi* (diet AP) and *T. molitor* (diet TM) were collected from the rearing factory. After rinsing the pupae of *A. pernyi* (9) and *T. molitor* (120) were dried of any extraneous moisture using the filter paper, then labeled and weighted individually. The pupae were frozen dried at -40 °C for 72 h, weighted again for calculating the water content, then grounded and analyzed the nutrient component using the method described by Jiang et al. (2016). The nutrients of pupae of *A. pernyi* and *T. molitor* were showed in *Table 1*.

Design of cold storage treatment

20 adults for each treatment were placed in a culture dish (11 cm in diameter) with filter paper at the bottom, then were placed into a low temperature incubator without illumination at the temperature of 4 ± 1 °C and the humidity of 65 ± 5% RH. The preliminary test showed no significant difference in biological indexes for male and female adults fed either AP or TM and subjected to 3 weeks of cold treatment. Therefore, the minimum cold storage period was set as 30 days without considering the sex, followed by 10-day extensions in cold storage period until all adults in the treatment dead. Five cold storage periods were established with a control group held at 25 ± 1 °C and humidity of 65 ± 5% RH. All the *A. chinensis* were provided with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1532915347

sufficient water but no food during the cold storage, and were discarded after measuring biological indexes (Coudron et al., 2007).

At each cold storage time point, 400 adults were collected for survival rate measurement from each diet treatment after holding at 25 ± 1 °C and 65 ± 5% RH for 24 h. Then 20 pairs of survivors (one male and one female per pair) were placed in paper cups (7 cm in diameter and 8 cm in height) for each diet treatment. Fresh diet (1 silkworm pupa or 4 mealworm pupae) and water via a wet cotton ball was provided every day in each cup. The quantity of eggs laid, the time of egg oviposition, and time of death were recorded for two weeks. Egg viability was determined using 15 to 20 eggs from each cup.

Table 1. *Main ingredients and amounts of Antherea pernyi (AP) and Tenebrio molitor (TM)*

Influences of different diets on biochemical indexes of A. chinensis

The physiological and biochemical indexes related to cold resistance of adult of *A. chinensis* were measured after 30-days cold storing period, including super-cooling points, low-molecular carbohydrates, fatty acids and glycerol, nutrient absorption and enzyme activities.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1532915347

Super-cooling points (SCPs) and freezing points (FPs)

Super-cooling and freezing points were determined for 40 adults from each diet after 30-day cold storage treatment. Individual adult was dried of any extraneous moisture, placed in a centrifuge tube and fixed to a thermocouple attached to an automatic recorder (UR100, Model 4152, Yokogawa Electric Co., Seoul, Korea) via a bridge. The thermocouple with the adult was lowered into a freezing chamber (VM04/100, Heraeus Co., Germany) at 0 °C for 20 min, and then was cooled to -40 °C at a rate of 1 °C/min, and the decreasing body temperatures were measured. The SCPs was taken as the lowest temperature before the increase in temperature caused by the latent heat of crystallization (Mohammadzadeh and Izadi, 2016).

Low-molecular-weight carbohydrates in the insect body

The content of low-molecular-weight carbohydrates were measured in 300 adults for each diet after 30-day cold storage treatment, freeze-dried for 48 h (2.5L FreeZone, LabconcoInc., USA), ground, and then measured by the method as described by Heydari and Izadi (2014). Briefly, 1 g of dried powder of *A. chinensis* was extracted with 20 ml of 80% ethanol, and heated at 75 °C for 20 min in a water bath, and then centrifuged for 3 min at 10000 rpm. The supernatant was analyzed with the Agilent 1200 liquid chromatograph (Agilent Technologies Inc., USA) for determining contents of trehalose, glucose, mannitol, sorbitol, and fructose. The other portion of freeze-dried powder of *A. chinensis* were used to the measurement of glycerol content and fatty acid content.

Glycerol content in the insect body

Briefly, 1 g of freeze-dried powder of *A. chinensis* was extracted with 1 ml of distilled water using a glass hand homogenizer placed in an ice bath and centrifuged at 4 °C and 5000 rpm for 15 min. The supernatant was analyzed with the Glycerol Assay Kit (Catalog Number MAK117, Storage Temperature -20 °C, Sigma-Aldrich, St. Louis, USA). The procedure followed the instruction of the test kit (Jehrke et al., 2018).

Fatty acids contents in the insect body

Briefly, 0.5 g of freeze-dried powder of *A. chinensis* was extracted with a 2:1 v:v solution of chloroform-methanol (Gołębiowski et al., 2008). Fatty acids in the organic phase were methyl esterified, and quantified by gas chromatography (Agilent 7890A, Agilent Technologies Inc., USA; adopting fused-silica capillary column as chromatographic column, 100 m × 0.25 mm × 0.2 μm, CP-Sil 88, Chrompack; Agilent Technologies Inc., USA).

Enzyme activities related to the transformation of cold-resistant substances

For each enzyme activity analysis, 20 adults were pooled for each diet after 30-day cold storage treatment. The insects were grounded with the liquid nitrogen freezing grinder (JXFSTPRP-II-01 Shanghai Jingxin Co., LD, China). Briefly, 0.1 g of powder of *A. chinensis* was extracted with 0.9 ml extracting solution using a glass hand homogenizer placed in an ice bath. Then centrifuged at 4 °C for 10 min with the speed 2500 rpm for Catalase (CAT), Peroxidase (POD), total superoxide dismutase (T-SOD), 8000 rpm for trehalase (THL) and Glyceraldehyde-3-phosphate dehydrogenase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1532915347

(GAPDH), 10000 rpm for Trypsin, and 2000 rpm for Adenosine triphosphatase (ATP) (Na^+K^+-ATP, $Ca^{2+}Mg^{2+}$-ATP), respectively. The extracted solution centrifuged at 4 °C and 16000 rpm for 40 min for fatty acid synthetase (FAS). Then the supernatants were taken to prepare the samples for analyses enzyme activity analysis.

Trypsin activity, GAPDH activity, THL activity, and FAS activity were determined with a kit (Suzhou Keying Biotechnology Co., Ltd., Suzhou, China) according to the instruction; CAT, T-SOD, ATP, and POD activities were determined with a kit produced by Nanjing Jiancheng Bioengineering Institute (Nanjing, China) according to instruction.

Data analysis

Prior to analysis, data for survival rate, longevity, fertility, the time of egg oviposition, fecundity, egg viability were ln (x + 1) transformed to achieve normality. The effect of diet and length of cold storage on cold tolerance of *A. chinensis* were analyzed using general linear models with LSD significant difference test ($P < 0.05$). The effect of the length of cold storage was analyzed with non-parametric tests (Cruskal-Wallis rank-sum test) of multiple independent samples ($P < 0.05$). The effect of diet on biological indexes (survival rate, longevity, fertility, egg oviposition time, fecundity, and egg viability), and biochemical indexes (super-cooling point, the content of micro-molecule carbohydrates, glycerol, and fatty acids) and enzyme activity were tested by the Independent sample T test ($P < 0.05$). The analysis were performed using SPSS statistical software (SPSS 17.0 for windows, SPSS Inc., Chicago, USA).

Structural equation modeling (SEM) was used to evaluate the general hypothesis that carbohydrate, glycerol, saturated fatty acid (SFA), and unsaturated fatty acid (UFA) content of adult affect survival rate, longevity, fertility, fecundity, egg viability of *A. chinensis*. We hypothesized that the adaptations of metabolic enzymatic strategies of the *A. chinensis* induced by diet and cold treatments influenced the content of energy reserves, which then altered the cold tolerance of *A. chinensis*. We constructed an a priori model including possible causal relationships among predictors, i.e. the enzymatic activity was the main factor influencing the content of carbohydrates, glycerol and fatty acids induced by diet and cold treatments, which then influenced fertility, survival rate, egg viability, fecundity and changed super-cooling points (SCPs). All of the predicators were treated as observed variables. Finally our results only showed the significant biochemical pathways. Mardia's test was used to estimate the multivariate normality of the dataset. The model fitness was assessed using the $\chi 2$-test, comparative fit index (CFI), and root mean square error of approximation (RMSEA). The analysis was performed with SPSS AMOS 21.0 software (SPSS Inc., Hong Kong) using the "robust" maximum likelihood estimation procedures.

Results

Effect of diet on the biological indexes after cold storage treatment

The effect of diet and cold storage time on the survival rate, longevity, and female fertility, egg oviposition time, fecundity, and egg viability varied with the length of time in cold storage (*Table 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1532915347

Survival rate

The length of time in cold storage significantly affected the survival rate of adults from colonies reared on either TM or AP (*Table 2*). The survival rate decreased significantly with increased time in cold storage (AP, H = 32.125, df = 5, P < 0.001; TM, H = 32.224, df = 5, P < 0.001). The effect of diet on survival rate varied with the length of time in cold storage (*Fig. 3*). The survival rate for TM was significantly higher than for AP (30-day, F = 0.225, T = -2.573, df = 10, P = 0.028; 40-day, F = 1.084, T = -2.349, df = 10, P = 0.041) at the 30-day and 40-day cold storage periods (*Fig. 3*). In addition, the survival rate for AP (90.83%) was significantly lower than for the control group (P < 0.05), but the survival rate for TM (96.67%) and the control group was not significantly different (P > 0.05) at the 30-day cold storage period. The survival rates for both AP and TM dropped to 12% at 70-day cold storage period.

D: diet; S: storage period

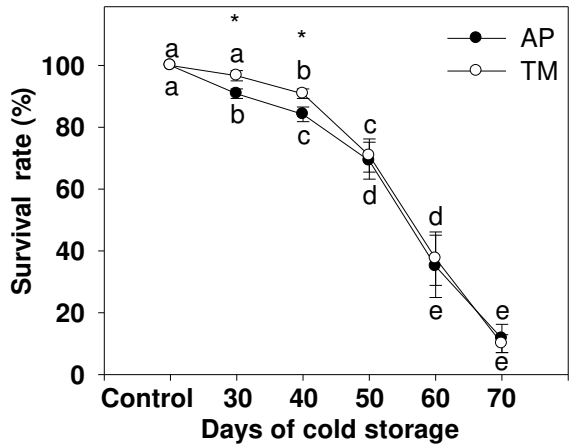

Figure 3. *Survival of A. chinensis adults from colonies reared on diets Antherea pernyi (AP) and Tenebrio molitor (TM) after cold storage for different lengths of time at 4 °C. The same colonies of A. chinensis reared at 25 °C is shown as the control. The different letters represent significant difference among the different cold storage periods at P < 0.05 level (Cruskal-Wallis Rank Sum Test). * represents a significant difference among the two diet treatments (T-test, P < 0.05)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1532915347

Longevity

Both diet and length of cold storage showed a significant effect on the longevity of adults (*Table 2*). The longevity of adults for both diets significantly decreased with the increasing length of time in cold storage (AP, $H = 109.548$, $df = 5$, $P < 0.001$; TM, $H = 107.922$, $df = 5$, $P < 0.001$), which was lower than 3 days at 60-day cold storage period (*Fig. 4*). Overall, the longevity of the adult for TM was higher than for AP at all the cold storage time periods and the control group (*Fig. 4*). Moreover the differences in the longevity of adults for both diets were significant at 30-day and 50-day cold storage periods, respectively (30-day, $F = 11.350$, $T = -2.439$, $df = 38$, $P = 0.019$; 50-day, $F = 0.417$, $T = -4.09$, $df = 38$, $P < 0.001$) (as shown in *Fig. 4*).

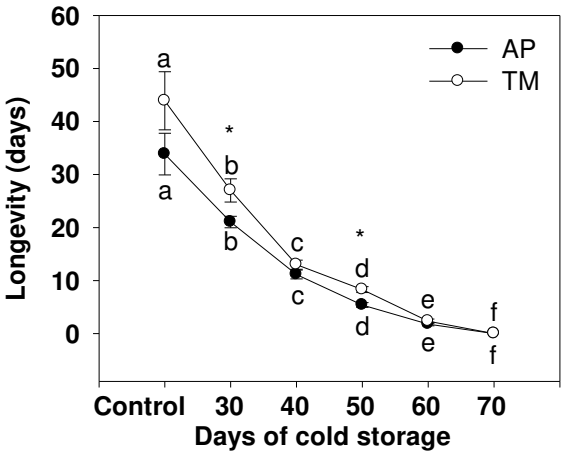

Figure 4. *Longevity of A. chinensis adults from colonies reared on diets Antherea pernyi (AP) and Tenebrio molitor (TM) after cold storage for different lengths of time at 4 °C. The different letters represent significant difference among the different cold storage periods at $P < 0.05$ level (Cruskal-Wallis Rank Sum Test). * represents a significant difference among the two diet treatments (T-test, $P < 0.05$)*

Fertility

Both diet and cold storage time showed a significant effect on fertility (*Table 2*). The fertility declined with the increasing cold storage time for both diets compared to the control group reared on 25 °C (the fertility was 70.19% and 79.93% for AP and TM, respectively) (*Fig. 5*). After 60 days of cold storage, fertility had dropped to below 10% for both diet treatments (AP, $H = 34.208$, $df = 5$, $P < 0.001$; TM, $H = 33.388$, $df = 5$, $P < 0.001$). The fertilities for TM were significantly higher than those for AP before cold storage (control, $F = 0.243$, $T = -6.247$, $df = 10$, $P < 0.001$), and from the 30-day to 50-day cold storage period (30-day, $F = 1.546$, $T = -6.043$, $df = 10$, $P < 0.001$; 40-day, $F = 1.091$, $T = -5.975$, $df = 10$, $P < 0.001$; 50-day, $F = 0.069$, $T = -8.344$, $df = 10$, $P < 0.001$) (*Fig. 5*).

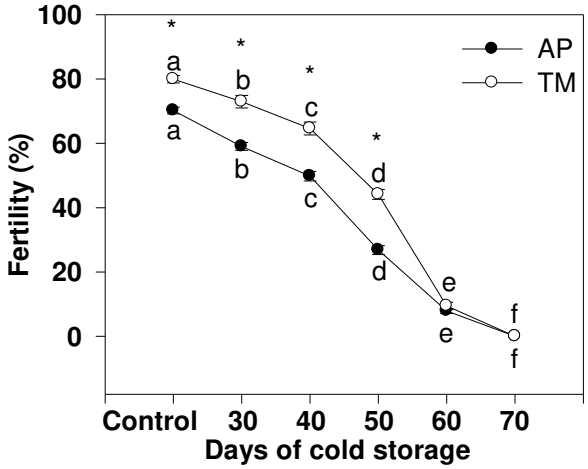

Figure 5. *Fertility of A. chinensis adult from colonies reared on Antherea pernyi (AP) and Tenebrio molitor (TM) after cold storage for different lengths of time at 4 °C. The different letters represent significant difference among the different cold storage periods at P < 0.05 level (Cruskal-Wallis Rank Sum Test). * represents a significant difference among the two diet treatments (T-test, P < 0.05)*

Egg oviposition time

The cold storage period had a significant effect on the time of egg oviposition (*Table 2*), which decreased with the increasing of the cold storage time for both diets (AP, H = 46.692, df = 5, P < 0.001; TM, H = 42.356, df = 5, P < 0.001) (*Fig. 6*). There was no significant effect of diet on the time of egg oviposition at all cold storage periods (P > 0.05) (*Table 2; Fig. 6*).

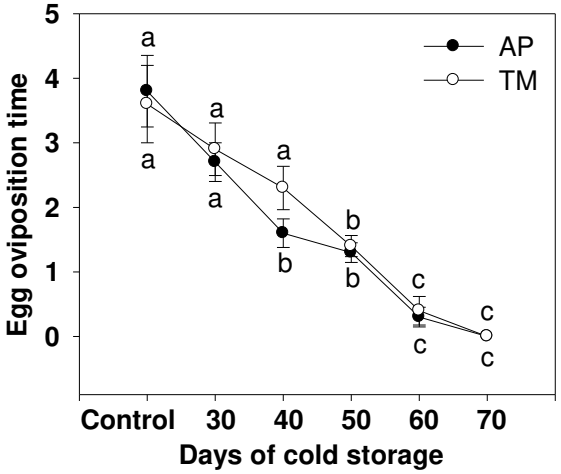

Figure 6. *Egg oviposition time of A. chinensis adults from colonies reared on Antherea pernyi (AP) and Tenebrio molitor (TM) after cold storage for different lengths of time at 4 °C. DOI: http://dx.doi.org/10.15666/aeer/1706_1532915347

Fecundity

Length of cold storage had a significant effect on the fecundity of *A. chinensis* reared on either diets (*Table 2*). Overall, fecundity decreased with the increasing length of time in cold storage (AP, H = 56.991, df = 5, P < 0.001; TM, H = 55.013, df = 5, P < 0.001) (*Fig. 7*). There was no significant difference in the fecundity for AP and TM (*Table 2*), but the average fecundity for TM was significant higher (by 30%) than that for AP at 40-day cold storage (F = 0.752, T = -3.018, df = 18, P = 0.008) (*Fig. 7*).

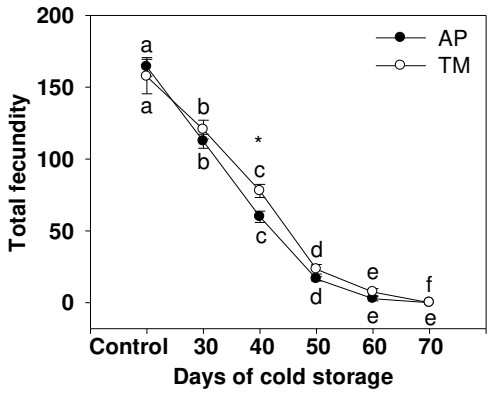

Figure 7. *Fecundity of A. chinensis adults from colonies reared on Antherea pernyi (AP) and Tenebrio molitor (TM) after cold storage for different lengths of time at 4 °C. The different letters represent significant difference among the different cold storage periods at P < 0.05 level (Cruskal-Wallis Rank Sum Test). * represents a significant difference among the two diet treatments (T-test, P < 0.05)*

Egg viability

Both diet and length of time in cold storage had a significant effect on egg viability for *A. chinensis* (*Table 2*). Egg viability declined for both diet treatments with the increasing length of time in cold storage (AP, H = 33.379, df = 5, P < 0.001; TM, H = 33.292, df = 5, P < 0.001) (*Fig. 8*). Egg viability for TM was higher than for AP, but the significant difference only occurred at 40-day cold storage period (F = 0.222, T = -4.592, df = 10, P = 0.001) (*Fig. 8*).

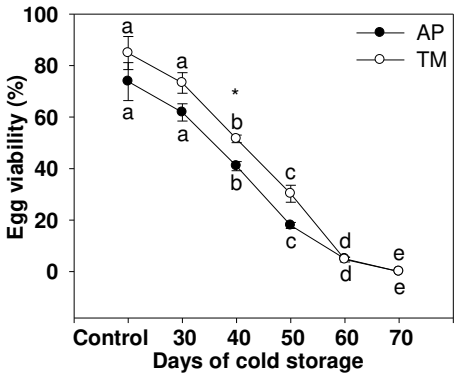

Figure 8. *Egg viability of A. chinensis adults from colonies reared on Antherea pernyi (AP) and Tenebrio molitor (TM) after cold different lengths of time in cold storage at 4 °C. Effect of diet and lengths of time in cold storage on physiological indexes

Super-cooling and freezing points

Diet treatments had a significant effect on the super-cooling and freezing points (SCPs, $F = 0.399$, $T = 19.294$, $df = 18$, $P < 0.001$; FPs, $F = 0.336$, $T = 16.512$, $df = 18$, $P < 0.001$). The super-cooling and freezing points for TM were 20% lower than for AP (*Fig. 9*).

Low-molecular-weight sugars and glycerol

Low-molecular-weight sugars (trehalose, mannitol, sorbitol) and glycerol were significantly higher for TM than AP, by 31%, 228%, 211% and 56%, respectively (*Fig. 10*, Trehalose, $F = 0.238$, $T = -3.153$, $df = 8$, $P = 0.014$; Mannitol, $F = 38.515$, $T = -3.157$, $df = 8$, $P = 0.013$; Sorbitol, $F = 0.436$, $T = -9.711$, $df = 8$, $P < 0.001$; Glycerol, $F = 2.860$, $T = -133.056$, $df = 8$, $P < 0.001$).

Fatty acids

There was no significant difference in the total content of fatty acids for AP and TM ($F = 6.51$, $T = 0.51$, $df = 6.06$, $P = 0.63$). However, the content of saturated fatty acids for AP was significantly higher by 129% than for TM ($F = 21.65$, $T = 12.95$, $df = 4.72$, $P < 0.001$), but the content of unsaturated fatty acids were significantly lower by 28% than for TM ($F = 1.97$, $T = 6.5$, $df = 8$, $P < 0.001$) (*Table 3*).

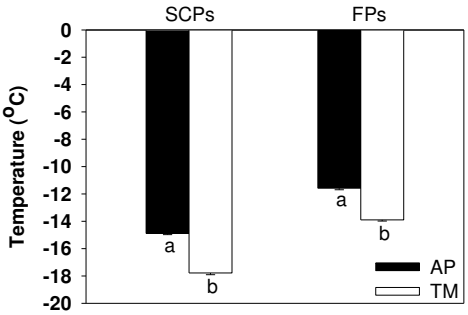

Figure 9. *Super-cooling and freezing points of A. chinensis adults from colonies reared Antherea pernyi (AP) and Tenebrio molitor (TM) after cold storage for 30 days at 4 °C. Different letters indicate significant differences between diet treatments at P < 0.05 level (T-test)*

Table 3. *Fatty acid content in A. chinensis adults from colonies reared on Antherea pernyi (AP) and Tenebrio molitor (TM) after cold storage for 30 days at 4 °C (means ± standard error)*

Fatty acids	**Contents (mg/g)**	
	***Antherea pernyi* (AP)**	***Tenebrio molitor* (TM)**

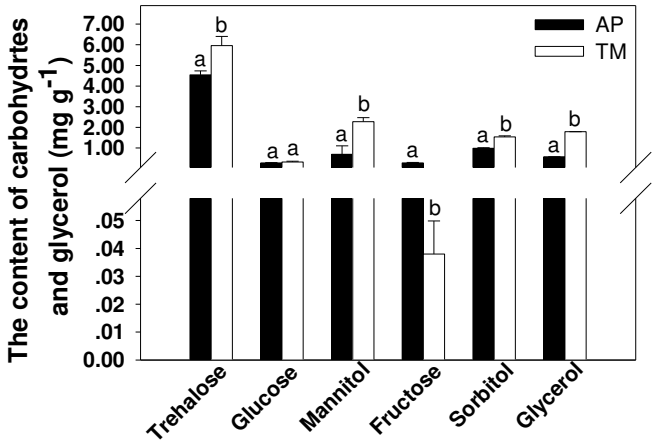

Figure 10. *Low-molecular-weight sugars and glycerol content of A. chinensis adults from colonies reared on Antherea pernyi (AP) and Tenebrio molitor (TM) after cold storage for 30 days at 4 °C. Different letters indicate significant differences between diet treatments at P < 0.05 level (T-test)*

Enzyme activities

The effect of diet on the enzyme activities in adults varied among the different enzymes (*Fig. 11*). Activities of GAPDH, Na^+K^+-ATPase, and $Ca^{2+}Mg^{2+}$-ATPase for TM were greatly higher, by 2.53 times, 2.00 times and 3.10 times, respectively, than for AP (GAPDH, F = 0.029, T = 40.782, df = 10, P < 0.001; Na^+K^+-ATPase, F = 0.309, T = 7.741, df = 10, P < 0.001; $Ca^{2+}Mg^{2+}$-ATPase, F = 4.774, T = 14.35, df = 10, P < 0.001). The FAS activity for AP was significantly lower, by 37%, than for TM (F = 1.285, T = -5.410, df = 10, P < 0.001).

The relationships between diets induced factors and cold tolerance

The SEM revealed that the predictors explained 50% of the variation in diet effect (*Fig. 12*). The content of glycerol, SFA and UFA directly contributed to the survival rate of *A. chinensis*. Activities of GAPDH and FAS were associated with the survival rate through the content of SFA and UFA, respectively. It was worth noting that diet influenced the survival rate of *A. chinensis* indirectly through the activity of GAPDH and the content of glycerol. The content of fructose directly contributed to the fertility, and the activity of $Ca^{2+}Mg^{2+}$-ATPase was associated with the fertility through the content of fructose. Diet influenced the fertility of *A. chinensis* indirectly through the activity of $Ca^{2+}Mg^{2+}$-ATPase. The content of glycerol, fructose, sorbitol, SFA and UFA directly contributed to SCPs. And the activity of $Ca^{2+}Mg^{2+}$-ATPase was associated with SCPs through the content of fructose, the activities of GAPDH and FAS was associated with SCPs through the content of SFA and UFA, respectively. Diet influenced SCPs of *A. chinensis* indirectly through the activities of $Ca^{2+}Mg^{2+}$-ATPase and GAPDH, and the content of glycerol, sorbitol and UFA (*Fig. 12*).

Discussion

Response to cold storage can be a combination of adaptation to low temperatures and to starvation (Renault, 2003). As part of the adaptation, insects require a large amount

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1532915347

of energy, which is derived solely from metabolic stores (lipids, proteins and eventually glycogen), and, therefore, body tissues are depleted because of catabolic activities (Hervant et al., 1999; Wang et al., 2017). With the depletion of energy reserves, starvation periods will have dramatic consequences on reproduction in adults (Leather, 1984).

Developmental and reproductive indexes used during cold storage can be affected by the diet consumed prior to the cold treatment. Previous studies demonstrated that species, diet, temperature and length-of-time affected the result of cold storage for insects (Colinet and Boivin, 2011; Koštál et al., 2016). We found that storage at 4 °C for less than 30 days had no significant effect on most biological indexes that we measured. However, survival rate, longevity, female fertility rate, fecundity, egg viability and time of oviposition for adults from colonies reared on the two diets we tested were affected when cold storage was extended beyond 30 days. Survival rate and longevity for TM were higher than for AP beyond 30-day cold storage. In contrast, the fecundity was significantly higher for AP than TM at 40-day cold storage.

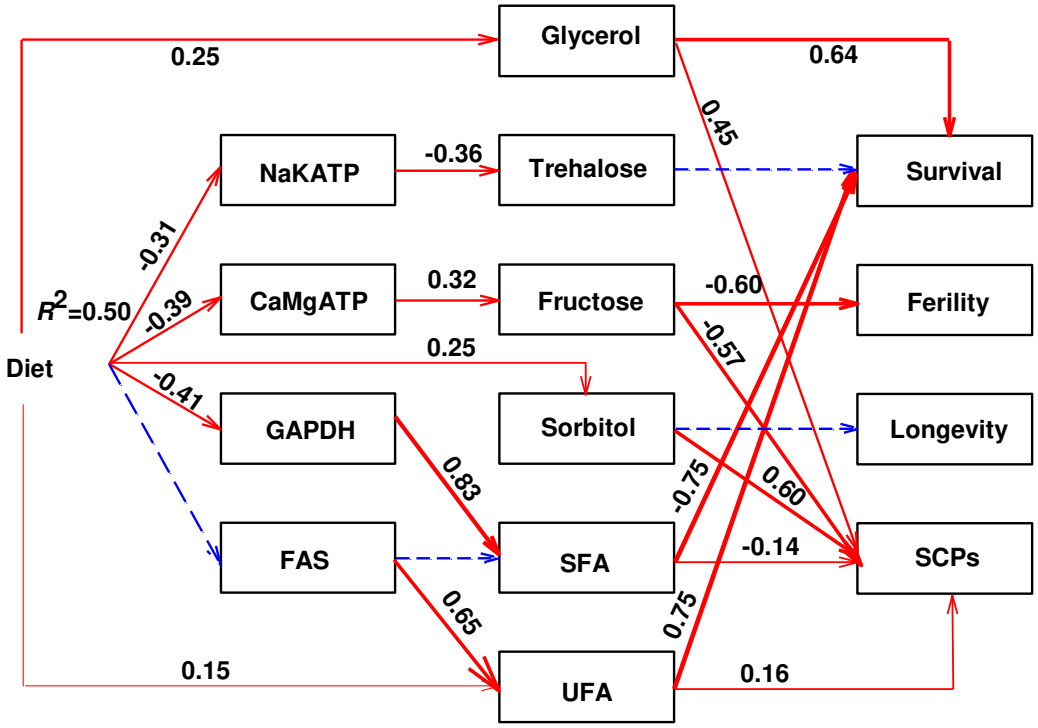

Figure 12. *Structural equation model showing the potential mechanism of diet effects on the cold tolerance of A. chinensis (χ^2 = 73.416; df = 72; P = 0.654; CFI = 1.000; RMSEA = 0.000). Arrow thickness represents the magnitude of the path coefficient, red solid line arrows represent significant paths (P < 0.05), and blue dotted lines represent non-significant paths. SFA: saturated fatty acid, UFA: unsaturated fatty acid, SCPs: super-cooling points*

The quality of food consumed prior to cold storage was an important endogenous factor affecting the cold storage tolerance of insects (Ayrinhac et al., 2004; Coudron et al., 2009; Li et al., 2014). The nutrient content of food not only influence the storage of energy-related substances (such as low-molecule-weight hydrocarbons, glycerol, and lipids, etc.) before cold storage (Liu et al., 2009; Mohammadzadeh and Izadi, 2018), but also the metabolic processes related to energy for insects during the cold storage (Han and Bauce, 1998; Naya et al., 2007; Teets and Denlinger, 2014). Those changes in the physiological and metabolic processes have been credited with cold tolerance in a polyphagous insect herbivore (Hunter and McNeil, 1997). In our research, the contents of proteins, fats, and carbohydrates in TM are higher than those in AP (*Table 1*). The different nutrients in food may influence the production and accumulation of low-molecular-weight cryoprotectants in insects under cold stress (Storey and Storey, 1991; Liu et al., 2007). The trehalose, glucose, mannitol, sorbitol and glycerol are proved to be cryoprotectants for many insects (Renault et al., 2006; Clark and Worland, 2008; Teets and Denlinger, 2013). Increased energy reserves, including glycogen, glycerol and total proteins were correlated with cold tolerance in Drosophila melanogaster (Chen and Walker, 1993). The SEM revealed that the content of glycerol and fructose directly contributed to the survival rate and the fertility of *A. chinensis*. In addition, diet influenced the survival rate and SCPs of *A. chinensis* indirectly through the content of glycerol and sorbitol (*Fig. 12*). The higher contents of trehalose, mannitol, sorbitol and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1532915347

glycerol in *A. chinensis* adults from a colony reared on TM after cold storage may be one of the reason that greater cold tolerance of *A. chinensis* fed on TM.

There were no significant differences in the total amount of fatty acids in adults from colonies reared on either of the two diets and subsequently exposed to the cold storage treatment. However, the content of unsaturated fatty acid in adults from colonies reared on TM was higher by 39% than for AP. This difference, may account, in part, to the 20% lower super-cooling and freezing points of adults from colonies reared on TM and AP, and the SEM results showed that diet influenced SCPs of *A. chinensis* indirectly through the content of UFA (*Fig. 12*). Fatty acids are not only one of the substrates for synthesizing fats, but also one of the basic substances of cell membranes which are important for growth and fertility of insects (Chang and Vargas, 2007). More unsaturated fatty acids in the cell membrane of insects can accelerate the movement of energy substances such as glycerol, lipids and carbohydrates into the cells (Matsuo et al., 2019); and decrease the phase transition temperature of the cell membrane, which ensure that bio-membranes are stable at low temperatures to overcome adverse conditions (Kasamo et al., 1992; Worland, 2005). Therefore, the different contents of fatty acids in *A. chinensis* induced by the different diets may contribute to the survival effects manifested during cold storage, especially the content of unsaturated fatty acids that is positively related to the survival of *A. chinensis*, but the saturated fatty acids were negatively related to the survival of *A. chinensis* (*Fig. 12*). However, it remains to be determined if types and contents of fatty acids in insect are an adaptive advantage in surviving exposure to low temperatures.

When diets with high carbohydrates were fed to *Drosophila melanogaster*, the expression of multiple enzymes such as glucosidase used for glycolysis and fatty acid synthase for fatty acid synthesis increased significantly (Baker and Thummel, 2007; Matsuda et al., 2014), while the expression of many carbohydrases and lipases were repressed (Chng et al., 2014). Similarly, the contents of nutrients in the diet also impacted the activity of enzymes related to glycometabolism, fat metabolism, and vitellogenin formation in insects (Chang et al., 2010; Chng et al., 2016). In our research, the GAPDH (related to gluconeogenesis), Na^+K^+-ATPase and $Ca^{2+}Mg^{2+}$-ATPase enzymes (related to energy release and transmembrane transportation) and glycolytic-related enzymes (energy source) in adults from colonies reared on AP were higher than those for TM, but the FAS activity was lower (*Fig. 11*).

In order to explain the effect diet type on the biological and biochemical parameters of *A. chinensis*, and explore the adaptations of *A. chinensis* to cold storage, we develop a conceptual model of the metabolic enzymatic strategies of the *A. chinensis* pathways that diet influence cold storage tolerance of insects. The SEM revealed that the diet influenced the survival rate, the fertility and SCPs of *A. chinensis* indirectly through the activities of GAPDH, FAS and $Ca^{2+}Mg^{2+}$-ATPase (*Fig. 12*). Those metabolic enzymatic activity (GAPDH, FAS and $Ca^{2+}Mg^{2+}$-ATPase) were related to energy reserves, the higher content of glycerol and sorbitol directly contributed to SCPs, which induced the greater cold tolerance of *A. chinensis* reared on TM.

Conclusion

The present study demonstrated a dietary effect on the response of adult *A. chinensis* to cold temperatures. The content of glycerol, trehalose, sorbitol and fatty acids (unsaturated and saturated) in the adults were identified as possibly contributing to cold

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1532915347

tolerance and dietary content was shown as affecting the level of those substances in the adults, thus providing an explanation for the observed differences in responses to cold storage treatments. Those results suggest that the diet with higher content of carbohydrates and mineral in *T. moliter* (TM) could enhance the cold tolerance of *A. chinensis* by increasing energy reserves (glycerol, trehalose, sorbitol and unsaturated fatty acids) and decreasing super-cooling points. Our results are helpful for the selection of natural diet and the optimization of artificial diet for *A. chinensis* and other predatory insects. Using modern molecular biology technology such as nutrigenomics and metabonomics to analyze the influence of specific nutrients of diet on the synthesis and metabolism of cold resistant substances of insects, which would be beneficial to optimize the formula of insect artificial diet.

Abstract. Present study aimed to investigate phytoconstituents, total phenolic and flavonoids content, antioxidant activity and biochemical composition of the leaf extract of *Artemisia argyi* L. Qualitative analysis was conducted using standard methods however, total phenolic, flavonoids content and antioxidant activity was assessed by Folin-Ciocalteu, aluminium chloride colourimetric method and 1, 1-Diphenyl-2-picrylhydrazyl (DPPH) assay, respectively. Compositional analysis was carried out by Gas chromatography-mass spectrometry (GC-MS). The outcome of the qualitative analysis suggested the presence of flavonoids, phenols, terpenoids, steroids, saponins, tannins and flavones except for alkaloids and glycosides. However, total phenols recorded were 16.89, 7.45 and 3.63 mg gallic acid equivalent GAE/g; flavonoids 20.80, 7.13 and 2.42 mg quercetin equivalent QE/g and DPPH inhibition percent was 81.48, 65.62 and 57.78% from 1st, 2nd and 3rd extraction, respectively. GC-MS analysis exposed the existence of ten biological compounds corresponding to 99.91% of the total extract. However, erucylamide (33.42%), 1-decene, 4-methyl- (12.63%), *myo*-Inositol, (10.42%), α-Cadinol (9.13%) and 2-pyrrolidinone (8.68%) were the major compounds with five minor compounds. It was concluded that the leaves of *A. argyi* contain biological constituents responsible for antioxidant properties which can be introduced as a natural antioxidant pharmacologically and as botanical alternative of synthetic chemicals. However further studies are required on identification of specific components responsible for such activities.
Keywords: *Chemical analysis, Artemisia argyi, total phenols, total flavonoids, DPPH, GC-MS*

Introduction

Free radicals are highly reactive species that can be produced either endogenously in the body or exogenously through ingestion of pollutants or chemicals. These free radicals are beneficial in the process of signaling, regulation of molecules and destruction of bacteria and viruses at physiological levels. However, excessiveness of free radicals in the body causes oxidative stress that negatively amend the cell structures by interacting with DNA, proteins and lipids, may ultimately lead to certain diseases like cancer, atherosclerosis, Parkinson's, stroke, diabetes, rheumatoid arthritis and senile dementia hence, antioxidants perform their function as reducing agents for neutralization of these free radicals (Fang et al., 2002; Lobo et al., 2010; Liu et al., 2011; Wong et al., 2012). Moreover, secondary metabolites, phenolic and flavonoids

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1534915362

content are beneficial for human health as well as animals and their usefulness is linked to their antioxidant properties (Meot-Duros and Magne, 2009). However, richness of phytoconstituents in plants food which are non-nutritive agents that protect from disease exploitation and interplays with nutrients, dietary material and also contain several properties like antioxidants, anti-microbial and physiological activities (Adesuyi et al., 2012).

Extensive studies have been conducted on antioxidants as preventative or illness curative associated with oxidative stress. They are also used in the food stuff business to protect from food deterioration, and skin aging in the cosmetic industry. Antioxidants also obstruct with the oxidation process because of their activity as scavenging free radicals (Büyükokuroğlu et al., 2001). Although, synthetically prepared antioxidants, such as *tert*-butyl hydroxytoluene (BHT), *tert*-butyl hydroxyanisole (BHA) and antibacterial peptides are available for therapeutic and food industry but, they are carcinogenic so, interest in searching for natural antioxidants from natural resources is increasing gradually (Ling et al., 2011). Natural compounds may have great commercial value in the food industry, but their use is limited due to their high cost. Hence, an effective and cost effective preparation of natural antioxidant is the need of time. The selection of an appropriate extraction method for natural antioxidants concerning extraction effectiveness and economic feasibility aspects to non-conventional extraction methods. Solvent extraction is helpful because of ease to conduct, take less time for extraction as well as higher extraction yields to recuperate maximum antioxidant compounds from medicinal plants (Xu et al., 2017).

Artemisia belongs to family Asteraceae is largest and widely found genus throughout the world, is important from medicinal view point and have got increased attention due to phytochemical activities, chemical and biological diversification (Tan et al., 1998). *Artemisia* species are well known in Chinese traditional herbal medicines and commonly used in the treatments of cancer, inflammation, hepatitis, menstrual disorders, malaria, metabolism disorders, circulatory system and some infectious diseases caused by viruses, bacteria and fungi (Reynold, 1996; Lis-Balchin and Deans, 1997; Adams et al., 2012; Zhang et al., 2014). It comprises of or more than 500 species (Abad et al., 2012) among which, *A. argyi* is a prevailing species, mostly found in North America, Asia and Europe (Bora and Sharma, 2011). Historically, *A. argyi* was first recorded in the Liang Dynasty in ‘‘Ming Yi Bie Lu’’(Zhou et al., 2000) however, the true region is considered to be Hubei Province in Qizhou County (Li, 2002). Several compounds were reported containing anti-inflammatory properties from *A. argyi* (Choi et al., 2013; Jeong et al., 2014; Zeng et al., 2014; Park et al., 2015). Essential oil extracted from this plant contains antioxidant properties, anti-melanogenic and insecticidal behavior (Lee and Vairappan, 2011; Huang et al., 2012; Zhang et al., 2014). It is also an imperative plant for nutritional concerns contain essential amino acids, vitamin C, polyunsaturated fatty acids, phenolic contents and possess good DPPH scavenging activity (Kim et al., 2015).

Several protocols have been used for the analysis of chemical compounds among which Gas chromatography-mass spectrometry (GC-MS) is a useful methodology to find out different biological compounds. However, biochemical composition of *A. argyi* oil from flowers and leaves possess major components such as sesquiterpenes, monoterpenes, ketones, alcohols, aromatic components and ethers, etc. (Hu et al., 2013). Moreover, due to its aromatic properties, essential oil of *A. argyi* could play a prominent function in food preservation and safety (Wang et al., 2006).

Although, some studies have been conducted on *A. argyi* but data on quantitative analysis, antioxidant activity and biologically active compounds of *A. argyi* is not well described. Therefore, the present research work was planned to evaluate phytochemicals, total phenolic contents, flavonoids content, antioxidant potential and investigations on biochemical compounds by GC-MS analysis from crude solvent extract of *A. argyi* for their appliances as a purposeful food and antioxidants source. The study was conducted at the Biopesticides lab at Shenyang Agricultural University Shenyang, Liaoning China during the year 2019.

Materials and methods

Collection and plant materials preparation

As aerial parts of the plants tend to have more interesting compounds and most of the photosynthesis/ respiration take place in the aerial parts. Also, most of the secondary metabolites from plants can be produced in leaves. Thus, young leaves of one month old plants were collected from surrounding locations of Shenyang Agricultural University Shenyang, Liaoning China in April 2019 (*Fig. 1a and 1b*).

a b

Figure 1 a and b. *Photographic views of A. argyi plant*

Ten samples of the same species were collected and mixed together and were washed out beneath tap water to remove impurities and allowed to dry under shade at room temperature. Then, dried leaves were ground to fine powder by electric blender and subjected to successive extraction three times for 72 h using methanol as solvent (6 ml/g) of plant sample. Contents were filtered and concentrated on rotary evaporator (Buchi Switzerland R-210) to remove solvent from extract. Extract yield was calculated using following *Equation 1* and stored at 4°C for further use.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1534915362

$$Extract\ yield\ (\%) = \frac{Weight\ of extract\ (g)}{Weight\ of\ the\ sample} \times 100 \qquad \text{(Eq.1)}$$

Qualitative phytochemical screening

Methanolic extract of *A. argyi* leaves was subjected to screening tests for the investigation of phytoconstituents using standard methods.

Test for alkaloids

Half ml of extract solution was permitted to dry in test tubes and in the consequent reside, 2 ml of 2% hydrochloric acid (HCl) was added and positioned in water bath at 100°C for 15 min. Then, the mixture was filtered on cooling and divided equally into two portions. Addition of few drops of Mayer's reagent into one portion and Dragendoff's to the other portion resulted in turbidity or yellow precipitate confirm alkaloids (Siddiqui and Ali, 1997).

Test for glycosides

Into 2 ml of extract solution, ferric chloride ($FeCl_3$) 5% and 2 ml distilled water was added and resultant mixture was placed on water bath for 15 min and then on cooling 1 ml of benzene was added, shacked and allowed to settle for 1 min. Next, addition of few drops of concentrated ammonia (NH_3) resulted in appearance of pink or red color which confirm glycosides (Siddiqui et al., 2009).

Test for terpenoids and steroids

Briefly, dried extract 0.5 g was added in to 2 ml of trichloromethane, shacked to dissolve the extract, filtered and placed on ice; following that 2 ml of glacial acetic acid was added. Next, addition of few drops of concentrated sulfuric acid (H_2SO_4) resulted in emergence of a pink or pinkish brown and, or blue/bluish green color indicate terpenoids and steroids respectively (Siddiqui and Ali, 1997).

Test for flavonoids and flavones

Into 3 ml extract solution 2 ml of diluted sodium hydroxide (NaOH) was added resulting in yellow colored solution. Solution become colorless on addition of 1 ml of 5 N hydrochloric acid (HCl) which is the indication of flavonoids however, the appearance of orange color confirms flavones (Sofowora, 1993; Siddiqui et al., 2009).

Test for tannins

To estimate tannins, 1 ml distilled water and few drops of ferric chloride ($FeCl_3$) were added to 0.5 ml extract. From the resulting mixture gallic tannins were confirmed by the appearance of blue color and catecholic tannin by green/black color (Iyengar, 1995).

Test for phenols

For the detection of phenols, 0.5 g of extract was added into distilled water and shacked until dissolve and then, 3 ml of 10% lead acetate ($Pb(C_2H_3O_2)_2$ was added to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1534915362

the solution resulted in appearance of white precipitation confirms phenols (Trease et al., 2003).

Test for saponins

To confirm saponins, addition of 1 g of extract into 20 ml of distilled water then, shacked strongly resulting in appearance of a foam layer confirms saponins (Siddiqui and Ali, 1997).

Quantitative phytochemical screening

Total phenolic content (TPC)

Folin-Ciocalteu reagent assay was employed for assessing the total phenolic stuffing in *A. argyi* leaves extract. Briefly, mixed 2.5 ml of 10% Folin-Ciocalteu reagent into 1 ml plant extract equivalent to (1 $mgml^{-1}$ of methanol) followed by addition of 2 ml of 2% sodium carbonate (Na_2CO_3). Then, incubation of substantial mixture was carried out for 15 min in the absence of light at 28°C. The mixture's absorbance was determined in ELISA 96-well plate at 765 nm using an absorbance microplate reader (SpectraMax 190, manufactured in China; designed in USA). Gallic acid (1 $mgml^{-1}$) was used with different concentrations (1, 0.50, 0.25, 0.10, 0.05, 0.02, 0.01 and 0 $mgml^{-1}$) for standard calibration curve construction and is shown as GAE (gallic acid equivalent) mgg^{-1} of extract (Aiyegoro and Okoh, 2010). Experiment was replicated three times.

Total flavonoid contents (TFC)

Total flavonoids contents in the *A. argyi* leaves extract were determined through aluminium chloride colourimetric method. Briefly, 1 ml of extract equivalent to (1 $mgml^{-1}$ of methanol) was added in to 3 ml methanol, 0.2 ml 1 M potassium acetate (CH_3COOK), 0.2 ml 10% aluminium chloride ($AlCl_3$) and distilled water 5.6 ml. Then, incubated the resulting mixture for half an hour at 28°C in the dark. After that, absorbance was calculated in ELISA 96-well plates at 420 nm on absorbance microplate reader (SpectraMax 190, manufactured in China; designed in USA). Quercetin was used as the standard (1 $mgml^{-1}$) to obtain standard curve at different concentrations (1, 0.50, 0.25, 0.10, 0.05, 0.02, 0.01 and 0 $mgml^{-1}$). Results were expressed as quercetin equivalent (QE) mgg^{-1} of extract (Aiyegoro and Okoh, 2010). Experiment was replicated three times.

DPPH radical scavenging activity

The antioxidant properties of the extract of *A. argyi* was measured with stable 1,1-diphenyl-2-picrylhydrazyl 'DPPH' (Yu et al., 2003). In brief, extract solution 0.5 ml ($1mgml^{-1}$) was added to 3.5 ml of freshly made solution of DPPH (0.002 g 50 ml^{-1} methanol) and incubated for half an hour in the dark at room temperature to measure absorbance in ELISA 96-wellplates at 517 nm on absorbance microplate reader (SpectraMax 190, manufactured in China; designed in USA). The inhibition percent of DPPH was calculated from the decrease of absorbance by using *Equation* 2. A lower absorbance value represents elevated scavenging activity of free radical. (Zhao et al., 2008).

$$Inhibition(\%) = \frac{A_{blank} - A_{sample}}{A_{blank}} \times 100 \qquad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1534915362

whereas; A_{blank}=(absorbance of control); A_{sample}=(absorbance of samples).

Biochemical analysis by Gas chromatography-mass spectrophotometry (GC-MS)

Gas chromatography-mass spectrophotometry analysis of crude extract of *A. argyi* leaves was assessed by using (Agilent 6890-5973N USA), and gas chromatograph (GC) which was equipped with capillary column HP1 model number (TG-5MS) polydimethylsiloxane (30 m × 250 µm × 0.25 µm) interfaced with Hewlett Packard mass selective detector 5973. Gas chromatographic parameters were;

- Temperature fixed for 2 min at 110°C primarily and finally raised to 200 and 280°C with increase rate of 10°C/min and 5°C/min, respectively.
- Inlet temperature was 250°C and 10:1 split ratio.
- MS temperature 230°C.
- MS Quadruple temperature 150°C.
- Thermal Aux temperature 285°C.
- Ionization current 60 µA.
- MS Scan ranges 40-450 units.
- Ionization energy 70 eV and Helium was selected as carrier gas with flow rate: 1.0 ml/min.

Compounds were recognized by elucidation on gas chromatography mass spectrum by literature data or database at Wiley/NIST.98.1 (Joulain and König, 1998; Sparkman, 2005). The comparative yield of each compound was assessed which was based on raw data areas of gas chromatography (GC) with no response factor correction of FID.

Statistical analysis

Recorded data for total phenols, flavonoids and DPPH inhibition (%) was analyzed through ANOVA (one-way analysis of variance) and mean values were calculated for significance test by Tukey's HSD at P=0.05 level. All statistical processes were administered by different statistical packages with IBM-SPSS statistics 25.0 version.

Results

Extract yield (%)

Extraction from natural plants material is depends upon polarity based solvents and type of the material used. Methanol is a high polarity solvent which is considered as the solvent of choice for higher extract yield, phenolic and flavonoids content. So, for extraction purposes in the current experiment, methanol was selected as solvent. However, according to our findings methanol produced prominent yield in each successive extraction which was 9.91, 2.58 and 1.45% for 1st, 2nd and 3rd extraction, respectively (*Fig. 2*).

Qualitative phytochemical screening

Preliminary evaluation tests are helpful in bioactive component determination which consequently leads towards discovery and development of drugs and also for agricultural prospects. Tests were conducted for screening of phytochemical like alkaloids, glycosides, terpenoids, flavonoids, flavones, steroids, tannins, phenols and

DOI: http://dx.doi.org/10.15666/aeer/1706_1534915362

saponins from *A. argyi* leaves. These screening tests led to the identification of bioactive compounds which are important form pharmacological and agricultural point of view. However, the confirmation of a bioactive compound during screening tests was referred as presence (+) and absence (-). Terpenoids were confirmed by pink or pinkish brown color of the solution. Flavonoids and flavones were observed by the conversion of the reaction mixture from yellow to colorless for flavonoids and orange for flavones. Appearance of a blue and green/black color confirms gallic tannin and catecholic tannin respectively. Phenols were confirmed by the appearance of blue or green color in the reaction mixture while, foaming character in extract solution confirms saponins. Phytochemical tests confirmed the existence of tannins, terpenoids, flavonoids, steroids, flavones, phenols and saponins except for alkaloids and glycosides from crude extract of *A. argyi* leaves (*Table 1*).

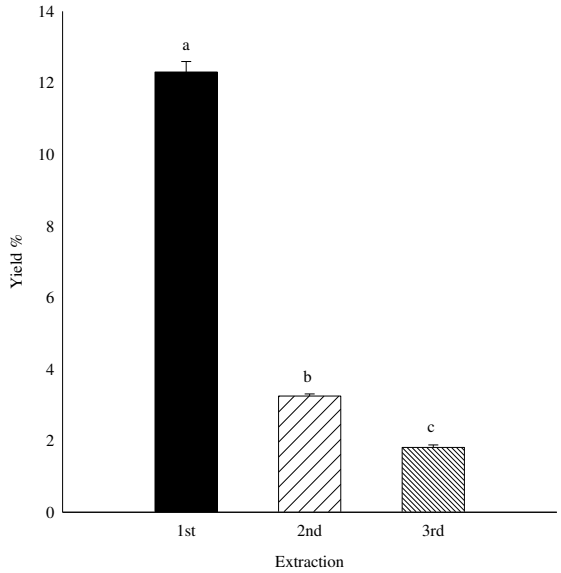

Figure 2. *Extract yield produced by methanol by three successive extractions. Values are offered as mean ± standard error. Same superscripts on the bars designate that values for mean are not significantly different referred to Tukey's HSD test (P > 0.05).*

Quantitative phytochemical evaluation of total phenolic and flavonoids contents

The total phenolic content and flavonoid content for three successive extractions are presented in *Table 2*. Obtained results demonstrated that phenolic content in total were 16.89, 7.45 and 3.63 mg gallic acid equivalent GAE/g for 1st, 2nd and 3rd extraction respectively while, total flavonoids for 1st, 2nd and 3rd extraction were 20.80, 7.13 and 2.42 mg quercetin equivalent QE/g, respectively. Results also revealed that extract afforded phenol and flavonoids in each extraction however, their quantity decreased gradually for each consequential extraction.

DPPH radical scavenging activity

1,1-Diphenyl-2-picrylhydrazyl (DPPH) is a constant and stable free radical that can easily dissolved in methanol. It showed prominent color absorption on spectrophotometer at 517 nm. The free radical antioxidant molecules were scavenged through contribution of hydrogen molecules and thus the DPPH assay solution's color changed to light yellow resulted in reduction of absorbance. Data obtained by the 1,1-Diphenyl-2-picrylhydrazyl of free radical scavenging commotion is given in *Table 2*. Results showed that inhibition recorded was 81.48, 65.62 and 57.78% for 1st, 2nd and 3rd extraction respectively which clearly demonstrate that inhibition percent did not more influenced by successive extraction from the same sample.

Table 2. *Total phenolic content (TPC), Total flavonoids contents (TFC) and DPPH inhibition percent of A. argyi leaf extract*

Solvent extract	Extraction	Total phenolic content mg (GAE/g)	Total flavonoid content mg (QE/g)	DPPH Inhibition (%)

Biochemical analysis

GC-MS analysis was performed to find out the occurrence of biochemical components in the crude extract of *A. argyi* leaves. Active compounds with their peak area (%) along with their molecular formula (M.F), molecular weight (M.W) and retention time (R.T) are presented in *Table 3*.

Table 3. *Biochemical composition of A. argyi leaf extract*

Peak #	R.T	Area%	Compounds	M.F	M.W (g/Mol)
1	3.485	8.68	2-Pyrrolidinone	C_4H_7NO	85.11
2	9.016	4.39	3-Ethylthiolane	$C_6H_{12}S$	116.22

10	25.727	33.42	Erucylamide	$C_{22}H_{43}NO$	337.58

R.T (retention time); M.F (Molecular formula); M.W (Molecular Weight)

The analysis of compounds from GC-MS, resulted in the detection of several biologically active compounds from methanol extract. Results showed the presence of ten biochemical components corresponding to 99.91% of total extract. Among the identified compounds erucylamide (33.42%), 1-decene, 4-methyl- (12.65%), *myo*-Inositol, 2-C-methyl- (10.42%), α-Cadinol (9.13%) and 2-pyrrolidinone (8.68%) were the main compounds while, other five compounds were considered as minor compounds because of their low abundance from 3.27-6.60%. The GC-MS chromatogram showing different peaks of major and minor compounds is presented in *Fig. 3*.

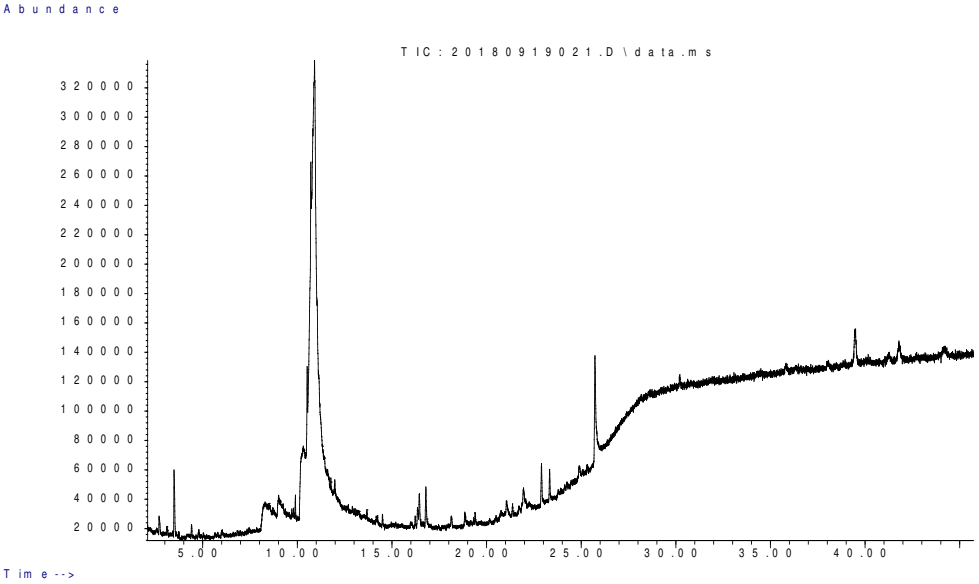

Figure 3. *Chromatogram obtained from crude extract of A. argyi leaf*

Discussion

The extraction process of bioactive components is immensely related to the method of extraction, used solvent and the biological and chemical properties of the extracted compounds. According to our findings methanol being a high polarity solvent produced higher extract yield in each successive extraction. However, similar results were documented by Ahmed et al. (2019) that methanol produced elevated extract yield from *C. colocynthis* and *C. sativa* leaves. Moreover, the result indicated the existence of flavonoids, flavones, saponins, steroid, terpenoids, phenols and tannin with exception of alkaloids and glycosides. The existence of secondary metabolites and a variety of phytoconstituents in natural plant resources could be beneficial for humans in multitude of ways. The phenolic and flavonoids contents exhibited the ability to scavenge free radicals, anti-inflammatory properties, anti-carcinogenic potential, depressurization, immunoregulation, analgesia and anti-lipid peroxidation. However, tannins are well known because of their anti-fungal, anti-tumor, anti-allergic and anti-aging while,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1534915362

saponins as well as steroids possess anticancer, anti-inflammatory, antioxidant and have potential for cholesterol reduction and also responsible for insecticidal properties (Prabuseenivasan et al., 2006; Thamaraiselvi and Jayanthi, 2012; Mei et al., 2013; Zhang et al., 2014). Moreover, the existence of phytoconstituents like flavonoid, saponins, tannins, essential oil and steroid of *A. argyi* lead the plant toward increasing potential with nutritional or pharmacological values. However, similar finding were reported by Dhanapal et al. (2016) that dry matter of *A. argyi* contain maximum phenolic and flavonoid contents 234.52±0.99 and 737.72±25.55 mgg^{-1}, respectively, Extract also demonstrated EC_{50} values of DPPH 63.34±1.10 μgmL^{-1}.

Mostly flavonoids and phenolic contents were corresponded to antioxidant activities of the extracts. Some studies reported that flavonoids and phenol from plant extracts not only related with antioxidant activities but, some other phytoconstituents such as peptides and polysaccharides may also influenced antioxidant potential of plants (Borkataky et al., 2014). However, our results showed higher phenolic and flavonoids content and high inhibition percent of DPPH radical.

GC-MS analysis of crude extract of *A. argyi* leaves showed the existence of ten chemical compounds responsible for antioxidant activities. Our findings were supported by Chen et al. (2017) who reported 17 chemical compounds by GC-MS analysis including cineole, camphor, borneol and thujone from essential oil of *A. argyi* were found to contain anti-inflammatory activities. Moreover, 33 chemicals constituents were reported from essential oil of *A. argyi* leaves were ether, alcohols, sesquiterpenes, esters, monoterpenes, ketones and aromatic compounds 23.66, 16.72, 15.21, 11.78, 11.63, 6.09 and 5.01% respectively which account for 90.10% of its chemical composition and all these compounds contribute to antioxidant activities except for alcohols. Similar findings were documented by Rather et al. (2012) who reported 25 phytoconstituents from *Artemisia amygdalina* leaf essential oil which was dominated by monoterpenes oxygenated monoterpenes, hydrocarbons and other compounds constituting 43.8, 38.2 and 82.0% respectively, of whole oil composition. Additionally, essential oil extracted from stem, reported to be contain 32 compounds including monoterpenes, and sesquiterpenes hydrocarbons, oxygenated monoterpenes with ratio 66.1:11.2:12.8% respectively were responsible for antioxidant profile.

Chemical compounds occupied by *A. argyi* contain curative values against diseases and other humans related issues, such as erucylamide is a monounsaturated fatty acid omega-9 which is necessary for adults with an average of around 500 $mgday^{-1}$ for normal body functioning, accordingly for Food Standards Australia (Zealand, 2003). Demecolcine also called as colcemidis closely related to natural alkaloid known as colchicine is a type of drug which is used in chemotherapy. Phenylephrine is used as a decongestant and available in the market as solid form, an oral medicine and as nasal spray. It can also be used for the prevention of hemorrhoids. Phenylephrine is used as an eye drop to dilate the pupil to facilitate visualization of the retina (Demopulos et al., 2016) and to control blood pressure effects (Shih and Chen, 2004). Another compound Inositol also called as *myo*-inositol is a carbocyclic sugar which is considered as efficient for the treatment of polycystic ovary syndrome (Monastra et al., 2017), effective in restoration of normal ovary functioning and metabolic stability in patients (Monastra et al., 2017), effectual in restoring FSH/LH ratio and of regularization menstrual cycle (Unfer et al., 2012). α-Cadinol is a famous chemical compound contained by *A. argyi* possess anti-fungal properties (Ho et al., 2011) and also used as hepatoprotective (Tung et al., 2011). Various pharmaceutical drugs derived from 2-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1534915362

pyrrolidone including Cotinine, Piracetam, Ethosuximide, Doxapram and Povidone are effective medicines while, 2-pyrrolidone also used in ink cartridges (Borase et al., 2014).

However, limited studies have been conducted on quantification of total phenols and flavonoids contents and antioxidant activities from *A. argyi* as pharmacological and alternative of synthetic chemicals and recognition of biologically active components from biomass of crude extract of *A. argyi*. This study fulfills the present research gap and provides comprehensive findings concerning with phytochemicals, phenol and flavonoids contents and antioxidant properties of *A. argyi* leaves.

Conclusion

Results suggested the presence of important phytoconstituents like flavones, terpenoids, steroids, saponins and tannins, phenols and flavonoids responsible for antioxidant activities which are sources of pharmacological and agricultural applications. Moreover, GC-MS profile presents ten chemical compounds which are linked with antioxidant potential. Therefore, *A. argyi* might be introduced as an alternative of synthetic antioxidant. However, comprehensive study is required on separation, purification and identification of specific compounds exibit antioxidant activities and their evaluation against insect pest as safer alternative of synthetic chemicals.

(Received 11th Jul 2019; accepted 16th Oct 2019)

Abstract. Diversification of vegetation communities could be associated with the change of groundwater depth (GD). To get a better understanding of this relationship, a field survey assessing GD, and herbaceous plants etc. was carried in Tongliao plain (TP), northwestern China, where GD has declined significantly mainly due to pumping for agricultural irrigation. The photos data method was used to identify vegetation characteristics including coverage, biomass, height, ecological type, and name etc. Some diversity indexes were applied to identify the relationship between the groundwater table and the plant features. Growth and composition of vegetation were affected by the depth of groundwater and the degree of utilization of herbaceous vegetation on water resources. Different depth of groundwater had different influence on vegetation. The ecotype distribution of vegetation following depth based on survey data demonstrated that mesophytes, mesoxerophytes and xerophytes were found over groundwater depths between 1.38 and 3.43 m, 1.4 and 3.4 m and 2.4 and > 4.0 m respectively. This study proved that the depth of 3.4 m may be the transition range for the evolution of vegetation in TP.
Keywords: *vegetation characteristic, diversity, ecotype, transition range, water resources*

Introduction

Semi-arid regions cover ~22% of the land surface and supports 6% of the population in China. The ecosystems in such regions are fragile and sensitive (Fu and Burgher, 2015). Herbaceous vegetation is an important part of ecosystem, which could be very sensitive to a series of environmental factors (Boyd et al., 2017; Hedl et al., 2017; Singh et al., 2017). Especially in arid and semiarid regions, growth status and distributions of herbaceous plants could extremely associate with buried depths of groundwater table. The effects of groundwater utilization to the vegetations have become increasingly interested in eco-environment protection and restoration (McLendon et al., 2008; O'Grady et al., 2006). Plant communities (Liu et al., 2016), morphological characteristics and vegetation (Galassi, 2001) respond to soil and groundwater quality and vegetation productivity, vegetation and other factors between groundwater. For the Tongliao plain (TP), the researches concentrate on the ecological level, suitable water level, ecological warning level and the relationship between research and critical depth saline vegetation (Liu et al., 2013; Qian et al., 2017; Yang and Chui, 2017), etc. Many studies also focused on the relationship between trees, shrubs and groundwater (Monteleone et al., 2018; Nolan et al., 2017); the trees and shrubs include poplar, elm, and microphyll etc. However, our knowledge on the relationships between the dominant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1536315374

herbaceous vegetation of the large watershed and groundwater depth (GD) is still limited. Some models (Liu et al., 2006; Zhu et al., 2010) were often qualitatively considered with the lower boundary of the bottom of the root, and it should be further clarified.

To obtain a comprehensive understanding of grassland degradation requires a combination of change detection by remote sensing, field investigation and literature review. The purpose of this study is to enhance the understanding of grassland degradation and to find the role of GD in changes in vegetation diversity for the study area of TP using such a portfolio of methods. The novelty of this paper lies in linking grassland degradation and perceived change to GD and providing lower boundary of the bottom of the root for hydrological mathematical model. On the basis of the dominant herbaceous vegetation species in TP area, the observed data was used to analyze the relationship between ecotype plants, species diversity, importance value and GD. This research will not only provide data for the scientific research model, but also provide scientific support for the management of local environment.

Within this paper, the specific aims of this study are to (1) investigate the spatial patterns and trends of vegetation diversity and cover change; (2) link grassland degradation with the GD; and (3) explore the role of changes of GD in grassland.

Materials and methods

Study area

The study area is located in a typical ecotone in North of China, which is a climate transition zone from sub-humid to semi-arid with an annual rainfall of 350-450 mm and evaporation of 1817 mm (20 cm pan). The root layer soil is mainly meadow, Aeolian sandy, and sandy chestnut etc. The plain is mainly formed by dunes, sandlot, lowland, and pasture land etc. Spatial distribution of vegetation is strong heterogeneity with dominant plant species of *Salsolacollina, Setariaviridis, Artemisiafrigida, Cleistogenessquarrosa, Poapretensis, and Artemisia campbellii Hook etc*.

From July to August, 2015, based on grassland type distribution under remote sensing images in study areas, 32 investigation sites (100 m × 100 m) centered on herbaceous plant communities were investigated (*Table 1*). Typical points were selected within each investigation site. Three random sampling plots were surveyed with a diameter of 1 × 1 m, including plant height, ecological style, name, wet weight, and biomass etc. The vegetation coverage was analyzed by ENVI 5.3 software through the supervised classification method. Meanwhile, soil sampler (specification: L is 4 m, Φ is 10 cm) was used to measure the corresponding GD data in each sample plot. Kriging interpolation and draw contour lines of depth were worked out based on the groundwater table data (*Fig. 1*). To detect the soil type of each survey plot, spatial distribution data of soil types in China were used that were got from Chinese Academy of Science (http://www.resdc.cn) at a scale of 1:1,000,000.

Methods

Vegetation importance value (Ma et al., 2009), niche breadth (Feinsinger, 1981), richness index (Li et al., 2008), community species diversity index (Hejda and Pyšek, 2006), evenness index (Ma, 2005), and dominance index (Wood et al., 2005) were applied to identify the change of species diversity.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1536315374

Important value:

$$IV = (RD + RF + RC)/3 \quad \text{(Eq.1)}$$

Niche breadth:

$$Bi = (1/r)\sum_{j=1}^{r} P_{ij}^2 \quad \text{(Eq.2)}$$

Margalef richness index:

$$D = (S-1)/InN \quad \text{(Eq.3)}$$

Shannon community species diversity index:

$$D = -\sum_{i=1}^{S}(p_i Inp_i) \quad \text{(Eq.4)}$$

Alatalo evenness index:

$$D = \left[1/\sum_{i=1}^{S}(\frac{N_i}{N})^2 - 1\right] / \left[e^{(-\sum_{i=1}^{S}\frac{N_i}{N}In\frac{N_i}{N})} - 1\right] \quad \text{(Eq.5)}$$

Simpson dominance index:

$$D = 1 - In\sum_{i=1}^{S}\left(\frac{N_i}{N}\right)^2 \quad \text{(Eq.6)}$$

where: *IV* is the important value, *Bi* is the niche breadth, *RD, RF, RC* are the relative density, relative frequency, and relative coverage of vegetation, *D* is the diversity index, *S* is the total number of species, *N* is the number of trees of all species, *P* is the vegetation density, *i* is the i^{th} vegetation.

Results

Vegetation composition

41 species of herbaceous vegetation were identified, which belonged to 2 classes, 12 families and 24 genuses. Perennial and annual herbaceous vegetations presented 58%, and 48% respectively. They were classified as mesophytes, mesoxerophytes, xerophytes, psammophyte, ultra-xerophytes, and halophytes that presented for 38%, 8%, 38%, 15%, 3%, and 5% respectively. The most important is that 11 species of the dominant herbaceous species were recognized. They belonged to 2 classes, 3 families and 7 genuses, among which perennial and annual herbaceous vegetation accounted for 45% and 55% respectively.

Geographical elements of herbaceous plant

Based on the previous studies and the vegetation survey results, the geographical elements of the dominant herbaceous plants were World, Eastern Asia and variations, Central Asia - Mongolia, Pantropic, Old World and North Temperate in the study area (*Table 1*).

Relationship between GD and herbaceous plant

Ecological niche is a concept in ecology that describes how a species responds to the distribution of resources and competitors. Niche breadth represents the sum of a variety of different resources utilized by a species. Through field investigation and laboratory data collation, important value proportion and niche breadth of each survey point dominant species were analyzed corresponding to the different groundwater tables.

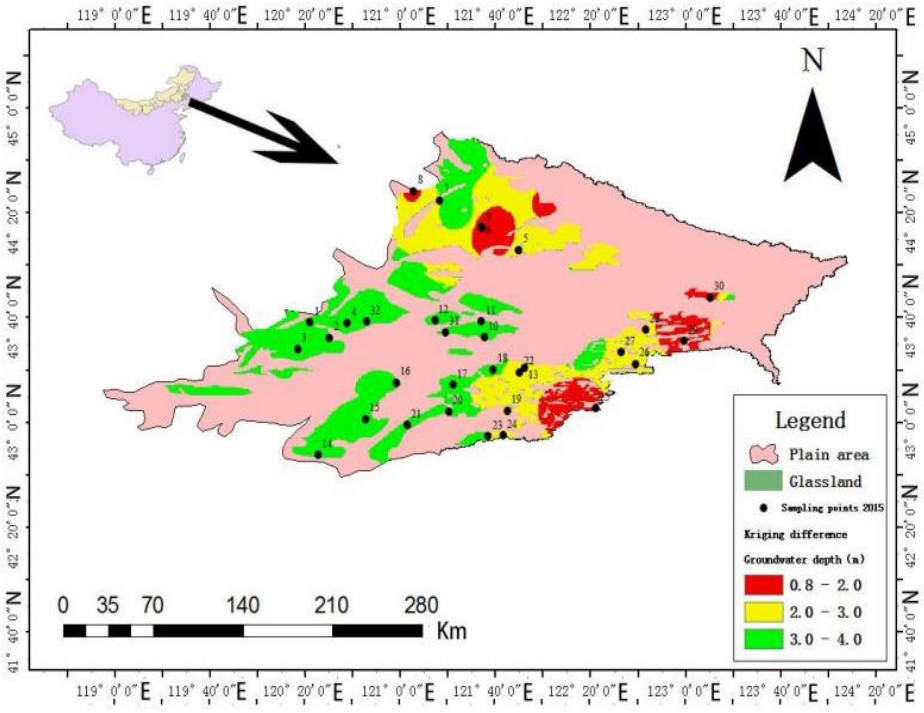

Figure 1. *Field survey sites and groundwater depth contour*

The data in *Table 2* shows that, in the direction of increasing depth gradient, corresponding vegetation types changed with slight difference. There are five dominant vegetation species at the depth of 1~2 m. Their importance value ratio and niche breadth were lower, indicating that the depth range is not suitable for the growth of these species; eight types of vegetation were found at about 2~3 m and > 4 m respectively. *Chloris virgata. Leymus chinensis and Artemisia frigida Willd* appear concentrated with the higher value of the proportion and niche breadth. At the depth of 2~3 m, vegetation species decreased, but the proportion of importance value and niche breadth increased.

Table 2*. Proportion and niche breadth of each species corresponded to TP*

Species	Groundwater depth (m)			
	1~2	2~3	3~4	> 4

(): niche breadth

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1536315374

The value of the *Artemisia campbellii*, *Artemisia pubescens*, *Corispermum hyssopifolium*, *Setaira Viridis* and *Echinochloa crusgalli* significantly increased, indicating that they were the main vegetation community composition in this depth. *Softwood Artemisia*, *Corispermum hyssopifolium* and *Suaeda glauca* were widely distributed ranging from 1~4 m, the proportion of importance value and niche breadth were relatively balance.

The same dominant vegetation at the different GD, the proportion and niche breadth are different, which indicates that the growth and distribution of vegetation are affected by groundwater. The proportion and niche breadth of different dominant vegetation at the different GD were different too, which suggests there are differences in the utilization degree of water resources by different species. However, under the same groundwater level, some dominant species vegetation with the same characteristics had similar proportion and niche, which indicated that the same species had similar adaptation strategies to groundwater or have a similar competition on demand for groundwater.

Variation of herbaceous vegetation cover and biomass

Through correlation analysis, the correlation coefficients between GD and vegetation characteristics below 0.5 only very weak. However, the correlation coefficients between GD and biomass and vegetation coverage were significant at the 0.05 level (2-tailed), which meant that the GD has the most significant effects on the plant communities.

To further understand the relationship between them, we analyzed vegetation characteristics of survey sites to different depth gradient. Wet weight, biomass and vegetation coverage of survey sites increased first, and then decreased with the rising of GD; It shows that the groundwater has a certain influence on them (*Fig. 2*). Ranging from 1.4~2.4 m, these indexes that highlight rising trends with the coefficient of variation were 0.24, 0.45 and 0.32. There was a rapid decrease in these indexes at the depth of 2.65~3.4 m. In addition, the maximum value of the coefficient of variation of the three were 0.62, 0.75 and 0.44. At the same time, the dominant species vegetation, *Leymuschinensi* and *Artemisiapubescens*, which have lower value of each index was mostly the perennial at the depth of 2.9 m and 3.3 m. However, the dominant species vegetation, *Chloris virgata* and *Echinochloa crusgalli*, which have higher value of each index is mostly the annual at the depth of 2.8 m and 3.0 m. Every index continues the downward trend at the depth of 3.4~ > 4 m with the value of 0.62, 0.59 and 0.31. The trend line shows that the depth of about 3.4 m was the evolution of vegetation transition zone, which became elevated by the reduced. With the increase of depth gradient, the dominant species of survey sites evolved from the mesophytes to the xerophytes. Although each index declines overall, the individual differences in levels of groundwater, it suggests that different depth of groundwater has different influence on vegetation.

Herbaceous vegetation ecological variation

Based on the average GD data of field survey of 32 points and dominant species vegetation ecological values of survey sites, the correlation coefficient calculated. The results showed that the plant ecotypes and GD were significantly correlated. To a certain extent, GD determines the type of plant ecological distribution (*Fig. 3*). By superimposing dominant species vegetation and the corresponding GD of each survey

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1536315374

point, the quantitative relationship was revealed. The ecotype of dominant vegetation, such as mesophytes, meso-xerophytes and xerophytes correspond to a depth range, namely 1.38~3.43 m, 1.4~3.45 m and 2.40~ > 4.00 m. Only the planting of mesophytes and meso-xerophytes dominant species exist in the GD of 1~2 m; they have significant depth transition phase. Only the dominant species planting of xerophytes coexist in the GD of more than 3.5 m. In the 2.65~3.43 m, mesophytes appeared more concentrated. Meso-xerophytes rooted in uniform distribution ranging from 1.4~3.45 m. Because the distribution of dominant species vegetation was increasing, the depth at about 3.4 m would be the evolution of vegetation transition zone.

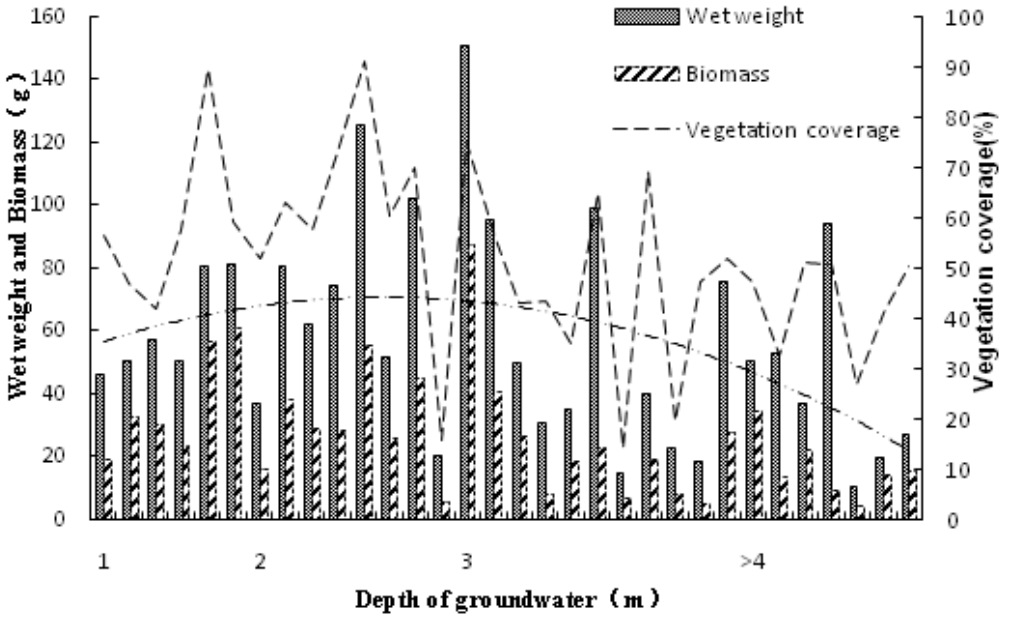

Figure 2. *Vegetation characteristics of survey sites to different depth gradient*

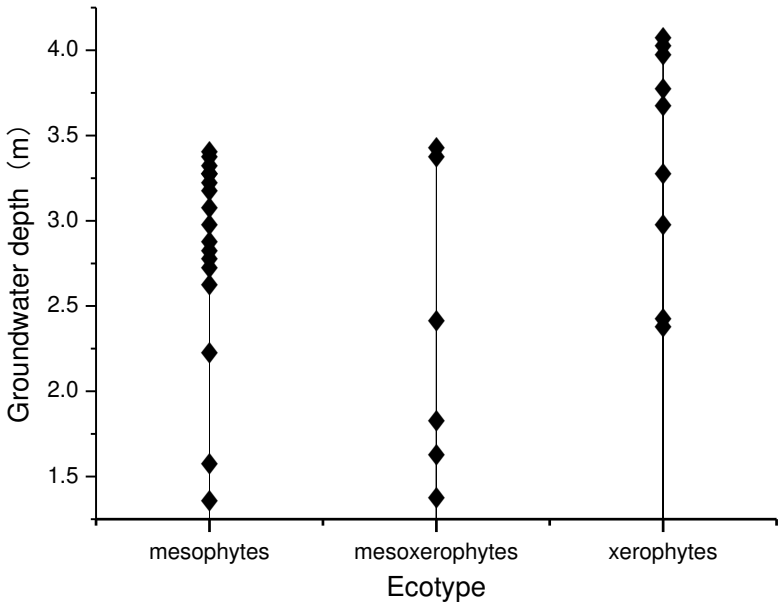

Figure 3*. Dominant species pattern distribution with groundwater level*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1536315374

Variation of species diversity index

Through field investigation and laboratory data collation, the distributions of each diversity index were analyzed following the direction of depth gradient, in order to study the internal correlation between GD and herbaceous vegetation species diversity (*Fig. 4*).

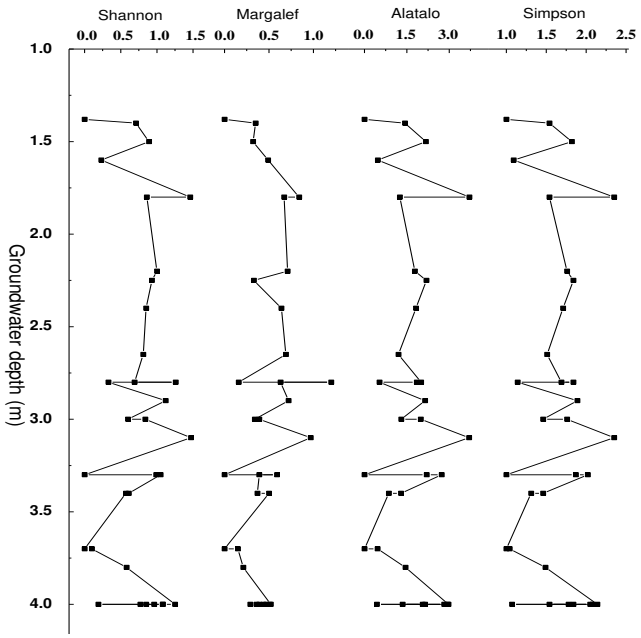

Figure 4. *The result of diversity ordination to different depth gradient*

At depth ranging 1.8~2.4 m, species diversity was relatively stable, means were 0.91, 0.59, 1.76 and 1.71, expressed as per survey quadrate vegetation types ranged from 2-6 species. As the depth gradient increases, at depth ranging about 2.65~3.4 m, the diversity index fluctuated frequently, the various diversity index means were 0.82, 0.54, 1.74 and 1.67; at depth ranging 3.4~ > 4 m, diversity index showed slight fluctuations, means were 0.67, 0.35, 1.59 and 1.58, expressed as per survey quadrats vegetation types ranging from 1-5 species. With the increase of depth, the diversity index value of vegetation species fluctuated, about 1.8~2.4 m > 2.65~3.4 m > 3.4~4 m > 1.4~1.8 m. With the increase of depth, all index increased firstly, then decreased, generally in the 1.8~2.4 m up to the maximum. The values of Margalef, Shannon-Wiener and Simpson index at the 1.8~2.4 m were slightly higher than the values at other depths, while the Alatalo index value is 2.56 ~3.4 m below the value of 1.8~2.4 m. The smallest variation is the Magalef index, and the maximum variation range is Alatolo index. The result suggests that the most suitable depth of groundwater for plant growth in the region is 1.8~3.4 m, after as the underground water level decline gradually, the diversity of the species evenness and abundance emerged decline trend. The relationships between species diversity index and groundwater revealed that with the increase of depth gradient, the diversity index value of vegetation species fluctuated, closely related with each other.

Based on the four indexes, most scholars have studied the relationship between them and vegetation, climate, groundwater, soil water and so on. Most predecessors considered that, as the depth increases, the diversity of vegetation shows an obvious

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1536315374

decreasing trend. However, because of the complexity of the natural ecosystem and the actual situation of the local pastoral transitional zone, the diversity of vegetation at the depth of the transition zone was deeply influenced.

Discussion

In arid and semiarid regions, herbaceous vegetation is among the most important ecosystem components. Each vegetation is also very sensitive to environmental factors, so it is necessary to reveal the basis (Chauhan and Johnson, 2008) for the evolution of groundwater on vegetation. In arid and semiarid regions, the evolution of herbaceous vegetation will be affected in addition to precipitation and temperature, may also be affected by other environmental factors (Tao et al., 2017). TP is a typical semi-arid region where the ecological environment is fragile. Between groundwater and the characteristics of herbaceous vegetation, there obviously will be some intrinsic link.

Groundwater-Dependent Ecological systems (GDEs) refers to the survival and development of vegetation ecosystem which depends on groundwater systems. GDEs belongs to interdisciplinary. For now, it is not very clear on the relationship between the groundwater system and vegetation ecosystem; there are full of challenges and opportunities in this area. Deeper GDEs (Kløve et al., 2011; Zhu et al., 2012) have been divided into three categories according to the exposed conditions. On the basis of previous studies, domestic scholars also have made a lot of research and field investigation on the relationship between vegetation ecosystems in large areas and groundwater systems.

This paper will determine GD at about 3.4 m to divide completely dependent and semi-dependent GDEs basis: Completely dependent GDEs is at 2.65~3.4 m of the GD, mainly refers to the vegetation ecosystem which relies on capillary action to recharge in semi-arid zones; semi-dependent GDEs is at 1.4~2.4 m of the GD, mainly refers to the vegetation ecosystem which not only relies on irrigation, precipitation or river bank to recharge but also relies on groundwater; completely independent GDEs is at 3.4~ > 4 m of the GD, mainly refers to the vegetation ecosystem which does not rely on groundwater. According to available data, with the increase of depth, vegetation coverage, wet weight and biomass, their segmentation coefficient of variation have a significant difference; they have fluctuated downward trend, which reveals: (1) the dominant vegetation evolved from the annual shallow-rooted vegetation to the perennial deep rooted vegetation; (2) Differences in surface characteristics of completely dependent, semi-dependent and completely independent GDEs vegetation are significant, which also shows that in addition to the impact of groundwater, the herbaceous vegetation is also affected by the multiple effects of precipitation (Sneva,1982), topography (Hardin and Wistendahl, 1983), man-made and other factors; within the range of groundwater, importance value proportion of the value and diversity index shows the trend of different frequency fluctuations, namely the increasing direction along the depth gradient, showing Mesozoic - in xerophytic - xerophytic vegetation types, quantity and life - form evolution trend. This article was also based on the frequency of appearance and niche theory of dominant species survey sites, using niche breadth and other indicators, analyzed the degree of utilization of herbaceous vegetation on water resources in the study area, obtained niche breadth of a variety of dominant species at different depth gradient. It shows that *Artemisia*, *Echinochloa crusgalli* and *Setairaviridis* constitute a more dominant community of survey sites, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1536315374

can be widely distributed. The overall survey sites niche breadth of dominant species was small, and it also shows that the degree of utilization of water resources is not high; they may be affected by other factors. The evolution of the transition range of herbaceous vegetation in the study area is at about 3.4 m. In this range of more than 3.4 m, a variety of species diversity indexes decreased significantly, proportion and niche breadth were obviously shrunk, vegetation coverage wet weight and biomass firstly decreased.

Conclusions

This paper has attempted to recognize the groundwater as the key factors affecting the activity and distribution of vegetation. The topic is perhaps too obvious, but born under the perspective to explore the pattern of vegetation characteristics under groundwater change conditions in TP. Through correlation analysis, there is a certain relationship between them groundwater and characteristics of vegetation. Following the change of GD, the trend of vegetation characteristics is increasing first, and then decreasing. Different ecotype of dominant vegetation corresponds to different depth of groundwater. Mesophytes, meso-xerophytes and xerophytes have their own depth transition zone which are 1.38~3.43 m, 1.4~3.45 m and 2.4~ > 4 m. The important value proportion, niche breadth and each species diversity index of dominant herbaceous vegetation in each survey point have apparent indication. There is obvious intrinsic link between them and GD. When the groundwater is too shallow, the growth of the height, crown and so on of the herbaceous plants will be inhibited, because the surface due to evaporation and the accumulation of much salt limits the growth of herbs. Our results also suggest that the evolution of the transition range of herbaceous vegetation in TP is at about 3.4 m.

It is well known that groundwater has a significant effect on regional vegetation growth and distribution. Scarcity of water resources, great changes of the groundwater extraction volume and depth are some of the main factors in the evolution of natural vegetation in TP. Because vegetation growth and distribution are affected by many factors, such as climate, grazing and soil, how to determine the impact of groundwater change on vegetation growth and distribution is very important. However, we lack more adequate information and method on the relationship between grassland community characteristics and GD. The depth of groundwater in this study is less than 4.0 m, and whether it still has a good correlation still needs to be further studied under the condition of more than 4.0 m? Moreover, how to determine the water source of natural herbaceous vegetation in agropastoral ecotone in semi-arid region?

Further work needs to be done to determination of critical area of groundwater and water source for different vegetation evolution. Additionally, relationships between GD and vegetation characteristics need to be investigated at high spatial and temporal resolutions.

Abstract. Maize-straw biochar (BC) was applied in a black soil area in Northeast China for investigating its effects on crop yield, soil physical properties and nitrifying bacteria. In this study, BC forms BC1, BC2 and BC3 were incorporated at levels of 15.75, 31.50 and 47.25 t ha^{-1}, respectively, from 2013 to 2014. The control soil was treated with chemical fertilizer (NPK). The results showed that yields of soybean were significantly improved overall due to BC applications, compared with the control. Meanwhile, average soil compaction values of 0 – 20 cm deep soil were decreased from 17.9% to 47.4%. Biochar supplementation decreased the soil wilting coefficients, but increased saturated water content. The available soil water content increased from 0.211 to 0.329 cm^3 cm^{-3} ($R^2 = 0.97$), whereas the bulk density decreased from 1.42 to 1.40 g cm^{-3} ($R^2 = 0.97$) in response to BC supplementation. Unexpectedly, soybean yields began to decline at 31.50 and 47.25 t ha^{-1} of BC application. as well as soil aggregate stability, available water content, and capillary pores, mainly. Moreover, the BC supplementation significantly affected soil ammonia-oxidizing archaea (AOA) abundance. These results demonstrate that BC has positive potential for enhancing crop and soil properties performances in black soil at the level of 15.75 t ha^{-1} under continuous soybean system.

Introduction

Given the growth rates since 1960, the global population is expected to reach 9.7 billion by 2050 (Gonzalo et al., 2016). The consequences of human population growth have great impacts on the environment, and also on social and economic development. China accounts for approximately 22% of the world's population which is expected to increase to 14.53 billion by 2030 (Yin and Guo, 2015). Consequently, the additional food required to feed future generations would challenge the production capacity of arable land in the years to come (Golley and Zheng, 2015). The agricultural sustenance of a growing population in the black soil area of Northeast China is threatened by excessive exploitation of soil resources, leading inevitably to soil degradation. In the long run, the current production capacity of the soil may not sustain the long-term needs of a growing population under the current agricultural management level. Thus, control of soil erosion and prevention of organic matter loss have been proposed as critical strategies for sustained agriculture in this area (Luo et al., 2017; Lenka et al., 2017). In Northeast China, manure and corn straw have been used to improve soil fertility and crop yields (Hui et al., 2017; Tong et al., 2017; Liang et al., 2016). Moreover, carbon sequestration and bacterial soil contents have been improved using corn straw and manure (Yang et al., 2017; Ding et al., 2016). However, in contrast to these substrates, biochar (BC) is highly recalcitrant and unavailable to soil microorganisms (Sizmur et al., 2016).

Biochar, being a carbonaceous compound, has been used as a soil additive to counter the degradation of arable land (Luo et al., 2017). Several studies have been carried out on the effects of BC supplementation on soil aggregate formation and the physical properties of a variety of soils (Obia et al., 2016; Pratiwi and Shinogi, 2016; Lim et al., 2016; Guo, 2016). Indeed, Burrell et al. (2016) have reported that BC from straw improved the stability of soil aggregates in Planosol and Cambisol soils, and also improved the water availability to plants in Planosol soil by 38%. A soil study in the Huang-Huai-Hai Plain, China revealed that treatment with BC significantly decreased the bulk density, but increased its total porosity (Du et al., 2016). Moreover, studies have been carried out on the effect of BC supplementation level on the physical and hydraulic properties of soil. In these studies, Igalavithana et al. (2017) applied corn residue BC at levels of 2.5, 5.0, 7.5 and 10% ($w \cdot w^{-1}$) in sandy loamy soil, and after equilibration for 30 days, there were highly significant exponential reductions in Ksat as a result of incorporation of BC500 at levels of up to 7.5%, with Ksat approaching an asymptote at 10% BC500. In another study, it was shown that incubation of soil for 36 days with BC at levels of 1, 2, 5 and 10% (by wt.) reduced the water losses through evaporation and stabilized the activities of some extracellular enzymes (Elzobair et al., 2016). In field experiments, Ippolito et al. (2016) reported that graded applications of BC (1, 2, and 10% by wt.) improved the water content of calcareous soil. Supplementation of podzolic soil with BC at levels of 10, 20 and 30 t ha^{-1}) for 3 years produced significant and positive effects on the yield of winter rye (Kraska et al., 2016) However, most recent studies focused on low-fertility soils or under-leached, acidic saline soils. Thus, not much is known about the effect of levels of application of BC on crop yield and physical conditions of soil in degraded soils containing higher organic matter. The objective of the present study was to investigate the influence of different levels of maize straw-derived BC on continuous soybean production and soil properties such as physical environment and soil nitrifying bacteria. It was hypothesized that higher BC levels should exert positive and negative effects on soybean yield, as well as

DOI: http://dx.doi.org/10.15666/aeer/1706_1537515391

the physical properties of black soil. Three levels of BC supplementation (15.75, 31.5 and 47.25 t ha^{-1}), each mixed with a chemical fertilizer (NPK) separately in a selected field of black soil (Mollisols), were used. Crop yield and physical and hydraulic properties of soil such as compaction, aggregation stability, bulk density, hydraulic parameters and soil surface area were analyzed. The nitrifying bacteria in the BC-supplementaed soils were also evaluated.

Materials and methods

Site, soil and biochar

A long-term BC field experiment was initiated in Minzhu town, Daowai district in Haerbin city, China (E126°51'05", N45°50'3", *Fig. 1*). Climatological data, soil properties of surface layer and biochar properties can be seen in *Tables 1, 2,* and *3* respectively. Biochar applied in this study was derived from maize straw and manufactured by Liaoning Biochar Engineering Technology Center.

Treatments

A field experiment with soybean was carried out in 2013 and 2014. The treatments consisted of 3 levels of BC supplementation viz: NPK only, NPK + BC at level of 15.75 t.ha^{-1} (BC1), NPK + BC at level of 31.50 t.ha^{-1} (BC2), and NPK + BC at level of 47.25 t.ha^{-1} (BC3). Each treatment was replicated thrice. In order to guarantee soil and plant samling, every experiment plot was set up by covering an area of 39 m^2 (6 ridges×0.65 m width× 10 m ridge length). The sowing density of soybean was 300,000 plants per hectare. Soybean received sub-surface fertilizer application of 47 kg N ha^{-1}, 78 kg P_2O_5 ha^{-1} and 68 kg K_2O ha^{-1}, with which insecticide were applied of 0.13 to 0.2 kg chlorpyrifos granules ha^{-1} for controlling grubs. Spring soybean cultivar Heinong 58 was planted in May 2013 and harvested in October 2013, while the one planted on May 10, 2014 was harvested on October 5 in 2014. Prior to planting, the chemical fertilizer (NPK) for soybean was applied. In the 2013 period, the BC was spread over the furrow by the ridges. It was thoroughly mixed with soil using a ploughing machine (a tractor with a rototiller, *Fig. 2*), and then plowed to a depth of over 20 cm and then mainary ranked for a leveling. Herbicide applied over the ridges just after soybean sowing (*Table 4*).

Measurements

Particle size distribution of BC

The particle size distribution of BC was determined by dry-sieving the samples using a sieve shaker (Endecott Test Sieve Shaker, Watson Victor Ltd.). Seven different fractions were obtained using 2.00, 1.00, 0.50, 0.25 and 0.106 mm sieves. Three consecutive shakings were conducted, and it was observed that the weights of different fractions remained unchanged. The first shaking was continued for 3 min, and the other two shakings were done for only 2 min. Measurements of N_2 gas adsorption for the determination of BET (Brunauer-Emmett-Teller) surface area of BC were carried out using a Micromeritics ASAP 2020 volumetric adsorption system.

Soil compaction

In the field, the soil compaction values were measured with in 2014 after the harvest of soybean with a soil compaction meter (SC-900, *Fig. 3*). The data for the top layer (0-20 cm) were automatically recorded once every 2.5 cm as the soil compaction meter descended from the surface.

Figure 3. *Soil compaction meter (SC-900)*

Soil aggregates and their stability parameters

The size distribution of wet-sieving aggregates was determined with a rototap machine containing a nest of eight 100-mm diameter sieves with screen openings of 10, 7, 5, 2, 1, 0.5 and 0.25 mm. The weight of soil retained on each sieve was measured after dry-sieving 0.5 kg of soil for 2 min. Moreover, 50 g of soil aggregates retained on 100 mm sieve was used for the analysis of wet-sieving which was carried out mechanically using Yoder's apparatus.

The nest of sieves used had mesh sizes of 2, 1, 0.5, 0.25 and 0.106 mm. Wet sieving was continued for 20 min with 40 oscillations per min. The aggregates retained on each sieve were transferred to a set of pre-weighed beakers, oven-dried at 105 °C for 24 h,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1537515391

and weighed. The mean weight diameter (MWD) and geometric mean diameter (GMD) were calculated as indices of aggregation as shown in *Equations 1* and *2:*

$$MWD = \frac{\sum_{i=1}^{n}(\bar{d}_i W_i)}{\sum_{i=1}^{n} W_i} \quad \text{(Eq.1)}$$

$$GWD = \text{EXP}\left[\frac{\sum_{i=1}^{n} W_i \ln(\bar{d}_i)}{\sum_{i=1}^{n} W_i}\right] \quad \text{(Eq.2)}$$

where $\bar{d}_i$ is the mean diameter of the class (mm), and W_i is the proportion of aggregate retained on the sieves. The fractal dimension was determined in line with method of Yang et al. (1993), as shown in *Equation 3:*

$$\frac{M(r< \bar{X}_i)}{M_T} = \left(\frac{\bar{X}_i}{X_{max}}\right)^{3-D} \quad \text{(Eq.3)}$$

where $M(r < \bar{X}_i)$ is the cumulative mass of objects or fragments of the i^{th} size, $r < \bar{X}_i$; M_T is the total mass of particles; $\bar{X}_i$ is the mean particle diameter (mm) of the i^{th} size class; and X_{max} is the mean diameter of the largest particle.

Hydraulic parameters

The water retention curve θ (h) of soil was determined using the pressure plate method. Saturated hydraulic conductivity (Ks) was determined using a fixed-head permeameter instrument, and the parameters of θ (h) and unsaturated hydraulic conductivity K (h) were obtained using the van Genuchten–Mulem model (*Eq. 4*).

$$\theta(h) = \theta_r + \frac{\theta_s - \theta_r}{[1+|\alpha h|^n]^m} \quad \text{(Eq.4)}$$

This equation was fitted on the moisture retention data of soil, and the parameters i.e. saturated water content (θs), residual water content (θr), inverse of suction at the inflexion point of the moisture curve (α), and shape parameters (*m* and *n*) were estimated through a non-linear least-squares optimization using RETC (RETention Curve) software.

Pore size distribution

The soil pore size distribution (PSD) was determined using mercury intrusion porosimetry (MIP) (Autopore IV 9500, Micromeritics Inc. USA). In the MIP method, the mercury pressure was increased stepwise, and the intruded volume of mercury was monitored for each pressure in the range of 0.0036–310 MPa. The MIP test indicates the volume of cumulative mercury intruded as a function of equivalent pore radius (EPR). The results obtained were plotted in two graphical forms: cumulative pore volume versus logarithmic EPR, and differential PSD versus logarithmic differentiation (dV/dlog r). The values of pore radii on the cumulative curve and differential curve were 0.003 μm and 360 μm, respectively. This wide range allowed for the detection of diverse soil pore classes along the PSD curve. The pores were classified according to their equivalent pore diameter (EPD) into five classes of sizes: macropores (>75 μm),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1537515391

mesopores (30–75 μm), micropores (5–30 μm), ultramicropores (0.1–5 μm), and crytopores (0.1–0.007 μm) according to the method of Camerson and Buchan (2006).

Soil ammonia bacteria [ammonia-oxidizing archaea (AOA) and ammonia-oxidizing bacteria (AOB)]

Total DNA was extracted from frozen soil samples (0.5 g wet weight) using a FastDNA® SPIN Kit For Soil (MP Biomedicals, LLC) in line with the manufacturer's instructions. The concentration and quality of the extracts were determined using UV spectrophotometer (Implen, München, Germany), and the extracts were kept at -20 °C prior to further molecular analysis. Real-time PCR assays (total reaction volume = 20 μL) were carried out using SYBR®Premix Ex TaqTM Perfect Real Time (Takara, Dalian, China), and multicolor real-time PCR detection system (Bio-Rad Laboratories Inc., Hercules, CA, USA). The primer sets (AOA: Arch-amoAF/Arch-amoAR; AOB: amoA-1F/amoA-2R) and thermal profiles used to amplify each target gene with real-time PCR are listed in *Table 1*. The abundance (copy number) of bacterial AOA and AOB genes were calculated using a regression equation to convert the cycle threshold (Ct) values to the known number of copies in the standard curves.

Statistical analysis

All data were analyzed using Microsoft Excel (2003). The significance of differences among different treatments and sampling dates were tested with ANOVA using SPSS software package (SPSS Inc., 2003). Differences between values were considered statistically significant at $p < 0.05$. The coefficient of determination (R^2) of non-linear regression was used to determine the best fit of the water retention model of soil.

Results

Site, soil and BC

The effect of BC application on soybean yields (2013 and 2014) is shown in *Figure 4*. Soybean yields were significantly influenced by BC over two years, when compared with the control (NPK). In the first year, BC1, BC2 and BC3 increased soybean yields by 18.5, 12.5 and 9.7%, respectively, when compared with NPK. Similarly, in the next year, increases in the soybean yield ranged from 15.4% (for BC1) to 4.6% (for BC3). The predominant yield for each year was produced by BC1.

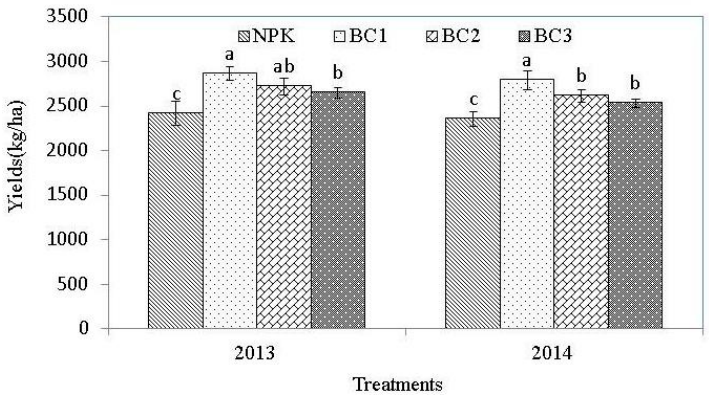

Figure 4. *Effect of BC application on soybean yields from 2013 to 2014*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1537515391

Effect of field application of BC on the distribution of soil compaction in the top layer (0-20 cm)

Soil compaction reflects the conditions of pores in the soil and the strength of the junction force in the soil particles. After two years of field application of BC, there was an 'S' trend in the distribution of soil compaction values from the top of the soil (0–20 cm layer) for all treatments, and the compactability increased with increase in soil depth (*Fig. 5A*).

Compared with NPK treatment, BC1, BC2 and BC3 decreased average values of soil compactability distribution within 0-20 cm of soil by 47.4, 38.4 and 17.9%, respectively. The order of average soil compaction values was NPK > BC3 > BC2 > BC1. Except for NPK treatment, the strength of soil compaction was positively related to the supplementation level of BC i.e. BC3 > BC2 > BC1.

*MWD = mean weight diameter; **GWD = geometric mean diameter

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1537515391

Aggregate and its stability

The results from wet-sieving (*Table 5*) showed that the addition of BC significantly affected the amounts of macroaggregates (> 0.25 mm), which were increased by 12.5, 7.5 and -11.7% for BC1, BC2 and BC3, respectively, when compared to control (NPK). The changes in the aggregate sizes of 2-0.25 mm showed a positive relationship with MWD values with a correlation coefficient of 0.64 ($P < 0.05$). The mean weight diameter (MWD), geometric mean diameter (GMD) can be used for amended-soil aggregates in the evaluation of the aggregation stability of soil. Higher values of these indices indicate the predominance of the more stable aggregates over the smaller, less stable fractions (Nath and Rattan, 2017; Rabot et al., 2018). From *Table 5*, after two years of the field application of BC in 2014, the MWDs of the of soil aggregate of the three treatments (BC1, BC2 and BC3) were enhanced by 26.6, 15.4 and 3.8%, respectively over the control. No significant differences in GMD were found among the four treatments.

Effect of BC on the hydraulic characteristics of soil

Hydraulic parameters were significantly influenced by the level of BC incorporation, except in a few items in this study such as θs (for BC1, BC2 and BC3) and total porosity (for BC2 and BC3) compared with the control (*Table 6*). Compared to NPK, the incorporation of maize BC at levels of 15.75, 31.5 and 47.25 t.ha^{-1} increased field capacity to 0.379, 0.381 and 0.326 cm.cm^{-1}, respectively, from initial value of 0.291 cm. cm^{-1}. As shown in *Table 6,* wilting coefficient (θ_r) values were significantly reduced, while saturated water content (θ_s) values were not significantly increased at all levels of BC treatments ($p < 0.05$). Smaller particle fraction in BC increased water holding space in black soil more significantly than larger particles (*Tables 2* and *5*). The results showed clearly that incorporation of BC at the level of 15.75 t.ha^{-1} increased the soil k_s, θ_s and available water content by 50.14, 17.94 and 55.92%, respectively, when compared to NPK control ($p < 0.05$). The available water content refers to the difference between field capacity and wilting point; it is the quantity of soil water available for the usage of plants. The highest available water content was 0.332 cm.cm^{-1} for the soil containing BC at the level of 15.75 t.ha^{-1}, while BC at levels of 31.5 and 47.25 t.ha^{-1} decreased available water content to 0.316 and 0.266 cm.cm^{-1}, respectively. The regression equation for the available water capacity of soil as a function of level of incorporation of BC is shown in *Equation 5:*

$$\text{Available water content} = -0.0002(\text{t ha}^{-1}\text{biochar})^2 + 0.0126(\text{t ha}^{-1}\text{biochar}) + 0.2684 \quad \text{(Eq.5)}$$

It is clear from the quadratic equation that the addition of BC at the level of 15.75 t.ha^{-1} increased available water content in the soil, but decreased it at levels of 30.5 and 47.25 t.ha^{-1} ($R^2 = 0.9355$). Field capacity was enhanced by BC incorporation, reaching the highest value of 0.382 cm.cm^{-1}), but wilting point was significantly lower with BC3 than BC2. Thus, the difference (available water content) determined by the two coefficients for BC level of 15.75 t.ha^{-1} was lower (0.329) than that for BC level of 31.5 t.ha^{-1} (0.328).

Figure 6 shows the regression models developed from the results on *Table 6*, which indicates the positive effect of BC on bulk density and available water content. The lower bulk density of the biochar-supplemented soil resulted directly from the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1537515391

contribution of pores of BC, since the bulk density of BC-excluded treatment was significantly lower than that of the unamended NPK control. This may be due to changes in total porosity. The results of hydraulic conductivity revealed an initial increase at BC level of 15.75 t.ha^{-1}, which was followed by decreases at BC supplementation levels of 31.5 and 45.25 t.ha^{-1}. This may be due to the hydrophobic nature of organic matter in BC.

Effect of BC on the pore distribution of soil

The results of pore analysis porosity and pore size distribution of BC-amended soils are shown in *Table 7*. Total pore volume and porosity of soils were higher ($p < 0.05$) in BC-treated soils than in NPK control soil. The degree to which the total porosity values increased with the BC incorporation level varied among the treated soils. The relative increases in total porosity due to BC1, BC2 and BC3 were 17.6, 14.4, and 9.6%, respectively, relative to NPK control. The BC treatment caused significant changes in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1537515391

the pore in the ranges of > 75, 30-75, 5-30, and 0.1-5 μm, which indicates that it indeed altered the macro-, meso-, and micropores. However, BC did not significantly affect the crytopores (< 0.1 μm). In SB-amended soil, approximately 32% of the total porosity was in > 75 μm pores, followed by 0.1-5 μm class (approximately 25%), 5-30 μm class (approximately 14%), and 0.01-0.1 μm class (approximately 8%). The changes in pore size distribution brought about by BC treatments could possibly reflect the particle size distribution of BC. Compared with BC1, BC at the higher level of 31.5 $t.ha^{-1}$ increased the total volume, but decreased the macropores and mesopores by 53.54 and 16.50%, respectively, indicating that BC2 produced more unavailable pores leading to less available water in the soil. Compared with BC2, the 78.76% increase in 5-30 μm micropores, and 74.42% decrease in 30-75 μm mesopores are in agreement with the hypothesis that direct changes in capillary pores are caused by the occupation of finer BC particles, leading to decreased available water content at BC levels of 31.5 and 47.5 $t.ha^{-1}$.

Table 7. *Total porosity and pore-size distribution of BC-amended soils*

Treatment	Total volume ($cm^3 g^{-1}$)	Pore size distribution ($cm^3 g^{-1}$)						
		Total porosity (%)	> 75 μm	30-75 μm	5-30 μm	0.1-5 μm	0.1-0.01 μm	< 0.01 μm
NPK	0.2559 ± 0.01d	47.16 ± 1.52d	0.0975± 0.03b	0.0234 ± 0.01c	0.0365 ± 0.0028c	0.0600 ± 0.0041c	0.0261 ± 0.0017c	0.0124 ± 0.0005b

Effect of BC incorporation level on the soil nitrifying oxidizers

Changes in soil nitrifying bacteria [soil ammonia-oxidizing archaea (AOA) and soil ammonia-oxidizing bacteria (AOB)] of BC-treated soils are presented in *Table 8*. Values of AOA and AOB ranged from 0.91 to 1.16×10^8 $cfu.g^{-1}$, and from 0.65 to 0.76×10^7 $cfu.g^{-1}$, respectively.

Table 8. *The abundance of soil nitrifying bacteria of biochar-amended soils during harvest in 2014*

Treatment	AOA (10^8)	AOB (10^7)	pH
	$Cfu.g^{-1}$	$Cfu.g^{-1}$	
NPK	1.09 ± 0.03b	0.65 ± 0.03b	6.80 ± 0.23a
BC1	1.16 ± 0.02a	0.81 ± 0.02a	7.13 ± 0.51b
BC2	0.97 ± 0.04c	0.73 ± 0.02b	7.29 ± 0.34c
BC3	0.91 ± 0.05cd	0.76 ± 0.04ab	7.65 ± 0.13b

Similar to pH, AOA abundance was significantly enhanced by the addition of BC, when compared to NPK, but AOB was not significantly increased. The ratio of AOB to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1537515391

AOA increases with increasing pH gradient in the rhizosphere (Yu et al., 2019). Biochar at the level in BC1 enhanced AOA and AOB copies, but decreased them in BC2 and BC3.

Discussion

The application of BC enhances crop yields as well as a range of physical properties of soil (Laird et al., 2017; Agegnehu et al., 2016; Burrell et al., 2016; Du et al., 2016). In addition, BC influences soil nitrifying bacteria (Pan et al., 2017; Radwan et al., 2018; Azerang et al., 2018). The application of BC significantly increased the yield of soybean due to soil structure and improvement in moisture content as a result of changes in soil nitrifying bacteria. This can be attributed to the enhanced specific surface area and higher porosity as seen in the present study, which have been shown to enhance microbial activity and increase SOM (Chen et al., 2017; Ren et al., 2018; Sripreechasak et al., 2018; Sangdee et al., 2017). When BC is applied under the influence of tillage and cultivation operations, the distribution of soil compaction in the top layer of soil could be due to a dilution effect for the lighter fraction at the top layer (0-20 cm) (Soane, 1990). It has been reported that microaggregate formation and aggregate stability are significantly improved by the addition of BC (Kaiser et al., 2017; Hartley et al., 2016). The macroaggregates of black soil were significantly increased by incorporation of maize straw-derived BC at the levels of 15.75 and 31.5 $t.ha^{-1}$, and the stability of BC1 (15.75 $t.ha^{-1}$) was enhanced in the additive treatments. On the other hand, BC at levels of 31.5 and 47.25 $t.ha^{-1}$ produced negative effects on aggregate formation, leading to decreases in percentage of macroaggregates and lower MWD values, relative to BC1. This may be partially due to the fine particles with excessive biochar occupying the exist capillary under the external forces of mechanical cultivation and rainfall (Busscher et al., 2010) and then the restrict of microbial activity and nitrogen mineralization (Dempster et al., 2012) leading to less soil cement existed in unit soil mass. Another reason could be the effect of excessive BC which effectively decreased the risk of surface sealing in the BC-amended soils, relative to BC1 (Sun and Lu, 2014). Moreover, the C:N ratio of BC1 was the highest (10.05, *Table* 4), whereas the O:C and H:C ratios were the lowest (1.32 and 0.35, respectively, *Table* 4) among the four treatments (*Table 4*). Generally, a critical C:N ratio of < 25 is important because it indicates the probability of net mineralization of nitrogen (Chapin et al., 2002). The stability of BC-amended soil with a dominant level of BC could also be reflected in O:C and H:C ratios, the correlation coefficient of which was positive 0.97. The lower values of the two ratios resulted in a more stable BC-amended soil (Spokas, 2010; Budai et al., 2013), which could be a major factor that influences the formation of soil aggregates.

The effect of application of BC on water retention capacity is linked to the improvement of soil aggregation or structure (Ibrahim et al., 2017). The available water content in the soil was increased by BC addition at the level of 15.75 t.ha-1, but was decreased at BC levels of 31.5 and 47.25 $t.ha^{-1}$ mainly due to the changes in the capillary pores of the BC-amended soil. The negative effect of these changes could be due to the partial replacement of the clay particles by the finer particles in the BC, followed by a decrease in wilting point. Studies by Nadeem et al. (2017) showed that BC enhanced field capacity, which is consistent with the outcomes of this study. In a series of well constrained laboratory experiments, Liu et al. (2017a) showed that BC particle sizes affected soil water content by changing the pore spaces between particles

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1537515391

(interpores), and by adding pores that are part of the biochar (intrapores). Moreover, it has been reported that BC treatment either decreases (clogs) or increases pore spaces in the mixture, based on the quantity of fine BC fraction, which in turn could decrease or increase the hydraulic conductivity of the mixture (Trifunovic et al., 2018).

The addition of excess amount of BC (15.75 $t.ha^{-1}$) probably led to filling up of some of the capillary pores existing in the BC-amended soil by the additional dust (< 0.1 mm) that accompanied BC. Thus, the water holding capacity of the soil was reduced at higher BC levels. It has been reported that fine particles of excessive BC fill the soil pores, thereby reducing the permeability while increasing the water retention of BC-amended soil (Uzoma et al., 2011; Busscher et al., 2010). This provides the physical environment in response to changes in soil nitrifying bacteria. Similar to the available water content of soil, bulk density is a parameter which is useful for measuring the relative mass of a solid relative to the bulk volume that the solid occupies, including void spaces. For the non-amended soil, the bulk density was 1.40 $cm.cm^{-1}$, and was decreased to 1.28, 1.18, and 1.22 $g.cm^{-3}$ by BC1, BC2 and BC3, respectively. Bulk density also showed a quadratic regression relationship with increasing level of BC ($R^2 = 0.97$). Recent studies on the negative effect of high BC application on soil-plant system revealed that addition of BC at levels of 10, 20 and 30 t ha^{-1} produced positive influence on grain yield of winter rye, with 20 t ha^{-1} resulting in the highest grain yields (Kraska et al., 2016). Pot experiments revealed that *S. salsa* yield increased from 11.7 to 115% with WS application in the range of 5–10 g kg^{-1}, when compared with control (Sun et al., 2016). However, as BC level increased to 20 g kg^{-1}, the yield decreased to 102%. Usowicz et al. (2016) have reported that incorporation of BC under the fallow led to reduction of soil bulk density and particle density from 1.18–1.20 mg m^{-3} and 2.48–2.55 mg m^{-3} from 0 $t.ha^{-1}$ and 10 t ha^{-1} to 1.00 Mg m^{-3} and 2.20 Mg m^{-3} under 30 t ha^{-1}, respectively. In a field experiment conducted by Liu et al. (2017b), it was found that BC supplementation at levels of 10 and 20 g kg^{-1} soil increased peanut nitrogen fixation by 15.52 and 14.11%, respectively, in an intercropping system where maize (*Zea mays* L.) was intercropped with either soybean (*Glycine max* L.) or peanut (*Arachis hypogaea* L.).

The results obtained in this study reveal that BC exerts both positive and negative effects on the physical environment of black soil, and provide a real growth condition for crop yield, depending on the level of application. Higher concentrations of AOA and AOB improve the conversion of other forms of nitrogen to available nitrogen fertilizer so as to enhance the fertility of soil and promote plant growth (Luo and Lin, 2013). The bacterial indices AOA and AOB are the real driving forces, with AOA being more sensitive to changes in soil rhizosphere environment, especially pH. Indeed, AOA may be regarded as a factor for direct assessment of the benefits of BC, which is in agreement with the results observed in a hydroagric Stagnic Anthrosol and an entic Halpudept (Lin et al., 2017). In this study, increases in pH occurred along with increases in AOB: AOA ratio, leading to increased nitrogen mineralization by stimulating mircrobial activity (Teutscherova et al., 2017). On the other hand, AOA was reduced at higher BC levels mainly due to adverse physical condition of soil, especially decreased availability of water and capillary pores, which negatively affected rhizosphere soil nutrient supply required for crop growth.

DOI: http://dx.doi.org/10.15666/aeer/1706_1537515391

Conclusion

Maize-derived BC incorporation increased the yields of soybean, and improved the physical properties of black soil such as aggregation stability, water holding capacity and pore size distribution. It is evident that as the level of application of BC increased to 37.5 and 47.25 t ha^{-1}, soil aggregation became less stable, possibly due to the negative effect on microbial habitat, leading to decreased stability of soil aggregates and lower levels of binding agents per unit of soil volume. Similarly, available water holding capacity started to decreases at BC level of 37.5 t ha^{-1}, due mainly to the filling of the capillary pore space of BC-soil mixture with finer ashes in excess BC. Moreover, AOA and AOB were enhanced by the lowest BC level (BC1), but inhibited at higher levels (BC2 and BC3), which resulted in direct reduction of crop yield by affecting the nitrogen supply capacity of rhizosphere soil. It is necessary that these results are verified in long-time field observations. Therefore, it can be concluded from these results that the maize straw-derived BC can be applied to black soils as a strategy for optimization of sustainable agricultural production.

Abstract. Using the method of pot culture, the effect of different water and nitrogen conditions on the growth of King grass [*Ponnisetum purpureum* Schumacher × *P. Glaucum* (Linnaeus) R. Brown] and its physiological response mechanisms were examined. The results showed that under the soil moisture conditions designated as W1 (35%-45%), W2 (55%-65%) and W3 (75%-85%), the application rate of nitrogen corresponded to maximum yields of 271.78, 355.05 and 329.06 kg hm^{-2}, and protein contents of 361.54, 505.44 and 647.88 kg hm^{-2}. With the increase of water stress, the proline content of King grass increased, while the CAT enzyme significantly decreased, and the CAT enzyme increased significantly with the nitrogen content under the same moisture condition. Soil moisture conditions had a greater effect on the yield and quality of King grass than the application rate of nitrogen, but there was a synergistic effect between them. Therefore, if water and nitrogen are properly matched, higher yield and quality can be obtained. The best conditions for water and nitrogen were found to be a soil moisture content of 75%-85% of field capacity and an application rate of 329.06 kg hm^{-2} for nitrogen.
Keywords: *nitrogen, filed capacity, proline, catalase activity, Hainan*

Introduction

King grass [*Ponnisetum purpureum* Schumacher × *P. Glaucum* (Linnaeus) R. Brown] is a perennial grass, also called Napier, in Colombia or Pennisetum and elephant grass or Africa Pennisetum (Xu et al., 2006). King grass has a short growing season, high yield, more tillers, regeneration capacity and other characteristics (Zhao et al., 2015). Under moderate water and fertilizer conditions, King grass can grow for up to 9 months each year (Xie et al., 2012), fresh yield of 2.25×10^5 kg hm^{-2}, stump tiller 50 to 80, the second year of high fresh yield $(3.0\text{-}3.75)\times10^5$ kg hm^{-2}. King grass not only provides high yield, but nutritious protein, the per hectare of which can reach that of 8-10 hm^2 corn. In addition, King grass is soft and juicy, highly palatability, and is one of the best feeds for herbivorous livestock and fish (Li et al., 2015).

Irrigation and application of chemical fertilizer are two major factors for agricultural production, and they are two important technical measures that also offer productivity control. In crop production, irrational use of water and chemical fertilizer resources can waste water and fertilizer and pose a serious threat to the environment (Zhou et al., 2016). Therefore, a study of rational application of water and chemical fertilizer aspect cannot be ignored. For the purpose of detect the effects of the coupling of water and nitrogen on the yield and quality of King grass, soil moisture and nitrogen fertilizer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1539315401

were used as dependant variables in trial pot experiments to determine the impact of water and nitrogen coupling on King grass growth traits. In addition, the response of proline and catalase (CAT) and other physiological traits under different water and nitrogen conditions was also examined (Meng et al., 2019).

Material and methods

Materials

The *P. purpureum* × *P. Glaucum* CV. Reyan No. 4 was selected as test materials. The latsol granite was applied for pot culture of King grass. Soil texture is sandy loam soil, and the main physical and chemical properties shown in *Table 1*.

Table 1. *Soil physical and chemical characteristics*

pH	Organic matter g kg^{-1}	Alkaline hydrolysis N mg kg^{-1}	Available P mg kg^{-1}	Available K mg kg^{-1}
6.12	6.9	101.5	7.2	47.1

Experimental design

The soil was air-dried and passed through 2 mm mesh. Each pot, which was 31 cm × 29 cm (D × H), fitted 20 kg soil.

Set three soil moisture levels, namely: W1: saturation field capacity of 35%-45%; W2: saturation field capacity of 55%-65%; W3: saturation field capacity of 75%-85%. Soil moisture of each pot was measured using a moisture meter (DELMHORST) at 4:30pm each day, and water was added to maintain the preset moisture level in each pot. To the pots containing these three soil moisture conditions, four nitrogen contents were applied as follows: N0: 0 g kg^{-1}; N1: 0.0675 g kg^{-1}; N2: 0.135 g kg^{-1}; N3: 0.2025 g kg^{-1}. These applications were equivalent to the following amount of nitrogen fertilizer per hectacre 0 kg hm^{-2}, 151.875 kg hm^{-2}, 303.75 kg hm^{-2}, 455.625 kg hm^{-2}. All the treatments were conducted with completely randomized block design and three replicates. In addition, each pot was treated with 0.0668 g P_2O_5 kg^{-1} and 0.0668 g K_2O kg^{-1}. Phosphate fertilizer was applied as basic fertilizer. Potassium fertilizer was applied in two batches, 50% as basic fertilizer and 50% used as additional fertilizer after 60 days of planting. Nirtrogen fertilizer dissolved in water and was applied in three batches, which were after planting 30, 60 and 90 days. Fertilizer types were: urea nitrogen, phosphate with calcium magnesium phosphate and potassium chloride.

These tests were conducted in August 10th to 20th December, in 2017 at greenhouse of Danzhou County (Hainan, China), Hainan University, College of Agriculture campus bases.

Analytical methods

Fresh yields and dried yields above ground were weighted after planting 130 days (Bao, 2000). The field capacity was determined by Wilcox method (Jiang et al., 2006). All crude fiber contents of King grass were determined with acid elimination decomposition method. The crude grass protein contents were converted from total

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1539315401

nitrogen contents, which was determined by semi-micro Kjeldahl method (He, 1983). Proline content was measured using ninhydrin colorimetric method (Wang, 2011). Catalase activity was determined by potassium permanganate titration method (Wang, 2011).

Statistical analysis

Description statistics, Anova test were performed by SAS 9.0 on Windows. And the none linear regression model was applied to estimate the optimized soil moisture and application rate of nitrogen in King grass. The figures were conducted by Sigmaplot 10.0 on Windows.

Results

Effects of different water and nitrogen treatments on King grass yield

As shown in *Figure 1*, at a constant level of nitrogen fertilizer, the yield of grass was directly related to the soil water content. This is confirmed by the fact that the W1, W2, W3 moisture conditions, resulted in yields of 37.33%-62.41%, 56.69%-76.42%. At W3 each fertilization yields are the highest and significantly higher than other water treatment levels, indicating that W3 is optimum moisture content of the soil for growing King grass. As can be seen from the figure at the W1, W2 and W3 water level, the correlation coefficient of nitrogen fertilizer rates and yield were: 0.998, 0.994 and 0.998 (n=12, P<0.001). According to nitrogen contents at different water levels, it can be seen that the corresponding moisture conditions Nitrogen yield the highest point of the King grass were 2.42 g pot^{-1}, 3.16 g pot^{-1}, 2.92 g pot^{-1}, equivalent hectare fertilizer were: 271.78 kg hm^{-2}, 355.05 kg hm^{-2} and 329.06 kg hm^{-2}.

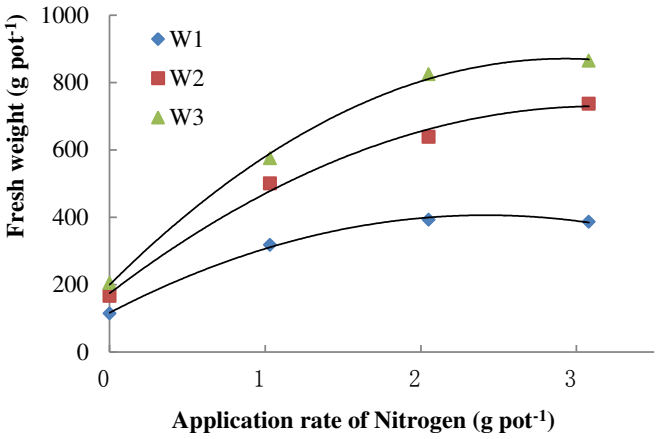

Figure 1. *Effect of application rate of N on the production of King grass in different moisture conditions*

Effects of different water and nitrogen treatments on the crude protein content

The contents of crude protein in King grass with decreasing soil moisture content at a fixed nitrogen level (*Fig. 2*). At a fixed nitrogen content, the King grass crude protein content under moderate water (W1) treatment was significantly higher than the other

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1539315401

two soil moisture content levels and the mild water treatment (W2) is slightly higher than the appropriate water treatment (W3). Within a range, the Nitrogen content can result in higher protein yields form King Grass. In the W1, W2 and W3 water levels, the correlation coefficient between nitrogen fertilizer rates and crude protein were: 0.937, 0.868 and 0.939 (n=12, P<0.001). At different soil water contents the crude protein content of the highest levels of nitrogen were 3.21 g pot^{-1}, 4.49 g pot^{-1} and 5.76 g pot^{-1}, equivalent hectares of 361.54 kg hm^{-2}, 505.44 kg hm^{-2} and 647.88 kg hm^{-2}.

Effects of different water and nitrogen treatments on crude fiber content

Figure 3 shows that at a constant moisture content, the crude fiber content of King grass increased as the with nitrogen soil content decreased. Beyond a minimum nitrogen content the grass crude fiber content increased, but there is an optimum soil nitrogen content as the data show. When nitrogen levels were in the range of N1-N2, the crude fiber content of the King grass was in the range of 28.06%-30.93%. Therefore, the optimum application rate of nitrogen is between 28.17%-34.08%.

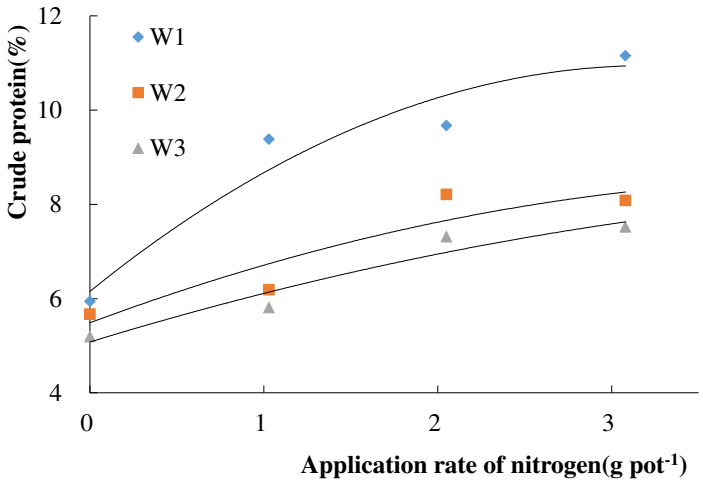

Figure 2. *Effect of application rate of N on the crude protein of King grass in different moisture conditions*

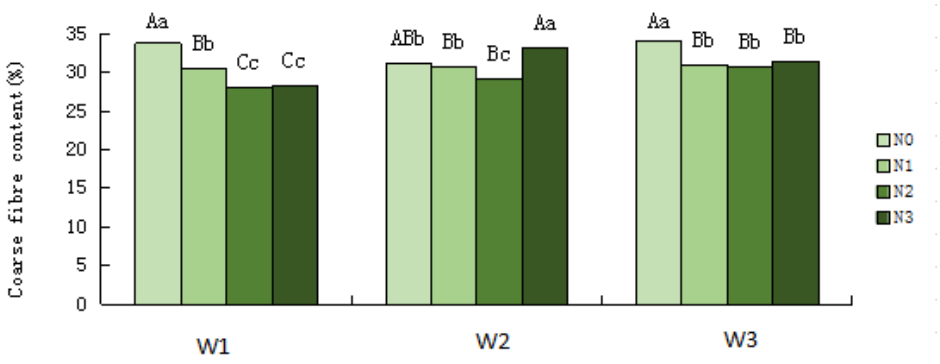

Figure 3. *Effects of water and nitrogen coupling on the crude fibre content of King grass*[†]

DOI: http://dx.doi.org/10.15666/aeer/1706_1539315401

Effects of different water and nitrogen treatments on Proline content

As the water stress on the grass increased, there was a significant increase in the accumulation of proline in the King grass (*Fig. 4*). Under moderate water deficit level W1, proline content was between 109.02-215.91 ug g^{-1}. Conditions W2 and W3 led to average increase of 54.64% and 135.73%, The water level in W1 caused the King grass proline content to increase with increasing nitrogen rate. As can be seen, compared with N0, N1, N2, N3, resulted in, an increase of 6.38%, 60.63%, 98.04% of proline content. Moisture levels in W2 caused, the King grass proline content to be in the range of 75.22-125.61 ug g^{-1} also exhibiting increases with the amount of nitrogen fertilizer. This increase for N, N1, N2, N3, respectively, was 23.91%, 38.70%, 67.00% proline content. Proline accumulation was lowest in the W3 water treatment condition, its content was between 50.76-81.73 ug g^{-1}, significantly lower than the other two under each N treatments moisture levels.

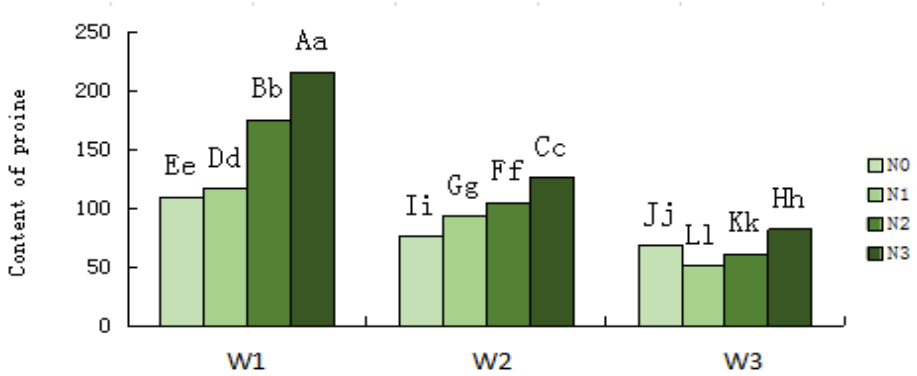

Figure 4. *Effects of different water and nitrogen on the proline of King grass*[†]
[†]*Among columns followed by different miniscule (capital) letters are significantly different at P <0.05 (P<0.01)*

Effects of different water and nitrogen treatments on catalase activity

The effect of water and nitrogen on CAT enzyme activity in the King grass is shown in *Figure 5*. As water stress increased, CAT activity in the King grass decreased, while at constant soil moisture content CAT activity increased gradually with increasing amounts of nitrogen. CAT activity was the highest at the highest level of nitrogen, N2. Under moderate water deficit situation W1, the CAT activity was the lowest, between 1.76-1.99 mg g^{-1} min^{-1}. At the W3 water treatment, the CAT activity exhibited the highest performance, between 1.98-2.12 mg g^{-1} min^{-1}, but at the N2, N3 levels it was 2.12 mg g^{-1} min^{-1}, significantly higher than the other treatments.

King grass yield and fertilizer coupling model building

With the King grass yields as the dependent variable, the relative soil moisture content, and nitrogen rate as the independent variables, regression analysis, yields the following regression model:

$$Y=-48.3549+203.1436X_1+0.1547X_2+0.3259X_1X_2-142.6219X_1^2-0.000545X_2^2 \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1539315401

where: X_1 for soil moisture (%), X_2 is nitrogen rate (kg hm^{-2}), Y is yield of King grass (t hm^{-2}). Upon examination, the F value is 130.25, the coefficient of determination R^2 is 0.99 ($P<0.001$), indicating that the regression equation was highly significant. Factor levels are the dimensionless linear encoder substitution, standardized partial regression coefficient, it can affect the primary and secondary status on yield trial judge according to their size factors, factors which characterize the role of sign direction. Considering the partial regression coefficient 1, 2 times the item, we can see the level of soil moisture (X_1) the degree of influence on the King grass yield is higher than the amount of nitrogen fertilizer (X_2) the degree of influence.

A term X_1 (soil moisture), X_2 (nitrogen) coefficients 203.1436, 0.1547 are positive, indicating increased soil moisture and nitrogen fertilizer applied were significantly increased yield, soil moisture coefficient is higher than nitrogen rate coefficient, indicating that the soil water is the more important factor affecting the King grass production; independent variables X_1, X_2 interaction term coefficient of 0.3259 is greater than zero, indicating that there are obvious synergies between soil moisture and nitrogen fertilizer application, so a reasonable match between the two, the King grass can obtain a higher yield; since squared variable coefficients are negative, indicating that the King grass yield and moisture content and the amount of nitrogen fertilizer as a function of diminishing returns, that is, when the moisture content and the amount of excess nitrogen can lead to lower yields.

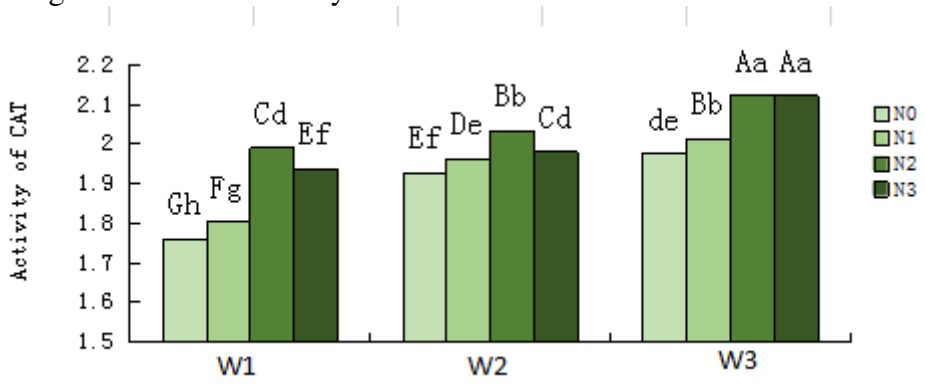

Figure 5. *The effect of different water and nitrogen treatments on activity of CAT of king grass*[†]
[†]*Among columns followed by different miniscule (capital) letters are significantly different at P <0.05 (P<0.01)*

Discussion

Water and Nitrogen Conditions relationship with King grass yield and nutrition

This study shows that under different moisture conditions, although King grass yields increase with increasing nitrogen, the increase in production gradually reduced, showing a decreasing rate fertilizer law (Si et al., 2017). Under this condition, the moisture content is a major factor limiting the growth of the King grass. The soil moisture at a mild deficit (W2) condition, results in an inadequate supply of water so that increases in nitrogen are needed to compensate (Luo et al., 2019). This weakens the degree of production caused by inadequate water supply; while under appropriate moisture (W3) condition, an insufficient supply of nitrogen fertilizer can compensate for low soil moisture content demonstrating the synergistic effect required to achieve the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1539315401

"water promote fat" effect, reducing the King grass yield caused by the lack of nitrogen to reduce hazards (Wang et al., 2019).

At various levels of soil moisture content, the highest crude protein content of King grass required fertilizer inputs that were higher than the required amount of nitrogen to maintain the highest yield. So simply increasing nitrogen to increase the proportion of crude protein in the grass, will reduce yield, but will also lead to reduction in the utilization of nitrogen and eventual nitrogen leaching which will present environmental risks (Liu et al., 2012). Soil moisture levels and nitrogen inputs are the main limiting factor affecting crop yield and quality (Huang, 2003), and are the two factors that offer significant synergies (Hajaji et al., 2013). Therefore, the King grass yield can be based on the actual production to adjust the ratio of water and nitrogen.

Physiological response to different water and nitrogen conditions

Osmotic adjustment is an important physiological mechanism of plant adaptation to drought stress. Increasing the intracellular concentration of solute plants through metabolic activity, lowers osmotic potential and maintains turgor pressure, so a variety of physiological processes are related normal turgor (Xu et al., 2016). Currently crop drought resistance is closely related to the penetration of regulating substances of which there are three, namely, proline (Pro), betaine and soluble sugars. Often in the free state of proline widespread in plants, when the plants are exposed to environmental stress, free proline increasingly accumulates in plants (Li et al., 2017), the largest accumulation of proline results from drought stress. For the King grass, under moderate water deficit (W1) cases, the highest accumulation of proline, is when nitrogen increases, which is consistent with findings Nadzariah et al. (2018). The moisture deficit (W2) condition, causes proline accumulation which is secondary only to the W1 condition, but also exhibited an increase with nitrogen rate rise phenomenon. As shown under water stress, proline accumulation is closely related to the ability of King grass to react to water stress. But on the other hand, studies have shown that nitrogen levels can improve the ability of the plant to adjust to osmotic changes while strengthening the crop's sensitivity to drought, this aspect needs further study (Zhang, 2008; Li et al., 2014).

Conclusions

Within the scope of this study, under W1, W2 and W3 water level, the highest yield of the corresponding amount of nitrogen fertilizer were 271.78 kg hm^{-2}, 355.05 kg hm^{-2} and 329.06 kg hm^{-2}. The impact of soil moisture on grass yield is higher than the influence of the King grass amount of nitrogen, and there are significant synergies between the two facots, both with a reasonable, King grass can get a higher yield, to meet the needs of herbivorous livestock in order to maintain the balance of ecological environment. Under the experimental conditions, when soil moisture is W3 (75%-85%), nitrogen rate was 329.06 kg hm^{-2}, the King grass can significantly increase yields and improve its quality. The nitrogen can be applied by water solution, the concentrations and application volumes should be studied in future.

Abstract. As the most commonly grown afforestation species in southeast China, China-fir (*Cunninghamia lanceolata*) shows a huge ecological service function. Generalized individual-tree growth models were developed for *C. lanceolata*. Data was obtained from 61 plantation-grown China-fir trees in 17 single-species plots located in four sites by stem analysis. The best base models were chosen from five theoretical growth equations for modeling increases in diameter at breast high, tree, height and stem volume using ordinary nonlinear least squares regression; selection criteria were the smallest absolute mean residual, root mean square error and the largest adjusted coefficient of determination. To account for autocorrelation in the data with repeated measures, we developed a nested multi-level nonlinear mixed-effects (NLME) model, constructed on the selected base model; the NLME models incorporated random effect for tree, plot and site. The best random-effects combinations for the NLME models were identified by Akaike's information criterion, Bayesian information criterion and -2 logarithm likelihood. Heteroscedasticity was reduced and autocorrelation was also addressed. For diameter and height growth, the NLME models including the exponential function and ARMA(1,1) performed best, and the NLME models including the power function and ARMA(1,1) performed best for stem growth. The NLME models were considered to be the best approach to analyze the variation of tree growth and yield.
Keywords: *individual-tree model, autocorrelation, heteroscedasticity, nonlinear mixed-effects models, Cunninghamia lanceolata*

Introduction

China-fir (*Cunninghamia lanceolata* (Lamb.) Hook.) is the most commonly grown afforestation species in southeast China. According to the National Continuous Forest Inventory, about 10.96 million ha and 726.09 million m^3 of China-fir is distributed in more than ten provinces in China in 2015, making it the number one species in terms of harvest volume. As a result, a sustainable forest management plan for the species needs to be established.

The availability of growth information, such as growth models for individual tree characteristics including diameter at breast height (d), total tree height (h) and stem volume (v), enables a more detailed description than stand-level models (Burkhart, 2003; Vanclay, 2003). This important asset in sustainable forest management allows the selection of tree species for estimation of cutting cycles as well as for logging or

DOI: http://dx.doi.org/10.15666/aeer/1706_1540315418

protection (Adame et al., 2008). These basic growth models simplify the study of the variability of individual-tree increments and the estimation of yields directly; they also serve as the main tool used to estimate dynamic variability of biomass and carbon storage indirectly. In addition, they allow silvicultural treatments to be simulated and enable comparison of alternative thinning regimes (Mabvurira and Miina, 2002).

Individual-tree growth models are established based on tree growth increments as the dependent variable and the comparable factors, such as age, as the independent variables. They can simulate growth for individual trees (Sharma et al., 2016) and provide an invaluable tool for forest management planning at any level (Uzoh and Oliver, 2008).

The ordinary non-linear least squares (ONLS) regression, is the most commonly used statistical method in forest modeling (Grégoire et al., 1995). Individual-tree growth models have been fitted to growth increment data collected repeatedly over time on the same tree. The hierarchical nature of the data results in spatial and temporal correlation among observations made in the same sampling unit (i.e., site, plot and tree). However, the stochastic structure is often ignored and independence of observations is assumed (Gutzwiller and Riffell, 2007; Hao et al., 2015). Furthermore, when data are autocorrelated they cannot be considered to be independent samples of the basic tree population (Fox et al., 2001). Therefore, a violation of the ONLS regression assumption of independent residuals exists and results in biased estimates of the standard error of parameter estimation (Dumont et al., 2018).

Nonlinear mixed-effects (NLME) models incorporate both fixed and random effects. Fixed effects are parameters associated with an entire population or with certain repeatable levels of experimental factors, while random effects are associated with individual experimental units drawn at random from a population (Zhu et al., 2019). Random effects account for spatial and temporal correlation by defining the covariance structure of the model's random components and by using this structure during parameter estimation. Therefore, the evolution of NLME models provides an efficient statistical method for explicitly modeling hierarchical stochastic structure (Sharma et al., 2016; Abiyu et al., 2018; Huff et al., 2018). Because of their flexibility, NLME models have become increasingly used to forest growth and yield modeling (Fu et al., 2013; Matos et al., 2013; Xu et al., 2014; Huff et al., 2018).

The main objective of this study was to develop individual-tree growth models for *C. lanceolata* in Fujian Province, southeast China. The data were derived from 61 trees in 17 sample plots located in four sites. A multi-level nonlinear mixed modeling approach that included both fixed and random components was applied to the hierarchical structure of the data. This diminished the level of variance among the sampling units, which were included as covariates. In developing the growth models, we considered the use of nested three-level models. The first, second, and third levels are the site, the plots nested within the site, and the tree, nested within the plot within site, respectively. Our preliminary analysis showed that the NLME models with random effects effectively removed the heteroscedasticity and autocorrelations in repeated-measure data, and therefore could be important tools for sustainable management of the China-fir species within the study area. The predictive ability of the model developed here and the applicability of the NLME model were demonstrated using separate validation data.

Materials and methods

Data

Pure China-fir stands located in Jiangle County (26°26′–27°04′N, 117°05′–117°40′E), Fujian Province, in southeast China with a red soil type were used in this study. Average mean precipitation, frost-free length, and temperature were about 1699 mm, 287 days, and 18.7°C, respectively.

The sampling period took place over 2016-2017 during the summer. The data were obtained from 61 trees in 17 single-species plots of plantation-grown China-fir that located in four sites, identified as the Qiantan, Shuinan, Yuhua and Yuandang areas, which were numbered I, II, III and IV, respectively (*Fig. 1*).

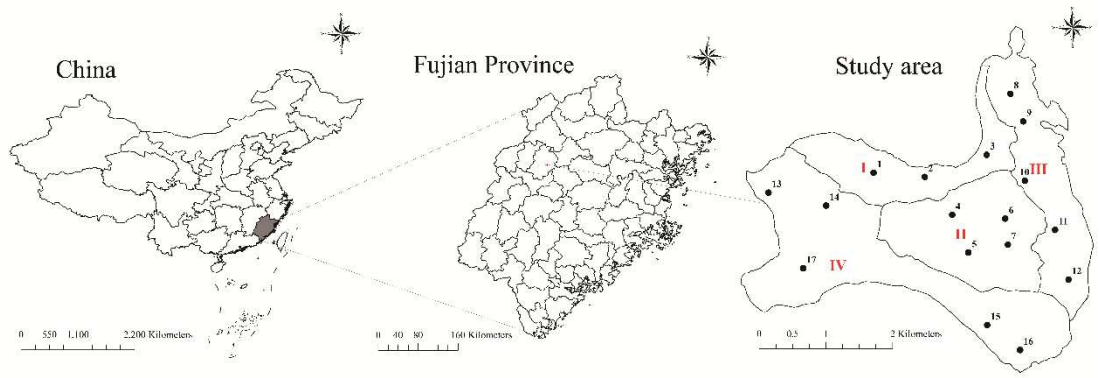

Figure 1. *Seventeen sample plots located in four regions in Fujian Province, southeast China*

Sample plots were square and varied in size from 400 to 600 m^2. The increments of *d*, *h* and *v* per year were measured or calculated, using the stem analysis approach. The data were randomly divided into two groups; 75% of the points were used for model fitting, and 25% were used for model validation. The fitting data and the validation data included 23 trees from eight plots, and eight trees from four plots, respectively. To achieve more confidence in the results, the fitting and validation data were chosen three times and the model estimation and prediction procedures were also iterated. However, the procedures and results were listed only once in this paper, including summary statistics for both fitting and validation data (*Table 1*). The increments data of *d*, *h* and *v* are graphically depicted in *Fig. 2*.

Methods

Individual-tree growth equations

Five theoretical nonlinear growth equations (NLs), the Richards, Weibull, Korf, Logistic and Schumacher equations, were selected as candidates for modeling individual-tree growth. These equations are widely used for the simulation of individual-tree growth, particularly the Richards and Korf equations (Zhang et al., 2011; Xu et al., 2014). *Table 2* shows the mathematical expressions of the equations.

The five equations mentioned above are all S-shaped growth equations with inflection points and asymptotes. One characteristic of the Richards, Weilbull and Korf equations is that the coordinates of inflection points are variable multiples of asymptotic values; in contrast, the equivalent of the Logistic and Schumacher equations are fixed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1540315418

multiples. The five equations were initially fit by ONLS regression without considering random parameters. Different initial values for the parameters were tried to ensure that a global minimum was achieved. The best performing function was selected as the base model by applying three statistical criteria; absolute mean residual (AMR), root mean square error (RMSE), and adjusted coefficient of determination (adj-R^2) (Zhang et al., 2011). The function with the smallest AMR and RMSE and the largest adj-R^2 provides the best fit. Similarly, the adjusted coefficient of determination is used as an unbiased estimator in both multiple regression and canonical redundancy analysis. The formulas of the fit statistics are:

$$\text{AMR} = \sum_{i=1}^{M}\sum_{j=1}^{M_i}\sum_{k=1}^{n_{ij}}\frac{\left|y_{ijk}-\hat{y}_{ijk}\right|}{n_{ij}} \quad \text{(Eq.1)}$$

$$\textbf{RMSE} = \sqrt{\sum_{i=1}^{M}\sum_{j=1}^{M_i}\sum_{k=1}^{M_{ij}}\sum_{l=1}^{n_{ijk}}\frac{\left(y_{ijkl}-\hat{y}_{ijkl}\right)^2}{n_{ijk}-r}} \quad \text{(Eq.2)}$$

$$\textbf{adj-R}^2 = 1-\left(n_{ijk}-1\right)\left[\frac{\sum_{i=1}^{M}\sum_{j=1}^{M_i}\sum_{k=1}^{M_{ij}}\sum_{l=1}^{n_{ijk}}\frac{\left(y_{ijkl}-\hat{y}_{ijkl}\right)^2}{n_{ijk}-r}}{\sum_{i=1}^{M}\sum_{j=1}^{M_i}\sum_{k=1}^{M_{ij}}\sum_{l=1}^{n_{ijk}}\left(y_{ijkl}-\bar{y}\right)^2}\right] \quad \text{(Eq.3)}$$

where M is the number of sites, M_i is the number of plots within the i^{th} site, M_{ij} is the number of trees within the j^{th} plot of the i^{th} site, n_{ijk} is the number of observations (increments), r is the number of parameters in the model, y_{ijkl} is the value of increments of k^{th} tree taken from the j^{th} plot in the i^{th} site, $\hat{y}_{ijkl}$ is the increment prediction, and $\bar{y}$ is the average of observations. The accuracy of the models was tested against the modeling data and against independent data from the same site and plot (Adame et al., 2008).

Multi-level NLME models

Available data were based on the measured annual increment of the sample plots located at different sites. The nested sampling structure created a high degree of correlation among observations taken from the same tree, plot and site. To alleviate this, a mixed-effects model approach has been proposed by other authors (Laird and Ware, 1982; Palmer et al., 1991; Grégoire et al., 1995). A general expression for a NLME model can be defined as (Lindstrom and Bates, 1990; Vonesh and Chinchilli, 1997):

$$y_{ijkl}=f\left(\phi_{ijkl},x_{ijkl}\right)+\varepsilon_{ijkl}\ i=1,...,M,\ j=1,...,M_i,\ \ k=1,...,M_{ij},\ l=1,...,n_{ijk} \quad \text{(Eq.4a)}$$

where x_{ijkl} is the age, ϕ_{ijkl} is a parameter vector, $r\times 1$, f is a nonlinear function of the predictor variables and the parameter vector, and ε_{ijkl} is the within-group error including the within-group variance and correlation (Davidian and Giltinan, 1995) which is assumed to be normally distributed with zero expectation and a positive-definite variance-covariance structure R_{ijkl} (Meng and Huang, 2009):

$$\varepsilon_{ijkl}\sim \mathrm{N}\left(0,R_{ijkl}\right) \quad \text{(Eq.4b)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1540315418

Moreover, ϕ_{ijkl} can be expressed as:

$$\phi_{ijkl} = A_{ijkl}\lambda + B_{i,jkl}\mu_i + B_{ij,kl}\mu_{ij} + B_{ijkl}\mu_{ijk} \quad \text{(Eq.4c)}$$

$$\mu_i \sim \mathrm{N}(0,\psi_i),\ \mu_{ij} \sim \mathrm{N}(0,\psi_{ij}),\ \mu_{ijk} \sim \mathrm{N}(0,\psi_{ijk}) \quad \text{(Eq.4d)}$$

where λ is the $p \times 1$ vector of fixed population parameters (where p is the number of fixed parameters in the model). μ_i, μ_{ij} and μ_{ijk} are the $q_1 \times 1$, $q_2 \times 1$ and $q_3 \times 1$ vectors of random effects associated with the first, the second and the third levels, respectively (where q_1, q_2, q_3 are the numbers of random parameters of different levels in the model). μ_i, μ_{ij} and μ_{ijk} are assumed to be normal (or Gaussian) with a mean of 0 and have the variance-covariance matrices ψ_i, ψ_{ij} and ψ_{ijk}, which are the $q_1 \times q_1$, $q_2 \times q_2$ and $q_3 \times q_3$ variance-covariance matrices of random effects in three levels, respectively. A_{ijkl}, $B_{i,jkl}$, $B_{ij,kl}$ and B_{ijkl} are design matrices of size $r \times p$, $r \times q_1$, $r \times q_2$ and $r \times q_3$ for the fixed and random effects of different levels specific to each sampling unit, respectively.

Determining the variance-covariance structure

The variance-covariance matrices Ψ_i, Ψ_{ij} and Ψ_{ijk} are positive-definite and symmetric, which is to say that all their eigenvalues must be strictly positive (Pinheiro and Bates, 2000). A hypothetical 2×2 variance-covariance matrix is shown as follows (Calama and Montero, 2004; Fu et al., 2013):

$$\begin{bmatrix} \sigma_u^2 & \sigma_{uw} \\ \sigma_{wu} & \sigma_w^2 \end{bmatrix} \quad \text{(Eq.5)}$$

where σ_u^2 and σ_w^2 are the variances for the random effects u and w, respectively, and $\sigma_{uw} = \sigma_{wu}$ is the covariance among random effects u and w.

Determining the structure of R

The matrix R_{ijkl} can be proposed to include both correlation effects and weighting factors to account for within-tree heteroscedasticity and autocorrelation (Davidian and Giltinan, 1995; Calama and Montero, 2004; Meng and Huang, 2009). In this study, a general expression for the matrix is given by (Calama and Montero, 2004; Crecente-Campo et al., 2010):

$$R_{ijkl} = \sigma^2 G_{ijk}^{0.5} I_{ijk} G_{ijk}^{0.5} \quad \text{(Eq.6)}$$

where G_{ijk} is an $n_{ijk} \times n_{ijk}$ diagonal matrix within-tree heteroscedasticity variances and I_{ijk} is an $n_{ijk} \times n_{ijk}$ matrix showing the within-tree autocorrelation structure of errors, and σ^2 is a scaling factor for the error dispersion (Calama and Montero, 2004; Crecente-Campo et al., 2010).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1540315418

In individual-tree growth models, the variance is often found to be dependent of the means, and the variance will generally increase with increasing mean tree diameter. To remove this effect, we modeled the variance as an exponential function or power function (Pinheiro and Bates, 2000). Autocorrelation structures were used to address the within-tree correlations observed in the data. A method was selected from among three commonly used approaches: first-order autoregressive structure [AR (1)], a combination of first-order autoregressive and moving average structures [ARMA (1,1)], and the compound symmetry structure (CS) (Pinheiro and Bates, 2000).

$$V\left(\varepsilon_{ijkl}\right)=\sigma^2\exp\left(2\delta x_{ijkl}\right) \quad \text{(Eq.7)}$$

$$V\left(\varepsilon_{ijkl}\right)=\sigma^2 x_{ijkl}^{2\delta} \quad \text{(Eq.8)}$$

$$\mathbf{AR}(1)=\sigma^2\begin{bmatrix}1 & \rho & \rho^2\\ \rho & 1 & \rho\\ \rho^2 & \rho & 1\end{bmatrix} \quad \text{(Eq.9)}$$

$$\mathbf{ARMA}(1,1)=\sigma^2\begin{bmatrix}1 & \gamma & \gamma\rho\\ \gamma & 1 & \gamma\\ \gamma\rho & \gamma & 1\end{bmatrix} \quad \text{(Eq.10)}$$

$$\mathbf{CS}=\begin{bmatrix}\sigma^2+\sigma_1 & \sigma_1 & \sigma_1\\ \sigma_1 & \sigma^2+\sigma_1 & \sigma_1\\ \sigma_1 & \sigma_1 & \sigma^2+\sigma_1\end{bmatrix} \quad \text{(Eq.11)}$$

where δ is an estimated parameter, ρ is the autoregressive parameter, γ is a moving average component, σ^2 is the residual variance, and σ_1 is the residual covariance (Leak, 1996).

Mixed parameter evaluation

A crucial issue in fitting mixed-effects models is deciding which parameters should be considered random effects and which can be treated as fixed effects. A common approach is to start with random effects for all parameters and then to examine the fitted object to decide which, if any, of the random effects can be eliminated from the model (Pinheiro and Bates, 2000). Therefore, different combinations of model parameters were tested to ascertain their contribution to predictions of individual-tree growth (Adame et al., 2008).

Parameter estimation

The parameters in the equation were estimated by maximum likelihood (ML) using the Lindstrom and Bates (LB) algorithm implemented in the R nlme function (Lindstrom and Bates, 1990; Pinheiro and Bates, 2000). Several articles provide details related to the LB algorithm and nlme function (Lindstrom and Bates, 1990; Pinheiro and Bates, 2000).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1540315418

Predicting the random effects parameters is more problematic during model application and prediction than during the fitting process. In this case, they were estimated by the EBLUPs (Vonesh and Chinchilli, 1997), using the increment data.

$$\hat{b}_{ijk} \approx \mathrm{D}\mathrm{Z}_{ijk}^{\mathrm{T}}\left(\mathrm{R}_{ijk}+\mathrm{Z}_{ijk}\mathrm{D}\mathrm{Z}_{ijk}^{\mathrm{T}}\right)^{-1}\hat{e}_{ijk} \quad \text{(Eq.12)}$$

where D is the estimated variance-covariance matrix for the random effects $\hat{b}_{ijk}$, R_{ijk} is the estimated variance-covariance matrix for the error term, Z_{ijk} is the estimated partial derivatives matrix, which contains the values of partial derivatives with respect to random effects parameters for the new observation.

Model evaluation

To compare the candidate models and to determine the fixed- versus random-effects parameters for each candidate model, Akaike's information criterion, Bayesian information criterion and -2 logarithm likelihood (Zhao et al., 2012) were used. AIC is the log-likelihood penalized by the number of parameters. BIC is similar but penalizes more for models with more parameters. Based on the AIC, BIC and -2 LL statistics, one or more candidate models were selected for further evaluation (Yang et al., 2009; Hao et al., 2015). The appropriate variance function and autoregressive structure for the NLME models were determined by the likelihood ratio test (LRT) (Pinheiro and Bates, 2000; Fang and Bailey, 2001). The predictions were calculated by *Equation 4* based on the fixed- and random-effects parameters. All models presented in this paper were calibrated using the nlme function in the R statistical environment (Ihaka and Gentleman, 2004; Pinheiro et al., 2005).

Results

Function selection

The R nls function was used to evaluate the parameter estimates and model fit statistics of the five equations (*Table 2*). For *d* and *h* growth models, the Korf equation has slightly better predictive ability than the others do. For *v* growth models, the Richard's equation performs better than the others perform. Therefore, the Korf equation was selected as the basic nonlinear model for estimating *d* and *h* growth models and the Richards equation was selected as the *v* growth model. The final base models are given by:

$$d_{ijkl} = a\exp\left(-b/x_{ijkl}{}^{c}\right)+\varepsilon_{ijkl} \quad \text{(Eq.13)}$$

$$h_{ijkl} = a\exp\left(-b/x_{ijkl}{}^{c}\right)+\varepsilon_{ijkl} \quad \text{(Eq.14)}$$

$$v_{ijkl} = a\left(1-\exp\left(-bx_{ijkl}\right)\right)^{c}+\varepsilon_{ijkl} \quad \text{(Eq.15)}$$

where *a*, *b* and *c* are fixed effects parameters, and ε_{ijk} is the residual noise term.

Construction of NLME models

AIC, BIC and −2 LL fit statistics were compared among different combinations of random effects parameters (*Table 3*). The models represented by *Eqs. 16–17* based on the Korf equation and incorporating the nested effects of site as well as plot and tree on *a* and *b*, yielded the smallest AIC, BIC and −2 LL. Meanwhile, the model represented by *Eq. 18* based on the Richards equation with the nested effects of site, plot and tree on *a* and *b* performed better.

$$d_{ijkl} = \left(\alpha + u_i + u_{ij} + u_{ijk}\right)\exp\left(-\left(\beta + w_i + w_{ij} + w_{ijk}\right)\Big/ x_{ijkl}^{\ \gamma}\right) + \varepsilon_{ijkl} \quad \text{(Eq.16)}$$

$$h_{ijkl} = \left(\alpha + u_i + u_{ij} + u_{ijk}\right)\exp\left(-\left(\beta + w_i + w_{ij} + w_{ijk}\right)\Big/ x_{ijkl}^{\ \gamma}\right) + \varepsilon_{ijkl} \quad \text{(Eq.17)}$$

$$v_{ijkl} = \left(\alpha + u_i + u_{ij} + u_{ijk}\right)\left(1 - \exp\left(-\beta x_{ijkl}\right)\right)^{\left(\gamma + w_i + w_{ij} + w_{ijk}\right)} + \varepsilon_{ijkl} \quad \text{(Eq.18)}$$

where α, β and γ are fixed-effects parameters, u_i and w_i are random-effects parameters generated by site, u_{ij} and w_{ij} are random-effects parameters generated by plot, and u_{ijk} and w_{ijk} are random-effects parameters generated by interaction by tree.

Table 3. *Evaluation indices of each NLME model*

Mixed parameters	*d*			*h*			*v*

a, *b*, *c*	not converge			not converge			not converge		

Note: *a*, *b*, and *c* are fixed parameters; *d*, *h*, and *v* are growth models; AIC, Akaike's information criterion; BIC, Bayesian information criterion; -2 LL, -2 logarithm likelihood

NLME models with heteroscedasticity and autocorrelation

The power function or the exponential function were used as the variance functions and the AR(1), ARMA(1,1) or CS were used as the autocorrelation structures to fit growth models incorporating different random effects (*Table 4*). The selected models had the smallest AIC, BIC and -2 LL. Thus, the final models of the three nested effects of site, plot and tree for *d*, *h*, *v* growth are, respectively:

Eq.16+Eq.7+Eq.10 (Eq.19)

Eq.17+Eq.7+Eq.10 (Eq.20)

Eq.18+Eq.8+Eq.10 (Eq.21)

Parameter estimates

We can conclude the general growth models for China-fir individual-tree in southeast China become:

$$d_{ijkl} = \left(21.1384 + u_i + u_{ij} + u_{ijk}\right)\exp\left(-\left(12.4464 + w_i + w_{ij} + w_{ijk}\right)\Big/ x_{ijkl}^{1.0994}\right) + \varepsilon_{ijkl} \quad \text{(Eq.22)}$$

$$h_{ijkl} = \left(32.7823 + u_i + u_{ij} + u_{ijk}\right)\exp\left(-\left(7.5768 + w_i + w_{ij} + w_{ijk}\right)\Big/ x_{ijkl}^{0.7240}\right) + \varepsilon_{ijkl} \quad \text{(Eq.23)}$$

$$v_{ijkl} = \left(0.2527 + u_i + u_{ij} + u_{ijk}\right)\left(1 - \exp\left(-0.0982 x_{ijkl}\right)\right)^{\left(5.3620 + w_i + w_{ij} + w_{ijk}\right)} + \varepsilon_{ijkl} \quad \text{(Eq.24)}$$

where *Table 5* lists the random effect matrix, residual error, heteroscedasticity and autocorrelation of *d*, *h* and *v* growth NLME models.

Model prediction

The predictive ability of *Eqs. 13–15* was evaluated using prediction procedures and *Eqs. 1–3* on both fitting and validation data. The performance of the NLME models was evaluated using cross-validation procedures for both fitting and validation data; the random effects were predicted with EBLUPs (*Eq. 12*), using the measurement data.

Table 6 lists the three fit statistics for *Eqs. 13–15* and *22–24*. *Eqs. 22–24* were the best predictors, with increases in adj-R^2 and decreases in RMSE for both fitting and validation data. In *Fig. 3*, the residuals of *Eqs. 13–15* and *22–24* are plotted against the fitted values; the fitted values are plotted against the observed values (*Fig. 4*). Based on the above analysis, we can conclude that the NLME models, such as *Eqs. 22–24*, incorporating nested multi-level effects of site, plot and tree, have sufficiently high predictive power. Therefore, the NLME models incorporating the random effects of site, plot and tree were the best model for predicting *d*, *h* and *v* growth of individual China-fir trees in the single-species plantations of the study area.

Discussion

Of the five theoretical growth equations tested, the Korf equation provided the best fit for *d* and *h* growth data of China-fir when evaluated based on AMR, RMSE and adj-R^2, while the Richards equation showed the best performance for *v* growth. The results were consistent with the ones of the other two groups of data (*Table 7*). In general, the Korf and Richards equations have been widely used for forest growth and yield simulation models (Birch, 1999; Li et al., 2000; Malik et al., 2005; Gea-Izquierdo et al., 2008; Rugmini and Jayaraman, 2009; Bontemps and Duplat, 2012; Xu et al., 2014). ONLS regression is commonly used to build forest growth and yield models, but its usefulness is limited because tree data typically violate the assumption of independence and identically distributed errors (West et al., 1984; Grégoire et al., 1995). NLME models are useful tools for analyzing repeated measures data and spatially correlated data (Pinheiro and Bates, 2000; Fang and Bailey, 2001). A model can be constructed with a unique variance-covariance structure that eliminates the influence of random effects (site, plot and tree effects in this study) (Zhu et al., 2019). The two primary challenges in fitting NLME models are determining the mixed parameter and calculating the random effects (Uzoh and Oliver, 2008; Yang et al., 2009; Dumont et al., 2018; Huff et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1540315418

The Richards and Korf equations have been widely used as the base NLME model for modeling forest growth and yield. For example, Fang and Bailey (2001) successfully used a modified Richards equation with an NLME model to build a slash pine (*Pinus elliottii* Engelm.) dominant height growth model. In their study, the Korf equation was chosen as the base model of the NLME model to fit loblolly pine (*Pinus taeda* Linn) *d*-age relationships (Cheng and Gordon, 2012); in that case, the nested three-level individual-tree NLME models (*Eqs. 22–24*) provided the best fit. Parameters *a*, *b*, *c* are the asymptotic values, the values associated with the growth rate of the tree and the values associated with the curve shape of both the Richards and Korf equations, respectively (Zhang and Sun, 2010). Therefore, the random effects (site, plot and tree) mainly influence the growth rate and the maximum value of the tree for *d* and *h* growth, and the maximum value and curve shape for *v* growth.

Table 7. *Performance criteria of each model for the other two groups of data*

Factor	Model	Fitting data			Validation data			Fitting data			Validation data

v	NL	0.0508	0.0573	0.7739	0.0604	0.0340	0.6756	0.0827	0.0561	0.7583	0.0904	0.0572	0.7263
	NLME	0.0055	0.0178	0.9782	0.0095	0.0129	0.9535	0.0049	0.0170	0.9778	0.0084	0.0217	0.9438

Note: *d*, *h*, and *v* are growth models

Sometimes, no prior information is available from which the random parameters can be predicted. In this case, the mixed-effects model with the random parameters set to 0 is not the same as the population average model and will give biased predictions. Instead, the population average model, fit without random effects, should be used.

Conclusions

China-fir trees play an important role in ecological service functions in Fujian Province of southeastern China. In order to estimate accurately the ecological values, five theoretical growth equations were evaluated for estimating the *d*, *h* and *v* growth for China-fir trees grown in monospecific plantations. The equations can be evaluated for both a biological perspective and for statistical meaning. All five equations and the Korf and Richards equations in particular have commonly and successfully been used to model individual-tree growth. A multi-level NLME models based on the Korf and Richards equations, with variance functions and correlation structures, were used to estimate *d*, *h* and *v* growth of individual trees; this approach was necessitated by the hierarchical structure of the experimental design and the autocorrelated increment data. The results showed that the NLME models (*Eqs. 22–24*) with random effects provided a better fit than the other models (*Eqs. 13–15*) (*Table 6*, *Figs. 3 and 4*). For the other two groups of data, the adj-R^2 of the NLME models were more than 0.9 and better than the results of the NLMs (*Table 7*). Therefore, we recommend using a nonlinear mixed-effects model to estimate individual-tree growth and yield models.

Abstract. Wetlands play an important role in conserving water sources, regulating climate, and protecting biodiversity and have extremely high ecological value. However, global natural wetlands are rapidly degrading. Therefore, protecting wetlands is of strategic importance for ensuring ecological and environmental security. Based on the Landsat remote sensing images from 1975 to 2015 and the monthly meteorological data during the same periods, this study analyzed the landscape pattern change and explored the relationship with climate change and wetland change in Xiaoxing'anling, using the methods of landscape ecology and mathematical statistics. The results showed that the degree of landscape fragmentation was unused land < water area < forest land < urban land < cultivated land < wetland and the number of patches had increasing trend. The wetlands were mainly converted into cultivated land and the wetland areas have significantly degraded in the past 40 years in Xiaoxing'anling. The change of landscape diversity had a close correlation with annual precipitation and average summer precipitation. This study provides a theoretical basis for regional wetland protection.
Keywords: *wetland, cumulative anomaly analysis, canonical correlation analysis, Landsat, transfer matrix*

Introduction

Wetlands have a role in regulating water sources, regulating climate, purifying water quality, protecting species and regional ecological security (Zhu and Li, 1996), and significantly affect on economic development, human living environment, and climate change of regionally, and even globally (Liu, 2005). There are many wetlands in Northeast China, but the wetland areas were rapidly declining due to global warming and human activity (Gong et al., 2016). Using remote sensing measures to study wetlands has the advantages of low cost and easy access (Dogan et al., 2009; Lane et al., 2014). The classification methods of wetland include supervised classification, unsupervised classification, object-oriented classification and machine learning classification. Dronova et al. (2011) analyzed wetland classification accuracy by object-oriented and supervised classification methods. Sadeghi et al. (2012) used the support vector machine (SVM) to predict the distribution of invasive water ferns in the Anzhali wetland of Iran.

Wetland landscape has become closely related to many factors such as regional and resource distribution, anti-interference ability, self-recovery and biodiversity, and has become an important research field of landscape ecology (Li and Zeng, 2002). The quantitative method is the main method to study the change of wetland landscape pattern, for example, Fan et al. (2014) analyzed the change characteristics of wetland landscape

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1541915429

patterns in Nansi Lake of Shandong Province from 1982 to 2012 by landscape pattern index. Wang et al. (2012) compared the wetland landscape pattern changes in different time and space scales in the Yellow River Delta in 2000 and 2009 year from the aspects of landscape area change, landscape patch characteristics and overall landscape pattern. Chen et al. (2006) applied the landscape gradient model to analyze the landscape pattern characteristics of the Xianghai Nature Reserve in different periods. Luo et al. (2015) studied the temporal and spatial change of the landscape pattern of the Kazakhstan Delta through cellular automaton (CA)-Markov model.

In the study, using the Landsat remote sensing data with a 30-m resolution of 1975, 1985, 1995, 2005 and 2015 year and the monthly meteorological data, by the landscape ecology and mathematical statistics methods, we analyzed the landscape pattern change in Xiaoxing'anling. Our aim was to find the correlation between landscape pattern change and climate change in Xiaoxing'anling, and reveal the relationship between landscape pattern change and climate change. The study provides scientific theoretical basis and important guiding significance for landscape protection of Xiaoxing'anling wetland.

Materials and Methods

Study area

Xiaoxing'anling lies in the northern part of Heilongjiang Province, where the north and northeast are bounded by the Heilongjiang River, the northwest, the Aihui District of Heihe city and Nenjiang County are connected to Daxinganling, the east is adjacent to the Sanjiang Plain, the southeast is separated from the Zhangguangcai Mountains by the Songhua River Valley, and the southwest is connected to the Nenjiang Plain (*Fig. 1*).

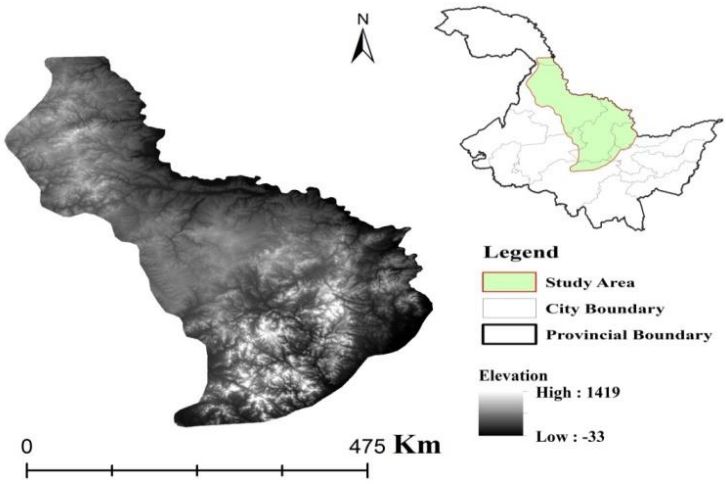

Figure 1. *Location and elevation of the study area*

The geographical coordinates are 45 50' - 51 10'N, 125 20' - 131 20'E (Liu, 2012). The altitude of the mountain range is approximately 500~800 meters, and the individual peaks are above 1000 meters. The average annual precipitation in the study area is approximately 550~700 mm. This area is one of the most concentrated areas of wetland, with abundant wetland types such as forest swamps, shrub swamps, and herb swamps et al. (Liu, 2012).

DOI: http://dx.doi.org/10.15666/aeer/1706_1541915429

Dataset

The Landsat remote sensing data with a 30-m resolution of the study were downloaded from https://glovis.usgs.gov/. The images with less 5% cloud cover from June to August in 1975, 1985, 1995, 2005 and 2015 year were select. Band combination, geometric correction, image mosaic and cropping for every period were completed using ENVI5.1 software. Based on the land use classification standard in China, we collected 1011 training samples from field data (collected using GPS) and classified the land use types as wetland, cultivated land, forest, urban, waters, and unused land using the support vector machine method.

The meteorological data used in the study came from the National Meteorological Information Center (http://www.cma.gov.cn/2011qxfw/2011qsjgx/). We collected the monthly and annual average minimum temperature, average maximum temperature, average temperature, average relative humidity, and precipitation from 1975 to 2015 for in Huma, Aihui, Sunwu, Yichun, Tieli, Hegang, Jiamusi and Yilan eight meteorological stations in Xiaoxing'anling and its surrounding areas.

Methods

Landscape pattern index

The landscape pattern index can quantify the complex landscape pattern and its changing process, condensing its information and reflecting its structure and configuration (Peng, 2006). The landscape pattern index that included the number of plaques (NP), percentage of landscape types (PLAND), aggregation index (AI), largest patch index (LPI), plaque density (PD), perimeter area fractal (PAFRAC), Shannon diversity index (SHDI) and Shannon evenness index (SHEI) were used to reflect the size of patches, the fragmentation, and the diversity of landscapes in the study area (Wang et al., 2017; Du et al., 2018; Wu and Li, 2018). The literature described the above eight landscape pattern indices in detail (Li et al., 2016; Ma et al., 2018).

Moving average method

The moving average method could visually reflect the trend of changes in meteorological sequences and eliminated the effects of sequence fluctuations. In general, a new sequence y_1 was obtained by calculating 2k or 2k+1 continuous averaging in the meteorological sequence $x_1, x_2 \ldots\ldots x_n$. The specific equation was as follows (Xu et al., 2015).

$$y_1 = \frac{1}{2k+1} \sum_{-k}^{k} x_{i+1} \quad \text{(Eq.1)}$$

The trend analysis of the meteorological sequence was calculated using a 5-year moving average in our study (k=2).

Canonical correlation analysis

The canonical correlation analysis was used to analyze the correlation between the two groups of variables. The core idea was that the correlations between (the independent variable group and the standard variable group) were indicated by selecting several representative comprehensive indicators from the two sets of random variables. In the study of landscape pattern change, because different landscape types interact and restrict

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1541915429

each other, the canonical correlation analysis was often used to analyze the relationship between landscape patterns and various natural and socio-economic drivers (Huang, 2010).

Results

Land use transfer matrix

The land use transfer matrix (*Table 1*) from 1975 to 2015 was obtained using the SVM classification method to classify the remote sensing images in the study area in1975, 1985, 1995, 2005 and 2015 year.

From the perspective of transfer, the land use transfer in the study area was that the forest with the area of 10430.13 km^2 was converted into wetland and cultivated land; the wetland with the area of 24706.11 km^2 was converted into forest and cultivated land; the cultivated land with the area of 3175.67 km^2 was converted into forest and wetland from 1975 to 2015. From the perspective of transition, the changes mainly occurred that the water was mainly converted from forest and wetlands with the area of 302.9 km^2; the unused land was mainly converted from wetland, forest and cultivated land with the area of 628.82 km^2; urban was mainly converted from wetland, cultivated land and forest with the area of 1022.02 km^2. In short, the landscape type transfer in Xiaoxing'anling mainly occurred between cultivated land, forest and wetland.

Table 1. *Land use transfer matrix in the study area from 1975 to 2015 (km^2)*

1975 - 2015	water	forest	unused land	urban	wetland	cultivated land
water	395.30	146.05	3.68	25.23	156.40	58.67
forest	72.48	44261.30	53.00	83.76	13713.55	2164.02
unused land	13.78	139.10	6.58	14.70	388.56	101.16
urban	27.02	296.31	10.37	138.20	417.00	309.02
wetland	59.67	5478.66	25.30	65.74	9121.86	1011.65
cultivated land	74.23	4951.47	83.12	270.72	10992.56	4030.91

Landscape pattern change analysis

The Landscape pattern index at plaque type level (*Table 2*) and Landscape pattern index on landscape level (*Table 3*) in Xiaoxing'anling from 1975 to 2015 year were calculated by Fragstats software.

The number of plaques (NP) increasing and the aggregation index (AI) decreasing from 90.53% to 84.13% indicated that the number of plaques increased continuously, and the landscape became more and more fragmented in Xiaoxing'anling from1975 to 2015. At the landscape level, the largest plaque index (LPI) in Xiaoxing'anling decreased from 48.94% to 16.79% from 1975 to 2015, indicating that the maximum plaque area was declined, and the landscape dominance decreases with the decrease of the total area of the landscape. The diversity index in the study area has increased year by year, and the growth trend of uniformity index is consistent with the decreasing trend of landscape dominance difference, indicating that the distribution of landscape elements tends to be balanced. The perimeter area fractal (PAFRAC) first increased and then decreased and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1541915429

the fractal dimension was the largest in 1985 year, indicating that the shape of the plaque in the study area was closer to the square since 1985. It could be inferred that the study area had been disturbed by humans, and was still moving in the direction of increased interference.

Table 2. *The landscape pattern index at plaque type level in study area from 1975 to 2015*

year	Land use type	Plaque type level landscape pattern index

Climate change analysis

The climatic characteristics were represented by the annual climatic data of the eight meteorological stations for 40 years. The climate change trend was shown in *Fig. 2*. The annual relative humidity in Xiaoxing'anling was decreasing and annual decrease rate was 0.0174%. The annual precipitation in Xiaoxing'anling showed an increase trend with the rate 1.59 mm and passed 0.1. significance level test ($p < 0.1$).

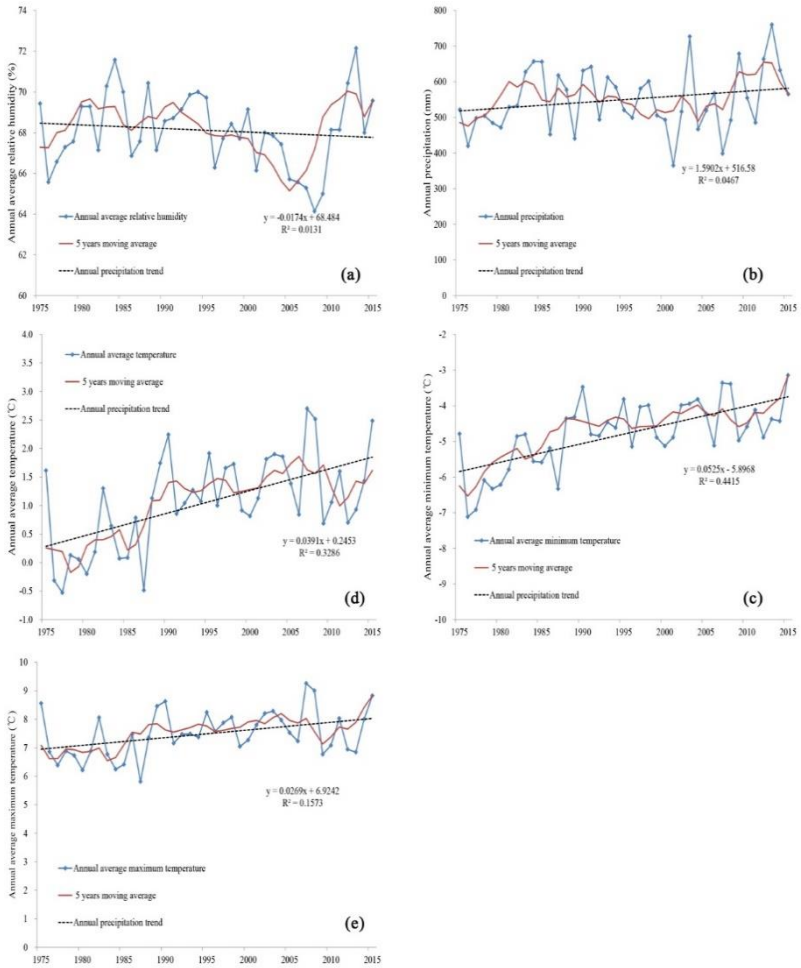

Figure 2. *Climate trend analyzing in Xiaoxing'anling from 1975 to 2015*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1541915429

The trends of annual average temperature, annual average minimum temperature and annual average maximum temperature in Xiaoxing'anling had increased, and the increasing rates were 0.39℃/10a, 0.525℃/10a and 0.27℃/10a, respectively, which passed 0.05 significance level test ($p < 0.05$). The annual warming trend of the study area was synchronized with the background of continuous warming since the 1950s in the Northeast, and the growth rate of the annual average minimum temperature was higher than the annual average maximum temperature and the annual average temperature, so the temperature was more affected by the increase in the annual average minimum temperature.

By monthly data, the average temperature and precipitation data of spring (March-May), summer (June-August), autumn (September-November) and winter (December-February) are counted. 5 years moving average seasonal and annual climatic factors were obtained in *Fig. 3*.

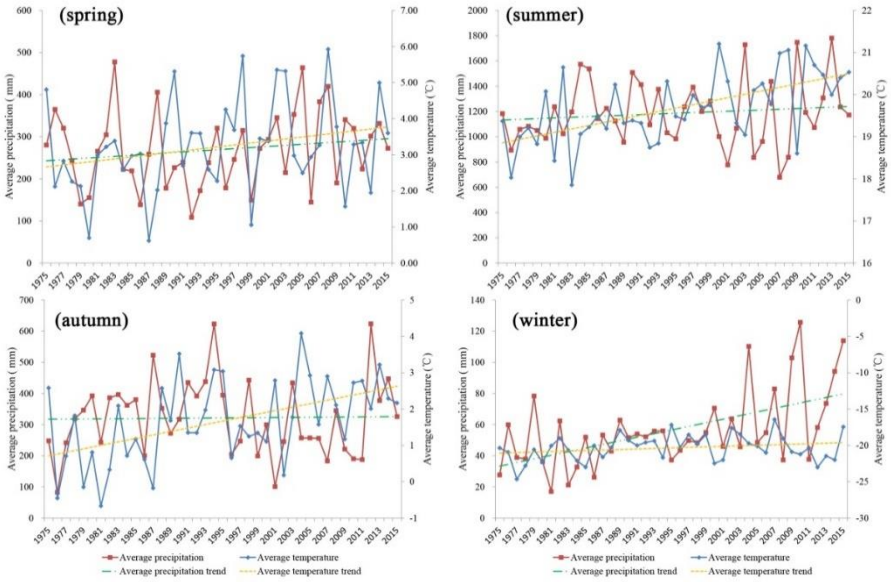

Figure 3. *Climatic trend in each quarter from 1975 to 2015*

From 1975 to 2015, the temperature and precipitation in the Xiaoxing'anling showed an upward trend, and the increase rates of the temperature from spring to winter were 0.28/10a, 0.41℃/10a, 0.48℃/10a and 0.35℃/10a, respectively. In addition, the average temperature in summer and autumn passed the 0.05 significance level test ($p < 0.05$). The change rates of precipitation from spring to winter were 13.09 mm/10a, 26.45 mm/10a, 18.9 mm/10a and 15.96 mm/10a, respectively. Although the seasonal precipitation was on the rise, only the precipitation trend passed the 0.05 significance level ($p < 0.05$) in winter.

Response relationship between climate change and wetland landscape pattern change

According to the basic data and our research purpose, the analysis results with confidence greater than 95% ($p < 0.05$) were used for all correlation coefficients. The canonical correlation analysis result of wetlands was shown in *Table 4*. There was a typical correlation coefficient of 0.881, and the statistical test reached a significant level,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1541915429

so the first pair of typical variables was selected for analysis. According to *Fig. 4*, the first linear combination (canonical) of the climatic factor variables was x2 (annual precipitation) and x9 (summer average precipitation), and canonical variables for maximum correlation were y1 (NP) and y5 (PD). There was a close correlation between the annual precipitation and the average summer precipitation and the wetland landscape fragmentation index. From 1975 to 1985 year, the annual precipitation decreased first and then increased, the wetland areas decreased and the change was the smallest in the five periods. However, from 1995 to 2005 year, the annual precipitation decreased continuously, the wetland areas decreased and the landscape fragmentation increased sharply. It was concluded that due to the change of annual precipitation, it was likely to cause changes in the wetland areas at the same time and thus the change of landscape fragmentation.

Table 4. *Canonical correlation coefficient*

Typical variables	Canonical Correlations	Chi-SQ	DF	Sig
1	0.881	111.088	65.000	0.000
2	0.791	65.337	48.000	0.249
3	0.709	35.326	33.000	0.359

Discussion

Previous studies showed that climate change and the human activities played a key role in the fragmentation of wetland landscapes (Xiao et al., 2010; Hu et al., 2015; Cong et al., 2019). Our findings are similar to the above studies. From 1975 to 2015, the areas of forest and wetland accounted for the largest proportion and they were the type of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1541915429

substrate landscape in Xiaoxing'anling. However, the proportion of cultivated land and urban was gradually increasing, indicating that the wetland degradation trend in Xiaoxing'anling was obvious. The wetland change in Xiaoxing'anling was consistent with the shrinking trend of wetland in Northeast China (Gao et al., 2018; Yu et al., 2018). The landscape type transfer in Xiaoxing'anling mainly occurred between cultivated land, forest and wetland. At the plaque level, the wetland landscape dominance continued to decline significantly from 1975 to 2015, the dominant degree of forest land decreased first and then increased, and the dominance of cultivated land gradually increased. The overall dominance trend of each landscape type tended to balance development; the landscape fragmentation degree of Xiaoxing'anling was ranked as unused land < water area < forest land < urban land < cultivated land < wetland.

At the landscape level, the NP value had increased year by year from 1975 to 2015, and the number of patches in Xiaoxing'anling has been increasing, indicating the landscape of the whole study area has become more and more fragmented. The AI and the largest plaque index (LPI) decreased from 90.53 % to 84.13% and from 48.94% to 16.79% during 1975 - 2015 year respectively, indicating the diversity index increasing. The fractal dimension was the largest in 1985, indicating that the study area was interfered with human activities and the interference had been larger and stronger since 1985.

In the past 40 years, the annual minimum temperature, annual maximum temperature and annual average temperature in Xiaoxing'anling had increased significantly. The wetlands in the study area were significantly correlated with annual precipitation and average summer precipitation. The landscape level had the greatest correlation with climate change factors. Typical variables were PAFRAC and SHEI. The change of landscape diversity of Xiaoxing'anling wetland had a close correlation with annual precipitation and average summer precipitation.

Conclusions

Based on Landsat images and meteorological data, using landscape ecology and mathematical statistics methods, the changes of landscape pattern of wetland and response of climate change on landscape pattern change in Xiaoxing'anling were analyzed. The results showed that substrate landscapes in Xiaoxing'anling were forest and wetland, but the proportion of cultivated and urban was gradually increasing; the landscape type transfer in Xiaoxing'anling mainly occurred between cultivated land, forest and wetland; and the wetland degradation trend was obvious. The landscape fragmentation ranking was unused land < water area < forest land < urban land < cultivated land < wetland. At the landscapelevel, the number of patches and diversity index in Xiaoxing'anling were increasing year by year. The wetlands in the study area were significantly correlated with annual precipitation and average summer precipitation. The landscape level had the greatest correlation with climate change factors. The canonical variables were PAFRAC and SHEI. The change of landscape diversity of Xiaoxing'anling had a close correlation with annual precipitation and average summer precipitation. This paper revealed the response of landscape pattern change to climate change macroscopically from 1975 to 2015 in Xiaoxing'anling. We will furtherly research the driving mechanism of landscape pattern change in the future, and provide scientific basis for wetland planning and protection.

Abstract. The objective of this work was to evaluate the effect of different canopy management practices on canopy microclimate and consequently berry quality components of the Merlot (*Vitis vinifera* L.) grape variety. Different microclimate effects were created by the limitations of 1 m, 1.25 m and 1.5 m main shoot lengths and full lateral shoots (FLS), half lateral shoots (HLS) and no lateral shoots (NLS). Microclimatic data was gathered by the sensors placed in the canopies of FLS, HLS and NLS vines located under the 1.25 m main shoot length parcel. In the study, total soluble solids content, titratable acidity, pH, total phenolic content, total anthocyanin content, total tannin content, tartaric and malic acid content and potassium content in the juice were evaluated as the biochemical quality properties. The results of two years indicated that canopy microclimate arrangements may provide some manipulation on grape berry quality according to the vegetation period's climate characteristics and the desired target quality within limits of macro-meso climate effects.
Keywords: *canopy management, summer pruning, phenolic content, anthocyanins, must quality*

Introduction

Canopy management applications may have some adverse affects on the physiological properties of the vine as a result of the isolation of vine-canopy microclimate from environmental factors, such as temperature, light exposure, atmospheric humidity and air flow when they are not considered as serious cultivation practices. As the green pruning is not performed according to a methodology, appropriate to the characteristics of the vegetation period, the production/consumption balance may deteriorate in the physiological sense. Exposure of clusters to direct sunlight can also cause physical damage and deterioration of the chemical structure of the berries under high temperatures.

There is an important amount of knowledge about the relationship between microclimate parameters and quality components. Temperature is the main factor controlling growth and quality. Improvements in criteria such as total phenolic, anthocyanin content, main components of sensory characteristics of wines, aroma, color and taste can be seen at certain stress levels (Matthews et al., 1990). Similarly, the positive effects of polyphenol components and antioxidant activity on human health can be increased (German and Walzem, 2000; Dixon et al., 2005). However, high evaporative demand during high temperature periods and growing period may play a role in limiting yield, berry wine quality (Escalona et al., 1999; Chaves et al., 2007). This can lead to wine acidity problems by reducing the coloration and sugar accumulation of the berry (Medrano et al., 2003; Romero et al., 2010). In addition, under the total intertwined impact of environmental stress factors, instant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1543115446

photosynthesis reduction and risky losses in total carbon assimilation and even total canopy area may occur (Flexas et al., 1998, 2002; Maroco et al., 2002; Santos et al., 2007). The effect of light exposure on the vine (often not easily separated from temperature) is observed in physiological activities, shoot development and wooding, berry formation, fall, ripening processes and quality (Reynolds et al., 1986; Crippen and Morrison, 1986; Rojas-Lara and Morrison, 1989; Schubert et al., 1996; Haselgrove et al., 2000; Bertamini and Nedunchezhian, 2003; Spayd et al., 2011; Profio et al., 2011).

The effects of the climate crisis that are going on beyond the traditional interaction between viticulture and climate are also discussed by researchers in a multi-dimensional context (Schultz, 2000; Nemani et al., 2001; Jones, 2007; Webb et al., 2008; Fraga et al., 2012; Vrsic and Vodovnik, 2012; Donat et al., 2013). As climate change is inevitable (Carbonneau and Bahar, 2009), different canopy management practices are an important tool for managing and adapting this process (This et al., 2006; Olsen et al., 2011). Canopy microclimate arrangements may provide some manipulation on grape berry and wine quality within limits of macro-meso climate affects and climate crisis.

There is a close relationship between the quality of grapes and wine and the composition of the berries. Therefore, quality depends on many components such as grape varieties, total soluble solids (TSS), organic acids, pH, phenolic substances, the thickness of the berry skin, the berry skin area, the ratio of the skin area/berry volume, the effect of ecological conditions, maturity time, the effect of diseases, rootstock and canopy management (Ribéreau-Gayon et al., 2000; Blouin and Guimberteau, 2000; Keller, 2010; Treutter, 2010).

The aim of the present study was to provide a better understanding of the effect of different canopy management practices on canopy microclimate and consequently berry quality components.

Materials and methods

Location, plant material and trial design

The two-year study (2014 and 2015) was conducted at the Tekirdağ Viticulture Research Institute, located in Northwest of Turkey (in Thrace), within the coordinates 40.969184°N-40.973562°N latitudes and 27.461911°E-27.477504°E. longitudes. The climate of Tekirdağ, is defined as a transitional climate among the Continental climate, the Black Sea climate and the Mediterranean climate with an average annual temperature of 14 °C, annual precipitation of 581.80 mm and 1887.00 growing day-degree Winkler Index for the years of 1939-2017 period. The altitude of vineyard was approximately 36 m and was approximately 4 km away from the sea. Merlot/5BB grafting combination 12-13 years old vines were oriented North-South on a high groundwater and clay-loam soil. Vines were arranged in a between-row and within-row spacing of 2.5 × 1.5 m respectively. Double Guyot training vines pruned 16-18 bud per vine.

Different microclimate effects were created by the limitations of 1 m, 1.25 m and 1.5 m main shoot lengths while they reached 170-180 cm (EL 31-33) shoot lengths for main parcels. Lateral shoot applications were sub-parcels which created by full lateral shoots (6-7 leaves), half lateral shoots (3-4 leaves) and no lateral shoots (no leaf) performed in verasion (EL 35) according to Lorenz et al. (1995). Both applications were kept at the same length until the harvest period.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1543115446

Data was gathered from meteorological stations located in Tekirdag Viticulture Research Institute in order to determine mesoclimatic and microclimatic conditions. A climate station which located 2 m high from ground was used to collect mesoclimatic data reflecting the general climatic characteristics of the vineyard. Mesoclimatic measurements; temperature, relative humidity, light intensity, wind speed, total precipitation and microclimatic measurements from the insides of the vine canopies which were the descriptive features such as temperature, relative humidity, light intensity, wind speed and leaf wetness were monitored during the years 2014 and 2015.

Microclimatic data sensors were placed in the canopies of full lateral shoot (FLS, 6-7 leaves), half lateral shoot (HLS, 3-4 leaves) and no lateral shoot (NLS) sub-parcel vines that located under 1.25 m main shoot length main parcel, from the beginning of the vegetation period and measurements were continued until the end of harvest by SHT11 Temperature, humidity and leaf wetness sensor module (Sensirion AG, Switzerland) for temperature, humidity and leaf wetness. TEMT 6000 light sensor (Vishay Intertechnology, Inc., Germany) and WGR800 wind sensor (Oregon scientific, USA) readings were gathered by a cloud based datalogger (Mrme AR-GE Bilişim, Turkey). The 5 min averages of two-second readings from each sensor derived as the station's hourly value.

The inside of the three canopies were equipped with one temperature, humidity, leaf wetness, wind and four light intensity sensors (*Fig. 1*). Also light intensity sensors positioned two each around cluster zone and center canopy. The wind sensor in the canopy is enclosed in a suitably sized wireframe that does not stop the wind flow to prevent contact with leaves and shoots. Maintenance and control of the sensors placed inside vines were done regularly to avoid any data loses after cultivation practices such as spraying, green pruning etc.

Figure 1. *Placing of different sensors and loggers in vineyard (a) main electric and GSM unity, (b) cloud based datalogger, (c) wind sensor, (d) temperature, humidity, leaf wetness, (e) light sensor*

Although the data received from all of the above sensors for all growing process, only outputs of temperature and light intensity effects between verasion-harvest period are evaluated in this publication due to the important effects on must composition.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1543115446

Despite the equal number of (16) buds left in the winter pruning, the plants that disrupt homogeneity in the number of shoots and bunches were balanced when the shoots reached an average length of 30-40 cm (EL 15-17) or excluded from the trial. Standard cultural practices in the region were applied to all treatments during research. The vines data taken were selected from the same development period and with the approximate charge and those without spaces.

Must composition

The total soluble solids (%), pH, total acidity (g/L of tartaric acid), and the concentration of tartaric acid (g/L), malic acid (g/L) and potassium (mg/L) in must from grapes collected from each experimental replication at the harvest date was determined using the official methods of the Organisation Internationale de la Vigne et du Vin (OIV) (OIV, 2012). Also, total phenolic content (mg/kg), total anthocyanin content (mg/kg) and total tannin content (g/kg) were found out as biochemical analysis (AOAC, 1998; Waterhouse, 2002).

Statistical analysis

The experiment consisted with combination of 3 different main shoot length and 3 different lateral shoot length applications. A randomized block design was used with 3 replications of a total of 108 vines under 27 parcels. JMP 13.2.0 statistical program was used for determining of differences in applications and years. In order to determine differences in findings, LSD test was used at 5% significance level.

Results and discussion

Phenological development stages

As a result of the phenological observations made throughout the trial, the day green shoot tips seen clearly in the buds was 02.04.2014 (91st calendar day) for the year 2014, for 2015 it was observed as 12.04.2015 (101st calendar day) (*Table 1*).

Table 1. *Phenological development stages of Merlot variety during the experiment years*

Budburst (EL 04-07)	Flowering (EL 23-25)	Verasion (EL 35)	Harvest (EL 38)
02.04.2014	29.05.2014	30.07.2014	16.09.2014
12.04.2015	28.05.2015	01.08.2015	05.10.2015

Climatic conditions

General climatic conditions of 2014-2015 years'

While the average temperature was recorded as 16.08 °C in 2014 and 16.00 °C in 2015, the average temperature in Tekirdağ province for long years (1939-2017) was 14 °C. 2014 was an extraordinary year in terms of precipitation. The annual total precipitation was 770.50 mm, which is significantly higher than the average of 589.10 mm for long years. Vegetation period precipitation was also remarkable with 475.20 mm which is also above 139.00 mm average of long years. In 2015, the total annual precipitation was 507.90 mm and 187.40 mm precipitation in the vegetation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1543115446

period is around the average for long years. Due to the general characteristics of 2014, light exposure (PFD) and wind speed were lower than 2015 in 2014 both during the year and vegetation period. Average proportional humidity was also higher for year and vegetation period in 2014.

In 2014, the maximum temperature was measured as 33.50 °C, while the lowest temperature was recorded as 16.10 °C. Also verasion-harvest periot average temperature ranged from 22.00 to 27.60 °C. The light intensity (PFD) ranged between 62.53 µmol m²/s and 1976.27 µmol m²/sec, with an average of 1134.53 µmol m²/s in 2014.

In 2015, the highest temperature was recorded as 39.70 °C and the lowest temperature was 12.30 °C and the average temperature was between 14.30 and 29.00 °C. In the same period, while PFD measurements ranged from 44.37 µmol m²/s to 1894.88 µmol m²/sec, the average period was recorded as 1042.43 µmol m²/s (*Fig. 2*).

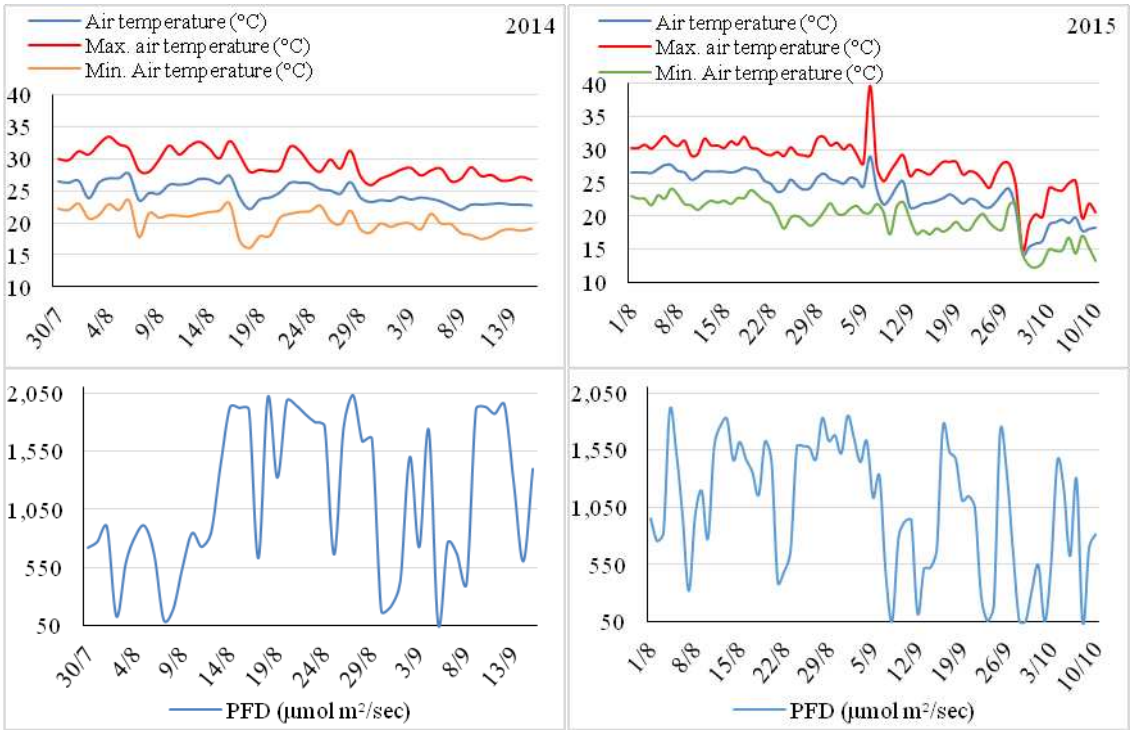

Figure 2. *General temperature and light intensity data of verasion-harvest period in year 2014 and 2015*

Microclimatic conditions inside canopies between verasion and harvest period

Temperature related microclimatic assessments were made for 5 critical intervals per hours/day in terms of the duration of exposure for lateral shoot applications. In addition, the average, lowest and highest temperatures in the related phenological periods were determined.

All lateral shoot leaf removal applications were completed in the first week of August in both years and targeted canopy architectures were created. The most remarkable issue in terms of temperatures for 2014, while the highest temperature in the whole of the vineyard was recorded as 30.10 °C in August and 27.70 °C in August-September mean, the temperature of the canopy was exposed to temperatures in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1543115446

range of 30-35 °C and over 35 °C in all lateral shoot applications. It is noteworthy that temperatures below 20 °C in 2015 are 3-4 times more than in 2014. In both years; temperatures above 35 °C were observed in the NLS application for the longest period, while the temperature above 30 °C was measured at the maximum HLS application. It was observed that in the period between verasion and harvest; most seen temperature range was between 20 and 25 °C in 2014 and 2015. Another remarkable point is that the FLS application remains the longest at temperatures below 20 °C. Temperatures above 35 °C were observed for longer periods with the removal of the lateral leaves (*Table 2*). The positive and negative aspects of this phenomenon will be mentioned in the headings on must analytical analysis.

Table 2. *Verasion-harvest period temperature intervals in canopy (hours/day)*

Verasion-harvest period	≤20 °C		20-25 °C		25-30 °C		30-35 °C		≥35 °C	
	2014	2015	2014	2015	2014	2015	2014	2015	2014	2015
NLS	2.45	6.18	9.34	8.14	3.44	3.19	4.34	3.43	3.23	2.25
HLS	2.36	5.49	8.55	6.49	3.53	4.20	8.1	5.51	0.27	1.11
FLS	2.53	8.29	7.41	6.15	4.47	5.11	6.39	3.20	0.16	0.43

NLS, HLS, and FLS represent no lateral shoots (no leaf), half lateral shoots (3-4 leaves) full lateral shoots (6-7 leaves)

While the mean temperature in the canopy ranged between 26.16 and 26.92 °C in of 2014 verasion-harvest period, the average outside canopy temperature at 2 m was recorded as 23.02 °C. In 2015 verasion-harvest period in canopy mean temperature was changed between 23.36 and 25.26 °C and average temperature at 2 m outside canopy was recorded as 24.40 °C.

During the same period in 2014, the highest average temperature was 27.70 °C at 2 m, while the maximum high temperature was 46.06 °C (NLS) and the lowest high temperature was 37.80 °C (HLS). The highest average temperature was 35.90 °C at 2 m and in canopy measurement was found 49.77 °C for NLS application and 42.77 °C for HLS application in 2015.

In canopy low temperature averages range between 14.46 °C and 15.70 °C and 2 m was recorded as 18.70 °C in year of 2014. Two meters low temperature averages were also recorded as 15.40 °C in 2015, and ranged between 5.12 °C (NLS) and 11.18 °C (FLS) in canopy (*Table 3*).

In both years, outside canopy low temperatures are higher than in canopy low temperatures. Cold weather is trapped inside the canopy at night. In summary, there are no significant differences between the inside and outside of the canopy in terms of average temperatures, but dramatic differences can be observed at low and high temperatures. In the case of high temperatures, it is observed that in canopy temperatures have increased by 18.36 °C for 2014 and 13.87 °C in 2015 for the NLS application due to loss of shade effect created by lateral shoot leaves.

Light intensity averages based on phenological periods

The light intensity measurements were evaluated by calculating the mean data from the canopy microclimates and the data mean obtained from the overall vineyard according to phenological periods.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1543115446

In 2014 Verasion-harvest period NLS, HLS and FLS applications were measured as 51.29 µmol m²/sec, 45.75 µmol m²/s and 30.30 µmol m²/sec, respectively and the outside canopy light at 2 m level was recorded as 1155.14 µmol m²/s (*Table 4*). In this period, it was seen that the total light intensity that reached to the whole of the vineyard could only reach the canopy center and clusters in 4.44% NLS application, 3.96% in HLS application and 2.62% in FLS application (*Fig. 3*).

Table 3. *In and outside canopy temperature averages according to the applications between the periods of verasion-harvest in 2014 and 2015 (°C)*

Verasion-harvest period	Max. temperature (°C)		Mean temperature (°C)		Min. temperature (°C)	
	2014	2015	2014	2015	2014	2015
NLS	46.06	49.77	26.92	24.83	15.70	5.12
HLS	37.80	42.77	26.42	25.26	15.58	10.36
FLS	41.91	43.33	26.16	23.36	14.46	11.18
Outside canopy 2 m.	27.70	35.90	23.02	24.40	18.70	15.40

NLS, HLS, and FLS represent no lateral shoots (no leaf), half lateral shoots (3-4 leaves) full lateral shoots (6-7 leaves)

Table 4. *In and outside canopy light intensity averages according to the applications between the periods of verasion-harvest in 2014 and 2015 (µmol m²/s)*

Verasion-harvest period	2014	2015
NLS	51.29	28.71
HLS	45.75	21.43
FLS	30.30	23.05
Outside canopy 2 m.	1155.14	1068.69

NLS, HLS, and FLS represent no lateral shoots (no leaf), half lateral shoots (3-4 leaves) full lateral shoots (6-7 leaves)

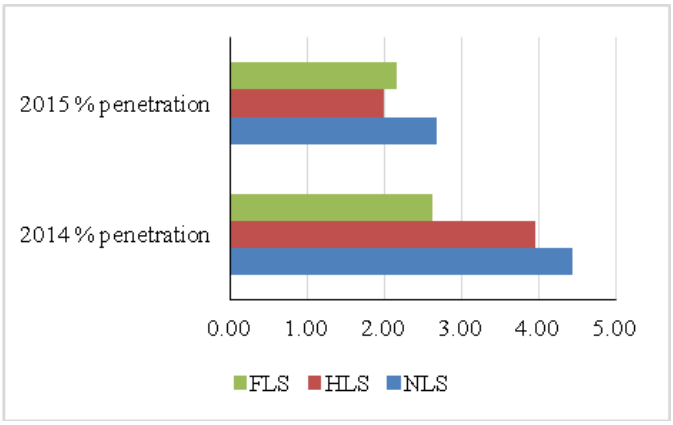

Figure 3. *Penetration percentage of light into the canopy from outside in version-harvest period in years' 2014 and 2015*

Although 2015 was a year with a higher number of cloudless skies compared to the previous year, the late harvest date led to a decrease in the overall average light

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1543115446

intensity across the vineyard. Thus, the average light intensity of the outside canopy at 2 m was measured as 1068.69 µmol m²/s while the application of NLS was 28.71 µmol m²/s, HLS application was 21.43 µmol m²/s and FLS application was 23.05 µmol m²/s. The penetration rates into the canopy were calculated as 2.19% for NLS application, 2.01% for HLS application and 2.16% for FLS application (*Fig. 3*). In addition, the damage to the leaves and the relative reduction in total leaf area due to the severe *Plasmopara viticola* outbreak in 2014 may have resulted in higher light penetration into the canopy this year. Although not statistically significant, this phenomenon is supported by the decrease in yield and the increase in anthocyanin amounts this year.

Although these values appear to be very low, Smart et al. (1990) stated that approximately only 6% of the intense light from the sun is absorbed by the leaf, and that when the intense canopy formation is seen in the grapevine, the light penetration into the canopy is very low and only 1% of the upper leaves are able to be illuminated. Escalona et al. (2003) also have obtained similar results in double-cordon trained Monte Negro grapes from measurements of outer and inner surfaces of canopies. On the other hand, in Taiz and Zeiger (2010), indicated that only 5% of the total energy presence was used in carbohydrate production while explaining the process of converting solar energy into leaves by carbohydrates.

Must analytical analyzes

Yield (kg per vine)

As stated before, in both years, 16 buds per vine were left in winter prunings, and shoots and clusters were equalized when the shoots reached 30-40 cm in length. Thus, the differences between the yield values were not statistically significant. Yield values were seen the lowest for NLS application with 4.60 kg/vine and highest for FLS application with 5.00 kg/vine.

Total soluble solids (%)

As known, the amount of sugar in the berry is one of the most important components of industrial maturity. While the effects of lateral shoot applications were found to be statistically significant in both years, differences in main shoot practices were found to be insignificant in terms of TSS values. In the average of two years, 1.25 m main shoot length application reached 21.88% highest TSS quantity while FLS application remained at 21.67%. Differences in years averages were insignificant (*Table 5*).

It is observed that the application of NLS in water-soluble dry matter gives different results in both years. In 2014, the extreme rainfall and high proportional moisture occurring during the vegetation period affected the physiological activity positively in the application of full-fledged seat shoot and accelerated the availability of photosynthesis and hence the accumulation of dry matter throughout the vine. Under the relatively hot and dry conditions of 2015, the microclimate, in which the NLS application was affected, in particular in terms of high temperatures, slowed down the accumulation of TSS.

Therefore, it can be seen that the manipulations made at the right time and in the right way on the canopies provide options for the struggle against the negativity caused by the general climate characteristics.

Total acidity (g/L)

The effects of different main and lateral shoot applications on total acidity were found to be statistically significant in 2014 and for the mean of two years in terms of lateral shoot applications, whereas in 2015 the differences were not significant. At the two-year average, the HLS and FLS applications were in the same statistical class with higher values, while the NLS application created another statistical class with lower total acidity (*Table 5*).

Table 5. *Effects of main shoot and lateral shoot treatments on total soluble solids, total acidity and pH*

Treatments	2014			2015			Mean of years

NLS, HLS, and FLS represent no lateral shoots (no leaf), half lateral shoots (3-4 leaves) full lateral shoots (6-7 leaves). MSME means main shoot main effect, LSME means lateral shoot main effect and YME means year main effect. Different lowercase superscript letters in same column and uppercase letters in same line represent statistically significant differences between means at $p < 0.05$ according to least significant difference test. n.s. means not significant

The most significant relationship between temperature and berry quality appears by reduction of organic acid concentration in berry with high temperatures (Kliewer, 1973).

Tartaric and malic acids are the predominant organic acids which are effective in all stages of berry development and cause significant effects on acidity and pH (Morris et al., 1983). In particular, the malate is stored in berries until the verasion period as a potential source for the carbon demand in the maturation process (Ruffner, 1982). In this period, the decrease in malic acid decreases the total acidity and balances the sugar and acid ratios (Kliewer, 1965). The decrease in titratable acid levels for 2014 and 2015 was directly proportional to the daily exposure time at temperatures between 20-25 °C. At temperatures near 30 °C, seems to reduce the consumption of malic acid by inhibiting photosynthesis. Sweetman et al. (2014) states that enzymes and metabolic pathways that are effective in regulating organic acids during berry growth and development should be further investigated, especially in temperature rise and day/night temperature changes. On the other hand, the increase in the main shoot length caused an increase in titratable acid in years. According to a different study in the same location; Although it is not statistically significant, the main shoot length increase leads to a decrease in total acidity (Yasasin et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1543115446

pH

Ph values were found to be very close among the applications in 2015. In 2014 and the average of years, the NLS application reached the highest values and created a different statistical class. Thus, it can be said that in the years of unusual precipitation in vegetation period such as 2014, lateral shoot applications made a difference (*Table 5*).

Total anthocyanin (mg/kg)

When total anthocyanin contents of grape varieties were examined, it was determined that the highest mean of total anthocyanin content was obtained from NLS application in 2014 (*Table 6*). The amount of high anthocyanin in the lateral shoot applications in both years between verasion harvest period was observed to be proportional to the time spent in 20-25 °C temperature range. But similar relationships were not determined at temperatures above 30 °C as found by Kliewer (1970), Kataoka et al. (1984), Mori et al. (2004), Tomana et al. (1979) or in Yamane et al. (2006) for the night temperatures below 20 °C. Maybe, the lower number of berries in cluster, lower berry fresh weights and lower leaves of pH and factors like higher skin/flesh ratio and acidity in 2014 (data not shown) may have appeared as more important factors than temperature and rainfall.

In our study, it is seen that the increasing stress tendency caused higher anthocyanin levels in mean of years with increasing main shoot lengths, but not statistically. According to Yasasin et al. (2018), although it is not statistically significant, the total amount of anthocyanin in the main shoot length of 1.5 m is higher than the 1 m main shoot length.

Observing the direct effects of canopy management practices on the total amount of anthocyanins is quite difficult, as the mechanisms affecting the synthesis, deposition and degradation of anthocyanin are related to a number of factors. However, it is possible to influence the amount of anthocyanins by specific applications selected according to the prescribed climatic characteristics.

Total tannin (g/kg)

In terms of tannins, there was no significant relationship between lateral and main shoot length applications and total tannin amount except for the different climatic characteristics of the two years (*Table 6*).

Total phenolic (mg/kg)

The statistical significance differences between the applications for phenolic substances were only seen in 2014. The highest phenolic substance content was found in the application of NLS (*Table 6*). Roby et al. (2004) and Chacon et al. (2009) reported that increased water stress increases the total phenolic content. In our study, it is seen that the relationship with the increased main shoot length did not significantly affect the total phenolic substance on the basis of years or years. However, it should be kept in mind that water stress did not occur at the levels that can be considered significant in the years when the trial was conducted. The increase in light intensity level and the relative increase in photosynthesis rates due to the removal of all lateral leaves under the effect of the climate conditions of 2014 is thought to have led to this increase.

Tartaric acid (g/L)

It was observed that different lateral shoot length and main shoot length applications did not significantly affect the amount of tartaric acid in grape berries in 2014 and 2015. However, in the rainy 2014 year, the year main effect of tartaric acid was found to be 6.28 g/L, whereas in it was found lower and statistically significant with 4.28 g/L. the drier and warmer 2015 (*Table 7*).

Malic acid (g/L)

Significant differences were found in malic acid amount in lateral shoot practices in 2015. While HLS application reached the highest amount of malic acid with 1.30 g/L,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1543115446

NLS application was measured as 1.01 g/L and FLS application was measured as 0.82 g/L and they produced different statistic classes. In 2014, no significant differences were found between the practices. As the main effect of the year, in 2015, as in tartaric acid, lower amounts of malic acid were detected (*Table 7*).

Potassium (mg/L)

One of the prominent features in the determination of maturity is the accumulation of potassium in the skin in parallel with the accumulation of sugar in berry flesh. Although it is one of the most important mineral substances in berry composition, very high potassium levels may decrease quality and may have a negative effect on wine quality especially in red wines (Davies et al., 2006).

It also plays an important role in the rapid phase of the cell division during the first stage of berry development due to the potent role in osmotic regulation. Potassium levels during berry development can be affected by many external factors such as soil, grape variety and cultivation practices (Mpelasoka et al., 2003).

However, although potassium levels were not significantly affected by different main shoot and lateral shoot applications, it was observed that higher potassium accumulation occurred in berries in 2014, when precipitation occurred above normal conditions. However, potassium levels were within the expected values in both years (*Table 7*).

Conclusion

As a result, Merlot/5BB combination vines are affected positively in terms of physiological activities and quality criteria when the lateral shoots are kept with 3-4 leaves from the verasion to the harvest in hot years like 2015 (187.40 mm precipitation, 73.43% relative humidity, 1243.56 µmol m²/s light intensity) when rainfall and proportional humidity are relatively low in vegetation period. It is recommended that the lateral shoots should be completely removed during verasion to harvest period, in cool years like 2014 (475.20 mm precipitation, 77.53% relative humidity, 790.31 µmol m²/s light intensity) when vegetation period has high rainfall and proportional humidity and low light intensity.

In terms of main shoot lengths, as the shoot length increases, stress and some quality criteria tend to increase, but these effects are generally not statistically significant. Even when the main shoot length is kept at 1 m, leaf area can reach a sufficient level in terms of yield and quality.

It is considered that future studies should be carried out with modeling studies related to clustermicroclimate, especially with regard to lighting and wind movements within the canopy. In addition, it is considered necessary to transfer green pruning applications to mechanization in practical terms.

Acknowledgements. This study is based on a part of the doctoral thesis of the corresponding author and supported by Republic of Turkey Ministry of Agriculture and Forestry General Directorate of Agricultural Research and Policies with the project number TAGEM/BBAD/2013/A08/P04-08.

(Received 16th Jul 2019; accepted 15th Nov 2019)

Abstract. Determining the genotypic effect on yield and fiber quality of cotton grown especially as a second crop is an important production strategy in some regions. The aim of this study was to determine the effects of different planting dates on cotton grown as second crop under the ecological conditions of the Harran Plain in Sanliurfa Turkey. The experiment was conducted on the experimental area of Agricultural Faculty of Harran University at Eyyubiye Campus in 2014 and 2015 growing seasons. Seeds of cotton cultivars were sown at different sowing dates with the randomized complete block design using split plot experimental design with three replications. Sowing dates (1th of June, 10th of June and 20th of June) were arranged as main plots and four cotton (Stoneville 468, BA 119, DP 499 and PG 2018) varieties were distributed to sub plots size of 2.8 m x 10 m and row spacing and intra-row spacing of 70 cm and 15 cm, respectively. Results indicated that seed cotton yields varied between 1440 kg ha^{-1} and 4560 kg ha^{-1} in this study and that the most suitable planting date was June 1st to June 10th. As the planting dates delayed, seed cotton yield, number of bolls per plant and seed cotton weight per boll decreased while number of days from sowing to first boll opening, plant height and fiber fineness increased. Sowing dates were not significantly different concerning number of sympodia, seed index, ginning outturn, fiber length, fiber strength and fiber uniformity. Cultivars Stoneville 468, BA 119, DP 499 and PG 2018 had preferable seed cotton yields compared to the other ones.
Keywords: *cotton, planting time, cultivars, yield, fiber quality*

Introduction and literature review

Among the industrial crops, cotton has the highest planting area and production value and has an important place in Turkish exports. Cotton is a plant that requires more input usage than many agricultural products. Low prices due to inadequate support policies and high production costs in cotton farming have negatively affected cotton cultivation in recent years and cultivation areas have decreased. Cotton was planted in an area of 518 000 hectares from which 976 000 tons of cotton fiber was produced in 2018 in Turkey (Anonymous, 2019). Turkey had been characterized as an exporter country of cotton in past years. However, depending on the developments in the textile and confection sector, especially after the 1990s, it started to import a significant amount of cotton and today it has become the fifth country with 680 000 tons after Bangladesh, China, Indonesia and Pakistan. In other words, the amount of cotton production in our country cannot fully meet the demands of the textile and confection sector and the increasing demand is met through imports.

Aegean, Mediterranean (Cukurova and Antalya) and Southeastern Anatolia Regions were the main cotton production places in Turkey although 56% of the cotton produced in Southeastern Anatolia Region, especially 40% is produced in the province of Sanliurfa (Anonymous, 2019). Therefore Sanliurfa province has an important role in cotton production in Turkey. This ratio is expected to increase with the completion of SAP (Southeastern Anatolian Project) irrigation and energy project.

Producing the amount of fiber cotton needed in Turkey by using our own resources will reduce our dependence on foreign sources and prevent foreign exchange losses for imports. The way to increase cotton production is by expanding plantation areas, using available resources economically or by increasing productivity per unit area. In the fields where wheat-cotton alternation is applied in Turkey, the fields remain empty for about 10 months until the cotton or another main product is sown after the wheat harvest. Especially in areas where irrigation is possible, plants such as corn, soybean and peanut can be sown as second crop. In these areas, spreading the cultivation of early cotton cultivars like a second crop can be an economic cultivation aimed at increasing production since cotton can yield in a shorter period. In Sanliurfa province, first crop was cultivated in approximately 210 000 ha area and second crop was cultivated in 20 000 ha area (Anonymous, 2019).

All of the cotton varieties cultivated in Turkey belong to *Gossypium hirsutum* L. species. Cotton production is a form of production depending on environmental conditions. In addition to the ecological differences, the differences in the cotton production techniques applied as well as genetic structure of the varieties grown in cotton production regions can lead to the formation of the yield and quality quite differently from each other (Killi, 2005). Nowadays, the main purpose of cotton production is to improve the technological properties of fiber as well as high yield, to increase earliness, ginning efficiency, resistance to diseases and pests and to reduce production costs.

In recent years, especially in the studies conducted for cotton production after barley and wheat in Turkey, early cultivation of varieties can be done successfully but yield is reduced and fiber technology features are partially adversely affected respect to the main product planting (Killi, 2005; Killi and Bolek, 2006). There is a need to search the effect of different sowing times on yield and fiber technological properties of mid-early cotton cultivars that grow as second crop conditions especially considering lentil, barley and wheat production. In the second crop conditions, it is possible to tolerate the decrease in yields in cotton production by determining the varieties of cotton which are efficient in sowing time, having grater fiber-technological features, earlier, resistant to diseases and pests. As a matter of fact, in the study carried out with the varieties belonging to different mature groups under the second crop conditions, it is stated that cotton production can be made with early or middle early varieties (Copur and Yuka, 2016).

In the Sanliurfa Harran and Viransehir Plains, producers have recently turned to second crop cotton after lentil, barley and wheat. Producers have problems in choosing the cultivar and the date of planting.

This study was carried out in order to determine yield and fiber properties of some cotton cultivars at different sowing times in the second crop conditions of Sanliurfa Harran Plain and to give practical information to the producers about the second crop cotton cultivation and to shed light on the studies to be done on this subject.

Materials and methods

Field trials were carried out on a clay textured soil (vertic calciorthid aridisol) during the 2014 and 2015 double crop cotton-growing seasons at Faculty of Agriculture Research and Application Centre of Harran University located in Sanliurfa, Turkey. The experimental site is located in Harran Plain (altitude: 465 m; 37° 08' North and 38° 46' East), near to the Turkish-Syrian border (*Figs. 1* and *2*). The soil texture was of clay loam-type (Anonymous, 2006). Average field capacity, permanent wilting point, dry bulk density and pH of the site at 90 cm soil depth were 32%, 22%, 1.41 g cm^{-3} and 7.2, respectively (*Table 1*).

The average air temperatures were in 12 °C-32.5 °C range during the double crop cotton growing season, while relative humidity was below 50% in June, July and August for the both treatment years (*Table 2;* Anonymous, 2016). After the wheat had been harvested, the tillage was done in the trial area and the seeds of the cotton were drilled and then the trial area was irrigated by sprinkler system according to sowing times. In the scope of the study, seeds of cotton cultivars were sown according to sowing dates with the randomized complete block with split plot experimental design with three replications. Sowing dates (June 1st, June 10th and June 20th) were kept in main plot and cultivars (Stoneville 468, BA 119, DP 499 and PG 2018) were in sub plot and cultivars are widely cultivated in southeast of Turkey. The plots consisted of four rows, 10 m in length with inter-row spacing of 70 cm and intra-row spacing of 15 cm; oriented in south-north direction; and hand-thinned to 6 to 7 plants per meter row when the seedlings had approximately three true leaves. The cotton was sown in each plot at 4-5 cm depth by an experimental driller on June 1st, June 10th, and June 20th, 2014 and 2015. Pre-plant fertilizer was applied at a rate of 70 kg N ha^{-1} and 70 kg P ha^{-1} as 20-20-0 compose fertilizer and followed by 90 kg ha^{-1} N as 46% urea applied at the initiation of flowering. K_2O was not applied due to its abundance in the soil. A total of 900, 860 and 800 mm of water were applied in respect to sowing times from cotton sowing to harvest. The first irrigation was applied 4 weeks after each sowing time and the other irrigation was done 9, 8 and 7 times in 10-day intervals respectively. Last irrigation was done when 10% of the bolls in the plots opened.

During the cultivation season in the trial years, the plots were hoed twice by hand and three times by tractor hoe. 1500 g ha^{-1} *fluazifop-p-butyl* herbicide was used against narrow-leaved weeds. 1500 ml ha^{-1} dose of *lambda cyhalothrin* and 200 ml ha^{-1} *thiamethoxam* insecticide were used against the cotton boll worm and aphid pest. No fungicides were used for the diseases.

A 2-m border spacing was left between blocks to reduce edge effects. Also before harvesting, 0.5 m was left in each plot's top and bottom, and 1 row was left as side effect from each side of every plot. Seed cotton samples were hand harvested from all plants, from 9-m sections of the two middle rows in each four row plot. The first hand-picking was done on October 23rd, 2014 and October 15th, 2015, and the second hand-picking was done on November 6th, 2014 and November 4th, 2015.

Seed cotton yield, number of days from sowing to first boll opening, plant height, number of sympodia, number of bolls per plant, seed cotton weight per boll, ginning outturn and seed index were determined according to Worley et al. (1976).

Approximately a 300-g seed cotton sample collected from each plot was ginned to determine fiber length, fiber fineness, fiber strength and fiber uniformity. Fiber tests were conducted at a relative humidity of 65 ± 2% and a temperature of 20 ± 1 °C to determine fiber characters were measured by High Volume Instrument (HVI-1000) test device (Anonymous, 1997). Statistical analysis was performed using the MSTATC statistical program (Anonymous, 1989). Means were separated using Fisher's protected least significant differences (LSD) test and $P < 0.05$ denotes the level of significance.

Results and discussion

Seed cotton yield (kg ha^{-1})

The averaged seed cotton yield (SCY) in terms of cultivars changed between 2579.36 kg ha^{-1} and 3374.97 kg ha^{-1} in both years and the average was 2961.30 kg ha^{-1} and 3019.30 kg ha^{-1} in 2014 and 2015, respectively (*Table 3*). The highest averaged SCY was obtained from Stoneville 468 and the lowest SCY was obtained from PG 2018 cultivar (*Table 3*). In terms of sowing times, SCY varied from 1932.93 kg ha^{-1} to 4154.64 kg ha^{-1} (*Table 3*). According to LSD (Least Significant Difference) test, different cotton yield groups were formed in terms of sowing times and cultivars and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1544715462

that SCY decreases with delay of sowing time. This may be due to the lack of sufficient photosynthesis and the reduction of dry matter accumulation, since there was not enough temperature for the development of plants with the delay of sowing time. Therefore, plantings at June 10th and 20th requires a longer period of time for the development and opening of the bolls with the cooling during boll opening period (Gormus and Yucel, 2002). Sowing date x cultivar interaction was statistically significant meaning that SCY was affected by both sowing time and cultivars (*Table 3*). SCY is the result of interaction of genotypes with the environment. Therefore, the highest SCY was obtained from June 1st sowing in addition to cultivars Stoneville 468 and BA 119. This may be due to the similar adaptability of these cultivars to ecological conditions. These varieties have high adaptability and are medium-early varieties, thus opening earlier bolls and higher seed cotton yield. Therefore, Stoneville 468 and BA 119 varieties can be recommended under second crop conditions. Our findings are in agreement with the findings of Copur (1999), Copur et al. (2001), Dong et al. (2006), Barradas and Bellido (2009), Braunack et al. (2012), Baran (2013), Karademir et al. (2013), Copur and Yuka (2016), Wumbei (2014) and Du et al. (2015).

Number of days from sowing to first boll opening (days)

The average number of days from sowing to first boll opening (DTB) ranged from 98 days to 116 days; the mean was 107.25 days in 2014 and 108.53 days in 2015. In terms of cultivars, the highest averaged DTB belonged to PG 2018 while Stoneville 458 was the earliest (*Table 3*). In terms of sowing times, DTB varied between 104.25 and 111.33 days. As a result of the variability analysis there was a significant (0.01) difference between sowing dates and cultivars in both years in terms of DTB (*Table 3*). According to the LSD test, different groupings formed for DTB that increases with the delay of sowing time. It can be observed that plants open bolls with a delay of approximately 5 days compared to June 1st and June 20th. Stoneville 468 and BA 119 varieties are middle early varieties, thus forming bolls earlier than other varieties. As a matter of fact, these varieties also produced higher cotton yields than other varieties. Our findings are consistent with the findings of Copur (1999) that the number of days has increased with the delay of sowing date. It is seen that there is a 4-5 day difference between cultivars in terms of DTB. This difference may be due to the genotype effect, as well as the different response of the varieties to climate and soil conditions. Our findings have similarities of Soyler and Temel (2007), Ozbek et al. (2009), Baran (2013) and Iqbal et al. (2018).

Plant height (cm)

The plant height (PH) values of the cultivars varied between 96.44 cm and 120.96 cm in 2014 and the average was 106.16 cm while the values ranged from 98.91 cm to 118.73 cm and the average was 106.71 cm in 2015. In terms of cultivars, the highest PH was obtained from DP-499 and the lowest was obtained from Stoneville 458 variety (*Table 3*). In terms of sowing times, the averaged PH in 2014 was between 100.8 cm and 112.78 cm and between 103.69 and 110.32 cm in 2015 (*Table 3*). As a result of the variability analysis, sowing dates, cultivars and sowing date x cultivar interaction were significantly (0.05 and 0.01) different regarding to PH (*Table 3*). According to the LSD test, different PH groups were formed in terms of sowing dates and that it increases on the 10th of June and with the delay of sowing time it decreased

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1544715462

on June 20th. This is due to the shorter vegetation period in late sowing and the limitation of the growth of plants due to the difference in day and night temperature (Usman et al., 2016). Sowing date x cultivar interaction was also important in both years. The highest plants were obtained from June 10th and DP-499 cultivars and the shortest plants were obtained from June 20th and Stoneville-468 cultivars. Specifically, DP-499 was taller than other varieties and thus plants were more vegetatively developed. The lower yield values of the DP-499 cultivar compared to the Stoneville 468 and BA-119 cultivars support our findings. This may be due to the effects of the growth and development cycles of cotton cultivars on different environmental conditions planted in different sowing dates. Our findings are in line with the findings of Copur (1999), Soyler and Temel (2007), Ozbek et al. (2009), Baran (2013) and Copur and Yuka (2016) that plant height increases with delay of sowing date.

Number of bolls per plant (no. plant^{-1})

The number of bolls per plant (BPP) is one of the most important characteristics affecting the cotton yield. The genotypic structure and cultivation techniques of the varieties may affect the number of bolls (Usman et al., 2016). With increasing BBP, cotton yield increases. Variance analysis showed that the BBP was affected by different sowing dates and different cultivars in both years. Although different BBP groups were formed, but the sowing date x cultivar interaction was not significant (*Table 4*). BPP decreased with the delay of sowing time. On the other hand, the BPP obtained in June 1st sowing has led to 40% more bolls compared to June 20th sowing. Decreasing BPP because of late sowing is due to short vegetation time led to decrease number of flowers formed on the plant and insufficient carbohydrate production effecting flowers not to develop into bolls thus shed off the plant. As a matter of fact, the decrease in cotton yield with delayed sowing supports our findings. The average BPP was between 7.96 plant^{-1} and 11.89 plant^{-1} in 2014, with an average of 9.98 plant^{-1} and similar results occurred in 2015. In terms of cultivars, the highest BPP was obtained from Stoneville 468 and the lowest BPP was obtained from PG 2018 (*Table 4*). There were also differences in terms of BPP among the cultivars and that the cultivars yielding the least seed cotton constitute the least BPP (*Table 4*). This may be due to the different reactions of the cultivars to different genotypic structure and environmental conditions. Stoneville 468 variety constitutes the highest number of bolls, thus producing the highest seed cotton yield. Copur (1999), Arshad et al. (2007), Soyler and Temel (2007), Ali et al. (2009), Ozbek et al. (2009), Baran (2013), Copur and Yuka (2016) and Usman et al. (2016) reported that the number of bolls decreased with delay in planting and there were significant differences between cotton varieties.

Number of sympodia (no. plant^{-1})

The number of sympodia (SYM) affects the number of bolls per plant and hence the cotton yield. Number of fruit branches was affected by different sowing dates and varieties according to statistical analysis, but sowing date x cultivar interaction was insignificant in 2014 and significant in 2015 (*Table 4*). Thus SYM decreased with the delay of sowing time. Similar findings were found by Copur (1999), Gur et al. (2001) and Soyler and Durmus (2007) and Baran (2013). The average SYM of cotton cultivars ranged from 11.58 to 13.80 number plant^{-1} averaging 12.57 number plant^{-1} in 2014 while it was between 9.62 and 11.93 number plant^{-1} averaging 11.05 number plant^{-1} in 2015. DP 499 and Stoneville 458 had the highest SYM in 2014 and 2015, respectively while PG-2018 had the lowest SYM in both years (*Table 4*). Different groups were formed in terms of SYM in cotton cultivars. Although the cotton cultivars used in the experiment are in the same maturation group, they can form different SYM due to differences in genotype structure in adaptation to different environmental conditions (Copur, 2006; Soyler and Temel, 2007; Ozbek et al., 2009; Baran, 2013; Copur and Yuka, 2016 and Iqbal et al., 2018).

Seed cotton weight per boll (g boll^{-1})

Seed cotton weight (SCW) was significantly influenced by different sowing dates and cultivars. According to the LSD test, different SCW groups were formed in terms of sowing dates and the SCW decreases with delay of sowing time. The highest SCW was obtained from June 1st sowing and DP 499 cultivars while the lowest SCW was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1544715462

obtained from June 20th and BA 119 cultivars in both years. The average SCW was 4.75 g in 2014 and 4.67 g in 2015. The decrease in SCW compared to sowing date shows that plants cannot produce enough carbohydrates for boll development due to low night temperature during the boll development period (Copur, 1999; Ali et al., 2009; Usman et al., 2016 and Iqbal et al., 2018). Therefore, a higher yield of cotton was obtained in June 1st sowing. In addition, there were differences in terms of SCW (*Table 4*). The highest SCW was obtained from DPL 499 variety but it did not produce the highest yield of cotton per hectare. This may be due to the fact that the number of bolls in the mentioned variety was low compared to other productive cultivars and the resulting carbohydrates were used in a less number of bolls (Pettigrew, 2002; Dong et al., 2006; Baran, 2013 and Copur and Yuka, 2016). For this purpose, DPL 499 variety can be selected as a parent in breeding studies that will be carried out for the seed cotton weight.

Seed index (g)

One of the characteristics affecting the cotton yield is seed index. Seed index (SI) was not affected by sowing time in 2014, but there were significant differences between cultivars, and in 2015, both sowing date and cultivars were significantly different (*Table 5*). The sowing date x cultivar interaction was significant in 2014 and insignificant in 2015. The highest SI was obtained from a June 1st planting and SI decreased in both years with the delay of sowing time (*Table 5*). In terms of cultivars, the highest SI was obtained from DP 499 and the lowest was obtained from PG 2018 variety in both years. Since the number of bolls was low in DP 499, all of the carbohydrates were used in a few bolls. Therefore, the seed weight of DP 499 variety was higher than other varieties. Also, the differences between the cultivars may be due to the genotypic structure as well as the adaptability of the cultivars to environmental conditions. Our findings were parallel with the reports of Arshad et al. (2007), Ali et al. (2009), Barradas and Bellido (2009), Baran (2013) and Copur and Yuka (2016), and are partially consistent with the findings of Copur (1999). This may be due to the fact that the trials were conducted in different years and places and the cultivars used in the trials were different.

Ginning outturn (%)

Ginning outturn (GO) was not affected by different sowing times in both years, but there were significant (0.01) differences between cultivars and sowing date x cultivar interaction was not significant (*Table 5*). In terms of cultivars, the highest GO was determined in PG 2018 and the lowest GO was determined in Stoneville 468 (*Table 5*). Average GO was 41.05% in 2014 and 41.58% in 2015. According to LSD test, different GO groups were formed in terms of cultivars and GO partially decreased with delay of sowing time but it was not statistically significant. The partial reduction in GO with the delay of planting is may be due to weak boll development and consequently the fibres in the seeds did not grow well. In addition, there were differences between the cultivars in terms of GO. PG 2018 variety produced higher gin turnout value compared to other varieties. This may be due to the fact that the cultivars have different genotypic structure in terms of GO. Similar findings are found in Copur (1999), Pettigrew (2002), Arshad et al. (2007), Ali et al. (2009) and Copur and Yuka (2016), Usman et al. (2016), and partially contradicts the findings of Barradas and Bellido (2009) and Baran (2013). This may be due to the fact that the experiments were carried out under different ecological conditions and that the cultivars used in the trials were different.

Fiber length (mm)

Although fiber length (FL) is an inherited property, it may partially be affected by environmental conditions (Bradow and Davidonis, 2000). FL was not affected by different sowing dates and different cotton cultivars, but the sowing date x cultivar interactions were insignificant in 2014 and statistically significant in 2015 (*Table 5*). In 2015, fiber length was affected by variety and environmental interaction. According to the sowing dates and cultivars, the average FL was between 28-29 mm in both years. When the FL values were examined, all of the cultivars are in the medium-length fiber group (Anonymous, 1997) and all of the fiber values obtained can be used in the textile industry. Bauer et al. (2000), Gormus and Yucel (2002),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1544715462

Dong et al. (2006), Killi and Bolek (2006), Ali et al. (2009), Barrdas and Bellido (2009), Saeed et al. (2014) and Saleem et al. (2014) stated that FL was not affected by sowing time, while Copur et al. (2001) stated that FL increases with delay of sowing. This may be due to differences in environmental conditions and genotypic differences.

Table 5. *Seed index, ginning outturn, fiber length and their contributions in response to different sowing date and cultivars in 2014 and 2015*

Sowing date (SD)	Seed index (g)		Ginning outturn (g)		Fiber length (mm)

Fiber fineness (micronaire)

There were statistically significant (0.05) differences at sowing date and cultivars in terms of fiber fineness (FF) in 2014 and 2015 but the sowing date x cultivar interaction were not significant (*Table 6*). According to LSD test, different FF groups were determined in terms of sowing date and cultivars. According to the same table, the average FF obtained for cultivars was 3.83-4.80 micronaire (mic) in 2014 and the average was 4.21 mic and changed between 3.45-4.43 mic in 2015 the average was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1544715462

3.94 mic. The coarser fibres were obtained from DP 499 variety in both years and the finest fibres were obtained from PG 2018 and BA-119 cultivars in 2014 and 2015, respectively. In terms of sowing dates, the average FF in 2014 varied between 3.99-4.52 mic and the average was 4.21 mic, in 2015, it was 3.45-4.43 mic and the average was 3.94 mic (*Table 6*). The FF value increased by 20% from June 1st to June 20. It can be seen that FF increases with delay of sowing time. FF is an inherited property, but it is influenced by many factors (Jost and Cothren, 2000). In particular, temperature and the consequent accumulation of carbohydrates associated with photosynthesis can affect FF. Moreover, the FF (3.99-4.52 mic) values that occurred with sowing time were positively affected due to temperature change (*Table 6*). In addition, there were differences in FF between cultivars. This is due to the fact that the cultivars have different genotypic structure. In the obtained values, except DP 499 variety, other cultivars are in the middle and fine fiber group (Anonymous, 1997). Fibres are thin with delay of sowing (Dong et al., 2006; Ali et al., 2009, Braunack et al., 2012 and Baran, 2013) but Gormus and Yucel (2002), Pettigrew (2002), Barradas and Bellido (2009) and Saleem et al. (2014) reported that fiber fineness is not affected by different sowing times. This may have been due to the different locations and years of the trials and the diversity of the cultivars used.

Fiber strength (g tex^{-1})

Fiber strength (FS) was not significantly affected by sowing date in 2014 but it was significant in 2015 (*Table 6*). With the delay of sowing, FS was partially increased in 2014 but it was not statistically significant while FS was decreased in 2015 but it was not stable. This may be due to the differences in temperature during the day and night and the change in temperature towards the end of the vegetation period (Bradow and Davidonis, 2000; Killi and Bolek, 2006; Braunack et al., 2012). Significant differences between cultivars occurred in both years; sowing date x cultivar interaction was insignificant in 2014 but significant in 2015 (*Table 6*). The average FS was 37.19 g tex^{-1} in 2014 and 36.12 g tex^{-1} in 2015. In terms of cultivars, the highest FS was obtained from DP 499 and the lowest one was obtained from PG 2018 variety. This may be due to the fact that the cultivars have different genotypic structure in terms of fiber strength (Copur and Yuka, 2016; Usman et al., 2016).

Fiber uniformity

Fiber uniformity (FU) ratio was not affected by different sowing dates and different cotton cultivars and sowing date x cultivar were found to be insignificant in both years (*Table 6*). It can be seen from the same table that the FU ratio was 86.35% in 2014 and 86.25% in 2016. In addition, all cultivars (85-87%) were ranked as high or good when FU values were examined (Anonymous, 1997). All of the fiber values obtained can be evaluated in the textile industry. Our results indicate that FU rate is not affected by sowing time, whereas it is similar to the findings of Killi and Bolek (2006), Barradas and Bellido (2009) and Saleem et al. (2014) while Usman et al. (2016) reported that FU is affected by different sowing dates and there were differences between the cultivars used in the experiment. This may be due to the fact that the cultivars used in the experiments have different genotypic structure, the application of different cultural processes and different climatic conditions.

Conclusion

As a result of the research, seed cotton yield, plant height, number of bolls per plant, seed cotton weight and seed index decreased with delayed sowing while the number of days from sowing to boll opening and fiber fineness values increased. The number of fruiting branches per plant, ginning outturn, fiber length, fiber strength and fiber uniformity ratio were not affected by different sowing dates.

When the cultivars were investigated according to sowing dates, Stoneville 468 for seed cotton yield and number of days to open bolls; Stoneville 468 and BA 119 for number of bolls; DP-499 for plant height, number of fruiting branches, seed cotton weight, seed index and fiber strength; PG 2018 for ginning outturn and fiber fineness were promising. In addition, there was no significant difference between the cultivars in terms of fiber length and fiber uniformity ratio.

The most important issue that cotton producers have focused on in cotton production is the seed cotton yield. In this study; cotton yield was found to be varied between 1440 kg ha^{-1} and 4560 kg ha^{-1}. Autumn rainfall was early in the 2014 and 2015 cotton growing season. It is a major disadvantage for the trial years. Four cotton varieties used in the experiment; Stoneville 468 and BA 119 are medium early and have high adaptability. In addition, it was found that these varieties were not statistically different in terms of cotton yield. For this purpose, after wheat production under Harran Plain ecological conditions, Stoneville 468 and BA 119 cultivars may be preferred for second crop conditions.

Fiber properties were generally not affected by late sowing. However, a general decrease in fiber fineness values was observed. This is expected for late sowing. Therefore, for the development of cotton fibres and high seed cotton yield, sowing of cotton seeds must be completed immediately after the main crop harvest. For this purpose, stubble cultivation applications should be emphasized, early cultivars should be preferred and early cotton cultivars should be improvement for second crop cotton farming. In addition, since the vegetation period is short in the second crop cotton cultivation, studies on plant growth regulators should be carried out for the development of cotton plants.

Abstract. The removal of oil-drilling mud contaminated soil generated from oilfields in the Algerian Sahara by bioaugmentation with *Yarrowia lipolytica* and biostimulation with carrot peel waste amendment during 45 days was investigated. Initially, the evaluation of growth and gasoil degrading ability of *Yarrowia lipolytica* in carrot peel waste, and carob kibbles media were compared. Afterwards, the effect of bioaugmentation and organic amendment on oil-drilling mud contaminated soil was studied for 45 days of study period. Total petroleum hydrocarbon (TPH) was measured by distillation using distiller mud. The results indicated that, higher augmentation in growth was observed in carrot peel waste medium and when the concentration of gasoil was increased from 15% to 30%. TPH decreased to 35 ± 1.66% and 30.60 ± 1.50% the first 15 days, 33 ± 2.30% and 26.8 ± 1.66%, respectively at the end of study. TPH rate did not undergo any significant change from its initial value in the control for the entire period of incubation. This study demonstrated the effectiveness of co-application of bioaugmentation with *Yarrowia lipolytica* and biostimulation with carrot peel waste amendment for bioremediation of oil-drilling mud contaminated sites.
Keywords: *bioremediation, carrot peel waste, Yarrowia lipolytica, soil remediation, oil-drilling mud*

Introduction

The mud generated from oil-drilling, causes considerable ecological and health problems like toxicity and carcinogenicity (Singh and Chandra, 2014). About 20% of generated waste drilling mud is treated by thermal treatment, solidification, solvent washing, landfilling of contaminated soils, stabilization and transport which are some of the available techniques that are highly expensive, ineffective, rarely neutral, and environmentally destructive (Lu et al., 2010; Minai-Tehrani et al., 2009; Dadrasnia et al., 2014). While the rest is temporarily deposited in so-called mud pits. Bioremediation of mud pits has proven to be an effective, non-invasive, eco-friendly and clean-up technology (Cerqueira et al., 2014; Silva-Castro et al., 2015). Bioremediation is utilization of specific microorganisms to reduce or transform petroleum products into less toxic forms (Esmaeil and Akbar, 2015). Biostimulation and bioaugmentation are bioremediation methods that have been successfully used earlier (Esmaeil and Akbar, 2015). Bioaugmentation involves introducing allochthonous degrading microorganisms to detoxify petroleum contaminated soils (Taccari et al., 2012; Ceci et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1546315475

2019). Biostimulation is based on stimulation of the catabolic activity of degrading microorganisms by adding nutrient-rich organic and inorganic materials to avoid metabolic limitations (Taccari et al., 2012). Bioaugmentation studies using *Yarrowia lipolytica* were reported by Sekova et al. (2015) to degrade hydrocarbons and triglycerides. The yeast *Candida maltosa* was used to degrade phenyl alkanes, which constitute refined gasoline fuel oil, by Awe et al. (2008). In arid areas, addition of nutrients may be necessary to stimulate the growth of biodegrading microbiota in contaminated soils poor in organic matter (Nyman, 1999). Addition of pure nutrients and organic waste material as biostimulants has been well documented, to support microbial activity in the contaminated soils (Decesaro et al., 2016). Compared to pure nutrients, organic waste material supplementation is a cost-effective method (Andreolli et al., 2015). Organic biostimulants, containing enzymes, enhance substantially the growth of microbial activity (Shahi et al., 2016). Besides, biostimulants release biosurfactants that increase the bioavailability of poorly soluble hydrocarbon petroleum compounds (Yi and Crowley, 2007; Yoshitomi and Shann, 2001). In the few last years, few studies have shown the efficiency of co-application of bioaugmentation by yeast with addition of organic amendment for biodegradation of petroleum contaminated soils (Zhang et al., 2011; Qin et al., 2013). Zhang et al. (2011) used bioaugmentation in combination with biostimulation to treat hydrocarbons contaminated soils by incubating *Fusarium* sp. with a mixture of leaves, branches, and biowastes. Qin et al. (2013) used biochar produced from rice straw in bioremediation of hydrocarbons. These authors demonstrated that application of amendment and yeasts simultaneously, gave promising results compared to bioaugmentation only. The aim of this study was to examine the efficiency of this combination strategy for biodegrading of oil-drilling from contaminated soil using carrot peel waste as organic amendment. However, review of the literature shows that there is no information on the application of this organic matter and *Y. lipolytica* for bioremediation of crude oil contaminated soil.

Materials and methods

The oil-drilling mud contaminated soil origin

The oil-drilling mud was collected in the Hassi Messaoud field (Algeria), located at 30° 25.006' N and 5° 23.637' E (*Fig. 1*).

Samples were collected at 0-50 cm depth using a stainless steel sampler, placed in appropriate containers thoroughly mixed therein. The oil-drilling mud contaminated soil was sterilized by heating at 180 °C for 2 h in a closed stainless container which prevents loss of volatile fractions, then cooled down overnight before use. The significant characteristics of the oil-drilling mud contaminated soil are listed in *Table 1*.

Physico-chemical characterization of oil-drilling mud contaminated soil

Preparation of the lixiviate

10 g of oil-drilling mud contaminated soil was placed in the beaker containing 100 mL of distilled water. After agitation during 1 h and filtration (Whatman 125 mm), lixiviate obtained was then diluted at 1/100 and used for analysis.

Determination of the indicating organic pollution parameters

HACH DR900 Colorimeter was used for the determination of dissolved oxygen, chemical oxygen demand (COD), nitrate, nitrite, phosphorus, sulphates, and ammonia nitrogen content in the oil-drilling mud contaminated soil. Analytical methods were used to determine alkalinity, and chloride by volumetry. Calcium, magnesium were measured by complexometric titration with standard solution of EDTA. Total iron and potassium were measured by an atomic absorption spectrophotometer (PerkinElmer A-Analyst 200).

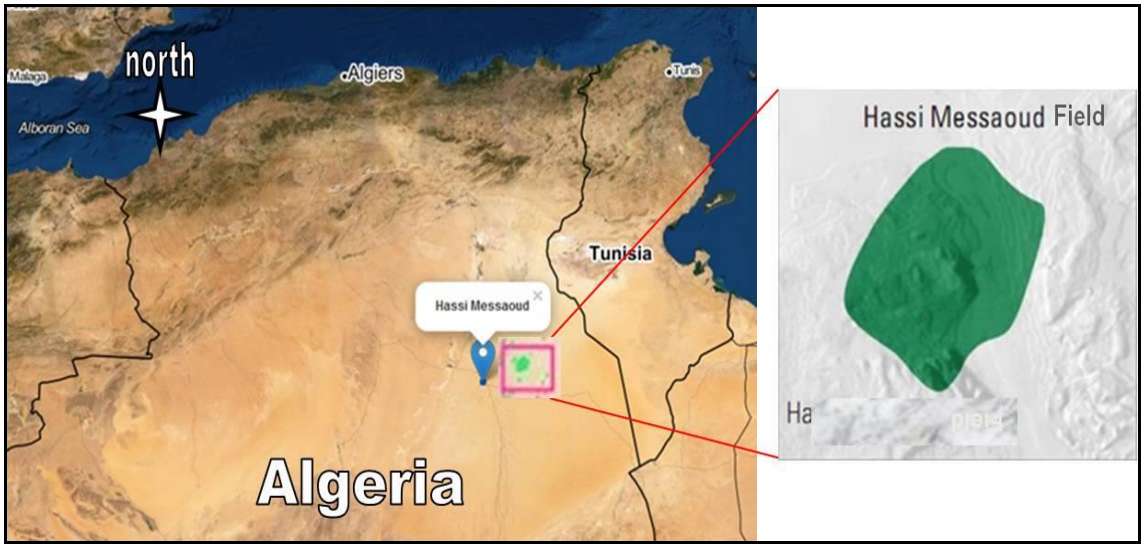

Figure 1. *Location map of the study area*

Biochemical oxygen demand after 5 days (BOD_5)

The Biochemical Oxygen Demand measured for 5 days (BOD_5), was carried out by respirometry (Khodja, 2008).

Evaluation of growth and gasoil degrading ability of Yarrowia lipolytica in carrot peel waste, and carob kibbles media

Carrots were purchased from a local vegetable market and dry pods of carob were obtained from locality of Ighil-Ali (Bejaïa, Algeria). Carrot peels and carob kibbles were macerated separately at a ratio of 1 kg in 2.5 L of distilled water at 85 °C for 45 min with continuous stirring (Acourene and Tama, 2001). After filtration and decantation, media were autoclaved at 120 °C for 20 min and stored at 4 °C before use as biostimulating media.

The yeast *Yarrowia lipolytica* used in this study was isolated and identified earlier in our previous work (published results by Hamoudi-Belarbi et al., 2016). *Y. lipolytica* was grown in 500 mL Erlenmeyer flasks containing 100 mL of Yeast Extract Glucose (YEG broth) prepared using: 10 g/L yeast extract (Himedia, Mumbay, India), 20 g/L glucose (Sigma, Switzerland) in an orbital shaker cabinet maintained at 25 °C under an agitation rate of 80 rpm for 24 h. This 1st culture was then used to inoculate (3% v/v) a carrot peels waste, and carob kibbles media which were incubated at 25 °C for 48 h in an orbital shaker (80 rpm). Gasoil (15% or 30%) was added to the 500 mL Erlenmeyer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1546315475

flasks containing 100 mL of sterilized carrot peels waste or carob kibbles media and then incubated at 25 °C in an orbital shaker (80 rpm) for 12 days. At four days regular intervals, turbidity was measured at 600 nm. A volume of 1 mL of each Erlenmeyer flask containing carrot peel waste or carob kibbles media was diluted in 9.9 mL of peptone water solution (Difco, Detroit, USA). After serial dilutions, 1 mL aliquots of suitable dilutions were pour plated in potato dextrose agar medium (Difco). The number of viable cells was counted after 48 h of incubation at room temperature (25 °C).

Bioaugmentation using Yarrowia lipolytica in combination with biostimulation using a selected medium

Experimental design

200 g of sterilized oil-drilling mud in the slurry was used for bioremediation studies and conducted by the following: (i) addition of only yeast (3% v/v); (ii) addition of both the organic amendment and yeast; (iii) sterilized oil-drilling mud in the slurry without yeast and organic amendment (control). Each slurry mixture was placed in circular cell, run in the open air and mixed thoroughly every 3 days to ensure homogenous distribution during 45 days of remediation studies. Each treatment was carried out in duplicate (*Fig. 2*).

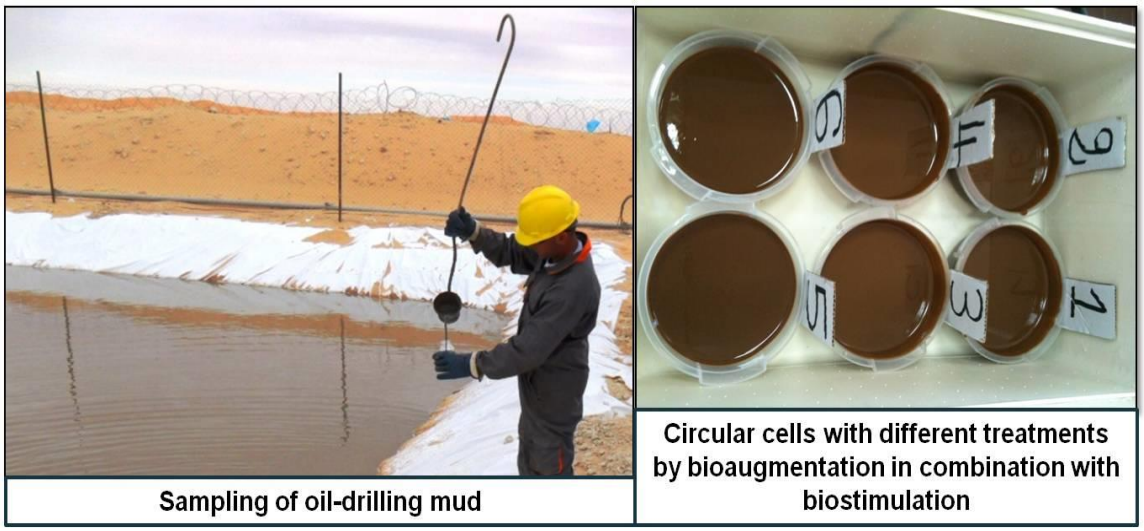

Figure 2. *Experimental design of oil-drilling mud remediation under laboratory scale*

Physico-chemical characterization

Temperature, pH and residual moisture measurements

The temperature and pH were determined using thermometer (MRC 201, France) and, pH meter (Accumet AE150 instrument; Fisher Scientific, France), respectively. The residual moisture (RM) of oil-drilling mud contaminated soil samples was determined (in duplicate) by the difference in weight before and after drying in a vacuum oven at 105 °C for 3 h in the presence of P_2O_5.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1546315475

Total petroleum hydrocarbon (TPH) measurement by distillation

TPH percentage of oil-drilling mud samples was measured by distillation using Fann distiller and by determination of the percentage of water/oil in the mud. 20 mL of each soil sample is placed in a distiller, then heated up to 800 °C. The vapors of water and oil are then condensed back into liquid form and collected (distillate). After about 30 to 60 min of decantation, the volumes of water and oil are read directly. After distillation, the remaining mass of mud is weighed. The percentages of water and oil are directly determined. Two replications were conducted for all measurements.

Microbiological analysis

Two replicate samples from each oil-drilling mud (i) with yeast only; (ii) with both the organic amendment and yeast; (iii) without yeast and organic amendment (control) were withdrawn at the end of the second, fourth and sixth week of study for the enumeration of yeast. A volume of 1 mL of each sample was diluted in 9.9 mL of peptone water solution (Difco, Detroit, USA). After serial dilutions, 1 mL of aliquots from suitable dilutions was pour-plated in potato dextrose agar (PDA) medium (Difco). The PDA agar was acidified to pH 3.5 using 100 g/L of tartaric acid solution.

Statistical analysis

Data were analyzed by Data Analysis Tool pack of Microsoft Office Excel 2007 (Microsoft, New York, NY, USA).

Results and discussion

Physicochemical properties of oil-drilling mud contaminated soil

Table 1 lists the physico-chemical properties of oil-drilling mud contaminated soil. The temperature of oil-drilling mud was approximately 21.8 °C ± 0.28; the effect of temperature on the physical nature and chemical composition of the oil, rate of hydrocarbon metabolism by microorganisms and composition of the microbial community, influences oil biodegradation (Atlas, 1981). Moisture content of oil-drilling mud was 51.0 ± 2.12%; according to Kumari et al. (2016), moisture is a limiting factor during biodegradation. As shown in the table, dissolved oxygen is low (7.6 mg/mL). Indeed, a high chemical oxygen demand (COD) (1362 mg O_2/L), that is a measure of the oxygen required to degrade the organic matter present in oil-drilling mud, is an indicator of strong pollution at the site studied (Damo and Icka, 2015). Total organic carbon (TOC) is considered as the most relevant parameter for quantifying organic pollution in soil (Wang et al., 2013). The highest value observed in this study (17.94%) confirmed that the soil studied was polluted by hydrocarbons present in the oil-drilling mud contaminated soil. pH value of oil-drilling contaminated soil used in this study was basic (8.5 ± 0.26). In arid areas, soils tend to be alkaline (Ma et al., 2015), mainly due to the dry environmental conditions. According to Khodja (2008), alkalinity of oil-drilling contaminated soil is maintained between 9.5 and 10.5 in order to prevent corrosion and control the solubility of calcium and magnesium salts. Oil-drilling contaminated soil was mineralized with predominance of ions such as Cl^-, Ca^{+2}, SO_4^{-2}, and Mg^{+2}. However, nitrites (HNO_2^-), nitrates ($N\text{-}HNO_3^-$), phosphorus (PO_4^{-3}), and Fe^{+2} were negligible. According to Abd-Alla et al. (2014), alkaline soils are characterized by poor

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1546315475

availability of phosphorus and micronutrient transition metals. Analysis of carrot peel waste showed that it contains 25.10 ± 1.20 mg/L phosphorus, and 1.4 mg/L nitrogen (Hamoudi-Belarbi et al., 2018). Therefore this waste can compensate for the nutrient deficiencies in the oil-drilling mud contaminated soil.

Table 1. *Physicochemical properties of oil-drilling mud contaminated soil*

Parameters	Values
Temperature	21.7
Residual moisture %	51.0 ± 2.12
pH	8.5 ± 0.26
COT (%)	17.94
$N\text{-}HNO_3^-$	0.152

Fe^{++}	21.45

Evaluation of growth and gasoil degrading ability of Yarrowia lipolytica in carrot peel waste, and carob kibbles media

Figure 3 shows the growth of *Yarrowia lipolytica* after incubation using biostimulating media (carrot peel waste, and carob kibbles) with adding gasoil at 15%, and 30% concentration as sole source of carbon, in comparison with a control without adding gasoil, during 12 days. The nature of biostimulating media and concentration of gasoil affected the growth of *Y. lipolytica*. Higher augmentation in growth was observed in carrot peel waste medium and when the concentration of gasoil was increased from 15% to 30%, indicating that phosphorus and nitrogen nutrients present in carrot peel waste played a major role in growing the cultures. As an example, at 4 days of incubation at 15% concentration, log (CFU/mL) was 11.93 (*Fig. 3A* and *B*). At 8 days of incubation, log (CFU/mL) decreased to 9.00 for 15% and 7.97 for 30%. After 8 days of incubation, log (CFU/mL) increased to reach 11.27 for all 15% and 30% concentration at 12 days of incubation. Carob kibbles are widely used as biostimulating medium during bioremediation of petroleum (Hamoudi-Belarbi et al., 2017, 2018). Carob kibbles did not provide a good biostimulating medium to *Y. lipolytica*, with log (CFU/mL) of 10.38 for 15% and 30% concentration simultaneously at 4 days of incubation. Log (CFU/mL) increased then decreased to 11.16, and 10.41 for 15% and 30%, respectively at 8 days of incubation. A drastic decreasing was observed at 12 days

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1546315475

of incubation with log [CFU/mL] of 8.34 for 15% and 30% concentration simultaneously. This better growth using carrot peel waste than carob kibbles can be explained by the fact that phosphorus and nitrogen nutrients present in carrot peel waste played a major role in growing the cultures of *Y. lipolytica*. Vidali (2001) demonstrated that the additional nutrient nitrogen and phosphorus contained in the carrot peel waste stimulated microbial growth and led to synthesized enzymes required to degrade hydrocarbon compounds. On the other hand, carrots are known to release linoleic acid, which can increase the bioavailability of poorly soluble hydrocarbon compounds (Yi and Crowley, 2007; Yoshitomi and Shann, 2001; Kosaric, 2001).

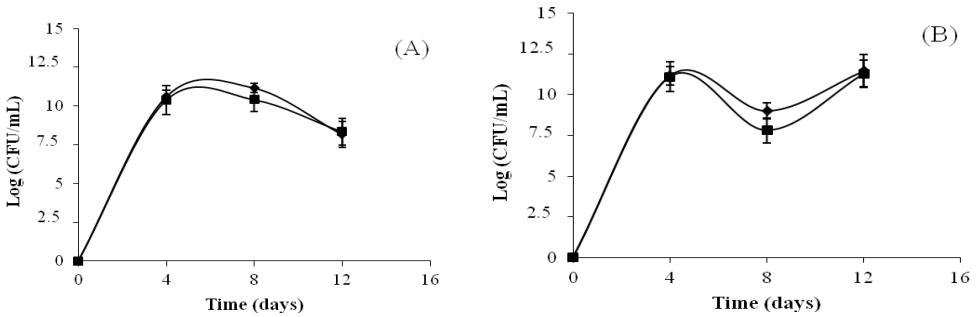

Figure 3. *Growth and gasoil degradation by Yarrowia lipolytica during 12 days at concentrations (♦) 15% and (■) 30% v/v. Y. lipolytica was grown in (A) carob kibbles medium; (B) carrot peel waste medium. Error bars represent the standard error of replicates*

Effect of bioaugmentation and organic amendment on oil-drilling mud contaminated soil

Figure 4A, B, and *C* illustrate variation of temperature, moisture content and pH of oil-drilling mud contaminated soil using bioaugmentation by *Y. lipolytica* and biostimulation with carrot peel waste for one week intervals and during 45 days of study period. *Figure 4A* shows the evolution of temperature as a function of time throughout the study. The effect of temperature on the chemical composition and physical nature of the oil, metabolism of hydrocarbon by microorganisms, influences oil-petroleum biodegradation (Atlas, 1981). At the beginning of the study, the temperature of oil-drilling mud with both the organic amendment and yeast, and without yeast and organic amendment (control) was approximately 21.8 °C ± 0.28.

At the beginning of study, the temperature of crude oil unamended and amended soil was approximately 21.8 °C ± 0.34. An increase in soil temperature was obtained for all samples after 15 days followed by gradual decreasing then stabilisation at 21.3 °C ± 1.5 for unamended soil control at the end of the study, while temperature values of amended samples continue their progression. After 15 days of treatment, an increase in oil-drilling mud temperature was obtained for all samples, followed by gradual decreasing then stabilization at 21.3 °C ± 0.42 for control at the end of the study, while temperature values continue their progression followed by gradual decreasing then stabilization at 22.85 °C ± 0.42 for oil-drilling mud with yeast only at the end of the study, while temperature values of amended samples continue their progression. These results may be due to the intensity of the metabolic activity of *Y. lipolytica* present in carrot peel waste amended oil-drilling mud soil. According to Insam et al. (2010), during microbial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1546315475

activities, fragmentation of complexes molecules liberates energy; some of this energy is used for anabolism and the rest is dissipated as heating. At the laboratory scale, the metabolism of hydrocarbons occurs in the temperature range from 4 to 30 °C (Aislabie et al., 2006).

Moisture content of the oil-drilling mud with both the organic amendment and yeast ranged between 51.0 ± 2.12% and 56.50 ± 2.32% at the end of the treatment while that of oil-drilling mud amended with yeast only ranged from 51.0 ± 2.12% and 53.11 ± 2.63% at the end of treatment, respectively (*Fig. 4B*). However, the moisture content of control stabilized at 51.01 ± 1.11% at the end of treatment. According to Kumari et al. (2016), moisture is a limiting factor during biodegradation; further more during microbial catabolism, energy and water are produced.

pH value of all oil-drilling mud contaminated soil with yeast only, with both the organic amendment-yeast, without yeast and organic amendment (control) was basic at the beginning of study (8.5 ± 0.26) (*Fig. 4C*). pH value of organic amended samples with yeast decreased gradually then increased to reach, at the end of study, 8.08 ± 0.10 for carrot peel waste amended oil-drilling mud and yeast and 7.61 ± 0.11 for yeast only. According to Vero et al. (2019), solubilization and formation of ammonia by organic nitrogen ammonification by *Y. lipolytica* results in increased pH. It has also been reported that alkaline condition enhances hydrocarbon degradation in contaminated soil (Morgan and Atlas, 1989).

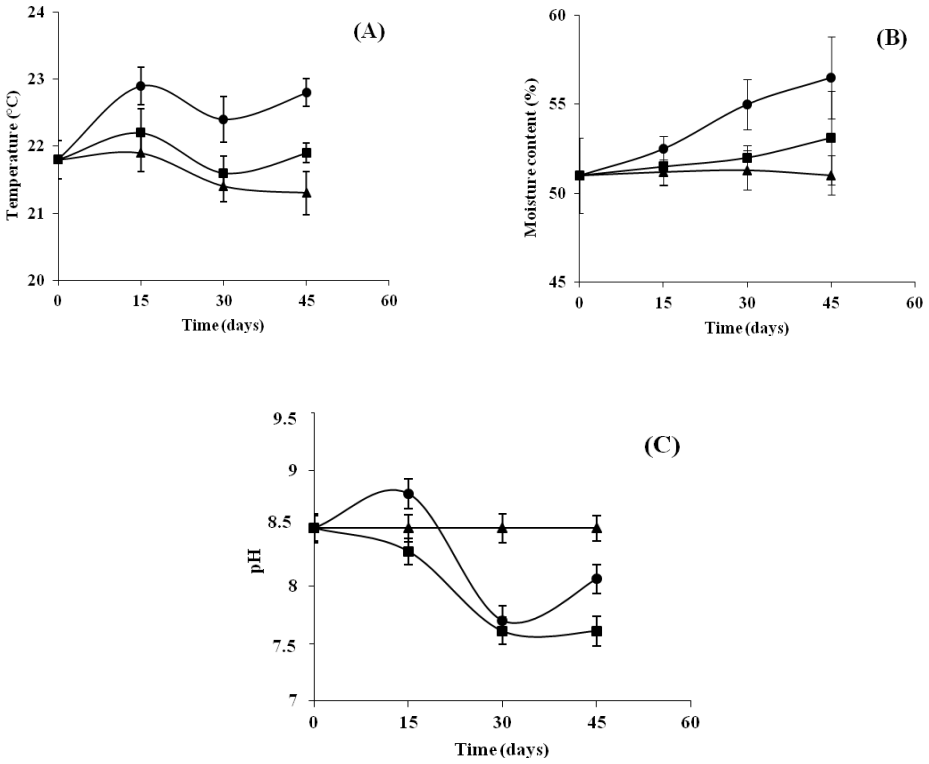

Figure 4. *Evolution of temperature (A), moisture (B), and pH (C) during 45 days of treatment. Mud + Carrot + Yeast (•); Mud + Yeast (■); Mud (▲). Error bars represent the standard error of replicates*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1546315475

Figure 5 shows the degradation of total petroleum hydrocarbons (TPH) of the oil-drilling mud contaminated soil using the various bioremediation strategies and during 45 days. At the beginning of study, initial concentration of TPH was about 38 ± 1.4% (corresponding to 3.60 g/kg) for all samples (*Fig. 5*). When oil-drilling contaminated soil was incubated with only *Y. lipolytica* (6 mL, 3×10^7 CFU/mL) and both *Y. lipolytica* (6 mL, 3×10^7 CFU/mL) and carrot peel waste amendment (4 mL), TPH decreased to 35 ± 1.66% and 30.60 ± 1.50% the first 15 days, 33 ± 2.30% and 26.8 ± 1.66% respectively at the end of study. TPH rate did not undergo any significant change from its initial value in the control for all the period of incubation. These results indicate that combining application of *Y. lipolytica* with carrot peel waste has a positive effect on TPH biodegradation in oil-drilling contaminated soil. Without organic amendment, *Y. lipolytica* activity was slow due to low organic matter content in the oil-drilling mud contaminated soil. This low TPH removal was attributed to nutrition deficiency in the soil. Mancera-López et al. (2008) found that *Rhizopus* sp., *Penicillium funiculosum* and *Aspergillus sydowii* fungi removed, respectively, 36%, 30% and 17% more polycyclic aromatic hydrocarbon (PAH) from crude oil in comparison with biostimulation alone. Besides, Ataikiru et al. (2018) demonstrated that yeasts have great potentials to degrade hydrocarbons, and their use is one of the cheaper solutions to remediation in comparison to highly expensive physical and chemical techniques.

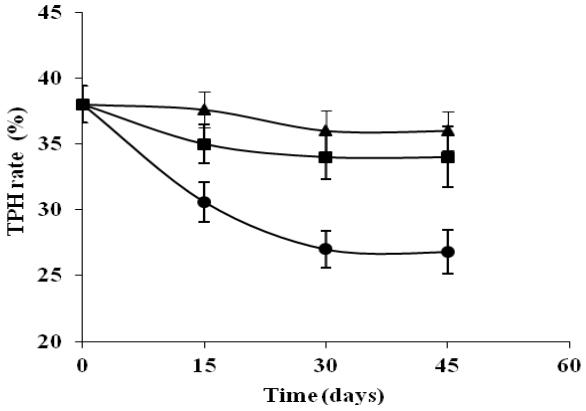

Figure 5. *The rate of TPH during 45 days of treatment. Mud + Carrot + Yeast (•); Mud + Yeast (■); Mud (▲). Error bars represent the standard error of replicates*

The growth and evolution of *Y. lipolytica* cells in the oil-drilling mud contaminated soil, as function of incubation time, is represented in *Figure 6*. At the end of the second week, the log (CFU/g) reached a value of 7.47 ± 0.53 for both *Y. lipolytica* and carrot peel waste amendment and 7.50 ± 0.77 for yeast only. At 30 days of incubation, log (CFU/g) of oil-drilling mud contaminated soil reached a value of 8.20 ± 0.55 for both *Y. lipolytica* and carrot peel waste amendment and 7.60 ± 0.51 for yeast only. At 45 days of incubation, log (CFU/g) increased to reach a value of 8.90 ± 0.54 for both *Y. lipolytica* and carrot peel waste amendment and 7.80 ± 0.60 for yeast only. The log (CFU/g) of oil-drilling mud soil (control) did not change from its initial value. Without organic amendment, the activity of *Y. lipolytica* was slow due to the low organic matter content in the oil-drilling mud contaminated soil. Li et al. (2015) and Borowik et al.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1546315475

(2017) had also reported increase of biomass on bioaugmentation with microorganisms and organic amendment. Presence of considerable quantities of P in carrot peel waste (25.10 ± 1.20 mg/L), which is a necessary nutrient for microbial biodegradative activities (Hamoudi-Belarbi et al., 2018). In addition, production of linoleic acid biosurfactant by carrot increases the solubility and availability of hydrocarbons to biodegrading microorganisms (Marinescu et al., 2017) and contributes to the biodegradation of petroleum hydrocarbons. Desert soils have been previously shown to be nutrients-limited (Al-Saleh and Hassan, 2016).

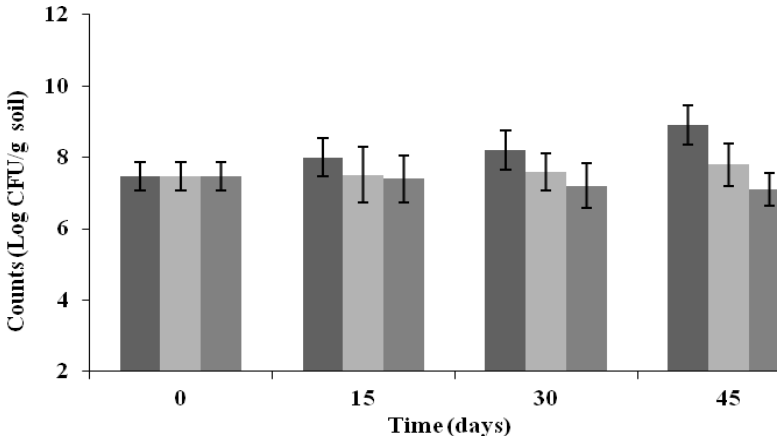

Figure 6. *Evolution of cell count during 45 days of treatment. Mud+ Carrot + Yeast (■); Mud + Yeast (■); Mud (■). Error bars represent the standard error of replicates*

Conclusion

This study demonstrated that combination of bioaugmentation by the isolate *Yarrowia lipolytica* and biostimulation with carrot peel waste as an organic amendment is a good strategy for bioremediation of oil-drilling mud contaminated soil. The TPH degradation in the oil-drilling mud contaminated soil was enhanced by biostimulation with nutrients present in the carrot peel waste and bioaugmentation by *Y. lipolytica* in comparison to *Y. lipolytica* only and control. Carrot peel waste, containing high amounts of phosphorus, enhanced bioremediation of oil-drilling mud contaminated soil by increasing activities of yeast *Y. lipolytica*. Besides, linoleic acid produced by carrot peel waste, increased the solubility and availability of hydrocarbons to biodegrading yeast. For future research, the selection of other bioproducts as biostimulants in combination with consortium of yeasts and bacteria for bioremediation should be recommended. It will be interesting to select the efficient combination for the better results.

(Received 22nd Jul 2019; accepted 16th Oct 2019)

Abstract. The baseline ecological exploratory studies of floristically rich areas like the western Himalaya are very important to determine the diversity variations. Based on research gaps detected in ecological literature of the western Himalayan forests of Sudhan Gali and Ganga summit, the study area is revisited. Plots data was collected during 2016, and advanced multivariate statistical tools were used to analyze it. Some of multivariate tools including permutation test, indicator species analysis and variation partitioning (partial CCA) were used for the first time in the area. The results of hierarchical clustering and permutation test revealed that there were four ecologically meaningful vegetation groups (1. *Berberis-Micromeria-Desmodium* (BMD), 2. *Pinus-Rubus-Persicaria* (PRP), 3. *Viburnum-Abies-Dryopteris* (VAD) and 4. *Sibbaldia-Thymus-Bistorta* (STB) associations) in the area. A significant ($p \leq 0.05$) pairwise compositional difference of all the detected plant communities was observed. The results of canonical correspondence analysis (net effect) depicted that all the studied environmental variables were significantly important, and explains about 73.1% variations in the species data. The higher ($r > 0.9$) species-environment pseudo-canonical correlations values for the first four CCA-axes revealed that the selected explanatory variables were determinants of the response (species) data variations, and the high values for the CCA axes 2 to 4 indicated that there was no single dominant environmental gradient in this part of the western Himalaya. The highest β diversity value of Himalayan alpine scrubland at the Ganga summit depicted that even a minor variation in environment affects the high altitude vegetation more rapidly than the vegetation of low elevation areas. The vegetation of the study area is under continuous deterioration, and this exploratory work can be used as a baseline study for the future management, sustainable use, and conservation programs in the area.

Keywords: *canonical correspondence analysis, biodiversity, indicator species analysis, Monte Carlo permutation test, variation partitioning, vegetation types, phytosociology*

Introduction

The ecological studies of the forests are necessary to determine the state of biodiversity pattern, vegetation structure, and species compositional dynamics over time and space. These baseline ecological studies further help in development of forest management, sustainable use of forest resources, and conservation strategies. Therefore, identification of environmental requirements of especially vulnerable plant species of any region is important and can be further used to model and identify suitable habitats. Being placed at the bottom of trophic level, plants not only serve as baseline resources for the biotic components of the higher levels, but also effectively remained engaged in maintaining the biodiversity of an area and mitigate the adverse impacts of the threatening climate changes (Khan et al., 2018a, 2019). The interactions of the various environmental factors like climate, soil, topography and anthropogenic activities strongly influence and control the vegetation structure, types, species composition and their distribution patterns (Salama et al., 2016). Therefore, the impacts of these changes on the vegetation of a given area should be studied on regular basis including species-environment relationships, both on temporal and spatial scale (Akhlaq et al., 2018; Ilyas et al., 2018). The Himalayan ecosystem in general and the western Himalayan area in particular is a floristically rich area. The western Himalayan region of Pakistan is also the most fragile, comprised of about 67% of total forest cover of the country, and under serious threat of climate changes amplified by overpopulation (Qamer et al., 2016; Tewari et al., 2017). Therefore, the area need immediate attention of the ecologists to understand the biodiversity and its distribution pattern (Rahman et al., 2017; Haq, 2018; Saima et al., 2018; Kamran et al., 2019).

Community ecology deals with the documentation of number and composition of plant species/assemblages within a geographic unit. Ecologists record multivariate field data of plots, releves or quadrats, and perform multivariate analyses to test their hypotheses. Classification of vegetation types, structure and composition of any area can be evaluated more easily and efficiently by using the tools of computer modelling and multivariate statistics (viz. hierarchical clustering, indicator species analysis, ordination etc.) for the last 04 decade (Legendre and Legendre, 1998; Khan et al., 2015; Abdel Khalik et al., 2017; Bürzle et al., 2017; Devetter et al., 2017; Chandra et al., 2018; Salama et al., 2018; Zakaria et al., 2019). Constrained ordination models or direct gradient analyses techniques including unimodal model like canonical correspondence analysis (CCA) and linear model like redundancy analysis (RDA) are the most popular ones in this regard. CCA was developed by Ter Braak (1986) by arranging a marriage between multiple regression and correspondence analysis (CA). It can be used to assess the species-environment relationships and its strength. In CCA, statistical significance can be evaluated by using the permutation test for overall the model, CCA axes, and explanatory variables. The CCA ordination diagram can be interpreted by following the centroid rule; species/response points are located at the centroid (weighted average) of the samples points where it is distributed. Similarly, all the samples having a set of particular species are scattered around the same species. The other information in such ordination biplot/triplot includes the importance of explanatory variables (arrow lengths), correlation of the variables to the CCA axes (direction of the arrows), correlation amongst the variables (angle amongst the arrows), ranking of the species response (optimum) and samples values for the environmental variable (perpendiculars drawn from species/samples points to environmental arrows). CCA calculates species-environment correlation which is actually a correlation between two types of site scores i.e. linear

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1547715505

combinations of the environmental variables (LC's) and the weighted averages of the species scores (WA's) (Ter Braak, 1986; Legendre and Legendre, 1998).

Sudhan Gali and Ganga hills remained the focal site for vegetation analyses in the past (*Table 6*) due to its complex pattern of topography, extended elevation range, thick woody vegetation cover, species richness and scenic beauty of the area. However the complex interactions between the local vegetation and its environment, classification and ordination by using the multivariate tools are not documented. First ecological exploration (vegetation structure, composition and phenology) in the study area was conducted by Khan (2001), but environmental influence was not tested by using any multivariate statistical analysis. The same is true about the subsequent study conducted by Malik et al. (2007). The use of multivariate statistical methods to vegetation data of the area was started by Siddiqui et al. (2010a, b) followed by Siddiqui et al. (2014) and Shaheen et al. (2016, 2017, 2018). An unconstrained linear ordination model (PCA) was used in all of these earlier studies, therefore the real contribution of the studied predictors was missing. A total of two separate studies conducted by Shaheen et al. (2011c, 2012) attempted to use constrained unimodal ordination (CCA) to determine the species-environment relationship, but error like model overfitting was detected. The assessment of edaphic predictor's contribution was also missing in all of these earlier studies. In Pakistan, the major issue was the modest understanding about the use of advanced multivariate statistical methods in ecology, which is now improving over time. By considering this, many geographical areas of Pakistan need revisit and attention of ecological workers. It was hypothesized in every earlier vegetation study that the local environment is significantly controlling the species distribution pattern in the area but until this study, the following un-answered questions were thoroughly investigated for the first time to achieve the set objectives. (1) What are the number of biological meaningful vegetation groups, their composition and indicator species? (2) What about the species-environment relationships and contribution of the studied environment? (3) How diversity and richness in the area is related to the studied environment? (4) How the groups of the studied variables are important (partial CCA/variations partitioning) in the area? Therefore, the findings of this study will serve as the first detailed document and help in future biodiversity conservation and management projects in the region.

Materials and methods

Study area

Sudhan Gali and Ganga hills are part of the western Himalayan mountainous area in the district Bagh, Azad Jammu and Kashmir, Pakistan. It is located toward the north and about 20 km road distance from the Bagh city. It lies between 34°02' to 34°04'N latitude and 73°44' to 73°45'E longitude, and elevation ranges from 1195 to 3004 m above sea level (m.). It is bounded by the Hattian Bala and Muzaffarabad districts in the north, Haveli district towards the east, Poonch in the south, and Murree and Hazara hills in the west. The total land area is 770 km^2, and human population of 0.434 million in 2013 with an annual growth rate of 2% (Shaheen et al., 2011a; Anonymous, 2015) (*Fig. 1*).

Climate, soil, and natural vegetation

The climate of the study area is humid, sub-continental highland type, and during the last ten years (2007-2016), the mean monthly maximum temperature in June varied from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1547715505

20-26 °C, whereas the winter temperature mostly drops to or below freezing point. Similarly, the mean annual minimum temperature varied from 6.31-13.19 °C, and the mean maximum temperature varied from 20.36-27 °C. The mean annual rainfall of the same period varied from 463 mm in the year 2009 to 2242 mm in the year 2015, whereas only two months including July and August received the maximum (> 50%) during monsoon showers. During the year 2016, the mean annual minimum temperature, maximum temperature, and precipitation remained 7.91 °C, 22.45 °C, and 1798 mm respectively (PMD, 2018). Snowfall frequently occurs from December to February and mountains remain covered with snow until the end of April each year (Waseem et al., 2006; Saeeda and Zakir, 2012). Temperature and precipitation data (2007-2016 = 10 years) of the study area was acquired from the United States National Centers for Environmental Prediction (US-NCEP) Climate Forecast System Reanalysis (CFSR) by using the climate engine (https://app.climateengine.org/). The temperature data source was CFSv2 19200 m (1/5-deg) daily reanalysis dataset (NOAA). The wind blows from west to east during the day time, and from south-east to north during the night. The wind velocity was higher in the afternoon as compared to morning time. There is no river in the study area, although a big seasonal stream "*Nala Mahl*" flows through the area.

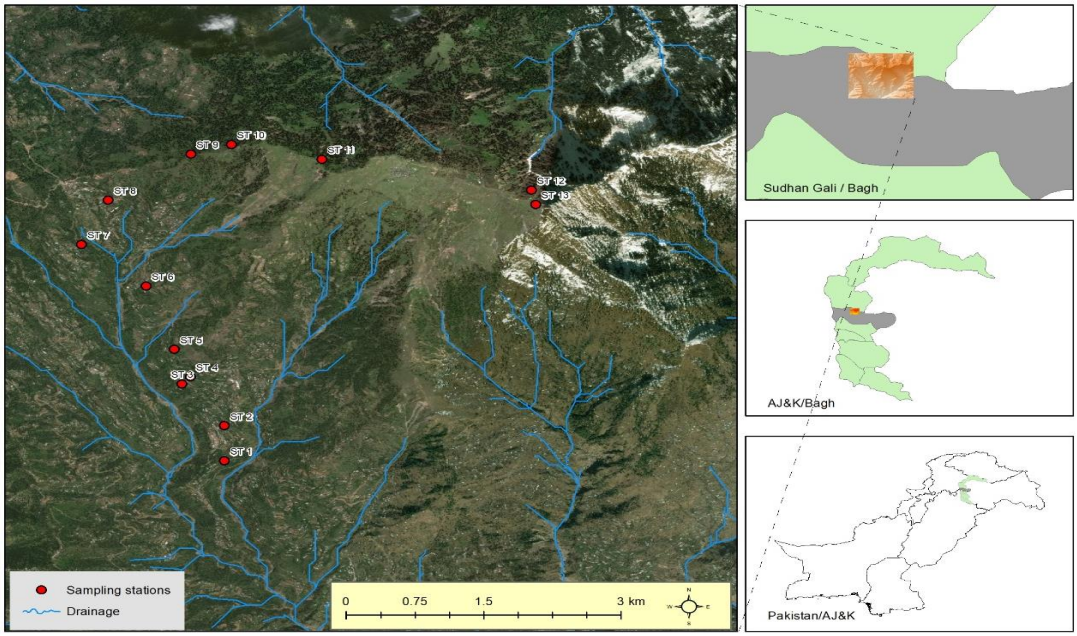

Figure 1. *A GIS map of the Sudhan Gali and Ganga hills showing the distribution of 13 sampled stations in the study area*

The soil of the study area is varied from clay loam to sandy loam in texture, and from yellowish brown to dark brown or to black in color. The bedrock is comprised of two types of rocks; light grey to black coloured Dogra slates of early Cambrian area (comprised of slates with quartz and feldspar, phyllites, and trilobites) and sedimentary Murree formations of the Miocene (shale and red clastic sand or sandstone) (Khan, 2001).

The natural vegetation of the area is mainly comprised of three eco-zones. These include humid sub-tropical Chir-pine, moist temperate blue-pine, and Himalayan sub-alpine coniferous zones. The important tree element of the natural vegetation includes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1547715505

Pinus roxburghii, P. wallichiana, and *Abies pindrow*. Similarly, the shrub layer is comprised of *Berberis lycium, Rubus niveus, Rosa moschata, Indigofera heterantha,* and *Viburnum grandiflorum*. The important herbaceous elements includes *Micromeria biflora, Galium elegans, Veronica laxa, Oenothera rosea, Rumex nepalensis, R. dentatus, G. wallichianum, Achillea millefolium, Trifolium repens, Sibbaldia procumbens, Thymus linearis,* and *Persicaria amplexicaulis*.

Vegetation (plot) data collection

A stratified random method of vegetation sampling by using plots was adopted to study the vegetation types and intensity of anthropogenic disturbance in the area. The study area was surveyed during the growing season (Monsoon) of the years 2016. A total of 13 sampling stations were randomly selected along the altitudinal gradient. At each station, three sub-stations were again randomly selected, and based on minimal area method, at each of 39 sub-station, 3 plots were randomly laid and studied to record the data of tree layer (size: 30×30 m^2). Nested plots for shrub layer (size: 5 × 5 m^2) and herb layers (size: 1×1 m^2) were also studied. The absolute values of density, frequency and cover of each plant species were recorded, averaged, relative values were calculated, followed by calculation of importance values index (IVI) of each species (Curtis and McIntosh, 1950; Cox, 1967; Khan et al., 2018b, 2019). First three alphabets of each of generic and specific binomials separated by a dot of each plant species were created and used in all multivariate analyses.

Geographic coordinates (locations) of each studied plot were recorded by using Garmin, 76CSx handheld GPS device and topographic variables say altitude, slope, and slope aspect were calculated by using 30 m digital elevation model (URL: https://asterweb.jpl.nasa.gov/gdem.asp) of the study area. The ArcGIS (ver. 10.3) was used to extract the values. Cos-transformation of the slope aspect (CTA) values was performed prior to use in the multivariate analysis. The number of stumps and herbivore dungs were also counted to measure and test the deforestation and grazing pressure respectively in each plot (Khan et al., 2019).

The collected plant specimens were pressed, dried and mounted on standard sized herbarium sheets and identified by using the available local and regional taxonomic literature (Stewart, 1972; Nasir and Ali, 1971-1995; Ali and Qaiser, 1995-2009; Nakaike and Malik, 1992; EFLORAS, 2012; TROPICOS, 2012; Khan et al., 2016), cross-matched with herbaria collections at the University of Azad Jammu and Kashmir, Muzaffarabad and deposited in the same herbarium for future references and record.

For edaphic contribution, soil samples (about 500 g) were collected from each plot and topsoil layer (about 30 cm depth), and a composite mixture (about 1.5 kg) was prepared for each sub-station. A total of six physicochemical parameters of the soil samples were studied at the Soil and Water testing Laboratory Rawalpindi, Pakistan. The soil samples were dried at room temperature followed by sieving (2 mm sieve) and storage. The soil pH was assessed by using 1:5 soil-water suspension and pH meter (Schofield and Taylor, 1955), whereas electrical conductance (mS cm^{-1}) ability of the soil samples was tested as conveyed by Richards (1954). Soil organic matter (%) was calculated by using the standardized solutions of $FeSO_4$ and $K_2Cr_2O_7$ as communicated by Nelson and Sommer (1982). Available phosphorus (ppm) in soil was determined by using $NaHCO_3$ solution as extracting agent (Olsen et al., 1954). Similarly, available potassium (ppm) in soil was calculated by using the standardized solutions of CH_3COONH_4 and KCl (Richards, 1954). The nitrate-N (mg/kg) of soil samples was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1547715505

measured by using 1:5 soil-water suspension, and LAQUA twin Nitrate Ion meter (Othman et al., 2014).

Statistical analyses

The decision about the number of biologically meaningful plant associations in the areas was made on the basis of Monte Carlo permutation test results. A total of two to six (2-6) possible groups were tested, and the mean p-value and the number of significant indicator species were observed. A criterion of minimized p-value and/or maximized significant species was used to decide the number of plant association (Khan et al., 2018b, 2019). For ecological classification of the studied samples, two-way agglomerative hierarchical clustering (distance "Euclidean"; linkage "Ward") dendrogram of the studied vegetation samples (sub-stations) and their allied plant species was developed. Multi-response permutation procedure (MRPP) test was used to identify the pairwise compositional difference of the identified vegetation groups. Indicator species analysis (Dufrêne and Legendre, 1997) was used to identify the indicators of each group. The different diversity measure including species richness (Margalef, 1958), Shannon's diversity (Shannon and Weaver, 1949), Simpson's reciprocal diversity index (1/D; Magurran, 1988), and evenness (Pielou, 1975) were calculated for each plant association. Unimodal ordination models including detrended correspondence analysis (DCA) and canonical correspondence analysis (CCA) were used to seek the beta-diversity variations and species-environment relationships respectively. The significance of the studied variables was tested by using both simple (marginal) and conditional (net) terms effects via permutation test available in Canoco software (Ter Braak and Smilauer, 2012). Similarly, the significance of the constrained axes and pairwise comparasion of the three groups of variables (viz. topographic, edaphic and anthropogenic) was tested by using variation partitioning (partial CCA) method to seek their contribution towards the species distribution pattern in the study area (Khan et al., 2019).

Results

Taxonomic and life form classification

A total of 90 plant species of the vascular plants were recorded in the studied samples (39 sub-stations × 9 plots at each sub-station = 351 total plots studied), and were allied to 78 genera and 41 families. The majority of plant species (81, 90.01%) were belonged to the angiosperms and found distributed in 71 genera and 38 families. The gymnosperms were represented by a single Pinaceae family, further comprising of 3 genera and 4 coniferous species (4.45%) in the area. Pteridophytes were represented by 2 families, 4 genera and 5 species (*Table 1*).

Life form classification of the same 90 plant species depicted that there were 14 (15.56%) megaphanerophytes, 9 (10%) nanophanerophytes, 30 (33.3%) hemicryptophytes, 21 (23.3%) therophytes, 5 (5.56%) chamaephytes, 10 (11.1%) geophytes and 1 (1.1%) liana species in the area (*Table 4*).

Biologically meaningful vegetation associations in the area

The first-ever results of Monte Carlo permutation testing from the area for two to six (2-6) possible vegetation groups depicted that the minimum mean p-value of 0.098, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1547715505

maximum number of significant indicator species of 59 were recorded at the 4th level of division. Therefore, this study recognized a total of four (4) biologically meaningful (significant) vegetation clusters in the study area (*Fig. 2*). The two-way agglomerative hierarchical clustering dendrogram of the vegetation associations (grouping pattern of the 39 studied samples) and their allied plant species (90) is presented in *Figure 3*. A pairwise comparasion of the detected plant association was made by using MRPP test for further confirmation. The results showed that all the 6 pairwise comparisons of the 4 groups were statistically significant ($p < 0.001$), therefore depicting a reasonable species compositional differences amongst the detected groups. The higher negative T-values were observed for all the pairwise comparisons, and we know that a more negative T-value represent stronger separation of the compared plant communities. On the basis of three leading diagnostic plant species of each group (detected by using indicator species analysis, ISA), the vegetation associations were renamed as BMD (group 1), PRP (group 2), VAD (group 3) and STB (group 4). The maximum compositional separation (T-value: -17.26; p-value < 0.01) was observed between BMD and VAD associations because the former one belong to sub-tropical and the latter one to sub-alpine zone in the area. This analysis also gave A-values (within-group agreement) in the range of 0.2 to 0.37 for overall and all the 6 pairwise comparisons of the plant communities. This proves that within groups heterogeneity equals expectation by chance. The maximum A-value can be $A_{max} = 1$, which means that all items/samples within the group are identical. Conversely, A = 0 mean that within groups heterogeneity equals expectation by chance and if the A-value is < 0, it mean that within groups heterogeneity is higher than expected by chance (*Table 2*).

Table 1. *A table showing the summary of taxonomic classification of the plant species*

Phyto-taxa	Families (%)	Genera (%)	Species (%)
Pteridophytes	2 (4.88%)	4 (5.13%)	5 (5.56%)
Gymnosperms	1 (2.44%)	3 (3.85%)	4 (4.45%)
Monocots	3 (7.32%)	11 (14.11%)	12 (13.34%)
Dicots	35 (85.37%)	60 (76.93%)	69 (76.67%)
Total	41 (100%)	78 (100%)	90 (100%)

Vegetation types, composition and their key factors

A total of three leading significant indicator species of each vegetation group were used to rename the vegetation groups as; 1. *Berberis-Micromeria-Desmodium* (BMD) association, 2. *Pinus-Rubus-Persicaria* (PRP) association, 3. *Viburnum-Abies-Dryopteris* (VAD) association and 4. *Sibbaldia-Thymus-Bistorta* (STB) association (*Table 4*). The details of each association is presented below:

Berberis-Micromeria-Desmodium (BMD) community (sub-tropical chir-pine forest)

This plant community was recorded at and around the Birpani town at an elevation range of 1700-2100 m (a), longitude (in dd) varied from 73.749-73.756 E, latitude from 34.046-34.066 N, and comprised of 18 samples/sub-stations (*Fig. 3*). This association was mostly located at the western faces (solar aspect) with moderate slope inclination ($22.49 \pm 5.73°$). A total of 63 plant species were recorded in this association out of which 41 appeared as indicator species (IS) and 20 as significant indicator species (SIS) of this community. The average species count per sample was 22.89 ± 4.13, and the absolute value varied from 14-30 in the studied samples. The leading ones were *Berberis lycium*, *Micromeria biflora* and *Desmodium multiflorum*. The least indicator value was recorded for *Avena barbata* and *Solanum pseudocapsicum* species. The Shannon's diversity index value was 2.87 ± 0.18, whereas Simpson's diversity index (0.94 ± 0.02), Inverse Simpson's/Fischer's diversity (14.47 ± 2.52), Pielou's evenness (0.93 ± 0.03), Margalef's richness (5.05 ± 0.68), and β-diversity (mean Euclidean distance: 67.3) were also recorded. The mean soil pH of this group was 7.22 ± 0.61, whereas soil EC (mS/cm), nitrate-N (mg/kg), phosphorus (ppm), potassium (ppm), and organic matter (%) values were 28 ± 0.111, 14 ± 1.11, 1.44 ± 1.04, 82.67 ± 21.51, and 2.25 ± 0.61 respectively. Some of the key factors of this association includes the highest values of mean soil pH (basic soils), species, richness, α-diversities, and household density as compared to other associations. Similarly, the least values of altitude, nitrate-nitrogen, phosphorus, potassium, and organic matter, fuelwood collection (deforestation) and grazing pressure were other important factors (*Tables 3* and *4*). This scrubland association represents the remnants of stable Chir-pine forest, and extreme anthropogenic pressure in the past might be responsible of takeover of *Berberis*, *Micromeria* and *Desmodium* species.

Pinus-Rubus-Persicaria (PRP) community (Himalayan moist temperate forest)

This community was studied at the Sudhan Gali at an elevation range of 2100-2500 m (a.), and comprised of 6 samples. It was located at 73.742-73.745 E longitude, and 34.071-34.076 N latitude (*Fig. 3*). This community was recorded at the south-eastern faces having maximum mean slope (34.13 ± 6.49; range: 28.2-40.05) value. A total of 36 species with 21 IS and 17 SIS species were recorded in this group. The average species count was 23.50 ± 3.08 (20-29) for this association, and was highest as compared to all other associations but least β-diversity (mean Euclidean distance: 47.8) value depicting the homogeneity and least compositional dissimilarity amongst the studied samples (*Table 3*). It was dominated by *Pinus wallichiana*, *Rubus niveus* and *Persicaria amplexicaulis*, whereas the least IV was observed for *Picea smithiana* and *Robinia pseudoacacia* (*Table 4*). Total species (richness) and α-diversities were lower than the BMD association but higher than the other two (VAD and STB) associations of the higher elevation areas. The mean values of edaphic variables including soil pH, soil EC, nitrate-N (mg/kg), phosphorus (ppm), potassium (ppm), and organic matter (%) were 7.63 ± 0.04, 0.24 ± 0.04, 0.84 ± 0.08, 1.16 ± 0.08, 108 ± 52.59, and 2.2 ± 0.22, respectively. Some key factors of this association includes the highest values of slope, average species count in the plots, proportion of significant indicators to indicators (2nd), basic soil, and grazing pressure (17.17 ± 1.17 dungs/ha), and the least values of β-diversity, soil EC, nitrogen, phosphorus, and organic matter as compared to other associations (*Tables 3* and *4*).

Viburnum-Abies-Dryopteris (VAD) community (Himalayan sub-alpine forest)

This association was studied at upper Sudhan Gali areas and an elevation range of 2500-2800 m (a.), comprised of 9 samples (81 plots). It was located at 73.753-73.766 E longitude, and 34.081-34.083 N latitude (*Fig. 3*). It was studied at north western faces with mean slope value of 29.54 ± 10.62° (range: 21.98-43.67°). It was comprised of 34 species, 14 indicator species and 10 significant indicator species. The leading significant ones were *Viburnum grandiflorum*, *Abies pindrow*, and *Dryopteris stewartii*. The species with minimum IV were *Urtica dioica* and *Rumex dentatus* (*Tables 3* and *4*). Total species (richness) and α-diversities were further decreased as compared to both BMD and PRP associations of low elevation areas, and were almost alike to STB association of the higher elevation areas of the Ganga summit. The mean values of edaphic variables including soil pH, soil EC, nitrate-N (mg/kg), phosphorus (ppm), potassium (ppm), and organic matter (%) were 6.16 ± 0.49, 0.29 ± 0.1, 4.76 ± 1.68, 4.05 ± 2.02, 183.34 ± 86.75, and 3.47 ± 1.39 respectively. The grazing (dungs/ha) and deforestation (stumps/ha) pressure values were 13.12 ± 8.33 (2-23), and 14.78 ± 2.54 (11-19) respectively. Key factors of this association includes the highest values of soil EC, soil fertility (NPK), organic matter, vegetation cover, deforestation and higher grazing pressure (2nd), and proportion of significant indicators to indicators species. Similarly, least values of indicator species, SIS, α-diversities, evenness, and relatively lower soil pH (acidic) values were other important factors (*Tables 3* and *4*). The interactions of the least values of soil pH, higher soil fertility in term of NPK and thickest vegetation cover variables are all very important and correlated. The core areas of this association

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1547715505

were least diverse with conifer dominancy, and no human settlements, therefore recorded under severe deforestation pressure and activities of the timber mafia.

Sibbaldia-Thymus-Bistorta (STB) community (Himalayan alpine scrubland forest)

This plant association was recorded at and around Ganga summit areas, elevation ranged from 2900 to 3000 m (a.), and comprised of 6 samples. It was located at 73.787 E longitude, and 34.076-34.078 N latitude (*Fig. 3*). This vegetation cluster was comprised of a total of 26 species, 14 indicator species, and 12 significant indicator species (*Tables 3* and *4*). The proportion of significant indicators to indicators was highest in this community, therefore, representing the uniqueness of this microhabitat in the area, and the important determining factors includes high altitude and associated least mean minimum temperatures. Three leading significant indicator species of this community were *Sibbaldia procumbens*, *Thymus linearis,* and *Bistorta affinis*, whereas the least IV was recorded for *Gentiana kurroo, Geum urbanum* and *Salix alba* species. During the ecological surveys, it was also observed that local inhabitants visit the areas of this association frequently during the growing season for collection of variety of medicinal plant species. Similarly, except Margalef's richness (2.87 ± 0.55), all other diversity values (viz. Shannon's diversity 2.48 ± 0.17; Simpson's diversity 0.91 ± 0.02; Simpson's reciprocal diversity 10.51 ± 1.65; Pielou's evenness 0.95 ± 0.04; and β-diversity 78.65) were higher than the previous sub-alpine VAD vegetation type, and lower than the first two (viz. BMD and PRP) vegetation types of low elevation area (*Tables 3* and *4*). This might be due to increase of anthropogenic activities (other than deforestation) above the timberline in the area. The mean values of edaphic variables including soil pH, soil EC, nitrate-N (mg/kg), phosphorus (ppm), potassium (ppm), and organic matter (%) were 5.33 ± 0.2, 0.28 ± 0.24, 4.3 ± 2.8, 1.61 ± 1.32, 67 ± 3.29, and 2.65 ± 0.06 respectively.

The key factors controlling this association were the highest values of altitude, evenness, β-diversity, and proportion of significant indicator to indicator species, and the least values of slope, total species (richness), average species, IS, SIS, soil pH, and potassium contents of the soil (*Tables 3* and *4*).

Ordination analyses

Detrended correspondence analysis

The gradient length in the compositional response data was above 4 SD (standard deviations of species turnover) units, therefore, unimodal ordination models like DCA and CCA were analyzed. DCA was used to confirm the results of hierarchical clustering of the vegetation samples collected from the western Himalayan forests of Sudhan Gali, Pakistan. Total variations in the species response data were 2.84, whereas the first four axes cumulatively represents 37.3% variations. The gradient length of the first four DCA-axes was 4.4, 2.09, 2.49, and 1.25 respectively. DCA biplot of the plant species and studied samples allied to four vegetation types showed that both species and samples are reasonably separated in the ordination space (*Fig. 4*). Along the DCA axis-1, the plant species of the low elevation areas are distributed in the left half and species of higher elevation areas in the right hand side of the biplot. This species distribution pattern depicted the prominent role of altitude in the area. Secondly, this biplot is also depicting the pattern of diversity

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1547715505

variations along the DCA axis-1 (or altitude), which continuously decreased up to VAD association and then again increased for the alpine STB association (*Fig. 4*).

Canonical correspondence analysis (CCA) and variation partitioning

The contribution of five topographic (altitude, Cos-trans aspect, slope, latitude, and longitude), six edaphic (soil pH, organic matter, EC, N, P, and K), and two anthropogenic (grazing pressure, and deforestation) variables toward explaining the variations in the response data were tested by using CCA. All the richness, evenness, and diversity variables were not included in this test. The CCA model (overall) was detected as significant (Pseudo F-value = 4.61; p-value = 0.001). Therefore, all the 13 constrained axes and variables were further tested by using permutation test. The results showed that first seven (7) CCA axes were significant (p-value ≤ 0.003) (*Fig. 5*). Out of total inertia of 2.84 of the response data, all the explanatory variables explained 73.1% variations, whereas the adjusted explained variations were 59.2%. First four CCA axes cumulatively explained 50.15% and 68.57% of variations and fitted variations respectively. A very high values of species-environment pseudo-canonical correlations of the first four CCA axes were observed (viz. r 0.99, 0.98, 0.97 and 0.92). This showed that the selected explanatory variables were determinants of the response (species) data variations. Similarly, the high values of species-environment correlation for the CCA axes 2-4 indicated that there was no single dominant environmental gradient in this part of the western Himalaya. By using permutation test, both simple (marginal) and conditional (net) term effects were tested for all the 13 explanatory variables. The results of simple term effect testing revealed that only the soil EC was not much important towards explaining variations in the species data, whereas the net effect testing made the same as significant as well (*Table 5*). The ranking (order of importance) results of the studied variables depicted that altitude is the leading factor followed by grazing pressure, deforestation, nitrate-N, soil pH, potassium, slope, longitude, phosphorus, cos-trans aspect, organic matter, latitude, and soil EC in the area (*Table 5*).

The graphical results of the CCA (first three CCA axes) are presented in *Figure 6*. These CCA biplots revealed that the species distribution of the four detected associations are controlled by the studied environment. The species of STB community got the maximum score along CCA axis 1, and the species of BMD community got the least, therefore primarily controlled by altitude, followed by N, P, K, grazing and organic matter. Similarly, BMD and PRP associations are found separated along CCA axis-2, and controlled by deforestation, soil pH, longitude and slope variables (*Fig. 6*).

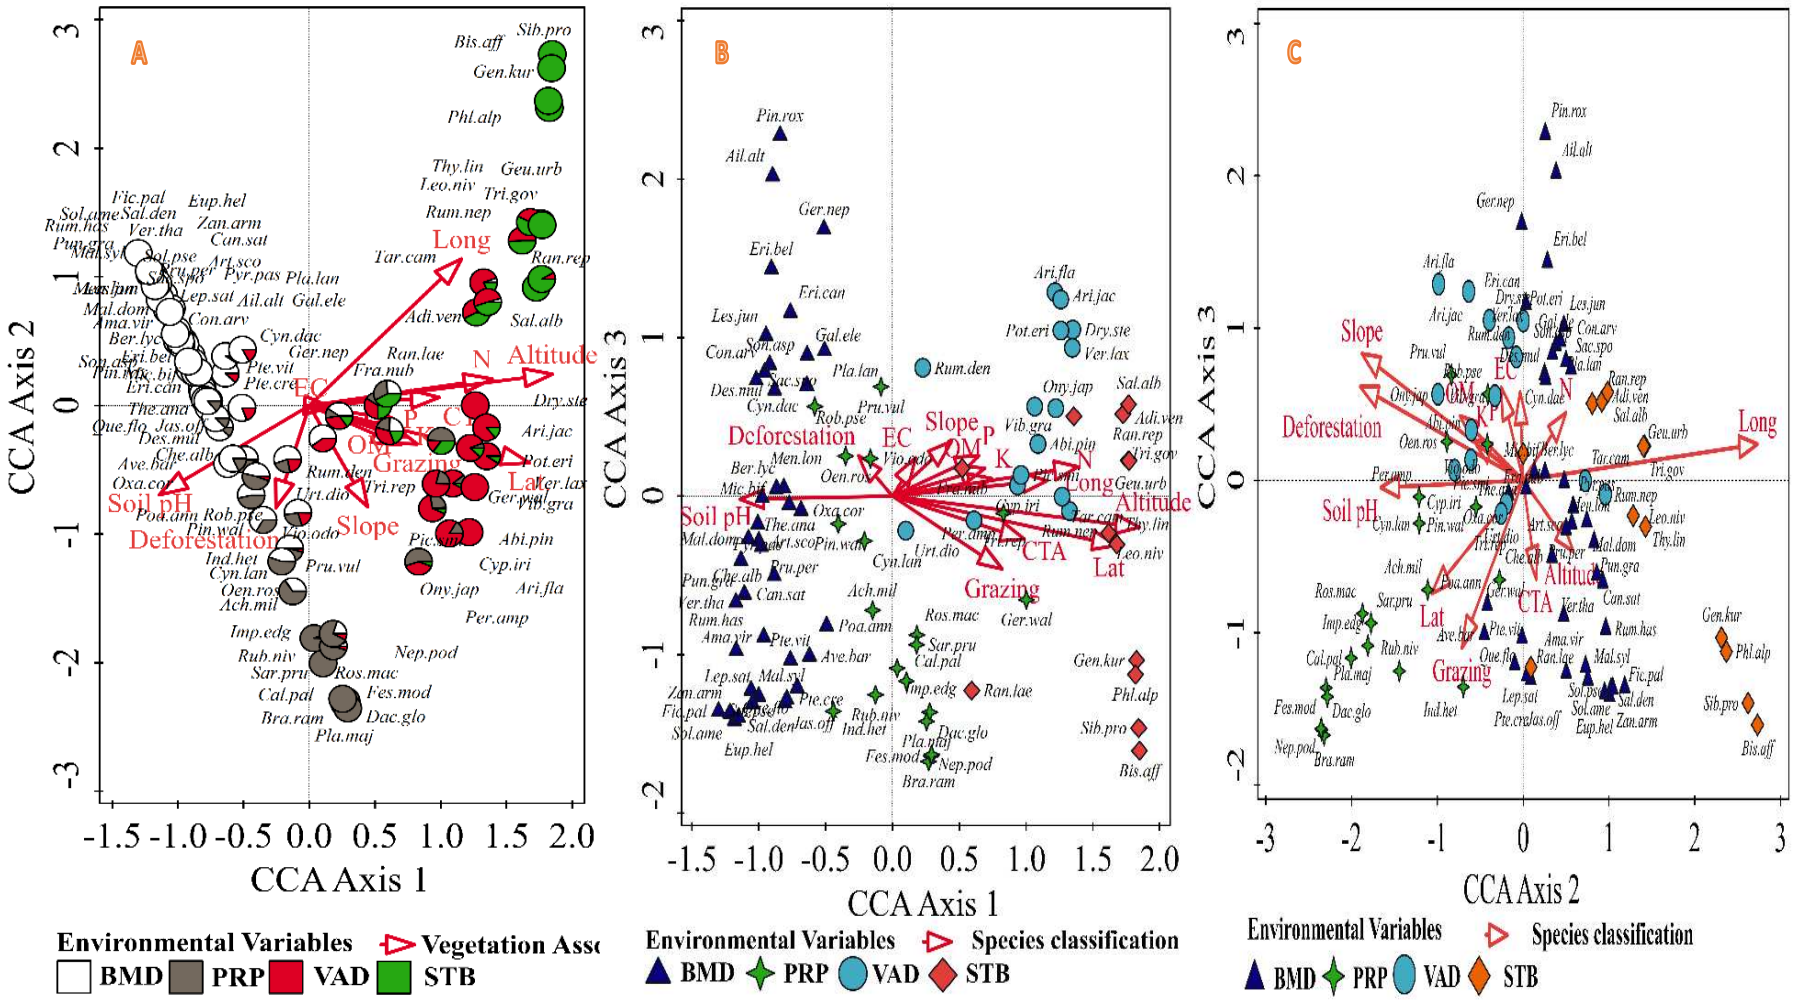

Figure 6. *A group of CCA biplots depicting the species-environment relationships of the four vegetation types of the western Himalayan forests of Sudhan Gali, AJ&K, Pakistan (CCA axes: A = 1&2; B = 1&3; C = 2&3)*

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 17(6):15477-15505.
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1547715505

A total of two leading factors of each of topographic (altitude and slope), edaphic (nitrate-N and soil pH), and anthropogenic (grazing pressure and deforestation) class were used to perform variation partitioning (partial CCA) to seek the contribution of each class and their interactions. Like CCA, permutation test was performed for net effects of each class. This analysis results depicted that topography was the leading (explained variations 32.6%) class, followed by anthropogenic (25.8%), and topographic vs. edaphic interaction (25.5%). Similarly, least variations were explained by the interactions of all classes (-5.5%). This negative value of the adjusted explained variations can be interpreted as zero, and linked to the samples where the explanatory variables explain less variations than what the random normal variables do (*Fig. 7*). However, at this moment, higher contribution of anthropogenic than the edaphic class is a major concern in the study area.

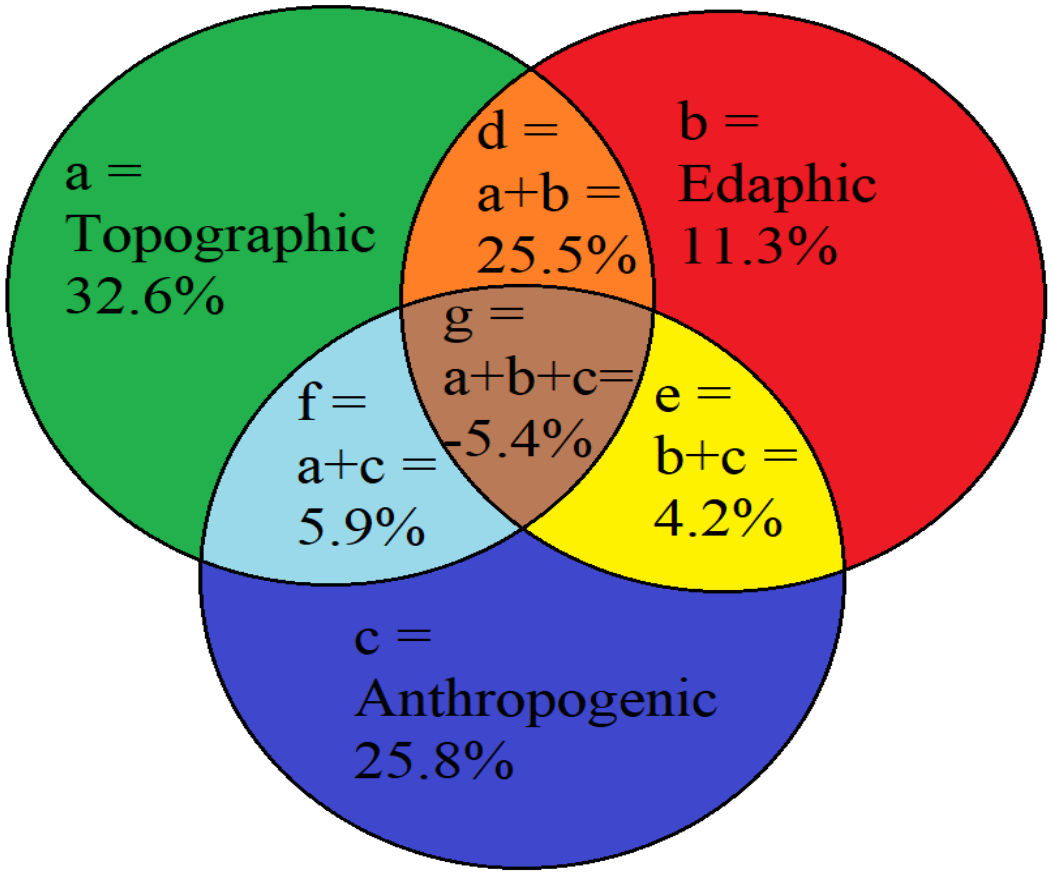

Figure 7. *A Venn diagram showing the amount of explained variations (%) in the species data by the three groups of explanatory variables*

Discussion

A detailed ecological exploration of the western Himalayan forests is necessary for future biodiversity management, sustainable utilization and conservation (Shaheen et al., 2012; Khan et al., 2019). This study thoroughly and comparatively reviewed the history of forest ecological work conducted at the Sudhan Gali and Ganga summit of Bagh, AJ&K, Pakistan, and identified few research gaps that needed to be explored. Prior to this study, a total of 14 different ecological studies were conducted from 2007 to 2018, but a lot

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1547715505

of questions remained un-answered (*Table 6*). Therefore, this study represents the first ever detailed ecological exploration of the area. Majority of earlier studies rarely used agglomerative hierarchical clustering for classification, and mostly used a linear un-constrained model (PCA) for arranging the species along the environmental gradients. The drawback of using PCA include the Horseshoe Effect (an artifact of the ordination diagram similar to the Arch Effect), therefore, PCA axis-2 did not truly represent the secondary gradient. A study close to this one was conducted by Shaheen et al. (2012) in the study area, however, Monte Carlo permutation test to decide the ecological meaningful number of vegetation types, significant indicator species of each type by using indicator species analysis, pairwise compositional significance of the plant associations, contribution of edaphic variables, order of importance of studied environment, and variation partitioning were performed for the first time from the study area.

A total of four plant associations (1. *Berberis-Micromeria-Desmodium* (BMD), 2. *Pinus-Rubus-Persicaria* (PRP), 3. *Viburnum-Abies-Dryopteris* (VAD) and 4. *Sibbaldia-Thymus-Bistorta* (STB) associations) were recorded in this study, and confirmed by using different multivariate statistics. Sher et al. (2013) studied the vegetation at 13 different stations along the altitudinal gradient from the Sudhan Gali and Ganga area like this study, but communicated the composition of each station as a plant community and further place them in the higher hierarchy of four plant associations. Secondly, the elevation gradient of their studied stations was ranged from 2200 to 2500 m (a.) unlike this study which ranges from 1700 to 3000 m (a.). Malik and Malik (2012) also recorded four plant associations from the same area. Both these earlier studies did not employ any multivariate analysis tool. Therefore, a sufficient compositional differences were observed while comparing this with both prior studies. Unlike this study, both prior studies also communicated that there is no significant correlation between species turnover and altitudinal variations. However, the status of overall dominant species (especially *Pinus wallichiana* and *Abies pindrow*) in the area are same. The composition of alpine meadow (Ganga) matches with the results of Shaheen et al. (2011c), who also reported the similar community composition and leading dominants in the other areas of district Bagh. We recorded low indicator values of *Pinus roxburghii* and *Pinus wallichiana* (Blue Pine) at the lower elevation in the BMD vegetation type. Khan et al. (2019) reported the dominancy of Chir pine at the low elevation areas of adjacent Muzaffarabad district, whereas this study detected the dominancy of *Berberis lycium* and *Micromeria biflora* at the similar elevation areas. This might be due to higher rate of fuelwood collection and consumption than regeneration as compared to other related adjacent areas (Shaheen et al., 2011b). The other contributing factor might include the findings of Saeeda and Zakir (2012), which communicated the highest correlation between forest deterioration and poor socioeconomic status of the inhabitants of the Bagh area. The mid-elevation areas (2100-2500 m) of PRP vegetation type is relatively more stable than the other three types, but higher grazing pressure needs immediate attention. The shrub species of *Viburnum grandiflorum* has taken over the *Abies pindrow* and *Picea smithiana* in the sub-alpine VAD type (elevation: 2500-2800 m). This type was recorded under sever deforestation pressure, possibly because located far from the human settlements, therefore a relatively easy target for timber mafia. Secondly, the local government has completed a new metallic road up to 2700 m elevation, and this provide an easy transportation tool for illegally obtained forest resources. The study area (especially STB type: 2900-3000 m is receiving a huge number of tourist's visits especially during the growing season which sometime get involved in uprooting of rare medicinal species.

×: No; ✓: Yes

The study area is diverse and the mean Shannon's diversity values of the four plant communities varied from 2.47-2.87, Simpson's diversity index from 0.89-0.94, reciprocal Simpson's diversity from 8.44-14.47, Pielou's evenness from 0.88-0.95, and Margalef's richness from 2.87-5.05. These values are comparable with the earlier work of Shaheen et al. (2011c), Malik and Malik (2012) and Sher et al. (2013) conducted in the same area. These diversity variations are also comparable with the other vegetation surveys in the Himalayas (Roy and Behera, 2005; Kharkwal, 2009). The β-diversity (amongst studied samples) in the study area varied from 47.88-78.65. It was observed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1547715505

that the number of species, indicator and significant indicator species of groups continuously decreased along the increasing elevation, whereas diversity values also showed the similar pattern except it again started to increase at the Ganga summit. However, the proportion of significant indicator species to indicators continuously increased along the elevation gradient, therefore depict the uniqueness of sub-alpine to alpine microhabitats in the Himalayas. The results of this study also suggested that the forests edges of the Sudhan Gali are more diverse than the forest interiors, and the similar results are also reported by Khan et al. (2019).

The role of topography and especially altitude is well documented (Shaheen et al., 2011c; Khan et al., 2019) in the Himalayas, however, CCA net effect testing proved that anthropogenic influences has come very close to topography and taken over the edaphic contribution in this regard. The order of importance of the studied environment is presented in *Table 5* and *Figure 7*. All these disturbances and the rarest plant species are presented in *Figure 8*. Therefore, the study area need development and implementation of management plans for the restoration of important and valuable forest resources in this part of the western Himalaya.

Conclusion and recommendations

The species composition and vegetation structure of the observed four vegetation groups of the study area was significantly different. Therefore, these groups are supporting some rarest plant species and unique composition. The topography is detected as the leading driver of species distribution pattern variation followed by grazing and deforestation pressures. The highest correlation was observed between deforestation and thick coniferous forest patches, and grazing intensity and temperate grassland pastures in the area. Therefore, this study concluded that vegetation composition of the sub-alpine to alpine areas is changing at faster rates than the low elevation areas. The results of CCA (net effect) depicted that all the studied environmental variables (thirteen in total) were significantly important, and explains 73.1% variations. This study also concluded that the selected explanatory variables were determinants of the response (species) data variations and there was no single dominant environmental gradient in this part of the western Himalaya. Similarly, the highest β-diversity value of west Himalayan alpine scrubland association as compared to others, is representative of variety of microhabitats with unique flora. This also mean that even a minor variation in environment affects the high altitude vegetation more rapidly than the vegetation of low elevation areas.

An effective management plan for the restoration of vegetation in area are required including provision of fuel alternatives for the local masses. This study recommend that the importance of local biodiversity and consequences of its depletion should be regularly addressed and communicated to local masses. The launching of afforestation and reforestation programs, and their continuous monitoring will prove effective. Similarly, stimulus of medicinal species cultivation can help a lot in this regard. The provision of free seedlings of valuable native species, strict enforcement of biodiversity protection law, periodic monitoring of endangered species populations are some other effective tools. All this is necessary because these wild relatives can serve as an important germplasm for the future drugs, and different stress and disease tolerance characteristics which can be used for the improvement of masses health, and existing valuable agricultural species respectively.

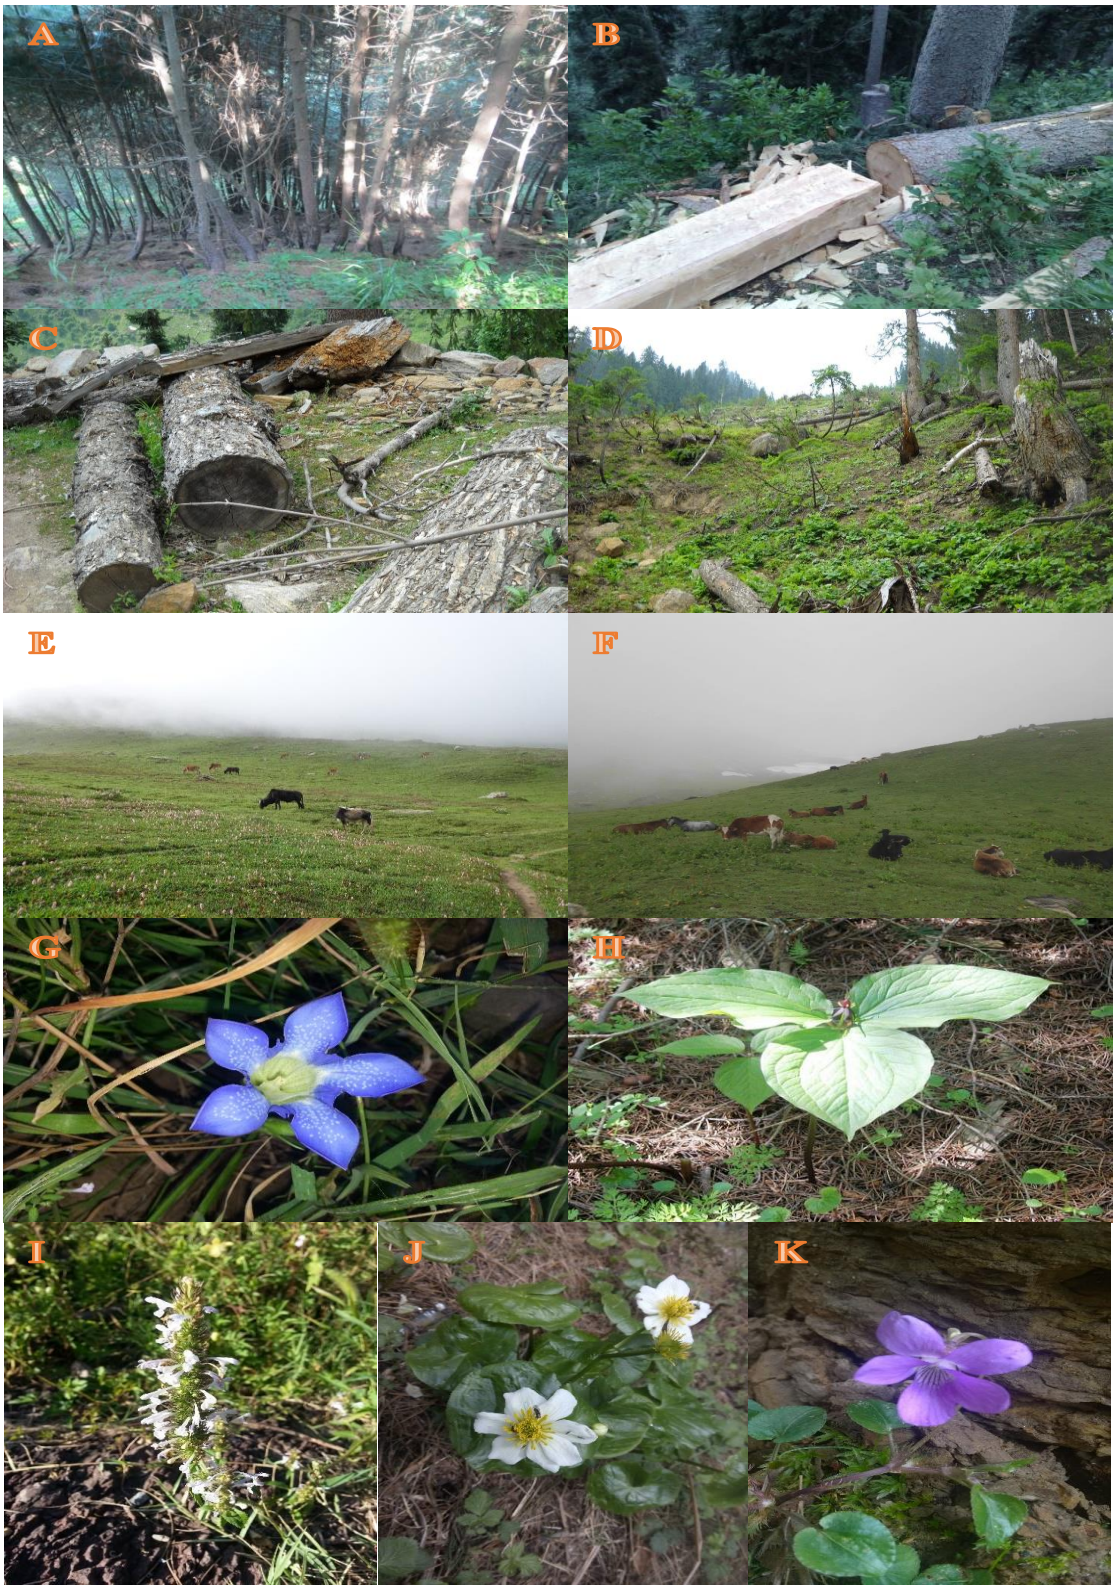

Figure 8. *Some visuals depicting the influential anthropogenic factors (A: forest fire; B-D: deforestation; E-F: grazing), and extremely rare plant species (G: Gentiana kurroo; H: Trillium govanianum; I: Nepeta podostachys; J: Caltha palustris var. alba; K: Viola odorata) of the western Himalayan forests of AJ&K, Pakistan*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1547715505

We concluded that overall vegetation of the area is under heavy anthropogenic pressure and sustainable use of these natural resources is recommended. Various concerned departments like wildlife, forest, environment, tourisms and local government should play their role in launching of awareness campaigns, conservation/management plan development, execution and implementation to save this wealth of the area.

This study observed that over-exploitation of medicinal plant species especially from the Ganga summit and adjacent alpine area is resulted in least population size of *Geum urbanum*, *Gentiana kurroo, Nepeta podostachys, Caltha palustris var. alba, Viola odorata* and *Trillium govanianum*. According to literature, species like *Saussurea costus* and *Rheum australe* were once surviving and now become extinct in the area. Therefore, future studies like documentation of rate of population fluctuation, potential habitat mapping under present, past and future climate scenarios should be conducted immediately to ensure their sustainable use, forest management and conservation.

(Received 23rd Jul 2019; accepted 15th Nov 2019)

Abstract. The study was carried out in the International GAP Agricultural Research and Training Centre (GATEA) between the years 2010-2014 in Diyarbakır, Turkey. The aims of this study were 1) to compare 8 different models (MG, Dhanoa, Nelder, Wood, CLD, and 2nd-, 3rd- and 4th-degree polynomial) used to describe the lactation curve for Awassi sheep by using 557 completed lactation milk yield records, and 2) to identify the suitable model. In addition, the most effects of birth season, parity, and birth type on the lactation milk yield and parameters on the identified model were investigated. As a result of this study, it was determined that the 4th-degree polynomial (POL4) model is the most suitable. In addition, it was found that all the factors, excluding birth type, have significant effects on the model parameters and lactation milk yield ($P < 0.05$).
Keywords: *sheep, milk yield, lactation curve,mathematical model, curve fitting*

Introduction

In Turkey, seventeen percent of the total sheep population is raised in the Southeastern Anatolia Region of Turkey (Anonymous, 2017). The Awassi sheep is the prevalent in the region due to high milk yield. However, the milk yield of Awassi shows wide variation depending on the level of breeding in milk yield, age and weight at birth, lambing month, birth type, production system, and lactation period. Average lactation milk yield of the sheep raised in Southeastern Anatolia is about 80-100 kg/lac (Kaymakçı, 2006), and some breeding studies must be performed in that region in order to benefit from the higher milk yield potential of the Awassi sheep.

In the case of milk production, the appropriate description of the lactation curve is a useful tool in management decision making and in design genetic improvement strategies for the group of animals evaluated (Vázquez-Peláez et al., 2014). A lactation curve is defined as the variation of milk yield depending on time, representing of the milk yield with respect to time using a figure, or the milk yield shown in a figure after lambing (Keskin, 2006; Koncagül et al., 2012). Lactation curves can be beneficial in terms of biological and economic efficiency, selection, monitoring of animal health, ration formulation, and determination of type of care and feeding methods (Wood, 1967; Ruiz et al., 2000; Dağ et al., 2005; Koncagül et al., 2012). Moreover, it is possible to use lactation curve models to estimate the total lactation milk yield from partial lactations and to use the peak yield and persistency values as selection criteria in developing a model for the improvement of milk yield (Wiggans and Gangler, 1999;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1550715517

Takma et al., 2009). The shape of the lactation curve and environmental factors that affect the curve can be used to determine the biological affectivity (Grossman and Koops, 1988). The environmental factors that affect the milk yield and lactation curve have been determined by many researchers, and different mathematical models have been proposed for determining the lactation milk yield in dairy cattle (Koncagül and Yazgan, 2011). Most of these models developed for dairy cattle can also be used to identify the lactation curves of sheep and goats (Fernandez et al., 2002; Koncagül et al., 2012; Angeles-Hernandez et al., 2013). Among them, Wood's model (1967) has been the most widely used (Nezamidoust et al., 2013; Angeles-Hernandez et al., 2013)

Lactation curve studies have conducted rarely in Awassi sheep. The aims of this study were to compare 8 different models (MG, Dhanoa, Nelder, Wood, CLD, POL2, POL3, and POL4) used to define the lactation curve for the Awassi breed and to identify the suitable models. In addition, the effects of birth season, parity, and birth types on lactation milk yield and model parameters were investigated.

Material and Methods

Data

The experiment was conducted in the International GAP Agricultural Research and Training Centre (GATEA) between the years 2010-2014 in Diyarbakır, Turkey (37°57'41 N and 40°13'54 E, 650 m asl) (*Fig. 1*). Study area has a semi-arid climate and is very hot during the summer months. The temperature rises above 40°C in summer. Rainfall is almost non-existent during the summer months. Winters are cool and wet. Spring and automn are warm and wet as well.

Figure 1. *Study location map (https://www.express.co.uk)*

The animal material consisted of 557 Awassi sheep raised in training center above mentioned. Semi-intensive care and feeding was applied in addition to 10 hours of pasture time each day, and supplementary feeding was provided following pasture. The milk controls were started 15 days after the first lambing occurred in the herd, and the amount of milk was measured on a scale with 50 g of precision and repeated every 14 days interval until the end of lactation. The test day of the milking were made at 14 days intervals (Gürsu and Aygün, 2014). Lactation milk yield (LMY) was calculated using the Fleischmann method (Barillet et al., 1992).

Data Analysis

The models used in this study were chosen from among the models applied previously to describe lactation curves of sheep. For the analyses of the lactation, the following models were used.

MG model (Morant and Gnanasakthy, 1989):

$$y_t = e^{(a - bt_1 - ct_1^2 - d/t)} \quad \text{(Eq.1)}$$

Nel model (Nelder, 1966):

$$y_t = t/a + bt + ct^2 \quad \text{(Eq.2)}$$

Wood model (Wood, 1967):

$$y_t = at^b e^{-ct} \quad \text{(Eq.3)}$$

CLD model (Cobby and Le Du, 1978):

$$y_t = a - bt - ae^{-ct} \quad \text{(Eq.4)}$$

Dhanoa model (1981):

$$y_t = at^{bc} e^{-ct} \quad \text{(Eq.5)}$$

Three polynomials: the second degree (POL2):

$$y_t = a + bt + ct^2 \quad \text{(Eq.6)}$$

The third degree (POL3):

$$y_t = a + bt + ct^2 + dt^3 \quad \text{(Eq.7)}$$

The fourth degree (POL4):

$$y_t = a + bt + ct^2 + dt^3 + et^4 \quad \text{(Eq.8)}$$

The parameters of the models defined above were as follows: yt is the milk yield on the tth day after lambing; a, b, c, d and e are the model parameters; t is the tth day after lambing; and t1 = (t –lactation period / 2) / 100. Starting values for the parameters of the models mentioned in "a, b, c d and e" were taken from various analyses conducted by many researcher such as Dağ et al. (2005).

Analyses were performed using the Proc Nlin procedure in the SAS program (SAS, 2000). For the comparison of the models, the coefficient of determination (R^2), mean square error (RMSE), and correlation coefficient (r) between observed and estimated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1550715517

lactation curves were considered as the comparison criteria. After identifying the best mathematical model description of the lactation curve, the estimated lactation milk yield (ELMY) for each sheep was calculated using the parameters of the identified model. Then, the ELMY was compared with the LMY calculated by the Fleischmann method (Barillet et al., 1992) described below:

$$LSV = S_1 x A_1 + \sum_{i=2}^{n} \frac{S_i + S_{i-1}}{2} A_i + S_n x15 \quad \text{(Eq.9)}$$

where LMY is lactation milk yield, Ai is the number of days between lambing and first milk control day, A_I is the number of days between the ith and (i-1)th control milking, Si is the amount of milk in the ith control milking day, and 15 is the number of days assumed to have passed between the last day of control milking and the end of the lactation. The values of LMY and ELMY were adjusted to 180 days of lactation length.

The correlation coefficients between LMY and ELMY were calculated by the Proc Corr procedure in SAS (2000).

In order to examine the effects of environmental factors on the model parameters, LMY and ELMY, the linear model given below was used in the Proc Glm procedure in SAS (2000):

$$Yijkl = \mu + Pi + LSj + BTk + eijkl \quad \text{(Eq.10)}$$

where Yijklm is the model parameters, LMY or ELMY, μ refers to the average value for the trait being analyzed, Pi is the effect of the ith parity, LSj is the effect of the jth lambing season, BTk is the effect of the kth birth type, and eijkl refers to the random residual. Differences among the means of the environmental factors were tested using the Tukey-Cramer test option.

Results

Model Selection

Fit statistics of the mathematical model are given in *Table 1*. In terms of mean square error (MSE), the highest value was observed in the Dhanoa model, followed by the Wood, CLD, MG, and Nelder models, respectively. It has also been determined that MSEs obtained from polynomial models were not different from zero. The best performance in terms of determination coefficient (R^2) belonged to the polynomial and Nelder models. POL4 has the highest R^2 value (0.99), followed by the POL3, POL2, and Nelder models (0.98, 0.97, and 0.93, respectively). R^2 values of the other models were below 0.85. A similar situation was also observed in terms of the correlation coefficient (r) between observed and estimated lactation curves. POL4 (0.90) had the highest value in terms of correlation coefficient, followed by the POL3, POL2, and CLD models (0.84, 0.74, and 0.69, respectively). The correlation coefficients obtained from the other models were found to have lower values.

Considering the MSE, R^2, and r parameters all together, it was concluded that the best model to properly identify the lactation curves of the Awassi sheep breed was POL4. Therefore, the characteristics of lactation curve and environmental factors affecting the LMY were investigated by taking into account the POL4 model.

Model Parameters

The model parameters, standard deviations and correlations between model parameters are given in *Table 2*. Accordingly, parameter (a) refers to the milk yield when standardized time was equal to zero. Standardized time is in the range between -1 and +1; when time is at 0, it has been accepted as the middle of lactation (midpoint). Therefore, parameter (a) represents the estimated milk yield in the middle of lactation. Parameters (b) and (c) refer to the increases and decreases in milk yield until the midpoint of lactation, and parameters (d) and (e) refer to the increases and decreases in milk yield after the midpoint of lactation.

a, b, c, d, e: model parameters of POL4; LMY: lactation milk yield corrected for lactation length

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1550715517

Relationship Among Parameters

The correlation coefficients among model parameters are given in *Table 2*. As expected from polynomial functions, the correlations between sequential parameters (a-b, b-c, c-d, and d-e) have taken negative and increasing values, whereas the correlations between other parameters (a-c, b-d, and c-e) have taken positive and increasing values, respectively. Because linear interpolation is the basis of determination of LMY using the Fleischmann method, the possibility of errors for estimating milk production between two consecutive control days would increase as the interval between two consecutive milk control days increases. However, there were 14 days between the two milk control days in our study; therefore, LMY was assumed to be estimated closer to the actual amount of milk production.

Effects of Environmental Factors

The mean and standard errors of LMY and model parameters based on environmental factors are given in *Table 3*. All factors except birth type had significant effects with varying degrees on the model parameters and LMY. The differences between average values of 1st, 5th and 6th lactations and 2nd, 3rd and 4th lactations have been found significant ($P < 0.05$). The difference between milk yield of the sheep lambing in the December-January season and the February-March season was found significant ($P < 0.05$). The type of birth did not have any significant effect on the LMY.

Table 3. *Descriptive statistics of LL, LMY, ADMY and LMY180 day*

	N	Mean	Std.Err.	Min	Max.	CV%
LL	1077	150.3	0.77	100.0	213.0	16.9
LMY	1077	123.9	1.23	40.9	268.8	32.6
ADMY	1077	819.7	6.60	361.7	1551.6	26.4
LMY180	1077	147.6	1.19	65.1	279.3	26.4

N: Number of observation, Std.Err.: Standard error, Min: minimum, Max: maximum, CV%: coefficient of variation, LL: Lactation length, LMY: Lactation milk yield, ADMY: Avarege Daily milk yield

In this study, all factors except type of birth had significant effects with varying degrees on the model parameters and LMY (*Table 2*). The differences between average values of 1st, 5th, and 6th lactations and 2nd, 3rd, and 4th lactations were found statistically significant ($P < 0.05$). As indicated by Mavrogenis (1996), this situation was to be expected because the milk yield of the Awassi sheep increases in the first 4 parities and has a tendency of decreasing in the following parities. The difference between milk yield of the sheep lambing in December-January season and February-March season was found statistically significant ($P < 0.05$). This can be explained by the fact that the pasture conditions in the December-January season are better than those of other seasons, and thus sheep can benefit from pastures more than others lambing in other seasons. These pastures lose their efficiency after April due to the rapid warming of the weather in the area where this study was conducted.

The differences between means of 1st lactation and 3rd and 4th lactations have been found statistically significant ($P < 0.05$). This shows that the peak yield values of 1st lactation sheep were lower than the peak yield values of 3rd and 4th lactation sheep in terms of parameter (a). The effect of lambing month on parameter (a) was found insignificant, which shows that the peak yield is not affected by the lambing month. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1550715517

differences between levels of birth types in terms of parameter (a), when the time is equal to zero, were found insignificant.

Descriptive statistics of the research data set in lactation milk yield has shown in *Table 3*.

The effect of parity on the parameter (a) was insignificant, whereas its effect on parameters c, d, and e was found to be statistically significant ($P < 0.05$). The differences between 1st, 2nd, and 3rd lactations in terms of upward oscillation speed (parameter c) before the peak yield were found statistically significant ($P < 0.05$). In addition, the differences between 1st, 2nd, and 6th and 3rd lactations in terms of upward and downward oscillation speeds after the peak yield were found statistically significant ($P < 0.05$) (*Fig. 2*).

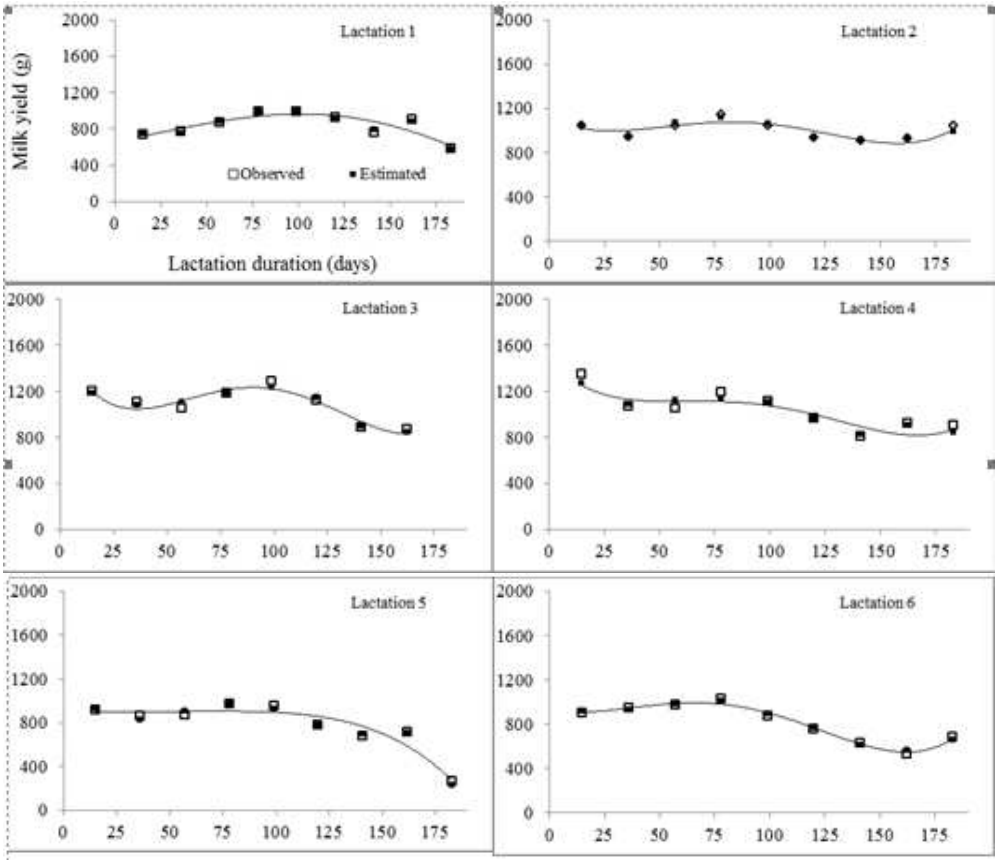

Figure 2. *Milk yield vs. lactation duration in different lactation stages*

It was found in this study that the best fit model identifying the lactation curve is the POL4 model. Ruiz et al. (2000) reported that in the case of a higher positive correlation between parameters of the mathematical model identifying the lactation curve, the lactation curve model cannot be identified properly. However, in this study, as can be seen in *Table 2*, because there is a negative correlation between 4th-degree polynomial model parameters in general, this model sufficiently identified the lactation curve of the Awassi sheep breed. Moreover, the highest correlation between LMY and ELMY (0.90) was obtained when the POL4 model was applied, and this indicates that the POL4 model can be used for LMY estimations of the Awassi breed.

Discussion

The lactation milk yields found in this research are consistent with the values reported by Dağ et al. (2005), Şeker et al. (2000), and Tekel et al. (2007). In addition, the lactation curve *(Fig. 3)* shows consistency with the lactation curve given by Kaymakçı (2006). As can be seen in *Fig. 3*, there was an increase in the first 2 months of lactation, and the peak value was reached; then, a gradual decline was observed. As shown in *Fig. 3*, the decrease in milk yield accelerates after the first 100th day of lactation approximetly. These changes in ambient temperature and pasture conditions are thought to have an effect on this situation. As a matter of fact, the climatic and pasture conditions in the first 3 months of lactation constitute a suitable environment for milk production of Awassi ewes. However, in the later stages of lactation, the air temperature increases and the pasture conditions decrease significantly due to the temperature increase.

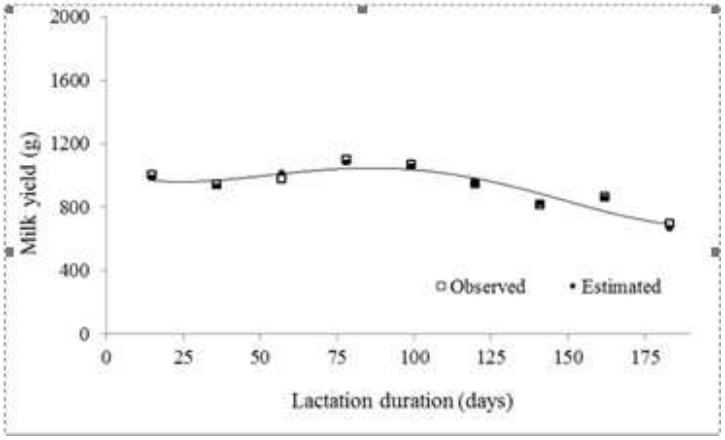

Figure 3. *An overall view of the lactation course in Awassi sheep*

All of the factors considered in this study, except for the type of birth, had significant effects on model parameters or LMY at various degrees. These results were similar to other studies on the milk yield characteristics of Awassi sheep (Özbey and Akcan, 2000; Reiad et al., 2010; Üstüner and Ogan, 2013). Differences between 1th, 5th, 6th lactations and 2nd, 3rd, 4th lactations were statistically significant ($P < 0.05$) in terms of LMY. As Mavrogenis (1996) states this sitiuation is expected due to an increase in milk yield in the first 4th lactation and later tendency to decrease in Awassi sheep. The difference between the milk yield of sheep gave birth in December-January and February-March season were statistically significant ($P < 0.05$). This can be explained by the fact that those who give birth in December-January season have the opportunity to benefit from the pasture for a longer period when the pasture conditions are good. Because the pastures in the region lose their qualities after April due to the rapid heating of the weather.

It has been reported that if there is a high correlation between the parameters of a mathematical model defining the lactation curve, the model used will not define the lactation exactly (Ruiz et al., 2000). When polynomial functions are used in this research, the correlations between sequential parameters (a-b, b-c, c-d, and d-e) have negative and increasing values, whereas the correlations between other parameters (a-c, b-d, and c-e) have positive and increasing values respectively. Because linear

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1550715517

interpolation is the basis of determination of LMY using the Fleischmann method, the possibility of errors for estimating milk production between two consecutive control days would increase as the interval between two consecutive milk control days increases. However, the POL4 model showed the best performance in terms of comparison criteria due to high correlation between LMY and ELMY (0.90) was obtained. This indicates that the POL4 model can be used for LMY estimations of the Awassi breed.

Lactation milk yield is determined by genotype and environmental conditions in addition to other quantitative properties. Therefore, the suitability of lactation curve models used by researchers may vary depending on the breed and species. Accordingly, the most appropriate model defining the lactation curve differ from breeds to breeds in different environmental conditions (Ünal et al., 2007). It has been reported that the Pollott Additive and Fractional Polynomial models are the best ones for Lacaune breed (Elvira et al., 2013). In addition, the Wilmink model is the most suitable one, followed by Wood and Dhanoa models, for studies conducted in Akkaraman, Kıvırcık-Akkaraman, and Sakız-Akkaraman crossbred sheep (Ünal et al., 2007). It has been determined that Wood, Wilmink, POL2 and POL3 models can be used to estimate milk yield in F_1 cross-breeds (Angeles-Hernandez et al., 2013). It has been determined that the Wood model can be used to estimate lactation milk yield in organically raised sheep such as East Friesian, Pelibuey, Suffolk and Black Belly (Angeles-Hernandez et al., 2014). On the other hand, in a study conducted on Awassi sheep, the most suitable model was found to be the Cubic model (Dağ et al., 2005), whereas the Wood model was found to be the best one in another study (Yıldız, 1997). Furthermore Wood, Cobby and Le Du, Dhanoa, and Wilmink models have been found equally suitable for studies conducted on the Awassi sheep breed.

Conclusions

Using of the best suitable lactation model will affect the efficiency and profitability of production. In addition, suitable model provide increasing of the genotypic gain in breeding program. The POL4 model used in the study give better results compared to the other 7 models. The value of ELMY calculated by POL4 was very close to the value of LMY calculated by using the Fleischmann method ($r = 0.90$). This result shows that the POL4 model can be used for LMY estimations of the Awassi sheep breed.

Further researchers are needed to understand different predictive power of models. It is important that different models must be tested by different researchers due to Awassi breed raised in various countries and under different envoirmental conditions.

Abstract. Amino acids, being the primary products of inorganic assimilation and precursors of proteins, play an essential role in plant metabolism. The objective of this study was to compare guar plants which were grown under salt-stress conditions (150 mM NaCl), in terms of the effect of different amino acid treatments (300, 600, 1200, and 1800 mg L^{-1} amino acid) on physiological, morphological, and enzymatic activity. Amino acid (AA) applications significantly increased fresh and dry weight, relative water content, photosynthetic pigments, total phenolic, flavonoid and free amino acid contents, K^+ and Ca^{++} ion concentration, ascorbate peroxidase (APX), catalase (CAT), glutathione reductase (GR), and superoxide dismutase (SOD) activity of guar plants compared to the salt stress treatment the ones under no AA treatment. According to the results, the malondialdehyde (MDA) content, Na^+ and Cl^- ion contents were significantly decreased. Hence, the results support the application of the amino acid in 600 mg L^{-1} doses in order to increase the defense system of the guar plant, enabling it to tolerate the negative effects induced by salinity.
Keywords: *biostimulant, cluster bean, enzyme activity, ion regulation, oxidative stress, seconder metabolite*

Introduction

Salinity is a significant abiotic stress factor that threatens agriculture in both arid and semiarid environments, affecting over 20% of the world's irrigated land (Wu et al., 2017). Salt stress induces changes in a plant's biochemical, physiological, and morphological responses resulting in reduced growth, yield, biomass, and quality of crop plants.

Salinity in growth mediums have an unfavorable impact on the growth of plants and their development, which could presumably be the result of the presence of salt in the soil, thus reducing the plant's water uptake (low osmotic potential), resulting in high levels of salt entering the plant via transpiration, which causes damage to the transpiring leaf cells (specific ion toxity) (Parihar et al., 2015; Rady et al., 2018).

Salt stress, like other environmental stresses, induces the accumulation of reactive oxygen species (ROS) such as hydrogen peroxide (H_2O_2), superoxide (O_2^-), and hydroxyl radicals (OH-) (Sekmen et al., 2013). Increased ROS concentration causes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1551915530

oxidative damage for plant tissues in various ways (e.g., decrease in chlorophyll content, damage to cell membrane, protein oxidation, strand breaks in nucleic acids, etc.), leading finally to cell death. The degree of stress injuries to plants is reflected by membrane permeability. Furthermore, ROS levels above threshold cause lipid peroxidation (LPO) in both cellular and organelle membranes, which not only directly affects cellular functioning, but also aggravates the oxidation stress through the production of lipid-derived radicals (Patel et al., 2013). In response to salinity, plants have developed a series of enzymatic (e.g., super oxide dismutase (SOD), catalase (CAT), ascorbate peroksidase (APX), glutathione reductase (GR) and several peroxidases) and non-enzymatic (ascorbate, carotenoids, flavonoids and other phenolic compounds etc.) detoxification systems to counteract reactive oxygen species, and protect cells from oxidative damage (Taibi et al., 2016). SOD converts O_2^- to H_2O_2, which is detoxified to water and oxygen by CAT, POX, and APX. SOD is localized in almost all cellular compartments and the water–water cycle in chloroplasts. The components of the ascorbate–glutathione cycle are localized in chloroplasts, cytosol, mitochondria, and apoplast, while both glutathione peroxidase (GPX) and CAT are localized in peroxisomes (Sekmen et al*.,* 2013).

Plants have developed various approaches to reduce the negative effects resulting from abiotic stressors, several of which have been related to the metabolism of amino acids (Batista Silva et al., 2019). They have improved the ability to physiologically and/or behaviorally respond and adapt to environmental stressors through organic solute accumulation or ion movement control, which enables the increase of solute concentrations at the intracellular level. Osmotic adjustment involves the accumulation of low molecular weight compounds in the cytosol, compatible osmolytes, which do not interfere with normal biochemical reactions (De Freitas et al., 2018) and these osmolytes that do not interfere with plant metabolism even at high concentrations and may also act as ROS scavengers (Batista Silva et al., 2019). Amino acids are organic nitrogenous compounds that are the building blocks in the synthesis of proteins (Sarojnee et al., 2009). El-Din et al. (2005) reported that, in higher plants, amino acids have the ability to behave like growth factors, because they are protein synthesis building blocks, and may be enzymes significant for metabolic activity. These components are particularly important for cell growth stimulation, because they behave like buffers that aid in maintaining an appropriate pH value in plant cells. Moreover, because they comprise both acidic and basic groups, they are able to aid in ammonia removal within the cell (Nahed et al., 2010). Furthermore, amino acids assist in the synthesis of various organic compounds, including alkaloids, amines, enzymes, terpenoids, proteins, purines and pyrimidines, vitamins, etc. (Talaat et al., 2014).

Cluster bean, or Guar, has gained an important commercial status as a result of its gum and is now the most significant product exported in the farming sector, due to it being a cash crop that is highly-valued in both arid and semi-arid areas because of its tolerance to drought and vast array of uses (Pathak, 2015).

It has been reported that amino acids that were applied exogenously to plants exposed to abiotic stressors brought about a preventive or recovery effect. Therefore the following two hypotheses were tested: 1) the effect of AA concentrations on the growth, and 2) how AA reveal a change in biochemical composition, ion regulation and oxidative status in guar seedlings.

Materials and methods

The study was conducted at an experimental site of Cankiri Karatekin University in Turkey. For this experiment, a mixture of peat:perlite substrate (2:1) was used to germinate the guar seeds, which were then housed in a greenhouse kept at day/night temperatures of 26 ± 2°C and 18 ± 2°C, and a relative humidity of 65% ± 5. Growth chamber and nutrient solution (following that of Dasgan and Koc, 2009) irrigation was used to grow the plants. Each pot contained 5 plants and each of the 3 replications also every treatment included 5 pots (total 90 pots). According to our previous studies were determined NaCl doses (data not shown). Starting from 39 days of after sowing (DAS), the saline treatment began with 50 mM NaCl on the first day and was increased by 50 mM NaCl each day until the 2th day, where it reached 150 mM NaCl. For this experiment, the amount of water applied was calculated based on the ratio of water drained: water applied (Schubert and Lauchli, 1990). In the control plant were not exposed to saline stress. Amino acid treatments were added in the irrigation water with salinity treatments. The commercial product "Amino gold" was used as a source of amino acids and it contains 29% free L. amino acids, 70% total organic matter, 14% organic carbon, 3% organic nitrogen, 20% humidity and 2.5-4.5 pH. The experiment involved the following treatments; 1) control (nutrient solution irrigation void of NaCl) (C), 2) Salts treatments (salinity at 150 mM NaCl) (S), 3) Salinity+300 mg L^{-1} amino acid (AA1), 4) Salinity+600 mg L^{-1} amino acid (AA2), 5) Salinity+1200 mg L^{-1} amino acid (AA3), 6) Salinity+1800 mg L^{-1} amino acid (AA4).

The end of the experiment (61 DAS), plants were evaluated using some plant physiological (shoot fresh and dry weights, shoot diameter, shoot length, and number of leaves and leaf area per plant, relative water content (RWC), photosynthetic pigments (Chl-a, Chl-b, total carotenoid), Na^+, K^+, Ca^{2+}, and Cl^- ions content) and biochemical parameters such as total phenolic content (TPC), flavonoids, total free amino acid, and lipid peroxide content (malondialdehyde, MDA); ascorbat peroxidase (APX), catalase (CAT), glutathione reductase (GR), superoxide dismutase (SOD), and antioxidative enzyme activities.

For ion determination, the plants were harvested and dried at 65°C for 48 h. The leaves of were burned at 550°C, and dissolved in 1% (v/v) hydrochloric acid, and then analyzed for Na^+, K^+, and Ca^{2+} using an atomic absorption spectrometer (Varian Spectra AA 220 FS). The Cl concentration was determined using the Mohr method (Dasgan and Koc, 2009).

Determination of the chlorophyll (Chl) a and b and contents were done according to the method of Arnon (1949). Extraction of the leaf pigment was done using 80% (v/v) acetone and the extraction absorbance was measured with a spectrophotometer (Shimadzu UVmini-1240; Shimadzu Corporation, Kyoto, Japan) at 663, 645, and 470 nm. The total phenolic content was determined using a Folin-Ciocalteu reagent. The phenolic content of leaves and stems was expressed in milligrams. Gallic acid was used as a standard (Singleton et al., 1999). The colorimetric assay was used to establish the flavonoid content (Molina-Quijada et al., 2010; Medina-Juárez et al., 2012). Total flavonoids were expressed on a fresh weight (fw) basis as milligrams of quercetin equivalents per gram. Total free amino acid content was determined with the ninhydrin reagent method (Yemm and Cocking, 1955).

A mortar and pestle, along with an extraction buffer (5 mL) comprised of a potassium-phosphate buffer (50 mM, pH 7.6) and disodium ethylene diamine tetra acetate (0.1 mM) was used to extract the enzymes from 0.5 g of leaf tissue. After centrifugation of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1551915530

homogenate at 15.000 × g for 15 min, the supernatant fraction was then used for the enzyme assay. All of the enzyme extraction preparation operations were carried out at 4°C. Nitro blue tetrazolium (NBT) was used to reduce the superoxide radical, which was monitored at 560 nm to essay the SOD, according to the method of Karanlik (2001). Monitoring the disappearance of HO was used to determine the CAT activity, while measuring the ascorbate consumption from its absorbance at 290 nm was used to determine the APX activity. One unit of APX activity was determined as the amount of enzyme necessary to consume 1 µMol of ascorbate min^{-1} (Cakmak and Marschner, 1992). Determination of the GR activity was performed via measurement of NADPH enzyme-dependent oxidation based on its absorbance at 340 nm. One unit of GR activity was determined as the amount of enzyme necessary to oxidize 1 µMol of NADPH min^{-1}.

The amount of MDA ascertained via the thiobarbituric acid reaction was used to measure the lipid peroxidation (Heath and Packer, 1968). The calculation of the MDA content was based on the MDA molar extinction coefficient; 155 mM^{-1} cm^{-1}.

The experimental plot design was randomized, comprising 3 replications. A comparison of the parameter mean values was performed via the least significant difference test. Statistical significance was determined as $p<0.05$ using JMP statistical software, ver. 5.1 (SAS Institute Inc., USA). Data are presented as the mean ± standard deviation. and in all figures error bars are representing standard errors of the means.

Results

An improvement value in growth parameters of the guar plants which were grown under saline conditions by using amino acids is shown in *Table 1*. Guar plants were treated with NaCl and these values were reduced by 41-87%, respectively, compared to the control. However, amino acid applications under salt stress significantly enhanced the growth components such as shoot fresh and dry weight, shoot length, shoot diameter, number of leaves per plant, leaf area per plant, compared to the salt-stressed groups. These reactions changed between 16-67% ratios. When compared to S, S+AA enhanced the amelioration for growth by 39-392%. Among to these applications the highest effect was determined in AA2 and the improvement was identified by 76-883%.

Table 1. *Effects of AA applications on growth parameters of guar plants under saline condition (C: control; S: salt stress (150 mM NaCl); AA1: 150 mM NaCl+300 mg L^{-1} amino acid; AA2: 150 mM NaCl+600 mg L^{-1} amino acid; AA3: 150 mM NaCl+1200 mg L^{-1} amino acid; AA4: 150 mM NaCl+1800 mg L^{-1} amino acid*

Guar seedling treated with salt stress demonstrated a decrease in RWC at 44% ration, compared to control (*Table 2*). However, a significant improvement in the RWC of AA-treated plants was observed an increase 48, 60, 34, and 25% in AA1, AA2, AA3, and AA4, respectively, compared to the plant that was treated with 150 mM NaCl solely ($p<0.05$). Under salt (150 mM) stress, photosynthetic pigments such as total Chl-a, Chl-b, and total carotenoid were reduced by 43, 47, and 61%, in guar plants, respectively (*Table 2*). Auxiliary addition of amino acids to the salt-stressed guar plants induced a significant increase in photosynthetic pigments by 8-46%, 37-96%, and 54-143%, compared to salinity conditions, respectively.

Table 2. *Effects of AA applications on relative water content (RWC) and photosynthetic pigments of guar under saline condition (C: control; S: salt stress (150 mM NaCl); AA1: 150 mM NaCl+300 mg L^{-1} amino acid; AA2: 150 mM NaCl+600 mg L^{-1} amino acid; AA3: 150 mM NaCl+1200 mg L^{-1} amino acid; AA4: 150 mM NaCl+1800 mg L^{-1} amino acid)*

To confirm the salinity-induced oxidative stress conditions, intercellular levels of stress biomarker MDA were evaluated (*Table 3*). The MDA content was the lowest in control plants and increased significantly in 150 mM NaCl conditions. When compared to the control groups, the MDA levels increased by 189% (6.72 µmol g^{-1} FW).

Table 3. *Effects of AA applications on MDA content, total phenolic, flavonoid and free amino acid contents of guar under saline condition (C: control; S: salt stress (150 mM NaCl); AA1: 150 mM NaCl+300 mg L^{-1} amino acid; AA2: 150 mM NaCl+600 mg L^{-1} amino acid; AA3: 150 mM NaCl+1200 mg L^{-1} amino acid; AA4: 150 mM NaCl+1800 mg L^{-1} amino acid)*

However, AA mitigated the stress effects on plants and further decreased the contents of MDA. In point of fact, through AA treatments, MDA content was decreased by 19-48% ratios. In addition to this, the lowest values were recorded at AA1 and AA2 treatments compared to with corresponding salinity.

Under salt stress, total phenolic and flavonoid contents decreased in guar (19 and 11% decreases, respectively) compared to the control group (*Table 3*). Contrarily, AA treatments proved to result in a significant increase in the mean values of total phenolic and flavonoid contents, compared to both control group (23-74% increase) and 150 mM NaCl (54-97% increase) individually. The maximum mean values were obtained in the AA2 application (30.09 µgGAE mL^{-1} of total phenolic; 16.88 mgQE 100 g^{-1}) and with AA2 treatment in guar total phenolic and flavonoid contents demonstrated an increase between 77% and 45%, compared to salinity conditions.

Total free amino acid content slightly increased with AAs applications, there after a constant increment in this content was recorded at AA1 (48%), AA2 (108%), AA3 (126%), and AA4 (157%) compared with untreated control (*Table 3*).

Compared to the control groups, salt stress increased the Na and Cl contents of all applications (320-545% increase in Na and 571-890% in Cl) (*Table 4*). However, these values were clearer in without AA application under salt stress condition (Na: 3.10%; Cl: 3.17%). With AA application, salt-stressed plants accumulated less Na and Cl, and these ion accumulations decreased by 16-18% compared to the salt application only. On the contrary of toxic Na and Cl ions, K and Ca ion accumulation decreased in salt conditions. These reactions were determined as 52% and 53% under salt stress conditions, respectively. The AA applications alleviated the stress effects on these parameters and significantly increased the K and Ca contents, compared to NaCl contents. According to results, AA applications ensured an increase of the K content by 11-53 % and Ca content by 23-70%. Under salt stress, the best effect was determined in AA2 applications and in this treatment, K and Ca values increased by 53 and 70% compared to salt stress.

Table 4. *Effects of AA applications on Na, K, Ca and Cl contents of guar under saline condition (C: control; S: salt stress (150 mM NaCl); AA1: 150 mM NaCl+300 mg L^{-1} amino acid; AA2: 150 mM NaCl+600 mg L^{-1} amino acid; AA3: 150 mM NaCl+1200 mg L^{-1} amino acid; AA4: 150 mM NaCl+1800 mg L^{-1} amino acid)*

Antioxidative enzyme activity (SOD, CAT, GR, and APX) levels were evaluated in C, S, and S+AA treatments (*Table 5*). Salt stress caused an increase in SOD, CAT, GR and APX activities at different levels. It is evident from the figure that AA treatments had

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1551915530

a serious effect on antioxidative enzyme activities such as SOD, CAT, GR, and APX of the guar seedlings under salt stress. In S+AA applications, enzyme activities (SOD, CAT, GR, and APX) increased by 9-48, 12-51, 14-112, and 14-129%, compared to the 150 mM treatment. In addition to these results, the highest enzyme activities were noted at AA2 treatment (SOD: 510.46 U min^{-1} mg^{-1} FW; CAT: 637.26 μmol min^{-1} mg^{-1} FW; GR: 229.62 μmol min^{-1} mg^{-1} FW, APX: 220.19 μmol min^{-1} mg^{-1} FW) compared with control and salinity.

Table 5. *Effects of AA applications on SOD, CAT, GR, and APX enzyme activities of guar under saline condition (C: control; S: salt stress (150 mM NaCl); AA1: 150 mM NaCl+300 mg L^{-1} amino acid; AA2: 150 mM NaCl+600 mg L^{-1} amino acid; AA3: 150 mM NaCl+1200 mg L^{-1} amino acid; AA4: 150 mM NaCl+1800 mg L^{-1} amino acid) (SOD U min^{-1} mg^{-1} FW; CAT, GR, APX: μmol min^{-1} mg^{-1} FW)*

	SOD	CAT	GR	APX

Discussion

Salt stress is a major environmental factor which prevents crop plants from attaining their full genetic potential; therefore, salt stress in plants induces several growth limitations. The increase in fresh weight of shoots by 205.1% (AA1), 809.7% (AA2), 140% (AA3), and 115.2% (AA4) compared with salt treated plants, as well as dry weight of shoot by 431.3% (AA1), 883.5% (AA2), 146.3% (AA3), and 109.6% (AA4) (*Table 1*). Generally, all growth parameters effected positively with AA treatment under salt stress condition. Goss (1973) reported the positive effect that amino acids have on growth and indicated that they can be used as an energy and carbon source, when there is a carbohydrate deficiency and the plants amino acids have been determined, via the release of the organic acid and ammonia that originally formed the amino acid. Nahed et al. (2010) reported that it was possible to indirectly explain amino acid regulatory effects, as some amino acids had been observed to affect the development of plants via the influence they had on the biosynthesis of gibberellins. In plant cells, amino acids are a source of nitrogen that is instantly available and can usually be more rapidly used than inorganic nitrogen. Additionally, amino acid conversion into some plant growth regulators may be the result of growth promotion in plants (Afifipour and Khosh-Khui, 2015). Amino acids can directly or indirectly influence the physiological activities in plant growth and development such as exogenous application of amino acids have been reported to modulate the growth, production and quality of tomato in plastic greenhouse (Boras et al., 2011). Also, Sadak et al. (2015) reported that also, amino acids are commonly known as a biostimulant that positively effects plant growth and yield, and significantly reduces

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1551915530

damage as a result of abiotic stressors, and amino total, as an amino acid source, may have a significant part in the metabolism of plants and assimilation of protein, which is very important in the formation of cells and thus, results in a fresh and dry matter increase.

It is well known that, when transpiration exceeds water absorption, cell turgor falls as relative water content and cell volume decreased and low turgor and RWC slow plant growth and decrease of stomatal conductance (Hammad and Ali, 2014). In this study, concerning the effect of treatment guar plants with amino acids, data in *Table 2* showed clearly significant increments in RWC compared to untreated plants at 150 mM NaCl. While RWC values decreased under salt stress between 44% in salty plants, with the AA applications to RWC demonstrated an increase by 25-60% in the same conditions. The accumulation of osmolytes in cells aids in the preservation of turgor pressure in the cell and provides protection for cell membranes, metabolic machinery, protein against cell dehydration (Krishnan et al., 2013). Amino acids contribute to osmotic adjustment by acting as osmolytes (Cuin and Shabala, 2007).

Salt stress results in significantly reduced photosynthesis, which is related to the photosynthesizing tissue (i.e. the leaf area) and photosynthetic pigments (Sadak et al., 2015). The pigments declined in plants when salt stress was introduced. In here, the favorable effects of the AA treatments were identified on the chlorophyll components and increased between 8-46 and 37-66%, compared to salinity (*Table 2*). The other component carotenoid content increased in guar plants that were treated with AA under salt stress (52-143% increase). In plants, pigments like carotenoids have various roles, in addition to the specific role they play in photosynthesis, one of which is their involvement in defense mechanisms against oxidative stress (Taibi et al., 2016). It is possible that the increased photosynthetic pigments were the result of the effect of amino acids on metabolism instigation and metabolically processes to increases plant efficiency (Starck, 2005). It seems that the mentioned amino acids were able to enhance the tolerant ability of the wheat against salt stress by increment the photosynthetic pigments (Bahari et al., 2013). Amino acids play a role in increasing the concentration of chlorophyll in plants, resulting in more efficient photosynthesis. Any influence that results in increased photosynthetic pigment levels will subsequently result in increased carbohydrate content. As a significant photosynthetic energy repository, carbohydrates encompass the plant's structural polysaccharides, specifically cellulose, hemicelluloses, lignin, and pectin, which have been deemed as significant structural compounds (El-Ghamry et al., 2009). Additionally, the effect that amino acids have on the total carbohydrate content could be the result of their vital involvement in chlorophyll molecule biosynthesis, which also affects the metabolism of carbohydrates (Talat et al., 2014).

In plants, phenolic and flavonoid compounds also perform many other roles, such as in cell wall structural components, taking part in the developmental process and growth regulation, in addition to defense mechanisms against abiotic and biotic stressors (Taibi et al., 2016). Talat et al. (2014) reported that compounds are some of the most widespread molecules among plant secondary metabolites, and are of great significance in plant development. Flavonoids represent the main and most complex subgroup of polyphenols with a wide array of biological functions including lipid peroxidation inhibition (Taibi et al., 2016). Our results indicated that the utilization of amino acid maintained an important increase in total phenolic, total flavonoid contents and total free amino acid content compared to untreated plants under salt stress (33-77, 16-44, and 53-156% increase). These results clearly indicate that the amino acid play a stimulatory influence in phenolic accumulation in guar (*Table 3*). The metabolism of AA has a significant regulatory affect,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1551915530

not merely due to AAs as protein constituents, but also due to the potential of free AAs as regulatory and signaling molecules, and energy-associated metabolite precursors, in addition to various secondary metabolites that play a role in the growth of plants and their ability to adaptively respond to numerous stresses (Planchet et al., 2015). Sadiq et al. (2016) explained that abiotic stress causes hydrolysis of proteins into free amino acids, and foliar treatment of antioxidants enhances the biosynthesis of free amino acids and their utilization into protein. As lipid peroxidation is the mostly ascribed symptom to oxidative damage, it is often used as a marker of oxidative stress (Taibi et al., 2016). In this study, lipid peroxidation of guar seedlings increased with salt stress (189.7% increases). The results showed that AA treatments reduced the MDA levels, presenting a favorable effect in reducing the oxidative stress emerging from salt stress.

Ion toxicity in plant cells is the result of the salt-stress caused by a significant Na^+ and Cl^- cell influx, as well as the reality that the majority of plants amasses a high concentration of Na^+ and Cl^- ion in their shoots when cultivated under salt stress, which is a significant cause of decreased growth (Parihar et al., 2015; Liang et al., 2018). The uptake of K^+ and Ca^{2+} was reduced by Na^+ in guar under salinity conditions. Sodium concentration increased in plants grown under salinity; however amino acid application significantly reduced Na^+ concentration in guar leaves. Application of AA resulted in improvement uptake K^+ and Ca^{2+} ions. Thereby AA applications counteracted partially or completely the adverse effect of salinity as it increased the accumulation of K^+ and Ca^{2+}, in the same time it decreased the absorption of Na^+ and Cl^- in guar leaves compared with the corresponding salinity (*Table 4*). Increased K^+ concentration and reduced Na^+ in leaves may be one of the possible mechanisms of increased salinity tolerance by amino acid application in guar plants. Calcium is considered as an important factor for the maintenance of cell membrane integrity and the regulation of ion-transport. Ca^{2+} is essential for K^+ vs Na^+ ion selectivity and membrane integrity (Rady, 2012). Increasing potassium uptake is also a known strategy to counteract the entry of sodium. Rai (2002) indicated that amino acids promoting stomatal opening promoted K^+ influx into the guard cells while amino acids inhibiting stomatal opening inhibited K^+ flux into the guard cells. According to these results exogenous amino acid can modulate membrane permeability and ion uptake and apparently this is the major component by which amino acids help in mitigating salt stress effects (Rai, 2002). Sadak et al. (2015) indicated that amino acid has a chelating effect on micronutrient when applied, that make the absorption and transportation of micronutrients inside the plant easier due to its effect on cell membrane permeability. Similarity, exogenous amino acids have been shown to promote K^+ uptake by 15% in radish and Ca^{++} uptake by 20-60% in bean (Rai, 2002).

ROS in plant cells are generated via normal cellular metabolism or stressful environmental conditions such as drought, heavy metals, herbicides, nutrient deficiency, radiation, or salinity. A direct consequence of salinity is the induction of stress and antioxidant enzymes by exposed plants to minimize the damage caused by reactive oxygen species (Amar and Nourredine, 2016). Enzymatic antioxidant defense systems, such as APX, CAT, DHAR, GR, MDHAR, POX, SOD; and non-enzymatic antioxidant defense systems, such as ascorbate, carotenoids, glutathione, glycine betaine, phenolic compounds, polyamines, proline, and sugar (Sen, 2012). In here, responses to AA applications in the salt-stressed medium were examined and researchers reported an increase in antioxidative enzyme activities such as SOD, CAT, GR, and APX. These increases were statistically significant and determined by average 27-48% ratios (*Table 5*). Amino acids are important components of antioxidant systems in plants. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1551915530

action of these molecules involves the reduction of free radicals and osmoprotection. Our results showed that, treatment of amino acid had a stimulating effect on antioxidative enzyme activities. Thus, Darwesh (2013) reported that CAT and POD enzymes activity increased with salt treatment, same to be found at amino acid applications, all levels significant were enhanced activity of CAT and POD particular the highest levels of 6.0 ml L^{-1} of amino acids treatment.

Conclusion

Salinity stress led to significant reductions in growth parameters, photosynthetic pigments, seconder metabolites such as total phenolic compounds and flavonoid contents, potassium and calcium concentrations of guar seedlings while induced higher contents of sodium, chlorine, and malondialdehyde. The application of amino acid to salinity condition appeared to be favorable to growth and development, in addition to biochemical and physiological processes of the guar. Therefore, amino acid application has been achieved to be helpful strategy for enhancing the tolerance of the guar plants when grown under salinity conditions. Moreover, 600 mg L^{-1} amino acid treatment was the stronger effect in alleviating the harmful effect of salt stress compared to the other amino acid applications. The effects of 600 mg L^{-1} amino acid administration on yield under salt stress conditions can be examined in future studies.

(Received 2nd Aug 2019; accepted 14th Nov 2019)

Abstract. This study was conducted in May 2017 to investigate vegetation and soil properties of a floodplain rangeland, which is located in the continental climate zone of Turkey. In the study, vegetation surveys were performed in the rangeland areas with two different slope degrees (0-1% and 2-5%), and the Modified Wheel Point method with loop was used in vegetation measurements. A total of 23 different species belonging to 20 genera from 9 families, were identified in the rangeland where vegetation surveys were conducted. It was determined that 2 of the identified species were decreaser, 2 of them were increaser, and 19 of them were invasive species. The plant cover ratio of the studied rangeland area where the study was conducted covered with the plant was 76.87%. In general, the ratio of the Poaceae in the botanical composition of the examined rangeland was 35.32%, the ratio of legumes was 28.60%, and the ratio of other families was 36.08%. The examined rangeland soils had medium structure, mild alkaline character, and no salinity problem. It was determined that organic matter, available phosphorus and potassium content of the rangeland's moderately calcareous soils were higher in the base areas than in the slightly inclined areas.
Keywords: *rangeland, botanical composition, plant cover percentage, Fabaceae, soil properties*

Introduction

Meadows and rangelands covering approximately 25% of the Earth's land area (Alkemade et al., 2013), in addition to providing important ecosystem products and services to many people (Sala et al., 2017), being the most important source of roughage for livestock (Seydoşoğlu et al., 2019) and hosting wildlife, are also known as important areas in terms of having rich biodiversity and storing about 10-30% of the world's terrestrial carbon (Derner et al., 2006; Booker et al., 2013). While in Turkey these areas covered about 44 million hectares in the 1940s, nowadays they have been decreased to 14.6 million ha, and they constitute 38% of the total agricultural area (Anonymous, 2019a). In Turkey, available meadow and rangeland areas can meet about 20% of the roughage need of existing animals (~16 million animal unit) (Çaçan and Yüksel, 2016; Demiroğlu Topçu and Özkan, 2017). Meadows and rangelands, which provide the cheapest input for animal production, seem to be far from meeting the need for feed, and the reason for this is undoubtedly them having low feed production and/or yield. The free grazing system is effective on low amount of feed obtained from rangelands around the World as well as in Turkey. However, the full implementation of sustainable rangeland management can be achieved by following the principles of correct use and management.

According to the results of many studies conducted on rangelands in Turkey, it is reported that dry herbage yield of rangelands range between 640-2920 kg ha^{-1} according to the differences in ecology, vegetation and application and they have lost their yield

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1553115546

ability (Terzioğlu and Yalvaç, 2004; Polat et al., 2018; Sürmen and Kara, 2018), that in many rangeland vegetations, the ratios of plant species with high feed yield and quality were found to be low, while the ratios of invasive species were found to be high (Gür and Altın, 2015; İspirli et al., 2016; Seydoşoğlu et al., 2019; Seydoşoğlu and Kökten, 2018, 2019; Tutar and Kökten, 2019), in other words, that rangelands are away from climax vegetation and produce feed below their potential (Aydın and Uzun, 2005, 2008), and that there is an urgent improvement need in Turkey's rangelands (Yavuz et al., 2011, 2012; Alay et al., 2016).

In order to achieve success in rangeland improvement, which aims to create better vegetation and bring the rangeland to a position so that it can produce high-quality feed with high yield, knowing the vegetation structure of the rangeland to be improved. (Çınar et al., 2019) and listing the species from which the vegetation is composed, i.e. the plant species composing it, are important. Determination of the botanical composition, which is the main character of plant communities, constitutes the first and primary step of investigating meadow and rangeland vegetations (Gençkan, 1985).

Together with the biotic factors constituting the living environment, abiotic factors such as climate, soil, and topography are effective in the formation, development, and extinction of meadow and rangeland vegetations. For this reason, it is extremely important to know and/or reveal some physical and chemical properties of rangeland soils, especially in order to shed light on rangeland improvement studies. On the other hand, slope differences in rangeland areas affect soil fertility, the ratio of plant-covered areas, and ultimately, the meadow and rangeland crop significantly (Sürmen and Kara, 2018). This study aimed to determine vegetation and soil properties of a floodplain rangeland, which is located in the continental climate zone of Turkey.

Materials and methods

General description and some geographical features of the study area

The study was conducted in 2017 in the floodplain rangeland of Gözpınar village in Kurtalan district of Siirt province, which is located in the Southeastern Anatolia Region of Turkey (*Fig. 1*). Kurtalan district is located between 37° 55' 36" north latitude and 41° 42' 9" east longitudes, and Gözpınar village, where the study was conducted, is located between 37° 58' 35.0328" north latitude and 41° 27' 24.5304" east longitudes (Anonymous, 2019b).

Siirt province is located within the borders of the Dicle Region of Turkey's Southeastern Anatolia Region, and it is surrounded by Şırnak and Van provinces to the east, Batman and Bitlis provinces to the north, Batman province to the West, and Şırnak and Mardin provinces to the south. Siirt province consists of mountains and hills topographically, and the western part of the province including Kurtalan district is composed of plains that are mainly flat and close to flat. Some flatlands extend from Kurtalan district center to Batman province border and are severed from each other. The average elevation of the plain, which displays a rough structure and spreads over an area that is not very wide, is between 550-850 m (Anonymous, 1997). Areas with low slope values, lands entering in the "no or little erosion" class, and deep and medium-deep soils are also located in the western part of the province. The dominant large soil group in the study area is brown soils (Özyazıcı et al., 2014). The examined rangeland has a homogeneous area in terms of the drought index, aspect, and altitude (Avağ et al., 2012).

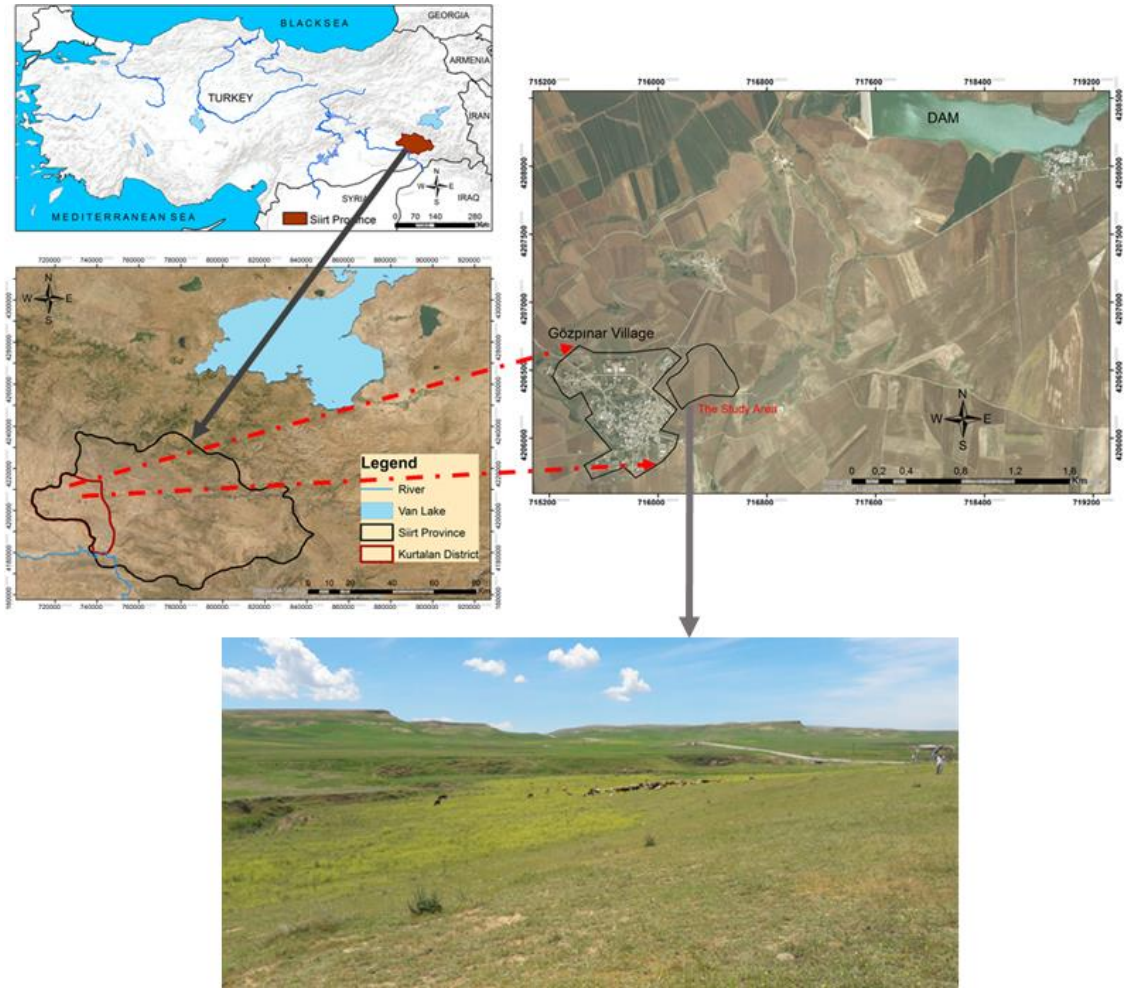

Figure 1. *Location of the study area*

A continental climate generally dominates Siirt province. Summers are hot and dry. Not much rainfall is observed between June and October. According to the long-term climatic data (1980-2017), the average annual temperature of the study area was 16.4 °C, and the average of annual rainfall was 700.3 mm. The average annual temperature in 2017, when the study was conducted, was recorded to be 17.2 °C and the total annual rainfall amount was recorded to be 547.9 mm (*Fig. 2*).

Vegetation measurement methods

In the study, vegetation surveys were performed in May 2017 in the Gözpınar village rangeland, in the regions with two different slope degrees (0-1% and 2-5%). The Modified Wheel Point method with loop was used in vegetation measurements (Koç and Çakal, 2004). The measurements were carried out in the Gözpınar village rangeland, in the part with two different slope degrees, during the flowering period of dominant plants in the rangeland, in 3 different part (in the block) which were very homogeneous in terms of vegetation and soil, and along four 20-m long lines, which extended from a point considered as the center towards 4 main directions (east, west, north, and south) in each part (in the block). Plant reading was performed to be 100 in total on each 20-m line and 400 in each block (Gökkuş et al., 2000).

DOI: http://dx.doi.org/10.15666/aeer/1706_1553115546

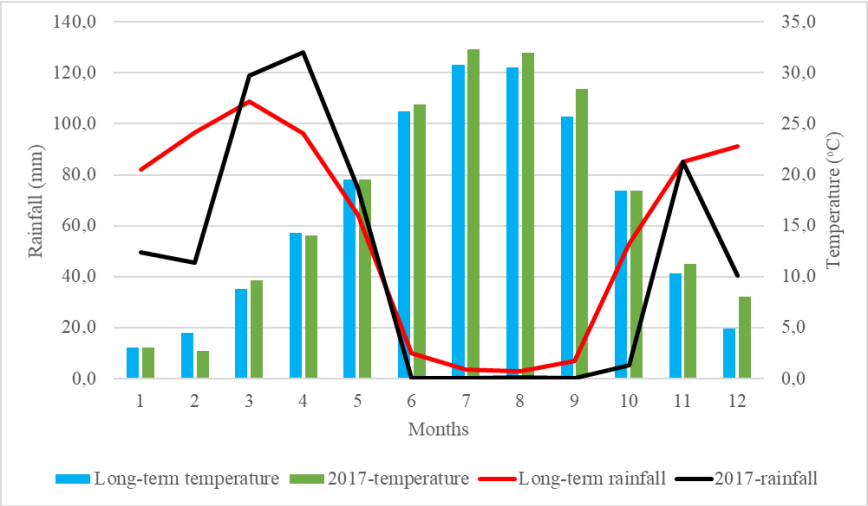

Figure 2. *Long-term (1980-2017) and 2017 climate diagram for Siirt province*

Identification of plants found in vegetation surveys was performed by benefiting from the studies carried out by Edgecombe (1964), Garms et al. (1968), Davis (1969), Polunin and Huxley (1974), Huxley and Taylor (1977), Weymer (1981), Demiri (1983), and Öztan and Okatan (1985).

The lifespan and families of the species and the degree of effect which expresses the plant species' palatability and response to grazing (decreaser, increaser, and invasive species) were determined according to Anonymous (2008).

In the rangeland, the plant coverage ratio (PCR) was determined by proportioning the number of points, where a plant was observed during the vegetation survey, to the total number of measured points, and it was expressed as a percentage (%) according to Gökkuş et al. (2000). By proportioning the values of each plant species to the total number of plants, the botanical composition ratio (BCR) was determined (Gökkuş et al., 2000). The BCR were calculated by separating the plant species observed in each loop line in the studied rangeland into three different plant groups, such as the Poaceae, Fabaceae, and other families.

Soil analysis methods

In the rangeland area, in each block where vegetation measurement was made, soil samples were taken from 0-20 cm soil depth with a stainless steel shovel following the general rules (Jackson, 1958). Soil samples were laid on clean packaging paper under laboratory conditions, stone and plant particles were picked over, and they were allowed to air dry. All dried soils were ground with wooden mallets, passed through a 2 mm steel sieve, and made ready for analysis.

The particle size distribution of soil was performed with the Bouyoucus hydrometer method; soil reaction (pH) was determined in the prepared saturated soil paste using a pH meter with a glass electrode; total salt was determined with the extract obtained from saturated soil paste using a conductivity device; lime was determined using a Scheibler calcimeter; organic matter was determined by the modified Walkley Black method; the available phosphorus was determined according to the Olsen method; the available potassium was determined with the extraction method by using 1 N ammonium acetate (pH = 7.0) (Anonymous, 1982, 1986).

Results and discussion

Vegetation characteristics

The species detected at different slope degrees in the Gözpınar village rangeland during the study and vegetation characteristics of these species were presented in *Table 1*. As it can be observed from *Table 1*, in the rangeland of Gözpınar village, 23 species belonging to 20 different plant genera from 9 different families were detected in the region which has 0-1% slope degree, 21 species belonging to 19 different plant genera from 8 different families were detected in the region which has 2-5% slope degree, and in general, a total of 23 different species belonging to 20 genera from 9 families were detected in the Gözpınar village rangeland.

In similar studies conducted in natural rangelands of Turkey, the number of species was reported to be 207 in the rangelands of Samsun by Yavuz et al. (2011), 186 in Amasya rangelands by Yavuz et al. (2012), 53 in a rangeland in Derik district of Mardin province by Aydın et al. (2014), 41 in the floodplain rangelands of Kırıkhan district of Hatay province by Çınar et al. (2014), 122 in the Zengi rangeland of Isparta province by Babalık and Sarıkaya (2015), 206 in the rangelands of Karahisar village of Tekirdağ province by Gür and Altın (2015), 90 in Çanakkale rangelands by Özaslan Parlak et al. (2015), 43 in the floodplain rangelands of Silvan district of Diyarbakır province by Seydoşoğlu et al. (2015a), 35 in the steppe rangelands of Eğil district of Diyarbakır province by Seydoşoğlu et al. (2015b), 103 in the rangelands of Taşköprü district of Kastamonu province by İspirli et al. (2016), 176 in the rangelands of Antalya province by Öten et al. (2016), 89 in the Karaören village rangeland within the boundaries of Seyitgazi district of Eskişehir province by Babalık and Ercan (2018), 117 in the rangelands of Beşiri district of Batman province by Seydoşoğlu and Kökten (2018), 202 in Batman province rangelands by Seydoşoğlu and Kökten (2019), and 53 in the Ormanardı village rangeland of Bingöl city center by Tutar and Kökten (2019). The difference in terms of the number of species between the data reported in the literature and the results of our study could be explained by the differences in grazing pressure, climate, soil structure, and topographic structure between the rangelands.

The family with the highest number of species in the examined rangeland area is the Poaceae, and this family was followed by the Fabaceae, and by the Brassicaceae, Asteraceae, and Umbelliferae families with two plant species in each of them (*Table 1*).

The lifespan that expresses a meaning within the "Life Form," which constitutes one of the qualitative characteristics of meadow and rangeland vegetation, is important in terms of plant sociology and ecology, and it is an important feature that needs to be emphasized in the subject of culture, management, and rehabilitation of meadows and rangelands (Gençkan, 1985). In this study, according to the life spans, in the rangeland section with a slope degree of 0-1%, 15 of the plant species were detected to be annual and 8 of them to be perennial; in the region section with a slope degree of 2-5%, 13 of the plant species were detected to be annual and 8 of them to be perennial (*Table 1*). In vegetation studies carried out in similar ecologies, for example, in the studies carried out in the rangelands of Derik district of Mardin province (Aydın et al., 2014), in the floodplain rangelands of Silvan district of Diyarbakır province (Seydoşoğlu et al., 2015a) and in steppe rangelands of Eğil district of Diyarbakır province (Seydoşoğlu et al., 2015b), as in the results of our study, annual species were reported to be present more in vegetation. The fact that annual species constitute the majority means that the rangeland loses its natural vegetation characteristics.

As a matter of fact, Wester (1981) reported that the perennial Poaceae are more common in rangelands with natural vegetation characteristics, and Gökkuş (1994) reported that annuals are commonly found in re-created areas where natural vegetation is degraded.

According to the responses of the species to grazing, in other words, when the distribution of the species according to their quality degrees was examined, of the species determined in the rangeland section with a slope degree of 0-1%, 2 were decreaser, 2 were increaser, and 19 were invasive; and in the rangeland section with a slope degree of 2-5%, 2 of the species were decreaser, 2 were increaser, and 17 were invasive. In the rangeland section with a slope degree of 0-1%, the ratio of decreaser species in the botanical composition of the examined rangeland was 4.51%, the ratio of increaser species was 5.43%, and the ratio of invasive species was 90.06%; and the ratios of the same species were 4.24%, 7.42%, and 88.34%, respectively, in the rangeland section with a slope degree of 2-5% (*Table 1; Fig. 3*). The invasive species were observed to be more proportionately in the base parts, which have flat or close to the flat slope, of the examined rangeland than the slightly inclined parts of the rangeland. This situation may be explained by the fact that animals prefer flat areas instead of slightly sloping areas and as a result of overgrazing of these areas, plant species with a low feed value replace plant species with a high feed value constituting the vegetation.

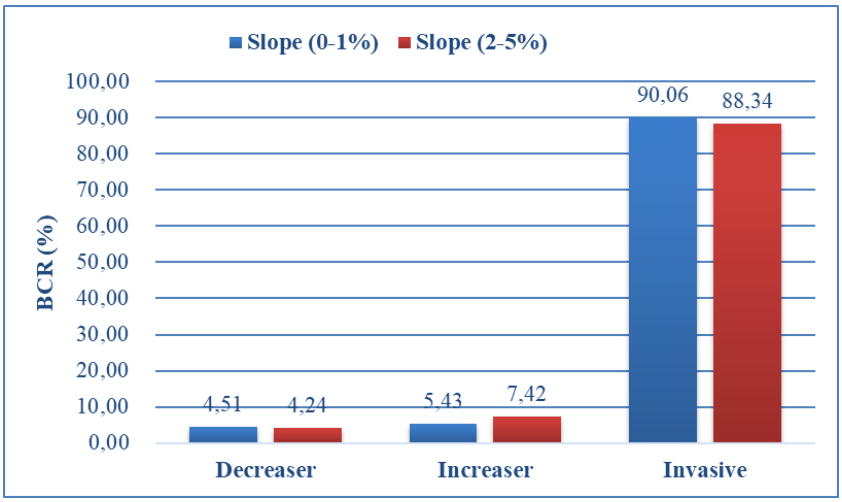

Figure 3. *The ratios of species with a different quality degree in the botanical composition in the Gözpınar village rangeland (%)*

Furthermore, in the study, invasive plants had the highest value with 68.63% in terms of the soil covering ratio, invasive plants were followed by increaser and decreaser plant species with the ratios of 4.87% and 3.37%, respectively (*Table 1*).

Studies conducted in different regions of Turkey reported that invasive species form the majority of rangeland vegetation (Uzun et al., 2010; Ünal et al., 2013, 2014; Yavuz et al., 2012; Çınar et al., 2014, 2019; Seydoşoğlu et al., 2015a, b; Alay et al., 2016; İspirli et al., 2016; Öten et al., 2016; Seydoşoğlu and Kökten, 2019; Tutar and Kökten, 2019).

Decreaser species, which symbolize dominant and most valuable forage plants of climax vegetation, are species that are grazed by rangeland animals firstly due to the superiority of their palatability (Gençkan, 1985). *Lolium perene* (3.31% and 2.83%) and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1553115546

Dactylis glomerata (1.20% and 1.41%) were determined as the decreaser species in terms of their ratios in the botanical composition at both slope degrees of the examined rangeland (*Table 1*).

At both slope degrees, *Poa bulbosa* (2.42% and 4.24%) and *Teucrium polium* (3.01% and 3.18%) were found to be increaser species, of which feed values and palatability were lower than those of decreaser species and which are grazed less by rangeland animals (Gençkan, 1985) (*Table 1*).

In rangeland vegetations, there are foreign plant species, which are not the leading members of climax vegetation, but which are found in the climax rangeland vegetation even at a small ratio, which are not grazed or grazed to a small extent by animals, which are tasteless, which have a low feed value, and which are expressed as invasive species (Gençkan, 1985). In our study, in the rangeland, where vegetation surveys were performed, in both regions having different slope degrees (0-1% and 2-5%), according to the ratio in the botanical composition, *Hordeum murinum* (14.15% and 13.43%), *Astragalus hamosus* (8.44% and 13.43%), *Hordeum spontaneum* (6.63% and 7.07%) and *Taraxacum aleppicum* (6.63% and 7.07%) were determined as prominent invasive species (*Table 1*).

In the Gözpınar village rangeland where vegetation survey was carried out, the plant covered area ratio (PCR) in the parts of the rangeland having different slope degrees were presented in *Table 2*. Upon examining *Table 2*, while the plant covered area value was detected to be 83.00% in the region of the rangeland having 0-1% slope degree, it was detected to be 70.75% in the region having 2-5% slope degree. In other words, it was found out that the total plant cover decreased with increasing slope degree. The vegetation surveys carried out by İspirli et al. (2016) in 12 different village rangelands which are located in Taşköprü district of Kastamonu province and of which altitudes vary between 612 m and 1414 m reported that in parallel with the increase in slope degree, the total plant cover generally decreased. Similarly, Öten et al. (2016) stated that the total plant cover was low in rangeland areas with a high slope degree.

Table 2. *PCR values for families according to different slope degrees of the Gözpınar village rangeland compared to BCR*

Slope degree	Family	PCR (%)	Total (%)
0-1%	Poaceae	29.00	83.00
	Fabaceae	24.00	
	Other families	30.00	
	Empty space	17.00	17.00
	Total (BCR)	100.00	100.00
2-5%	Poaceae	25.25	70.75
	Fabaceae	20.00	
	Other families	25.50	
	Empty space	29.25	29.25
	Total (BCR)	100.00	100.00
Average	Poaceae	27.13	76.87
	Fabaceae	22.00	
	Other families	27.74	
	Empty space	23.13	23.13
	Total (BCR)	100.00	100.00

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1553115546

The average PCR of the Gözpınar village floodplain rangeland of Kurtalan district of Siirt province was detected to be 76.87% (*Table 2*). When the vegetation survey studies conducted in different rangeland areas of Turkey were examined, the PCR was determined to vary between 46.2%-72.0% in the floodplain rangelands of Silvan district of Diyarbakır province (Seydoşoğlu et al., 2015a), between 26.60-60.36% in the steppe rangelands of Eğil district of Diyarbakır province (Seydoşoğlu et al., 2015b), between 75.00%-98.25% in the rangelands of Antalya province (Öten et al., 2016), between 74.00%-91.25% in the rangelands of Beşiri district of Batman province (Seydoşoğlu and Kökten, 2018), between 90.3%-97.9% in the rangelands of Tufanbeyli district of Adana province (Çınar et al., 2019), and between 47.50%-93.00% in the rangelands of Batman province (Seydoşoğlu and Kökten, 2019). In addition, the average TPC was reported to be 21.75% in the Zengi rangeland of Isparta province (Babalık and Sarıkaya, 2015), 88.2% in the natural rangelands of Sinop province (Alay et al., 2016), 83.34% in the natural rangelands of Taşköprü district of Kastamonu province (İspirli et al., 2016), 71.35% in the rangelands of Mardin province (Seydoşoğlu et al., 2018), and 85.8% in the Ormanardı village rangeland of Bingöl city center (Tutar and Kökten, 2019).

As a result of the study, our findings obtained in terms of the PCR were observed to display similarities and differences with the studies carried out under many ecological conditions. As these differences may be caused by the method differences used in vegetation measurements, it is thought that differences in climate, soil structure, and rangeland management (grazing capacity, animal species, grazing period) applications may also cause this result.

In the Gözpınar village rangeland, in the rangeland region with a slope degree of 0-1%, 29.00% of the PCR was constituted by the Poaceae, 24.00% by the Fabaceae, and 30.00% by plants from other families. In the study, in the region with a slope degree of 2-5%, the PCR ratios of the Poaceae, Fabaceae, and other family plants were detected to be 25.25%, 20.00%, and 25.50%, respectively. When the Gözpınar village rangeland was examined in general, 27.13% of the PCR was observed to be the Poaceae, 22.00% were observed to be the Fabaceae, and 27.74% were observed to be the plants from other families (*Table 2; Fig. 4*).

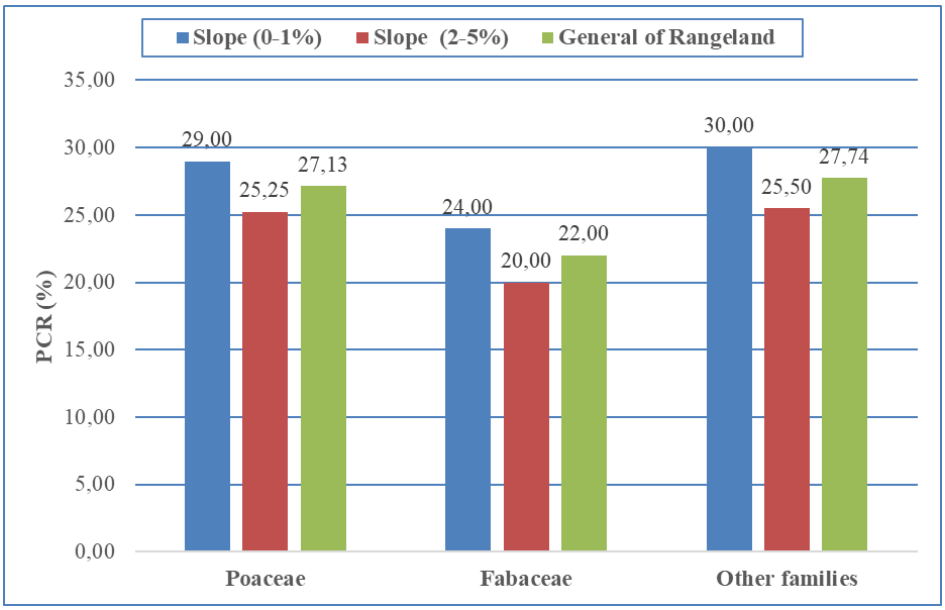

Figure 4. *Distribution of the PCR according to families (%)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1553115546

Plant species in the rangeland area were examined by being gathered in three groups as plants from the Poaceae family, Fabaceae family, and other families, and their ratios in the botanical composition were determined according to the PCR (*Table 3*).

In the Gözpınar village floodplain rangeland, where vegetation surveys were performed, in the rangeland region having 0-1% slope degree, of the identified species, 7 (34.94%) were the Poaceae, 6 (28.92%) were the Fabaceae, and 10 (36.14%) were species belonging to other families. In the examined rangeland, in the region having a slope degree of 2-5%, of the identified species, 7 (35.69%) were the Poaceae, 5 (28.27%) were the Fabaceae, and 9 (36.04%) were species belonging to other families. In general, the botanical composition of the examined rangeland was composed of the Poaceae with a ratio of 35.32%, the Fabaceae with a ratio of 28.60%, and other families with a ratio of 36.08% (*Table 3; Fig. 5*). In this case, it is possible to say that plants belonging to other families constitute the dominant plant group in vegetation. Similar results were also reported by Aydın et al. (2014), Seydoşoğlu et al. (2015b), Alay et al. (2016), İspirli et al. (2016), Öten et al. (2016), Seydoşoğlu and Kökten (2018, 2019), Sürmen and Kara (2018) and Çınar et al. (2019).

Table 3. *Ratios of families in the botanical composition ratio*

Families	Botanical composition ratio (%)		
	0-1%	2-5%	Average
Poaceae	34.94	35.69	35.32
Fabaceae	28.92	28.27	28.60
Other families	36.14	36.04	36.08
Total	100.00	100.00	100.00

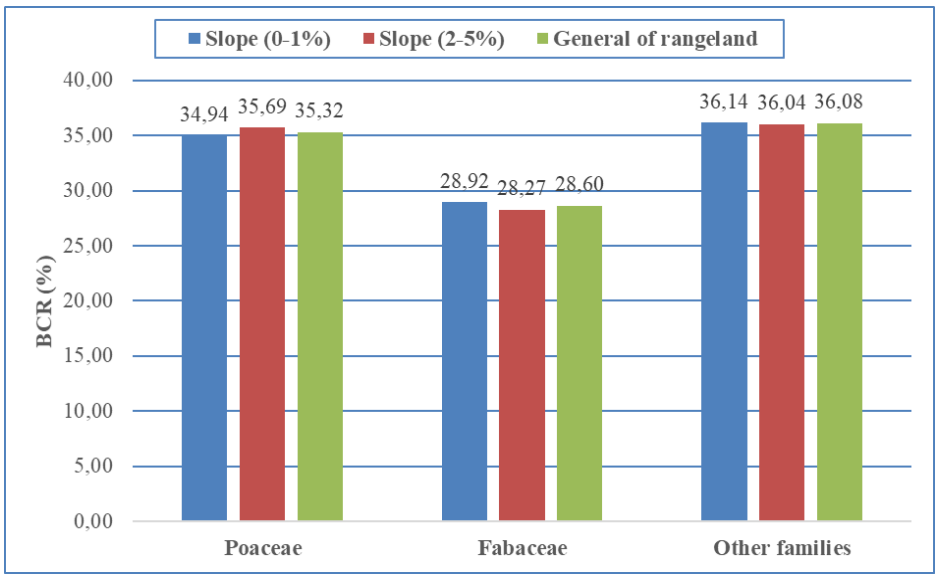

Figure 5. *Botanical composition ratios grouped by families*

While the most common Fabaceae in the vegetation were *Astragalus hamosus* (8.44%, 13.43%), *Trifolium campestre* (6.03%, 5.30%), *Medicago rigidula* (5.72%, 3.18%), and *T. subterraneum* (4.52%, 3.53%); *Hordeum murinum* (14.15%, 13.43%),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1553115546

H. spontaneum (6.63%, 7.07%) and *Avena sterilis* (6.03%, 5.30%) were the most commonly observed Poaceae. In vegetation, the most common species belonging to other families were detected to be *Scandix stellata* (7.52%, 5.30%), *Taraxacum aleppicum* (6.63%, 7.07%), and *Torilis leptophylla* (6.03%, 6.36%) (*Table 1*).

Some physical and chemical properties of rangeland soils

Some physical and chemical analysis results of the soil samples taken from the regions of the Gözpınar village rangeland with different slope degrees were presented in *Table 4*. The sand content of the soils belonging to the flat and close to flat (0-1%) and slightly sloping (2-5%) rangeland regions was determined to be high. As a result of the classification made according to Anonymous (1951), the texture class was determined to be sandy-loam in the slightly sloping rangeland region and sandy-clayey-loam in the flat rangeland region. According to the general grouping, rangeland soils are loamy soils. Bilgin and Özalp (2016) reported that in the soils belonging to the rangeland vegetation, the texture class did not differ at low elevations (1900, 2000, and 2200 m), but the sand content of the soils was high. Özaslan Parlak et al. (2015) reported in the study they conducted in different rangeland regions that sand, silt, and clay contents of rangeland soils significantly differ from each other and that coastal rangeland has sandy loam, lowland shrubland has clayey loam, reseeded rangeland has clayey, protected and overgrazed rangeland has sandy loam structure. Some other studies reported that rangeland soils were loamy or clayey-loamy (Ağın and Kökten, 2013; Çaçan and Kökten, 2014; Taşdemir, 2015).

Table 4. *Some physical and chemical properties of soils of the Gözpınar village rangeland according to slope degrees*

Soil properties	Slope degree		Average
	0-1%	2-5%	
Sand, %	47.32	55.36	51.34
Clay, %	27.44	18.98	23.21
Silt, %	25.24	25.66	25.45
pH	8.25	8.25	8.25
Total salt, %	0.054	0.080	0.067
Lime ($CaCO_3$), %	4.1	5.4	4.8
Organic matter, %	1.88	1.25	1.57
Available phosphorus (P), kg P_2O_5/da	29.2	5.4	17.3
Available potassium (K), ppm	6233	5116	5675

In terms of soil reaction and salinity, no difference was determined between the examined rangeland regions, and the rangeland soil was detected to have slightly alkaline character and be salt-free (*Table 4*). In the studies conducted in different regions of Turkey, rangeland soils had slightly acid (Şengönül et al., 2009; Bilgin and Özalp, 2016; Çaçan and Kökten, 2014), slightly alkaline (Babalık and Sarıkaya, 2015; Babalık and Ercan, 2018), and neutral character (Ağın and Kökten, 2013; Özaslan Parlak et al., 2015; Taşdemir, 2015), and it was reported that there was no problem in terms of salinity in rangelands.

DOI: http://dx.doi.org/10.15666/aeer/1706_1553115546

While the lime content of the soil was 4.1% in the regions of the Gözpınar rangeland that were flat or close to flat, this amount was detected to be 5.4% in the slightly sloping rangeland region (*Table 4*). According to the classification reported by Ülgen and Yurtsever (1995), the rangeland soils examined were found to be "calcareous" and/or "medium calcareous." The amount of lime varying under the effect of climate and main material was reported to vary at non-calcareous, low calcareous, high calcareous levels in the rangelands of different ecology areas (Bolat, 2007; Sengönül et al., 2009; Ağın and Kökten, 2013; Çaçan and Kökten, 2014; Taşdemir, 2015; Babalık and Sarıkaya, 2015; Özaslan Parlak et al., 2015; Babalık and Ercan, 2018).

The organic matter content of the soil was detected to be 1.88% in the regions of the Gözpınar village rangeland that were flat or close to flat, and 1.25% in the slightly sloping rangeland region, and the average organic matter content of the mentioned rangeland was 1.57% (*Table 4*). The high organic matter content in the flat region of the rangeland can be explained by the accumulation of nutrients in these areas depending on both soil and water transport towards the base of the rangeland by erosion. However, the organic matter content in both regions was found to be low according to the classification based on the study by Ülgen and Yurtsever (1995). It is thought that the total plant cover and the ratio of the Fabaceae in the botanical composition were effective in the low level of the organic matter content of rangeland soils. In the studies carried out in rangeland areas with different elevation and slope degrees, soil organic matter was generally reported to be at good levels (Babalık and Sarıkaya, 2015; Bilgin and Özalp, 2016; Özaslan Parlak et al., 2015). On the other hand, Birhan (1999) noted that there was no excessive difference between topographic positions in terms of organic matter content and that there was no significant relationship between organic matter content and topographic factors. In the study carried out by Kadıoğlu and Canbolat (2014) in order to reveal the change in soil quality index parameters in agricultural and rangeland areas located in different topographic positions, it was determined that from the topographic positions, the structure was thinned and the organic matter content increased from the peak position to the skirt position.

When rangeland soils were examined in terms of the P and K content available to plants, the base regions were found to contain higher amounts of P and K compared to slightly sloped regions (*Table 4*). According to the classification reported by Ülgen and Yurtsever (1995), while the available P level of the soil is "very high" in the rangeland regions where the slope degree is flat or close to flat, it is "low" in the slightly sloped regions of the rangeland. According to the classification made by Pizer (1967), the K content of the soil is very high in both rangeland regions. Our findings on the available P and K contents of the rangeland soils were found to be compatible with the findings of Ağın and Kökten (2013), Çaçan and Kökten (2014) and Özaslan Parlak et al. (2015).

Conclusion

There were 23 species in the examined rangeland, and the majority of these species (19 sp.) were found to be invasive. Although the ratio of plant covered area (76.87%) was high, the determined ratio of plants belonging to fabaceae, which is important in terms of feeding of animals, was very low. According to these results, it was concluded that in the floodplain rangelands with continental climate, grazing of animals in accordance with the management rules, and improvement of rangeland with fertilization will have a positive effect on the botanical composition of the rangeland.

(Received 3rd Aug 2019; accepted 14th Nov 2019)

Abstract. Studying the phenological characteristics of landscape trees can determine the optimal afforestation time for local landscaping, while also providing a theoretical basis for garden design, plant configuration and garden phenology prediction. In order to grasp the leaf pheniological rhythm of common landscape tree species in Nyingchi Prefecture, optimize the garden plant configuration of Nyingchi Prefecture, 53 kinds of landscape tree species were selected as the object for continuous 5a parallel observation and analysis of their leaf phenology. The results showed that: the budding period lasts from early March to mid-April, and that of 20 species concentrates in late March. It is recommended that afforestation be completed before mid-April. The leaf expansion period lasts from early March to mid-June, and the peak period is from mid-April to early May. It is recommended to arrange the seasonal landscape according to the leaf expansion characteristics of the tree species. The 53 tree species were classified into 5 types based on leaf phenological characteristics. Finally, corresponding measures and suggestions were proposed for local garden afforestation and tree arrangement.
Keywords: *Tibet, phenological phase, budding, leaf expansion, leaf phenology classification*

Introduction

The phenology of plants refers to their cyclical changes with the climate during annual growth, including budding, branching, leaf expansion, flowering, fruiting, defoliation and dormancy. The external features exhibited by plant organs in different phenological stages are known as phenophase (Zhao et al., 2016). Phenology is often used to study the natural seasonal variation of plants, which has long been valued by biologists (Zhao, 1983). The data for phenological changes can not only provide guidance on afforestation (Wang, 2006; Chang et al., 2011), but also offer certain reference value for optimal configuration of plant landscapes (Yang and Chen, 2000; Xu et al., 2004; Chen et al., 2011), so that the matching relationship of landscapes between different time periods is coordinated, thus exhibiting the temporal and special beauty of the landscape (Hu et al., 2006; Zhang et al., 2008; Gu and Zhang, 2011).

The dynamic landscape of a region's gardens is, to a large extent, a result of phenological seasonal variations of garden plants. The phenological phases differ for different regions. Studying the phenological changes of local garden plants can provide certain basis and reference for local plant community construction and seasonal landscape, garden plant landscaping. So far, there have been garden phenology related researches mainly in Beijing (Zhang et al., 2018), Shanghai (Zhao et al., 2016), Nanjing (Zhang et al., 2016), Xi'an (Bai et al., 2016), Changchun (Chen et al., 2015), Hengshui (Liu et al., 2013) and Hohhot (Gu and Zhang, 2015), while phenological studies on

DOI: http://dx.doi.org/10.15666/aeer/1706_1554715558

Nyingchi in Tibet Autonomous Region are few. Only a few scholars such as Liu et al. (2015), Xue et al. (2014), Ma et al. (2010), and Wang et al. (2019) have done research from different perspectives of forestry. Study on garden phenology of Nyingchi is extremely scarce. In view of this, with 53 kinds of common landscape trees in Nyingchi as testing pieces, this study researched and analyzed the characteristics of budding and leaf expansion phenology, with a view to providing a useful reference for optimizing the garden plant configuration of Nyingchi Prefecture and upgrading the connotation and quality of garden landscape.

Research method

Overview of the study area

The study area is located in Fujian Park and Wetland Park in Nyingchi Prefecture, Tibet (*Fig. 1*), which is at the densely populated commercial and cultural center of Nyingchi Prefecture. It is located in the lower reaches of the Yarlung Zangbo River in southeastern Tibet (E93°25', N29 °50'), with an elevation of 2,960 m, an average annual temperature of 8.7°C, an average annual rainfall of 650 mm, an average relative humidity of 71%, annual sunshine hours of 2,022.2 h, a sunshine percentage of 46% and a frost-free period of 180 d (Ran et al., 2013).

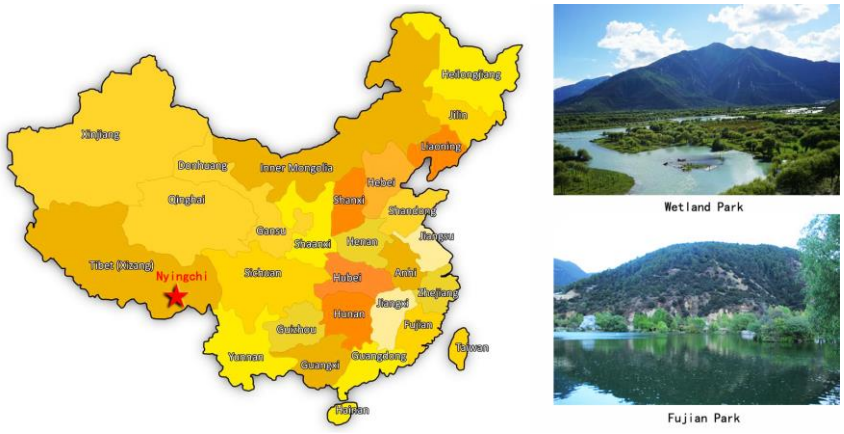

Figure 1. *Sample area location and habitat status map*

The humid climate belongs to the warm and humid climate zone in southeastern Tibet. Known as the “Snowy Regions South of the Yangtze River”, it boasts rich and varied garden plants. The park's greening is mainly native tree species like local wild ornamental seedlings, together with sporadic and small-scale landscape trees introduced from the interior areas. Fujian Park covers an area of 12.4 hm^2. 59 species of woody garden plants were introduced and cultivated from the interior area at its construction (Liu et al., 2015). With the continuous construction of the park, there are 72 species of arbors and 46 species of shrubs in general overall growth. The wetland park covers an area of 35.1 hm^2. Mainly composed of native plants, the near natural urban forest has 68 species of arbors and 56 species of shrubs in good overall growth. These two parks serve as key city-level parks in Nyingchi Prefecture, which play an important role in improved ecological balance, citizens' recreation and enhanced physical and mental health.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1554715558

During the study period (2014-2019), the average annual temperature of the study area is 8.9°C, the average annual rainfall is 648 mm and the average relative humidity is 71%. The annual average temperature is slightly higher than previous years, the rainfall and the relative humidity are almost the same as previous years. The climate change has a certain impact on the observation results (Nyingchi, 2014-2019).

Sample selection

In this study, 53 species of deciduous trees with large planting area, large number and strong group representation were selected as observation objects (*Table 1*), including 31 species of arbors, 20 species of shrubs and 2 species of vines (which were omitted in this study due to the relatively simple phonological ornamental function of coniferous evergreen species). Three strains of representative plants (middle-aged trees in an open area, enjoying healthy growth without plant disease or insect pests, and with flowering and fruiting for 3a) were selected from each plant type, and the community and soil type, elevation, slope data were recorded.

Observation methods

According to the "Chinese Phenology Observation Method", the selected 53 species of trees were subject to fixed-strain (marked by tag), fixed-person, regular observation for budding and leaf expansion phenology from March to June of 2014~2019. The observation period was 1 time every 2 d in the early stage and 1 time every week in the late stage, which lasted for 122 d. To reduce the error, fixed personnel made observations mainly based on visual inspection using combination of tools like telescope, magnifying glass, etc. (Wan et al., 1978; Zhang, 1985). Phenology data were recorded at 14:00-17:00 on the observation day. To facilitate observation and comparison, south side of all samples was selected for observation. To facilitate comparison between different years, all data are preprocessed first, then Julian Day conversion was applied for phenological date, which was to calculate the period from March 1 to the date as Julian Day (Zhu and Wan, 1980).

Phenological observation criteria: the budding period refers to the period when buds of the plants display green leaf opex (in the case of scales, the time shall prevail when scales are cracked to reveal bright colors at the bud top). The leaf expansion period is divided into initial stage of leaf expansion, peak period of leaf expansion and end of leaf expansion. Initial leaf expansion means the buds of individual branches of the observed object show the first batch of flat leaves; peak period of leaf expansion means leaflets on half of the branches of the observed object are completely flattened; end of leaf expansion means over 90% of the leaflets of the observed object are completely flattened. The duration of leaf expansion refers to the interval between the initial and end of leaf expansion (Wan and Liu, 1979).

Data processing

Correlation analysis on different parameters in this study was conducted by Pearson correlation coefficient test, and phenological phase load analysis was performed by principal component analysis. Data processing was completed by Excell 2007 and SPSS25.0. In order to facilitate the query and distinguish the phenological phases, the results took 10 d as the unit in which month was divided into three segments: first, middle and last ten days.

Results and analysis

Phenological phase observation on budding and leaf expansion

It can be seen from *Table 1* and *Fig. 2* that the budding period of the 53 common landscape tree species in Nyingchi Prefecture lasts from the beginning of March to the beginning of May, and the concentration period is mid-to-late March (26 species, 49.06%). The budding characteristics of different plant species vary greatly, with the earliest budding in *Salix alba*, *Piptanthus nepalensis* (March 5), while *Caragana bicolor*, *Lagerstroemia indica* have the latest budding (May 6), with a discrepancy of 62d between the two.

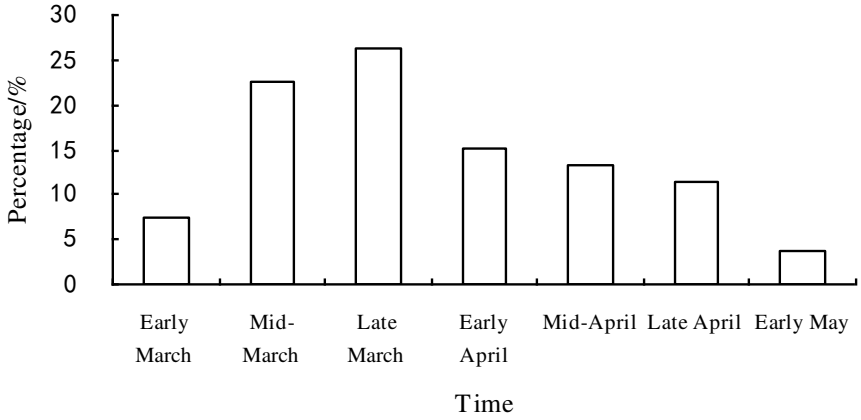

Figure 2. *Budding characteristics of 53 landscape trees*

Phenological characteristics of leaf expansion

It can be seen from *Table 1* and *Fig. 3* that the leaf expansion period of the 53 common landscape tree species lasts from the beginning of March to the middle of June. Initial stage of leaf expansion lasts from early March to mid-May. Where, *Salix alba* has the earliest initial leaf expansion (March 5), *lagerstroemia indica* has the latest initial leaf expansion (May 17), with a discrepancy of 73 d between the two. Peak period of leaf expansion lasts from mid-March to late May. Where, *Salix alba* is the earliest in peak leaf expansion (March 17), *Caragana bicolor* is the latest in peak leaf expansion (May 28), with a discrepancy of 72 d between the two. End of leaf expansion lasts from late March to mid-June. Where, *Salix alba* has the earliest end of leaf expansion (March 26), *Caragana bicolor* has the latest end of leaf expansion (June 18), with a discrepancy of 84 d between the two. The average duration of leaf expansion is 26.81 d, which is relatively long. In terms of the duration of leaf expansion, the longest is *Hippophae rhamnoides* subsp. *gyantsensis* (47 d), the shortest is *Piptanthus nepalensis* (16 d), with a discrepancy of 31 d between the two.

The initial stage of leaf expansion is mainly concentrated in early April (14 species, 26.41%) and mid-April (12 species, 22.64%), the peak period of leaf expansion is mainly concentrated in mid-April (15 species, 28.30%) and late April (14 species, 26.41%), and the end of leaf expansion is mainly concentrated in mid-May (18 species, 33.96%) and late May (12 species, 22.64%). It provides a theoretical basis for the construction time to local landscape.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1554715558

The analysis shows that there exists a significant correlation between the initial stage of leaf expansion and budding period, the peak period of leaf expansion and the budding period, the end of leaf expansion and the budding period (*Table 2*). It indicates close correlation between leaf expansion time and budding time. Tree species with earlier budding period have earlier leaf expansion stage，the result is consistent with Zhao et al. (2016). The average interval between budding period and initial stage of leaf expansion is 7.11 d. The result showed that: Some species had no budding period and they are mainly Salicaceae, such as *Populus szechuanica* var. *Tibetica*,*Malus hallian*, *Salix alba* et al. On the other hand, the longest interval between budding period and initial stage of leaf expansion was *Hypericum choisianu* (28 d). In addition, the duration of leaf expansion is significantly correlated with the end of leaf expansion, but not with other parameters of leaf phenology.

Leaf phenology classification of 53 tree species

According to the classification of phenological differences between tree species, to more clearly study the occurrence and duration of phenology of different tree species, this study conducted principal component analysis on budding and leaf expansion phenology of 53 tree species (*Table 3*). The analysis shows that the two main components of budding period and initial stage of leaf expansion play a significant role, with a contribution rate of 77.203% and 20.908%, respectively, and the cumulative variance is 98.111%. At the same time, it can be seen from *Table 4* that the budding and leaf expansion parameters of the first principal component have high factor loading,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1554715558

which can represent the budding period, the initial stage, the peak and the end of leaf expansion respectively. Duration of leaf expansion in the second principal component has a higher factor loading, which can represent the duration of leaf expansion. The results are consistent with the correlation analysis (*Table 2*) between the various phenological parameters.

From the results of the above correlation analysis combined with *Fig. 4*, the leaf phenology of the 53 tree species can be divided into five categories. First, according to leaf budding time, there are three types of early, middle and late budding, each of which can be further divided into two categories according to the duration of leaf expansion.

Category 1: Early budding - short-medium duration of leaf expansion. The budding time is concentrated on March 5 and 6, and the leaf duration is 16～28 d. The tree species include *Salix alba*, *Piptanthus nepalensis*, and *Malus halliana* (5.66%). Where, *Piptanthus nepalensis* has the shortest duration of leaf expansion among the 53 species (16 d).

Table 3. *Correlation coefficients matrix for phenological parameters*

Component	Initial eigenvalue			Extraction sum of squared load		
	Total	Variance %	Cumulative %	Total	Variance %	Cumulative %
1	3.860	77.203	77.203	3.860	77.203	77.203
2	1.045	20.908	98.111	1.045	20.908	98.111
3	0.084	1.678	99.789			
4	0.011	0.211	100.000			
5	0.005	0.110	100.000			

Table 4. *Statistics of the first 2 PCs of leaf phenology for each tree species*

	PC1	PC2
Budding period	0.953	-0.174
Initial stage of leaf expansion	0.977	-0.189
Peak period of leaf expansion	0.992	0.006
End of leaf expansion	0.986	0.148
Duration of leaf expansion	0.202	0.979

Category 2: Early budding-long duration of leaf expansion. There is only one species (1.89%), i.e. *Hippophae gyantsensis*, whose budding time is March 10, and the duration of leaf expansion is the longest (47 d) among the 53 tree species.

Category 3: Medium budding –medium-short duration of leaf expansion. The budding time is concentrated between March 11 to April 16, and the duration of leaf expansion is 17~38 d. There are 40 tree species (75.47%), including *Larix griffithii*, *Populusszechuanicavar.tibetica*, *Hypericum choisianum*, *Prunus mira*, *Desmodium callianthum Franch*, *Morus mongolica var. Diabolica*, *Celastrus stylosus*, *Sorbus rehderiana*, *Acer caudatum*, *Sorbaria arborea*, *Myricaria elegans Royle*, *Salixaureo-pendula*, *Cerasus yedoensis*, *Syringa oblata*, etc.

Category 4: Late budding – medium-short duration of leaf expansion. The budding time is concentrated on April 18-May 6, and the duration of leaf expansion is 18～31 d. There are 8 tree species (15.09%), including *Chionanthus retusus*, *Rosa xanthina*, *Zanthoxylum motuoense*, *Fructus Crataegi*, *Chinese wisteria*, *Caragana bicolor*,

DOI: http://dx.doi.org/10.15666/aeer/1706_1554715558

Lagerstroemia indica. Where, *Lagerstroemia indica* has the latest end of leaf expansion among the 53 tree species (June 16).

Category 5: Late budding- long duration of leaf expansion. There is only one species (1.89%), i.e. *Cercis chinensis*, whose budding time is April 21, and the duration of leaf expansion is 42 d.

It can be seen from the above that the spring leaf phenology of the landscape tree species in the prefecture mainly features "medium budding-medium-short duration of leaf expansion". The type accounts for 75.47% of the investigated tree species.

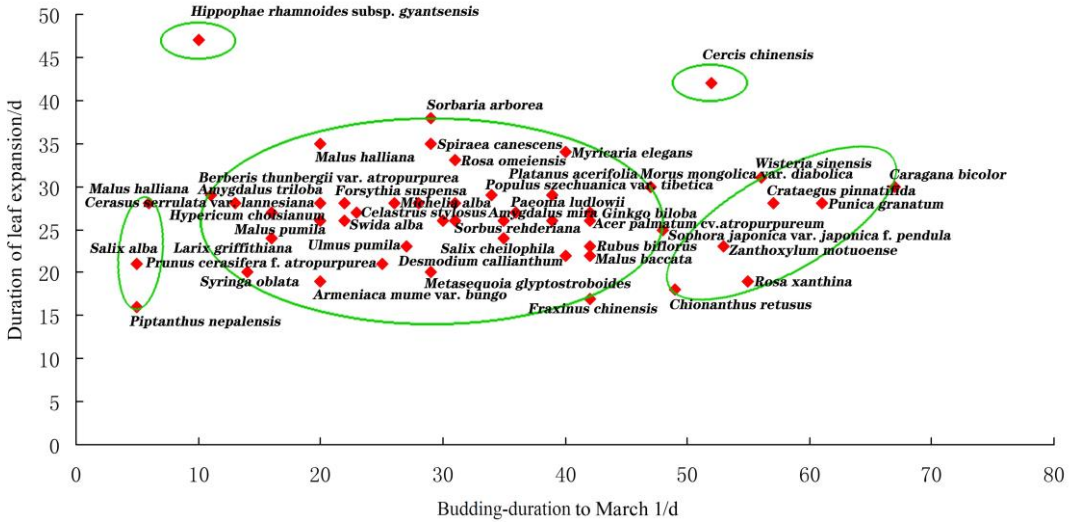

Figure 4. *Scatter plot of budding-duration of leaf expansion*

Discussion

Sequential correlation of budding phenology

Zhao et al. (1979) proposed sequential correlation law of phenology through correlation analysis on tree phenology, who believed that phenological phenomena were related to the emergence of another phenological phenomenon. Cao and Liu (1999) conducted clustering analysis on 16 broad-leaved trees in Nanchang Arboretum for the management of forest culture time, while phenological combination of urban landscape trees was not much studied. The phenological studies in Europe show that the phenology of plants in the mid-latitudes such as budding and leaf expansion depends mainly on temperature (Sparks et al., 2000; Kramer et al., 2000; Chmielewski and Rotzer, 2001; Fitter et al., 2002; Broadhead et al., 2003), which is consistent with the conclusion of phenological study by Zhang et al. (1995) on Beijing. Nyingchi Prefecture located in the western part of China has relatively cold winter and spring. Temperature is the dominant factor affecting the budding and leaf expansion of trees. The various trees have concentrated budding and leaf expansion, with difference weakened by the dominant environmental factors, which is consistent with phenological study by Hu et al. (2016) on Shenyang.

With the recent increase of temperature, the plant growth season is prolonged and the spring phenology is advanced (Ahas et al., 2000; Anderson et al., 2005). At present, phenological research focuses on the relationship between phenology and climate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1554715558

change (Zhao et al., 1983; Menzel and Fabian, 1999; Schwartz and Reiter, 2000; Walther et al., 2000), phenology response to the environment (Snyder et al., 2001; Augspurger, 2008; Ahas, 2009). Constructing different predictive models (Li et al., 2000) for corresponding studies on communities and above is an important aspect of future phenological research.

Budding phenology and afforestation

Due to its special natural environmental conditions, Tibet has difficulty in afforestation, and the budding period of different tree species varies greatly. “Not high survival rate of afforestation, frequent phenomenon of repeated replanting”, “no tree despite years of afforestation” are prominent problems in most areas for a long time (Liu et al., 2015; Zhang et al., 2016). Afforestation faces easy damage and difficult recovery, further increasing the pressure on Tibet's ecological environment.

Practice has proved that planting before leaf budding can significantly improve the afforestation survival rate of local landscape tree species. Examples of planting failures are frequent in Nyingchi Prefecture due to improper planting seasons (especially old tree transplants). According to the leaf phenological characteristics of the landscape trees in the Prefecture, the first and second types of tree species with earlier budding are recommended to be planted in late February. The third type of tree with moderate budding time is suitable for planting in March. Where, *Larix griffithii*, *Prunus triloba*, *Syringa oblate*, etc. with relatively early budding are suitable for planting in early March, while *Morus mongolica Schneid*, *Chinese pagoda tree*, *Fraxinus chinensis*, etc. with relatively late budding are suitable for planting in late March. The 4th and 5th category of tree species with the latest budding time are suitable for planting before mid-April. Recent years have witnessed vigorous development of ecological construction projects in the Prefecture. Under the premise of respecting nature, adapting to local conditions and planting at the right time can effectively improve survival rate of landscape tree planting, enhance the water source conservation function, effectively curb sandstorm hazard, especially the “air drying phenomenon” prevalent in the Prefecture (Liu et al., 2015), and improve the green looking ratio and the ornamental and ecological effects, greatly promote the gradual transition of the Prefecture's green space from “single-layer structure” to “multi-layer ecological structure”, thus creating unique plateau urban garden landscape in Tibet.

Leaf expansion phenology and landscape construction

Studies have shown concentrated phenology in Nyingchi Prefecture. There are few tree species with early budding and late budding. Medium budding time is the main case, which is mainly concentrated in mid-March to mid-April. This is not conducive to seasonal aspect and continuous landscape construction. Garden landscaping should consider the influence of plant budding period, seasonal distribution and duration of leaf expansion on landscaping. The landscape trees with early leaf expansion and late leaf expansion should be rationally combined in planting to optimize plant collocation, which can enrich seasonal scenery in spring, extend the viewing time, enhance ecological benefits and also provide biological basis for the local garden planning and design, cultivation management and plant configuration to form rich urban landscape. It is suggested that 5 types of leaf phenological species be combined with each other to better construct local characteristic garden landscapes and enrich the community levels.

Garden phenology forecast

With the development of local tourism, Nyingchi Prefecture has become an international tourism city with increasingly developed relevant tourism industry. Affected by natural factors such as climate fluctuations, phenology of local landscape plants varies from year to year. Studies on garden phenology to accumulate relevant phenological data is conducive to the accurate implementation of relevant garden phenology prediction work, thus providing guidance for the annual "Peach Blossom Festival", garden visit, travel and tourists' sightseeing.

Conclusion

1). Budding and leaf expansion phenology features long duration. The budding period of the 53 common landscape tree species in Nyingchi Prefecture is concentrated in the middle and late March, with a total duration of 62 d and an average duration of 7.56 d. The entire leaf expansion period lasts from early March to mid-June, with a total duration of 108 d and an average duration of 26.81 d. The total duration and average duration of budding and leaf expansion periods are longer than those of Shanghai (Zhao et al., 2016), which may be related to the local cold climate and the difference between seed selection objects. Therefore, it is recommended the afforestation should be completed before mid-April according to the leaf phenological characteristics of Nyingchi Prefecture.

2) There is a significant correlation between the initial stage of leaf expansion and budding period, the peak period of leaf expansion and the budding period, and the end of leaf expansion and budding period. The duration of leaf expansion is significantly correlated with the end of leaf expansion, but not with other parameters of leaf phenology. It is recommended to arrange the seasonal landscape according to the leaf expansion characteristics of the tree species.

3) The leaf phenological type is mainly "medium budding – medium-short duration of leaf expansion". Corresponding suitable planting time was proposed based on tree species with different phenological types in Nyingchi Prefecture.

Abstract. Saline soil is widely distributed in western Jilin province, China, agriculture and engineering are affected by the saline soil. Its formation and development process are influenced the most by factors of the natural geological environment. For the purpose of investigating the salinization process and influence factors in western Jilin, this study analyzes the saline soil of Nong'an in western Jilin Province, which was sampled during a field investigation. Thereafter, the characteristics of the water and salt migration in the soil have been investigated in the laboratory, the environmental factors of the study area, and the influence of the ecological environment on salinization have also been discussed. The results show that the water and salt migrate with seasonal changes in soil. The water content is low in autumn, and high in spring and summer. The salt content of the soil near the ground surface is low in autumn, and high in spring and summer, meanwhile, the salt content in the deep soil layers is low in spring and autumn, and high in summer. During both the unfrozen period and the frost-thawing periods, the soil salinization continues to enhance, and salinization eventually causes land desertification. This study can provide the theoretical basis for the protection of fragile ecological environments.
Keywords: *saline soil, soil enviroment, salinization process, secological environment, desertification*

Introduction

Saline soil is widely distributed in western Jilin province, China, which has caused decline in soil fertility and reduction in grain production (Wang, 1993). Further, the saline soil has also caused several engineering problems, such as road sinking, salt heaving and corrosion. In western Jilin, agricultural and engineering works are affected by saline soil. Western Jilin is located in a seasonally frozen ground area, in which the formation and process of development are influenced by the especial natural geological environment of the area.

According to earlier studies, the formation of saline soil in western Jilin is caused by the natural conditions and aggravated by the human activities (Wang et al., 2011; Zhang et al., 2013; Xu and Dou, 2013). Zhang and Li (2000) considered Songnen plian salinization development was exacerbated by the unreasonable land exploitation by humans, which caused secondary salinization. Yang and Luo (1999) studied the dynamic characteristics relationship between Songnen plain soil salinization and the underground water characteristics. He concluded that the salty underground water was a major

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1555915572

contributor to the formation of the saline soil on the Songnen plain. Liu (2001) monitored the water and salt content movements of the saline soil in the Hongqi irrigation area in Songnen plain, China. Zheng (2005) discussed the driving force for the water and salt accumulation in winter. Wang et al. (2011) named the saline soil in western Jilin as dispersive soil and analyzed the influence factors of dispersibility and frost heaving characteristics. Bao et al. (2018) took laboratory test of salin soil in west Jilin to find out t the frost-heaving rate of soil.

This study aims to investigate the saline soil in Nong'an area of western Jilin, China. In this study, laboratory tests have been carried out to determine the characteristics of the soil samples. The environmental factors of the study area have also been analyzed, and the salinization process in western Jilin has been discussed. The results of this study can be used as a theoretical foundation of salinization treatment in western Jilin and the whole Songnen plain.

Material and Methods

The soil samples were collected from Nong'an area in western Jilin province, China. The study area is located in north of Song'nen plain in China, which is a typical temperate continental semiarid and arid monsoon climate area. This region has severe cold winters and torrid summers, with low annual precipitation. Based on the local salinizated distribution characteristics, two representative sampling locations have been chosen, which have been named as Location I (N: 44°22'43.02", E: 124°58'4.20") and Location II (N: 44°22'26.88", E: 125° 0'52.56"). The sampling locations are shown in *Fig. 1*.

Figure 1. *Sampling locations*

The ground surface of Location I was dry ang barely grass covered (*Fig. 2)*. The ground surface of Location II was grassland which is mostly covered by green grass in summer (*Fig. 3*). For the purpose of comparing the salinization processs, the soil samples were collected in May, June, September and November in 2015. The collected samples were at the depths of 0 cm, 20 cm, 30 cm, 40 cm from the ground surface.

The natural water content, salt content were tested in laboratory of soil samples to investigate the water and salt migration law of saline soil of western Jilin, then the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1555915572

environmental factors of the study area have also been investigated to analysis the salinization process. According to earlier studies, the salinization of western Jilin was due to the strong evaporation effect of the earth's surface (Chen, 2013; Kusmiyati, 2014; Wang et al., 2015). The evaporation effect is influenced by natural facotors such as temperture and rainfall, so this study choose 3 environment factors as temperture, precipitation and evaporation to discusse the salinaztion process. The enviroment data was investaged and processed from Chinameteorological Data Sharing Service System of China (CDSSSC).

Figure 2. *Location I*

Figure 3. *Location II*

Results

Water content seasonal variations

The soil samples were first weighed at the sampling location, and then dried in the laboratory in order to gain the natural water content. Water content was caluted by *Formula 1*.

$$W = \left(\frac{m_0}{m_d} - 1\right) \times 100\% \quad \text{(Eq.1)}$$

where
W - water content of soil, %.
m_d - mass of dry soil, kg.
m_0 - mass of wet (natural) soil, kg.

The water content variations with depths are shown as *Fig. 4*.

As shown in *Fig. 4*, natural water contens of soil water are between 5.0%~34.1%, water migrates with depth, but the migration laws are quite different in diffent seasons. For the purpose of studing the water seasonal migration law, water content seasonal variations of the soil samples at two locations are shown as *Fig. 5*.

As shown in *Fig. 4* and *Fig. 5*, for the soil samples at the two locations, the water contents are high in spring and summer, and low in autumn. For the soil samples near the ground surface, the water contents are low in spring, highest in summer, and then fall in autumn. For the soil samples at 20-30 cm depth, the water contents are highest in spring, and fall in summer. The gradients of the water seasonal variation curves are large in this range, and the water contents fall in autumn. For the soil samples at 40 cm depth, the water contents are relatively constant, which means that the water contents of these

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1555915572

samples are about the same in spring and summer, but they are lower in autumn. Hence, it can be concluded that seasonal rainfall affect the soil near the ground surface more than that deep underground. Further, the surface soil always shows the variation of being dry in spring and autumn, and wet in summer as influenced by the short-term rainfall.

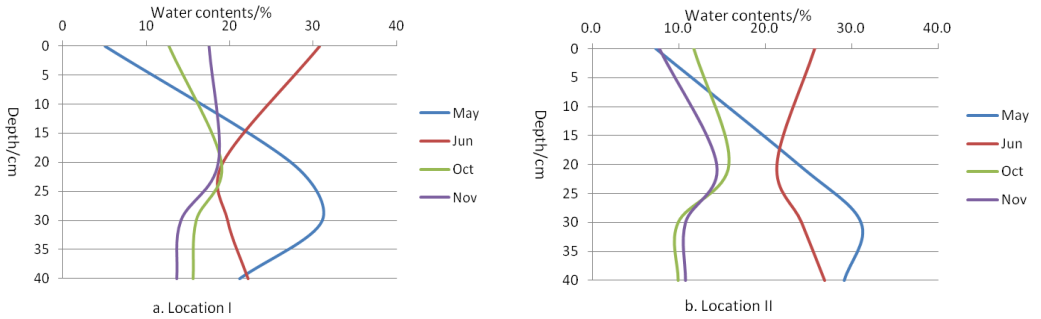

Figure 4. *Water content of soil samples at two locations*

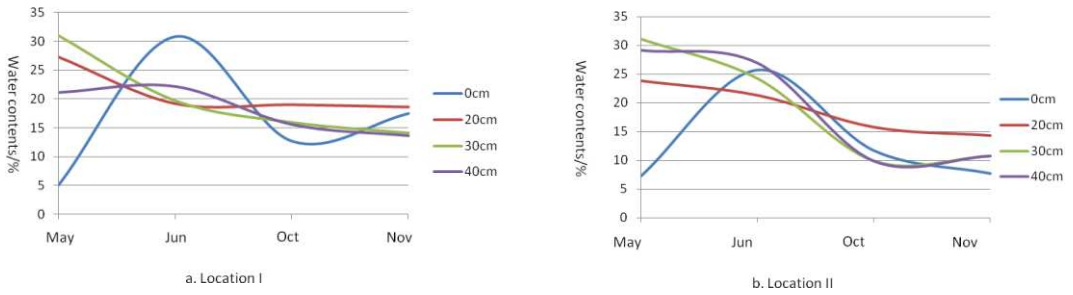

Figure 5. *Water content seasonal variations of soil samples at two locations*

Salt content seasonal variations

The salt contents of the soil samples have been tested by the distillation method, salt content variations with depths are shown as *Fig. 6*.

As shown in *Fig. 6*, salt migrates with depth in general. But the migration law are not only different between 2 locations, but also different in different seasons. For the purpose of studing the salt seasonal migration law, the salt content seasonal variations of the soil samples at two locations and at different depths are shown in *Fig 7*.

As shown in *Fig. 6* and *Fig. 7*, except for the soil samples near the ground surface, the salt contents of the soil samples at the other depth are all higher in summer, and lower in spring and autumn. Thus, for these soil samples, the salt content seasonal variations show a "n" shape. However, the salt content seasonal variations of the soil samples near the ground surface show an inverse "n" shape, i.e., "u" shape. The salt content of a soil obviously changes with season, and weather affects the salt accumulation in the soil, which varies with season and soil depth.

Meanwhile, the composition of salt in soil were tested by titration and flame photometry methods. The test results are shown as *Table 1*.

As shown in *Table 1*, the Na^+ contents are high and other positive ion are relatively low of soil samples. The salinization types can be determined by calculating the Cl^-/SO_4^{2}

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1555915572

or $(CO_3^{2-}+HCO_3^-)/(Cl^-+SO_4^{2-})$. When meet the *Formula 2* or *Formula 3*, the soil can be named as carbonate saline soil.

$$A= Cl^-/SO_4^{2-} < 0.3 \quad \text{(Eq.2)}$$

$$B=(CO_3^{2-}+HCO_3^-)/(Cl^-+SO_4^{2-}) > 0.3 \quad \text{(Eq.3)}$$

According to *Table 1*, since the SO_4^{2-} of all samples are 0, it can only be calculated as B value using *Formula 2*. After calculating the datas from *Table 1*, the B values of soil samples are between 0.31-1.67, soil samples of study area are *carbonate saline soil*.

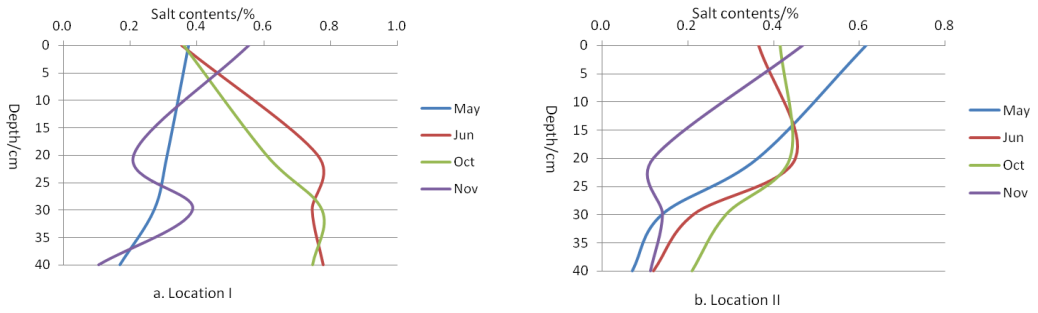

Figure 6. *Salt content of soil samples at two locations*

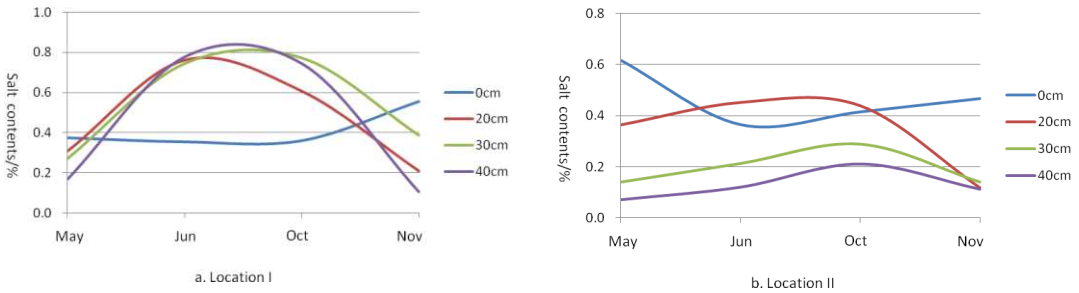

Figure 7. *Salt content seasonal variations of soil samples at two locations*

The salinization progress and salinization types are relevant to local environment. Therefore, it is necessary to research both the environmental and climatic factors in the investigation of the salinization progress of soil in western Jilin.

The changes in seasonal climate and environment affect evaporation, eluviations and frost-thawing. These changes produce different driving force in moving the water in soil in different directions, i.e. water migration. Further, as salt is dissolved in water, it also migrates with the water in the soil. Different environmental processes cause the migration in different directions and the accumulation of salt in different amounts.

Weather environment has an important influence on the migration of water and salt, accumulation and transportation of saline soil in western Jilin. It is the driving force of saline soil's formation.

Temperature factors in wester Jilin

The daily temperature of Nong'an during 2003-2013 ten years has been analyzed (CDSSSC). These data have been organized into average monthly temperature, as shown in *Fig. 8*.

As shown in *Fig. 8*, western Jilin has four distinctive seasons. The monthly average temperature varies between 19.55℃ and 23.06℃. The monthly average temperature in January is the lowest, and in July is the highest. From January to December, the temperature varies in a parabola shape. The four seasons in western Jilin can be concluded

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1555915572

by the variations in the temperature, i.e. April to May is spring, June to August is summer which has the highest temperature, September to October is autumn, and winter is from November to next March, which is the longest season in western Jilin. The average temperatures for the four months in winter are always below 0℃. As a conclusion, western Jilin has hot summer, frigid and long winter, which causes the soil to freeze in winter and thaw in spring. The frost and thawing processes cause the water and salt to migrate with a temperature gradient. Further, during an unfrozen season, the evaporation and elucidation in spring, summer and winter affect the soil salinization process. So, these two factors should also be investigated.

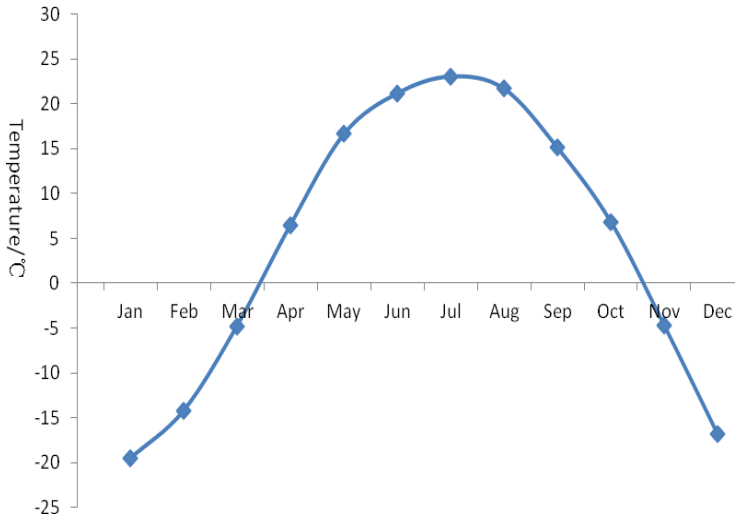

Figure 8. *Average monthly temperature of Nong'an*

Precipitation factors in wester Jilin

The daily rainfall precipitation of Nong'an during 2003-2013 has been analyzed (CDSSSC). These data have been organized into average monthly precipitation, as shown in *Fig. 9*.

As shown in *Fig. 9*, in the last ten years, the average annual precipitation is 523.07 mm. The main rainfall months are May to August, which receive 73.74% of the precipitation for whole year. The highest precipitation is in July, which is 27.11% of the precipitation for the whole year. The rainfall is low in January to March, especially in January. These data show that summer is short in western Jilin, but the elucidation caused by rainfall cannot be ignored in a salinization study.

Evaporation factors in wester Jilin

In order to compare the effects of precipitation and evaporation, the evaporation during 2003-2013 has also been analyzed (CDSSSC). *Fig. 10* shows the average monthly precipitation and evaporation.

As shown in *Fig. 10*, the average annual evaporation is 1104 mm, which is much higher than the average annual precipitation. The evaporation amount is quite different from the precipitation amount, which is high in March to October. Evaporation is highest in April, which is 16.53% of the evaporation for the whole year. The evaporation effect is influenced by the especial climatic characteristics in western Jilin as windy springtime.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1555915572

As shown in *Fig. 10*, the precipitation and evaporation differ significantly in spring and autumn. Evaporation has a major effect on the water in the soil. In summer, precipitation and evaporation are about the same. Only in July, the precipitation amount is higher than the evaporation amount.

In conclusion, western Jilin has an arid and semi-arid monsoon climate, which has high temperature and rainy in summer, windy spring and autumn, cold and long winter, and the annual evaporation amount is much higher than the precipitation amount. This especial climate characteristic provides the condition for salt accumulation on the ground surface. The soluble salt produced by rock wreathing during the soil formation period migrates and accumulates with water at different directions with frost effect in winter, evaporation effect in spring and autumn, and precipitation effect in summer. Eventually, the soil is salinized.

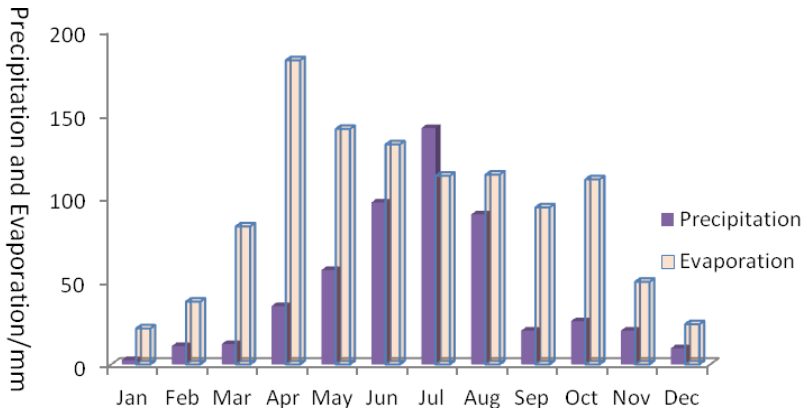

Figure 10. *Average monthly precipitation and evaporation of Nong'an*

Discussions

According to the analyses in Section 3, different seasons have different climatic conditions, which cause the water and salt in the soil to have different movements. The salinization process during unfrozen period and frost-thawing period is discussed in this section.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1555915572

Water and salt migration in unfrozen period

According to the water and salt migration curves (*Fig. 5* and *Fig. 7*), the salt accumulation in western Jilin is uncontinuous, which is influenced by the seasons, i.e. spring and autumn are the salification period, and summer is the desalination period.

Accoding to *Fig. 4* and *Fig. 6,* firstly, the initial salt in soil comes from soluble salt produced by parent rock wreathing effect, this salt dissolves into water during rainy season and migrates from high terrain areas to low terrain areas. This is why most saline soil is distributed in the low terrain areas. However, during a rainy season, little salt is accumulated on the ground surface as it migrates with direct surface runoff (*Fig. 7*), in which most of the salt is leached with water to the soil deep underground. So, the salt and water migrate downward during this period, and there is little salt accumulated on the ground surface.

By the end of rainy seasons, dry seasons begin, and the evaporation effect comes in during this period. The evaporation effect provides the driving force for the water to flow from the ground surface the deep soil (*Fig. 4*), in which salt migrates with soil upwards. The surface water evaporates into air, causing the salt to stay in the soil. Hence, salt accumulates near the ground surface as *Fig. 6* shown. As time passes, soil becomes salinized.

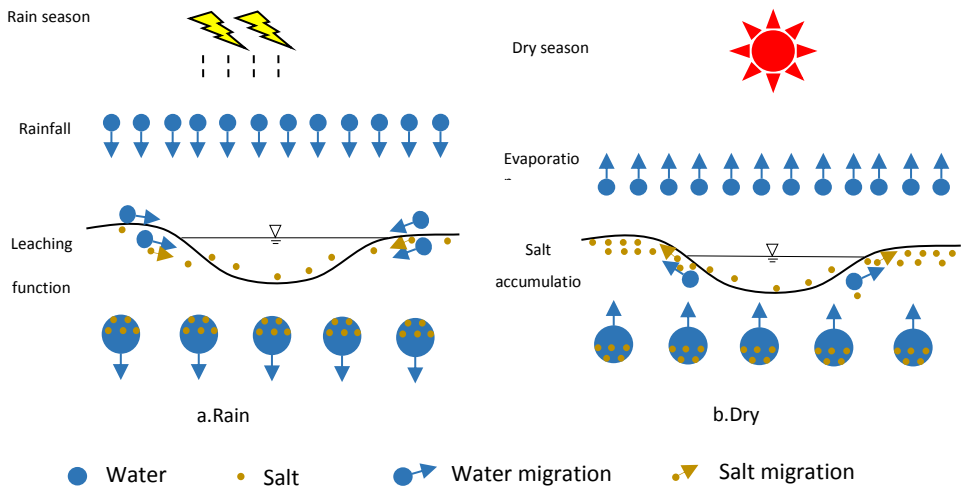

Figure 11. *Salt migration during unfrozen periods*

In conclusion, although salt accumulates in dry season and desalinizes in rainy season during unfrozen period which makes the soil salinization process discontinuous. However, according to the former discussions, the salification effect is much stronger than desalination effect. Therefore, salt is still accumulated in long term and the soil in western Jilin is still saline. Gradually over time, the soil becomes more saline.

Water and salt migration in frost-thawing period

Based on the *Fig. 8*, western Jilin has long winters. So, the soil goes through long freezing periods, and then thaws at spring. During the freezing period, according to the temperature gradient, frost is formed on the soil surface (Jozef and Katarina, 2014). So, the freezing depth increases gradually. In the frozen soil, free water freezes into ice.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1555915572

Hence, it cannot migrate freely in the soil. But some unfrozen water becomes bound water. The freezing point of this strong bound water is -78℃ (Bouyoucos, 1920). The freezing point of the loose bound water is between -20℃ and -30℃ (*Fig. 12*). This bound water in western Jilin cannot be freezed. The bound water can still migrate due to the temperature gradient effect, which is from high temperature to low temperature. Therefore, during the frost period, the direction of water migration is upwards. Salt that is dissolved in the bound water can also migrate upwards with it.

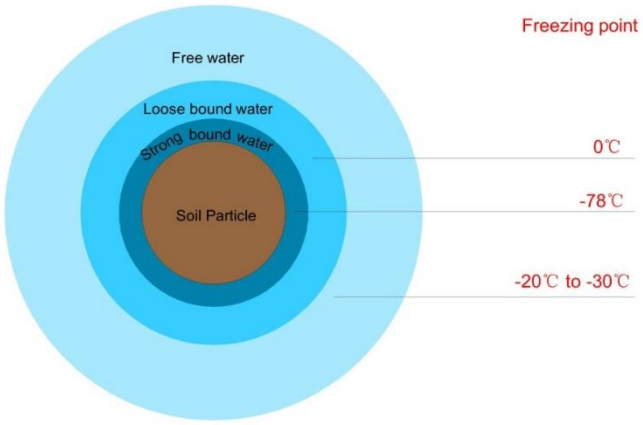

Figure 12. *Freezing points of free and bound water*

Salt migration requires a supply source. During the freezing process in winter, the frozen frontal moves downwards continually. Hence, the distance between the unfrozen soil layer and the underground water level becomes smaller and smaller. Finally, the distance becomes less than maximum that the underground water can rise to. The salt in the underground water therefore migrates into the frozen soil layer. Under this circumstance, the salt comes from the underground water that migrates towards the frozen frontal surface, which makes the salty underground water stays in the pores of soil as ice. Meanwhile, some salt in the soil dissolves into water during the underground water movement. Besides, salt migrates also requires a driving force. Salt in the frozen soil layer crystallizes during the freezing process, causing the solution concentration in the soil's pores to change. Since the extents of freezing of whole soil freezing profile are different, as well as the degrees of salt crystallization are different, which results in a potential gradient in the pore solution. Salt migrates with unfrozen water upwards driven by the temperature gradient and solution potential gradient.

When spring comes, soil starts to melt from frozen top layer and bottom layer at the same time. During the melting process, some soluble salt comes from the melting snow water, rainfall water and irrigation water migrates into the soil. Further, between the frozen layer and the unfrozen layer, there is a potential gradient in the solution. Moreover, the ground surface temperature is getting higher during this period, the solubility of water in the top soil layer is getting greater, which is the condition for carrying more salt. That's why *Fig. 7* shows the law that salt contents are high in spring. Based on the climatic characteristics of western Jilin, the rainfall is low in February to April. During spring in western Jilin, the evaporation capacity is much higher than precipitation. This causes the migration rate in spring to be higher and water evaporates faster, which enhances the soil salinization process.

Ecological environment influnces of salinization in western Jilin province

According to the analyses in *Section 4.2* and *4.3*, salinization process enhanced during forzen and unfrozen periods effected with seasonal environmental conditions. Salinization function can cause land dererioration and ecological system gets fragile, which can harm the agriculture, engineering and ecological enviroment. In recnt years, annually financial loss reached up to 8.9 million RMB caused by salination in northeast China (Lin, 2016).

Western Jilin is locted in south Songnen plain, which is the crucial agriculture production area in China. Soil salinization deduced productivity of land, according to Lin (2016), since the 1950s, 22% land turned into salinization and desertification of Songnen plain, the ecological deterioration rates in western Jilin are shown as *Fig. 13*. As those rates, the 1/2 land will turn to desert of western Jilin.

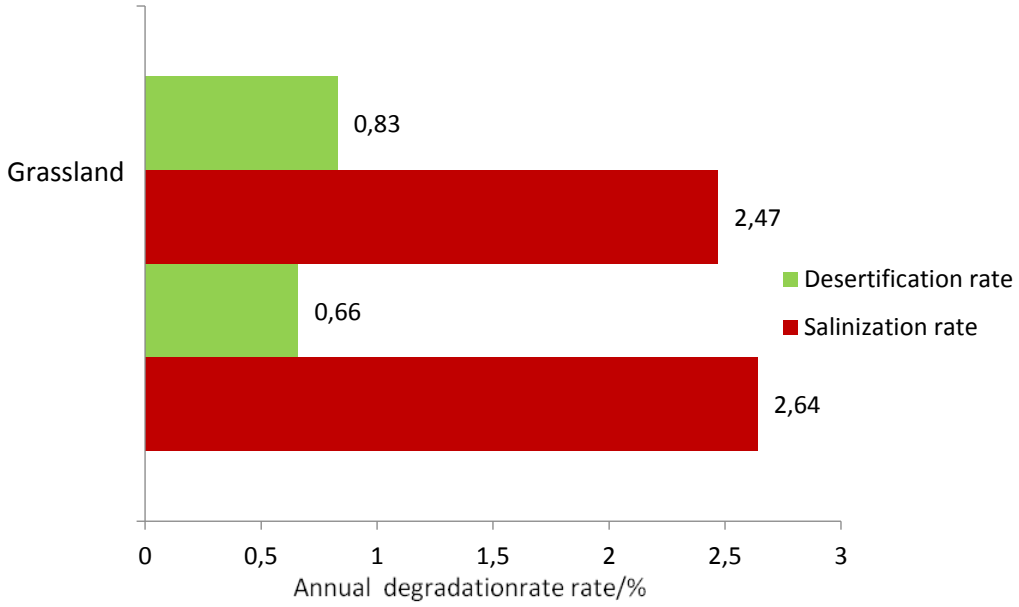

Figure 13. *Ecological deterioration rates of wester Jilin*

Based the analyses above, *Fig. 14* shows the salinization process in western Jilin. Soil salinization destroys ecological system, changes physical behavior and chemical component of soil, deduces nurient of soil, causes the productivity decline, as the result, land turns desertification eventually.

According to earlier studies, saline soil was caused by weather conditions. Zhou and Zhao (1979) considered the harmful climatic conditions that aggravate the salinization progress are spring drought and summer waterlogging. Xu and Dou (2013) considered flooding tillage method causing underground water level to rise increased the degree of salinization. Most of the earlier studies discussed salinization progress in the unfrozen period. In this study, water migration and salt migration have been tested to provide the basic data to show the migration process in soil, and the salinization progress has been discussed particularly during the unfrozen period and the frost-thawing period. Discussion of the salization fuction and process of Jilin province in this sudy can provide the theoretical basis of fragile ecological enviroment protection.

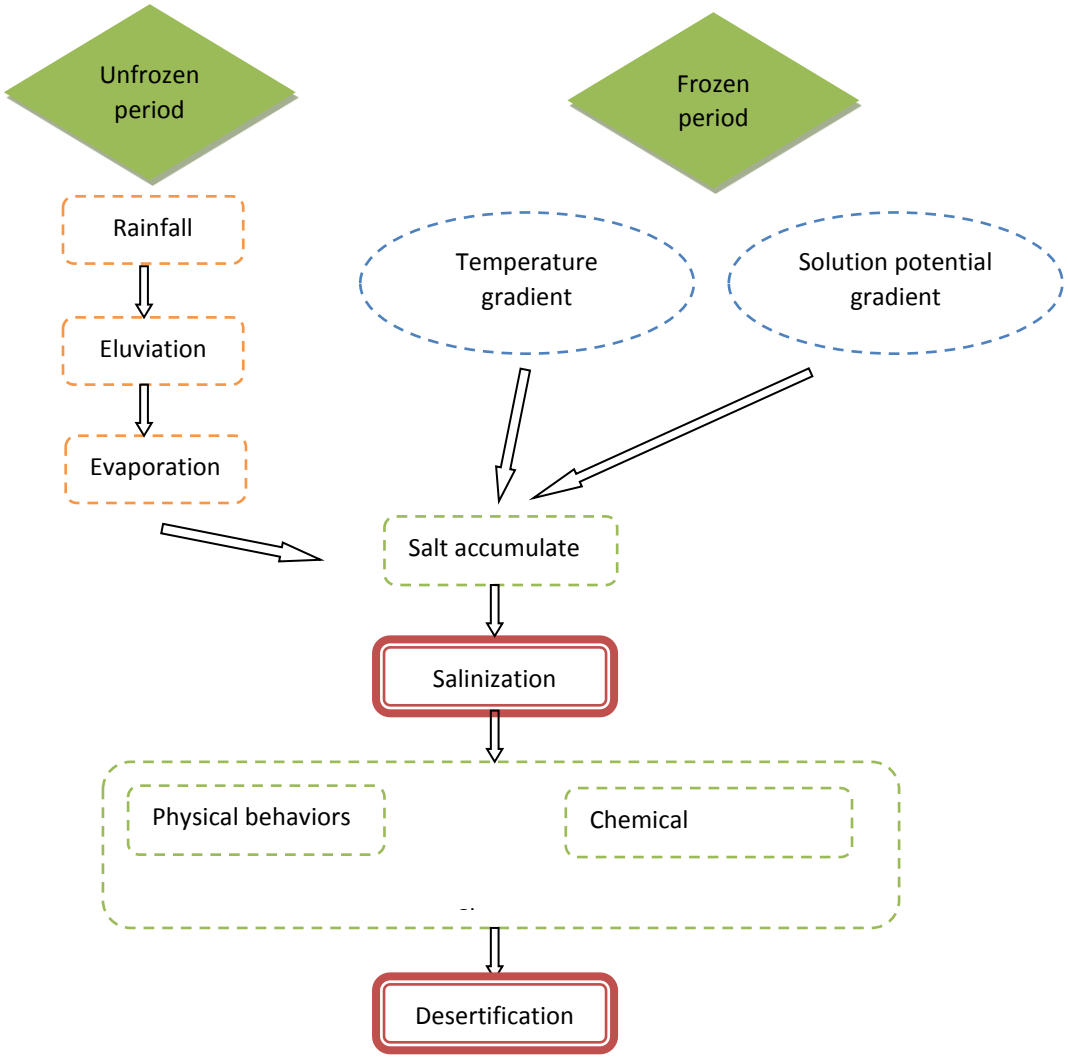

Figure 14. *Salinization process in western Jilin*

Conclusions

In this study, the saline soil water and salt migration characteristics and the environmental characteristics in western Jilin in relation to the salinization progress have been investigated. The conclusions are:

a. Water in soil migrates with seasonal changes, the water content is high in spring and summer, and low in autumn. Salt in soil also migrates with seasonal changes. The salt content of the soil near the ground surface is high in spring and summer, and low in autumn. However, the salt content of deep soil layer is low in spring and autumn, and low in summer.

b. Soil salinization continues to develop both in unfrozen period and frost-thawing period. During the unfrozen period, the process is: rainfall→direct surface runoff movements→salt goes into soil with eluviation function→evaporation→salt migrates upwards and accumulates.

c. During the unfrozen period, underground water supplies soil‘s water and salt. Salt migrates upwards driven by the temperature gradient and solution potential gradient, which enhances soil salinization progress in western Jilin.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1555915572

d. The salinization progress is related to the environmental characteristics of western Jilin. Therefore, the salinization prevention in western Jilin should focus on ecological environment management, and the engineering should focus on frost-heaving prevention in western Jilin. This conclusion has great significance for the agriculture and engineering developments in western Jilin province, China.

e. There are other environmental variables such as the groundwater level, soil parameters furthermore the irrigation strategy could influence the salt concentration, which should be tested in further study. So it will be draw more comprehensive conclusion due to further study.

Abstract. The noninvasive sampling was applied to analyze the winter home range of the Manchurian wapiti (*Cervus canadensis xanthopygus*) in the east of the Wanda Mountains, north-eastern China's Heilongjiang Province. A total of 210 feces samples of the animal were collected from the study area during two consecutive winters. The DNAs were successfully extracted from 167 samples, and all genotypes of 7 microsatellite loci were obtained. Individual identification shows that the 167 samples belonged to 66 individuals. Through gender identification by the SRY gene, it was learned that the 66 individuals were 22 females and 44 males. Then, the winter home ranges of seven individuals (5 males and 2 females) were determined by Minimum Convex Polygons estimation. The results show that the winter home ranges of male individuals varied from 169.26 to 1,085.61 hm^2 (mean: 557.62 ± 411.83 hm^2), while those of female individuals were 43.72 hm^2 and 14.71 hm^2 (mean: 29.21 ± 20.51 hm^2). Finally, it is concluded that the noninvasive sampling is a feasible way to study the home range of endangered animals. This technique can be applied in the future to acquire more comprehensive information about the home range of animals.
Keywords: *home range, noninvasive sampling, gender identification, minimum convex polygon method, animal movement, spatial distribution, Cervus canadensis xanthopygus*

Introduction

The home range is the area in which animals perform daily activities such as feeding, mating, and breeding, and guarantees the normal survival and reproduction of animals (Burt, 1943). Home range research is very important for us to understand ungulate society organizations, improve the quality of their habitats, determine the optimal carrying capacity of their habitats, protect and reintroduce endangered species, and other projects (Howell, 1954; Dunbar and Dunbar, 1974; Inglis et al., 1979; Green, 1986; Cederlund and Okarma, 1988; Arcese, 1999; Woolnough and Toit, 2001). For large ungulates, traditional home range research methods are mainly radio telemetry and GPS collar tracking, the premise of which is to capture the wild animals, the capture process may cause injury to the individuals, and the collars worn by the animals may produce certain effects on their behaviors (Ensing et al., 2014; Kropil et al., 2015). The noninvasive sampling method can extract the DNA from the feces, hairs and urine left by the animals without disturbing them, and then through molecular marker individual identification and gender identification, and analysis of repeated sampling positions, the home range information could be obtained (Taberlet et al., 1997; Kohn et al., 1999; Smith et al., 2006). The combination of noninvasive sampling and GIS analysis overcomes the interference of traditional research methods on animals, and it receives

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1557315583

wide attention from endangered wild animal researches as an auxiliary method for home range research.

The number of Manchurian wapiti (*Cervus canadensis xanthopygus* Milne-Edwards, 1867) within Chinese territory has continued to decline due to illegal hunting and habitat loss (Ohtaishi and Sheng, 1993). At the beginning of the 19th century, the Manchurian wapitis in Shanxi and Hebei provinces were extinct (Jiang et al., 2007). The current distribution of Manchurian wapiti is mainly limited to some parts of Northeast China (Heilongjiang, Inner Mongolia, and Jilin Provinces), Ningxia, Xinjiang, Gansu, Qinghai, Sichuan, and Tibet (Xu et al., 2000), and it has been listed as a secondary national protected wild animal (Wang, 1998).

The body size of the Manchurian wapitis distributed in northeastern China is big. The body weight of male individuals is 200-250 kg and that of female ones is about 150 kg (*Fig. 1*). Female individuals are mature sexually at 2 years old and usually give birth to one cub each time (Chen et al., 1997). The Manchurian wapitis are the main prey for the extremely endangered species Amur tiger (*Panthera tigris altaica*) and Amur leopard (*Panthera pardus orientalis*) (Li et al., 2001; Qi et al., 2015). In recent years, there has been a significant decline and retreat in the population and distribution of Manchurian wapitis in Northeast China (Xu et al., 2000). The Wanda Mountains area in northeastern China was once the largest population density distribution area of Manchurian wapiti in Heilongjiang Province (Chen et al., 1997). Habitat fragmentation and illegal hunting have led to a sharp decline in the number of Manchurian wapitis in the region (Zhang and Zhang, 2011; Zhou et al., 2015). The survey found that the population density of Manchurian wapiti in Wanda Mountains area was 1.05 individuals per km^2 in 1989, and 0.20 individuals per km^2 in 2002, with a annual decline rate of 13.48% between 1989 and 2002 (Zhang and Zhang, 2011); while between 2004 and 2010, the annual average decline rate of relative population abundance was 37.30% (Zhou et al., 2015); and the survey in 2015 showed that the Manchurian wapitis in Wanda Mountains were on the verge of extinction (Zhou, 2019, personal communication).

Therefore, this study analyzes the home range size of Manchurian wapiti in east Wanda Mountains area based on noninvasive sampling method, in the hopes of providing references for formulating restoration and protection strategies for Manchurian wapitis, and meanwhile discussing the feasibility of applying noninvasive sampling to the study of home range of endangered animals.

Materials and methods

Research area overview

The research area is located in the Wupao Forest Farm of Yingchun Forestry Bureau in the eastern part of Wanda Mountains in Heilongjiang Province. The geographical coordinates are 46°27′ - 46°38′N, 133°04′ - 133°16′E, and the total area of the forest farm is 155.6 km^2 (*Fig. 2*). The area is in the cold temperate zone, and the weather condition is continental monsoon climate, with long winter and a frost-free period of about 120 days. The freezing period is relatively long and generally freezes in October and unfreezes in late April. The annual average temperature is 2.5-3.0 °C, the annual rainfall is 500-600 mm, and 60-70% rainfall is concentrated between June and August. The terrain of the area is low hills with an altitude of 300-500 m, and the forest area accounts for more than 80% of the total area. The large mammals distributed in this area include Siberian tiger (*Panthera tigris altaica*), Manchurian wapiti (*Cervus elaphus xanthopygus*), lynx (*Lynx lynx*), black bear (*Ursus thibetanus*), wild boar (*Sus scrofa*), roe deer (*Capreolus capreolus*), and sable (*Martes zibellina*), etc.

Sample collection and DNA extraction

During the winter of 2006 and 2007, samples were collected in the whole area of Wupao forest farm. Along the fresh footprint chains on the snow, feces of Manchurian wapiti were found, several feces were taken and put into the sealed bags, and the positions of the samples were located with GPS. Then other fresh footprint chains were followed and samples were collected as well. A total of 210 samples (120 in 2006 and 90 in 2007) were collected and stored and frozen at -20 °C (*Fig. 2*). Four pieces of muscle samples of culled Manchurian wapitis were obtained from the Harbin Changcheng Deer Farm (Heilongjiang, China). DNA extraction of the feces was performed using the QIAamp DNA Stool Mini Kit (Qiagen, Germany) according to the manual; and muscle DNAs were extracted by phenol/chloroform; all extracted DNAs were stored at -20 °C.

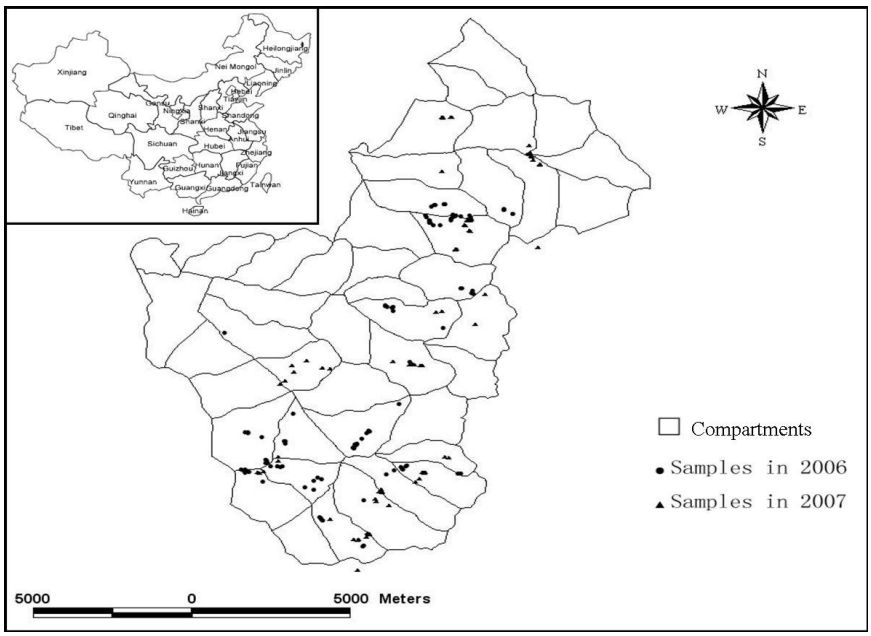

Figure 2. *Sampling locations in the study area*

DOI: http://dx.doi.org/10.15666/aeer/1706_1557315583

Individual identification

Seven microsatellite loci (T507, CSSM19, T530, T501, C143, T123, T156) with high polymorphism were selected, and the 5' ends of the upstream primers of all microsatellite loci were fluorescently labeled (FAM, HEX, TAMARA). Primer information, PCR amplification and genotype identification procedures are described in the literature (Tian et al., 2010). Genotyping was performed using multi-tube PCR amplification method (Bellemain et al., 2005), for each locus, positive amplification was performed for 3-4 times to determine the final genotype (Tian and Zhang, 2010). Then the software Excel Mircosatellite Tool kit (Park, 2001) was adopted to find matching genotypes in the data. For different samples, if the genotype of all loci was the same or there's difference in only one allele in one locus, then the samples were judged to be from the same individual (Bellemain et al., 2005; Tian and Zhang, 2010). And then software Cervus 3.0 (Kalinowski et al., 2007) was used to calculate the joint P_{ID} value and P_{sib} value of the 7 loci.

Gender identification

SRY12 and BMC1009 2 were used to carry out gender identification on the prime multiplex amplification, SRY12 was used to amplify the SRY12 segment of the Y chromosome, and BMC1009 2 was used as a positive control to amplify the autosomal microsatellite loci (Huber et al., 2002). Each sample had bee amplified for 3 times, if double bands appeared at least 2 times, then the sample was judged to be a female; if single band (300 bp BMC1009) appeared at least 2 times, then it is judged to be a male; for other situations, the PCR was performed again for the identification. The prime information and PCR amplification conditions are available in the literature (Tian and Zhang, 2010).

Home range analysis

According to the individual identification results, individuals that had been sampled 4 times, or more than 4 times had been selected, and home range analysis was performed according to each GPS position of the same individual. And the size of the home range was calculated by the Minimum Convex Polygons (MCP) using the ArcView 3.3a's amplification module Home Range Analysis (ESRI Inc.).

Results

In the 210 samples of extracted fecal DNA, some of the DNAs were yellow, no amplification product could be obtained, and these samples were subject to the second-time DNA extraction. At last, 90 samples from 2006 and 77 samples from 2007 were used, and a total of 167 DNA samples were subject to subsequent analysis.

In the individual recognition, the combined discrimination rate of the 7 microsatellite loci was very high ($P_{ID} = 1.3\times10^{-7}$ and $P_{sib} = 0.19\%$), which means that for unrelated individuals, the probability of having the same genotype is 1.3×10^{-7}. Even in the case of twins, the probability of misjudgment is only 0.19%. Individual identification results: there are 39 individuals in the 90 samples of 2006, 36 individuals in the 77 samples of 2007, the 167 samples of the two years belonged to 66 individuals. Out of the individuals of 2006, 9 individuals appeared repeatedly in 2007.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1557315583

To verify the accuracy of gender identification, 4 muscle samples (2 Male, 2 Female) and 4 fecal samples (2 Male, 2 Female) of known gender Manchurian wapitis in Harbin Changcheng Deer Farm (Heilongjiang, China) were analyzed. At the same time, 8 fecal samples (6 Male, 2 Female) whose gender was determined by the urinary positions of wild Manchurian wapitis' lying trace had been analyzed as well, and correct results were obtained (*Fig. 3*). Gender identification results: there are 28 male and 11 female individuals in the 39 individuals of 2006; there are 21 male and 15 female individuals in the 36 individuals of 2007; in the 66 individuals of the two years, there are 44 male and 22 female individuals.

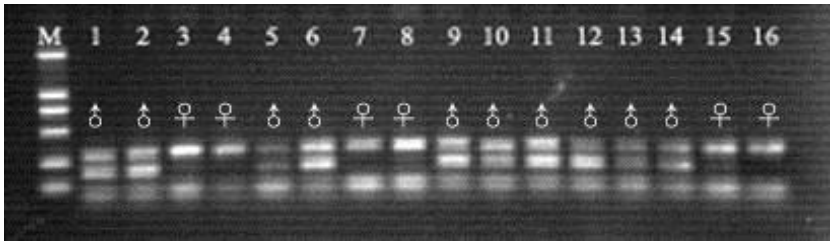

Figure 3. *Amplification results of SRY12 and BMC1009 loci of samples with known gender; M: Marker DL-2000; 1-16: samples with known gender*

In different years, there are fewer individuals that appeared repeatedly, so the home range analysis was performed for different years. Among the 66 individuals, 10 individuals with ≥ 4 repeated samples were selected. As for the No. 1, No. 4 and No. 8 individuals, since the sampling time interval is too short, the range of activity is smaller, so these 3 individuals' home range values were removed as abnormal values. Finally, the winter home range size of 7 individuals was analyzed. The number of repeated samples of the 7 individuals was 4-9 times, with an average of 6.43 times (see *Table 1*). Based on MCP, the size of home range was calculated, the home range size area of male individuals was 169.26-1085.61 ha with an average of 557.62 ± 411.83 ha; the home range areas of the 2 female individuals were 43.72 ha and 14.71 ha, with an average of 29.21 ± 20.51 ha. Compared with male individuals, female Manchurian wapiti's home range area is smaller (see *Table 1; Fig. 4*). There is a certain overlap in the range of activity between male individuals and between female and male individuals (see *Fig. 4*). Manchurian wapitis are gregarious animals. Since we cannot determine whether these 7 individuals are from the same group, the overlap of the Manchurian wapitis' home ranges had not been analyzed further.

Discussion

The size of the home range is the result of animal individual movement and spatial distribution of the population. Various factors such as age, gender, population density, season, food richness, predation risk, landscape spatial heterogeneity and human disturbance can affect the size of home range (Anderson et al., 2005; Reinecke et al., 2014; Kropil et al., 2015). According to the noninvasive sampling analysis, this study determined that the average size of winter home range of male wapiti individuals was 557.62 ha, this number for female individuals was 29.21 ha, and the male/female HRS ratio was 19.09. Compared with female wapitis, the male wapitis are larger in body size

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1557315583

(Clutton-Brook et al., 1982; Chen et al., 1997), so they need to enlarge the home range to meet their physiological needs (Jetz et al., 2004), therefore, the home range size of most male wapitis is larger than that of the female ones (see *Table 2*). The study of Kamler et al. (2008) on wapiti home range shows that the male/female HRS ratios vary from 1.58 to 4.29, and the home ranges of female individuals (IDs 9 and 10, 43.72 ha and 14.71 ha) and male individuals (IDs 2 and 5, 169.26 ha and 205.23 ha) are quite small (see *Table 1*), and these results are closer to the winter home range of wapitis in related researches of Germany (female: 14 ± 2.4 ha, male: 12 ± 2.5 ha), Denmark (12-February: 33.8 ± 23.4 ha, March: 53.3 ± 19.2 ha) and Poland (female: 106 ± 12 ha, male: 112 ± 17 ha) (Georgii, 1980; Georgii and Schröder, 1983; Jeppesen, 1987; Kamler et al., 2007). The home range sizes of male individuals (IDs 3, 6 and 7) were 438.13 ha, 1085.61 ha and 889.85 ha, respectively, which is closer to the winter home size of wapitis in Europe and North America (see *Table 2*). We believe that the home ranges of female and male individuals (IDs 2 and 5) were smaller, the male/female HRS ratio is too high, insufficient sampling had resulted in deviations in these results, and the home range size of these individuals can only represent the range of activity of wapitis on a certain day or a few certain days in winter.

This study suggests that it is feasible to study the home range of animals using noninvasive sampling method. Although traditional home research methods are still the mainstream methods of animal home range research, the noninvasive sampling method does not require animals to be captured, so it could obtain a large amount of genetic information without causing any interference to animals. Especially for rare and endangered wild animals with high alertness and complex distribution terrain, the noninvasive sampling method is more feasible for home range research of these animal species (Taberlet et al., 1997; Kohn et al., 1999; Smith et al., 2006). The analysis results

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1557315583

suggest that using noninvasive sampling method to study animal home range requires larger sampling intensity, and it should be combined with the footprints, lying traces, feeding marks, and other location information to obtain more distribution points of a same individual so as to obtain the accurate size of home range. At the same time, the multi-tube approach should be performed strictly so as to eliminate allele dropouts and false alleles during fecal DNA microsatellite genotyping, and avoid false individual identification (Taberlet et al., 1996; Bellemain et al., 2005; Pérez-Espona et al., 2008). Moreover, by applying noninvasive sampling method for future studies we could obtain more comprehensive information of animal home range, such as individual daily home range, winter home range size, home range overlapping, core area, sub-herd home range, kinship, and diffusion, etc. At the same time, combining with factors such as population density, food richness, snow density, predation risk and human disturbance, the influencing factors of home range changes could be revealed.

Conclusion

Based on noninvasive sampling, the winter home ranges of male individuals of the Manchurian wapiti varied from 169.26 to 1,085.61 hm^2 (mean: 557.62 ± 411.83 hm^2), while those of female individuals were 43.72 hm^2 and 14.71 hm^2 (mean: 29.21 ± 20.51 hm^2). The winter home ranges of both females and several males were too small, due to the limited sample size.

Our analysis revealed that the noninvasive sampling is a feasible way to study the home range of endangered animals. It requires larger sampling intensity to obtain more accurate size of home range. The footprints, lying traces, feeding marks, and other location information should be considered to obtain more distribution points of the same individual. This study suggests that the noninvasive sampling method and traditional home range research method should be combined to reveal individual daily home range, winter home range size, home range overlapping, core area, sub-herd home range, kinship, diffusion and the influencing factors of home range changes. It proposes speeding up the construction of the reserve in Wanda Mountains to reduce the disturbance of human activities on the survival of the Manchurian wapiti.

(Received 6th Aug 2019; accepted 15th Nov 2019)

Abstract. A two-year field experiment was conducted to evaluate the physiological response of eggplant stomatal resistance (r_s) and yield to different deficit irrigation levels using surface and subsurface drip methods under Mediterranean climatic conditions. Treatments consisted of surface (SDI) and subsurface drip (SSDI); 3-day and 6-day irrigation frequencies (IF_3, IF_6); and full irrigation (FI), deficit irrigations (DI_{50}, DI_{75}) and partial root-zone drying (PRD_{50}). Irrigation systems, frequencies and levels produced significantly different eggplant yields. IF_3FI treatment produced the greatest yield in the experimental years and followed by IF_3DI_{75}. The results revealed that 3-day interval resulted in significantly greater yields than 6-day frequency. Water deficit in the root-zone decreased fresh eggplant yield drastically and IF_6PRD_{50} produced the lowest yield. Smaller r_s values were observed in FI treatment in SDI and SSDI systems under 3-day frequency than deficit irrigated and 6-day frequency plots. Significant relationships among r_s and yield, dry matter yield, SWC, ET, and LAI were obtained. A value of 60 s m^{-1} could be considered as the threshold to regulate rs for high eggplant yield. Therefore rs could be utilized for scheduling irrigations. The r_s response to water stress can be used for sustainable crop production in water scarce regions.
Keywords: *deficit irrigation, partial root-zone drying, water use efficiency, irrigation scheduling*

Introduction

Vegetable production in many countries relies on irrigation. Optimizing irrigation amount and frequency is thus essential to ensure yield increase without compromising quality. All over the world, the reduction in the amount of water which is used for irrigation and environmental concerns make obtaining the most benefit from a unit of water necessary. Therefore micro irrigation systems such as surface drip (SDI) and subsurface drip systems (SSDI) are necessary for efficient use of scarce water resources in irrigated agriculture for increasing yield and saving water. A number of field studies indicated relevant benefits of managing SSDI for production of vegetables (Lamm and Camp, 2007; Kong et al., 2012; Bozkurt and Sayilikan Mansuroğlu, 2018).

Deficit irrigation (DI) is an important water-saving practice in irrigated agriculture (English et al., 2002). DI could decrease vegetative growth, while having little effect on fruit growth and development through balancing the relationship between reproductive and vegetative growth (Goodwin and Boland, 2002). Moreover, DI significantly reduces irrigation amount (Pérez-Pérez et al., 2008).

Several field trials on eggplant irrigation have been conducted in various locations around the world (Chartzoulakis and Drosos, 1995; Gaveh et al., 2011; Diaz-Perez and Eaton, 2015; Mohawesh, 2016; Müller et al., 2016; Bozkurt Çolak et al., 2017) indicating that eggplant production can be realized at moderate water stress levels without major reduction in crop yield.

DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

Irrigation scheduling methods is usually categorized on soil, plant, and meteorological basis. Plant-based irrigation scheduling techniques are more advantageous since plants respond to both the soil and aerial environmental conditions (Yazar et al., 1999). For that reason, crop based irrigation scheduling is used more and more in recent years. The irrigation time can be determined by detecting the water stress status of the plant. Among the possible measures of some aspect of plant water status include direct measuring stomatal resistance or conductance (Yao et al., 2001; Agele et al., 2006; Lianga et al., 2011) that is known to respond sensitively to water stress.

Stomatal have an important task in regulating water losses through transpiration and CO_2 uptake for photosynthesis and plant growth (Gerosa et al., 2012). Also, stomatal control is a major physiological way for optimizing water use under drought condition (Makbul et al., 2011). Crop water use estimation based on scaling up from leaf stomatal conductance to canopy conductance is of paramount importance for improving efficient use of limited water resources in agriculture (Zhang et al., 2011).

It is believed that virtually most of the plants' first reaction to severe water stress is the stomatal closure to prevent the water losses by transpiration (Berry et al., 2010; Brodribb and McAdam, 2011; Nemeskeri et al., 2015). Stomatal closure occurs due to from direct evaporation of water from the guard cells without any metabolic action. When available soil water content is decreased, the stomata open little or even remain closed in response to severity of water deficiency. The crop prevents dehydration by maintaining stomata closed under drought conditions (Anjum et al., 2011; Osakabe et al., 2014; Clauw et al., 2015). Behboudian (1977) reported that eggplants have greater resistance to water stress than the other vegetable crops.

For sustainable eggplant production and making decision on the best irrigation practice, a comprehensive assessment of the yield and physiological response of the crop to a specific soil type, production method and irrigation strategy is required. Therefore, determination of the critical threshold values (beyond which yield loss or reduction is inevitable) of stomatal resistance (r_s) is important for a specific crop growing under different climatic and soil conditions so that they can be utilized effectively for irrigation scheduling purposes. The main objectives of this research were to evaluate the physiological response of eggplant such as stomatal resistance (r_s) to different deficit irrigation strategies under subsurface and surface drip systems; and to establish threshold levels for stomatal resistance for irrigation scheduling of eggplant for high and good quality yield under the semi-arid climatic environment in the Mediterranean region.

Materials and methods

Experimental site description

Field experiments were conducted during 2013 and 2014 growing seasons on the experimental farm at the Alata Horticultural Research Institute in Tarsus in Mediterranean region of Turkey. The experimental site is located between latitude 36°53' N and longitude 34°57' E with an elevation of 60 m. Mediterranean climate prevails in the experimental site. Monthly mean climatic data for the study years along with long-term means are depicted in *Figure 1*. The mean annual rainfall, temperature, evaporation and relative humidity are 616 mm, 17.8°C, 1487 mm, 70.5%, respectively. The amount of rainfall recorded during the eggplant growing season (May through August) was 163.0 mm in 2013, and 126.0 mm in the 2014 growing season.

DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

The experimental soil has a clayey-silt texture with volumetric water content at field capacity 29.6% and wilting point 19.2% and mean bulk density of 1.39 g cm^{-3}. Plant available water in the effective root depth of 60.0 cm was estimated as 88 mm.

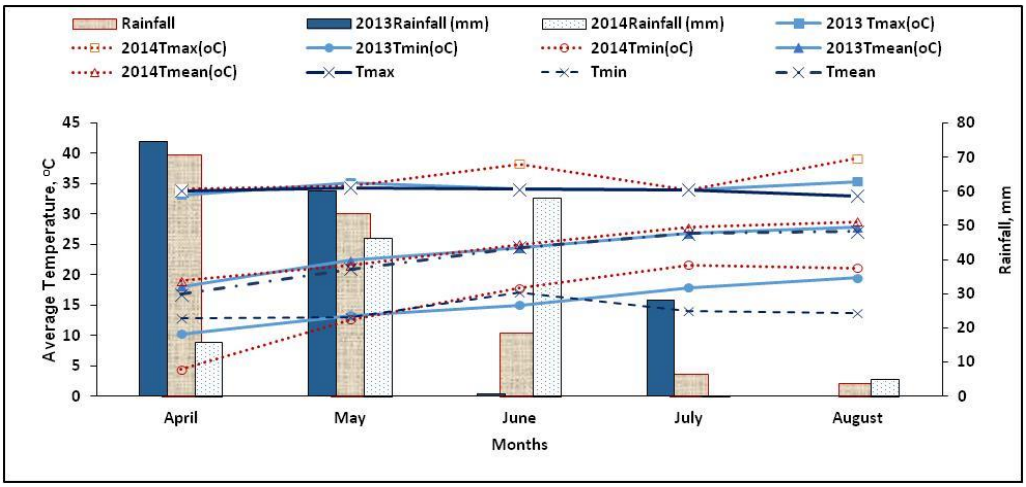

Figure 1. *Mean monthly climatic data in the experimental years along with long-term means*

Agronomic practices

Four weeks old eggplant seedlings of *Solanum Melongena* L. (cv. Anamur Karası) were transplanted into the experimental plots in 90 cm row spacing and with 70 cm plant spacing on May 6 and April 14 in 2013 and 2014, respectively.

Compound fertilizers were incorporated into the plant beds at a rate of 50 N; 50 P_2O_5; and 50 kg ha^{-1} K_2O prior to transplanting. About 21 days after transplantation, plots received Nitrogen via fertigation every 6 days (160.0 kg ha^{-1} N) during the eggplant growth period.

Agronomic and plant protection practices carried out during the growing seasons are summarized in *Table 1*.

Design of the experiment and treatments

The experiment was designed split-split plots with four replicates. Experimental treatments consisted of surface drip (SDI) and subsurface drip systems (SSDI); 3-day 6-day (IF_3; IF_6) irrigation frequencies; and Full irrigation (FI); deficit irrigations, DI_{50} and DI_{75}; and Partial Root-zone drying (PRD_{50}). Irrigation was launched when 25% of available water in the root-zone depth of 60 cm was depleted and replenished to field capacity in all treatments. Then treatment irrigations were scheduled based on replenishment of soil water deficit in effective root-zone depth of 60 cm to field capacity in fully irrigated treatments (FI) in the two irrigation frequencies considered. In the deficit irrigation plots of DI_{50} and DI_{75}, respectively received 50 and 75% of water applied to full irrigation plots. PRD_{50} plots were irrigated alternately from the two laterals on both side of the crop row and received 50% of water applied to full irrigation plots. In the experiment, subplots were 10 m long and 5.4 m (6 plant rows) wide. A general view of the experimental plots is shown in *Figure 2*.

In the surface drip system plots (SDI), drip lateral pipes were placed in every plant row for FI and DI_{50}, and DI_{75} treatments. Drip tapes had inline emitters with discharge

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

rate of 1.6 l h^{-1} spaced at 0.20 m. In the PRD_{50} treatment, two drip laterals were laid on each side of the plant row 25 cm away from the eggplant rows. In the subsurface drip irrigation plots (SSDI), laterals were buried at 25 cm depth in the soil under the plant rows. Lateral with in-line emitters spaced at 0.20 m intervals and with flow rate of 2.3 l h^{-1} were used (Geoflow Corte Madera, CA, USA). Since the same flow rate and emitter interval surface and subsurface drip systems were not available in the local market, we used the abovementioned systems in the study. The irrigation amount in each plot was measured by a flow meter.

Measurements

Soil water content

A neutron moisture meter was used to measure the soil water content (SWC) with (Model 503 DR, Martinez, CA) at 0.2 m depth intervals down to 0.80 m prior to irrigation applications with 3- and 6-day frequencies during the eggplant growing seasons. Access tubes were placed in the mid plant rows between two plants in the experimental subplots. Average of four replications was taken as mean soil water content for each depth to reduce spatial variability. Gravimetrical sampling method was used to measure SWC in the upper soil layer of 20 cm during the growing seasons.

Eggplant evapotranspiration and water use efficiency

Seasonal evapotranspiration (ET) or crop water use was estimated using the water budget equation *Eq. (1)*.

$$ET = R + I \mp \Delta W - Dp - Roff \quad \text{(Eq.1)}$$

In this equation, ET is seasonal crop water use or evapotranspiration (mm), R is rainfall (mm), I is seasonal total irrigation water applied (mm), ΔW is change in soil water storage in the root zone depth (mm), Dp is downward soil water movement or deep percolation below the root-zone depth (mm), and Roff is surface runoff (mm). Dp and Roff were neglected since the amount of irrigation water applied via drip systems was precisely controlled and rainfalls received during the growing season was less than soil storage capacity in 60 cm profile depth.

Water use efficiency (WUE) values were estimated as the ratio of fresh eggplant yield over seasonal crop water use or evapotranspiration (Gong et al., 2017).

Leaf area index

Leaf areas for experimental treatment plots were estimated using LAI-2000 Plant Canopy Analyzer equipment (Li-Cor 2000, Lincoln, NE) at weekly interval throughout the growing season. In this method of LAI measurement, four measurements below the plant canopy and one measurement above the canopy were taken for each treatment plots to account for the canopy light interception in crop canopy at five different angles, from which LAI was estimated employing radiative transfer model.

Dry matter yield

Variation of dry matter yields with time in each experimental sub-plot was determined at two-week intervals until harvest by cutting the plants in 2.10 m of a row section in each subplot at the ground level. The plant samples taken were dried in an oven at 65°C for several days until constant dry weight reached.

Stomatal resistance

A diffusion porometer (AP4 Leaf Porometer, Delta–T Devices, Cambridge, England) was used to determine the stomatal resistance of eggplant leaves (*Figure 3*).

Measurements were taken at 6-day intervals prior to irrigations until harvest between 12:00 and 14:00 O'clock on the fully developed upper two leaves and under clear sky conditions. Soil water contents were also measured on the same day with porometer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

readings. The porometer was calibrated before making each reading. Using the calibration values, the lower and upper surface resistances of the leaf were calculated with the *Equation 2* given by Clawson and Blad (1982).

$$r_S = \frac{r_u + r_l}{r_u \cdot r_l} \quad \text{(Eq.2)}$$

where r_s is the average stomatal resistance s m^{-1}; r_u and r_l are stomatal resistance of the upper and the lower surface of the leaf, respectively.

Diurnal variations of stomatal resistance were also measured in mid-growth stage once each year before an irrigation application.

Figure 3. *Measurement of stomatal resitance in eggplant with porometer*

Statistical analysis

Statistical analysis of the data was carried out using the JMP Statistical software (SAS Institute, Inc., Cary, NC, USA). Two-way variance analyses (ANOVA) were conducted, and to determine the differences among treatment means Least Significant Difference (LSD) at a 5% probability level was made (Steel and Torrie, 1980).

Results

Irrigation and crop water use results

The data on total irrigation water applied, seasonal evapotranspiration, yield and water use efficiency for the treatments in the experimental years were presented in *Table 2*. Seasonal irrigation amounts differed between the treatment plots in the growing seasons due to prevailing weather conditions and distribution and quantity of rainfall received during each season. The rainfall received during the growing season in the experimental years was 163 and 126 mm, respectively, which wre greater than long-term mean of 86 mm. Mean maximum temperatures in 2014 in June was 38.2°C was higher than 2013 and long-term mean. Mean minimum temperatures in June through August in 2014 were greater than those in 2013 and long-term mean. The data revealed that the seasonal irrigation amount varied between 243 mm in IF_6DI_{50} and IF_6PRD_{50} and 495 mm in IF_3FI plots in the SDI plots, and ranged from 228 mm IF_6DI_{50} and IF_6PRD_{50} to 450 mm in IF_3FI

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

plots the SSDI in 2013 (*Table 2*). The total irrigation water changed between 229 mm in IF_6DI_{50} and IF_6PRD_{50} to 444 mm in IF_3FI in SDI plots; and varied from 216 mm IF_6DI_{50} and IF_6PRD_{50} to 418 mm in IF_3FI in the SSDI treatment plots in 2014. PRD_{50} and DI_{50} plots received the same quantity of irrigation water.

* LSD grouping at 5 % level; each year was analyzed separately

Soil water content variation in different treatments with time in the experimental years are characterized by a gradual decrease in SWC in response to deficit irrigated treatments towards the end of the season as compared with full irrigation plots. In the two drip systems with 3-day frequency plots, plant available water in FI and DI_{75} treatments were greater than 50% during the growing seasons. On the other hand, in DI_{50} and PRD_{50} treatments SWC values were below the 50% available soil water level (soil water data not presented). The detailed information on soil water content variations in the experimental treatments and years can be found in previous publication by Bozkurt Çolak et al. (2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

Irrigation systems and irrigation levels resulted in significantly different ET values in the first experimental year, but only irrigation levels had significantly different effect in the second year (*Table 3*). Seasonal evapotranspiration changed between 339 mm in DI_{50} with 3-day frequency treatment and 543 mm in IF_3 FI under the SDI in the first experimental year, and 363 mm in IF_6 DI_{50} and 527 mm in IF_3 FI in the second year. In SSDI treatment plots, ET values changed between 306 mm in IF_3 DI_{50} to 495 mm in IF_3 FI plots in 2013; and 349 mm in IF_6 DI_{50} to 494 mm in IF_3 FI in 2014 (*Table 2*). In the second growing season slightly lower ET values were determined compared with ET values in 2013 probably due to occurrence of the lower monthly minimum temperatures in April 2014, and prevailing high maximum air temperatures in June and August in the second season. Prevaling considerably lower air temperatures in April (4.4°C) in the second year hampered the plant establishment and growth. The results revealed that DI_{50} plots in both drip systems resulted in an average of 3% less crop water use values than PRD_{50} plots despite of receiving the same quantity of irrigation water.

Eggplant yield

The fresh eggplant yields obtained from the experimental treatment plots in the study years are given in *Table 2*. *Table 3* presents statistical analysis on the mean eggplant yields. The effects of various treatments on eggplant yield differed in the experimental

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

years. Since the years were statistically different in combined variance analysis, we analyzed the data for each experimental year separately. The results indicated that irrigation systems, frequencies and levels resulted in significantly different eggplant yield values ($P < 0.01$). SDI system performed better than the SSDI in the first year, however they performed similarly in the second growing season.

Eggplant yields varied from a minimum of 40.90 t ha^{-1} in subsurface drip irrigated IF_6 PRD_{50} treatment plots to greatest 78.7 t ha^{-1} in the surface drip irrigated IF_3 FI in 2013, and changed between 58.8 t ha^{-1} in IF_6 PRD_{50} in SSDI and 92.7 t ha^{-1} in the IF_3 FI in SSDI 2014 growing season. PRD_{50} treatments produced the least yields in the experimental years. The second growing season resulted in significantly higher yields than in the first season because of prevailing favourable climatic conditions in the 2014.

Water use efficiency

Water use efficiency values were significantly affected by drip irrigation systems, irrigation frequencies and levels in the experimental years (*Table 3*). WUE values varied between 12.2 kg m^{-3} in IF_6 PRD_{50} under SSDI and 21.9 kg m^{-3} in the IF_3 DI_{50} in SSDI in 2013 and ranged from 16.6 kg m^{-3} in the IF_6 PRD_{50} treatment under SDI to 24.5 kg m^{-3} in the IF_3 DI_{50} under SSDI in 2014. The results revealed that WUE increased with decreasing irrigation water amounts except in the PRD_{50} treatment which resulted in minimum WUE values in both growing seasons.

Dry matter yield and leaf area index

The evolution of the dry matter yield with time for different treatments under the surface and subsurface drip systems in the experimental is depicted in *Fig. 4a-d*. The IF_3FI under the SDI system resulted in the maximum dry matter yield of 6329 and 6400 kg ha^{-1} in 2013 and 2014 growing seasons, respectively; and the least dry matter yields were observed in the IF_6 PRD_{50} treatment under the SSDI.

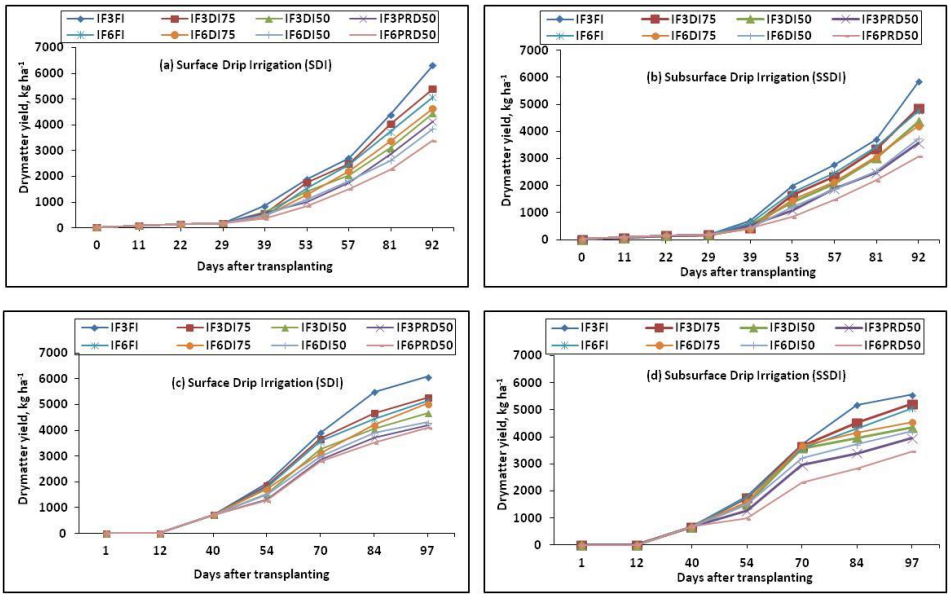

Figure 4. *Dry matter yield variation during the 2013 and 2014 eggplant growing season in all treatments under surface and subsurface drip irrigation. (a) SDI, 2013; (b) SSDI, 2013; (c) SDI, 2014; (d) SSDI, 2014*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

The maximum leaf area index (LAI) values for the different treatments under both drip systems in the experimental years are presented in *Table 2*. Irrigation systems, frequency and level resulted in significantly different LAI values (*Table 3*). The IF_3 FI treatment under SDI produced the maximum LAI of 4.13 and 4.30 in the first and second growing seasons, respectively; the minimum LAI values of 2.6 and 2.1 were observed in the IF_6 PRD_{50} treatment under SSDI in 2013 and 2014, respectively.

Stomatal resistance

Stomatal resistance (r_s) evolution with time in the experimental years for different treatments under SDI and SSDI systems are depicted in *Fig. 5a-d*, respectively. The stomatal resistances showed tendency to increase with increasing water stress. Smaller r_s values were observed in FI plots under the two drip systems with 3-day irrigation frequency than DI_{50} and PRD_{50} treatments with 6-day irrigation frequency. Generally, the lower r_s value was measured in the beginning of the growing season, and the r_s rises towards the end of the growing season. In the SDI treatments, stomatal resistance values ranged between 40 s m^{-1} in IF_3FI and 132 s m^{-1} in IF_6PRD_{50} in 2013, and varied between 36 s m^{-1} IF_3FI and 136 s m^{-1} IF_6PRD_{50} in the 2014. In SSDI plots, r_s values varied between 34 s m^{-1} IF_3FI plots and 121 s m^{-1} IF_6PRD_{50} in 2013, and varied from 30 s m^{-1} IF_3FI to 132 s m^{-1} IF_6PRD_{50} in the 2014. Higher stomatal resistance values were observed in the PRD_{50} than those in the DI_{50} plots under both drip irrigation systems. We also observed that the values of stomatal resistance (r_s) in SSDI plots were slightly lower than those of SDI plots in general.

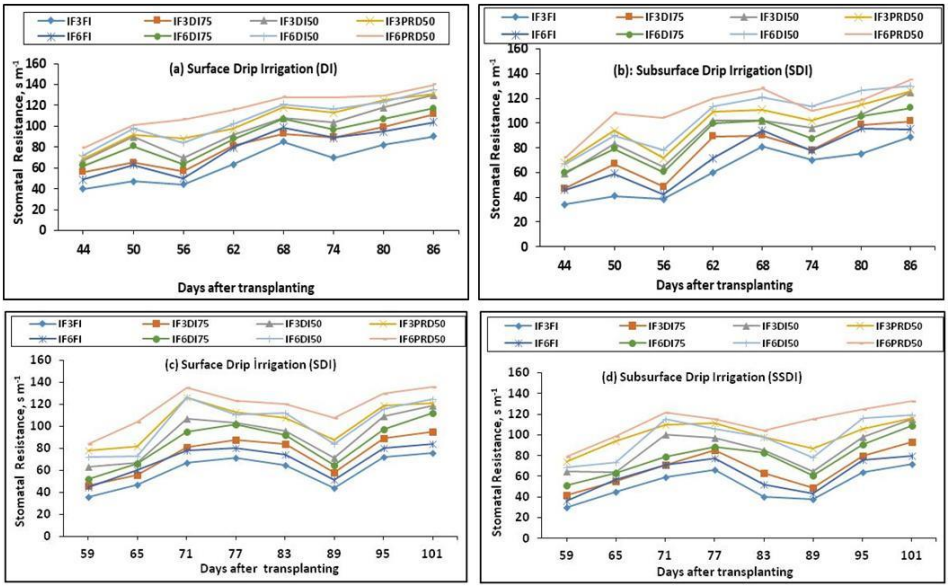

Figure 5. *Stomatal resistance variation during the experimental years in all treatments. (a) Surface drip irrigation (2013); (b) Subsurface drip irrigation (2013); (c) Surface drip irrigation (2014); (d) Subsurface drip irrigation (2014)*

Diurnal variation of stomatal resistance values for the different treatments in the study years are presented in *Figure 6a-d*, respectively. As shown in these figures rs values were lower in the morning hours and gradually increased with time and reached their maximum at solar noon time (13:00-14:00). Then r_s values started to decrease towards the sunset

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

time in all treatments due to lower air temperatures. The lowest rs values were observed in the IF_3FI plot in both study years; maximum r_s values were measured in IF_6PRD_{50} and IF_6DI_{50} treatments.

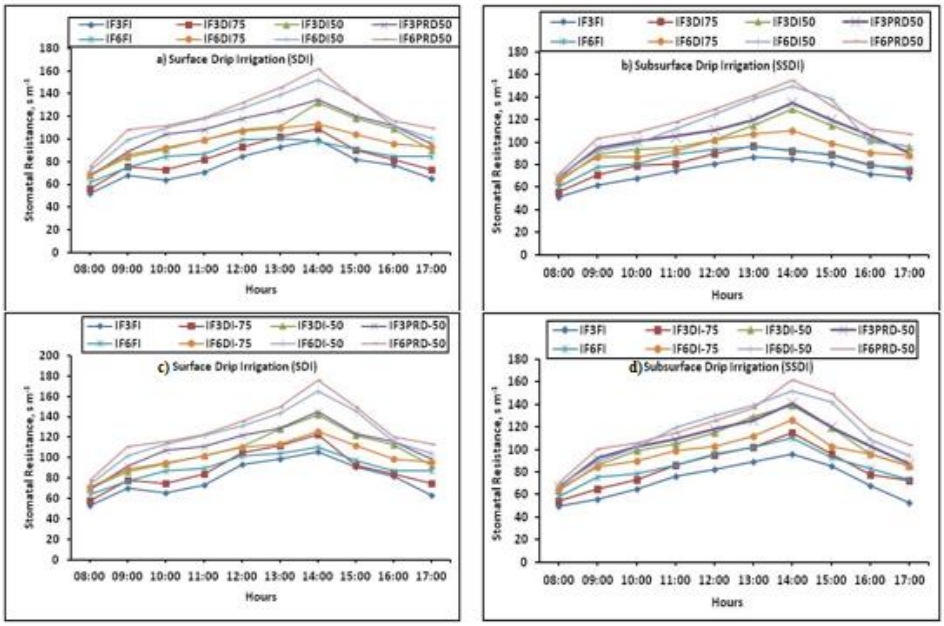

Figure 6. *Diurnal variation of stomatal resistance values in all treatments. (a) Surface drip irrigation (2013); (b) Subsurface drip irrigation (2013); (c) Surface drip irrigation (2014); (d) Subsurface drip irrigation (2014)*

Relations between soil water content, yield, dry matter, evapotranspiration, water use efficiency and stomatal resistance

The relationships between soil water content and stomatal resistance (r_s) prior to irrigations in treatments in the 2013 and 2014 growing seasons for surface and subsurface drip systems are depicted in *Fig. 7a-d*, respectively. Mean stomatal resistance was calculated by taking average of the readings taken before irrigation throughout the growing season.

Significant second order polynomial relations were obtained between soil water content in the effective root-zone depth and stomatal resistance in the experimental years. Stomatal resistance values decreased as the soil water content increased towards the field capacity (245 mm) under both drip systems.

The relationships between mean stomatal resistance and total eggplant yield values for SDI and SSDI treatments in the experimental years are presented in *Fig. 8*. Significant relations were found between fresh eggplant yield and stomatal resistance. The relationship between yield and stomatal resistance was expressed with a second order polynomial in the first year (R^2=0.66), and strong linear equation in the second year (R^2=0.83). Sezen et al. (2019) also expressed significant relationships among the stomatal resistance, evapotranspiration and red pepper yield in the Mediterranean region.

The relationship between stomatal resistance and dry matter yield for SDI and SSDI treatment plots were presented in *Fig. 9*. We found significant linear relations between

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

dry matter yield and stomatal resistance for eggplant with the coefficient of determination (R^2) for the stomatal resistance was 0.84 and 0.85 in 2013 and 2014, respectively.

The relationships between stomatal resistance and evapotranspiration for SDI and SSDI treatments were shown in *Fig. 10*. We found significant linear equations between evapotranspiration and stomatal resistance for eggplant with the coefficient of determination (R^2) for the stomatal resistance was 0.68 and 0.74 in 2013 and 2014, respectively. Liu et al. (2016) reported that transpiration rate linearly increased with increasing stomatal conductance. It was observed that plants experiencing water deficit generally increase r_s, thereby decreasing transpiration rate, increasing leaf temperatures (Ballester et al., 2013).

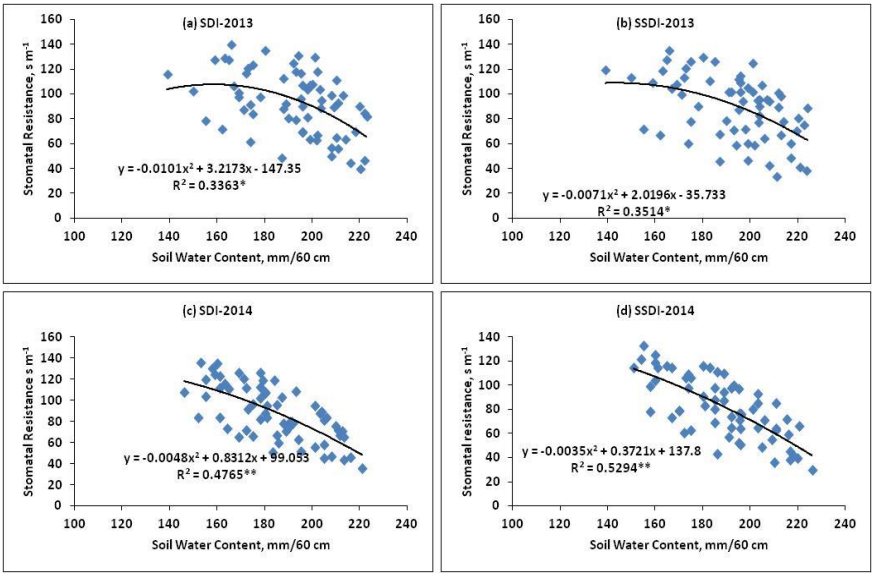

Figure 7. *The relationship between soil water content and stomatal resistance (rs) in treatments in the experimental years (a) SDI-2013; (b) SSDI-2013; (c) SDI-2014; (d) SSDI-2014*

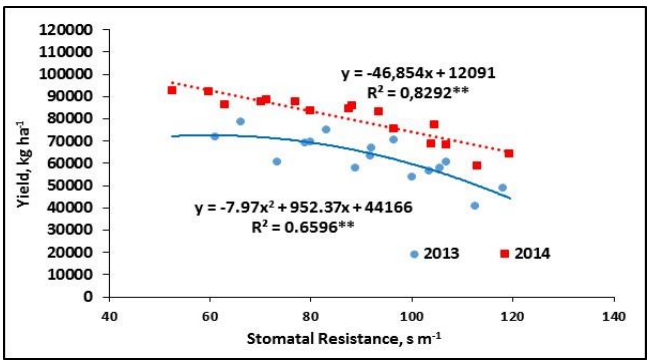

Figure 8. *The relationship between total yield and stomatal resistance in the 2013 and 2014 growing seasons*

The relationships between stomatal resistance and water use efficiency values for SDI and SSDI treatment plots were depicted in *Fig. 11*. We found significant second order equations between WUE and stomatal resistance for eggplant with the coefficient of determination (R^2) for the rs was 0.27 and 0.42 in 2013 and 2014, respectively. The

DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

relationship between LAI and stomatal resistance for the different treatments were depicted in *Figure 12*. Significant linear relation was obtained between LAI and rs for the 2013 and 2014 growing seasons with high coefficient of determination (R^2) values as 0.90 and 0.84, respectively.

Discussions

Studies were made to see whether physiological responses of SDI and SSDI irrigated eggplant to full and various deficit irrigation regimes and frequencies could be utilized for irrigation scheduling.

The research results revealed that the effects of SDI and SSDI systems, irrigation frequencies and levels were found to be significant on total yield and evapotranspiration of eggplant for obtaining greater yield in the Mediterranean environment.

The full irrigation with more frequent irrigation frequency (3-day) under the two drip systems produced significantly greater eggplant yields, followed by DI_{75} treatment which produced slightly lower yield (about 5%) than FI in both experimental years but resulted in water saving of 22.5%. The improved yield under high irrigation frequency as observed in our experiment might be due to the enhanced nutrients uptake (Silber et al., 2003; Ta et al., 2012), consistent with studies on tomato (Pires et al., 2011; Rodriguez-Ortega et al., 2017) and other crops such as bell pepper (Sezen et al., 2006) and melon (Sensoy et al., 2007).

The results revealed that water stress occurring in DI_{50} and PRD_{50} treatments under both drip systems resulted in decreased eggplant yield significantly. These reductions for 6-day irrigation frequency were much greater than those in 3-day frequency. Our findings are in agreement with those found by Kırnak et al. (2002) who reported that deficit irrigations caused a decrease in yield and fruit size of eggplant. The most sensitive growth periods of eggplant to water stress are during flowering and fruit formation. Therefore, occurrence of any water stress in these growth stages might lead to the development of blossom end rot and malformed fruits. Kemble et al. (1998) reported that fruit size and yield as well as dry matter yield (Sarker et al., 2005) are decreased by water stress. Aujla et al. (2007) obtained eggplant yields changing between 43.10 and 103.10 t ha^{-1} in India; Kuşcu et al. (2009) reported maximum marketable eggplant yield of 46.40 t ha^{-1} when irrigations were scheduled at 80% replenishment of the evaporation form Class A pan in Turkey. Karam et al. (2011) determined fresh eggplant yields changing from 13.40 to 33.80 t ha^{-1} for full and deficit irrigations under Lebanease conditions. Douh and Boujelben (2010) investigated the effects of subsurface and surface drip systems on eggplant yield Tunisia and they concluded that SSDI had better performance than SDI. Rakhymzhanov et al. (2015) reported that drip irrigation produced 41% greater yield than

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

furrow method and resulted in water saving of 29% as compared to furrow irrigation in Kazakhstan.

Three-day irrigation frequency (IF_3) produced significantly higher yields than six-day (IF_6) frequency for the corresponding treatments. The reason for greater yield under the more frequent irrigations is that plants can uptake water more easily without experiencing any stress effect compared with longer irrigation frequency treatments. There was no significant difference between the SDI and SSDI systems with regard to eggplant yields although SDI performed slightly better than the SSDI in the first year but they performed similarly in the second year. The results indicated that both SDI and SSDI full irrigation with 3-day irrigation frequency (IF_3 FI) treatment can be recommended. Deficit irrigation DI_{50} and PRD_{50} produced lowest eggplant yields. Although the DI_{75} received approximately 22.5% less water as compared to the FI, yield was reduced only by an average of 4.3%. Therefore, considering water deficiency in dry years DI_{75} irrigation practices can be a good alternative for high yields. The physiological response of eggplant to different water stress levels can be used for optimization and sustainability of crop production in areas where water sources are limited or expensive.

The 3-day irrigation frequency produced higher dry matter yields than the 6-day frequency treatments in both drip methods. The significantly greater reduction in dry matter yields for plants under water stress in DI_{50} and PRD_{50} treatments during fruit ripening stage might be due to decrease in fruit dry-matter yields, as reported by Chaves et al. (2003), and Lovelli et al. (2007). Passioura and Angus (2010) indicated that decreases in plant growth in semi-arid agriculture might be the results of reductions in assimilate transfer from leaves to fruits due to increasingly unfavourable water supply conditions. This observation is apparently pertinent to eggplant produced under water stress conditions.

Water stress resulted in lower leaf area index values under both SDI and SSDI treatments in the experimental years. Madramootoo and Rigby (1991) indicated that water stress reduced the leaf areas of eggplants. Karam et al. (2011) observed the highest LAI in the full irrigation plots, while 44 and 10% reductions were reported for deficit irrigations. Mohawesh (2016) found that water deficit resulted in reduction in growth of eggplant which in turn reduced LAI. The main reason for the decreased vegetative growth of vegetable crops under water stress might be acceleration of leaf senescense, as pointed out by Kırnak et al. (2002) on eggplant and Karam et al. (2009) on bell pepper plants. Passioura and Angus (2010) demonstrated that under water stress, the life cycles of annual plants are shortened and leaf senescense accelerated due to reduced water uptake by the roots. These findings are similar with our results obtained in the present study.

Our finding indicated that the highest WUE was not associated with the least irrigation quantity is because increasing water stress hindered plant growth and consequently reduced the final yield, consistent with previous studies on tomato, and eggplant (Kang et al., 2004; Cantore et al., 2016). Similarly, the minimum WUE was not associated with the highest irrigation amount because it enhanced non-productive transpiration, alluding that increasing irrigation amount benefited yield but not WUE (Du et al., 2017). It is suggested that high WUE should be associated with high (or acceptable) yields, particularly in water scarce areas. Karam et al. (2011) reported the maximum WUE in the deficit irrigated plots as 5.6 kg m^{-3} in Lebanon, while Lovelli et al. (2007) observed the greatest WUE value of 10.3 kg m^{-3} in full irrigation in Italy. Other researchers reported increased WUE in deficit irrigation treatments for red pepper (Sezen et al., 2014), eggplant (Kırnak et al., 2002). The reason for greater WUE in crops under water stress is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

because stressed plants wilt far more than unstressed plants and wilting invariably occurs in times when the vapour pressure deficit of the atmosphere is large (Bloch et al., 2006).

It was observed that slightly lower rs values were recorded for SSDI plots than the SDI treatments in general. Stomatal resistance values influenced by changing weather conditions especially they were sensitive to changes in vapour pressure deficit, wind speed, and air temperature as well as soil water content variation at measurement times. Thus, this parameter fluctuates significantly with changing soil water and weather conditions. Therefore, utilizing rs values for irrigation scheduling requires considerable attention for reliable and practical applications.

Weng et al. (2011) stated that stomata play a significant role in determining the carbon and water cycle between the plants and the atmosphere. One of the first physiological responses of plants exposed to water restriction is to control the stomatal opening and closing movements in order to decrease water loss via transpiration. However, since CO_2 entry is also inhibited, the photosynthesis activity of the plant is directly affected by these movements (Arve et al., 2011). It is noted that water stress decrease stomatal conductance (gs) and transpiration rate (Tr), and the photosynthesis rate primarily decreased in response to reduced stomatal conductance (Ma et al., 2015). It is also mentioned that lower stomatal conductance would decrease CO_2 assimilation very slightly, however would significantly reduce Tr, since transpiration rises linearly with stomatal conductance, due to constant difference in water vapor concentration between leaves and the air (Liu et al., 2016).

In this study, the evapotranspiration rates of the eggplant reduced with decreasing amount of applied irrigation water, resulting in increased stomatal resistance and subsequent reduction in yield and plant growth. These results confirm many earlier studies on different crops (Ma et al., 2015; Liu et al., 2016). Thus, our findings demonstrated that the stomatal resistance is a good indicator for describing the plant water status.

Water shortage resulted in greater stomatal resistance values. The current study results demonstrated that there were strong linear relations among the yield, dry matter yield and stomatal resistance (rs). In addition, we found strong significant linear relations between crop water use (ET) and stomatal resistance. Significant curvilinear relationships were obtained between the soil water content and WUE and rs. All these relations indicated that an average value of 60 s m^{-1} stomatal resistance value prior to irrigation is the threshold value for irrigation scheduling of eggplants. Since rs values were lower in the early season and increased towards the end of season as shown in *Figs. 5 and 6*, rs value range of 30-40 s m^{-1} in the vegetative stage until flowering; 40-60 s m^{-1} during flowering and yield formation stage, and 60-80 s m^{-1} during late growth stage can be used for irrigation scheduling purpose.

Conclusions

Studies were made to see whether physiological responses such as stomatal resistance of SDI and SSDI irrigated eggplant to full and various deficit irrigation regimes and frequencies could be utilized for irrigation scheduling. Water shortage resulted in greater stomatal resistance values. The current study results demonstrated that there were strong linear relations among the yield, dry matter yield and stomatal resistance (rs). In addition, we found strong significant linear relations between crop water use (ET) and stomatal resistance. Curvilinear relationships were obtained between the WUE and rs.

DOI: http://dx.doi.org/10.15666/aeer/1706_1558515604

Stomatal resistance values in subsurface drip irrigated eggplant were generally lower than those in the surface drip irrigated plots. Frequent irrigations also resulted in lower stomatal resistance values when compared with 6-day irrigation frequency in this study. Lower rs values were observed in FI plots under two drip systems with 3-day frequency than DI_{50} and PRD_{50} plots and 6-day frequency. The results indicated that threshold value of stomatal resistance was approximately 60 s m^{-1} for eggplant for irrigation scheduling. Therefore, it is proved that rs can be used for irrigation scheduling. The predicting the yield response to stomatal resistance is important for developing strategies and making decisions for use by farmers as well as researchers for managing irrigation under scarce water resources conditions.

The research results also revealed that the effects of SDI and SSDI systems, irrigation frequencies and levels were found to be significant on total yield and evapotranspiration of eggplant for obtaining greater yield in the Mediterranean environment. The results indicated that both SDI and SSDI full irrigation with 3-day irrigation frequency (IF_3 FI) treatment can be recommended. Deficit irrigation DI_{50} and PRD_{50} produced lowest eggplant yields. Although the DI_{75} received approximately 22.5% less water as compared to the FI, yield was reduced only by an average of 4.3%. Therefore, considering water deficiency in dry years DI_{75} irrigation practices can be a good alternative for high yields. The physiological response of eggplant to different water stress levels can be used for optimization and sustainability of crop production in areas where water sources are limited or expensive.

Abstract. Heterogeneity, the most prominent feature of karst ecological conditions, makes the restoration of areas experiencing Karst Rock Desertification (KRD) difficult. Soil temperature is one of the most important ecological factors creating KRD, but little research on this topic has been conducted. The present study was causing to understand whether the exposure of bedrock during the process of KRD changes the soil temperature of karst microhabitats. Thus, a simulated soil temperature of KRD microhabitat in different time periods and with varied soil thickness was quantified. The results showed that bedrock exposure can change soil temperature. The trend varied with soil depth. In the high temperature period, the exposure of bedrock resulted in heating of soil, but in the low temperature period the exposure of bedrock resulted in cooling of soil. Both soil depth and bedrock exposure have a significant effect on soil temperature. However, the influence of bedrock exposure on soil temperature changed dramatically during different periods.

Introduction

Human activities and interference can easily degrade a fragile karst ecosystem that normally degenerates into an area of karst rock desertification (KRD). Ecosystem restoration has proved difficult in areas of KRD (Peng et al., 2008). Also, one main feature of karst areas is that they have shallow soil with a limited total amount, a phenomenon that is exacerbated by KRD. Therefore, KRD results in discontinuous soil cover, a change in the composition of energy conducting media, and enhanced heterogeneity. The smallest classification unit of habitat heterogeneity is the microhabitat level. The earliest classification of karst divided karst microhabitat into six categories: stony surface, stony gully, stony crevice, stony trough, stony cave, and soil surface (Zhu, 1993). Other scholars have proposed more categories or new classification methods (Li, 2002; Yang et al., 2008), but the most widely used classification methods identify six types of microhabitats. Early scholars paid attention to the distribution of

DOI: http://dx.doi.org/10.15666/aeer/1706_1560515614

karst microhabitats as well as their morphological and spatial characteristics of microhabitats by comparing soil temperature, soil moisture, and the light environment of microhabitats (Zhang et al., 1996; Zhu, 2003). Later, scholars paid attention to the relationship between complex microhabitats and biodiversity (Yu, 2006; Yu et al., 2007), physical and chemical properties of soil (Tang et al., 2016; Liao et al., 2010, 2012a, b; Liu et al., 2008), and soil ecosystem processes (Hu et al., 2016a, b; Du et al., 2011; Liao et al., 2013).

Almost no research has been conducted on soil temperatures in karst areas because of its need for long-term observations and high temporal resolution; this is complicated by the fact that field conditions are impossible to reproduce, measuring tools are expensive, and older analytical methods were employed in previous studies (Yu et al., 2011; Yuan, 2015a). However, soil temperature is one of the most important ecological factors; it has important effects on the soil microbial community, respiration, and enzyme activity (Yuan et al., 2015b); it will also affect plant metabolic activity. The present study was established to imitate the characteristics of KRD microhabitat which occur on bare bedrock with the goals of filling the gap in research related to soil temperatures in the areas of KRD and discover the effects of KRD on changing ecological factors. The present study compared areas of the soil surface with KRD on bedrock that was not bare by conducting research on the features and regular daily changes in soil temperature under varied meteorological conditions.

Materials and methods

The typical karst microhabitats soil is shallow (Li et al., 2016). According to the field investigation, it is found that the soil thickness is about 30 cm. To simulate KRD microhabitat, the present study used man-made devices filled with lime soil and limestone having a soil thickness of 5, 25, 35, and 45 cm (The sensor of 15 cm was damaged by water invasion), it was carried out in Guizhou, China. Plants of *Pueraria lobata* var. *thomsonii* were planted in each type of soil, and button thermometers (DS1923, Wdsen Electronic Technology Co., Ltd.) were buried in these devices (*Fig. 1*).

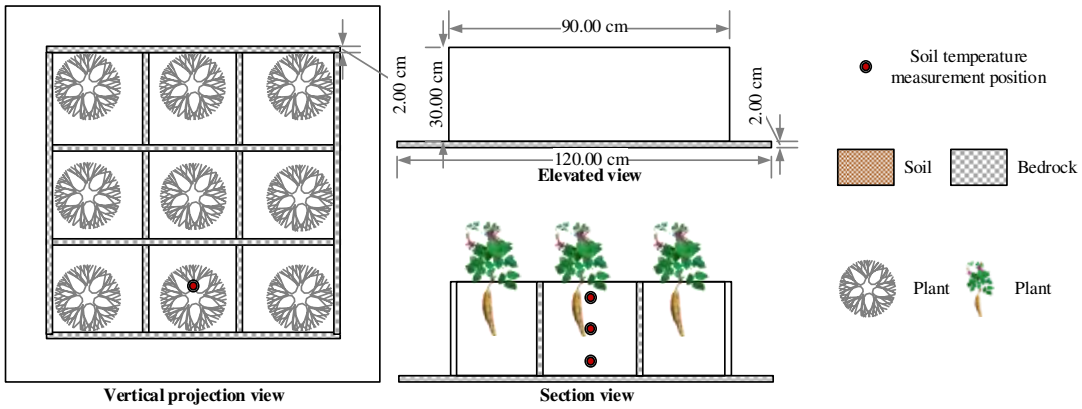

Figure 1. *Experimental device, take the soil thickness of 30 cm as an example*

Under natural precipitation conditions, soil temperature at different depths was measured record once per hour. The resulting data that were compared with a natural

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1560515614

habitat having deep soil and unexposed bedrock. Valid data for 3680 groups data point collections were recorded from 00:00 on July 13 to 23:00 on December 14, 2017. These devices and data were represented by codes representing each type of treatment (*Table 1*). Data were analyzed and figures were draw using software packages known as change-point (Killick and Eckley, 2015) and ggplot2 (Wickham, 2016) in R software (Team, 2019).

The effects of different sites and layers on soil temperature were analyzed by the method of analysis of variance, and the mean value was tested by *t*-test. Difference markers are marked by Tukey's method.

Table 1. *Comparison of the meanings of experimental design codes*

Code	Mean	Code	Mean
CK	Experimental control habitat, unexposed bedrock, soil thickness > 1 m	T	Air temperature at 1.4 m high
O1	KRD habitat, soil thickness is 10 cm	A	Depth range is 0-10 cm
O3	KRD habitat, soil thickness is 30 cm	B	Depth range is 10-20 cm
O4	KRD habitat, soil thickness is 40 cm	C	Depth range is 20-30 cm
O5	KRD habitat, soil thickness is 50 cm	D	Depth range is 30-40 cm
		E	Depth range is 40-50 cm

Results

Time series segmentation

The image (*Fig. 2*) of air and soil temperature time series shows that during the period from 13 July to 14 December air and soil temperature exhibited a stepwise decline with different amplitudes of fluctuations. Based on the mean and variance of change point analysis the change points were obtained for the critical time points of falling temperatures and the amplitude of the change.

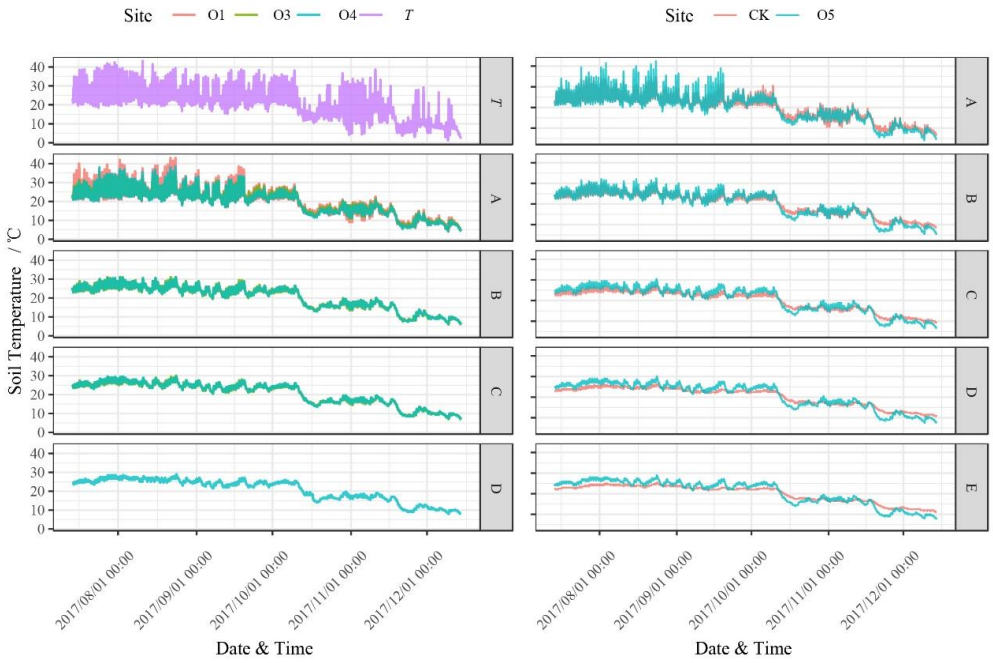

Figure 2. *Time series of air and soil temperatures for sites T, CK, O1, O3, O4, and O5. A, B, C, D and E are the soil layer, all abbreviations have the same meaning as listed in Table 1*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1560515614

The results show that the critical time point was 11 October when the temperature fell and 18 November when the amplitude changes. The two time points were used to divide the air and soil temperature time series to three periods; these were named based on the meteorological characteristics of each period (*Table 2*). The three periods were the high temperature period (13 July to 11 October), mid-range temperature period (12 October to 18 November), and low temperature period (19 November to 14 December).

Table 2. *Meteorological characteristics of three periods*

Period	Precipitation mm/d	Evaporation mm/d	T °C	RH %	Soil temperature °C				
					A	B	C	D	E
High	2.4±5.1	3.4±1.2	25.4±0.1	74.8±0.4	24.3±0.1	24.2±0.0	23.6±0.0	23.7±0.0	23.2±0.0
Mid-range	1.9±4	1.8±0.9	16.2±0.2	77.3±0.6	15.7±0.0	16.4±0.0	16.5±0.0	17.4±0.0	17.4±0.0
Low	0.6±1.1	0.8±0.5	8.9±0.2	80.5±0.6	9.8±0.1	10.8±0.0	11.3±0.0	12.4±0.0	12.8±0.0

T: air temperature; RH: relative humidity; high, mid-range, and low temperature periods were 13 July to 11 October, 12 October to 18 November, and 19 November to 14 December, respectively. The codes for soil depth are provided in *Table 1*

Each of the three time periods exhibited different climatic conditions. The high temperature period featured more precipitation and higher evaporation rates. The mid-range temperature period featured average precipitation, evaporation, and relative humidity (RH). The low temperature period featured less precipitation, low evaporation rates, and high humidity. In the entire soil layer from to top to a depth of 40-50 cm, the soil temperature declined in the high temperature period, and rose in the mid-range and low temperature periods. The temperature differences between the upper and lower soil layers was 1.0 °C in high, 1.5 °C in mid-range, and 3.0 °C in the low temperature periods.

The analysis of variance results (*Table 3*) showed that temperature of air and every soil layer were extremely significantly ($P < 0.001$) different in the three time periods. Based on the F value of layers and sites in different periods, the soil layers caused a wide variation in temperatures. However, in the high temperature period, the difference caused by the site (devices with different soil thicknesses) were variable. It was higher than the effects of soil layers in the high (Judging from the F value) temperature period, relatively small in the mid-range temperature period and generally high but lower the lower layers during the low temperature period.

High temperature period

For find the temperature pattern the soil layer and site, and also based on multiple comparisons using Tukey's honestly significant difference test ($P < 0.05$), means of temperature were drawn (*Fig. 3*) and compared. The trend of soil temperature rose in the KRD microhabitat experiment but the CK treatment had reduced temperatures during the high temperature period. In addition, the mean soil temperatures in the O1, O3, O4, and O5 treatments designed to imitate KRD microhabitats were higher than in the CK treatment.

Differences in air and soil temperature were compared for different soil thicknesses in the same habitat. For the O1 treatment, the temperature difference between air (T, 25.4 ± 0.12) and soil layer A (25.05 ± 0.1) was insignificant. For the O3 treatment, T and temperatures of soil layer C (25.1 ± 0.04) > soil layer A (24.75 ± 0.07), while the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1560515614

temperature differences between soil layer B (25.07 ± 0.05) and T, soil layers C and A were insignificant. For the O4 treatment, T, temperatures of soil layers D (25.23 ± 0.03), C (25.23 ± 0.04), and B (25.11 ± 0.05) > A (24.35 ± 0.08). For the O5 treatment, temperatures of T and soil layers D (25.6 ± 0.04), C (25.28 ± 0.04) > B (24.84 ± 0.05), A (24.84 ± 0.09), the temperature differences of soil layers E (25.17 ± 0.03) with C and B were insignificant. However, the soil temperature of soil layer E was significantly lower than D; for the CK treatment, T > temperatures of B (24.23 ± 0.04) and A (24.32 ± 0.06) > C (23.62 ± 0.03) and D (23.77 ± 0.02) > E (23.18 ± 0.02).

Table 3. *Analysis of variance of soil layer and sites at the three periods: high, mid-range, and low temperature periods were 13 July to 11 October, 12 October to 18 November, and 19 November to 14 December, respectively*

		Df	Sum sq.	Mean sq.	F value	P

	Residuals	12316	51959	4.22		
	Total	12326	68446			

Differences in air and soil temperatures in different habitats were compared with the same soil thickness. For soil layer A, T (25.4 ± 0.12) > O5 (24.84 ± 0.09) and O3 (24.75 ± 0.07) > O4 (24.35 ± 0.08) and CK (24.32 ± 0.06). The temperature difference between habitat O1 (25.05 ± 0.1) with T, O5, and O3 were insignificant. Soil temperature of O1 treatment was higher than O4 and CK. For soil layer B, T > O5 (24.84 ± 0.05) > CK (24.23 ± 0.04), the temperature differences between O4 (25.11 ± 0.05) and O3 (25.07 ± 0.05) with T and O5 were insignificant. The soil temperatures for the O4 and O3 treatments were higher than those of the CK treatment. For soil layer C, T, O5 (25.28 ± 0.04), O4 (25.23 ± 0.04) and O3 (25.1 ± 0.04) > CK (23.62 ± 0.03). For soil layer D, O5 (25.6 ± 0.04) and T > O4 (25.23 ± 0.03) > CK (23.77 ± 0.02). For soil layer E, T and O5 (25.17 ± 0.03) > CK (23.18 ± 0.02).

Mid-range temperature period

Soil temperature rose consistently in the experimental KRD microhabitats and in the CK treatment during the mid-range temperature period.

Air and soil temperatures were compared in treatments with different soil thicknesses in the same habitat. For the O1 treatment, T (16.16 ± 0.19) > A (15.23 ± 0.08). For the O3 treatment, C (16.52 ± 0.04), T and B (16.14 ± 0.05) > A(15.4 ± 0.06). For the O4 treatment, D (17.05 ± 0.04) and C (16.63 ± 0.05) > T > A (15.02 ± 0.06). The temperatures were significantly different between layer B (16.23 ± 0.05) when

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1560515614

compared with C and T. The temperature of layer B was lower than that of D and higher than A. For the O5 treatment, the temperature differences were D (17.02 ± 0.05) > C (16.46 ± 0.05) > B (15.77 ± 0.06) and A (15.42 ± 0.06), but temperature differences between layer E (16.85 ± 0.04) with D and C were insignificant; The temperature differences between T with C and B were insignificant, The temperature of layer E was higher than that of B. The air temperature (T) was lower than that of D and higher than that of A. For the CK treatment, E (17.38 ± 0.04) and D (17.36 ± 0.04) > C (16.48 ± 0.03) and B (16.36 ± 0.04) > A (15.72 ± 0.07). The temperature differences of air T with C, B, and A were insignificant, and air temperature was lower than layer E and D.

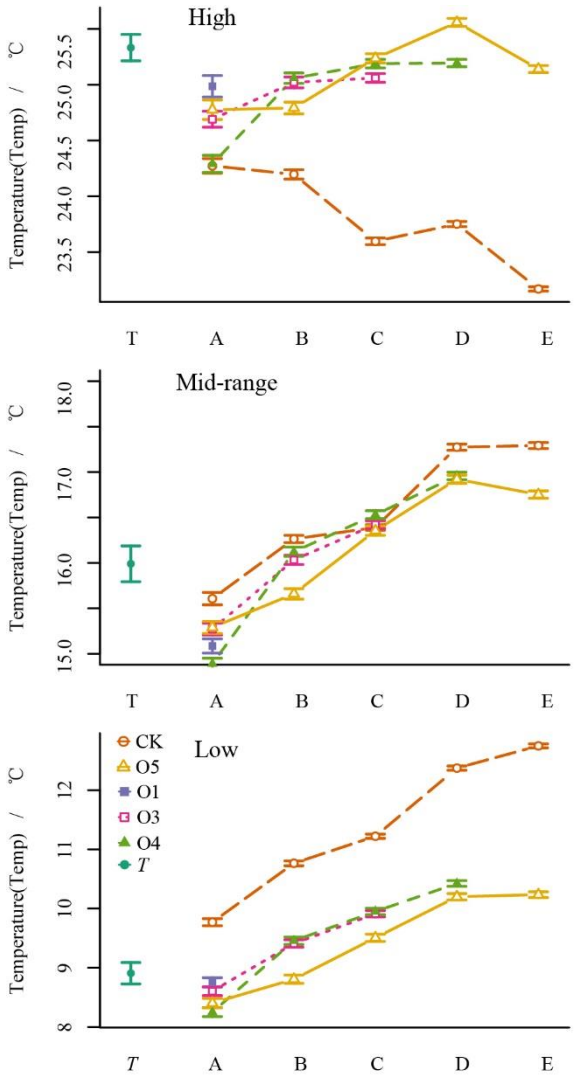

Figure 3. *Temperature features of air and soil in the high, mid-range, and low temperature periods: 13 July to 11 October, 12 October to 18 November, and 19 November to 14 December, respectively. T, CK, O1, O3, O4, and O5 are the sites. A, B, C, D and E are the soil layer, all abbreviations have the same meaning as listed in Table 1*

Air and soil temperatures were compared in different habitats with the same soil thickness. For the layer A treatment, T (16.16 ± 0.19) and CK (15.72 ± 0.07) > O3

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1560515614

(15.4 ± 0.06) and O5 (15.42 ± 0.06) > O1 (15.23 ± 0.08) > O4 (15.02 ± 0.06). For the layer B treatment, CK (16.36 ± 0.04), T and O4 (16.23 ± 0.05) > O5 (15.77 ± 0.06), but the temperature differences of O3 with other habitats were insignificant. For the layer C treatment, O4 (16.63 ± 0.05) > T, and the temperature differences of O3 (16.52 ± 0.04), CK (16.48 ± 0.03) and O5 (16.46 ± 0.05) with O4 and T were insignificant. For the layer D treatment, CK (17.36 ± 0.04), O4 (17.05 ± 0.04) and O5 (17.02 ± 0.05) > T. For the layer E treatment, CK (17.38 ± 0.04) > O5 (16.85 ± 0.04) > T.

Low temperature period

The soil temperatures tended to increase in the experimental KRD microhabitats and increased in the CK treatment during the low temperature period. The difference between the low and mid-range temperature periods was that soil temperature in the experimental KRD microhabitats were lower than the CK treatment in the same layer.

Differences in air and soil temperature with different soil thicknesses were compared in the same habitat. For the O1 treatment, the temperature difference of layer A (8.76 ± 0.08) with T (8.87 ± 0.18) was insignificant. For the O3 treatment, C (9.96 ± 0.05) > B (9.44 ± 0.06) > T and A (8.62 ± 0.07). For the O4 treatment, D (10.49 ± 0.05) > C (10.01 ± 0.06) > B (9.49 ± 0.06) > T > A (8.26 ± 0.07). For the O5 treatment, E (10.31 ± 0.05) and D (10.26 ± 0.06) > C (9.55 ± 0.06) > B (8.83 ± 0.07) and A (8.41 ± 0.08), and the difference in T with layer B was insignificant, while T was lower than layer C and higher than A. For the CK treatment, E (12.82 ± 0.04) and D (12.44 ± 0.04) > C (11.28 ± 0.04) > B (10.81 ± 0.04) > A (9.8 ± 0.06) > T.

Differences in air and soil temperature with different habitats were compared with the same soil thickness. For the layer A treatment, CK (9.8 ± 0.06) > O1 (8.76 ± 0.08) > O4 (8.26 ± 0.07), and differences between O3 (8.62 ± 0.07) and O5 (8.41 ± 0.08) with O1 and O4 were insignificant, the temperatures of O3 and O5 were lower than CK, differences of T (8.87 ± 0.18) with O1 and O3 were insignificant, and the temperature of T (8.87 ± 0.18) was lower than CK and higher than O5. For the layer B treatment, CK (10.81 ± 0.04) > O4 (9.49 ± 0.06) and O3 (9.44 ± 0.06) > T and O5 (8.83 ± 0.07). For the layer C treatment, CK (11.28 ± 0.04) > O4 (10.01 ± 0.06) and O3 (9.96 ± 0.05) > O5 (9.55 ± 0.06) > T. For the layer D treatment, CK (12.44 ± 0.04) > O4 (10.49 ± 0.05) > O5 (10.26 ± 0.06) > T. For the layer E treatment, CK (12.82 ± 0.04) > O5 (10.31 ± 0.05) > T.

Discussion

The changes in the vertical space feature of soil microhabitats may be caused by differences in the thermo-physical properties of soil and bedrock that could make a difference under the same heat release and absorption conditions. In karst areas, the bedrock was mainly limestone and dolomite which develop into a lime soil type. Here, we reviewed their thermo-physical properties based on a review of the literature (*Table 4*).

Specific heat of soil was calculated according to the formula of Hanks (1992): where $c_v=\rho_b(0.8374+4.187\theta_m)$ $kJ\cdot m^{-3}\cdot ℃^{-1}$ is specific heat of soil, ρ_b is soil density, θ_m is volumetric soil water content. The reference range for soil density is 2.21-2.81 $g\cdot cm^{-3}$ (Lu, 2006). Soil volumetric water content was based on long-term monitoring data (0-25%).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1560515614

When comparing the thermo-physical properties of soil and bedrock, soil has a greater amount of specific heat, lower thermal conductivity, and slower thermal diffusivity than bedrock. When the same amount of heat is input to soil and exposed bedrock, these features would be make the temperature of bedrock increase more quickly and the thermal energy of bedrock is then transmitted to the bottom more effectively and faster than in soil. This will cause the soil temperature of KRD microhabitats to be higher than soil surface, something that does not occur in KRD microhabitat, unexposed bedrock, and deep soil.

Table 4. *Thermo-physical properties of major bedrock and soil types*

	Specific heat $MJ \cdot m^{-3} \cdot ℃^{-1}$		**Thermal conductivity** $W \cdot m^{-1} \cdot K^{-1}$		**Thermal diffusivity** $\times 10^{-6} m^2 \cdot s^{-1}$	
	Range	**Mean**	**Range**	**Mean**	**Range**	**Mean**
Limestone (Lei et al., 2018)	1.298-2.396	1.861	2.648-5.273	3.742	0.886-3.442	2.031
Dolomite (Lei et al., 2018)	1.497-2.385	1.798	1.664-6.327	4.330	0.886-3.442	2.481
Lime soil (Zhang, 2007)	1.85-5.29	-	0.2-1.5	-	0.2-0.5	-

A higher base soil temperature during the high temperature period in the bare bedrock microhabitats would result in stronger air transfer to roots for plants growing in these areas. These high temperatures will cost more energy to be used by plants and to expend more water to maintain their increased metabolic activity. As a result, the higher temperatures must exacerbate related problems for the plant that limit its ability to survive. Also, to circumvent this restriction, the plant root may find lower temperature soil and deeper underground water by increasing the length of the root system, resulting in a lower root-crown ratio and higher costs.

Conclusions

When bedrock becomes exposed this can change the soil temperature of karst microhabitat. Bedrock serves for heating karst in summer with high temperature and relatively greater amounts of precipitation and for cooling in winter with relatively low temperature and high humidity. Variations in karst microhabitats has a greater influence during the high temperature period (summer) than the effects of soil depth in the range of 0 to 50 cm. Variations in karst microhabitats have a significant but smaller than the effects of soil depth on soil temperature during the mid-range temperature period (autumn). During the low temperature period, variations in karst microhabitats have a significant and greater effect but the effect is also lower than the effect of soil depth. Furthermore, soil temperatures of KRD microhabitats were significantly different in different seasons.

In the high temperature period, the soil temperatures at the same depth in different KRD microhabitats were higher than at the soil surface microhabitat. The trends of soil temperature changing with soil depth were different for different habitats. For soil surface microhabitat the temperature fell with increasing soil depth, but for the KRD microhabitats, from 0 to 40 cm, temperatures increased with increasing depth. In natural soil surface habitat, soil temperature of any depth was lower than air temperature. But in the KRD microhabitat, the mean difference of soil temperature at a depth of 40 cm with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1560515614

air temperature was insignificant. Soil temperature at a depth of 40 cm or so in KRD microhabitat may have been at the turning point in the trend of soil temperature changing with depth.

In the mid-range temperature period, the trends of soil temperature changing with depth were same between the soil surface microhabitat and KRD microhabitat, with increasing temperature as the depth of soil increased. At the surface (0-10 cm), soil temperatures of KRD microhabitats were uncommonly lower than air temperature. But the difference between surface temperature at the soil surface microhabitat with air temperature was insignificant.

In the low temperature period, the soil temperature at the same depth of different KRD microhabitats were lower than that of soil surface microhabitat. The trends of soil temperature changing with soil depth were the same, because temperature increased with an increase in the depth of soil. At the surface (0-10 cm), soil temperature of KRD microhabitats was lower than air temperature but soil temperature at the surface was higher than air temperature.

This study employed a quantifiable and repeatable experimental device and resulted in an increased level of soil temperature. Future research could also be conducted that is more in-depth. Such research could be designed to consider factors such as rock volume, exposed bedrock area, soil water content, and soil water-holding capacity with a dependent variable of soil temperature to verify the relationships between them. One could also study characteristics of variation over time and the effects of change.

YIELD AND QUALITY PERFORMANCES OF ALFALFA (*MEDICAGO SATIVA*) CULTIVARS SOWN AT VARIOUS DATES UNDER SUB-MEDITERRANEAN ECOLOGICAL CONDITIONS

TURAN, N.

Department of Field Crops, Faculty of Agriculture, Siirt University, Siirt, Turkey
(e-mail: nturan49@siirt.edu.tr)

(Received 8th Aug 2019; accepted 15th Nov 2019)

Abstract. In this study it was aimed to determine the best sowing date and cultivar for the cultivation of alfalfa (*Medicago sativa* L.) in the Southeastern Anatolian Region of Turkey, using a randomized split-block design with three replicates. The study was conducted from 2015 to 2017 using alfalfa cultivars of Kayseri, Magnum V, Gea, and Nimet and these cultivars sowed at three different sowing dates March 10, April 5, and April 30, 2015. The mean plant height of the cultivars was 66.04 cm, mean number of main stems was 10.77 number/plant, mean fresh herbage yield was 50020.1 kg ha^{-1}, mean hay yield was 13509.2 kg ha^{-1}, mean crude protein yield was 2464.0 kg ha^{-1}, mean crude protein rate was 17.88%, mean acid detergent fiber (ADF) rate was 34.01%, and mean neutral detergent fiber (NDF) rate was 39.49%. The highest mean plant height, fresh herbage yield, hay yield, and crude protein yield were observed at first and second sowing times. The results clearly indicate that the first and second sowing dates were the most suitable periods for alfalfa planting in the region studied. Additionally, Magnum V cultivar was the highest cultivator for fresh herbage and hay yield.
Keywords: *alfalfa, sowing dates, varieties, yield, forage quality*

Introduction

Among forage crops, alfalfa (*Medicago sativa*) has the highest forage yield. Alfalfa's herbage is rich in vitamins and high in protein. Because its herbage and hay are quite beneficial and nutritious for farm animals, alfalfa is known as "the queen of forage crops" (Demiroglu et al., 2008).

The seed-sowing dates for alfalfa planting change from region to region. In coastal regions dominated by a Mediterranean climate, winter sowing is common. On the other hand, in regions having a terrestrial climate such as the Central Anatolian and Eastern Anatolian Regions, sowing are generally performed in spring periods. Some regions in which alfalfa is sown in spring might not produce yield in that first year. Nevertheless, the Southeastern Anatolian Region has the ecological conditions that are suitable for harvesting a considerable yield during the sowing year; however, according to Lowe et al. (1972), the main limiting factors affecting cultivar spreading and growth are precipitation and temperature. Thus, temperate and semitropical regions such as the Mediterranean regions alfalfa can harvest up to eight or nine times per year; however, this yield of alfalfa reduce up to two to three times in colder regions. In another study (Eginlioglu et al., 1996) it was reported that the number of sowings, soil fertility, and climate factors also have an effect on alfalfa yield. In that study, it stated that number of harvest for alfalfa can range from 2 to 4 for Eastern Anatolian and Central Anatolian Region, whereas in the coastal regions harvesting of 7 or 8 can be foreseen.

Saruhan and Kusvuran (2011) have reported for several alfalfa cultivars in the Southeastern Anatolian region that the highest fresh herbage yield (48960 kg ha^{-1}) and hay yield (12660 kg ha^{-1}) was produced by the Elci cultivar, while the highest crude

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1561515631

protein rate (22.67%) was obtained from Bilensoy cultivar. Aka and Avcioglu (2003), who investigated the adaptation of seven alfalfa cultivars to the conditions within the Aegean Region, indicated that the height of the main stem varied between 61.56 and 67.50 cm, and that the highest hay yield was obtained from Pioneer-5715 (15730 kg ha^{-1}), whereas it was the lowest for Elci (11780 kg ha^{-1}). In Similar studies on alfalfa cultivars it showed that hay yield of alfalfa was 11020 - 12660 of kg ha^{-1}, 9820 - 17970 of kg ha^{-1} and 12910 - 17810 of kg ha^{-1} (Sengul and Tahtacioglu, 1996).

Moreover, Yılmaz and Albayrak (2016) sowing the some cultivars such as Bilensoy, Verko, Gea, Prosementi or candidate alfalfa cultivars under Isparta conditions found that the highest crude protein rate was produced by candidate cultivars (17.3 7%). In that study it was detected that acid detergent fiber (ADF) and neutral detergent fiber (NDF) rates in Bilensoy cultivar were the lowest (34.50 and 42.20%, respectively). Engin and Mut (2017) conducted at to identify some quality parameters in alfalfa fodder and determine hay yield under Yozgat conditions using alfalfa cultivars of Bilensoy, Kayseri, Verko, Gea, Plato, Victoria, Emiliano, Sunter, Nimet and Basbag during the 2013 and 2015. The mean plant height was the highest in Emiliano cultivar (86.90 cm), whereas it was lowest in Kayseri cultivar (57.50 cm). Authors detected that total hay yield for two year was 21070.0 and 43305.0 kg ha^{-1} for Bilensoy and Sunter, respectively. Again, in that study, the crude protein rate was between 24.20% and 26.10% of percent, and the total protein yield was the highest for Sunter (5906.0 kg ha^{-1}), whereas it was the lowest for Gea (3251.0 kg ha^{-1}).

Alfalfa can be effectively grown for both silage and grain production in Southeastern region of Turkey and thus increasing forage shortage currently encountered will considerably be decreased. The aim of this study was to determine the optimum sowing date for alfalfa under the Southeastern conditions of Turkey, and identify the alfalfa cultivars with the highest quality and yield.

Materials and methods

This research was conducted in researching and application fields of Siirt University Faculty from 2015 through 2017 (*Fig. 1*). As plant material we used four cultivars of alfalfa cultivars such as Gea, Magnum V, Kayseri, Nimet obtained from different research institutes and private seed companies in Turkey. These cultivars sown three different sowing dates (March 10, April 05, and April 30, 2015) are more plant height and more resistant to lodging, and the characters of growing is upright. These cultivars in Turkey have been also recommended for the Southern Marmara, Aegean, Thrace, Black Sea, Southeastern and Eastern Anatolia, Central Anatolia, and Mediterranean regions.

According to the randomized split-block trial design with three replications, the whole plot was divided according to the alfalfa cultivars, and subplot parcels were determined by sowing date. There were eight rows in each parcel with 25 cm between them, and the seeds were sown to a depth of 1 - 1.5 cm. Three kilograms of seeds were sown over each 0.1 hectare and fertilized with 150 kg ha^{-1} diammonium phosphate. The parcel was 2 m wide and 5 m long. There were 2 m of distance between each block and 1 m between each parcel. The entire experimental field was 19 m wide and 35 m long, encompassing a total area of 0.0665 ha.

DOI: http://dx.doi.org/10.15666/aeer/1706_1561515631

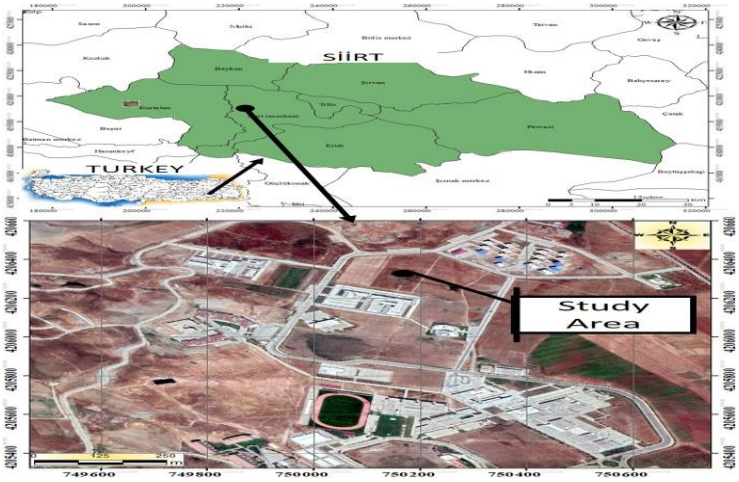

Figure 1. *The location of study area*

Seeds sown in three different sowing dates (March 10, April 05, and April 30, 2015) had the high performance and harvested during 10 - 15% of blooming. 6 rows of plants in the middle of the parcels were harvested after removing one row from the beginning and end of each plot. The processes for pre and post-harvesting were conducted on trial site. Because alfalfa is grown under wet conditions in 2015, five cutting were conducted in the first and second sowing periods, while four cutting were conducted in the third sowing date. In 2016 and 2017, 5 cutting were performed from each sowing period. From each parcel, 0.5 kg samples were randomly collected, air dried under shadow, placed in an oven set to 78 °C for 24 h, and dried until there were no further changes in the sample. At this point, the samples were ground and prepared for analyses.

The characteristics measured in the study were plant height (cm), number of main stems (number/plant), fresh herbage yield (kg ha^{-1}), and hay yield (kg ha^{-1}). In addition, crude protein rate, ADF, and NDF were determined by near infrared analysis using the Near Infrared Reflectance Spectroscopy (NIRS) instrument (Hoy et al., 2002).

The 3-year mean values obtained from the study were used for the analysis of variance with JUMP at 0.05 and 0.01 significance levels (SAS, 1998). The differences among the mean values were compared using Fisher's Least Significant Difference multiple comparison test (Gulumser et al., 2006).

Climate characteristics of the research area

Climate characteristics of the research area are presented in *Table 1*. The Siirt climate has a long-term precipitation (713.10 mm/year), their relative humidity and temperature are 44.73%, and is 16.03 °C, respectively. During this study, the relative humidity was highest in January, and the temperature was generally low. The highest precipitation in 2015 was at 188.00 mm in October 2015, at 162.40 mm in January 2016, and at 126.60 mm in March 2017 (*Table 1*).

As shown in *Table 1,* in the time periods of research, temperatures and relative humidity had higher than the long-term mean climate values. In 2015 and 2017, the total precipitation was 668.00 and 540.80 mm, respectively, which were lower than the long-term average of 713.10 mm; however, in 2016, total precipitation at 731.20 mm, which was higher than the long-term average (*Table 1*). Because region performed in this study are hot and dry, the field was irrigated after each sowing.

Soil properties in the research area

The results of the soil analysis of research area performed by Siirt University Science and Technology Application and Research Center Laboratory are presented in *Table 2*.

The soil analysis showed that the soil of research field had a neutral pH, was highly calcareous, non saline, had low organic matter and plant-available phosphorus, and had sufficient potassium, copper and iron but was low in zinc and manganese concentrate (*Table 2*).

Table 2. *Soil analysis results of the research area*

Soil analyses were conducted at the Siirt University Science and Technology Application and Research Center Directorate (2015).

Results and discussion

Plant height

The plant height of the alfalfa cultivars sown at different dates under Siirt conditions and the results of their multiple comparison are presented in *Table 3*. The results of the effect of cultivar, sowing date, and sowing date x year interaction for the mean plant height of the alfalfa were significant at $p < 0.05$, while those of year and cultivar x year interaction were significant at $p < 0.01$. Effects of interactions of cultivar x sowing date and the cultivar x sowing date x year were not significant.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1561515631

When the findings were examined (*Table 3*), the mean plant height of the cultivars in the study ranged from 62.62 to 67.91 cm. The mean plant height were the highest for cultivars of Kayseri (67.91 cm), Gea (67.35 cm), and Magnum V (66.28 cm), whereas Nimet cultivar was the lowest for this characteristics (62.62 cm). The mean plant height according to sowing dates was 66.04 cm. In the first and second sowing dates, plant height was the highest (67.81 and 67.76 cm, respectively). However, it was 62.55 cm in plants from the third sowing date. The mean plant heights in different years were 52.39, 71.96, and 73.77 cm for years of 2015, 2016, and 2017, respectively.

In the current study, varieties investigated were significantly affected form interaction of sowing date x year, showing that there are differences based on sowing dates. Through the years, the height of plants was the lowest at first planting period, but there were a ongoing increase in the following years. Thus, the height of plant was affected form variety x year interaction. For example, Magnum V was the lowest for plant height at first year of trial, but there was a significant increase for plant height in the following years compared with the other cultivars.

DOI: http://dx.doi.org/10.15666/aeer/1706_1561515631

The results obtained in this study are similar those of plant height taken from another study done in Izmir and Selcuk regions in Turkey (61.56 - 67.50 cm) (Aka and Avcioglu, 1999); however, the plant heights in our study were higher than those observed in the studies done in the Eastern Anatolian Region (54.7) (Cacan et al., 2018), Southeastern Anatolian Region (40.1 - 49.7) (Saruhan and Kusvuran, 2011), Kirşehir (53.91 - 63.47 cm) (Inal, 2015). But our findings for plant height were lower than those from the studies in the Aegean region (Kavut et al., 2014) and Yozgat (Engin and Mut, 2017) at 73.97 - 81.50 and 57.50 - 86.90 cm, respectively.

Number of main stems

According to the mean number of main stems in the alfalfa cultivars sown at different dates and their multiple comparisons (*Table 4*), effect of cultivar, sowing date, and cultivar x sowing date x year on the number of main stems were significant at $p < 0.05$; again, year and cultivar x year were significant at $p < 0.01$. Nonetheless, effect of sowing date x year and cultivar x sowing date were not statistically significant. When these results were examined, we observed that the mean number of main stems in the cultivars ranged between 10.33 and 11.05 number/plant, and the differences in the mean number of main stems in the cultivars were not statistically significant, except for Nimet cultivar (*Table 4*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1561515631

There were no differences between the first and second sowing dates for number of main stems, except for third sowing date. The highest mean number of main stems was 11.22 number/plant from the second sowing date, and the lowest was 10.36 number/plant observed from the third sowing date. The mean number of main stem in different sowing years was 8.31, 11.80, and 12.22 number/plant, respectively, for years of 2015, 2016, and 2017. The differences in the mean number of main stems in the alfalfa cultivars changed throughout the years, and cultivar x year interaction was significant as statistical. Magnum V cultivar had an increase for numbers of main stems over the years and it was the highest compared to the other cultivars at the end of the year.

The values obtained for the number of main stems were lower than those obtained in the studies performed by Turan et al. (2017), Demiroglu et al. (2008), Kavut et al. (2014), Petkova et al. (2003) and Seker et al. (2003), but higher than those from obtained in the study performed by Inal (2015).

Fresh herbage yield

The difference in mean fresh herbage yield from the alfalfa cultivars sown at different dates and their multiple comparisons indicated that effect of sowing date x year were statistically significant at $p < 0.05$, and sowing date and years were significant at $p < 0.01$. On the other hand, the differences in mean fresh herbage yields for cultivar, cultivar x year, cultivar x sowing date, and cultivar x sowing date x year were not statistically significant (*Table 5*).

Mean fresh herbage yields in different sowing dates ranged between 42948.0 and 54893.3 kg ha^{-1}. There were no differences between the first and second sowing dates whereas, there was a difference in the third sowing date. The mean fresh herbage yield according to year was 36549.1, 55548.0, and 57963.3 kg ha^{-1}, respectively, for 2015, 2016, and 2017. Cultivars had different fresh herbage yields according to different sowing dates, and the ones with lower fresh herbage yields had increasingly higher yields in the following years; however, among the sowing dates used, the second had the highest fresh herbage yield. There were statistically significant differences for year x sowing date (*Table 5*).

The fresh herbage yields detected in this study were lower than the results reported by Demiroglu et al. (2008), Kavut et al. (2014), Avci et al. (2013), Petkova et al. (2003), Aka and Avcioglu (1999), and Seker et al. (2003). However, our findings for fresh herbage yield were higher than the values reported by Turan et al. (2017), Cacan et al. (2018) and Inal (2015), and it was in accordance with findings Saruhan and Kusvuran (2011).

Hay yield

Table 6 illustrates the values for mean hay yield of alfalfa cultivars sown on different dates. These values clearly show that effect of cultivar x sowing date on mean hay yield is statistically significant at $p < 0.05$, and that sowing date and years are statistically significant at $p < 0.01$.

In the present study, the effect of the cultivars, cultivar x year, sowing date x year, and cultivar x sowing date x year on mean hay yield was not statistically significant. While the fresh herbage and hay yield of the cultivars examined in the study (Kayseri, Magnum V and Gea) were higher than the second year; the values of the second year was higher than values of the third year.

The difference between the averages indicated by the same letter in the same group is not statistically significant, *:Significant difference at $P < 0.05$ level, **:Significant difference at $P < 0.01$ level, CV: variation coefficient, LSD: least significant difference, NS: non-significant.

The fresh herbage and hay yield were 37133.3 - 9139.5 kg ha^{-1} in the first year, in the second year increased to 56347.7 - 15946.0 kg ha^{-1}, then decreased to 54977.7 - 15534.6 kg ha^{-1} in the final year. This situation is believed to be related to the characteristic differences in cultivars and their different responses to varying ecological conditions.

The mean hay yields of the groups from the different sowing dates ranged from 11932.7 to 14589.1 kg ha^{-1}, with the highest hay yield observed from the second sowing date and the lowest from the third sowing date. Mean hay yields were 8 635.7, 15 557.4, and 16334.7 kg ha^{-1}, respectively, for years of 2015, 2016, and 2017. Considering the three-year values together with the year of the sowing, fresh herbage and hay yield values had an similar increase. However, the hay yield in second sowing date was the highest, indicating that cultivar x sowing date interaction lead to these differences (*Table 6*).

In the present study, the hay yield were higher than that of values reported in the Eastern Anatolian Region (13154.0 and 12270.0 kg ha^{-1}) (Turan et al., 2017; Cacan et

DOI: http://dx.doi.org/10.15666/aeer/1706_1561515631

al., 2018) and in Europe, North Africa, and the United States (14200.0 kg ha^{-1}) (Pecetti et al., 2008). However, our findings for hay yield were lower than those observed in the study done in Bornova and Odemiş in Turkey (Demiroglu et al., 2008), with yields ranging from 18920.0 to 24740.0 kg ha^{-1}.

Table 6. *Effect of cultivar and sowing date on dry herbage yield (kg ha^{-1})*

Moreover, the hay yields in our study were in accordance with findings of Aka and Avcioglu (2003), in which the adaptations of alfalfa to Aegean Region conditions were examined with hay yield values for seven different alfalfa cultivars ranging from 11780.0 to 15730.0 kg ha^{-1} with those observed in another study done under Erzurum conditions with different alfalfa cultivars (Seker, 2003), which showed the highest hay yield of 13335.0 kg ha^{-1}. Because of that the development of root and storing of spare nutrients in the root region. Thus, it is understood that the development of subsoil parts is given more importance rather than above ground ones. Despite this five cutting were performed in second year of trial and an increase was observed an increase over years (*Tables 3–8*).

Crude protein content

The effect of cultivar x year, cultivar x sowing date, and cultivar x sowing date x year on the mean crude protein rates in the alfalfa cultivars sown at different dates were statistically significant at $p < 0.05$, and also the effect of cultivars and years were significant at $p < 0.01$. On the other hand, the impacts of sowing date and sowing date x year were not statistically significant. Cultivars had a mean crude protein rate of 17.88% with a high value of Magnum V (18.54%) and a low value of Nimet (17.40%).

The mean values for the different years were 16.18, 16.60, and 20.87%, respectively. Mean crude protein rate was the highest for all cultivars in 2017 (*Table 7*). Cultivar x year interaction was statistically significant at $p < 0.05$. In the cultivar x sowing date, the highest mean crude protein rate was 18.57% in first Magnum V sowing date, and the lowest rate one was observed from the third Nimet sowing date at 17.03%.

Table 7. *Effect of cultivar and sowing date on crude protein ratio (%)*

DOI: http://dx.doi.org/10.15666/aeer/1706_1561515631

Under different environmental conditions, different crude protein rates were observed in many studies. The values reported in the literature were from Awad and Bakri (2009) at 19.99 - 26.96%, Geleti et al. (2014) at 18.15 - 19.56%, Katic et al. (2009) at 17.3 - 19.7%, Saruhan and Kusvuran (2011) at 22.67%, Yilmaz and Albayrak (2016) at 17.37%, Zeinab et al. (2013) at 18.5 - 23.0%, Engin and Mut (2017) at 24.2 - 26.1%, Kir and Soya (2008) at 17.86 - 20.26%, Kir (2010) at 22.21 - 23.31%, Saruhan and Kusvuran (2011) at 17.94 - 22.67%, Kavut and Avcioglu (2015) at 19.83 - 20.11%, Inal (2015) at 18.38 - 20.45%, Yuksel et al. (2016) at 15.14 - 19.13%, Cinar and Hatipoglu (2015) at 20.6%, Yilmaz and Albayrak (2016) at 16.23 - 17.53%, Avci et al. (2013) at 18.5 - 19.4%, Turan et al. (2017) at 16.55 - 17.55%, Strbanovic et al. (2017) at 20.00%, Oten et al. (2018) at 18.39%, Walie et al. (2016) at 18.06%, Holman et al. (2016) at 19.50 - 26.50%, Titei et al. (2018) at 23.00%, Mazza et al. (2001) at 19.99 - 21.70%, Toricelli et al. (2001) at 19.99 - 21.70%, Stanacev et al. (2010) at 19.70%, and Scholtz et al. (2009) at 13.90 - 27.80%.

When the values obtained in this study are compared with those above, we see that they are in accordance with some higher and some lower. The differences in crude protein rates were considered to be related to the differences among soil, cultivar, sowing date, and other environmental conditions.

Crude protein yield

Table 8 presents the statistically significant results in mean crude protein yield of the different groups. According to these results, the effect of sowing date x year and cultivar x sowing date on mean crude protein yield were statistically significant at $p < 0.05$, and also the effect of sowing date and year were statistically significant at $p < 0.01$. On the other hand, the effect of cultivar, cultivar x year, and cultivar x sowing date x year were not statistically significant for crude protein yield.

The effect of sowing time on crude protein yield was statistically divided into two groups, first and second sowing time was the highest group, while the third sowing time was the lowest group. When the crude protein yield of the years is examined (*Table 8*). The highest crude protein yield with 3409.7 kg ha^{-1} was obtained in 2017, while the lowest crude protein yield with 1385.7 kg ha^{-1} was obtained in 2015.

Nimet and Magnum V were in the same statistically significant groups and had the highest mean crude protein yield from their second sowing date and the lowest from the third sowing date, while Gea had the highest crude protein yield from its first and second sowing dates. These results were statistically significant at $p < 0.05$ for cultivar x sowing date.

In current study, year x sowing date interaction was statistically significant and was between 1385.7 and 3409.7 kg ha^{-1}. These values obtained for crude protein yield were higher than those from Inal (2015) at 881.9 - 1129.3 kg ha^{-1}, Turan et al. (2017) at 1348.0 - 2827.0 kg ha^{-1}, Cacan et al. (2018) at 3010.0 kg ha^{-1}, and Kir and Soya (2008) at 372.5 - 522.3 kg ha^{-1} and also these values were lower than those from Hansen and Krueger (1973) at 2700.0 - 3250.0 kg ha^{-1}, Avci et al. (2013) at 4020.0 - 4220.0 kg ha^{-1}, Yilmaz and Albayrak (2016) at 3173.6 - 3837.9 kg ha^{-1}, and Engin and Mut (2017) at 3251.0 - 5906.0 kg ha^{-1}.

Even though the differences in the mean crude protein rate were not statistically significant, there were statistically significant differences in crude protein yields, which can be explained by the differences in hay yields from the cultivars and sowing years (*Table 8*). The correlation between increasing hay yield and crude protein content is also indicated by other researchers (Kir and Soya, 2008).

Acid detergent fiber (ADF) rates

According to the ADF rates in this study (*Table 9*), the effect of sowing date, cultivar, year, and cultivar x sowing date on ADF rate were statistically significant at $p < 0.05$, while cultivar x year and sowing date x year were statistically significant at $p < 0.01$; nevertheless, the effect of cultivar x sowing date x year were not statistically significant.

The lowest ADF rate at 31.99% was observed in Magnum V cultivar and the highest was observed in Kayseri cultivar (34.78%). When examined in terms of sowing date, the first and second sowing dates were once again in the same statistically significant group and had lower ADF rates compared with third sowing date.

Magnum V had always the lowest ADF rates, although Gea cultivar had the lowest ADF rate in 2017. For this reason cultivar x year interaction was significant ($p < 0.05$). The effect of cultivar x sowing date indicated that Magnum V's lowest ADF rate was in the second sowing date at 30.58%, and that Kayseri cultivar (35.90%) and Nimet cultivar (36.82) were the highest for ADF rate in the second sowing date and third sowing date, respectively (*Table 9*).

The ADF values obtained in this study were higher than those of Geleti et al. (2014) at 21.49 - 26.19%, Engin and Mut (2017) at 27.5 - 29.7%, Toricelli et al. (2001) at 28.89 - 32.29%, Markovic et al. (2008) at 16.3%, and Kanani et al. (2006) at 26.50%. In several similar studies, the ADF rates ranged from 35.16 to 36.03% (Kir, 2010) and from 31.97 to 41.5% (Gungor et al., 2008), which were higher than those from our study; however, the results of our study were in accordance with values reported by Cacan et al. (2015) at 31.86% and Yilmaz and Albayrak (2016) at 34.50%.

Neutral detergent fiber (NDF) rates

When the NDF rates were examined by cultivars and sowing dates, the effect of cultivar, year, and cultivar x sowing date were statistically significant at $p < 0.01$; whereas it were not statistically significant for sowing date, sowing date x year, cultivar x year, and cultivar x sowing date x year for NDF rates (*Table 10*).

The difference between the averages indicated by the same letter in the same group is not statistically significant, *:Significant difference at P < 0.05 level, **:Significant difference at P < 0.01 level, CV: variation coefficient, LSD: least significant difference, NS: non-significant.

Considering the different NDF rates in different cultivars, Magnum V had the lowest at 37.51%, while Nimet had the highest at 40.90%. In terms of sowing dates, there are two different statistically significant groups, and the lowest NDF rate was in the first sowing date group, while other sowing dates are in another group together. The NDF rates were 40.85, 40.28, and 36.78%, respectively, for years of 2015, 2016, and 2017. The cultivar x sowing date group values ranged between 36.80 and 42.93%. The NDF values obtained in this study were higher than those of Kanani et al. (2006) at 34.20%, lower than those of Kir (2010) at 42.68 - 44.13% and Yilmaz and Albayrak (2016) at 42.20%, and comparable to those of Engin and Mut (2017) at 40.0 - 42.9% and Geleti et al. (2014) at 36.86 - 43.53%.

The ADF and NDF rates can be altered by environmental conditions, soil, sowing date, and cultivar.

Conclusion

Throughout this study, domestic and foreign alfalfa cultivars obtained from various sources were sown in Siirt city of Turkey and the effect of sowing date and type of the cultivar over yield and other properties related to its agricultural value were investigated. Our results showed that the highest crude protein rate and yield, and the lowest ADF and NDF rates were founded in Magnum V cultivar. According to the sowing date mean values, the plant height, number of main stems, fresh herbage, and hay yields were higher from the first and second sowing dates on 10 March 2015 and 5 April 2015, respectively. Taken together, the most suitable dates to sow alfalfa in Siirt city of Turkey were the dates of 10 March and 5 April. Our results also showed that the Magnum V alfalfa cultivar is the best option for the production of herbage and high-quality hay.

DAMAGE CAUSED BY THE EUROPEAN BEAVER (*CASTOR FIBER* L.) IN AGRICULTURAL AND FOREST FARMS IN VIEW OF SELECTED ATMOSPHERIC FACTORS AND ANIMAL BEHAVIOR

JANISZEWSKI, P.* – HERMANOWSKA, Z.

(Received 20th Aug 2019; accepted 14th Nov 2019)

Abstract. The aim of this study was to track and characterize damage caused by the European beaver in private farms in the Region of Warmia and Mazury (NE Poland) in 2009-2016. The influence of selected atmospheric factors and beaver behaviour aspects on the number of compensation claims was also analyzed. The majority of damages resulting from beavers' negative impact on the human economy were related to the flooding of grasslands. The second and third most prevalent types of damage were tree cutting and flooding of tree stands, respectively. Most losses were reported in spring and summer months, which suggest that preventive measures should be undertaken mainly during that period. There were no significant relationships between the number of filed claims, temperature and precipitation levels in the analyzed years.
Keywords: *Castor fiber, population increasing, beaver damage, forests, arable areas, flooding*

Introduction

Beavers exert a positive influence on their occupied ecosystems, reflected in increasing biodiversity. However, beaver activity can also have negative implications for private agricultural and forest farms (Derwich and Mróz, 2008; Janiszewski et al., 2014). Beavers can substantially modify the structure of forests by foraging on the preferred tree species, which can lead to the devastation of valuable tree stands (Ciechanowski, 2010; Janiszewski and Hanzal, 2015; Tajchman et al., 2018). Beaver activity can directly or indirectly contribute to landslides and local floods. Rational management of local beaver populations poses a challenge due to the animals' unique lifestyle as well as the fact that beavers often inhabit hard-to-reach biotopes. The prevalence of active family groups is difficult to determine, and attempts to control the beaver population through harvest or hunting may be impossible or ineffective (Janiszewski et al., 2007; Janiszewski and Misiukiewicz, 2012; Januszewicz et al., 2018). Estimates of the damage caused by beavers in private farms based on the filed damage claims provide reliable information on beaver activity.

The aim of this study was to track and characterize the damage caused by the European beaver *Castor fiber* in private farms in the North-Eastern Poland (Region of Warmia and Mazury) in 2009-2016 in view of selected atmospheric factors and animal behavior.

Materials and methods

The study relied on data from the estimation of losses sustained due to the activity of the European beaver *Castor fiber* in the Region of Warmia and Mazury (NE Poland) in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1563315642

2009-2016 (*Fig. 1*). The relevant data was obtained from the Regional Directorate for Environmental Protection in Olsztyn (20°30'E; 53°47'N). Damage claims contained the following information:

- Date of loss
- Type of damage

The effects of the following atmospheric factors on the number of damage claims were analyzed:

- Total annual precipitation
- Mean annual temperature
- Mean temperature between March and November

Data on total annual precipitation were obtained from the Regional Inspectorate of Environmental Protection (2018), and temperature data were acquired from Statistics Poland (Statistics of Poland, 2010-2017).

In view of the legal regulations in force (Journal of Laws 2017, item 142, as amended), losses caused by beavers on private land constitute the liability of the State Treasury represented by the Regional Director of Environmental Protection.

The Region of Warmia and Mazury spans an area of 24,173.47 km^2, and it accounts for 7.7% of Poland's territory. Forest cover in the region was estimated at 3.12% at the end of 2015 (Statistics of Poland, 2017).

The results were processed in Microsoft Excel 2013 and presented in tabular and graphic forms with an indication of absolute values and percentages. The coefficients of linear correlation between the total number of damage claims, flood damage claims and the analyzed atmospheric factors were calculated in Statistica 12 PL.

Results

The number and type of beaver damage reported each year during the analyzed period were evaluated. The results are presented in *Table 1*.

The number of beaver damage complaints continued to increase in the first years of the analyzed period from 640 in 2009 to 1807 in 2013. These observations could point to a higher prevalence of beaver damage in the evaluated region (due to migration and/or population growth) or growing levels of awareness about financial compensation options among land owners. A minor decrease in the number of claims was noted in the following two years of the examined period (2014-2016), which could testify to the effectiveness of the implemented protective measures (such as the construction of overflow channels in beaver dams). However, the total number of compensation claims was considerably higher than in the first years of the studied period.

An analysis of the proportions of various types of damage during the studied period indicates that nearly 53% of the submitted compensation claims involved flooding and inundation of grasslands (meadows and pastures) (*Fig. 2*). More than 40% of the reported losses were sustained in private forests and coppices, including tree cutting (28.41%) and flooding of tree stands (12.67%). The relevant losses were least

DOI: http://dx.doi.org/10.15666/aeer/1706_1563315642

frequently sustained in crops (0.03%). However, damage due to floods in grasslands, arable land and private forests accounted for 68% of all damages caused by beavers in the studied region.

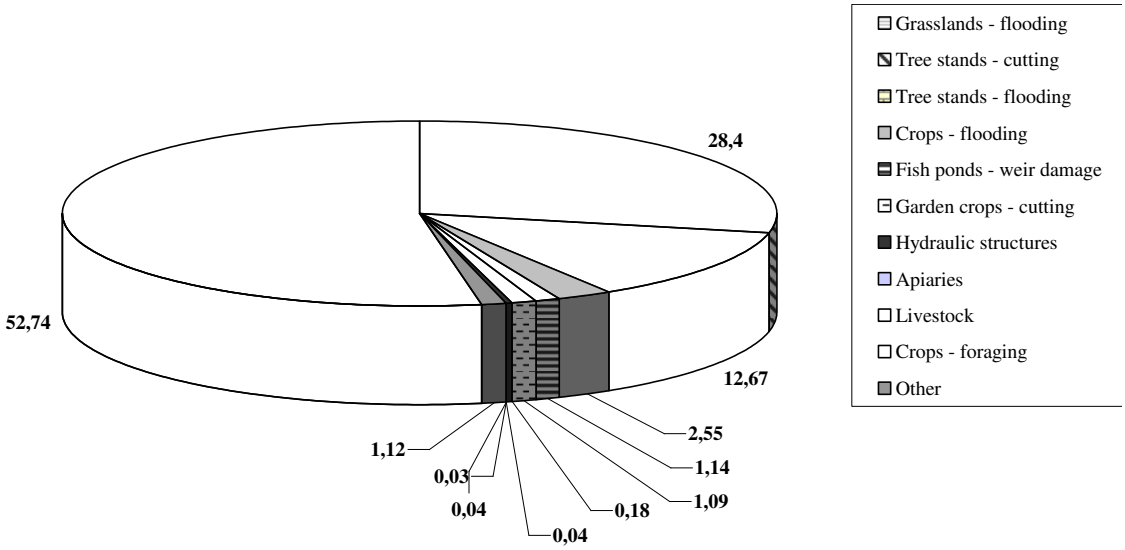

Figure 2. *Different types of damage caused by beavers in 2009-2016*

The number of compensation claims differed across months. The distribution (%) of beaver damage in each month of the year is presented in *Figure 3.*

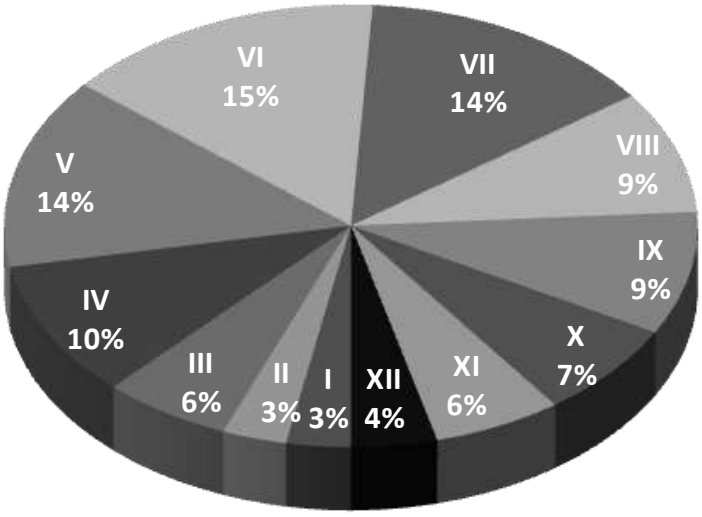

Figure 3. *Distribution (%) of reported damage caused by beavers in each month of the year*

The highest number of damage claims was noted in late spring and in summer: May (14%), June (15%) and July (14%), followed by April (10%), August (9%) and September (9%).

Precipitation and temperature data (*Table 2*) and the correlations between selected atmospheric factors that could potentially influence the severity of beaver damage and the number of compensation claims in each year were analyzed (*Table 3; Fig. 4*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1563315642

The coefficients of correlation between the total number of damage claims, the number of flood damage claims and selected atmospheric factors were calculated. The results are presented in *Table 3*.

An analysis of the above data (*Tables 2* and *3; Fig. 4*) indicates that special attention should be paid to the correlations between annual temperature, the total number of damage claims and the number of flood damage claims. These relationships were not statistically significant, but the above variables were bound by positive correlations, and the correlation coefficient exceeded 0.4. The above implies that higher temperature intensifies beaver activity and prompts these animals to build more dams which raise water levels in rivers and increase the risk of flooding on arable land and in forests. Total precipitation and the number of compensation claims were bound by a negative correlation (-0.23), which suggests that higher precipitation discourages beavers from building dams and minimizes flooding in areas directly adjacent to watercourses.

Discussion

The severity of damage caused by beavers has not been analyzed in detail often in relevant literature (Reynolds, 2000). Various types of beaver damage were evaluated by Brzuski and Kulczycka (1999) based on the compensation claims filed in 1995-1997 in the former Polish voivodeships (before the reform of Poland's administrative division system). A total of 790 claims describing different types of damage caused by beavers had been filed in Poland in the analyzed period. The total amount of compensation payments for damage caused by beavers reached the equivalent of USD 141,000. According to the cited authors (Brzuski and Kulczycka, 1999), field and grassland floods accounted for 30% of all reported damages. In our study, flooding was the most common cause of the reported losses, but the prevalence of flood-related damage in the Region of Warmia and Mazury was higher at around 50% (from 47.76% to 66.41%) (*Table 1; Fig. 2*). A comparison of our findings with the cited results points to a rapid increase in the population size of beavers in north-eastern Poland, which is associated with a higher incidence of damage caused by beavers and, consequently, an increase in the amount of compensation payments.

Various types and extent of damage caused by beavers were also investigated in 2002-2003 by Czech (2010). In his study, the destruction of flood embankments and pond levees by burrowing beavers was the most prevalent type of damage, followed by farm flooding. In a study by Derwich et al. (2007), the most severe losses associated with beaver activity in the region of Podkarpacie (South-Eastern Poland) also included damage to flood embankments and tree stands.

Different results were noted by Wajdzik et al. (2013) who reported a total of 262 beaver damage, complaints totaling PLN 150,000 in the Region of Małopolska (South Poland). In their study, the most extensive losses (120 compensation claims) were observed in forests where beavers felled more than 14,000 of trees with a combined volume of 752 m^3. The most affected tree species were willows (5850), poplars (3550), alders (2100) and oaks (1500). Beavers had a preference for trees whose diameter at breast height did not exceed 11 cm. A total of 116 damage claims were filed by farms where beavers damaged mostly root and tuber crops (beets, carrots, parsnips) and cereals (maize, wheat). Flooding and seasonal inundation of meadows and pastures were also prevalent on agricultural land. The predominant types of losses in fish ponds included burrowing and weakening of levees, blockage of culverts, and restricted water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1563315642

flow in ditches. Kłoskowski (2011) conducted a detailed analysis of damage caused by beavers in fish farms. Severe losses were reported in 21.2% and moderate losses – in 46% of the 110 surveyed fish farms in eastern Poland. Fish ponds were not affected by beaver activity in 32.8% of the examined cases.

The expansion of the existing and potential beaver populations after reintroduction can have serious financial consequences if beaver colonies private forest and agricultural area. The relevant risks can be minimized through monitoring, which is not easily accomplished with regard to beavers, partly because of difficulties in determining the exact number of beaver colonies (Januszewicz et al., 2018). Campbell-Palmer et al. (2015) estimated the costs associated with the payment of compensation for damages caused by beavers. In Denmark, where the first beaver reintroduction scheme was introduced only in 1999, equipment costs range from EUR 1000 to 3000 per year, the cost of field staff dealing with beaver conflicts was estimated at EUR 50,000 per year, whereas EUR 40,000 is additionally spent on monitoring. In the Czech Republic which has a stable beaver population, more than EUR 2.8 million has been paid in state compensation for damages to crops and forestry in the last 15 years (average of EUR 187,000 per year). In Bavaria, voluntary state compensation for beaver damage is estimated at EUR 450,000 per year, and around 1000 beavers are now culled annually. However, while the costs associated with the mitigation of human-beaver conflicts and the payment of compensations can be estimated, the potential benefits of beavers are much more difficult to determine.

Road damages caused by beaver (*Castor canadensis*) were a costly problem for transportation department in the U.S. Population control and dam destruction were the most widely used methods to reduce conflicts but benefits of such measures in some situations were often very short-term (Boyles and Savitsky, 2008). To determine the potential benefits of using flow devices were installed 40 devices in 21 sites. It was important, that the costs to install and maintain the devices were significantly lower than preventative road maintenance, damage repairs, and/or population control costs.

Similar results were obtained in the territory of Alberta, Canada (Hood et al., 2018). There were 12 pond levelers devices installed to prevent flooding by *Castor nanadensis* and the Authors developed a cost-benefit analysis for these areas. It was found that one of the devices required constant maintenance and modification during 3 years, while the other devices required almost no maintenance. Based on a "willingness-to-pay" (WTP) of 0$ and discount rate of 3% was found that installing pond levelers resulted in a present value net benefit of 81 519$ over 3 years and 179 440$ over 7 years. Scenarios incorporating discount rates of 3% and 7%, horizons of either 3 or 7 years, and varying WTPs resulted in significant net benefits. Hood et al. (2018) also found that provincially, municipalities employed up to seven different methods to control damages caused by beavers, but the most commonly were: lethal control and dam removal. Total annual costs provided by 48 municipalities and 4 provincial parks districts were 3,139,223 $.

Czyżowski et al. (2009) compared the extent of damage to tree stands caused by beavers based on the species' foraging preferences in urban and protected areas. They found that unlike in protected areas, beavers did not have clear preferences regarding tree species and tree diameter in urban areas.

Janiszewski and Misiukiewicz (2012) analyzed the compensation claims submitted to Regional Directorates for Environmental Protection across Poland in 2009. The incidence of beaver damage was highest in the Region of Podlasie and the Region of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1563315642

Warmia and Mazury, and it was lowest in the Region of Silesia. Grassland flooding was the most prevalent type of beaver damage which was reported in 69.72% of the examined cases. The number of approved compensation claims was twice lower in the Region of Warmia and Mazury than in the Region of Podlasie, but the amount of paid compensation was highly similar in both regions. In the cited study, the following types of damage were most prevalent: flooding of meadows and pastures (30.4%), damage to embankments and levees in fish ponds (20.12%), tree damage (19.28%) and losses sustained in horticulture (18.04%).

The distribution of beaver-induced losses in different months of the year can be influenced by the biological characteristics of the species as well as the annual cycle of agricultural and forestry operations. The number of damage claims was highest in the months when many field operations are performed, in particular on grasslands which are most susceptible to beaver damage (*Table 1*). The summer months are also a season of beaver migration (Janiszewski et al., 2014). Offsprings are typically born in May and June which is also a period during which other members of beaver family groups temporarily leave their habitats, and individuals who attain sexual maturity (at around 3 years of age) migrate in search of mating partners and new habitats (Hartman 1997). Annual migration patterns and behaviors can also contribute to the severity of damage because migrating beavers build dams in new locations and cause floods in areas adjacent to rivers and water bodies (Gorshkov and Gorshkov, 2011).

The number of damage claims was lower in October and November (*Fig. 2*), which is not correlated with beaver activity, but could be linked with a small number of field operations (mainly in grasslands). However, tree cutting and felling can be intensified in autumn when beavers attempt to harvest sufficient amounts of material for reinforcing dams or accumulate food reserves before winter (Hartman, 1997; Janiszewski and Hanzal, 2015).

Janiszewski and Misiukiewicz (2012) analyzed the factors that affect the extent and type of damage caused by beavers. In addition to the size and density of beaver populations, the type and severity of the inflicted losses were directly associated with the proportion of arable land and private forests in the studied area. The area of agricultural land intersected by large rivers is one of the key factors that determine the type and extent of beaver damage. These areas are readily colonized by migrating beavers.

Tajchman et al. (2018) reported interesting findings in a study evaluating beaver damage to tree stands. The number of damaged trees was bound by a negative and non-significant correlation with the hardness of the analyzed tree species. A similar relationship was noted between the diameter of damaged trees and their distance from beaver lodges: the diameter of trees cut by beavers decreased with an increase in distance from beaver habitats.

The increasing Canadian beaver population has caused forest damage in Finland (Härkönen, 1999). The most important type of damage was flooding (50%) caused by the damming activity of beavers, according to own results. The trees were dead or dying in 18% of the damage areas. Prevention of beaver damage has been carried out in 80%of the damage area. In the study area (Härkönen, 1999) beaver numbers have steadily increasing, although the number of beavers taken by hunting have sharply increased too. It can suggest that the methods used to prevent beaver damages should be improved.

In the light of legal regulations, land owners and tenants are entitled to compensation in virtue of damage caused by beavers (Art. 126, section 1, point 5 of the Nature Conservation Act of 16 April 2004; Journal of Laws 2017, item 142, as amended). However, land owners and tenants are not compensated for lost profits. It should be noted that until 2013, the State Treasury (represented by the Regional Director for Environmental Protection in the relevant matters) was liable only for losses sustained in agricultural, forest and fish farms. The above regulation was repealed on 26 July 2013 pursuant to a decision of the Constitutional Tribunal of 3 July 2013 (Journal of Laws 2013, item 842). The Constitutional Tribunal ruled that Art. 126, section 1, point 5 of the Nature Conservation Act violates the provisions of Art. 32, section 1 and Art. 64, section 2 of the Constitution in the part limiting the State Treasury's liability for beaver damage to agricultural, forest and fish farms. As a result, land owners and tenants became able to claim compensation for damage to agricultural equipment, vehicles, residential buildings, farm buildings and fencing caused by the collapse of trees cut by beavers or floods provoked by burrowing animals.

The consequences of this legal amendment are reflected in the results of this study. Beginning from 2014, the number of compensation claims for losses in hydraulic structures, livestock farms and apiaries, and the value of claims in the 'other' category increased dramatically (*Table 1*).

Conclusions

The analysis of the losses sustained due to the activity of the European beaver (*Castor fiber*) in the Region of Warmia and Mazury in North-Eastern Poland in 2009-2016 revealed a gradual increase in the number of damage compensation claims until 2014. The number of compensation claims relating to beaver damage decreased and stabilized after 2014. These findings could indicate that the implemented protective measures are effective. The majority of damages resulting from beavers' negative impact on the human economy were related to the flooding of grasslands, and they accounted for 50% of all beaver-induced losses. The second and third most prevalent types of damage were tree cutting and flooding of tree stands, respectively. Most claims were made in spring and summer months, which suggests that preventive measures should be undertaken mainly during that period, in particular in years characterized by low precipitation.

Abstract. Flooding is one of the environmental stresses that cause a reduction in rice yield and the effect varies between rice varieties. This study aimed to investigate the response of different rice varieties (Hnan Gar, Swarna-Sub1, Bio-6, and Bio-8) to the application of various combinations of nutrient doses (110:0:75, 110:50:0, 110:50:75, 110:80:75 and 110:50:110 of $N:P_2O_5:K_2O$ kg ha^{-1}) under natural submergence conditions in Myanmar. The survival percentages of the different rice genotypes were found not to be significantly varied after 20 days of submergence. Swarna-Sub1 and Bio-8 produced lower underwater shoot elongation, which tended to save energy to be used for later growth, and this resiliency contributed to higher grain yield. Varying the fertilizer application rates produced no significant effect on the percentage of shoot elongation. The Swarna-Sub1 and Bio-8 varieties produced much higher yields compared to Hnan Gar and Bio-6 as a result of a higher filled grain percentage and panicle number m^{-2}. In addition, fertilizing with a dosage of 110:50:110 kg ha^{-1} ($N:P_2O_5:K_2O$) provided better crop performance and higher yield. These results demonstrate that appropriate nutrient management by combining tolerant varieties is able to help in the mitigation of the adverse effect of submergence stress.
Keywords: *survival, shoot elongation, nutrient, submergence, Myanmar*

Introduction

Flooding is one of the abiotic stresses that cause severe rice yield reduction in Southeast Asia and threaten global food security (FAO, 2016; Yin et al., 2017). Flooding can be categorized into water logging and submergence. Water logging is a condition in which excess water is in the root zone, and water covers on the soil surface while it covers partial or whole plant in submergence condition (Nishiuchi et al., 2012; Sasidhran et al., 2017). The most common and damaging type of submergence which can occur during the vegetative growth of rice is short-term complete inundation (generally less than 2 weeks), also referred to as a flash flood. Grain yield in rainfed lowland rice is constantly challenged by this type of flooding (Iftekharuddaula et al., 2016; Pradhan et al., 2019; Gautam et al., 2019), and can result in severe damage and plant mortality if sustained for more than a week. More than 22 million ha of rainfed lowland rice are affected by submergence in Asia (Gautam et al., 2014a). The FAO (2015) estimated that USD 7.8 billion worth of crops were damaged by major floods

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1564315655

around the world between 2003 and 2013. Further, in the so-called rice bowl of Myanmar, the Ayeyarwaddy delta, in which the research reported in this paper was conducted, which covers a total of 2.89 million ha each year, as much as 371990 ha are inundated because of seasonal heavy rainfall and the low lying topography (FAO/WFP, 2016). The extent of damage to rice crops caused by complete submergence during their vegetative stage depends on environmental conditions, such as higher temperatures, greater water turbidity, and lower solar radiation, which worsen the severity of the stress (Das et al., 2009; Ye et al., 2018a, b).

Energy shortage caused by anoxia may lead to reduced nutrient uptake by plants, resulting in the cessation of root elongation, leading to pronounced root injury and death of the tips (Bui et al., 2019; Liu et al., 2015; Singh et al., 2014). Moreover, the plant hormone, ethylene accumulates under submergence conditions because its diffusive escape is slower than the synthesis induced by flooding. Several researchers have reported that ethylene promotes internode elongation, chlorophyll degradation and leaf senescence, causing a reduction in photosynthetic carbon fixation during and after submergence (Ella et al., 2003; Jackson, 2008; Yin et al., 2017). Both the excessive use of energy for shoot elongation and the reduction in carbon fixation during submergence accelerate the depletion of carbohydrate. This leads to the increased mortality of submerged plants (Das et al., 2005; Bui et al., 2019; Ye et al., 2018b). In addition, chlorophyll and non-structural carbohydrate retention after submergence has been found to be positively correlated with plant survival (Gautam et al., 2014a).

The mechanism of plant adaptation to flooding depends on the water regime. In deep water areas, internode elongation is necessary to maintain portions of foliage above the water surface for photosynthesis and oxygen transport. On the other hand, reduced elongation is desirable during flash floods since stem or internode elongation may compete with the plant's maintenance processes for energy, and as a result, reduce the chances of survival during flash floods (Bui et al., 2019; Ram et al., 2002). Das et al. (2005) also reported that the survival of seedlings is negatively correlated with stem elongation.

Although traditional cultivars are moderately tolerant to complete submergence, their yield potential is lower (Singh et al., 2014). Gribaldi et al. (2017) stated that fertilizing with half dose of N and the remaining half at 42 days after planting gave better crop performance and higher yield. Additional potassium and nitrogen application post-submergence has been noted to increase their survival and yield (Dwivedi et al., 2018). However, farmers in flood-prone area usually use only nitrogenous fertilizer and small amount of phosphorus and potassium sources (FAO/WFP, 2016; Soni and Soe, 2016). In view of this, proper nutrient management is vital for achieving better performance from submergence-tolerant rice varieties, and there is limited information available regarding the appropriate application rate of nutrients in specific areas under natural conditions. Thus, the aim of the research reported herein was to establish the most suitable fertilizer application rate to increase the grain yield of rice in flash flood-prone areas along with the most tolerant genotypes.

Materials and methods

This research was conducted between June and October 2015 at Thayaungchaung Seed Farm in the Ayeyarwaddy Region, in lower Myanmar (GPS coordinate: 16° 45' 41.2" N, 94° 44' 54.1"E, *Fig. 1*). The research employed a split plot design with three

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1564315655

replications. The main factor tested was the nutrient application rate, as follows (all figures $N:P_2O_5:K_2O$, kg ha^{-1}): N_1 = control (no fertilizer application), N_2 = 110:0:75, N_3 = 110:50:0, N_4 = 110:50:75, N_5 = 110:80:75 and N_6 = 110:50:110, and the sub-factor investigated was the rice variety, as follows: V_1 = Hnan Gar, V_2 = Swarna-Sub1 (local name Yemyoke Khan 1), V_3 = Bio-6, V_4 = Bio-8. The seeds were soaked for 24 h on 27th June, 2015 and incubated for 24 h. Then, the pre-germinated seeds were carefully sown on raised bed. Care and management of seed beds were done as per standard method. Twenty seven-day old seedlings were transplanted to the main field. The spacing was 20 cm x 15 cm with 2-3 seedlings per hill. Main plots (fertilizer treatments) were separated by bunds of 0.30 m width and 0.30 m height, and there was a 1 m wide alley between the bunds (Pimratch et al., 2015; Atapattu et al., 2018). The plots were subdivided into four unbunded subplots for variety treatments. Each subplot occupied 7.35 m^2. The seed source of the Swarna-Sub1 and Hnan Gar was Thayaungchaung Seed Farm and that of Bio-8 and Bio-6 was Aung Myay Ya Seed Farm. *Table 1* shows the soil properties of the experimental site. All the doses of triple super phosphate ($Ca(H_2PO_4)_2$; source of P) and potassium chloride (KCL; source of K), and 25% of the dose of urea ($CO(NH_2)_2$; source of N) were applied during final land preparation of the main field. Of the remaining N dose, 50% was added at the maximum tillering stage and 25% at the panicle ignition stage.

Table 1. *Mean values of soil characteristics from experimental field (n = 20)*

Characteristics	Mean
Soil pH	4.69
Total N (%)	0.24
Available P (ppm)(Bray)	0.90
Extractable K (meq/100 g soil)	0.45
Soil texture	Silty clay

Meteorological data during the experiment were recorded in Thayaungchaung Seed Farm. Mean daily temperature was from 20 to 37 °C during the experiment. As a result of successive heavy rain and overflow of river, accumulated water in upstream brought to flood the experimental field from 7 to 27 days after transplanting the seedlings (see *Fig. 2*) and flooding occurred for 20 days to a depth of between 35 and 60 cm (*Fig. 3*). After that, complete submergence was not occurred although it rained fairly.

The plant height was measured from the base of the plant to the longest leaf tip before and after submergence at vegetative stage. It was measured from the base of the plant to the tip of longest panicle at harvesting stage. In order to calculate the underwater shoot elongation, the height before submergence was subtracted from the height after submergence and expressed as a percentage of the plant height before submergence. Surviving plants with at least one new leaf were recorded 10 days after the recession of water and the survival was expressed as a percentage of the number of plants before flooding.

Twelve hills from each sub-plot were randomly selected at harvest time for the determination of the plant height and yield components such as filled grain percentage, 1000-grain weight, and spikelets per panicle. The whole sub-plot except two border rows was harvested, threshed, dried (to a 14% moisture content), and the grain yield was recorded and converted to yield of kg per hectare.

Statistical analysis

To test for significant differences in rice growth parameters among the different fertilizer treatments and rice varieties, two-way analysis of variance (ANOVA) was employed using the SPSS statistical package (SPSS Statistics Bass 17.0 for Windows EDU). All tests were performed with a significant level of 95%, and Tukey's honestly significant difference post-hoc test was used to identify the statistically distinct groups.

Results

Effect of submergence and nutrient application on survival and under-water shoot elongation

The Hnan Gar variety showed higher plant survival than the other varieties; however, the differences were not significant ($P > 0.05$). Applying fertilizer at different rates also had no significant effect on survival when the rice experienced flooding to a depth of 35-60 cm starting from 7 days after transplanting for 20 days (*Table 2*). The Hnan Gar variety was taller than the other three varieties tested before submergence ($P < 0.001$). The shortest plant height was observed in Bio-8 although this was not significantly different from the heights of Swarna-Sub1 and Bio-6. The individual effect of fertilizer application and its interaction with the rice variety variable was not significant ($P > 0.05$). A similar trend was noted at desubmergence. All the varieties revealed submergence-induced shoot elongation. However, the Hnan Gar variety showed a significantly higher elongation percentage under water than those of Swarna-Sub1 and Bio-8 ($P < 0.001$). There were no significant differences ($P > 0.05$) in the percentage shoot elongation during submergence based on the various rates of fertilizer application (*Fig. 4*).

Effect of submergence and nutrient application rates on plant height at harvesting time and days to maturity of Hnan Gar, Swarna-Sub1, Bio-6 and Bio-8

Local variety was significantly taller than those of other tested varieties ($P < 0.001$) while the heights of Swarna-Sub1, Bio-6 and Bio-8 were statistically similar. The effect

of fertilizer application rates on plant height can be seen only between the control and the fertilizer applied treatments. The crop duration of Hnan Gar variety was significantly longer than those of other three varieties ($P < 0.001$). The shortest crop duration was occurred in Bio-6, followed by Swarna-Sub1, Bio-8 and Hnan Gar variety (*Table 3*).

Number of panicles per m^2

The local variety, Hnan Gar produced the lowest number of panicles per m^2, which was significantly different from Swarna-Sub1, Bio-6 and Bio-8 ($P < 0.001$). The highest number of panicles per m^2 was observed in Swarna-Sub1, followed by Bio-8, and Bio-6. The effect of different fertilizer application rates on the number of panicles was not significantly different among the treatments.

1000-grain weight

Genotype Bio-6 produced the heaviest thousand-grain weight among the varieties tested ($P < 0.001$). Hnan Gar, Bio-8 and Swarna-Sub1 had similar thousand-grain weights. In the case of the effect of the fertilizer application rate, N_6 produced the heaviest seeds and the difference from other potassium omitting treatments (N_1 and N_3) was significant $P < 0.05$). There were no significant differences in seed weight among treatments N_1, N_2, N_4 and N_5. The interaction effect of fertilizer application and variety produced significant differences, showing that the Bio-8 and Hnan Gar varieties were more responsive and produced heavier grain under the N_6 treatment.

Filled grain percentage

The highest filled grain % was observed in Swarna-Sub1 which was not significantly different from that of Bio-8. On the other hand, the Bio-6 genotype showed the lowest filled grain percentage after submergence ($P < 0.001$). In the case of the fertilizer effect, N_6 produced significantly higher filled grain percentage than those of the potassium

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1564315655

omitting treatments (N_1 and N_3; $P < 0.05$). The filled grain percentages for the N_2, N_4 and N_5 treatments were not significantly different.

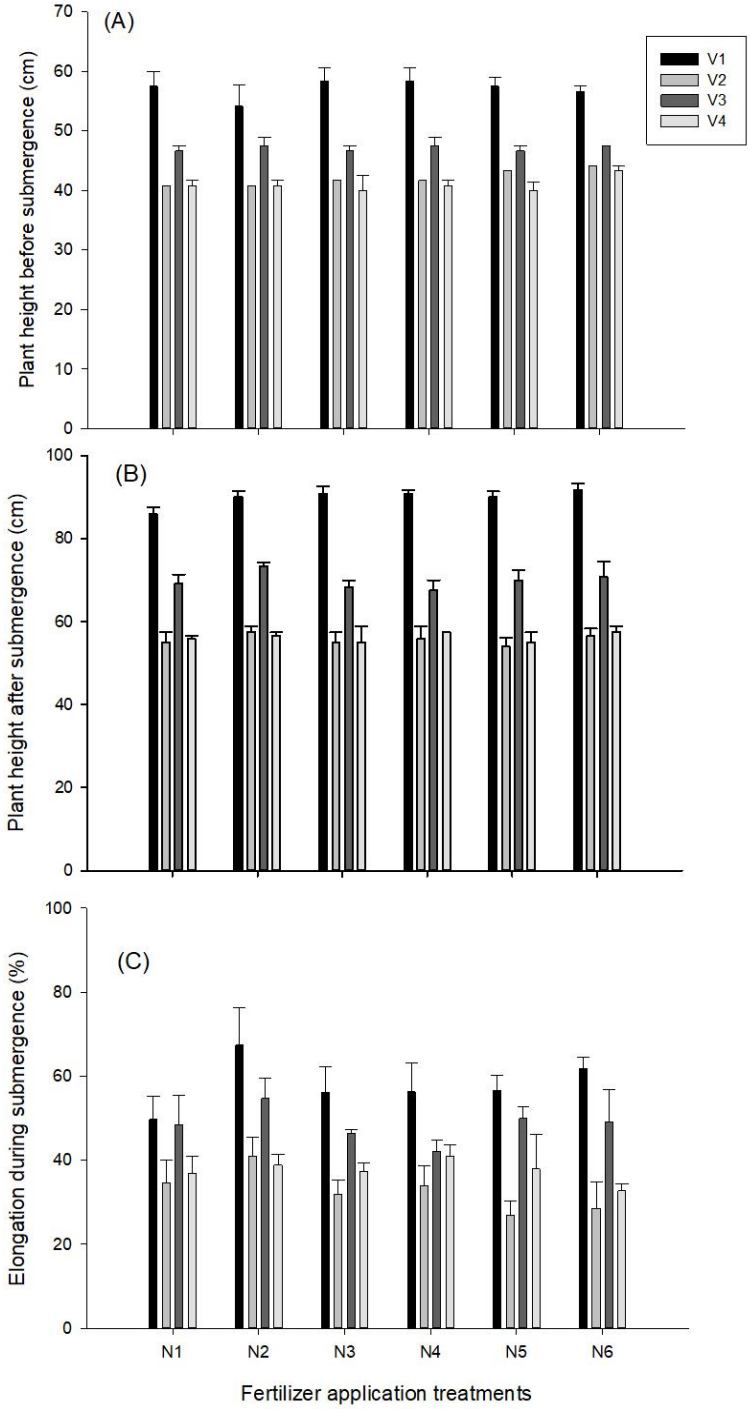

Figure 4. *Responses of combination of nutrient application rates and varieties to plant height (A) before submergence (B) after submergence and (C) elongation percentage during submergence. Data are means ± standard error (SE). Error bars indicate SE. V_1 = Hnan Gar, V_2 = Swarna-Sub1, V_3 = Bio-6, V_4 = Bio-8. N_1 = control, N_2 = 110:0:75, N_3 = 110:50:0, N_4 = 110:50:75, N_5 = 110:80:75, N_6 = 110:50:110; N:P_2O_5:K_2O kg ha^{-1})*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1564315655

Grain yield (t ha^{-1})

The grain yield was higher in Swarna-Sub1 (4.22 t ha^{-1}) and Bio-8 (4.27 t ha^{-1}) than those of Bio-6 and Hnan Gar (2.20 and 2.35 t ha^{-1}, respectively; $P < 0.001$) which were almost half those of the two higher yielding varieties. The maximum grain yield was observed in the N_6 fertilizer treatment, followed by the N_2, N_5 and N_4 treatments. N_3 There were no significant differences in grain yield among the control (N_1) and N_3, N_4 and N_5 treatments. The interaction effect of fertilizer application and variety was not significantly different.

Discussion

The soil test results before the experiment revealed an acid soil with low to moderate content of nitrogen, phosphorus and potassium, suggesting that the optimal application of nutrients could increase performance and yield of the rice plants (*Table 1*). Flash flood or submergence of rice frequently occurs in monsoon rice production and adversely affects crop establishment and grain yield. In combination with varietal development, submergence tolerance of rice could be manipulated through crop management practices (Sarkar et al., 2014). In the present study, the local variety, Hnan Gar and other three varieties: Swarna-Sub1, Bio-8 and Bio-6 were tested to depict their tolerance capacity of inundation under natural condition.

There were no significant differences observed in the plant survival percentages among the different genotypes under varying fertilizer application rates. Minimizing shoot elongation during complete submergence is a desirable characteristic of rice plants, which can save energy for the regeneration of plant growth after the recession of flood water (Bailey-Serres et al., 2010). On the other hand, varieties which produce greater shoot elongation under flooding have poorer ability to recover quickly after inundation (Jackson and Ram, 2003). In this study, Swarna-Sub1 and Bio-8 exhibited lower shoot elongation percentages in comparison with a local variety, demonstrating a quiescence strategy (*Fig. 4*). However, no significant differences in shoot elongation percentages were observed based on the different nutrient application treatments. In a previous study, applying post-submergence N and basal P was found to decrease the extent of shoot elongation and increase plant survival while the application of N, 2 days prior to submergence increased elongation (Gautam et al., 2014b).

Local variety was the tallest among the tested varieties. The response of plant height to fertilizer application was occurred only between the fertilizers applied treatments and no applied one. Regarding with crop duration, submergence tolerant variety that has shorter days to maturity is a desirable character for increasing cropping intensity in rainfed lowland areas (Iftekharuddaula et al., 2016). In the present study, Bio-6 variety can be harvested about one month earlier than Swarna-Sub1 and Bio-8, while the crop duration of Bio-6 was about 45 days shorter than that of local variety (*Table 3*).

The differential performance of cultivars regarding with yield and yield components was observed in this study (*Table 4*). The grain yields of the Swarna-Sub1 and Bio-8 varieties were close to double those of the Bio-6 and Hnan Gar varieties and this resulted from their higher filled grain percentage and grain number per panicle following exposure to inundation. It was observed that Swarna-Sub1 and Bio-8 recovered quickly after the recession of the flood water and they also demonstrated higher tillering capacity even after being submerged for 20 days starting from 7 days after transplanting. The early-developed tillers resulted in a higher filled grain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1564315655

percentage. According to Gribaldi et al. (2017), submergence-tolerant rice not only survives but also grows quickly after submergence. On the other hand, genotypes without *SUB1* have revealed a delay in tiller emergence during the recovery period (Singh et al., 2014).

Appropriate crop and nutrient management increased the grain yield of rice under stagnant flooded condition (Sarangi et al., 2015). In the current experiment, applying fertilizer at the rate of 110:50:110, $N{:}P_2O_5{:}K_2O$ (kg ha^{-1}) produced a higher filled grain percentage and 1000-grain weight leading to a higher grain yield. Similar finding was occurred in the report of Bhowmick et al. (2014), in which, higher seed setting rate contributed to higher grain yield of submergence rice. In addition, filled grain percentage was affected by increase water depth and flooding duration (Zhang et al., 2015). In the present study, the treatments in which no potassium was applied (N_1 and N_3) adversely affected the yield and its components. This result was supported by the finding of Gautam et al. (2016) which stated that adding sufficient K can alleviate the impairment of rice due to submergence stress. Potassium has been found to be involved in many abiotic stress toleration processes and contributes to sustainable crop growth, yield and quality, and also influences plant health and reduces environmental risks (Wang et al., 2013). Potassium was sensitive to water logged condition and it affect negatively to the plant growth in flood-prone area. Application of higher dose of potassium to the rice field increased the survival of rice after submergence (Dwivedi et al., 2017). Furthermore, in a previous study, the basal application of P enhanced for the development of effective tillers (Gautam et al., 2015). Therefore, application of proper nutrient management helps in alleviation of damage caused by submergence.

Conclusions

Higher grain yield was produced by the Swarna-Sub1 and Bio-8 varieties after 20 days of natural flooding, showing their better performance and yield potential. In addition, application of fertilizer at the optimal rate of 110:50:110, $N{:}P_2O_5{:}K_2O$ kg ha^{-1} aided the plants' ability to recover quickly from inundation. The results of this study will be useful in mitigating the adverse effects of inundation on rice grown on low land during the rainy season and increase the potential of submergence-tolerant rice varieties.

It can be concluded that Bio-6 variety can be a good candidate in term of crop duration for promoting cropping intensity while Swarna-Sub1 and Bio-8 varieties are good for offering higher grain output toward global food security. Further studies in different location and rainfall conditions and more seasons of study might be needed.

Abstract. Poyang Lake is the largest freshwater lake in China. Extreme flooding and drought occurred in 1998 and 2011, respectively, resulting in a massive loss of aquatic plants. To compare the effects of flooding and drought on aquatic plants and the subsequent recovery process, field investigations were conducted in Poyang Lake National Nature Reserve (PLN) in 2012 and 2014. Historical data from 1984, 1999, and 2001 were also used for comparison. The results revealed that the species composition of aquatic plants after extreme flooding differed from that after extreme drought. After flooding, the species composition was basically the same as the historical records from 1984 under normal hydrological conditions; however, after drought, *Najas marina* and *N. minor* disappeared. Moreover, the resilience ability of aquatic plants was higher after extreme flooding than following extreme drought. The dominant species also differed after the two hydrological events. *Vallisneria* spp. and *Hydrilla verticillata* were first to recover after flooding, while *Vallisneria* spp. and *Nymphoides peltata* recovered fastest after drought. Since extreme drought is more damaging to aquatic vegetation than extreme flooding, we suggest that lakes in the Yangtze River basin aim to maintain a minimum water level through rational regulation of water resources.
Keywords: *macrophytes, extreme hydrological events, ecological restoration, resilience ability, regulation*

Introduction

Natural interference is an essential component of most intact ecosystems (Lytle and Poff, 2004). Flooding and drought, as the main disturbances affecting freshwater ecosystems, play important roles in regulating aquatic plant diversity and population size across a range of spatial and temporal scales (Jentsch et al., 2007; Lake, 2007). Under natural conditions, aquatic plants have adapted to periodic flooding and drought through morphological or life-history strategical changes (Lytle and Poff, 2004). However, anthropogenic disturbances (such as overuse of water resources, and building of sluices and dams) and climate change are severely affecting the periodic rhythms of flooding and drought, increasing the occurrence frequency and magnitude in many freshwater ecosystems (Meehl et al., 2007; Miao et al., 2009). Non-periodic high-intensity extreme hydrological events can severely destroy the ecosystem structure of wetland environments, altering the natural habitat conditions required by aquatic plants (Li et al., 2004; Lake, 2007). However, studies on aquatic plants in freshwater lakes tend to focus on the effects of water depth, rates of water level change, fluctuation amplitude, and fluctuation duration, with little known about the impact of extreme hydrological events such as flooding and drought, and subsequent restoration and succession.

Poyang Lake (N: 28°22′-29°45′, E: 115°47′-116°45′) is the largest freshwater lake in China, located on the south bank of the Yangtze River in Jiangxi Province. It is an internationally important wetland, and one of three river-connected lakes in the middle and lower Yangtze River. Poyang Lake mainly collects water from five rivers, the Ganjiang, Xiushui, Raohe, Fuhe and Xinjiang River, flowing into the Yangtze River in Hukou County (*Figure 1*). In the flooding season, when the water level in the Yangtze River is higher than that of Poyang Lake, water flows back into the lake. The perennial average water level of Poyang Lake is 12.86 m above mean sea level (amsl), but the annual variation can exceed 10 m (Li et al., 2008). The surface area also differs significantly between flooding and drought periods, from 2933 km^2 at a flood water level of 21.69 m amsl to only 146 km^2 at a water level of 10.20 m amsl (Wang and Dou, 1998). Because of this unique hydrological rhythm, Poyang Lake consists of diverse habitats with high species diversity, and enormous ecological and service functions. However, due to the impact of climate change and the Three Gorges Reservoir, extreme hydrological events have occurred frequently during the past few decades (Xu et al., 2014), the most serious of which were the extreme floods of 1998 and extreme drought of 2011.

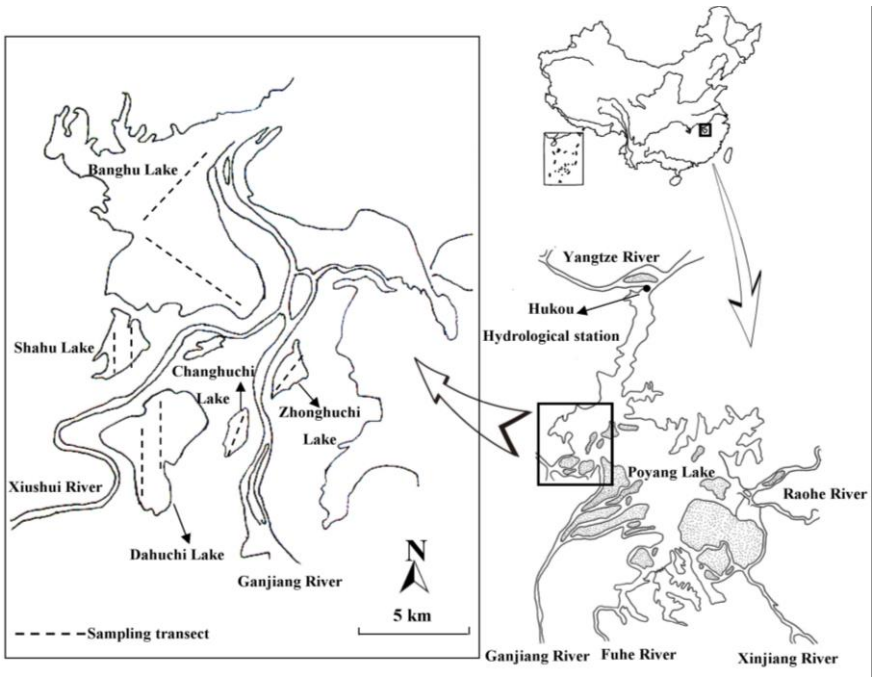

Figure 1. *Sampling transects in PLN*

Poyang Lake National Nature Reserve (PLN) is located northwest of Poyang Lake, and is mainly composed of sub-lakes with differing mean lake bottom elevations. In this study, we selected five sub-lakes (*Figure 1*) in PLN and, combined with historical data, determined the following: 1) The difference in community structure and resilience ability of aquatic plants in PLN following extreme flooding and extreme drought; and 2) Differences in the resilience ability of aquatic plants in the five sub-lakes with increasing mean lake bottom elevation. Since flooding and drought have differing effects on aquatic plants, the former largely affecting aboveground parts and the latter acting both aboveground and underground, we hypothesized that the community

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1565715668

structure would also differ after each hydrological event, with greater resilience after flooding. In addition, since under normal circumstances, increasing distribution elevation gradually weakens the impact of flooding, while increasing that of drought, we further hypothesized that aquatic plants in sub-lakes with a higher mean lake bottom elevation would show stronger resilience ability after flooding than drought. The results of this study not only enrich our understanding of extreme hydrological events, but also have significant implications for the restoration of aquatic plants in other lakes with similar situations.

Materials and methods

Research area

PLN (N: 28°22′-29°45′, E: 115°47′-116°45′) was established in 1983 and listed in the International List of Wetlands in 1992, forming the main habitat for a number of rare animals and plants (Ji et al., 2007). It has a subtropical monsoon climate with an average annual temperature of 17.1°C and average annual rainfall of 1426.4 mm. The protected area of PLN covers 224 km^2, and is mainly composed of nine sub-lakes with differing mean lake bottom elevations (*Figure 1*, *Table 1*). When the water level in the main area of Poyang Lake is higher than 16.0 m amsl, all these sub-lakes merge into Poyang; however, when the water level is less than 12.92 m amsl, these sub-lakes gradually emerge and become independent lakes (Li et al., 2004).

Table 1. *Area, bottom elevation and sampling transects in the five sub-lakes in PLN. Bottom elevation data was obtained from Lu and Cheng (2003). All other data were from Zhang (2013)*

Item	Banghu	Zhonghuchi	Changhuchi	Dahuchi	Shahu
Area (km^2)	73	6	7	30	14
Maximum length (km)	10.08	3.84	3.70	7.43	4.46
Maximum width (km)	8.04	1.82	2.22	4.36	3.48
Mean water depth (m)	0.46	1.07	0.50	0.70	0.45
Bottom elevation (m)	12.6	13.5	14.5	14.7	15.1
Total nitrogen content of the substrate (mg/g)	0.68	1.08	1.17	0.68	1.33
Total phosphorus content of the substrate (mg/g)	0.68	0.66	0.74	0.62	0.92
Organic matter content of the substrate (%)	20.88	28.93	28.94	19.88	33.93
Number of sampling transects (sites)	2 (12)	1 (10)	1 (4)	2 (11)	2 (11)

In 1998 and 2011, Poyang Lake experienced the most serious flooding (Min et al., 2006) and drought (Li et al., 2019) events in nearly 60 years, respectively (*Figure 2*). In the summer of 1998, the water level of Poyang Lake reached a maximum of 22.54 m, and remained higher than warning level for 58 consecutive days. Following this extreme hydrological event, almost all aquatic plants in the nine sub-lakes were reported extinct (Li et al., 2004). Subsequently, in the spring of 2011, Poyang Lake remained at a consistently low level, causing all nine sub-lakes (except Banghu Lake) to dry up, seriously damaging the aquatic plant populations.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1565715668

Sampling method and data analyses

In July 2012 and June 2014, following the extreme drought of 2011, analysis of the aquatic vegetation in five sub-lakes was carried out; namely, Banghu, Dahuchi, Zhonghuchi, Changhuchi and Shahu lakes. According to differences in lake area (*Table 1*), 1-2 sampling transects were set in each sub-lake, and in each sampling transect, 4-10 sampling sites were established (*Figure 1*). Aquatic plant populations were quantitatively sampled using a scythe three times in each site. Samples were then cleaned and superfluous water removed before weighing using an electronic balance to determine wet biomass. In this study, aquatic plants only included submerged and floating macrophytes, not hygrophytes and emergent macrophytes.

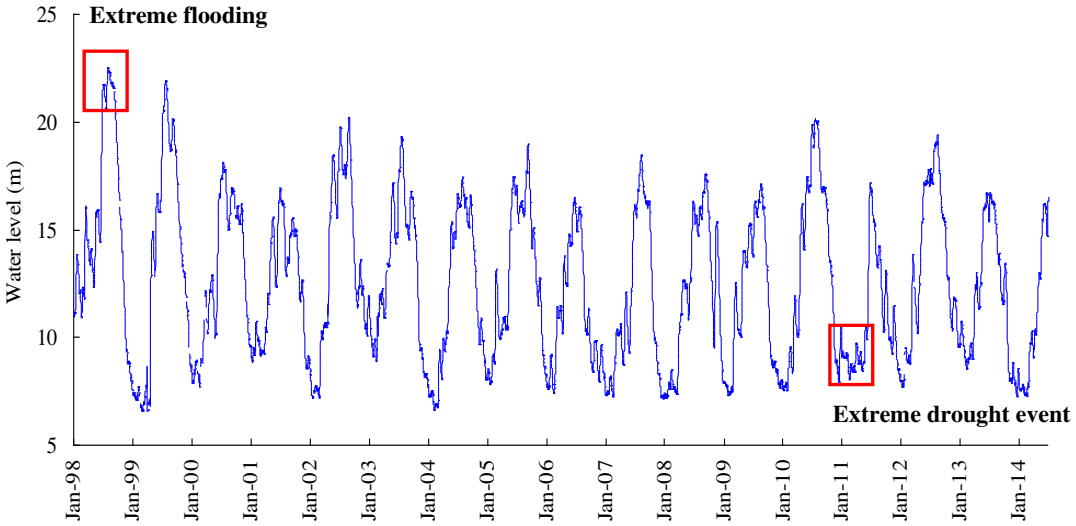

Figure 2. *Water level fluctuations in Poyang Lake from 1998 to 2014*

Hydrological data for 1998 to 2014 were obtained from Hukou Hydrological Station of Poyang Lake and from the Hubei Province Water and Rain Information Inquiry System (http://219.140.162.169:8800/rw4/report/fa02.asp). Aquatic vegetation data for PLN in 1984 (normal hydrological year), 1999 and 2001 (after flooding), and 2012 and 2014 (after drought) were used for comparative analyses. Data for 1984 were obtained from Guan et al. (1987) and, since the scope of his investigation covered entire Poyang Lake, were corrected to represent PLN area. Data for 1999 and 2001 were derived from Li et al. (2004), and corrected by removing the hygrophyte and emergent plant data. All the five field investigations were conducted during summer to early autumn, and the sampling methods were similar. Therefore, the results of different investigations are comparable and can reflect the actual situation of aquatic plants in PLN in different periods. One-way analysis of variance (ANOVA) was used to analyze the difference of species number and biomass among 1999, 2001, 2012, and 2014. Before conducting the ANOVA, the normality and homogeneity of the variances were tested, and transformed if necessary to meet the assumption of ANOVA. Post-hoc multiple comparisons were conducted to examine the differences between groups using Tukey's HSD (Honestly Significant Difference) multiple comparisions. Due to the lack of occurrence frequency data for each aquatic plant in PLN at different times, this study used relative biomass to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1565715668

calculate the dominance of each species. The resilience ability of each aquatic plant in different years following each extreme hydrological event was determined using the following formula (*Eq.1*):

$$R_i = \frac{B_i}{B_h} \times \frac{N_i}{N_h} \quad \text{(Eq.1)}$$

where R_i indicates the resilience ability in the i-th year, B_i indicates the aquatic plant biomass in the *i*-th year, B_h indicates historical data of aquatic plant biomass in a normal hydrological year, N_i indicates the species number of aquatic plants in the *i*-th year, and N_h indicates historical data of species number in a normal hydrological year. Both B_h and N_h values in this study represent historical data from 1984. All data analyses were carried out using SPSS version 13.0.

Results

Species composition

In 2012 and 2014, the species composition in PNL was the same, with eight genera and eight species (*Table 2*). However, in 2012, all species, except *Vallisneria* spp. were only sporadically found. Meanwhile, in 2014, the occurrence frequency of *Nymphoides peltata* and *Trapa* spp. markedly increased. Compared to the normal hydrological year of 1984 (*Table 2*), the species composition was notably different after the droughts of 2012 and 2014, with the disappearance of *Najas marina* and *N. minor*, and emergence of *Charaphyte*. Meanwhile, the species composition following the flood in 2001 was basically the same as that in 1984, with the emergence of only one species, *Charaphyte*.

Table 2. *Species composition and biomass (g/m^2) in PLN*

Species	1984	1999	2001	2012	2014
Charaphyte		0.1	43.9	0.1	0.2
Vallisneria spp.	840.3	159.8	944.5	58.9	100.8
Hydrilla verticillata	514.7	139.3	742.7	8.4	38.6
Potamogeton malaianus	796.3	0.5	25.26	2.4	2.3
Potamogeton pectinatus		8.2			
Najas minor	119.7	0.1	12.4		
Najas marina	11.3		1.0		
Nymphoides peltata	134.7	1.0	0.7	39.5	119.8
Trapa spp.	93	18.0	31.7	9.3	100.1
Ceratophyllum demersum	307.7		0.8	0.8	34.8
Myriophyllum pectinatus	84.3		34.8	0.1	2.5

In 1999, after the flood in 1998, the number of aquatic plant species in Banghu, Zhonghuchi, Changhuchi, Dahuchi and Shahu lakes was 3, 5, 3, 3 and 4, respectively (*Figure 3*). In 2001, the species number in all sub-lakes, except Zhonghuchi, and the entire PLN region increased significantly. In 2012, after the drought of 2011, the number of aquatic plant species in the five sub-lakes was 7, 1, 3, 2 and 3, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1565715668

Meanwhile, in 2014, an obvious increase in species number was observed in Zhonghuchi, Changhuchi, and Shahuchi Lakes only (*Figure 3*). However, ANOVA analysis showed that the species number did not have significant difference among the four years ($F = 1.327$, $P = 0.300$).

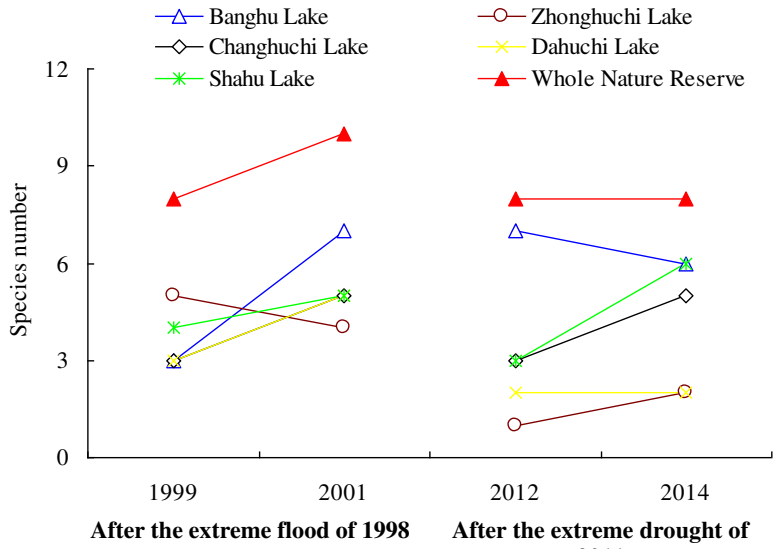

Figure 3. *Changes in species numbers after extreme flooding (1998) and drought (2011) in five sub-lakes in PLN*

Biomass

The biomass of aquatic plants in PLN was low in 1999 and 2012 at 327 and 120 g/m^2, respectively, while in 2001 and 2014, biomass was restored to 1838 and 391 g/m^2, respectively, although both values were obviously lower than that in 1984 (2902 g/m^2) (*Figure 4*). ANOVA analysis indicated that the biomass has significant difference among the four years ($F = 8.545$, $P = 0.001$), and the biomass in 2001 was significantly higher than in the other three years. Of the five sub-lakes, Banghu and Zhonghuchi lakes recovered fastest after flooding, reaching a biomass of 2454 and 2534 g/m^2 in 2001, respectively. In 2014, following drought, the biomass of aquatic plants in each sub-lake was low, with a maximum value of 782 g/m^2 in Zhonghuchi Lake (*Figure 5*).

Vallisneria spp. and *Hydrilla verticillata* recovered fastest after flooding, and in 2001, their biomass exceeded historical levels (*Table 2*). Meanwhile, *Vallisneria* spp. and *Nymphoides peltata* recovered fastest after drought, but their biomass remained lower than historical levels (*Table 2*). *Potomageon malaianus* had the highest historical biomass, but recovered slowly after both drought and flooding, and had a very low biomass.

Dominant species

Differences in the dominant species in PLN were observed between years (*Figure 6*). In 1984, the main dominant species were *Vallisneria* spp. and *P. malaianus*, while in 1999 and 2001 *Vallisneria* spp. and *H. verticillata* were dominant. In 2012, the dominant species were *Vallisneria* spp. and *N. peltata*, while in 2014, *Trapa* spp. as well as *Vallisneria* spp. and *N. peltata* dominated.

DOI: http://dx.doi.org/10.15666/aeer/1706_1565715668

Resilience ability

In 1999, 2001, 2012 and 2014, the resilience ability of aquatic plants in PLN was 0.10, 0.70, 0.04 and 0.12, respectively. Aquatic plants apparently showed greater resilience ability after flooding than drought. No obvious differences in resilience ability were observed with increasing bottom elevation of the sub-lakes (*Figure 7*). The largest resilience ability was observed in Zhonghuchi (0.14) and Banghu lakes (0.66) in 1999 and 2001, respectively. Meanwhile, in 2012 and 2014, Banghu Lake showed the largest resilience ability at 0.05 and 0.11, respectively.

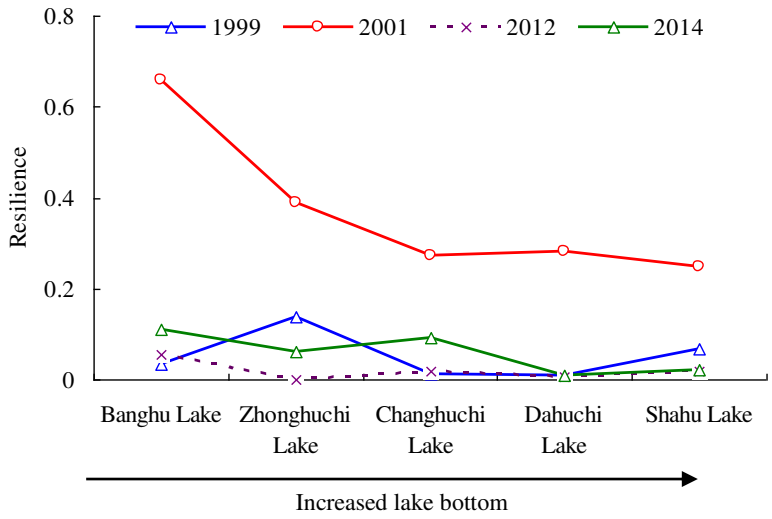

Figure 7. *Resilience ability of aquatic plants in each sub-lake in PLN*

Discussion

The increasing frequency and magnitude of extreme hydrological events are highlighting the negative effects on freshwater ecosystems (Jentsch et al., 2007). The results of this study suggest that drought has a greater impact than flooding on the species composition of aquatic plants. In PLN, the species composition after flooding was basically the same as that in 1984, while after drought, *N. marina* and *N. minor* disappeared. Both species are annuals, germinating in March-April, flowering and fruiting in July and August, and mainly propagated by seed. The aboveground stems are fragile and easily broken in turbulent water (Chen, 1984). Moreover, their roots are largely fibrous, and grow poorly in soil with high viscosity (Handley and Davy, 2005; Hoffmann et al., 2013). The sediment is mainly composed of clay in PLN (Ding et al., 2014), and the water level fluctuations are extremely large. These two species therefore tend to have only limited distribution. Before the summer flood in 1998, a small number of *Najas* plants may have completed flowering and fruiting, thereby supplementing the seed bank, aiding survival after the flood, despite the reduction in biomass. However, following the drought in spring 2011, most *Najas* seedlings were probably killed, preventing replenishment of the seed bank and resulting in extinction.

The changes in species number in the five sub-lakes may also suggest that drought has a more damaging effect on aquatic plants. After the flood in 1999, the species number in all sub-lakes, except Banghu, was higher than after the drought in 2012

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1565715668

(*Figure 3*). Banghu Lake did not completely dry up during the drought of 2011; therefore, the species number remained high in 2012. Meanwhile, *Charaphyte* emerged after both flooding and drought, although its dominance was very low. Studies in a number of temperate lakes suggest that *Charaphyte* is not only a pioneer species in the restoration of aquatic plants, but one of the main dominant species (Blindow, 1992; van den Berg et al., 1999). These findings suggest that the recovery process of aquatic plants in subtropical lakes is different from that in temperate lakes. Although *Charaphyte* can be a pioneer species under low light conditions, it has no real roots and is easily uprooted by wind and waves (Havens et al., 2004). Thus, since the water level fluctuations are frequent and extreme in PLN, it is thought to be difficult for *Charaphyte* to establish in large numbers.

The results of this study also suggest that the resilience ability of aquatic plants is higher after flooding than drought. The resilience ability was 0.10 and 0.70 in 1999 and 2001, and 0.04 and 0.12 in 2012 and 2014, respectively. This is thought to be related to the differing effects of flooding and drought. Although flooding destroys the aerial parts of aquatic plants, most underground parts remain; however, drought can have adverse effects both aboveground and underground. Nevertheless, compared with 1984 (Guan et al., 1987), the biomass after both events was much lower than the historical level of 2902 g/m^2, suggesting that full recovery is difficult in the short term. However, no obvious differences in the restoration of aquatic plants were observed with increasing mean lake bottom elevation of the five sub-lakes. Although lake bottom elevation can significantly affect infiltration between sub-lakes and adjacent water bodies, the sediment type and distance from adjacent water also play important roles (Van Geest et al., 2005). In general, sub-lakes with sandy sediment and close to the main area of Poyang Lake experience larger water level fluctuations. Moreover, human disturbances, such as fishing during the flooding season, also affect the restoration of aquatic plants in different sub-lakes.

Obvious differences in the recovery rate of different species after flooding and drought were observed. *Vallisneria* spp. and *H. verticillata* were fastest to recover after flooding. Li et al. (2004) suggested that this is largely related to asexual reproduction. That is, although flooding caused the disappearance of aboveground parts, it had little effect on asexual propagules in the lake sediment; therefore, species possessing specialized propagules or underground rhizomes recovered rapidly. Of the nine aquatic plants that existed in the normal hydrological year of 1984, *Vallisneria* spp., *H. verticillata* and *P. malaianus* were not only rich in biomass, but also possess specialized vegetative propagules or underground stems, aiding recovery after flooding. However, in the 1999 and 2001 field surveys, the *P. malaianus* biomass was extremely low after flooding, possibly due to its small population size before flooding (Cui et al., 2000). The first species to recover after drought were *Vallisneria* spp. and *N. peltata*, but the biomass of both species was lower than historical levels. This was possibly due to the effect of drought on underground parts, which is also related to their burial depth. *Vallisneria* spp. and *N. peltata* could therefore be considered pioneer species, with recovery aided by the deep burial depth of their underground parts. In line with this, studies suggest that the burial depth of *Vallisneria* spp. winter buds can reach 30 cm, while that of *P. malaianus* underground stems is only 10 cm (Li et al., 2005). In addition, *N. peltata* is an amphibious species that is more resistant to drought than submerged plants (Brock and Casanova, 1997), providing further advantages for the establishment of its dominant position.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1565715668

The analyses of dominant species further suggest that extreme hydrological events also have a significant impact on succession. As part of Poyang Lake, PLN experiences large water level fluctuations, and therefore, the species composition and dominant species are relatively simple. In 1984, the dominant species were *Vallisneria* spp. and *P. malaianus* (Guan et al., 1987), both of which have flexible aboveground parts that allow them to adapt to fluctuating water levels and strong wave disturbances. After flooding, *H. verticillata* replaced *P. malaianus* as one of the main dominant species; however, due to the lower burial depth of its asexual propagules, its dominance status was replaced by *N. peltata*.

The results of this study also suggest that the resilience ability of aquatic plants is higher after flooding than drought. Nevertheless, compared with 1984 (Guan et al., 1987), the biomass after both events was much lower than the historical level of 2902 g/m^2, suggesting that full recovery is difficult in the short term. As one of the most important wetlands in the world, Poyang Lake plays important roles in biodiversity conservation. With the increasing occurrence frequency and magnitude of extreme hydrological events in Poyang Lake basin (Ye et al., 2014), it is therefore necessary to implement effective measures to prevent further degradation of aquatic vegetation. In the future, experiments should be carried out to determine the tolerance thresholds of dominant aquatic plants such as *Vallisneria* spp. and *P. malaianus* in response to drought and flooding to provide a quantitative basis for the recovery of aquatic plants. Besides, compared with flooding, drought had more destructive effects; however, it is relatively easier to control. Strengthening the regulation of water resources should be considered to reduce the adverse effects of drought on dominant aquatic plants (such as *Vallisneria* spp.). At present, there are a number of small water conservation projects in the Poyang Lake basin, with plans to build Poyang Lake dam in the foreseeable future, which will further help regulate water levels in PLN. This study also suggests that aquatic plants are generally slow to recover after extreme hydrological events, highlighting the need for artificial methods aimed at supplementing seed banks or propagules to promote recovery.

Conclusion

The species composition and subsequent recovery process of lake plants after extreme flooding and drought are obviously different in the PLN. In general, extreme drought is more damaging to lake plants than extreme flooding. Therefore, the lakes should maintain a minimum water level in dry year through rational regulation of water resources to prevent the degradation of lake plants. Besides, the resilience ability of aquatic plants was higher after extreme flooding than following extreme drought; however, artificial methods aimed at supplementing seed banks or propagules are also needed to promote the recovery of aquatic plants in a short time. Finally, it is highly recommened that future researches carry out more studies to determine the tolerance thresholds of dominant aquatic plants (such as *Vallisneria* spp. and *P. Malaianus* in this study) in response to drought and flooding, thus providing a quantitative basis for the recovery of aquatic plants.

Abstract. A research was conducted on runoff and sediment yield variations under different precipitation and land-use conditions was performed based on the Soil and Water Assessment Too1 (SWAT) model using China Meteorological Assimilation Driving Datasets (CMADS). The observation data was collected in the Fangxi Lake Watershed, a typical irrigation district in the Poyang Lake basin of China. The results indicated a positive correlation between annual runoff and precipitation, as well as between annual sediment yield and precipitation. The correlation coefficient of annual runoff yield and precipitation was 0.94, whereas that of annual sediment yield and precipitation was 0.85. The monthly yield of runoff and sediment of a typical year (2004) was simulated. The runoff and sediment yields had the same tendency of changes with precipitation variations. Differences were found among the per unit area yield of total runoff from different land-use types in 2004. The order from highest to lowest was paddy land > rural residential land > dry land > water area. For the per unit area yield of total sediment from different land-use types, the order from highest to lowest was rural residential land > dry land > water area > paddy land. The results of this study might provide guidance for soil erosion control in irrigation districts.
Keywords: *land-use, precipitation, runoff and sediment yield, SWAT model, CMADS*

Introduction

The Soil and Water Assessment Too1 (SWAT) model is one of the distributed hydrological models. It is a physically based model developed by the Blackland Research and Extension Center and the United States Department of Agriculture – Agricultural Research Service to predict the effect of land management practices on water, sediment, and agricultural chemical yields in large, complex basins with varying soil types, land use, and management conditions over long periods of time (Gassman et al., 2007). The SWAT model can respond to the changes in land use, weather, topography, and soil data. The effectiveness and applicability of this model has been validated by numerous studies worldwide (Binh et al., 2011; Daggupati et al., 2018; Hao and Cheng, 2006; Himanshu et al., 2017; Koua et al., 2013; Lam et al., 2010; Loliyana and Patel, 2018; Santhi et al., 2006; Zettam et al., 2017).

Runoff and sediment simulation is one of the most basic and important functions of SWAT model. The SWAT model has been improved by numerous investigators by combining it with the local watershed. Some researchers demonstrated the applicability

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1566915685

of SWAT model for runoff and sediment simulation under different temporal and spatial scales and different hydrogeological conditions in the Mississippi River basin and other river basins in the United States (Arnold et al., 1999; Green and Griensven, 2008). Several studies analyzed different aspects of SWAT model simulation, such as the correlation between runoff and precipitation and the impact of land use on sediment and non-point source pollution in other countries and districts (Bärlund and Kirkkala, 2008; Di Luzio et al., 2005; Lee and Kim, 2017; Min and Shibata, 2016; Panagopoulos et al., 2011; Weber et al., 2001).

Most of the studies were based on a natural watershed. However, huge differences were found between irrigation district and natural watershed on account of intensive human activities on land cover and hydrological cycle system in irrigation districts. The SWAT model has been improved with the practical situation of irrigation district to enhance the simulation accuracy. Some researchers (Dai and Cui, 2009a, b; Dechmi et al., 2012; Li et al., 2014) improved the SWAT model based on specific irrigated watershed considering the water cycle in paddy land, irrigation, and drainage management, and other irrigation channel management actions. The results indicated that the improved SWAT model could show more accurate and better simulation performance than the original SWAT model.

Although the SWAT model has been widely used across the world, it is difficult to apply in areas where meteorological data are scarce (Meng et al., 2018). Therefore, the meteorological data is needed for runoff and sediment simulation in a watershed with scarce data (Meng et al., 2016). The China Meteorological Assimilation Driving Datasets for the SWAT model was developed by Meng from the China Institute of Water Resources and Hydropower Research (IWHR). It covers the entire East Asian region between 2008 and 2014 (Meng and Wang, 2017). Some studies demonstrated that the SWAT model yielded better results for runoff simulation with CMADS (Liu et al., 2017, 2018). Meng et al. also used three different datasets to simulate runoff in the Heihe basin, and the results indicated that the simulation accuracy of the CMADS was higher than that of other datasets (Meng et al., 2016).

The SWAT model and CMADS data were used in the present study to simulate the runoff and sediment yield under different precipitation and land-use conditions in the study area, a small irrigated plain district of Poyang Lake region. The correlation between runoff and precipitation, as well as between sediment and precipitation, was investigated. In addition, the diversities of runoff yield and sediment yield from different land-use types were simulated and analyzed. The results obtained in this study might provide guidance for soil and water conservation and land-use management of the study area as well as other irrigation districts of Poyang Lake region.

Materials and methods

Study area

The Fangxi Lake Watershed is located in the southwestern region of Poyang Lake basin, which is in the southeastern of China, between 116°0’E and 116°5’E and between 28°29’N and 28°33’N, covering an area of 3080.20 ha (*Fig. 1*). The Fangxi Lake Watershed features a subtropical monsoon climate and has four distinct seasons, where summers are warm with abundant precipitation whereas winters are cold and dry with little precipitation. The multi-year average precipitation is 1624.4 mm per year, and the annual rainy days are about 147.3 days. The annual average temperature is 17.6 °C.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1566915685

The main soil type in this watershed is paddy clayey soil, which occupies 90.69% of the total area. It includes three subclasses: yellow clayey soil (76.52%), lake clayey soil (12.38%), and sand clayey soil (1.79%). The main land-use types in the study area are paddy land (79.27%), water area (12.63%), rural residential land (6.11%), dry land (1.71%), forest and grass land (0.24%), and bare land (0.04%). The main crop is rice and the double-cropping paddy area occupies approximately 95% of the total cultivated area. Other crops include watermelon, muskmelon, garlic, and fragrant-flowered garlic.

The area has 17,404 permanent residents, and the main types of livestock and poultry industry are ducks, chickens, pigs, cattle, and sheep. Aquaculture is highly developed because of its abundant water resources in this area. The aquaculture area occupies 30% of the water area.

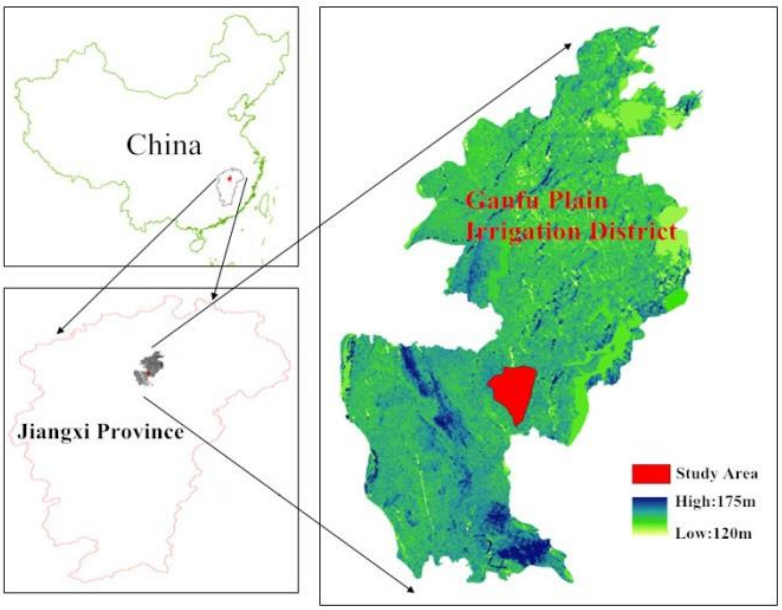

Figure 1. *Location of the study area*

Data collection

The distributed model based on the SWAT model requires spatial and attribute data. Furthermore, the spatial data includes digital elevation model (DEM), water distribution map, and land-use and soil maps. The attribute data includes the physical and chemical properties of soil, meteorological and hydrological information (including rainfall, temperature, wind speed, relative humidity, and net solar radiation.), observed runoff, and farmland management measures. The sources and main types of data collected are shown in *Table 1*. The DEM, land-use map, and soil maps are shown in *Figure 2a-c.*

The simulation accuracy of SWAT model depends largely on the description of the watershed characteristics of the input data. For runoff and sediment simulation, high-precision meteorological data can accurately describe the meteorological characteristics of the watershed and lead to better simulation results (Chen et al., 2016). Only one precipitation station exists near the study area. The China Meteorological Assimilation Driving Datasets for the SWAT model version 1.1 (CMADS V1.1) was introduced in this study to get the entire meteorological data for the study area. The climate data used in this study were downloaded from the official website (http://www.cmads.org).

Table 1. *Sources and types of data collected for the SWAT model*

No.	Data type		Temporal/spatial resolution	Source
1	Spatial data	Digital elevation model (DEM), 25 m	Grid format, 30 m/grid	Geospatial Data Cloud of China (http://www.gscloud.cn/)
2		Water distribution map	Shape format	Drawn by the authors of this manuscript based on the water distribution of the study area
3		Soil map	At the scale of 1:100,000, compiled in 2009	Nanchang County Agricultural Bureau
4		Land-use map	At the scale of 1:100,000, compiled in 2009	Computer Network Information Center of Chinese Academy of Science (http://www.cnic.cas.cn)
5	Attribute data	Meteorological data, daily	Daily data	China Meteorological Assimilation Driving Datasets for the SWAT Model (CMADS) (calculated temperature, solar, wind data between 2008 and 2014), Jiangxi Irrigation Experimental Center (observed precipitation data between January 1, 1978 and November 30, 2011)
6		Hydrological data	Daily runoff yield	Jiangxi Irrigation Experimental Center (observed data between May to October in 2011)
7		Farmland management measures	Daily data during crop growth period	Field investigation based on the study area (observed data in 2011)

The farmland management measures are also important information for runoff and sediment yield research in the study area. Double-cropping rice is cultivated in most of the study area. The growing period of early rice is April to July and that of late rice is July to October. Irrigation and drainage measures of double-cropping rice are gained by farm surveys. The surveyed data are shown in *Table 2*.

Table 2. *Irrigation and drainage measures*

	Date	Measures
Early rice	April 14	Irrigation, 50 mm
	April 23	Irrigation, 50 mm

SWAT model setup

Model construction

In this study, the spatial data in *Table 1* were loaded into the SWAT model, and the distributed hydrological model based on the study area was constructed. Nine sub-basins were calculated based on the DEM and river network distribution of the study area, and then 51 hydrological response units (HRUs) were subdivided based on the spatial distribution of the land-use type, soil type, and slope. The results are shown in *Figure 3* and *Table 3*.

The meteorological data were loaded into the SWAT model after HRU subdivision. Then, a distributed hydrological model based on the SWAT model was constructed in the study area.

Table 3. *Area of sub-basins and HRUs in the study area*

Sub-basins	Number of HRUs	Area (ha)	Area percentage (%)
1	4	253.59	8.23
2	8	685.23	22.25
3	6	122.63	3.98
4	6	571.78	18.56
5	7	127.43	4.14

7	10	105.14	3.41
8	5	232.73	7.56
9	3	358.12	11.63
Total	**51**	**3080.20**	**100**

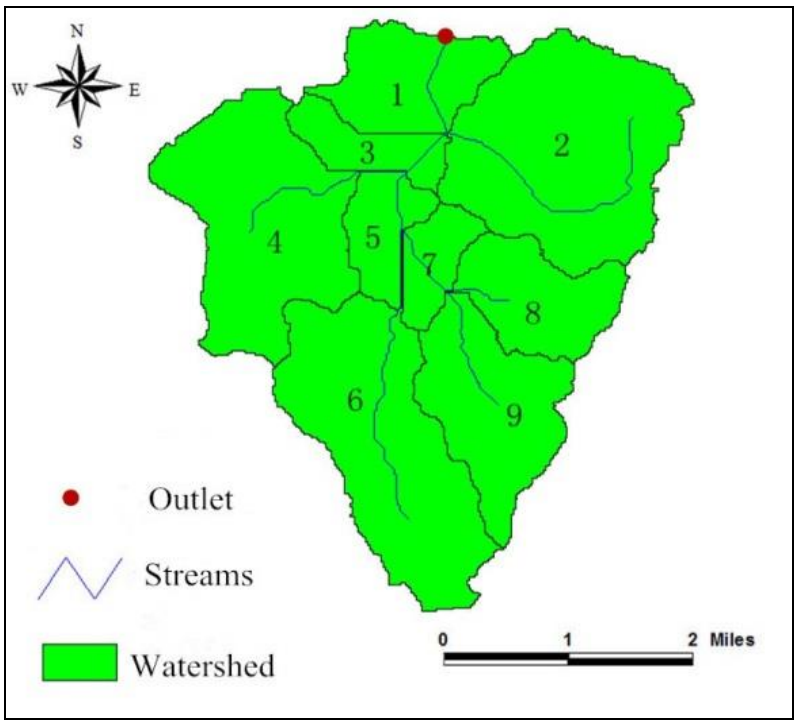

Figure 3. *Sub-basins of the study area*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1566915685

Model calibration and evaluation

Model calibration was based on the optimization of the parameter values by adjusting the simulated runoff and sediment yield data at the outlet of the basin with observed data. That is to say, the parameters of runoff and sediment yield in the SWAT model were adjusted to a reasonable range to get accurate simulation results in this study.

Some parameters called sensitive parameters can have an evident impact on the results of model simulation. These parameters were adjusted to a reasonable value for better simulation results. On the basis of some studies on the sensitivity analysis of SWAT model (Me et al., 2015; Yang et al., 2013), the main sensitive parameters of runoff and sediment yield adjusted in this study are shown in *Table 4*.

Table 4. *Main parameters of runoff and sediment yield in the SWAT model*

	Parameter	Description
Runoff parameter	CN_2	SCS runoff curve calculating parameter
	ESCO	Soil evaporation compensation coefficient
	EPCO	Crop transpiration compensation coefficient
	SOL-AWC	Soil available water capacity
	REVAPMN	Water table threshold for shallow groundwater re-evaporation
	GW-REVAP	Groundwater re-evaporation coefficient
	GWQMN	Runoff coefficient of shallow groundwater
Sediment parameter	USLE_C	Minimum value of vegetation coverage factor
	USLE_P	Soil and water conservation factor of USLE equation
	USLE_K	Soil erosion coefficient of USLE equation
	CH_EROD	Channel scour coefficient
	CH_COV	Channel coverage coefficient
	SPCON	Linear coefficient of sediment transport
	SPEXP	Index coefficient of sediment transport

The relative error (R_e), correlation coefficient (R^2), and Nash–Sutcliffe efficiency (Ens) were used to evaluate the model performance. The formulas used for calculating these indexes are as follows:

$$R_e = \frac{Q_p - Q_0}{Q_0} \times 100\% \quad \text{(Eq.1)}$$

$$R^2 = \left[\frac{\sum_{i=1}^{n}(Q_0 - \overline{Q_0})(Q_P - \overline{Q_P})}{\sqrt{\sum_{i=1}^{n}(Q_0 - \overline{Q_0})^2 \sum_{i=1}^{n}(Q_P - \overline{Q_P})^2}} \right]^2 \quad \text{(Eq.2)}$$

$$Ens = 1 - \frac{\sum_{i=1}^{n}(Q_0 - Q_P)^2}{\sum_{i=1}^{n}(Q_0 - \overline{Q_0})^2} \quad \text{(Eq.3)}$$

where Q_p is the simulation value, $\overline{Q_P}$ is the average simulation value, Q_0 is the observed value, $\overline{Q_0}$ is the average observed value, and n is the number of observed data. The

evaluation standard indexes of model simulation efficiency are shown in *Table 5*. Generally, the model performances are identified to be good enough to apply in actual numerical simulation if R_e < 10%, R^2 > 0.79, and Ens > 0.59.

Table 5. *Evaluation standard of model simulation efficiency*

Standard	Relative error (R_e, %)	Correlation coefficient (R^2)	Nash–Sutcliffe efficiency (*Ens*)
Excellent	–5 to + 5	1.00–0.95	1.00–0.80
Good	± 5 to ± 10	0.94–0.80	0.79–0.60
Medium	± 10 to ± 20	0.79–0.70	0.59–0.40
Awful	> 20 or < –20	< 0.70	< 0.40

For runoff parameters, the observed runoff data at the outlet of the study area from May to October 2011 were used for model calibration and evaluation. Especially, the meteorological data of CMADS were used for model simulation to increase the accuracy of model simulation. In addition, the daily runoff data during the period 2008–2011 were simulated, choosing 2008–2010 as the warm-up period of SWAT model simulation. Some studies showed that the warm-up could make better simulation results for SWAT model simulation (Li et al., 2013; Nyeko, 2015; Wang et al., 2017, 2015). *Figure 4* shows the comparisons between the observed and simulated runoff yield of the study area outlet during the model calibration and validation period. *Table 6* shows the performance of SWAT model during the calibration and validation periods. The optimum values of the calibrated runoff parameters are shown in *Table 7*.

For sediment parameters, the model was calibrated by experience according to the related studies due to the lack of observed data (Qiu et al., 2012; Wang and Cui, 2011; Xu et al., 2008; Zhang et al., 2003). The optimum value of the calibrated sediment parameters is shown in *Table 8*.

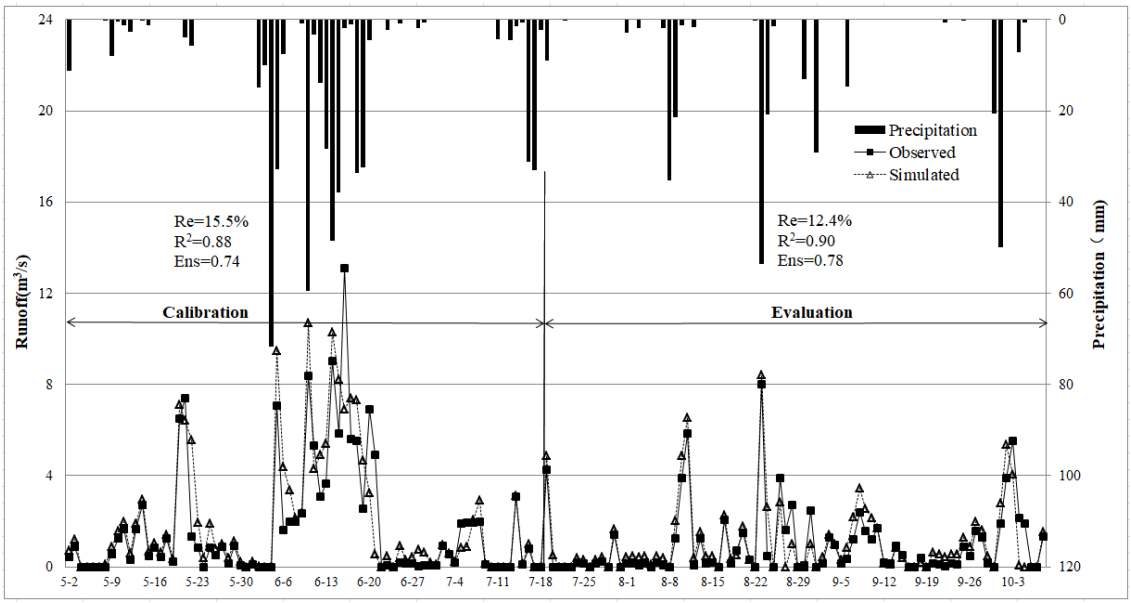

Figure 4. *Comparisons between the observed and simulated daily runoff during the calibration and validation period*

The SWAT model simulated value reflected the actual changes in the runoff yield, and the SWAT model could be used for runoff simulation in the study area. Hence, the distributed hydrological model of the study area based on the SWAT model was successfully constructed.

Results

Runoff and sediment yield variations in response to precipitation

Statistical analysis of precipitation data

In this study, the annual precipitation data of the study area during 1978–2010 were used for frequency calculation and the characteristic hydrological years were identified. The empirical frequency is calculated using the equation as follows:

$$P = \frac{m}{n+1} \quad \text{(Eq.4)}$$

where P is the empirical frequency of the annual precipitation of a particular year, m is the number in order from largest to smallest of the precipitation (*Table 9*), n is the total number of annual precipitation data.

Table 9 shows the precipitation and the result of empirical frequency calculation. As shown in *Table 9*, the multi-year average precipitation was 1523.19 mm.

2000	1680.1	10	29.41	1990	1228.2	27	79.41
1983	1670.7	11	32.35	1988	1221.9	28	82.35
1980	1583.7	12	35.29	1986	1211.8	29	85.29
1994	1517.2	13	38.24	2009	1086.1	30	88.24
1984	1501.2	14	41.18	2007	1045.3	31	91.18
2004	1485	15	44.12	1978	986.9	32	94.12
1981	1483.4	16	47.06	1991	940.9	33	97.06
1982	1481	17	50.00	Average	1523.19	Cv	0.23

The variation coefficient and ocular estimation method was used to draw theoretical frequency curve of the annual precipitation data, the best-fitted theoretical frequency curve was drawn when the coefficient of variation (Cv) was 0.23, as shown in *Figure 5*. The characteristic hydrological years were chosen with the frequency of 5%, 20%, 50%, 70%, and 95% according to the theoretical frequency curve. According to *Table 1*, the soil map and land-use map were compiled in 2009, so 2002 (8.82%), 2006 (17.65%), 2004 (44.12%), 2008 (67.65%), and 2009 (88.24%) were chosen as the corresponding years, which are close to 2009 and will decrease the impact of land-use and soil change on simulation results in SWAT model.

Analysis of runoff and sediment variation response to precipitation change

At first, the annual yield of runoff and sediment of characteristic hydrological years was analyzed. The results are shown in *Table 10* and *Figure 6.* The runoff and sediment yields increased with an increase in precipitation. The correlation coefficient of runoff yield and precipitation was 0.94, whereas that of the sediment yield and precipitation was 0.85. Hence, a strong positive correlation was observed between the runoff yield and precipitation, as well as between sediment yield and precipitation.

Table 10. *Precipitation and the result of frequency calculation*

Year	2002	2006	2004	2008	2009
P (%)	5	20	50	70	95

Runoff and sediment yield under different land use type

During sub-basin calculation, the land-use area threshold setting method was used to reduce the calculation amount of SWAT model and the HRU amount of the study area. Therefore, the land-use type was readjusted to another type if the area percentage was less than the area threshold. In this study, 1% was used as the land-use area threshold. The changes in the land-use area before and after HRU calculation are shown in *Table 11*.

Table 11. *Land-use area changes before and after HRU calculation*

Type	Before		After	
	Area (ha)	Percentage (%)	Area (ha)	Percentage (%)
AGRR (dry land)	52.67	1.71	73.30	2.38
RICE (paddy land)	2441.67	79.27	2442.60	79.30
URLD (rural residential land)	188.20	6.11	186.40	6.05
WATR (water area)	389.03	12.63	377.90	12.27
FRST (forest and grass land)	7.39	0.24	0	0
BARE (bare land)	1.23	0.04	0	0
Total	3080.20	100	3080.20	100

Then, the per unit area yield of runoff and sediment of different land-use types in 2004 was calculated. The results are shown in *Figure 8*.

As illustrated in *Figure 8a*, the order of per unit area yield of total runoff from high to low was paddy land, rural residential land, dry land, and water area. Specially, the total yield from paddy land was much more than that from other land-use types in the study area. Likewise, the ground water runoff from paddy land was also much more than that from other land-use types in the study area. Further, the surface runoff yields from different land-use types were almost the same.

As illustrated in *Figure 8b,* the order of sediment yield from high to low was rural residential land, dry land, water area, and paddy land.

Discussion

Based on the SWAT model with CMADS data, observed data from Jiangxi Irrigation Experimental Center, and field observation, the distributed hydrological model of the study area was constructed and the runoff and sediment yield variations under different precipitation and land-use conditions were simulated and analyzed.

For model calibration and evaluation, the observed runoff yield data were used to finish runoff parameter calibration. The sediment yield parameters were calibrated based on the results of other studies in different study areas due to the lack of observed data. For further study, the sediment simulation would be more accurate if the observed sediment data in the study area are used for model calibration.

At first, the observed annual precipitation data from 1978 to 2011 were used to finish frequency calculation and characteristic hydrological year identification. The runoff yield and sediment yield of characteristic hydrological years were simulated. A strong positive correlation was observed between the annual runoff yield and annual precipitation, as well as between sediment yield and precipitation, such results are also available from other studies (Li and Gao, 2015; Ruan et al., 2017; Zhu et al., 2015).

Then, 2004 was chosen as the typical year (50%), and the monthly yield of runoff and sediment was simulated. Runoff and sediment had the same tendency of changes with precipitation variation. Specifically, a small spike for runoff, as well as for sediment, was observed in March with the decrease in precipitation, while a sharp decrease appeared in April with a relatively high increase in precipitation. That is to say, precipitation variation was not the only influencing factor for runoff and sediment changes. Several studies explored the influencing factors for runoff and sediment yield in different watersheds around the world (Jiang et al., 2008; Nguyen et al., 2017; Perry, 2015; Tong et al., 2018; Xiang et al., 2012; Alibuyog et al., 2009). Some other studies also indicated that the land-use type was one of the most important influencing factors for runoff and sediment yield variation (Gyamfi et al., 2016; Huang and Lo, 2015; Zhang et al., 2010).

In this study, the per unit area yields of runoff and sediment in 2004 of different land-use types were calculated.

The total runoff, surface runoff, and ground water runoff yield of different land-use types were analyzed. No significant difference was found in surface runoff yields from different land-use types. However, the underground runoff yields from different land-use types varied greatly. The ground water runoff from paddy land was also much more than that from other land-use types in the study area. This might be attributed to the fact that the paddy land is irrigated during the growing period of double-cropping rice, and the underground water maintains a relatively high level for a long time. Therefore, it is not comprehensive to only consider the surface runoff in the simulation of watershed runoff. The difference between surface runoff and subsurface runoff may increase, and hence the change and difference in runoff can be assessed from the time and space scale in the future studies.

The order of per unit area yield of total sediment from high to low was rural residential land, dry land, water area, and paddy land. The sediment yields from the rural residential land and dry land were much more than that from paddy land and water area. Thus, the rural residential land and dry land should be the major focus of soil erosion control and soil conservation.

Conclusions

A distributed hydrological model was constructed in this study based on the SWAT model with CMADS data in the Fangxi Lake Watershed, a typical irrigation district in the Poyang Lake basin. The SWAT model was calibrated with observed runoff data. The results showed that the model was accurate enough for runoff and sediment yield simulation in the study area.

The runoff and sediment yield variations under different precipitation and land-use conditions were analyzed. The correlation coefficient of annual runoff yield and precipitation was 0.94, whereas that of annual sediment yield and precipitation was 0.85. Therefore, a positive correlation was observed between the annual runoff yield and precipitation, as well as between annual sediment yield and precipitation. When the monthly yield of runoff and sediment of typical year (2004) was simulated, the runoff and sediment yields had the same tendency of changes with precipitation variations. Then, the per unit area yield of runoff and sediment of different land-use types in 2004 was calculated. The order of per unit area yield of total runoff from high to low was paddy land, rural residential land, dry land, and water area. The order of per unit area yield of total sediment from high to low was rural residential land, dry land, water area, and paddy land. These findings figured out that the rural residential land and dry land are the main source of soil erosion.

However, several limitations in this study merit further research and investigation. The space distribution law of runoff and sediment should be taken into consideration in further studies. In addition, the transfer law of underground runoff and sediment in underground water under different rainfall and land-use conditions should be the focus of these studies.

(Received 29th Aug 2019; accepted 15th Nov 2019)

Abstract. *Sclerotinia sclerotiorum* (SC) is one of the most destructive soil-borne diseases in lettuce cultivation. In the present study, the effectiveness of single and combined use of *Coniothyrium minitans* (C) and *Trichoderma harzianum* (TH) as biological alternative to chemical SC control was investigated in two lettuce fields in the 2018-2019 production seasons in the province of Mersin/Turkey. In both lettuce trial plots, it was determined that the SC disease rates under single and combined use of *C* and TH were significantly reduced when compared to both the control and application of chemical fungicide that contained active substances Fluopyram + Pyrimethanil (Luna Tranquility). In all parcels where the biological preparations were applied alone and in combination, the obtained results suggest that these treatments may be a viable alternative to chemical methods. Thus, the highest impact on SC in both lettuce trial fields was 80-86.05% in C (4 kg/ha) + TH combination, while the lowest effect was obtained of only TH application with 54-60.47%. Analysis of the lettuce plant yield demonstrated that the application led to a significant increase in the yield in all lettuce cultivation fields when compared to control. The increase in yield ranged between 13-34% and 16-27% in the experimental fields and the highest increase was obtained with *Coniothyrium minitans* (4 kg/ha) + *Trichoderma harzianum* co-administration.
Keywords: *Biological control agent, Lactuca sativa L., Sclerotinia sclerotiorum, Trichoderma harzianum, yield*

Introduction

Lettuce (*Lactuca sativa* L.), which is a popular agricultural produce worldwide, is a cool climate vegetable that plays an important role in human nutrition. China is the leader in lettuce production followed by the USA, India and Spain, respectively. Different varieties are produced in different regions in Turkey with open field and greenhouse cultivation of this vegetable varieties with edible leaves. Turkey is the eighth largest lettuce producer in the world with 419 066 tons according to FAO statistics (Anonymous, 2017). In Turkey, lettuce farming is most popular in the Mediterranean, Marmara and Aegean regions.

The fungal diseases reduce the market value in the cultivation of lettuce, which has a rich nutritive value. *Sclerotinia sclerotiorum* is the most important and most common cause of fungal diseases that lead to major problems in lettuce cultivation fields. *S. sclerotiorum*, a soil-borne pathogen, is a member of *Sclerotiniaceae* family of the *Helotiales* group of the Discomycetes class. The host sequence of the disease agent is quite extensive and it leads to root, trunk and fruit rot in about 400 plant species (Purdy, 1979; Elshestawi et al., 2017; Smolinska and Kowalska, 2018). The disease agent spends the winter as sclerotium in the soil or in plant residues. The *S. sclerotiorum* sclerotia, which are prevalent in temperate regions, were recorded to survive in the soil for more than 10 years (Adams and Ayers, 1979; Clarkson et al., 2004). It was reported

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1568715701

that the product losses due to white mold disease caused by *Sclerotinia sclerotiorum* agent were up to 95% worldwide and in Turkey (Purdy, 1979; Young et al., 2001; Hao and Subbarao, 2005; Chitrampalam et al., 2010). It was reported that the crops are completely lost in completely infected fields and loses its market value due to losses in crop size and weight in partially infected fields (Clarkson et al., 2014).

In several studies conducted on the control of *Sclerotinia sclerotiorum* disease agent, it was reported that fungicide use harms the environment, as well as the reliability of the products consumed fresh, and increased the tolerance of the diseases against fungicides. In several studies, it was reported that mycoparasite fungi were effective against *Sclerotinia* diseases. Among these, *Coniothyrium minitans* and *Trichoderma* spp. are the most commonly used species (Turner and Tribe, 1976; Whipps and Budge, 1990; Budge and Whipps, 1991, 2001; Jones and Whipps, 2002). In the control of sclerotia diseases, it was emphasized that biological preparations were extremely important, since their action paths are not similar to fungicides and they directly destroy the sclerotia in the soil (Porter et al., 2002; Villalta et al., 2012). *C. minitans* produces secondary metabolites such as macrosphelide A, benzo furanones and chromans, which increase the colonization and degradation of *S. sclerotiorum* sclerotia and a wide range of cell wall degrading enzymes such as chitinases and glucans (Giczey et al., 2001; Tomprefa et al., 2011). Trichoderma fungi are highly competitive when compared to other soil-borne microorganisms due to its rapid growth and abundant spore production. The ability to secrete active compounds differs significantly among *Trichoderma* species and isolates. Thus, the mechanisms used by *Trichoderma* spp. in biological control vary based on the species, the pathogen and the host plant. In the case of antifungal activity against *S. sclerotiorum*, Trichoderma's mycoparasite properties play an important role. Trichoderma enzymes that break down the cellular wall of the pathogens were identified as chitinases, glucans, proteases and cellulases (Qualhato et al., 2013; Lopez-Mondejar et al., 2011; Naher et al., 2018). It was reported that Trichoderma species may be an important factor in the induction of plant growth and yield, as well as the control of plant phytopathogenic fungi in various plant species (Vinale et al., 2008; Bal and Altıntaş, 2008; Çolak, 2007; Çolak and Biçici, 2013; Elias et al., 2016).

Several studies were conducted globally that aimed to discover alternatives to fungicides in sclerotia diseases. Porter et al. (2002) preferred control with biological preparations in the control of *Sclerotinia* diseases and utilized *Coniothyrium minitans* and *Trichoderma* spp. species. Their findings were more successful when compared to fungicidal and Metham sodium applications. Villata et al. (2012), in a study conducted with biological preparations of *T. hamatum* 6sr4, *C. minitans* A69 and *C. minitans* in lettuce, reported that biocontrol agents could be used as an effective management tool against S. minor, the factor for white mold disease, in lettuce cultivation. Matheron and Porchas (2003) used Boscalid and Iprodion in lettuce cultivation fields against *S. sclerotiorum* and *S. minor*, which lead to white rot disease, while *Coniothyrium minitans* (Contans) was used as biological control agent. It was reported that their effectiveness was 33-38% and 52%, respectively in lettuce fields contaminated with *S. sclerotiorum*, and 53-35-32%, respectively in *S. minor* infected fields. Chitrapalam et al. (2008) conducted a two-year field study at Yuma County to investigate the effects of several biological agents against the disease induced by Sclerotinia species. Commercial formulations of biological preparations such as *Trichoderma harzianum* (Plantshield, Supersivit), *Gliocladium virens* (Soilgard), *Coniothyrium minitans* (Contans) and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1568715701

Bacillus subtilis (Companion), and a chemical fungicide, Iprodione (Rovral) were evaluated and compared against *Sclerotinia sclerotiorum* and *S. minor*. In the study, it was found that using the preparations once was not sufficient, however it was determined that the severity of the disease decreased when the administrations were conducted twice. At the end of the study, *Coniothyrium minitans* (Contans) biological preparation provided the most effective control against *Sclerotinia sclerotiorum.*

The preparation that contains *Coniothyrium minitans* isolate is a mycoparasite fungus species that was not certified in Turkey, however used successfully in the control of white mold disease in the USA and G8 countries with the commercial brand of Contans WG in greenhouses and fields. However, in Turkey, no studies were conducted to assess the success criteria for these biological preparations in the control of white mold disease induced by *Sclerotinia sclerotiorum* in lettuce fields (Anonymous, 2017). In Turkey, several studies were conducted on the prevalence of *S. Sclerotiorum* disease agents, which determined the mycelial fitness groups (MFG), and in-vivo and in-vitro biological control opportunities (Çarkacı and Maden, 1986; Aksay et al., 1991; Mert-Turk and Mermer, 2004; Çolak, 2007; Çoşkun and Yildiz, 2017; Soylu et al., 2017). In studies on the prevalence of disease factor in lettuce conducted in Turkey, the prevalence was determined as 82.5% in Çanakkale (Mert-Türk and Mermer, 2004), 25-57.1% in Hatay province and districts (Soylu et al., 2017), 3.3% in Adana province Karataş district, 10.6% in Tarsus district and 4.6% in Osmaniye province (Çolak and Fidan, 2018). However, the studies on the control of the disease agent with biological control agents in the field are rather recent, and the effectiveness of the *Coniothyrium minitans* biological preparation on *Sclerotinia sclerotiorum* was investigated for the first time in the present study. Studies on the parasite effect on sclerotia and reduction of apothecia density of *Trichoderma harzianum* that we tested in control of *S. sclerotiorum* were mostly conducted in greenhouse and laboratory conditions (Bal and Altintaş, 2008; Geraldine et al., 2013; Smolinska et al., 2016). The number of studies on the antagonistic activity of *Trichoderma* in the field is very limited (Knudsen et al., 1991; Zeng et al., 2012a; Geraldine et al., 2013).

S. sclerotiorum is a disease agent difficult to control due to the resistant structures created by the disease agent in the soil. Currently, the losses due to the rapid degradation of the fungicides in the soil range between 5% and 40% in the control of the disease (Chitrampalan et al., 2011). The majority of the chemicals used in control aim to protect the parts of the host plant that are above the ground, especially the flowers, from ascospore infection. Thus, the application time should be carefully selected and the green parts should be covered with medication for an effective chemical control. In this context, due to the residual risks caused by the use of chemicals in control, the research on possibilities of biological control became popular in recent years. In biological control studies, it was observed that the studies mostly focused on the parasite infection of sclerotia mainly by mycoparasite fungi. The present study investigated the effectiveness of single and combined applications of *Coniothyrium minitans* and *Trichoderma harzianum,* which are biological agents alternative to chemical control, in the control of white mold disease (*Sclerotinia sclerotiorum*) that causes economic damages in lettuce cultivation.

Materials and methods

The study area

Control experiments were set up under producer conditions in the study lettuce fields to determine the effectiveness of *Coniothyrium minitans* (strain CON/M/91-08, 1 x 10^{12} CFU/kg, Contans, Bayer) and *Trichoderma hazianum* (*Trichoderma harzianum* Rifai race KRL-AG2 (TH, T-22 Planter Box, 1x10^{7} CFU/g, Bioglobal) biological preparations against white mold disease. Yonca 80 lettuce variety was used as material. For this purpose, field experiments were set up in two lettuce fields in Mersin province Kazanlı (KA) and Demirhisar (DE) regions that are naturally inoculated and in which the disease was prevalent in the previous cultivation season in the 2018-2019 cultivation season. However, for homogenous distribution of the disease agent in all experiment plots, artificial inoculation (25 g/m^2) was conducted with *Sclerotinia sclerotiorum* (SC) after the soil was plowed and ready for seeding. For this purpose, SC region isolate obtained from lettuce plant was used in field trials. The SC isolate was incubated in PDA for 10 days at 25 °C and the disks obtained from the SC isolate were inoculated to humidified and sterilized wheat medium (1000 g wheat + 800 ml water) in Erlenmeyer flasks and allowed to incubate another 10 days at 25 °C. The inoculum developed in the incubation was broken down and 25 g was applied per 1 square meter experimental soil. Then the soil was processed with a rotovator at a depth of 5-10 cm to allow homogenous distribution of the inoculum in the soil (Chitrampalam et al., 2008; Elshestawi et al., 2017). Lettuce seedlings were planted in the fields of sandy loam soil structure in a distance of 40 cm on the row and between rows. The experiment was designed in 4 replicates for each application and 20 lettuce plants per replicate (total 80 plants) based on randomized blocks experimental design.

Biological preparation and fungicide application

Coniothyrium minitans and *Trichoderma harzianum* biological preparations were applied to the soil via absorption immediately after the lettuce seedlings planted. Biological preparations were applied to the plant for the second time as recommended in the thinning period after the initial single and combined applications. For this purpose, *Coniothyrium minitans* (C) biological preparation was applied in recommended three doses (C2: 2 kg/ha, C3: 3 kg/ha; C4: 4 kg/ha), while *Trichoderma harzianum* (TH) biological preparation was applied in the recommended (50 g/100 lt/T-22) dose. In the study, Luna Tranquility SC (125 g/L Fluopyram + 375 g/L Pyrimethanil/SC, Bayer) was used as a chemical fungicide which was used extensively in *Sclerotinia sclerotiorum* control in lettuce fields. Luna Tranquility SC was applied once in the thinning period on green sections in a single dose of 100 lt/da as recommended in manufacturer's instructions (*Table 1*). A row of safety lanes was left between the application plots. The control plot plants were applied only water (without biological preparat and fungicide) (Elsheshtaewi et al., 2017). In the harvest, the plants were evaluated as sick and healthy.

At the end of the count, percentage of infected and non-infected plants were determined among the plants divided as sick and healthy and the percentage of the impact of the treatments were evaluated with Abbott's formula (% effect = [control (%) – application (%) / control (%)] × 100) and statistical analyzes were conducted (Karman, 1971). The analyses of variance and mean values were compared with the LSD test (P: 0.05).

Determination of the effect of applications on the yield and certain physical properties

In the study, when the lettuce in the experimental fields were ready for harvest, 10 plants were removed from each replicate to represent the average in all application plots and mean marketable head weight (kg/plant), root weight (g), root length and crown diameter (mm) were measured. After the weights of the plants harvested from each plot were determined, the mean plant weight (kg/plant) and parcel yield (kg/da) were calculated. For this purpose, marketable head weight (kg/plant) was determined after poor quality leaves and the roots were removed using precision scales. Crown diameter (mm) was measured by a digital caliper (SC Mitutoyo, Japan), which was sensitive to 0.02 mm, using the plants harvested from inoculated fields. Mean root length (cm) and weight (g) were determined by measuring from the crown (cm) and by weighing with a precision scale (g) after the plants were harvested and washed without damaging the roots (Tüzel et al., 2011).

Table 1. *Information on products tested against white mold disease in lettuce*

Active ıngredient	Product name	Formulation type	Application rate
Coniothyrium minitans (strain CON/M/91-08, 1 x 10^{12} CFU/kg)	Contans	Wettable granule-WG	2-4 kg/ha
125 g/L Fluopyram + 375 g/L Pyrimethanil	Luna Tranquility	Suspension concentrate-SC	100 ml/da
Trichoderma harzianum Rifai race KRL-*AG2*, 1×10^7 CFU/g	T-22 Planter Box	Wettable powder-WP	50 g/100 lt

Results and discussion

The effects of biological preparation applications on White mold disease

The data obtained in the studies conducted to demonstrate the efficiency of single and combined use of biological agents *Coniothyrium minitans* and *Trichoderma harzianum* that are alternatives to chemical control of white mold disease (*Sclerotinia sclerotiorum*) that causes significant economic damages in the cultivation of lettuce, which is an edible vegetable are presented in *Table 1*. *Table 1* demonstrated that the differences between the applications in both trial fields were statistically significant ($P < 0.05$). The disease infection rates in control plots in both lettuce trials were 62.50% and 53.75%. It was observed that the rate of disease rate significantly decreased in both single and combined use of *Coniothyrium minitans* and *Trichoderma harzianum* when compared to both the control and chemical fungicide use. In this context, the lowest infected plant rate was 12.5% in C4 + TH applied plots among the biological preparation applications in SC control when compared to control and pesticide applications and that was followed by C3 (3 kg/da) + TH and C4 (4 kg/da) applications (*Table 1*). Certain studies also reported that a combination of certain antagonists could lead to a higher level of protection, however improved control could not be observed in all cases (Spadaro and Gullino, 2005). The success of biological preparations could differ based on the soil type, type of biological agent, plant interactions and disease pathogen (Celar, 2002; Smolinska and Kowalska, 2018). It was reported that high soil moisture is important in degradation of the sclerotia in the soil by *C. minitans* (Trutmann et al., 1980). Budge et al. (1995) successfully integrated *C. minitans* and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1568715701

Trichoderma virens combinations in *S. sclerotiorum* control in greenhouse studies. The greatest decrease in the number and viability of sclerotia was obtained with the combination of *C. minitans* and *Trichoderma virens* in the second harvest, while in the third harvest the only significant reduction was achieved with *C. minitans* applications. In another study, *T. harzianum* T-22 isolate (PlantShield) protected the soybean against S. sclerotiorum and reduced the disease severity index by 38.5% in the field crops (Zeng et al., 2012a). Gerlagh et al. (1999) reported that mycoparasite *C. minitans* had the potential to keep soil contamination at low levels in crop rotations in various sclerotiorum-sensitive crops.

In the present study, the statistical analyzes conducted on the data obtained in KA plot trials demonstrated that the lowest infected plant rate was obtained with Luna (11.25%), C4 + TH (12.50%) and C3 + TH (15%) applications, while the highest infected plant rate was obtained with TH application (28.75%). In DE plot, the lowest infected plant rate was obtained with Luna (6.25%), C4 + TH (7.50%) and C3 + TH (8.75%), while the highest infected plant rate was obtained with TH application (21.25%). The most successful alternative to chemical applications was obtained with C4 + TH application (86.5%) in DE plots, followed by C3 + TH and single C4 application with 83.72% (*Fig. 1*). Chitrampalan et al. (2008) investigated the action of *Trichoderma harzianum* (Plantshield), *Gliocladium virens* (Soilgard), *Coniothyrium minitans* (Contans), *Bacillus subtilis* (Companion) biological preparations and the fungicide with Iprodione (Rovral) active agent in control of *Sclerotinia sclerotiorum* and *S. minor* disease agents that are destructive in lettuce cultivation. It was reported in the study that single applications of biological preparations and fungicide were not effective in the control of disease agents. It was reported that twice *Coniothyrium minitans* application during the planting and post-thinning periods reduced *Sclerotinia sclerotiorum* incidence and improved the yield. There was no significant decrease in disease rates in other biocontrol products. The study findings demonstrated that *Coniothyrium minitans* (Contans) was the most effective application in control of *S. sclerotiorum* induced white mold disease in lettuce. These findings were consistent with the present study. Similar to the current study, it was reported that successful results were achieved with twice application of biologic preparations in disease control in several studies (Chitrampalam et al., 2010). The effects of single application of Contans (*Coniothyrium minitans*) and in combination with Radix (*Trichoderma asperellum* and *Trichoderma gamsii*), Kraft pine lignin and Rovral were compared in disease control in naturally S. Sclerotiorum-infected lettuce greenhouses. Single application of 4 kg/ha Contans had a negative effect on sclerotia viability, however did not reduce the disease incidence in lettuce. In the study, the highest impact on disease rate in different harvest periods was obtained in the third harvest and the lowest disease rate was obtained with Contans + lignin application (4.7%). In the study, this was followed by Contans + lignin + Radix application with a 6.7% rate among biological applications when compared to chemical combinations. In the study, it was reported that the significant decrease in sclerotia viability that was observed in the soil treated with Contans could be due to the long incubation time, repeated application, different climatic conditions and the use of different varieties (Van Bendeneden et al., 2010).

Commercial Luna was successful as a standard fungicide in the control of Sc in lettuce trial fields. However, significant losses in lettuce due to white mold despite excessive fungicide applications continue today. Chitrampalam et al. (2011) investigated the effectiveness of *C. minitans* (Contans) application in different doses

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1568715701

and times on white mold in lettuce in 2011. In field experiments, lower sclerotia was detected in all Contans applications when compared to Endura chemical fungicide and control applications. It was found that the disease rate was low in other applications similar to Endura fungicide application plots. As a result of the study, it was reported that Contans use to lower the sclerotia count in the soil was the key to long-term success in white mold disease control and Endura fungicide application was also useful to protect the plant from disease infection. The findings of the study were consistent with our findings.

Figure 1. *Sclerotinia sclerotiorum which causes white mold disease in lettuce, black sclerotia, white mycelium and brown, soft, watery decays in lettuce leaf in control plant*

In our study, the impact rates of the applications in disease control demonstrated that the highest effect was obtained with Luna chemical application in the field experiments (*Table 2*). In both field experiments where the biological preparations were applied alone and in combination, hopeful results that may be an alternative to the success of the chemical applications were obtained. Thus, the highest effect was obtained with C4 + TH application (80-86.05%), while the lowest effect was obtained with TH application (54-60.47%). The low variation among the effects of biological agents on the disease in both experiment fields was due to the fact that, as stated by Howel (2003), the biological control factor was dependent on the pathogen and host plant interaction and the presence of other microorganisms in soil microflora. The studies on parasite infection of Trichoderma isolates and S. sclerotiorum induced sclerotia and on reduction of apothecia concentration were mostly conducted in greenhouse and laboratory conditions (Inbar et al., 1996; Matroudi et al., 2009; Smolinska et al., 2016). In a study conducted in greenhouse, Inbar et al. (1996) determined that *Trichoderma harzianum* applications reduced white mold disease by 46-72% in lettuce when compared to control plants. However, the number of studies on antagonistic activity of Trichoderma in field conditions is quite limited (Knudsen et al., 1991; Zeng et al., 2012a; Geraldine et al., 2013). The effects of biological control agents *Coniothyrium minitans* CON/M/91-08, *Trichoderma harzianum* T-22, *Bacillus subtilis* QST 713 and *Streptomyces lydicus* WYEC 108 on Sclerotinia sclerotiorum production and sclerotia survival were investigated under controlled conditions. In the study, it was determined that *C. minitans* decreased apothecia and sclerotia by 81.2% and 50%, respectively, while *Trichoderma harzianum* decreased apothecia and sclerotia by 80.5% and 31.7%, respectively (Zeng et al., 2012b). Budge and Whipps (1991) investigated the effects of *Coniothyrium minitans*, *Trichoderma harzianum* (HH3) and *Trichoderma* sp (Bl) in Sclerotinia sclerotiorum induced disease control in two lettuce greenhouses and in a celery greenhouse. It was found that single C. Minitas applications reduced white mold

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1568715701

disease in lettuce and improved marketable yield. In the study, it was found that the tested Trichoderma species had no significant effect on the disease and had virtually no effect on the survival of sclerotia. In the study, the lowest S. sclerotiorum disease rate in lettuce was obtained with C. minitas application (48.2-50.3%) in the first and second harvest when compared to control (90.3-58.5%), and it was followed by *T. harzianum* Rifai (HH3) isolate application (62.8-56.2%). These findings were similar to the present study findings. In the study, the significant gradual reduction of sclerotia count in time, especially in the second lettuce crop, led to the idea that sclerotes caused an attack by natural microflora and micro-fauna. Huang et al. (2000) reported that *C. minitans* spore suspension spray during bean plant flowering reduced white mold disease rate by 56%. In the study conducted by application of *C. minitans* on the upper soil before soybean seeding, it was determined that the application reduced the *S. sclerotiorum* disease severity index by 68% and the sclerotia count in the soil by 95.3% (Zeng et al., 2012a).

In the present study, it was concluded that combined use of Contans (4 kg/da) + *Trichoderma harzianum* (50 g/100 lt, T-22) that included *Coniothyrium minitans* biological agent could an alternative to chemical applications in control of the white mold disease that leads to losses in market value of the lettuce crop, as well as significant yield losses (*Fig. 2*).

Figure 2. *An image from the most effective C. minitas and TH applications to control white mold disease in lettuce parcel*

Determination of the effect of the applications on the yield and certain physical properties

The data on the effects of the single and combined use of *Coniothyrium minitans* and *Trichoderma harzianum* biological preparations in control of SC disease agent that causes significant yield losses in lettuce cultivation on marketable mean head weight (kg/plant), yield (kg/da), root weight (g), root length (cm) and crown diameter (mm) of Iceberg lettuce cultivar are presented in *Table 3.*

Analysis of the lettuce plant yield demonstrated that KA and DE resulted in significant yield increases in lettuce cultivation. The increase in yield ranged between 13-34% and 16-27% in the experimental fields and the highest increase was obtained with 7560-6701 kg/da C4 + TH application and the lowest was obtained with control with 5640-5240 kg/da. An important parameter in yield and quality in lettuce cultivation is marketable head weight. The effects of biological preparation applications on marketable head weight were found to be statistically significant. In the study, an increase was observed in marketable head weight with all combined *Coniothyrium minitans* and *Trichoderma harzianum* applications. The highest marketable head weight

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1568715701

was obtained with combined C4 + TH (1.260-1.117 kg/plant) application in both experimental plots, followed by Luna chemical application (1.257-1.107 kg/plant). Chitrampalam et al. (2008) did not report statistically significant differences between the lettuce head weigh and yield with *Trichoderma harzianum* (Plantshield), *Gliocladium virens* (Soilgard), *Coniothyrium minitans* (Contans) and *Bacillus subtilis* (Companion) biological preparation applications used to control *S. sclerotiorum* in lettuce. However, in both lettuce locations, it was found that the twice *Coniothyrium minitans* application in planting and thinning periods effectively suppressed S. sclerotiorum, thus indirectly increasing the lettuce head weight. These findings were followed by *Gliocladium virens*, *Trichoderma harzianum* and *Bacillus subtilis* applications. These findings were consistent with the findings of our study.

Under field conditions, Knudsen et al. (1991) found that Trichoderma isolates contributed to an increase in lettuce head weight by releasing Trichoderma isolates to the soil for *S. sclerotiorum* sclerotia infection, and the experiments reduced the infection by 100%. In a study, Bal and Altıntaş (2008) investigated the effects of *Trichoderma harzianum* on lettuce plant development. It was determined that *T. harzianum* applications did not lead to a significant increase in lettuce yield and root growth. Rabeendran et al. (2000) reported that two *Trichoderma harzianum* isolates applied to the lettuce plant in the field increased the yield significantly. It was reported in several studies that various Trichoderma species increased the growth, development and plant yields at different rates in studies conducted with different plants. *Trichoderma* species are not only found on plant root surfaces, but also in various parts of the plant endophytically. It was also reported that these endophytic species promoted plant growth and protected the plant against biotic and abiotic factors (Bae et al., 2009 Poldma et al., 2002; Altıntaş and Bal, 2005; Elad et al., 2006; Druzhinina et al., 2011).

In the present study, the effects of single and combined *Coniothyrium minitans* and *Trichoderma harzianum* biological agent application in lettuce cultivation were statistically significant on lettuce root weight, root length and root diameter. When compared to the control application, the root weight increased in all applications in both experimental plots. The highest root weight was obtained in the KA plot with C4 + TH and Luna applications (45.59 g – 44.87 g) and in the DE plot, with C3 + TH and TH 3 + TH and C4 + TH applications (48.47 g – 46.59 g).

When compared to the control application, the highest increase in the root length in all applications in both experimental plots was 32-31%. The highest root length measurements were 18.82 cm with Luna and 18.61cm with C4 + TH applications. In DE parcel, the highest root length of 18.80 cm was obtained with combined C4 + TH biological preparation application, followed by C3 + TH application with 18.21 cm. Yedidia et al. (2001) reported that *Trichoderma harzianum* increased the root length in cucumber plant by 75% and root area by 95% in a study they conducted. In another study on the effects of *Trichoderma harzianum* on the development of lettuce plant, it was determined that TH application did not significantly increase the root growth in lettuce (Bal and Altintas, 2008).

The effects of the single and combined use of biological preparations compared to the control and chemical application (*Table 2*) demonstrated that the application led to an increase in crown diameter of the lettuce in KA and DE plots by 18% to 36%, respectively. The increase in crown diameter in both experimental plots was obtained in all plots where *Coniothyrium minitans* and *Trichoderma harzianum* were applied in combination. The highest increase in KA plot in crown diameter was obtained with C4

+ TH and C3 + TH applications (31.44 mm – 31.35 mm), while it was obtained with C4 + TH application (37.30 mm) in DE plot, followed by combined C3 + TH application (35.48 mm). The crown diameter was determined as 26.54-27.29 mm in the two experimental plots, respectively.

Discussion

Although certified chemical fungicides are available in Turkey, especially in control of white mold disease in lettuce, the number of disinfestations or doses are increased due to the severity of the disease. This does not improve the control success, as well as causing environmental pollution and residual product threatens human health and disrupts the balance of nature. The emergence of plant resistance to agents used in these products is one of the most important problems induced by chemical control. The best way to limit the application of pesticides used in *Sclerotinia sclerotiorum* control in lettuce is cultivation of resistant varieties. However, due to the specific character of the disease induced by this pathogen, breeding programs had a limited success (Uloth et al., 2014). Today, in the absence of disease-resistant varieties, the research on environment-friendly methods such as biological methods have intensified for long-term destruction of *Sclerotinia sclerotiorum* in the soil.

In this context, the present study findings suggested that the use of Contans that contains *Coniothyrium minitans* biological agent (4 kg/da) + *Trichoderma harzianum* (50 g/100 lt/T-22) combination could be an alternative to chemicals in control of white mold disease that leads to market value losses and significant losses in the yield, especially in highly infected fields in lettuce cultivation. It was observed that several studies were conducted worldwide on biological control of white mold disease induced by *Sclerotinia sclerotiorum* disease agent. In both field and greenhouse experiments conducted to determine the impact of *Coniothyrium minitans* as a biological control agent against white mold disease, it was determined that single use of the biological preparations were not sufficient, however twice application of the agent significantly to reduces the severity of the disease (Chitrampalam et al., 2008).

The application of biological methods to control plant pathogens is known to be safer for the environment when compared to the use of pesticides. Chemical control of *Sclerotinia sclerotiorum* is quite difficult since ascospores can infect any part of the lettuce head. Also, it is more difficult to prevent after the presence of apothecia in the plant (Patterson and Grogan, 1985). Biological control methods may be partially sufficient to completely reduce the populations of plant disease pathogens. The complete destruction of the disease in the soil can only be possible if the pathogen concentration is already low in the soil. The most successful method, thus, is the combined application of antagonistic fungi with strong parasitic properties such as *C. minitas* and *Trichoderma* genus fungi (Smolinska and Kowalska, 2018).

However, in order to ensure a long-term and effective biological control in soil-borne diseases such as plant pathogens, especially *Sclerotinia sclerotiorum*, crop rotation, the use of resistant varieties, solarization (soil disinfection) and taking all cultural measures in combination are important (Subbarao, 1998; Villata et al., 2012; Çolak Ates et al., 2019). Therefore, an integrated approach that adopts multiple control measures could provide sustainable control against sclerotia. In the success of such a strategy, selection of agricultural and crop management practices that reduces the accumulation of pathogen inoculum and the risk of disease propagation is important (Koike et al., 2003).

Conclusion

In this study, it was concluded that Contans containing *Coniothyrium minitans* biological agent (4 kg/da) + *Trichoderma harzianum* (50 g/100 lt/T-22) could be an effective alternative to chemicals in the control against white mold disease by *Sclerotinia sclerotiorum.* Furthermore, *S. sclerotiorum* in areas where the risk of disease is very high, in order to prevent high *S. sclerotiorum* levels, very detailed control studies with biological preparations and existing fungicide applications and at different application doses are required.

PHYSIOLOGICAL CHANGES OF CULTIVATED EGGPLANT (*SOLANUM MELONGENA* L.) IN RESPONSE TO WATER DEFICIT

AL-MUWAYHI, M. A.

Department of Physics and Chemistry, Faculty of Science, Shaqra University
P.O. Box 33, Shaqra, 11961, Kingdom of Saudi Arabia
(e-mail: malmuwayhi@su.edu.sa; phone: +966-11-6224-4118)

(Received 5th Sep 2019; accepted 15th Nov 2019)

Abstract. The effects of drought on the physiology of eggplants (*Solanum melongena* L. cv., Madona) were studied. Drought stress treatment had been done by irrigating the plants with 80%, 60% and 40% of water needed to reach soil pot capacity, plus normal irrigation (control treatment). The objective of this research was to reveal physiological response of eggplant to different levels of drought stress, as well as, its nutrient. The obtained results showed that, nutrients concentrations of the studied eggplants grown in pots under different irrigation treatments decrease according to water stress levels. Drought stress significantly reduced the ammount of total chlorophyll, chlorophyll a, chlorophyll b and total carotenoids resulting in damaged leaves. Carotenoids decreased in response to water stress from 8.65 mg/g FW under control in comparison to 5.84 mg/g FW the fourth water deficit treatment. All water stress treatments increased the accumulation of proline content in plant. Lack of water in plant modified anti-oxidative enzyme activities in order to alleviate the water stress. The results indicate that irrigation treatment with 80% of pot capacity have more efficient water use than 60% and 40%, which reduces drought stress and improves ionic balance of the plants.
Keywords: *eggplant, water stress, nutrients, antioxidant enzymes, pigments, proline*

Introduction

Eggplant (*Solanum melongena* L.) is a popular nightshade crop plant commonly cultivated in tropical and subtropical farmland. The stunted growth, lack of yield and poor quality of plant product caused by water stress has been well studied by researchers and agriculturists, and many physiological processes involved for this reduction in variable crop plants. Many studies has been carried out in Asia, Africa, Europe and different region on eggplant irrigation (Gaveh et al., 2011; Karam et al., 2011) showing that eggplant can be produced at moderate levels of water stress without severe effect on fruit yield. There is a complex relationship between yield, physiological responses and vegetative growth to different level of water stress, especially in eggplant under semi-arid conditions (Kirnak et al., 2001). Plants experience water stress during intense transpiration rate or when there is limited water supply around their roots. Plants attempt to eleviate the negative effect of drought stress using a set of biochemical and physiological mechanisms.

Concerning water scarcity, Saudi Arabia is an arid high temperature zone and faced with increased competitions for water resources between different sectors (agriculture, industry or domestic consumption). So economic and effective irrigation regimes is an important matter to solve.

High yield of crop production and water savings are some of the benefits in optimizing irrigation water management. Appropriate strategies in agriculture practices are need to be found to get efficient use of limited water in semi arid zones. Abd El-Ghany et al. (2004) stated that the identified varieties that had high and/or moderate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1570315711

yield potential besides desirable specific adaptation traits are useful for drought stress and could be combined to achieve optimum performance. One important strategy is to better manage water and increase its productivity (Molden, 1997; Molden et al., 2001; Gupta et al., 2016; Tani et al., 2018). Effective irrigation scheduling needs to be designed to ensure the optimal use of limited water. Díaz-Pérez and Eaton (2015) indicated that eggplant may tolerate moderate drought stress, since plants watered at 67% Evapotranspiration level (Etc). A comprehensive knowledge of drought stress effect on plants is critical to enhanced management practices and crops breeding efforts in agriculture under semi arid condition. Many works in this field were developed over the past twenty years, covering topics from plant approaches to control water status under drought, to the physiological and biochemical processes underlying plant response to water deficits (Chaves, 1991; Cornic and Massacci, 1996; Kurniawati, 2014; Buhtz et al., 2017). Kurniawati (2014) found that during the drought treatment, plant growth, biomass, media water content, relative water content, chlorophyll content concentration were reduced while proline and polyamines were increased and reached the high levels on 14 to 21 days after the treatment.

The present research was carried out to study the effect of drought stress on physiological characters of studied eggplants, i.e., leaf chlorophyll, carotenoids, proline and enzyme activity, as well as, some nutrients (K, P, C and N) uptake.

Materials and Methods

Within the experimental researches to evaluate many of solanaceae plants at the Agricultural Experimental and Research Station (24°42'N 44°46'E, 600 Alt.) in Dirab region, Saudi Arabia, during the spring growing season (March to June), it is worth mentioning like research Almohisen (2015). Seeds had been planted at nursery in greenhouse until seedlings have three foliage leaves and reached 15 cm shoot height, then were transported to 30 cm pots size (30 cm top dimeter, 25 cm base dimeter and 30 cm pot height) after filled with sandy loam (1:1) media in the outfield. Irrigating treatment started on 1st of March and the harvest were done on 1st of June. All agronomy practices and plant protection had been done according to the agricultural region. Randomized complex block design with three replications were used. Soil physical and chemical properties measured according to Cassel and Nielsen (1986), Klute et al. (1986) and Rhoades (1982). Also, chemical properties of irrigation water were estimated according to Bock (1984) as shown in *Table 1*.

Irrigation treatments

Irrigation treatments depended on measuring the deficit of soil moisture contents from the pot capacity, the potential evaporation was calculated using the Pan evaporation as described by Richards (1969). Irrigation treatments included 4 levels of water deficit stress that were control T1 (100% pot capacity), T2 (80% pot capacity), T3 (60% pot capacity) and T4 (40% pot capacity).

Physiological parameters

Elements were estimated according to Doorenbos (1975). Regarding to Chlorophyll and carotenoid content, the extraction of leaf pigments was performed with 80% acetone, and the absorbance at 663 and 645 nm was measured with an Ultrospec 2100

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1570315711

pro spectrophotometer (Amersham Biosciences). Total carotenoid content, chlorophyll a, chlorophyll b, and total chlorophyll quantities were calculated according to the method of Arnon (1949) using the following formula:

$$A_{663} = 82.04\ Chl_a + 9.27\ Chl_b \quad \text{(Eq.1)}$$

$$A_{645} = 16.75\ Chl_a + 45.6\ Chl_b \quad \text{(Eq.2)}$$

where A is the density values at the respective wavelengths as obtained on the spectrophotometer and Chl_a, Chl_b are grams per liter of chlorophyll a and b, respectively. From the solving previous equations we will obtain the following:

$$\text{Chl a (mg/l)} = 12.7\ (A_{663}) - 2.69\ (A_{645}) \quad \text{(Eq.3)}$$

$$\text{Chl b (mg/l)} = 22.9\ (A_{645}) - 4.68\ (A_{663}) \quad \text{(Eq.4)}$$

$$\text{Total Chl (a and b) (mg/l)} = 20.2\ (A_{645}) + 8.02\ (A_{663}) \quad \text{(Eq.5)}$$

Then carotenoid content can be calculated as following:

$$\text{Car (mg/l)} = A_{480} \text{ x } 200 \quad \text{(Eq.6)}$$

The pigment concentration was calculated in mg/g FW of samples.

Table 1. *Physical and chemical properties of soil and irrigation water*

		Irrigation water	Soil

	Saturation point %		27.3
	Pot capacity (at 1 bar)		13.6
	Wilting point (at 15 bar)		6.8

Extraction and determination of proline were directed according to the techniques described by Bates et al. (1973). Plant tissues (0.5 g) were homogenized with 5 ml of 3% sulfosalicylic acid and the homogenates were centrifuged at 3000×g for 20 min. One ml of the supernatant was mixed with 1 ml acid ninhydrin reagent and 1 ml of glacial acetic acid in a test tube and incubated in 100°C in water bath for 1 h, and then the absorbance value at 520 nm was noted. Free proline content in sample is determined by referring to a proline standard curve of known concentrations and the results were expressed as μmol proline g^{-1} FW (fresh weight).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1570315711

For extraction and analysis of antioxidant enzymes, leaf samples (0.5 g fresh weight, FW) were homogenized in 3 ml extraction buffer (0.1 M pH 7.0 potassium phosphate buffer, 1 mM EDTA, 0.05% Triton X-100) in a pre-chilled pestle and mortar, centrifuged at 15,000 g for 20 min at 4°C. The supernatant was used for the estimation antioxidant enzyme activities. Superoxide dismutase activity (SOD EC 1.15.1.1) activity was estimated by the ability of this enzyme to impede the photochemical decrease of nitrobluetetrazolium salt (NBT). The SOD activity was measured at 560 nm according to the technique of Beyer and Fridovich (1987) and the assays were carried out at 25°C. The final assay volume of 3 ml contained 50 mM Tris-HCl buffer (pH 7.8), 33 µM NBT, 10 mM L- methionine, 0.66 mM disodium EDTA, 0.0033 mM riboflavin and 50 µl of supernatant. Reaction was underway under fluorescent light for 15 minutes by adding 10 µl of riboflavin solution. One unit of antioxydant SOD was defined as the amount of enzyme activity that inhibited the photo reduction of NBT to blue formazan by 50%. The SOD activity of each extract was expressed as Ug^{-1} FW. Peroxidase (POX) activity was estimated by the method of Sakharov and Ardila (1999). Peroxidase enzyme activity was determined by the oxidation of guaiacol in the presence of H_2O_2. The increase in absorbance was recorded at 470 nm for 1 min with a spectrophotometer. The reaction mixture contained 50 µl of 28 mM guaiacol, 900 µl of 50 mM potassium phosphate buffer (pH 6.0), 50 µl of 5 mM H_2O_2, and 10 µl of crude extract. POX activity of the extract was expressed as the POX Ug^{-1} FW. Catalase (CAT EC 1.11.1.6) activity was measured spectrophotometrically according to the method of Aebi (1974). The disappearance of H_2O_2 were determined at 240 nm wavelength in a mixture containing 50 mM sodium phosphate buffer (pH 7.0), 20 mM H_2O_2 and 5 µl of supernatant. The decrease in the absorption was followed for 1 min at 240 nm, and 1 mmol H_2O_2 oxidized ml^{-1} min^{-1} was defined as 1 U of CAT activity. Ascorbate peroxidase (APX EC 1.11.1.11) content was determined according to the means of Wang et al. (1991). The mixture contained in a test tube, 50 mM pH 7.0 potassium phosphate buffer, 0.5 mM ascorbic acid, 0.1 mM hydrogen peroxide, and 20 µl of enzyme extract were added in a total volume of 1 ml. The concentration of oxidized ascorbate was calculated by the decrease in absorbance at 290 nm. The absorption coefficient was 2.8 mM^{-1} cm^{-1}. One unit of APX was counted as 1 mmol ml^{-1} ascorbate oxidized min^{-1}.

Statistical procedures

Data obtained were subjected to statistical Analysis Of Variance (ANOVA), according to Gomez and Gomez (1984). Averages of the main effects of stress water irrigation were associated using the revised Least Significant Difference test (LSD) method at 0.05 probability level. Computations and statistical analysis were done using Statistical Analysis System computerized package program (SAS).

Results and discussion

The statistical analysis of variance for the resulting data showed that, the four water stress levels had significant differences on the all physiological studied traits except nitrogen percentage in regard to the examined genotype eggplant (*Table 2*). Studied plants content of Potassium (K), Phosphorous (P), Carbon (C) and Nitrogen (N) were measured. Results show that highest average of potassium (14.30 mg/g DW) was obtained from irrigation treatment with 80% of pot capacity (T2), while the lowest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1570315711

(6.13 mg/g DW) was recorded by the irrigation treatment with 60% of pot capacity (T3) without any significant differences with (T4) 40% of pot capacity (6.23 mg/g DW). There was significant difference in Phosphorous content between treatments, highest was in T2 by (54.9 mg/g DW), while the lowest was (19.53 mg/g DW). Similar trend was obtained with carbon content, where the highest value (37.61 mg/g DW) was obtained by (T2) and the lowest value (31.54 mg/g DW) was obtained by (T4). The water stress treatments resulted in no significant (at $P<0.05$) regarding to nitrogen percentage in all treatments. Eggplant total yield affected by leaf N and decreased at the lowest irrigation rate 33% Etc (Díaz-Pérez and Eaton, 2015). In general, T2 shows the highest values of mineral content NPK. Farghali and El-Sharkawl (1988) found that total K^+ content in Cotton seedlings roots and aerial parts increased progressively with decreasing water stress, particularly under light condition. Data are agree with Kirnak et al. (2001) whose, found that nutrient concentrations in mature leaves of eggplants grown in pots under different irrigation treatments decrease according to water stress levels. In addition, Almohisen (2015) found that similar trend with Carbon, Potassium, Phosphorous content and Nitrogen percentage in tomato.

The effect of water stress treatments on total chlorophyll, chlorophyll a, chlorophyll b and total carotenoids resulted in significant decrease (at $P<0.05$) in accumulation of pigments. Total chlorophyll was (1.17, 0.70, 0.92, and 0.76 mg/g FW) in T1, T2, T3 and T4 of water stress, respectively. Kirnak et al. (2001) found that total chlorophyll content in water stress treatment was lowered by 55% compared to control treatment. Regarding to chlorophyll a data obtained was (0.80, 0.36, 0.36 and 0.30 mg/g FW) for the four water deficit treatments; T1, T2, T3 and T4, respectively. The highest value of chlorophyll b was 0.38 mg/g FW in both T1 and T4, on the other side, T3 gave the lowest value (0.38 mg/g FW). Chlorophyll indexes have been used as subsidiary estimators of chlorophyll content and leaf nitrogen concentrations (Liu et al., 2006). Carotenoids decreased dramatically in response to water stress from 8.65 mg/g FW in T1 (control treatment) to 5.84 mg/g FW in the fourth treatment (the most stress).

Regarding the proline content, as mentioned in the first paragraph of results and discussion, the analysis of variance data showed that, the three water stress treatments (40, 60, 80%) had significant effect on increasing proline accumulation compared to control. Data showed that proline was 3.63, 6.24, 5.42 and 5.42 μmol g^{-1} FW in T1, T2, T3 and T4, respectively. In response to water stress, proline accumulation usually occurs in the cytosol which plays a significant role in adjustment of cytoplasmic osmotic (Anjum et al., 2012; Almohisen, 2015). In this study, the higher levels of proline accumulation in T4 followed by T3 then T2 enabled the water-stressed plants to maintain low water potentials. Data in *Table 2* show the effect of four water stress treatment on four enzymes content in eggplants. Peroxidase was 15.77 Ug^{-1} FW in control treatment (T1, 0% water deficit), in treatment number two (T2, 20% water deficit) Peroxidase was 2.64 Ug^{-1} FW, while it was 36.76 and 12.45 Ug^{-1} FW in (T3, 40% water deficit) and (T4, 60% water deficit), respectively. Ascorbate peroxidase and Catalase decreased significantly with water stress from 1.76 and 430.15 Ug^{-1} FW in control treatment (T1) to 0.54 and 109.45 Ug^{-1} FW in T4 (the high level from water scarcity), respectively. On the other hand, superoxide dismutase values varied significantly, where the accumulation of superoxide dismutase was 21.66, 28.49, 14.56 and 27.37 Ug^{-1} FW in T1, T2, T3 and T4, respectively. On the other hand, superoxide dismutase values varied significantly, where the accumulation of superoxide dismutase was 21.66, 28.49, 14.56 and 27.37 Ug^{-1} FW in T1, T2, T3 and T4, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1570315711

Drought stress brought different variations in the anti-oxidative enzymes activities (Anjum et al., 2012). Moreover, it has been reported that peroxidase, and catalase activities showed an increased or stabled in the early level of drought and then decreased with progression of water stress. It is conspicuous that, higher levels of antioxidants are interrelated to tolerance of plant toward water stress (Tahi et al., 2008). Superoxide dismutase is considered to form the first line of protection against reactive oxygen species (ROS), which catalyzed the superoxide radical (O_2-) to O_2 and H_2O_2 which are further quenched by diverse antioxidant enzymes.

These significant differences between all values for leaf chlorophyll, carotenoids, proline, enzyme activity and nutrients elements as impact to water stress treatments that may be reflecting the role of these components as a biological regulator in plant (El-Saidy et al., 2011; Ahanger et al., 2016), and may be due to the roll of each one in metabolism system in plant, plus the partial inhibition co-with vitamins of a few interaction in reactive oxygen species production (Ratnakar and Rai, 2013; Ahanger et al., 2017).

Conclusion

In Considering the previous results as a whole and in regard to the examined genotype, it can be concluded that, there are different physiological changes for all studied tratis exeptonly one (N contant) in response to drought stress treatments. The results indicate that irrigation treatment with 80% of pot capacity (T2) more effectively than 60% of pot capacity (T3) and 40% of pot capacity (T4) from the standpoint of more efficient water use. Which would help to diminish drought injury, retain healthy plants to achieve optimum performance and adaptation under drought stress and saving irrigation water usage by 20%.

Change history: The online version of this paper was modified on 27th April 2020. In the following sentence of the Abstract the last percentage data was mistyped (it was corrected from 20% to 40%): "Drought stress treatment had been done by irrigating the plants with 80%, 60% and 40% of water needed to reach soil pot capacity, plus normal irrigation (control treatment)."

(Received 6th Sep 2019; accepted 15th Nov 2019)

Abstract. There are in plenty of microbial resources in Panjin Red Beach, which is a unique wetland in Liaoning province. In this experiment, we investigated bacterial diversity and community in order to understand internal soil microbial community characteristics composition of the soil. Soil samples were collected in five different areas. The bacterial diversity and community were investigated using combined culture-dependent and culture-independent approaches (high-throughput sequencing technology). Through the high-throughput sequencing of the Panjin Red Beach soil, bacterial community turned out to be mainly composed of 13 phyla in the samples collected from the five studied areas, which were Tenericutes, Spirochaetae, Latescibacteria, Verrucomicrobia, Planctomycetes, Cyanobacteria, Actinobacteria, Gemmationadetes, Chloroflexi, Acidobacteria, Firmicutes, Bacteroidetes and Proteobacteria. By cultivable methods, 80 halophilic and alkalophilic bacteria were isolated, and 42 bacteria were selected to be identified by 16S rDNA, and were determined to belong to nine genus and four phyla. *Bacillus* and *Planococcus* was the dominant genus. Accordingly, the bacterial diversity was rich in Panjin Red Beach. Moreover, the data gathered using high-throughput technology is far more accessible than culture-dependant methods.
Keywords: *microbial resources, extreme environment, culture-independent, culture-dependent, bacterial diversity*

Introduction

Extreme environmental microbes are groups of microbes which can grow and reproduce in the extreme regions. For example, thermophilic microbes growing in environments such as hot springs and craters (Stetter et al., 1990), cold-loving microbes growing in extreme cold regions such as the Antarctic, snowy mountains and deep oceans (Liu et al., 2001), acidophilic microorganisms growing in metal deposits, saline soils and sulfur-bearing hot springs (Olson et al., 2003; Zettler et al., 2002), halophilic bacteria growing saline-alkali soil, alkaline lake and ocean environment (Horikoshi, 1999; Margesin and Schinner, 2001; Shi et al., 2012). A broad-spectrum of salt- and alkali-tolerant, and even drought-resistant microbial species resources were found in saline-alkaline soil (Shi et al., 2012). Panjin Red Beach is a very rare shallow shoal, in which soil belongs to saline-alkaline type. Though the microorganisms in extreme environments of saline-alkaline soil has been reported in former researches (Rietz and Haynes, 2003; Zahran, 1997), an in-depth study on the microbial resources in Panjin Red Beach extreme saline-alkaline soils is particularly rare. Therefore, we investigated structure and diversity of soil microbial communities in Panjin Red Beach region.

DOI: http://dx.doi.org/10.15666/aeer/1706_1571315720

Not only the survival status of the microbes was understood in a given habitat under certain culture conditions, but also the new species resources were obtained with potential application value by the traditional cultivable method (Bever et al., 2012). However, diversity of microbial communities is affected by culture-dependent methods in laboratory due to some uncertain factors. Moreover, 0.001-15% of the microbes in the environment can be cultured by culture-dependent methods. For the microorganisms existing in extreme environments, a large number of them are not allowed to be cultured. The microbial information obtained by culture-dependent methods is greatly limited. Some researchers explored methods and techniques by DGGE, clone library and T-RFLP for microbial community structure, but not explain the composition, diversity and function of microbial communities (Theron et al., 2000; Vanwonterghem et al., 2014). High-throughput sequencing technology provides an efficient method for analyzing species composition and relative abundance of microbial communities in complex environments, which can directly sequencing 16S rRNA gene PCR products and simultaneously analyze hundreds of different samples (Chistoserdova, 2010; Rinke et al., 2013). At present, it has been widely used in studies on the structural diversity of microbial communities in ocean, soil, human intestinal tract and other samples (Herlemann et al., 2011; Xia et al., 2011; Passalacqua et al., 2009). Therefore, traditional culture methods combining with High-throughput sequencing technology can comprehensively reflect the diversity of soil microbial. At present, the study on the diversity of microbial resources in Panjin Red Beach mainly focused on the soil microbes in *Suaeda salsa* the roots and endophyte (Zhao et al., 2015; Tian et al., 2016). In the present study, we used traditional culture methods combining with High-throughput sequencing technology to study the diversity of soil microbial in Panjin Red Beach.

Materials and methods

Samples collection and analysis

Soil samples were collected from Panjin Red Beach in Panjin city of Liaoning province, China in July and September, 2016. Samples collected from 0-15 cm depth soil by five dot collection methods were homogeneously mixed and placed in sterile PVC bag, respectively, at five representative plots selected in the test area. All treatments were conducted in triplicate at each plot. Soil samples were put into ice box and brought lab. Some of them were kept in -80 °C and sent to Shanghai Majorbio Corporation (Shanghai, China) to analyze bacteria community structure by high-throughput sequencing. The microbial species richness was represented by the number of unique OTUs (16S rDNA). Chao and Shannon's diversity index were also calculated based on 16S rDNA for comparison of alpha-diversity.

The others were used to determine soil character and analyzed bacterial diversity by culture-dependent methods.

Determination of soil pH and electric conductivity

Soil samples were put into clean paper and dried in shade place at temperature. The dried samples screened by 1 mm net. Samples (10 g) were put into 50 mL bottle. After adding 25 mL distilled water, samples were violently vibrated 5 min on magnetic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1571315720

agitator and let stand for 1 h. Then, pH was determined by pH meter. All samples were conducted in triplicate. All samples were conducted in triplicate.

Samples (20 g) adding 100 mL water (1:5 m/V) were vibrated 5 min at 20 ± 1 °C. The 30 mL extraction buffer was used to determine electric conductivity at 25 ± 1 °C by conductivity meter.

Solid medium

Beef extract 0.3%, peptone 1%, NaCl 1.5%, agar 2%, pH 9.0, 121 °C autoclave steam sterilization 30 min (Shen et al., 2006).

Isolation and purification of microorganisms

Five studied areas samples (10 g) were gradient diluted with sterile saline, respectively. Different gradient bacterial suspension (10^{-3}, 10^{-4}, 10^{-5}) were uniformly spread on the surface of solid isolation medium plate. Each dilution was conducted in triplicate. Aseptic water was used as control. All treatments were cultured 2 days at 37 °C in incubator. According to clone morphology, different single clone was purified and inoculated in solid slope media for other treatments.

Molecular identification of cultured bacteria

The total genomic DNA of the cultured bacteria strain was extracted and purified using Bacterial DNA Isolation Kit (Sangon Biotech Co., Ltd, China) according to manufacturer's instructions. The 16S rDNA of the isolate was amplified through PCR reaction using the universal primers 27f (5'-AGAGTTTGATCATCCTGGCTCAG-3') and 1492r (5'-TACGGTTACCTTGTTACGACTT-3') synthesized by Sangon Biotech Co., Ltd (Shanghai, China). PCR reactions were performed in 50 μL mixture PCR reaction system containing 27f (10 μM) and 1492r (10 μM) primer 1 μL, respectively, DNA template 2 μL, 2×Premix Taq (5.0 U/μL) 25 μL, ddH_2O 21 μL. PCR reaction condition was 95 °C 5 min, 95 °C 1 min, 55 °C 1 min, 72 °C 2 min, 35 cycles, 72 °C 10 min. PCR products were sent to Shanghai Sangon Biotech Co. Ltd to sequence. Homology comparison was conducted online in EzBioCloud database (https://www.ezbiocloud.net/).

Results and discussion

Soil electric conductivity and pH value

Soil electric conductivity and pH value reflected degree of soil saline-alkali. In five geographical regions studied, the highest pH value is 8.66, and the lowest pH value is 8.09. The highest electric conductivity is 10.6 mS/cm, and the lowest value is 3.65 mS/cm (*Table 1*). These data showed that the soil of five geographical regions studied is saline-alkali soil.

Table 1. *Soil electric conductivity and pH value in five checked plots*

	HHT-1	HHT-2	HHT-3	HHT-4	HHT-5
pH	8.57	8.66	8.46	8.36	8.09
Electric conductivity	6.05	4.92	10.6	5.21	3.65

DOI: http://dx.doi.org/10.15666/aeer/1706_1571315720

Diversity of cultured bacteria by culture-dependent

Cultured bacteria of five studied areas samples were isolated and purified in solid medium by culture-dependent methods, respectively. A total of 80 strains were isolated and purified from the plates that could grow steadily and fast in solid medium. Forty-two strains were selected as the representative strains according to the morphological characteristics of the colonies and the Gram stains. However, Tian et al. (2016) isolated and purified 22 strains in *Suaeda* rhizosphere soil in Panjin delta. This circumstance may be partly due to the difference in sampling time and location, and may also be due to the different media used. In the present study, the selected 42 selected isolates were identified by 16S rDNA sequence analysis (*Table 2*), which belonged to four phyla containing Actinobacteria 14.29%, Bacteroidetes 4.76%, Firmicutes 50%, Proteobacteria 30.95%. Forty-two isolates were divided into nine genera respectively, for example *Agromyces*, *Arthrobacter*, *Kocuria*, *Pseudarthrobacter*, *Zhihengliuella, Cellulosimicrobium*, *Pontibacter*, *Myroides* and *Bacillus.* Among nine genera, *Bacillus* and *Pseudomonas* were dominant genus.

Diversity of uncultured bacteria by high-throughput sequencing

Rarefaction curves of five samples were gradually towards flatness, and index reached saturation, which indicated that amount of sequencing data was reasonable and covered composition of flora in five samples (*Fig. 1*). Sequencing data represented microbe level of five samples, respectively. The number of unique operational taxonomic units (OTUs) (16S rRNA gene) represented the microbial species richness (Li et al., 2018). In this study, there were 184079 reads and 10154 OTUs at a cutoff of 97% sequence similarity across all soil samples. The observed bacterial OTU numbers varied between 1854 and 2322 in samples of five studied areas (*Table 3*). The coverage frequency was 99.26%, 99.44%, 99.53%, 99.6% and 99.57%, respectively. These showed that the information of microbial species in each region studied is basically fully reflected.

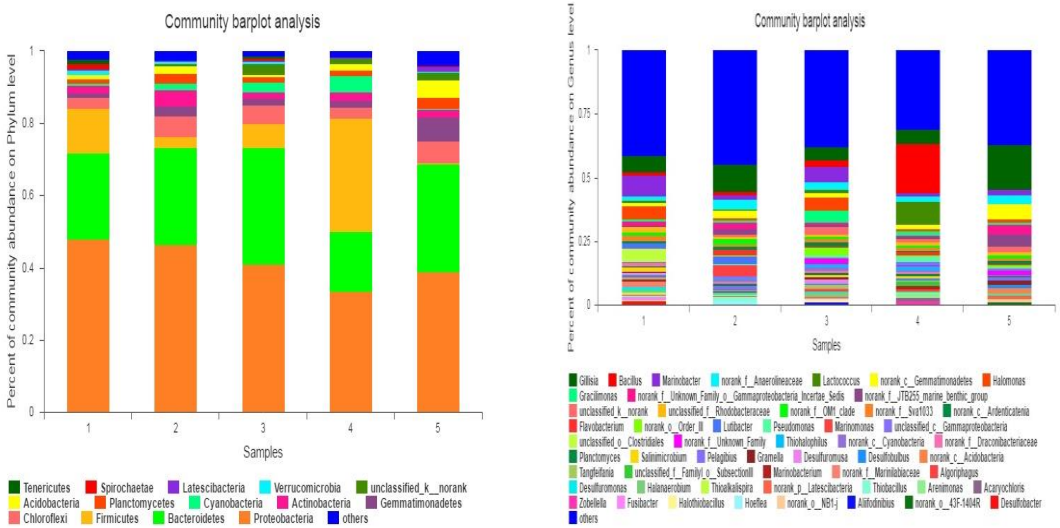
Table 3. *Community indices of five samples*

Sample	reads	OTUs	Chao index	Shannon index	Coverage (%)
HHT1	32030	1854	2181	5.72	99.26
HHT 2	40125	2167	2256	5.64	99.44
HHT 3	36007	1891	2413	5.76	99.53
HHT 4	38580	1920	2267	5.01	99.61
HHT 5	37337	2322	2497	5.87	99.57

The Chao and Shannon diversity index are the indicator of the abundance and an assessment of the diversity of bacteria in the biological environment, respectively (Chao, 1984; Shannon, 1948; Smalla, 2001). The index Chao across all soil samples was very high (*Table 3*). The index Chao of the HHT5 sample was the highest among them. However, the value of the HHT1 samples was the lowest, which indicated that the abundance was the lowest. The index Shannon of the HHT5 sample was the largest among them, which indicated that the diversity of bacteria was the most abundance.

There were mainly 13 phyla in five samples, which were Tenericutes, Spirochaetae, Latescibacteria, Verrucomicrobia, Planctomycetes, Cyanobacteria, Actinobacteria, Gemmationadetes, Chloroflexi, Acidobacteria, Firmicutes, Bacteroidetes and Proteobacteria. The relative abundance of each category varied across the five samples. The relative abundance of Proteobacteria of HHT1 sample was the highest among five samples, which reached 48.03%. Firmicutes was also the widely distributed bacterial phylum in the other four studied samples, but it was completely missing in the HHT5 sample (*Fig. 2A*). The dominant phyla across soil samples were Proteobacteria (from 33.54 to 48.03% in five studied samples) and Bacteroidets (from 16.6 to 32.3% in five studied samples), which were consistent with the observation of Tian et al. (2016). The *Aliifodinibius* was the most abundant genus in all the samples accounting for 41.06%, 44.57%, 37.78%, 31.06% and 36.9%, respectively, followed by *Gillisia* and *Bacillus*. And, there were many bacteria unidentified in genus level in five samples (*Fig. 2B*).



A B

Figure 2. *Bacterial relative abundance of five studied areas samples in phylum (A) and genus (B) level*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1571315720

In comparison with the culture-dependent methods, more bacteria were observed by high-throughput sequencing in phylum. Only four phyla bacteria were isolated by culture-dependent methods. However, there were 13 phyla, and more Chloroflexi bacteria of five studied areas samples and Gemmationadetes bacteria of HHT5 sample were observed by high-throughput sequencing (*Fig. 2A*), but these bacteria were not isolated by the culture-dependent methods (*Table 2*). Maybe, a special medium is needed to thrive for those bacteria. Therefore, the media suitable for saline-alkali environment should be developed to isolate species or strains that are best adapted to grow in saline-alkali soil.

Conclusion

The soil of five geographical regions studied is saline-alkali soil. By cultivable methods, 42 bacteria selected to identify by 16S rDNA belonged to nine genus and four phyla. *Bacillus* and *Planococcus* was the dominant genus. Through the high-throughput sequencing in five studied areas samples, bacterial community was mainly composed of 13 phyla, which were Tenericutes, Spirochaetae, Latescibacteria, Verrucomicrobia, Planctomycetes, Cyanobacteria, Actinobacteria, Gemmationadetes, Chloroflexi, Acidobacteria, Firmicutes, Bacteroidetes and Proteobacteria. Therefore, the bacterial diversity was very rich in Panjin Red Beach. The bacteria strains should further be explored for agricultural and industrial use.

EFFICACY OF MASS TRAPPING OF TOMATO LEAFMINER (*TUTA ABSOLUTA*) WITH DIFFERENT TYPES AND COLOURS OF TRAPS IN OPEN- FIELD TOMATO

POLAT, B.

Çanakkale Onsekiz Mart University, Faculty of Agriculture, Department of Plant Protection
17020 Çanakkale, Turkey
(e-mail: brkpolat@gmail.com; phone: +90-286-218-0018; fax: +90-286-218-0545)

(Received 6th Sep 2019; accepted 15th Nov 2019)

Abstract. As a limiting factor on tomato production, tomato leafminer *Tuta absoluta* (Meyrick, 1917) (Lepidoptera: Gelechiidae) has recently been considered as the main tomato pest. Different control methods should be considered for integrated pest management. This study was carried out to control *T. absoluta* by using pheromones and traps of five different colours (red, yellow, blue, white, black) and three different types (ferolite, water pan, roll) in combination at trial plots in Dardanos and Dumrek and Cıplak villages in Çanakkale province, Turkey. A randomized plot experimental design was implemented and traps were controlled and counted twice a week. Ferolite traps were determined to have the most success in capturing adults, followed by water and roll traps. The highest number of adults was captured with the colours black and white regardless of trap type, whereas the lowest number of adults was captured with yellow traps. It was observed upon comparing the capture rates of T. absoluta adults subject to trap type that 49% of the adults were counted in the ferolite traps. Water pans and roll traps followed the ferolite trap with 38% and 13%, respectively. Results indicate that mass trapping is effective in reducing the pest population in open-field tomato cultivars.
Keywords: *Çanakkale, light trap, water pan trap, roll trap, pest management*

Introduction

The tomato leafminer *Tuta absoluta* (Meyrick, 1917) (Lepidoptera: Gelechiidae) of South American origin was first encountered in Europe in 2006 in tomatoes cultivated under greenhouse conditions. The pest had spread rapidly causing significant damage in countries located in the Mediterranean basin (Urbaneja et al., 2007; Zappalà et al., 2013). It was first discovered in Turkey in open-field tomatoes in 2009 (Kılıc, 2010; Kasap et al., 2011). *Tuta absoluta* is a multivoltine and oligophagous pest and may damage many solanaceous crops (Torres et al., 2001; Desneux et al., 2010; Portakaldalı et al., 2013; Gozel and Kasap, 2015; Uzun et al., 2015). The larvae of this invasive pest feed on all above-ground parts of the tomato plant and cause 100% damage in the plant when not taken under control (EPPO, 2005). Male longevity was observed by Polat et al. (2016) as 3.37-6.14 days while female longevity was 7.7-9.75 days. The total number of eggs per female for each generation varied between 31 and 186. The females laid 68-72% of their eggs in the first five days, while data indicated that 81-83% of the eggs were laid on the 6th day (Polat et al., 2016).

The tomato is grown in many countries but is one of the most important vegetables produced in Turkey where it was ranked fourth in the world in 2016 with 12.600.000 tons of tomato production and a total plantation area of 180.670 ha (TUIK, 2017). As a major pest, similarly to its global prominence, the tomato leafminer poses a significant threat to tomato cultivation in the province of Çanakkale. It has been determined that 88% of all tomato growing areas in Çanakkale province are infested with *T. absoluta* (Polat et al., 2015).

DOI: http://dx.doi.org/10.15666/aeer/1706_1572115730

Comprehensive and alternative control methods should be investigated for use in integrated pest management programs (IPM), especially in terms of issues related to resistance and extensive insecticide use (Polat and Tiryaki, 2019). Among the alternative methods, pheromones are used to monitor the population of insects to identify the correct timing to apply various control strategies, such as the introduction of natural enemies, intensification of mass trapping and application of insecticides (Megido et al., 2013; Braham, 2014). Different types of traps such as water pans and coloured traps also interfere in the attraction of the adults of *T. absoluta*. This pest has been controlled in many countries in the world by way of IPM programs, based on the use of pheromones and mass trapping applications (Gonzales-Cabrera et al., 2011; Cherif and Lebdi-Grissa, 2014; Aksoy and Kovancı, 2016; Bayram et al., 2017). On the other hand, light traps have also been used as part of the mass trapping method for pest control (Stol et al., 2009; Cocco et al., 2012; Ozkan et al., 2017). In other research, roll traps were designed to reduce the *T. absoluta* population for tomato growing in greenhouses (Hassan and Alzaidi, 2010). However, these studies were performed with a limited number of traps of different colour and type. In addition, roll traps with pheromones have not been used yet to determine *T. absoluta* in open-field tomato production.

Therefore, the purpose of the present research was to define the efficacy of mass trapping *T. absoluta* with five different colours (red, yellow, blue, white, black) and three different types of trap (ferolite, water pan, roll) in open-field tomato cultivation.

Materials and methods

Experimental area

The mass trapping experiments were carried out in 2017 on open-field tomato crops at the villages of Dumrek and Cıplak in the province of Çanakkale located in northwest Turkey (*Figure 1*, *Table 1*).

Figure 1. *Location of 3 trial areas in study*

Tomato was cultivated at Faculty of Agriculture Application Area in Dardanos. In addition, producer-controlled trial parcels were also established in the villages of Dumrek and Cıplak near the site of ancient Troy. Each experimental area was four da in size. The tomatoes were transplanted on 12.05.2017 at Dumrek, on 14.05.2017 at Cıplak, and on 24.05.2017 at Dardanos and the traps were placed on the same days.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1572115730

The pest population did not reach an intensity which could result in economic damage and hence no insecticide was applied during the study. Fungicides (Penconazole, Copper oxychloride) were used to ensure the healthy growth of the tomatoes and drip irrigation applied to fulfil their water requirement. Furthermore, the parcels were fertilized according to soil analysis that was carried out at the beginning of the season.

Table 1. *Study areas and parcel data*

Study Area	Tomato variety	GPS Coordinates
Dardanos	*Lycopersicum esculentum* Mill. cv. Troy F1	40°4'29.67" N 26°21'51.13" E
Dumrek	*Lycopersicum esculentum* Mill. cv. Troy F1	39°58'17.05" N 26°18'4.10" E
Cıplak	*Lycopersicum esculentum* Mill. cv. Troy F1	39°56'24.42" N 26°15'19.48" E

Agricultural applications

Five different colours (red, blue, yellow, white, black) and three different types of trap (ferolite, water pan, roll) were used for the mass trapping applications. To obtain data on the colour of the traps, a Minolta CR-400 Chroma meter (Konica, Minolta, Japan) was used in the study (*Table 2*).

Table 2. *Colour data used in traps*

Colour of trap	L	a	b	c	Hue
White	65.23	0.17	-3.36	3.6	272.99
Black	17.67	-0.24	4.03	4.04	93.41
Blue	32.12	11.07	-40.83	42.51	285.17
Yellow	76.44	-6.56	79.97	80.24	94.69
Red	37.49	40.73	39.26	50.15	38.92

The water pan traps (Tutasan, Turkey) and ferolite (with light source, Russell IPM Ltd., UK) used in this study contain pheromone lures (E3, Z8, Z11-Tetradecatrienil). Roll traps (Russell IPM Ltd., UK and Tutasan, Turkey) which make use of high attraction pheromone film were also used. The dimensions of the traps were as follows. The height of the water pan traps from bottom to top was 7 cm and the diameter was 36 cm. For ferolite traps the lamp height was 30 cm, base length 26 cm, and the diameter 40 cm. To prepare the roll traps, the film was glued on a pipe with a diameter and length of 7.5 cm and 150 cm, respectively, thereby covering the whole pipe. Traps were placed in the field with four traps per day (Aksoy and Kovancı, 2016; Cherif et al., 2018). The traps used in the trial were placed in the parcels in the pattern indicated below (*Figures 2 and 3*).

Adults in the traps were counted twice per week; after that they were removed and the traps were cleaned for the new count. The water level was checked during inspection and the traps were refilled when necessary. Pheromone lures were replaced every four weeks. However, the roll traps were replaced every three weeks due to dryness of the sticky film.

DOI: http://dx.doi.org/10.15666/aeer/1706_1572115730

Statistical analysis

The data were analyzed by Minitab R18 (StatSoft, Inc. Tulsa OK, USA) statistical software. Differences between the data were evaluated by means of variance analysis (ANOVA) using GLM. Tukey's method was applied as a group comparison test.

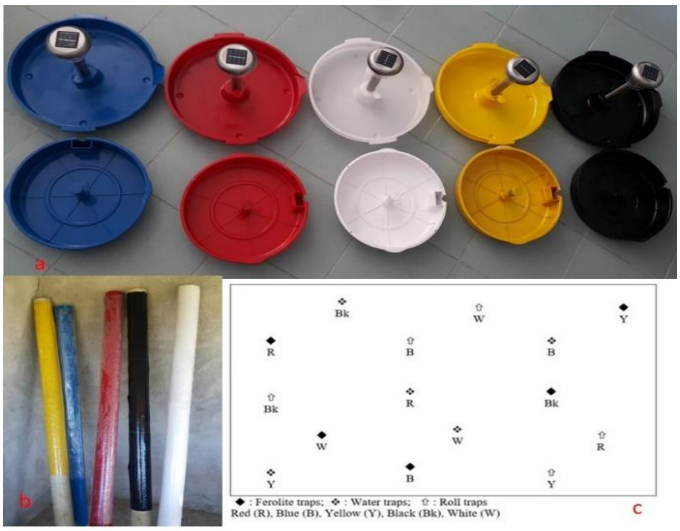

Figure 2. *Three different traps used in ferolite and water traps (a), roll traps (b) and their placement pattern (c)*

Figure 3. *Different traps and colours placed in trial plots*

Results and discussion

The first adult *Tuta absoluta* at the Dardanos experimental site were trapped on 25.05.2017 when the average temperature was 11.1°C. The highest number of captured adults in the season was 267 on 24.08.2017 in the white ferolite traps. The proportional average humidity was measured in this 4-day interval (21-24.08.2017) as 75.2%, while the average temperature was 22.1°C. The highest total number of adults captured was 3.864 in the white ferolite traps. This was followed by the black ferolite traps with 3.678 and blue ferolite traps with 2.955 adults (*Figure 4*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1572115730

The first adult at the Dumrek trial area were captured on 18.05.2017 when the average temperature was 17.1°C. The highest number of captured adults during the season was 401 on 24.08.2017 in the black ferolite traps. The proportional average humidity was measured in this time interval (21-24.08.2017) as 70.5%, while the temperature average was 24.6°C. Overall, the highest total number of adults captured was 4.645 in the white ferolite traps. This was followed by the black ferolite traps with 4.599 and the black water pan traps with 4.520 adults (*Figure 5*).

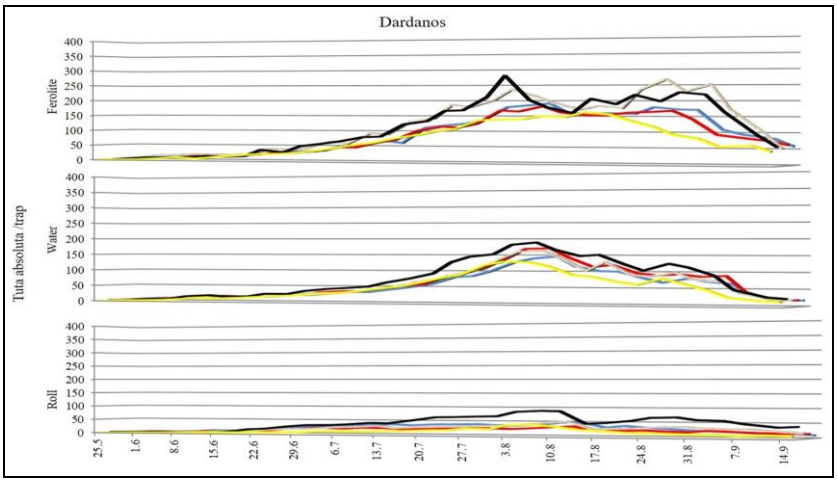

Figure 4. *Tuta absoluta captured at Dardanos by type and colour of trap*

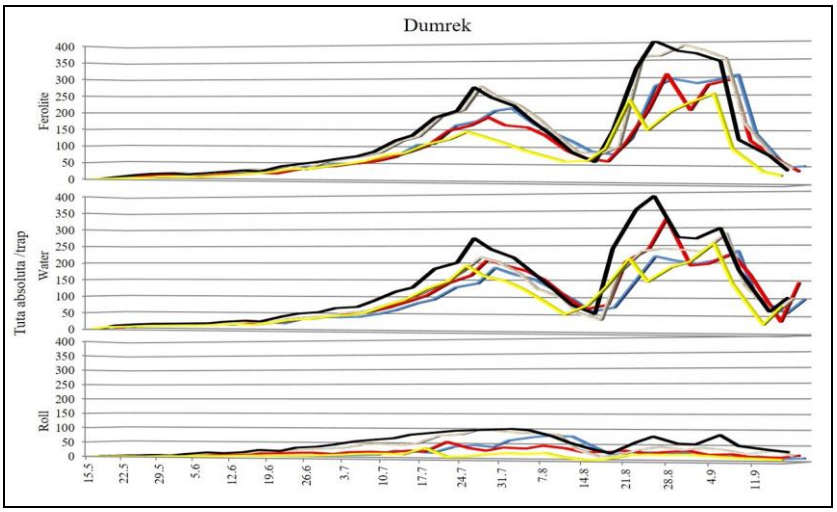

Figure 5. *Tuta absoluta captured at Dumrek by type and colour of trap*

The first leafminer adults at the Cıplak trial area were captured on 18.05.2017 when the average temperature was 17.1°C. The highest number of captured adults throughout the season was 282 on 27.07.2017 in the black ferolite traps. The proportional average humidity was measured in this time interval (24-27.07.2017) as 61.2%, while the temperature average was 22.6°C. The highest total number of adults captured was 4.028 in the white ferolite traps. This was followed by the black ferolite traps with 3.969 and blue ferolite traps with 3.518 adults (*Figure 6*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1572115730

A statistically significant difference was determined between the traps based on the adult count (P<0.05; F=91.54). As can be seen in *Figure 7*, a difference was observed between the trap types. In all study areas, ferolite traps were the most successful in catching adults and this was followed by the water pan traps and roll traps. The effectiveness of trap types does not change between different locations. A total of 108.043 *T. absoluta* adults were captured in the traps. The proportional distribution is given in *Figure 8*.

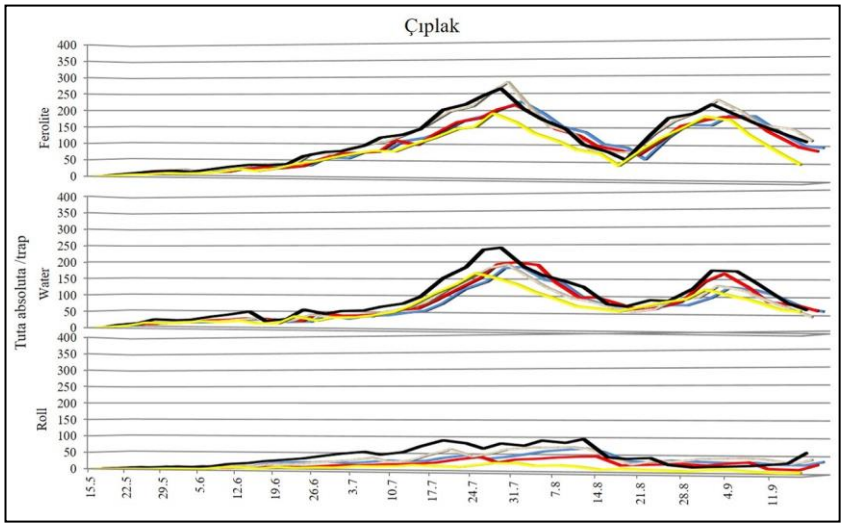

Figure 6. *Tuta absoluta captured at Cıplak by type and colour of trap*

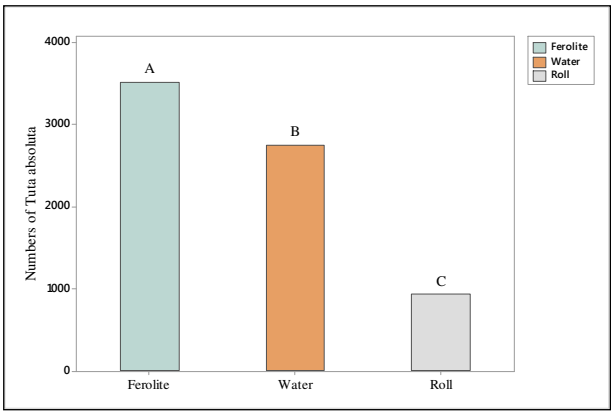

Figure 7. *Tuta absoluta captured by different trap type.*
**Different letters indicate statistical significance (P<0.05) for in-column comparisons*

The highest number of adults was captured in ferolite traps with a total of 52.748 (49%), followed by water pan traps and roll traps with 41.257 (38%) and 14.038 (13%) captured adults, respectively. As can be seen in *Figure 9*, while the highest number of adults among the ferolite traps was captured in white traps (12.537), a statistically significant difference was not determined with those captured in black traps (12.246). The lowest number of tomato leafminer adults was captured in yellow ferolite traps with 8.029. Stol et al. (2009) stated that light traps in greenhouses attract both females and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1572115730

males in the struggle against *T. absoluta*, whereas pheromones attract only males, leading to minimum damage in greenhouses. Similar results were found in studies by Matos et al. (2012) and Özkan et al. (2017) in which it was shown that a greater number of adults were captured with light traps. However, Aksoy and Kovancı (2016) carried out a study in which the damage rates were compared for ferolite and water pan traps; as a result of which it was found there is no difference except for the fact that the ferolite trap is not economically feasible since it has a higher unit cost in comparison with the other trap.

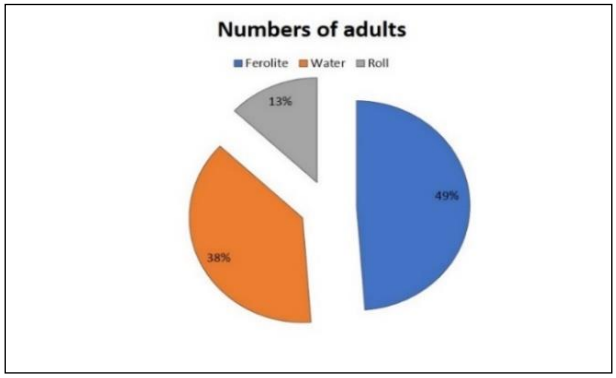

Figure 8. *Total number of Tuta absoluta captured by type of traps (%)*

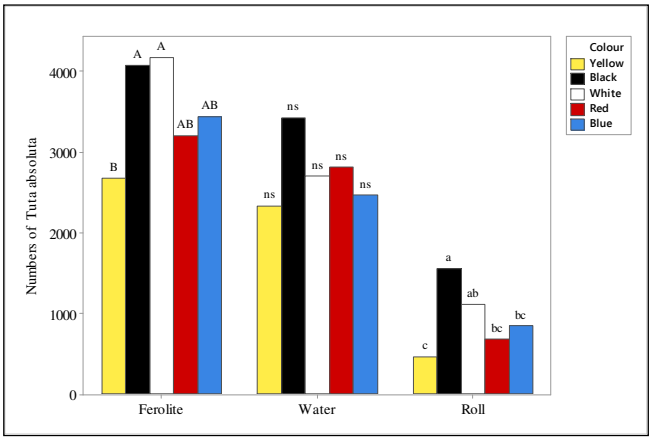

Figure 9. *Tuta absoluta captured by type and colour of traps.*
**Different letters indicate statistical significance (P<0.05) for in-column comparisons.*
ns = no significant difference

Despite the lack of a statistically significant difference between the water pan traps, the highest number of adults was captured in black traps with 10.299; this was followed by red, white, blue and yellow traps with 8.441, 8.106, 7.395 and 7.016, respectively. Taha et al. (2012) carried out a study with red, blue, green and yellow traps in which it was found that the highest number of *T. absoluta* adults was captured in the red water pan traps, and sequentially by blue, green and yellow traps, respectively. Similar to the results of Taha et al. (2012), in our study the yellow water pan traps were found the least attractive for adults of *T. absoluta*, whereas red traps were found the most attractive.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1572115730

It was observed as a result of analysis carried out based on the colour, independent of trap type, that black and white attracted the highest number of adults whereas yellow attracted the least number of adults ($P<0.05$; $F = 6.57$). Mahmoud et al. (2014) found that white and yellow were more attractive, while Shiberu and Getu (2017) reported that the highest number of adults was captured in white and blue sticky traps, whereas the lowest number of adults was captured in green and red traps. These studies show that the white traps have the highest potential to attract *T. absoluta*. A statistically significant difference was observed between the roll traps with the highest number of adults captured in the black trap (4.690). This was followed by white, blue, red and yellow traps with 3.353, 2.550, 2.036 and 1.409, respectively.

Hassan and Alzaidi (2010) reported that yellow rolls can be used to catch *T. absoluta* but their use is not recommended in greenhouses because yellow traps could also attract beneficial insects. However, yellow was found to have the lowest efficiency for capturing tomato leafminer in all trap types in the current research. Therefore, yellow-coloured traps are not recommended for use in open-field tomato cultivation to capture *T. absoluta*. On the other hand, more adults were captured in all traps that were black and white. Therefore, black and white traps are highly recommended for attracting *T. absoluta* in open-field tomato production.

Conclusion

As a result, the mass trapping method is effective with low pest populations. Even though it is not directly effective in reducing *T. absoluta* in high pest populations, when it is used together with other control methods, the tomato leafminer population can be kept below harmful economic levels. Consequently, it can also be useful to increase the producer's profits by decreasing the use of insecticides. In addition to its impact on reducing costs, this aspect of the mass trapping method is also important due to the adverse impact that insecticides have on human health and the balance of nature. Also, studying different hues of black and white colours, which were the most effective colours in further researches, would be beneficial to increase the effectiveness of the traps.

Abstract. The vegetation in fragile ecological areas easily degrades and the original ecosystem is hard to preserve. This paper attempts to disclose the effects of different plant communities on the physical properties of the soil in the Yimeng Mountains of eastern China. For this purpose, the relative weight of soil particles in varied sizes was measured by the mechanical sieving method firstly. Next, the fractal dimensions of soil particles were computed based on their mass. After that, the uniformity and curvature were calculated for soil particles in varied sizes, under the cumulative percentage contents of 10%, 30%, and 60%. The results show that the local soil is predominately coarse sandy soil and the soil structure of forests is way better than that of slope wasteland; by fractal dimension, the coverage types were ranked in descending order as mixed forest > pure forest > economic forest > farmland > slope wasteland; the fractal dimension has a significant positive correlation with the particle size of fine sandy soil and coarse powder. The research findings shed new light on how to select tree species and design vegetation types to recover and reconstruct the vegetation in mountainous regions of eastern China.
Keywords: *fractal dimension, soil structure, uniformity, plant diversity, ecological protection*

Introduction

More than 60% of China is covered by fragile ecological areas, where vegetation easily degrades and the ecology is hard to preserve. The vegetation growth largely depends on the soil properties. In return, the soil properties are directly and indirectly affected by the overlying vegetation. The plant communities provide above- and belowground litterfall, release and recycle nutrients, modify the microclimate, regulate the water cycle, and alter the composition of fauna and flora in soil (Jose, 2009; Li et al., 2016). However, the soil structure is extremely complex. Some soil properties are too irregular and stochastic to describe by traditional statistical methods (Turcotte, 1986; Xiao et al., 2014; Luo et al., 2015).

The above problem can be solved effectively by fractal theory, powerful tool to tackle complex phenomena. The fractal theory has been widely adopted in numerous fields (Li and Wei, 2014). Since the 1980s, fractal theory has been applied to soil science (Turcotte, 1986; Gao et al., 2014; Sun et al., 2019). In the following decade, many scholars explored the feasibility of characterizing particle size distribution with fractal theory (Tyler and Wheatcraft, 1992; Su et al., 2004; Wei et al., 2016). The particle size distribution is an important physical attribute of soil that changes with the soil conditions (Xu et al., 2013; Lyu et al., 2015). The variation of the soil particle size distribution helps to identify the structure, dynamics and physical processes of soil (Ghorbani et al., 2012; Peng et al., 2014).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1573115743

The fractal dimension is a useful metric to quantify various soil properties, namely, structure, erodibility (Perfect, 1997; Xia et al., 2015; Deng et al., 2018) and water permeability (Yu et al., 2015; Zhao et al., 2016; Zhao et al., 2017). The fractal information facilitates the design of soil conservation measures and selection of vegetation types in plateaus and mountainous regions (Liu et al., 2009; Wei et al., 2016). However, the fractal theory has not been extensively applied to analyze the soil particle size distribution in the Yimeng Mountain of central Shandong, China. In addition, the impacts of plant communities on the composition and distribution of soil particles remain unclear.

To make up for the gaps, this paper analyses the fractal features of soil particles under 11 plant communities in the Yimeng Mountains of eastern China. The analysis results shed new light on how to select tree species and design vegetation types to recover and reconstruct the vegetation in mountainous regions of eastern China, laying the technical basis for erosion control in fragile ecological areas.

The remainder of this paper is organized as follows: Section 2 describes the test materials and methods; Section 3 analyzes the composition, fractal dimension and size distribution of soil particles under 11 plant communities, and discusses the impacts of fractal dimension on the composition and uniformity of soil particles; Section 4 puts forward the research conclusions. This study attempts to disclose the effects of different plant communities on the physical properties of the soil in the Yimeng Mountains of eastern China. For this purpose, 11 local plant communities were selected, and the fractal theory was employed to examine their effects on the composition and size distribution of soil particles.

Materials and Methods

Study area

As shown in *Figure 1*, the study area lies in the upstream of the Taihe Reservoir, a large water conservancy project on the Zihe River. Located in the southeast of Zichuan District, Zibo Prefecture, Shandong Province, the northern part of the Yimeng Mountain of eastern China (117.9°E-118.2°E, 36.3°N-36.7°N), this area spans across several counties and towns, covering a total area of 278.02 km^2.

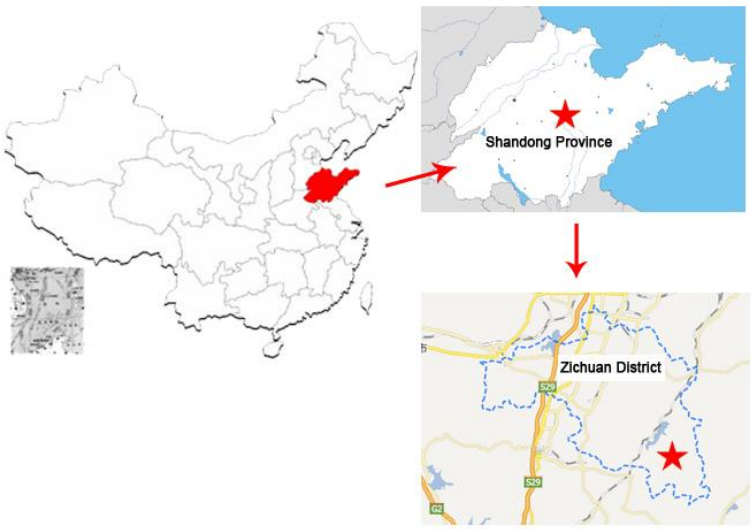

Figure 1. *Location and satellite map of the study area*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1573115743

The maximum south-to-north distance is 18.2 km and the maximum east-to-west distance is 26 km. The region is a warm-temperature and semi-arid continental monsoon climate, with annual average temperature of 12.9°C. Annual average precipitation is 664 mm with 70% occurring between June and August. Annual average sunshine time is 2364 h, and the frostfree period is 189 days.

The soil type in the project area is mainly brown soil, and there are three subclasses: the brown soil subclasses, the leaching brown soil subclasses and the brown soil subclasses. The vegetation type has three types of natural vegetation, artificial vegetation and cultivated crops, among which, the natural vegetation is mainly grass and wild shrubs, and the natural vegetation is mainly of grass and wild shrubs, and the main tree species of the artificial vegetation are *pinus thunbergii*, *pinus densifla*, *Quercus acutissima*, *Robinia pseudoacaca* and *Castanea mollissima*, etc. The cultivated crops are sweet potato, *scutellaria baicalensis*, and the rest are wheat, corn and soybean. Typical plant communities and soil types in the Yimeng Mountain can be found in the study area (*Figure 2*).

Figure 2. *Photos of the study area*

Test materials

As shown in *Table 1*, eleven typical plant communities were selected from the study area to identify the size distribution of soil particles, and disclose the effects of vegetation types on the fractal dimension of soil particles (*Figure 3*). The eleven plant communities belong to five vegetation types, namely, pure forest (*Pinus thunbergii* and *Robinia pseudoacacia*), mixed forest (*Robinia pseudoacacia- Quercus acutissima* and *Pinus densiflora- Pinus thunbergii*), economic forest (*Castanea mollissima* and apple), farmland (*Scutellaria baicalensis*, sweet potato, other crops) and slope wasteland (wild grass 1 and wild grass 2). Three test plots were set up in each land use type, and the test sample points were determined according to the diagonal 3-point sampling method in each sample plot, repeat three samples (average analysis) at each test sample point.

Test methods

Composition of soil particles

The size and weight distributions of soil particles were tested by the mechanical sieving method (dry sieving). Firstly, soil samples (particle size: 0~40cm) of each plant community from five points, dried and then mixed. The gravels with diameter greater than 2 mm were filtered out. Next, the relative weight contents of soil particles in varied sizes were measured by a ZBSX-92A standard electric sieve shaker (sieve swaying times: 221 times/min; shaking times: 147 times/min; shaking amplitude: 25 mm; motor power: 0.37 kW) with sieve sizes of 1.00, 0.50, 0.25, 0.10 and 0.05 mm.

Fractal dimension of soil particles

After the soil samples were dry-sieved, the weights and percentage contents of soil particles in varied sizes were measured and calculated. On this basis, the fractal dimensions of soil particles were computed based on their mass weight, assuming that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1573115743

soil particles in varied sizes have the same density. The quantitative distribution of soil particles was represented by weight distribution (Yang et al., 1993). Then, the fractal dimension (D) can be derived by the method of limits.

$$D = 3 - \lg\left(\frac{w_i}{w_o}\right) / \lg\left(\frac{d_i^*}{d_{max}^*}\right) \quad \text{(Eq.1)}$$

where w_i is the cumulative mass of soil particles smaller than d_i*; w_0 is the total weight of all soil particles; d_i^* is the mean particle diameter (mm) between d_i and d_{i+1} of two adjacent particle size; d_{max}^* is the mean diameter of the largest soil particle. The mean particle diameter is the arithmetic mean of the upper and lower sieve sizes.

Size distribution of soil particles

Based on the weights of soil particles in varied sizes, the size distribution of soil particles was described by the tabular method and the cumulative curve method. The particle sizes corresponding to the cumulative percentage contents of 10%, 30% and 60% were denoted as d_{10}, d_{30}, and d_{60}, respectively. The index d_{10} means the particles smaller than this size account for 10% of the total soil mass. The meanings of d_{30} and d_{60} can be derived by analogy. The size distribution was measured by two coefficients, namely, uniformity (C_u) and curvature (C_c):

$$C_u = d_{60}/d_{10} \quad \text{(Eq.2)}$$

$$C_c = d_{30}^2/ (d_{60} \times d_{10}) \quad \text{(Eq.3)}$$

where d_{10} is the effective particle size, i.e. the pore diameter of the sieve; d_{60} is the control particle size. The uniformity is a key evaluation index of particle size distribution. A high uniformity means a wide distribution of particle sizes (If $C_u < 5$, the soil is uniform but poorly graded; if $Cu > 10$, the soil is well graded), but an excessively high uniformity may cause discontinuous grading, i.e. the absence of medium particle size. Thus, the curvature index was introduced to measure the overall shape of the cumulative curve.

Results and Analysis

Composition of soil particles

Size distribution of soil particles

Most soil particles were irregular, some varied greatly in three-dimensional (3D) size, and coarse and fine soil particles differed markedly in properties. For simplicity, the soil particles were viewed as smooth solid spheres, and divided into several groups based on diameter according to a standard for soil size fraction in China (*Table 2*) (Huang, 2000).

Composition of soil particles

The relative contents of dry-sieved soil particles in varied sizes are displayed in *Table 3* below. As shown in *Tables 2 and 3*, the soil particle sizes ranged between 0.25 and 1.0 mm under different plant communities, indicating that the local soil is predominately coarse sandy soil. This soil structure is a typical pattern in rocky hills of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1573115743

northern China. The lack of fine particles (e.g. powder and clay particles), coupled with the high content of sandy soil, makes the soil structure extremely weak, loose and permeable, which is unfavorable to soil conservation (Deng et al., 2008).

By plant communities, the sampling sites of PT, RP and RQ were all rich in clay and powder particles; the sampling sites of A, WG1 and WG2 had high contents of fine sandy soils; the sampling sites of SP, SB and OC were dominated by sandy soils. The results show that both mixed and pure forests have a much better soil structure than slope wasteland, and mixed forest has more rational soil structure than pure forest. Therefore, needle-broad leaved or broad-leaved mixed forest can increase the contents of fine particles (e.g. clay and powder particles) in soil, and reduce the content of sandy soils. This is conducive to the soil structure and soil conservation. By contrast, the farmland witnesses a gradual reduction of fine sandy soils, which undermines the soil texture. This calls for prompt improvement of cultivation and irrigation methods.

Table 2. *The standard for soil size fraction*

Name of particle		Size (mm)
Gravel	Gravel	2~1
Sand	Coarse sand	1~0.5 0.5~0.25
	Fine sand	0.25~0.2 0.2~0.1 0. 1~0.05
Powder	Coarse powder	≤ 0.05

Fractal features of soil particles

Fractal dimension of soil particles under different plant communities

The fractal dimensions of soil particles were calculated by linear regression with *Equation 1*. The results are recorded in *Table 4*. Based on the data in *Table 4*, a graph (*Figure 4*) was plotted with fractal dimension as the y-coordinate and plant community as the x-coordinate.

As shown in *Table 4*, the calculated fractal dimensions fell within a small interval: 2.0044~2.4925. The results are basically within the range of sandy soil in China

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1573115743

(1.834~2.641) (Hu et al., 2003). This conclusion agrees with the data in *Table 3*. It can be seen from *Figure 4* that RQ corresponded to the highest fractal dimension, followed by PP, RP, A, PT, CM, SB, OC, WG2, WG1 and SP in succession.

Table 4. *D-value of soil particles under different plant communities*

Types	Code	Sample plot	Slope	D
Pure forest	PT	1	0.98	2.3574

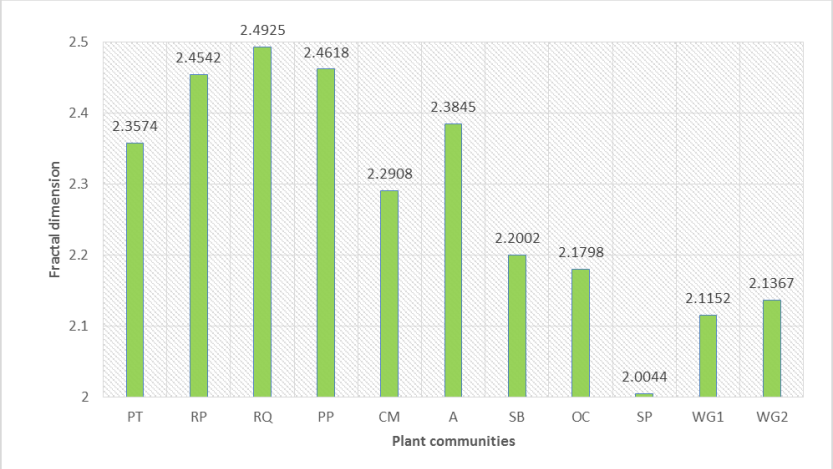

Figure 4. *The fractal dimensions of soil particles under different plant communities*

Effects of coverage type on fractal dimension

The effects of coverage type on fractal dimension are manifested as soil improvement and protection of plant communities. In *Table 4* and *Figure 4*, the fractal dimensions of the 11 plant communities fell between 2.0044 and 2.4925. Thus, all types of plant communities have a major impact on fractal dimension.

By fractal dimension, the coverage types were ranked in descending order as mixed forest > pure forest > economic forest > farmland > slope wasteland.

The forests had higher dimensional values than the other vegetation types, revealing that forest species can greatly enhance soil structure. Among forest lands, mixed forest (RQ > PP) is the most effective vegetation type to ameliorate soil structure, followed by pure forest and economic forest. The advantage of forests is attributable to the importance of forest species in soil development. The soil beneath forests often features small particle

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1573115743

size, good air permeability and coexistence of large and small pores. This type of soil is easy to conserve.

By contrast, farmland and slope wasteland showed similarly small fractal dimensions. This means the coarse soil texture under crops can slightly improve the soil structure. The soil texture is coarsen by the erosion of gravel surface.

Relationship between content and fractal dimension

Based on *Tables 3 and 4*, the relationship between content and fractal dimension of soil particle in each size was plotted (*Figure 5*). It can be seen that the percentage contents of soil particles in varied sizes differed in their impacts on fractal dimension. Overall, fractal dimension has a linear correlation with the content of soil particles in each size. The linear correlation was significantly positive for fine sandy soil and coarse powder, as evidenced by the correlation coefficients (R^2): 0.2888 and 0.901. By contrast, the linear correlation was significantly negative for coarse sandy soil, with the R^2 being 0.7342; the linear correlation was not evident for gravel. The results show that the percentage contents of soil particles in varied sizes have different correlations with fractal dimension. This finding may be related to the high percentage contents of soil particles in other sizes within the study area. The fractal dimension failed to reflect the non-uniformity of soil texture in the study area correctly, implying that it cannot clearly measure the content variation of soil in each particle size.

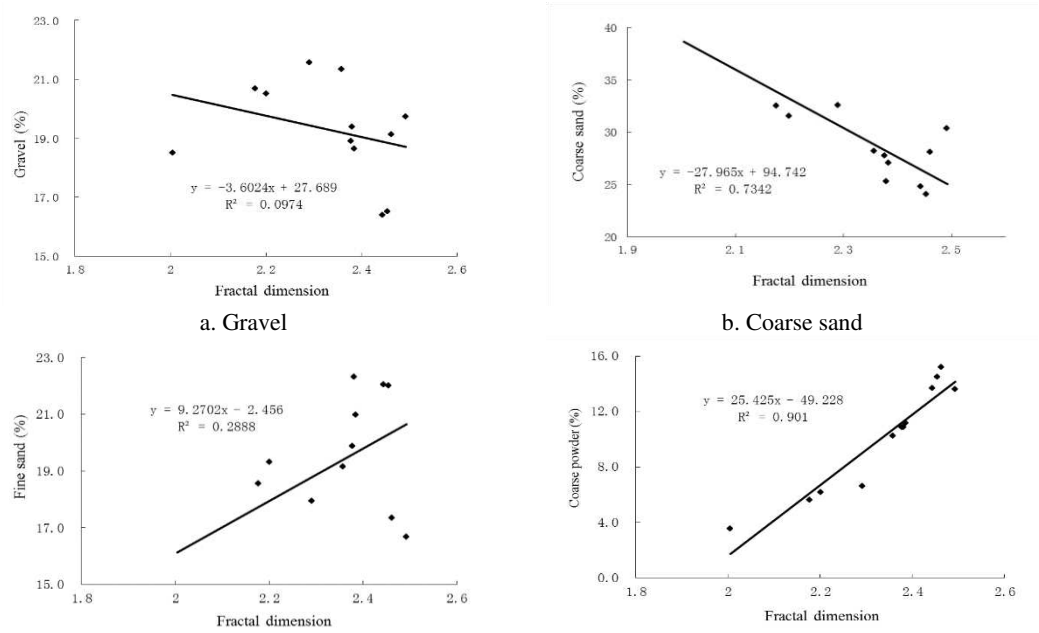

Figure 5. *The relationship between percentage content and fractal dimension of soil particle in each size*

Combining with existing research results, the author found that fractal dimension is closely related to the size, quantity, and distribution uniformity of soil particles. The fractal dimension changed evidently with soil particle size. The above results show that the fractal dimension is an important index to evaluate soil texture. Small soil particles tend to have a high fractal dimension, because of their fine texture and high content of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1573115743

fine particles, while large soil particles usually have a low fractal dimension. In other word, the fractal dimension increases with the size of soil particles. The fractal dimension of sandy soil was significantly lower than that of loam and clay soils. High fractal dimensions mean good soil texture but poor air permeability, which contribute to soil conservation. The inverse is also true. Furthermore, since water and wind erosions mainly induce losses of superficial clay and powder particles, a low content of fine particles indicates serious soil erosion. Therefore, the prediction of fractal dimension is critical to the evaluation of the degree of soil erosion.

Uniformity and curvature of soil under different vegetation types

The uniformity and curvature of soil under each plant community were computed by *Equations 2 and 3*, respectively. The computed results (*Table 5*) show that PT led to the highest uniformity, followed in descending order by RQ, RP, PP, A, CM, SB, OC, SP, WG1 and WG2. By uniformity, the five vegetation types were ranked in ascending order as of slope wasteland < farmland < economic forest < mixed forest < pure forest.

Table 5. *The uniformity and curvature of soil under each plant community*

Plant community	d_{60}	d_{30}	d_{10}	C_u	C_c
PT	0.56	0.18	0.02	28.00	2.89
RP	0.65	0.19	0.03	21.67	1.85
RQ	0.72	0.22	0.03	24.00	2.24
PP	0.66	0.25	0.04	16.50	2.37
CM	0.95	0.29	0.09	11.88	1.11
A	0.65	0.23	0.04	16.25	2.03
SB	0.90	0.37	0.08	11.25	1.90
OC	0.96	0.30	0.12	8.00	0.78
SP	0.58	0.25	0.09	6.44	1.08
WG1	0.80	0.32	0.15	5.33	0.85
WG2	0.95	0.55	0.20	4.75	1.59

* Abbreviations of plant communities please refer to table 1 in detail

Specifically, slope wasteland and farmland possessed a relatively uniform soil texture, showing a small difference of content between coarse and fine soil particles. The curvatures of these two vegetation types fell between 0.78 and 1.90, indicating that their soil particles are poorly graded.

For economic and mixed forests, the uniformities ranged from 11.88 to 24, and the curvatures varied between 1.11 and 2.37. Thus, these two vegetation types have well graded soil particles. For pure forest, the uniformity was 21.67~28 and the curvature was 1.85~2.89, a signal of good grading.

Discussion

The soil texture can be evaluated by the contents and uniformities of soil particles in varied sizes. Being a porous medium, soil has a self-similar structure and certain fractal features. The fractal dimension is the main index of fractal features. Therefore, the relationship between uniformity and fractal dimension is conducive to the analysis on soil structure and texture. The relationship curves between the two factors were plotted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1573115743

(*Figure 6*) based on *Tables 4 and 5*, with fractal dimension as the x-coordinate and uniformity as the y-coordinate.

The linear fitting results were Y = 40.94X − 79.325 and R^2 = 0.7039, indicating a significantly positive linear correlation between fractal dimension and uniformity, that is, the fractal dimension increases with uniformity. The complexity of soil texture depends on the quantitative distribution of soil particles in varied sizes (texture uniformity) and the soil aggregates (excluding small particles). It is found that the fractal dimension has a good linear correlation with the two feature parameters of soil texture, namely, the content of clay and powder particles and the uniformity. Hence, fractal dimension is a good index to quantify the soil structure and texture.

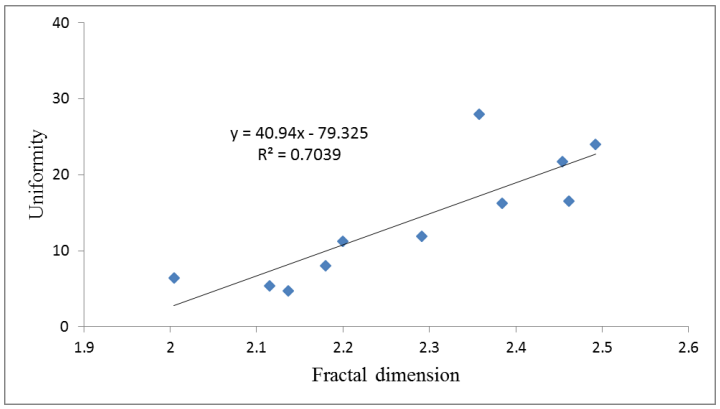

Figure 6. *Correlation between fractal dimension and uniformity*

In the aspect of soil fractal dimension used to quantitatively describe soil texture, physical properties and fertility characteristics, the existing studies show that when the soil texture changes from coarse to fine, the fractal dimension of soil particle composition changes from small to large (Yang et al., 1993; Zhao et al., 2016). The fractal dimension of soil with good texture structure and fertility is about 2.60 ~ 2.80 (Zhao et al., 2016), while the soil fractal dimension of different plant communities in this study area is between 2.0044 and 2.4925 (average 2.2798, *Fig. 4*), which is smaller than the fractal dimension of well-structured soil and belongs to the range of sandy soil (1.834 ~ 2.641) (Lyu et al., 2015; Wei et al., 2016). Obviously, the higher the fractal dimension of soil, the stronger the function of improving soil structure.

The effect of the forest community on the soil physical structure is related to the nature of the fractal dimension of the soil particles, because the fractal dimension of the soil is used as the parameter to describe the soil structure geometry, and the filling capacity of the soil particle to the space is essentially reflected (Luo et al., 2015; Zhao et al., 2017). That is, the smaller the diameter of the soil particles, the higher the content of the fine-grained material (the particles, the powder, the organic matter, etc.), the stronger the filling capacity of the space, the larger the fractal dimension of the soil, the better the formation of the better texture and the pore structure, and vice versa. This relationship is particularly evident in relatively coarse soil, such as sandy soil. It can also be said that in the mountainous area of coarse bone soil, forest community can increase the fractal dimension of soil by increasing the content of fine matter in soil, which is the fractal mechanism to improve the physical structure of soil and give full play to the function of soil and water conservation.

Conclusions

The vegetation in fragile ecological areas easily degrades and the ecology is hard to preserve. This paper explores the effects of different plant communities on the physical properties of soil in the Yimeng Mountains of eastern China. Firstly, the composition, fractal features and size distribution indices (uniformity and continuity) of soil particles under 11 plant communities were discussed based on fractal theory. Next, the relationships between fractal dimension, particle size composition and uniformity were analyzed in details. The main conclusions were drawn as follows:

(1) The soil composition shows that the soil particle sizes ranged between 0.25 and 1.0 mm under different plant communities, indicating that the local soil is predominately coarse sandy soil. Both pure and mixed forests have high contents of clay and powder particles; the slope wasteland possesses high contents of fine sandy soils; the farmland witnesses a high content of sandy soils. The soil structure of forests is way better than that of slope wasteland, and the soil structure of mixed forest is markedly better than that of pure forest.

(2) The fractal dimensions of the 11 plant communities fell within a small interval: 2.0044~2.4925. RQ corresponded to the highest fractal dimension, followed by PP, RP, A, PT, CM, SB, OC, WG2, WG1 and SP in succession. The forests had higher dimensional values than the other vegetation types, revealing that forest species can greatly enhance soil structure. Among forest lands, mixed forest is the most effective vegetation type to ameliorate soil structure, followed by pure forest and economic forest.

(3) Fractal dimension has a linear correlation with the content of soil particles in each size. The linear correlation was significantly positive for fine sandy soil and coarse powder, as evidenced by R^2: 0.2888 and 0.901. By contrast, the linear correlation was significantly negative for coarse sandy soil, with the R^2 being 0.7342; the linear correlation was not evident for gravel.

(4) PT led to the highest uniformity, followed in descending order by RQ, RP, PP, A, CM, SB, OC, SP, WG1 and WG2. By uniformity, the five vegetation types were ranked in ascending order as of slope wasteland < farmland < economic forest < mixed forest < pure forest. Thus, economic forest and mixed forest can significantly improve soil texture. Moreover, a positive linear correlation was observed between the uniformity and fractal dimension of each plant community ($R^2 = 0.7039$).

The above results shed new light on how to select tree species and design vegetation types to recover and reconstruct the vegetation in mountainous regions of eastern China, laying the technical basis for erosion control in fragile ecological areas. Further research will combine fractal analysis with the correlation analysis between fractal dimension and infiltration features in the study area.

Abstract. The multi-layer biofilter (MBF) is a promising tool for low-strength wastewater treatment. This paper investigates the microbial composition of a full-scale MBF system in the suburb of Shanghai, China, and analyzes the structure of the bacterial community with 454-pyrosequencing. The results show that different parts of the MBF, namely, the second, fourth and sixth layers (L2, L4 and L6) differed in bacteria composition. A total of 7,385, 7,042 and 5,974 sequences with high-quality 16S rRNA genes were recovered from L2, L4 and L6, respectively, and subjected to community analysis. The libraries of L2, L4 and L6 consist of 1,457, 1,310 and 1,197 operational taxonomic units (OTUs), respectively. In addition, L2, L4 and L6, had 89, 87 and 80 classes of bacteria, respectively. However, 73 classes of L2, 70 classes of L4 and 62 classes of L6 had an abundance lower than 1%. Besides, Thermus was only found in L2. This research is the first one ever to study the microbial communities in the biofilm of full-scale MBF systems in wastewater treatment. The research findings shed new light on the biological mechanism of contaminant removal in the MBF, and promote the application of the MBF in wastewater treatment.
Keywords: *biofilter, 454 pyrosequencing, bacterial composition, community richness, wastewater*

Introduction

Extended from conventional trickling filters, multi-layer biofilter (MBF) is a new wastewater treatment tool that effectively eliminates organic and nutrient contaminants, using a mixture of microorganisms (Ou et al., 2009).

Previously, the bacterial community in wastewater treatment plants has often been identified by culture-dependent methods. However, these methods can only cultivate and characterize less than 1% of the microorganisms in different habitats (Torsvik et al., 2002). In recent years, pyrosequencing has emerged as a popular method to examine the structure of bacterial communities. This approach can obtain varied genetic information on the microbes in the environment. For example, 454 Life Sciences (Branford, US) designed the 454 pyrosequencing, a high-throughput analytical method that utilizes a single strand of DNA with a length of 400~500bp. With the aid of 454 pyrosequencing, Wen et al. (2017) found that the population of ammonia oxidizing bacteria (AOB) shrank with the decline of ammonia concentration, but failed to observe a dramatic drop in the percentage of anammox bacteria. Lautenschlager (2014) applied 454 pyrosequencing to three biofilters with similar microbial composition, yet the results go against the actual situation. As an emerging microbial research method Roche 454-high throughput pyrosequecing have been used widely to analyze the microbial community in WWTPs (Ye et al., 2011; Zhang et al., 2012; Hu et al., 2012; Ye and Zhang, 2013; Pervin et al., 2013; Zheng et al., 2017; Liu et al., 2017).

Despite the above studies, there is little report that fully discloses the variation in microbial composition in wastewater treatment plants, especially in biofilters. Yang et al.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1574515753

(2013) compared vermifilter and the conventional biofilter, and drew the following conclusions: the biofilm of vermifilter has two types of bacterial strains (firmicutes and γ - proteobacteria), while that of conventional biofilter has four types (firmicutes, γ- proteobacteria, β-proteobacteria and actinobacteria).

This paper attempts to characterize and compare the bacteria community at different positions along the MBF. For this purpose, the author probed deep into the microbial composition of a full-scale MBF system in the suburb of Shanghai, China, and analyzed the structure of the bacterial community with 454-pyrosequencing.

Materials and Methods

Research object

Located in the suburb of Shanghai, China, our research object, i.e. a full-scale MBF system, has been operating stably for nearly 7 years (GPS, 31.587,121.656). The system consists of multiple modules of the same size (L×W×H: 675 cm×485 cm×400 cm). A vertical gap of 15 cm is maintained between adjacent modules. The biofilm on the filler surface is in full contact with the air, allowing the microorganisms to get enough oxygen. From top to bottom, the biofilter chamber can be divided into seven layers. The upper four layers are filled with ceramists, and the lower three layers, volcanic rocks. The treatment efficiency is 500 m^3 per day.

The technological process involves an equalization tank, a lifting pump, a MBF, an intermediate tank, and a constructed wetland. After being collected by the pipe network, the wastewater from the equalization tank is pumped by the lifting pump to the MBF, and be dispersed to all places through the water channel. From top to bottom, the sewage flows through MBF, and then converges from the bottom to the sedimentation tank at the rear. and comes into full contact with the biofilm on the filler. The spilled part flows back to the middle pool. Then, the contaminants are absorbed and degraded by the microorganisms on the biofilm.

Sample collection and processing

The biofilm samples were collected from the second, fourth and sixth layers, and denoted as L2, L4 and L6, respectively. In order to ensure the reliability and uniformity of the samples, five-point sampling method is adopted, that is, sampling from five different positions of the same level, and mixing. Each sample was obtained from the filler by 5 min ultrasonic treatment, and then flushed with deionized water. Then, the sample was relocated to a 50 mL tube, and centrifuged at 8,000×g for 10 min. The sediments were stored at -80°C until DNA extraction.

DNA extraction and polymerase chain reactions (PCRs)

The total genomic DNA was extracted by E.Z.N.A.® Soil DNA Kit (Omega Bio-tek, US). To construct the clone library, the primer set 341F (5'-CCTACGGGAGGCAGCAG-3') and 907R (5'- CCGTCAATTCMTTTRAGT-3') was used to amplify the hypervariable V3~V5 region (about 560bp) of bacterial 16S rRNA gene. The fused forward primer includes a10-base long barcode inserted between the 454 adapter and the 341F primer, aiming to distinguish each sample in the mixed reaction.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1574515753

The PCRs were performed in a 25 μL volume containing 2.5 μL 10×buffer , 2 μL dNTP, 1 μL of each primer (10 μM), 2 μL of DNA (20 ng/μL) and 0.125 μL pyrobest polymerase (5 U/μL, Takara, China). The thermocycling was carried out in the following steps: 94℃ for 4 min, followed by 27 cycles at 95℃ for 30 s, 55℃ for 45 s, 72℃ for 1 min and a final extension at 72℃ for 7 min. In this study, the number of PCR cycles is reduced to ensure the accuracy and reliability of the subsequent analysis. The PCR products were run on a 0.8% agarose gel, with the amplicon size of 500bp.

Pyrosequencing

The PCR products were purified using the AMPure XP beads, quantified by Quant-iT PicoGreen dsDNA Assay Kit (Thermo Fisher Scientific, US), and pyro-sequenced on 454 Gs Flx Titanium Platform (Roche, US) in Shanghai Personalbio Co., Ltd.

Sequence analysis

Following pyrosequencing, the genetic sequences were analyzed on QIIME, an open-source bioinformatics pipeline for performing microbiome analysis from raw DNA sequencing data. Firstly, the ineffective sequences were filtered out, leaving only sequences satisfying the following requirements: the length falls within 200~1,000bp, fewer than 6 consecutive bases are identical, no ambiguous base is included, and the quality score is above 25.

The uchime_denovo command was called to remove chimera, which would otherwise affect sequence quality. Then, sequences with similarities of greater than 97% were clustered into one operational taxonomic unit (OTU), using the QIIME program. Community richness and diversity indices (i.e. Chao1 estimator, ACE estimator and Simpson's diversity) and rarefaction curves were obtained with mothur. The larger the Chao / ACE index is, the higher the community richness is. The larger the Simpson index is, the lower the community diversity is.

Results and Discussion

MBF performance

The water quality of MBF obtained by measuring three parallel water samples at different positions is as follows. The project has been in stable operation for several years, and the effluent quality has reached the national water quality discharge standard of China (GB 8978-1996).

Table 1 lists several water quality indices before and after the water treatment. During the treatment, the mean chemical oxygen demand (COD) of influent was 306 mg/L, while the mean COD of effluent was 232, 215 and 227 mg/L for L2, L4 and L6, respectively. Thus, the COD removal rate of the MBF was 25.8%.

The mean ammonia nitrogen (NH_3-N) was 19 mg/L before the treatment. After the treatment, the mean NH_3-N of effluent was 15.33, 10.83 and 9.54 mg/L, for L2, L4 and L6, respectively. Thus, the MBF removed 50% of the NH_3-N from the wastewater.

The mean total nitrogen (TN) was 31.82 mg/L in the influent. After the treatment, the mean TN of effluent was 20.94, 29.48 and 27.76 mg/L, for L2, L4 and L6, respectively. Therefore, the TN removal rate of the MBF was 12.8%, lower than that of NH_3-N.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1574515753

The mean total phosphorus (TP) was 3.89 mg/L in the influent. After the treatment, the mean TP of effluent was 3.75, 3.8 and 3.7 mg/L, for L2, L4 and L6, respectively. Hence, the MBF removed 4% of the TP from the influent.

Table 1. *Water quality indices (temperature: 19.45±0.49°C)*

	pH	DO	COD (mg/L)	NH_3-N (mg/L)	TN (mg/L)	TP (mg/L)
Influent	7.544	1.42	306	19	31.82	3.89
L2	7.806	5.43	232	15.33	20.94	3.75
L4	7.643	5.65	215	10.83	29.48	3.8
L6	7.739	3.29	227	9.54	27.76	3.7

Bacteria diversity

As shown in *Table 2*, a total of 7,385, 7,042 and 5,974 sequences with high-quality 16S rRNA genes were recovered from L2, L4 and L6, respectively, and subjected to community analysis. The libraries with L2, L4 and L6 consist of 1,457, 1,310 and 1,197 OTUs, respectively.

Table 2. *Community richness and diversity indices*

Sample number	Number of effective sequences	Number of high-quality sequences	OTUs	ACE estimator	Chao1 estimator	Simpson's diversity	Coverage
L2	11,239	7,385	1,457	3,164.202	2,791.603	0.002979	0.907651
L4	10,840	7,042	1,310	2,905.24	2,476.287	0.004794	0.912099
L6	9,611	5,974	1,197	2,446.65	2,164.788	0.004775	0.907934

The rarefaction curves were plotted (*Figure 1*) based on the OTUs at 3% cutoff to compare the community richness of the three samples. As shown in *Figure 1*, none of the curves approached a plateau, suggesting that further sequencing will continue to increase the number of OTUs in each sample. However, the coverage of all three samples had already reached 90%. Pyrosequencing analysis output numerous OTUs, providing the genetic information needed to find scarce species (Zhang, 2011).

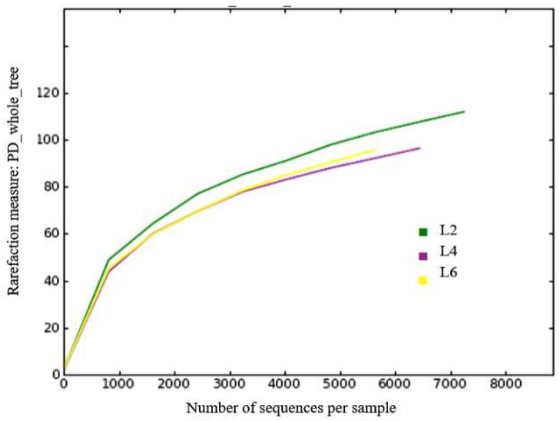

Figure 1. *Rarefaction curves of OTUs in L2, L4 and L6*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1574515753

It can also be seen from *Table 2* that L2 contained richer species than any other sample. Besides, the values of ACE estimator, Chao1 estimator, and Simpson's diversity show that L2 had the highest bacterial diversity, followed by L4 and then L6. The ranking of bacterial diversity agrees with the positions of the three layers in the MBF: the wastewater first flows through L2 first, then through L4, and finally through L6. In other words, the bacteria diversity decreases along the MBF. This conclusion echoes with the number of OTUs in these layers.

Next, the samples were sorted in descending order of OTU abundance, and the distribution curves of OTU abundance were plotted (*Figure 2*), taking log2 of abundance. In *Figure 2*, the horizontal length of each curve reflects the community richness of the corresponding sample, while the curve shape demonstrates species evenness. Obviously, the three samples were ranked as L2>L4>L6 in abundance, that is, the abundance also decreased along the MBF. It means that the more abundant the species are, the higher the evenness is reflected by the curve shape. By contrast, there was no significant difference among the samples in species evenness.

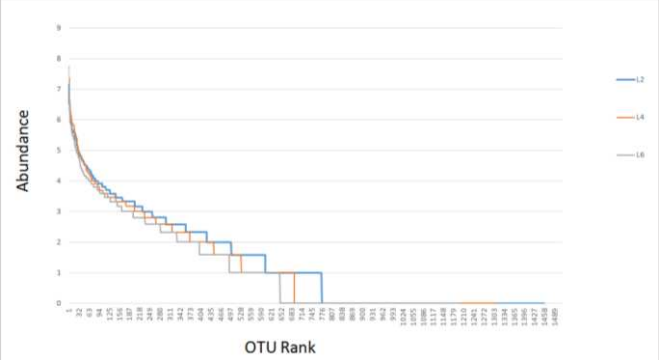

Figure 2. *Distribution curves of OTU abundance*

The Venn diagram of OTUs (*Figure 3*) was drawn by Venny 2.1.0 (http://bioinfogp.cnb.csic.es/tools/venny/index.html). An evident difference could be observed along the MBF at the genus-level. The difference between L4 and L6 was particularly obvious, revealing the function division in the filter. This result is confirmed by the subsequent analysis on bacterial composition.

Bacteria composition

The total number of phyla identified in L2, L4 and L6 was 34, 32 and 29, respectively, which, as previously discovered, decreases along the MBF. Here, a phylum with no less than 0.5% relative abundance is called a major phylum. *Figure 4* shows the proportion of sequences in each phylum in the total number of sequences in each sample. The sequences that do not belong to any known phylum were categorized as unclassified bacteria.

As shown in *Figure 5*, L2 mainly contains proteobacteria (54.18%), Bacteroidetes (14.07%), actinobacteria (9.13%) and nitrospirae (5.06%). The bacteria in L4 mostly belong to proteobacteria (52.47%), acidobacteria (15.04%) and bacteroidetes (11.87%). The major bacterial groups in L6 include proteobacteria (54.18%), acidobacteria (12.45%), bacteroidetes (12.29%) and nitrospirae (6.58%). To sum up, the three samples differed slightly in major bacterial groups.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1574515753

According to the comparison between the vermifilter and the conventional biofilter (Yang, 2013), the bacteria composition of the MBF is distinct from that of these two filters.

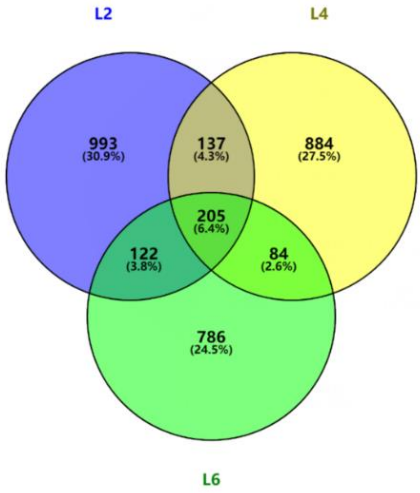

Figure 3. *The Venn diagram of OTUs*

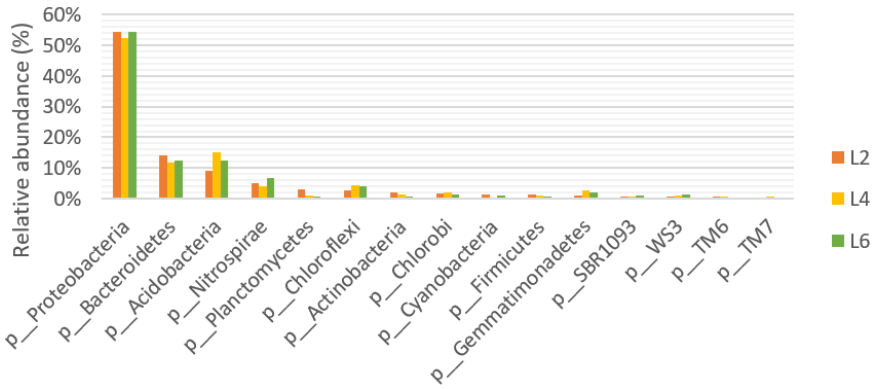

Figure 4. *Proportion of sequences in each phylum*

However, the three samples had marked differences in the class level of taxonomic classifications. As shown in *Table 3*, α-proteobacteria, β-proteobacteria, δ-proteobacteria and γ-proteobacteria and TA18 were found in all three samples, but the content of each component varied greatly from sample to sample. Along the MBF, the content of α-proteobacteria increased first and then decreased; the content of β-proteobacteria declined all the way; the contents of γ-proteobacteria and δ-proteobacteria reduced first and then rebounded. Meanwhile, zetaproteobacteria, exclusively belonging to L6, was rare and represented by a single described species, *Mariprofundus ferrooxydans*. It is an iron-oxidizing neutrophilic chemolithoautotroph first discovered in 1996, at the hydrothermal vents at Loihi Seamount, Hawaii (Emerson, 2002, 2007). Then, the dominant classes were δ-proteobacteria, clostridia and γ-proteobacteria.

DOI: http://dx.doi.org/10.15666/aeer/1706_1574515753

The differences in bacteria content are attributable to various factors, such as climate zone, wastewater composition and weather condition. Most bacteria in the biofilter are not involved in the key processes of the wastewater treatment.

In total, a total of 89, 87 and 80 classes of bacteria were identified for L2, L4 and L6, respectively. However, 73 classes of L2, 70 classes of L4 and 62 classes of L6 had an abundance less than 1%. In addition, Thermus was only found in L2.

The research of MBF mainly focuses on the improvement of structure and the selection of filler (Cui, 2014), but there is no research on microorganism.

Most of the biofilters with stratification, such as tower biofilters, are mostly anaerobic, and most of the microorganisms are anaerobic, which is far from the MBF in this paper (Malakar, 2017).

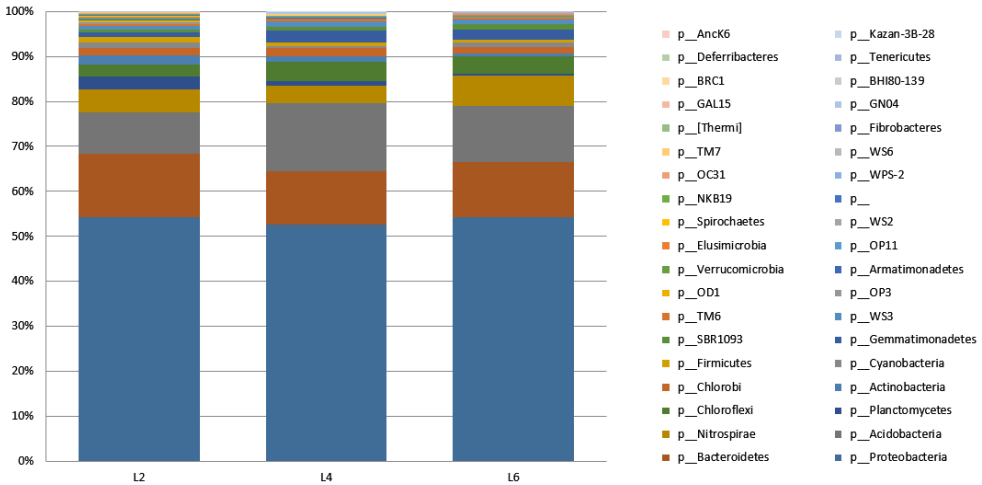

Figure 5. *The proportions of sequences in different classes*

Table 3. *The class level of proteobacteria*

L2	(%)	L4	(%)	L6	(%)

Conclusions

To our knowledge, this is the first time to investigate microbial communities in the biofilm of the full-scale MBF system for wastewater treatment. Through the analysis on MBF performance, bacteria diversity and bacteria composition, it is concluded that different parts of the MBF system vary greatly in bacteria composition. The bacteria of L2, L4 and L6 belong to 89, 87 and 80 classes, respectively. However, 73 classes of L2, 70 classes of L4 and 62 classes of L6 had an abundance less than 1%. In addition,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1574515753

Thermus was only found in L2. The research findings provide new insights into the biological mechanism of contaminant removal in the MBF system.

Suggestions for future improvement are as follows. In engineering, the ventilation performance is increased while the aesthetics is ensured, for example, more louvers are used. Microorganisms need certain temperature conditions. It is suggested that heat preservation and dissipation should be considered when using this process in other places. Improving the efficiency of biological treatment can increase the porosity and specific surface area of the material. The particle size of the material has a certain influence on the good sample condition and sludge removal, which can be further studied. The roughness of the material surface also has a positive effect on the formation of biofilm. If the cost allows, increasing the number of layers within a certain range can improve the diversity of microorganisms. The nitrification of the lower layer is stronger than that of the upper layer. It is suggested that the materials should also be studied from the environment suitable for the growth of nitrifying bacteria.

(Received 10th Sep 2019; accepted 14th Nov 2019)

Abstract. This study was carried out to determine the silage quality characteristics of some switchgrass (*Panicum virgatum* L.) cultivars. Kanlow, Shelter, Shawnee, BoMaster, Alamo, Trailblazer, Cave in Rock and Long Island cultivars of switchgrass constituted the plant material of the study. For silage purposes, the plants were harvested 10-15 days after reaching the flowering period. The harvested plants were allowed to ferment for 70 days. According to the results, the silage of switchgrass cultivars was statistically significantly at $p<0.01$ level for both physical and chemical properties. In the study, pH content, the dry matter, lactic acid, butyric acid, acetic acid, crude protein, acid detergent fiber, and neutral detergent fiber ratios of the silage of switchgrass cultivars varied between 3.84-4.86, 39.0-51.0%, 1.78-2.35%, 0.05-0.33%, 0.35-1.55%, 3.76-5.57%, 39.30-41.73%, and 70.96-75.41%, respectively. In terms of the Fleig score, it was determined that the quality of the silage obtained from switchgrass cultivars could be classified as "very good". According to result, it was determined that BoMaster, Alamo, and Trailblazer cultivars, especially Long Island and Cave in Rock cultivars of switchgrass that came to the forefront in terms of silage quality, could be successfully used in silage production.
Keywords: *switchgrass, physical properties, acetic acid, lactic acid, butyric acid*

Introduction

Switchgrass (*Panicum virgatum* L.) is a perennial warm-season C4 plant, which is one of the grass species specific to North American meadows (McLaughlin and Kszos, 2005; Missaoui et al., 2006; Jiang et al., 2019). It is used as an energy plant in the United States, Canada, and some European countries (Elbersen et al., 2001; Casler and Boe, 2003; Belanger et al., 2012). Furthermore, it is also an important species used for many purposes such as soil and water conservation, grazing and forage (Sanderson et al., 1999; Muir et al., 2001; Vogel et al., 2002; Vogel, 2004; Lee et al., 2007; Sanderson and Burns, 2010; Belanger et al., 2012; Jiang et al., 2019). In the studies carried out, it were reported that high yield and high-quality feed was obtained from some genotypes of switchgrass, and it had the potential to be used as an animal feed (Ameen et al., 2018; Davis et al., 2018; Milenković et al., 2018; Sena et al., 2018).

Few studies were conducted on switchgrass, which is a new plant for Turkey. In this sense, the first basic information about the growing techniques of switchgrass was produced within the scope of the TUBITAK project developed by Soylu et al. (2010). Within the scope of that project, adaptation studies were conducted on switchgrass cultivars as an introductory material in the Central Anatolia Region with an arid and/or semi-arid climate in Turkey, and the cultivars suitable for Turkey were determined. Within the scope of the same study, the necessary information about the growing techniques of high-performance switchgrass cultivars from planting to harvest in Turkey, and their potential to be utilized as a bio-fuel was obtained (Soylu, 2012). As a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1575515773

result of these studies carried out by Soylu et al. (2010), it was emphasized that the facts that the switchgrass cultivars examined yielded a green biomass in quantities ranging 60-70 tons/ha, that dry matter ratios ranged between 31.84-40.97% during the flowering period, the protein ratio in green biomass increased up to 9-10% in many cultivars, and acid detergent fiber (ADF) and neutral detergent fiber (NDF) values revealed positive results regarding the consumption and digestibility of the feed to be obtained from this plant were the indications that the silage quality of switchgrass plant would also be high, and it was reported that switchgrass plant had a high economic growing potential especially for silage purposes.

The studies carried out around the world mostly focused on the bioenergy value (Brodowska et al., 2018; Kimura et al., 2018), adaptation (Ma et al., 2011), morphological and biological properties (Brunken and Estes, 1975), forage yield (Wolf and Fiske, 1995; Kimura et al., 2018) and biomass yield (Sanderson et al., 1999; Piscioneri et al., 2001; Lemus et al., 2002; Kimura et al., 2018), genetics and genetic variation (Quinn, 1969; Hopkins et al., 1995, 1996; Quinn and Wetherington, 2002) of switchgrass. There are very few studies on the silage and silage quality of switchgrass.

On the other hand, in silage plant production, it is possible to obtain high quality and high yield by the cultivation of varieties suitable for ecologies. In this sense, the selection of variety is also an important cultural practice to achieve a sustainable yield from plant production (Ileri et al., 2018). Undoubtfully, the difference of cultivars, as well as the factors such as climate and soil factors, cultural practices, and harvesting period, significantly affects the silage quality. This study was carried out to determine the silage quality of some switchgrass (*Panicum virgatum* L.) cultivars.

Materials and methods

Silage material and growing conditions

The plant material of the study consisted of Kanlow, Shelter, Shawnee, BoMaster, Alamo, Trailblazer, Cave in Rock, and Long Island cultivars of switchgrass. In the study, the plant materials of the second year (2017) of switchgrass cultivars established on July 10, 2015, under the conditions of Siirt province (*Figure 1*), which is located in the Southeastern Anatolia Region of Turkey with a semi-arid climate, were used for silage purposes.

According to long-term (1960-2017) meteorological data (Anonymous, 2017) of the Siirt province, the current climate in the region is semi-arid. Summers are warmer than winters (the average temperature in July is 30.6 and in January is 2.8°C). The mean annual temperature, rainfall, and evapotranspiration are 16.2ºC, 691.4 mm, and 937.5 mm, respectively. According to the soil climate regime of the Newhall simulation model (Van Wambeke, 2000), it was determined that the study site has a thermic soil temperature regime and xeric (dry xeric in the subgroup) soil moisture regime (*Figure 2*).

Some physical and chemical properties of the soils where the switchgrass is grown are given in *Table 1*. Organic matter content of soil was determined according to Nelson and Sommers (1982) and other parameters were determined according to Anonymous (1992). The soils where switchgrass is grown are clayey textured, salt-free, slightly alkaline and have moderate lime content, less organic matter and available phosphorus (P) coverage, and high available potassium (K) content (*Table 1*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1575515773

In the study, the field experiment was established according to the randomized block experimental design with 4 replications. In sowing, row spacing was 20 cm, and the number of rows in a parcel was 10. Sowing was performed so that there would be 400 live seeds per square meter. Before sowing, diammonium phosphate (18-46-0%, N-P-K) fertilizer was applied equally to each parcel with the calculation of 100 kg/ha pure P_2O_5 according to the soil analysis results. A drip irrigation system was established immediately after sowing, and irrigation was performed. When plants were 10-15 cm, ammonium nitrate (33% N) fertilizer was given equally to each parcel with the calculation of 60 kg/ha pure nitrogen (N) (*Figure 3*).

Figure 3. *Switchgrass experimental site and harvest*

Silage making technique

For silage purposes, switchgrass cultivars were harvested separately for each parcel 10-15 days after reaching the flowering period (Soylu, 2012). The harvested plants were brought to the laboratory environment, and all green plant materials were manually chopped into 0.5-1 cm sizes with a knife. The chopped plant particles were mixed with 0.5% table salt (NaCl) for protection purposes (Kılıç, 1986; Geren et al., 2011). Then, the material of each parcel was filled in 3-liter glass jars by pressing well in accordance with the sequential filling technique (Petterson, 1988), and the lid borders of the jars tightly closed with silicone plastic lids were wrapped with thick packaging tape for 3-4 rounds for airtightness. The silage jars prepared in this way were allowed to ferment for 70 days at room temperature in a dark environment.

Physical and chemical analysis methods of silage samples

After the fermentation process was completed, the matured silage was opened, a 3-4 cm portion was discarded from the cap opening, and then physical and chemical analyses were performed in the remaining silage samples.

In the samples taken to represent the mass in the opened silage jars, physical examinations such as odor, structure, and color were subjectively performed by three subject matter experts. The evaluation of physical analyses was based on the scoring

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1575515773

method developed by Anonymous (1987). The silage quality class according to the physical properties of the silage was determined by the DLG (Deutsche Landwirtschafts-Gesellschaft) score (*Table 2*). The DLG score is the total physical score (0-20 points) obtained from the sum of odor, structure, and color scores (Akyıldız, 1984; Anonymous, 1987; Ergün et al., 2013).

Table 2. *Physical examination key developed by DLG and silage quality class*

Physical examination key	
1. Odor	**Score**
No butter acid odor, slightly sour, fruity and aromatic odor	14
A small amount of butter acid, strong sour odor, and slight escalation	8
Moderate butter acid odor, strong escalation-musty odor	4
Strong butter acid or ammonia odor, very slight sour odor	2
Strong decomposition, ammonia or musty odor	0
2. Structure	
Intact leaves and stems	4
A slightly deteriorated structure of leaves	2
A deteriorated structure of leaves and stems, musty and dirty	1
Rotten Leaf and Stalk	0
3. Color	
Preserved its color at the moment it was silaged (brown in withered silage)	2
Slightly changed color (yellow to brown)	1
Completely changed color (reseda green)	0
Quality class according to the physical properties of silage	
Quality class	**DLG score**
I- Very good	20-18
II- Good	17-14
III- Medium	13-10
IV- Low (low value)	9-5
V- Corrupted (useless)	4-0

Some silage material was taken from each silage jar to represent the jar and mixed homogeneously, and 25 g of the wet silage sample of this mixture was weighed on the precision balance and placed in the mixer. 250 ml of distilled water was added to the sample, and it was mixed for 10 minutes, then filtered through filter paper (Whatman™ No. 1441-125, GE Healthcare Life Sciences, Marlborough, MA, USA), and pH was determined by means of a pH meter in a 200 ml strainer taken into glass beakers (Anonymous, 1993). Lactic acid (LA), acetic acid (AA), and butyric acid (BA) were determined using high-performance liquid chromatography (HPLC) as per the methods of Canale et al. (1984). 300 g of the wet sample was taken from matured silage separately in each silage jar, and it was dried in an oven at 70°C for 48 hours. Dried silage samples were weighed on the precision balance, and their weights were determined, and the dry matter (DM) ratio was determined by proportioning to wet weight (Bulgurlu and Ergül, 1978).

The dried silage samples were ground separately for each jar. The ADF, NDF, and crude protein (CP) ratios in the ground samples were determined by NIRS (Near Infrared Reflectance Spectroscopy) and #IC-0904FE calibration set (Anonymous, 2018) in the laboratory of Ondokuz Mayıs University Faculty of Agriculture Department of Field Crops (Brogna et al., 2009).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1575515773

Quality of silage according to the Fleig score

One of the most common methods used to determine the silage quality practically is the Fleig score (FS), which is determined by using the relationship between the DM content and pH value of silage. FS was calculated using *Equation 1* created by DLG (Anonymous, 1987).

$$FS= [220 + (2 \times \text{silage DM ratio} - 15)] - 40 \times \text{silage pH value} \quad \text{(Eq.1)}$$

Considering the FS values obtained from the above-mentioned equation, the silage quality class was evaluated according to the score criteria presented in *Table 3*.

Table 3. *Quality classes of silo feeds according to FS (Anonymous, 1987)*

Calculated FS	Silage quality class
100-81	I- Very good
80-61	II- Good
60-41	III- Satisfactory (Medium)
40-21	IV- Low (low value)
20-0	V- Bad

Statistical analyses

The data obtained from the study were subjected to the analysis of variance according to the randomized block experimental design. The differences between the groups according to the F-test results were determined by Tukey's multiple comparison test (Açıkgöz and Açıkgöz, 2001).

Results and discussion

Silage dry matter ratio of switchgrass cultivars and some chemical properties of silage

Silage dry matter ratio

The DM ratio has great importance in the full realization of chemical events during silage formation, and this ratio is the most important quality criterion used in the determination of silage quality (Geren, 2001; Çakmak et al., 2013). In the study, the highest DM ratio was found in the Alamo, BoMaster, Kanlow, Trailblazer, and Cave in Rock switchgrass cultivars that statistically constituted the first group. The DM ratios of these cultivars varied between 47.3-51.0%. The lowest DM ratio was found in the silage of Shawnee and Long Island cultivars by 39.0% and 39.7%, respectively. This difference between the cultivars in terms of the silage DM ratio was found to be statistically significant at $p<0.01$ level (*Table 4*). The reason for this difference between the cultivars can be explained by different amounts of DM they can produce by their genetic capacity. Furthermore, it is considered that the difference in the silage DM ratio between the cultivars was also affected by the difference in DM losses, caused by chemical events in the fermentation process, according to cultivars. While Luginbuhl et al. (2000) reported that the silage DM ratio was 27.2% in Kanlow switchgrass cultivar, Cassida et al. (2005) reported that the DM ratio in switchgrass varied between 39.4-45.1%, and Zhao et al. (2017) reported that the DM ratio varied between 24.68-26.43%. It is considered that the fact that the DM ratios determined in our study

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1575515773

were different from those reported in the literature was affected by different genotype, harvest time, and growing conditions.

On the other hand, in the adaptation study carried out by Soylu et al. (2010) with 9 switchgrass cultivars (Alamo, Forestburg, Cave in Rock, Carthage, Shelter, Dacotah, Blackwell, Shawnee, and Kanlow) under irrigated conditions in the Central Anatolia Region of Turkey, they reported that the DM ratios of cultivars varied between 31.84%-40.97% and that the DM ratio of above 30% in switchgrass cultivars was extremely important in terms of use both for silage and directly in animal feeding. Accordingly, although the DM ratio among cultivars varies, a high DM ratio is important for silage quality. Indeed, while Çayıroğlu et al. (2016) reported that the DM content of silage material was an important factor affecting aerobic stability, Filya et al. (2000) reported that the aerobic stability of silage made with the material with a low DM content decreased, and Barnes et al. (1995) and Mohd-Setapar et al. (2012) reported that the DM contents of the material to be silaged for good quality silage and/or successful fermentation should be between 28-42% and 25-40%, respectively. In view of these values reported by the researchers, it was observed that all switchgrass cultivars contained quite sufficient DM.

[**]: $p<0.01$ is significant within error limits, CV: Coefficient variation

No study was found on the silage characteristics of cultivars in switchgrass plant. Therefore, in view of the silage studies carried out with corn plant which is a physiologically C4 plant such as switchgrass, it was reported that there were significant differences between the cultivars in terms of DM, similarly to the results of our study, and that the DM ratio according to cultivars in corn silage varied between 18.35%-30.72% (Özdüven et al., 2009), 25.30%-31.58% (Güney et al., 2010), 20.3%-28.1% (Seydoşoğlu, 2017), 20.57%-23.35% (Ileri et al., 2018).

Lactic acid (LA) content of silage

The amount and composition of organic acids such as LA formed during silage fermentation determine the quality of fermentation, and LA is one of the main preservative organic acids in the silage (Filya, 2001). According to the results of statistical analysis, it was determined that the LA contents of the silage obtained from switchgrass cultivars showed significant differences ($p<0.01$). The most distinctive

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1575515773

difference was between Kanlow and all other cultivars. The highest LA ratio was found in the Long Island (2.35%) and BoMaster (2.22%) cultivars that were statistically included in the first group (*Table 4*).

It was reported that the LA ratio should be above 2.00% in high-quality silage feeds (Kılıç, 1986; McDonald et al., 1991; Alçiçek and Özkan, 1997; Weinberg and Ashbell, 2003) and that a high LA ratio was the assurance of a healthy fermentation (Johnson and Harrison, 2001). According to the results of our study (*Table 4*), it was found out that the LA values found in the Long Island, BoMaster, Cave in Rock, and Trailblazer silage of switchgrass cultivars were above the reference value and included in the high-quality silage group. In the silage made with corn and sorghum cultivars, it was reported that the LA ratio varied between 1.58%-8.57% by Reeves et al. (1989), 2.6%-3.1% by Hart (1990), 0.67%-2.35% by Geren and Kavut (2009), and 7.64%-12.33% by Seydoşoğlu (2017) depending on the maturity period.

Butyric acid (BA) content of silage

An important parameter in the determination of silage quality by analytical methods is the BA, which negatively affects silage quality (Geren and Kavut, 2009). In a quality silage feed obtained as a result of a good fermentation, the fact that BA was generally between 0.1-0.7% was considered to be normal although it was undesirable (Woolfort, 1984; Weinberg and Ashbell, 2003). On the other hand, Catchpoole and Henzell (1971) reported that the BA concentration in quality silage was less than 0.2%. When the data of our study were examined, it was observed that the BA content of the silage of switchgrass cultivars varied between 0.05-0.33% and that the BA content of all silaged switchgrass cultivars was within acceptable limits. Nevertheless, the difference between the cultivars in terms of BA was found to be statistically significant at $p<0.01$ level, and the BA ratios of Kanlow (0.33%), Shelter (0.29%), and Shawnee (0.21%) silage were higher than other cultivars (*Table 4*). It can be explained by the limited propagation and activity of LA bacteria during fermentation and/or the degradation of LA into BA, as it was indicated by Bolsen et al. (1996). Indeed, as it is seen in *Table 4*, the low LA values of the cultivars with a high BA ratio confirm this situation.

In the studies carried out with corn silage, the BA ratio was determined to be 0.07% (Phillip and Hidalgo, 1989) and 0.08% (Deswysen et al., 1993). On the contrary, while Geren and Kavut (2009) and Arslan et al. (2017) reported that the BA value was not measured in sorghum and corn silage and sorghum silage, respectively; Hart (1990) reported that the BA value varied between 0.006% and 0.037% in the sorghum silage, and Reeves et al. (1989) reported that the BA value varied between 0.06% and 0.43% in the corn silage. In our study, it is possible to say that the BA values determined in the silage of switchgrass cultivars were compatible with these values in the literature determined in corn and sorghum silage, which are C4 plants like switchgrass.

Acetic acid (AA) content of silage

When the AA ratios of the silage obtained from switchgrass cultivars were examined, the highest AA ratio was found to be 1.55% in Shawnee cultivar, and the difference in terms of AA between Shawnee cultivar and Kanlow, Shelter, Alamo, Trailblazer, and Cave in Rock cultivars was found to be insignificant. The lowest AA content was determined in Long Island (0.35%) and BoMaster (0.45%) cultivars. This difference between the cultivars was statistically significant at $p<0.01$ level (*Table 4*). While Weinberg and Ashbell (2003) reported that the AA ratio should be less than 0.8% in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1575515773

silage feed as a result of a good fermentation, McDonald et al. (1991) and Alçiçek and Özkan (1997) reported that the AA ratio should be between 0.3-0.7%. When these values reported in the literature are taken into consideration, it is possible to say that the AA ratios of the silage of BoMaster, Trailblazer, Cave in Rock, and Long Island switchgrass cultivars were below the critical value.

It was reported that the AA ratio varied between 0.6-1.42% in the sorghum silage (Hart, 1990; Arslan and Çakmakçı, 2011; Arslan et al., 2017) and between 0.2-3.71% in the corn silage (Phillip and Hidalgo, 1989; Reeves et al., 1989; Deswysen et al., 1993; Sucu and Filya, 2006). These results obtained from sorghum and corn silage, which are physiologically included in the C4 group such as switchgrass, were similar to the results of our study.

pH of silage

pH formed during silage fermentation is one of the most important parameters determining the quality of fermentation (Kiermeier and Renner, 1963; Filya, 2001). In our study, a statistically significant difference at $p<0.01$ level was found in terms of the pH of silage between switchgrass cultivars. The lowest silage pH value was found to be 3.84 in the Long Island switchgrass cultivar. The highest silage pH value was found in the Shawnee (4.86), Kanlow (4.73), and Shelter (4.72) cultivars that were statistically included in the same group (*Table 4*). The difference in terms of pH between cultivars can be explained by the fact that LA production varies by cultivars. In other words, as it is seen in *Table 4*, the silage pH was found to be low in the cultivars with a high LA ratio. This decrease in pH was due to the accumulation of LA. Indeed, Ohmomo et al. (1995) reported that it was important that pH was less than 4.2 in silage fermentation, which was possible with the efficient production of LA from sugar in a silo.

The way to remove odors, prevent spoilage, and protect nutrients in silage feeds is to make silage protected by good fermentation. Protection is based on high acidity depending on LA formation (Isnandar et al., 2010). Furthermore, low pH may also prevent the growth of parasites and some pathogenic microorganisms (Göhl, 1981). Church (1986) and Ergün et al. (2013) reported that the optimum pH range for the growth of milk acid bacteria growing in the acid medium was 3.8-4.2 and that bacteria causing spoilage and decomposition did not live in the silage with a value in this pH range. Some other researchers (Danley et al., 1973; Comberg, 1974; Kılıç, 1986; Roth, 2001; Açıkgöz et al., 2002; Kılıç, 2006) reported that the pH value of very good silage was between 3.5 and 4.5. It can be said that Long Island, Cave in Rock, BoMaster, Alamo, and Trailblazer from switchgrass cultivars were within the appropriate limits in terms of silage pH. Therefore, a successful fermentation process took place in the silage formation process, especially with respect to these cultivars. While Belanger et al. (2012) reported that pH varied between 4.0-4.3 in the switchgrass silage, Zhao et al. (2017) reported that the pH value was 5.4 in the 30-day silaged switchgrass material.

In the studies carried out on corn and sorghum cultivars that are C4 plant such as switchgrass, it was reported that the silage pH value was different between the cultivars and the pH value ranged between 3.03-5.20 (Hart, 1990; Deswysen et al., 1993; Geren, 2000, 2001; Kavut and Soya, 2012; Canbolat et al., 2016; Seydoşoğlu, 2017; Ileri et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1575515773

Crude protein (CP) ratio in silage

A statistically significant difference at $p<0.01$ level was found between switchgrass cultivars in terms of the CP ratio. While the highest CP ratio was found to be 5.57% in the Long Island silage, the difference between the Long Island, Shawnee, BoMaster, Trailblazer, and Cave in Rock cultivars in terms of the CP ratio was found to be statistically insignificant. The lowest silage CP ratio was found in the Shelter cultivar by 3.76% (*Table 4*). The CP ratio emerges a result of the genetic and morphological characteristics of plants (Güney et al., 2010). Therefore, it is possible to say that it is an expected result that there are significant differences between the cultivars with different properties. Indeed, in some studies carried out with the corn plant (Seydoşoğlu, 2017; Ileri et al., 2018), it was also reported that cultivars had a significant effect on the silage CP content.

It was observed that the CP ratio values determined in the silage of switchgrass cultivars were consistent with the results of Sanderson et al. (1999) and Mantino et al. (2017), slightly higher than the data of Cassida et al. (2005), and lower than the values obtained by Anderson et al. (1988), Soylu et al. (2010), Çiçek (2017), and Mohammed and Desta (2017). Milenković et al. (2018) reported that the CP ratio of switchgrass cultivars varied between 5.62% (Alamo) and 8.74% (Kanlov). The difference between the values obtained in our study and the literature in terms of the CP ratio can be explained by different ecologies, cultural processes, and genotypic structures of plants.

In the silage made with the corn plant which is a C4 plant like switchgrass, CP values varied between 5.01%-10.63% (Filya, 2001; Polat et al., 2005; Güney et al., 2010; Çakmak et al., 2013; Rafiuddin et al., 2016).

Silage acid detergent fiber (ADF) and neutral detergent fiber (NDF) ratio

The difference between switchgrass cultivars in terms of the ADF ratio was found to be statistically insignificant. However, the NDF ratio showed a statistically significant difference at the level of $p<0.01$ between the cultivars. The ADF ratio of silage varied between 39.30-41.73%. The lowest NDF ratio was found in the Shawnee cultivar by 70.96%. The highest NDF ratio was found in the Kanlow (75.41%) and BoMaster (75.25%) cultivars that statistically constituted the first group. Nevertheless, a statistically significant difference in terms of the NDF ratio was between the Shawnee and Trailblazer cultivars and other cultivars (*Table 4*). This difference between the cultivars in terms of NDF can be explained by different temperature, moisture, and fertilizer utilization during the period from sowing-time to harvest.

The ADF and NDF ratios, which are the plant cell wall components, are a good indicator of total digestible nutrients, and the ADF and NDF ratios are desired to be low in roughage (Van Soest, 1994; Gürsoy and Macit, 2014). When the roughage quality standard for farm animals (<31%= top quality, 31-35%= very good, 36-40%= good, 41-42%= medium, 43-45%= bad and >45%= unacceptable for ADF; <40%= top quality, 40-46%= very good, 47-53%= good, 54-60%= medium, 61-65%= bad and >65%= unacceptable for NDF) reported by Rohweder et al. (1978) is considered, it can be said that the silage of switchgrass cultivars was of good and/or medium quality in terms of the ADF ratio and unacceptable in terms of the NDF ratio. The fact that the NDF ratio, which expresses the whole fiber including hemicellulose, cellulose, and fiber in the plant, was high in the silage of switchgrass cultivars is considered to be due to the slowdown of the degradability of cell wall agents such as NDF as a result of the low

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1575515773

number of LA bacteria in the silage medium although some cultivars were slightly more than 2% (*Table 4*), as it was also indicated by Filya (2001).

In the studies conducted for different purposes with switchgrass cultivars, it was reported that the ADF and NDF ratios varied between 21.3%-66.9% and 57.6%-86.5%, respectively (Madakadze et al., 1999; Sanderson et al., 1999; Soylu et al., 2010; Mantino et al., 2017; Mohammed and Desta, 2017).

Fleig score (FS)

One of the most important criteria used in the determination of the quality of silage feed is the FS, which is calculated based on the regression equation between DM and pH of the silage (Woolfort, 1984; Kılıç, 1986; Geren, 2001). In terms of the FS, the difference between the silage of the switchgrass cultivars examined in the study was found to be statistically significant at $p<0.01$ level. Although the highest FS was determined in the BoMaster (144.7 points) cultivar, the difference between the Alamo, Trailblazer, Cave in Rock, and Long Island cultivars was found to be statistically insignificant. The lowest FS was found in the Shawnee cultivar by 88.6 (*Table 5*).

Table 5. *Fleig scores of the silage obtained from switchgrass cultivars*[*]

Cultivars	FS
Kanlow	111.9 b
Shelter	105.5 bc
Shawnee	88.6 c
BoMaster	144.7 a
Alamo	134.2 a
Trailblazer	130.9 a
Cave in Rock	144.3 a
Long Island	130.6 a
$F_{cultivar}$	30.658[**]
CV (%)	5.00

[*]: The difference between the means indicated by the same letter is not significant, [**]: $p<0.01$ is significant within error limits, CV: Coefficient variation

In the study, when the FS of the silage of switchgrass cultivars ranging from 88.6-144.7 were evaluated according to *Table 3*, the quality of silage obtained from switchgrass cultivars was found to be "very good". When the FS calculated by considering the DM and pH contents of silo feeds is compared with the studies carried out in corn (Geren, 2000, 2001; Demirel et al., 2001; Kavut and Soya, 2012), it can be said that similar results have been achieved.

When the desired pH and DM ratio is ensured in the silo feed, the FS is also high. In our study, it was observed that the FS of all switchgrass cultivars other than the Shawnee cultivar was above 100 (*Table 5*). Similar results were also achieved in corn (150.5 points) and sorghum (123.3 points) silage by Öten et al. (2016) and in corn (104.2 points) silage by Seydoşoğlu (2017).

Physical properties of the silage of switchgrass cultivars

The scores of the physical properties (odor, structure, and color) of the silage obtained from switchgrass cultivars, the DLG score, and the silage quality class according to physical properties are presented in *Table 6*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1575515773

While the difference between the cultivars in terms of odor and structure was found to be statistically significant at p<0.01 level, the difference between the cultivars in terms of color was found to be insignificant. The Long Island cultivar had the highest score in terms of all three physical properties. Nevertheless, the difference between the Long Island cultivar and the Cave in Rock cultivar in terms of odor and the difference between the Cave in Rock, Alamo, BoMaster, and Shelter cultivars in terms of the structure were found to be statistically insignificant (*Table 6*). In the silage made with switchgrass, the fact that the physical appearance was largely preserved, especially in terms of the above-mentioned cultivars producing high scores, indicates that successful silage can be achieved with switchgrass plant. On the other hand, silage quality also varies depending on the fermentation process (Geren, 2001). Therefore, as it was also indicated by Comberg (1974) and Akyıldız (1984), the silage feed of an ideal quality may have a pleasant acidic, slightly sour and aromatic odor resulting from the odor of the products produced by LA bacteria. Furthermore, it was reported that the physical structure of the feed (Geren, 2001) and the color of the silage (Woolfort, 1984) could be largely preserved if the silage was made well.

Table 6. *Mean scores of the physical properties of the silage obtained from switchgrass cultivars, and the quality class*[*]

Cultivars	Odor	Structure	Color	DLG score	Quality class
Kanlow	8.0 e	2.0 b	1.3	11.3 d	Medium
Shelter	8.7 de	3.3 ab	1.3	13.3 cd	Medium
Shawnee	9.3 cde	2.0 b	1.3	12.7 d	Medium
BoMaster	11.3 bc	3.3 ab	1.3	16.0 bc	Good
Alamo	10.7 bcd	4.0 a	1.7	16.3 b	Good
Trailblazer	10.3 bcd	2.0 b	1.0	13.3 cd	Medium
Cave in Rock	12.0 ab	4.0 a	1.7	17.7 ab	Very good
Long Island	13.7 a	4.0 a	2.0	19.7 a	Very good
$F_{cultivar}$	18.58[**]	7.40[**]	1.06	24.78[**]	
CV (%)	7.09	12.85	6.08	6.55	

[*]: The difference between the means indicated by the same letter in the same column is not significant,
[**]: p<0.01 is significant within error limits, CV: Coefficient variation

When the DLG scores were considered, the highest value was determined in the silage of the Long Island cultivar by 19.7 points, followed by the Cave in Rock cultivar by 17.7 points. The lowest DLG score was found in the Kanlow (11.3 points) and Shawnee (12.7) cultivars. This difference between the cultivars in terms of DLG was found to be statistically significant at p<0.01 level. According to the classification of the DLG score obtained by adding the odor, structure, and color scores of the silage (Anonymous, 1987) in the evaluation of the physical properties of silage feed, it was observed that "good" quality silage was obtained from the BoMaster and Alamo cultivars and "very good" quality silage was obtained from the Long Island and Cave in Rock cultivars (*Table 6*).

The harvest time (10-15 days after the beginning of flowering) was effective in obtaining high-quality silage from switchgrass cultivars in terms of physical properties. In the silage study carried out with corn and sorghum plants in a different flowering period (Rafiuddin et al., 2016), it was reported that the color, odor, structure, and total physical score values of the silage increased from early flowering to the full flowering period (as the developmental stage progresses), and the silage quality class became

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1575515773

"very good" from a physical aspect. The improvement in the physical properties of silage as the harvest period progressed was also indicated by Khan et al. (2011) and Khan et al. (2012). Moreover, it is considered that the high score in physical properties was affected by low pH, high DM, and high LA values, as it was also indicated by Rafiuddin et al. (2016).

With respect to the switchgrass plant, there was no study on the physical characteristics of silage. However, when compared to the properties of silage made with plants such as corn, sorghum, sorghum x sudangrass hybrid which are physiologically C4 plants such as switchgrass plant, it was observed that the results similar to the results of our study were achieved. In the silage studies carried out with these C4 plants (Geren, 2000; Güney et al., 2010; Öten et al., 2016; Rafiuddin et al., 2016; Seydoşoğlu, 2017), it was reported that the physical score of silage odor varied between 8-14, the silage structure varied between 2-4 points, and the silage color varied between 1-2, and good and/or very good quality silage was obtained according to the DLG score, as in the switchgrass cultivars in the results of our study. Furthermore, our results indicating that cultivars had no significant effects on silage color were found to be consistent with the results obtained by Geren (2000), Güney et al. (2010), Kavut and Soya (2012), and Seydoşoğlu (2017).

Conclusions

According to the study results, it was determined that the Long Island and Cave in Rock cultivars came to the forefront in terms of silage quality and that the BoMaster, Alamo, and Trailblazer cultivars could also be used successfully in silage production. In this study carried out with switchgrass which is used as an alternative plant for the production of bioethanol and forage plants in the world but is a new plant for Turkey, it was concluded that promising results were achieved in terms of silage quality and it could be an alternative source of roughage for livestock businesses. Since switchgrass is a perennial plant with 10 to 15 years lifespan, it would be a longterm resource for silage production.

(Received 15th Sep 2019; accepted 15th Nov 2019)

Abstract. Exploring the effects of urbanization on the conservation status of geomantic forest containing rare and endangered plants is very important for the ecological development of southern China. We studied the community structure and habitat characteristics of geomantic forest in Guangzhou City, southern China, as well as the population characteristics of the rare and endangered plant *Aquilaria sinensis* that resides there. The results showed that, within geomantic forest, there were 23 species vascular plants belonging to 23 genera and 14 families. This community was dominated by tropical and subtropical species. This community was mainly composed with mesophanerophytes, miphanerophytes and mesophyll. The community was less diverse than natural forests in the same region and contained one adult and eight seedling individuals of *Aquilaria sinensis*. This geomantic forest is a secondary evergreen broad-leaved forest with poor soil. In order to protect rare and endangered plants, as well as native species in this region, we suggest that all geomantic forests with rare and endangered plants in Guangzhou be set as small natural reserves that can be strictly managed. This kind of small natural reserve can facilitate the conservation of regional plant diversity and provide more ecosystem service.
Keywords: *floristic composition, Shuixi Village, Aquilaria sinensis, soil property, urbanization*

Introduction

Geomantic forest is purposely preserved to maintain the ecological environment in Southern China, Japan, and Korea, and is also shaped by both religion and the traditional culture of geomancy (Kim, 2014, 2017; Fan et al., 2019). The geomantic forest refers to the evergreen broad-leaved forest that has grown on edge of the villages for many years. The geomantic forest not only protects local plant resources but also contains rare and endangered species. In addition to protecting the environment, the geomantic forest also serves as a gene bank for the development and utilization of biological resources in the future (Cheng, 2011; Ye et al., 2013). Monsoon evergreen broad-leaved forests, with their complex community structure and rich biodiversity, are the typical zonal vegetation in southern China. They are an important part of the subtropical terrestrial ecosystem and play an important role in ecosystem services (Ren et al., 1996; Song et al., 2005). The monsoon evergreen broad-leaved forests in Southern China are mainly preserved in the form of nature reserves. Most of the geomantic forests in Guangzhou are inhabited by the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1577515785

rare, endangered *Aquilaria sinensis* plant, but the forests are scattered and have been seriously damaged by deforestation and related human activities (Ye et al., 2013).

Aquilaria sinensis is a perennial tropical and subtropical evergreen tree that belongs to the Thymelaeaceae family. It is listed as a national second-class protected plant and an internationally protected tree. *Aquilaria sinensis* is a valuable resource in Chinese herbal medicine and is listed as one of the top ten broad-spectrum drugs (Mao et al., 2017; Wang et al., 2012). Due to over-harvesting, few *Aquilaria sinensis* individuals remain in the wild.

As a typical Chinese traditional forest, geomantic forest has mainly been studied in China, where research has been conducted to analyze their classification and conservation value (Hu et al., 2011; Luo et al., 2011; Tang et al., 2012; Deng, 2013; Gao et al., 2013), species composition and diversity (Liu et al., 2005; Mo et al., 2011; Lee et al., 2017; Lü et al., 2009c), community structure characteristics (Cai et al., 1998; Yang et al., 2012; Kong et al., 2013; Chen, 2017; Zhu et al., 2011; Lü et al., 2009a, b), biomass and carbon storage (Lu, 2017), spatial form and distribution (Lin et al., 2013), plant resources and utilization (Li et al., 2013), landscape reconstruction and planning, related human settlements and environmental culture (Cheng, 2011; Ye et al., 2013). The community characteristics and protection of *Aquilaria sinensis* in Guangzhou were also analyzed by several scholars (Zhu et al., 2011). In general, however, there are few studies on rare and endangered plants and their habitats in geomantic forest. The geomantic forest, home to many local native species, endemic species, and rare and endangered plants, is a local source of species diversity and provides shelter for rare and endangered plants (Ye et al., 2013). Within the Luogang District in Guangzhou City there are 15 geomantic forests, all with similar species composition and community structure (Ye et al., 2013).

For this analysis, we focused our research on the geomantic forest in Shuixi Village, which is representative of the geomantic forest in Guangzhou and is inhabited by *Aquilaria sinensis*. Shuixi Village is located in the eastern suburbs of Guangzhou. After relocation to the Huangpu District in 2014, it has become an important area for development and transformation. Shuixi Village was listed as one of the old village reconstruction projects in Guangzhou in 2016. With the growing population and increased economic development of the village, the forest faces the negative effects of human interference and climate change caused by urbanization. In this study, we examined the community structure of the geomantic forest in Shuixi Village, as well as the structure and community habitat of the *Aquilaria sinensis* population within this forest. Specifically, we addressed the following three topics: (1) the community structure and habitat of the geomantic forest, (2) the population status of *Aquilaria sinensis* in the geomantic forest and (3) the strategies to protect the geomantic forest, as well as its rare and endangered plants.

Materials and methods

Research site

The geomantic forest (*Fig. 1*), with an area of approximately 6 hectares, is located at the rear of Shuixi Village, in northeast Guangzhou, Guangdong Province, China, 113°28’41.6”N, 23°11’49.2”E. The forest is located about 50 m above sea level, and has an eastern slope of 15°. It belongs to the lower subtropical monsoon climate, and has an average annual temperature of 23 °C. The lowest temperature occurs in January and is 13 °C, and the highest temperature is 28 °C and occurs in August (Mao et al., 2017). The annual average humidity is about 79%, the annual average rainfall is about 1700 mm, and the rainy season is from April to October (Zhu et al., 2011; Yi et al., 2012). The zonal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1577515785

vegetation in this area is the lower subtropical monsoon evergreen broad-leaved forest, and the zonal soil is laterite. Shuixi Village covers a significant area with a large population. It is surrounded by artificially planted *Acacia mangium*, *Cinnamomum burmanni*, and *Manglietia glauca*. In the geomantic forest, *Acacia mangium* covers the most area, and native species only cover about 900 m^2. There are some signs of deforestation and we find that human activities have affected the geomantic forest, as there are traces of raising chickens, stacking garbage and walking around the forest.

Figure 1. *The community structure and habitat of the geomantic forest*

Investigation and analysis methods

The typical community sampling method was used to investigate the vegetation of the geomantic forest in Shuixi Village in November 2017. Samples of soil and leaf litter were also taken for analysis. As mentioned above, the area of the geomantic forest where native species remain is about 900 m^2. Only eight 10 m × 10 m quadrates were established in the area containing native species. We investigated the crown density, species, plant height, and diameter at breast height (DBH) in the arbor layer, where the DBH is ≥ 1 cm. A 5 m × 5 m shrub quadrate was randomly selected from each 10 m × 10 m quadrate, and a 1 m × 1 m herb layer was randomly set in the shrub quadrate (Ren et al., 1996). The species name, height, and coverage of each individual in the shrub and herb quadrates were recorded. Three 1 m×1 m litter layers were randomly collected from each 10 m × 10 m square to measure the litter standing crop in the ground layer (Ren et al., 1998).

Five 10 m × 10 m quadrates were selected for soil property analysis. In each of the five quadrates chosen, six soil samples (0-20 cm) were randomly collected using drilling tools and mixed. Soil samples were brought back to the laboratory. Samples were air-dried and sieved for analysis of soil organic matter, pH, N, P, and K contents. The analysis method followed Peng (1996) and Ren et al. (1996). There were five replicates per site (i.e. one replicate per quadrat). In addition, the leaf area index and extinction coefficient were analyzed using the LAI-2000 plant canopy analyzer (Ren et al., 1996).

Data analysis

Based on the standards of Raunkiaer's Life-form Spectrum and the Flora of China and Guangdong Flora (Cai et al., 1998), various life forms of plants were comprehensively determined. Field observations and survey data were used to determine the leaf type. The basal area, frequency, relative frequency, relative density, relative significance, importance value, diversity index, ecological dominance and uniformity index were calculated (Ren et al., 1996). The species composition of the shrub layer in the community, the spatial structure, the species structure of *Aquilaria sinensis* and the soil chemical properties were determined. The relevant equations are as follows:

$$\text{Important value } IV = 100 \times (\text{relative degree} + \text{relative frequency} + \text{relative significance}) / 3 \quad \text{(Eq.1)}$$

$$\text{Shannon} - \text{Wiener index } HP = -\sum (Pi \times \ln Pi) = -\sum |(Ni / N) \times \ln(Ni / N)| \quad \text{(Eq.2)}$$

$$\text{Ecological dominance } C = Ni\ (Ni - 1) / [N\ (N - 1)] \quad \text{(Eq.3)}$$

$$\text{Pielou evenness index } JSW = -\sum (Pi \ln Pi) / \ln S \quad \text{(Eq.4)}$$

where Pi is the relative abundance of the i-th species, Ni is the number of plants of the i-th species, N is the total number of plants, and S is the total number of species (Peng, 1996; Luo et al., 2011).

The data were processed using Office Excel.

Results and analysis

Community structure

Geomantic forests are evergreen all year round, with an overall height of about 10 m and a canopy closure of about 70%. The leaf area index (LAI) of the community is 4.98 and the extinction coefficient, K, is 0.325. The canopy layer is discontinuous, and there is a notable vertical stratification of tree layer, shrub layer and herb layer.

In the 800 m^2 area, there are 167 individuals, some of which are monoecious, bringing the total to 178 individuals in the arbor layer. These individuals belong to 14 families and 23 genera, and have an average DBH of 6.8 cm and an average height of 5.5 m. Among 178 individuals, there are three genera and three species in each family of Euphorbiaceae, Rubiaceae and Polygonaceae. The arbor layer is dominated by families and genera of tropical and subtropical plants. There are 115 individuals shorter than 5 m, making up 65% of the total; 43 individuals between 5-10 m tall, accounting for 24% of the total and 20 individuals taller than 10 m occupying 11% of the total. There are 124 individuals with a DBH within 5 cm, accounting for 70% of the total, 33 individuals with a DBH between 5 and 10 cm, making up 18% of the total, and 21 individuals with a DBH greater than 10 cm, occupying 12% of the total. In general, the community is relatively short, with the majority of trees being small in size.

The geomantic forest community is made up of a diverse array of species. In the arbor layer, four species, including *Engelhardia roxburghiana* Wall., *Acacia mangium* Willd., *Psychotria rubra* (Lour.) Poir., and *Aporosa dioica* (Roxb.) Muell. Arg., account

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1577515785

for about 65% of the importance value (*Table 1*). There are only seven large *Acacia mangium* individuals, which have the largest height and DBH within the community. This species has no young individuals. As the pioneer species, it will gradually withdraw from the community. *Astragalus membranaceus*, which is the most dominant species in the arbor layer, has 31 individuals. *Psychotria rubra* and *Aporosa dioica* have the largest number of individuals, all of which are short, small trees. There are 13 species of shrubs, 10 of which are also present in the arbor layer, and one of which is also present in the herb layer (*Table 2*). There are seven species within the herbaceous layer, four of which also in the arbor layer, one of which is present in the shrub layer, and two of which are ferns (*Tables 1-3*).

According to the Raunkiaer's Life-form Spectrum, among the 23 species in the arbor layer, only five species are middle phanerophytes, and the other 18 species are small phanerophytes. Moreover, two species have large-sized leaves and five species have small-sized leaves. The other 16 species have medium-sized leaves. In the wild, plants in this community predominantly have leathery, single medium-sized leaves. The Shannon-Wiener biodiversity index of the arbor layer is 2.458, which is significantly lower than the diversity index of 4.01 in the Dinghu Mountain zonal vegetation–monsoon evergreen broad leaved forest in 1992. The indexes of ecological dominance and uniformity have little difference, as they are 0.13 and 0.784, respectively (Ren et al., 1996).

Population structure of the rare species Aquilaria sinensis

There is one *Aquilaria sinensis* individual in the arbor layer, with a DBH of 8 cm and a height of 6.5 m in the geomantic forest. There are six *Aquilaria sinensis* individuals in the shrub layer, one with a basal diameter of 1.3 cm and a height of 1.7 m, four with a basal diameter of 0.7 cm and a height of 0.7 m, and one with a basal diameter of 0.4 cm and a height of 0.6 m. Two *Aquilaria sinensis* individuals occupy the herbaceous layer, with a height of 0.2 m. The importance value of *Aquilaria sinensis* is 0.72, accounting for 0.7% of the community. *Aquilaria sinensis* is a mesophanerophyte, a group which makes up a small portion of the community. *Aquilaria sinensis* is also a species with medium-sized leaves, and these types of species occupy a large portion of the community.

Soil properties of the community

The soil in the sample plot consists of a thick layer of fertile laterite. The average weight of the litter layer is 530 ± 50.99 g m^{-2}, and the litter layer is rich in humus. The A layer of soil, with a thickness of 0-20 cm, has a pH of 4.46, making it acidic. The organic content is 30.48 g kg^{-1}, and the total nitrogen content is 1.18 g kg^{-1}. The main chemical properties of the soils are shown in *Table 4*. The soil of this community is similar to that of nearby Changlong Village in Longgang District and Zhongling Village in Zengcheng District, but there are some differences. Overall, the soil fertility of the sample plot is not as high as that of the zonal climax vegetation in Dinghu Mountain. This indicates that the soil fertility of the small-size geomantic forest has been influenced by human activities and needs to be improved to be on par with that of the natural soil in a large-size nature reserve. The content of organic matter and available potassium in this plot is particularly high, which may be related to activities of local villagers, such as raising chickens and stacking garbage.

Discussion

The community structure indicates that the geomantic forest is a secondary monsoon evergreen broad-leaved forest. There are artificially planted *Acacia mangium* individuals outside the native species community. The community species are somewhat similar to those seen in the monsoon evergreen broad-leaved forest at Dinghu Mountain, despite the presence of *Acacia mangium*. However, the geomantic forest in Shuixi Village also shows tropical and subtropical properties in its floristic composition, community life type and leaf type spectrum. However, there are no plate-like roots, cladanthy, drip-tip plants, or woody vines that are typically observed in natural vegetation. Compared with natural forests, the number of species in the geomantic forest in Shuixi Village is smaller, the population density is lower, the overall height of the vegetation is shorter and the DBH of the vegetation is smaller. There are only three layers in this community, arbor, shrub and herb, meaning that the liana layer, three sub-layers of the arbor and five sub-layers of shrub and herb that are present in natural forests are missing in the Shuixi village forest. Although the community is mainly composed of species with medium-sized leaves, it is different from the structure of natural forests, which have reasonable proportions of species with various types of leaves. The mesophanerophytes and miphanerophytes are the main components of the community, and there are no phaenerophytes. This is mainly due to the fact that the community is not mature enough. In addition, the community's diversity index is significantly lower than that of Dinghu Mountain (Ren et al., 1996). Therefore, this geomantic forest is a lower subtropical monsoon evergreen broad-leaved forest displaying secondary growth after human disturbances. However, the species coefficient of this forest is 100%, indicating that it still has a large development trend with its species richness (Cai et al., 1998).

In terms of the soil chemical properties, the fertile lateritic soil of this geomantic forest is the same as that of the monsoon evergreen broad-leaved forest in Dinghu Mountain. However, aside from the organic matter and available potassium levels, other indicators of the soil health in the geomantic forest are lower than those for the soil in the Dinghu Mountain forest. Moreover, soil indicators in the geomantic forest in Shuixi Village are also different from those of the other nearby geomantic forests (Fan et al., 2019). There are two possible reasons for the increased soil fertility in this geomantic forest. First, the geomantic forest is close to the village where there are chickens and garbage, which may contaminate the soil. Second, the vegetation is inferior to what is observed in natural forests, which is the result of various types of disturbances. Despite this, the geomantic forest in Shuixi Village still has high soil fertility and can ensure the growth of the native vegetation.

There are nine *Aquilaria sinensis* individuals in the geomantic forest in Shuixi Village. These individuals have a certain age structure, indicating that they are still capable of self-renewal, and the habitat of this community is suitable for the regeneration and growth of *Aquilaria sinensis*. In particular, the acidic soil (pH 4.46) of the geomantic forest in Shuixi Village makes it suitable for *Aquilaria sinensis* growth. The nutrient content of the soil in the Shuixi Village geomantic forest is generally lower than that of the forest in Dinghu Mountain, however, *Aquilaria sinensis* can adapt to nutrient-poor environments (Wang et al., 2012). The poor soil affects the secretion of the resin from *Aquilaria sinensis*, and in terms of resin quality, growth in barren soil may be better than growth in fertile soil (Luo et al., 2011).

DOI: http://dx.doi.org/10.15666/aeer/1706_1577515785

With the rapid development of society and the acceleration of urbanization in Southern China, the disturbance of the monsoon evergreen broad-leaved forest in Shuixi Village is becoming more serious. Both the distribution and area of the forest are shrinking. Meanwhile, the forest quality is decreasing, leading to a simplified community structure, decreased function, invasion of exotic species, and the disappearance of a large number of rare species. In this area, the ability of the forest to positively influence climate regulation and water conservation will be weakened to some extent, and the soil will be degraded. The geomantic forest in Shuixi Village is a natural secondary forest but it is also part of the urban landscape. The geomantic forest is well-preserved compared to other types of forests, but it also reveals the influence of urbanization and human disturbance on natural forest (Chen et al., 2018). This forest is a local species bank and the provenance of rare and endangered plants in the region. It is also part of a unique environmental and cultural tradition in Southern China, making it an important resource for studying zonal forest communities, local culture and history. Furthermore, the forest provides certain ecological services, as well as landscape cultural value. Overall, the geomantic forest is an important element in the construction of rural landscapes and it needs to be actively preserved (Lin et al., 2013).

Conclusion

Shuixi Village in Guangzhou is representative of the other villages located in the center of the Guangdong-Hong Kong-Macao Greater Bay Area and its geomantic forest is characteristic of those seen in urban cities. The geomantic forest in the region can help preserve and recover the monsoon evergreen broad-leafed forest in the region, and maintain the harmony between humans and nature, thus promoting sustainable ecological development in the Greater Bay Area. The nature reserves were effectively protected by regulations and laws. However, there are no such regulations or laws in place to protect geomantic forests. Therefore, setting environmental regulations for geomantic forests, where most rare and endangered plants grow, will provide ecological support for sustainable development and will improve the ecological civilization in the Greater Bay Area. In addition, the dynamic monitoring and ecosystem service on geomantic forest is needed in future.

Abstract. Many illicit drugs have been linked to cardiovascular diseases, but large epidemiological studies are still needed to unveil the full effect of their use on the cardiovascular system. The aim of this study was to explore the relationship between illicit drug use and the prevalence of abnormal arterial stiffness in young and middle-aged illicit drug users. In total, 1247 illicit drug users and 107 non-illicit drug users were recruited for the Cardiovascular Damage Study, and 731 illicit drug users and 55 non-illicit drug users completed the cross-sectional analysis. Data was collected using questionnaires and a noninvasive vascular screening device. The value of brachial-ankle pulse wave velocity (baPWV) varied in a statistically significant manner depending on the type and duration of illicit drug use. The prevalence of abnormal baPWV varied significantly among different illicit drug user groups ($\chi^2 = 10.69$, $p < 0.01$). Multivariate logistic regression analysis revealed that age, sex, and the type of illicit drug used were crucial risk factors for abnormal baPWV. Older male narcotic drug users were associated with a significantly higher prevalence of abnormal baPWV. The main risk factors of arterial stiffness in young and middle-aged drug users were age, sex, and the type of illicit drug used.
Keywords: *vascular elasticity, brachial-ankle pulse wave velocity, cardiovascular disease, narcotic drug, psychotropic drug, risk factor*

Introduction

Abuse of illicit drugs results in a variety of pathophysiological changes to the cardiovascular system, such as the constriction of coronary vessels, dysfunction of the vascular endothelium, and decreased aortic elasticity. The cardiovascular impact of illicit drug use can lead to death, which is a growing public concern as the consumption of illicit drugs is increasing annually (Devlin and Henry, 2008; Maceira et al., 2014; Akkina et al., 2012). For example, cocaine abuse affects the elastic properties of the aorta and leads to increased systolic blood pressure and aortic stiffness (Bigi et al., 2008; Zhu et al., 2018). Other illicit drugs, including cannabis, amphetamines, and 3-4 methylenedioxymethamphetamine (MDMA), are also reported to be associated with hypertension, arrhythmia, and sudden death (Kaye et al., 2008; Heal et al., 2013; Singla et al., 2012; Wolff et al., 2011; Satoh et al., 2009).

DOI: http://dx.doi.org/10.15666/aeer/1706_1578715797

A means of early detection of cardiovascular system damage in illicit drug users would be significantly helpful for clinical and emergency treatment. Currently, an easily obtained, reproducible, and non-invasive parameter, known as brachial-ankle pulse wave velocity (baPWV), is considered to be a useful tool for the management of cardiovascular disease and its risk factors in illicit drug users. BaPWV mainly reflects segmental arterial elasticity (Kim et al., 2015). Since an increase in arterial stiffness will increase the propagation speed of a pulse wave in the artery (Tomiyama et al., 2016), baPWV can serve as a marker of arterial stiffness. A baPWV more than or equal to 1400 cm/s indicates severe arterial stiffness (Yamashina et al., 2003; Wang et al., 2014) and a strong and independent association with coronary artery calcium (CAC), which is a powerful marker of coronary atherosclerosis (Cainzos-Achirica et al., 2015).

The cardiotoxic properties of illicit drugs have been studied for decades. Reports of the actual effects of illicit drugs on the cardiovascular systems of illicit drug users have not been well documented. Furthermore, the relationship between the abuse of various illicit drugs and arterial stiffness has not been reported.

According to the Illicit Drug Classification of United Nations Convention, illicit drugs were divided into two categories based on their pharmacological properties: narcotic and psychotropic. In this study, users of illicit narcotic drugs (opium, heroin, morphine, dolantin, marijuana, and cocaine) and illicit psychotropic drugs (methamphetamine, ketamine, and MDMA) were enrolled in the analysis. Users were divided into three groups: illicit narcotic drug users, illicit psychotropic drug users and users of both narcotic and psychotropic drugs (poly drug users). The possible relationships between the type, duration, and method of illicit drug abuse and arterial stiffness were evaluated using baPWV. The results of this study may provide new clues for the prediction and prevention of illicit drug abuse-related cardiovascular disease.

Materials and methods

Subjects

The illicit drug users were recruited from the drug rehabilitation centers of Hunan, Yunnan, Guangxi, Shanxi, and Guizhou provinces of China. The duration of survey was eight months which is from August 2017 to March 2018. A total of 1247 illicit drug users agreed to participate in the Cardiovascular Damage Study and signed the informed consent forms approved by the Institutional Ethics Committee of Hunan Normal University describing the procedures and assessments of the study. Subsequently, 878 cases completed the data collection. According to the results of the physical examination that participants completed when entering the drug rehabilitation center, 147 users did not meet the following selection criteria: (1) no history of metabolic diseases and organic diseases; (2) no cardiovascular drug treatment in the past five years; and (3) ≤ 45 years of age. As such, 731 cases were enrolled in the final analysis. Non-illicit drug users were recruited from the local communities of Hunan, Yunnan, Guangxi, Shanxi, and Guizhou provinces of China. 107 non-illicit drug users agreed to participate and signed the informed consent forms of Cardiovascular Damage Study. After screening, 55 non-illicit drug users met the above mentioned selection criteria and were enrolled in the final analysis.

DOI: http://dx.doi.org/10.15666/aeer/1706_1578715797

Questionnaires and quality control

The questionnaires assessed demographic data and illicit drug abuse history including the type, duration, and method of illicit drug abuse. Participants were interviewed face-to-face by investigators trained to complete the questionnaire. All responses were reviewed by other trained investigators at the time of the interview.

Measurements

Blood pressure, baPWV and ankle-brachial index were measured using a BP-203 RPE III networked noninvasive vascular screening device produced by OMRON according to the manufacturer's instructions. The examination process was the same as previously descried (Wang et al., 2016). The subject was asked to sit for at least 5 min in an air-conditioned room (22-25 °C). Participants wore light clothing and were instructed to lay in a supine position. Cuffs were placed on both arms and ankles and participants were asked to keep quiet during the examination process. All technicians were well-trained and familiar with the device. The measurements were performed by a single technician and were monitored by another researcher throughout the duration of the study.

Statistical methods

Statistical analysis was performed using R software, version 3.3.1 (R Core Team, 2016), and SPSS 20 (SPSS, Chicago, IL, USA). Continuous variables were presented as means±standard deviations (SD) and categorical variables were presented as percentages (%). For multiple comparisons of means, a pairwise t-test was used and p values were adjusted by false discovery rate (FDR) using the Benjaminni-Hochberg (BH) method. ANOVA was used to compare non-paired samples of normally distributed parameters. Pearson's chi-square test was used to compare prevalence differences. The aforementioned functions we used for data analysis were included in the R base package (R Core Team, 2016R Foundation, Australia). baPWV multivariate unconditional logistic regression analysis was analysed by both R base package and SPSS 20. A p value less than 0.05 was considered statistically significant.

Results

General characteristics of study illicit drug users

In the end, 731 illicit drug users with complete personal information who fulfilled the selection criteria were included in the final analysis. The general characteristics of the subjects are presented in *Table 1*. Among the 731 illicit drug users, 535 (73.2%) were male and 196 (26.8%) were female. The mean age was 36.06±4.52 years (range 23–45 years old). A total of 374 cases (51.2%), 283 cases (38.7%), and 74 cases (10.1%) were narcotic drug users, psychotropic drug users, and ploy drug users, respectively. Age, height, blood pressure, baPWV, and other indicators were significantly different among different illicit drug users (*Table 1*).

Statistical analysis revealed that baPWV exhibited significant differences based on the type and the duration of illicit drug used (*Tables 1* and *2*). No significant difference was observed in baPWV value based on the method of illicit drug abuse (*Table A1* in the *Appendix*).

RbaPWV: right brachial-ankle pulse wave velocity. One-way ANOVA was used to analyze the difference among different drug abuse duration groups

Analysis of the prevalence of abnormal baPWV in different sex, age, and drug user groups

The total detection rates of abnormal baPWV in illicit drug users (14.4%) were significantly greater than those of non-illicit drug users (3.6%) ($\chi^2 = 4.13$, $p < 0.05$) (*Table 3*). To investigate the risk factors for abnormal baPWV in illicit drug users, the prevalence of abnormal baPWV in different sex, age, and drug user groups were analyzed. The results showed that the prevalence of abnormal baPWV was not significantly different between male and female illicit drug users ($\chi^2 = 3.76$, $p > 0.05$) (*Table A2* in the *Appendix*). It has been reported that peripheral vascular resistance increases and arterial elasticity decreases with age, which results in a higher prevalence of abnormal baPWV in the elderly population (Ishida et al., 2018). Therefore, according

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1578715797

to the age composition of the illicit drug users, the cases were divided into three groups. The detection rate of abnormal baPWV in illicit drug users between the ages of 21–30, 31–40, and over 40 was 8.0%, 14.3%, and 19.3%, respectively. There was no significant difference in the prevalence of abnormal baPWV among different age groups ($\chi^2 = 5.32$, $p > 0.05$) (*Table A3*).

Table 3. *Comparison of abnormal baPWV prevalence rates between illicit drug users and non-illicit drug users*

	baPWV ≥ 1400	**baPWV < 1400**	**Total**
Illicit drug users	626 (85.6%)	105 (14.4%)	731
Non-illicit drug users	2 (3.6%)	53 (96.4%)	55

baPWV: brachial-ankle pulse wave velocity. The difference between each group was analyzed by Pearson's chi-square test $\chi^2 = 4.13$, $p < 0.05$

Since the value of baPWV showed significant differences among different illicit drug abuse duration groups, the prevalence of abnormal baPWV differences among them was further analyzed. The detection rate of abnormal baPWV in different illicit drug abuse duration groups of 0–12, 13–36, 37–72, 73–144 and over 144 months was 20.1%, 14.4%, 13.0%, 11.3%, and 9.4%, respectively, but no significant difference was found among these groups ($\chi^2 = 7.90$, $p > 0.05$) (*Table A4*). Nevertheless, our further investigation of cardiovascular damage in illicit drug users based on baPWV revealed that the prevalence of abnormal baPWV showed a significant difference between the different illicit drug user groups: 18.4% in the narcotic drug user group, 10.6% in the psychotropic drug user group, and 8.1% in the poly drug user group ($\chi^2 = 10.69$, $p < 0.01$) (*Table 4*).

Table 4. *Comparison of abnormal baPWV prevalence rates of different type illicit drug users*

	baPWV ≥ 1400	**baPWV < 1400**	**Total**
Narcotic	69 (18.4%)	305 (81.6%)	374 (51.2%)
Psychotropic	30 (10.6%)	253 (89.4%)	283 (38.7%)
Poly	6 (8.1%)	68 (91.9%)	74 (10.1%)
Total	105 (14.4%)	626 (85.6%)	731

baPWV: brachial-ankle pulse wave velocity. The difference between each group was analyzed by Pearson's chi-square test $\chi^2 = 10.69$, $p < 0.01$

Analysis of the relevant risk factors for abnormal baPWV in illicit drug users

To avoid possible interactions between each risk factor, multivariate logistic regression analysis was used to evaluate the effect of illicit drug abuse on arterial stiffness. The result showed that significant predictors of abnormal baPWV were age, sex, and the type of illicit drug used. In males, the risk of abnormal baPWV was 1.97-fold higher (OR = 1.97, 95% CI = 1.11–3.47) than that in females. The risk of developing abnormal baPWV increased by 1.10-fold per year of age (OR = 1.10, 95% CI = 1.04–1.17). Compared with narcotic drug users (OR = 1), the risk of abnormal baPWV in psychotropic drug users (OR = 0.49, 95% CI = 0.28–0.84) and poly drug users (OR = 0.63, 95% CI = 0.23–1.72) was lower (*Table 5*).

A predictive model of the risk of arterial stiffness of illicit drug users (ASIDU) was developed based on multivariate logistic regression analysis according to the value of baPWV collected in this study. This ASIDU model contains six factors, including sex, age, Body Mass Index (BMI), the type of illicit drug used, the duration of illicit drug used and the method of taking illicit drugs. To evaluate the predictive performance of the ASIDU model, Receiver Operating Characteristic (ROC) analysis was used. The ASIDU model exhibited an area under the ROC curve (AUC) of 0.70 (95% CI = 0.64–0.75). The cut-off point (male, 29 years old, overweight, narcotic drug users and 12–36 months of illicit drug abuse) showed 60% sensitivity and 72% specificity in predicting arterial stiffness of illicit drug users according to the value of baPWV (*Fig. 1*).

Discussion

The present study indicates that cardiovascular damage in illicit drug users is significantly associated with age, sex, and the type of illicit drug used. Among the 731

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1706_1578715797

young and middle-aged illicit drug users in our study, 105 cases (14.4%) exhibited various degrees of abnormal arterial stiffness. It is significantly higher than the detection rate of that in the young and middle-aged normal population (3.6%). This indicates that abnormal arterial stiffness occurs in illicit drug users at a relatively young age. The incidence of cardiovascular disease and cerebral infarction induced by arterial stiffness is increasing year by year (Mikael et al., 2017; Hatanaka et al., 2011). Thus, detection of the changes in arterial stiffness in high-risk drug users can effectively predict the occurrence and development of cardiovascular and cerebrovascular diseases, which may reduce mortality among illicit drug users.

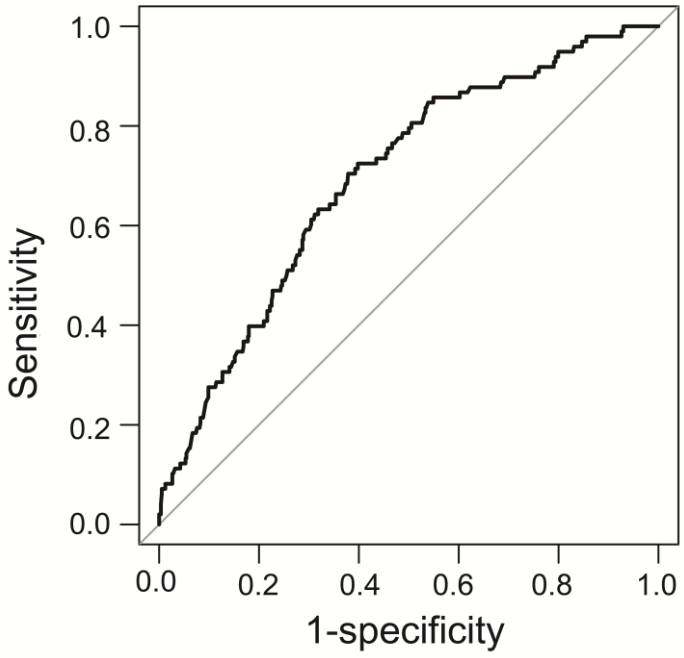

Figure 1. *ROC curve analysis of the predictive performance of the ASIDU model. AUC = 0.70, 95% CI = 0.64–0.75. (ROC: Receiver operating characteristic; ASIDU: arterial stiffness of illicit drug users; AUC: area under curve)*

Previous reports demonstrated that age is a major determinant of arterial stiffness (Lee and Oh, 2010). During the aging process, the vessel wall undergoes a variety of changes, including increased calcium deposition, quantitative and qualitative changes in medial layer collagen, and arterial wall hypertrophy. These results in disorganized microarchitecture, decreased vessel wall compliance and elasticity, and increased arterial stiffness (Tomiyama et al., 2003). Individuals more than 45 years old are more susceptible to arterial stiffness (Ishida et al., 2018). In addition, metabolic problems and a sedentary lifestyle also are critical factors affecting the arterial stiffness process (Satoh et al., 2009; Garcia-Hermoso et al., 2015). Thus, individuals less than 45 years old without metabolic and organic diseases were recruited to better evaluate the effect of illicit drugs on the cardiovascular system.

Some illicit drugs have been found to be associated with cardiovascular problems, such as arrhythmia, hypertension, myocardial infarction (MI), and atherosclerosis. In the United States, cocaine is the cause of 25% of MIs in people under 45 years of age (Qureshi et al., 2001). Up to 83% of asymptomatic cocaine users suffer from silent

myocardial injuries such as myocardial edema and myocardial fibrosis (Aquaro et al., 2011). Cardiovascular pathology, typically atherosclerosis, has been detected in 58% of MDMA users. This detection rate is higher than that expected among similarly aged members of the general population (Kaye et al., 2009). Amphetamine and cannabis are also thought to be linked to various cardiovascular problems, such as hypertension, cardiac arrhythmia and increased heart rate (Vitiello, 2008). Although the cardiotoxic properties of some of these illicit drugs have been well documented theoretically, the exact effect of different types of illicit drugs on humans has not been fully investigated. Our study revealed that illicit narcotic drug users have a higher detection rate of abnormal baPWV than illicit psychotropic drug users, which indicates that illicit narcotic drugs have a stronger effect on cardiovascular damage than that of illicit psychotropic drugs.

In a study of 121 intravenous drug abusers, 95 had systolic murmurs and 44 had extra-cardiac infections (Hecht and Berger, 1992). Vitiello et al. found that the effect of illicit abuse via intravenous injection is more pronounced that that associated with other methods of illicit drug abuse (Vitiello, 2008). However, in this study, we did not find a significant difference between different methods of drug abuse. This discrepancy may be a result of differences in the characteristics of the studied populations. Equal sample selection criteria are required to make a parallel comparison between the results.

Conclusion

In summary, age, sex and type of illicit drug used were crucial risk factors for abnormal arterial stiffness in young and middle-aged illicit drug users. The effects of different durations of illicit drug abuse on the cardiovascular system were compared, but no significant difference was found after multivariate logistic regression analysis. This may be due to the fact that the effect of illicit drug abuse is generated by the accumulation of cardiotoxicity, which is not only determined by the duration of drug abuse but is also related to the frequency of drug abuse and the average amount of illicit drug used in each time. Therefore, in order to further explore the cardiovascular impact illicit drug use, the duration and frequency of drug abuse and the average amount of illicit drug used should be taken into consideration.

Table A2. *Comparison of abnormal baPWV prevalence rates between males and females*

	baPWV ≥ 1400	**baPWV < 1400**	**Total**
Male	85 (16.9%)	450 (83.1%)	535 (73.2%)
Female	20 (10.2%)	176 (89.8%)	196 (26.8%)
Total	105 (14.4%)	626 (85.6%)	731

baPWV: brachial-ankle pulse wave velocity. The difference between each group was analyzed by Pearson's chi-square test $\chi^2 = 3.76$, $p > 0.05$

Table A3. *Comparison of abnormal baPWV prevalence rates among different age groups*

Age, years	**baPWV ≥ 1400**	**baPWV < 1400**	**Total**
21–30	7 (8.0%)	81 (92.0%)	88 (12.0%)
31–40	75 (14.3%)	449 (85.7%)	524 (71.7%)
>40	23 (19.3%)	96 (80.7%)	119 (16.3%)
Total	105 (14.4%)	626 (85.6%)	731

baPWV: brachial-ankle pulse wave velocity. The difference between each group was analyzed by Pearson's chi-square test $\chi^2 = 5.32$, $p > 0.05$

Table A4. *Comparison of abnormal baPWV prevalence rates of different type illicit drug abuse durations*

Duration, months	**baPWV ≥ 1400**	**baPWV < 1400**	**Total**
0–12	36 (20.1%)	143 (79.9%)	179 (24.5%)
13–36	28 (14.4%)	166 (85.6%)	194 (26.5%)
37–72	18 (13.0%)	120 (87.0%)	138 (18.9%)
73–144	14 (11.3%)	110 (88.7%)	124 (17.0%)
>144	9 (9.4%)	87 (80.6%)	96 (13.1%)
Total	105 (14.4%)	626 (85.6%)	731

baPWV: brachial-ankle pulse wave velocity. The difference between each group was analyzed by Pearson's chi-square test $\chi^2 = 7.90$, $p > 0.05$
